Received (in Cambridge, UK) 20th April 2001, Accepted 4th June 2001
First published as an Advance Article on the web 27th June 2001

A new class of remarkably stable B-BOXate complexes has been synthesised, isolated and employed as chiral catalysts for asymmetric reduction of variously substituted prochiral ketones.

Enantioselective catalytic processes have emerged as among the most powerful of methodologies for the preparation of enantiomerically enriched compounds.[1] Of all the catalytic asymmetric procedures, the use of metal complexes bearing chiral ligands is receiving a great deal of attention from the chemical community.[2] In the class of the 'privileged ligands' reported in literature, chiral bis-oxazoline (BOX) ligations have been demonstrated to be effective motifs in many stereocontrolled reactions.[3] Normally, bis-oxazoline metal complexes are designed to behave as chiral Lewis acids, and free coordination sites are available for the incoming electrophile. Our attention was addressed towards the design of stable and coordinatively saturated BOX complexes where simultaneous binding of electrophiles and nucleophiles is possible.[4] With this in mind our interest was drawn to the preparation of coordinatively saturated boron bis-oxazolinate complexes. We discovered that the achiral BOX[5] **1** reacted smoothly with catecholborane (CATBH) in CH_2Cl_2 affording, after removal of the solvent, the boron bis-oxazolinate adduct **3** (B-BOXate) as a white solid stable to moisture in 85% yield.† The ^{1}H NMR, ^{13}C NMR and ^{11}B NMR spectroscopy investigations supported the formation of a single symmetric complex derived from the reaction between the CATBH and the BOX **1** (Scheme 1). To the best of our knowledge, B-BOXate complexes have not been reported until now. As a matter of fact, although the BOX ligands are easily deprotonated, only a few cases of BOXate–metal complexes have been described.[6] Diagnostic signals for **3** are the singlet for the proton bridge at δ = 4.45 ppm, the ^{13}C signal at δ = 57.8 ppm for the methine carbon of the ligand and the ^{11}B signal at δ = 8.87 ppm typical for a tetrahedral coordination of the boron atom.[7] These findings were also confirmed by an X-ray crystallographic analysis of **3**.‡ The structure reported in Fig. 1 shows that the BOX and the catechol motifs lie in two perpendicular planes, whereas the boron atom adopts a tetrahedral coordination slightly deviating from the idealised geometry as a consequence of the ring constraints. The molecule would conform to an idealised C_{2v} symmetry, but

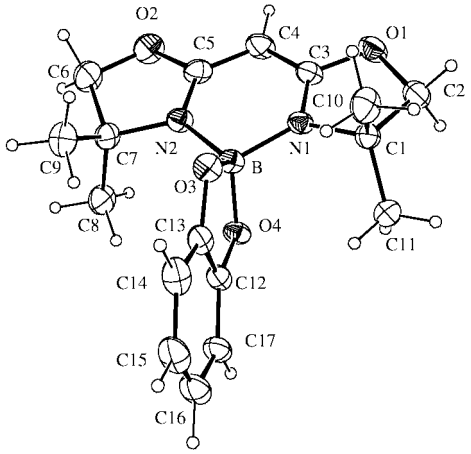

Fig. 1 An ORTEP plot of the molecular structure of **3**. Thermal ellipsoids are drawn at the 30% probability level. Selected bond lengths (Å) and angles (°): B–N(1) 1.541(2), B–N(2) 1.548(2), B–O(3) 1.479(2), B–O(4) 1.481(2), N(1)–C(1) 1.494(2), N(1)–C(3) 1.316(2), N(2)–C(5) 1.319(2), N(2)–C(7) 1.493(2), C(3)–C(4) 1.375(2), C(4)–C(5) 1.370(2); O(3)–B–O(4) 104.5(1), N(1)–B–N(2) 105.8(1), O(3)–B–N(1) 111.8(1), O(4)–B–N(1) 111.3(1), O(3)–B–N(2) 111.6(1), O(4)–B-N(2) 111.9(1). Dihedral angle between plane N(1)–B–N(2) and O(3)–B–O(4) is 89.69(8).

C(2) and C(6) atoms lie out the plane of their oxazoline rings [±0.223(5) Å] therefore the actual idealised symmetry is only C_2.

Employing chiral BOX ligands, the corresponding B-BOXate complexes can be isolated as stable solids. For instance, starting from the 2,2′-methylenebis[(4*R*,5*S*)-4,5-diphenyl-2-oxazoline] **2** and CATBH following the synthetic protocol employed for **3** the chiral B-BOXate **4** is isolated (diagnostic signals for **4** are as follows: ^{1}H NMR δ = 5.03 ppm and ^{13}C NMR δ = 57.8 ppm). In the course of our studies on the enantioselective reduction of prochiral ketones in the presence of M-BOX complexes,[6a,8] we found that the complex **3** was able to catalyse effectively the reduction of acetophenone with CATBH yielding the corresponding 1-phenylethanol in 86% yield after 18 h (Scheme 2). The use of **4** in catalytic amount (8 mol%) gave the desired (*R*)-1-phenylethanol (**6a**) in 80% yield and 44% enantiomeric excess. With the aim of searching for the optimal reaction protocol we screened, in the asymmetric

reduction, other chiral C_2 bis-oxazoline ligands (BOX **7**–**9**, Fig. 2) preparing the catalytic precursors *in situ*, in order to simplify the procedure.[9]

The best result was obtained using 8 mol% of the BOX **9** that furnished the enantioenriched alcohol in 76% ee (Table 1, entry 4),§ while the use of non-enolizable BOXs such as the PyBOX **8**, significantly decreased the enantioselectivity (ee = 18%, entry 3). Moreover, the catalytic protocol can be successfully applied in the reduction of branched aromatic ketones and α-halo ketones[10] (Table 1, entries 5–8). Although the mechanism of the present reduction is still unclear, a cooperative action in which ketones and CATBH simultaneously bind to the chiral catalyst (chemzyme) could be invoked. In summary, the design of a new class of B-BOXate complexes and their use in the catalytic asymmetric reduction of ketones is presented. The fine-tuning of the stereo-electronical features (both the bis-oxazoline and the catechol motifs can be opportunely matched), makes these systems promising catalysts for a variety of stereocontrolled organic transformations.

Dr Rossana Perciaccante thanks C.I.N.M.P.I.S. for a research grant. Dr Chris Senanayake (Sepracor INC.) is acknowledged for the generous gift of chiral (1*R*,2*S*)-*cis*-1-amino-2-indanol.

Notes and references

† *Synthesis of the B-BOXate* **3***:* A 25 mL round-bottom flask containing a stirring bar was charged with dry CH_2Cl_2 (4 mL), BOX **1** (105 mg, 0.5 mmol) and CATBH (80 μL, 0.75 mmol) at 0 °C. The resulting solution was stirred 4 h, then the solvent was evaporated under reduced pressure. The crude white product obtained was washed with dry Et_2O (5 mL), collected by filtration and dried under vacuum. Yield = 85%. δ_H ($CDCl_3$, 300 MHz) 6.71 (m, 4H), 4.46 (s, 1H), 4.10 (s, 4H), 1.30 (s, 12H); δ_C ($CDCl_3$, 50 MHz) 150.7, 119.1, 109.3, 109.0, 81.7, 62.8, 57.8, 26.3; δ_B (Ref. $BF_3{\cdot}OEt_2$): 8.87; diagnostic chemical shifts for **1** and CATBH: δ_H (**1**) 3.95 (s, 4H), 3.29 (s, 2H), 1.26 (s, 12H); δ_C (**3**) 160.2, 79.5, 67.3, 28.6, 28.2; δ_B (CATBH) 29.92 (d, $J_{B\text{-}H}$ = 554.1 Hz).

‡ *Crystal data* for **3**: $C_{17}H_{21}O_4BN_2$, M = 328.17, triclinic, a = 8.9871(3), b = 9.4340(4), c = 11.1411(4) Å, α = 67.378(2), β = 75.067(2), γ = 77.487(2)°, U = 835.12(5) Å^3, T = 293 K, space group $P\bar{1}$ (No. 2), Z = 2, μ(Mo-Kα) = 0.092 mm^{-1}, 11678 reflections measured by Bruker AXS SMART 2000 diffractometer with a CCD detector, 4866 unique (R_{int} = 0.0293) which were used in all calculations. Final $R1(F)$ = 0.0455 [$I > 2\sigma(I)$] and $wR2(F^2)$ = 0.1260 (all data). Software contained in the SHELXTL (5.1) library (G. M. Sheldrick, Bruker AXS, Madison, WI). CCDC 163357. See http://www.rsc.org/suppdata/cc/b1/b103571c/ for crystallographic files in .cif format.

§ *Catalytic reduction reaction*: To a stirring solution of **9** (13.2 mg, 0.04 mmol) in dry CH_2Cl_2 (2 mL) at 0 °C was added CATBH (100 μL, 1 mmol). The clear mixture was stirred for 2–3 h at the same temperature then acetophenone (58 μL, 0.5 mmol) was added by syringe. The reaction was kept without stirring for 48–72 h at 0 °C, quenched with NaOH (2 mL, 2 M) and then stirred for 10 min. After the usual workup (Et_2O, Na_2SO_4) the crude product was purified by flash chromatography (cyclohexane–Et_2O 85 : 15) to afford the (*R*)-(+)-phenylethanol as a pale yellow oil in 78% yield and 76% ee (Chiral GC analysis, Megadex-5 column).

The formyl C–H···O hydrogen bond as a critical factor in enantioselective Lewis-acid catalyzed reactions of aldehydes

E. J. Corey* and Thomas W. Lee

Department of Chemistry and Chemical Biology, Harvard University, Cambridge, MA 02138, USA. E-mail: corey@chemistry.harvard.edu

Received (in Cambridge, UK) 1st June 2001, Accepted 18th June 2001
First published as an Advance Article on the web 11th July 2001

X-Ray crystallographic studies have provided experimental evidence for the existence of intramolecular formyl C–H hydrogen bonds to oxygen or fluorine ligands in complexes of aldehydes and boron Lewis acids. This type of hydrogen bond can be regarded as 'induced' or 'cooperative' in the sense that its strength can be expected to increase as the bonding between the formyl oxygen and the Lewis acid becomes stronger. Coplanarity of the formyl group and the metal–X subunit to which it is bound in a five-membered ring effectively restricts rotation about the donor–acceptor bond between the formyl oxygen and the metal center of the Lewis acid, thus creating an additional organizing element in these complexes. This organizing element provides a simple and logical basis for understanding the mechanistic basis for enantioselectivity in many reactions of achiral aldehydes which are catalyzed by chiral Lewis acids. These reactions include aldol, allylation and ene addition to the formyl C=O group and Diels–Alder reactions of α,β-unsaturated aldehydes with 1,3-dienes. The idea of the induced formyl C–H hydrogen bond can serve as a guide in the design of new enantioselective catalysts as well as a mechanistic principle for understanding preferred transition state assemblies.

Introduction

One important aspect of research on enantioselective catalysis is the study of the detailed mechanistic basis of enantioselectivity in terms of transition-state structure. A clear understanding of the origin of enantioselection is crucial to the rational development of new synthetic methodology and to the successful application and/or extension of enantioselective reactions. Indeed, highly enantioselective catalytic reactions provide an unparalleled opportunity to discern the fine details of transition-state structure for many key synthetic processes.

Recent X-ray crystallographic studies[1] have provided evidence for a new kind of hydrogen bond in complexes of Lewis acids with the formyl group, exemplified generally by structures **1** and **2** (Fig. 1). The X-ray crystal structures of boron trifluoride

Fig. 1 Examples of formyl C–H···F and C–H···O hydrogen bonds.

complexes with benzaldehyde, methacrolein, 2,3-methylenedioxybenzaldehyde and dimethylformamide (DMF) show a preference for conformer **1** in which the formyl group and one of the B–F bonds are coplanar (eclipsed).[1] The H···F distances of 2.35–2.36 Å in these complexes are within the sum of the van der Waals radii of 2.67 Å (H = 1.20 Å and F = 1.47 Å).[2] Formyl C–H···O hydrogen bonding is indicated by the X-ray structures of [catecholborane·$(DMF)_2$]$^+Br^-$ (**3**) and [2-(*N*,*N*-dimethylamino)phenoxyboron·$(DMF)_2$]$^+I^-$ (**4**) (Fig. 2); the H···O distances of 2.41–2.59 Å in these complexes are well below the sum of the van der Waals radii of 2.72 Å (H = 1.20 Å and O = 1.52 Å).

Although the formyl proton of an uncomplexed substrate normally lacks the electrophilicity (*i.e.* acidity or positive charge) required for hydrogen bonding, coordination to a Lewis acid greatly enhances the positive charge at the formyl hydrogen while increasing the electron density at the oxygen or fluorine atoms attached to boron. Thus, the observed formyl hydrogen bonds shown in **1** and **2** (Fig. 1) are logical from an electronic structural point of view and in agreement with molecular orbital calculations.[3] There may also be a contribution from an anomeric effect in which electrons from the non-complexed lone pair on aldehyde oxygen delocalize into the σ* orbital of the eclipsed B–F or B–O bond (n → σ*). The authors of one study[3a] attributed a value of 6 kJ mol^{-1} to the anomeric effect and 9 kJ mol^{-1} to the formyl hydrogen bond.[4]

A recent publication[5] from this laboratory has provided the first discussion of the role of formyl hydrogen bonding in determining transition-state geometry in chiral Lewis acid-catalyzed reactions of aldehydes.[6] For instance, the highly enantioselective Diels–Alder reactions of 1,3-dienes with 2-bromoacrolein under the control of two very effective boron catalysts[7,8] can be explained in terms of the transition-state assembly shown in **5** or **6**, which contains a key formyl hydrogen bond as an organizing factor (Fig. 3). The *N*-

Elias J. Corey, born in 1928 in Methuen, 30 miles north of Boston, studied chemistry from 1945–1950 at the Massachusetts Institute of Technology, where he gained his doctorate for work on synthetic penicillins under the supervision of John C. Sheehan. In January 1951 he joined the University of Illinois at Urbana-Champaign as an Instructor in Chemistry and was promoted in 1956 to full Professor. Since 1959 he has been at Harvard University. For as long as he can remember he has enjoyed study, adventure and discovery.

Thomas W. Lee was born in 1973 in Hong Kong, and obtained his bachelor's degree in chemistry in 1995 at the Massachusetts Institute of Technology where he also worked for three years in the laboratory of Rick L. Danheiser as an undergraduate research assistant. He then joined the PhD program at Harvard University under the direction of E. J. Corey to study novel catalytic enantioselective Diels–Alder reactions and their applications in natural product synthesis. He received the PhD degree in chemistry in June 2001.

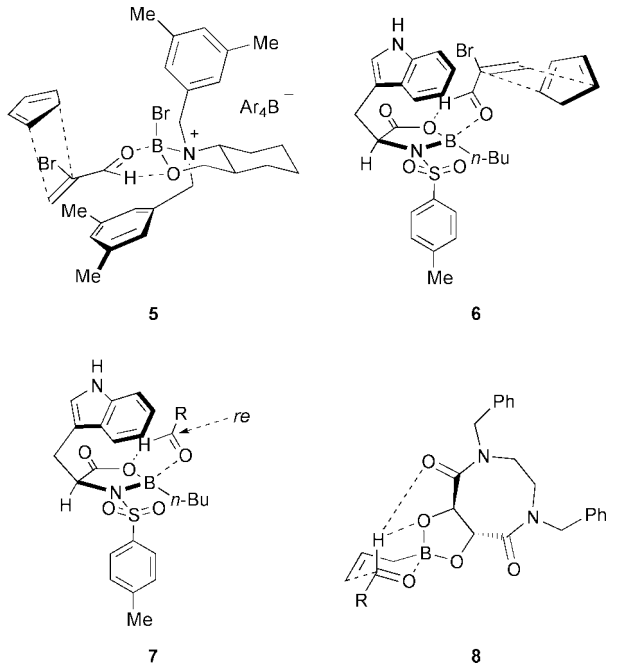

Fig. 3 Formyl hydrogen bond as an organizing element in enantioselective reactions.

tosyltryptophan-derived oxazaborolidine structure which appears in assembly **6** can also function very effectively to direct catalytic Mukaiyama aldol reactions.[9] The *re* face selectivity of these carbonyl additions can be predicted using the same line of analysis (see **7**). In addition, the Roush enantioselective allylboration of aldehydes,[10] a stoichiometric reaction for which there was no satisfactory explanation previously, can be understood in terms of a preference for the doubly hydrogen bonded structure **8**. It should be noted that the formyl hydrogen bond is only one of several structural elements contributing to the high enantioselectivities observed in these reactions.[7–10]

Pathways for enantioselective reactions of aldehydes involving formyl C–H···O hydrogen bonding

This section describes the application of the formyl hydrogen bond as an organizing stereochemical element to the understanding of a number of catalytic reactions involving aldehydes and chiral Lewis acids (*e.g.* Diels–Alder, aldol, ene reaction, hydrocyanation, allylation and alkylation) which have recently been developed and for which there has been no clear mechanistic rationale.

It has been pointed out[5] that the absolute stereochemical course of aldol reactions which are promoted by Yamamoto's chiral acyloxyborane (CAB) catalyst can be explained readily by formyl hydrogen bonding to *two* oxygens of the chiral ligand. The favored mode of binding of the (*R*,*R*)-tartrate-derived CAB catalyst with benzaldehyde as ligand is shown in **9** of Fig. 4.[11] The combination of the double (bifurcated) hydrogen bond and the π-attractive interaction of the bound formyl group with the neighboring substituted aromatic ring defines a unique structure which involves strong screening of the *si* face of the aldehyde formyl group. On the basis of a preference for this structure for the complex, it is expected that an enol silyl ether would attack benzaldehyde at the *re* face of the formyl carbon to form the (*R*)-Mukaiyama aldol product, as has been observed experimentally.[12] This simple explanation of the absolute stereochemical course of the CAB-catalyzed Mukaiyama aldol reaction can also be applied to CAB-catalyzed allylations of aldehydes[12d,e] and Diels–Alder reactions of α,β-enals.[13]

Formyl hydrogen bonding also seems to be a significant factor in determining the stereochemical course of reactions of aldehydes which are mediated by chiral complexes of Ti(IV). Keck and coworkers have described allylation[14] and aldol[15] reactions catalyzed by a 2 : 1 complex derived from (*R*)-1,1′-bi-2-naphthol ((*R*)-BINOL) and Ti(O*i*-Pr)$_4$. The catalytic species in these reactions is probably the bis-BINOL titanate ester, $BINOL_2Ti$. In the case of catalytic allylation of an aldehyde with allyltri-*n*-butyltin, the latter reagent probably allylates Ti(IV) while the Bu_3Sn group attaches to one of the BINOL oxygens and causes dissociation of that oxygen from Ti. Coordination of benzaldehyde to this species with formation of the trigonal bipyramidal, hydrogen bonded structure **10** (Fig. 4) should be preferred since this arrangement uniquely satisfies three conditions: (1) minimize non-bonded steric repulsion, (2) allow formation of a stereoelectronically and entropically favorable formyl hydrogen bond to one of the oxygens of the bidentate BINOL ligand, and (3) place the allyl group in the basal position and the formyl oxygen in the apical position, ideal for the allylation reaction. Structure **10** leads to the observed absolute configuration of the homoallylic alcohol adduct ((*R*) from (*R*)-BINOL; (*S*) from (*S*)-BINOL).[14] It should be noted that interchanging allyl and benzaldehyde ligands in **10** places the aldehyde in a basal site which does not allow formation of a good formyl hydrogen bond to oxygen.[16]

For the Keck catalytic aldol process using $BINOL_2Ti$, an aldehyde and $H_2C{=}C(St\text{-}Bu)OSiMe_3$ as nucleophile, a structure analogous to **10** with $H_2C{=}C(St\text{-}Bu)O$ replacing allyl leads unambiguously to the observed absolute configuration of the predominant Mukaiyama aldol adduct.[15,17]

A Ti-based system related to that of Keck for the catalytic enantioselective Mukaiyama acetate aldol reaction of aldehydes with $H_2C{=}C(OMe)OSiMe_3$ using a catalyst derived from Ti(O*i*-Pr)$_4$, a Schiff base of 2-amino-2′-hydroxy-1,1′-binaphthyl and 3-bromo-5-*tert*-butylsalicylaldehyde, and 3,5-di-*tert*-butylsalicylic acid has been described by Carreira.[18] The Schiff base probably serves as a tridentate ligand with a coplanar arrangement of the two phenolic oxygens and the imine nitrogen, while

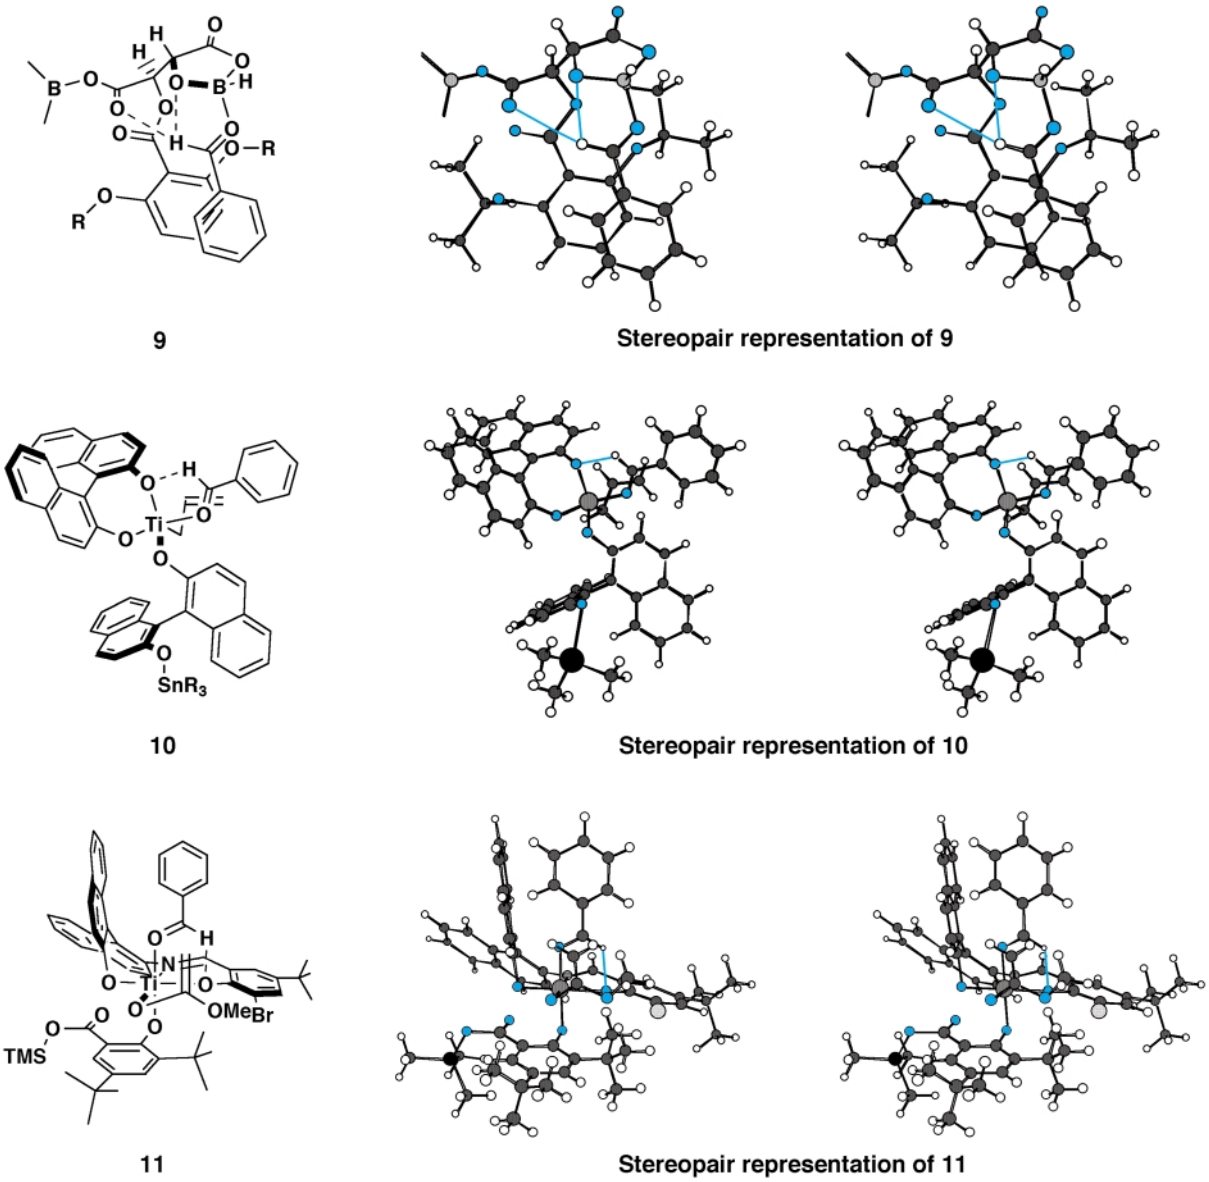

Fig. 4 Transition-state structures of Yamamoto's CAB aldol (**9**), Keck allylation (**10**) and Carreira aldol reaction (**11**). (Blue circles represent oxygen atoms and blue lines represent hydrogen bonds).

the salicylic acid acts as a bidentate ligand which is capable of accepting a trimethylsilyl group at the carboxy oxygen by reaction with $H_2C{=}C(OMe)OSiMe_3$. The reactive complex in the aldol-forming step is thus likely to have the following ligands coordinated octahedrally to Ti(IV): (1) the tridentate Schiff base, (2) an aryloxy group, (3) the aldehyde, and (4) the enol of methyl acetate. Clearly, the aldehyde and enolate ligands must be *cis* to one another in the octahedral arrangement in order to react. Although there are two possible arrangements of the complex which satisfy this condition, only that which is shown in **11** (Fig. 4) permits formyl C–H···O hydrogen bonding while minimizing steric repulsion involving the bulky 2,4-di-*tert*-butyl-6-trimethylsilyloxycarbonylphenoxide ligand. Structure **11** unambiguously leads to the observed enantiomeric aldol product.[18] The use of the formyl C–H···O hydrogen bond concept simplifies the analysis of the absolute stereochemical course of the Carreira aldol and, simultaneously provides a simple explanation of the effectiveness of the *bulky* substituted salicylic acid ligand.

Yamamoto has prepared a catalyst (Brønsted acid-assisted chiral Lewis acid, BLA) for enantioselective reactions of α,β-enals from trimethyl borate and (*R*)-3,3′-bis(2-hydroxyphenyl)-2,2′-dihydroxy-1,1′-binaphthyl.[19] Although a possible transition state was proposed for this process which involved s-*trans*-complexed α,β-enal, the corresponding structure with the s-*cis*-complexed α,β-enal seems equally plausible, even though it would lead to the enantiomer of the observed product in each case. Probably for this reason, the s-*cis*-α,β-enal transition state was ignored. If the condition of formyl C–H···O hydrogen bonding is imposed on the Yamamoto BLA system, a unique explanation of the absolute stereochemical result emerges, as shown in **12** (Fig. 5) for the (*R*)-catalyst. A favorable hydrogen bond is only possible to the terminal aryloxy oxygen as is shown in Fig. 5. In **12** the α,β-enal is coordinated to boron in the s-*cis* form. Addition of the diene to the unobstructed *si* face of the α,β-enal (*i.e.* top face of **12** as viewed) then leads to the observed Diels–Alder adduct. This mode of addition minimizes steric repulsion involving the α-substituent of the α,β-enal and the cofacial neighboring π-aromatic ring in the transition state. This steric compression factor[8a] in the transition state clearly favors reaction *via* the s-*cis*-α,β-enal in this system.

Recently, Yamamoto has described another (*R*)-BINOL-based BLA Diels–Alder system (**13** in Fig. 5) which produces adducts of opposite absolute configuration in comparison with (*R*)-BINOL-based **12**.[20] A simple explanation for this difference is provided by the formyl hydrogen bonded transition structure shown in **13**, which contains the s-*cis*-complexed α,β-

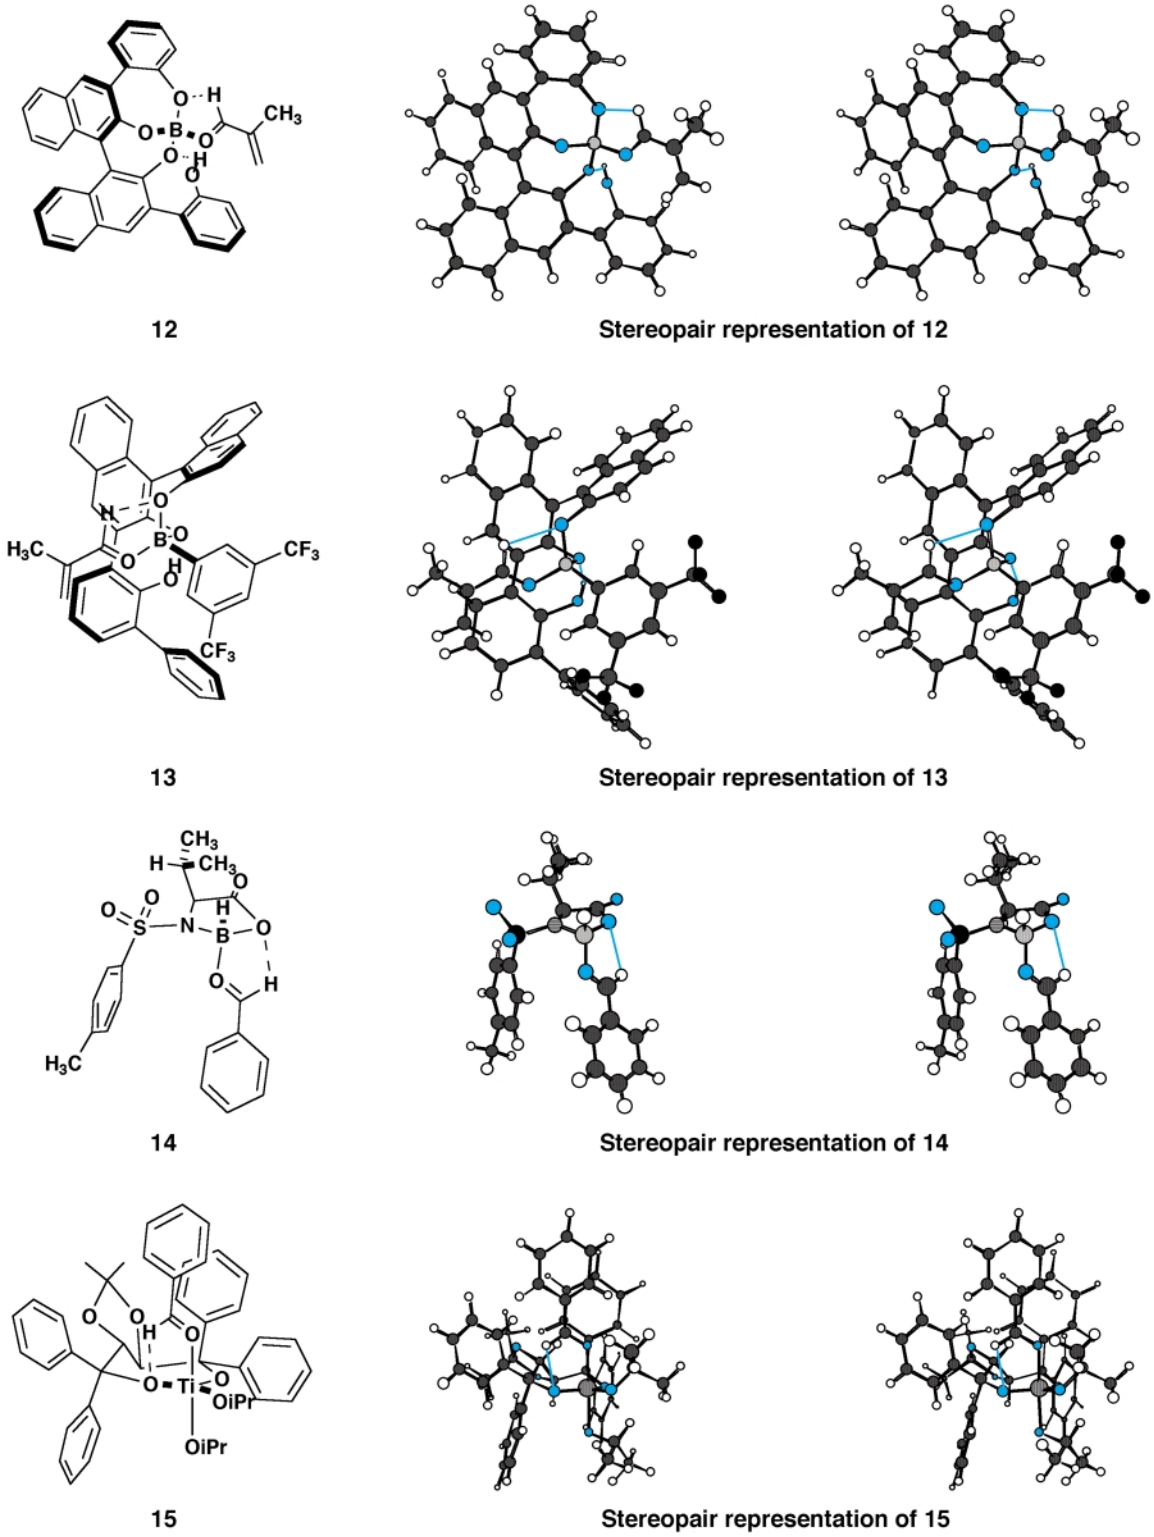

Fig. 5 Favored binding modes of Yamamoto's BLA catalysts (**12** and **13**), Kiyooka's oxazaborolidine catalyst (**14**) and Ti–TADDOL catalyst (**15**) with aldehyde substrates. (Blue circles represent oxygen atoms and blue lines represent hydrogen bonds.)

enal for the reasons described for **12**. Structure **13** is optimal with regard to favorable stereoelectronics for the hydrogen bond and conformation of the coordinated ligand.

Kiyooka and coworkers[21] have studied enantioselective Mukaiyama aldol reactions of aldehydes with various silyl enol ethers using an *N*-arylsulfonylvaline-derived oxazaborolidine catalyst. Structure **14** (Fig. 5) illustrates the proposed transition-state assembly in which the isopropyl and arylsulfonyl appendages are disposed *trans* to one another about the oxazaborolidine ring and in the sterically most stable arrangement. The aldehyde can coordinate to the face of boron *trans* to isopropyl, thereby minimizing steric repulsion and providing for the necessary hydrogen bonding between the formyl hydrogen and the oxazaborolidine oxygen. Preferential attack of the nucleophilic enol ether at the *si* face of the formyl group (corresponding to the front face in **14**) is predicted, in agreement with the experimental findings.[21] Kiyooka *et al.*[21a] have proposed a transition state which is the same as **14** with respect to the Lewis acid moiety, but which differs with regard to the absence of a formyl C–H···O hydrogen bond and the rotational orientation of the complexed aldehyde about the B–O bond (arbitrarily assumed by them).[22]

Seebach, Narasaka and coworkers have pioneered the use of titanium alkoxide catalysts containing a chiral tartrate-derived tetraaryl-1,3-dioxolane-4,5-diyldimethanol (TADDOL) bidentate ligand as a promoter of reactions of aldehydes with diethylzinc[23] and trimethylsilyl cyanide.[24] The transition-state assembly shown in **15** possesses the following features: (1) the pentacoordinate Ti has trigonal bipyramidal geometry with the TADDOL ligand bound to basal positions, both to minimize angle strain and to allow access to the Lewis acidic Ti by the aldehyde; (2) coordination of the aldehyde to Ti occurs through one of the two symmetry equivalent apical bonds (apical binding of the aldehyde is favored because it is the least basic ligand[25] and because it allows formyl C–H···O hydrogen bonding); (3) the orientation of the complexed aldehyde is fixed by a stereoelectronically favorable formyl C–H···O hydrogen bond and avoidance of steric repulsion with the axial phenyl group; (4) attack on the formyl group by the nucleophile EtZnX occurs at the more open *si* face of the formyl carbon, leading to the observed predominant product. The hydrocyanation of the benzaldehyde could also proceed *via* **15** with attack of cyanide ion on the *si* face of the formyl carbon, again in accord with experiment.[23,24] These models for the TADDOL-catalyzed ethylation and hydrocyanation of aldehydes are consistent with the less specific scheme proposed by Seebach and coworkers,[23] which does not contain the key formyl C–H···O hydrogen bond but which assumes a similar orientation of the complexed aldehyde. It should be pointed out that in the event that the aldehyde was coordinated to Ti in a basal position (unlikely because it is the most electronegative ligand[25]) the formyl C–H···O hydrogen bond would not be possible and little or no enantioselectivity would result.

Oguni and coworkers have introduced a chiral reagent which is derived from the reaction of titanium tetraisopropoxide with the Schiff base of 3,5-di-*tert*-butylsalicylaldehyde and (*S*)-valinol for the catalyzed reaction of aldehydes with diketene (aldol)[26] or trimethylsilyl cyanide.[27] The mechanistic basis for enantioselectivity in these cases has been unclear. Our analysis of the Oguni enantioselective diketene aldol reaction of aldehydes has led unequivocally to the favored transition-state assembly **16** which is shown in Fig. 6. In this structure there is octahedral hexacoordination to titanium with the three donor groups of the ligand coplanar with the metal, and the five-membered chelate ring is puckered to allow an equatorial[28] isopropyl group. Axial coordination of the aldehyde, so as to allow the best formyl C–H···O hydrogen bond, occurs at the top face of Ti in **16** (hydrogen bond to the axial lone pair on O). The enolate ligand is coordinated *cis* to the aldehyde to allow carbonyl addition *via* a six-membered chair transition state; the remaining isopropoxy ligand is *trans* to the coordinated aldehyde. In the model shown in **16** attack by the enolate occurs at the *si* face of the aldehyde to produce the (*S*)-aldol enantiomer, the observed product.[26] Switching the aldehyde and enolate ligands of **16** to the arrangement shown in **17**, does not allow good formyl C–H···O hydrogen bonding because each of the two lone pairs on the valinol oxygen of the tridentate chiral ligand is poorly positioned to interact with the formyl hydrogen.

Hydrocyanation of aldehydes using the (*S*)-Oguni catalyst, which also occurs by attack at the *si* face of the coordinated aldehyde, can be explained by a transition-state structure similar to **16** except for an isopropoxy replacing the enolate ligand. Rearward (*si* face) attack by CN^- then occurs on the rigidly held formyl group to give the observed (*R*)-cyanohydrin derivative.[27]

Kagan and coworkers have reported a Diels–Alder catalyst system derived from (*S*)-1,1-diphenyl-1,2-dihydroxypropane and $EtAlCl_2$ (1 : 1).[29] A linear relationship was demonstrated for $\ln R_e$ *vs.* $1/T$ where R_e is the ratio of enantiomeric products (*R*/*S*) and *T* is the Kelvin temperature, and values were obtained for $\Delta\Delta G^{\ddagger}$ (−0.74 kcal mol^{-1}), $\Delta\Delta H^{\ddagger}$ (−2.46 kcal mol^{-1}) and $-T\Delta\Delta S^{\ddagger}$ (+1.73 kcal mol^{-1}). The enthalpic barrier is lower for formation of the predominating enantiomer, but this is partly counterbalanced entropically due to the more ordered transition state for the major pathway. The most likely structure for the effective catalyst is the dioxaluminolidine **18** shown in Fig. 7. Steric repulsion between the adjacent phenyl and methyl substituents fixes the conformation of the five-membered dioxaluminolidine ring and thus orients one of the four oxygen lone pairs suitably for hydrogen bonding. This complex also minimizes steric repulsion between the aldehyde and the phenyl or methyl substituent and allows for a favorable π,π-attractive interaction between the positive formyl carbon and the neighboring phenyl group (spacing *ca.* 3.5 Å). The s-*trans* arrangement of the complexed dienophile can be expected to lead to a lower energy transition state than the s-*cis* form, because in the former there will be less repulsion between the α-methyl substituent of the dienophile and the phenyl of the catalyst in the transition state. As shown in **18**, the α-methyl group remains clear of the neighboring phenyl group as C(α) goes from sp^2 to sp^3 hybridization. Diene addition to the *si* face of **18** leads to the observed[29] predominating enantiomer. The high degree of organization in the transition state corresponding

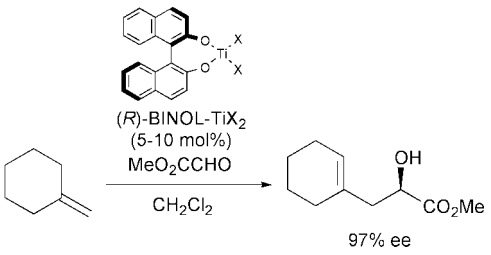
to **18** is consistent with the observed greater loss of entropy for the pathway leading to the major enantiomer.[29]

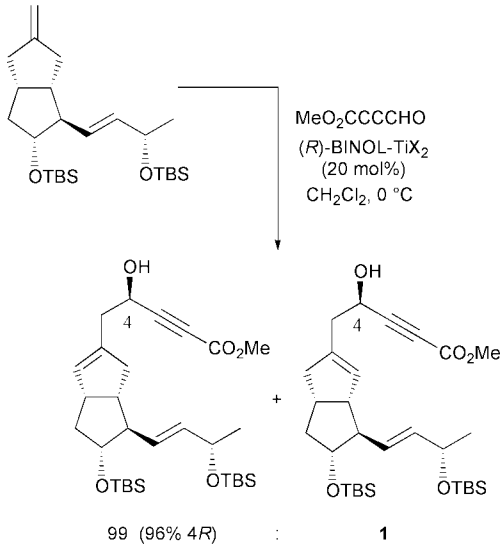
A highly enantioselective Diels–Alder reaction using a catalyst derived from diethylaluminum chloride and a substituted 2,2′-bi-1-phenanthrol (vaulted biphenanthrol, VAPOL) has been described by Wulff.[30] No transition-state structure was proposed, and indeed it is difficult to understand the absolute stereochemical course of this reaction without the organizing influence of a formyl C–H···O hydrogen bond. A favorable hydrogen bond is only possible in the arrangement depicted in **19** (Fig. 7). The addition of cyclopentadiene to the accessible *si* (front) face of the coordinated s-*cis*-2-methylacrolein leads to the correct absolute configuration of the observed major enantiomer.[30] In this case the α-methyl substituent of the dienophile is clear of the neighboring π-aromatic group in the s-*cis* but not in the s-*trans* rotamer, leading to faster reaction *via* the s-*cis* form.

One of the most interesting findings in the field of catalytic enantioselective synthesis is the development by the Mikami group of a family of enantioselective ene reactions between unusually electrophilic (*e.g.* glyoxylic) aldehydes and a series of terminal olefins under the influence of chiral Lewis acids, especially BINOL–TiX_2 (derived from 1,1′-bi-2-naphthol and $TiCl_2$(O*i*-Pr)$_2$ and 4 Å molecular sieves).[31,32] Numerous examples of the ene reaction have been described by Mikami which proceed with excellent enantioselectivity, as illustrated by the example shown in eqn. (1).[33]



(1)

In addition to the high facial selectivity of this process with regard to the aldehyde component, remarkable selectivity for the olefinic component with regard to π-facial attack and C–H cleavage has been observed, as shown in eqn. (2).[34] The detailed

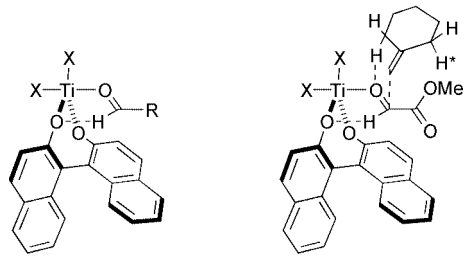


(2)

mechanistic basis for such high stereoselectivity has remained obscure, although a chair-like six-membered pericyclic transition state has been proposed for the $SnCl_4$-catalyzed diastereoselective reaction of glyoxylate esters and olefins, with the glyoxylate substrate chelated to the metal through the 1,2-dicarbonyl subunit.[31e,35]

A transition-state structure has been derived for the Mikami ene reaction by use of the following logical steps. (1) The aldehyde is activated by complexation with the chiral catalyst (*R*)-BINOL–TiX_2 *via* the formyl lone electron pair which is *syn* to the formyl hydrogen to form a pentacoordinate Ti structure. The comparable behavior of glyoxylic esters (eqn. (1)) and 3-methoxycarbonylpropynal (eqn. (2)) in the Mikami ene reaction argues against bidentate coordination of both carbonyl groups of glyoxylic esters since bidentate coordination is clearly not possible with the latter. (2) The resulting complex prefers trigonal bipyramidal geometry with the apical substituents being the coordinated aldehyde and one of the chlorines. This arrangement follows from the preference for the two most electronegative (*i.e.* weakest) ligands to be in the apical

positions for d^0 pentacoordinated structures such as Ti(IV) complexes.[25] (3) Formyl CH···O hydrogen bonding occurs to the stereoelectronically most favorable oxygen lone pair of the BINOL ligand to generate structure **20** (Fig. 8). In this structure,



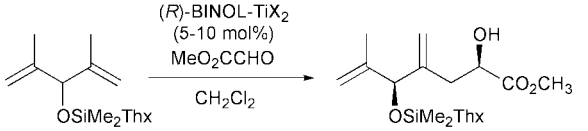
20 **21**

Fig. 8 Mechanistic rationale for the Mikami ene reactions.

the top (*re*) face of the formyl group is much more accessible to a nucleophile than the bottom (*si*) face since the latter is strongly shielded by the nearby naphthol subunit. Formyl C–H···O hydrogen bonding to the other BINOL oxygen is stereoelectronically and sterically disfavored (strong steric repulsion exists between the formyl group and the proximate naphthol ring). (4) The transition-state structure for the ene reaction is likely to involve some degree of proton transfer from the scissile allylic C–H to the formyl oxygen as the new C–C bond is being formed and the olefinic substrate is gaining positive charge β to the scissile C–H. Structure **21** exemplifies that type of transition-state structure for the reaction described in eqn. (1). It also predicts the absolute configuration of the Mikami ene product as shown in eqn. (1) and, as well, preferential cleavage of the allylic C–H shown rather than C–H* of **21**. Cleavage of C–H* is obviously unfavorable because it necessitates strong steric repulsion (clash) between the cyclohexane ring and the nearby basal chlorine ligand.

The favored transition-state structure **22** (Fig. 9) for the ene reaction described in eqn. (2) can be derived in the same way with the additional proviso that the face of the olefinic component which binds to the aldehyde is that on the convex side of the bicyclo[3.3.0]octyl ring pair. Structure **22** predicts the stereochemistry and structure of the product shown in eqn. (2).[36] The corresponding transition-state structure for forming the position isomeric olefin in the Mikami ene reaction is depicted in **23**. It is clearly very unfavorable because of a serious steric clash between the basal chlorine substituent and the proximate five-membered ring.

Mikami and coworkers have also applied the BINOL–$TiCl_2$ catalyzed ene reaction to the desymmetrization of a symmetrical diolefinic substrate as shown in eqn. (3).[37] Outstanding enantio-



(3)

>99% ee, >99% de

and diastereoselectivity were observed (> 99% ee and > 99% de). Our analysis leads to the proposed transition-state structure **24** (Fig. 10) as most favorable. In this structure the approach of the complexed aldehyde to the olefin occurs so as to minimize steric repulsion, with the bulky $SiMe_2Thx$ (Thx = thexyl, 1,1,2-trimethylpropyl) substituent remote and the small H* in proximity to the attacking electrophile, as indicated. An analogous transition state for reaction at the diastereotopic double bond is less stable than **24** for steric reasons. Transition-state structure **24** leads to the overall stereochemistry shown in eqn. (3).

Ene reactions such as those described herein are calculated to be exothermic by *ca.* 20 kcal mol^{-1}.[38] The reaction of the Lewis acid coordinated aldehyde will be much more exothermic—possibly 30 kcal mol^{-1}. Therefore, the transition state for the

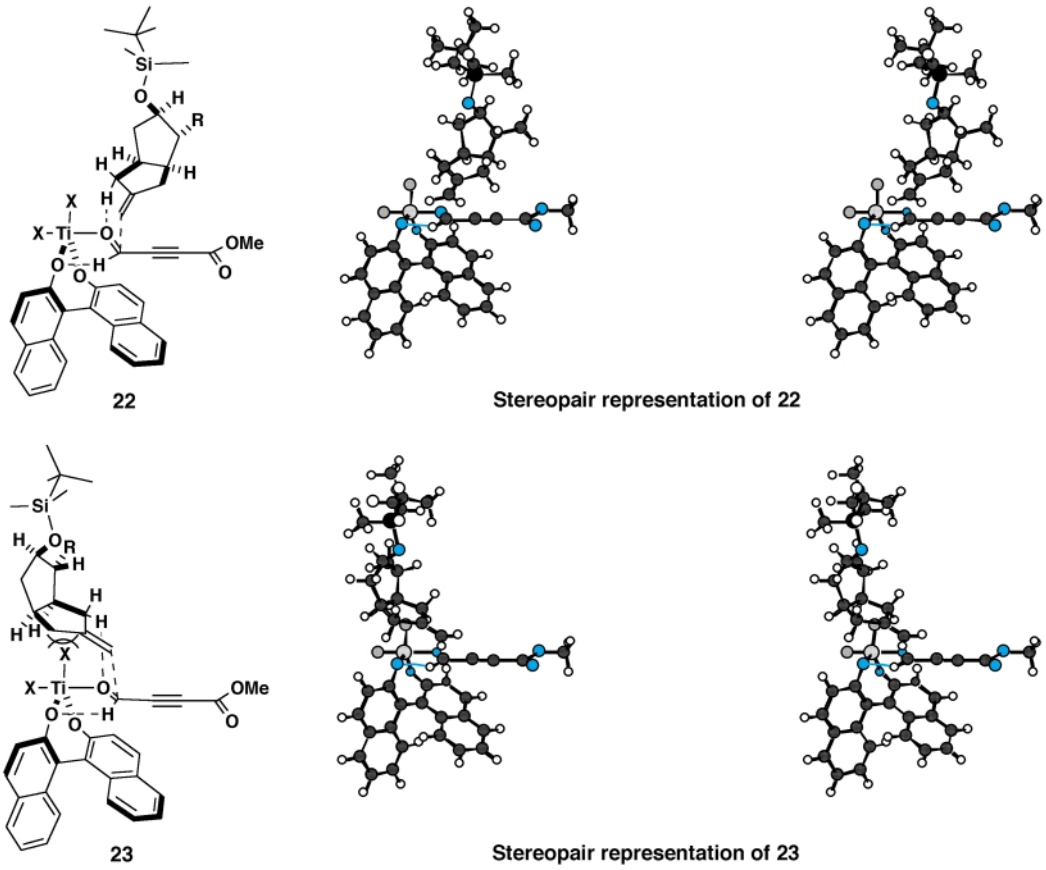


Fig. 9 Mechanistic rationale for the Mikami ene reaction shown in eqn. (2). (Blue circles represent oxygen atoms and blue lines represent hydrogen bonds.)

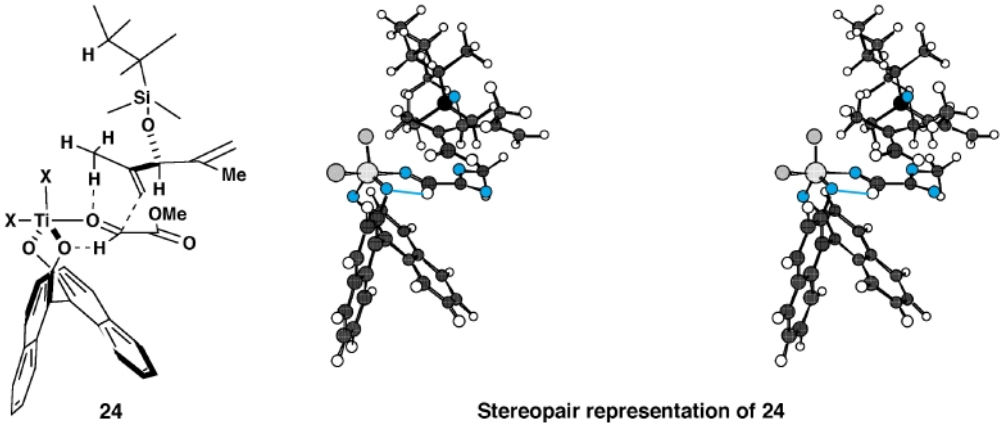

Fig. 10 Mechanistic rationale for the Mikami ene reaction shown in eqn. (3). (Blue circles represent oxygen atoms and blue lines represent hydrogen bonds.)

reaction of an unhindered olefin and a Lewis acid–aldehyde complex should be early, *i.e.* 'starting-material like', and the organizing structural elements in the complex are likely to be preserved in the transition state. Because highly organized, activated and sterically favored reactant complexes can lead to products *via* early transition states, the type of analysis presented herein should be valid since structural factors such as steric repulsions which disfavor alternative complexes also disfavor the corresponding transition states.

(*R*)- and (*S*)-BINOL–TiX_2 catalysts have also been utilized successfully to promote enantioselective Mukaiyama aldol, allylic silane mediated allylation and hetero-Diels–Alder reactions of glyoxylic esters.[39] The absolute stereochemical course of these reactions can be readily explained by the same considerations which are outlined herein for the Mikami ene reaction.

Conclusion

The understanding of the catalytic enantioselective reactions discussed in this appendix would be very difficult without some restriction of rotation of the bond between the catalytic Lewis acidic metal and the carbonyl group of the aldehyde. In each of approximately thirty known enantioselective reactions of aldehydes under chiral Lewis acid catalysis, the rational use of the formyl C–H···O hydrogen bond and strongly precedented structural principles has led to a transition-state assembly which predicts the observed absolute configuration of the predominating enantiomer. The success of the formyl C–H···O hydrogen bond idea in clarifying and unifying such a large and varied body of reactions, together with supporting evidence from X-ray crystallographic studies of formyl-Lewis acid complexes add credence to its validity. We believe that this formyl C–H···O hydrogen bonding concept will be useful in future catalyst design.

Doyle, JAI Press, Greenwich, Connecticut, 1995, vol. 1, pp. 123–149; (*d*) K. Mikami, M. Terada, S. Narisawa and T. Nakai, *Synlett*, 1992, 255; (*e*) K. Mikami and M. Shimizu, *Chem. Rev.*, 1992, **92**, 1021.

32 The exact structure of the effective Mikami catalyst is unclear. Since the presence of water in the 4 Å molecular sieves seems to increase catalyst effectiveness (with regard to rate and yield, but not necessarily with regard to enantioselectivity), the actual catalytic species could be BINOL–$TiCl_2$, BINOL–TiCl(OH), or BINOL–Ti(μ-O,μ-O)Ti–BINOL. In the following discussion, these catalysts are referred to generically as BINOL–TiX_2. See M. Terada, Y. Matsumoto, Y. Nakamura and K. Mikami, *Chem. Commun.*, 1997, 281.

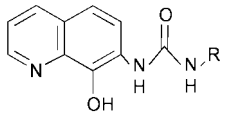
Received (in Cambridge, UK) 5th April 2001, Accepted 21st June 2001
First published as an Advance Article on the web 11th July 2001

8-Hydroxyquinoline derivatives HL[1] with urea moieties in the 7-position form hexa-stranded trinuclear coordination compounds with a helicate-type arrangement of the ligands; the chiral ligand HL[2] stereoselectively produces *P*-[$Zn_3(L^2)_6$].

Supramolecular architectures and molecular machines can be formed from simple components by self-assembly, which is controlled by the programming ('molecular recognition') which is encoded in the molecular building-blocks.[1] In this respect the control of stereo- and regio-chemistry during the self-assembly process is essential for the formation of specific, well-defined aggregates.[2]

Helicates are chiral di- or oligo-nuclear coordination compounds which are formed in self-assembly processes. One or more linear oligodonor ligand-strands wrap around the metal centers and thus possess a helical twist (left-handed *vs.* right-handed). Single-, double-, or triple-stranded helicates are obtained depending on the preferred coordination chemistry of the metal ions and on the kind of the ligands.[3] Only a few examples of analogous quadruple-stranded complexes are known.[4]

To our knowledge helicates with more than four ligand strands are not known although some complexes were described in which six ligands wrap around a metaloxo-cluster containing eight metal ions (M = Zn^{2+}, Cd^{2+}, Mn^{2+}) and two bridging μ_3-O^{2-} ligands.[5]



R = *n*-C_8H_{17}: HL^1
R = (*S*)-CH(Me)Ph: HL^2

The urea-substituted 8-hydroxyquinoline derivatives H**L** can be formed by reaction of 7-amino-8-hydroxyquinoline[6] with the *n*-octyl- or (*S*)-1-phenylethylisocyanate. Reaction of H**L** with zinc(II) acetate in methanol leads to zinc complexes which exhibit a metal/ligand ratio of 1:2. ^{1}H NMR spectroscopy (in $CDCl_3$) shows only one distinct set of signals for the coordinated ligand (Fig. 1) which possesses significant differences to those observed for the free ligand. For the zinc complex of $\mathbf{L}^1$ two signals are observed for the methylene unit which is attached to the urea-NH at δ 2.42 and 1.69 indicating diastereotopic behavior and thus a chiral environment. The remarkable high field shift of the protons in the 2- and 3-position of the alkyl chain [δ = 0.05 and 0.33 with $\Delta\delta$(ligand − complex) = 3.04 and 1.07] should be due to a close contact to the aromatic system of the hydroxyquinoline ligand. Indeed cross-peaks of alkyl signals with protons of the hydroxyquinoline can be observed by NOESY or ROESY NMR spectroscopy.

The complex of the chiral ligand $\mathbf{L}^2$ shows similar NMR spectroscopic features (Fig. 1) and a high optical rotation

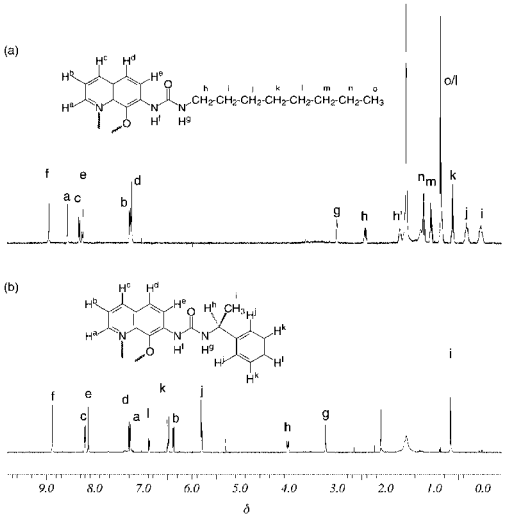


Fig. 1 ^{1}H NMR spectra of [$Zn_3(\mathbf{L}^1)_6$] (a) and *P*-[$Zn_3(\mathbf{L}^2)_6$] (b) in $CDCl_3$.

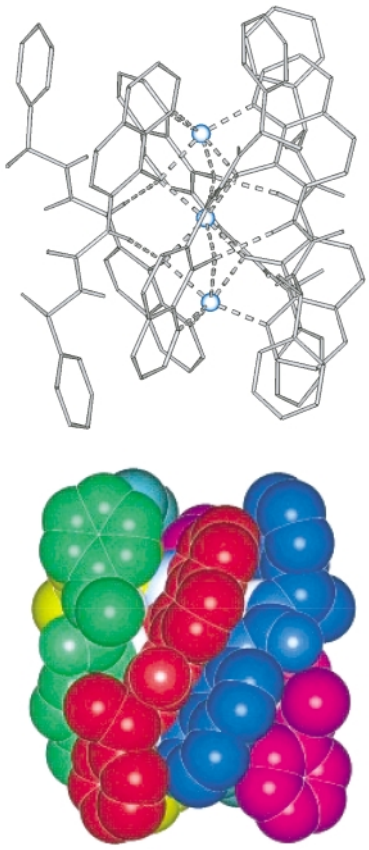

Fig. 2 Representations of the structure of *P*-[$Zn_3(\mathbf{L}^2)_6$] as found in the solid state, showing the helical arrangement of the six ligands around the three metal centers.

 DOI: 10.1039/b103090f

{$[\alpha]_D$ = −1762 (dioxane, c = 0.1); *cf.* **L²**: $[\alpha]_D$ = +27,6 (dioxane, c = 0.5)} which indicates a helical arrangement of the ligands in the complex.[7] The ^{1}H and ^{13}C NMR spectra reveal that this complex is formed in a highly stereoselective fashion; only one stereoisomer is present. The enantiomeric trinuclear zinc(II) complex of the corresponding (*R*)-configurated ligand leads to $[\alpha]_D$ = +1815 (dioxane, c = 0.1).

For the zinc(II) complex of the chiral ligand **L²** we obtained X-ray quality crystals from dioxane and the structural analysis shows that a trinuclear helicate-type complex $[Zn_3(\mathbf{L^2})_6]$ is formed.† Three zinc atoms are arranged linearly with the central atom possessing a separation of 2.884(3) and 2.879(3) Å to the two terminal ones. Six ligands are coordinating in a helical fashion to the metal centers with an alternating 'up' or 'down' orientation of the urea moieties (Figs. 2 and 3). Due to the chiral (*S*)-phenylethyl substituent *P*-helicity is induced at the hexa-stranded helix. This substituent at the urea is located close to the hydroxyquinoline units of a neighboring strand and thus leads to the anisotropic shifts found in the NMR spectra.

The complex $[Zn_3(\mathbf{L^2})_6]$ is made up from two terminal tris(8-hydroxyquinolinato) zinc complex units in which the chelating ligands are orientated *cis* to each other.[8] The three oxygen-donor atoms of each complex unit are located at facial positions and are able to bridge to the central zinc(II) ion (distances: O–$Zn_{terminal}$ 2.137–2.130 Å, O–$Zn_{central}$ 2.055–2.131 Å).[9,10] The trinuclear complex additionally is stabilized by interstrand hydrogen-bonding interactions between the aryl-NH protons and the quinolinato oxygen atoms. Thus, the oxygen-donors possess a tetracoordinated environment, bridging two metal centers and binding to one carbon and one hydrogen atom.

To summarise, we have presented the self-assembly of the first trinuclear hexa-stranded helicate-type complexes $[Zn_3(\mathbf{L})_6]$ from a total of nine components (six ligands and three metals). Alternatively, the compounds can be described as hexahelices made up from two interlocking triple-helical complexes '$[Zn(\mathbf{L})_3]^-$' connected by a zinc(II) ion and six hydrogen bonds. The unusual structure in the solid state is proven by an X-ray structure analysis of the chiral complex *P*-$[Zn_3(\mathbf{L^2})_6]$. NMR spectroscopy indicates that the same structure is present in solution and that the chiral complex *P*-$[Zn_3(\mathbf{L^2})_6]$ is formed highly stereoselective.

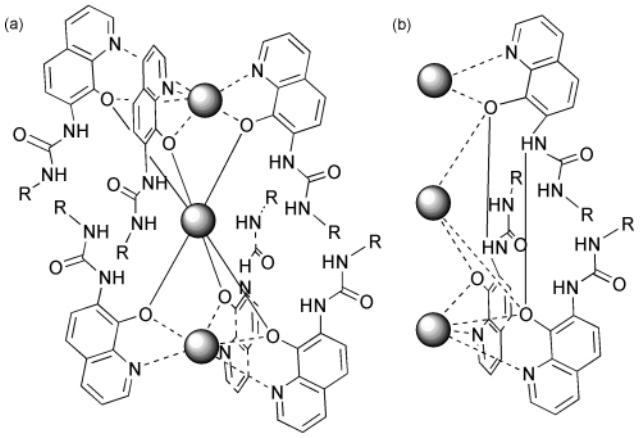

Fig. 3 Schematic representation of the structure of the complexes $[Zn_3(\mathbf{L})_6]$ (a), and the intramolecular interstrand hydrogen bonding (b).

Received (in Cambridge, UK) 17th January 2001, Accepted 12th June 2001
First published as an Advance Article on the web 4th July 2001

A hydrothermal polymerization and simultaneous sulfidation (HPSS) process and the mechanism for the fabrication of one-dimensional (1-D) nanocomposites of well dispersed CdS nanoparticles self-assembled in the polymer nanorods is presented.

Low dimensional, especially 1-D arrays of metal and semiconductor nanoparticles, owing to their potential applications in optical and electronic sensors,[1,2] nanoscale electronics,[2,3] and catalysis,[4] are receiving extensive attention. The synthesis and characterization of such materials, especially of inorganic–polymer nanocomposites has aroused much research interest.[5–7]

Many methods have been applied to prepare semiconductor–polymer nanocomposites with different sizes and/or morphologies. Meissner *et al.*[8] first reported a system involving dispersed semiconductor/polymer arrangements by physically embedding monograin CdS particles of *ca.* 40 μm diameter in a thin, nonconducting polyurethane membrane and various photoprocesses were examined. Marinakos *et al.* synthesized interconnected arrays of Au/polypyrrole colloids of 1-D morphology using Al_2O_3 membranes as the template.[9] However, few reports have appeared regarding the synthesis of coupled 1-D nanoparticle systems. Notable exceptions are 1-D strands of iron oxide particles used for navigation by magnetotactic bacteria,[10] self-organized 1-D CdS chains observed by Chemseddine *et al.*,[11] and dithiol-linked CdSe dimers and DNA-linked Au trimers synthesized by Alivisatos *et al.* [12]

Polymers have advantages over other templates due to the maintenance of the superstructures of the monomers during the polymerization. Thus, a series of inorganic–polymer composites with different sizes and morphologies can be synthesized.[13] Here we report a novel hydrothermal polymerization and simultaneous sulfidation (HPSS) process to fabricate 1-D CdS nanoparticle/poly(vinyl acetate) (PVAc) nanorod composites. This method is based on the mechanism that the polymerization of organic monomers and the formation of the CdS nanoparticles simultaneously take place in aqueous solution. The CdS nanoparticles were well dispersed in the PVAc nanorods to form 1-D composites.

In a typical experiment, 0.005 mol thioacetamide (taa) was added to 50 ml 2×10^{-2} mol l^{-1} $CdCl_2 \cdot 2.5H_2O$ aqueous solution in a Teflon lined autoclave of 60 ml capacity. Then 0.4 ml vinyl acetate (VAc) was added to the above solution. 0.008 g of 2,2′-azobisisobutyronitrile (AIBN) as initiator was then added. The autoclave was maintained at 80 °C for 12 h then allowed to cool to room temperature. The products were filtered off and washed with distilled water and absolute ethanol, dried in a vacuum at 60 °C, and collected for further characterization.

Powder X-ray diffraction (XRD) patterns for the products were collected on a Japan Rigaku D/max-γA diffractometer equipped with graphite-monochromatized high-intensity Cu-Kα radiation (λ = 1.51478 Å) at a scanning rate of 0.02° s^{-1} in the 2θ range 10–70°. IR spectra were measured on a Bruker Vector-22 FT-IR spectrometer from 4000 to 400 cm^{-1} at room temperature. Samples were ground with KBr and pressed into pellets. UV–VIS absorption spectra were recorded on a Shimadzu UV-2100 spectrophotometer scanning from 700 to 300 nm at room temperature with ethanol as the reference. TEM images were taken on a Hitachi H-800 transmission electron microscope, using an accelerating voltage of 200 kV. The samples were dispersed in absolute ethanol ultrasonically, then the suspension was dropped onto copper grids coated with amorphous carbon film.

A representative XRD pattern is shown in Fig. 1. All the diffraction peaks can be indexed to the wurtzite structure CdS with cell constants a_0 = 4.136, c_0 = 6.713 Å. The values are close to those in the JCPDS card (card No. 41-1049). Applying the Scherrer equation, the average crystallite size was estimated to be 10 nm. Although there is no apparent broad peak corresponding to the polymer matrix in the XRD pattern, which may be due to the low content of PVAc in the final product and the low crystallinity of PVAc, the existence of PVAc was fully verified by FT-IR spectroscopy. The presence of PVAc in the 1-D nanocomposite was also detected in TEM micrographs.

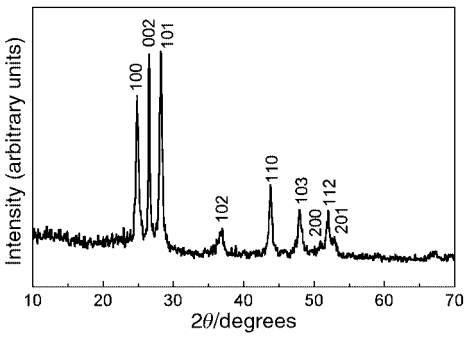

Fig. 1 XRD pattern of a CdS nanoparticle/PVAc nanorod composite fabricated by the HPSS technique at 80 °C for 12 h.

A representative FT-IR spectrum of a sample is illustrated in Fig. 2. The peak at 1739.4 cm^{-1} ($\upsilon_{C=O}$), and characteristic peaks at 1239.9, 1020.9 cm^{-1} (υ_{C-O}), and 1375.7 cm^{-1} (δ_{CH_3}) corresponding to PVAc are clearly seen. The IR spectrum is similar to the standard IR spectrum curve of PVAc (Sprouse collection of IR, card No. 187–189) and distinctly different from that of the VAc monomer (Standard IR Grating Spectra,

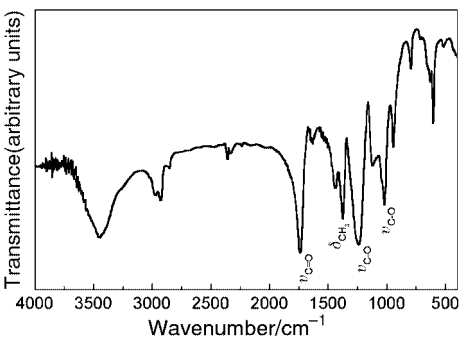

Fig. 2 FT-IR spectrum of the CdS/PVAc composite.

 DOI: 10.1039/b100632k

card No. 8112), which indicates the successful polymerization of VAc and confirms the existence of PVAc in the final product.

Fig. 3 shows a typical TEM micrograph of nanorods in the CdS/PVAc composite. The image shows that the nanorods are *ca.* 75 nm in width and several hundred nm in length. The average crystalline size for the CdS particles in the polymer nanorods is *ca.* 13 nm, well consistent with that calculated by the Scherrer equation from half-widths of the diffraction peaks. Because polymers show low contrast in TEM micrographs, light areas in the spaces among the CdS nanoparticles suggest the existence of PVAc in the composite.

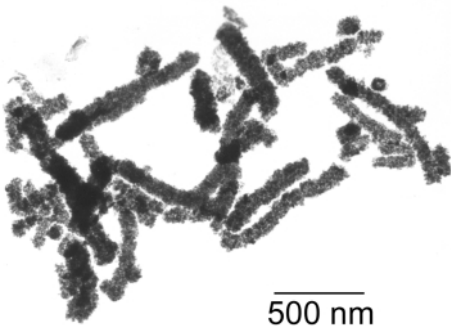

Fig. 3 TEM micrograph of the CdS/PVAc nanocomposite.

According to a typical UV–VIS spectrum, the wavelength of the maximum absorption peak, λ_{max}, for the CdS nanoparticles in the CdS/PVAc nanorod composite is at *ca.* 478 nm, which is blue shifted relative to that for bulk CdS, 515 nm.[14] This can be explained as due to a size confined effect as a result of the tiny dimensions of the nanoparticles in the CdS/PVAc composite.

It is well known that the radical initiator AIBN decomposes at 45–65 °C, according to eqn. (1).

(1)

The produced radicals initiate the polymerization of VAc. Accompanying the polymerization, CdS nanoparticles are also simultaneously formed by the hydrolysis of taa as described in eqns. (2) and (3).

(2)

(3)

The formation of VAc emulsions, the subsequent maintenance of the superstructure by polymerization, the simultaneous sulfidation of Cd^{2+}, and the sticking of polymer spheres explain the self-assembly of the 1-D CdS nanoparticles/PVAc nanorod composites. In 1962, a spherical morphology of PVAc was reported by Napper, *et al.* when the monomer, VAc, was polymerized thermally.[15] Computer simulations of the development of rodlike semiconductor–polymer hybrids from hybrid spheres was reported by Stoll and Buffle.[16] In the present HPSS process, VAc emulsions are formed in aqueous solution.[17] At the same time, Cd^{2+} cations originally coordinated to carboxyl groups in the monomer react with released S^{2-} to form CdS clusters. With increasing reaction time, VAc emulsions are polymerized into PVAc spheres. Owing to their glutinosity the PVAc spheres stick together to form polymer nanorods. The increasing viscosity of these polymer nanorods inhibit growth of the CdS nanoparticles. This mechanism is further suggested by the fact that spherical CdS/PVAc nanocomposites are observed in samples reacted for only short reaction times.

In summary, a hydrothermal polymerization and simultaneous sulfidation (HPSS) process to prepare CdS nanoparticle/poly(vinyl acetate) nanorod composites has been presented. CdS nanoparticles of *ca.* 10 nm were self-assembled and well dispersed in the nanorods of PVAc to form 1-D nanocomposites. The experiments indicated that the 1-D morphology was favored by agglomeration of several PVAc spheres. The polymerization of VAc turns the VAc emulsions into polymer spheres and prevented further growth of CdS nanoparticles. The present HPSS technique may provide a new route to prepare other 1-D metal sulfide semiconductor–polymer hybrid nanocomposites.

This work was supported by the Nation Science Foundation of China. Kun-song Chen, Xian-ming Liu, and Wan-qun Zhang are gratefully thanked for their help on the IR, TEM and XRD measurements.

Strong evidence for stereoselective 1,3-additions of transient nitrilium phosphane-ylide complexes: synthesis of the first 1-aza-3-phosphabuta-1,3-diene complexes†

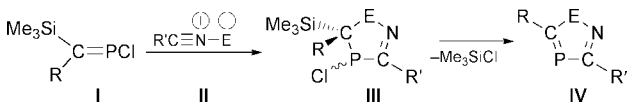
First published as an Advance Article on the web 4th July 2001

Synthesis of the first 1-aza-3-phosphabuta-1,3-diene complexes was achieved by heating solutions of 2*H*-azaphosphirene tungsten complexes, 1-piperidinonitrile and [bis(trimethylsilyl)methylene]chlorophosphane; X-ray structure analysis of one new complex revealed a *cisoid* position of the chlorine atom and the phosphaalkene unit at the C,N,P-core of the trapped nitrilium phosphane-ylide complex and a distorted heterobutadiene π-system.

[3+2] cycloaddition reactions of *P*-chlorophosphaalkenes[1] **I** with nitrilium betaines **II** such as nitrile ylides[2] and sulfides[3] are very useful in phosphorus heterocycle synthesis, especially if an elimination of chlorotrimethylsilane occurs subsequently (**III** → **IV**), thus yielding aromatic heterocycles **IV** (Scheme 1). Recently, we reported trapping reactions of nitrilium phosphane-ylide complexes with alkynes,[4] nitriles[5] and phosphaalkynes[6] giving five-membered phosphorus heterocycle complexes. If phenylacetylene was used as trapping reagent and solvent we obtained a product mixture that consisted of a 1*H*-phosphirene and a 2*H*-1,2-azaphosphole complex and two acyclic compounds, which, at least formally, resulted from two differently orientated 1,3-addition reactions of the C–H bond of phenylacetylene to the 1,3-dipole system of a transient nitrilium phosphane-ylide complex.[7] Because of this complicated situation, we were not sure about the mechanism and/or the concertedness of these 1,3-addition reactions.

Here we report the synthesis of the first 1-aza-3-phosphabuta-1,3-diene complexes using our thermal three-component methodology: 2*H*-azaphosphirene complexes, 1-piperidinonitrile and a *P*-chlorophosphaalkene. The products were obtained in pure form by column chromatography and fully characterized by various means; one complex was characterized additionally by an X-ray diffraction study.

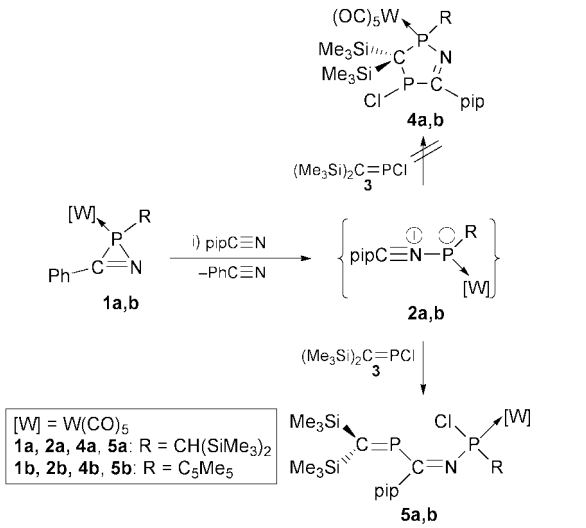
Heating toluene solutions of the 2*H*-azaphosphirene tungsten complexes **1a**[8] and **1b**[9] with 1-piperidinonitrile and [bis-(trimethylsilyl)methylene]chlorophosphane[10] (**3**) for 2 h afforded selectively the 1-aza-3-phosphabuta-1,3-diene complexes **5a,b** as trapping products of the transiently formed nitrilium phosphane-ylide complexes **2a,b** (Scheme 2). Complexes **5a**,**b** were confirmed by elemental analyses, NMR spectroscopy and mass spectrometry.‡ Only traces (< 5%) of other phosphorus-containing products were observed by ^{31}P NMR spectroscopy displaying resonances at δ 106.2 and 337.4 (reaction of **1a**) and at δ 104.1 and 349.9 (reaction of **1b**); complexes **4a**,**b** could not be detected. It is remarkable that the attack at the P–Cl σ-bond is preferred to that at the π-system of the *P*-chlorophosphaalkene, which might be caused by strong steric repulsion between the substituents of the carbon centre of the P=C unit and those of the phosphorus centre of the 1,3-dipole in the transition state of the cycloaddition reaction; if this interpretation of the reaction course is correct this example would be unprecedented in nitrilium betaine chemistry.



Scheme 1 Phosphaalkenes **I**, nitrilium betaines **II** and phosphorus heterocycles **III**, **IV** (**I–IV**: R, R′ = organic substituents; E = CR_2 or S).

† This work is dedicated to Professor Henning Hopf on the occasion of his 60th birthday.

The ^{31}P NMR spectra of complexes **5a**,**b** showed resonances at low field (**5a**: δ 339.5, $|^3J(PP)|$ 15.5 Hz; **5b**: δ 342.3, $|^3J(PP)|$ 8.0 Hz), which can be assigned to the phosphaalkene nuclei, and those at higher field (**5a**: δ 111.8, $|^3J(PP)|$ 15.5, $|^1J(PW)|$ 284.7 Hz; **5b**: δ 112.9, $|^3J(PP)|$ 8.0 Hz, $|^1J(PW)|$ 305.1 Hz) to the *N*-bonded phosphorus nuclei. With respect to the resonances of the low-coordinated phosphorus centres, the ^{31}P NMR data of **5a**,**b** are quite different from those found for non-coordinated 1-aza-3-phosphabuta-1,3-dienes, which have been synthesized using trimethylsilyl shift reactions, and which show resonances in the range δ 0–100.[11,12] These differences are probably associated with the different substituents at the P=C carbon atoms, which, in our case, represent acceptor groups and in the other cases donor groups. The structure of the complexes **5a**,**b** were unambiguously confirmed by the ^{13}C{^{1}H} NMR spectra, which displayed resonances of the C=N and C=P carbon atoms with two phosphorus–carbon couplings each, whereby the greater magnitude values establish the direct bonding of one phosphorus centre to two different sp^2-carbon centres. The molecular structure of complex **5a** (Fig. 1), as established for the solid state by X-ray crystallography,§ shows a significantly distorted heterobutadiene π-system [N(1)–C(6)–P(2)–C(7) −106.6°] with bond lengths typical of localized double bond systems



Scheme 2 *Reagents and conditions*: 615 mg of complex **1a** or 534 mg of complex **1b**, 100 μL 1-piperidinonitrile, 449 mg phosphaalkene **2**, 2.5 mL toluene, 75 °C, 2 h; column chromatograpy (Al_2O_3, −20 °C, *n*-hexane); **5a**: yellow solid, yield: 44%, mp 128 °C (decomp.); **5b**: yellow solid, yield: 34%, mp 118 °C (decomp.).

 DOI: 10.1039/b102250b

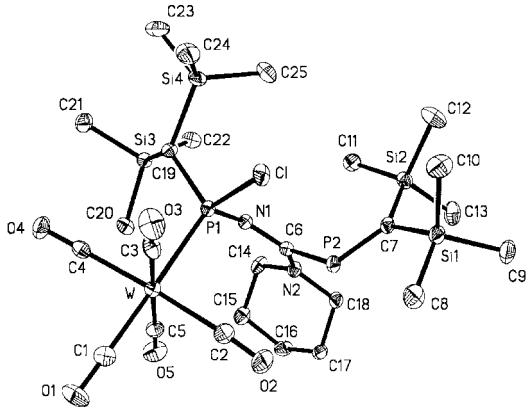


Fig. 1 Molecular structure of **5a** in the crystal (ellipsoids represent 30% probability levels; hydrogen atoms are omitted for clarity). Selected bond lengths (Å) and angles (°): W–C(1) 1.999(6), W–P(1) 2.5332(13), P(1)–N(1) 1.626(4), P(1)–C(19) 1.820(4), N(1)–C(6) 1.303(5), P(2)–C(6) 1.880(5), N(2)–C(6) 1.333(6), P(2)–C(7) 1.669(5); C(1)–W–P(1) 178.43(15), W–P(1)–C(19) 116.35(16), P(1)–N(1)–C(6) 134.4(3), N(1)–C(6)–P(2) 119.2(3), C(6)–P(2)–C(7) 110.7(2).

[N1–C6 1.303(5) and P2–C7 1.669(5) Å]. The P(2)–C(6) distance 1.880(5) Å represents a P–C single bond (average value: 1.885).[13] The coordination environment of the P1 atom is tetrahedral with a P1–Cl distance of 2.143(1) Å and a P1–W distance of 2.5323(16) Å. Furthermore, the structure confirmed the *cisoid* position of the chlorine atom and the phosphaalkene unit at the C,N,P-core of the trapped nitrilium phosphane-ylide complex and thereby strengthened the assumption of a concerted 1,3-addition process that is responsible for the product formation.

Currently we are investigating the role of sterically less bulky P-substituents of transient nitrilium phosphane-ylide complexes (*cf.* ref. 4*c*), in three-component reactions on the reaction course.

We are grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

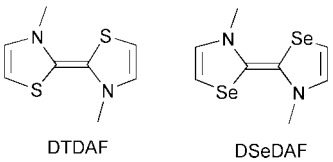
First published as an Advance Article on the web 27th June 2001

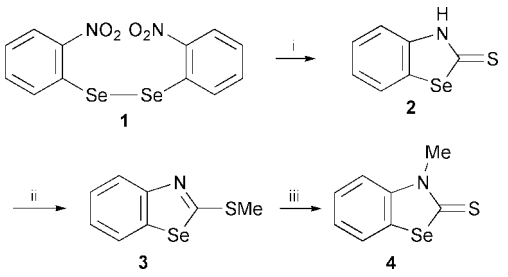
The first diselenadiazafulvalene has been chemically synthesised and electrochemically characterised, it presents similar air sensitiveness to its sulfur analogue and affords a spiroamide derivative upon oxidation as confirmed by its crystal structure.

Among the numerous π-donor molecules described in the literature as precursors of organic materials various heterocyclic derivatives have been studied, mainly conjugated frameworks including sulfur atoms, such as tetrathiafulvalene (TTF).[1] Several modifications of the TTF skeleton have been performed, for example replacement of two sulfur atoms by nitrogen atoms has led to dithiadiazafulvalene (DTDAF) derivatives which have recently attracted attention owing to their high electron donating properties.[2] DTDAFs present the disadvantage of being air-sensitive in the neutral form but they can be trapped *in situ* by organic or inorganic acceptors and form molecular materials.[3] As the physical properties of organic materials are close-knit to molecular assembly, it was thus of interest to replace the sulfur atoms by selenium atoms, in order to increase the interactions between the donor cores. Otherwise diselenadiazafulvalene (DSeDAF) should exhibit properties close to DTDAF. Herein, we report the synthesis and the electrochemical behaviour of the first DSeDAF, namely benzo-DSeDAF, starting from selenazole moieties.



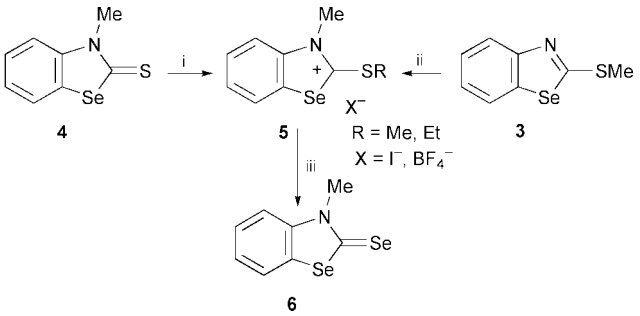
Compared to the chemistry carried out on 1,3-thiazole ring systems, 1,3-selenazole derivatives have been scarcely studied recently. Indeed, and as pointed out by Bogert *et al.*, selenazole derivatives are rather more difficult to prepare and less stable than their sulfur analogues.[4] Our approach for the synthesis of the 1,3-selenazole core consists of the preparation of bis(*o*-nitrophenyldiselenide) **1** starting from *o*-nitroaniline.[5]

We improved the chemical pathway to prepare benzo-1,3-selenazole-2(3*H*)-thione **2** by reaction of bis(*o*-nitrophenyldiselenide) **1** with sodium hydrosulfide in basic medium followed by the addition of carbon disulfide as described in Scheme 1.[6] Alkylation of **2** in the presence of base and methyl iodide led to 2-methylthiobenzo-1,3-selenazole **3**.[7] Preparation of the sulfur analog of **4**, the 3-alkylbenzo-1,3-thiazole-2(3*H*)-thione by rearrangement of 2-alkylthiobenzo-1,3-thiazole in the presence of a catalytic amount of iodine has been described.[8] Thus, we investigated the possibility of forming 3-methylbenzo-1,3-selenazole-2(3*H*)-thione **4** using the same strategy starting from **3**. Heating a mixture of **3** with iodine at 200–220 °C gave **4** in 67% yield (Scheme 1). Selenazole-2(3*H*)-thione **4** does not undergo intermolecular coupling by treatment with tertiary phosphorus derivatives. Therefore, we converted **4**,



Scheme 1 *Reagents and conditions*: i, NaSH, NaOH, CS_2, H_2O, reflux, 90%; ii, MeI, NEt_3, CH_2Cl_2, rt, 93%; iii, I_2, 200–220°C, 67%.

in the presence of boron trifluoride diethyl etherate and triethyl orthoformate into 2-alkylthiobenzo-1,3-selenazolium salts **5**, following literature precedent for thiazole derivatives.[2] Another method for the preparation of this salt **5** utilises the alkylation of **3** with methyl iodide (Scheme 2).

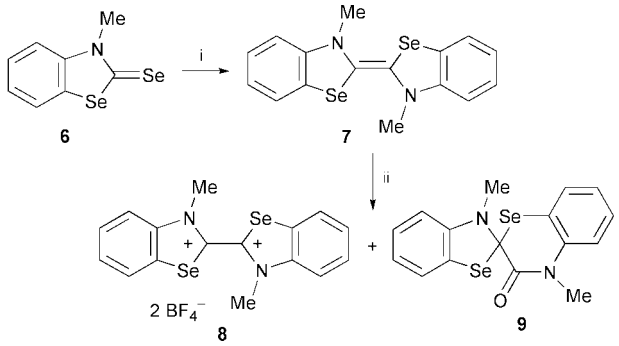


Scheme 2 *Reagents and conditions*: $BF_3{\cdot}Et_2O$, $CH(OEt)_3$, $CHCl_3$, reflux, 97%; ii, MeI, reflux, 81%; iii,NaHSe, EtOH, rt, 95%.

Then, we treated 2-alkylthiobenzo-1,3-selenazolium salts **5** with sodium hydrogen selenide and we isolated the 3-methylbenzo-1,3-selenazole-2(3*H*)-selone **6**.† Coupling of **6** in the presence of triethyl phosphite in refluxing toluene under an inert atmosphere afforded DSeDAF **7**. Formation of this novel π-donor molecule can be observed by the important change of colour of the medium, due to the formation of a conjugated framework (Scheme 3).

Presence of electroactive species can be confirmed by cyclic voltammetry directly on the medium where the donor was formed.[9] Therefore after the chemical coupling of **6** in the presence of triethyl phosphite we added, under inert atmosphere, a degassed solution of tetrabutylammonium hexafluorophosphate in CH_2Cl_2 and we performed electrochemical investigations. Two reversible monoelectronic waves are observed at low potentials on the cyclic voltammogram and are associated with the redox behaviour of the DSeDAF formed in the medium. They correspond respectively to the formation of the radical cation and dication of **7** (E_{pa1} = −0.07 V and E_{pa2} = +0.09 V *vs* SCE) and indicate an extremely good donor character of benzo-DSeDAF. These oxidation potentials are

 DOI: 10.1039/b101757h



Scheme 3 *Reagents and conditions*: i, $P(OEt)_3$, toluene, reflux; ii, $AgBF_4$, THF, rt.

slightly higher than the one observed for the benzo-DTDAF[10] also obtained *in situ* following the same experimental procedure (E_{pa1} = −0.15 V and E_{pa2} = +0.05 V *vs* SCE). In order to prepare the dicationic salt of benzo-DSeDAF, chemical oxidation was performed by adding a solution of $AgBF_4$ in the medium where **7** was formed. The first dicationic, benzo-DSeDAF **8**, was obtained as its BF_4 salt together with a minor amount of a neutral compound (Scheme 3). ^{1}H NMR data and X-ray crystal structure determination of the latter proved this compound to be the spiroamide **9**.‡ As shown Fig. 1, the 4-methylbenzo-2*H*-1,4-selenazin-3(4*H*)-one ring is folded along the Se2–C4 vector, where the angle between the planes formed by Se2, C3, C7, N2, C4 and Se2, C1, C4 is 122.3 (2)° and N2 lies 0.200(3)Å from the first plane. The benzoselenazole system is not planar owing to a slight fold along the Se1–N1 vector leading to a torsion angle of 155.3(3) ° between the two planes formed by Se1, C2, C6, N1 and Se1, C1, N1, respectively.

The behavior of **7** is closely related to what was observed with its sulfur analogue the benzo-DTDAF. Indeed, in the presence of air benzo-DTDAF is easily oxidised and converted into the spiro amide derivative or further into a ten-membered ring compound.[11–13]

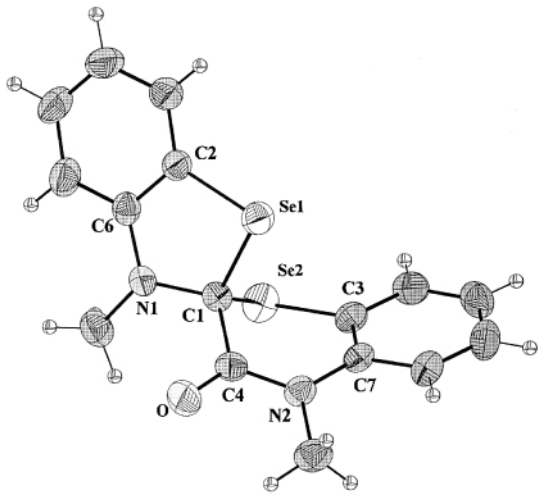


Fig. 1 Molecular structure of spiroamide **9** (50% displacement ellipsoids).

In summary, a novel heterocyclic donor has been synthesised, namely the benzo-DSeDAF, opening a route to a new family of π-donor molecules. This derivative exhibits similar redox behaviour and air-sensitivity to its sulfur analogue. Work is currently in progress in order to trap this derivative with appropriate acceptors and to analyse the potentialities of this new type of donor.

We thank Thierry Roisnel for performing the X-ray diffraction data collection.

The pK_a value of arrayed carboxy groups and that of groups dissolved in solution can easily be determined by electrochemical desorption of a self-assembled monolayer of carboxy-terminated thiols in aqueous solutions.

Monolayers composed of closely packed organic species are of great interest as models of biomembranes. In particular, monolayers containing acidic and basic groups are useful for understanding roles of those species in various functions of cell membranes, such as cell fusion, enzymatic catalysis, and ion transfers. One of the well-known specific properties of closely arrayed groups is that acidities of groups like carboxy and amino are different from their original values. Such behaviour has been first found by potentiometric titration of micellar solutions of various surfactants.[1] A self-assembled monolayer (SAM) of alkanethiols adsorbed on a gold surface provides another monolayer system. Ease of preparation of the organized monolayer with high reproducibility and high stability of the resulting monolayer facilitate investigation of the properties of monolayers.[2] If alkanethiols substituted by functional groups at ω-positions are used, one can prepare a surface in which the functional groups are closely arrayed. In this case also, determination of acidity of the arrayed groups is currently attracting great attention. To detect properties of the delicate monolayer surfaces special techniques must be adopted, paying deliberate attention to such matters as measurements of contact angles of water drops on the thiol-SAM,[3] the double layer interaction measurements using the atomic force microscope,[4] double layer capacitance measurements by AC impedance spectroscopy,[5] and quartz crystal microbalance measurements.[6] In some cases, the help of difficult theory and calculations is needed to determine the desired parameters. We would like to show herein that electrochemical desorption reaction of a thiol-SAM measured by conventional voltammetry becomes a useful method to evaluate acidity, *i.e.* pK_a, of the groups substituted to the terminals of alkanethiols. This method allows direct determination of not only pK_a value of the arrayed groups but also that of the groups dissolved in solution simultaneously from the obtained titration curve. In this paper, a typical method is introduced by showing the results obtained for a SAM of 3-mercaptopropionic acid (MPA) formed on a gold substrate.

The gold substrate used in this study was an Au-coated mica having a quasi (111) surface [Au(111)], which was prepared by vacuum evaporation of Au.[7] The mica sheet was heated at 300 °C for at least 2 h prior to evaporation and heating was maintained during deposition and post-annealing for 1 h. Formation of a MPA-SAM on the Au(111) electrode was conducted by immersion of the electrode in an ethanolic solution containing 1 mmol dm^{-3} MPA for 1 h. The resulting electrode is denoted here as MPA/Au(111). Reductive desorption experiments were carried out in 0.1 mol dm^{-3} phosphate buffer solutions prepared by using Milli-Q gradient A10 water (ρ > 18.2 MΩ cm). The electrolysis cell was a one-compartment cell having Ag/AgCl in KCl-saturated aqueous solution and a Pt foil electrode as reference and counter electrodes, respectively. The MPA/Au(111) electrode was placed at the bottom hole of the cell with a Teflon-coated O-ring, giving an effective surface area of 0.4 cm^2.[7]

Fig. 1 shows linear sweep voltammograms of the MPA/Au (111) electrodes taken at 200 mV s^{-1} in buffer solutions having pH 3.57, 5.98, 7.04, 8.04, 8.85, and 9.97. The cathodic waves representing reductive desorption of MPA-SAM appeared and their peak potentials were negatively shifted with increasing pH of the electrolyte solution. In general, the reductive desorption of an alkanethiol-SAM was made by using highly alkaline solutions.[8] In those cases, the reaction can be formulated as Au–S–R + e$^-$ → Au + $^-$S–R where R denotes an alkyl group. However, since pH values of the solutions chosen in this study were smaller than pK_a of thiol group in MPA, which is 11,[9] the group must be protonated when MPA is dissolved in the solutions. As a result, the desorption reaction can be given by eqn. (1).

$$\text{Au–S–R} + e^- + H^+ \rightarrow \text{Au} + \text{HS–R} \quad (1)$$

This equation including one proton and one electron predicts negative shifts of the reaction potential with an increase in pH of the electrolyte solution. The integration of each current peak shown in Fig. 1 gave a charge density of 71 (± 4) × 10^{-6} C cm^{-2}, allowing an estimate of the amount of adsorbed MPA to be 0.74 (± 4) × 10^{-9} mol cm^{-2}. The obtained values were close to the coverage (0.77 × 10^{-9} mol cm^{-2}) expected for a ($\sqrt{3} \times \sqrt{3}$)R30° overlayer structure of alkanethiols on a Au(111) surface.[8]

Plots of cathodic peak potentials as a function of pH of the electrolyte solution gave the relationship shown in Fig. 2. Since the obtained graph has two distinct bending points at pH = 4.3 and 7.5, the pH regions of pH < 4.3, 4.3 < pH < 7.5, and 7.5

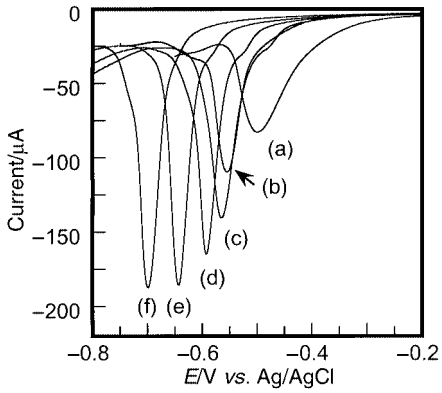

Fig. 1 Linear sweep voltammograms of MPA/Au(111) electrodes taken at 200 mV s^{-1} in 0.1 mol dm^{-3} phosphate buffer having pH of (a) 3.57, (b) 5.98, (c) 7.04, (d) 8.04, (e) 8.85, and (f) 9.97.

 DOI: 10.1039/b102601c

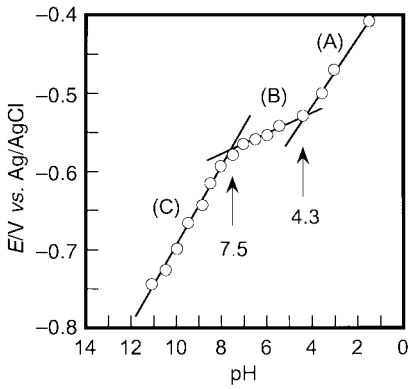

Fig. 2 Plots of peak potentials of cathodic waves due to reductive desorption of MPA as a function of pH of the electrolyte solution.

< pH are denoted here as the regions (A), (B), and (C), respectively. At the regions (A) and (C), linear relations were observed and the same slope of −50 mV per pH unit was estimated. If the eqn. (1) occurs, the experimentally obtained slope was a little smaller than the value (−59 mV per pH unit) expected from the Nernst equation. In the case of the reductive desorption of the thiol-SAM, protons in the electrolyte solution need to penetrate through the closely packed alkyl chains of the thiols in the initial stage. It is then suggested that some time is required for the pH around the sulfate groups to become the same as that of the solution bulk. Such kinetic factors seem to be the cause of differences between the experimentally obtained slope and the theoretical one.

The finding that one of the bending points appeared at pH = 4.3 coincident with the pK_a value of carboxy group of MPA,[9] allowed us to regard R in eqn. (1) as $(CH_2)_2$–COOH and $(CH_2)_2$–COO^- at the regions (A) and (C), respectively. However, a small pH dependence of −10 mV per pH unit was observed at the region (B). As mentioned in the introductory remarks, closely arrayed carboxy groups possess pK_a values that differ from the original. In the case of the MPA-SAM on Au(111) electrode, values ranging from 5.8 to 8 were evaluated by atomic force microscopy,[4] AC impedance,[5] and quartz crystal microbalance measurements.[6] If such a phenomenon is considered, one can imagine that there is a pH region where carboxylic acid groups in MPA-SAM are protonated but deprotonated in the solution. By combining this idea with the reductive desorption reaction given by eqn. (1), the reaction given in eqn. (2) is appropriate at that pH region.

$$Au–S–(CH_2)_2–COOH + e^- \rightarrow Au + HS–(CH_2)_2–COO^- \quad (2)$$

The deprotonation of the carboxy group and protonation of the generated thiolate take place simultaneously, resulting in the exclusion of protons from the reaction. The reaction having lower pH dependence observed at the region (B) is attributable to the reaction given by eqn. (2) and pH = 7.5 where another bending point appeared can be regarded as the pK_a value of the carboxy groups in MPA-SAM. Nevertheless a pH dependence of −10 mV per pH unit was observed at this region, but this might be also due to the kinetic factors mentioned above.

The desorption experiments were made at 10, 50, and 200 mV s^{-1}. The peak potential was positively shifted with a decrease in the sweep rate because of abatement of potential drop in the monolayer, as already shown in our previous paper.[10] Interestingly, however, the titration curves obtained from the voltammograms taken at different sweep rates (see Fig. S1) exhibited bending points at the same pH within experimental errors of ± 0.1, indicating that the above-mentioned kinetic factors did not affect pK_a values estimated by this method. The investigations aiming to elucidate the kinetic factors and applicability of the method developed in this study are underway.

We thank Dr Araki Masuyama for stimulating discussions. This research was supported by CREST of JST (Japan Science and Technology Corporation) and by the Millennium Project (No. 12310) from the Ministry of Education, Culture, Sports, Science and Technology, Japan.

First published as an Advance Article on the web 4th July 2001

Masked *o*-benzoquinones bearing a chiral center in the carbon-tether with a terminal olefin underwent diastereoselective intramolecular Diels–Alder reactions resulting in highly functionalized tricyclic ring systems.

The intramolecular Diels–Alder (IMDA) reaction is a powerful tool for the rapid construction of highly substituted polycyclic carbon skeletons.[1] Milder reaction conditions and superior reactivity and selectivities are often experienced as a result of the entropy factor in IMDA reactions in comparison to bimolecular Diels–Alder reactions. Recently, we have reported the IMDA reactions of masked *o*-benzoquinones (MOBs)[2] and masked *p*-benzoquinones (MPBs)[3] producing functionalized ring systems. Herein, we report our preliminary results regarding the diastereoselective IMDA reactions of MOBs bearing a chiral centre in the carbon-tether with a terminal olefin leading to highly functionalized tricyclic ring systems.

Masked *o*-benzoquinones,[4] a highly reactive class of 6,6-dialkoxycyclohexa-2,4-dienones, can be easily generated *in situ* by the oxidation of the corresponding 2-methoxyphenols with hypervalent iodine reagents in MeOH. The *in situ* generated MOBs undergo facile Diels–Alder reactions with a wide variety of dienophiles.[5] When the oxidation was carried out in the presence of an alkenol, MOBs undergo IMDA reactions *via* a tandem oxidative acetalization process.[2] It was envisioned that if MOBs bearing a chiral center in the alkenyl-tether undergo intramolecular cycloaddition, easy access to highly substituted tricyclic ring systems that are precursors for several linear and angular tricyclic skeletons (Scheme 1), could be achieved.

The substrates required for this strategy were prepared from benzaldehydes **1**, **2** and **3**. The Grignard reaction of **1** and **2** with alkenylmagnesium reagents of varying chain length afforded 2-methoxyphenols **4a**–**9a**, having a chiral center in the alkenyl-tether, in 80–92% yield. The oxidation of **4a** in MeOH to the corresponding MOB **4b** *via* the slow addition of diacetoxyiodobenzene (DAIB) at room temperature (Method A) did not give satisfactory results. However, the slow addition of DAIB to a methanolic solution of **4a** (n = 1) at reflux temperature (Method B) afforded IMDA adducts **4c** and **4d** of five-membered ring annulation *via* transiently generated **4b**, in 51 and 6% chemical yield, respectively, resulting from *endo*-addition, in addition to 17% of a mixture of dimers (Scheme 2, Table 1).† Similar results were obtained when the chain length was increased by one carbon (n = 2) (entry 2). However, when the reaction conditions were extended to **6a** (n = 3), only a mixture of dimers of MOB **6b** were obtained. To prevent the dimerization,[6,7] we have examined the reaction of 4-bromophenols **7a** and **8a** with DAIB in MeOH at room temperature, which furnished the single diastereomers **7c** and **8c** resulting from IMDA reaction of MOBs **7b** and **8b** in very good yields (entries 4 and 5). The reaction of bromophenol **9a** (n = 3) proceeded slowly and afforded only 4% of the seven-membered ring annulated cycloadduct **9c** in 12 h.

To ascertain whether the protection of the hydroxy function at the tetrahedral carbon of **4a**–**9a** has influenced the stereochemical outcome of the reaction, we have prepared their *tert*-butyldimethylsilyl derivatives **10a**–**15a** and evaluated the IMDA reaction of MOBs **10b**–**15b** (Scheme 2). Gratifyingly, the 2-methoxyphenols **10a**, **11a** and **13a**–**15a** furnished a single diastereomer in each case with an improved chemical yield. The reaction of phenol **12a** at either room temperature or reflux temperature failed to produce the cycloadduct. These results are summarized in Table 1.

Given the success in the IMDA reactions of *in situ* generated MOBs, it seemed to us that a related process could be used for the more stable MOBs to synthesize the tricyclic ring skeletons. To test this proposition, phenols **16a**–**18a** were synthesized from **3**. From our previous work, it was found that MOBs bearing substituents at C-5 are quite stable and could be isolated.[7] Likewise, **16a**–**18a** were oxidized with DAIB in MeOH to the MOBs **16b**–**18b** in excellent to quantitative yields (Scheme 3). Interestingly, the IMDA reaction of **16b** (n = 1) proceeded in toluene at reflux temperature to furnish the *endo*-diastereomeric adducts **16c**,**d** in 38 and 15%, respectively, in addition to 19% of *exo*-isomer **16e**. Nevertheless, the **17b** reacted intramolecularly in THF at reflux temperature to afford six-membered ring annulated adducts **17c** and **17d** in 93 and 4% yield, respectively, with complete *endo*-selectivity, albeit with longer reaction time. Similarly, **18b** (n = 3) when heated at reflux in mesitylene for 24 h, produced IMDA adducts **18c** and **18d** in rather poor yields. The MOB **19b** formed from TBS protected phenol **19a**, upon reflux in toluene produced quantitatively *endo*-**19c** and *exo*-**19e** in 3:2 ratio. In contrast, a single

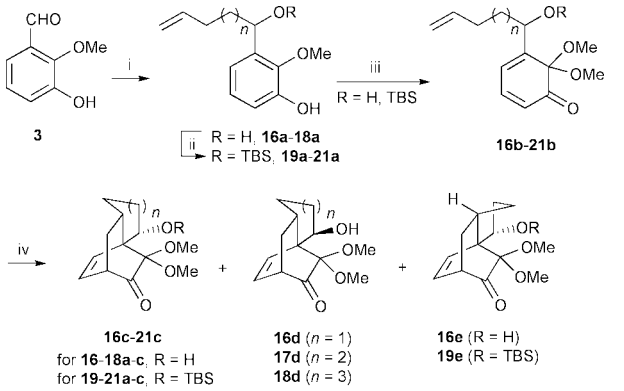
17	**20a** (R = TBS, *n* = 2)	C	**20b**	20 h	**20c** (98)
18	**21a** (R = TBS, *n* = 3)	C	**21b**	18 h	**21c** (10)

[a] Time during which DAIB was added. DAIB in MeOH was added to the phenol in MeOH at either rt (Method A) or reflux temperature (Method B). In Method C, MOB was isolated and the IMDA reaction was carried out at reflux temperature in a solvent (toluene for entries 13, 16 and 17; THF for entry 14; and mesitylene for entries 15 and 18). [b] The reaction time after the addition of DAIB in entries 1–12. [c] Yields are of pure and isolated adducts.



Scheme 3 *Reagents and conditions*: (i) $CH_2CH(CH_2)_{n+1}$ MgBr, THF, rt (71–77%); (ii) TBSOTf, 2,6-lutidine, CH_2Cl_2, −10 °C (89–99%); (iii) DAIB, MeOH, rt; (iv) solvent, reflux (Method C).

endo-diastereomer **20c** was produced in near quantitative yield from MOB **20b** (Scheme 3, Table 1).

The stereoselectivity of the cycloadduct of each successful case is completely analogous to the first example (entry 1), with the major, or sole, diastereomer arising from an approach in which all three rings adopt conformations of *endo*-mode with α-OH or α-OTBS in the transition state. The stereochemistries of **5c′** (3,5-dinitrobenzoate of **5c**), **7c**, **16c** and **16e′** (3,5-dinitrobenzoate of **16e**) were confirmed from their X-ray structures‡ and that of the other adducts were confirmed by chemical correlation and/or by comparing ^{1}H NMR data.

The IMDA reactions of the MOBs with 4-Br substitution proceeded in a highly diastereoselective manner leading to a single *endo*-, α-OR isomer. With one exception (**19b**), all the MOBs having OTBS functionality at the chiral center provided a single diastereomer (*endo*-, α-OTBS). The reduced reactivity of IMDA reactions with increased tether length as reflected in seven-membered ring annulations (*n* = 3) has been previously recorded.[8] However, the yields of these reactions (*n* = 3) were partially improved (**6c**: 28; **9c**: 25; **15c**: 59%) by the pyrolysis of the crude mixture which contains dimers, obtained after oxidation in mesitylene.

In summary, we have demonstrated here that masked *o*-benzoquinones bearing a chiral center in the carbon-tether underwent IMDA reactions to provide densely substituted tricyclic ring systems. Transformation of these adducts to linear and angular tricyclic skeletons, and the asymmetric version of the present protocol are under active investigation.

Financial support from the National Science Council (NSC) of the Republic of China is sincerely acknowledged. We thank Mr G.-H. Lee of NTU and Mrs F.-L. Liao of NTHU for X-ray diffraction studies. R. K. P. thanks NSC for a postdoctoral fellowship.

(100)-oriented NH_4MnF_3 perovskite with different morphologies have been obtained *in situ via* an organic template; experimental results can be rationalized in terms of electrostatic interactions and lattice matching between the organic template and the ions undergoing nucleation.

Recently, complex fluorides with perovskite structure have been extensively studied because of their interesting structures and particular physical properties such as magnetic, piezoelectric characteristics and photoluminescence behavior.[1–4] However, traditional preparation methods, to a great degree, have limited such studies on their properties since many exploitable properties are often related to the structure, size, morphology and orientation of inorganic materials. Such conventional preparation methods often fail to generate consistent results with respect to the control over the structure, size, morphology and orientation. Thus it is important to develop new synthetic strategies. A recent advance in this field involves the use of organic templates (Langmuir or SAM monolayers) for orientation nucleation of inorganic crystals.[5–7] One of the advantages of this method is that the crystal structure, size, morphology and orientation can be readily controlled *via* selection of the template and experimental conditions at room temperature. In this communication, the behenic acid (BA) monolayer template-directed room-temperature crystallization of NH_4MnF_3 is studied.

The experimental procedure was similar to that described elsewhere.[6] Throughout the experiment, the temperature was maintained at room temperature. Briefly, subphases **1** and **2** were prepared by mixing NH_4F (A.R.) and $Mn(NO_3)_2$ (A.R.) solutions. The concentrations of F^- ions in subphases **1** and **2** were 0.71 and 1.065 mol L^{-1} and that of Mn^{2+} ions were 0.355 and 0.533 mol L^{-1}, respectively. The monolayer template was prepared by spreading a measured quality of behenic acid (1 mg mL^{-1} in chloroform) over the surface of the subphase. After the evaporation of chloroform, the monolayer was compressed to the targeted pressure (28 mN m^{-1}) and the crystals formed under the monolayer transferred onto glass or wafer silicon substrates *via* a down stroke for further characterization. The aging time between the spreading and transferring was 55 and 45 min for subphases **1** and **2**, respectively. Crystals grown in the absence of monolayer were collected on a glass substrate placed at the bottom of the trough allowing a collection time of 5 h. The experiment of controlled crystallization under the BA monolayer was performed using a KSV 5000 instrument (Finland). The morphology of crystals formed under the monolayer were examined by scanning electron microscopy (SEM; JXA-840). The crystal faces of the samples were measured by X-ray diffraction (XRD; D/max2000, Rigaku, Cu-Kα). Elemental analysis of the samples was performed by energy dispersive X-ray analysis (EDXA).

In the absence of the monolayer, the majority of crystals were located at the bottom of the trough as a result of sedimentation. The crystals are obviously irregular in shape and the corresponding XRD pattern of crystals showed several groups of diffraction peaks roughly consistent with the reflections of cubic NH_4MnF_3 [Fig. 1A(a)] indicative of poor crystal quality.

In the presence of the monolayer, crystallization exclusively occurred at the monolayer–solution interface. Fig. 1B shows the typical morphology of crystals grown under the BA monolayer template over subphase **1**. As is evident from Fig. 1B, the crystals formed under the BA monolayer exhibit a square morphology and have a rather homogeneous size distribution with an average grain size of 6 μm. The corresponding XRD pattern of the crystals shows two sharp and strong diffraction lines at 2θ 20.90 and 42.56° [Fig. 1A(b)]. These diffraction lines correspond to the (100) and (200) reflections for cubic NH_4MnF_3 with perovskite structure indicating that the crystals are (100)-oriented. The high quality and uniformity of the crystals is evidenced by the sharp and strong (*n*00) reflections. Moreover, by comparison with the XRD pattern of the standard sample, we find that the crystals formed under the monolayer template are pure and no other impurity peaks were present. Interestingly, changing the concentration of the supersaturated solution has a marked effect on the morphology of crystal growns under the BA monolayer. For subphase solution **2**, the crystals grown under the BA monolayer exhibit a needle-like morphology (Fig. 2B) while in the XRD pattern (Fig. 2A), two sharp and strong diffraction lines together with a weak line appear at 2θ 20.90, 42.56 and 66.00°, which are assigned to the (100), (200), and (300) reflections, respectively, of cubic NH_4MnF_3 with perovskite structure.

 DOI: 10.1039/b102642a

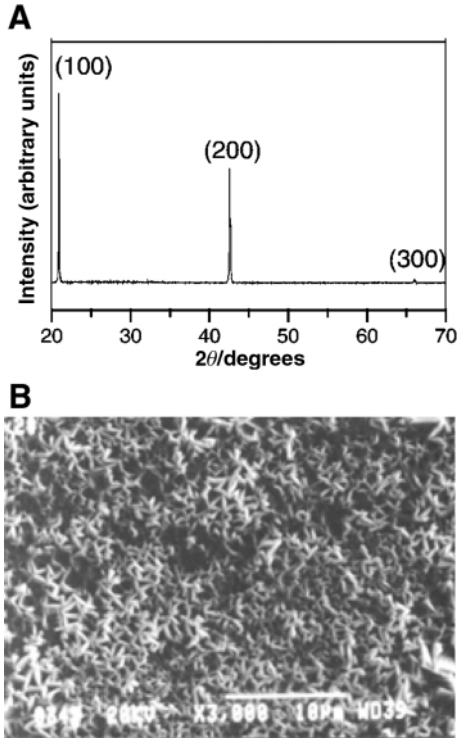

Fig. 2 (A) XRD pattern and (B) SEM image of NH_4MnF_3 crystals grown under the monolayer template from subphase **2**.

In addition, elemental analysis of crystals grown *via* the monolayer template was performed by EDXA. The EDXA patterns showed the presence of N, F, Mn, O and C peaks, which also further confirmed the XRD result. The C and O peaks originate from the BA monolayer indicating that the NH_4MnF_3 crystals are attached to the monolayer.

What aspects of the (100) face of NH_4MnF_3 crystal could be simulated by the interactions between the monolayer template and the crystal? According to an AFM study[8] on the compressed BA monolayer over the solution containing Mn^{2+} ions, the BA monolayer adopts rectangular packing with unit cell dimensions of 0.46 × 0.87 nm. We can compare the structure of the BA monolayer with the two-dimensional packing of Mn atoms in different crystal faces of cubic NH_4MnF_3 by simulation techniques. It is found that the superimposition of a rectangular lattice of the monolayer template on the (100) face of the NH_4MnF_3 crystal provides a good lattice matching. A comparison of the Mn–Mn distance (0.424 nm) along the (010) direction in the (100) crystal face with the monolayer lattice ***a*** (0.46 nm) reveals a misfit of 8%. Moreover, the interatomic Mn–Mn distance (0.424 nm) in the (001) direction of the (100) crystal face is approximately 0.5 times the monolayer lattice ***b*** (0.87 nm) with a misfit of only 2% (Fig. 3). However, such lattice matching does not exist with other crystal faces of NH_4MnF_3. Thus the rectangular packing arrangement of the monolayer generates a template similar to the (100) face of NH_4MnF_3 crystal which directs crystallization of NH_4MnF_3 along the (100) face.

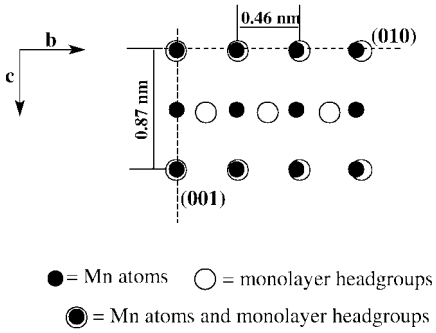

Fig. 3 Schematic two-dimensional representation of the proposed overlap between the monolayer template and Mn atoms in the (100) face of NH_4MnF_3 crystals.

The dependence of crystal morphology on the concentration of supersaturated solution can be explained as follows. A previous study[9] showed that the concentration/ionic strength of the reagents and the extent of nuclei–ion binding influence the structure and the morphology of the crystals grown under the monolayer. In the present study, the variation of the concentration of supersaturated solution results in a change of ionic strength and the extent of nuclei–ion binding, *i.e.* the Stern and boundary layers under the monolayer by electrostatic interactions. As a result, NH_4MnF_3 crystals with different morphologies were obtained under the BA monolayer.

A more detailed mechanism will be investigated further.

In summary, (100)-oriented NH_4MnF_3 perovskite crystals with different morphologies were prepared *via* a monolayer template at room temperature. The solution conditions, the electrostatic interactions and lattice matching between the organic template and ions undergoing nucleation are important factors for control over the morphology, size, and orientation of crystals. Compared with traditional methods, the organic template technique appears advantageous in terms of lower synthesis temperature, high purity, and providing controllable morphology and orientation of crystals.

First published as an Advance Article on the web 5th July 2001

When a monolayer of dioctadecyldimethylammonium bromide is formed on the surface of mixed aqueous solutions of $(NH_4)_2TiF_6$ and H_3BO_3 with a B/Ti molar ratio below 1.5, oriented crystallites of NH_4TiOF_3 are produced and grown at the hydrophilic interface of the monolayer to yield a self-supporting thin film within a few days.

In recent years, soft solution chemistry has attracted a great deal of attention from the viewpoint of low energy-consuming material processing and morphological control of inorganic materials. In this area, crystalline metal oxides have been synthesized in the liquid phase *via* ligand-exchange (hydrolysis) equilibrium reactions of the corresponding metal fluorides at an ambient temperature.[1,2] For example, the overall reaction (1) for TiO_2 synthesis consists of three equilibrium reactions (2)–(4),[3–5] in which H_3BO_3 acts as an F^- scavenger and forces the equilibrium to shift to the product side. By this liquid-phase deposition (LPD) method, TiO_2 crystalline films are successfully prepared on a substrate at room temperature.[2]

$$[TiF_6]^{2-} + 3/2\ H_3BO_3 + 2H^+ \rightleftharpoons TiO_2 + 3/2\ HBF_4 + 5/2\ H_2O \quad (1)$$

$$[TiF_6]^{2-} + n\ H_2O \rightleftharpoons [TiF_{6-n}(OH)_n]^{2-} + n\ HF \quad (2)$$

$$H_3BO_3 + 4\ HF \rightleftharpoons HBF_4 + 3\ H_2O \quad (3)$$

$$[Ti(OH)_6]^{2-} + 2\ H^+ = TiO_2 + 4\ H_2O \quad (4)$$

So far, we have been investigating inorganic synthesis using (multi)layered organic films as reaction fields and templates.[6–10] On the other hand, Langmuir monolayers have been successfully employed to direct the growth of oriented arrays of inorganic salts and metal sulfides.[11–13] These results motivated the present study to combine the LPD reactions and an air/water monolayer as a template. As reported below, self-supporting thin films of NH_4TiOF_3, which acts as a stable intermediate in LPD synthesis of TiO_2, were produced at the interface of the air/water monolayer, and were dominated by (00*l*) oriented crystallites. The conversion of NH_4TiOF_3 into TiO_2 while retaining the orientation was also suggested.

The LPD solution used for the subphase was a mixed aqueous solution of ammonium hexafluorotitanium [$(NH_4)_2TiF_6$, 0.1 mol dm^{-3}] and boric acid (H_3BO_3, 0.1–0.3 mol dm^{-3}). An air/water monolayer of dioctadecyldimethylammonium bromide (DODMABr) was formed at 298 K on the surface of the LPD solution by spreading a 100 μl portion of a toluene–ethanol solution (9:1, v/v) of DODMABr (*ca.* 1 mg cm^{-3}). After evaporating the spreading solvent for 20 min, two-dimensional compression was performed by using a computer-controlled film balance (USI system Co. Ltd., FSD 110). The DODMA monolayer on pure water showed an expanded surface pressure-area (π–*A*) isotherm characteristic of a liquid phase. On the LPD solution, on the other hand, the monolayer exhibited a condensed π–*A* isotherm, suggesting that the cationic DODMA monolayer interacts with inorganic ionic species such as TiF_6^{2-} and borate ions.[14] The monolayer-assisted crystal growth was performed at a constant π value of 20 mN m^{-1}, which is in the middle of solidus region of the π–*A* isotherms. The monolayer of octadecyl alcohol (ODA) was formed in the same manner using a toluene solution of ODA, but the π–*A* isotherms were almost the same on either pure water or the LPD solution, indicating no interaction between the neutral monolayer and the ionic species. The products were characterized by X-ray diffraction (XRD, Rigaku LINT-2200), scanning electron microscopy (SEM; HITACHI Co. Ltd., S-2250N) and transmission electron microscopy (TEM; JEOL, JEM-2010 UHR) equipped with an energy dispersive X-ray spectrometer (EDX, Oxford Link ISIS).

In the $(NH_4)_2TiF_6/H_3BO_3$ LPD solutions, a white precipitate was produced at room temperature within a few days, and the main products were different below and above the stoichiometry of the overall reaction (1) (B/Ti = 1.5). At B/Ti ⩾ 1.5, the main product was anatase-type TiO_2 [Fig. 1(b)], in agreement with a previous report.[2] The main product at 1 ⩽ B/Ti < 1.5 was NH_4TiOF_3 [Fig. 1(a)],[15] with the oxyfluoride convertable into anatase TiO_2 either by treatment with aqueous H_3BO_3 or by air-calcination at 873 K for 1 h [Fig. 1(c)]. These results indicate that NH_4TiOF_3 is a stable intermediate in the LPD synthesis of TiO_2.

On the surface of LPD solution with B/Ti = 1, no product was formed in the absence of the DODMA monolayer, but pale violet-colored transparent films were formed within a few days in the presence of the monolayer. The floating films thus formed were transferred onto quartz substrates by scooping up or by horizontal dipping. SEM observation showed that the thickness of the film after 3 days was *ca.* 0.5 μm [Fig. 2(a)]; thickness at the sub-micron level was also suggested by the interference UV–VIS absorption spectrum. It is seen that the surface of the film at the air or monolayer side was smooth while that of the solution or crystal-growth side was rough and that morphology

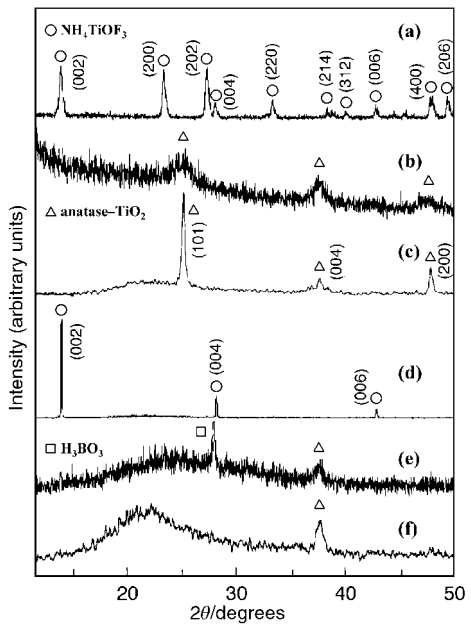

Fig. 1 XRD patterns of (a), (b) precipitates in the LPD solutions, (d), (e) thin films deposited at the surface of the DODMA monolayer after 3 days, and (c), (f) air-calcined precipitates of (a) and (d) at 873 K for 1 h. The solution compositions were B/Ti = 1 [(a), (d)] and B/Ti = 2 [(b), (e)].

 DOI: 10.1039/b101488i

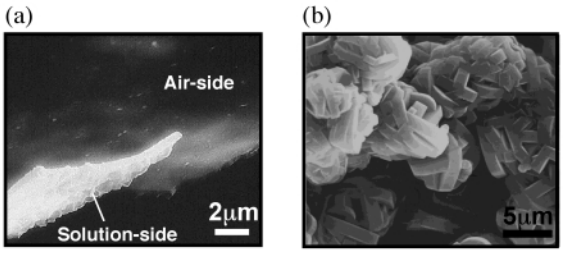

Fig. 2 SEM images of (a) NH_4TiOF_3 film deposited at the surface of DODMA monolayer and (b) NH_4TiOF_3 precipitate in the LPD solution. Solution composition: B/Ti = 1, deposition time: 3 days.

of the film was totally different from that of the precipitate [Fig. 2(b)]. XRD results on the quartz-supported films [Fig. 1(c)] showed that the crystalline product on the surface of solution (B/Ti = 1) was NH_4TiOF_3 *i.e.* the same as the precipitate from the same LPD solution but the NH_4TiOF_3 films was preferentially oriented with the (00*l*) crystal planes parallel to the solution surface.

In the presence of neutral octadecyl alcohol (ODA) monolayer, no crystalline product was observed on the solution surface, consistent with the suggestion from the π–*A* isotherm measurement that the ODA monolayer scarcely interacts with the ionic species. The result implies that electrostatic interaction between the cationic monolayer and inorganic species is indispensable to form stable and oriented NH_4TiOF_3 films. The importance of the electrostatic interaction was also confirmed by monitoring the deposition of NH_4TiOF_3 from the LPD solution (B/Ti = 1, pH = 4.5) with a QCM microbalance (Sogo Pharmaceutical Co., SF-105A). Here, three types of quartz resonators (AT cut, 9 MHz) with different Au electrodes (area: 0.34 cm^2) were used; bare, derivartized with mercaptoethylsulfonate (MES, anionic surface) and 2-amino-1-ethanethiol (AET, cationic at pH = 4.5). The amount of deposition of NH_4TiOF_3 was almost the same on the bare and anionic MES electrodes, while the amount on the cationic AET surface was much larger than those on the other two electrodes at the same immersion time; for example, deposited amounts on AET and bare electrodes were 300 ng and 50 ng after 2 h and 1100 ng and 200 ng after 6 h, respectively.

The initial stage of precipitate and film formation was studied by TEM and EDX. Products in solution and on the surface were mounted on TEM micro-grids covered with a carbon ultrathin film (Oken Shouji Co. Ltd) by dropping the solution and scooping up, respectively. In the LPD solution with B/Ti = 1, discoid crystallites, *ca.* 400 nm diameter by 150 nm thickness, on average, were observed 1 h after the preparation of the solution. The atomic composition of the crystallites measured by EDX was close to that for NH_4TiOF_3 (Ti:O:F = 1:1.2:2.8). With increasing time, the crystallites grew, aggregated and eventually precipitated as irregularly shaped particles [Fig. 2(b)]. On the surface of the LPD solution (B/Ti = 1) with the DODMA monolayer, discoid crystallites of NH_4TiOF_3 with nearly the same size as in the solution were present after 1 h the majority being oriented with the circular plane parallel to the monolayer surface [Fig. 3(a)]: smaller crystallites with diameter below 50 nm were also observed. Electron diffraction [Fig. 3(c)] showed each discoid crystallite was a single crystal with the circular plane corresponding to the (00*l*) or *ab* plane of tetragonal NH_4TiOF_3. The amount and size of the crystallites increased at the monolayer surface with increasing time and a continuous thin film composed of nanoparticulates was eventually produced after 12 h [Fig. 3(b)]. With further time, the thickness of the film increased to, for example, 0.45 μm after 3 days and 0.64 μm after 5 days as estimated from the UV–VIS interference. The results clearly indicate that the oriented deposition of NH_4TiOF_3 discoids is a crucial step in the monolayer-assisted formation of oriented NH_4TiOF_3 films. It is also reasonable to propose that in the initial stage the discoid crystallites deposited at the monolayer surface with the *ab* plane preferentially parallel to the surface and act as seeds for the subsequent crystal growth.

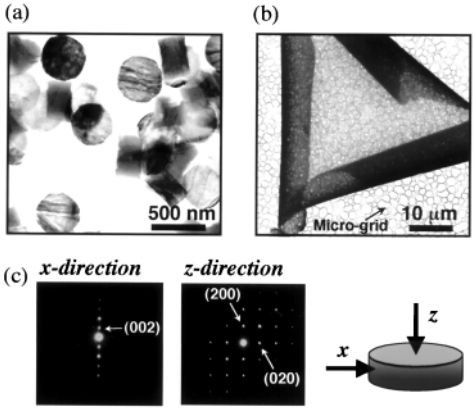

Fig. 3 TEM images of NH_4TiOF_3 crystallites deposited at a DODMA monolayer surface after (a) 1 h and (b) 12 h after the preparation of the monolayer. (c) Electron diffraction patterns of the crystallites of (a). Arrows indicate the direction of electron beam.

Monolayer-assisted LPD synthesis was also investigated for a B-rich LPD solution (B/Ti = 2), from which non-oriented anatase TiO_2 was precipitated [Fig. 1(b)]. The formation of the oriented NH_4TiOF_3 crystallites was observed by TEM electron diffraction measurements in the early stage up to 6 h. After 3 days, however, a weak XRD peak corresponding to the (004) peak of anatase TiO_2 was observed [Fig. 1(e)]. The absence of (101) and (200) peaks which are stronger than the (004) in non-oriented powder anatase indicates the presence of (00*l*) oriented crystallites in the film. In addition, when the (00*l*) oriented NH_4TiOF_3 film prepared from the B/Ti = 1 LPD solution was air-calcined at 873 K for 1 h, only the (004) XRD line of anatase TiO_2 was observed [Fig. 1(f)]: the broad peak around 2θ = 20–25° is due to the quartz substrate. These results suggest the possibility of synthesizing oriented TiO_2 films directly by the monolayer-assisted LPD method on a B rich solution or indirectly by heat-treatment of an oriented NH_4TiOF_3 film. Detailed investigation is in progress with respect to the conversion of NH_4TiOF_3 to TiO_2 with retention of orientation as well as the mechanism of the deposition and growth of oriented crystallites at the monolayer surface.

A one-pot reaction of three different components [Cu(II), fumarate dianion and piperazine] leads to the self assembly of a magnetic molecular fully interlocked 3D structure with (4,4) nets formed by equal 2D sheets.

One of the challenges in modern inorganic chemistry is the design of molecular extended systems possessing original architectures and predictable physical properties. Such novel molecular assemblies include networks mimicking zeolites or possessing magnetic metallic ions.[1,2] One of the intriguing assemblages encountered is that consisting of interlocked structures like catenanes where interlacing rings may be achieved by a rational synthetic approach.[3] A few systems with interpenetrated two-dimensional networks are known and during the last decade three examples of molecular systems containing paramagnetic ions with fully interlocked structures have been reported.[4,5]

We report, here, a new molecular magnetic system with a fully interlocked three-dimensional structure of general formula $[Cu(fum)(ppz)(H_2O)_2]$ (fum = fumarate dianion and ppz = piperazine) obtained from a one-pot synthesis of three different components *i.e.* Cu(II), piperazine and fumarate, using an unusual crystallization process. To the best of our knowledge, this is the first molecular interlocked system where the 2D sheets are assembled from two different types of organic bridges.

Reaction of $CuCl_2$, Na_2fum, and piperazine in H_2O–MeOH results in the formation of a sky blue insoluble solid. Deep blue single crystals were obtained by slow evaporation of an ammoniacal solution of the solid,‡ and the structure was determined by single crystal X-ray diffraction.§ As shown in Figs. 1 and 2, the present compound is a 3D polymeric, interpenetrating network consisting of equivalent 2D sheets, of composition $[Cu(fum)(ppz)(H_2O)_2]_n$ with a (4,4) topology, where copper ions provide the 4-connecting nodes bridging through ppz and fum ligands. In the structure Cu^{II} ions, ppz and fum ligands are situated at crystallographic centres of symmetry. The sides of the parallelogram forming the grid are provided by the ppz molecules in the direction of the crystallographic *c* axis (6.947 Å), the others are part of zigzag Cu–fum chains running parallel to the diagonal of plane *ab* (length of 8.960 Å). The coordinating dicarboxylate oxygen atoms are those in *anti* position with respect to the adjacent H atom of the ligand. The metals within a sheet are all coplanar in an essentially square planar environment, since two water molecules at pseudo-axial positions are at 3.058(6) Å, too far apart to attest an octahedral geometry around copper. The (4,4) nets are inclined interpenetrated to form an interlocked 3D structure. This is the highest dimensionality found for fum bridged Cu^{II} complexes since all previous such complexes are dimeric or 1D chains.[2] Along the line of intersection of any particular pair of interpenetrating sheets each $Cu(fum)_2(ppz)_2$ window encircles a Cu–fumarate–Cu entity of the other sheet, in such a way to allow the formation of weak hydrogen bonds [3.035(4) Å] between unligated oxygen O(2) and ppz nitrogen

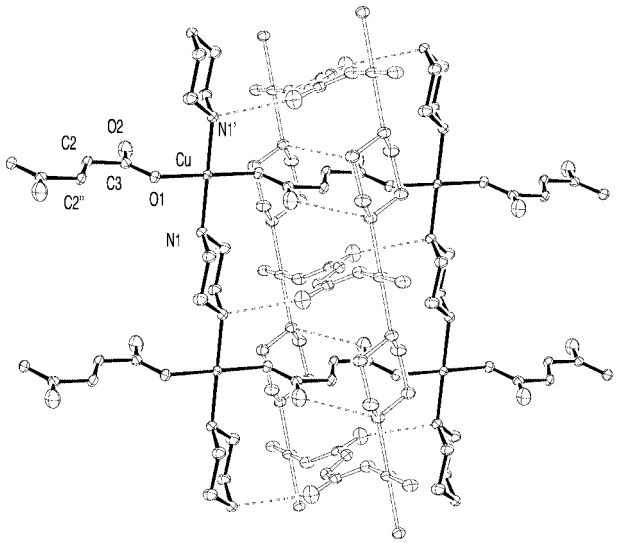

Fig. 1 Perspective view of two interpenetrated sheets (represented by open and filled bonds) showing the N(1)–H···O(2) hydrogen bonds (dashed lines). Selected bond lengths (Å), angles and torsion angles (°): Cu–O(1) 1.968(2), Cu–N(1) 2.047(3); O(1)–Cu-O(1′) 180.00(1), O(1)–Cu–N(1′) 93.05(9), O(1)–Cu–N(1) 86.95(9), N(1′)–Cu–N(1) 180.00(2), C(2)–C(3)–O(1)–Cu, −172.2(2), C(2″)–C(2)–C(3)–O(1) −8.3(5)°.

 DOI: 10.1039/b102072m

N(1). The dicarboxylate bridging ligands lie at a repeat distance of half the crystallographic axis *c*, suggesting π contacts among these groups (the closest C–C separation is 3.492 Å). When viewed along the *c* axis the structure is seen to contain 168 Å^3 channels filled with water of crystallization (Fig. 2). The crystallographically independent water molecule, located at 2.761(5) Å from O(2), is rather disordered and is weakly hydrogen bonded also to two close symmetry related units [2.95(1) and 3.02(1) Å]. This crystal structure which displays an inclined interpenetration of two (4,4) nets is unique and unprecedented. To the best of our knowledge, only one structure with this type of interpenetration has been reported to date where the sheets are different, formed by a 2D layer and 1D chains, the latter connected through H-bonds.[6] Thermogravimetric analysis reveals a weight loss at 155 °C corresponding to the loss of two water molecules per formula unit [calc. 12.0; obs. 11.8%].

The magnetic behaviour of the complex was investigated using a SQUID magnetometer in the temperature region 280–3 K within an applied magnetic field of 50 kOe. The $\chi_M = f(T)$ plot (Fig. 3) is consistent with the presence of an antiferromagnetic interactions between the Cu^{II} ions within the compound. It has already been reported that through-bond coupling leads to important magnetic interaction in Cu^{II}–piperazine–Cu^{II} entities while the interaction through fumarate is very small since through-bond coupling is negligible.[7] The susceptibility data were thus fitted by the theoretical law for an antiferromagnetic $S = 1/2$ regular infinite chain. The least square fit leads to the following parameters: $J = -15.3$ cm^{-1}, $g = 2.04$, $\rho = 0.011$, TIP $= 60 \times 10^{-6}$ and an agreement factor $R = 2.4 \times 10^{-4}$. The quality of the fit may be improved by introducing an intermolecular interaction parameter *zj* that takes into account the interaction between the magnetic chains in the framework of the molecular field approximation.[8] The inset of Fig. 3 shows that a better fit of the maximum can then be obtained with the following parameters: $J = -14.7$ cm^{-1}, $g = 2.04$, $\rho = 0.013$, $zj = -4.2$ cm^{-1}, TIP $= 60 \times 10^{-6}$ and an agreement factor of 6.5×10^{-6}. Since each piperazine bridged chain is surrounded by two other chains within the 2D layers, *z* is equal to 2 (we have neglected the interaction through H-bonds) which leads to an exchange coupling parameter of -2 cm^{-1} between the Cu^{II} ions through fumarate. DFT calculations is underway in order to rationalize in a more quantitative way the amplitude of the magnetic interaction between the two different bridges.

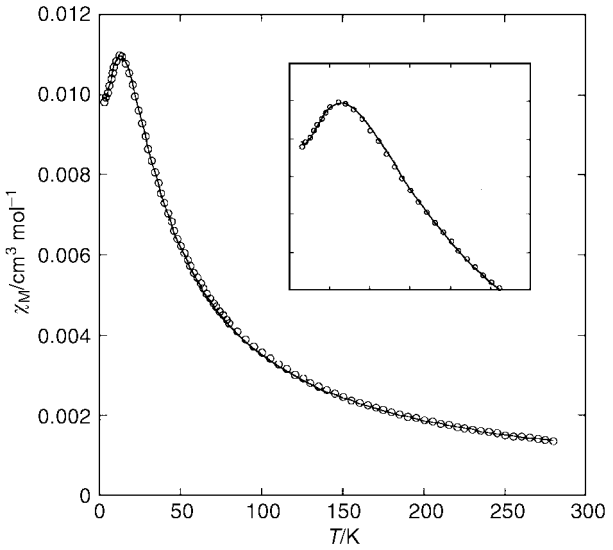

Fig. 3 Molar magnetic susceptibility *vs.* temperature plot for [Cu(fum)ppz$(H_2O)_2]_n$. Solid lines shows the best fit obtained considering the interchain magnetic interaction in addition to intrachain interaction.

We thank the Council of Scientific and Industrial Research, New Delhi for financial support (granted to N. R. C).

Notes and references

‡ A 5 mL aqueous solution of $CuCl_2 \cdot 2H_2O$ (1 mmol, 0.1705 g) was mixed with an aqueous solution (10 mL) containing Na_2fum (1 mmol, 0.1600 g) and piperazine (1 mmol, 0.0860 g). A sky blue solid, insoluble in common organic solvents separated out immediately. It was filtered off, washed with water and dissolved in a minimum amount of ammonia (14 M). Suitable blue single crystals for X-ray diffraction were obtained by slow evaporation of the ammoniacal solution of the solid in a refrigerator.

§ *Crystal data*: $C_8H_{16}CuN_2O_6$, $M = 299.77$, monoclinic, space group *C*2/*c*, $a = 12.785(8)$, $b = 12.556(8)$, $c = 6.947(5)$ Å, $\beta = 99.69(1)°$, $U = 1099.3(12)$ Å^3, $F(000) = 620$, $Z = 4$, $D_c = 1.811$ g cm^{-3}, μ(Mo-Kα) = 2.007 mm^{-1}. Intensity data collected on an Enraf-Nonius CAD-4 single crystal diffractometer employing the ω–2θ scan method; absorption correction was applied. The structure was refined using a full matrix refinement procedure (SHELXL97), with anisotropic thermal parameters assigned to all non-hydrogen atoms. All hydrogen atoms were observed in the difference map; those of fumarate and piperazine molecules were constrained at geometrical estimates, while coordinates of hydrogen atoms of water molecule were refined. At convergence $R1 = 0.0428$, $wR2 = 0.1081$ for 1292 unique reflections and 86 parameters, [3358 reflections collected, $R_{int} = 0.0701$, 1216 with $I > 2\sigma(I)$].

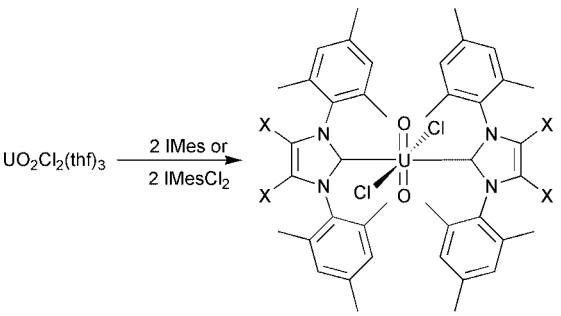
Received (in Irvine, CA, USA) 21st March 2001, Accepted 13th June 2001
First published as an Advance Article on the web 5th July 2001

Treatment of $UO_2Cl_2(thf)_3$ in THF with two equivalents of 1,3-dimesitylimidazole-2-ylidene (IMes) or 1,3-dimesityl-4,5-dichloroimidazole-2-ylidene ($IMesCl_2$) yields novel monomeric uranyl *N*-heterocyclic carbene complexes, representing the first examples of actinyl carbon bonds.

The coordination chemistry of *N*-heterocyclic carbenes (NHC) is a topic of much current interest, motivated in part by promising applications in homogeneous catalysis[1] and materials science.[2] NHC complexes have also been identified as principal species formed upon dissolution of certain metal salts in *N*,*N*′-dialkylimidazolium-based room-temperature ionic liquids (RTILs).[3] We have recently initiated a general program to characterise the basic coordination chemistry and electrochemical properties of lanthanide and actinide ions dissolved in RTILs with the goal of developing advanced, environmentally responsible, nuclear processing and purification strategies. In support of this effort, the reaction chemistry of isolable and easily handled NHC ligands with lanthanide[4] and actinide complexes is of interest. Given the central role of actinyl ions (*e.g.* MO_2^{2+}, M = U, Np, Pu) in nuclear chemistry,[5] we report here the synthesis and structural characterisation of uranyldichloride complexes stabilised by sterically demanding NHC ligands. Well characterised 1,3-dimesitylimidazole-2-ylidene ligands were chosen in this study in order to favour highly crystalline reaction products, amenable to detailed structural characterisation.

Addition of a THF solution containing two equivalents of IMes[6] or $IMesCl_2$[7] to a bright yellow solution of $UO_2Cl_2(thf)_3$[8] in THF rapidly gives a bleached yellow solution from which pale yellow powders separate that correctly analyse for $UO_2Cl_2L_2$ [L = IMes **1**, $IMesCl_2$ **2**, see eqn. (1)].† The isolated



(1)

powders are insoluble in aliphatic hydrocarbons, slightly to moderately soluble in THF and toluene, and readily decompose in CH_2Cl_2.

Crystals suitable for X-ray structural analysis could be obtained for **1** as the THF solvate, by carefully layering a cold solution of $UO_2Cl_2(thf)_3$ in THF with a second solution of IMes, followed by slow diffusion over several days at –30 °C. For **2**, simply cooling a saturated THF solution at –30 °C overnight gave well formed single crystals.‡ Thermal ellipsoid representations of **1** and **2** are shown in Fig. 1. For both complexes the uranium(VI) metal atom lies at the centre of a nearly perfect octahedron. The uranyl U–O bond lengths of 1.761(4) and 1.739(3) Å (**1** and **2**, respectively) are within the range previously observed in $UO_2Cl_2L_2$ complexes.[9–12] The significantly shorter U–O bond length observed for **2** is consistent with $IMesCl_2$ being a weaker σ-donor ligand compared to IMes, which is also reflected in UO_2 vibrational data (*vide infra*). The

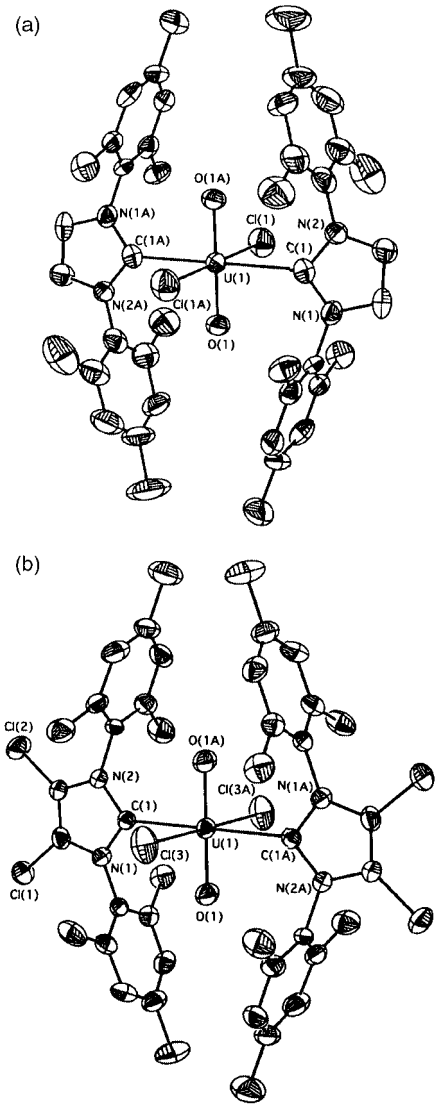


Fig. 1 Thermal ellipsoid representation of (a) **1** and (b) **2** shown at the 50% probability level. THF solvent of crystallisation and hydrogen atoms have been omitted for clarity.

 DOI: 10.1039/b102649f

U–Cl bond lengths also fall within the normal range. The uranium–carbene bond lengths are considerably lengthened at 2.626(7) and 2.609(4) Å (**1** and **2**, respectively) compared to the U–L bond lengths in $UO_2Cl_2L_2$ complexes [L = $OPPh_3$,[9] $OC(CHCHPh)_2$,[10] $OP(NMe_2)_3$,[11] or $OC(NMe_2)_2$[12]], which are observed between 2.27 and 2.30 Å. The electron-withdrawing 4,5-dichloro substituents of $IMesCl_2$ are expected to reduce the bonding radius of the carbene lone pair, which is reflected in the relative U–C bond lengths of **1** and **2** [2.626(7) and 2.609(4) Å, respectively]. The imidazol-2-ylidene rings lie nearly coplanar, twisted along the C(1)–U(1)–C(1A) axis by *ca.* 6° (**1**) and 8° (**2**). The plane defined by N(1)–C(1)–N(2) eclipses the O–U–O axis [torsion angles: *ca.* 11° (**1**) and 4° (**2**)], thereby minimising steric interaction between the mesityl substituents and the chloride ligands. Instead, the mesityl groups form a basket around the uranyl oxo ligands in which the closest non-bonded oxygen contacts are *ca.* 3.1–3.2 Å to the *ipso*-mesityl carbons.

A measure of the relative donor strength of the NHC ligands in $UO_2Cl_2L_2$ complexes can be estimated using vibrational spectroscopy. Within an isostructural series of uranyl complexes, the frequency of the symmetric (ν_1) and asymmetric (ν_3) UO_2 stretch is inversely proportional to the donor strength of the equatorial ligands which lie orthogonal to the $[UO_2]^{2+}$ moiety.[13] For **1** and **2**, the highest intensity peak in the IR spectra (Nujol), assigned to the asymmetric UO_2 stretch is observed at 938 and 942 cm^{-1}, respectively. These values are among the highest reported for $UO_2Cl_2L_2$ complexes,[14] suggesting correspondingly weak electron donation from the NHC ligands. A slightly higher frequency ν_3 observed for **2** is consistent with the electron withdrawing effect of the 4,5-dichloro substituted imidazol-2-ylidene ligand. It should be pointed out that the weak donor ability of NHC ligands in these uranyl complexes is in marked contrast to their exceptionally strong donor strength observed in low valent transition metal complexes.[15] The isolation of uranyl complexes stabilised by soft σ-donor ligands like NHCs is without precedent. Prior to this report, actinyl complexes have been exclusively stabilised by hard donor ligands (*e.g.* halide, oxygen and nitrogen ligation). In fact, even tertiary phosphine complexes are unknown in the actinyl series. A useful comparison can be made to a related tungsten complex, $WO_2Cl_2L_2$ (L = 1,3-dimethylimidazol-2-ylidene),[16] which further demonstrates the suitability of NHCs as competent stabilising ligands for hard, Lewis acidic metal complexes.

The synthetic and structural results reported in this work suggest that related actinide NHC complexes might reasonably be formed in RTIL solutions. Through control of the effective pH of these media, the concentration of free NHCs could be reversibly adjusted to allow manipulation of the coordination sphere of dissolved metal ions. Novel separations technology based on the imidazolium-RTIL/NHC interconversion is currently under development. Extension of this synthetic and structural investigation to transuranium actinyl complexes and to low valent actinides is being actively pursued.

We thank Dr David L. Clark of the Glenn T. Seaborg Institute for Transactinide Science for providing financial support of this work. Los Alamos National Laboratory is operated by the University of California for the U.S. Department of Energy.

Manganese(III) acetate mediated radical reactions in the presence of an ionic liquid

Gregory Bar, Andrew F. Parsons* and C. Barry Thomas

Department of Chemistry, University of York, Heslington, York, UK YO10 5DD. E-mail: afp2@york.ac.uk

Received (in Cambridge, UK) 19th April 2001, Accepted 13th June 2001
First published as an Advance Article on the web 5th July 2001

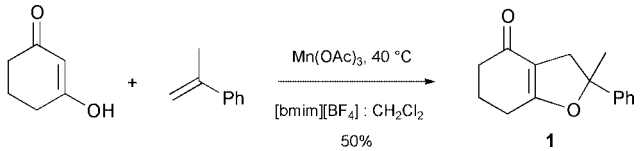
A new, mild and practical method for conducting manganese(III)-mediated radical reactions, which lead to the formation of carbon–carbon bonds, has been developed using the ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim][BF_4]).

Manganese(III) acetate is known to oxidise a variety of carbonyl compounds, including β-diketones and β-keto esters, to form radicals.[1] These α-carbonyl radicals can undergo cyclisation or intermolecular addition reactions to form radical adducts, which may be oxidised by a second equivalent of manganese(III) acetate. The resultant cations can undergo nucleophilic attack or β-deprotonation reactions leading, for example, to acetates or alkenes. These carbon–carbon bond forming reactions are synthetically attractive because manganese(III) acetate is inexpensive and, in contrast to related tributyltin hydride reactions, this oxidative method of radical generation leads to functionalised products.

One significant drawback to the use of manganese(III) acetate, however, is the harsh reaction conditions. As manganese(III) acetate has poor solubility in organic solvents, acetic acid is invariably used and this severely limits the range of substrates which can be employed, especially as many reactions require heating (often to ⩾70 °C). An additional drawback to the use of acetic acid involves the separation and recovery of the manganese acetate at the end of the reaction. The standard workup procedure involves addition of large quantities of water and/or aqueous sodium hydrogen carbonate to remove the acetic acid and so large-scale reactions would generate considerable amounts of aqueous waste. With a view to establishing milder reaction conditions, as well as facilitating the recovery of the manganese acetate, we have investigated the novel use of an ionic liquid in manganese(III)-mediated radical reactions.

Ionic liquids have recently been found to be excellent, environmentally benign solvents for a variety of reactions.[2] These liquids offer an attractive alternative to conventional organic solvents because, for example, they are easy to recycle and are non-volatile. Of particular note are air and moisture stable imidazolium ionic liquids, which have been used as solvents for a variety of transition metal catalysed reactions (*e.g.* oxidation,[3] allylation,[4] living radical polymerisation[5] and hydrogenation[6]). This suggested that ionic liquids such as 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim][BF_4]), which is miscible with polar solvents (*e.g.* methanol, dichloromethane) but immiscible with less polar solvents (*e.g.* ethyl acetate, diethyl ether, toluene), could be compatible with manganese(III)-mediated radical reactions.

Although our initial manganese(III) acetate reactions in neat [bmim][BF_4] were low yielding, we found that cyclised products could be isolated in good yield when 1,3-dicarbonyl compounds and alkenes were reacted in a mixed [bmim][BF_4]–dichloromethane solvent system (Scheme 1). Thus, reaction of cyclohexane-1,3-dione (1 equiv.), α-methylstyrene (5 equiv.) and manganese(III) acetate (2.1 equiv.) in a 1:4 mixture of [bmim][BF_4]–dichloromethane produced tetrahydrofuranone **1** in 50% yield after column chromatography.†‡ Similar yields of **1** were obtained when using different ratios of starting materials

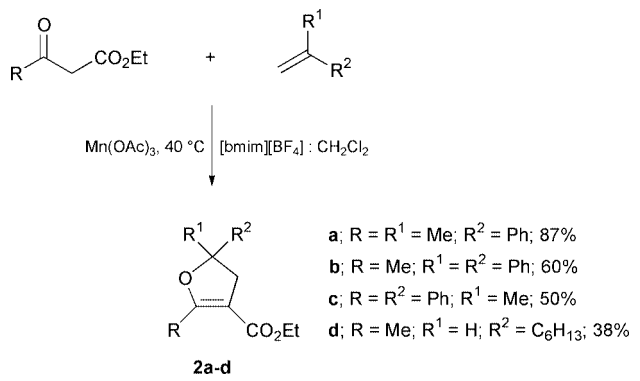


Scheme 1

and different amounts of the ionic liquid and dichloromethane. This showed that only small amounts of the ionic liquid are required for the reaction to proceed. For example, when a 1:19 mixture of [bmim][BF_4]–dichloromethane was used, **1** was isolated in 45% yield. The reaction could also be carried out using [bmim][BF_4] in the presence of alternative solvents to dichloromethane, including methanol, acetone or acetonitrile and **1** was isolated in 27–58% yield. Even solvents that are immiscible with [bmim][BF_4] can be employed. For instance, when the reaction was carried out in a 1:19 mixture of [bmim][BF_4]–ethyl acetate, **1** was isolated in 30% yield. It should also be noted that cerium(IV) ammonium nitrate (CAN), another efficient one-electron oxidant, can be used in place of manganese(III) acetate and when [bmim][BF_4]–dichloromethane was used as the solvent with this reagent, tetrahydrofuranone **1** was isolated in an excellent 82% yield. This is an interesting result because CAN, like manganese(III) acetate, has only limited solubility in organic solvents and so CAN oxidations are usually carried out in aqueous acetonitrile.

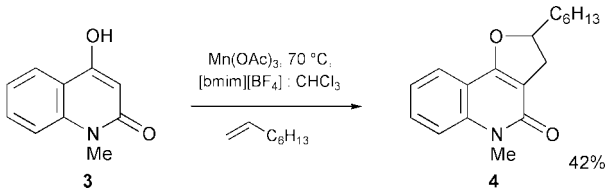
Related manganese(III)-mediated reactions can also be carried out using acyclic 1,3-dicarbonyl precursors (Scheme 2). Hence, β-keto esters can be reacted with electron-rich alkenes in the presence of 2.0 equiv. of manganese(III) acetate to give dihydrofurans **2a**–**d**. These types of reactions do not require a nitrogen atmosphere. For example, **2c** was isolated in 46 and 50% yield from reactions carried out in the presence or absence of a nitrogen atmosphere, respectively.

The yields of **1** and **2a**–**d** are similar or higher than those reported for related manganese(III) acetate/acetic acid reactions or alternative cyclisation methods.[7] This was also apparent using quinolone precursors when reaction of **3** (1 equiv.) with oct-1-ene (10 equiv.) in a mixed [bmim][BF_4]–chloroform



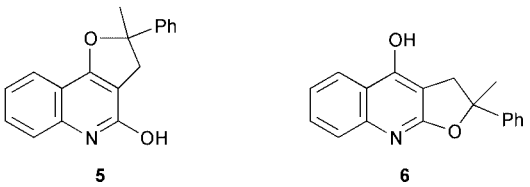
Scheme 2

 DOI: 10.1039/b103544b



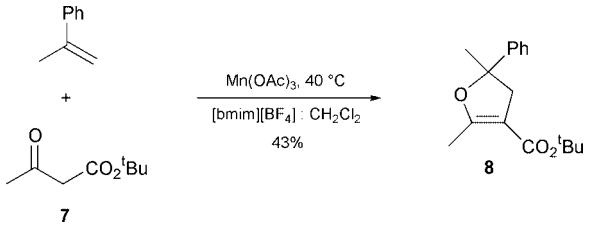
Scheme 3

solvent system produced the dihydrofuroquinolone **4** in 42% yield (Scheme 3).§ This can be compared to the corresponding manganese(III) acetate/acetic reaction at 60 °C, which required ultrasonic irradiation (because of the poor solubility of **3** in acetic acid) to give quinolone **4** in 50% yield.[8] A similar manganese(III)-mediated reaction using quinoline-2,4-diol (1 equiv.) and α-methylstyrene (5 equiv.) in [bmim][BF_4]–dichloromethane gave a 1:1 mixture of the angular and linear tricycles **5** and **6**, respectively, in a combined 78% yield.



This work has shown, for the first time, that manganese(III)-mediated radical reactions can be carried out in alternative solvents to acetic acid in the presence of the ionic liquid [bmim][BF_4]. The ability to carry out manganese(III) reactions in a variety of solvents, under much milder reaction conditions than when using acetic acid, should extend the range of precursors which can be employed in these types of reactions. For example, we have shown that the *tert*-butyl ester **7** can be reacted with α-methylstyrene in [bmim][BF_4]–dichloromethane to give **8** in 43% yield (Scheme 4). The same reaction at 50 °C in acetic acid afforded **8** in a much lower yield of 25%, presumably because of the harsher (acidic) reaction conditions.

At the end of the reaction, the manganese acetate can be easily recovered (on precipitation) by addition of further organic solvent to the reaction mixture. After filtration, the manganese acetate was reacted with potassium permanganate to re-oxidise the manganese(II) back to manganese(III).[9] The manganese(III) acetate can therefore easily be recycled although this does depend on the nature of ionic liquid. For example, when the related ionic liquid [bmim][PF_6] was used, complete removal of the manganese byproducts was problematic. The ionic liquid [bmim][BF_4], which is believed to act as a co-



Scheme 4

solvent in these reactions,¶ can also be recovered on workup (in ⩾95% yield) and we have shown that this can be reused without any detriment to the product yields. For example, dihydrofuran **2c** was isolated in similar yields (*ca*. 50%) when using freshly prepared ionic liquid or ionic liquid recovered from other reactions. This work offers the potential for carrying out a variety of metal-mediated radical reactions in ionic liquids and this is currently under investigation.

We thank BP Amoco Chemicals, the EU (under the ERASMUS scheme) and The University of York for funding.

Notes and references

† To a solution of [bmim][BF_4][10] (2 cm^3) and dichloromethane (8 cm^3) containing cyclohexane-1,3-dione (0.10 g, 0.89 mmol) and α-methylstyrene (0.53 g, 2.63 mmol, 5 equiv.) was added manganese(III) acetate dihydrate (0.50 g, 1.88 mmol, 2.1 equiv.) under an atmosphere of nitrogen. The reaction mixture was then heated overnight until the solution changed from brown to yellow. Dichloromethane (40 cm^3) was then added and manganese(II) acetate was removed by filtration. The filtrate was then washed with water (4 × 10 cm^3) to remove the ionic liquid from the organic phase. (The ionic liquid can be recovered by extracting the aqueous phase with dichloromethane). The organic phase was then dried ($MgSO_4$), evaporated and purified using column chromatography (silica) to give 2-methyl-2-phenyl-3,5,6,7-tetrahydro-2*H*-benzofuran-4-one **1** (0.10 g, 50%) as an oil.

‡ All spectral data were in accord with the structures assigned. *Selected data* for **1**: δ_H(300 MHz, $CDCl_3$) 7.30–7.15 (5H, m, aromatics), 2.98 and 2.89 (2H, dt, *J* 14.5, 1.9, CH_2CPh), 2.45–2.40 (2H, m, CH_2), 2.29–2.23 (2H, m, CH_2), 2.02–1.91 (2H, m, CH_2), 1.62 (3H, s, CH_3); δ_C(75 MHz, $CDCl_3$) 196.0 (C=O), 176.4 (O–*C*=C), 146.0 (PhC^1), 128.9, 127.9, 124.6 (PhC$^{2–6}$), 113.0 (*C*=C–O), 93.0 (OCPh), 41.0 (PhCCH_2), 36.8 (*C*H_2C=O), 30.2 (CH_3), 24.5, 22.1 (*C*H_2CH_2CH_2).

§ When the reaction was carried out in dichloromethane in the absence of the ionic liquid, quinolone **4** was not formed even after heating in an ultrasonic bath (300 W, 30–40 kHz) for 24 h.

¶ Addition of the ionic liquid presumably increases the polarity of the medium and similar reactions can be carried out using dichloromethane in the presence of $Et_4N^+{}^-$OTs. Reaction of cyclohexane-1,3-dione with α-methylstyrene in a 0.1 M solution of $Et_4N^+{}^-$OTs in dichloromethane also gave tetrahydrofuranone **1** in 50% yield.

Nitration of alkanes with nitric acid catalyzed by *N*-hydroxyphthalimide

Shinji Isozaki, Yoshiki Nishiwaki, Satoshi Sakaguchi and Yasutaka Ishii*

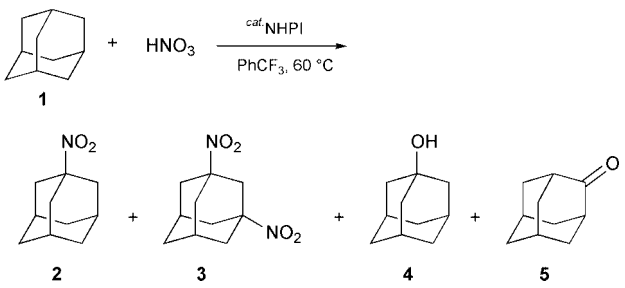
Department of Applied Chemistry, Faculty of Engineering and High Technology Research Center, Kansai University, Suita, Osaka 564-8680, Japan. E-mail: ishii@ipcku.kansai-u.ac.jp

Received (in Cambridge, UK) 13th March 2001, Accepted 11th June 2001
First published as an Advance Article on the web 5th July 2001

Catalytic nitration of alkanes with nitric acid was first successfully achieved by the use of *N*-hydroxyphthalimide (NHPI) under mild conditions; the key to the present nitration was found to be the *in situ* generation of NO_2 and phthalimide *N*-oxyl radical by the reaction of NHPI with nitric acid.

Nitration of saturated hydrocarbons using nitric acid is usually carried out at fairly high temperature (250–400 °C) because of difficulty in generating NO_2 from HNO_3.[1] The nitration under such severe conditions resulted in not only the homolysis of C–H bonds but also the cleavage of the C–C bonds of hydrocarbons. As a consequence, the reaction is messy and often difficult to control, and exhibits poor product selectivity. To carry out the nitration selectively, *in situ* generations of alkyl radicals from alkanes and NO_2 from HNO_3 must be achieved under mild conditions. Recently, we have developed a novel catalytic method for the nitration of aliphatic hydrocarbons with NO_2 using NHPI as the catalyst under mild conditions.[2] We now find that alkanes can be nitrated with nitric acid through the *in situ* generation of NO_2 and alkyl radicals by the use of NHPI as a catalyst under mild conditions.

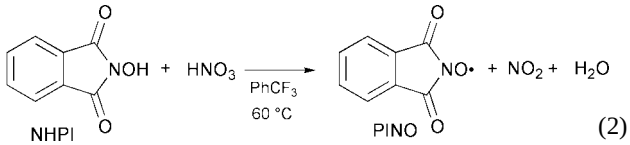
The nitration of adamantane (**1**) was chosen as a model reaction and carried out in the presence of nitric acid and a catalytic amount of NHPI in trifluorotoluene, affording 1-nitroadamantane (**2**) (64%) and 1,3-dinitroadamantane (**3**) (3%) along with oxygenated products, adamantan-1-ol (**4**) (9%) and adamantan-2-one (**5**) (5%) [eqn. (1), Table 1 entry 1]. In a previous paper, we showed that the nitration of **1** with NO_2 as a nitrating reagent affords **2** in 66% yield.[2] The nitration of **1** with HNO_3 which is easier to handle than NO_2 was found to be almost same as that with NO_2.



(1)

Table 1 shows the catalytic nitration of **1** with nitric acid by the NHPI under several reaction conditions.† Among the solvents examined, trifluorotoluene and acetic acid were found to be good solvents. Acetonitrile and ethyl acetate considerably retarded the nitration (entries 3 and 4). No reaction took place in the absence of NHPI (entry 5). The present nitration under air afforded oxygenated products, **4** and **5**, rather than nitro compounds (entry 6).

Upon treatment of NHPI with nitric acid at 60 °C, we found the evolution of brown gas attributed to NO_2. This finding suggests that the nitric acid reacts easily with the NHPI to generate NO_2 in the reaction system [eqn. (2)]. Importantly, nitric acid was easily converted into NO_2 in the presence of

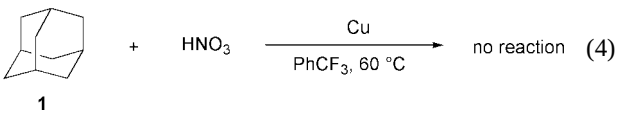


(2)

NHPI under relatively mild conditions, although it is known that the nitration of alkane with HNO_3 must be carried out at high temperature because of the difficulty in decomposing HNO_3 to NO_2.[1c] From EPR measurements, it was found that the phthalimide *N*-oxyl radical (PINO) was formed with the evolution of NO_2 by the reaction of the NHPI with nitric acid.‡ NHPI is known to be easily oxidized with $Pb(OAc)_4$ to the PINO.[3] In the present reaction, nitric acid serves as a good oxidizing agent of the NHPI to form the PINO and NO_2 [eqn. (2)].

In order to obtain further insight into the present nitration, **1** was allowed to react with nitric acid in the presence of copper in place of NHPI, since it is known that nitric acid reacts with copper metal, generating NO_2 according to eqn. (3).[4] However,

(3)



(4)

no nitration took place, although the generation of NO_2 was observed [eqn. (4)].

Table 2 summarizes the representative results for the nitration of various saturated hydrocarbons and their derivatives with nitric acid under the influence of the NHPI in trifluorotoluene at 60 °C for 15 h.

1,3-Dimethyladamantane (**6**) reacted with nitric acid under these conditions to give 1-nitro-3,5-dimethyladamantane (**7**) in 67% selectivity at 77% conversion (entry 1). When the NHPI used was increased from 0.1 mmol to 0.2 mmol, **7** was obtained in higher conversion and selectivity (entry 2). The nitration

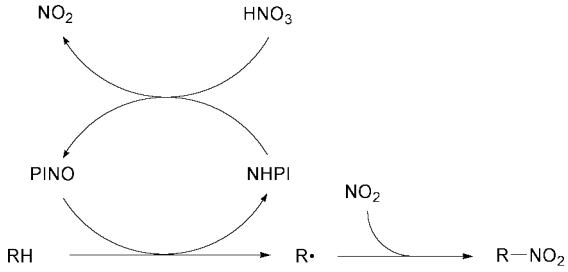
7[f]		—		60[dh]
8		80		65
9		59		61
10		73		79
11		32		91

[a] Reaction is shown in text. Parentheses show the conversion and selectivity in the nitration using NO_2 instead of HNO_3. [b] NHPI (0.2 mmol) was used. [c] Substrate (3.0 mmol) was used. [d] Based on HNO_3 used. [e] Dinitrocyclooctane (14%) and cyclooctanone (10%) were obtained. [f] Substrate (5 mL) was used. [g] Adipic acid (5%) was obtained. [h] Benzyl alcohol (21%) and benzaldehyde (19%) were obtained.

using excess **6** with respect to nitric acid resulted in **7** in excellent yield (95%). The nitration of *endo*-tricyclo-[5.2.1.$0^{2,6}$]decane (**8**) occurred selectively at the fused tertiary C–H bond to give the corresponding nitro compound **9** (57%). On the other hand, the nitration of **8** with NO_2 instead of HNO_3 resulted in **9** in low yield (47% selectivity, 74% conversion). Consequently, **8** was found to be nitrated with HNO_3 in higher selectivity. Cyclooctane was also nitrated to form nitrocyclooctane (56%) and a regioisomeric mixture of dinitrocyclooctane (14%) as well as a small amount of cyclooctanone (10%) at 75% conversion. Cyclohexane was difficult to nitrate selectively because of the formation of adipic acid (5%).[5] Aliphatic hydrocarbon like 2-methylhexane was nitrated at the tertiary position to lead to 2-methyl-2-nitrohexane in relatively good selectivity. Several substituted adamantanes were subjected to the nitration under these reacion conditions. Thus, 1-chloroadamantane, 1-nitroadamantane, and ethyl 1-adamantanecarboxylate were nitrated to the corresponding nitro compounds in fair to good selectivities (entries 9–11).



Scheme 1 A possible nitration path of alkanes with nitric acid by NHPI.

On the basis of these results, a possible reaction path for the present catalytic nitration of alkanes with nitric acid by the NHPI is shown in Scheme 1.

The nitration is initiated by the *in situ* generation of PINO and NO_2 from NHPI and nitric acid, respectively. The resulting PINO abstracts the hydrogen atom from alkanes to give NHPI and alkyl radicals which are readily trapped by NO_2 to form nitroalkanes.

In conclusion, the present alkane nitration with nitric acid provides a facile method for the preparation of nitroalkanes, by the use of cheap and easily available nitric acid compared with NO_2.

This work was partially supported by the Research for the Future program, JSPS and DAICEL Chemical Industries, Ltd.

Notes and references

† *A typical reaction was carried out as follows:* economic grade concentrated nitric acid (60% over) was used without any treatment. The reaction was carried out as follows: to a two necked flask was added adamantane (**1**) (1 mmol), NHPI (0.1 mmol) and nitric acid (1.5 mmol) in trifluorotoluene (3 mL), and the mixture was reacted under argon at 60 °C for 15 h. After evaporation of the solvent under reduced pressure, the reaction mixture was extracted with diisopropyl ether and the extracts were washed with aq. $NaHCO_3$. After separation of the organic phase, the mixture was subjected to silica gel chromatograph, giving 1-nitroadamantane (**2**) (57%), 1,3-dinitroadamantane (**3**) (3%) together with oxygenated products, adamantan-1-ol (**4**) (8%) and adamantan-2-one (**5**) (4%) (Table 1, entry 1).

‡ Electron paramagnetic resonance (EPR) measurements were carried out under selected conditions. To a two necked flask was added NHPI (0.1 mmol) and nitric acid (1.5 mmol) in trifluorotoluene (10 mL), and the mixture was reacted under argon at 60 °C for 1 h. The EPR spectrum attributed to PINO was clearly observed as a triplet signal based on hyperfine splitting (hfs) by the nitrogen atom (g = 2.0074, a_N = 0.46 mT). The g-value and hfs constant observed for PINO were consistent with those (g = 2.0073, a_N = 0.423 mT) reported by Mackor *et al.*[3b]

A new MFI-type zeolite containing uniform supermicropores: synthesis by structural transformation of CTA^+-MCM-41 and application in SCR of NO_x

Xiaoyin Chen and S. Kawi*

Department of Chemical and Environmental Engineering, National University of Singapore, 10 Kent Ridge Crescent, Singapore 119260, Republic of Singapore. E-mail: chekawis@nus.edu.sg

Received (in Cambridge, UK) 12th April 2001, Accepted 12th June 2001
First published as an Advance Article on the web 5th July 2001

A new MFI-type zeolite containing uniform 17 Å supermicropores has been successfully synthesized through structural transformation of CTA^+-MCM-41 and shows better activity for SCR of NO_x than conventional ZSM-5 under lean burn conditions.

The discovery of ordered mesoporous materials, due to their tailor-made pore sizes from 20 to 100 Å, has inaugurated potential pathways to selective catalysis and separation of large molecules.[1,2] Unfortunately, the hydrolysis of the amorphous silica framework and collapse of mesostructures under hydrothermal conditions or even at room atmosphere prevent practical applications of these surfactant-templated silicates.[3,4] Microporous zeolites are widely used as catalysts and sorbents due to their crystalline structure.[5] However, micropores restrict the diffusion rates of reactant and products,[6] hence limiting the activity of zeolite catalysts for certain reactions. Therefore, an attempt to synthesize or fabricate new porous crystalline materials having the advantages of both microporous and ordered macroporous structures is of interest recently for potential industrial applications.[7]

The difference between the synthesis of amorphous mesoporous and crystalline microporous materials lies primarily in the use of templates with different alkyl-chain quaternary ammoniumions. Long-chain quaternary ammoniumions ($\geqslant C_{12}$) form regular arrays of micelles to cast amorphous frameworks of mesostructures;[1] however, short-chain ones (C_1–C_4) template the formation of crystalline microporous zeolites.[8] Detailed investigation by different alkyltrimethylammonium surfactants $C_nH_{2n+1}NMe_3Br$ (n = 6, 8, 10, 12, 14, 16) showed that the shortest chain length (n = 6) gave predominantly MFI-type materials, while longer chains (n = 14, 16) produced mesoporous MCM-41 or amorphous materials.[9] Only mixed phases of MFI/MCM-41 were obtained using a mixed template consisting of C_6- and C_{14}-trimethylammonium ions.[10] Crystalline microporous structures can be formed in the presence of CTA^+ only.[11,12] Recently a two-step crystallization process was introduced into the amorphous framework of mesoporous materials to form MCM-41/ZSM5 composites, where mesoporous MCM-41 was first formed by CTA^+ and the amorphous framework of MCM-41 was then crystallized with TPA^+.[13] However, no literature has ever reported the formation of a crystalline composite containing both micropores and supermicropores (D_p = 15 and 20 Å) by using CTA^+ as the only template. This approach is of importance both for the investigation of the templating role of the surfactant and for the synthesis of a new shape-selective catalysts as supermicropores bridge the gap between micropores and mesopores. Here we report, for the first time, the transformation of the CTA^+–MCM-41 mesostructure into a hydrothermally stable MFI-type composite containing additional uniform supermicropores of 17 Å.

The new MFI-type material was synthesized according to the reported hydrothermal procedure.[12] However, in this work, the starting gel of sodium silicate was not acidified and a final molar composition of SiO_2: x Al_2O_3: y CTAB: z H_2O (x = 0–0.03, y = 0.05–0.5, z = 60–120) was used. After stirring for 60 min at room temperature, the white and viscous surfactant-silicate mixture was transferred to a Teflon-lined autoclave and then heated at 170 °C for different times. The resulting solids were recovered by filtration, thoroughly washed with distilled water and then dried at 100 °C overnight. The products were finally calcined at 550 °C in air for 10 h. For a comparison, conventional ZSM-5 material was synthesized using TPAOH according to the literature procedure.[14]

When SiO_2: y CTA^+: 120 H_2O was treated at 170 °C for 144 h, XRD and FTIR spectra showed that the products are of typical MFI structure. Fig. 1 shows different morphologies of products obtained under different crystallization times, which correspond to hexagonal MCM-41, lamellar phase and MFI structure in XRD patterns, respectively. Fig. 2 shows XRD patterns of the resulting products with varying crystallization times. For the sample formed under 6 h, the XRD pattern of the resulting CTA^+–silica composite clearly shows the hexagonal mesoporous structure of MCM-41. However, the calcined MCM-41 mesostructure completely collapsed when the calcined sample was kept in air at room temperature for two months or treated in boiling water for only 24 h, as shown in Fig. 3(a). For the sample formed under 12 h of crystallization, the hexagonal MCM-41 is transformed to a typical lamellar structure characterized by XRD and N_2 adsorption/desorption

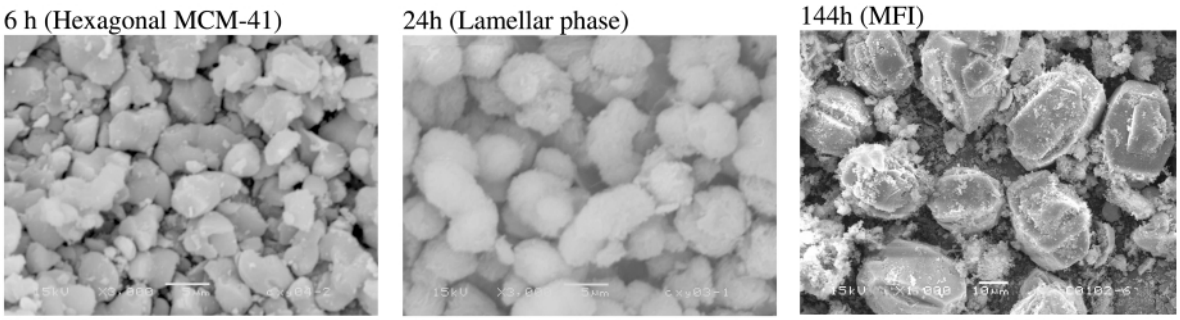

Fig. 1 SEM images of products obtained after crystallization times of 6, 24 and 144 h. SEM was performed on a JEOL JSM-5600LV scanning electron microscope operating at 15 kV.

 DOI: 10.1039/b103327c

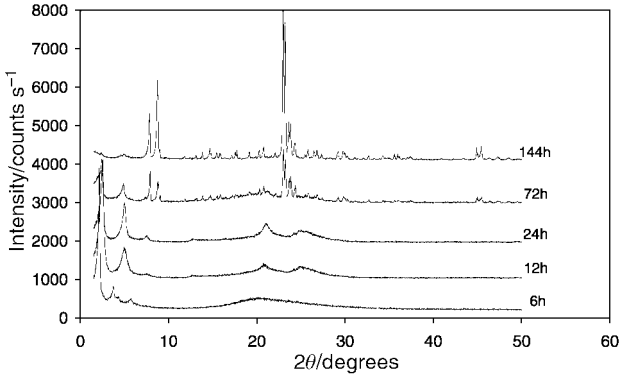

Fig. 2 XRD patterns of as-synthesized products obtained after different crystallization times.

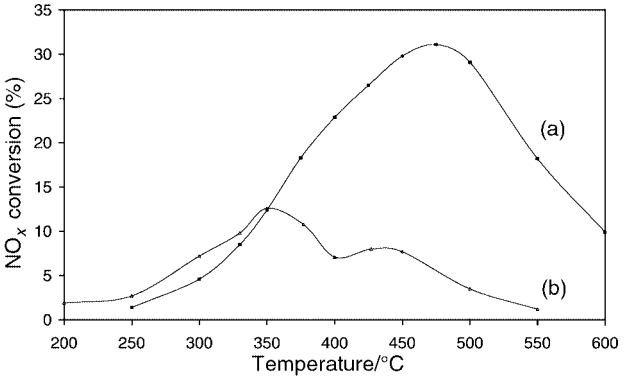

Fig. 4 Comparison of SCR of NO_x over new Co/MFI (a) and conventional Co/ZSM-5 (b). SCR of NO_x was carried out using a continuous flow reactor operating under 1 atm. *Reaction conditions*: 1000 ppm of NO, 1000 ppm of C_3H_8, 5% of O_2 (in He) and SV of 30 000 h^{-1}.

isotherms.[12] Once this product was calcined at 550 °C, all the XRD peaks disappeared and its N_2 adsorption/desorption isotherms remain unchanged after being kept in air at room temperature for two months, as shown in Fig. 3(b). After increasing the crystallization time to 72 h, XRD patterns show that both lamellar phase and MFI structure are present in the resulting product. After further crystallization for 144 h, XRD patterns corresponding to the MFI structure only are observed.

The ratios CTA^+/Si, Si/H_2O and Si/Al are found to be crucial factors influencing the structural transformation of the resulting material. The optimal values of y for successful synthesis of the new MFI materials is 0.1–0.4. Too low a value for CTA^+/Si results in the formation of a mixture containing MFI materials and cristobalite. However, amorphous silica was easily formed at $CTA^+/Si \geqslant 0.5$. Using $y = 0.2$, the new MFI possesses BET surface area and pore volumes of micropores of 409 $m^2\ g^{-1}$ and 0.172 ml g^{-1}, respectively, higher than those for a sample formed from TPA^+ (358 $m^2\ g^{-1}$ and 0.160 ml g^{-1}). Furthermore, N_2 isotherms of the new MFI-type material display capillary condensation characteristics. A H1-type hysteresis loop is clearly observed at $P/P_0 < 0.2$ [Fig. 3(c)], which corresponds to a narrow pore size distribution with a diameter of 17 Å. This pore size is much lower than that of CTA^+-templated MCM-41.[1]

CTA^+-templated MCM-41 readily becomes amorphous when subjected to refluxing in water for short periods of time (24 h).[3,4] In order to eliminate the possibility that the new material contains a mixture of MFI and MCM-41 as those reported elsewhere,[10] hydrothermal treatment was performed on the calcined sample in boiling water for 1 to 30 days. Fig. 3(d) and 3(e) show the N_2 isotherms for these samples, respectively. The hysteresis loops for samples treated in boiling water are similar to that of the untreated one. The pore size distribution of the sample treated in boiling water for 30 days, as shown in Fig. 3 (inset), is still maintained at 17 Å. Furthermore, its BET surface area, morphology and framework structure (which were characterized by SEM, XRD and FTIR) also remain unchanged.

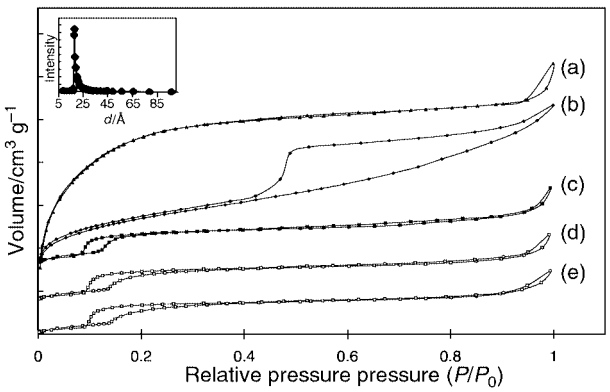

Fig. 3 N_2 adsorption/desorption isotherms of hexagonal MCM-41 (a), lamellar phase (b) and new MFI (c) after being kept in air at room temperature for 2 months prior to N_2 adsorption measurements. N_2 adsorption/desorption isotherms of the new MFI after being kept in boiling water for 10 days (d) and 30 days (e), and its BJH pore size distribution (Å) after 30 days in boiling water (inset).

Small crystals of Co/ZSM-5 were reportedly more active than larger ones for selective catalytic reduction (SCR) of NO_x by propane, showing the influence of mass transfer diffusion on the activities of the catalyst.[15] In this work, we used a new aluminium-containing MFI (Si/Al = 40) with a pore size of 17 Å, which was successfully synthesized using the above method, to investigate the effect of pore size of a catalyst on the conversion of NO_x by propane under lean burn conditions. 1.2 wt% cobalt-supported catalysts were prepared from the new MFI and conventional ZSM-5 by solid-state ion exchange with cobalt nitrate solution. Fig. 4 compares the conversion curves of NO_x on these two catalysts. It is obvious that the NO_x conversion over the new Co/MFI catalyst is much higher than that over conventional Co/ZSM-5 catalyst. The presence of uniform supermicropores of 17 Å in the new MFI catalyst is believed to be helpful for the mass transfer of reactants and reaction products across the pores, hence increasing the activity of the catalyst as diffusion control in microporous channels generally predominates in shape-selective catalysts such as MFI zeolite.[6]

Received (in Cambridge, UK) 27th February 2001, Accepted 13th June 2001
First published as an Advance Article on the web 5th July 2001

Ti-modified high silica zeolite with an Si/Al ratio of 1900 was found to be effective for the oxidation of propene to oxygenates such as propene oxide, in the presence of molecular oxygen at 573 K.

Propylene oxide is an important industrial intermediate which has traditionally been produced by the epoxidation of propene with organic hydroperoxides. In this proress, organic alcohols are stoichiometrically produced as by-products. Recently, titanium silicate-1 (TS-1) zeolite has been shown to be active for the reaction with H_2O_2.[1] This process is still liquid phase whereas the gas phase is more favorable due to product separation. Concerning the gas phase, Haruta and coworkers[2] and Moulijn *et al.*[3] have published work relating to epoxidation with propene/O_2/H_2 over Au dispersed on TS-1 and other Ti-containing supports. In these cases, selectivity to propene oxide is high ($>90\%$), but propene conversion is $<5\%$ and a large amount of H_2 is consumed to form H_2O. Direct propene oxidation by molecular oxygen without H_2 into propene oxide would be of value. The possibility to form propene oxide (PO), in particular, was shown, using $AgNO_3$ or KNO_3 supported on TS-1 and K_2CO_3 or KCl on the same matrix with a PO yield of 0.02%.[4] ARCO Chemical Technology has recently reported improved propene oxide yield in the presence of ethyl chloride.[5] In these cases without gaseous co-reactant such as hydrogen, acidic compounds such as nitrates and chlorides on the catalyst surface could be important for propene activation. In the course of our research program on direct oxidation of propene without any co-reactant, we have reported that titanium sulfate-modified amorphous zirconia was effective for this reaction,[6] although the propene conversion was below 6% and the PO yield only *ca.* 0.5%. Thus, in order to improve propene oxide yield, we tried the use of zeolite families as catalyst supports. In the present study, we report titanium-modified high silica zeolites with different ratios of Si/Al which are effective for the propene oxidation by O_2 without any co-reactant.

High silica zeolite (denoted silicalite) with Si/Al ratio of 3000 was prepared from $Si(OEt)_4$ and tetraethylammonium hydroxide by a hydrothermal method followed by calcination in a air flow at 823 K for 5 h. The other high silica zeolites (denoted HSZ) employed were provided by TOSO Co. Ltd. [HSZ(68),† HSZ(190)† and HSZ(1900)†]. Titanium-modified HSZ samples containing 7.5 wt% Ti[Ti/HSZ(68)] were prepared by the impregnation method.‡ All chemicals were purchased from Wako Pure Chemicals Co.. The amounts of adsorption of ammonia or CO_2 were estimated by using a Thermal Analysis System 001 instrument (MAC SCIENCE Co.).§

The catalytic reaction was performed under atmospheric pressure at temperatures between 473 and 673 K. A tubular fixed-bed reactor (OD = 1.25 cm, length = 60 cm) was filled with 1.0 g of catalyst powder and quartz sand (2.0 g). A pretreatment was done prior to each reaction at 673 K under air flow (25 ml min^{-1}) for 2 h. The reactant feeds were C_3H_6 (7.5 ml min^{-1}) and air (17.5 ml min^{-1}). Hydrocarbons and oxygenated compounds were detected by TCD and FID gas chromatography, the former with Porapack Q (1 m) at 673 K, the latter with 20 wt% FFAP on Chromosorb W (3 m) at 373 K. Products in the gas phase was analyzed by another TCD equipped with a Porapak Q column (3 m) and molecular sieve 5 Å column (3 m) kept at 343 K. The reaction products were also confirmed by mass spectrometry. In order to check the initial activities of catalysts, GC analyses were started 15 min after reaching the reaction temperature. The products were propene oxide (PO), acetaldehyde (AA), C_1–C_8 hydrocarbons (HC), CO and CO_2 (CO_x) and small amounts of other oxygenates [propanal, acetone, formaldehyde, alcohols (MeOH, EtOH, Pr^iOH)] were also detected.

The catalytic performances at 573 K are summarized in Table 1. No product was formed through the reactor in the absence of catalyst. Both Ti/SiO_2 (run 1) and Ti/TiO_2 (run 2) exhibited low propene conversion and only hydrocarbons (HC) and CO_x were produced. For the HSZ family we found that the catalyst

7.5% Ti/silicalite(3000)	0.0104	0.0080	76.9	0.0129	0.00956	74.1
7.5% Ti/HSZ(1900)	0.0187	0.0143	76.6	0.0495	0.042	85.3
7.5% Ti/HSZ(68)	0.0196	0.0147	75.0	0.0339	0.0233	68.7

[a] Thermogravimetric analysis conducted in argon in the range 300–673 K. [b] The acid or base sites were estimated by the amounts of NH_3 or CO_2 desorbed within each prescribed temperature. [c] These values, calculated [100 (*y*/*x*)] can be regarded as the percentage of *weak* base or acid sites.

performances were strongly dependent on the Si/Al ratio of the supports. For 7.5% Ti/HSZ(68) (run 3), propene conversion was very high (97.8%) and some oxygenates were produced with CO_x and a substantial amount of residue, but the PO yield was only 3.11%. The 7.5% Ti/HSZ(190) (run 4) also showed high propene conversion of 95.5% and both CO_x and the amount of residue were decreased, while the selectivities to oxygenates were increased. In this case the PO yield was 8.90%.

On the other hand, the conversion of propene on 7.5% Ti/HSZ(1900) was approximately half the propene conversion of 7.5% Ti/HSZ(190), while selectivities to CO_x and residue (0.13%) were dramatically lower than for 7.5% Ti/HSZ(190). For 7.5% Ti/HSZ(1900) (run 5) the selectivity to PO was found to be 36.3% and major by-products were acetaldehyde (AA) and hydrocarbons (HC). As a result, the PO yield (17.3%) on 7.5% Ti/HSZ(1900) was twice that of 7.5% Ti/HSZ(190). 7.5% Ti/silicalite (3000) (run 6), on the other hand, showed much lower propene conversion (1.89%) than 7.5% Ti/HSZ(1900). Therefore, it is indicated that titanium-modified HSZ with an Si/Al ratio of 1900 not only has a moderate ability to activate propene using molecular oxygen, but also properties suitable for predominant formation of oxygenates (in particular, PO) over hydrocarbons (HC).

The 15% Ti/HSZ(1900) catalyst (run 7) exhibited higher propene conversion (78.2%) than 7.5% Ti/HSZ(1900), although the PO selectivity was slightly decreased, while HC selectivity was increased. In this case, the PO yield was 20.4%, > 10 times those previously reported under O_2/H_2 conditions[2,3] and, at least, > 3 times recently reported for Ag-containing catalyst[4,5] or photocatalyst[7] systems. At 523 K, the PO selectivity on 15% Ti/HSZ(1900) was as high as 40.9%, while the propene conversion was 9.03% (run 8). HSZ(1900) alone (run 9) showed higher propene conversion and HC selectivity than 7.5% Ti/HSZ(1900), while less selectivity to oxygenates was observed. This indicated that surface properties for oxygenate formation were improved by Ti modification.¶

The mechanism of oxidation of propene over Ti/HSZ catalysts is not clear. However, catalyst performances are dependent on Si/Al ratio of the HSZ supports (Table 1) and, therefore, it seems likely that surface acid–base properties are responsible for the catalyst behavior, in particular, propene conversion and residue yield. In fact, as shown in Table 2, where NH_3- or CO_2-TPD was conducted by using thermogravimetric methods, 7.5% Ti/silicalite(3000) catalyst exhibited weaker adsorption for NH_3 as well as CO_2 than the other two catalysts; This is in good accordance with much lower propene conversion of this catalyst relative to the other catalysts (Table 1, runs 3, 5 and 6).

NH_3 adsorption on 7.5% Ti/HSZ(1900) catalyst was slightly larger than that on 7.5% Ti/HSZ(68), while the amount of CO_2 adsorbed was similar (Table 2). However, as much as 85.3% of NH_3 adsorbed on 7.5% Ti/HSZ(1900) was found to be desorbed below 440 K (Table 2, *y*/*x* ratio and Fig. 1), whereas the ratio of NH_3 desorption below 440 K on 7.5% Ti/HSZ(68) was only 68.7%; These findings indicated that the ratio of strong to weak acid sites on 7.5% Ti/HSZ(1900) is smaller than that on 7.5% Ti/HSZ(68). This could be consistent with the fact that the 7.5% Ti/HSZ(1900) catalyst showed lower propene conversion and smaller amounts of residue product than those for 7.5% Ti/HSZ(68) (Table 2, runs 3 and 5). The calcination of

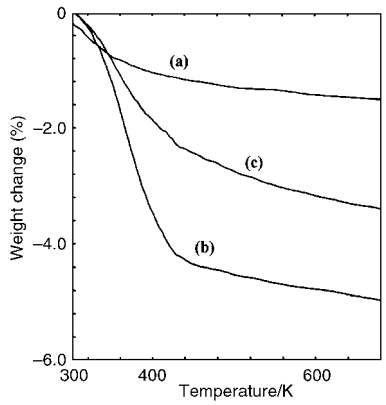

Fig. 1 NH_3-TPD data for (a) 7.5% Ti/silicalite(3000), (b) 7.5% Ti/HSZ(1900) and (c) 7.5% Ti/HSZ(68).

7.5% Ti/HSZ(1900) at 1073 K, higher by 100 K than the standard calcination temperature (973 K), would result in a decrease in weak acid sites, while strong acid sites might still be retained. As a result, propene conversion was decreased to 37.3% and selectivity to hydrocarbon formation (HC) was raised to 59.7% (Table 1, run 10).

In summary, Ti-modified HSZ(1900) was found to catalyse the oxidation of propene to oxygenates, such as propene oxide, by molecular oxygen at 573 K. The catalyst performances are affected by the Si/Al ratio of the HSZ supports as well as the presence of titanium. Cooperation between moderate acid properties of HSZ(1900) and titanium favors oxygenate formation. It is expected that fine control of acid properties of these supports and titanium content well enhance the catalyst performances for propene oxide formation.

Notes and references

† These zeolites are of H-ZSM-5 type where the number in parentheses is the Si/Al ratio.

‡ The calcined HSZ was evacuated at 673 K for 3 h in order to eliminate a small amount of water. Then, the HSZ was impregnated with $Ti(OPr^i)_4$ in Pr^iOH, followed by addition of H_2O (25 g) leading to precipitation of titanium oxide. The sample was then dried at 373 K for 10 h and finally calcined at 973 K for 3 h.

§ The sample was evacuated at 673 K for 2 h then, after cooling to 373 K, ammonia adsorption on to the surface was allowed to occur to saturation. Evacuation was then applied for 1 h at the same temperature followed by thermal gravimetric (TG) analysis. CO_2 adsorption was carried out at 300 K.

¶ The TS-1 catalyst contains 1.68 wt% Ti and an Si/Al ratio of 46,[1] in contrast to 7.5% Ti and Si/Al ratio of 1900 for 7.5% Ti/HSZ(1900). TS-1 is thus less effective for selective PO formation than 7.5% Ti/HSZ(1900) catalyst under propene/O_2.

Received (in Cambridge, UK) 13th March 2001, Accepted 6th June 2001
First published as an Advance Article on the web 5th July 2001

Novel receptors featuring a 2,6-diamidopyridine 'head' group and bearing sulfonamidopeptide sidearms have been prepared on the solid-phase; one receptor showed high selectivity for *N*-Cbz-D-Ala-D-AlaOH over its enantiomer *N*-Cbz-L-Ala-L-AlaOH, but absolute binding constants were relatively weak, which can be understood in terms of receptors which have to unfold, breaking intramolecular hydrogen bonds, in order to accommodate the guests.

While several macrocyclic hosts have been prepared and shown to bind amino acids or peptide fragments with excellent selectivity,[1] during the last decade a different class of receptors for peptides called 'tweezer receptors' or 'two-armed' receptors have been developed.[2,3] Many of these systems bind substrates, and particularly peptides, with selectivities which are in many ways surprising, given the apparent flexibility of such acyclic receptor structures.

Whereas in many such 'two-armed' receptor systems the head group plays only a limited role in the binding of the guest, the group in Southampton have recently developed receptors utilising a diamidopyridine as the head group which can specifically bind to carboxylic acid functionality, and such receptors, with peptidic arms, have proven to be selective receptors for peptides with a carboxylic acid terminus.[3] In this paper we report studies on novel 'two-armed' receptors consisting of a 2,6-diamidopyridine head group bearing sulfonamidopeptide sidearms,[4] one of which, in particular, shows high binding selectivity for the dipeptide *N*-Cbz-D-Ala-D-AlaOH (Cbz = benzyloxycarbonyl) over its enantiomer *N*-Cbz-L-Ala-L-AlaOH. In contrast to the CONH moiety of peptides, which provides both a strong hydrogen-bond donor and acceptor, the SO_2NH moiety of sulfonamidopeptides provides a very strong donor NH, but the SO_2 group is only a weak acceptor.[5,6]

The synthesis of the novel receptors was accomplished on the solid phase starting from *N*-Fmoc-Gly Wang resin **1** (loading 0.88 mmol g^{-1}) (Scheme 1). After deprotection of the amino-group, diamidopyridine derivative **2**[3] was coupled using a 20% excess of resin, and the unreacted amino groups on the resin were capped with acetylimidazole. Deprotection of the Fmoc groups and coupling with the L-valine-derived β-*N*-Fmoc-amino sulfonyl chloride using DMAP as catalyst and dimethylketene methyl trimethylsilyl acetal (MTDA) as HCl scavenger,[5,7] gave a resin bound disulfonamide. Cleavage of Fmoc protection, followed by acetylation gave the desired disulfonamide derivative, which was cleaved from the resin by a direct basic methanolysis or by acidic TFA–H_2O cleavage followed by esterification to give receptor **4**. Alternatively the resin bound sulfonamide could be deprotected and subjected to a further coupling with the L-valine-derived β-*N*-Fmoc-amino sulfonyl chloride, followed by deprotection, acetylation and cleavage to give receptor **5**.

Binding studies with receptors **4** and **5** were carried out with a series of substrates in deuteriochloroform, using a standard NMR titration experiment.[8] Titration of **4** with simple amino acid derivatives such as *N*-Cbz-L-AlaOH or *N*-Boc-L-AlaOH gave modest binding constants (K_{ass} = 207 and 119 M^{-1} respectively) and little apparent enantioselectivity (*N*-Cbz-L-AlaOH: K_{ass} = 207 M^{-1}, *N*-Cbz-D-AlaOH: K_{ass} = 270 M^{-1}, Table 1). Binding of all three amino acid substrates led to significant downfield shifts of the amidopyridine NH[1] (≥0.5 ppm).[9] Binding of dipeptide guests gave slightly higher binding constants, and titration of **4** with, for example, *N*-Cbz-L-

 DOI: 10.1039/b102383g

Ala-L-AlaOH gave a binding constant of 245 M^{-1} and led to downfield shifts of both the amidopyridine and sulfonamide NH's (NH^1: $\Delta\delta$ = 0.25 ppm, NH^2: $\Delta\delta$ = 0.30 ppm) and an upfield shift of acetamide NH^3 ($\Delta\delta$ = 0.12 ppm). Binding of dipeptides was also associated with downfield shifts for both the amide and carbamate NH signals of the guest ($\Delta\delta$ = 0.10–0.35 ppm). Titration with *N*-Cbz-D-Ala-D-AlaOH led to little change to the amidopyridine NH^1 ($\Delta\delta \leqslant 0.03$ ppm), but analysis of the downfield shift of sulfonamide NH^2 ($\Delta\delta$ = 0.28 ppm) and the upfield shift of acetamide NH^3 ($\Delta\delta$ = 0.19 ppm) gave a binding constant of 242 M^{-1} indicating that **4** also shows little enantioselectivity for dipeptides (K_{ass} for *N*-Cbz-L-Ala-L-AlaOH = 245 M^{-1}, Table 1). Thus receptor **4** does appear to bind dipeptides and simple amino acid derivatives, but the absolute binding constants are rather low in comparison to other diamidopyridine based receptors, and the shifts of the various NH signals on binding are also rather small in comparison to those seen in other related receptor systems.[1b,10,11] We therefore studied receptor **5**, reasoning that with additional binding functionality in the longer sidearms it might show increased affinity for peptide guests. In practice, receptor **5** initially gave absolute binding constants somewhat lower than **4** (Table 1) and again only small shifts were observed for the various NH signals on addition of guest. However, binding of the *N*-Cbz-Ala-AlaOH dipeptide enantiomers showed marked selectivity. Titration of **5** with *N*-Cbz-L-Ala-L-AlaOH gave a binding constant of 107 M^{-1} and led to a downfield shift of 0.3 ppm for the amidopyridine NH^4 but only small changes to the sulfonamide and acetamide NH's (NH^5, NH^6, NH^7, $\Delta\delta \leqslant 0.07$ ppm). In contrast, titration of **5** with *N*-Cbz-D-Ala-D-AlaOH gave a binding constant of 2404 M^{-1} with a particularly large downfield shift for the sulfonamide NH^6 ($\Delta\delta$ = 0.72 ppm) but an upfield shift for sulfonamide NH^5 ($\Delta\delta$ = 0.38 ppm) and even a small upfield shift for the amidopyridine NH^4 ($\Delta\delta$ = 0.05 ppm)! Binding of *N*-Cbz-D-Ala-D-AlaOH was also accompanied by significant shifts of several CH signals of the host (up to 0.37 ppm) and significant shifts for the guest NH protons ($\Delta\delta \approx 0.5$ ppm).[9]

The small shifts on binding for the NH signals, and generally low absolute binding constants, for receptors **4** and **5**, can be rationalised by considering the unbound conformation of the receptors, which were investigated in detail by NMR.

In the ^{1}H-NMR spectra of **4** and **5** in $CDCl_3$ peaks are rather broad, indicating slow conformational equilibria at room temperature (on the NMR time scale). The NH protons, for both **4** and **5** display a very small concentration dependence in $CDCl_3$ indicating that the receptors do not aggregate in the concentration range considered (0.5–20 mM). At a concentration of 8.5 mM in $CDCl_3$ the signals of the amidopyridine NH protons appear at unexpectedly low field [$NH^1$1(**4**): 9.41, NH^4(**5**): 9.32 ppm compared to standard values[1b,11] 8.0–8.5 ppm], and the sulfonamide NH protons are also strongly deshielded [NH^2(**4**): 6.32, NH^5(**5**): 5.78, NH^6(**5**): 6.32 ppm compared to their standard values[5] 4.50–4.74 ppm], while the acetamide protons, NH^3(**4**) and NH^7(**5**), are closer to their normal chemical shifts (6.2 compared to 6.0–6.2 ppm). In comparison, the spectrum of the control compound **3** (Scheme 1) in $CDCl_3$ is perfectly resolved, and the amidopyridine NH signal is found at 8.83 ppm (for a concentration of 8.5 mM), whereas the acetamide NH proton is found at 6.56 ppm. This suggests that receptors **4** and **5** collapse to give folded structures stabilised by intramolecular hydrogen bonds. Such a conclusion is supported by NOESY and ROESY experiments, which revealed a large number of NOE contacts consistent with a folded structure.

Thus binding of substrates by **4** or **5** involves a degree of unfolding of the receptor, and breaking of intramolecular hydrogen bonds (with an associated energetic cost), to allow interaction with the guest, resulting in rather low binding constants and only small overall changes to the signals for the hydrogen bonding NH protons. In particular, the only significant change in the NMR for **5**, on binding of *N*-Cbz-L-Ala-L-AlaOH, is a downfield shift of the amidopyridyl NH^4, indicating breaking of an intramolecular hydrogen bond to this NH and binding with the carboxylic acid of the guest. In contrast, the binding of *N*-Cbz-D-Ala-D-AlaOH by **5** leads to significant shifts of several CH as well as NH signals throughout the spectrum (although there is little overall shift to the amidopyridine NH^4) suggesting a much more dramatic conformational change for the receptor on binding this guest[12] and that binding of this guest is sufficiently strong to overcome the penalty of unfolding the receptor. In any event such high enantioselectivity, > 20 : 1 (effectively discriminating between methyl groups and hydrogen atoms), has rarely been observed in synthetic receptors,[1,10] and is particularly noteworthy in such a structurally simple acyclic receptor, which appears to lack much, if any, preorganisation for binding.

Table 1 Binding constants[a] (K_{ass}) for the 1 : 1 complexes[b] formed between receptors **4** and **5** and various amino acid and dipeptide derivatives, in $CDCl_3$ at 25 °C

	K_{ass}[a]/M^{-1}	
Substrate	**4**	**5**

Hydroformylation of 1-hexene with rhodium in non-aqueous ionic liquids : how to design the solvent and the ligand to the reaction

Frédéric Favre, Hélène Olivier-Bourbigou,* Dominique Commereuc and Lucien Saussine

Institut Français du pétrole, 1-4 Avenue de Bois-Préau, 92852 Rueil-Malmaison, France. E-mail: helene.olivier-bourbigou@ifp.fr

Received (in Cambridge, UK) 10th May 2001, Accepted 7th June 2001
First published as an Advance Article on the web 6th July 2001

A wide range of ionic liquids based on imidazolium and pyrrolidinium cations and weakly coordinating anions proved to be efficient solvents for the biphasic rhodium catalyzed hydroformylation of 1-hexene; the reaction rate and regioselectivity, and the retention of the rhodium can be optimized by fitting the nature of the anions and cations of the ionic liquid and the modified phosphite or phosphine ligands.

Ionic liquids are good solvents for transition-metal complexes in many homogeneously catalyzed reactions, *e.g.* olefin hydrogenation, hydroformylation, oligomerization and Pd mediated carbon–carbon coupling reactions.[1] In many cases the reaction products are very weakly soluble in the ionic phase so that the catalyst can be separated by simple decantation and recycled. The aqueous two-phase catalysis concept, which has been already applied industrially for propene hydroformylation,[2] can then be extended to substrates and ligands that are poorly soluble or non stable in water. Higher olefin Rh-hydroformylation has been performed using different 1-butyl-3-methylimidazolium room-temperature liquid salts as solvents, in the presence of phosphine ligands. The main difficulty is to immobilize the rhodium catalyst in the ionic liquid phase while maintaining its activity and selectivity. A solution is to modify the neutral phosphine ligands with ionic groups.[3] Thanks to their chemical and physical versatility,[4] ionic liquids can be specially designed to fit with the ligand and the operating conditions that provide the best performances in catalysis.

In this communication, for the first time we report the effect of the nature of the cations and anions of the ionic liquids on the Rh-catalyzed hydroformylation of 1-hexene. We also provide our preliminary study on the performances of different phosphorus ligand–ionic liquid systems.

We have prepared a wide range of ionic liquids by varying the nature of the cation *e.g.* 1,3-dialkylimidazolium, 1,2,3-trialkylimidazolium and *N*,*N*-dialkylpyrrolidinium and the nature of the anion *e.g.* BF_4^-, PF_6^-, $CF_3CO_2^-$, $CF_3SO_3^-$ (OTf^-) and $N(CF_3SO_2)_2^-$ (NTf_2^-). The BF_4^-, NTf_2^- and PF_6^- ionic liquids were prepared by anion exchange starting from imidazolium or pyrrolidinium chloride. The $CF_3SO_3^-$ and $CF_3CO_2^-$ salts were prepared by direct methylation of 1-alkylimidazole or 1-alkylpyrrolidine with the corresponding methyl esters.[5] We have measured the solubility of 1-hexene in these ionic liquids (Fig. 1). For a given anion, *e.g.* $CF_3CO_2^-$, the solubility of 1-hexene increases upon increasing the length of the alkyl chain of the 1,3-dialkylimidazolium *e.g.* 1-butyl-3-methylimidazolium (BMI^+) *vs.* 1-hexyl-3-methylimidazolium (HMI^+). Methylation of the C(2) atom of the imidazolium ring tends to decrease the solubility of 1-hexene *e.g.* 1-butyl-2,3-dimethylimidazolium $BDMI^+NTf_2^-$ *vs.* $BMI^+NTf_2^-$. No significant differences are observed by changing the 1-butyl-3-methylimidazolium cation for *N*,*N*-butylmethylpyrrolidinium (BMP^+). For a same cation, *e.g.* BMI^+, the solubility of 1-hexene increases as follows: $BF_4^- < PF_6^- < OTf^- < CF_3CO_2^- < NTf_2^-$.

In a first series of experiments, we performed 1-hexene hydroformylation using these different ionic liquids as solvents for the $Rh(CO)_2(acac)$ precursor associated with the sodium salt of monosulfonated triphenylphosphine (TPPMS) (Fig. 1). The results reveal that there is a correlation between the reaction rates (TOF min^{-1}) and the solubility of 1-hexene in ionic

Table 1 Hydroformylation with different ligand–ionic liquid systems[a]

Entry	Ligand L	L/Rh	Ionic liquid	Reaction time/min	Conversion[b] (%)	Aldehydes[c] (mol %)	n/i[d]	TOF[e]/min^{-1}
1	**1a**	10	$BMI^+BF_4^-$	180	77	74	3.7	3
2	**1b**	7		210	83	78	4	3
3	**2**	4		180	87	96	2.6	4
4	**3**	9.5	$BMI^+PF_6^-$	180	96	88	12.6	4
5[f]	**3**			240	85	89	11.2	2
6[g]	**3**			330	42	88	11.7	1

[a] *Reaction conditions*: $Rh(CO)_2(acac)$ 0.075 mmol, 1-hexene/Rh = 800, CO/H_2 (molar ratio) = 1 ; $P(CO/H_2)$ = 2 MPa, T = 80 °C, heptane (internal standard) = 2 mL, 1-hexene = 7.5 mL, ionic liquid = 4 mL. [b] Conversion = [(initial 1-hexene) − (1-hexene after reaction)]/(initial 1-hexene). [c] The other products are 2- and 3-hexenes. [d] Linear to branched aldehyde ratio. [e] Mol of aldehydes per mol Rh per minute at 25% conversion. [f] Recycling of 4. [g] Recycling of 5.

liquids. In all cases, the selectivity in aldehydes is > 97%, the remainder being isomerized hexenes. Surprisingly, in the NTf_2^- based ionic liquids, lower TOF are obtained despite the relatively good solubility of 1-hexene in these media. As suggested by the determination of ionic liquid relative polarity,[6] the NTf_2^- based salts could be more coordinating than the PF_6^- salts. In all cases, the n/i ratio is not affected by the nature of the solvent.

In a second series of experiments, we have synthesized the monosubstituted guanidinium triphenylphosphine ligands **1a** and **1b**,[7] and the pyridinium diphenylethylphosphine ligand **2** (Scheme 1). Ligand **2** was prepared in two steps according to Scheme 2. Ligands **1a** and **1b** show good solubility in the ionic liquid $BMI^+BF_4^-$. They give good selectivities towards the linear aldehydes. Similar catalytic performances were obtained by using **1a** or **1b** (Table 1, entries 1 and 2). However, the retention of the Rh in the $BMI^+BF_4^-$ phase was more efficient with **1a** (the Rh content in the organic phase was lower than the detection limit according to ICP analysis for **1a**, while the level was 0.8% of the initial Rh for **1b**). Ligand **2** (entry 3) presents higher reaction rates and higher selectivity towards aldehydes than **1a** and **1b**. However, the leaching of the Rh in the organic phase was found to be higher for **2** (2% of the initial Rh).

Phosphites and bisphosphites are well known ligands for Rh-hydroformylation to afford higher reaction rates.[8] Because of their instability toward hydrolysis, examples of their use in aqueous two-phase hydroformylations are rare.[9] Ionic liquids offer suitable alternative solvents. We describe here the first use of phosphite based ligands for the biphasic hydroformylation of 1-hexene in ionic liquids. Ligand **3**, a mixture of tetrabutylammonium salt of the mono- di- and tri-sulfonated triphenylphosphites, has been prepared by transesterification of triphenylphosphite with the tetrabutylammonium salt of *p*-hydroxyphenylsulfonic acid.[9] In the reaction with the ligand **3**, using $BMI^+PF_6^-$ as the solvent, good catalytic activity is observed (entry 4). The selectivity for the linear aldehyde is much higher than the selectivity obtained with phosphine ligands (enties 1–3). The use of the modified phosphite **3** limits the loss of the Rh in the organic phase (leaching is 2% of the initial Rh used). At the end of the run, the organic phase is decanted and separated from the ionic liquid which is reused (entry 5 and 6). Despite a loss of activity which could be ascribed to a partial degradation of the Rh active catalyst during the separation, the n/i ratio remains high after two recyclings.

In conclusion, it is shown that thanks to the great versatility of ionic liquids, it is possible to optimize Rh-hydroformylation performances by adjusting the nature of the anions and cations present in the solvent and the nature of the ligands. Phosphite ligands, which are unstable in an aqueous two-phase system, can be used. The problem of Rh leaching can be minimized by the modification of phosphorus ligands with cationic (guanidinium or pyridinium) or anionic (sufonate) groups. By adjusting the ligand and the ions of the solvent, excellent Rh retention has been achieved.

Received (in Cambridge, UK) 10th May 2001, Accepted 15th June 2001
First published as an Advance Article on the web 5th July 2001

By the novel *in situ* stopped-flow MAS NMR technique allowing the observation of adsorbates on a solid catalyst after stopping the continuous reactant flow, *N*-methyleneaniline was identified as an intermediate in the formation of *N*-methylaniline by methylation of aniline with methanol on a basic CsOH/Cs,Na-Y zeolite.

In the past decade, *in situ* MAS NMR spectroscopy has been developed as a powerful tool for investigating heterogeneously catalyzed reactions.[1] Since 1995, a number of new *in situ* MAS NMR techniques have been developed allowing the study of reactions under continuous flow conditions.[2] With these techniques, a direct NMR investigation of the formation and transformation of surface compounds under steady-state conditions and a simultaneous gas chromatographic analysis of the reaction products are possible. In the present communication we report on the application of a new *in situ* stopped-flow (SF) MAS NMR experiment which is suitable to determine intermediates of heterogeneously catalyzed reactions. With this method, an intermediate involved in aniline methylation on basic zeolite CsOH/Cs,Na-Y under flow conditions was determined for the first time.

The zeolite CsOH/Cs,Na-Y used as catalyst in the present work had an n_{Si}/n_{Al} ratio of 2.6 and was prepared as described elsewhere.[3] After the sodium/caesium exchange (sodium exchange degree of 70%), zeolite Cs,Na-Y was impregnated with an aqueous solution of caesium hydroxide such as to arrive at a loading of 14 CsOH per unit cell. Subsequently, the material was calcined for 12 h at 723 K. The NMR experiments were performed on a Bruker MSL 400 spectrometer at a resonance frequency of 100.4 MHz, with direct excitation ($\pi/2$ pulse), a repetition time of 5 s and *ca*. 500 scans per spectrum. For the *in situ* measurements, the equipment described in ref. 2(*f*) and a modified 7 mm high-temperature Doty MAS NMR probe were used. The protocol of the 'stopped-flow' experiment is shown in Fig. 1. After filling the calcined catalyst into the MAS rotor and transferring the rotor into the spectrometer, the temperature was raised to 473, 498 and 523 K while the carrier gas (nitrogen) loaded with the reactants was flowing. In all experiments, a methanol (^{13}C-enriched) flow according to a modified residence time of W/F = 40 g h mol^{-1} (m_{cat} = 250 mg, $\dot{n}_{me}$ = 6.25 mmol h^{-1}) was used. The molar ratio of the methanol–aniline (natural ^{13}C-abundance) mixture was 4:1. After recording the ^{13}C MAS NMR spectra under steady-state conditions at reaction temperatures of 473, 498 and 523 K, the reactant flow was stopped, and the further conversion of the adsorbate compounds was observed, without purging the catalyst (see Fig. 1).

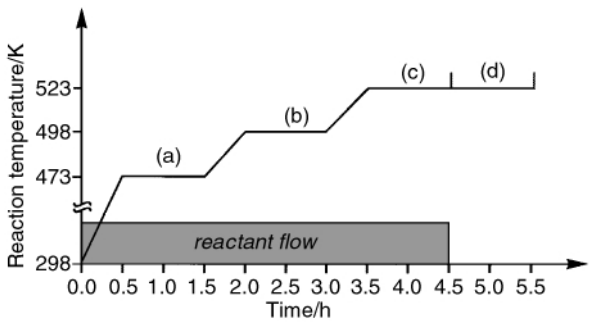

Fig. 1 Protocol of the *in situ* SF MAS NMR experiment consisting of periods (a) to (c) for the study of heterogeneously catalyzed reactions under steady-state conditions at different temperatures and a period (d), in which the consecutive conversion of previously formed compounds can be investigated.

Methanol was applied as methylating agent, and the conversion of this reactant alone on zeolite CsOH/Cs,Na-Y was investigated in the first experiments. Fig. 2(a)–(c), left, show the *in situ* ^{13}C MAS NMR spectra obtained at reaction temperatures of 473–523 K under steady-state conditions. The signal at 49 ppm is due to adsorbed methanol molecules. With increasing reaction temperature, a second signal appears at 166 ppm which is caused by surface formate species.[4] In an earlier work on methylation of toluene on a basic zeolite CsOH/Cs,Na-X it was shown that surface formate species occurring at 166 ppm are consumed by the reaction which indicates that these species can act as methylating agents.[4c] The ^{13}C MAS NMR spectrum recorded immediately after stopping the methanol flow at 523 K shows a significant decrease of the methanol signal at 49 ppm and only a weak decrease of surface formate species at 166 ppm [Fig. 2(d), left]. This indicates that the surface formate species are quite stable at 523 K.

Fig. 2(a)–(c), right, show the ^{13}C MAS NMR spectra recorded during conversion of the methanol–aniline mixture on zeolite CsOH/Cs,Na-Y at reaction temperatures of 473–523 K. While the spectrum obtained at 473 K consists only of a single signal due to methanol molecules at 49 ppm, in the spectrum obtained at 498 K additional signals occur at 29 and 157 ppm. The signal at 29 ppm is due to the reaction product *N*-methylaniline.[5] The signal at 157 ppm can be assigned to *N*-methyleneaniline, based on work by Kamachi and coworkers who observed a signal at *ca*. 155 ppm in the ^{13}C NMR spectrum of *N*-methyleneaniline in THF-d_8.[6] Further increase of the reaction temperature to 523 K leads to the formation of surface formate species at 166 ppm and a strong increase of the signal at 29 ppm due to the reaction product *N*-methylaniline.

To find out whether the *N*-methyleneaniline species at 157 ppm is an intermediate in the formation of *N*-methylaniline on zeolite CsOH/Cs,Na-Y, a stopped-flow experiment was performed: the reactant flow was suddenly stopped, and a spectrum was recorded while keeping the temperature at 523 K. In the spectrum obtained [Fig. 2(d), right], the signal at 166 ppm remained constant. On the other hand, the signals of methanol at 49 ppm and of *N*-methyleneaniline at 157 ppm disappeared completely, while the signal of the reaction product *N*-methylaniline at 29 ppm gained significantly in intensity. Hence, not only methanol, but also the *N*-methyleneaniline species are consumed by the formation of *N*-methylaniline. This finding indicates that the *N*-methyleneaniline species occurring

 DOI: 10.1039/b104115k

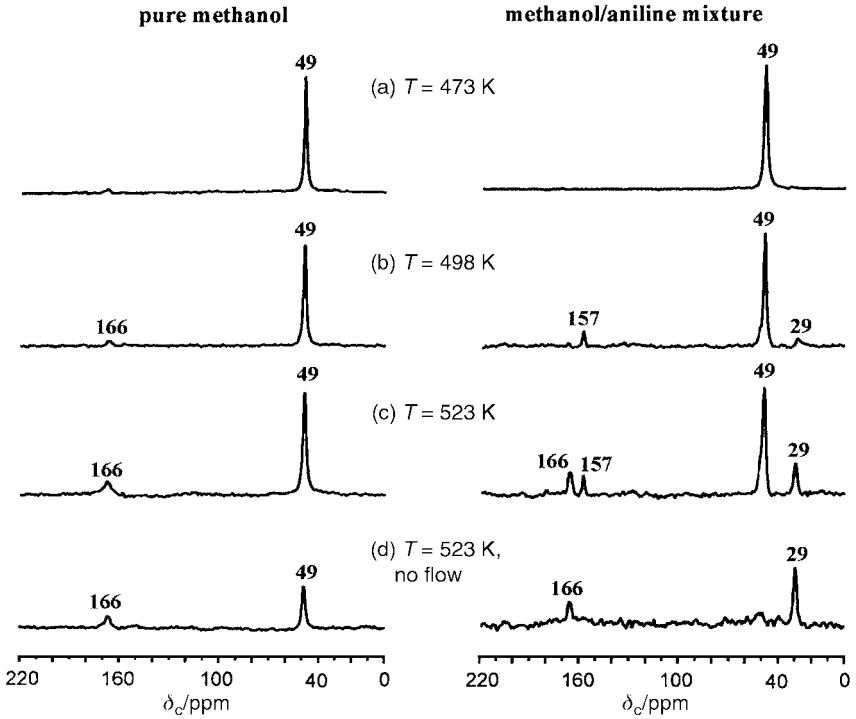

Fig. 2 *In situ* ^{13}C MAS NMR spectra obtained during the conversion of pure methanol (left) and a methanol–aniline mixture (right) on zeolite CsOH/Cs,Na-Y under flow conditions (W/F = 40 g h mol^{-1}) at reaction temperatures of 473 (a), 498 (b) and 523 K (c) and after stopping the reactant flow at 523 K (d).

at 157 ppm acts as an intermediate in the methylation of aniline.

The detection of *N*-methyleneaniline as an intermediate species can be accounted for by a mechanistic pathway which includes dehydrogenation of methanol to formaldehyde, [eqn. (1)], condensation of aniline with formaldehyde leading to *N*-methyleneaniline [eqn. (2)] and hydrogenation of *N*-methyleneaniline to *N*-methylaniline by H_2 produced during the methanol dehydrogenation [eqn. (3)]:

$$^{13}CH_3OH\ (49\ ppm) \rightarrow H^{13}CHO + H_2 \quad (1)$$

$$C_6H_5NH_2 + H^{13}CHO \rightarrow C_6H_5N{=}^{13}CH_2\ (157\ ppm) + H_2O \quad (2)$$

$$C_6H_5N{=}^{13}CH_2\ (157\ ppm) + H_2 \rightarrow C_6H_5NH^{13}CH_3\ (29\ ppm) \quad (3)$$

Based on the results of the present study we cannot decide whether the formate species observed at 166 ppm, or formaldehyde directly formed by conversion of methanol, acts as the methylating agent in the first reaction step. Our previous results demonstrated that the formation of formate species and aniline alkylation are parallel, *i.e.*, competing reactions on basic zeolites and that formate species most probably do not participate in the alkylation.[8] The fact that we did not observe formaldehyde species in the *in situ* MAS NMR experiments is due to its high reactivity on basic zeolites and, consequently, can be explained by a higher rate of reaction (2) compared to reaction (3).

It should be mentioned that the mechanism proposed for aniline alkylation in the present study is consistent with those suggested previously for side-chain alkylation of toluene on basic zeolites.[4b,7] Furthermore, it is also in line with the mechanism proposed on the basis of a recent *in situ* MAS NMR spectroscopic study of aniline methylation performed under batch conditions.[8] However, a direct proof for the role of *N*-methyleneaniline as an intermediate is now possible for the first time by applying the novel *in situ* SF MAS NMR method. It is obvious that this new NMR technique is an extremely useful tool in heterogeneous catalysis and possesses high potential for elucidating the mechanisms of a broad variety of reactions.

Hierarchical zeolite structures with designed shapes were fabricated by a ceramic processing method—gel-casting of colloidal nanocrytal suspensions.

There is considerable interest in porous zeolite and zeolite-type materials with designed shapes.[1–4] Hierarchical porous structures with different levels of porosity can significantly aid the diffusion of guest species through the inorganic network of pores and channels to improve their performance. Nanometer-sized zeolite particles have been used as building blocks to construct hierarchical porous structures such as films, spheres and fibers *via* templated self-assembly.[2–4] Very recently, a bulk-material dissolution technique has been developed for the preparation of various shaped MFI structures including tubes and fibers.[5] The shaped zeolite structures can faithfully reproduce the shapes of the starting bulk material. However, the conversion process is extremely slow (*e.g.* 1–2 months) and the final structure is usually a composite of the starting material and the zeolite with non-uniform microstructure.

Ceramic forming techniques such as pressing, extrusion, tape casting, dip (slip)-casting, and gel-casting are powerful for shaping inorganic materials due to their simplicity and versatility. In particular, gel-casting is a method for fabrication of complex-shaped ceramic bodies from ceramic particle suspensions by means of *in situ* polymerization, where a macromolecular network is created to hold the ceramic particles together before sintering.[6,7] Zeolite nanocrystals such as silicalite, ZSM-5, TS-1, Beta, A and FAU have been synthesized from precursor solutions,[9–13] and can be readily handled in colloidal systems. In this communication, we report the first demonstration of fabrication of shaped hierarchical zeolite structures with well-controlled microstructures using a ceramic forming technique—gel-casting. As an example, the gel-casting of colloidal silicalite nanocrystal suspensions was used to prepare hierarchical tubular silicalite structures (HTSSs).

Silicalite nanocrystals were hydrothermally synthesized using a clear synthesis solution.[4,14]‡ The silicalite nanocrystals with diameter *ca*. 50 nm and with narrow particle size distribution were re-dispersed in water with a solid loading of 30–40 wt%. Water soluble organic monomer acrylamide, crosslinker *N*,*N*′-methylenebisacrylamide, and initiator ammonium persulfate $(NH_4)_2S_2O_8$ were added to the colloidal silicalite suspension.‡ The gel-casting of the resulting colloidal suspension was carried out in a home-made mold. The fabrication process of HTSSs is illustrated in Fig. 1. Since the suspension with monomer, crosslinker, and initiator has low viscosity and good fluidity, it can be readily transferred into the mold. The suspension-filled mold was hand-shaken for a few minutes to release air bubbles inside the suspension. Once the temperature was increased to 50 °C, the monomers in the suspension were quickly polymerized and crosslinked free-radically into an elastic hydrogel.[6,7] A highly crosslinked polyacrylamide hydrogel obtained is expected to be compatible to silicalite nanocrystals whose surface silanol groups interact

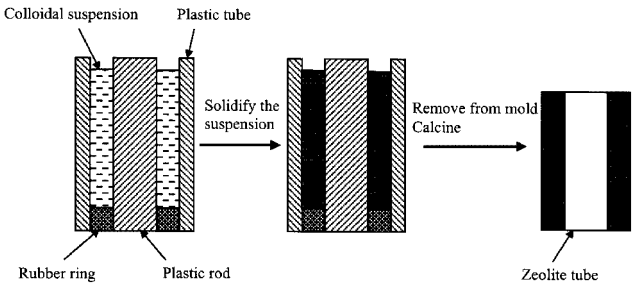

Fig. 1 Schematic representation of the gel-casting forming process for a hierarchical tubular silicalite structure (HTSS). The colloidal suspension consists of zeolite silicalite nanocrystals and organic monomer (AM), crosslinker (MBAM), and initiator $(NH_4)_2S_2O_8$.

favorably with $-NH_2$ groups. The solidified suspension (a gelcast) was mechanically strong and was easily removed from the mold. The tubular gelcast was dried under ambient laboratory conditions for 2–3 days, and was then further dried at 100 °C overnight. A linear shrinkage of 4.0–4.5% of the gelcast was observed during the drying process. After drying, the tubular gelcast was sintered under air at a heating rate of 1 °C min^{-1} up to 500 °C, and kept at that temperature for 8 h to burn off the organic polymer and the structure-directing agent (tetrapropylammonium hydroxide),[14] and to sinter together the silicalite nanocrystals through condensation crosslinking of surface silanol groups of nanocrystals.[4,14] The sintering leads to a linear shrinkage of $< 0.5\%$. In order to examine the thermal stability of the HTSSs, another sample was sintered at 1000 °C for 2 h with the same heating rate.

Fig. 2 shows a photograph, SEM micrographs and XRD pattern of an HTSS. SEM images show uniformly distributed

 DOI: 10.1039/b104275k

submicrometer-sized pores in the HTSS at low magnification, and a hierarchical morphology of densely packed silicalite nanocrystals at high magnification. The submicrometer-sized pores were formed by packing of nanocrystal agglomerates during gel-casting. Small nanocrystals tend to agglomerate to minimize surface energy when the nanocrystal loading is high (30–40 wt%). This is confirmed by SEM observation that shows that there are already micrometer-sized pores in the dried gel-cast. The XRD pattern of the sample sintered at 1000 °C for 2 h matches the pure silicalite structure. This suggests that the HTSS sintered at 1000 °C retains the silicalite structure.

N_2 adsorption–desorption measurements were used to determine the mesopore and micropore structures of HTSSs. N_2 adsorption–desorption isotherms of samples sintered under different conditions are shown in Fig. 3. The adsorption steps at low relative pressures signify the filling of silicalite micropores, and the hysteresis loops at higher relative pressures are the consequence of N_2 filling the textural mesopores, and clearly the sample has a bimodal pore size distribution (see S-Fig. 1, ESI).† The pore size distribution is narrow in both the micropore and mesopore range. The sintering temperature has an influence on the pore structure of the HTSS. When the sintering temperature is increased from 500 to 1000 °C, the micropore volume and mesopore volume slightly decrease from 0.16 to 0.12 $cm^3\ g^{-1}$, and from 0.35 to 0.33 $cm^3\ g^{-1}$, respectively. The corresponding Brunaer–Emmett–Teller (BET) surface area drops from 516 to 423 $m^2\ g^{-1}$. The maximum pore size in the micropore range of HTSSs is 5.5 Å, which is characteristic of silicalite. The average mesopore size varies from 16.7 to 13.1 nm, which are similar to that of hierarchical materials self-assembled by pure silicalite nanocrystals.[4]

The HTSSs have three-level porosities including macropores (submicrometer), mesopores (16–13 nm) and micropores (0.55 nm). Based on a measured HTSS density of 0.85 g cm^{-3} and assuming a dense silica density of 2.3 g cm^{-3}, the total pore volume is estimated to be 0.74 $cm^3\ g^{-1}$. From the micropore and mesopore volumes obtained from nitrogen adorption–desorption isotherms, the macropore volume is calculated to be 0.29 and 0.23 $cm^3\ g^{-1}$ for HTSSs sintered at 500 and 1000 °C, respectively.

Gel-casting processing also offers an effective way to add functionalities to HTSSs by doping with other components.[7] Unlike commonly used impregnation methods, the dopant can be introduced easily into the colloidal suspension system so that the dopant concentration can be precisely controlled. The uniformity of dopant distribution also will be significantly improved. Here the doping of nickel is used as an example to illustrate that dopant can be easily incorporated. Ni-based catalysts are useful for various catalytic processes such as alkylation, methanation, hydrogenation of aromatic compounds and methane reforming. Elemental mapping images (S-Fig. 2)† clearly show Ni is uniformly distributed in the silicalite matrix.

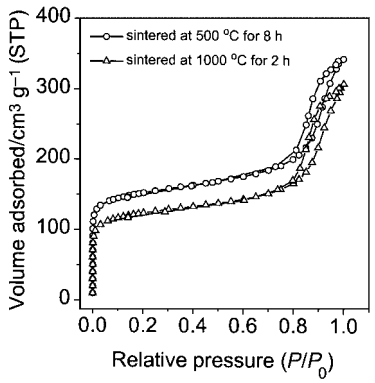

Fig. 3 Nitrogen adsorption–desorption isotherms of hierarchical tubular silicalite structures (HTSSs) sintered under different conditions.

We have demonstrated that hierarchical zeolite structures with designed shape can be readily obtained from colloidal zeolite nanocrystal suspensions simply by applying ceramic gel-casting processing. The hierarchical (macro-, meso- and micro-porous) zeolite structure can be readily functionalized by incorporation of a functional component, or by chemical grafting of organic functional groups. Zoned zeolite structures[15] with designed shapes can also be generated by adding a secondary growth step[8] to our gel-casting process. Our process should also allow the fabrication of shaped structures with mixed zeolites by using suspensions of two or more types of zeolite nanocrystals. It is believed that the strategy described here is promising for the preparation of various functional zeolite-based structures with designed shapes, in catalysis, separation membranes, and microelectronics, and work in these areas are in progress.

Notes and references

‡ Aqueous colloidal suspensions of silicalite nanocrystals were synthesized as follows.[4,14] A clear synthesis solution was prepared by dropwise adding tetrapropylammonium hydroxide solution (TPAOH, SACHEM) into tetraethyl orthosilicate (TEOS, Aldrich) with strong agitation followed by 1–3 days of aging at 30 °C under stirring. The final solution has a molar composition 1 TPAOH : 2.8 SiO_2 : 11.2 EtOH : 40 H_2O. Crystallization was carried out at 80 °C for 3 days with a constant stirring at 250 rpm. A stable aqueous suspension of silicalite nanocrystals was obtained by repeated cycles of centrifugation at 15 000 rpm, decanting, and ultrasonic redispersion in pure water until the pH of the suspension was < 8. The solid loading of the suspension is 30–40 wt% for gel-casting. Water soluble organic monomer acrylamide, CH_2=$CHCONH_2$ (AM, Aldrich), crosslinker *N*,*N*′-methylenebisacrylamide, CH_2=$CHCONH_2)_2CH_2$ (MBAM, Aldrich), and initiator ammonium persulfate, $(NH_4)_2S_2O_8$ Aldrich) were added under stirring into the silicalite colloidal suspension. Final composition (weight ratio) : 5–10 AM : (0.05–0.1) MBAM : (0.01–0.025) $(NH_4)_2S_2O_8$: 90–95 silicalite solid. After the monomer, the crosslinker, and the initiator were dissolved, the whole suspension was ultrasonicated for 5–10 min to ensure good homogeneity.

Nitrogen adsorption–desorption measurements were carried out at −196 °C on a Micromeritics ASAP 2010 instrument. HTSS samples were crushed and ground for X-ray diffraction analysis (Siemens D-500 diffractometer using Cu-Kα radiation). SEM imaging and elemental mapping were conducted with a scanning electron microscope (SEM, Philips XL30-FEG at 20 kV) equipped with an EDAX detector.

Received (in Cambridge, UK) 24th April 2001, Accepted 8th June 2001
First published as an Advance Article on the web 5th July 2001

The synthesis, separation and isolation of a new [84]fullerene isomer from arc-burned soot of dysprosium-doped graphite composite rods is reported; high-resolution ^{13}C NMR and electronic absorption UV-VIS-NIR spectroscopy were used to characterize this material, which was found to possess C_2 molecular symmetry; the successful synthesis of the new [84-C_2]fullerene isomer can be ascribed to a catalytic role played by the doped Dy metal atoms in the composite rods.

[84]Fullerene, C_{84}, has been solvent extracted in macroscopic quantities since the early stages of fullerene research.[1] It is the third most abundant fullerene having 24 structural isomers that obey the so-called isolated pentagon rule (IPR).[2] Taylor *et al.* reported ^{13}C NMR measurements on a partially separated [84]fullerene mixture.[3] However, to date only nine of these isomeric materials have been isolated and structurally characterized by high resolution ^{13}C NMR spectroscopy. Two of them, abundantly produced, possess D_2(IV) and D_{2d}(II) molecular symmetry,[4] while the other five minor isomers having C_s(a), C_s(b), C_2, D_2(II) and D_{2d}(I) symmetries[5] and a mixture of D_{3d}/D_{6h}[6] have already been isolated and structurally characterized.

One important aspect on the production and isolation of the above minor [84]fullerene isomers is that some of them have been produced only from metal-doped/graphite composite rods and not from pure graphite rods. This means that such isomers can be produced by catalytic effects of the doped metal atoms. For example, the D_{3d}/D_{6h} isomers have been identified in the arc burned soot of gadolinium doped composite rods[6] while they were absent in the arc burned soot of calcium doped composite rods.[5] In the latter, only the C_s(a), C_s(b), C_2, D_2(II) and D_{2d}(I) symmetrical [84]fullerenes were found, in different yields compared to Gd-doped soot, together with the most abundant D_2(IV) and D_{2d}(II) isomers. These findings led us to consider the possibility that the doped metal atoms play a significant role not only in the relative production yield of these isomers but also in the nature of the isomer that is formed.

In this communication, we report the production of a new isomer of [84]fullerene, C_{84}, by using arc burning of dysprosium-doped composite rods. Briefly, soot containing various dysprosium metallofullerenes[7] was produced by the direct current arc discharge method of Dy_2O_3–graphite composite rods (12.5 × 12.5 × 300 mm, 0.8 wt%, Toyo Tanso Co.). The dysprosium composite rods were heat treated at a high temperature of 1600 °C. The soot produced was collected under totally anaerobic conditions to avoid any degradation from air during the collection procedure. It was then soxhlet extracted first by carbon disulfide and then by pyridine. The separation of [84]fullerene isomers was achieved by multi-stage high-performance liquid chromatography (LC-908-C60, Japan Analytical Industry) using a Buckyprep (20 × 250 mm, nakalai tesque) and a 5PYE (20 × 250 mm, nakalai tesque) columns.[4–7] The purity of the newly synthesized material (> 99.9%) was confirmed by both positive and negative laser-desorption time-of-flight (LD-TOF) mass spectrometry. The UV-VIS-NIR spectrum was recorded between 400 and 2000 nm in carbon disulfide solutions by using a Shimadzu UV-3101PC spectrophotometer. Finally, the high resolution ^{13}C NMR measurements were performed on a Varian Inova-600 spectrometer at 600 MHz (CS_2 solution, $Cr(acac)_3$ relaxant, acetone-d_6 lock at 25 °C).

In the first HPLC stage, the fraction that contains the [84]fullerene isomeric mixture was separated from the empty [76], [78] and [86]fullerenes as well as from the endohedral metallofullerenes Dy@C_{82} and Dy_2@C_{84} by using a Buckyprep column (15 ml min^{-1} flow rate, toluene eluent).[7] In the second stage, the fraction, which was identified by LD-TOF mass spectrometry as empty [84]fullerenes, was re-injected into a 5PYE column (15ml min^{-1} flow rate, toluene eluent) and a recycling HPLC was performed. After recycling for 90 min, the mixture of the two most abundant [84]fullerene isomers with D_2(IV) and D_{2d}(II) symmetry was separated from a mixture of various minor [84]fullerene isomers. In the last HPLC stage, the fraction that contained the mixture of the minor isomers was re-injected into a 5PYE column (15 ml min^{-1} flow rate, toluene eluent) for the final separation. Four different compounds were identified after recycling for more than 3 h, all of which corresponded to [84]fullerene isomers. The purity of the isolated material was more than 99.9% as determined by both negative and positive laser desorption time-of-flight mass spectrometry.

Three of the four isomeric [84]fullerenes described above (hereafter referred as I, III and IV in order of increasing retention time) showed identical UV-Vis-NIR absorption spectra with those of the known minor [84]fullerene isomers with molecular symmetries C_2, C_s(b) and C_s(a), respectively,[5] albeit in different yields. However, the material corresponding

 DOI: 10.1039/b103679n

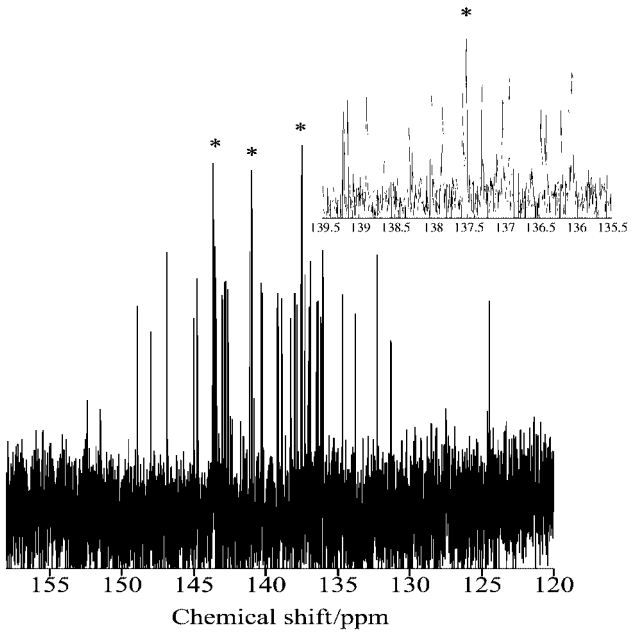

Fig. 2 High-resolution ^{13}C NMR spectrum [600 MHz, CS_2 solution, $Cr(acac)_3$ as relaxant and acetone-d_6 for the internal lock] of the purified minor isomer of C_{84}(II) with C_2 molecular symmetry. The chemical shifts for the forty-two lines are at δ: 148.93, 148.00, 146.87, 145.01, 144.77, 144.72, 143.66 (double line), 143.55, 143.48, 143.03, 142.98, 142.86, 142.76, 142.63, 141.12, 140.99 (double line), 140.32, 140.25, 139.21, 139.14, 138.88, 138.30, 138.00, 137.84, 137.56, 137.50 (double line), 137.29, 137.00, 136.91, 136.47, 136.42, 136.19, 136.09, 136.04, 134.67, 133.80, 132.28, 131.31 and 124.47 ppm. The * corresponds to two signals which are overlapped with each other. Inset is an expanded region between 139.5–135.5 ppm for clarity.

to the second fraction on the 5PYE column, C_{84}(II), showed an entirely different absorption profile from those of the previously isolated [84]fullerene isomers.

Fig. 1 shows the UV-VIS-NIR electronic absorption spectrum of [84]fullerene (II) in carbon disulfide solution. There are characteristic absorptions at 444, 506, 631, 715, 782, 1231 nm and a broad profile from 830 to 1400 nm with the onset around 1500 nm. From all isomeric [84]fullerenes, this particular isomer has the lowest energy onset. Since the onset of a UV-VIS-NIR electronic absorption spectrum corresponds to the lowest electronic transitions, this is a good measure for the HOMO–LUMO energy gap of fullerenes. Because of the red shift of the absorption onset relative to the other [84]fullerene isomers, the HOMO–LUMO band gap of [84]fullerene (II) should be smaller than that of the rest materials.

Fig. 2 shows the high resolution ^{13}C NMR spectrum of the newly synthesized and isolated [84]fullerene (II) in carbon disulfide solution with chromium tris(acetylacetonate) as relaxant and acetone-d_6 as internal lock after accumulating more than 120,000 scans. The spectrum consists of forty-two equal intensity lines which are spread over a wide range of the chemical shift from 125 to 150 ppm. The current isolated [84]fullerene isomer is thus unambiguously assigned to possess C_2 molecular symmetry. Rotation of 180 degrees around the symmetry axis generates 42 equivalent carbon atoms. There are six structural isomers of [84]fullerene with C_2 symmetry that satisfy the isolated pentagon rule.[2] Two-dimensional high resolution ^{13}C NMR spectroscopy could reveal which one, out of the six possible isomers, is the present [84-C_2]fullerene, in the future.

Theoretical calculations on the relative stability of isomeric [84]fullerenes have shown a relatively good agreement between the theoretical stability order and the observed abundance of the isomers.[8] These calculations predict that the most stable isomers after D_2(IV) and D_{2d}(II) are those with C_2(IV), C_s(V), D_{3d} and D_{6h} molecular symmetries. We have found, however, that under similar experimental conditions employing different metal-doped composite rods not only the produced amounts of minor isomers of [84]fullerenes are different but more importantly different isomers are formed. This implies a catalytic effect for the doped-metal in the early stage of the growth of these isomers. Although progress in this research area is rapid, there are still lots of questions opened concerning the growth mechanism of fullerenes and metallofullerenes.[9] The current finding that the doped metal atoms play a crucial role in producing a new [84]fullerene isomer strongly suggests the presence of interplay between an encapsulation and a catalytic role of the doped metal atoms in the early stage of fullerene growth.

First published as an Advance Article on the web 5th July 2001

A novel porous framework $[\{Cu_2(medpt)_2Ni(CN)_4\}(ClO_4)_2\cdot 2.5H_2O]_n$ 1, [medpt = bis(3-aminopropyl)methylamine] is prepared where all the CN groups of $Ni(CN)_4^{2-}$ are involved in bridging; this material retains single crystallinity upon removal of water guest molecules and the dehydrated species 2 selectively binds organic molecules.

The design and synthesis of microporous inorganic materials mimicking zeolites finds widespread application in heterogeneous catalysis, adsorption, ion exchange processes, selective binding of guest molecules *etc.*[1] Self assembly is the most efficient approach towards elaboration and construction of such types of molecular systems. Currently, a successful example of this process is the construction of cyano bridged complexes[2] in which the cyanometallate anion [*e.g.* $Ag(CN)_2^-$, $Cu(CN)_3^{2-}$, $Ni(CN)_4^{2-}$, $M(CN)_6^{3-}$ (M = Cr(III), Fe(III) *etc.*)] behaves as the bridging moiety to build a multidimensional structure with a second coordination centre and the resulting complexes demonstrate unique properties. Usually the second coordination centres are transition metal ions since $\sigma \rightarrow \pi$ back-bonding stabilizes the resulting complex. The rigidity and stability of such frameworks allow for shape and size selective inclusion of organic solvents, water molecules, aromatic amines,[3] *etc*. to fill up the void space so stabilizing the crystal structure.

The reaction of $Cu(medpt)(H_2O)_2(ClO_4)_2$ [medpt = bis(3-aminopropyl)methyl amine] and $K_2Ni(CN)_4\cdot 2H_2O$ in aqueous medium leads to the formation of deep blue plates of $Cu_2(medpt)_2Ni(CN)_4(ClO_4)_2\cdot 2.5H_2O$ **1**.‡ The IR spectrum of compound **1** shows one sharp ν_{CN} band at 2150 cm^{-1} which is at a higher wavenumber than that of the free $Ni(CN)_4^{2-}$ unit (ν_{CN} band at 2128 cm^{-1}), indicating that all the CN groups act as bridging ligands with the copper(II) centre. Although one discrete square cyano-bridged compound[2c] has been reported, to our knowledge, 1D square compounds where all the cyano groups are involved in bridging have not yet been reported in the literature.

The structure determination§ of **1** discloses a 1D square type open microporous material, consisting of infinite chains elongated in the direction of the crystallographic *b* axis (Fig. 1). In the polymer there are intra-chain H-bonds [2.94(1) Å] between amino nitrogens [N(1), N(1″)] and the bridging water molecule O(3w), the latter interacting also with O(2w) at 2.79(2) Å. A third crystallization water molecule O(1w) connects through hydrogen bonds the amino nitrogens N(3) of adjacent chains, in a diamond shape pattern. These inter-chain interactions of 2.913(9) and 3.021(9) Å, illustrated in Figs. 1 and 2, give rise to a 2-D structure. The water molecules, all at half occupancy, are guests in the crystalline channels and, from a topological point of view, have the ability to leave the host lattice. The dehydration process, detected by thermogravimetric analysis, occurs but leads to no deterioration of crystallinity, indicating that the structure can be envisaged as an inclusion compound and that removal of the H-bond network does not lead to destruction of the structure. A similar behaviour was described for the structure $[Ni(en)_2Ni(CN)_4]\cdot 2.5H_2O$,[4a] where the role of the water molecules was interpreted using a molecular mechanics investigation. Other examples, with phenol and aniline as guest molecules accommodated among $[M(en)_2Ni(CN)_4]_n$ chains (M = Ni, Cu, Zn or Cd), were reported by Iwamoto *et al.*[4b]

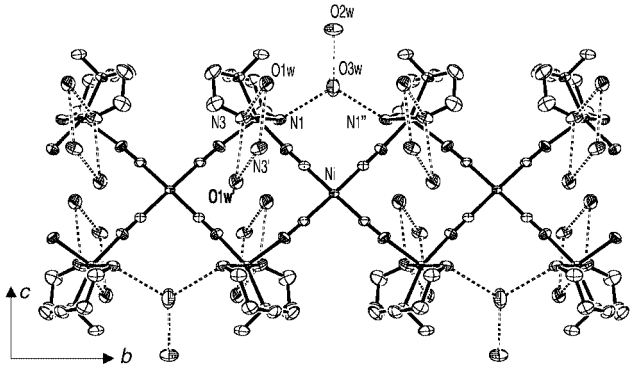

Fig. 1 ORTEP drawing of the polymeric structure of **1**, extending in the direction of crystallographic *b* axis, with guest water molecules (dotted lines indicate H-bonds; ClO_4^- anions omitted for clarity).

The copper presents a square pyramidal coordination where the medpt ligand donors and a cyanide nitrogen occupy the basal plane, the metal being slightly displaced by 0.27 Å from the N4 mean plane towards the apical position occupied by a cyanide ligand of a different $Ni(CN)_4^{2-}$ anion. The latter Cu–N bond distance is significantly longer [2.186(4) Å] with respect to those in the basal plane [2.000(4)–2.072(3) Å]. The $Ni(CN)_4^{2-}$ anion, with the metal located on a symmetry plane, coordinates four adjacent copper ions. The cyanide groups show different geometries, being linear coordinated in the basal plane

 DOI: 10.1039/b103823k

of copper, but significantly bent at the apical position of the pyramidal Cu environment [Cu–N≡C bond angles of 176.0(4) and 155.3(3)°, respectively].

Thermogravimetric analysis of a crystalline sample showed a weight loss of 5.5% at 70 °C, corresponding to the loss of the guest water occupying the channels. The remaining compound was heated to 180 °C without any additional weight decrease, indicating a robust open Cu–Ni framework. Examination of the single crystals with an optical microscope at 100 °C showed that they retained their morphology and crystallinity upon loss of the water molecules.

The X-ray structural determination of a dehydrated single crystal of **2**§ sealed in a glass capillary reveals a 1D open microporous framework and confirms the $[\{Cu_2(medpt)_2Ni(CN)_4\}(ClO_4)_2]_n$ formulation. Besides a contraction in cell volume, the space group changes from $P2_1/m$ to $P2_1/c$, which requires the loss of the crystallographic symmetry plane in which nickel atoms, as well as water molecules Ow2 and Ow3, were located (Fig. 1). The polymer backbone of Ni atoms is now almost collinear, and the angle and distance between the consecutive metals are 169.12(4)° and 7.109(2) Å, respectively, *cf.* the zigzag Ni arrangement in the hydrated species **1** where the corresponding values are 156.95(3)° and 7.460(3) Å. In addition, the conformation of the Cu(medpt) moiety appears to change slightly, and a noteworthy modification related to the dehydration process is the change in distance between nitrogens N1··N1″ (5.37 Å), which for the corresponding atoms involved in H-bonding with bridging water molecules in **1**, is 4.81 Å (Fig. 1).

To examine the inclusion chemistry of this material, the synthesised microcrystalline solid was heated at 100 °C for 30 min, in order to remove the guest molecules. It is worth noting that upon reintroducing water into the pores over a period of 1 h, the XRD pattern¶ of the resulting solid is simultaneously regenerated with the peak positions and their intensities being fully coincident to those observed for the original solid, serving as evidence to the reversibility of the inclusion process (Fig. 3).

It is also interesting that the evacuated solid selectively binds MeOH (**1a**) and MeCN (**1b**)‖ in the pores among the number of organic solvents tested (ethanol, benzene, carbontetrachloride, chloroform, dichloromethane *etc*). In DMF and DMSO, the morphology of the complex breaks down. The XRD patterns of these two solids containing guest MeOH or MeCN molecules show diffraction peaks which are sharp but with slightly different positions and line widths compared to the original species containing water as guest molecules. IR spectra also corroborate the retention of morphology with MeOH or MeCN as guest molecules. Thermogravimetric analyses of **1a** and **1b** show weight losses at 130 and 170 °C, respectively, that can be attributed to the loss of *ca.* two methanol and two acetonitrile molecules per formula unit, respectively. It is also important to note that the reversibility of the inclusion process found for water guest molecules is also observed for **1a** but not **1b** for which removal of the two acetonitrile molecules per formula unit leads to instantaneous decomposition.

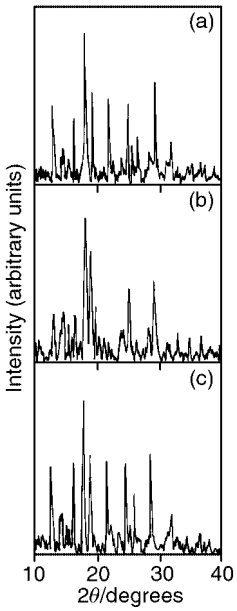

Fig. 3 The XRD patterns of (a) as-synthesized material, $[\{Cu_2(medpt)_2Ni(CN)_4\}(ClO_4)_2\cdot 2.5H_2O]_n$ **1**; (b) dehydrated solid, $[\{Cu_2(medpt)_2Ni(CN)_4\}(ClO_4)_2]_n$ **2** and (c) regenerated solid, resulting from the reintroduction of water molecules into the channels of the dehydrated solid.

Notes and references

‡ *Experimental procedure and selected data*: bis(3-aminopropyl)methylamine) (medpt) (2 mmol, 0.290 g) was added dropwise to an aqueous solution (10 cm³) of $Cu(ClO_4)_2\cdot 6H_2O$ (2 mmol, 0.741 g) with constant stirring. $K_2[Ni(CN)_4]\cdot 2H_2O$ (1 mmol, 0.276 g) dissolved in water (5 cm³) was poured to the resulting blue solution and instantaneous deep blue precipitation occurred. The reaction mixture was stirred for 30 min and then filtered. After a few days suitable shining deep blue single crystals of **1** were obtained from the filtrate. IR: ν(N–H): 3200–3400; ν(CN): 2150; $\nu(ClO_4)$: 1098–984 cm^{-1}.

§ *Crystal data*: for **1**: $C_{18}H_{43}Cu_2NiCl_2N_{10}O_{10.5}$, M = 824.31, monoclinic, space group $P2_1/m$, a = 7.806(2), b = 14.619(7), c = 15.069(5) Å, β = 97.41(2)°, V = 1705.3(11) Å^3, Z = 2, D_c = 1.605 g cm^{-3}, μ(Cu-Kα) = 4.075 mm^{-1}, 3247 unique reflections, $R1$ (F_o) = 0.0559 for 2960 reflections with $I > 2\sigma(I)$, $wR2$ (F_o^2) = 0.1672.

For **2**: $C_{18}H_{38}Cu_2NiCl_2N_{10}O_8$, M = 779.27, monoclinic, space group $P2_1/c$, a = 14.410(6), b = 14.154(4), c = 16.014(5) Å, β = 91.86(2)°, V = 3264.5(19) Å^3, Z = 4, D_c = 1.586 g cm^{-3}, μ(Mo-Kα) = 2.080 mm^{-1}, 5018 unique reflections, $R1$ (F_o) = 0.0690 for 3110 reflections with $I > 2\sigma(I)$, $wR2$ (F_o^2) = 0.1983.

The structure determination was affected by the low crystallinity ($2\theta_{max}$ = 48°), leading to geometrical data of poor accuracy, with disordered perchlorate anions being observed.

CCDC reference numbers 154468 and 163231. See http://www.rsc.org/suppdata/cc/b1/b103823k/ for crystallographic data in CIF or other electronic format.

¶ X-Ray powder diffraction data were collected using Seifert XRD-3000P instrument, where the source of X-rays was Cu-Kα radiation.

‖ For the preparation of complexes **1a** and **1b**, the parent species **1** in a micro-conical flask was heated to 100 °C for 30 min and cooled to ambient temperature whilst keeping it in a fused $CaCl_2$-vacuum desiccator. Dry methanol (**1a**)/acetonitrile (**1b**) was then added in excess and the sample kept in the desiccator for a day.

Synthesis and characterization of the heteroaromatic MF_6^- (M = As, Sb) salts of the 1,2,4-trithiolanylium dication $[PhCSSC(Ph)S]^{2+}$†

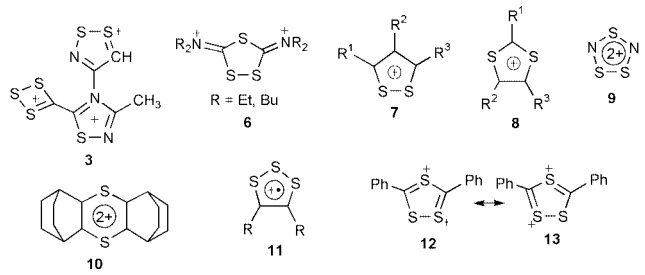
T. Stanley Cameron,[a] Andreas Decken,[b] Min Fang[b] and Jack Passmore*[b]

[a] *Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J3*
[b] *Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick, Canada E3B 6E2*

Received (in Cambridge, UK) 2nd January 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 5th July 2001

$PhCSSC(Ph)S(MF_6)_2$ (M = As, Sb), (X-ray crystal structure, FT Raman, ^1H, ^{13}C NMR and theoretical calculations) containing the first example of a dicationic 6π five-membered C–S heterocycle and sulfur were formed on disproportionation of $PhCSSS(MF_6)$ in liquid SO_2 solution.

We previously prepared **3** in low yield, containing the first structurally characterized example of the $RCSSS^+$ ring.[1] In an



attempt to prepare a simple derivative of this ring system in good yield we reacted the previously reported[2] $PhCS_3Cl$ with $AgSbF_6$ and to our surprise obtained $PhCSSC(Ph)S(SbF_6)_2$ **2**$(SbF_6)_2$. On further investigation we obtained $PhCSSS(SbF_6)_2$ **1**SbF_6 and found that it disproportionates in SO_2 solution to give **2**$(SbF_6)_2$ and elemental sulfur. **2** is the first example of a dicationic 6π five-membered C–S heterocycle. RCS_3Cl (R = Ph, *p*-$MeOC_6H_4$, 1-naphthyl) are known.[2] Therefore the synthesis of $RCSSC(R)S(MF_6)_2$ is likely general, although it may require an R group onto which some of the +2 positive charge on the C_2S_3 ring can be delocalized. There are many examples of five- and six-membered C–S containing heteroaromatic rings,[3,4] however the only aromatic dication previously reported is **10**. Related analogues of **2** are **6** (R = Et, Bu), in which the $C_2S_3^{2+}$ ring is non-planar and charges are largely localized on the exocyclic N atoms as drawn.[5] The other C–S containing 6π five-membered cyclic heterocylcles are thiophene, 1,2-dithiolium **7**, and 1,3-dithiolium **8**.[3] **2** is isolobal to $SNSSN^{2+}$ **9** in $(SNSSN)^{2+}(MF_6^-)_2$ (M = As, Sb).[6] However unlike the $S_3N_2^{2+}$ ring, which dissociates to SNS^+ and SN^+, **2** retains its identity in SO_2 solution. The isomeric 1,2,4-trithiolanylium dication $RCSSSCR^{2+}$ has not been reported, although the 7π 1,2,3-trithiolynium monocation radical **11** is known.[7]

2$(SbF_6)_2$ was first prepared by adding the soluble product (0.586 g, 1.697 mmol) of the $PhCS_2H/SCl_2$ reaction to $AgSbF_6$ (1.331 g, 3.874 mmol) in liquid SO_2.‡ The mixture was stirred for 2 h in bulb 1 of a two-bulb Pyrex glass vessel incorporating a medium sintered-glass frit (see ref. 8). A solution over a precipitate was obtained in bulb 2 by repeatedly extracting the soluble material into bulb 2 leaving the insolubles (including AgCl) in bulb 1. The solvent in bulb 2 was then condensed back to bulb 1. About 2 ml SO_2 was condensed back (three times) onto the precipitate (in bulb 2) and the obtained solution containing the most soluble components (*e.g.* unreacted $AgSbF_6$ and other impurities) filtered to bulb 1. **2**$(SbF_6)_2$ was recovered with a trace of S_8 (Raman) from bulb 2 as an orange solid (0.446 g, 0.600 mmol, 35% yield). Single crystals of **2**$(SbF_6)_2$§ were grown from SO_2 solution. This implies the presence of $[PhCSSC(Ph)S]Cl_2$ as a main component of the soluble product of the $PhCSSH/SCl_2$ reaction. Crystals of **2**$(AsF_6)_2$ were obtained similarly by using $AgAsF_6$. An ORTEP diagram of **2** in **2**$(SbF_6)_2$ (−60 °C) is shown in Fig. 1. The observed and calculated (MPW1PW91/3-21G*)¶ bond distances and angles are in reasonable agreement. The structure of **2** in **2**$(AsF_6)_2$ (−100 °C)§ is similar. The FT Raman spectrum of **2**$(SbF_6)_2$ in the 50–800 cm^{-1} region is shown in Fig. 2 (full Raman spectra of **2**$(SbF_6)_2$ is shown in S-Fig. 1†). The observed and calculated Raman frequencies and ^{13}C, ^1H chemical shifts are in good agreement (Fig. 2, Table 1 and S-Table 1†).

The precipitate in the $PhCSSH/SCl_2$ reaction was found to be $PhCS_3Cl$.‖ $PhCS_3Cl$ (0.570 g, 2.59 mmol) was reacted with $AgSbF_6$ (0.953 g, 2.79 mmol) in liquid SO_2 (9.1 g) to give **1**SbF_6 (0.492 g, 1.17 mmol, 45% yield). The procedure was the same as described above except that the reaction time was < 30 min and light was excluded. The initial failure to obtain **1**SbF_6 is because the soluble rather than the insoluble product of the $PhCSSH/SCl_2$ reaction was reacted with $AgSbF_6$. ^1H (Fig. 3) and ^{13}C NMR spectra of **1**SbF_6 in liquid SO_2 were studied as a function of time. Observed and calculated chemical shifts of **1** are in good agreement and are given in Table 1 (Similar ^1H NMR spectra found for **1**AsF_6).** Peaks due to **1** decreased over time with the appearance of those of **2** and precipitation of

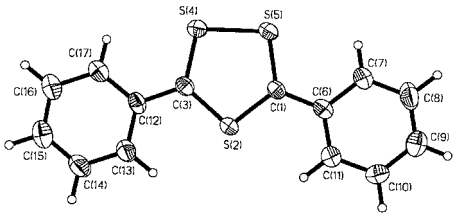


Fig. 1 ORTEP of **2** in **2**$(SbF_6)_2$ (−60 °C) drawn at the 50% probability level. Fig. 3 *In situ* ^1H NMR study of **1**SbF_6 in liquid SO_2.

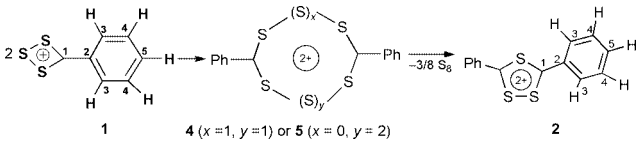
S_8 (Raman) and an intermediate we propose could be either **4** or **5** (see Scheme 1), the mechanism of which warrants further study. Light was found to facilitate this process.



Scheme 1 Proposed mechanisms for the rearrangement of **1** to **2** in liquid SO_2.

The phenyl and C_2S_3 ring of **2** are planar [Σ angles for C_2S_3 rings: 539.9° (25 °C), 540.1° (−60 °C) in **2**$(SbF_6)_2$, 540.0° in **2**$(AsF_6)_2$ (−100 °C)]. The benzyl rings and the dication ring are nearly coplanar in **2**$(MF_6)_2$ (M = Sb, As) with $Ph_1/\overline{CSCSS}^{2+}$, $Ph_2/\overline{CSCSS}^{2+}$ and Ph_1/Ph_2 torsion angles of 3.4° (12.6°), 7.0° (168.3°) and 3.8° (176.7°) respectively in **2**$(SbF_6)_2$ (25 °C) and **2**$(AsF_6)_2$ (−100 °C) (angles in parentheses). This implies the π electrons and charges are delocalized over the three rings, supported by the short Ph–C bond distance†† and the significant F–H and F–S contacts. The sum of the Pauling bond orders (BOs)‡‡ for the C_2S_3 ring is 6.8–6.9 in both salts (S-Fig. 2†) and the π bonding mostly in the C–S region, *cf.* **12** and **13**. The S–S bond distance of 2.024(3) [in **2**$(SbF_6)_2$, −60 °C] and 2.032(3) [in **2**$(AsF_6)_2$ (−100 °C)] implies the BO is slightly greater than 1 (*cf.* S–S distance: 2.05 Å in S_8 and 2.08 Å in C–SS–C containing compounds with C–S–S–C dihedral angle of 0°[10]). Consistently, the S–S stretching frequency at 504 cm^{-1} (see Fig. 2) is greater than that of S_8 (473 cm^{-1}).

Table 1 Observed[a] [in **1**SbF_6 and **2**$(SbF_6)_2$] and calculated[b] (in parentheses) ^1H and ^{13}C NMR chemical shifts of **1** and **2**

[a] Chemical shifts were obtained at room temperature in liquid SO_2, using TMS in liquid SO_2 as external standard. [b] Isotropic NMR shielding tensors were calculated at the MPW1PW91/6-311G(2DF)//MPW1PW91/3-21G* level and referenced against calculated TMS values; d = doublet, t = triplet.

We thank Dr. Larry Calhoun (UNB) for his assistance with NMR experiments, and NSERC for an operating grant (J. P.) and the Province of New Brunswick for a Women's Doctoral Fellowship (M. F.).

Notes and references

‡ Filtration of the $PhCS_2H/SCl_2$ reaction mixture about 10 min after initial $PhCS_2H$ addition, followed by immediate removal of solvent *in vacuo*, gave the soluble product as a mixture of yellow powder and some red sticky material. (Campaine *et al.*[2] obtained red sticky oil as the soluble product, as they did not immediately remove the solvent.) The product was reacted with $AgSbF_6$ according to: $[PhCSSC(Ph)S]Cl_2 + 2\ AgSbF_6 \rightarrow$ **2**$(SbF_6)_2 + 2$ AgCl and assuming it was all $[PhCSSC(Ph)S]Cl_2$.

§ *Crystal data*: for **2**$(SbF_6)_2$ (room temp.): $C_{14}H_{10}S_3F_{12}Sb_2$, M = 745.89, monoclinic, space group $P2_1/n$ (no. 14), a = 9.359(5), b = 15.148(2), c = 15.762(2) Å, β = 104.56(2)°, U = 2162.8(9) Å^3, Z = 4, D_c = 2.291 g cm^{-3}, T = 296.0 K, $F(000)$ = 1408.00, μ(Mo-Kα) = 28.85 cm^{-1}. 6923 reflections measured, 6564 independent reflections, $R(R_w)$ = 0.051 (0.202), $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2}$.

For **2**$(SbF_6)_2$ (−60 °C): $C_{14}H_{10}S_3F_{12}Sb_2$, M = 745.89, monoclinic, space group $P2_1/n$ (no. 14), a = 9.345(4), b = 15.005(5), c = 15.745(4) Å, β = 104.71(3)°, U = 2135(1) Å^3, Z = 4, D_c = 2.320 g cm^{-3}, T = 213 K, $F(000)$ = 1408.00, μ(Mo-Kα) = 29.22 cm^{-1}. 6683 reflections measured, 6334 independent reflections, $R1$ ($wR2$) = 0.0391 (0.1487).

For **2**$(AsF_6)_2$ (−100 °C): $C_{14}H_{10}S_3F_{12}As_2$, M = 652.24, monoclinic, space group $P2_1/c$ (no. 14), a = 9.1371(9), b = 14.850(2), c = 15.427(2) Å, β = 107.747(7)°, U = 1993.6(4) Å^3, Z = 4, D_c = 2.173 g cm^{-3}, T = 173(1) K, $F(000)$ = 1264.00, μ (Mo-Kα) = 37.77 cm^{-1}. 5041 reflections measured, 5041 independent reflections, R (R_w) = 0.076 (0.214). CCDC 156699–15670. See http://www.rsc.org/suppdata/cc/b1/b100001m/ for crystallographic data in CIF or other electronic format.

¶ GAUSSIAN 98W, Revision A. 3, Gaussian, Inc., Pittsburgh PA, 1998.

‖ $PhCS_3Cl$ was prepared by a modification of the reported method.[2] The molar ratio of $PhCSSH:SCl_2$ was changed from 1:2 to 1:1 and the solvent from diethyl ether-CCl_4 to diethyl ether. The melting point (90–93 °C) and Raman spectrum are identical to the product obtained following the procedure of Campaine *et al.*.[2]

** **1**(SbF_6) was characterized also by Raman and elemental analysis [found (calc): C, 19.63 (19.90); H, 1.26 (1.20); S, 24.65 (22.80); Sb, 29.39 (28.90), F, 28.63 (27.10)%]. The observed and calculated (MPW1PW91/3-21G*) Raman frequencies are in good agreement (S-Fig. 3, S-Table 3†). A preliminary X-ray crystal structure confirms the atom connectivity [a = 6.899(3), b = 6.905(2), c = 14.651(4) Å, α = 88.78(1), β = 88.44(1), γ = 60.34(1)°].

†† The average Ph–C bond distance is 1.41(1) Å in **2**$(SbF_6)_2$ and 1.44(1) Å in **2**$(AsF_6)_2$, which are slightly shorter than a C_{sp^2}–C_{sp^2} single bond distance (1.48 Å).

‡‡ The Pauling bond order is given by $D_b = D_1 - 0.71 \log b$ where D_b is the observed bond distance and D_1 is the single bond distance [D_1(S–S) 2.05; D_1(C–S) 1.81, D_1(C_{sp^2}–C_{sp^2}) 1.48 Å]; see ref. 9.

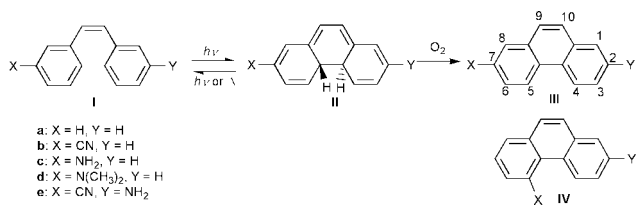
Irradiation of (*Z*)-3-cyano-3′-aminostilbene in the absence of oxygen yields a push–pull substituted dihydrophenanthrene with substantial quinoidal character as evidenced by the pronounced solvent dependence of its absorption spectrum.

The photocyclization of diarylethenes is among the most extensively studied of photochromic reactions.[1–5] The prototype for this reaction is the photocyclization of the colorless (*Z*)-stilbene **Ia** to the yellow 4a,4b-dihydrophenanthrene **IIa**, which is rapidly converted to phenanthrene in the presence of oxygen (Scheme 1). In the absence of oxygen **IIa** undergoes ring opening to reform **Ia** both thermally and photochemically. Lack of thermal stability and sensitivity to oxygen has limited the utility of stilbene photocyclization in photochromic applications. The search for photochromic molecules which are thermally stable even in the presence of oxygen has led to the development of diarylethenes with heterocyclic aryl groups.[5,6] The presence of an electron donating group on one heterocycle and an electron accepting group on the other has provided photochromic systems that absorb throughout the visible and into the infrared. Curiously, the photochemical generation of push–pull stabilized 4a,4b-dihydrophenanthrenes has not been investigated.

The effects of single electron donating or accepting substituents on the quantum yield for phenanthrene formation (Φ_p) from (*Z*)-stilbenes in the presence of oxygen was investigated by Güsten and co-workers.[7,8] They report higher values of Φ_p for 3-cyanostilbene **Ib** and 3-aminostilbene **Ic** (0.012 and 0.28, respectively) than for their 4-substituted isomers. Irradiation of either **Ib** or **Ic** in the presence of oxidizing agents results in the formation of both 2- and 4-substituted phenanthrenes (**III** and **IV**), in a *ca*. 3.5 : 1 ratio. Muszkat *et al.*[9] have investigated the anaerobic irradiation of several monosubstituted (*Z*)-stilbenes and report a higher quantum yield for formation of dihydrophenanthrene **IIb** from **Ib** (0.012) than for its 4-substituted isomer. The photochemistry of a large number of push–pull 4,4′-disubstituted stilbenes including 4-cyano-4′-aminostilbene has also been investigated.[10–13] These stilbenes undergo reversible *trans–cis* photoisomerization. However, to our knowledge there have been no reports of their photocyclization. As part of our study of the photochemical behavior of aminostilbenes,[14–17] we have investigated the anaerobic irradiation of **Ic**, its *N*,*N*-dimethylamino analog **Id**, and (*Z*)-3-amino-3′-cyanostilbene **Ie**.



Scheme 1

Irradiation of the (*Z*)-3-aminostilbenes **Ic**, **Id**, and **Ie** in freeze–pump–thaw degassed cyclohexane (C_6H_{12}) or acetonitrile (CH_3CN) solution promptly followed by acquisition of the absorption spectrum results in the observation of a broad absorption band at long wavelengths.[18] The deconvoluted absorption spectra of **IIc**, **IId**, and **IIe** in acetonitrile solution are shown in Fig. 1. These spectra are obtained by means of singular value decomposition (SVD)-self modeling from a matrix of absorption spectra obtained at different conversions (see: supplementary information). This procedure also establishes the presence of one major dihydrophenanthrene product along with the (*Z*)- and (*E*)-stilbenes in each case. The major products are assigned structures **IIc**–**IIe** on the basis of formation of the corresponding 2-aminophenanthrenes **IIIc**–**IIIe** as the major products obtained from the irradiation of aerated solutions. In the case of **Ie** irradiation of an aerated solution results in the formation of **IIIe** and **IVe** in a 4.3 : 1 ratio, but no detectable 4-amino-7-cyano isomer.[19] The absence of evidence for the presence of 4-aminodihydrophenanthrene products under anaerobic conditions may reflect more rapid thermal ring opening of the 4-amino-substituted dihydrophenanthrenes.

The absorption band of **IIc** (Fig. 1) is rapidly bleached by visible light but is stable in the dark for a period of several days in CH_3CN solution and undergoes repeated formation and bleaching without degradation. This permits acquisition of the ^{1}H NMR spectrum of **IIc** as a mixture with **Ic**.[20] Salient features of the spectrum include singlets at 3.23 and 3.27 ppm assigned to the 4a,4b protons and unresolved multiplets between 5–7 ppm assigned to the vinyl protons.[3] Optimum conversions of **Ic** to **IIc** are obtained using monochromatic 276 nm irradiation as observed for conversion of **Ia** to **IIa** by Muszkat and Fischer.[21] The absorption bands of **IId** and **IIe** bleach rapidly in the dark and thus no attempt was made to obtain their NMR spectra.

Absorption spectral data for the (*Z*)-stilbenes **Ia**–**Ic**, and **Ie** in C_6H_{12} and CH_3CN are summarized in Table 1. The presence of 3-amino substituents in **Ic** and **Ie** results in a large red-shift in their absorption bands compared to that of **Ia**. Similar red-shifts are observed for the *trans* isomers of **Ic** and **Id** and are attributed

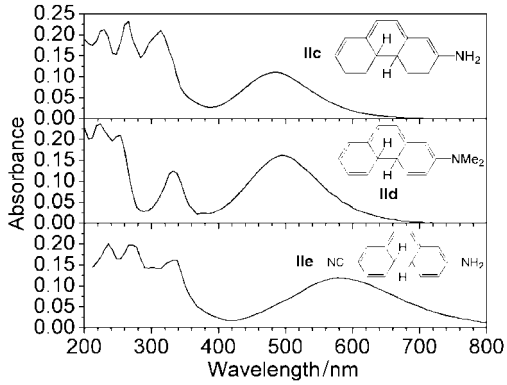


Fig. 1 Deconvoluted absorption spectra of the aminodihydrophenanthrenes **IIc**, **IId**, and **IIe** in acetonitrile solution.

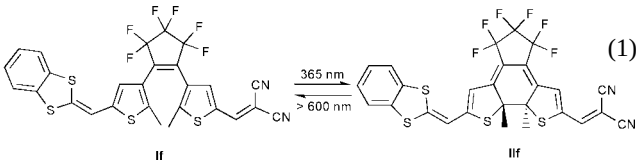
 DOI: 10.1039/b104510p

Table 1 Absorption spectral data and calculated dipole moments for (*Z*)-stilbenes and dihydrophenanthrenes

Compd.	λ_{max}/nm (C_6H_{12})	λ_{max}/nm (CH_3CN)	μ_g/D[a]	μ_e^{FC}/D[b]
Ia	276	276		
Ib[c]	277			
Ic[d]	315	320		
Ie	317	328		
IIa[e]	450	450	0.7	0.7
IIb[e]	467			
IIc[d]	470	482	2.4	11.4
IId	482	494	2.1	11.7
IIe	530	578	7.2	16.0

[a] Calculated ground state dipole moment. [b] Dipole moment of the Franck–Condon singlet state calculated using eqn. (2). [c] Data from ref. 8. [d] Data from ref. 17. [e] Data from ref. 3.

to splitting of the long-wavelength band which results from configuration interaction.[15,16] Much smaller shifts are observed for the 3-cyano substituents in **Ib** (*vs.* **Ia**) and **Ie** (*vs.* **Ic**).[9] Also reported in Table 1 are the absorption maxima for the dihydrophenanthrenes **IIa**–**IIe**. The substituent-induced red-shifts are larger than those observed for the corresponding (*Z*)-stilbenes and similar shifts are observed for the 3-amino and 3-cyano substituents in **IIb** and **IIc**. The shift for **IId** is larger than that for **IIc**, as previously observed for (*E*)-3-dimethylamino- *vs.* 3-aminostilbenes.[16] The aminodihydrophenanthrenes **IIc** and **IId** display large solvent-induced red-shifts in CH_3CN *vs.* C_6H_{12} solution and an exceptionally large red-shift is observed for **IIe** (1600 cm^{-1}). This shift is nearly as large as that reported for **IIf**, the ring-closed form of the more elaborate diarylethene **If** (eqn. (1), $\Delta\nu \approx 2000$ cm^{-1} in DMSO *vs.* hexane).[6]



(1)

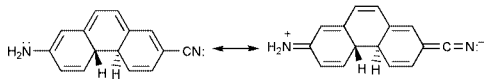
If **IIf**

The solvent-induced red-shift for the absorption maximum **IIe** is exceptionally large for an uncharged molecule, indicative of both a large ground state dipole moment and a change in the dipole moment upon electronic excitation. Ground state dipole moments calculated using the INDO/S-SCF-CI (ZINDO) algorithm[22] for **IIa** and **IIc**–**IIe** are reported in Table 1. The values calculated for **IIc** and **IId** are larger than that for (*E*)-4-dimethylaminostilbene (μ_g = 1.8 D) and the value calculated for **IIe** is larger than that for (*E*)-4-dimethylamino-4′-cyanostilbene (μ_g = 6.6 D).[16] The dipole moment of the Franck–Condon excited state (μ_e^{FC}) may be estimated by using the Lippert equation [eqn. (2)]

$$\bar{\nu}_a = -\frac{2\mu_g(\mu_e - \mu_g)}{4\pi\varepsilon_0 hca^3}\Delta f;\ \Delta f = \frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{n^2 - 1}{2n^2 + 1} \qquad (2)$$

where $\bar{\nu}_a$ is the absorption maximum, h is Planck's constant, ε_0 is the vacuum permittivity, c is the speed of light, a is the radius of the solvent cavity, ε is the relative permittivity, and n is the solvent refractive index.[23] Calculated values of μ_e^{FC} for **IIc** and **IId** (Table 1) are larger than that for (*E*)-4-dimethylaminostilbene (μ_e^{FC} = 7.7 D)[16] and the calculated value for **IIe** is much larger than that for (*E*)-4-dimethylamino-4′-cyanostilbene (μ_e^{FC} = 9.0 D).[12]

The relatively large ground and excited state dipole moments of the aminodihydrophenanthrenes **IIc**–**IIe** reflect the important contributions of quinoidal resonance structures to both the ground and excited states [eqn. (3)]. These values are larger than



(3)

those for the corresponding 4- or 4,4′-substituted (*E*)-stilbenes, even though the distance between the donor and acceptor substituents is smaller for the dihydrophenanthrenes. Thus the extent of charge separation must be significantly larger for the dihydrophenanthrenes. Photocyclization of push–pull 4,4′-substituted stilbenes would result in the formation of 3,3′-substituted dihydrophenanthrenes for which quinoidal resonance is not possible. This may explain the absence of reports of photocyclization of these stilbenes. In addition to providing the first example of a simple push–pull stabilized dihydrophenanthrene, these results provide a design principle which may prove useful in the development of new photochromic systems. While the dihydrophenanthrene **IIe** reacts with oxygen, its stability in the absence of oxygen, ease of synthesis and compact molecular structure may provide advantages for **Ie** when compared to more complex photochromic molecules such as **If**.[5,6]

Funding for this project was provided by NSF grants CHE-9734941 and CHE-0100596. We thank Dr Wilfried Weigel for providing a sample of **Id**.

18 Typical experiments used 50 μM–5 mM solutions that were degassed by five freeze–pump–thaw cycles at < 0.1 mTorr followed by flame sealing of the cuvet. Irradiation was carried out in a Rayonet RPR-100 photochemical reactor fitted with RPR-3000A bulbs. All UV–Vis spectra were promptly acquired on a Hewlett-Packard HP8452A diode array spectrometer.
19 ^{1}H NMR of **IIIe** (500 MHz, $CDCl_3$) δ: 7.08 (d, 2.3 Hz), 7.11 (dd, 8.8, 2.3 Hz), 7.63 (2H, s), 7.74 (dd, 8.6, 1.6 Hz), 8.14 (d, 1.6 Hz), 8.46 (d, 8.6), 8.56 (d, 8.8). **IVe**: 7.08 (d, 2.5 Hz), 7.12 (dd, 8.5, 2.5 Hz), 7.49 (dd, 7.1, 7.6 Hz), 7.61 (2H, s), 7.98 (dd, 7.1, 1.7 Hz), 8.01 (dd, 7.6, 1.7 Hz), 9.59 (d, 8.5 Hz).

First published as an Advance Article on the web 6th July 2001

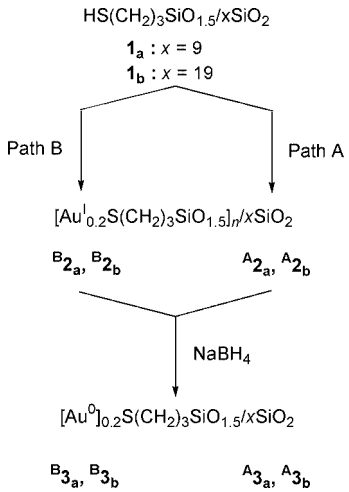
Functionalized SBA-15 type materials containing mercaptopropyl groups have been used for controlling the growth of gold(0) nanoparticles from $HAuCl_4$ or AuCl(THT) which were chemically complexed within the channels prior to mild chemical reduction.

Metal particles in the nanosize range represent a transition between the molecular and solid states and are therefore of great interest due to their unique properties attributed to quantum confinement or surface effects.[1] Thus, selective synthesis of such nanomaterials with well-defined size[2] and their dispersion in an insulator like SiO_2 is a significant challenge.[3] One approach to obtain such materials consists of using the regular channels of hexagonal mesoporous silica[4] as matrices either for the inclusion of already prepared metal particles[5] or for controlling the growth of metal particles. Such matrices should give rise to composite materials organised at the nano- and the mesoscopic length scales. Thus, the ordered mesoporous silica MCM-41,[6–10] MCM-48,[11] and FSM-16[12] materials have been used as matrices for the growth of mono-[7–12] or bimetallic[6] transition metal nanoparticles. The general procedure was to generate the nanoparticles by calcination of the metallic precursor onto the support. The final nanoparticle size is controlled by the pore size but depends also on the calcination temperature. Furthermore, outer pores growth of nanoparticles is a major frequently encountered drawback of the impregnation/calcination method. This problem has been circumvented by suspending the previously impregnated material in deionised water in order to allow complete migration of the metal salt within the pores[9] or by adding the metal salt during the preparation of the material.[10] Here, we describe a new methodology based on the chemical control of the growth of nanoparticles from organometallic precursors previously reported.[13] The precursor is chemically complexed within the channels of functionalised mesoporous silica[14] and the metal nanoparticles growth is achieved by mild chemical reduction which makes the final particle size only dependent of the pore size on the matrix used.

Materials $HS(CH_2)_3SiO_{1.5}/xSiO_2$ **1** (with $\mathbf{1_a}$: x = 9, $\mathbf{1_b}$: x = 19) were elaborated by the co-condensation route of 3-mercaptopropyltrimethoxysilane (MPTMS) with tetraethoxysilane (TEOS) in the presence of Pluronic 123 [$PEO_{20}PPO_{70}PEO_{20}$ with PEO = poly(ethylene oxide) and PPO = poly(propylene oxide)] as structure directing agent in acidic media.[15] After extraction of the surfactant by using a Soxhlet apparatus, the materials were vacuum dried at 120 °C.

^{29}Si MAS NMR spectroscopy showed resonances for siloxane (Q^n) and organosiloxane (T^n) centres with a predominance of T^3 compared to T^2 or T^1 centres indicative of extensive condensation of the organic moiety in the wall structure. The solid state ^{13}C CP MAS NMR spectra show signals at δ 27 (C1, C2) in addition to a slightly shifted downfield CH_2–(Si) (C3) signal at δ 11 for the $-(CH_2)_3SH$ moiety. This confirms the presence of mercaptopropyl groups anchored to the pore walls. Furthermore, IR spectra of $\mathbf{1_a}$ (x = 9) display a characteristic S–H stretching vibration of low intensity at 2575 cm^{-1}. High values for the BET surface areas were obtained (Table S1†). The BJH pore size distribution was calculated from adsorption and desorption branches (53/46 Å for $\mathbf{1_a}$ and 71/61 Å for $\mathbf{1_b}$). These values show a significant decrease with increasing the content of thiol groups on the channel surface (Table S1†). The low angle X-ray diffraction (XRD) patterns of the materials show the (100) reflection while higher order (110) and (200) reflections were not well observed.[15]

Anchoring of gold within materials **1** was performed by using two gold precursors with a similar strategy (Scheme 1). The protocols used were based on procedures affording gold(0) nanoparticles in solution.[16] Path A: hydrogenotetrachloroaur-



Scheme 1 Preparation of the gold(0) nanoparticle-containing materials. *Reagents and conditions*: path A: i, $HAuCl_4{\cdot}3H_2O$; ii, $HOC(CO_2Na)(CH_2CO_2Na)_2$. Path B: i, AuCl(THT); ii, Na(acac); H_2O.

 DOI: 10.1039/b102575a

ate(III) hydrate ($HAuCl_4 \cdot 3H_2O$) was added to a suspension of the material in water heated under reflux and allowed to stir until the yellowish solution colour was transferred onto the solid. Then, sodium citrate [$HOC(CO_2Na)(CH_2CO_2Na)_2$] was added. This is the well known Turkevitch method which affords in solution particles of mean size centred near 12 nm. Using this procedure it will therefore be easy to discriminate between nanoparticle growth inside or outside the channels of the mesoporous material previously prepared. Path B: chloro-(thiophene)gold(I) [AuCl(THT)] was added at 60 °C to a suspension of the material in THF followed by addition of sodium acetylacetonate hydrate [Na(acac)·H_2O]. This procedure is expected to be milder and to lead to a more homogeneous system.

The presence of gold in the expected quantities for the resulting materials **2** was established by elemental analysis. The decrease in BET surface area as well as the decrease in pore volume are consistent with pore filling (Table S1†).

In all cases, it was observed for the X-ray diffractograms that when comparing the results on empty materials **1** and composite materials **2**, the intensity of the reflections was reduced in the latter case. This provides a confirmation of the pore filling of the host material, which reduces the scattering contrast between the pores and the walls of the materials.[17] For materials **2**, absence of plasmon band absorbances in the UV–VIS spectra or of diffraction peaks in the X-ray diffractograms (their presence being characteristics of gold(0) nanoparticles-containing materials) were observed. TEM images show weakly contrasted particles with diameter sizes less than 1.5 nm. These particles, the size of which is not dependent on the host material pore size, were attributed to formation of $(–Au^{I}SR–)_n$ polymers.[18] Therefore, the colourless solids **2** obtained at this stage were treated with an ethanolic sodium borohydride ($NaBH_4$) solution at 60 °C. This mild reduction afforded, after 12 h, purple solids **3** for which further decrease in BET surface area and pore volume was observed (Table S1†). Materials **3** exhibit intense plasmon band absorbance at 520 nm indicative of gold(0) nanoparticles. XRD patterns of materials **3** for the high angle region (2θ = 20–70) show broad reflections characteristic of gold(0) nanoparticles. TEM studies clearly show a narrow gold(0) nanoparticle distribution size for materials **3** whatever the pathway followed (A or B) (Fig. S5 and S6†). It is also clear that in both cases the growth of the particles occurs within the channels of the silica matrix since the size of the particles is quite small (centred near 2.5 and 4.5 nm). The size distribution was found to be more narrow *via* path B ($^{B}\mathbf{3_b}$) than *via* path A ($^{A}\mathbf{3_b}$) in agreement with the milder conditions needed for the reduction of the gold(I) precursor. In all cases, a good correlation was demonstrated between the pore size values derived from BET and the gold nanoparticles diameter size observed on TEM micrographs when taking into account experimental uncertainties (Fig. 1).

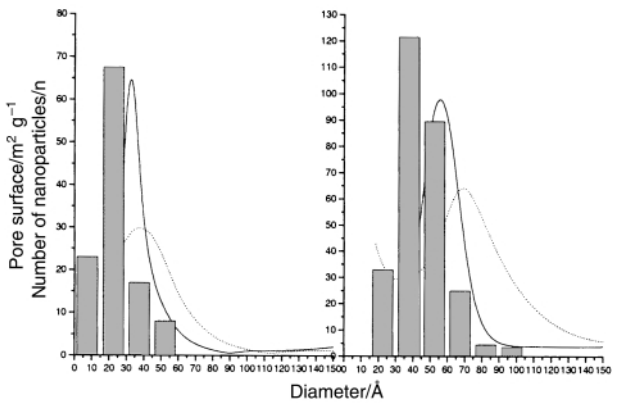

Fig. 1 Correlation between the pore diameter (solid/dotted lines for adsorption/desorption data from N_2 studies) and the gold(0) nanoparticle size (columns) for: left $^{A}\mathbf{3_a}$, right $^{B}\mathbf{3_b}$.

In conclusion, two main results are reported in this communication:

(i) The growth of gold nanoparticles can be achieved selectively within the pores of a mesoporous silica previously functionalized with thiol substituents. The nanoparticle growth follows a two step procedure implying first the anchoring of the gold precusors and secondly a chemical reduction.

(ii) This procedure allows a strict control of the size of the particles, which in each experiment, remain smaller than the pore size determined by BET and which furthermore adopt a narrow size distribution. Further work is in progress to explore the scope and limitations of this process.

The effect of *N*-methylation on the chemical reactivity of binuclear Ni amine-thiophenolate complexes†

Berthold Kersting* and Gunther Steinfeld

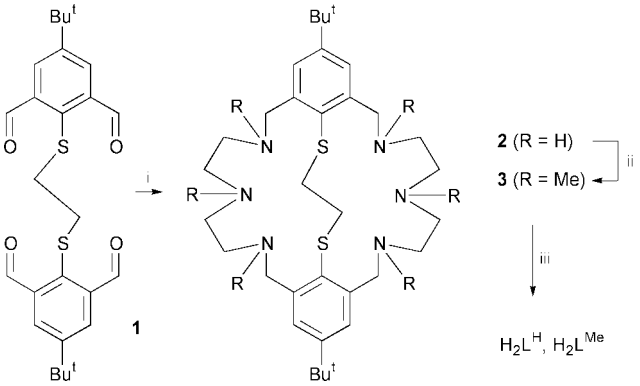
Institut für Anorganische und Analytische Chemie, Universität Freiburg, Albertstr. 21, D-79104 Freiburg, Germany. E-mail: kerstber@sun2.ruf.uni-freiburg.de

Received (in Cambridge, UK) 4th April 2001, Accepted 20th June 2001
First published as an Advance Article on the web 6th July 2001

Macrocyclic amine thiophenolate ligands are shown to form face-sharing bioctahedral nickel complexes with a central $N_3Ni(\mu\text{-}SR)_2(\mu\text{-}Cl)NiN_3$ core structure. The bridging halide ion can be readily replaced when all six nitrogen atoms are tertiary amine donors.

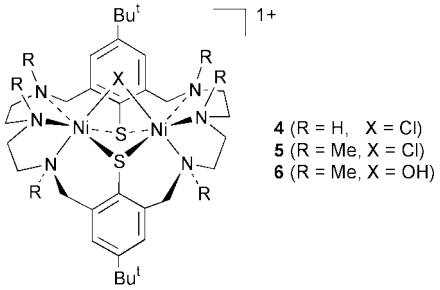
Thiolate complexes of first row transition metals are generally labile and it is therefore difficult to control their chemical reactivity. This is true in particular for binuclear species.[1,2] For systematic investigations, complexes of macrocyclic thiophenolate ligands seem to be ideal, because of their greater thermodynamic stability and proper positioning of free coordination sites for substrate binding. However, traditional routes developed for the corresponding phenolate macrocycles[3] fail for the synthesis of sensitive thiophenolates. This situation has changed greatly in the last few years due to the work by the groups of Brooker,[4] McKee[5] and Schröder[6] who have used (*S*)-(2,6-diformyl-4-methylphenyl)dimethylthiocarbamate as thiophenolate precursor in metal templated Schiff-base condensation reactions with α,ω-diamines. The resulting thiophenolate macrocycles bear additional imine, secondary amine, and even hydroxy groups in the linking side arms. However, it has not been possible to access derivatives with tertiary amine functions. We describe here the syntheses, X-ray crystal structures and properties of binuclear Ni complexes of such ligands.

Macrocycle **2** was obtained by a [2 + 1] condensation reaction between tetraaldehyde **1**[7] and bis(aminoethyl)amine in an ethanol–dichloromethane mixed solvent system using medium-dilution conditions followed by reduction with $NaBH_4$ (Scheme 1). The yields of the new bicyclic amine-thioether are excellent (> 90%). An attractive feature of **2** compared to unprotected thiolate ligands is that its secondary amines are readily alkylated without affecting the masked thiolate functions. Thus, reductive methylation of **2** with formaldehyde and formic acid under Eschweiler–Clarke conditions gave the permethylated derivative **3** in nearly quantitative yield. Compound **3** displays only twelve resonances in its ^{13}C NMR spectrum ruling out the possibility that it exists as a mixture of conformationally stable isomers. Both the unmethylated and the permethylated thioether could be converted to the corresponding thiophenols H_2L^H and H_2L^{Me} by using sodium in liquid ammonia as reducing agent.



Scheme 1 *Reagents and conditions*: i, $NH(CH_2CH_2NH_2)_2$, CH_2Cl_2–EtOH (high-dilution); ii, CH_2O, HCO_2H, reflux; iii, Na, NH_3, −70 °C.

The reaction of $NiCl_2{\cdot}6H_2O$ with $H_2L^H{\cdot}6HCl$ in methanol using NEt_3 as base (2 : 1 : 8 molar ratio) was found to produce the



green, air-stable complex $[(L^H)Ni^{II}_2(\mu\text{-}Cl)]^{1+}$ **4**. The cation was isolated as the perchlorate salt **4**·ClO_4 in 80% yield. Crystallographic characterization of **4**·ClO_4,‡ using crystals obtained by recrystallization from methanol, confirmed the structure of **4** to consist of a confacial bioctahedral species (Fig. 1). The coligand is found in a bridging position. In the context of coordinatively unsaturated Ni thiolate complexes, the presence of a bridging halide ligand in **4** is without precedent. Most binuclear

† Electronic supplementary information (ESI) available: Characterization data for all new compounds. ORTEP plots for complexes **5** and **6**. See http://www.rsc.org/suppdata/cc/b1/b103050g/

 DOI: 10.1039/b103050g

complexes feature a dithiolate bridged Ni(μ-SR)$_2$Ni core structure.[4–6] However, all attempts to replace the halide substituent in **4** have failed so far.

On these grounds, we synthesized the complex [(L^{Me})Ni$^{II}_2$(μ-Cl)]$^{1+}$ **5** by using reaction conditions similar to those described above for **4**. It was isolated as the yellow microcrystalline perchlorate salt **5**·ClO$_4$ in 85% yield. Electronic absorption spectroscopy (ESI†) and X-ray crystal structure determination‡ provided new insights into the coordination chemistry of the permethylated amine-thiolate ligand H$_2$L^{Me}. Two bands assigned as ν_1 ($^3A_{2g} \rightarrow {}^3T_{2g}$, splitting due to lower symmetry) are observed at 920 and 1002 nm in the UV–VIS spectrum of **5**·ClO$_4$. Compared to **4** (894 and 941 nm) these bands are shifted to lower energies indicative of a significantly weaker ligand field strength of H$_2$L^{Me}. The crystal structure determination of **5**·BPh$_4$‡ revealed the structure of the μ-chloro complex **5** to be very similar to **4**. The structure of **5** may be simply derived from that of **4** by replacing the six NH hydrogen atoms by methyl groups. The conversion of secondary into tertiary amines results in an increase of the average Ni–N bond length by 0.139 Å, which in turn results in a decrease of the average Ni–Cl distance by 0.178 Å. Similar effects have also been observed for nickel complexes of other azamacrocycles and their methylated derivatives.[8]

Preliminary binding studies demonstrate that utilization of the permethylated ligand H$_2$L^{Me} in place of H$_2$L^H drastically alters the ease of substitution of the bridging halide substituent, presumably because of the more hydrophobic microenvironment about the μ-Cl function in **5**. Thus, while the latter reacts with NBu$^n_4$OH in acetonitrile to produce the μ-OH complex **6**, complex **4** was found to be unreactive. Even the addition of a halide scavenger such as Pb^{II}(ClO$_4$)$_2$ did not lead to substitution of the Cl$^-$ ion.

A crystallographic analysis of **6**·BPh$_4$‡ revealed **6** to be isostructural with **5**. The OH group replaces the μ-Cl ligand, demonstrating that the substitution reaction takes place without gross structural changes of the parent complex. The average Ni–O bond length at 2.10 Å is typical for hydroxide-bridged dinickel centers.[9] The Ni–N and Ni–S bond lengths are similar to those in **5**, however, the separation of the Ni atoms has decreased to 3.037(3) Å. It is also worth mentioning that the OH unit [ν(OH) = 3543 cm^{-1}] is not involved in hydrogen bonding interactions.

Cyclic voltammetry experiments have shown that **4**·ClO$_4$ undergoes two one-electron oxidations at $E^1_{1/2}$ = +0.27 V [≡ $E_{1/2}$(Ni^{III}Ni^{II}/Ni^{II}Ni^{II}), ΔE_p = 91 mV] and at $E^2_{1/2}$ = 1.05 V [≡ $E_{1/2}$(Ni^{III}Ni^{III}/Ni^{III}Ni^{II}), irrev.] *vs.* SCE. The cyclic voltammogram of **5**·ClO$_4$ is very similar, but this complex is oxidized at more positive potentials at $E^1_{1/2}$ = +0.43 V (85 mV) and at $E^2_{1/2}$ = +1.37 V (irrev.) *vs.* SCE. The first oxidation of complex **6**·BPh$_4$, on the other hand, occurs at less positive potentials [$E^1_{1/2}$ = +0.26 V (94 mV); the value for $E^2_{1/2}$ could not be determined due to oxidation of the BPh$_4^-$ anion; a ClO$_4^-$ salt of **6** could not be obtained in a pure form]. The shifts of the redox potentials can be explained by the different coordination environments about the Ni ions. Tertiary amine donors exert weaker ligand fields than secondary amine functions. Complex **5** is thus more difficult to oxidize than **4**. The OH ligand in **6**, on the other hand, exerts a stronger ligand field than the halide ion in **5** and the former complex is thus more easily oxidized. Remarkably, all Ni^{III}Ni^{III} species are not stable on the timescale of a cyclic voltammetry experiment. This is in marked contrast to the behavior of coordinatively saturated Ni amine-thiolate complexes,[10] which can be reversibly oxidized to Ni^{III}Ni^{III} species. It is assumed that the different electrochemical properties are due to redox transformations of the bridging coligand or decomposition reactions of the Ni^{III} species.

In summary, the macrocyclic amine-thiolate ligand H$_2$L^H gives rise to an unprecedented type of coordinatively unsaturated amine-thiolate complex. The use of H$_2$L^{Me} in place of H$_2$L^H facilitates rapid substitution reactions at the bridging position, which encourages further exploration of the chemical reactivity of complex **5** and its derivatives.

This research was supported by the Deutsche Forschungsgemeinschaft. We thank Professor Dr H. Vahrenkamp for his generous support of this work.

Development of acidic sites in WO_x/ZrO_2

Thomas Onfroy, Guillaume Clet and Marwan Houalla*

Laboratoire de Catalyse et Spectrochimie (UMR CNRS 6506), ISMRA-Université de Caen, 6 Bd. du Maréchal Juin, 14050 Caen (cedex), France. E-mail: marwan.houalla@ismra.fr

Received (in Cambridge, UK) 28th March 2001, Accepted 20th June 2001
First published as an Advance Article on the web 6th July 2001

Evidence is shown of the appearance of Brønsted acidic sites in WO_x/ZrO_2 at a given W loading and of a direct correlation between the abundance of 'strong' Brønsted acidic sites in these catalysts and propan-2-ol decomposition activity.

It is well established that addition of W onto zirconia induces the formation of acid sites. With suitable preparation methods solid acid catalysts can be obtained which can isomerise *n*-hexane.[1] However, the genesis of acidity and the actual nature of the acid sites have not been fully investigated. Previous work with WO_x/ZrO_2 obtained by the incipient wetness impregnation method, indicated that a threshold of W loading was required for any activity for propan-2-ol decomposition to develop.[2] Similar behaviour was already reported for solids obtained by impregnation of zirconium hydroxide, for different reactions such as *o*-xylene[3] and *n*-pentane[4,5] isomerisation. It was proposed,[2] but not verified, that the origin of this behaviour is due to the formation of different types of acid sites at a given W loading. Furthermore, the simultaneous presence of polymeric surface WO_x and bulk WO_3 in active catalysts complicated any attempt to elucidate the nature of the active sites.

In the present work, a series of WO_x/ZrO_2 catalysts was prepared by the equilibrium adsorption method.[6] This procedure was shown to prevent WO_3 formation. A direct correlation between the surface structure and the catalytic activity for propan-2-ol decomposition is reported.

Tungsten surface species were monitored by Raman spectroscopy. The number, the strength and the type of acidity were characterised by IR spectroscopy. Propan-2-ol decomposition was used as a probe reaction to assay the acidity of the solids.

Catalysts were prepared by adsorption of W from aqueous solutions of ammonium metatungstate on zirconia (ZrO_2).[6] The support was prepared by hydrolysis of zirconium *n*-propoxide [$Zr(OPr)_4$, 70% in *n*-propanol; Aldrich]. The precipitate thus obtained was washed free of propanol, dried and calcined at 823 K in air for 24 h.[7] The original zirconia had a BET surface area of 43 $m^2\ g^{-1}$. A series of WO_x/ZrO_2 catalysts was prepared by suspending a known amount of ZrO_2 in a large volume of aqueous ammonium metatungstate solution [$(NH_4)_6H_2W_{12}O_{40}$, Aldrich] at a given pH. The samples were filtered off, dried and calcined at 773 K in air for 24 h. Solids with various W loadings ranging from 1.1 to 4.6 wt% W were obtained by modifying either the pH of the adsorption solution (adsorption time = 96 h) or the adsorption time (at pH = 12). No significant surface area loss was observed on W deposition.

Raman spectra were recorded with a Nicolet FT-Raman spectrometer attachment for a Nicolet Nexus FTIR spectrometer between 100 and 1100 cm^{-1} (resolution: 8 cm^{-1}). The samples were analysed in powder form and under ambient conditions without any pre-treatment. The technique was used to monitor the structure of the support (monoclinic; tetragonal), WO_3 formation and the evolution of surface W species.

IR spectra were recorded with a Nicolet 710 FT-IR spectrometer (resolution: 4 cm^{-1}). Samples were pressed into discs (*ca.* 20 mg; 2 cm^2) and activated alternatively in vacuum and O_2 at 723 K. Acidic properties (type and abundance) of the samples were characterised by two basic probe molecules (CO and 2,6-dimethylpyridine). CO was introduced at room temperature by doses (from 2.6 to 664 μmol g^{-1}) up to an equilibrium pressure of 133 Pa. 2,6-dimethylpyridine (lutidine) was introduced at room temp. ($P_{equilibrium}$ = 133 Pa) followed by thermodesorption from 373 to 573 K.

The catalytic conversion of propan-2-ol was measured in a fixed bed flow reactor. A mass of 100 mg of sample was pretreated at 723 K in N_2 for 2 h. The reaction was carried out at atmospheric pressure with 120 ml min^{-1} N_2 as carrier gas ($P_{propan\text{-}2\text{-}ol}$ = 1.23 kPa) at 413 K. Reactants and products were analysed with an on line Gas Chromatograph (HP 5890 Serie II) equipped with a capillary column (CP WAX 52 CB) and an FID detector. Catalytic study was conducted in non diffusional conditions, with conversions typically below 10%. Neither an induction period nor deactivation were observed during the analysis time (2 h). The rate of propene formation was calculated from eqn. (1), assuming a first order reaction for propan-2-ol:

$$r = -\frac{F_0}{W}\ln\left(\frac{100 - C}{100}\right) \quad (1)$$

where r is the rate of propene formation (mol h^{-1} g^{-1}), F_0 is the propan-2-ol molar flux (mol h^{-1}) and C is the % conversion to propene.

Raman spectra of WO_x/ZrO_2 catalysts and the zirconia support showed intense peaks between 100 and 700 cm^{-1} characteristic of the monoclinic phase of zirconia.[8] No Raman peaks which can be ascribed to bulk WO_3 were detected.[9] A band at 935 cm^{-1} attributed to the W surface phase appears on W deposition and increases in intensity with W loading. A shift in the position of this band to higher wavenumbers is observed with W content in accordance with previous results.[10] This is indicative of monomeric to polymeric transformation of W species.

The IR spectra of tungstated zirconias show significant dehydroxylation which increases with W loading. This indicates that W deposition occurs *via* replacement of the hydroxyl groups.

The presence of Lewis acid sites was monitored by FTIR and CO adsorption. The amount of CO required to saturate the sites decreased on W addition but it remained the same for all the tungstated solids.

The adsorption of lutidine at room temp. followed by evacuation at 423 K evidenced the presence of Brønsted acidic sites on the surface of WO_x/ZrO_2 catalysts. This is illustrated in Fig. 1(a) by the appearance of a doublet at 1645 and 1628 cm^{-1} attributed to lutidinium species and the subsequent increase of its intensity with increasing W loading. The peaks at 1610 and 1580 cm^{-1} are attributed to Lewis acid sites. After desorption of lutidine at 423 K, Brønsted acid sites were still observed for a W loading of 1 atom nm^{-2}. However, following desorption at 523 K only the Brønsted acid sites of solids containing more than 1.4 atom W nm^{-2} were sufficiently strong to retain the probe molecule on the surface [Fig. 1(b)]. These results are comparable to those reported by Wachs[11] concerning the appearance of Brønsted acidity on molybdenum, vanadium and niobium oxide supported on alumina.

The catalysts were tested for the reaction of propan-2-ol decomposition. Only two products, propene and diisopropyl ether were observed. For all catalysts, the selectivity to propene was high (≥ 85%) and increased with temperature as expected

 DOI: 10.1039/b102867g

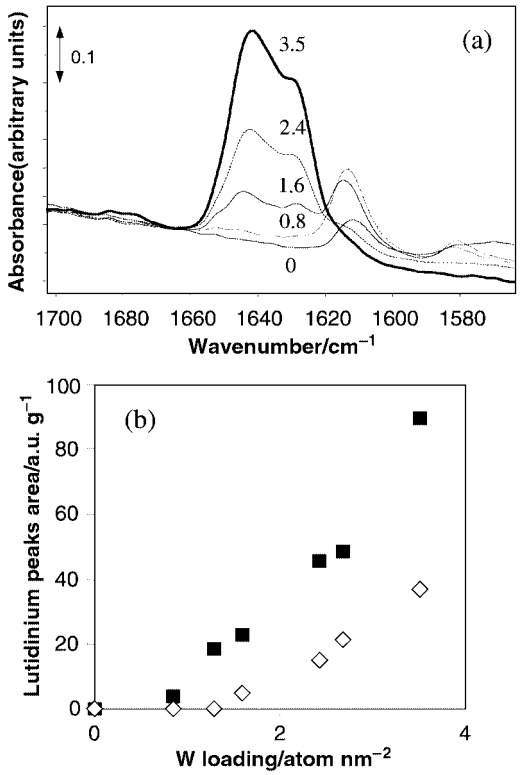

Fig. 1 Evolution of the lutidinium band. (a) IR spectra of lutidine evacuated at 423 K. (b) Evolution of the area of the band (1620–1660) after desorption of lutidine at 423 K (■) and 523 K (◇). [Numbers in (a) refer to the W loading in W atom nm^{-2}].

from thermodynamics. These results are consistent with acid catalysis.[7] In Fig. 2 the rate of propene formation was plotted *vs.* W content. The results show a very low rate up to 1.4 atom W nm^{-2}, followed by a steep increase for higher loadings. Similar behaviour was observed for measurements performed with different flows and temperatures. Fig. 2 compares the evolution of catalytic activity with that of the intensity of lutidinium band. Note that the onset of catalytic activity coincides with the appearance of 'strong' Brønsted sites. In addition, the evolution of the rate of decomposition parallels that of the abundance of Brønsted acid sites. The decomposition of propan-2-ol appears, thus, directly related to the presence and abundance of 'strong' Brønsted acid sites. Note that in the present study Brønsted acid sites are formed *prior* to any reductive treatment. This is in variance with previous studies[12] where strong Brønsted acid sites were reportedly formed on reduction of WO_x clusters in H_2 or by the reactant mixture. The appearance and the evolution of the abundance of the Brønsted sites on our catalysts suggest that

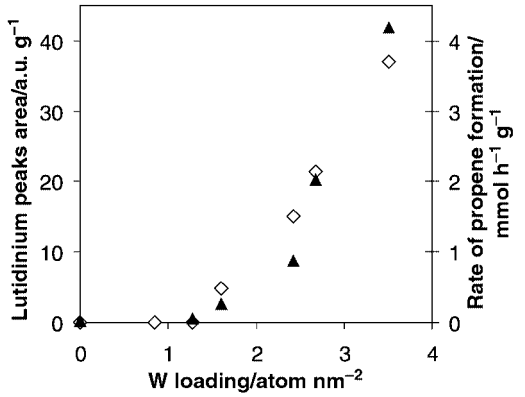

Fig. 2 Correlation between propene formation rate (▲) and abundance of "strong" Brönsted sites as evidenced by lutidinium peaks area after desorption at 523 K (◇).

a minimum degree of polymeric WO_x units may be necessary for the formation of acidic sites. A similar behaviour was observed for WO_x/Al_2O_3 catalysts and was attributed to an enhanced stabilisation of the proton by delocalisation among adjacent W atoms.[13,14] This interpretation is consistent with the observed lack of activity for low loading catalysts where W is reportedly present in a monomeric form. These results highlight the importance of extended W coverage for the development of Brønsted acid sites on supported catalysts.

Synthesis and structure of an unprecedented high-symmetry $[Fe_4S_4Cl_4]$ cubane-type unit in supramolecular $[K_4(FeCl_4)(C_{12}H_{24}O_6)_4][Fe_4S_4Cl_4]$†

Received (in Cambridge, UK) 30th April 2001, Accepted 18th June 2001
First published as an Advance Article on the web 6th July 2001

The reduction of SCN^- ions with iron containing zirconium chloride clusters in the presence of 18-crown-6 gives crystals of $[K_4(FeCl_4)(C_{12}H_{24}O_6)_4][Fe_4S_4Cl_4]$ which contain $[Fe_4S_4Cl_4]$ cubane-type clusters with full T_d symmetry, as well as supramolecular $[K_4(FeCl_4)(C_{12}H_{24}O_6)_4]$ complex cations.

The chemistry of iron–sulfur clusters has attracted much scientific interest due to the occurrence of such structural units in biological systems like ferrodoxines, high potential iron proteins, nitrogenases, and others.[1–5] For the class of cubane-type $[Fe_4S_4]$ clusters which are believed to be involved in biological electron transfer processes, synthetic investigations have revealed a large number of compounds with the general formula $[Fe_4E_4X_4]^{n-}$ with E = S, Se or Te; X = SR (R = organic group), SH, OR, NO, Cl, Br, I; $n = -1, -2,$ or -3.[1,2,6] They all contain cubane-type iron–sulfur cores which can be described as a tetrahedron of iron atoms, superimposed by a larger tetrahedron of chalcogen (E) atoms such that the E atoms are triply bridging the faces of the Fe tetrahedron. The tetrahedral coordination environment of each Fe atom is completed by an additional ligand X, bonded at each exo position of the Fe tetrahedron. The symmetry of the metal–chalcogen core of all the so far characterised molecular examples deviates significantly from the ideal T_d case. The core is usually compressed or elongated in one direction leaving an overall D_{2d} symmetry. This observation holds so far for all structurally characterised cubane-type iron–sulfur clusters, including those with $[Fe_4S_4Cl_4]^{2-}$ cores. The latter have been described with $[Et_4N]^+$, $[Pr^n{}_4N]^+$, $[Fe^{II}(MeCN)_2(POMe)_3]^{2+}$ and $[Ph_4P]^+$ counter cations.[10,13–15] This deviation from ideal symmetry has been discussed in terms of crystal packing and Jahn–Teller type electronic effects.[7,8]

Here we present the synthesis and structure of $[K_4(FeCl_4)(C_{12}H_{24}O_6)_4][Fe_4S_4Cl_4]$ **1** which contains the $[Fe_4S_4Cl_4]^{2-}$ cluster **2** of T_d symmetry as well as the uncommon $[K_4(FeCl_4)(C_{12}H_{24}O_6)_4]^{2+}$ complex cation **3**. **1** was an unexpected product from the reaction of $K[(Zr_6Fe)Cl_{15}]$[9] with KSCN in MeCN, to which 18-crown-6 (1,4,7,10,13,16-hexaoxacyclooctadecane) was added. In a typical synthesis, 20 mg (0.017 mmol) $K[(Zr_6Fe)Cl_{15}]$, 10 mg (0.102 mmol) KSCN, and 31 mg (0.12 mmol) 18-crown-6 were dissolved in 5 ml thoroughly dried acetonitrile. The initially dark blue solution loses its colour within *ca.* 3 h. Diisopropyl ether was slowly added by diffusion and after 4 weeks **1** was isolated as a black, crystalline material (yield 3.1 mg; 76% with respect to the cluster starting material). Apparently, the Zr-cluster becomes oxidised in solution, thereby releasing Fe cations, whereas the SCN^- ions are reduced, leaving S^{2-} ions. In a further reaction step the $[Fe_4S_4Cl_4]^{2-}$ cluster anions are formed. The structure of **1** was determined by single-crystal X-ray crystallography.‡

Within crystals of **1** the three symmetry independent atoms of the $[Fe_4S_4Cl_4]^{2-}$ cubane-type complex anion are located on 16e Wyckoff-sites (*x*,*x*,*x*) of the cubic space group *F*23 nearby the 4d site such that with the symmetry elements present, molecular units with full T_d symmetry are formed, even though the point symmetry of the 4d site does not imply full T_d symmetry (23 instead of $\bar{4}$ symmetry). This is shown by the equivalence of all the twelve Fe–S bonds [with a length of 2.294(2) Å] and Fe–Fe–Fe angles of exactly 60°. An ORTEP plot of the structure of **2** is shown in Fig. 1. The Fe–S, Fe–Cl, and Fe–Fe distances compare well with the average values of the $[Fe_4S_4Cl_4]^{2-}$ clusters in other compounds with different cations.[10] Because of the equivalence of all the Fe atoms in **2** the charge is delocalized completely with a net charge of +2.5 on each metal atom.

In crystals of **1** the central iron atom of the $[K_4(FeCl_4)(C_{12}H_{24}O_6)_4]^{2+}$ complex cation is located on the 4c Wyckoff site of the space group *F*23. Similar to the cluster anion on the 4d site the supramolecular entity also shows full T_d symmetry. The molecular structure of **3** is shown in Fig. 2. Compound **3** is composed of a central $[FeCl_4]^{2-}$ tetrahedron (with perfect tetrahedral Cl–Fe–Cl angles of 109.5°) and Fe–Cl distances of 2.260(4) Å. Above each triangular face of the tetrahedron a potassium cation is located which is encapsulated within a 18-crown-6 molecule. Comparable supramolecular complex cations are found so far only in a series of thallium compounds with the general formula $[A_4(MX_4)(C_{12}H_{24}O_6)_4][TlX_4]_2$ with A

= Tl, K, Rb, Ba, NH_4; M = Cu, Mn, Zn; and X = Cl, Br which all crystallise in the same cubic space group $F23$.[11,12]

The recognition of a molecular $[Fe_4S_4Cl_4]^{2-}$ cubane-type cluster with full T_d symmetry, as reported here demonstrates clearly that intramolecular electronic Jahn–Teller type effects are not responsible for the symmetry reduction as observed in many other examples of compounds with such clusters. Rather the lattice symmetry which is, besides other factors, also affected by the local symmetry of the counter cation determines the cluster symmetry.

Financial support from the Gerhard-Mercator-University Duisburg, from the Deutsche Forschungsgemeinschaft (DFG), and from the Fonds der Chemischen Industrie (FCI) is gratefully acknowledged. We thank M. Wickleder (University of Köln) for collecting X-ray data, and G. Henkel (University of Duisburg) for his support.

Notes and references

‡ *Crystal data*: $[K_4(FeCl_4)(C_{12}H_{24}O_6)_4][Fe_4S_4Cl_4]$: M = 1904.74, cubic, a = 21.241(2) Å, U = 9583(4) Å^3, T = 293(2) K, space group $F23$ (no. 196), Z = 4, μ(Mo-Kα) = 1.277 mm^{-1}, 23259 reflections collected, 1973 unique (R_{int} = 0.093) which were used in all calculations, two constraints, $R1(F)$ = 0.0645, $wR2(F^2)$ = 0.1750.

All thermal ellipsoids of the atoms of the 18-crown-6 molecules are elongated tangentially to the three-fold axis which cuts through the enclosed K cation, indicating that these almost flat molecules have some rotational freedom within the crystals. A thermal ellipsoid plot of the $[K_4(FeCl_4)(C_{12}H_{24}O_6)_4]$ cation in crystals of $[K_4(FeCl_4)(C_{12}H_{24}O_6)_4][Fe_4S_4Cl_4]$ is given as ESI.†

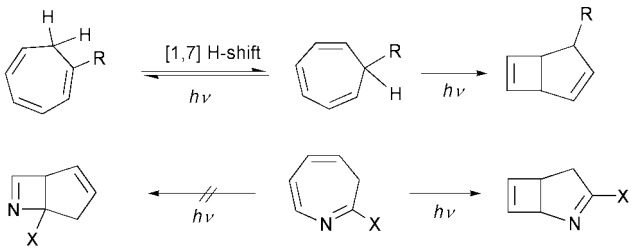
First published as an Advance Article on the web 2nd July 2001

Hitherto unknown photochemical behavior of 3*H*-azepine giving cyclopent[*c*]azete and a (4π + 4π) photodimer is reported on the basis of an unexpected formation of a tricyclic dicyclopenta[*b,e*]pyridine derivative and a ten-membered-ring dicarbaldehyde by irradiation of 2,5-di-*tert*-butyl-3*H*-azepine in hexane.

Photochemistry of cycloheptatriene (CHT) derivatives has been extensively examined, whereas those of 3*H*-azepines have rarely been explored in spite of having a similar profile in both molecular and electronic structure to each other. Generally, irradiation of CHT derivatives has resulted in the formation of bicyclic compounds *via* intramolecular 4π photochemical electrocyclic reaction[1] and/or isomerized CHT *via* photochemically allowed [1,7] hydrogen shift.[2] Under gas-phase conditions, a ring contraction reaction leading to toluene derivatives was also observed.[3] A few photochemical researches have examined 3*H*-azepine with an electron donating group (–OR or $–NR_2$) at the 2 position. The reaction was rationalized by the formation of a cyclobuta[*b*]pyrrole derivative *via* ring closure between the 4 and 7 positions, exclusively.[4] Although 3*H*-azepine without any substituents has been found to be a labile substance[5] an electron donating group, imino ether or amidine conjugation, has been found to stabilize it.



We have reported the synthesis of dialkyl 3*H*-azepines, the stability of which was sufficient for treatment under atmospheric conditions when substituents were *tert*-butyl groups.[6] Since the stability of our 3*H*-azepines is not owing to conjugative stabilization, but steric protection by the bulky substituents, the behavior upon photoirradiation can be expected to be different from those reported. We wish to report the hitherto unknown photochemical behavior of 2,5-di-*tert*-butyl-3*H*-azepine **1**.

A solution of **1** (112 mg, 0.55 mmol) in hexane (100 ml) was irradiated using a high-pressure mercury lamp (100 W) with pyrex filter for 3 h at rt. Chromatography on silica gel of the resulting mixture gave 1,4a,7-tri-*tert*-butyl-3-pivaloyl-3,3a,4,4a,5,7a,8,8a-octahydrodicyclopenta[*b,e*]pyridin-8-ol **2** (63 mg, 61%) as colorless needles and 5,10-diamino-2,5,7,10-tetra-*tert*-butylcyclodeca-2,7-diene-1,6-dicarbaldehyde **3** (5 mg, 5%) as a yellow oil along with recovered 3*H*-azepine **1** (11 mg, 10%).[7] Fortunately, the structure of crystalline product **2** was determined by X-ray structural analysis (Fig. 1).[8] The obtained structure is considered to be an indirect product from the starting material because the molecule contains oxygen atoms which strongly suggests that it comes from a kind of dimer of **1**. The other product, **3**, showed a negative ion peak at *m*/*z* 445 (M − H, 7%) in the FAB MS spectrum. The mass number observed is compatible with two moles of **1** and two moles of water, therefore the precursor for **3** is also considered to arise from the dimer of **1**. The ^1H and ^{13}C NMR spectra of **3** suggest a symmetrical structure having formyl groups owing to δ_H 9.55 (d, J = 5.4 Hz) and δ_C 205.6 (d). The IR absorption bands at 3399 and 1707 cm^{-1} are attributable to amino and formyl groups, respectively. Therefore, the structure of **3** is considered to be a *cis,cis*-cyclodeca-1,6-diene skeleton formed from the hydrolysis of the imine moiety of the (4π + 4π) dimer **5**. According to the conformational analysis for *cis,cis*-cyclodeca-1,6-diene based on molecular mechanics, a chair form has been found to be the most stable form.[9] When the conformation of the ring maintains a chair form, the stereochemistry of **3** is determined to be as illustrated in Scheme 1 owing to both W-letter coupling, J = 2.1 Hz, between an *ipso*-proton of a formyl group and a methylene proton at δ_H 2.28 and molecular symmetry suggested by NMR spectra.

To obtain more detailed information about the reaction, we observed the *in situ* ^1H NMR spectrum during irradiation of **1** in cyclohexane-d_{12} under similar conditions. A gradual inverse relationship varying in time was observed between the peaks of 3*H*-azepine **1** and the peaks of **3** and a new compound **4**. No peaks corresponding to **2** were found during the irradiation. This means **3** formed quickly from (4π + 4π) photodimer **5** by hydrolysis with a trace of water in the solvent, but **2** formed

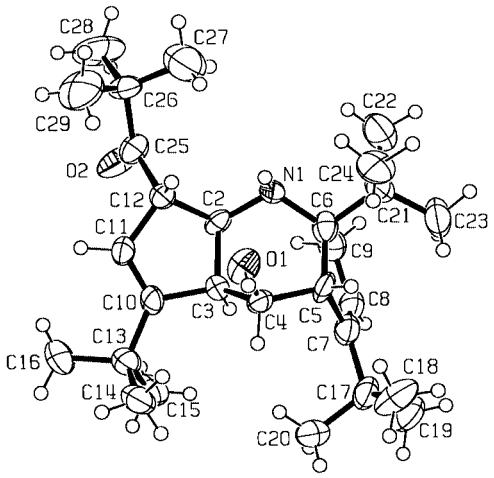


Fig. 1 Ortep drawing of structure **2**.

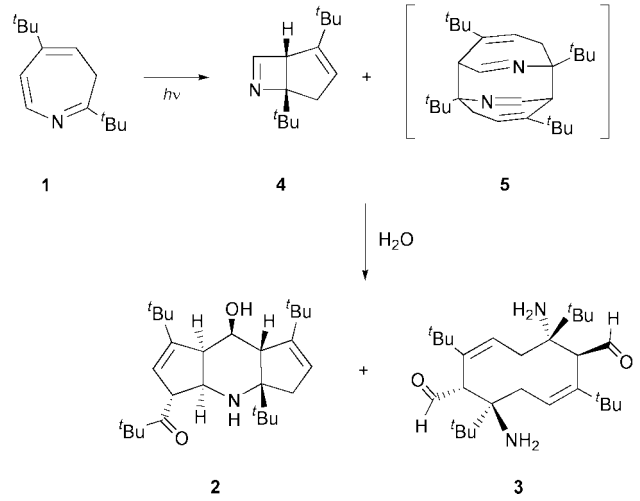
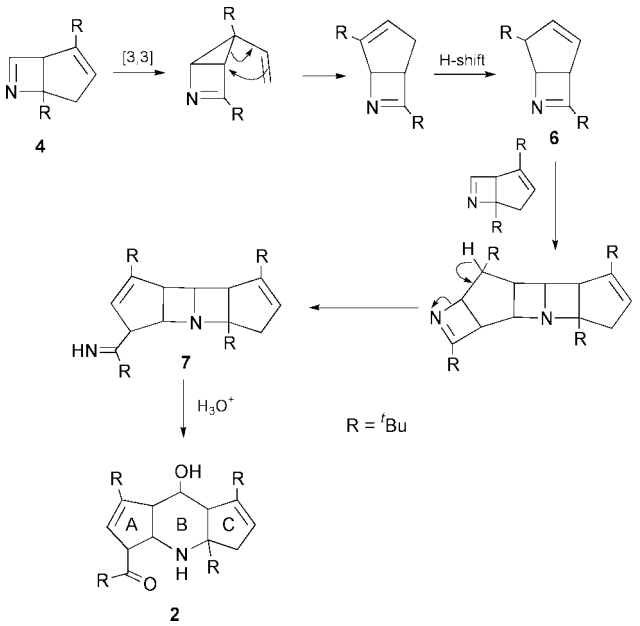
 DOI: 10.1039/b101225h



Scheme 1



Scheme 2

during chromatographic work from the initially formed photoproduct **4**. Attempts to isolate compound **4** were unsuccessful, however, GCMS showed *m*/*z* 205 (M^+, 0.4%) which is the same mass number as **1**. ^{1}H NMR data for **4** was obtained by the subtraction of known peak sets of **1**, **2** and **3** from the spectrum of a reaction mixture. The structure of **4** is estimated as 3,5a-di-*tert*-butyl-5,5a-dihydro-2a*H*-cyclopent[*c*]azete because of the doublet signal at δ_H 8.16 which is attributable to a –CH = N– moiety.

A possible route to **2** is illustrated in Scheme 2. The structure of the C-ring and a half of the B-ring of **2** are already in photoisomer **4** itself, but the pivaloyl group on the A-ring is not in the structure **4**. To access compound **2**, it is necessary to consider a formal ($2\pi + 2\pi$) addition between **4** and **6** which arises from **4** through the following sequence, [3,3] sigmatropic rearrangement, vinylcyclopropane rearrangement and finally 1,3-prototropy. Appropriate ring opening with participation of water on the adduct **7** leads to dicyclopenta[*b*,*e*]pyridine **2**.

We report here a new photochemical intramolecular ring closure at the 2 and 6 positions of 3*H*-azepine and ($4\pi + 4\pi$) photodimerization, although the yield of ($4\pi + 4\pi$) dimerization is relatively low compared to that of 4π electrocyclic reaction. An investigation is underway to clarify the photochemical behavior of 3*H*-azepine.

We are grateful to Professor S. Kashino of Okayama University for his helpful advice for X-ray structural analysis. We thank the SC-NMR Laboratory of Okayama University for ^{1}H and ^{13}C NMR measurements.

8 Crystal data for **2**: $C_{28}H_{47}NO_2$, M = 429.68, orthorhombic, a = 11.400(2), b = 21.835(6), c = 10.935(5) Å, V = 2721.9(12) Å^3, T = 298 K, space group $P2_12_12_1$, Z = 4, μ(Mo-K$_\alpha$) = 0.060 mm^{-1}, 2693 unique ($2\theta_{max}$ = 50°, R_{int} = 0.050) reflections were used in refinement. The final $wR(F)$ was 0.178 for the unique reflections and $R(F)$ was 0.089 for 1468 reflections larger than $2\sigma(I)$. The reflections in the high 2θ range were weak probably because of the large thermal displacements of the four *tert*-butyl groups in the molecule. Relatively large final $wR(F)$ and $R(F)$ may be caused by this fact. The absolute configuration has not been determined. CCDC 158826. A practical catalytic Wittig-type reaction

Zheng-Zheng Huang, Song Ye, Wei Xia and Yong Tang*

Laboratory of Organometallic Chemistry, Shanghai Institute of Organic Chemistry, 354 Fenglin Lu, Shanghai 200032, China. E-mail: tangy@pub.sioc.ac.cn

Received (in Cambridge, UK) 9th May 2001, Accepted 12th June 2001
First published as an Advance Article on the web 9th July 2001

Soluble PEG-supported telluride 2 was synthesized and found to be an effective catalyst for the catalytic Wittig-type reaction to give a variety of α,β-unsaturated esters in high yields with excellent *E*-stereoselectivity in the presence of sodium bisulfite as well as triphenyl phosphite.

In the past decades, highly efficient catalysis has become one of the most important frontiers in exploratory organic synthetic research.[1] Although the ylide reaction is one of the most useful approaches in both constructing C–C double bonds[2] and forming small ring compounds,[3] surprisingly, relatively few catalytic ylide reactions, in particular Wittig-type reactions, were reported in literature.[4] The first example of catalytic Wittig-type reactions appeared in 1989, in which Huang *et al.* found tributylarsine could be used as the catalyst in the presence of triphenyl phosphite.[5] Later on, they described the catalytic ylide olefination, epoxidation, and cyclopropanation reactions mediated by *n*-butyl telluride or isobutyl telluride.[6] Dai *et al.* also reported the first catalytic ylide aziridination and provided a facile way to the synthesis of vinyl-type aziridines.[7] Aggarwal *et al.* realized excellent catalytic asymmetric ylide epoxidation, cyclopropanation and aziridination reactions by a carbene approach.[8] In this process, the ylide was formed directly from phenyldiazomethane in the presence of a catalytic amount of both chiral sulfide and rhodium acetate. In all of the reactions described above, however, the amount of catalyst used was 20 mol%. Reduction of the catalyst means low yield even if the reaction time was prolonged.[9] Needless to say, these processes need to be improved before it can be considered as a useful synthetic tool. In our continuing studies on the application of ylides in organic synthesis,[10] we focused on the economy of ylide reactions. In this paper, we wish to report a highly effective Wittig-type olefination catalyzed by the soluble poly(ethyleneglycol) (PEG)-supported telluride **2** (PEG–Te–Bu).[11]

When *p*-chlorobenzaldehyde was mixed with ethyl bromoacetate in the presence of triphenyl phosphite and 1 mol% of compound **2** in toluene at 80 °C, we found that the Wittig-type reaction product was afforded in 88% yield with excellent stereoselectivity.† This meant that the catalytic efficiency of this reaction was improved greatly compared with other catalytic ylide reactions reported to date. By optimizing the reaction conditions, the desired olefin could be obtained in quantitative yield when 2 mol% of telluride **2** was used. To determine the generality of this reaction, a variety of structurally different aldehydes were employed. Some results are summarized in Table 1 (entries 1, 3, 5, 7, 9, 11, 13, 15 and 17). From Table 1, both aliphatic and aromatic aldehydes worked well with high stereoselectivity in reasonable yields.

To make this reaction more practical, we tried to use inorganic reducing reagents instead of triphenyl phosphite and found excellent results were achieved when sodium bisulfite

[a] Isolated yields. [b] The ratio of *E*:*Z* isomers was determined by ^1H NMR. [c] 5 mol% catalyst used. [d] The aldehyde used in this reaction was the crude product by Swern oxidation of 2,3-epoxy-5-benzyloxypentan-1-ol. The yield refers to the total yields of oxidation reaction and Wittig-type reaction based on 2,3-epoxy-5-benzyloxypentan-1-ol.

 DOI: 10.1039/b104100m

was used as the cocatalyst. Both aromatic aldehydes and aliphatic aldehydes could react with *tert*-butyl bromoacetate to afford the corresponding products in high yields with high stereoselectivity (enties 2, 4, 6, 8, 10, 12, 14, 16 and 18) in the presence of sodium bisulfite. It was noteworthy that phthalaldehyde could react with bromoacetate under these conditions and both aldehyde groups could be olefinated in high yield (entry 19 in Table 1). γ,δ-Epoxy-α,β-unsaturated ester, a useful building block, could also be synthesized by the current method in moderate yield with excellent stereoselectivity (entry 20 in Table 1).

This modification simplified the purification greatly and realized a phosphorus-free catalytic reaction. One could get the product just by filtering off the solid inorganic compounds and precipitating the catalyst after the reaction was completed.

Further study showed that α,β-unsaturated esters can be mass-produced under these reaction conditions and the catalyst could be recovered in quantity but lost its activity partially through multiple cycles. 2-Furaldehyde (10.85 mmol) was reacted with *tert*-butyl bromoacetate in the presence of sodium bisulfite and the desired product was obtained in 90% yield when 2 mol% of PEG-telluride was used. The catalyst was recovered in 100% yield by filtering off the solid of the reaction mixture, followed by addition of ether and collection of the precipitate. The recovered catalyst could be used in the second run but only 69% yield was obtained probably due to the decomposition of PEG-telluride during the catalytic olefination.[12]

Despite the advantages of easy separation and purification of products, the uses of polymer-supported catalysts suffered from lowered catalytic activity and stereoselectivity due to the restriction of polymer matrix that resulted in limited mobility and the accessibility of the active site. The PEG-telluride for catalytic ylide olefination reported here represents a novel, highly efficient polymer-supported catalyst that shows higher catalytic activity as compared to the free corresponding catalysts. Thus, we have developed an effective catalytic ylide olefination, which involves a simple procedure, mild reaction conditions, the use of catalytic PEG-telluride, and in particular, the use of sodium bisulfite as cocatalyst. The high catalytic efficiency, together with the ability to easily purify the product, demonstrates our method to be practical for the synthesis of α,β-unsaturated esters. The extension of our method to other olefination, epoxidation, cyclopropanation and aziridinations is in progress in our laboratory.

This research was supported by 'Hundred Scientist Program' from Chinese Academy of Sciences and State Key Project of Basic Research (PROJECT 973, No.2000 48007).

Notes and references

† Typical procedure for the synthesis of α,β-unsaturated esters. A, $P(OPh)_3$ as the cocatalyst: a mixture of catalyst **2** (0.0680 g, 2 mol%), ethyl bromoacetate (0.06 mL, 0.5 mmol), $P(OPh)_3$ (0.36 mL, 1.4 mmol) in toluene (3.0 mL) was stirred at 80 °C for 10 min and then K_2CO_3 (0.1796 g, 1.3 mmol) was added. The resulting suspension was stirred for 1 min, followed by addition of a mixture of aldehyde (1.0 mmol) and ethyl bromoacetate (0. 1 mL, 0.90 mmol) in toluene (1.0 mL) in portions in 3.5 h. After the reaction was completed (monitored by TLC), the mixture was filtered rapidly through a glass funnel with a thin layer of silica gel and washed with ethyl acetate. The filtrate was concentrated and the residue was purified by flash column chromatography to afford the desired product.

B, $NaHSO_3$ as the cocatalyst: a mixture of catalyst **2** (0.0680 g, 2 mol%), *tert*-butyl bromoacetate (0.06 mL, 0.4 mmol), $NaHSO_3$ (0.1664 g, 1.6 mmol) and in THF (3.0 mL) was refluxed for 10 min and then H_2O (0.04 mL) was added. The resulting mixture was stirred for 10 min, followed by addition of K_2CO_3 (0.2760 g, 2.0 mmol). After being stirred for 1 min, to this suspension was added a mixture of aldehyde (1.0 mmol), *tert*-butyl bromoacetate (0.12 mL, 0.8 mmol) and water (0.03 mL) in THF (1.0 mL) in portions in 3.5 h. The reaction was quenched by anhydrous $MgSO_4$ after the reaction was complete (monitored by TLC). The resulting mixture was filtered rapidly through a glass funnel with a thin layer of silica gel and washed with ethyl acetate. The combined filtrate was concentrated and the residue was purified by flash column chromatography to afford the desired product.

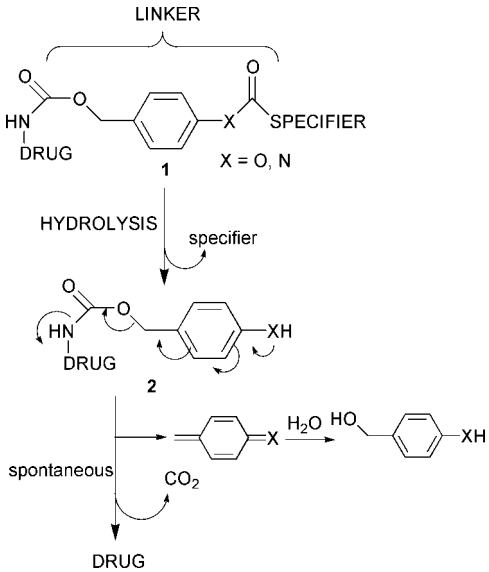
First published as an Advance Article on the web 11th July 2001

Activation of a model tripartate prodrug was achieved by abzyme-catalyzed hydrolysis of an *N*-methylcarbamate moiety followed by a spontaneous 1,6-elimination reaction.

Researchers have long been searching for ways of delivering drugs specifically to cancer cells. One such tactic is known as antibody-directed enzyme prodrug therapy (ADEPT).[1] In this approach, an enzyme–antibody conjugate is used to target an enzyme to the surface of tumour cells. An inactive prodrug is administered which is converted into the drug only by the tumour-bound enzyme. This results in a high concentration of the drug in the vicinity of the cancer cell while minimizing its presence at healthy cells. One of the key requirements for a clinically useful ADEPT system is the absence of an equivalent endogenous enzyme in humans. Consequently, the enzyme component has commonly been of non-human origin. However, the immunogenicity of the non-human enzymes has severely limited the clinical potential of ADEPT. To overcome this problem, researchers have suggested replacing the enzyme component with a catalytic antibody (antibody-directed abzyme prodrug therapy—ADAPT).[2a–d] Abzymes can be designed to act upon substrates that are not readily acted upon by human enzymes. In addition, antibodies can be humanized thus reducing the serious problem of immunogenicity.[3]

A number of abzymes have been developed that convert prodrugs into drugs.[2a–d] In most instances, the transition state analogues (TSA's) to which these abzymes were raised contained the drug or a structural analogue of the drug.[2a–c] Such abzymes were designed to activate bipartate prodrugs in which the moiety acted upon by the abzyme (known as the specifier[4]) is directly attached to the drug. An alternative to using bipartate prodrugs is to use tripartate prodrugs. In tripartate prodrugs, the specifier is separated from the drug by a linker. After cleavage of the specifier from the linker, the linker–drug product is designed to spontaneously fragment to release the drug. An example of a tripartate prodrug system is outlined in Scheme 1. Here, specific hydrolysis of the moiety separating the specifier and linker in **1** releases unstable intermediate **2** which undergoes a spontaneous 1,6-elimination reaction to release the drug. This prodrug design was first described by Katzenellenbogen and coworkers.[4] Prodrugs based upon this general design have been used extensively in ADEPT and for other applications.

Several years ago, we suggested that abzymes that are designed to activate tripartate prodrugs might be more versatile for ADAPT than those that act upon bipartate prodrugs.[5] If an abzyme could be designed to recognize only the specifier and linker of a tripartate prodrug, then a single abzyme could be used to activate a variety of different prodrugs.[5] This would be advantageous both in terms of economy and for dealing with tumours that have developed resistance to a certain drug. We reasoned that this could be accomplished by raising antibodies



Scheme 1

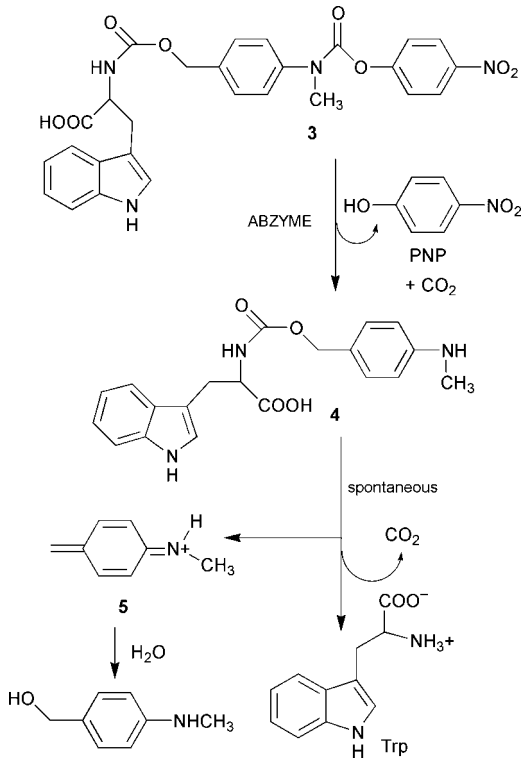
to TSA's in which the drug was *not* incorporated into the TSA.[5] Instead, the carrier protein (necessary for antibody production) could be attached to a position on the TSA that is equivalent to the point of attachment of the drug to the prodrug. Since abzymes are usually insensitive to changes in the region of the substrate that corresponds to the part of the TSA that is attached to the carrier protein,[6] then abzymes raised to such TSA's might be capable of acting as generic activators of tripartate prodrugs.

To test this approach we constructed the model tripartate prodrug **3**† (Scheme 2). In this system, drug release is triggered by abzyme-catalyzed hydrolysis of the *N*-methylcarbamate moiety to release *p*-nitrophenol (PNP, the specifier), CO_2 and intermediate **4**. Intermediate **4** then undergoes the spontaneous 1,6-elimination reaction to produce the amino acid L-tryptophan (Trp) as the model 'drug'.[7] Abzymes were raised to TSA-hapten **6**,[8] which mimics the rate-determining transition state for the hydrolysis of the *N*-methylcarbamate moiety in **3**. We recently reported that an antibody raised to **6**, called ST51, is capable of catalyzing the hydrolysis of *N*-methylcarbamate **7**.[8] Since the carrier protein in **6** was attached to a position on the TSA that corresponds to the point of attachment of tryptophan to **3**, we reasoned that ST51 should be capable of activating model prodrug **3**.

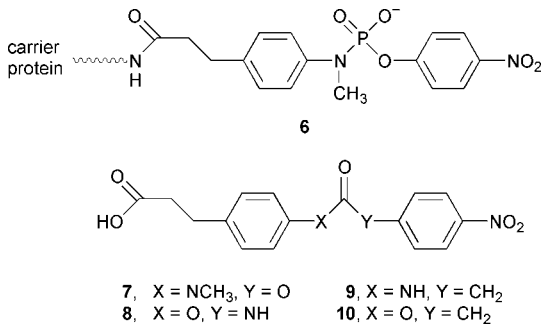
Model prodrug **3** was examined as a substrate for ST51 by removing aliquots from solutions containing ST51 (5 μM) and varying amounts of **3**, in buffer at pH 9.0 (100 mM bicine, 100 mM NaCl, 5% DMSO, 25 °C), at various time intervals, and then examining the aliquots for production of both PNP and Trp by HPLC. Under these conditions, we were unable to detect any PNP or Trp in the absence of ST51 after 40 hours. However, in the presence of ST51, both of these products were readily detectable. The antibody-catalyzed reaction obeys saturation

† Electronic supplementary information (ESI) available: the synthesis and characterization of **3**, and **9**–**11**, and experimental details for kinetic studies and Lineweaver–Burk plots. See http://www.rsc.org/suppdata/cc/b1/b103971g/

 DOI: 10.1039/b10371g



Scheme 2



kinetics, and approximately equimolar quantities of PNP and Trp were detected for the duration of the time the reactions were monitored. When following the production of PNP, ST51 exhibited a k_{cat} = 0.075 h^{-1} and a K_m = 137 μM. Similar values were obtained from data following the production of Trp. We also found that ST51 was unable to catalyze the hydrolysis of Z-Trp. Taken together, these results indicate that the production of Trp is not a result of hydrolysis of the *N*-H carbamate moiety, but rather initial hydrolysis of the *N*-methylcarbamate followed by the spontaneous fragmentation reaction and that the abzyme-catalyzed step is slow compared to the fragmentation reaction. We also found that ST51 was capable of catalyzing the activation of **3** with multiple turnover. This indicates that **5**, which is produced as an intermediate during the reaction, does not inactivate the abzyme after a single turnover by reacting with crucial residues in the active site.

Assuming that the spontaneous rate of hydrolysis of the *N*-methylcarbamate moiety in **3** is similar to that of **7** ($t_{\frac{1}{2}}$ = 5.7 years in 100 mM bicine, 100 mM NaCl, 5% DMSO, pH 9.0) then the rate enhancement (k_{cat}/k_{uncat}) with **3** is about 5000-fold. This is only slightly less than the rate enhancement found for ST51 using substrate **7** (6500-fold).[8] It is also important to note that **3** and **7** exhibit similar K_m values (266 μM for **7** and 137 μM for **3**). These results indicate that the 'drug' portion of the prodrug is not an important recognition site for the antibody-catalyzed reaction and this is consistent with our hapten design.

In summary, we have reported the first example of antibody-catalyzed activation of a model tripartate prodrug of type **1** by a tandem hydrolysis–1,6-elimination reaction.[9] We have demonstrated that it is possible to obtain an abzyme that can activate a tripartate system without incorporating the 'drug' into the TSA by attaching the carrier protein to a position on the TSA that corresponded to the point of attachment of the 'drug' to the tripartate prodrug. Although ST51 can catalyze the hydrolysis of *N*-methylcarbamates at physiological pH, the rate of the reaction is too slow for an accurate kinetic analysis and effective prodrug activation. It has been estimated that for ADEPT systems, a k_{cat} value of about 1.0 s^{-1} is required.[2c] Nevertheless, the approach outlined here should be readily applicable to tripartate prodrugs of type **1** bearing moieties that are more amenable to antibody–catalyzed hydrolysis, under physiological conditions, than *N*-methylcarbamates, which are highly challenging substrates for antibody catalysis.[8] An *N*-H carbamate linkage between the specifier and linker, of the type recently exploited by Blackburn and coworkers for abzyme catalysis,[2c] should be very suitable to the approach reported here.[11] However, tripartate prodrugs of type **1** bearing such a moiety cannot be used as substrates for ST51 since ST51 will not hydrolyze *N*-H carbamate **8**, amide **9**, or even ester **10**. Studies to elucidate the mechanism of ST51 are in progress and we are continuing our work to develop abzymes that can trigger tripartate prodrugs of type **1** under physiological conditions.

We thank the Canadian Institutes of Health Research (CHIR) for financial support of this work. We would also like to thank Katherine Majewska and Parham Daneshvar for assistance in synthesizing compounds **8**–**10**.

7 Since the primary objective of these studies was to determine if ST51 could trigger the tripartate system, it was not necessary to use an actual drug to make the model 'prodrug'. Indeed, for these studies any amine-bearing molecule would have sufficed for the 'drug' so long as it (1) had no resemblance to the specifier (PNP) portion of the prodrug, (2) was relatively easy to detect and quantitate, (3) had a charged moiety that would enhance the solubility of the prodrug and, (4) was readily available and allowed for economic and facile synthesis of the model prodrug. Tryptophan was chosen since it satisfied all of these requirements.

8 A. N. Dinaut, M.-J. Chen, A. Marks, R. A. Batey and S. D. Taylor, *Chem. Commun.*, 2000, 385.

9 While our work was in progress, Shabat *et al*. reported abzyme-catalyzed activation of tripartate prodrugs by a tandem retro-aldol–retro-Michael reaction (see ref. 2*d*). Although the abzyme was not originally designed to act as a prodrug activator (see also ref. 10), generic tripartate prodrug activation was achievable because of the broad substrate specificity of the abzyme.

11 For tripartate prodrugs of type **1** based upon *N*-H carbamates of the kind examined by Blackburn and coworkers (see ref. 2*c*), the specifier would be an amino acid and atom X in Scheme 1 would be oxygen and so the self-immolative intermediate **2**, would be a phenol derivative. Phenols also undergo the spontaneous 1,6-elimination reaction. For a recent example of this see: I. Niculescu-Duvaz, D. Niculescu-Duvaz, F. Friedlos, R. Spooner, J. Martin, R. Marais and C. J. Ligand exchange reactions reveal unexpected lability of the carbene ligands in two coordinate palladium(0) *N*-heterocyclic carbene complexes; the latter are found to be very effective catalysts for amination of aryl chlorides.

In recent years it has become clear that *N*-heterocyclic carbenes can offer an interesting alternative class of ligand to the ubiquitous phosphines, especially for catalytic applications.[1] The extraordinary advantage that this class of ligand has afforded to metathesis catalysts is a testament to the potential of metal complexes derived from these ligands for organic synthesis.[2] Palladium catalysed protocols utilising imidazolium salts have also been shown to offer a significant advantage for a range of synthetically valuable coupling processes.[3] These salts can be precursors to heterocyclic carbenes and the *in situ* generation of metal–carbene complexes has been suggested as a key step in such reactions. However, although there are a number of reports describing structures of four-coordinate metal(II) carbene species[4] there is relatively little structural, mechanistic or theoretical work pertaining to the two-coordinate palladium(0) carbene species which might be expected to be generated under many of the reaction conditions.[5] It is important to establish whether such isolated complexes are indeed able to effectively mediate coupling reactions; this approach would also facilitate mechanistic studies essential for further developments. Herrmann and coworkers have recently reported the use of pre-formed two-coordinate palladium(0) carbene complexes for Suzuki reactions and noted significant differences in activity between the pre-formed complexes and those assumed to be generated *in situ*.[6] We have embarked upon a programme of work, which has been directed toward the synthesis and characterisation of a range of two-coordinate palladium(0) carbene complexes[7] and examination of their reactivity. Here we describe the synthesis and reactivity of two-coordinate palladium carbene complexes shown in Fig. 1.

We have previously prepared complex **1**, initially using metal vapour synthesis and more recently *via* a solution phase method,

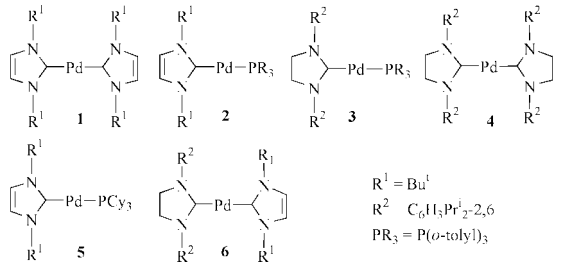

Fig. 1 Two-coordinate palladium carbene complexes.

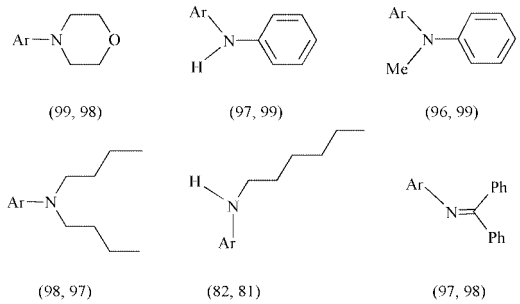
† Electronic supplementary information (ESI) available: details of experimental procedures and characterisation data for complexes **2**–**6**, ligand substitution reactions and general procedure for coupling reactions. See http://www.rsc.org/suppdata/cc/b1/b104297c/

and we reported that **1** can be used to mediate a Sonogashira and an amination reaction.[8] However we found procedures using **1** to be less general than protocols already available and so from a preparative sense this was disappointing. Seminal work by Hartwig and coworkers suggested that a key aspect of pre-catalyst design would be the presence of a ligand which could dissociate to generate a mono(carbene)palladium species which, if consistent with other catalytic systems, could then undergo oxidative addition.[9,10] Moreover given the precedents in both palladium and ruthenium catalysis, we also decided to explore saturated *N*-heterocyclic carbenes as ligands since these would offer improved donor capabilities and render catalytic species more active.[11] For these reasons we have prepared the new, two-coordinate palladium complexes **2**, **3** and **4** and evaluated their ability to promote the amination of *p*-chlorotoluene under catalytic conditions.[12]

Displacement of both phosphine ligands in [Pd{P(*o*-tolyl)$_3$}$_2$] by *N*-heterocyclic carbenes has been previously employed to prepare the corresponding [Pd(carbene)$_2$] complexes;[6] however, careful control of stoichiometry enabled the synthesis of the mixed carbene–phosphine complex **2** in good yield.

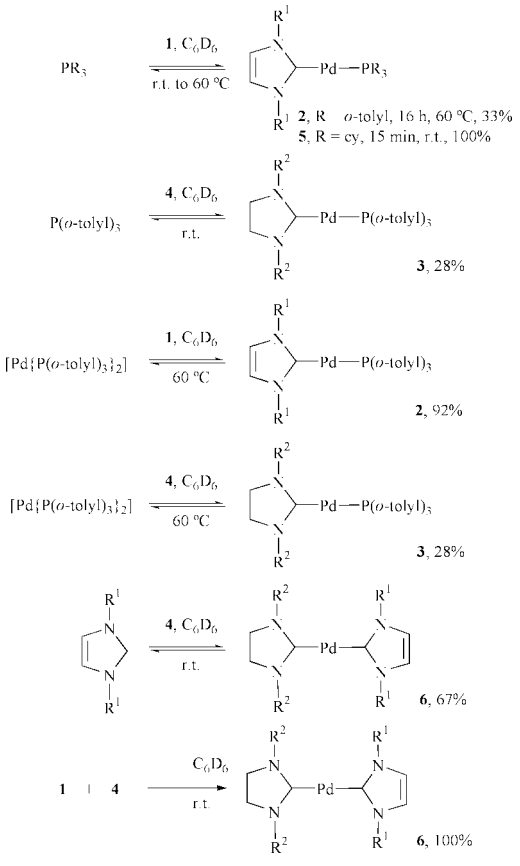
Contrary to our expectation we found that attempted amination of 4-chlorotoluene with morpholine using **2** led to a disappointing yield of 56% for the coupling which compared poorly to the yield obtained with the bis-carbene complex **1** (95%). We decided to examine two further pre-catalysts **3** and **4**, both of which incorporate the saturated heterocyclic carbene as ligand. The mixed catalyst **3** was prepared in very good yield, again by phosphine displacement from [Pd{P(*o*-tolyl)$_3$}$_2$]; however bis-carbene **4** could be more readily prepared using our alternative route employing sodium dimethyl malonate.[8]

We examined the ability of these complexes to promote amination reactions of 4-chlorotoluene and both catalysts gave excellent yields of isolated products shown in Scheme 1 for the amination of 4-chlorotoluene using primary, secondary and aryl-amines. Isolated yields were generally in excess of 95% using either catalyst and the reactions were generally complete within 1 h at 100 °C. Reactions utilising hexylamine required an



Scheme 1 Products prepared from 4-chlorotoluene using **3** and **4**.‡ Numbers in parentheses refer to isolated percentage yields from reactions employing catalysts (**3**, **4**); Ar = C_6H_4Me-4.

 DOI: 10.1039/b104297c



Scheme 2 R^1 = Bu^t; R^2 = $C_6H_3Pr^i_2$-2,6.

excess of amine (4 equivalents), and proceeded in slightly lower yield. In general the overall yields indicate that these are extremely good catalysts for amination, however in contrast to reported *in situ* methods, we were unable to promote these reactions at room temperature.[9]

The ability of the sterically encumbered catalysts **1** and **4** to undergo facile oxidative addition required for these amination reactions is surprising, as is the similarity in catalytic behaviour between **3** and **4**. Given the currently accepted view that metal *N*-heterocyclic carbene bonds are relatively strong compared to metal phosphine bonds,[1c] we had expected that the mixed species **3** would offer a superior class of pre-catalyst, as phosphine dissociation to generate a mono-carbene palladium species, followed by oxidative addition,[10,13] should be more facile than the required carbene dissociation in **4**. However the efficient behaviour of **4** as a pre-catalyst led us to conclude that carbene dissociation from palladium may be more facile than generally envisioned and this is borne out by further experimentation (Scheme 2).

Treatment of **1** with P(*o*-tolyl)$_3$ at 60 °C for 16 h resulted in a 33% conversion to the mixed carbene–phosphine **2**; prolonged heating had no effect on the product ratio. Similar behaviour was also observed in reaction of **1** with PCy_3, to give **5**, although in this case the reaction proceeded to 100% completion in < 15 min at room temperature, and in the reaction of **4** with P(*o*-tolyl)$_3$, which gave the mixed complex **3** (28%). Ligand redistribution reactions between **1** and [Pd{P(*o*-tolyl)$_3$}$_2$] and between **4** and [Pd{P(*o*-tolyl)$_3$}$_2$] were also found to occur to give **2** and **3** (92% and 28%, respectively). Finally we found that treatment of complex **4** with free unsaturated carbene gave the mixed bis-carbene complex **6** (67%); the latter could also be obtained quantitatively by ligand redistribution between **1** and **4** at room temperature. These experiments demonstrate that ligand substitution at palladium between phosphine and carbene is fairly general and that the metal carbene bond may be more labile than previously thought. This would explain the ability of complexes **1** and **4** to mediate amination and Sonagashira reactions and could be consistent with a mechanism requiring ligand dissociation prior to oxidative addition in the latter,[14] although associative pathways for the ligand exchange reactions in Scheme 2 cannot be ruled out at this stage.

In conclusion we have shown that two-coordinate palladium bis-carbene and mixed carbene–phosphine complexes will efficiently promote amination of aryl halides and demonstrated an unexpected lability of the palladium–carbene bond. These findings may be important in the design of new palladium–carbene catalysts for organic synthesis.

We are grateful to AstraZeneca and EPSRC for support of this project. We are grateful to Dr Abdul Sada for his contribution.

Notes and references

‡ *General procedure*: KOBu^t (1.18 mmol) and complex **3** or **4** (0.016 mmol) were weighed into an ampoule (fitted with a Youngs tap) in a glove-box. Dioxane (10 ml) was added and then 4-chlorotoluene (0.79 mmol) and amine (0.95 mmol) added and the mixture heated at 100 °C. The reaction was allowed to cool to room temperature, the solvent removed and the resulting mixture loaded directly onto a silica-gel plug and eluted using ethyl acetate in hexane (20%). The solvent was evaporated and the product was determined to be > 95% pure by spectroscopic and analytical methods.

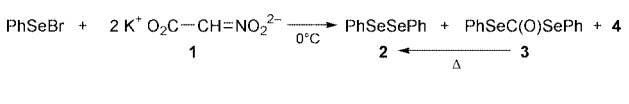
First published as an Advance Article on the web 3rd July 2001

Reaction of dipotassium nitroacetate with benzeneselenenyl bromide produces the title compound as a thermally unstable product, which has been characterized by X-ray crystallography.

Dipotassium nitroacetate, **1**, was first synthesized by Steinkopf[1] in 1909. Since that time the yield and simplicity of preparation of **1** has been improved a number of times.[2] The reported utility of employing this easily prepared dianionic organic salt in reaction with electrophilic reagents has been somewhat limited however. Reaction with electrophilic reagents such as the halogens,[3] the strong mineral acids,[4] and several transition metal salts[5] have been noted but our preliminary attempts to directly react **1** with organo-electrophilic reagents proved frustrating.† One exception, we discovered, was the direct reaction of benzeneselenenyl bromide with **1** in methanol,‡ which produced CO_2 and diphenyl diselenide, **2**, along with two other organic products, **3** and **4**. This communication thus reports our characterization of one of these three organic products, **3**, and additionally elaborates upon its easy thermolytic conversion to produce **2**. (The chemical characterization of **4** is still under investigation.§)

Addition of **1** to an ice-cold solution of benzeneselenenyl bromide in methanol resulted in three TLC separable organic compounds after effervescence of CO_2 had subsided. Separation of the three organic compounds using silica gel chromatography could be achieved by elution with hexane–methylene chloride mixtures. The initial band off the column was easily identified as **2**. The compounds **3** and **4** were then eluted in sequence, with both compounds decomposing to **2** if strict cooling conditions were not maintained (see Scheme 1). Compound **3** could be crystallized by slow evaporation of the elution solvent at 0 °C to deliver X-ray quality crystals. Initial observations on crystals of **3** indicated that yellow crystals of **2** began to grow from the colorless crystals if **3** was allowed to sit at room temperature or above for any extended period of time. (Storage in the refrigerator was mandatory.)

Spectral analysis of compound **3** yielded the following important information: (1) the solution IR spectrum (CCl_4) exhibited a carbonyl stretch at 1711 cm^{-1} in addition to bands similar to those exhibited by **2**. Attempts to obtain the IR spectrum of **3** as a KBr pellet resulted in a spectrum identical to that of **2**. (2) The ^{1}H-NMR spectrum of a solution ($CDCl_3$) of **3** exhibited phenyl resonance lines only. (3) The ^{13}C-NMR spectrum ($CDCl_3$) of **3** exhibited a carbonyl resonance at δ = 182.7 in addition to four resonance lines in the aromatic region. (4) The ^{77}Se-NMR spectrum ($CDCl_3$) of **3** exhibited a single resonance line at δ = 749 relative to dimethyl selenide.[6] (5) The



BnSeC(O)SeBn **5** PhOC(O)OPh **6** PhSC(O)SPh **7**

Scheme 1

CI/MS spectrum of **3** exhibited a molecular ion centered at 343 amu with appropriate isotopic satellite peaks for a compound having two selenium atoms in its molecular structure. Major fragment peaks were observed at 312, 237 and 159 amu as well as the base peak at 78 amu. The EI/MS spectrum was identical to that of **2**. (Carbonodithioates fragment in a similar manner in the EI/MS.[7]) (6) The UV-VIS spectrum of **3** exhibited no absorbance above 300 nm in contrast to **2** which has a characteristic thermochromic[8] band at 337 nm (log ε = 3.1). While this spectral information was indicative that **3** had a molecular structure that contained two phenyl selenium moieties, in addition to a carbonyl group, we were uncertain whether our compound was similar to *Se,Se′*-dibenzyl carbonodiselenoate (**5**) prepared by Devillanova *et al.*[9] (Reported spectral information available for **5** consisted only of an IR band at 1680 cm^{-1} which was attributed to a carbonyl band.) Consequently we determined the X-ray crystal structure for **3** which confirmed our suspicions that we had isolated *Se,Se′*-diphenyl carbonodiselenoate as a rather unstable molecular entity. We hoped that the reasons for the instability of **3** might then become apparent.

A perspective view of the molecular structure obtained for **3** is shown in Fig. 1. (We had to collect the data at 173 K because of the instability of **3** in the X-ray beam.¶) The space group was found to be *C*2/*c* with a twofold axis passing through the carbonyl function.‖ The unit cell contained four molecules of **3**. The bond lengths for the phenyl selenium moieties were found to be almost identical[10] to those of **2** including the Se–C_{ipso} bond length = 191.5(3) pm. The bond angles around the carbonyl function of **3** are somewhat different from those of diphenyl carbonate (**6**);[11] for **3** Se–C(O)–Se is 110.2(2)°, Se–C = O is 124.9(1)°, and C(O)–Se–C_{ipso} is 97.1(1)° while for **6** O–C(O)–O is 104.6°, O–C = O is ~127.5° and C(O)–O–C_{ipso} is ~118.5°. The bond lengths around the carbonyl function of **3** appeared to be normal, and similar to those of **6** when comparable: for **3** Se–C(O) is 193.5(2) pm, and C = O is 118.5(5) pm while for **6** C = O is 119.1 pm.

There are several interesting interactions within **3**. That exhibited between the two intramolecular selenium atoms is one of them. These two selenium atoms are separated by a distance of 319 pm which is well within the sum of two Van der Waals radii for selenium (~400 pm). Whether there is a partial

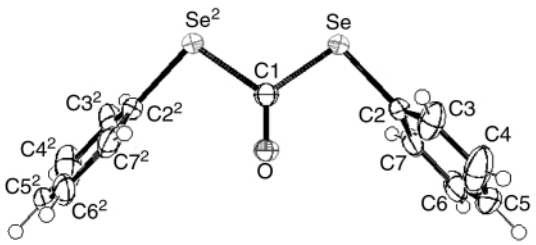


Fig. 1 ORTEP representation of **3** with the *b* axis being the 2-fold axis and roughly in the plane of the page. Atoms with the same label, but superscripted 2, are related by a crystallographic 2-fold axis.

 DOI: 10.1039/b103499p

intramolecular bond between the two selenium atoms of **3**, implying some hypervalency,[12] is not immediately obvious. Secondly, while the overall molecular structure for **3** is similar to that exhibited by **6**, the comparative bond angles around the carbonyl function are different implying that any interaction between selenium atoms in **3** is very different from those manifested by the oxygen atoms in **6**. It was therefore of interest to determine the thermodynamic activation parameters associated with the thermal conversion of **3** to yield **2**.

Dilute solutions of **3** could be quantitatively converted to **2** while monitoring changes in the visible spectrum at 350 nm. (A clean isosbestic point was observed at ~300 nm.) Compound **3**, which is colorless, smoothly and completely converted to yellow **2** in ethylene glycol solvent within 2 h at 60 °C and ½ h at 90 °C. The first order (or pseudo-first order) kinetics were linear over the entire temperature range studied, after taking into account the thermochromic properties of **2**.[8] The thermodynamic activation values of E_a = +65.8 kJ mol^{-1} and ΔS_a = −227 J deg^{-1} could be derived using the method of Arrhenius. The low activation energy for the thermolysis reaction thus indicated that the process of forming the 229 pm bond in **2** may be partially on the way to completion within the molecular structure of **3** itself. Consequently the preliminary conclusion that there may be a partial Se–Se bond in **3** seems plausible. (See footnotes ** and †† which were added in proof.)

The negative entropy of activation generated during the thermolysis reaction of **3**, where one molecule fragments to two molecular products, may imply that the associated disorder in the overall reaction can be offset, to some extent, by some factors of orderliness in the activated complex. The first factor implied is that the solvent (ethylene glycol) could be involved in creating more order during the thermolysis process. This possibility is buttressed by our observation that thermolysis of **3** in hydrocarbon solvent requires higher temperatures and is thus slower than in $HOCH_2CH_2OH$.** A second factor implicated is that a shorter than usual movement of the phenyl selenium substituents, during the extrusion of CO, may be inherent in **3**. As the crystal structure‖ of **3** shows the angle between the phenyl selenium groups is compressed in comparison to a normal sp^2 hybridized situation around a carbonyl group. (It has to be noted here that the compression of the analogous angle in **6** is even greater.[11]) And a third possible factor is the proposed hypervalent interaction between the selenium atoms of **3**. This proposal bolsters a hypothetical mechanistic process where the thermolytic transition state structure is a loosely organized diselenacyclopropanone ring structure. Consequently contrasting the thermal lability of **3** with the thermal stability of **6** suggests that these factors may not be available during analogous bond formation processes associated with the parent chalcogen.†† Comparing the molecular structures of *Se*,*Se*′-diphenyl carbonodiselenoate, **3**, and *S*,*S*′-diphenyl carbonodithioate (**7**) to that of diphenyl carbonate,[11] **6**, should prove interesting.‡‡

We (ROD and AC) would like to thank NSF (CHE-9974648) and the University of Massachusetts for funds to purchase the Nonius KappaCCD diffractometer. JTL and WR would like to thank the URI Foundation for partial support to fund this research and to Michael Callahan for recording the CI/MS for us.

Notes and references

† For example: reaction of **1** with simple alkyl halides in methanol (or other solvents) produced no identifiable materials other than the starting compounds.

‡ *Preparation of* **3**: 1.0 g of benzeneselenenyl bromide was dissolved in 15 ml of cold (0 °C) methanol and placed in a round bottom flask containing a stir bar. Solid, freshly prepared **1**, 0.77 g, was added in a controlled manner so that effervescence did not become too vigorous. Monitoring of progress was done by TLC over the duration of the ~1 h reaction. During the course of the reaction the color changed from dark red to a light yellow. Rotary evaporation of the resultant mixture was done under vacuum at approximately 0 °C after adding some silica gel. The product, adsorbed onto silica gel, was then mixed with 70:30 hexane–CH_2Cl_2 and added to the top of a chromatography column. Elution was commenced and the fractions were monitored using TLC. The organic products were eluted from the column in sequence (numerically). The fractions containing **3** were combined and allowed to evaporate in the cold until clear colorless crystals had formed. % Yield of **3** = 19%; mp = 48–50 °C.

§ The molecular characterization of **4** has proven difficult since it more readily decomposes to **2** than even **3**. We believe **4** may be either a hydrate or hemihydrate of **3**, since **4** exhibits CI/MS data with ion peaks centered around major masses, having two and four selenium atoms respectively, at 359 and 699 amu.

¶ The compound **3** decomposed in the X-ray beam within 5 min at rt.

‖ *X-Ray study of* **3**: Data was collected on a Nonius KappaCCD diffractometer. Satisfactory crystal stability was obtained by mounting the crystal inside of a sealed, thin walled glass capillary and by collecting the data at 173(2) K. *Crystal data for* **3**: $C_{13}H_{10}OSe_2$, *FW* = 340.13, monoclinic space group *C*2/*c*, *a* = 2140.38(5), *b* = 523.60(2), *c* = 1291.76(4) pm, β = 119.960(2)°, *V* = 1.25423(7) × 10^9 pm^3, *Z* = 4, *D*calc = 1.801 g cm^{-3}, μ = 5.871 mm^{-1}. Intensities were obtained for 2055 reflections ($2\theta_{max}$ = 50.1°) of which 1104 were unique. Refinement on F^2 was based on all of the data. The final agreement factors for the 941 unique reflections with $I > 2\sigma_I$ are *R* = 0.0262 and *Rw* = 0.0595. CCDC 163698.

** As pointed out by referee K this observation '…strongly argues for a polar transition state…' that is '…hydrogen bonded resulting in increasing order in the transition state.' We agree with this comment and note that a diselenacyclopropanone molecular entity would most likely be polar and H-bonded in ethylene glycol.

†† This same referee K has stated: '…the factors that the authors ascribe to the thermal lability of **3** are said to be not available for thermally stable **6**. A more obvious difference for this differing reactivity is that the thermodynamic driving force is substantially different *i.e.* a C(O)–O bond is stronger than a C(O)–Se bond and an O–O bond is much weaker than an Se–Se bond.' We again agree and we wish to thank this referee for these cogent ideas lending further support to our diselenacyclopropanone transition state proposal.

‡‡ Thermolytic studies of carbonodithioate esters have been referenced[13] to **7** but the molecular structure of **7** has not been determined as far as we are aware.

First published as an Advance Article on the web 11th July 2001

Treatment of acyclic tetraketone 8 with HF·py in MeCN afforded the pentacyclic system 1 in pinnatoxins with a high selectivity in good yield.

The intramolecular acetal functionalities widely appear as subunits of many biologically active natural products, including polyether ionophores, and the construction of these acetal systems represents a synthetic challenge.[1,2] The favored conformation of the spiroacetal is predictable on the basis of stabilizing anomeric and *exo*-anomeric effects that direct C–O bonds to axial positions on the respective rings.[3] Pinnatoxins, which were isolated from *Pinna muricata* by Uemura, included the unique dispiroacetal and bicycloacetal moieties in their skeletons.[4] Recently, Kishi and co-workers accomplished the total synthesis of pinnatoxin A, and the absolute stereochemistry was determined at the same time.[5,6] Independently, we reported an efficient formation of the trioxadispiroacetal moieties,[7] and also the construction of the BCDEF ring system of pinnatoxins, however acetal formation of the BCDEF ring system was rather problematic as an undesired acetal was generated as a major product.[8] On our way to the syntheses, it was found that both of the BCD-fragment and the EF-fragment could be constructed under the same conditions. These results suggested the possibility of a one-step formation of two intramolecular acetals, which would allow fewer steps and seemed to be more attractive. Herein, we describe a one-step assembling reaction to the pentacyclic system of pinnatoxin A, **1**† (Fig. 1).

In our initial efforts, tetra-TBS‡ compound **2** was selected as a precursor for the cyclization in the unnatural enantiomeric form (Scheme 1). Various conditions were examined, however, none of the acidic conditions provided compound ***ent*-1**. Upon terminating the reaction after 1 hour, it seemed that the TBS groups at C-29 and 30 positions still remained intact, while the BCD-ring moiety might be gradually formed. At longer reaction time, the cyclic products were overreacted to afford a complex mixture, including β-eliminated and retro-aldol compounds. These results suggested that the formation of the EF-ring should precede the cyclization of the BCD-ring, which implied the faster hydrolysis of the protective groups at C-29 and 30 than the others. Therefore, 29,30-di-TES compound, which would be more detachable than di-TBS, was directed at the next stage.

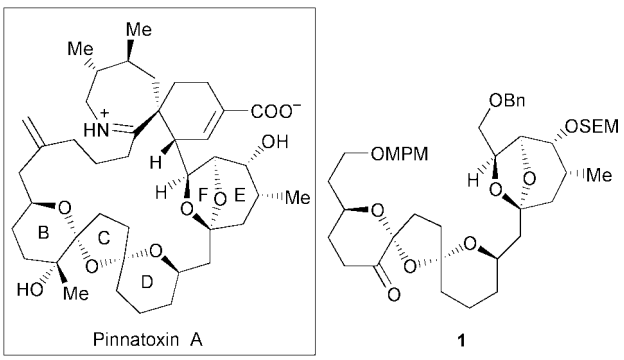

Fig. 1

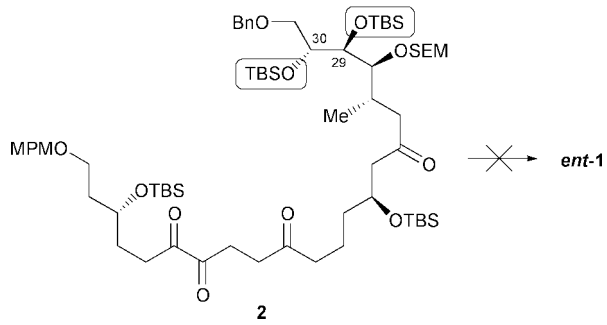

Scheme 1

Prior to one-step assembling reaction, stepwise acetalization was elucidated, which involves the construction of the BCD-ring after formation of diacetal moiety (Scheme 2). The acetalization reaction of **3**[9] was performed with HF·py in MeCN at 23 °C for 4 h to afford the desired compound **1** in 90% yield as a sole component of the pentacyclic compounds in spite of the possibility of eight products.[10] According to our previous results, the acetal formation of BCD-ring would be controlled by the thermodynamic effect,[11] which is based on the anomeric effect enhanced by the presence of an α-ketone.[12]

Since formation of the BCD-ring acetal proceeded independently of the EF-ring, the one-step assembling reaction to the pentacyclic system seemed to be realized. Reaction of **4** and **5**, followed by oxidation and desulfurization,[13] gave a coupled ketone in 84% yield in 4 steps (Scheme 3). The MMTr‡ group was detached with PPTS in MeOH and CH_2Cl_2 to the alcohol in 86% yield,[14] which was subsequently oxidized to aldehyde **7** in 99% yield. Analogous reaction of the sulfone **6** and **7** proceeded moderately to furnish another coupled ketone in 60% yield in 3 steps, which was converted to tetraketone **8** by ruthenium oxidation in 77%. Now the precursor for cyclization was obtained in our hands. When **8** was exposed to HF·py in MeCN at 24 °C for 7.5 h, the desired pentacyclic acetal compound **1** was produced as a single pentacyclic isomer in 71% yield, which was accompanied by a mixture of by-products lacking the pentacyclic system. The incompletely cyclized by-products were convertible to **1** under the same conditions. Eventually, the desired **1** was provided in an 83% combined yield from **8**. On the other hand, in the case of THF as a solvent, the reaction afforded the pentacyclic compound as a mixture of three isomers (**9**:**10**:**1** = 2:1:1) in 83% yield (Scheme 4). When this

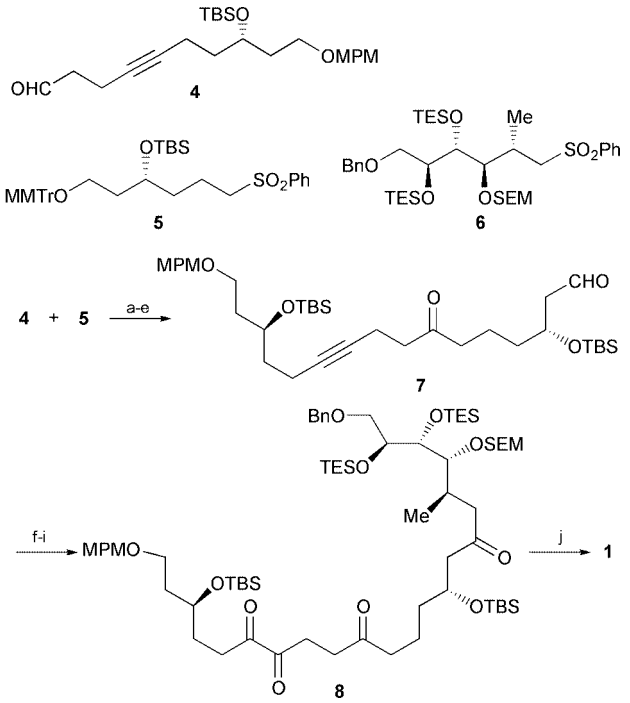
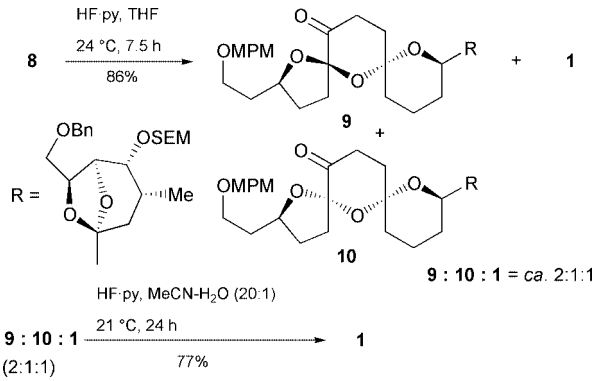


Scheme 3 (a) **5**, BuLi, THF, −78 °C, 30 min, then **4**, −78 °C, 30 min; (b) Swern oxidation; (c) (i) SmI_2, MeOH, THF, 0 °C, 30 min, (ii) Al(Hg), THF–H_2O (10:1), 23 °C, 16 h (84% in 4 steps); (d) PPTS (cat.), MeOH–CH_2Cl_2 (1:50), 21 °C, 10.5 h (88%); (e) DMPI,‡ $NaHCO_3$, CH_2Cl_2, 23 °C, 20 h (99%); (f) **6**, BuLi, Et_2O, −78 °C, 30 min, then **7**, −78 °C, 15 min; (g) DMPI, $NaHCO_3$, CH_2Cl_2, 23 °C, 11.5 h; (h) SmI_2, MeOH, THF, 0 °C, 30 min (60% in 3 steps); (i) $RuO_2·H_2O$, $NaIO_4$, CCl_4–MeCN–pH 7 buffer (1:1:1.5), 23 °C, 195 min (77%); (j) HF·py, MeCN, 24 °C, 7.5 h (83% after one recycle).



Scheme 4

mixture of **9**, **10**, and **1** was treated with HF·py in MeCN–H_2O (20:1) at 21 °C for 24 h, **1** was generated in 77% yield. The exclusive formation of **1** seems to be reasonable judging from the results of MM2* calculation using MacroModel 6.5 for the relative energies of the compounds, which suggested that the potential energy of **1** would be > 3.5 kcal mol^{-1} lower than any others. In addition, the axial preference of the C–O bond of the cyclic acetal would be enhanced by the presence of an α-ketone due to the cyclic stereoelectronic effect of π-electron donation. The acetalization in THF proceeded under the kinetic control, while the thermodynamic effect played an important role in the case of MeCN. The difference between the selectivities in MeCN and THF were induced by the solvation effect, which appeared in the glycosidation, involving the intermediacy of the acetonitrilium ion.[15] Thus, the one-step assembling reaction of the tetraketone to the complicated acetal was achieved to provide selectively the pentacyclic compound in an excellent yield. Further synthetic study is now under way in our laboratory.

This study was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture, Japan (11780410, J. I.).

Received (in Cambridge, UK) 2nd April 2001, Accepted 20th June 2001
First published as an Advance Article on the web 11th July 2001

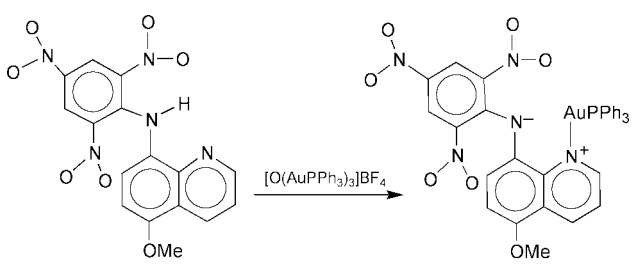
It has been shown by an X-ray crystallographic analysis of *N*-(triphenylphosphinegold)-*N*-(5-methoxyquinolyl-8)-2,4,6-trinitroaniline 1 and quantum chemical calculations on *N*-(5-methoxyquinolyl-8)-2,4,6-trinitroaniline 2 that H^+ and $(AuPPh_3)^+$ sub-units in 1 and 2 occupy different positions at the amine and quinoline nitrogen atoms, respectively.

This paper is part of our systematic investigations into the structural chemistry of gold(I) compounds. It is well known that the singly charged heavy-metal complex cation AuL^+ (L = neutral ligand) is isolobal with the cation HgR^+ (R = acido ligand). Both these metals commonly form 14-electron linear complexes QAuL or QHgR (Q = organic ligand). In real structures, the strict collinearity of metal bonds can be disturbed because of weak interactions (secondary bonds) of the metal with a heteroatom (X) involved in Q.[1] Commonly, the HgR^+ moiety behaves like a proton. Structures of chemically related organic and organomercury compounds display high similarity and secondary bonds M···X formed by Hg in QHgR are analogous to hydrogen bonds H···X in the corresponding organic compounds QH.[2] In accordance with isolobal analogy, it could be expected that the AuL^+ moiety also behaves like a proton; that is, in QAuL compounds, it forms a covalent bond with the same atom as the proton in QH compounds.

To explore the limits of the analogy between the corresponding isolobal particles AuL^+, HgR^+ and H^+, we subjected compound **2** to auration and investigated the structures of compounds **1** and **2** (Scheme 1.)

The X-ray structure of complex **1** and selected geometric parameters are shown in Fig. 1. The gold atom of the $AuPPh_3$ moiety forms a chemical bond with the quinoline nitrogen N(2) in **1**. The Au(1) atom adopts a T-shaped coordination. Two covalent bonds Au(1)–N(2) and Au(1)–P(1) are of normal length [2.121(8) and 2.231(3) Å, respectively].[3–6] The Au(1)···N(1) distance [2.621(9) Å] corresponds to a secondary bond. A similar distance [2.627(9) Å] was found in (8-Squ)$AuPPh_3$ (8-Squ = 8-mercaptoquinolinate) for the Au···N(quinoline) secondary bond.[6] The N(2)–Au(1)–P(1) bond angle is equal to 168.4(2)° with the Au(1)–P(1) bond bent away from N(1). In contrast to $AuPPh_3^+$ in **1**, the proton in *N*-substituted 2,4,6-trinitroanilines is always located at the amino nitrogen atom. According to the CSD,[2] the N(amino)–C(Ar) bond length varies within 1.33–1.37 Å, the C(*ipso*)–C(*ortho*) bond lengths range within 1.41–1.45 Å, and the other C–C bonds in the aniline Ph ring lie within 1.37–1.39 Å. Thus, the bonds C(*ipso*)–C(*ortho*) are longer than the others in the ring and no bond length alternation is observed within the C(*ortho*)···C(*para*) fragment. The C(*ortho*)–C(*ipso*)–C(*ortho*) angle varies within 112–115°.

The formation of the Au–N covalent bond with the quinoline rather than amine nitrogen atom is the most interesting property of molecule **1**. This fact means that the formal zwitterionic bond structure is characteristic of this molecule. As a result, a



2 **1**

Scheme 1

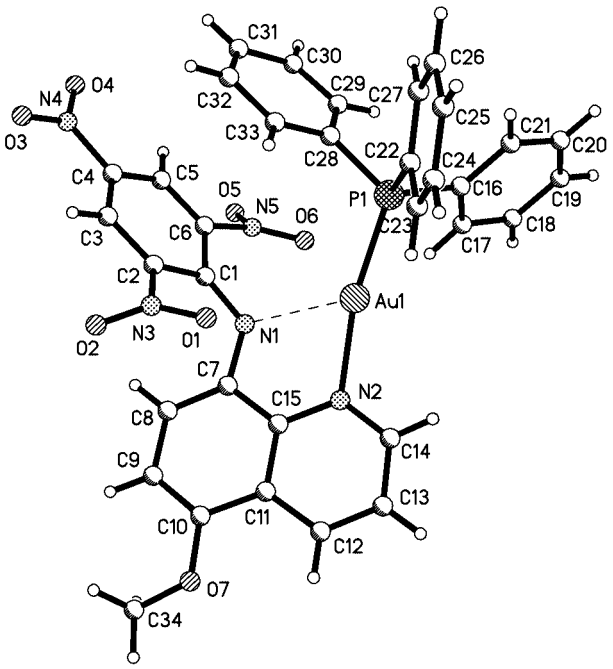


Fig. 1 Molecular structure of **1**. Bond lengths (Å) and bond angles (°) are: Au(1)–P(1) 2.231(3), Au(1)–N(2) 2.121(8), N(2)–Au(1)–P(1) 168.4(2), Au(1)···N(1) 2.621(9), N(1)–Au(1)–N(2) 71.6(3), N(1)–Au(1)–P(1) 120.0(2), N(1)–C(1) 1.30(1), C(1)–C(2) 1.47(1), C(1)–C(6) 1.47(1), C(2)–C(3) 1.36(1), C(6)–C(5) 1.35(1), C(3)–C(4) 1.38(1), C(4)–C(5) 1.39(1), N(1)–C(7) 1.44(1), C(1)–N(1)–C(7) 120.5(8), N(2)–C(15) 1.36(1), N(2)–C(14) 1.33(1), C(14)–N(2)–C(15) 121.4(8).

 DOI: 10.1039/b102938j

significant redistribution of bond lengths in the trinitroaniline moiety should be observed for molecule **1**. Actually, in **1**, the N(1)–C(1) bond 1.30(1) Å is shorter, both the C(1)–C(2) and C(1)–C(6) bonds 1.47(1) Å are longer, and the C(2)–C(1)–C(6) angle is more strongly reduced [109.5(8)°] than the analogous parameters in *N*-substituted 2,4,6-trinitroanilines. A pronounced alternation of bond lengths corresponding to the *para*-quinoid structure of the aniline sub-unit is observed; the C(2)–C(3) and C(5)–C(6) bonds [1.36(1) and 1.35(1) Å] are systematically shorter than the C(3)–C(4) and C(4)–C(5) bonds [1.38(1) and 1.39(1) Å]. Apparently, because of the contribution of the *para*-quinoid structure to the total molecular structure of **1**, the colour of this compound is deeper (black) than those of *N*-aryl-2,4,6-trinitroanilines (tones of red).†

The structure of **1** also contrasts with that of *N*-(5-methoxyquinolyl-8)-2,4,6-trinitroaniline **2**. To provide an insight into subtle geometric changes in the molecular skeleton caused by substituting the proton for the $AuPPh_3$ moiety, *ab initio* quantum chemical calculations were performed for **2**.

Geometry optimisation[7] resulted in the structure shown in Fig. 2. Molecule **2** exists in the same neutral form as all substituted trinitroanilines.

The distribution of bond lengths in **2** agrees well with that observed for *N*-(naphthyl)-2,4,6-trinitroaniline **3**.[8] However, the general conformation of **2** differs significantly from that found for **3**. For instance, dihedral angles between the C(1)–N(1)–C(7) fragment and C(1)···C(6) and C(7)···C(15) rings are 27.3 and 12.3° in **2**, whereas these angles are of 17.4 and 49.8°, respectively, in **3**. The N–H group in **2** forms a bifurcated hydrogen bond with the quinoline nitrogen (H···N 2.104 Å) and one of the oxygen atoms of one *ortho*-nitro group (H···O 1.862 Å). Therefore, the geometry of **2** is somewhat flattened compared to that of **3**, where the N–H group forms only one hydrogen bond with the oxygen of the *ortho*-nitro group. This particular *ortho*-nitro group is twisted from the C(1)···C(6) plane by only 16.8°, whereas another *ortho*-nitro group is twisted by 52.0°. In **2**, these values are equal to 5.3 and 38.0°.

In **1**, the C(1)–N(1)–C(7)/C(1)···C(6) dihedral angle is also rather small (27.0°). The flattened conformation at the formally double N(1)–C(1) bond is a result of a compromise between two effects. One of these is conjugation between the formally double N(1)–C(1) bond and the C(1)···C(6) benzene ring while the other is steric interaction between two ring systems. There is no weak interaction between Au(1) and the nearest *ortho*-nitro group N(5)–O(5)–O(6). Because of steric interactions both *ortho*-NO_2 groups are strongly twisted from the C(1)···C(6) plane by 43.4 and 38.1°.

On the other hand, the C(1)–N(1)–C(7)–C(8) torsion angle in **1** is 41.7° (*cf.* 49.8° in **3**), indicating that there is no significant conjugation between the amine nitrogen lone pair and the quinoline moiety. The coordination of Au(1) with the aminoquinoline moiety causes only minor changes in the geometry of the quinoline fragment. Only the endocyclic angle at N(2) increases to 121.4(8)° *vs.* 117.0° in aminoquinolines and 117.7° in **2**. Such an increase in this angle is typical for *N*-protonated pyridines (CSD).

We wish to thank The Royal Society, the RFBR for financial support (projects No. 99-03-33180 and 01-03-32474) and the EPSRC for a Senior Research Fellowship (J. A. K. H.).

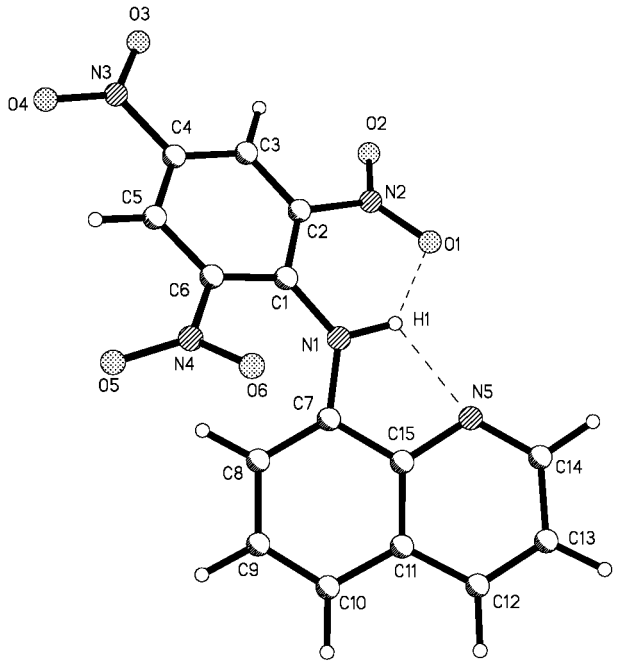

Fig. 2 Structure of **2** on the basis of *ab initio* quantum chemical calculation (MP2). Bond lengths (Å) and bond angles (°): N(1)–C(1) 1.374, C(1)–C(2) 1.426, C(1)–C(6) 1.436, C(2)–C(3) 1.390, C(6)–C(5) 1.388, C(3)–C(4), 1.388, C(4)–C(5) 1.388, N(1)–C(7) 1.405, C(1)–N(1)–C(7) 131.0, N(2)–C(15) 1.386, N(2)–C(14) 1.347, C(14)–N(2)–C(15) 117.7.

[Ru(η⁶-*p*-cymene)Cl$_2$(pta)] (pta = 1,3,5-triaza-7-phosphatricyclo-[3.3.1.1]decane): a water soluble compound that exhibits pH dependent DNA binding providing selectivity for diseased cells

Claire S. Allardyce, Paul J. Dyson,* David J. Ellis and Sarah L. Heath

Received (in Cambridge, UK) 4th May 2001, Accepted 20th June 2001
First published as an Advance Article on the web 11th July 2001

The water soluble complex [Ru(η⁶-*p*-cymene)Cl$_2$(pta)] (pta = 1,3,5-triaza-7-phosphatricyclo[3.3.1.1]decane), exhibits pH dependent DNA damage; the pH at which damage is greatest correlates well to the pH environment of cancer cells.

Current inorganic drugs such as cisplatin are successfully used in the treatment of many cancers, including testicular, ovarian, oropharyngeal, bronchogenic, cervical and bladder carcinomas, lymphoma, osteosarcoma, melanoma and neuroblastoma.[1] However there are problems associated with their use including general toxicity (leading to side effects) and drug resistance. The general toxicity of cisplatin has been reduced by the development of special drug-dosing protocols,[2] but the need for further improvements remains. In contrast, the ruthenium based anticancer drug, recently launched in the clinic ImH[*trans*-RuCl$_4$(DMSO)Im] (NAMI-A), shows a remarkably low general toxicity.[3] Since ruthenium complexes have been shown to specifically accumulate in tumour cells,[4] the reduced general toxicity of NAMI-A compared to platinum drugs could be due to ruthenium selectivity. In this paper we describe a new ruthenium compound that exhibits pH dependent DNA damage, which could show increased selectivity towards cancer cells and reduce toxic side effects in healthy cells.

The reaction of [Ru(η⁶-*p*-cymene)Cl$_2$]$_2$ with two equivalents of 1,3,5-triaza-7-phosphatricyclo[3.3.1.1]decane, pta,[5] under reflux in methanol, for 24 h affords [Ru(η⁶-*p*-cymene)Cl$_2$(pta)] **1** in high yield.[6] Characterisation of **1** was achieved using mass spectrometry and NMR spectroscopy.[7]

The molecular structure of **1** (Fig. 1) has been determined by single crystal X-ray diffraction [8] and contains two independent molecules in the asymmetric unit. The C$_6$-ring is coordinated to the ruthenium(II) centre with an average Ru–C bond length of 2.20 and 2.21 Å in each molecule. Two chlorine ligands (mean Ru–Cl 2.42 Å and 2.43 Å in each molecule) and the pta group [Ru–P 2.296(2) and 2.298(3) Å in each molecule] make up the rest of the coordination sphere. All parameters are in keeping with previously determined structures related to **1**, which vary in the nature of the arene and phosphine ligands.[9]

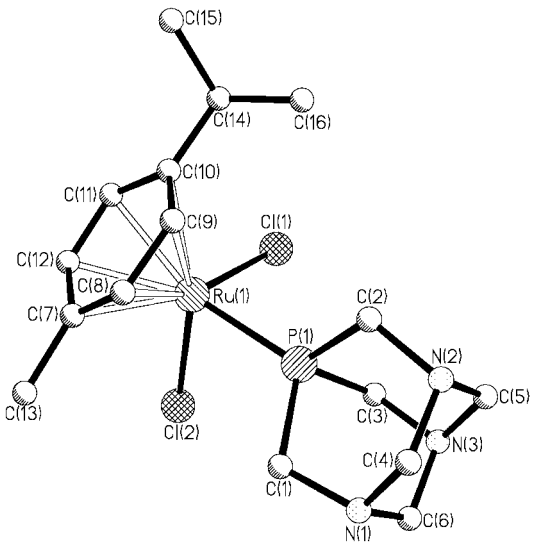

Fig. 1 The molecular structure of one of the independent molecules of **1**.

The presence of the pta ligand provides **1** with versatile soluble properties. For example, **1** and **1** + H$^+$ are soluble in water and polar organic solvents such as $CHCl_3$, CH_2Cl_2 and $(CH_3)_2CO$. Protonation of the pta ligand influences the solubility properties, with the deprotonated species having a higher solubility in organic solvents. The pK_a of **1** was estimated as 6.5 by monitoring the change in absorbance at 455 nm. We recognised that the pH dependant solubility of phosphaamine ligands like pta could also be exploited in biological systems, with the possibility of providing clinical uses. At physiological pH the predominant species carries no charge and hence can diffuse through lipid membranes and move freely into and within cells. In some diseased tissues the pH is reduced due to the associated changes in metabolism and in this environment the pta ligand is protonated, trapping **1** in the cell. In addition, we have shown that the protonated species induces DNA damage more readily than unprotonated **1** (see below).

The DNA substrate used in agarose gel electrophoresis[10] is 95% supercoiled (SC) and 5% open circular (OC), and their positions can be distinguished on the gel (Fig. 2). The results show that when DNA is incubated with **1** at pH 7.5 or above, the DNA migrates similarly to the DNA substrate. These results are in accordance with independent studies using a ruthenium(II)–arene compound, with a DMSO ligand in place of the pta in **1**, that did not detect an interaction with DNA.[11] However, at pH 7.0, the SC form of DNA incubated with **1** is slightly retarded compared to the substrate DNA and the retardation is progressively increased as the pH is reduced. At all pH values the position of OC DNA in the gel remains the same, indicating that the pH dependent retardation of SC DNA by **1** is not due to charge neutralisation.

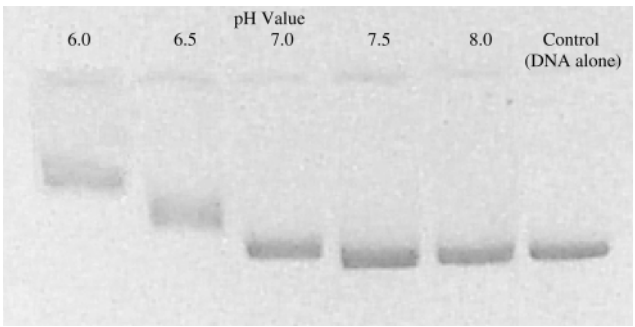

Fig. 2 Comparison of DNA damage induced by **1** incubated at different pH values; visualised by electrophoretic DNA migration in an agarose gel.

 DOI: 10.1039/b104021a

The pH range over which **1** retards DNA migration closely matches the pK_a of the pta ligand, and as DNA is negatively charged, it would be expected that the interaction between these two species would be promoted if they each carried opposite charges. The importance of this result is that DNA binding is not favoured at physiological pH. Many diseased cells have a reduced pH, due to metabolic changes in part associated with the accelerated cell division.[12] Thus, **1** would have a higher affinity for DNA in diseased cells, compared to healthy cells, providing a means of selectivity.

Further studies are currently in progress to delineate the way in which **1** with interacts with DNA. We are also comparing the effect that the type of arene ligand has on DNA and the results obtained from these studies will be reported in due course.

We would like to thank to thank The Royal Society for a University Research Fellowship (P. J. D. and S. L. H.) and The University of York for financial support (D. J. E).

10 In this assay 2.5 mM **1** in 10 mM phosphate buffer, pH 5.5–8.0 in 0.5 step increments, was incubated for 4 h with 0.05 mg ml^{-1} pBR322 DNA. The DNA damage was assessed by comparing the electrophoretic migration of the species in a 1% agarose gel, prepared in TAE buffer [40 mM tris(hydroxymethyl)aminomethane acetate and 1 mM EDTA] with similar migrations of the control incubations: control 1 tested the activity of **1** under similar assay conditions known to result in DNA retardation (as above but with no phosphate buffer) and control 2 was DNA under the same conditions without **1**. From each assay, 8 μl were mixed with 1 μl dye (0.025 mg bromophenol blue, 1 ml glycerol and 1 ml distilled water) and pipetted into wells on the horizontal gel. A potential difference of 30 mV was applied over the gel for 4 h and the bands visualised by staining with ethidium bromide. The effect of pH alone on DNA was assessed by performing a similar experiment in the absence of **1**.

First published as an Advance Article on the web 4th July 2001

The crystal structure of a methylviologen dication (MV^{2+})–mesitylene clathrate, one of a newly synthesized polycyano–polycadmate host clathrates, including a charge-transfer complex of MV^{2+} and an aromatic molecule, has been revealed by X-ray diffraction.

As a trial to develop functional materials using a polycyano–polycadmate host, we previously synthesized a series of polycyano–polycadmate host clathrates including a methyl viologen dication (MV^{2+} = 1,1′-dimethyl-4,4′-bipyridinium ion) as a guest.[1] MV^{2+} is widely used in the fields of photochemistry, electrochemistry, *etc*. owing to its strong electron accepting nature.[2,3] MV^{2+} is easily reduced to become a monopositive cation radical $MV^{\cdot+}$ whose color is blue, and forms a charge-transfer (CT) complex with a donor. Although some of our previous clathrates showed a color change from colorless to blue on UV irradiation, the formation of a CT complex in the clathrates was not confirmed clearly.[1] In this study we have newly synthesized nine polycyano–polycadmate host clathrates including a CT complex of MV^{2+} and an aromatic molecule, and have determined one crystal structure.

The polycyano–polycadmate host is a Cd cyano complex of chemical formula $[Cd_x(CN)_y]^{2x-y}$. The cyano group links two Cd atoms to from a framework host structure. Two typical structure types of the host are known.[4] One is a zeolite-like structure, which has a 3-D framework host while the other is a clay-like structure, which is a layered structure of 2-D Cd cyano complexes. Another important feature of the host complex is that it is anionic. Therefore, the polycyano–polycadmate host clathrate has a cationic guest that neutralizes the negative charge of the host, and a neutral guest that is an ordinary neutral organic molecule. Depending on the combination of the cationic guest and the neutral guest, the formation of a wide variation of clathrates is possible.[5] In this study, we attempted to form a CT complex of MV^{2+} (a cationic guest) and a donor (a neutral guest) in a polycyano–polycadmate host.

The synthetic procedure was as follows: into water (50 cm^3), $K_2Cd(CN)_4$ (5 mmol, 1.47 g), $CdCl_2{\cdot}2.5H_2O$ (5 mmol, 1.14 g) and methylviologen dichloride (2 mmol, 0.50 g) were dissolved. After the solution was filtered, a neutral guest solution was poured onto the filtrate. Various aromatic compounds were tried as neutral guests diluted 1–50 times with *n*-propylbenzene and the mixture left at 277 K. After several days, colored clathrates were obtained in a crystalline or a powdered state. The presence of a polycyano–polycadmate host, MV^{2+} and a neutral guest was confirmed by IR spectroscopy. The new clathrates and their absorption maximum wavelengths as determined from UV–VIS diffuse reflectance spectra are listed in Table 1.

Among the clathrates, the crystal structure of the MV^{2+}–mesitylene clathrate **1** was determined by single crystal X-ray diffraction.[6] The host Cd complex of **1**, $[Cd_3(CN)_6Cl_2]^{2-}$, contains two chloride ions together with cyano groups. Each cyano group bridges Cd atoms to form a 3-D framework structure, and each chloride ion coordinates to each Cd atom [Fig. 1(a)]. The host structure of **1** can be classified as a zeolite-like structure, but its framework structure is new. Although the host is a 3-D framework, the cavity formed within has a 1-D channel-like structure running along the *b* axis of the crystal. Each chloride ligand protrudes from the wall of the channel cavity into the inside of the cavity.

One MV^{2+} and one mesitylene molecule are stacked to form a CT complex as shown in Fig. 1(b). The twist angle of the two rings of MV^{2+} is 0°. The molecular plane of MV^{2+} is almost parallel to that of the mesitylene molecule. The center of the aromatic ring of the mesitylene molecule is directed toward one of the N atoms of MV^{2+}. This overlapping arrangement of MV^{2+} and the donor is typical for a π donor.[2,7] The interspacing between MV^{2+} and the mesitylene molecule of 3.30(1) Å[8] is apparently shorter than van der Waals contact of stacked aromatic rings. The diffuse reflectance spectrum of **1** and absorption spectrum of an acetonitrile solution of $MV(PF_6)_2$ and mesitylene are shown in Fig. 2. The CT absorption band of **1** was red-shifted compared with that of the solution. It is considered that the short interspacing contributes to the red-shift. The CT complex lies in the channel cavity, and is related to neighboring CT complexes by a two-fold screw axis parallel to the *b* axis. The molecular planes of MV^{2+} and the mesitylene molecule are parallel to the two-fold screw axis, so that the CT complexes are not stacked mutually. The two chloride ligands are located near the reverse side of the MV^{2+} molecular plane that is in contact with the mesitylene molecule. The distances between MV^{2+} and the chloride ligands are 3.256(5) Å for Cl(1) and 3.841(6) Å for Cl(2^{I}).[9] This structural situation may suggest the existence of an interaction between MV^{2+} and the host Cd complex through the chloride ligands. The CT interaction between MV^{2+} and chloride ion in solution and in the solid state has been established,[10] and the existence of a host–acceptor(MV^{2+})–donor triad interaction was recently shown for a zeolite including an MV^{2+} CT complex.[11]

For *n*-propylbenzene, 1,2,3-trimethylbenzene, 1,2,4-trimethylbenzene, 1,2,4,5-tetramethylbenzene, pentamethylbenzene, hexamethylbenzene, naphthalene or anthracene as neutral guests, no clathrates was obtained. Considering their ionization

Table 1 Polycyano–polycadmate host clathrates including a MV^{2+}-donor CT complex

Neutral guest(donor)	Color	λ_{max}/nm
Ethylbenzene	Slightly yellow	400
Mesitylene	Yellow	420
Anisole	Orange	446
Phenol	Yellow	411
o-Cresol	Orange	424
m-Cresol	Yellow	406
p-Cresol	Orange	424
Aniline	Red	443
Pyrrole	Yellow	432

λ_{max} = wavelength at the maximum of diffuse reflectance spectrum.

potentials relative to that for mesitylene, the formation of complexes might be expected for some of them. However, they are less symmetrical or larger than mesitylene. As such, crystal packing and a limitation of inclusion ability of the polycyano–polycadmate host are considered. The cavity that the host must prepare for a CT complex with MV^{2+} and a neutral guest is very large. In our preparative experiments, mesitylene is the most symmetrical and largest clathrate forming molecule (Table 1).

In summary, it has been revealed that the polycyano–polycadmate host acts as a host for a MV^{2+} CT complex, and the presence of an interaction between MV^{2+} and the host is suggested. Considering the structural variety of the polycyano–polycadmate host clathrate,[4,5] it is expected that the host structure of the new clathrates depends on the neutral guest. Structure determinations of the other clathrates are now in progress. At the same time, the preparation of single crystalline samples suitable for spectroscopic experiments are in progress. Although intensive studies of MV^{2+} CT complexes confined in a solid state matrix have been carried out,[11,12] there have been few examples in which crystal structures have been clarified. Structural and spectroscopic data obtained from single crystals are useful for developing studies in this field. In this regard our clathrates have an advantage.

Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, UK G1 1XL. E-mail: R.E.Mulvey@strath.ac.uk

Received (in Cambridge, UK) 5th June 2001, Accepted 22nd June 2001
First published as an Advance Article on the web 12th July 2001

The first structurally characterised examples of the nitroxide TEMPO acting as a ligand towards Li, Na or Mg are described, through a series of hexamethyldisilazide complexes which reveals a remarkable breadth of variety in structure and in the mode of ligation.

TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy) is a molecule which attracts a phenomenal level of interest. A stable nitroxide free radical, it is utilised within a remarkably diverse assortment of areas. A key ingredient in the development of 'living' free radical polymerisations,[1] it is employed also as a spin label in the study of biological systems.[2] Often the reagent of choice for effecting the mild and selective oxidation of primary and secondary alcohols,[3] TEMPO also finds utility as a radical trapping agent.[4] It is also well established as a Lewis base in d-block coordination chemistry,[5] with crystal structures known where it binds to Co, Cu, Mn, Mo or Pd atoms. Surprisingly, however, the s-block group of metals has hitherto been a virgin territory for TEMPO in this regard.[6] Here this situation is redressed with the disclosure of the first reported TEMPO complexes of Li, Na, Mg or Zn. This series establishes that TEMPO is a versatile new ligand for these electropositive metal atoms, offering more flexibility in its modes of ligation and electronic structures than the conventional O-based donor molecules usually encountered in s-block chemistry.

To minimise the number of variables that could influence structure, the study was confined to 1,1,1,3,3,3-hexamethyldisilazide [HMDS, $(Me_3Si)_2N^-$] derivatives and reactions were carried out in the same bulk solvent (hexane). Hence the predominant discriminating factor in the structures obtained would be the particular metal cation/TEMPO combination/s used. Furthermore since this was explicitly a structural study, product yields were not optimised as the immediate aim was to perfect crystals of a quality suitable for X-ray crystallographic study. As revealed in Scheme 1, five crystalline products **1**–**5** were successfully obtained using this approach. This scheme also lists the components of each reaction mixture studied. The details of the synthesis of **3** serve to illustrate the similar methodology used for each new complex: under argon gas in a Schlenk tube, a 1:1 mixture of crystalline LiHMDS and TEMPO was dissolved in hexane and stirred at ambient temperature for one day, from which orange crystals of [{Li(μ-HMDS)·TEMPO}$_2$] **2** were isolated; these crystals were then mixed with an equimolar amount of crystalline $Mg(HMDS)_2$ and redissolved in warm hexane solution which, when surrounded by a hot water Dewar flask and left to cool slowly to ambient temperature, deposited orange–yellow crystals of [{Li_2(μ-HMDS)(μ-TEMPO)·2TEMPO}$^+${$Mg(HMDS)_3$}$^-$] **3**.

X-Ray crystallographic studies have been carried out on all five new complexes. ChemWin representations of their structures are shown in Scheme 1.‡ The structures of the aforementioned **2** and its sodium analogue [{Na(μ-HMDS)·TEMPO}$_2$] **4** warrant only a brief mention here as they belong to a familiar structural type. Filling the terminal coordination site on the alkali metal atom within a planar, dimeric $(MN)_2$ ring, TEMPO is acting here as an orthodox neutral, monodentate O donor molecule in the mould of THF (*cf.* the structure of [{Li(μ-HMDS)·THF}$_2$][7]). The third homometallic structure [{Mg(HMDS)(μ-TEMPO$^-$)}$_2$] **1** (Fig. 1) is also a dimer, but it is as remarkable and unpredictable as the first

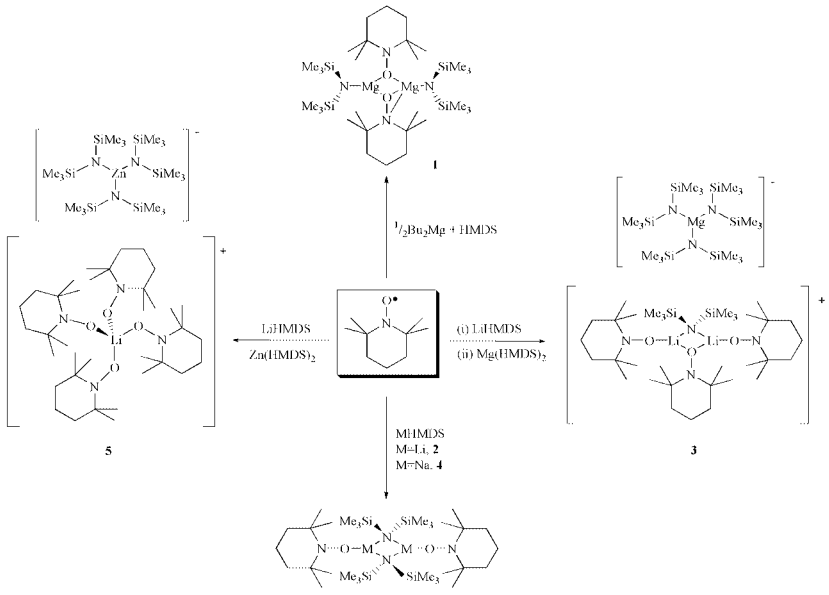

Scheme 1

 DOI: 10.1039/b104937m

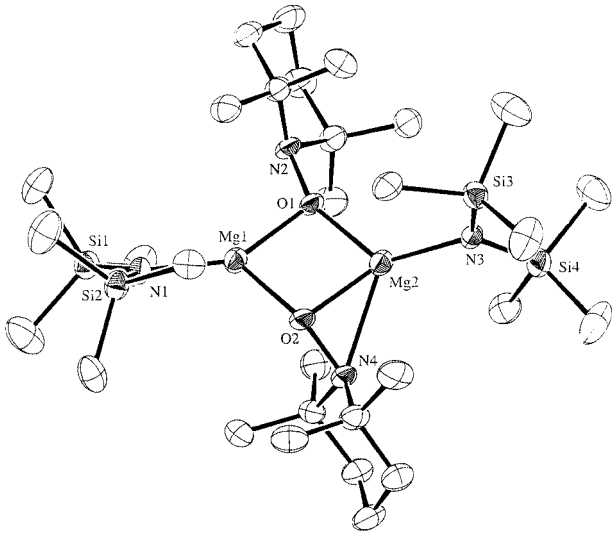

Fig. 1 Molecular structure of **1** without hydrogen atoms. Key dimensions (Å and °): Mg1–O1 1.944(3), Mg1–O2 1.946(3), Mg2-O1 1.967(3), Mg2–O2 1.979(3), Mg1–N1 1.952(3), Mg2–N3 1.965(3), Mg2–N4 2.395(3), O1–Mg1–O2 84.28(10), O1–Mg2-O2 82.80(10), Mg1–O1–Mg2 96.69(11), Mg1–O2–Mg2 96.22(11).

two structures are unremarkable and predictable. First, the positions of its ligands are mutually reversed relative to those in **2** and **4**, with HMDS occupying a terminal site and TEMPO occupying a bridging site. Second, there are two distinct types of TEMPO ligation: one involves a μ_2-O bonding mode through O(1), while the other involves a combination of μ_2-O bonding and η^2-O/N chelation through O(2)/N(4). Third, whereas in **2** and **4** the TEMPO ligands are neutral, free radicals, in **1** they must both be monoanionic (*i.e.*, reduced with respect to normal free TEMPO) to balance the charge of the $[Mg(HMDS)]_2^{2+}$ fragment: thus **1** contains a heteroleptic (anionic) ligand set. Several Lewis base complexes of this Mg bis(amide) have been structurally characterised,[8] but none in which the donor molecule bridges a pair of Mg atoms. TEMPO has therefore changed its ligating role here to be more like that of an anionic O donor such as the aldolate ligand in $[\{Mg(HMDS)[\mu\text{-}OC(Me)Bu^tCH_2C(Bu^t)=O]\}_2]$.[9] Furthermore, there also appears to be no precedent in the library of d-block metal TEMPO complexes for the nitroxide functioning as a μ_2-O donor ligand in either its neutral or anionic form, though the η^2-O/N chelating mode has been observed previously.[5] The dimensions of **1** show that the N–O and Mg–O bond lengths are insensitive to the TEMPO ligating mode with values of 1.461(3) and 1.471(3) Å for the former, and of 1.955 (mean) and 1.979(3) Å for the latter, for the monodentate O and didentate O/N types, respectively. There is significantly more discrimination between these bridging anionic ligands and the terminal radical type found in **2** and **4** in both N–O bond lengths (mean values: in **2**, 1.279 Å; in **4**, 1.275 Å) and the geometry of the N atom {sum of bond angles (mean): in **1**, 333.5° [discounting those involving Mg(2)]; in **2**, 357.9°; in **4**, 356.4°}. This ability of the N atom to oscillate between a highly pyramidal and a planar geometry is one important factor in TEMPO's coordinative flexibility. Yet another variation is revealed in the first heterometallic structure, **3**. Here, TEMPO acts simultaneously as a bridging and terminal ligand within an unusual dinuclear asymmetrical cation $[\{Li_2(\mu\text{-}HMDS)(\mu\text{-}TEMPO)\cdot 2TEMPO\}^+]$ (Fig. 2). Its Li–O bond lengths [(mean): bridging, 1.969 Å; terminal, 1.816 Å] are in accord with the different coordination numbers involved, but again the N–O bond lengths [bridging, 1.301(3) Å; (mean) terminal, 1.284 Å] appear rather insensitive to such differences. However, the N(5) atom of the bridging TEMPO ligand adopts a near-planar geometry (sum of bond angles, 357.8°) in contrast to the highly pyramidalised geometries of its bridging counterparts in **1**: hence the major discriminating factor is the electronic nature of the N–O unit (*i.e.*, free radical or anionic). The other half of the discrete ion pair structure of **3**, $[\{Mg(HMDS)_3\}^-]$, is

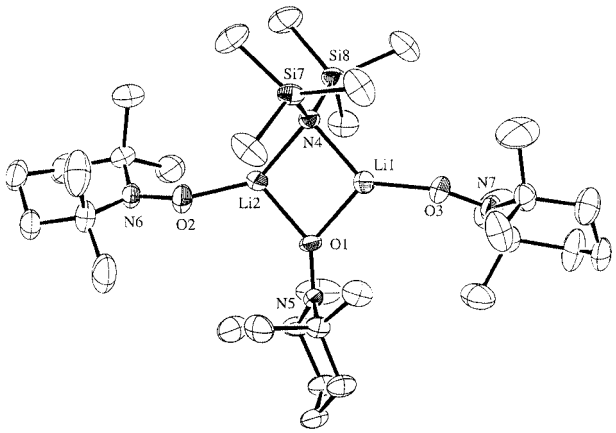

Fig. 2 The cationic moiety of **3** without hydrogen atoms. Key dimensions (Å and °): Li1–O1 1.982(6), Li1–O3 1.812(6), Li2–O1 1.957(6), Li2–O2 1.821(6), Li1–N4 1.993(6), Li2–N4 1.951(6), Li1–O1–Li2 83.0(2), Li1–N4–Li2 82.8(2), O1–Li1–N4 96.0(3), N4–Li2-O1 98.2(3).

also special. Examples are known where this metallate species is tethered to Li as in $[pyr\cdot Li(\mu\text{-}HMDS)_2Mg(HMDS)]$,[10] but this discrete arrangement is unprecedented. This comparison highlights the effectiveness of TEMPO relative to even strong donors such as pyridine. A more emphatic demonstration of this point is provided by the final structure, $[(Li\cdot 4TEMPO)^+\{Zn(HMDS)_3\}^-]$ **5**. Substituting Zn for Mg takes place with retention of the trigonal planar anionic moiety, but surprisingly the cationic moiety changes to a simple mononuclear arrangement with Li tetrahedrally surrounded by TEMPO radicals. Here the four TEMPO ligands co-operate to sequester a Li^+ cation and separate it from the anionic moiety.

In conclusion, using a single amido system as a case study, TEMPO has been established as a promising versatile new ligand for the s-block metals.

We thank the University of Strathclyde (Faculty Studentship to P. J. A. R.) and the EPSRC (grant award no. GR/M78113) for financial support, and Dr P. A. G. Cormack for helpful discussions.

Received (in Cambridge, UK) 4th January 2001, Accepted 19th June 2001
First published as an Advance Article on the web 12th July 2001

When carbon dioxide is in the supercritical state and reduced by Fe_3O_4, multicarbon bearing hydrocarbon molecules such as phenol (rather than CO or formate usually formed in electrochemical or photochemical techniques) can be obtained, the reduction yield is improved remarkably and the transformation yield for CO_2 to phenol can reach 7.6%.

The reduction of carbon dioxide has been extensively studied using electrochemical[1,2] and photochemical[3–5] reactions in light of the problems of global warming and depletion of fossil fuels.[6–8] Results obtained are still not satisfactory as to useful valuable reaction products and reaction rates need to be further improved. In addition the detailed reduction mechanism could not be established in most cases. At present, much interest has focused on the use of 14-membered transition-metal microcycles in CO_2 electrochemical reduction,[9–12] however, the catalysis efficiency for these transition-metal complexes is poor and the catalyst is rapidly destroyed by hydrogenation and/or carboxylation of the microcycles.[13] On the other hand, although research to optimise the reaction products is active, multicarbon containing hydrocarbon molecules such as products containing benzene rings have never been obtained. CO is often the main reduction product while formate may also be formed depending on the reaction condition.[9,14] Photochemical CO_2 reduction has been carried out in a catalytic system using $Ru(bpy)_3^{2+}$ as the sensitizer, cobalt or nickel macrocycles as the electron relay catalysts, and ascorbate as the sacrificial reductive quencher.[3,4] These systems, however, also produce CO. Furthermore, the rate of CO_2 reduction is limited by the low mass transfer of CO_2 both in electrochemical and photochemical techniques. Hence, the conversion of CO_2 to useful products by a simple effective method is clearly an interesting and important topic in CO_2 chemistry. Here we report that, when CO_2 is in the supercritical state and reduced with Fe_3O_4 powder, it can be transformed to phenol and diphenyl ether. In some cases, we can obtain ethanol, acetaldehyde and acetic acid. This novel reduction method could allow studies of continuous reduction systems for practical industrial applications.

An autoclave (flexible Au/Ti) capable of heating the system up to 400 °C was used. A sufficient amount of solid CO_2, freshly made from high purity CO_2 gas (99+%), was placed in an autoclave to ensure that the CO_2 is in a supercritical state at high temperatures. An appropriate amount of Fe_3O_4 (chemical purity reagent) and a small amount of water obtained from the Milli-Q water purification system were placed into the autoclave (50 ml), which was heated to 100–350 °C for 1–3 h and then rapidly cooled to room temperature naturally. The vapor phase was sampled and analyzed by GC–MS, (Shimadzu, GC-MS-QP-1100EX) to detect hydrocarbons. An appropriate amount of water was placed into the autoclave, then the product was collected, and filtered. After filtration, the filtrate was analyzed by GC–MS and quantified by gas chromatography (GC), while solid products were examined by X-ray diffraction (XRD). A gas chromatograph with a flame ionization detector (GC/FID) (Ohkura, GC-202 with Porapak R column packing) was used to determine the content of the hydrocarbon molecules formed.

A typical reaction used 8.0 g CO_2, 22 g Fe_3O_4 and 0.5 ml H_2O, in which CO_2 was in excess for the oxidation of Fe^{2+} in Fe_3O_4, to ensure a high pressure in the system when it was heated to appropriate temperatures. It was found that the degree of transformation in carbon dioxide reduction increases with increasing temperature and time, and reaches a maximum value after 2.5 h treatment, then remains nearly constant. The total yield of ethanol and acetic acid was around 4.2% (mol ratio) when the reaction was carried out at 200 °C for 2.5 h and was decreased with an increase of temperature and the amount of H_2O included. However, temperatures higher than 300 °C yielded aromatic compounds with phenol and diphenyl ether being the main products with ethanol, acetic acid and acetaldehyde also present. Fig. 1(a) depicts the mass spectrum of standard phenol while that of phenol formed in the experiment

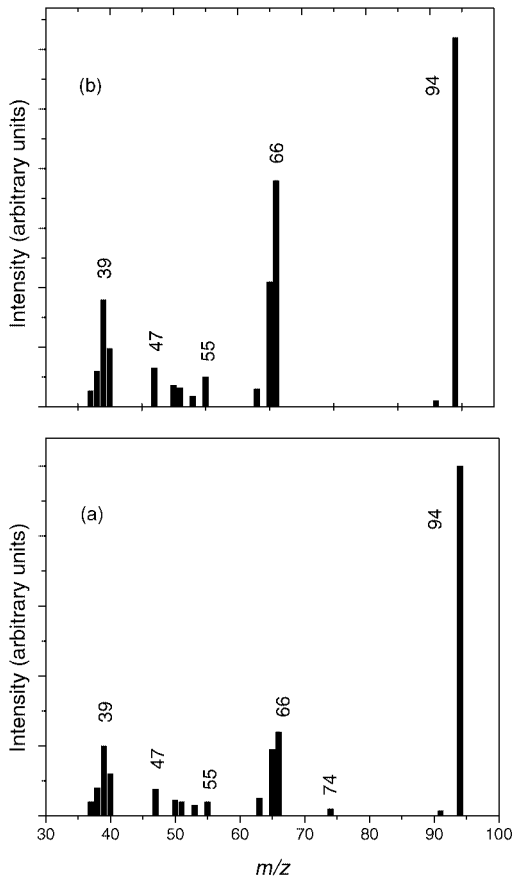

Fig. 1 Mass spectrum of phenol: (a) standard sample, (b) phenol formed *via* CO_2 reduction.

 DOI: 10.1039/b100183n

is shown in Fig. 1(b). The peak at *m*/*z* 94 in Fig. 1 is assigned to the molecular ion, $C_6H_6O^+$. Almost all of the corresponding peaks in Fig. 1(a) and (b) appear at the same positions, indicating that phenol formed in the reaction. On the basis of this result, the formation of diphenyl ether in the present system can be rationalized in terms of phenol production in the carbon dioxide thermal reduction system. Crystals of phenol can be obtained by slowly heating the aqueous filtrate. A scanning electron microscope image of the sample shows the sample consists of typical grains with size 0.2 × 0.3 mm (not shown). The total yield of phenol was nearly 7.6%. The GC–MS spectrum (not shown) shows no detectable organic compounds in the starting CO_2 gas ruling out contamination in the starting material. GC analysis showed ethane, propane and isobutane, were the main products in the vapor phase, while no CO in the vapor phase or formic acid in aqueous solution was detected (the main products in electrochemical and photochemical reduction techniques). These results indicate that the mechanism of the reduction in our reaction is different from that for an electrochemical reduction process. Carbon dioxide is a low-energy molecule, with the standard potential of the $CO/CO_2^{\cdot -}$ couple in an aprotic solvent such as *N*,*N*′-dimethylformamide (DMF) containing a non ion-pairing counter cation (NEt_4^+), being as negative as −2.2 V *vs.* SCE.[13] The potential for the Fe^{3+}/Fe^{2+} redox couple is not as negative as that for the CO_2 reduction to $CO_2^{\cdot}$ anion radical. Hence reduction most probably occurs on the surface of Fe_3O_4 particles, and a surface-mediated process may be involved. The XRD pattern of the solid product shows the coexistence of Fe_2O_3 and Fe_3O_4. This is possibly due to the surface layer of Fe_3O_4 being oxidized by carbon dioxide. Furthermore, hydrocarbon molecules containing more than one carbon atom are the products, suggesting that the mechanism of this reaction could involve multielectron reductive coupling of a pair of or several carbonyls to produce an intermediate bound to the surface of the solid Fe_3O_4 particles (at Fe^{II} sites). The presence of a small amount of water is required in this reaction system as this is the source of hydrogen. Too much water, however, is unfavorable for the reduction of carbon dioxide. It has also been found that the transformation ratio increases with a decrease of Fe_3O_4 particle size, which suggests the Fe_3O_4 surface area seems to have an influence on the reaction. All these results suggest that adsorption, formation of intermediates and hydrolysis processes are involved in the reaction. More work should be carried out to establish the reduction mechanism more fully.

It is known that the rate of CO_2 reduction is limited by the low mass transfer of CO_2 both in electrochemical and photochemical techniques. Under supercritical conditions, the polarity of CO_2 can be changed by controlling its density, the dielectric constant of CO_2 ranging from 1 to 1.6.[15] The increased polarity in a high pressure system is favorable for CO_2 absorption on the surface of Fe_3O_4 particles, and may accelerate the electron transfer from Fe^{II} ions to an intermediate due to the changed adsorption energy level in the energy gap of Fe_3O_4 semiconductor. Further details about the mechanism will be discussed later. The most significant feature is that the reductant used for CO_2 reduction is easily obtained and this reaction can be performed in a continuous autoclave, which could lead to practical applications.

In conclusion, we have reported, for the first time, the reduction of carbon dioxide in the supercritical state. Valuable products such as ethanol, acetaldehyde, acetic acid and, especially, phenol can be obtained. The maximum transformation ratio for CO_2 to phenol was found to be as high as 7.6% at temperatures > 300 °C. The reduction is suggested to occur on the surface of the Fe_3O_4 particles and to occur *via* a multielectron reductive coupling of a pair of or several carbonyls to produce an intermediate. This might open a route for industrial reduction of CO_2, which previously was only viable *via* an electrochemical technique.

First published as an Advance Article on the web 12th July 2001

Propene reduction of NO on SnO_2/γ-Al_2O_3 proceeds *via* the formation of acrolein and acetaldehyde, and the latter reduces NO_x to N_2 over Al_2O_3.

Catalytic reduction of nitric oxide (NO) from the exhaust of a lean-burn engine, which contains only a very low concentration (500 ppm level) of NO_x but much higher concentrations of oxygen (5–10%) and water (10–15%), has been a great challenge. Zeolite-supported catalysts are among the most promising known using a hydrocarbon reductant, but they lack the necessary durability because of hydrothermal degradation.[1] Alumina-based catalysts are more hydrothermally stable. Recently, they have shown promising activities for this reaction (*e.g.* refs. 2 and 3), especially under conditions of higher temperatures and partial pressures of oxygen that are suitable for treating heavy duty diesel engine or lean-burn gasoline engine exhausts. Nonetheless, higher activities are still very desirable for a practical catalyst, as well as a broader temperature window.

Understanding the reaction mechanism could facilitate improvement of these catalytic systems. On zeolite-based catalysts, a commonly observed first step of the reaction is the oxidation of NO to NO_2, which is a strong oxidant that activates the hydrocarbon.[4–7] However, the steps beyond that are not known. Various surface intermediates have been detected, and their involvement in the reaction implicated, such as organic nitro compounds,[8,9] isocyanate and nitrile,[10–12] and oxime,[13] but the steps leading to their formation and further reaction remain mostly speculative. As for alumina-supported catalysts, it is known that alumina itself is active for hydrocarbon reduction of NO,[14] and especially for NO_2,[2] but relatively inactive for NO oxidation to NO_2.[15] Various surface species are detected by IR spectroscopy in the reduction reaction, including nitrate, isocyanate, nitrile or cyanide.[16–18]

We have recently discovered that SnO_2/γ-Al_2O_3 is a bifunctional catalyst.[3,19,20] Using a standard reaction feed mixture of 0.1% propene, 0.1% NO, 10% H_2O and 15% O_2, it was found that a mixture of SnO_2/SiO_2 and γ-Al_2O_3 was as effective in reducing NO_x as an active SnO_2/γ-Al_2O_3 catalyst, while SnO_2/SiO_2 was completely unable to produce N_2.[20] In addition, the mixture of SnO_2/SiO_2 and γ-Al_2O_3 was only effective if SnO_2/SiO_2 was positioned upstream of Al_2O_3 and not *vice versa*. Since the NO_2 concentration at the exit of a reactor containing SnO_2/SiO_2 was the same as the background level within experimental uncertainty. Thus oxidizing NO to NO_2 is not the function of SnO_2. Therefore, this system provides a new opportunity to elucidate the hydrocarbon reaction pathway, which is the subject of this report.

When 0.1 g of SnO_2/SiO_2 was placed in a separate reactor upstream of 0.1 g γ-Al_2O_3, it was found that no N_2 was detected at the exit of the SnO_2/SiO_2 reactor, even when the propene conversion was 40%. Instead, a significant concentration of acrolein (C_3H_4O, *ca.* 120 ppm) and some acetaldehyde (CH_3CHO, *ca.* 40 ppm) were detected. Thus, the function of SnO_2 was selective oxidation of propene, primarily to acrolein. Removing NO from the reaction feed did not change the yield of acrolein. Thus, this selective oxidation step utilizes molecular oxygen as the oxidant.

Isotope labeling provides additional information. When 0.1% ^{13}C-prop-2-ene (99% purity) was used as the reductant, and the reaction feed mixture was passed over SnO_2/SiO_2, only 2-^{13}C-labeled acrolein was detected. This was similar to the results obtained using a Bi–Mo–O catalyst. Thus, the oxidation reaction proceeds *via* a symmetric π-allyl intermediate commonly observed in selective oxidation of propene [eqn. (1)].

$$CH_2{=}C^*H{-}CH_3 \xrightarrow[SnO_2]{O_2} CH_2{-}C^*H{-}CH_2 \xrightarrow[SnO_2]{O_2} CH_2{=}C^*H{-}CHO \quad (1)$$

The selective oxidation product acrolein is transported to γ-Al_2O_3 where its subsequent reaction resulted in the formation of N_2. This reaction was studied by using acrolein as the reductant at a concentration of 160–170 ppm instead of 0.1% propene. The concentrations of various products formed at 475 °C as a function of residence time are shown in Fig. 1. Sometimes, small amounts (< 10 ppm) of HCN could be detected. HCHO (not shown) was also formed but was difficult to quantify because of the high concentration of water used. The data showed that acrolein was rapidly converted to acetaldehyde over γ-Al_2O_3. Interestingly, this reaction was not accompanied by the production of N_2. Further reaction of acetaldehyde was much slower, and N_2 was produced.

This reaction sequence is substantiated by the experiment using acetaldehyde as the reductant instead of acrolein. CO, CO_2 and N_2 were formed, and their concentrations increased with increasing residence time. A large CO to CO_2 ratio was observed, similar to that shown in Fig. 1. Sometimes, trace amounts of HCN were detected.

When 2-^{13}C-labeled acrolein was passed over γ-Al_2O_3 at short residence time, the acetaldehyde in the product consisted of 85% $^{13}CH_3CHO$. Thus, the formation of acetaldehyde from acrolein is by cleavage of the C=C bond. Water is important for this cleavage reaction and the evolution of acetaldehyde from Al_2O_3. When NO reduction by acrolein on γ-Al_2O_3 was repeated but without water in the feed stream, no acetaldehyde was detected in the product. In addition, the N_2 yield dropped to *ca.* 60% of the yield with water. Since at 475 °C, it is unlikely that desorption of acetaldehyde requires displacement by water, the data suggest that the formation of acetaldehyde involves hydrolysis of a surface intermediate.

The following reaction [eqn. (2)] explains the formation of acetaldehyde that is consistent with the observations. It is the

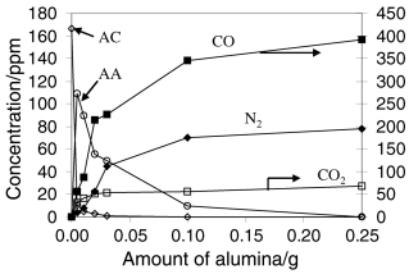

Fig. 1 Product distribution as a function of residence time for the NO_x reduction reaction over γ-Al_2O_3 using *ca.* 160 ppm acrolein. The residence time was changed by using different amounts of γ-Al_2O_3. AA: acetaldehyde, AC: acrolein.

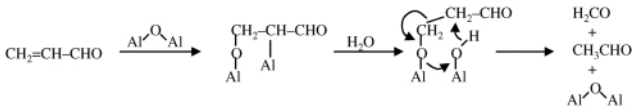
 DOI: 10.1039/b104630f

reverse of an aldol condensation reaction. We postulate that a bridging Al–O–Al is the catalytic site.



(2)

Thus, the primary hydrocarbon pathway in NO_x reduction for this catalyst system can be summarized in Fig. 2. The interesting features of this mechanism are the role of SnO_2 in the selective oxidation of propene using molecular O_2 and the role of γ-Al_2O_3 in N_2 formation. The reaction of acetaldehyde on alumina probably leads to the formation of surface nitrocompounds, nitrile or cyanide, isocyanate, and eventually N_2. The reactions of nitromethane have been studied over Cu-ZSM-5[9] and Al_2O_3.[16] Over Al_2O_3, nitromethane reacts to form isocyanate, carbamite, and eventually NH_3, the latter then reacts with NO to form N_2. It is quite possible that these steps apply to the system here.

In separate experiments, the reaction of acetaldehyde with O_2 on 0.1 g Al_2O_3 was compared with reaction with NO or NO_2 with and without O_2 under otherwise standard conditions. It was found that the reaction of acetaldehyde with NO alone was slow. Less than 40% of the acetaldehyde was converted. The reaction with a mixture of NO and O_2 was substantially faster and about the same as with only O_2. This is consistent with the low activity for NO oxidation to NO_2 on Al_2O_3.[15] The reaction of acetaldehyde with NO_2 or NO_2 + O_2 was the fastest, such that all the acetaldehyde was consumed. Thus, the initial step in the subsequent reaction of acetaldehyde under our reaction conditions does not involve adsorbed NO_x species. Instead, a possible pathway is its oxidation by oxygen to form adsorbed acetate, which has been observed by others.[21] The acetate decarboxylates in the presence of NO to form nitromethane.

In order to confirm the absence of a significant parallel reaction pathway for acrolein on γ-Al_2O_3, the N_2 production efficiencies of acrolein and acetaldehyde were compared. The results are shown in Fig. 3 for various NO_x/reductant ratios in the feed. Over a wide range of these ratios, the number of N_2 molecules produced for every reductant molecule consumed was independent of the reductant. Thus, the conversion of acrolein to acetaldehyde must be quantitative, and this step does not produce N_2. The N_2 production efficiencies for these two reductants approached the limit of unity, that is, one reductant molecule consumed per N_2 produced, consistent with the reaction mechanism in Fig. 2. Furthermore, the N_2 production efficiencies were higher using NO_2 than NO at low NO_x/reductant ratios.

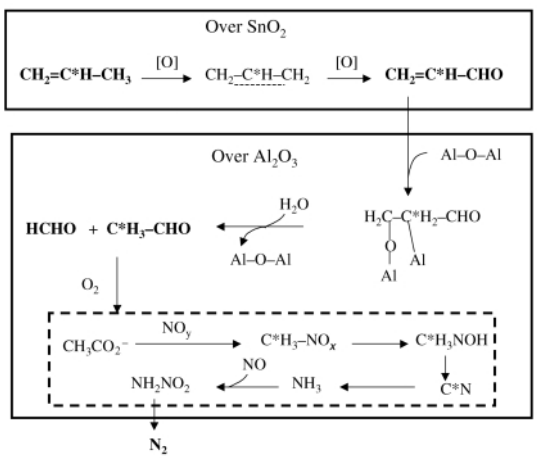


Fig. 2 Proposed mechanism for propene reduction of NO over SnO_2/γ-Al_2O_3. Reactions occurring over the SnO_2 or γ-Al_2O_3 are enclosed by solid lines, and reactions enclosed by dashed lines are formulated using literature information. Compounds in bold letters denote detected gaseous products and the remainder are surface intermediates. C* denotes labeled positions.

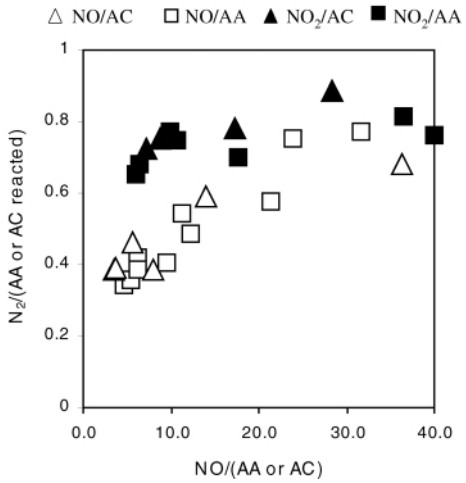

Fig. 3 N_2 formation efficiency, defined as number of molecules of nitrogen formed per acetaldehyde (AA) or acrolein (AC) molecule reacted, as a function of NO_x/reductant ratio in the feed. The NO_x/reductant ratio was changed by varying the concentration of NO (open symbols) or NO_2 (filled symbols) from 703 to 5921 ppm, and the concentration of the organic from 27 to 282 ppm. Standard concentrations of O_2 and H_2O were used, and the total flow rate was 200 ml min^{-1} with 0.1 g of Al_2O_3. The temperature was between 475 and 525 °C to obtain high conversions of the organic.

In summary, we have elucidated a substantial portion of the reaction pathway of the hydrocarbon for propene reduction of NO over SnO_2/γ-Al_2O_3. The slow step of this reaction has been identified to be the reaction of acetaldehyde on alumina. This information can be used to improve the catalytic activities for N_2 formation.

Solvent incorporation during *N*-iodosaccharin mediated glycosylation: facile synthesis of acetal linked disaccharides†

M. Aloui and A. J. Fairbanks*

Dyson Perrins Laboratory, Oxford University, South Parks Road, Oxford, UK OX1 3QY. E-mail: antony.fairbanks@chem.ox.ac.uk; Fax: +44 1865 275 674

Received (in Cambridge, UK) 14th May 2001, Accepted 15th June 2001
First published as an Advance Article on the web 12th July 2001

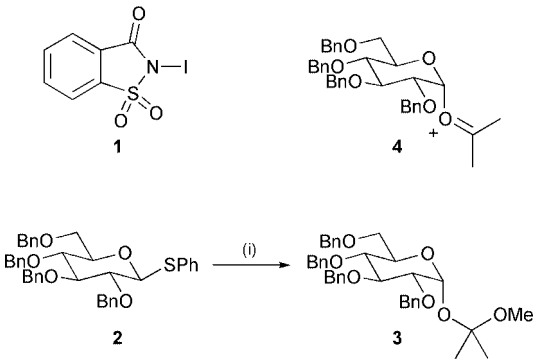
Solvent incorporation between glycosyl donor and acceptor occurs during glycosylation reactions initiated by *N*-iodosaccharin (NISac) performed in acetone and cyclohexanone solvents to stereoselectively produce acetal linked α-glycosides.

Considerable work has been performed to understand the role of solvent during the glycosylation process[1,2] However the situation is complicated by the identity of anomeric leaving group, the activator and the protecting groups on the donor. Therefore although there are several general 'guiding principles' as to how the choice of solvent may affect the stereochemical outcome of glycosylation for donors with non-participating OH-2 protecting groups, there is still requirement for further mechanistic insight into each particular glycosylation reaction.

One of the best-established examples of solvent participation during the glycosylation process is the preferential formation of β-glycoside products observed when using acetonitrile as solvent.[3] This β stereoselectivity has been ascribed to trapping of the glycosyl cation formed during the glycosylation reaction by solvent to produce an intermediate α-nitrilium ion, which then undergoes S_N2 type glycosylation, resulting in preferential formation of the β-product.[4] The isolation of α-nitrilium trapped species has provided substantial supporting evidence for this hypothesis.[5] Reported herein are investigations into glycosylation reactions performed in ketone solvents, in which solvent incorporation invariably occurs to produce good yields of mixed acetal linked α-glycosides and α-disaccharides, in an entirely stereoselective manner.

We recently reported the use of *N*-iodosaccharin (NISac) **1** for the activation of thiophenyl glycosides under mild conditions.[6] During the course of these studies it became clear that reduced yields of disaccharide products were obtained by saccharin trapping of the glycosyl cation, which is probably produced during the glycosylation reaction. In an attempt to promote *O*-glycosylation, and in particular increase yields of disaccharide products, studies turned to the use of more polar solvents. Use of acetonitrile as solvent[7] resulted in an increase in the yield of disaccharides, but saccharin trapping was still observed. For this reason acetone was also investigated as the solvent for glycosylation. Although acetone has frequently been employed as an organic co-solvent for enzyme catalysed glycosylation, it has not been particularly widely used for chemical glycosylation reactions.[8]

Glycosylation of perbenzylated thioglycoside **2** was undertaken with methanol as glycosyl acceptor in acetone with *N*-iodosaccharin (NISac, **1**) as activator. Quite surprisingly none of the desired methyl glycoside was observed, and the sole reaction product was identified as the pure α-glycoside **3** (Scheme 1). Moreover, **3** was produced entirely as the α-anomer. Formation of **3** can be explained by initial formation of the α-acetonium ion **4**, by solvent participation in a manner



Scheme 1 *Reagents and conditions*: (i) NISac **1**, MeOH (3 equiv.), acetone, −78 to 0 °C, 2.5 h, 76%.

analogous to glycosylation in acetonitrile. Nucleophilic attack on **4** by methanol then yields the mixed acetal. To the best of our knowledge solvent participation by acetone during a glycosylation reaction has only been observed on two previous occasions.[9,10] Investigations then turned to the use of carbohydrates as glycosyl acceptors to investigate if solvent trapping would occur to produce disaccharides linked as mixed acetals. Reaction of thioglycoside **2** with diacetonide galactose **5**, in acetone with NISac activation, produced acetal-linked disaccharide **6** in an excellent 84%, as the pure α-anomer (Scheme 2).‡§ Carbohydrates with secondary hydroxy groups also produced good yields of acetal-linked products. Thus reaction of donor **2** with the *manno* acceptor **7** produced the mixed acetal linked disaccharide **8**, as the pure α-anomer, in 78% yield.

Investigation then turned to the use of other solvents to determine the potential generality of the process. Initial attempted reaction of **2** with methanol and NISac as activator in butanal as an aldehyde solvent produced a complex mixture of products and no appreciable amount of acetal glycoside. However with cyclohexanone as solvent again good yields of pure α-glycoside products were isolated. Thus reaction of donor **2** with methanol in cyclohexanone initiated by NISac produced a good yield of the α-mixed acetal **9** (Scheme 3). Carbohydrate acceptors also reacted well; diacetonide galactose **5** produced the acetal linked α-disaccharide **10** in 73% yield.

In summary we have demonstrated that NISac[11] activation of thioglycosides in ketone solvents[12] leads exclusively to the formation of α-mixed acetal products, in which a solvent molecule is incorporated between the anomeric centre of the glycosyl donor and the hydroxy group of the glycosyl acceptor. Formation of these mixed acetal products probably occurs by trapping of an incipient α-acetonium ion **4** by the glycosyl acceptor, and provides substantial evidence for the intermediacy of such species during glycosylation reactions performed in acetone as solvent. Furthermore this synthetic route to pure α-acetal glycosides, which have been proposed as potential anti-cancer prodrugs, compares favourably with the other published routes.[13,14]

Further investigations into the generality of this novel glycosylation reaction, and its development for the synthesis of

Notes and references

‡ Typical experimental procedure: a mixture of the perbenzylated phenyl thioglucoside **2** (0.091 g, 0.14 mmol), diacetonide galactose **5** (0.056g, 0.21 mmol) and molecular sieves 4 Å (0.2 g) were stirred in dry acetone (3 ml) under an atmosphere of argon at −78 °C. *N*-Iodosaccharin **1** (0.066 g, 0.021 mmol) was then added rapidly. The reaction mixture was then stirred with warming to 0 °C until TLC (R_f 0.44, ethyl acetate–petroleum ether, 1:3) indicated complete consumption of the thioglycoside (*ca*. 2.5 hours). Triethylamine (1 ml) was added and stirring was continued for a further 15 minutes at 0 °C. The reaction mixture was then diluted with dichloromethane (30 ml) and then filtered through Celite®. The filtrate was then washed with 10% aqueous sodium thiosulfate (10 ml), saturated aqueous sodium bicarbonate (10 ml) and water (10 ml). The organic extracts were then dried (anhydrous sodium sulfate), filtered, and the solvent removed *in vacuo*. The residue was then purified by flash column chromatography (ethyl acetate–petroleum ether, 1:4) to give the acetal-linked disaccharide **6** (0.102 g, 84 %), as a colourless oil.

§ All new compounds possess NMR and high-resolution mass spectral data consistent with their structures.

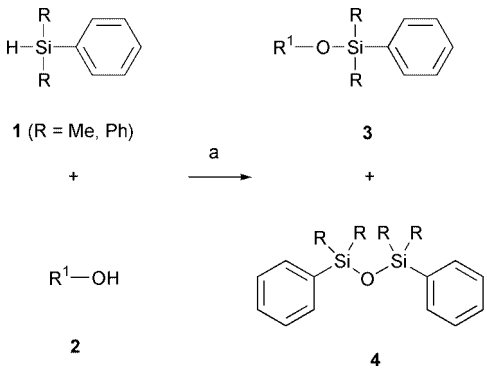
Received (in Cambridge, UK) 5th April 2001, Accepted 14th June 2001
First published as an Advance Article on the web 4th July 2001

KOH–18-crown-6 ether is a valuable system for the catalyzed dehydrocoupling of alcohols with phenylhydrosilanes (Ph_3SiH and $PhMe_2SiH$).

The importance of silyl ethers in organic synthesis as protecting groups for alcohols has been discussed.[1,2] The most common route to these compounds involves the reaction of a silyl chloride (or the corresponding triflate for hindered alcohols) with an alcohol in the presence of an amine (pyridine, triethylamine, imidazole…). The stoichiometric amounts of ammonium salts produced as well as the cost[3] of the silylating reagents has led chemists to study the dehydrocoupling process involving hydrosilanes. This reaction has been reported using a wide range of catalytic species such as transition metal complexes, Lewis acids[4] and salts.[5,6] In this work, we show that a new method involving KOH–18-crown-6 ether is simple, inexpensive and is valuable for the catalyzed silylation of alcohols with phenylhydrosilanes.

When hydrosilanes **1** were added to a mixture of KOH (9% mol)–18-crown-6 ether (3% mol) and alcohols **2** in CH_2Cl_2 (Scheme 1), a gas evolution occurred. Apart from the desired silyl ether **3**, small amounts of siloxanes **4** were produced so that a slight excess of hydrosilanes (1.4 eq.) was therefore required for the total conversion of the alcohols.† It is noteworthy that the reactions are generally clean as judged by the ^1H NMR spectra of the crude reaction mixtures and that under the same reaction conditions, no conversion of the starting materials in the absence of 18-crown-6 ether was observed. Dichloromethane was chosen because of its low boiling point and for being a good solvent for the reagents used, but other solvents such as THF, benzene or ether are also appropriate.

We found that Et_3SiH is less reactive under these conditions than the phenylhydrosilanes as shown by its reaction with 4-methylbenzyl alcohol, which led to only 33% conversion. Among the phenylhydrosilanes, Ph_3SiH is more reactive than $PhMe_2SiH$ judging from their different abilities to transform tertiary alcohols (Table 1, entry 1). The reactions of other hindered alcohols such as 2-methylpropan-2-ol or 2-methylpentan-2-ol were also unsuccessful using $PhMe_2SiH$ even in boiling THF.



Scheme 1 a. KOH–18-crown-6 ether (9% : 3%), argon, 18 h, CH_2Cl_2, rt or CH_2Cl_2, Δ, 3 h.

A better knowledge of the course of this reaction was provided by examining different alcohols (Table 1). The presence of a strong withdrawing group close to the hydroxy function inhibits the reaction. For instance, 2-chloroethanol is not reactive under the conditions used to transform 6-chlorohexan-1-ol into the corresponding silyl ethers (Table 1, entry 2). Phenol or 4-methoxyphenol, which show a poor nucleophilic character in comparison with aliphatic alcohols, are not reactive while benzylic alcohols (Table 1, entries 3 and 4) or 2-phenylpropan-1-ol (Table 1, entry 5) are converted into the desired products in good yields. Saturated alcohols (entry 6) are good substrates for the reaction, as long as they do not provide a strong steric hindrance as mentioned above (entry 1). Compared to other transition metal catalysts,[7] the KOH–18-crown-6 ether system has the advantage of being compatible with unsaturated alcohols (entries 7 and 8). Furthermore, this system is convenient for the protection of hydroxy epoxide glycidol (entry 9) since it does not lead to the loss of the oxirane ring as mentioned for Lewis acid catalyzed reactions.[4]

This reaction when performed on a larger scale (20 mmol of glycidol) gave the same yield of the desired product with $PhMe_2SiH$ as the silylating agent.

We have recently shown that KOH–18-crown-6 ether was an efficient system for catalyzed hydrosilylation and the

Table 1 Silylation of a number of alcohols in the presence of a catalytic amount of KOH–18-crown-6 ether: reactions were performed in CH_2Cl_2 at rt under argon for 18 h and isolated yields calculated following flash chromatography, unless otherwise stated.

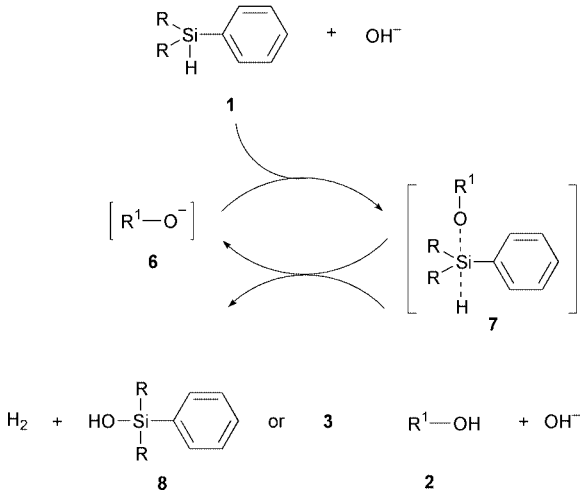
 DOI: 10.1039/b103130a



Scheme 2 A possible mechanism for the catalyzed silylation of alcohols.

Tishchenko reaction of aromatic aldehydes.[8] The KOH–18-crown-6 ether catalyzed reaction of 4-methylbenzyl alcohol with $PhMe_2SiH$ was therefore conducted with a stoichiometric amount of *p*-anisaldehyde, a good substrate in the hydrosilylation process.[8] The ^1H NMR spectrum of the crude reaction mixture showed 12% conversion of the aldehyde and 82% of the alcohol, thus demonstrating that the dehydrocoupling reaction predominates over hydrosilylation.

From a mechanistic standpoint, the catalytic cycle could be easily explained in terms of the anionic activation of the Si–H bond first reported by Corriu *et al.* for various salts.[5] Thus, it can be proposed that the Si–H bond is labilized by anionic coordination of the alcoholate **6** (or OH^-) to give the pentacoordinate intermediate **7** (Scheme 2). This activated species could give the desired product **3** or the silanol **8**, a possible precursor for the isolated siloxane **4**.

Thus we show above that KOH–18-crown-6 ether is an efficient system for the catalyzed silylation of nucleophilic alcohols with Ph_3SiH and $PhMe_2SiH$. The lack of reactivity towards non-nucleophilic and hindered alcohols could be profitable for the use of these phenylsilyl ethers as selective protecting groups in organic synthesis. Compared to most other catalyzed silylation reactions, this method has the advantage of being compatible with double or triple bonds, carbonyl functions, chlorine and oxirane.

A mechanistic study of this reaction is being undertaken. The role of OH^- in the catalytic cycle remains to be elucidated.

Notes and references

† *Typical procedure*: reaction vessels were dried under vacuum and the reactions carried out under argon. The silane (1.4 mmol) was added at rt to a solution of the alcohol (1 mmol) and KOH–18-crown-6 ether (5 mg : 6 mg) in CH_2Cl_2 (0.75 mL). After stirring for 18 h, the reaction mixture was concentrated and the residue was purified by flash chromatography or crystallization to give the silyl ether (see Table 1). All products were characterized by the usual spectroscopic techniques or compared with data reported in the literature.

Decarboxylative acylation approach of thiohydroxamate esters

Sunggak Kim,*[a] Chae Jo Lim,[a] Sang-Eun Song[b] and Han-Young Kang[b]

[a] *Center for Molecular Design and Synthesis and Department of Chemistry, School of Molecular Science, Korea Advanced Institute of Science and Technology, Taejon 305-701, Korea. E-mail: skim@mail.kaist.ac.kr*

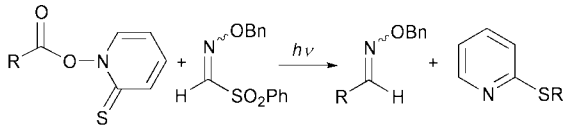
Received (in Cambridge, UK) 4th May 2001, Accepted 20th June 2001
First published as an Advance Article on the web 12th July 2001

A decarboxylative acylation approach is achieved with thiohydroxamate ester 6, which is less reactive and more stable than Barton's ester 1.

Since *O*-acyl thiohydroxamates were introduced in radical chemistry by Barton,[1] they have attracted a great deal of attention among synthetic chemists as useful radical precursors of alkyl[2] and aminyl radicals.[3] Radical chemistry of *O*-acyl thiohydroxamates **1** were further applied not only to the introduction of synthetically useful functional groups such as a halide[4] and a nitrile[5] but also to the formation of carbon-carbon bonds.[6] However, a highly reactive trapping agent is normally required because the alkyl radical could attack the thiocarbonyl group of **1** concurrently.

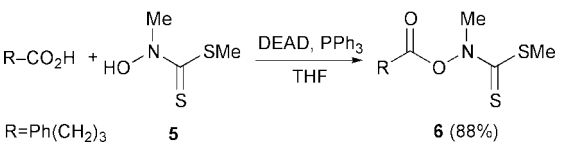
In connection with our recent interest in tin-free radical reactions,[7,8] we have studied the feasibility of decarboxylative acylation approaches of carboxylic acids *via O*-acyl thiohydroxamates **1** using phenylsulfonyl oxime ether **2a** as an acylating trapping agent (eqn. (1)).[9] Irradiation of a solution of **1** and **2a**



(1)

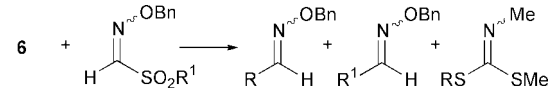
in benzene with a tungsten sun lamp (300 W) for 12 h gave a mixture of oxime ether **3** (32%) and pyridyl sulfide **4** (36%) in a roughly equal ratio, which was anticipated from the previously reported kinetic data.[10] Thus, the key feature for the success of the decarboxylative acylation approach is to reduce the rate of the alkyl radical additions onto the thiocarbonyl group to suppress the formation of **4**.

Our attention was given to somewhat less reactive thiohydroxamate esters that would not undergo aromatization upon radical-mediated fragmentation.[11] In this regard, we expected that a thiohydroxamate ester **6** would be well suited for our purpose. It is noteworthy that a very similar type of the reagent (RCO_2–NMe(C=S)SPh) was previously reported and would have similar properties.[2b] Thiohydroxamate ester **6** was obtained in high yield by treatment of a carboxylic acid with *N*-methylhydroxydithiocarbamate **5**, diethyl azodicarboxylate, and triphenylphosphine in THF and was stable thermally and hydrolytically (eqn. (2)). When **6** was treated with **2b** using 1,1′-



(2)

azobis(cyclohexanecarbonitrile) (V-40) as an initiator in octane at 120 °C for 10 h, a 71 : 16 mixture of oxime ether **3** and **7** was obtained, indicating the addition of the alkyl radical onto **2b** was much faster than the rearrangement to afford **8** (eqn. (3)).



R=Ph(CH$_2$)$_3$	**3**	**7**	**8**
2a: R^1= Ph (100 °C)	78%	0%	0%
= Ph (300 nm)	65%	0%	0%
2b: R^1= Me (120 °C)	71%	16%	0%

(3)

Furthermore, it is evident that a methyl radical, generated from thermal decomposition of a methanesulfonyl radical, attacked **2b** to some extent to yield **7**.[8] Thus, we performed the same reaction with **2a** and it was gratifying to find that thermal reaction of **6** with **2a** and V-40 in refluxing heptane afforded **3** in 78% yield without the formation of **7** and **8**. Furthermore, the decarboxylative acylation approach could be performed under photochemically initiated conditions. Unlike Barton's ester **1**, **6** required irradiation at 300 nm. Irradiation of a benzene solution of **6** with **2a** at 300 nm for 9 h afforded **3** in 65% yield. Thus, the remaining reactions were carried out with **2a** in refluxing heptane (0.25 M) for 12 h. Table 1 summarizes some experimental results and illustrates the efficiency of the decarboxylative acylation approaches. Primary and secondary aliphatic carboxylic acids worked well, yielding the corresponding oxime ethers in high yields. Sterically hindered tertiary

Table 1 Preparation of oxime ethers from thiohydroxamate esters

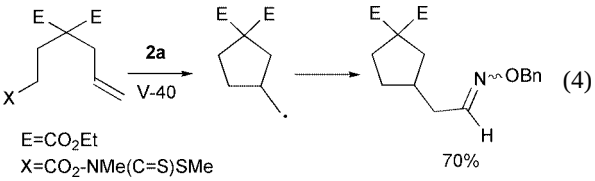
		R = H R = COOMe	75 (68) 68
		R = H R = COOMe	82 68
		R = H R = COOMe	88 (76) 70
		R = H R = COOMe	87 74
		R = H R = COOMe	84 71

[a] The numbers in parentheses indicate the yields at 300 nm.

 DOI: 10.1039/b104025c

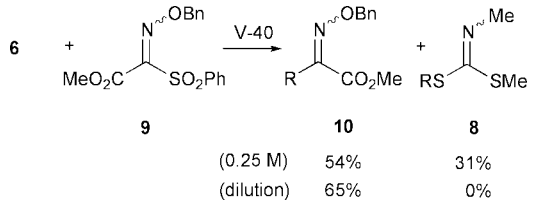
carboxylic acids underwent the decarboxylative acylation cleanly.

Thermal conditions gave somewhat higher yields than photochemical conditions and required 12 h for completion of the reaction. The major advantage of the present method is a sequential cyclization and acylation approach, which was demonstrated successfully in the present study (eqn. (4)).



(4)

To obtain an oxime ester, a synthetic equivalent of a α-keto ester,[12] when we repeated the reaction with methoxycarbonyl oxime ether **9** in refluxing heptane for 12 h, the desired oxime ester **10** was isolated in 54% yield along with a significant amount of the rearranged product **8** (31%) (eqn. (5)). Apparently,



(5)

the addition of the alkyl radical onto **9** was slowed down to some extent, thereby allowing the alkyl radical to attack **6**. The problem of the formation of the rearranged product was solved by the addition of **6** into **9** with a syringe pump. Thus, the addition of a 0.05 M chlorobenzene solution of **6** to a 0.1 M chlorobenzene solution of **9** at 120 °C by a syringe pump over 8 h with additional stirring for 2 h afforded the desired **10** in 65% yield without the formation of **8**. Similarly, the formation of several oxime esters worked equally well under highly diluted conditions as shown in Table 1.

In conclusion, we have developed a new thiohydroxamate ester, which is much less reactive and more stable than Barton's ester and demonstrated the first examples of decarboxylative acylation approaches under tin-free conditions.

We thank the Center for Molecular Design and Synthesis (CMDS) and BK21 project for financial support.

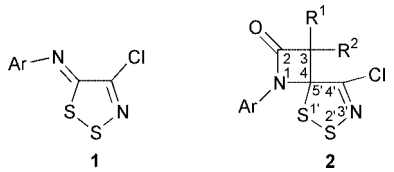
Received (in Cambridge, UK) 3rd May 2001, Accepted 13th June 2001
First published as an Advance Article on the web 12th July 2001

Treatment of 5-arylimino-4-chloro-5*H*-1,2,3-dithiazoles with *in situ* generated (chloro)phenylketene in CH_2Cl_2 at rt gave azetidin-2-one-4-spiro-5′-(1′,2′,3′-dithiazoles) as major products, which reacted with primary and secondary alkylamines in CH_2Cl_2 at rt to afford bis(2-oxo-azetidin-4-yl) trisulfides in good to excellent yields.

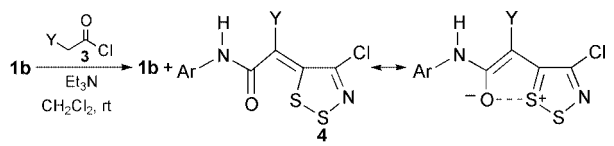
Azetidin-2-ones have been one of the most attractive classes of organic compounds due to their potential biological applications.[1] Numerous methods for the synthesis of azetidin-2-ones are known and these are well-documented in the literature.[1] In connection with our ongoing project for exploring the potential synthetic utility of 5-arylimino-4-chloro-5*H*-1,2,3-dithiazoles **1**,[2] we are interested in investigating the reactivity of the N=C-5 imine bond of **1** toward cycloaddition reactions with a ketene because a [2 + 2] cycloaddition with a ketene would give azetidin-2-one-4-spiro-5′-(1′,2′,3′-dithiazoles) **2**, which, to the best of our knowledge, has never been reported. Compound **2** is



1 **2**

of interest with respect to the stereochemistry at C-3 and C-4. In addition, it may be utilized as a precursor for the synthesis of hitherto unknown azetidin-2-ones created by cleaving the bond between S-1′ and S-2′ with nucleophiles, as shown in the ready conversion of **1** to diverse products.[3] With this in mind, **1** was treated with various ketenes which were generated *in situ*. This paper describes the preliminary results we have obtained.

For the generation of a ketene, a method involving acid chlorides and Et_3N[4] in CH_2Cl_2 at rt was employed since neither reagent reacts with **1** under conditions for the generation of ketenes. When Et_3N (1.22–2.87 mmol) in CH_2Cl_2 (30 ml) was added dropwise to a mixture of **1b** (Ar = 4-$MeOC_6H_4$) (0.773–0.935 mmol) and acid chlorides **3** (1.20–2.89 mmol) in CH_2Cl_2 (20 ml) at rt, followed by stirring for 0.5–1 h, only a small amount of **4a** (Y = Cl), **4c** (Y = MeO), and **4e** (Y = AcO), which comprised a single isomer in view of the ^1H and ^{13}C NMR spectroscopic data, and most of the unreacted **1b** were isolated (Scheme 1).



Ar = 4-$MeOC_6H_4$ **a**, Y = Cl, 26% **d**, Y = PhO, 0%
b, Y = Ph, 0% **e**, Y = AcO, 17%
c, Y = MeO, 2%

Scheme 1

Compounds **4a**, **4c**, and **4e**, derivatives of 5-(phenylcarbamoyl)methylidene-5*H*-1,2,3-dithiazole,[5] are all new. The (*E*)-stereochemistry of **4** was assigned based on the IR absorptions of the carbonyl group at 1603, 1613, and 1619 cm^{-1}, respectively, which suggests the possible interaction of the carbonyl oxygen with electron deficient S-1.[2] Surprisingly, the reactions of **1** with 2-chloro-2-phenylacetyl chloride (**3f**) under the foregoing conditions gave the desired compound **2** (R^1 = Cl, R^2 = Ph) in good to excellent yields (Scheme 2). Yields and mps of **2** are summarized in Table 1.

The structures of **2** were determined based on spectroscopic (^1H and ^{13}C NMR, IR, MS) and analytical data. The X-ray single crystal structure of **2d**‡ (Fig. 1) clearly shows *cis*-stereochemistry with *S* and *R* configurations at C-3 and C-4, respectively. The *cis*-stereochemistry of **2** may be ascribed to the avoidance of severe electronic repulsions between lone pair electrons on the two chlorine atoms at C-3 and C-4′.

Treatment of **2** (0.23–0.38 mmol) in CH_2Cl_2 (10 ml) with a slightly excessive molar amount of primary and secondary alkylamines at rt gave bis(2-oxo-azetidin-4-yl) trisulfides **5** along with alkylamino 2-oxo-azetidin-4-yl disulfides **6** and a considerable amount of unreacted **2** (Scheme 2). However, by employing 4 molar equivalents of alkylamines, **5** were obtained as major products along with **6** and a small amount of isothiazol-3-ones **7**, which were obtained only from the reactions of **2c** and

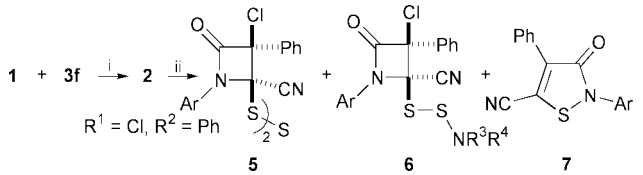
2d. Trisulfides of azetidin-2-ones have never been reported despite the existence of numerous methods for the synthesis of a variety of trisulfides.[6] Compounds **6** and **7** are also new. The stereochemistry at C-3 and C-4 of **5** and **6** are believed to be intact. Reaction times and yields of trisulfides **5**, disulfides **6**, and isothiazol-3-ones **7** are summarized in Table 2.

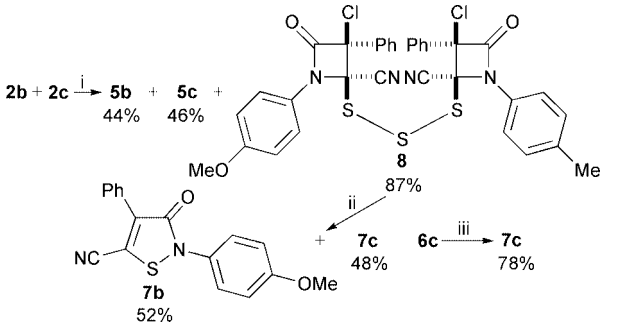


Scheme 2 *Reagents and conditions*: i, Et_3N, CH_2Cl_2, rt; ii, R^3R^4NH, CH_2Cl_2, rt.

Table 2 shows that **2** react with both primary (entries 1–4 and 7–9) and secondary (entry 5) alkylamines to give **5** but not with arylamine even at reflux temperature over a prolonged reaction time (entry 6). Among primary alkylamines, *i.e.* *n*-$PrNH_2$ and *t*-$BuNH_2$, the reactions with *n*-$PrNH_2$ proceeded more rapidly than those with *t*-$BuNH_2$, presumably due to the steric effect of a bulky *tert*-butyl group.

For a mechanistic study, a mixture of equal molar amounts of **2b** (0.253 mmol) and **2c** (0.253 mmol) was treated with *n*-$PrNH_2$ (2.07 mmol) for 3 h under the foregoing conditions. From the reaction were isolated **5b** (44%), **5c** (46%), and unsymmetrical trisulfide **8** (87%) (Scheme 3). The isolation of unsymmetrical trisulfide **8** coupled with its yield, which is approximately twice of that of either **5b** or **5c**, indicates that trisulfides **5** are formed *via* an intermolecular reaction. Furthermore, when the mixture of **2b** (0.070 mmol) and **2c** (0.069 mmol) was treated with a large exccss of *n*-$PrNH_2$ (1.1 mmol) for 24 h under the same conditions, isothiazol-3-ones **7b** (58%) and **7c** (62%) along with unknown mixtures were obtained. No trisulfides **5b** and **5c** were detected. The results indicate that **2** are converted to **7** *via* **5** in the presence of a large excess of *n*-$PrNH_2$ over a prolonged reaction time. In addition, the fact that **7c** (78%) together with an unknown mixture as obtained from the reaction of disulfide **6c** (Ar = 4-MeC_6H_4, R^3 = H, R^4 = *n*-Pr) (0.11 mmol) with *n*-$PrNH_2$ (0.49 mmol) in CH_2Cl_2 for 26 h indicates that **6** also act as intermediates for the formation of **7**.

In conclusion we have found that 5-arylimino-4-chloro-5*H*-1,2,3-dithiazoles reacted with (chloro)phenylketene in CH_2Cl_2 at rt to give spiro compound **2**, which undergoes a decomposition reaction in the presence of primary and secondary alkylamines in CH_2Cl_2 at rt, giving bis(2-oxo-azetidin-4-yl) trisulfides as major products. Study of the mechanism and scope of the reactions is in progress.



Scheme 3 *Reagents and conditions*: i, *n*-$PrNH_2$ (8 equiv.), CH_2Cl_2, rt, 3 h; ii, *n*-$PrNH_2$, (8 equiv.), CH_2Cl_2, rt, 24 h; iii, *n*-$PrNH_2$ (4 equiv.), CH_2Cl_2, rt, 26 h.

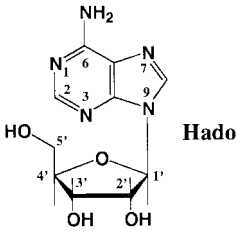
Received (in Cambridge, UK) 28th March 2001, Accepted 21st June 2001
First published as an Advance Article on the web 12th July 2001

A diastereomer with a C_3 cyclic trimer $[\{Rh(adenosine)(Cp^*)\}_3](CF_3SO_3)_3$, which was obtained selectively by a second-order asymmetric transformation, can include one methanol molecule into its triangle dome-like cavity.

Adenosine (Hado, **1**) is an important DNA/RNA nucleoside. In



Hado

1992 Fish and coworkers reported the synthesis of an interesting C_3 cyclic trimer complex containing the ligand $[\{Rh(Cp^*)(ado)\}_3](CF_3SO_3)_3$ **2** ($Cp^* = \eta^5$-C_5Me_5).[1] However this complex was a mixture of two diastereomers (**2a** and **2b**) due to chiralities of the ribose group in **1** and the pure diastereomers had not been isolated. Hence the structure of **2** was deduced from NMR spectroscopy and the crystal structure $[\{Rh(Cp^*)(Me\text{-}ade)\}_3](CF_3SO_3)_3$ (Me-ade = 9-methyladeninato).[1]

Here we report diastereomeric separations of **2** and the corresponding Ir^{III} complex $[\{Ir(Cp^*)(ado)\}_3](PF_6)_3$ **3** (**3a** and **3b**) and a novel crystal structure of an inclusion compound $[\{Rh(Cp^*)(ado)\}_3](CF_3SO_3)_3\cdot MeOH$ (**2a**·MeOH). The absolute configurations of all complexes can be assigned based on circular dichroism (CD) spectra.

A self-assembling reaction between $[Rh(Cp^*)(H_2O)_3]^{2+}$ and **1** gave **2**† in high yield. Fig. 1(a) shows the ^1H NMR spectrum of the reaction solution, which indicates the presence of two diastereomers. However fractional crystallization of this reaction solution gave only one diastereomer **2a** up to the end of evaporation [Fig. 1(b)]. This phenomenon, the selective crystallization of one of the diastereomers under conditions of relatively rapid isomer equilibration in solution, is denoted second-order asymmetric transformation,[2] as observed in fac(*S*)-[Co{(*R*)-cysteinato-*N*,*S*}$_3$]$^{3-}$.[3] Though shifts of the diastereomeric equilibria have been known in many organometallic systems, the above phenomenon is quite rare.[4] The electrospray ionization (ESI) mass spectrum of **2a** showed dominant peaks at *m/z* 504.1, 830.7 and 1811.1, which correspond to the ions $[3M-3X]^{3+}$, $[3M-2X]^{2+}$ and $[3M-X]^{+}$, respectively, where 3M and X represent the complex and $CF_3SO_3^-$, respectively. The result indicates that **2** has a cyclic trinuclear structure.

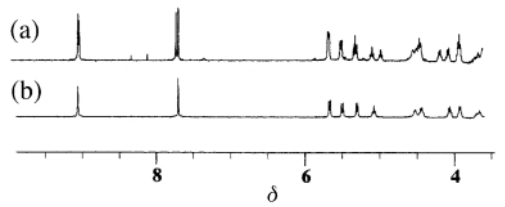


Fig. 1 Proton NMR spectra of **2** (a) and **2a** (b) in $(CD_3)_2SO$.

Fig. 2 shows a view of $[\{Rh(Cp^*)(ado)\}_3][CF_3SO_3]_3\cdot 2.5H_2O\cdot MeOH$ (**2a**·MeOH).‡ This complex has a trinuclear structure. Three Rh^{III} ions are crystallographically independent and form an almost equilateral triangle: Rh(1)···Rh(2) 5.6037(6), Rh(1)···Rh(3) 5.6353(6) and Rh(2)···Rh(3) 5.6285(6) Å. The ado ligand adopts a μ-1κN^1:2κ$^2N^6$,N^7 bridging mode: it coordinates to one Rh^{III} ion in a bidentate manner *via* the NH^6 and N(7) donors which form a five-membered chelate ring and bridges to another Rh^{III} ion through the N(1) donor. The three purine rings are located at the same side and form a triangular dome-like cavity. Interestingly one molecule of methanol just fits this cavity, forming an inclusion compound. There are two O–H···O hydrogen bonds between the oxygen of methanol and the hydroxyl groups of ribose [O(102)···O(401) 2.782(8) and O(205)···O(401) 2.748(8) Å]. Moreover three CH–π interactions are found: the three distances between the carbon atom of the methyl group and each of the least-square planes of the three purine rings are 3.53, 3.63 and 3.72 Å. These two types of interactions stabilize the inclusion of the methanol. The side length of the triangle formed by C(6), corresponding to a bottom of the cavity in Fig. 2, is 3.86 Å (av.) and the length by C(1′), at the top of the cavity, is 8.18 Å (av.). Three ribose groups close the cavity by acting as a cap. The side stereoview and the space-filling structure in Fig. 3 clearly show this triangle dome-like cavity. Fish and

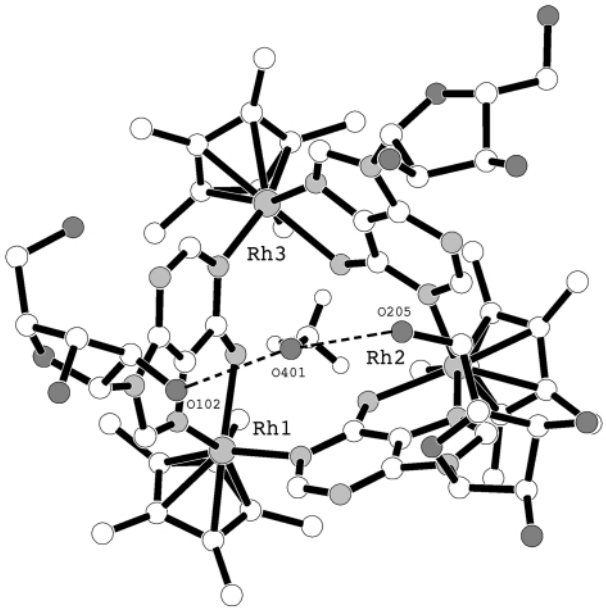

Fig. 2 The structure of the cation in $[\{Rh(Cp^*)(ado)\}_3][CF_3SO_3]_3\cdot 2.5H_2O\cdot MeOH$ (**2a**·MeOH): Selected average bond distances (Å) and angles (°) Rh–N(6) 2.161, Rh–N(7) 2.159, Rh–N(1′) 2.155, C(6)–N(6) 1.306; N(6)–Rh–N(7) 79.1, N(6)–Rh–N(1′) 89.9, N(7)–Rh–N(1′) 84.5, N(6)–C(6)–C(5) 115.6, Rh–N(7)–C(5) 106.5, Rh–N(6)–C(6) 113.4.

coworkers have reported that **2** and analogous cyclic trimer complexes are useful hosts for molecular recognition of aromatic amino acid guests.[5] The present study gives the structural support for such investigations.

Since the central Rh^{III} ions become chiral each unit complex has chirality C (clockwise) or A (anticlockwise).[6] **2a** has a chiral array of CCC, and the CD spectrum is shown in Fig. 4. The CD intensity is considerably stronger than those reported for nucleosido complexes which are mixtures of two diastereomers.[7] It should be noted that the present Rh^{III} system contains only the C_3 CCC diastereomer. A D_2O solution of **2a** produced 30% of **2b** at room temperature in ten days.

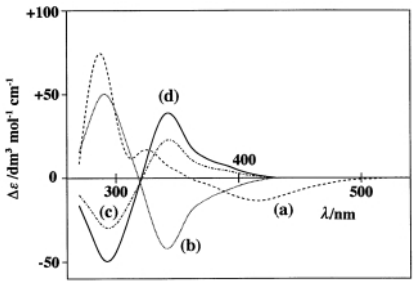

Fig. 4 CD spectra of $[\{Rh(Cp^*)(ado)\}_3](CF_3SO_3)_3$ (a) and $[\{Ir(Cp^*)(ado)\}_3](PF_6)_3$ (b, c and d). The pure CD spectrum (d) of **3b** was calculated from the spectra.

The corresponding Ir^{III} complex $[\{Ir(Cp^*)(ado)\}_3](PF_6)_3$ **3**§ was prepared in the same manner and showed a very similar ^1H NMR spectrum to that of **2** which is characteristic for a trimer.[1] Upon fractional crystallization, both diastereomers **3a** and **3b** were obtained as almost pure isomers (Fig. 5). The ESI mass spectrum of **3a** showed dominant peaks corresponding to the ions $[3M - 3X]^{3+}$ and $[3M - 2X]^{2+}$. Therefore we concluded that **3** has the same C_3 cyclic trinuclear structure as **2**. As shown in Fig. 4, both CD spectra (b) and (d) are almost enantiomeric. To our knowledge, this is the first example of isolating two diastereomers for nucleosido complexes. The CD spectra of the Ir^{III} complexes is blue-shifted by *ca.* 5000 cm^{-1} compared with those of Rh^{III} complexes. **3a** showed (−) and (+) CD peaks

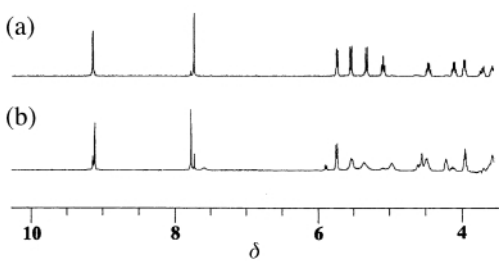

Fig. 5 Proton NMR spectra of **3a** (a) and **3b** (b) in $(CD_3)_2SO$.

from the lower energy side, the pattern of which is similar to that of the Rh^{III} complex **2a**. The ^1H NMR patterns of H^2 and H^8 are also analogous for **2a** and **3a**. Hence **3a** can be assigned as a CCC cyclic trinuclear structure and **3b** as AAA.

Notes and references

† For **2** (**2a**)**:** to a suspension of $[\{Rh(Cp^*)Cl_2\}_2]$[8] (0.2 g, 0.32 mmol) in water (30 cm^3) was added silver triflate (0.33 g, 1.3 mmol) and the mixture stirred at 40 °C for 1 h. The resulting silver chloride precipitate was removed by filtration and to the filtrate was added an aqueous solution (50 cm^3) of **1** (0.18 g, 0.64 mmol) adjusted to *ca.* pH 7 by adding aqueous NaOH. The mixed solution was stirred at room temp. for 1 d and then the resultant solution **2** was evaporated. Fractional crystallization of **2** always gave one diastereomer **2a** until the end of evaporation: that is, a second-order asymmetric transformation was found in this Rh^{III} system; hence the isolation of **2b** is impossible using $CF_3SO_3^-$. The yield was 70–85%. Found: C, 36.72; H, 4.49; N, 10.12. Calc. for $[\{Rh(Cp^*)(ado)\}_3][CF_3SO_3]_3\cdot 6H_2O$ **2a** ($C_{63}H_{93}F_9N_{15}O_{27}Rh_3S_3$): C, 36.58; H, 4.53, N, 10.16%. ESI MS (MeOH): *m/z* 504.1($[3M - 3X]^{3+}$), 830.7($[3M - 2X]^{2+}$), 1811.1 ($[3M - X]^+$). Crystals for X-ray crystal structure analysis were obtained from a methanol–ether solution.

‡ *Crystal data* for $[\{Rh(Cp^*)(ado)\}_3][CF_3SO_3]_3\cdot 2.5H_2O\cdot$MeOH **2a** were collected on a Rigaku RAXIS-RAPID Imaging Plate with graphite-monochromated Mo-Kα radiation (λ = 0.71069 Å); $C_{64}H_{90}F_9N_{15}O_{24.5}Rh_3S_3$, M_r = 2037.38, crystal size 0.15 × 0.15 × 0.35 mm; T = 23 °C; orthorhombic, space group $P2_12_12_1$ (no. 19), a = 21.0185(4), b = 21.3660(4), c = 19.4924(3) Å, V = 8753.7(3) Å^3, Z = 4, μ = 7.26 cm^{-1}, $F(000)$ = 4156, D_c = 1.546 g cm^{-3}, $2\theta_{max}$ = 55.0°. 20037 reflections were collected. Final $R1$ = 0.044 (wR = 0.137) for 13527 reflections with $I > 2\sigma(I)$ (993 parameters). All calculations were performed using the TEXSAN[9] crystallographic software package. CCDC reference number 157281. See http://www.rsc.org/suppdata/cc/b1/b102870g/ for crystallographic data in CIF or other electronic format.

§ For **3** (**3a** and **3b**): the corresponding Ir^{III} complex was prepared in the same manner but without adding aqueous NaOH. The reaction solution was stirred at room temperature for 6 d and then the resultant solution was evaporated. Since the desired complex is too soluble, an excess of NH_4PF_6 was added leading to crystals of **3** (85% yield). When an aqueous solution of **3** was fractionally recrystallized, **3a** was obtained first as the less soluble diastereomer (37% yield) and the more soluble diastereomer **3b** was obtained as a second crop (10% yield; 20% **3a** and 80% **3b**). The second-order asymmetric transformation in the Rh^{III}–CF_3SO_3 system was not observed in the Ir^{III}–PF_6 system. Found: C, 31.37; H, 3.77; N, 9.17. Calc. for $[\{Ir(Cp^*)(ado)\}_3][PF_6]_3\cdot 4H_2O$ **3a** ($C_{60}H_{89}F_{18}Ir_3N_{15}O_{16}P_3$): C, 31.50; H, 3.92, N, 9.18%. The self-assembly of discrete linear tapes claimed by the title communication is questioned on the basis of a rigorous thermodynamic analysis; moreover the reported thermodynamic data are not consistent with self-assembly of the square.

There is currently much interest in the preparation and isolation of monodisperse oligomers because of their technological applications.[1] In a recent communication in this journal,[2] Drain, Shi, Milic and Nifiatis (DSMN) reported ^{1}H NMR experiments aimed at supporting a strong bias in favour of well defined linear oligomers in solution simply by changing the stoichiometric ratio between monofunctional and bifunctional reactants capable of reacting with each other in a reversible addition reaction. In particular they claimed that mixing 5-[2,6-bis(acetylamino)-pyridin-4-yl]-10,15,20-tris(4-*tert*-butylphenyl)porphyrin and 5,15-bis[2,6-bis(acetylamino)pyridin-4-yl]-10,20-bis(4-*tert*-butylphenyl)porphyrin in a 2:1 stoichiometry leads essentially to a linear trimer (Scheme 1, $i = 1$) whereas using a 2:2 ratio a linear tetramer ($i = 2$) is formed in prevalence.

This approach which seems to be self-evident, would have a profound influence on the preparation of monodisperse linear oligomers, also in view of the fact that end-terminated oligomers would inhibit the competitive formation of cyclic species.[3] Owing to the importance of the observation, I believe that a warrant based on rigorous thermodynamic grounds is required.

At first consider a monomer A–A (L_1) bearing two identical functional groups, capable of reacting with each other in a reversible addition reaction. If rings are assumed to be completely absent, a system initially composed of monomer units L_1, after equilibration, contains in principle an infinite number of linear oligomers L_i, i being the polymerisation degree. Let K be the equilibrium constant for the dimerisation of a monofunctional reactant R–A, if the association between end groups is independent of the length of the chain, then the oligomer distribution can be expressed as follows:†

$$[L_i] = (\sigma K)^{-1} x^i \quad (1)$$

where σ is a symmetry number, that in the present case is equal to 4,§ and x is the fraction of reacted end-groups. Eqn. (1) is of course equivalent to the classical Flory distribution valid in the case of polycondensation.[4] The mass balance equation is given by eqn. (2)†

$$[L_1]_0 = (\sigma K)^{-1} x (1 - x)^{-2} \quad (2)$$

where $[L_1]_0$ is the initial monomer concentration. Solving eqn. (2) for x, the weight fraction w_i of the oligomer L_i, can be easily evaluated.† In Fig. 1 are reported plots of the weight fraction of the first five oligomers as a function of $\sigma K[L_1]_0$. Extensive polymerisation occurs at high values of the product $K[L_1]_0$, whereas for the highest yield of a specific oligomer a specific $K[L_1]_0$ value is required. By inspection of Fig. 1, it results that with simple oligomerisation the yield of the dimer can be 30% at best, that of the trimer 19%, that of the tetramer 14% and that of the pentamer 11%. It would be very useful if by addition of appropriate amounts of a chain terminator R–A one could selectively increase the yield of a specific oligomer as suggested by DSMN.

A mixture of a monofunctional reactant R–A (A) and of a bifunctional reactant A–A (L_1) will generate in solution the dimer of R–A (N_0) and three families of oligomers, namely L_i having both ends free, M_i having only one end free, and N_i having both ends terminated as the species shown in Scheme 1.¶ The oligomer distribution of L_i is still given by eqn. (1) whereas those of M_i and N_i are given by eqn. (3) and (4), respectively.†

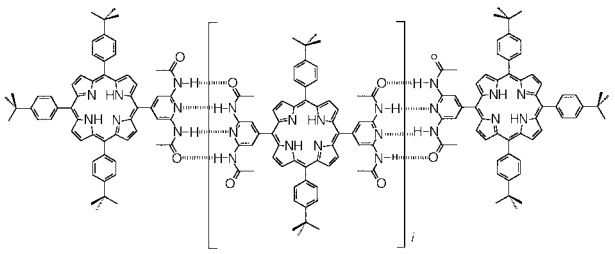
$$[M_i] = [A] x^i \quad (3)$$

$$[N_i] = K [A]^2 x^i \quad (4)$$

It is useful to consider the total concentration of the oligomers with the same polymerisation degree, $[R_i]$, obtained by summing eqn. (1), (3), and (4)

$$[R_i] = \{(\sigma K)^{-1} + [A] + K[A]^2\} x^i \quad (5)$$

Let us define the term in parentheses as $(\sigma K_{app})^{-1}$, where K_{app} is an apparent constant at a given concentration of $[L_1]_0$ and $[A]_0$, then eqn. (5) can be rewritten as eqn. (6)



Scheme 1

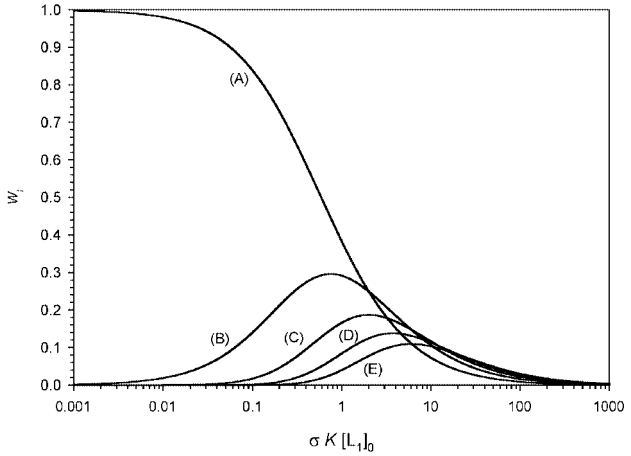


Fig. 1 Weight fraction of monomer, dimer, trimer, tetramer, and pentamer (curves from A to E, respectively) *vs.* $\sigma K[L_1]_0$.

† Electronic supplementary information (ESI) available: formal derivation of eqn. (1), (2), (3) and (4), and details about the construction of Figs. 1 and 2, and self-assembly of the square. See http: //www.rsc.org/suppdata/cc/b1/b101678b/

 DOI: 10.1039/b101678b

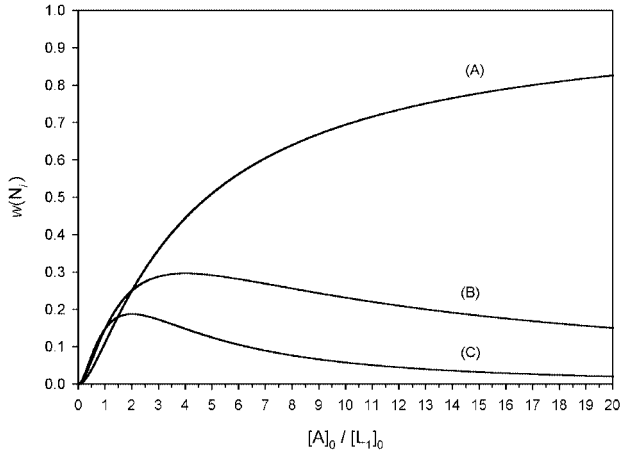

Fig. 2 Weighted fraction of N_0, N_1, and N_2 (curves A, B and C, respectively) *vs.* $[A]_0/[L_1]_0$ with K set very high.

$$[R_i] = (\sigma K_{app})^{-1} x^i \quad (6)$$

which has the same form as eqn. (1). It is easy to show that now the mass balance equation has the same form as eqn. (2) with K replaced by K_{app}, therefore Fig. 1 can now be used to predict the weight fraction of R_i. Of course in no case can the weight fraction of the end terminated oligomer N_i, which is a part of R_i, be greater than the weight fraction of R_i, thus disproving the idea that specific stoichiometric ratios between $[L_1]_0$ and $[A]_0$ can drive the reaction toward a certain oligomer, as suggested by DSMN. An increase of $[A]_0$, of course, will cause an increase of [A], and consequently a decrease of the K_{app} value. This involves a shift to the left in the abscissa of Fig. 1, *i.e.* depolymerisation. An increase of [A] will also cause a change of the relative weight of each oligomer type within R_i disfavouring the L_i type; thus in the limit of $[A]_0$ tending to infinity only N_1 will be present in solution, apart of course from A and N_0. To further illustrate the extent of polydispersity, in Fig. 2 is reported the fraction of N_0, N_1, and N_2, weighted according to the content of functional groups, against the ratio $[A]_0/[L_1]_0$, with K set very high so that $[L_i] = [M_i] = 0$ and $[R_i] = [N_i]$.† It is evident from Fig. 2 that, although DSMN realised that linear self-assembly does not give pure N_1 and N_2, they certainly undervalued the extent of polydispersity. It also appears that the best $[A]_0/[L_1]_0$ value to obtain N_i is not $2/i$ but $4/i$.

It should be noted that the equilibrium constants reported by DSMN for the formation of the trimer and the tetramer (Scheme 1, $i = 1$ and 2, respectively), 110 dm^6 mol^{-2} and 70 dm^9 mol^{-3}, respectively, are certainly wrong. Considering the value of the equilibrium constant for the dimerisation given by DSMN (K = 160 dm^3 mol^{-1}) as a *bona fide* value, the constant for the formation of the trimer should be equal to $4K^2$, *i.e.* of the order of 10^5 dm^6 mol^{-2}, and that of the tetramer $16K^3$, *i.e.* of the order of 10^8 dm^9 mol^{-3}. In fact ^{1}H NMR cannot be used to assess the distribution of linear oligomer ; ^{1}H NMR records the average chemical shift of bound and unbound end groups, and since all the associations between end groups have the same probability of occuring, any experiment in which the total concentration of end groups is identical, no matter if they come from monofunctional or bifunctional reactants, will give the same chemical shift even if the distribution of the species actually present in solution are very different. This is demonstrated by the fact that DSMN found very similar $C_{1/2}$ values (the concentration at the half maximum increase in the chemical shift) for different linear self-assembly experiments. DSMN also reported that 5,10-bis[2,6-bis(acetylamino)pyridin-4-yl]-15,20-bis(4-*tert*-butylphenyl)porphyrin undergoes self-assembly to form a cyclic tetramer (a square), however the equilibrium constant they reported for the formation of the square (K_{square} = 2400 dm^9 mol^{-3}) is not consistent with the reported $C_{1/2}$ value (0.8 mM). By assuming that the square and the monomer are the only species present in solution, a K_{square} value of 3.9×10^9 dm^9 mol^{-3} can be estimated.† It appears therefore that DSMN made some serious computational error in the evaluation of K_{square}. If the value of K_{square} were that indicated by DSMN, self-assembly of the square would not occur.

I have reported a treatment for self-assembly macrocyclisations of a monomer of the type A–B.[5] One of the principal results of my treatment is that in order for self-assembly to be virtually complete in a certain range of initial monomer concentration the following condition must be verified [eqn. (7)], where EM is the effective molarity[6] of the self-assembled

$$\mathrm{EM}\ \sigma K \geqslant 185\ n \quad (7)$$

ring, K is the equilibrium constant for the intermolecular model reaction, and n is the number of monomer units constituting the ring. Since $K_{square} = \mathrm{EM}(\sigma K)^4$, from a K_{square} value of 3.9×10^9 dm^9, an EM of $\approx$0.02 mol dm^{-3} can be calculated. According to eqn. (7) this value is too low to be compatible with complete self-assembly of the square. An approximate calculation indicates that the maximum molar fraction that can be reached by the square is about 67%.†

Another point regards the claimed quadruple hydrogen bonding. There is a general consensus that the most stable conformation of the amide linkage in 2,6-bis(acylamino)pyridines is *anti* and not *syn*,[7] as reported by DSMN; thus the subunits are probably just double hydrogen bonded. An example of a reversible polymer formed by a genuine quadruple hydrogen bond shows that such a bond can be very strong indeed ($K > 10^6$ dm^3 mol^{-1}).[8]

In conclusion the formation of discrete linear tapes by changing the stoichiometric ratio between monofunctional and bifunctional reactants is not supported by a rigorous thermodynamic analysis; the self-assembly of the cyclic tetramer should be re-examined in the light of actual knowledge in order to provide consistent thermodynamic data.

I thank both the referees for their helpful suggestions.

Selected nucleic acid mimics are discussed in the context of the antisense therapeutic strategy with focus on furanose conformation, RNA-binding affinity, and activation of the RNA-cleaving enzyme RNase H.

Introduction

In order to inhibit gene expression by targeting RNA with short antisense oligonucleotides, multiple chemically modified nucleoside and oligonucleotide analogues have been synthesized and evaluated during the last 15 years.[1,2] Selected examples of modified nucleic acids are described here with the emphasis on their hybridization properties and capability to activate RNase H, an RNA-degrading enzyme, in relation to their conformational and structural characteristics. The focus is on important recent developments and their prospects towards the realization of the antisense therapeutic strategy.

The antisense strategy

The carriers of all genetic information in living organisms are 2′-deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), polymers consisting of repetitive units of nucleotide monomers. Each nucleotide contains a phosphate group, a carbohydrate moiety and a nucleobase (Fig. 1). The natural nucleobases in

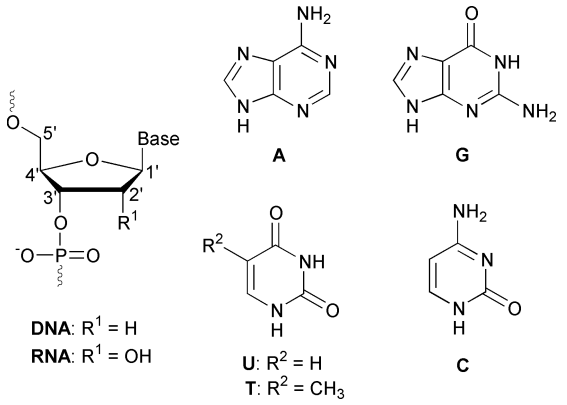

Fig. 1 Structures of a nucleotide monomer (left) and the nucleobases adenine (A), guanine (G), uracil (U), thymine (T), and cytosine (C).

DNA (R^1 = H) are A, G, T and C while U replaces T in RNA (R^1 = OH). Two complementary polymeric or oligomeric single strands hybridize in an anti-parallel fashion forming a right-handed duplex with the specific Watson–Crick base-pairing of G to C and A to T or U.

As depicted schematically in Fig. 2, the genetic information is transcribed from double-stranded DNA, located in the cell

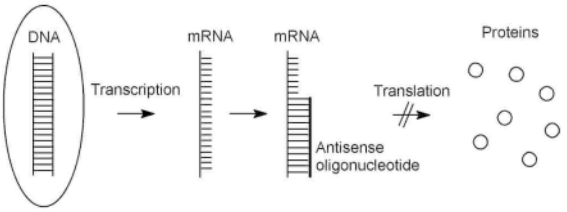

Fig. 2 Schematic overview of the antisense strategy.

nucleus, to single-stranded messenger-RNA (mRNA) which functions as a carrier of genetic information from the cell nucleus to the ribosomes in the cytoplasm. The principle of the antisense strategy is to target mRNA by duplex formation using a short (10–20 nucleotides long) antisense oligonucleotide, thereby preventing the translation of the mRNA into proteins. In principle, any genetic sequence, and thus any disease with a genetic origin, should be subject to selective targeting by varying the nucleotide sequence of an antisense oligonucleotide approximately 18 nucleotides long. This makes the antisense strategy general and attractive compared with the individual development of traditional drugs acting at the protein level. An antisense oligonucleotide has to fulfil several functional requirements, *e.g.* high binding affinity toward the RNA binding strand, resistance towards nucleases, low toxicity, and efficient delivery to the desired target site, *in vivo*, rendering

Lisbet Kværnø (b. 1974) received her BSc and MSc degrees in 1998 and 2000, respectively, from The University of Copenhagen under the supervision of Professor Jesper Wengel. She is currently pursuing a PhD within the field of total synthesis of natural products in the group of Professor David Tanner, The Technical University of Denmark.

Jesper Wengel (b. 1963) obtained his PhD within the field of nucleoside chemistry in the group of Dr Erik B. Petersen, University of Southern Denmark, Odense (formerly Odense University) in 1991 and joined the faculty immediately afterwards as an assistant professor. In 1996, he was appointed as a full professor in bioorganic chemistry at The University of Copenhagen. He returned to The University of Southern Denmark, Odense, also as a full professor, in August 2000. His main research interests are the synthesis and properties of chemically modified nucleosides and oligonucleotides, and the use of branched and functionalized oligonucleotides within supramolecular chemistry.

chemical modification of the natural nucleic acid structures needed.

Nucleic acid structure and furanose conformations

The pseudorotational circle[3] depicted in Fig. 3 describes the possible furanose conformations of the nucleotide monomers.

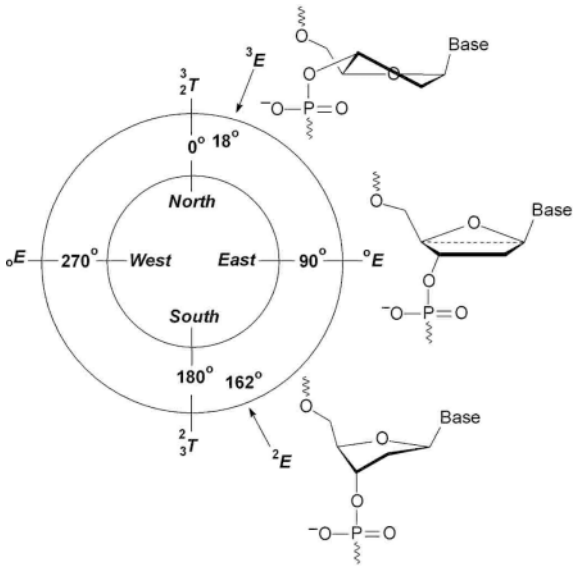

Fig. 3 The pseudorotation cycle showing the relation between the pseudorotation angle *P* (0–360°; calculated from the five torsional angles of the furanose ring[3]) and furanose ring conformations.

All distinct conformations (*i.e.* envelope, *E*, and twist, *T*, conformations) are separated by 18° with a superscript designating an atom above the plane described by the remaining three or four atoms of the furanose ring, and a subscript designating an atom below.

The two dominating furanose conformations for DNA and RNA generally give rise to two different duplex forms, as depicted in Fig. 4. Apart from having all furanose conformations in an *S*-type (*south*-type, C2′-*endo*, ^2E) conformation, the B-type helix seen in solution for DNA is characterized by 10 base-pairs almost perpendicular to the helix axis per helix turn, and a distinct difference in width of the major and the minor grooves.[4,5] In contrast, RNA adopts an A-type helix in which the furanose conformations are all *N*-type (*north*-type, C3′-*endo*, ^3E) with 11 base-pairs tilted 20° with respect to the helix axis per helix turn, and the minor and major grooves being almost equally wide.[4,5]

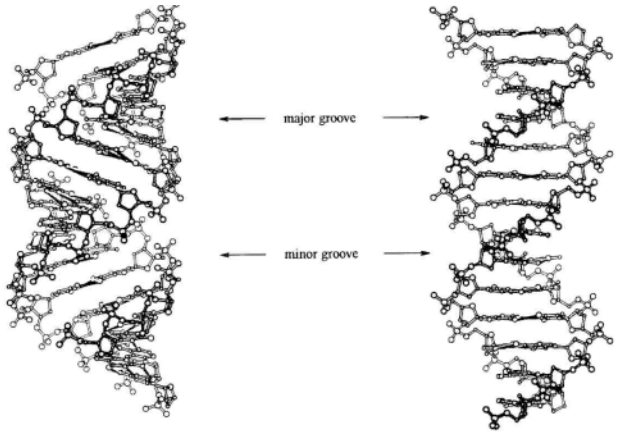

Fig. 4 Globular conformations of an A-type duplex (left) and a B-type duplex (right) generally seen for RNA:RNA and DNA:DNA duplexes, respectively.

Modes of action and conformational requirements of antisense molecules

An antisense oligonucleotide has basically two possible modes of action both depending on the duplex formation between the RNA target and the antisense oligonucleotide. One is a simple steric blocking of the mRNA, the other recognition of the RNA–antisense duplex as a substrate for the enzyme RNase H which cleaves the RNA strand of an RNA–DNA duplex. In the latter scenario, one antisense oligonucleotide is able to pacify multiple mRNA strands. A high binding affinity towards RNA is crucial, especially for the steric blocking approach. Conformational restriction of the single-stranded antisense oligonucleotides is believed to favour duplex formation entropically by diminishing the loss of conformational degrees of freedom upon duplex formation, and conformational restriction of the furanose rings of oligonucleotides has been successfully applied to the field in the recent years.[6–8] Studies of a large number of oligonucleotide analogues have been generalized to the hypothesis that oligonucleotides restricted into *N*-type furanose conformations, thus yielding A-type duplexes when hybridized to RNA, effect the highest duplex stabilities.[1,9]

However, no fully modified antisense oligonucleotide with restricted *N*-type furanose conformations has been reported to be able to activate RNase H. The RNA–DNA heteroduplexes being substrates of RNase H which has been reported to bind in the minor groove, adopt an intermediate duplex form with a minor groove width also intermediate between that of the A form and the B form.[10–14] The furanose conformations in the RNA strand are still *N*-type (3′-*endo*) while hybridization to the RNA strand causes the furanose conformations of the DNA strand to change from the typical *S*-type (C2′-*endo*) into *E*-type conformations (O4′-*endo* range, see Fig. 3).[10,11,14] Thus, the activation of RNase H proposedly requires antisense oligonucleotides with furanose rings able to adopt *E*-type (O4′-*endo*), or perhaps *S*-type (C2′-*endo*), conformations, and *not* the duplex-stabilizing *N*-type conformations.

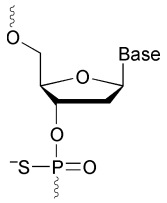
An appealing way to circumvent the lack of RNase H activation is the introduction of chimeric structures consisting of high-affinity nucleotide modifications in the terminal regions of the antisense oligonucleotide around a ‘gap’ of RNase H-activating nucleotides in the central part. To activate the mammalian RNase H, a gap size of five[15] to seven[16] unmodified 2′-deoxynucleotides has been suggested.

Selected oligonucleotide analogues

A number of the more promising nucleic acid mimics for the development of successful antisense oligonucleotides are discussed in the following. Emphasis is given to analogues in which the furanose ring is restricted into a distinct conformation by either stereoelectronical or constitutional (sterical) means. Average duplex stabilities for hybridization towards complementary RNA targets are reported as the change in the melting temperature per modified nucleotide (°C per mod.) relative to the corresponding unmodified DNA–RNA reference duplex, the melting temperature being defined as the temperature at which half of the duplex is dissociated as measured by the associated hyperchromic shift at 260 nm.

Phosphorothioates

In 1998, the first antisense drug, Vitravene™ (ISIS-2922), was approved by the FDA for the treatment of cytomegalovirus retinitis in immunocompromised patients.[17] This antisense oligonucleotide consists of phosphorothioate (thiophosphate) nucleotides, in which one of the non-bridging phosphate oxygens is substituted by sulfur (**5**, Fig. 5) resulting in improved nuclease stability while the capability to activate RNase H remains intact. Phosphorothioates are, however, considered as



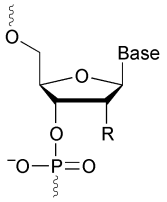
5

Fig. 5 Structure of phosphorothioates.

only 'first generation' antisense oligonucleotides due to less desirable features such as lowered duplex stabilities (approximately −0.8 °C per mod.), the existence of diastereomeric mixtures because of the chirality of the phosphorus atoms, and significant toxicity caused, *e.g.* by non-specific binding to proteins.[18]

Selected 2′-*O*-alkylated RNA derivatives

For 2′-*O*-alkylated RNA derivatives, the *gauche* effect between O2′ and O4′ (along the C1′–C2′ bond) induces a conformational shift towards an *N*-type (C3′-*endo*) furanose conformation resulting in A form duplexes as also seen for unmodified RNA. Provided that the 2′-*O*-alkyl group is not too sterically demanding (*i.e.* alkyls smaller than hexyl),[19] increased duplex stability is observed. A 2′-*O*-Me-RNA monomer (**6A**, Fig. 6)



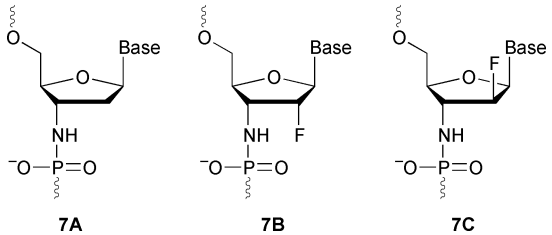
6A R = OCH_3
6B R = $OCH_2CH_2OCH_3$ (MOE)
6C R = $OCH_2CH_2CH_2NH_2$ (AP)

Fig. 6 Structures of selected 2′-*O*-alkylated RNA derivatives.

induces an increase in the melting temperature of *ca.* +0.5 to +1.0 °C per mod.,[20] while 2′-*O*-(methoxyethyl)- (MOE, **6B**) and 2′-*O*-aminopropyl- (AP, **6C**) monomers effect increases of *ca.* +1.0 to +1.5 °C per mod.[20,21] and *ca.* +1.0° C per mod.,[22] respectively. The nuclease stability of the 2′-*O*-Me derivatives is insufficient for antisense purposes,[9] which suggests the use of the more resistant MOE[21] or AP[22] modifications. Because of their preorganization into an *N*-type furanose conformation, none of the 2′-*O*-alkylated derivatives activate RNase H unless a gap-mer strategy is applied.[23]

N3′ → P5′-Phosphoramidates

Replacing the 3′-hydroxy group with an amino group introduces a non-chiral nuclease-resistant phosphoramidate internucleoside linkage. Such a modification (**7A**, Fig. 7) increases duplex



7A **7B** **7C**

Fig. 7 Structures of N3′ → P5′-phosphoramidates.

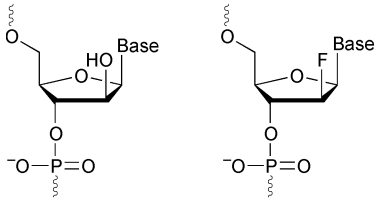
stabilities by +2.3 to +2.6 °C per mod.[24–26] which has been explained by the diminished *gauche* effect from the 3′-nitrogen atom preorganizing the furanose ring into an *N*-type (C3′-*endo*) conformation thus furnishing A-type duplexes with RNA targets as also shown by NMR[27,28] and X-ray studies.[29] Hybridized to RNA, fully modified phosphoramidates do not activate RNase H,[30] but this problem can be circumvented by the use of a gap-mer sequence with unmodified DNA monomers in the central gap[31] and also of a phosphoramidate mix-mer with alternating phosphoramidate and unmodified phosphordiester nucleotides.[32] The gap-mer phosphoramidates showed a lack of antisense activity which might be ascribed to the endonucleolytic degradation of the deoxynucleotide gap[9] while only fully modified phosphoramidates showed an RNase H-independent antisense activity.[31]

2′-Substitution with a *ribo*-configured fluorine atom (**7B**, *ribo*-configuration, Fig. 7) constrains the furanose ring entirely to a C3′-*endo* conformation due to the strong *gauche* effect from fluorine and induces increased duplex stabilities with as much as +4 to +5 °C per mod.[33] The RNA analogue of **7B** (a 2′-OH group instead of the fluorine atom) likewise afforded increased duplex stabilities (*ca.* +0.5 °C per mod.) relative to the parent phosphoramidates **7A**.[34] The *arabino*-configured 2′-fluoro phosphoramidate **7C**, too, displayed increased duplex stabilities (*ca.* +0.5 °C per mod.) relative to phosphoramidates **7A**, and, despite the opposing *gauche* effect from the 2′-fluoro substituent, a preorganized C3′-*endo* conformation, as shown by the analysis of coupling constants for trimers, still accounts for the improved hybridization properties.[35]

The results obtained for the various phosphoramidates convincingly demonstrate that stereoelectronic preorganization into a C3′-*endo* furanose conformation can be applied to induce increased duplex stabilities. It should be mentioned, though, that a considerable sequence-variation has been observed and that, *e.g.* increases as small as +0.6 °C per mod. have been reported for fully modified unsubstituted phosphoramidates **7A**.[36] A point of concern with phosphoramidates is their more difficult incorporation into oligonucleotides with step-wise coupling yields in the range of 94–97%.[25,33,35]

Arabino nucleic acids and 2′-fluoroarabino nucleic acids (ANA and 2′-F-ANA)

The inversion of the configuration around C2′ of natural RNA gives arabino nucleic acids (**8A**, Fig. 8) which show decreased



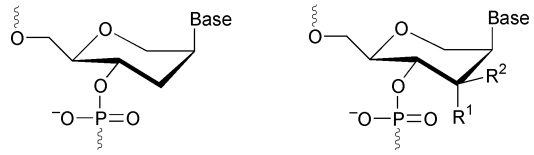
8A **8B**

Fig. 8 Structures of arabino nucleic acids.

duplex stabilities when hybridized to RNA while the corresponding 2′-fluoroarabino nucleic acids (**8B**), by contrast, enhance duplex stabilities by *ca.* +1.0 °C per mod.[37,38] The very interesting feature of both these modifications is that they were the first fully modified oligonucleotides with a chemically modified carbohydrate moiety to act as substrates for RNase H.[37–39] Their conformational similarity with natural DNA might account for this since duplexes, when hybridized to RNA, resemble an intermediate DNA–RNA duplex form as shown by CD spectroscopy.[38] The 2′-fluoro analogue **8B** adopts the O4′-*endo* furanose conformation when incorporated into DNA as shown by X-ray structure analysis.[40,41] In addition, molecular modelling[39,41] and NMR studies[39] of a fully modified 2′-F-ANA strand hybridized to RNA have confirmed an intermediate duplex form with a minor groove width intermediate between the minor groove widths of the standard A- and B-forms. The nuclease stability of the ANAs is improved compared with unmodified DNA though not as much as for the phosphorothioates.[37,39]

Hexitol nucleic acids (HNA)

Pyranose derivatives in general adopt one predominant conformation due to higher energy barriers for interconversion of ring conformers relative to furanose derivatives. To date, the 1′,5′-anhydrohexitol nucleic acids (HNA, **9A**, Fig. 9) and



9A **9B** R^1 = OH, R^2 = H
9C R^1 = H, R^2 = OH

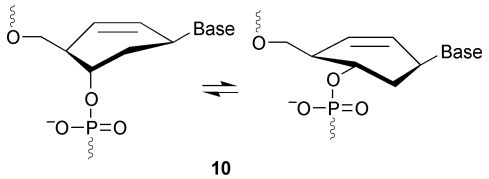
Fig. 9 Structures of hexitol nucleic acids.

derivatives constitute the most promising antisense candidates based on a pyranose moiety. Structurally, their substitution pattern makes them very good mimics of nucleotides preorganized into an *N*-type (C3′-*endo*) furanose conformation thus yielding A-type duplexes when hybridized to RNA as shown by CD spectroscopy,[42] molecular dynamics simulations,[43] and NMR studies.[44] Fully modified HNA displays enhanced duplex stabilities (typically +3.0 °C per mod.)[45] while sequence-specific variations of increases of duplex stabilities ranging between +0.9[45] and +5.8[42] °C per mod. have been observed. HNA acts only as a very poor substrate for RNase H,[42] while its nuclease-resistance[45] still allows it to display antisense effects ascribed to a mechanism of steric blocking.[46]

Interesting derivatives of HNA are the 1,5-anhydro-2-deoxy-D-altritol nucleic acids with an additional axial hydroxy group in the 3′-position (**9B**, Fig. 9) which show slightly enhanced duplex stabilities relative to HNA.[47] The altritol nucleic acids were designed to increase the surface hydrophilicity of the duplex thereby favouring duplex formation by improved hydratization.[8] In contrast, the inversion of configuration at the 3′-position, affording the corresponding 1,5-anhydro-2-deoxy-D-mannitol nucleic acids, leads to significantly reduced stability of duplexes with RNA[48] and obviously imposes a restricted conformation unfavourable for duplex formation.

Cyclohexene nucleic acids (CeNA)

Noteworthy results have been obtained for the conformationally rather flexible cyclohexene nucleic acids (CeNA, **10**, Fig. 10)



10

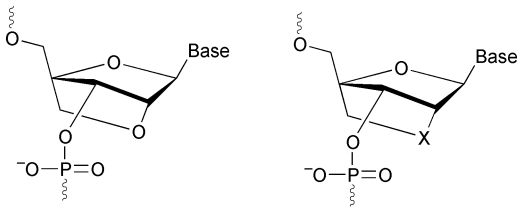
(*S*-type mimic) (*N*-type mimic)

Fig 10 Structure and conformational equilibrium of cyclohexene nucleic acids.

with a conformational equilibrium shifted towards *N*-type at the nucleoside level as shown by NMR and modelling studies (Fig. 10).[49] When incorporated into DNA strands, cyclohexene nucleotide monomers **10** induce increased duplex stabilities (+0.8 to +1.7 °C per mod.). Fully modified CeNA are nuclease-resistant and activate RNase H. The latter property establishes CeNA, next to ANA (Fig. 8), as the second fully modified oligonucleotide analogue with an altered carbohydrate part able to induce an RNase H cleavage of the target RNA strand.[50] This has been explained by the flexible conformational behaviour of the cyclohexane nucleotides allowing a $^2H_3$ (*S*-type mimic) conformation when hybridized to DNA and a $^3H_2$ (*N*-type mimic) conformation when hybridized to RNA as supported by CD spectroscopy, NMR studies of DNA duplexes with one cyclohexene nucleotide in each strand, and molecular dynamics simulations.[50]

Locked nucleic acids (LNA)

The synthesis of nucleosides and oligonucleotides containing furanose rings efficiently locked into a C3′-*endo* conformation has been accomplished by the introduction of an oxymethylene linkage between the C2′ and C4′ atoms generating the bicyclic locked nucleic acid (LNA, **11A**, Fig. 11). The incorporation of



11A **11B** X = NH
11C X = S

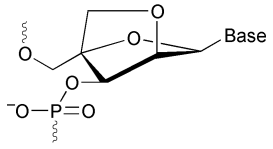
Fig. 11 Structures of locked nucleic acids (LNA), 2′-amino LNA and 2′-thio LNA.

one or more LNA monomers, or the use of fully modified LNA, induces unprecedented increases in duplex stabilities (typically +3.0 to +11.0 °C per mod.).[51–54] The preorganization into a C3′-*endo* furanose conformation has been demonstrated at the nucleoside level by X-ray crystallography[55] as well as NMR studies[51,52] and also by NMR studies at the oligonucleotide level both when hybridized to DNA[56–58] and RNA, the latter yielding the expected A-type duplexes.[59] LNA monomers in partly modified strands were shown to strongly preorganize flanking unmodified DNA nucleotides into *N*-type–C3′-*endo* furanose conformations and single-stranded LNA into an RNA-like conformation.[58,59] Fully modified[51] and mix-mer LNA consisting of alternating LNA and DNA monomers[60] have proved to be nuclease-resistant, and an antisense effect has been demonstrated in living rats.[60] LNA activates RNase H as gapmers[60] but not as fully modified strands.[60,61]

The LNA-type constitution leads in general to efficient C3′-*endo* preorganization and favoured duplex formation which has been demonstrated by the hybridization properties (+3.0 to +8.0 °C per mod.) obtained for the heteroatom derivatives 2′-amino-LNA[62] (**11B**, Fig. 11) and 2′-thio-LNA[63] (**11C**). A related C2′-methylene extended bicyclic nucleoside (thus containing a 2-oxapropylene linker between the O2′ and O4′ atoms), shown by X-ray crystallography and NMR studies at the nucleoside level likewise to be restricted into a C3′-*endo* furanose conformation,[64] induced less dramatic but still significantly increased duplex stabilities (+1.9 to +3.3 °C per mod.).[65]

α-L-LNA—a selected LNA stereoisomer

The inversion of the configuration around C3′ and/or C2′ and C4′ of LNA afforded three LNA stereoisomers which have been evaluated with respect to RNA binding.[66] Of these, 'α-L-LNA' (α-L-*ribo* configured LNA, **12**, Fig. 12) with inverted config-



12

Fig. 12 Structure of α-L-LNA.

uration around C2′, C3′ and C4′ compared to LNA, showed the most promising properties with respect to duplex formation as

shown by increased duplex stabilities of +4.3 to +5.7 °C per mod. for both partly and fully modified strands.[66–68] NMR and molecular modelling studies on duplexes of partly or fully modified α-L-LNA hybridized to DNA or RNA have established α-L-LNA as a DNA mimic and, in addition, that an α-L-LNA–RNA duplex adopts an overall conformation intermediate between the A and B form.[69–71] The possibility of RNase H activity has therefore been evaluated. Fully modified and mixmeric (consisting of alternating α-L-LNA and unmodified DNA nucleotides) α-L-LNA showed cleavage, albeit very slow, of the RNA targets at high enzyme concentrations.[61]

Summary and outlook

For efficient antisense action by the steric blocking mechanism, the use of antisense oligonucleotides containing preorganized furanose rings with *N*-type (C3′-*endo*, RNA-like) conformations and high binding affinities towards RNA target strands appears optimal. In contrast, the mechanism involving activation of RNase H demands analogues adopting *S*-type (C2′-*endo* or O4′-*endo*, DNA-like) furanose conformations.[2,41] It therefore appears impossible to take advantage of both mechanisms effectively with only one single nucleotide modification.

Despite the above points, the necessary armamentarium of chemically modified building blocks for development of efficient antisense therapeutics appears at hand. LNA, α-L-LNA and phosphoramidates, among others, offer excellent binding affinities towards RNA targets. In addition, as shorter strands (*e.g.* 10–14 nucleotides long) can be applied, good to excellent pairing selectivities are in general obtained. The binding affinity and pharmacokinetic properties are tuneable by combining these affinity-enhancing key nucleotide building blocks with, *e.g.* DNA, RNA, phosphorothioate-DNA, phosphorothioate-LNA, 2′-amino-LNA (or conjugated derivatives thereof), and 2′-*O*-alkyl-RNA nucleotides which have all been demonstrated to be applicable in DNA–LNA duplexes.[62,63,69] Whether the recruitment of RNase H is essential for efficient and general antisense action with these strongly RNA-binding nucleic acid mimics is currently not established. If RNase H activity turns out to be needed or beneficial, it is foreseen that the combination of one or more segment(s) of conformationally restricted or conformationally locked high-affinity *N*-type oligonucleotide(s) with a segment of nuclease-resistant, RNase H-activating *S*-type nucleotides with lower affinities should be ideal. A gap-mer structure is of course one possibility, but with the discovery of LNA and other extreme RNA-binders alleviating the need for binding cooperativity between the different segments, many other architectures appear possible. However, biological studies and pharmacological developments are needed to confirm these predictions.

The results obtained with ANA (**8**, Fig. 8), HNA (**9**, Fig. 9) and α-L-LNA (**12**, Fig. 12) are remarkable and need consideration. Firstly, very efficient RNA-binding is evidently possible for analogues based on a furanose skeleton with a non-natural stereochemical structure, or on an RNA-mimicking hexitol scaffold. Especially noteworthy is the dramatic RNA-binding of the α-L-*ribo* configured α-L-LNA in which the configuration at three out of the four chirality centers is inverted compared with RNA (or LNA). In addition, fully modified HNA and fully modified or mix-meric α-L-LNA have been demonstrated to induce very weak, but significant, RNase H activity. Results like these leave ample room for further curiosity-driven chemistry-based research on modified nucleic acids.

The pentadecadentate phosphazenate $[\{2\text{-}(MeO)C_6H_4N\}_6P_3N_3]^{6-}$: chelation of twelve lithium ions by a single ligand

Frederic Rivals and Alexander Steiner*

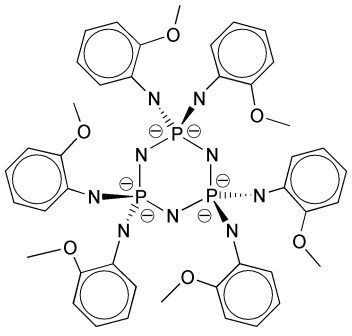
Department of Chemistry, University of Liverpool, Crown Street, Liverpool, UK L69 7ZD. E-mail: a.steiner@liv.ac.uk

Received (in Cambridge, UK) 10th May 2001, Accepted 21st June 2001
First published as an Advance Article on the web 19th July 2001

The hexaprotic phosphazene $\{2\text{-}(MeO)C_6H_4NH\}_6P_3N_3$ reacts with 12 equivalents of Bu^nLi in thf to give the monomeric dodecanuclear complex $(thf)_6Li_{12}[\{2\text{-}(MeO)C_6H_4N\}_6P_3N_3](CH_2{=}CHO)_6$ which contains six enolate anions resulting from fragmentation of thf; the hexaanionic pentadecadentate phosphazenate ligand $[\{2\text{-}(MeO)C_6H_4N\}_6P_3N_3]^{6-}$ accommodates a total of twelve lithium ions in bidentate chelation sites.

Ligands able to carry a high metal load (> 10 metal centres) have scarcely been investigated, although such systems bear the potential to stabilise well-defined multinuclear metal arrays. In contrast, a multinuclear metal arrangement held together by several counter ions in an oligomeric complex usually shows pronounced dynamic behaviour. Particularly, alkaline metal complexes are highly fluxional and their oligomerisation grades strongly depend on the nature of donor additives.[1] Recently, we have shown that cyclophosphazenes equipped with primary amino groups act as multiprotic acids in the presence of organometallic reagents yielding multianionic phosphazenates, highly charged ligands which complex multinuclear metal arrangements.[2–5] We observed that lithiated phosphazenates attract excess lithium ions and accommodate them by either dimer formation[3,4] or insertion of lithium enolate that is generated by fragmentation of thf.[5]

With the aim to increase the maximum metal load of phosphazenates we equipped the ligand with additional donor sites. The hexaanionic phosphazenate $\mathbf{A}^{6-}$ presented here



$\mathbf{A}^{6-}$

carries six *ortho*-anisidyl substituents and features an overall pentadecadentate ligand surface comprising nine N and six O donor functions. The ligand precursor $H_6\mathbf{A}$ (**1**) was synthesised by reaction of excess *ortho*-anisidine with hexachlorocyclotriphosphazene in the presence of triethylamine.† We have reacted **1** with 12 equivalents of Bu^nLi in thf in order to both deprotonate all six NH-functions and incorporate the excess Bu^nLi or lithium enolate into the ligand sphere of $\mathbf{A}^{6-}$. The reaction yields a white precipitate that re-dissolves upon heating. Crystallisation occurs on leaving the solution to cool to room temperature.‡ Spectroscopic data and X-ray structure analysis§ reveal the formation of the monomeric complex $(thf)_6Li_{12}\mathbf{A}(CH_2{=}CHO)_6$ **2** (Fig. 1), which contains six enolate and twelve lithium ions.

$$\underset{\mathbf{1}}{H_6\mathbf{A}} + 12\ Bu^nLi + 12\ thf \longrightarrow \underset{\mathbf{2}}{(thf)_6Li_{12}\mathbf{A}(CH_2{=}CH\text{-}O)_6} + 12\ C_4H_{10} + 6\ C_2H_4$$

^{31}P NMR spectroscopy shows a single peak at δ 16.4 and the P–N-ring stretching frequency appears as a very strong and broad band with a maximum at 1077 cm^{-1} in the IR spectrum which is considerably red shifted compared to that of **1** (1186 cm^{-1}). The ligand $\mathbf{A}^{6-}$ accommodates a total of twelve lithium ions in bidentate chelation sites. To our knowledge this is the largest number of s-block metal ions being chelated by a single ligand in a molecular complex.

Complex **2** crystallises in space group $R\bar{3}c$ with eight lattice bound thf molecules per formula unit and exhibits D_3 symmetry. The central P_3N_3 ring is arranged around the three-fold axis and each phosphorus along with the opposite ring N atom is located on a two-fold axis. The nine anionic N-centres and six O-donor atoms of the ligand form two large, bowl shaped, nonadentate cavities on either side of the central P_3N_3 ring providing an ideal coordination geometry for the accommodation of twelve lithium ions: six lithium ions (Li1) reside at 'inner' coordination sites represented by six N_{exo}–P–N_{endo} chelates. The other six lithium ions (Li2) occupy the 'outer' sites, which are the N_{exo}–O chelates of the anisidyl groups. The negative charge of the hexaanion is distributed over all nine N-atoms, each binds two lithium ions, the N_{endo} atom (N1) two 'inner' lithium ions and the N_{exo} atom (N2) one 'inner' and one 'outer' lithium ion, respectively. In addition, each 'inner' lithium is coordinated by one thf molecule (O3) and one enolate ion (O1); each 'outer' lithium by the O-donor function of the ligand (O2) and two enolate ions. All lithium ions are coordinated in a tetrahedral fashion. The ^7Li NMR spectrum of **2** recorded in thf at room temperature exhibits two signals at δ 2.15 and 2.81. This suggests that the presence of two non-equivalent lithium ions is retained in solution.

Bond lengths and angles of the P_3N_9 core in **2** are in agreement with those we found in other lithium phosphaze-

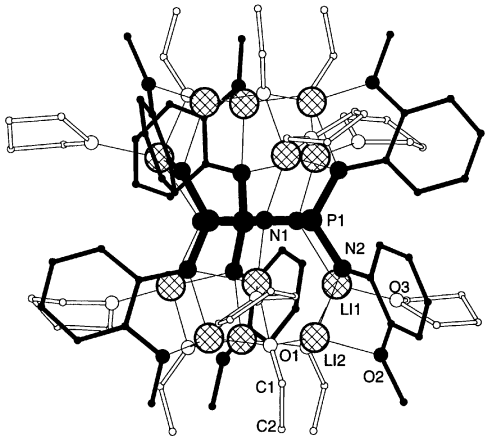


Fig. 1 X-Ray crystal structure of **2**. The $\mathbf{A}^{6-}$ ligand is drawn in black, thf and enolate moieties in white and lithium ions hatched.

 DOI: 10.1039/b104124j

nates.[3,4] P–N_{endo} and P–N_{exo} bonds are of similar length [1.638(2) and 1.637(3) Å, respectively], and the N_{exo}–P–N_{exo} angle [115.0(2)°] is similar to the N_{endo}–P–N_{endo} angle [113.4(3)°], showing equal P–N_{endo} and P–N_{exo} bond orders and distribution of negative charge over all nine N-atoms. In contrast, the neutral precursor **1** exhibits long P–N_{exo} bonds (av. 1.65 Å) and short P–N_{endo} bonds (av. 1.59 Å); and *endo* angles (av. 115°) are wider than *exo* angles (av. 104°) indicating a higher bond order in the P_3N_3 ring of **1**.§ Surprisingly, the central P_3N_3 ring in **2** is planar, which is in contrast to all other lithiated cyclotriphosphazenates we have investigated so far. All contain highly puckered central P_3N_3 rings of chair conformation. The P–N–P angle of **2** is 126.6(3)° and thus considerably wider than those observed in hexaanionic $[(CyN)_6P_3N_3]^{6-}$,[3] trianionic $[(CyNH)_3(CyN)_3P_3N_3]^{3-}$, $[(PhNH)_3(PhN)_3P_3N_3]^{3-}$,[4] and neutral H_6**A**, which are all around 120°. This shows that the P–N–P angle is rather flexible allowing a planar configuration of the central P_3N_3 ring in hexaanionic **2**.

We monitored the reaction of **1** with Bu^{n}Li in thf using ^{31}P NMR spectroscopy. Addition of 3 equivalents of Bu^{n}Li exclusively gives trianionic H_3**A**$^{3-}$ as indicated by a single peak at δ 8.7. Addition of 6 equivalents of Bu^{n}Li leads to three broad peaks at δ 13.1, 19.1 and 22.2 suggesting that the fully deprotonated species **A**$^{6-}$ is not present so far. However, **A**$^{6-}$ begins to form after addition of around 8 equivalents of Bu^{n}Li, as shown by the appearance of a sharp single peak at δ 16.4 amongst a pattern of broader signals. Finally there is only one single peak at δ 16.4 after addition of 12 equivalents Bu^{n}Li. This implies that both deprotonation of NH functions and enolate formation occur simultaneously once 3 equivalents of Bu^{n}Li are added.

The fragmentation of thf by Bu^{n}Li, which produces lithium ethenolate and ethylene, is well known[6] and also adduct formation of LiO–CH=CH_2 was observed in solid state structures of lithium complexes containing tetraanionic ligands.[5,7] However, the inclusion of six lithium enolate moieties into a molecular complex is unprecedented. We assume, once the ligand acquires a certain charge it acts as a 'Li$^+$ sponge': Bu^{n}Li is dragged into an 'outer' *N,O*-chelation site, which contains an already deprotonated *N*-function, and fragments a thf molecule, which is coordinated to a neighbouring 'inner' lithium ion. The resulting enolate ions are not sufficiently basic to deprotonate H_xA^{x-6} (x = 1, 2) any further, but remain within the complex by forming μ_3-bridges between one 'inner' and two 'outer' lithium ions.

Summarising, the generation of a ligand system with high metal loading capacity has been accomplished by combining the features of a multianionic ligand core with a multidentate ligand surface. The hexaanionic pentadecadentate phosphazenate ligand **A**$^{6-}$ accommodates twelve lithium ions in bidentate chelation sites. Currently, we are investigating self-assembly properties of this new ligand system in the presence of LiX, where X represents a monodentate monoanion (*e.g.* halide, alkoxide, amide, carbanion), potentially leading to complexes $Li_{12}A_6X_6$. Such systems promise interesting template effects, due to the potentially well-defined array of both lithium ions and counter ions X. In addition, the straightforward introduction of a variety of substituents into phosphazenes[8,9] might facilitate the generation of a wide range of other high metal loading ligands based on multidentate phosphazenates.

† *Preparation* of **1**: to a solution of 10 g hexachlorocyclotriphosphazene in 100 ml of toluene was added 40 ml of *ortho*-anisidine and 100 ml of triethylamine. The mixture was refluxed for several days (^{31}P NMR control). The solution was allowed to cool to room temperature, separated by filtration from the precipitate, which was washed with toluene. All volatile components of combined filtrates were removed *in vacuo*. The resulting residue was washed with hot hexane to give a white powder, which was re-crystallised from thf–hexane. Yield: 19.7 g (79%), mp 175 °C, ^{1}H NMR (300 MHz, d_8-thf) δ 3.55 (s, 18H, OCH_3), 5.72 (m, 6H, NH), 6.55 (m, 6H, aryl-H), 7.42 (m, 18H, aryl-H); ^{13}C{^{1}H} NMR (75.46 MHz, d_8-thf) δ 56.4 (OCH_3), 111.29, 119.10, 121.44, 121.90, 132.59, 149.72 (aromatic C); ^{31}P NMR (101.25 MHz, d_8-thf, 85% H_3PO_4 in D_2O ext.) δ 5.1; IR (Nujol) ν/cm^{-1} 3385 (N–H), 1596, 1247, 1186 (P–N-ring), 1111, 1026, 870, 734.

‡ *Preparation* of **2**: to a solution of **1** (300 mg, 0.345 mmol) in 20 ml of thf was added Bu^{n}Li (2.6 ml, 1.6 M in hexane, 4.14 mmol). The solution was stirred overnight at room temperature forming a white precipitate, which was re-dissolved by gentle heating. On cooling to room temperature colourless crystals formed, which disintegrated in the absence of mother-liquor by losing lattice bound thf to give a white powder. Yield: 340 mg (88%), decomp. >180 °C; ^{1}H NMR (300 MHz, d_8-thf) δ 3.79 (s, 18H, OCH_3), 3.41 (d, 6H, $^3J_{cis}$ 5.4 Hz, HC=), 3.96 (d, 6H, $^3J_{trans}$ 13.9 Hz, HC=), 6.05–6.47 (m, 18H, aryl-H), 6.51 (dd, 6H, $^3J_{cis}$ 5.4, $^3J_{trans}$ 13.9, =CHO), 7.55 (dd, 6H, aryl-H); ^{13}C{^{1}H} NMR (75.46 MHz, d_8-thf) δ 56.3 (OCH_3), 86.1 (=CH_2), 109.5, 114.2, 120.0, 123.1, 144.3, 150.9 (aromatic C), 159.2 (OCH=); ^{31}P NMR (101.25 MHz, thf, 85% H_3PO_4 in D_2O ext.) δ 16.43; ^{7}Li NMR (97.16 MHz, thf, LiCl in D_2O ext) δ 2.15, 2.81; IR (Nujol) ν/cm^{-1} 1621, 1590, 1377, 1316, 1282, 1258, 1216, 1178, 1077 (P–N-ring), 1056, 1030, 826, 781, 736, 634.

§ Crystallographic data were recorded on a Stoe-IPDS using Mo-Kα radiation (λ = 0.71073 Å), T = 200 K, structures were solved by direct methods and refined by full-matrix least squares against F^2 using all data (SHELX-97).

Crystal data: for **1**·0.5thf: M = 903.96, triclinic, $P\bar{1}$, a = 11.570(2), b = 12.059(2), c = 18.076(3) Å, α = 77.42(2), β = 79.85(2), γ = 67.35(2)°, U = 2259.4(5) Å^3, Z = 2, D_c = 1.329, μ(Mo-Kα) = 0.148, 6717 unique reflections. R_1 [$I > 2\sigma(I)$] = 0.037, wR_2 (all data) = 0.068.

For **2**·8thf: M = 2212.76, rhombohedral, $R\bar{3}c$, a = 14.506(8), c = 100.883(11) Å, U = 18384(2) Å^3, Z = 6, D_c = 1.199, μ(Mo-Kα) = 0.119, 2647 unique reflections, R_1 [$I > 2\sigma(I)$] = 0.069, wR_2 (all data) = 0.205. C-positions of coordinated thf are disordered and were split in two positions. There are 1⅓ lattice bound thf molecules per asymmetric unit: thf on general site is disordered and its C and O atoms were split in three positions, thf on 3 is disordered around the 3-axis generating three positions per atom. Disordered groups were refined using similar distance and similar U restraints and site occupancy factors. All non-H atoms were refined anisotropically, except lattice bound thf molecules, which were treated isotropically. H atoms were fixed in calculated positions on the parent C atoms.

Received (in Cambridge, UK) 24th April 2001, Accepted 20th June 2001
First published as an Advance Article on the web 19th July 2001

Two types of macrocyclic multi-telluranes with hypervalent Te–O apical linkages in the main chain were prepared by the reaction of a telluronium salt or a cationic ditelluroxane with phthalate *via* [3 + 3] and [2 + 2] assembly, respectively.

One of the characteristics of organic heteroatom chemistry is the formation of hypervalent compounds.[1] Telluranes have the trigonal bipyramidal geometry, in which the two apical ligands and the central Te atom construct a three-center–four-electron hypervalent bond with *ca.* 180° bond angle. A strategy for the formation of hypervalent telluranes is the use of n→σ* orbital interaction, where the σ* orbital of the Te–X bond of a telluronium salt interacts with the n orbital of a lone pair of electrons of a ligand.[1] In supramolecular chemistry, the field of macrocycles has advanced to the stage where self-assembly through transition-metal coordination has proved to be a reliable tool.[2] Hypervalent bonds *via* n→σ* orbital interactions in heteroatoms may also be a viable alternative for self-assembled macrocycles.[3–7] Recently, we have found that the cationic ditelluroxane **2** interacts with triflate as a counter ion in the solid state and with telluroxide in solution to form a pseudo-macrocyclic multi-tellurane and oligotelluroxanes, respectively, with hypervalent Te–O apical linkages *via* n→σ* orbital interaction.[8] Herein we report the synthesis of the macrocyclic multi-telluranes **4** and **5** by the reaction of the telluronium salt **1** or the cationic ditelluroxane **2** as building blocks with phthalate **3** as a convergent bidentate ligand. This is the first example of macrocycles composed of only hypervalent apical linkages in the main chain for group 13–17 elements, which are fully characterized both in solution and in the solid state.

The generation of the telluronium salt **1** *in situ* by the reaction of bis(4-methylphenyl) telluroxide with 1 equiv. of triflic anhydride in MeCN at −40 °C followed by the addition of 1 equiv. of sodium phthalate **3** at room temperature gave the hypervalent macrocycle **4** in 76% yield after recrystallization [Scheme 1(a)].§ Treatment of the cationic ditelluroxane **2** with 1 equiv. of **3** in MeCN at room temperature produced the hypervalent macrocycle **5** in 14% yield after recrystallization [Scheme 1(b)].§

The ^{125}Te NMR spectra of **4** and **5** in CD_2Cl_2 showed singlets at δ 997.0 and 1044.4, respectively, which are in the region of telluranes with hypervalent Te–O_2C apical bonds.[9] The ^{1}H NMR spectra of **4** and **5** exhibited doublet, double-doublet, double-doublet, and doublet peaks in the aromatic region in the integration ratios of 2 : 1 : 1 : 2 and 4 : 1 : 1 : 4, respectively. The IR spectrum of **5** showed the characteristic Te–O–Te stretching band at ν 639 cm^{-1}.[10] These data imply that **4** is the result of [3 + 3] assembly of **1** and **3** to give a 21-membered ring, and **5** is the result of [2 + 2] assembly of **2** and **3** to form an 18-membered ring; both structures are composed of the hypervalent Te–O apical linkages in the main chain. The FAB-MS spectra of **4** and **5** showed a parent peak at *m/z* 1423 ([M + H]$^+$) and at 1601 ([M + H]$^+$), respectively, the isotopic distribution patterns of which are consistent with the calculated ones. Distinctive fragment peaks also appeared at *m/z* 801 and 477 in both cases and at *m/z* 1509 and 1275 in **5**.

The ^{1}H and ^{125}Te NMR spectra of **4** and **5** in CD_2Cl_2 and CD_3CN remained unchanged in the range −90 to 80 °C. NOE experiments on **4** and **5** indicated −24 and −19% NOEs, respectively, at the *ortho*-hydrogens of the phthalate unit upon irradiation of the *ortho*-hydrogens of the *para*-tolyl unit. These results indicate that the cyclic structures of **4** and **5** are maintained in solution.

The molecular structures of the hypervalent macrocycles **4** and **5** were determined by X-ray crystallographic analysis, as shown in Fig. 1 and 2, respectively.¶‖ The macrocycle **4** is composed of three Te atoms and three phthalates, and possesses Te–O_2C bond lengths of 2.133–2.166 Å, CO_2–Te–O_2C bond angles of 161.8–168.3° and C–Te–C bond angles of 96.2–100.3°. The macrocycle **5** consists of two ditelluroxanes and two phthalates, and the unit cell contains four independent molecules.‖ The respective average bond lengths and angles are in the range of 2.23–2.29 Å for Te–O_2C, 1.99–2.03 Å for Te–O, 166.1–168.7° for O–Te–O_2C, 96–101° for C–Te–C and 114–126° for Te–O–Te. These data clearly indicate that both **4** and **5** have trigonal bipyramidal geometry for the Te atoms and hypervalent Te–O apical bonds.[11] In both cases, all the atoms of the respective macrocyclic rings are roughly coplanar. The halves of the carbonyl O atoms and the tolyl groups are directed inward and outward, respectively, to the respective macrocyclic rings. By contrast, the other halves of the carbonyl O atoms and the tolyl groups are vertically directed to the respective

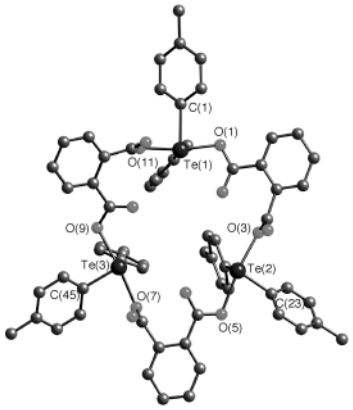

Fig. 1 Structure of **4** in the crystal; hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Te(1)–O(1) 2.166(4), Te(1)–O(11) 2.133(4), Te(2)–O(3) 2.141(4), Te(2)–O(5) 2.163(4), Te(3)–O(7) 2.151(4), Te(3)–O(9) 2.144(4); O(1)–Te(1)–O(11) 161.8(2), O(3)–Te(2)–O(5) 168.3(2), O(7)–Te(3)–O(9) 165.6(2), C(1)–Te(1)–C(8) 100.3(2), C(23)–Te(2)–C(30) 96.2(2), C(45)–Te(3)–C(52) 98.9(2).

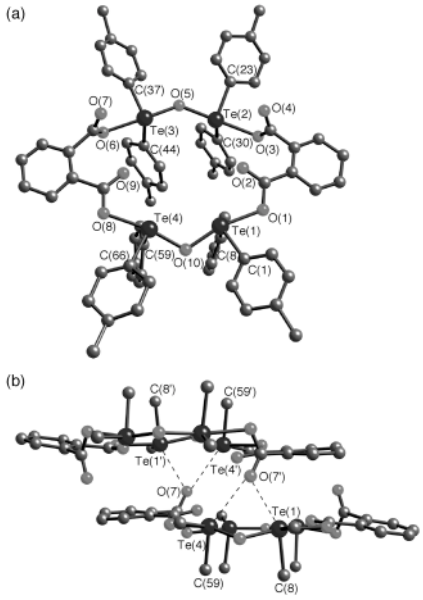

Fig. 2 (a) Structure of **5** and (b) its dimeric structure in the crystal; hydrogen atoms in (a) and (b) and *p*-tolyl groups in (b) are omitted for clarity. Selected average bond lengths (Å) and angles (°): Te(1)–O(1) 2.28(2), Te(2)–O(3) 2.23(2), Te(3)–O(6) 2.27(2), Te(4)–O(8) 2.29(2), Te(1)–O(10) 2.03(2), Te(4)–O(10) 2.01(2), Te(2)–O(5) 2.01(2), Te(3)–O(5) 1.99(2), O(7′)···Te(1) 2.95, O(7′)···Te(4) 3.20; O(1)–Te(1)–O(10) 166.6(7), O(3)–Te(2)–O(5) 167.2(7), O(5)–Te(3)–O(6) 168.7(7), O(8)–Te(4)–O(10) 166.1(8), C(1)–Te(1)–C(8) 96(1), C(23)–Te(2)–C(30) 101(1), C(37)–Te(3)–C(44) 98(1), C(59)–Te(4)–C(66) 98(1), Te(1)–O(10)–Te(4) 114(1), Te(2)–O(5)–Te(3) 126(1), O(7′)···Te(1)–C(8) 153, O(7′)···Te(4)–C(59) 149.

macrocyclic ring planes so as to be placed at the opposite side. It is noted that the Te(1) and Te(4) atoms in **5** interact with the carbonyl O(7′) atom of the adjacent molecule [O(7′)···Te(1) 2.95 and O(7′)···Te(4) 3.20 Å; O(7′)···Te(1)–C(8) 153 and O(7')···Te(4)-C(59) 149°],[12] the contact distances of which are shorter than the sum of the van der Waals radii (3.60 Å) of the Te and O atoms. Thus, **5** forms a head-to-head type of dimeric structure in the solid state [Fig. 2(b)].

In summary, we have demonstrated the synthesis of macrocyclic multi-telluranes **4** and **5** with hypervalent Te–O apical linkages in the main chain. Hypervalent bonds *via* n→σ* orbital interaction in heteroatoms can serve as a new supramolecular synthon for molecular assembly. Studies on the synthesis of hypervalent polymers using the building blocks **1** and **2** with divergent bidentate ligands are underway.

‖ Compound **4** has some high thermal parameters for the solvent molecules. The structural parameters for compound **5** reported here are still preliminary. Even from the data collected at −150 °C we have not yet obtained satisfactory parameters because of the severe disorder. Although the final level of refinement has not yet been reached, we believe the data obtained here is significant enough to demonstrate the molecular structure of **5**.

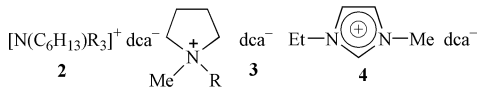
New families of salts *viz*. quaternary ammonium, *N*-alkyl-*N*-methylpyrrolidinium or 1-alkyl-3-methylimidazolium dicyanamides, $Cat^+N(CN)_2^-$, are low melting compounds, most being liquid at rt, water-miscible and have low (for ionic liquids) viscosity at rt, *e.g.* η = 21 cP for 1-ethyl-3-methylimidazolium dicyanamide.

Currently, many chemically inert ionic liquids, which are of interest as media in Green Chemistry,[1] have viscosities much higher than those of solvents normally used in synthesis. Thus the search for new, more versatile ionic liquids is driven in part by the need for materials of lower viscosity. High viscosities not only lead to handling difficulties *e.g.* in filtration, decantation, and dissolution, but may also lead to reduced reaction rates and competitive unimolecular side reactions. One of the most fluid, inert of families of ionic liquids is that based on the bis(trifluoromethanesulfonyl)amide, $N(Tf)_2^-$ ion,[2] for example, 1-ethyl-3-methylimidazolium bis(trifluoromethanesulfonyl)-amide (**1**) (η = 34 cP 20 °C;[2a] *cf.* H_2O, 1 cP; toluene 0.59 cP).

1 $N(Tf)^-_2 = N(SO_2CF_3)_2$

There is also a need for donor solvent characteristics. We now report several new series of salts based on the dicyanamide (dca) anion, *viz*. quaternary ammonium, pyrrolidinium, and imidazolium dicyanamides (**2**–**4**), most of which are liquids at rt. These have a different solubility profile from the corresponding bis(trifluoromethanesulfonyl)amides, potential donor characteristics as the anion is a powerful ligand,[3] and, in representative cases, lower viscosity.

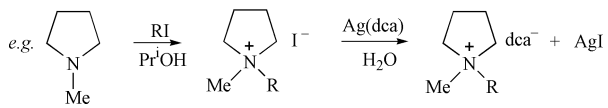


2 **3** **4**

dca = $N(CN)_2$

Quaternary iodide salts of triethylamine, tributylamine, *N*-methylpyrrolidine, and 1-methylimidazole were prepared by reported methods,[2,4] and were converted into the corresponding dicyanamides by reaction with a slight excess of silver dicyanamide in water or ethanol (Scheme 1).

Filtration to remove AgI and evaporation of water under vacuum gave the ionic liquid. Preparative details for two examples are provided;† more extensive details and discussion of properties will be published elsewhere.[5] Identification was by ^{1}H NMR and positive and negative electrospray MS.† The possible presence of residual I^- and Ag^+ were examined *via* inspection of the appropriate mass regions of the respective mass spectra. The sensitivity of the MS measurement to trace amounts of I^- was determined by spiking the ionic liquids with known iodide concentrations; the noise limited detection limit was thereby found to be 0.5% (w/w) I^-. No discernable I mass peaks were found in the dca salts, therefore indicating a residual I content of < 0.5% (w/w). The same considerations and lack of a detectable signal indicate residual Ag < 0.5% (w/w). It is known[6] that impurities such as halides and water can have an effect on properties such as viscosity, though the effect of water in particular is expected to be more dramatic when the viscosity differs greatly from that of pure water (*e.g.* emim BF_4[6]). After rigorous final drying, compounds were handled in a nitrogen drybox during preparation of thermal analysis samples. Viscosity measurements were carried out in a drybox.



Scheme 1

Thermal properties of the salts were investigated by differential scanning calorimetry. All of the dca salts, except the *N*,*N*-dimethylpyrrolidinium compound, are liquids at rt with well defined mps below 0 °C (Table 1), providing a large liquid range. Notably, the mps are 20–30 °C or even more below those of the corresponding salts,[2a] perhaps an unexpected result since charge delocalisation could be expected to be greater for dca, producing weaker ion–ion interactions. Many of the dca salts are glass forming, with very low glass transition temperatures, T_g (Table 1), and only very sluggish crystallization kinetics at any temperature. The dimethylpyrrolidinium compound shows evidence of multiple solid phases, with a solid–solid thermal transition around −6 °C (Table 1) which consumes a large fraction of the total entropy of melting. This behaviour is indicative of plastic crystal phase formation and in the case of these ionic compounds, the plastic phases are often highly conductive.[7]

The viscosities of representative compounds at 25 °C (Table 1) are lower than those of the corresponding salts, *e.g.* 1-ethyl-3-methylimidazolium dca (η = 21 cP) and (η = 34 cP); *N*-butyl-*N*-methylpyrrolidinium dca (η = 50 cP) and (η = 85 cP).[2c] This rather useful trend is possibly related to the smaller size of the anion and parallels the lower mps of the dca compounds. In practical terms, it is possible to filter at rt a precipitate from a suspension in the lower viscosity dca salt with a sintered glass frit under vacuum.

Table 1 Thermal properties of dicyanamide salts[a]

Compound[b]	T_g/ °C ±2	T_{s-s}/ °C ±2	Mp/ °C ± 2	ρ/gcm^{-3} ±5% (25 °C)	Viscosity/ cP ±5% (25 °C)
P_{11}(dca)		−6	115	—	
P_{12}(dca)			−10	—	
P_{13}(dca)			−35	0.92	45
P_{14}(dca)	−106		−55[c]	0.95	50
P_{16}(dca)	−100		−11	0.92	45
N_{6222}(dca)	−82				
N_{6444}(dca)			−43[c]		
emim(dca)	−104		−21	1.06	21

[a] T_g = glass transition temperature, T_{s-s} = solid–solid transition temperature. [b] P = *N*,*N*-dialkylpyrrolidinium, N = tetraalkylammonium, subscripts refer to the number of carbons in the alkyl chains. [c] In these cases the melting transition is weak and the reported value only approximate.

 DOI: 10.1039/b103064g

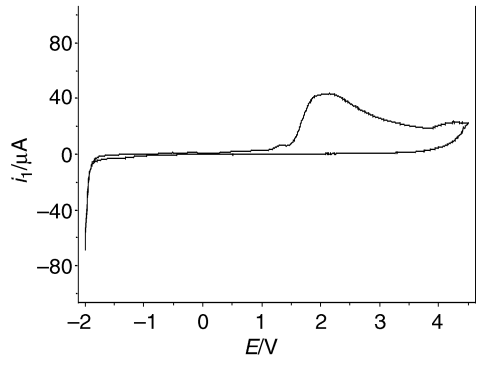


Fig. 1 Cyclic voltammetry of neat 1-ethyl-3-methylimidazolium dicyanamide (emim(dca)) carried out at 100 °C under a nitrogen atmosphere (dry box), on a glassy carbon microelectrode, with a platinum counter electrode and Ag/Ag^+ pseudo reference electrode.

The dca compounds which are liquid at rt are hygroscopic and are completely miscible with water, by contrast with the water-immiscible analogues.[2] The compounds also appear to absorb carbon dioxide readily. Extended periods at temperatures in excess of 100 °C have produced no evidence of breakdown. Qualitative tests showed that a number of hydrated cobalt(II), and copper(II) salts are appreciably soluble in 1-ethyl-3-methylimidazolium dca at rt with enhanced solubility on heating to 75 °C, whereas little dissolution of nickel salts and CuCl occurs. By contrast, the dca-soluble $CuCl_2{\cdot}2H_2O$ and $CoCl_2{\cdot}6H_2O$ are insoluble in the corresponding liquid at rt and only dissolved slightly at 75 °C. The solubility of the salts in the dca solvent may be due to its donor ligand properties, consistent with the rich coordination chemistry that is known of the anion,[3] though the inert behaviour of nickel salts is surprising. Of further interest is that glucose is soluble in the dca ionic liquid but not in the salt. Thus, the corresponding dca and salts show complementary solvent properties.

The electrochemical behaviour of these salts is illustrated by the example of the cyclic voltammogram in Fig. 1. The liquid is stable to quite low potentials, around −2 V *vs.* Ag/Ag^+, in common with other salts of this cation; the reductive limit presumably reflecting a reduction reaction of the cation. The stability in the oxidative range is reduced as compared to the analogue[2] but still leaves a large (>3.5 V) window for electrochemical use. The irreversible oxidation observed at *ca.* 1.5 V *vs.* Ag/Ag^+ may be indicative of the formation of a neutral dimer, $[N(CN)_2]_2$, a compound of theoretical interest but which has not been characterized.[8]

Thus new low melting, water-miscible, ionic liquids of relatively low viscosity which have considerable potential as a reaction medium and with a coordinating anion have been produced.

We are grateful for support from the Australian Research Council through the Centre for Green Chemistry.

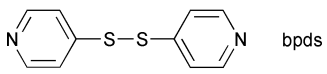
Received (in Cambridge, UK) 23rd April 2001, Accepted 20th June 2001
First published as an Advance Article on the web 19th July 2001

Three coordination polymers formed between CuI and bpds [bpds = bis(4-pyridyl)disulfide] have been prepared and fully characterised illustrating rare examples of solvent dependent topological isomerism in $[(CuI)_2(bpds)]_\infty$; tetrahedral Cu_4I_4 cubane junctions are linked to give either necklace or tubular polymers.

The study of inorganic coordination frameworks has received increasing attention over recent years with a growing range of structural motifs being discovered.[1–4] Many of these studies have heightened awareness of the influence not only of metal ion and ligand[2] but also of anion[3] and solvent.[4,5] Many of the architectures reported to date are based upon rigid linear linker ligands,[1–4] with only recent efforts focusing on the use of ligands showing conformational flexibility.[5–7] The term 'supramolecular isomerism' has been used by Zaworotko and coworkers[5] to describe the two forms of the coordination polymer $[Co(NO_3)_2(L)_{1.5}]_\infty$ obtained from the reaction of $Co(NO_3)_2$ with 1,2-bis(4-pyridyl)ethane (L). The two isomers differ due to the conformational flexibility of L which is *gauche* in one isomer and *anti* in the other.[5] More recently, the various different isomers of T-shaped metal–ligand building blocks have been recognised.[8] We prefer the term topological isomerism as we believe that this describes the differences in the topology and connectivity of the coordination polymer. We report herein an unusual example of topological isomerism in which both isomers (**2** and **3**) have the same stoichiometry, the same metal-fragment and ligand-linker combinations, the same ligand conformations, and the same metal ion stereochemistry. Compounds **2** and **3** differ purely in their metal to ligand coordinative connectivity to give isomers of different topology.

We were interested in developing neutral metal–organic networks and chose to investigate metal–halide aggregation with heterocyclic ligands.[9] The coordination polymers



$[CuI(bpds)]_\infty$ and $[(CuI)_2(bpds)]_\infty$ [bpds = bis(4-pyridyl)disulfide] can be prepared systematically as yellow powders. Bulk quantities of the compounds are obtained by the stoichiometric reaction of CuI with the ligand in MeCN or EtCN. Crystals of the compounds were grown by slow diffusion between CuI solutions in EtCN (or MeCN) and bpds in CH_2Cl_2. Regardless of the metal : ligand ratios used, crystals of both compounds were found in the same reaction solution. Over the period of a week, yellow needles of $[CuI(bpds)]_\infty$ **1** grew in the ligand-rich region of the solution while pale-yellow blocks of $[(CuI)_2(bpds)]_\infty$, **2** or **3**, grew in the metal-rich region.‡

Although the structure of $[CuI(bpds)]_\infty$ **1** consists of Cu_2I_2 cores connected by bpds to form a planar ribbon of known topology[10] (whether grown from MeCN–CH_2Cl_2 **1a** or EtCN–CH_2Cl_2 **1b**), the single crystal X-ray structure determinations of the 2 : 1 complex $[(CuI)_2(bpds)]_\infty$ revealed two different structural motifs depending upon the solvent used in crystallisation. In both cases the $[(CuI)_2(bpds)]_\infty$ consists of Cu_4I_4 cubane tetramers which are linked by two bpds ligands to form a square-shaped cavity (Fig. 1). Crystals of **2** grown from EtCN–CH_2Cl_2 reveals tetrahedral Cu_4I_4 cubane junctions§ linked by bpds ligands [C–S–S–C 77.4(2)°] to give a necklace structure (Fig. 1). However, in this case the tetrahedral geometry of the Cu_4I_4 cubane results in alternating square-shaped units being orientated perpendicular to each other in adjacent links of the necklace. The square-shaped cavities are packed to give channels which run parallel to the *b*-axis (potential solvent accessible volume 21.5%)[11] that accommodate EtCN molecules.

Using MeCN–CH_2Cl_2 as the crystallisation solvent results in a different structural isomer of $[(CuI)_2(bpds)]_\infty$ **3**. As in **2**, Cu_4I_4 cubane tetramers are linked by two bpds ligands to form a square-shaped cavity. However, the tetrahedral junctions§ of these cubane units now allow these squares to interlink *via* two further bpds ligands forming a tubular polymer[6] (Fig. 2). The conformation adopted by the bpds ligands is similar to that observed for the 1 : 1 compound [within the square C–S–S–C 78.4(3)°, interlinkers C–S–S–C 88.3(3)°]. In **3** the spaces between the bands of the square-shaped cavities are interdigitated by the bands of two adjacent tubes translated by half the repeat unit (Fig. 3). Despite the interdigitation this packing arrangement allows the formation of two criss-crossed channels parallel to the *a* and *b* axes, giving a potential solvent accessible volume of 14.4%.[11] Both of these channels run diagonally through the square-shaped cavities of adjacent tubes and are occupied by MeCN solvent molecules (Fig. 4).

Powder X-ray diffraction studies of **2** and **3** were used to study whether each solvent mixture results exclusively in a single isomer. Compound **2** was found to undergo irreversible and rapid desolvation during the period of the diffraction

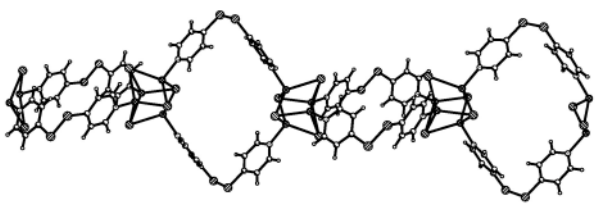


Fig. 1 The necklace isomer **2** of $[(CuI)_2(bpds)]_\infty$ showing alternating square-shaped units perpendicular to each other.

experiment giving a new diffraction pattern that was not consistent with the single crystal X-ray structure. In contrast, bulk samples of **3** were found to give diffraction patterns in good agreement with that expected from the single crystal studies. No evidence for the presence of the desolvated form of **2** was found in the diffraction pattern of **3** and *vice versa*. Thus, we conclude that the formation of each isomer is exclusively dependent on solvent of crystallisation, and that due to interdigitation **3** is a more robust framework for potential reversible solvent inclusion. Indeed upon heating single crystals of **3** to 100 °C for 10 h *in vacuo* up to 58% of the guest MeCN molecules can be removed as evidenced by single crystal X-ray diffraction experiments. Further details of the desolvation processes of compound **3** will form part of a future study.

As both isomers of $[(CuI)_2(bpds)]_\infty$ form under similar reaction conditions, but with a change in the nitrile solvent, it is reasonable to conclude that there are only minor energy differences in the formation of the two polymers. The two isomers of $[(CuI)_2(bpds)]_\infty$ **2** and **3** are very rare examples of metal–organic architectures which exhibit topological isomerism, and illustrate the profound effect of solvent-template effects in their formation.[5,8] We prefer the description 'topological isomerism' rather than 'polymorphism'[12] in this case to reflect the different coordinative connectivities between **2** and **3** rather than the different crystal packing.

First published as an Advance Article on the web 19th July 2001

Hybridization of complementary oligonucleotides mediated by a cationic surfactant at the water/hexane interface leads to hydrophobic, double-helical DNA which may be readily phase transferred to the organic phase and cast into thin films on solid substrates.

The development of synthetic, virus-like DNA vectors is a topical problem of considerable interest. Following the report of Felgner *et al.*[1] demonstrating that DNA pre-complexed with a cationic surfactant leads to its enhanced uptake by eucaryotic cells, DNA–cationic liposome complexes are being investigated in great detail as non-viral DNA vectors.[2]

Many studies have dealt with DNA–surfactant complexes in an aqueous environment.[3] In aqueous solutions containing equimolar amounts of DNA and the cationic surfactant, the complex formed was water-insoluble but soluble in low-polarity organic solvents.[3a,d] Reimer *et al.*[4] have shown that DNA molecules may be hydrophobized by complexation with cationic surfactants in a Bligh and Dyer monophase[5] and thereafter transferred into the organic phase by partitioning the monophase. We describe herein a simple method for the hybridization of complementary oligonucleotides employing electrostatic complexation with a cationic lipid, octadecylamine (ODA), at the water/hexane interface followed by phase transfer of duplex DNA into the non-polar organic environment. Furthermore, films of the DNA–ODA complexes may be easily deposited on solid surfaces by solvent evaporation. To the best of our knowledge, this is the first report on the surfactant-mediated hybridization of complementary oligonucleotides at the interface between two liquids.

Oligonucleotides of the sequences GGAAAAAACTTCGTGC (ssDNA1), GCAC-GAAGTTTTTTCC (ssDNA2) and AGAAGAAGAAAAGAA (ssDNA3) were synthesized as described elsewhere.[6] ssDNA1 and ssDNA2 are complementary oligonucleotides while ssDNA3 is non-complementary to both ssDNA1 and ssDNA2. In typical experiments, 10 mL of a 10^{-4} M solution of ODA (Sigma USA) in hexane was added to: (a) 10 mL of 10^{-6} M aqueous solution of ssDNA1 and ssDNA2 taken in an equimolar ratio (experiment **A**); (b) 10 mL of 10^{-6} M preformed duplex DNA constituted from complementary pairs ssDNA1 and ssDNA2 in water[7] (experiment **B**) and (c) 10 mL of 10^{-6} M aqueous solution of non-complimentary pairs ssDNA1 and ssDNA3 in an equimolar ratio (experiment **C**). The pH of the DNA solutions in all cases was 6.8. The hybridization of the complementary oligonucleotides ssDNA1 and ssDNA2 and the intactness of the duplex structure after phase transfer of the preformed duplex DNA was followed using the fluorescent intercalator, ethidium bromide, added to the aqueous solutions at a concentration of 10^{-5} M along with the DNA molecules. Vigorous mixing of the biphasic mixture was carried out at room temperature using a motor-driven overhead stirrer operating at 3000 rpm immersed in the liquid phase for 20 min. During the mixing process, a uniform and milky microemulsion-like phase was observed to form which, within one minute of cessation of stirring, resulted in a rapid separation of two clear layers.

Fig. 1A shows UV-vis spectra recorded from the hexane phase before and after the mixing protocols described in experiments **A** and **B**.[8] There is no indication of the presence of DNA in the organic layer before mixing (Fig. 1A, curve 3) but a strong resonance at 270 nm is induced in the hexane phase by the mixing process in experiments **A** and **B** (curves 2 and 1 respectively, Fig. 1A) and indicates phase transfer of the DNA molecules into hexane.[9] The mixing procedure resulted in the formation of a microemulsion-like phase which is clearly indicative of formation of extremely small droplets of hexane stabilized in the aqueous phase by the ODA molecules. This is likely given that hexane has a finite solubility in water (0.0138 g per 100 mL of water).[10] These droplets would increase the interfacial area between the water and hexane phases facilitating the interaction of DNA with the ODA molecules at the interface. At pH 6.8, the ODA molecules are positively charged (pK_B of ODA = 10.8) and the negatively charged DNA are thus electrostatically bound to the cationic ODA molecules. The DNA molecules are rendered hydrophobic upon complexation with ODA resulting in their phase transfer into hexane. The relative molar ratio of DNA–ODA is important in achieving a minimum critical hydrophobicity to accomplish the phase transfer. Equimolar ratios of DNA–ODA did not result in a detectable phase transfer of the DNA molecules into hexane. In the experiments described herein, a nearly 100-fold molar excess of ODA molecules (over DNA) was taken in the hexane phase.

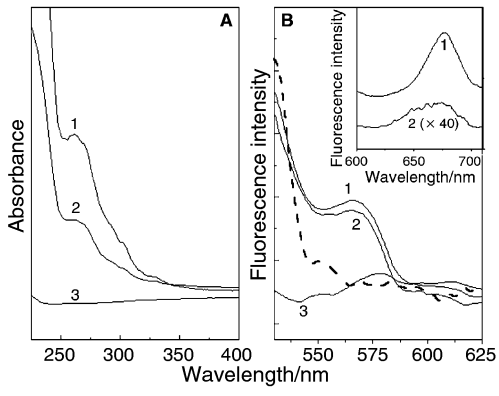

Fig. 1 (A) UV-vis spectra of the hexane phase before (curve 3) and after shaking biphasic mixtures of 10^{-4} M ODA in hexane and aqueous solutions of **A** (curve 2) and **B** (curve 1). (B) Fluorescence spectra of the hexane phase after transfer of DNA from aqueous solutions of experiment **A** (curve 1) and experiment **B** (curve 2). The fluorescence spectrum from the hexane phase in experiment **C** is also shown (curve 3). The dashed curve corresponds to the fluorescence spectrum from a mixture of ssDNA1–ODA and ssDNA2–ODA separately phase-transferred into hexane. The inset shows fluorescence spectra recorded from DNA–ODA complex films cast from the hexane phase on quartz substrates from experiments **A** (curve 1) and **B** (curve 2).

 DOI: 10.1039/b101110n

Fig. 1B shows the fluorescence spectra[11] from the hexane phase after transfer of DNA from aqueous solutions in experiments **A** (curve 1) and **B** (curve 2). A strong fluorescence signal at *ca.* 570 nm is seen in both cases. Ethidium bromide intercalates between the base pairs of DNA double helical structures and this process is detected by enhanced fluorescence.[12] The fluorescence results thus clearly indicate that the preformed double helical DNA molecules are phase transferred into hexane with retention of their double helical structure (curve 2, Fig. 1B). More importantly, the results show that not only have the single-stranded oligonucleotides ssDNA1 and ssDNA2 been transferred to the organic phase by complexation with ODA molecules, *they have hybridized into a duplex* (curve 1, Fig. 1B). No fluorescence was detected in the organic phase after the phase transfer of mixtures of ssDNA1 and ssDNA3 (non-complementary oligonucleotides, experiment **C**) even though the presence of the single-stranded DNA molecules was indicated by UV-vis measurements. To distinguish whether the transfer of DNA occurs in single-strand form followed by duplexation in hexane or directly as a duplex, hexane solutions of ssDNA1 and ssDNA2 separately phase transferred by complexation with ODA were mixed and the fluorescence measured (dashed curve, Fig. 1B). It is observed that there is no fluorescence in this experiment either. Thus, the hybridization inferred by the fluorescence measurements shown in Fig. 1B (curve 2) is clearly due to recognition of the complementary base sequences and occurs only at the hexane/water interface. In the absence of any added salts, the cationic ODA molecules act like counterions and screen the repulsive electrostatic interactions between the individual DNA strands to facilitate the hybridization process. The formation of double helical structures of ssDNA1 and ssDNA2 does not occur in the bulk of the aqueous phase in the absence of salt and these results clearly imply an interfacial process mediated by the cationic lipid molecules.

An exciting aspect of this is the possibility of depositing films of ODA-stabilized DNA by simple solvent evaporation. The fluorescence spectra obtained from films of DNA–ODA complexes cast from hexane solution onto quartz from experiments **A** and **B** are shown in the inset of Fig. 1B as curves 1 and 2 respectively. Strong emission signals from ethidium bromide are observed in both the films with an emission at *ca.* 675 nm. A large red shift in the emission wavelength is seen in the DNA–ODA films relative to the solution wavelength (main part of Fig. 1B). This is likely to be a consequence of the large increase in polarity of the intercalator environment in the film form and has support from the literature.[12] The low intensity fluorescence spectrum from the preformed DNA–ODA (curve 2, inset of Fig. 1B) is perhaps a consequence of non-uniformity of the film during evaporation of hexane and not due to a deterioration of the degree of hybridization of the DNA double helices.

Fig. 2 shows UV-melting curves from DNA–ODA complex films cast onto quartz from experiments **A** (curve 2) and **B** (curve 1). The preformed duplex DNA complexed with ODA shows a single melting transition at 55 °C (curve 1, Fig. 2) which is higher than the aqueous solution melting transition temperature of 41 °C[3b] indicating significant thermal stabilization of the duplex structure by the ODA molecules. The UV–melting transition curve for the DNA hybridized at the hexane/water interface-ODA film shows two T_M values at 39 and 61 °C (curve 2, Fig. 2). Such behaviour has been recently observed by Pattarkine and Ganesh in aqueous DNA–lipid complexes[3b] and was attributed to phase separation of lipid-free DNA double helical structures (lower T_M) and DNA double helices capped with a layer of surfactant molecules (higher T_M). DNA cannot exist in the organic phase without some degree of hydrophobization provided by electrostatically complexed ODA molecules. The above result may be attributed to two phase-transferred components wherein the degree of complexation of the DNA duplex with ODA molecules is different.

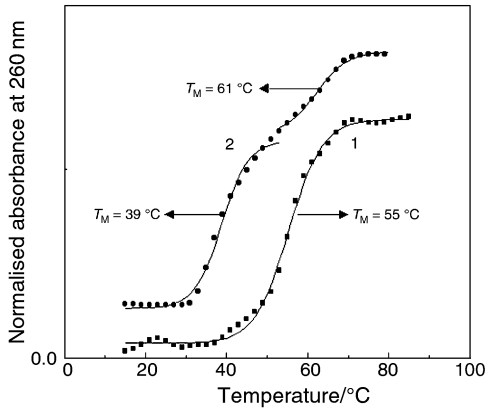

Fig. 2 UV-temperature plots of films of DNA–ODA complexes on quartz substrates in experiment **A** (curve 2) and experiment **B** (curve 1).

In conclusion, electrostatic complexation of DNA molecules with cationic lipid molecules at the organic/water interface and phase transfer of DNA into the organic phase has been demonstrated. An important finding is the surfactant-facilitated hybridization (and consequent hydrophobization and phase transfer) of complementary single-stranded DNA molecules at the liquid/liquid interface under conditions where the hybridization to form double helical structures does not occur in the bulk of the aqueous phase. The DNA molecules may be conveniently cast in the form of thin films onto any solid support by solvent evaporation. This approach is expected to facilitate the generation of lipid–DNA complexes for possible application in gene-transfer systems *etc.*

Copolymerization of carbon monoxide and aziridine†

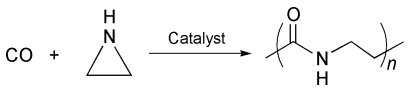
Li Jia,* Errun Ding and William R. Anderson

Department of Chemistry, Lehigh University, 6 E. Packer Avenue, Bethlehem, PA 18015, USA. E-mail: lij4@lehigh.edu; Fax: +1 610-758-6536; Tel: +1 610-758-5715

Received (in Cambridge, UK) 1st May 2001, Accepted 15th June 2001
First published as an Advance Article on the web 19th July 2001

Alternating copolymerization of carbon monoxide with aziridine was realized, which serves as a prototype of a novel route for synthesis of poly-β-peptides.

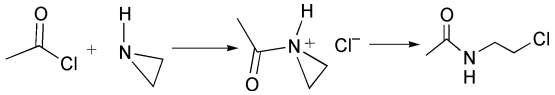
Rational discovery of new catalytic reactions is an important scientific challenge for synthetic chemists. We are interested in designing new catalytic polymerization reactions which involve reaction and incorporation of heteroatoms in the polymer chain to produce functional polymers. In light of the successful examples of carbonylation of aziridines and epoxides and alternating copolymerization of CO and alkenes,[1–4] we set out to develop metal-catalyzed alternating copolymerization of CO with aziridines [eqn. (1)].[5] This reaction in principle provides an



(1)

attractive route to poly-β-peptides, which have received considerable current attention as biomimetic materials.[7,8] Prior to this work, Sen and Arndtsen independently suggested the possibility of copolymerization of imines with CO to produce poly-α-peptides and demonstrated the first examples of imine insertion into Pd–acyl bonds.[9,10] We report here the initial identification of a catalyst for CO–aziridine copolymerization and that alternating polymerization can be achieved under carefully controlled experimental conditions.

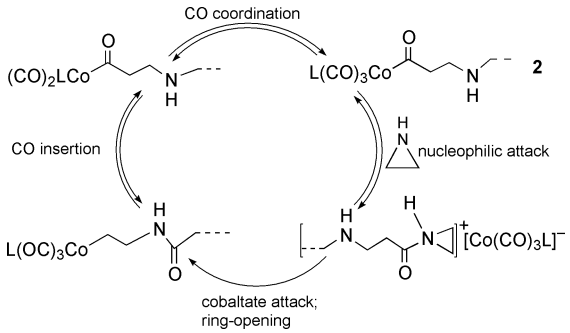
At the onset of this project, we conceived a catalytic cycle leading to the copolymerization. First of all, CO insertion and aziridine insertion into a metal–carbon bond are inevitable steps in any catalytic cycle that one might design for the copolymerization of CO and aziridine. Examples of the latter reaction are absent in organometallic chemistry to our knowledge. However, an interesting reaction of aziridine insertion into acetyl chloride was reported [eqn. (2)].[11] It is well established



(2)

that some metal–acyl species resemble organic acyl chlorides and undergo nucleophilic cleavage by alcohols and amines to afford esters and amides. By such analogy, insertion of aziridine into metal–acyl bonds might also occur. The aziridine insertion coupled with CO insertion into a metal–alkyl bond then forms a reasonable catalytic cycle leading to the alternating copolymerization (Scheme 1).

Under the above hypothesis, we screened a number of potential catalysts and arrived at Heck's complex $CH_3COCo(CO)_3PPh_3$ **1**. In the presence of 10 mol% of **1** under 1000 psi CO in THF solution, aziridine and CO was copolymerized to produce a crystalline, hot-water soluble polymer in good yield (entry 1, Table 1). The FT-IR and NMR spectra together confirm that the product is poly-β-alanine. In the IR spectrum, two prominent amide bands are present at 1645 and 1539 cm^{-1}.† The ^1H NMR spectrum reveals two triplet resonances (**a** and **b**) at δ 3.25 and 2.26 ppm (J = 6.5 Hz) (Fig. 1a), in agreement with the chemical shifts reported for poly-β-alanine prepared from acrylamide.[12] Additional fine features (labeled with asterisks) are present overlapping with or in close vicinities of **a** and **b**. The small differences in chemical shifts between them and the main peaks **a** and **b** lead us to believe that they belong to β-alanine units located at or close to the end of the chain. These resonances are not due to amine microstructures, which would possibly be present if repetitive aziridine insertions occurred (see below), because they do not move downfield in acid solutions in contrast to what should be expected for amines upon protonation. Work is in progress in our laboratory to positively identify these resonances. A resonance (**c**) at δ 1.80 ppm is observed due to the acetyl end group that originates from



Scheme 1 Working model for alternating copolymerization of CO with aziridine (L = PPh_3).

 DOI: 10.1039/b103899k

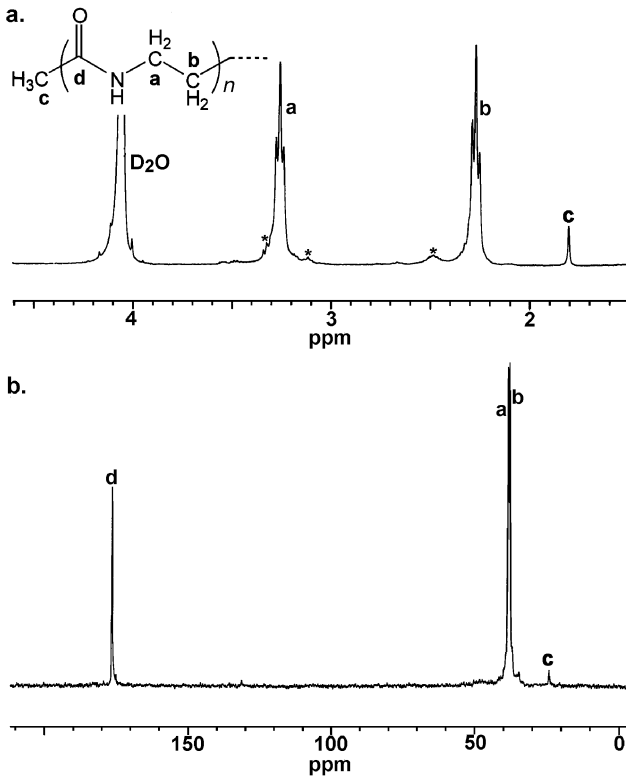

Fig. 1 a. ^{1}H NMR (360 MHz, D_2O, 95 °C) of poly-β-alanine produced from copolymerization of CO and aziridine (entry 1, Table 1). Integral ratio of **a**–**b**–**c** = 100:100:6. b. $^{13}C\{^1H\}$ NMR (90 MHz, D_2O, 95 °C, THF in D_2O as external standard) of the same sample.

1. Such assignment is consolidated by the observation that this peak disappeared when the methyl-deuterated **1** $CD_3COCo(CO)_3PPh_3$ was used for the copolymerization. In the ^{13}C spectrum (Fig. 1b), the amide carbonyl peak (**d**) is clearly shown at δ 176.2 ppm. The methylene ^{13}C resonances appear at δ 38.3 and 37.7 ppm. The peak at 24.2 ppm (**c**) in the ^{13}C spectrum is assigned to the methyl of the acetyl end group. All ^{13}C assignments are supported by ^1H–^{13}C HMQC and HMBC experiments.†

Varying CO pressure exerted little effect on the selectivity of the polymerization (entries 2 and 3, Table 1). However, the polymer yield decreased when the reaction was run under 250 psi of CO. The lower yield was likely caused by catalyst decomposition, not decrease of the reaction rate, as quadrupling the reaction time did not result in any alteration of yield.

When the initial aziridine concentration was increased (entries 4 and 5, Table 1), the selectivity of the reaction reduced, and additional peaks appeared in the ^1H spectrum.† The chemical shifts of these resonances and that they move downfield when the aqueous solution is acidified suggest that they belong to amines, which apparently arise from repetitive aziridine insertion. Extraction of the products using a wide range of solvents including methanol, ethanol, THF, and chloroform did not significantly change the relative amount of amine units, suggesting that the amine and β-alanine units are in the same chains. The problem of repetative aziridine insertion can be partially solved by slow addition of aziridine. When aziridine was added in portions under 1 atm of CO after the previously added aziridine was estimated to have been consumed, the selectivity was considerably improved without sacrifice of the yield (entries 6 and 7, Table 1).

The molecular weights and molecular weight distributions of the products are measured by gel-permeation chromatography (GPC) coupled with a light scattering-refractive index-viscometry triple detector (Table 1). The weight average molecular weights are determined with reproducibilities within 6%. The molecular weight distributions are complex and spread over a wide range, hampering accurate determination of the number average molecular weights. Thus, the polydispersities (PDI) listed in Table 1 should be taken as approximate values.

In regard to the mechanism of the polymerization, the complexity of molecular weight distribution profiles indicates that it is apparently not a simple one. However, the presence of the acetyl end group argues that complex **1** is indeed the catalyst.

The possibility that azetidin-2-one was the intermediate of the polymerization was ruled out by two parallel experiments. In the first experiment, equal molar amounts of azetidin-2-one and aziridine were subjected to the polymerization conditions. In the other experiment, only aziridine was added. The same amounts of polymer were produced in the two experiments. The requirement for high catalyst loading in order to achieve good selectivity for alternating enchainment indicates that the barriers for alternating enchainment and repetitive enchainment are not significantly different for the catalyst employed here. We are currently engaged in searching for catalyst systems that provide improved selectivity toward alternating enchainment and in elucidating the chain propagation/termination mechanisms.

This work was supported by the ACS-Petroleum Research Fund. We thank Dr Mark A. Scialdone of Du Pont Central R&D for GPC analyses and Professor James E. Roberts of Lehigh University for solid state ^{13}C NMR measurements of the polymers. L. J. thanks the Christian R. & Mary F. Lindback Foundation for a Minority Junior Faculty Award.

Hierarchical design of mixed metal oxides: novel macroporous VPO phases

Moises A. Carreon and Vadim V. Guliants*

Department of Chemical Engineering, University of Cincinnati, Cincinnati, OH 45221-0171 USA. E-mail: Vadim.Guliants@uc.edu

Received (in Cambridge, UK) 5th April 2001, Accepted 20th June 2001
First published as an Advance Article on the web 19th July 2001

Macroporous vanadium–phosphorus–oxide phases (macro-VPO) displaying ordered 0.2–0.4 μm pores and unprecedented high surface areas (44–75 m^2 g^{-1}) have been synthesized using colloidal arrays of polystyrene spheres as a template.

Mixed metal oxides possess promising catalytic properties for the selective oxidation of lower alkanes (C_2–C_5).[1] For example, Mo–V–Nb and Sb–V oxides are catalytically active in selective oxidation of ethane and propane[2] and propane ammoxidation and vanadium–phosphorus–oxides (VPOs) are selective in the oxidation of *n*-butane to maleic anhydride.[3]

The conventional synthesis methods, both wet chemistry and solid-state, offer limited control over the phase, bulk and surface compositions of mixed metal oxides, preferential exposure of active and selective surface planes, surface areas and pore architectures, which define their catalytic properties in selective oxidation of lower alkanes. There is a critical need for novel routes of assembling hierarchically designed mixed metal oxides, which display remarkable ordering on micro- (<3 nm for the surface region structure and composition), nano- (3–100 nm for the bulk and phase compositions) and macro- (>100 nm for pore architectures) scales.

Macroscale-templated synthesis of nanocrystalline mixed metal oxides represents an attractive approach for the synthesis of hierarchically designed catalytic materials. Several single-element macroporous oxides with very interesting structural properties have been synthesized by self-assembly using colloidal sphere templates.[4–9] However, macroporous mixed metal oxides for applications in oxidation catalysis have not, as yet, been reported. We report here the first successful example of a hierarchically designed macroporous mixed vanadium–phosphorus–oxide (macro-VPO) with desirable structural and compositional properties for selective oxidation of *n*-butane.

Macro-VPO phases were assembled using close-packed arrays of colloidal polystyrene (PS) spheres (0.4 μm diameter) as a template. Monodispersed PS spheres were synthesized by an emulsion polymerization process described elsewhere.[7] The ordered arrays of PS spheres were obtained by either centrifugation or filtration of PS sphere suspensions. Fig. 1 shows the SEM image (Hitachi, Model S-3200N) of colloidal PS spheres used as the template.

In a typical synthesis, an array of PS spheres was first impregnated with a phosphoric or phosphorous acid solution in ethanol. Then a solution of a vanadium-(IV) or -(V) source in ethanol or isobutyl alcohol was introduced into the voids of the array, where it reacted with a phosphorus source and condensed into a macro-VPO framework upon drying. It was found that the initial surface treatment with a phosphorus source was critical for the nucleation and growth of macro-VPO phases in the voids of the PS sphere arrays. In all experiments the P/V molar ratio was 1:1, which provides the optimal surface and bulk composition for selective oxidation of *n*-butane.[3] The PS spheres were removed from as-synthesized macro-VPO by either calcination in air at 723 K or Soxhlet extraction using a mixture of acetone and tetrahydrofuran (1:1 volume ratio). Typical synthesis conditions, crystallographic phases determined by powder XRD (Siemens D-500) and the BET surface areas (Micromeritics Gemini 2360) for selected calcined and Soxhlet-extracted macro-VPO phases are given in Table 1.

The ordered pore structure of the macro-VPO phases after the template removal is evident in Fig. 2. Interconnected pores appear as dark spots (*ca.* 0.2 μm diameter) inside spherical 0.4 μm cavities left after the removal of the PS spheres. The walls of the macropore structure are formed by the $(VO)_2P_2O_7$ nanocrystals. The wall thickness was estimated from the SEM images to be *ca.* 90 nm. The average nanocrystal size determined using the Scherrer formula[10] was *ca.* 20 nm, which indicated that the wall was only four crystals thick. Relatively large size of the nanocrystal building blocks explains the

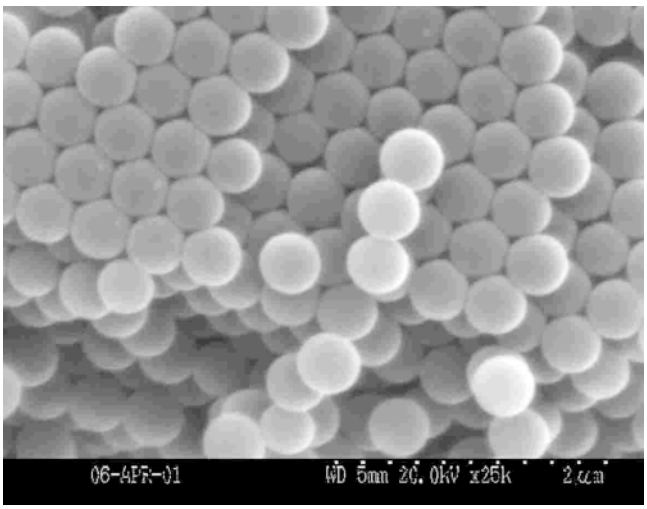

Fig. 1 SEM image of the synthesized monodispersed polystyrene spheres used as templates for the formation of macroporous VPO.

Table 1 Selected properties of macroporous VPOs

VPO sources	General description	Specific surface area/m^2 g^{-1}	Crystalline phase
$VO[CHO(CH_3)_2]_3$, H_3PO_3	Calcined in air at 723 K	64	$VOPO_4{\cdot}2H_2O$

 DOI: 10.1039/b103131g

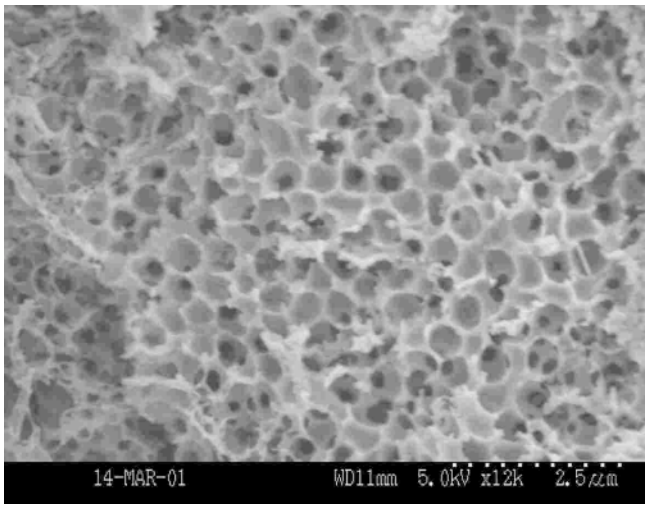

Fig. 2 SEM image for macroporous VPO.

somewhat rough and disordered appearance of the macropore structure in SEM images (Fig. 2).

The macroscale-templated synthesis produced the VPO phases with unprecedented high surface areas after the removal of the PS spheres. The macro-VPO phases displayed *ca*. 44–75 $m^2\ g^{-1}$ surface areas (Table 1) and the optimal bulk compositions (P/V *ca*. 1.05 by ICP elemental analysis). By comparison, the surface areas of VPO phases synthesized by conventional methods are in the range 5–20 $m^2\ g^{-1}$.[1,3] The surface areas of the macro-VPO phases are consistent with a theoretical estimate for 20 nm cubic crystals of $(VO)_2P_2O_7$ (90 $m^2\ g^{-1}$).

The present method of macroscale-templated synthesis of mixed metal oxides yielded $(VO)_2P_2O_7$ which preferentially exposed the active and selective surface (100) planes for the oxidation of *n*-butane. $(VO)_2P_2O_7$, which is the active and selective phase in *n*-butane oxidation to maleic anhydride,[1,3] was synthesized using the V(IV) and P(III) sources (Table 1). The intensity ratio of the interplanar (100) and in-plane (042) X-ray reflections of $(VO)_2P_2O_7$ (I_{100}/I_{042}) has been previously used to determine the prefential exposure and the stacking order of the surface (100) planes proposed to contain the active and selective catalytic sites.[3] The conventional VPO phases typically exhibited low intensity ratios, I_{100}/I_{042} *ca*. 0.4, indicating that the surface (100) planes were not dominant in these phases.[3] The macro-VPO phases are characterized by much higher intensity ratios, I_{100}/I_{042} *ca*. 2.48 suggesting that these phases preferentially expose the surface (100) planes of $(VO)_2P_2O_7$.

To the best of our knowledge, the hierarchical design of the mixed metal oxide phases with ordered macropore architectures, record high surface areas, as well as the phase compositions and the surface plane exposures critical for selective oxidation catalysis is achieved for the first time. This study demonstrated that the macroscale self-assembly route holds a great promise as a general method for the rational design of mixed metal oxides with desirable structural and compositional properties.

Further studies will focus on the catalytic performance of the novel macroporous mixed metal oxides in the oxidation of lower alkanes.

Control on the organized structure of monoalkylethylenediamine copper(II) coordinated bilayer membranes by counter ions

Chun Li, Xianchun Lu, Xuzhong Luo and Yingqiu Liang*

Lab of Mesoscopic Materials and Chemistry and State Key Lab of Coordination Chemistry, Nanjing University, Nanjing 210093, People's Republic of China. E-mail: yqliang@nju.edu.cn

Received (in Cambridge, UK) 23rd April 2001, Accepted 28th June 2001
First published as an Advance Article on the web 19th July 2001

The organized structure of Cu^{2+}-coordinated bilayer membranes formed by monoalkyl derivatives of ethylenediamine can easily be modulated by varying the counter ions, and their physical properties change correspondingly.

The design and construction of supramolecular organized assemblies utilizing non-covalent intermolecular interactions, such as hydrogen bondings, metal–ligand interactions, van der Waals interactions, π–π stackings *etc*. has become a topic of increasing interest in recent years, due to their fascinating structures and novel functionalities.[1–4] It is well-known that the structure and properties of these aggregates are determined not only by the chemical structures of the component molecules, but also by environmental factors, including pH variation, metal-ion complexation, heat, light *etc*. Recently, much work has focused on the control of the macroscopic morphology and microscopic structure of self-organized materials by changing physical or chemical environments.[5]

In our previous papers, we have reported that complexed bilayer membranes are formed from a series of single-chain amphiphiles $C_nH_{2n+1}NHC_2H_4NH_2$ dispersed in dilute aqueous $Cu(NO_3)_2$.[6] In the present work, our investigation has been concentrated on the control of the organized structure of monoalkylethylenediamine in dilute aqueous CuX_2 by changing the counter ions (X^- = Cl^-, Br^-, NO_3^- and ClO_4^-).†

Fig. 1 shows the typical transmission electron micrographs for amphiphilic aggregates of $C_nH_{2n+1}NHC_2H_4NH_2$ (n = 12, 14, 16, 18) in aqueous CuX_2 (X^- = Cl^-, Br^-, NO_3^- and ClO_4^-), which all revealed the presence of vesicular morphologies. However, there are drastic differences between the samples with Cl^-, Br^- on the one hand and NO_3^-, ClO_4^- on the other as counter ions in the appearance of the dispersion. In the former case the aggregates are blue while the latter are purple. Obviously for these four systems, the only difference lies in the X^- anion type and size, therefore, it can be inferred that the type of counter ion is of vital importance to the determination of the organized structures, and the amphiphilic aggregates can be categorized into two structurally differing types.

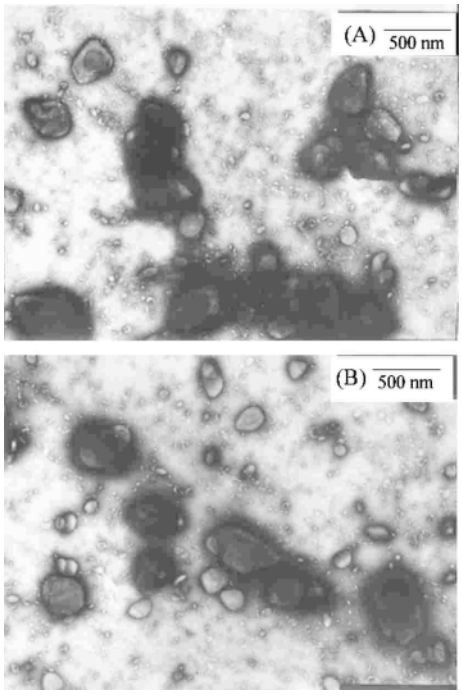

Fig. 1 Typical TEM morphologies of complexed bilayer membranes of $[Cu(C_nH_{2n+1}NHC_2H_4NH_2)_2]X_2$: (a) X^- = Cl^-, n = 14; (b) X^- = ClO_4^-, n = 14.

The differences between the two kinds of assemblies in solution colour and in their solid-state electronic spectra reveal configurational diversities in the structures of the Cu^{2+}-coordinated headgroups. Typical results (n = 14) are shown in Table 1. For asymmetric derivatives of ethylenediamine, ML_2 type complexes of Cu^{2+}-coordinated amphiphiles usually adopt planar CuN_4 structures with *cis*- and *trans*-isomers.[7] It has been established that complexes with *cis*-configuration show higher σ–σ* transition energies than those with *trans*-arrangement.[8] Additionally, square-coplanar CuN_4 complexes show d–d transition energies in the range (18–20) × 10^3 cm^{-1} while the range for tetrahedral CuN_4 is (12–16) × 10^3 cm^{-1}.[9] From the d–d and σ–σ* transition energies in Table 1, it can be deduced that when X^- = Cl^- or Br^-, the Cu^{2+}-coordinated headgroups adopt a *trans*-configuration which give a compressed tetrahedral CuN_4 environment, and the two tails in the $[Cu(C_nH_{2n+1}NHC_2H_4NH_2)_2]X_2$ (X^- = Cl^-, Br^-, n = 12–18) complexes adopt an approximately diagonal position [see Fig. 3(a)]; while for X^- = NO_3^- or ClO_4^- ions, a *cis*-configuration is adopted with the copper square-coplanar, with the two tails located at the same side of the plane and parallel to each other [see Fig. 3(b)]. Clearly the headgroup structures greatly influence the packing fashion of the hydrocarbon tails in the organized aggregates.

It has been demonstrated by many experiments that in cast films the self-aggregated structure of the amphiphiles in dilute aqueous dispersions is well preserved.[10] In order to elucidate the structural features of the assemblies in aqueous solution, small-angle XRD was applied to study the long spacing of the cast bilayer membranes. Powder diffraction experiments carried out on cast films of the complexed aggregates showed periodic peaks corresponding to bilayers with ordered structures, which are similar to those reported in the literature.[10] Fig. 2(a) shows

Table 1 The appearance of $C_{14}H_{29}NHC_2H_4NH_2$ aggregates in aqueous CuX_2, along with electronic transitions of their cast films

Counter ion (X^-)	Solution appearance	d–d Transition (10^{-3} $\tilde{\nu}$/cm^{-1})	σ–σ* Transition (10^{-3} $\tilde{\nu}$/cm^{-1})	
			I	II
Cl^-	Emulsion, blue	16.78	35.21	42.37
Br^-	Emulsion, blue	17.48	33.33	42.78
NO_3^-	Emulsion, purple	18.05	35.71	44.44
ClO_4^-	Emulsion, purple	19.23	36.50	43.10

 DOI: 10.1039/b103614a

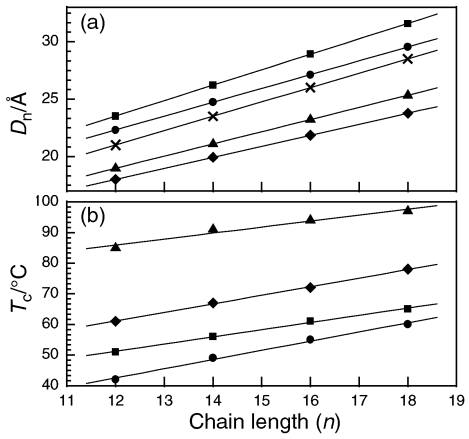

Fig. 2 (a) Bilayer thickness (D_n) values and the evaluated molecular length (L_n) as function of the tail length (n); (b) phase transition temperature (T_c) dependence on the tail length (n): X^- = (●) Cl^-; (■) Br^-; (▲) NO_3^-; (◆) ClO_4^-; (×) L_n.

the tail length (n) dependence of the bilayer thickness, *i.e.* the long spacing (D_n) of the cast bilayer membranes. As can be seen for each system the bilayer thickness shows good linearity with tail length (n = 12, 14, 16 and 18):

D_n (Cl^-) = 1.34n + 7.39
D_n (Br^-) = 1.21n + 7.83
D_n (NO_3^-) = 1.06n + 6.24
D_n (ClO_4^-) = 0.97n + 6.24

The cast bilayer thickness, for X^- = Cl^-, Br^- ions, falls between the monomolecular and bimolecular length of the amphiphile, while for X^- = NO_3^-, ClO_4^- ions the bilayer thickness is smaller than the corresponding evaluated molecular length (L_n) (CPK model). These results indicated that the amphiphilic molecules probably assume either a tail-to-tail chain packing mode or an interdigitated packing mode in the bilayer membranes.

Differential scanning calorimetry experiments of the complexed bilayer dispersions showed endothermic peaks (not shown here), indicating gel-to-liquid crystal phase transitions, one of the basic physicochemical properties of bilayer membranes. The value of the phase transition temperature (T_c) for each system exhibits fairly good linearity with n, as depicted in Fig. 2(b), indicating similar lateral packing in the membrane structure of each system. It is clear from Fig. 2(b), for X^- = Cl^-, Br^- samples, the T_c values are < 65 °C, which are similar to those of bilayer membranes showing tail-to-tail packing reported in the literature.[11] By contrast, for X^- = NO_3^-, ClO_4^-, the T_c values are > 60 °C. It has been shown that in many cases the extensively tilted tail-to-tail type bilayer assemblages possess relatively fluid chain packing and exhibit relatively low T_c, whereas interdigitated type bilayer membranes have tighter chain packing and display higher T_c values than tail-to-tail ones.[11] Thus, by combining XRD and DSC results, it can be inferred that for X^- = NO_3^-, ClO_4^- dispersions the amphiphiles adopt the partially interdigitated chain packing mode in the bilayer membranes. Two quite different structures in cast films from complexed bilayer membranes with different counter ions are thus observed. Based on the packing model of aliphatic chains in the bilayer membranes, the chain tilt angles (with respect to the bilayer normal) for each system, calculated from the slope of the linear equations[12] are 58.2° (Cl^-), 61.6° (Br^-), 33.4° (NO_3^-) and 40.2° (ClO_4^-).

In summary, this study shows a very simple method, changing the counter ion can modulate the headgroup configuration and packing mode of the aliphatic chains in synthetic bilayer membranes formed by monoalkylethylenediamines $C_nH_{2n+1}NHC_2H_4NH_2$ (n = 12–18) in dilute aqueous CuX_2 (Fig. 3). Furthermore, this molecular-level modification arising from the change of counter ions is amplified by the self-assembly process through cooperative effects of metal–ligand interactions and van der Waals interactions, on their macroscopic properties leading to variations in appearance and gel-to-liquid transition temperatures of the dispersions.

We acknowledge the National Natural Science Foundation of China (20073019) for financial support of this work.

Formation of robust mesoscopic ring structures by self-assembly of $SiCl_3$-terminated dendrimers

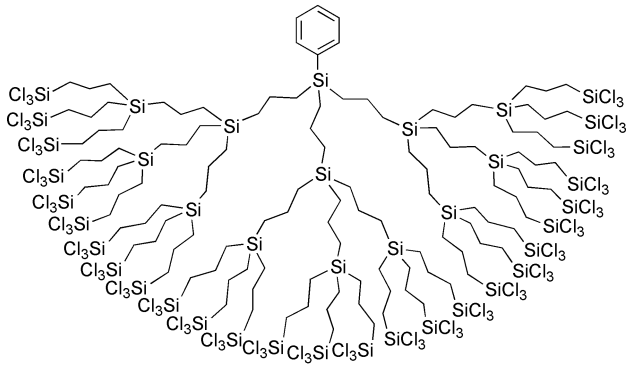
Zhongdang Xiao, Chengzhi Cai* and Xiaobin Deng

Department of Chemistry, University of Houston, Houston, Texas 77204-5003, USA. E-mail: cai@uh.edu

Received (in Cambridge, UK) 16th May 2001, Accepted 28th June 2001
First published as an Advance Article on the web 19th July 2001

Robust sub-micrometer ring structures are easily prepared using $SiCl_3$-terminated dendrimers.

The formation of submicrometer-scale structures *via* the self-assembly of molecules is of great current interest.[1] Recently, several groups have reported the formation of mesoscopic ring structures on solid surfaces using a variety of materials, including porphyrin derivatives, nanoparticles, and carbon nanotubes.[2–6] These ring structures were easily formed after the evaporation of a dilute solution of the materials deposited on substrate surfaces, through an intermediate morphology featuring droplets or holes. Unfortunately, the molecules/particles in these structures were held together only through weak intermolecular interactions. Consequently, the structures possess a limited stability that restricts their potential applications. During the course of systematic investigation of the chemisorption of a series of $SiCl_3$-terminated dendrimers on flat surfaces, we observed that the films of **1** deposited on mica spontaneously



1

adopted well-defined sub-micrometer ring structures across the surface. Notably, the dendrimers in the films polymerize upon curing, thereby affording robust and highly stable ring structures.

The ring structures were easily and reproducibly prepared by spin coating of a 10^{-5} M solution of **1**[7] in anhydrous THF on a freshly cleaved mica substrate. As revealed by AFM (Fig. 1), the isolated rings are randomly located over the entire substrate surface. Most of the rings possess an inner diameter of 450–550 nm. Although rings dominate the film surface, separated islands with a bottom diameter of 110–230 nm and a height of 2.0–3.5 nm are also present; these are located predominately outside the rings and on the rims. Root mean square roughness (R_q) measurements show that the film surface inside the rings (R_q = 0.160 nm) is much flatter than outside (R_q = 0.530 nm). Fig. 2 depicts a typical ring and a cross sectional plot of the ring diameter (R), height (h), and width (L) of the rim. Notably, the rims of all the rings possess a similar average width ($L \approx 150$ nm) and height ($h \approx$ 4–6 nm). Interestingly, the layer outside the rings is higher than that inside by $D \approx 1.1$ nm (Fig. 2). To measure the thickness of the layer inside the rings, part of the film was shaved by AFM using a square pyramid Si_3N_4 probe with a loading force of *ca.* 190 nN. Fig. 3 shows an AFM image of the region containing the shaved area. The average thickness of the flat layers outside and inside the rings was then measured

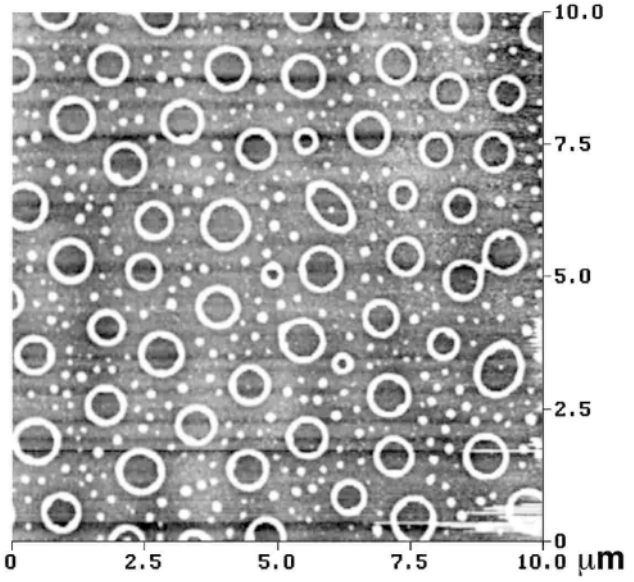


Fig. 1 An AFM image of a thin film formed by spin-coating of a THF solution of **1** onto a mica surface. The contrast covers height variations in the 0–15 nm range.

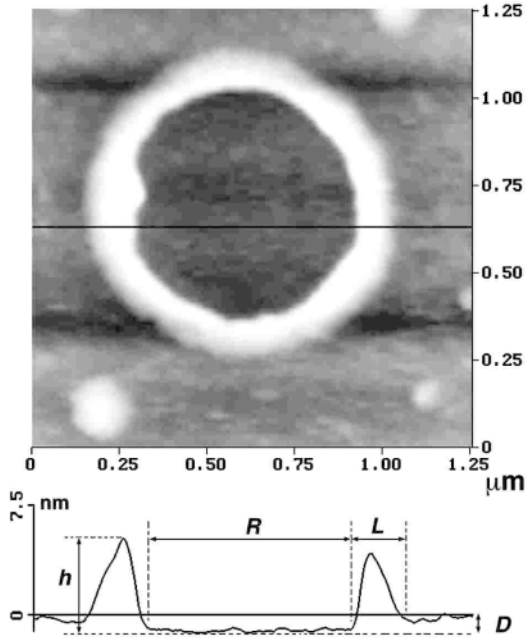

Fig. 2 An AFM image of a ring and a line scan for measurement of the ring diameter (R), height (h), and width (L) of the rim.

 DOI: 10.1039/b104306b

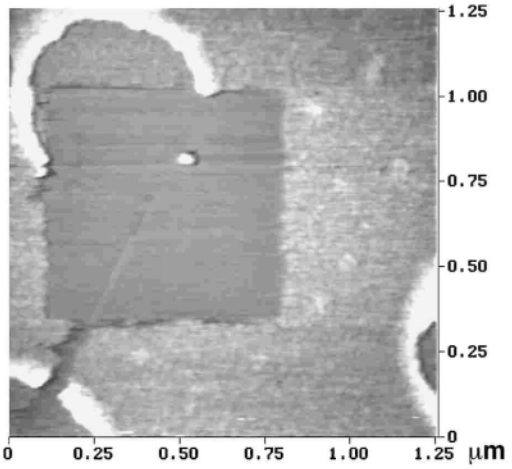

Fig. 3 Tapping mode AFM image of a film region containing an area shaved by contact mode AFM.

by AFM to be 2.2 ± 0.4 nm and 1.3 ± 0.3 nm, respectively. The former corresponds to a monolayer of densely packed dendrimers, as the height of **1** is calculated to be *ca.* 2.2 nm by molecular mechanics (MM2). The latter could correspond to a monolayer of flattened dendrimers. It is well known that flexible dendrimers can substantially flatten on a surface when their interaction with the surface is strong.[8]

Upon deposition of **1** (dissolved in THF) on mica in air, the $SiCl_3$ groups of **1** should be completely hydrolyzed to $Si(OH)_3$ groups by surface-bound and absorbed water.[9] Intermolecular condensation of the $Si(OH)_3$-terminated dendrimers may occur at room temperature, but apparently only to a limited extent. In fact, films that were kept at room temperature in air for two weeks can still be shaved by AFM. Although they cannot covalently bond to the mica surface which does not contain OH groups, the dendrimers can undergo substantial condensation to form a cross-linked network of Si–O–Si groups at elevated temperatures.[9] Indeed, after curing at 115 °C for 12 h, the unchanged ring structures became robust; they could no longer be scratched by AFM tips, even under a loading force as high as 250 nN. In addition, they remained intact after storage in air for months, and after repeated washing with water and organic solvents such as THF and chloroform.

Despite the presence of a large number of hydrophilic Si–O–Si groups in the dendrimers after hydrolysis and curing, the surface of the cured films possessed a surprisingly high water contact angle (advancing: 103°; receding: 92°; static: 100°) and hexadecane contact angle (advancing: 38°; receding: 31°; static: 35°). These contact angles are similar to those for a smooth solid surface exposing closely packed $–CH_2–$ or $–CH{=}CH_2$ groups.[10] In addition, force measurements by AFM showed that the attraction forces between the Si_3N_4 tip and the film were nearly the same inside and outside the rings, indicating a similar composition for both surfaces. These results suggest that the dendrimer molecules fully cover the hydrophilic mica surface with all of their SiOR groups (R = H, OSi), leading to a hydrophobic film surface composed mostly of $–CH_2–$ groups.

Based on the above results, it appears that the ring structures and islands ('dots') are formed on an underlying layer of the dendrimers physisorbed on mica. Preliminary results also indicated the absence of ring structures at a monolayer coverage.† During spin coating, when the liquid film of the excess dendrimers and the solvent (THF) on top of the monolayer thins below a critical thickness by evaporation, the instability of the film may cause film rupture into small droplets.[3] Some of the small droplets coalesce into larger ones, and the remaining isolated small droplets dry to form the observed islands ('dots'). AFM imaging of freshly prepared films showed that the rings were developed from larger droplets,† in agreement with the mechanism proposed by others.[3] The process involves a radial flow outward from the center of the droplet.[3,11] This outward flow of liquid can carry virtually all of the dissolved dendrimers as well as some of the dendrimers physisorbed on the substrate surface to the rim. The reduced number of dendrimers in the layer on the interior of the ring then flatten to cover the substrate surface. The observed similar heights and widths of the rims regardless of the ring diameters might be required for 'pinning' of the rim.[5]

In conclusion, we have described the preparation of robust submicrometer ring structures on mica surfaces using **1**. AFM studies revealed that the isolated mesoscopic ring structures and islands were grown on an underlying self-assembled layer of the dendrimers. The surface inside the rings is much flatter than ouside. Prior to curing, polymerization of the hydrolyzed dendrimers, if any, occurred only to a limited extent. Scanning probe lithography of the pre-cured films can be used to generate patterns (*e.g.* Fig. 3) on the film.[12] The structures become robust upon curing. Similar to the demonstrated application of graphite etch pits (3.5 Å high),[13] such ring structures (*ca.* 50 Å high) may be used to isolate ensembles of macromolecules or nanoparticles for study by scanning probe microscopy. We will explore the growth of ring structures using analogs of **1** that possess functional groups at the phenyl group.

A novel single azido bridged one-dimensional Ni(II) chain, which represents the first metamagnetic one-dimensional metal–azido system with only end-to-end azido bridges, has been synthesised and characterised by a low temperature magnetic study.

In the last decade chemists have dedicated their efforts to the study of molecular-based magnetic materials owing to the need to understand the fundamental science associated with magnetic interactions between the paramagnetic metal ions and the bridging ligand to develop magneto–structural correlation enabling the designed synthesis of interesting magnetic materials.[1] One strategy for the design of molecular-based magnets involves assembling of paramagnetic metal ions in one-, two- and three-dimensional networks using suitable bridging ligands.[1,2] The azido ligand has been widely used because of its diverse binding modes which yield different types of molecules such as dimers, tetramers, one-, two-, and three-dimensional arrays *etc*.[3] The prime coordination motif for bridging azido is end-on with ferromagnetic interaction and end-to-end having antiferromagnetic coupling.[4] To the best of our knowledge all compounds of Ni^{II} with end-to-end azido bridges are antiferromagnetic with the exception of two compounds which are weakly ferromagnetic: one is a dimer[5] and the other a one-dimensional chain of Ni^{II} using a non-chelating capping ligand.[6] Examples of metamagnetic molecular materials in the metal–azido system with only end-to-end bridging azido mode are still lacking. Here, we report the synthesis,‡ crystal structure and magnetic properties of a new one-dimensional compound, $[Ni(L)(N_3)_2]_n$ **1** (L is a tridentate Schiff base obtained by condensation of pyridine-2-aldehyde and *N*,*N*,2,2-tetramethylpropane-1,3-diamine) which represents the first example of a metamagnetic molecular material of Ni^{II} with only end-to-end azido bridges.

A crystal structure determination§ reveals that complex **1** is a single azido bridged one-dimensional Ni^{II} chain. A perspective view of the polymeric chain of complex **1** with the atom numbering scheme is shown in Fig. 1. Each nickel atom in the chain has an octahedral coordination environment with a NiN_6 core. In the chain, all nickel atoms are linked to one pendant azido in their axial positions. One nitrogen atom, N(7), of the bridging azido is linked to an equatorial position of one nickel while the other nitrogen atom N(9′) of the same azido is coordinated to an axial position of the neighbouring nickel centre. The equatorial least-square planes of the two Ni^{II} centres are not parallel and form a dihedral angle of 31.3(1)°. The deviation of Ni^{II} from the best fit square plane towards N(4) is 0.042(3) Å. The two Ni–N–N bond angles of the end-to-end azido group are different [N(8)–N(7)–Ni 133.3(4), $N(8)^{II}$–N(9)–Ni 124.5(4)]. The Ni–N_3–Ni torsion angle of 106.8(4)° is large for an azido Ni^{II} compound.[6,7] The intrachain distance between adjacent nickel centres is 5.662(1) Å.

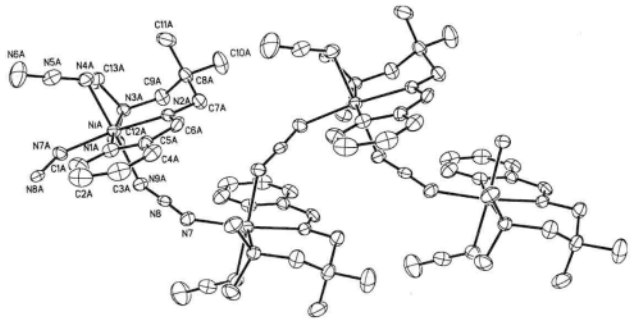

Fig. 1 View of the polymeric chain (40% thermal ellipsoids) with atom numbering scheme of complex **1** and selected bond lengths (Å) and angles (°): Ni–N(1) 2.126(5), Ni–N(2) 2.030(5), Ni–N(3) 2.179(5), Ni–N(4) 2.072(5), Ni–N(7) 2.091(6), Ni–N(9) 2.130(5), N(4)–N(5) 1.172(9), N(5)–N(6) 1.159(11); N(1)–Ni–N(2) 78.5(2), N(1)–Ni–N(3) 172.8(2), N(1)–Ni–N(7) 97.7(2), N(1)–Ni–N(9) 89.8(2), N(2)–Ni–N(9) 85.9(2), N(3)–Ni–N(4) 93.76(19), N(4)–Ni–N(7) 90.3(2), N(4)–N(5)–N(6) 178.4(8).

The thermal variation of $\chi_M T$ is shown in Fig. 2. The nature of the $\chi_M T$ *vs.* T plot is a signature of global intrachain ferromagnetic interaction. The solid line corresponds to the best fit obtained by considering an uniform ferromagnetically coupled chain of spin triplets (Fig. 2).[8] The best fitting parameters are $J = +13.5\ cm^{-1}$, $g = 2.08$ and $R = 2.3 \times 10^{-4}$. To the best of our knowledge this is the highest positive J value for end-to-end azido bridged complexes reported to date.[6] Fig. 2 indicates that it is only possible to fit the data from $T > 40$ K and below this temperature interchain magnetic interactions are present. In fact, the susceptibility curve shows a maximum at $T = 5$ K indicating that an antiferromagnetic ordering is present

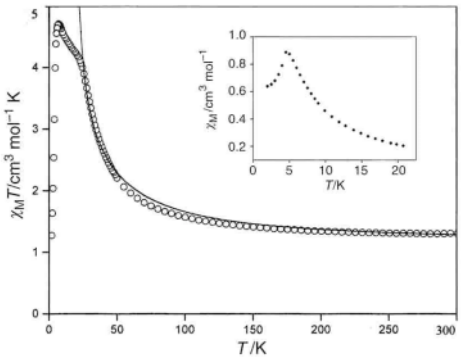

Fig. 2 Plot of $\chi_M T$ *vs.* T for **1**. Solid lines show the best fit indicated in the text. Inset: plot of χ_M *vs.* T at low temperature.

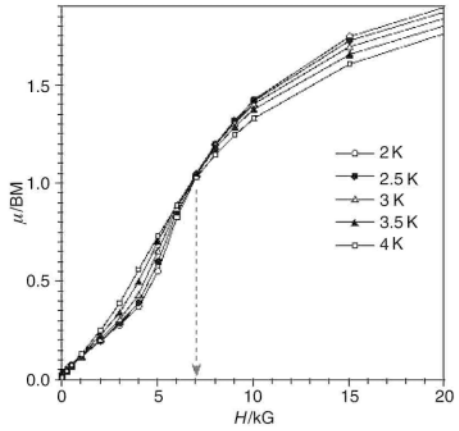

Fig. 3 Magnetization *vs.* applied field curves at different temperatures exhibiting sigmoidal shape with a common crossing point at $H = 7$ kG.

(see inset of Fig. 2). The magnetization curves for different temperatures (Fig. 3) exhibit a sigmoidal shape with a common crossing point for $H = 7$ kG. All these facts clearly indicate a metamagnetic behaviour of the complex with a critical temperature (T_c) of 5 K and critical field (H_c) of 7 kG. This magnetic order can be understood by considering that a spin canting structure may be involved, that is the interchain antiferromagnetic coupling does not imply a total antiparallel arrangement of the local spins but that a very weak canted angle should occur. The unusual intrachain ferromagnetic interaction is mainly due to the large deviation of Ni–N–N angles from 108°, the very high Ni–N_3–Ni torsion angle and the unusual axial–equatorial bridging mode of the azido. All these structural factors in complex **1** diminish the antiferromagnetic interaction to a greater extent to favour ferromagnetic interaction[9] as observed. The antiferromagnetic interactions operate between Ni^{II} of adjacent chains probably by means of electrostatic (dipolar) interactions between the aromatic ring of the coordinating Schiff base ligand due to a close contact between the parallel aromatic rings from two adjacent chains (the closest distance is 3.41 Å).[9] When present interchain hydrogen bonding interactions also play a vital role in intermolecular antiferromagnetic interaction. In our system, no classical hydrogen bonds are present, but only C–H···N bonds in which *d*(H–N) is *ca*. 2.5 Å (av.) and *d*(C–N) is 3.1 Å (av.), and so in our system the contribution of interchain hydrogen bonding interactions to interchain antiferromagnetic interaction is weak.

Previously reported results show that end-to-end azido bridged metal complexes are always antiferromagnetic.[10] However, two recently published results show the possibility of ferromagnetic materials with such bridging.[5,6] Our present result shows the possibility of a metamagnetic molecular material with only end-to-end azido bridged complexes. The present example is thus a new demonstration of the versatility of azido bridges for building molecular-based magnetic materials. In order to complete the magnetic studies, further experiments along with the DFT calculations and other theoretical calculations are in progress.

We wish to thank the Council of Scientific and Industrial Research, New Delhi for financial support (granted to N. R. C) and Prof. Joan Ribas, Universitat de Barcelona, Spain, for fruitful scientific discussion.

‡ The tridentate Schiff base was prepared by refluxing pyridine-2-aldehyde (2 mmol, 0.214 g) and *N*,*N*,2,2-tetramethylpropane-1,3-diamine (2 mmol, 0.260 g) in methanol (10 mL), according to the literature method.[11] A methanolic solution (10 mL) of nickel(II) perchlorate hexahydrate (2 mmol, 0.730 g) was added to the hot methanolic solution (10 mL) of the tridentate Schiff base ligand (2 mmol). The resulting solution was cooled to room temperature and an aqueous solution (5 mL) of sodium azide (4 mmol, 0.260 g) was added dropwise with continuous stirring. Suitable green single crystals for structure determination were obtained (50% yield) by slow evaporation of this solution. Anal. for $C_{13}H_{21}N_9Ni$: C, 43.15; H, 5.80; N, 34.85. Found: C, 43.60; H, 5.65; N, 34.80; IR: ν 2105 cm^{-1} [ν_a(azide)], 2095 cm^{-1}(pendant azide).

§ *Crystal data* for **1**: $C_{13}H_{21}N_9Ni$, monoclinic, space group $P2_1/n$, a = 11.922(3), b = 8.360(2), c = 17.121(5) Å, β = 101.42(2)°, V = 1672.6(8) $Å^3$, $Z = 4$, $T = 293$ K, μ(Mo-Kα) = 1.174 mm^{-1}, D_c = 1.438 g cm^{-3}, $R1$ = 0.061 based on F, $wR2$ = 0.160 based on F^2. Maximum and minimum heights in the final difference Fourier map are 0.910 and −0.360 e $Å^{-3}$. Intensity data collected on an Enraf-Nonius CAD-4 single crystal diffractometer employing the ω–2θ scan method; absorption correction was applied. The structure was refined using a full matrix refinement procedure (SHELXL 97), with anisotropic thermal parameters assigned to all non-hydrogen atoms. All hydrogen atoms were observed in the difference map.

Templated photochemical synthesis of a uracil *vs*. thymine receptor

Dario M. Bassani,* Xavier Sallenave, Vincent Darcos and Jean-Pierre Desvergne

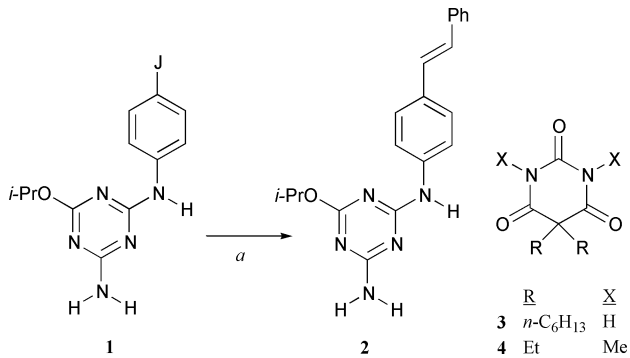
Laboratoire de Chimie Organique et Organométallique, CNRS UMR 5802, Université Bordeaux 1, 33505. Talence, France. E-mail: d.bassani@lcoo.u-bordeaux.fr

Received (in Cambridge, UK) 5th April 2001, Accepted 15th June 2001
First published as an Advance Article on the web 20th July 2001

The first templated photochemical synthesis of a receptor capable of differentiating between thymine and uracil is described.

Supramolecular self-assembly can be used to build structures of controlled size, shape, and functionality.[1] Of particular interest is the application of such processes to construct molecular receptors by moulding small fragments containing molecular recognition elements around a given substrate.[2] However, a means by which the reversibly-bound adduct can be captured to allow the isolation and identification of the receptor (lock-in) is invariably required. We have recently described a system in which the photoinduced dimerisation of cinnamates appended with molecular recognition units was affected by the presence of a template molecule.[3] A salient feature appeared to be the possibility to consolidate supramolecular assemblies *via* light-triggered photoreactions through a process analogous to the topochemical control achieved in the solid.[4] It therefore seemed interesting to further explore the use of light to trigger the covalent capture of reversibly-formed supramolecular receptors. The binding properties of this new class of hydrogen-bonding receptors, incorporating a diphenylcyclobutane scaffold, were investigated. In particular, their ability to discriminate between analogues of the naturally-occurring pyrimidine bases thymine and uracil makes them potential candidates in the development of RNA *vs*. DNA targeting agents.

Compound **2** was synthesised by Heck coupling between styrene and **1**(Scheme 1), prepared by sequential substitution of cyanuric chloride† according to literature procedures.[5] The binding of **2** to the template molecule, 5,5-dihexylbarbituric acid (**3**), was investigated[6] by ^{1}H NMR spectroscopy. In principle, one may expect the formation of five distinct (two 1 : 1 and three 2 : 1) complexes (Fig. 1), only one of which places the stilbene chromophores in close proximity. Because the interconversion between the hydrogen-bonded complexes is fast on the NMR timescale, the observed binding isotherm only allows determination of the overall 1 : 1 and 2 : 1 association constants. Binding of **2** to **3** in $CDCl_3$ is accompanied by a 2 ppm downfield shift of the N–H resonance of **3**, from which association constants $K_1 = 1200 \pm 60$ M^{-1} and $K_2 = 250 \pm 12$ M^{-1} can be extracted. A good fit to the experimental data was obtained only for a model comprised of sequential 1 : 1 and 2 : 1 complex formation.



Scheme 1 (a) Styrene, Et_3N, $Pd_2(dba)_3$ (5 mol%), acetonitrile, 85 °C, 24 h (71%).

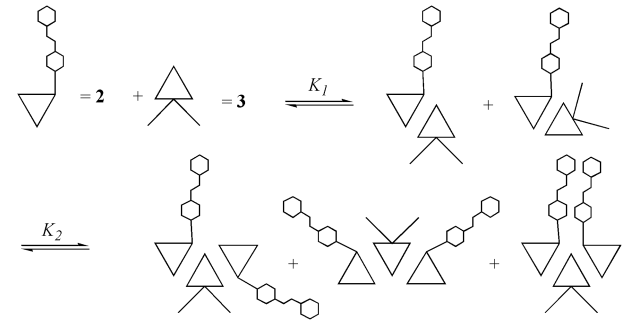


Fig. 1 Various hydrogen-bonded assemblies may be formed between **2** and **3**, only one of which places two stilbene chromophores in close proximity, favouring the formation of *syn* photodimers.

Irradiation of dilute (10^{-2} M) CH_2Cl_2 solutions of **2** results in rapid *E*, *Z* photoisomerisation of the stilbene chromophore leading to a photostationary equilibrium mixture enriched in the *Z* isomer (*Z*:*E* = 5.5), known to be unreactive towards cyclodimerisation.‡ Upon prolonged irradiation, slow grow-in of five additional products is observed by HPLC (Fig. 2). Isolation of four photoproducts by preparative HPLC allowed their characterisation by ^{1}H NMR and mass spectroscopy, which identified them as [2 + 2] cycloadducts. The structures of the isolated photoproducts **5a**–**5d** were assigned on the basis of their spectral properties by comparison with known stilbene dimers described in the literature.[7] The major cycloadducts are the head-to-head and head-to-tail dimers (**5a** and **5d**), accounting for roughly two thirds of the total dimer formation.

Under identical irradiation conditions, the presence of 0.5 eq. of **3** was found to enhance the formation of three of the photoproducts (**5b**, **5c**, and **5d**), while inhibiting the formation of **5a**. This difference in reactivity is attributed to the formation of a ternary supramolecular complex in which the stilbene moieties are held in a face-to-face geometry that is favourable to dimerisation. The preference for photodimers in which the

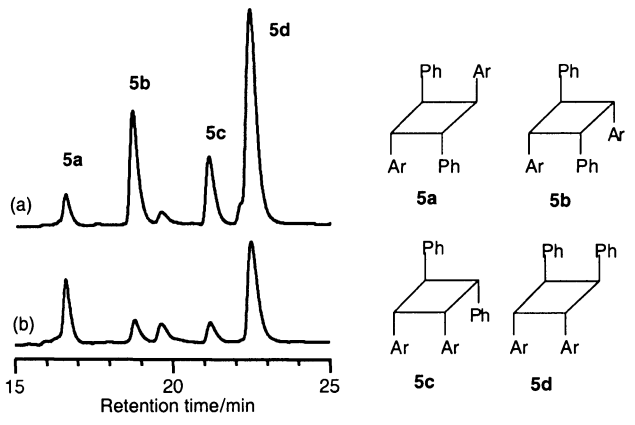

Fig. 2 Portion of the HPLC chromatograms showing the formation of photodimers in the presence (a) and absence (b) of **3** upon irradiation, and the proposed structures of dimers **5a**–**5d**.

triazine units are oriented *syn* is in agreement with the involvement of **3** as a template during the dimerisation reaction. This is further supported by the lack of activity of **4**, in which the hydrogen bonding sites are blocked by methylation. The reduced yield of **5a** is consistent with the inability of **3** to promote structures that are not suitable receptors for barbiturate derivatives. Quantum yields for the formation of dimers **5a**–**5d** in the presence and absence of **3** or **4** are given in Table 1. From the measured association constants, and assuming a statistical distribution of 1:1 and 1:2 complexes, one can estimate the quantum yield for the formation of dimer **5d** *within* the supramolecular assembly to be 0.1, approximately a 170-fold increase with respect to solution. A rationalization of the catalysis and product distribution for an analogous cinnamate derivative has already been described,[3] and will therefore not be discussed further.

Molecular modelling of **5d** indicates that it has a tweezer-like geometry, with both the aminotriazine groups oriented in the same direction. Concomitant binding of a substrate to both triazines is therefore restricted both by the hydrogen-bonding pattern of triazine and by the size and shape of the cavity. Titration of **5d** with Barbital (5,5-diethylbarbituric acid, **6**) in $CDCl_3$ was monitored using NMR spectroscopy by observing the barbiturate N–H protons, which underwent a large downfield shift (> 4 ppm) upon complexation. The association constant was found to be 2400 M^{-1}, much higher than the binding of **2** to **3**, for which the microscopic binding constant is calculated to be 300 M^{-1}.[8] The increase in the association constant is attributed to the binding of **6** within the cleft formed by the triazine groups in **5d**, resulting in the formation of multiple hydrogen bonds. *In this respect, **5d** is an example of substrate-induced receptor synthesis*. The magnitude of the binding constant between **6** and **5d** is very similar to that of an analogous recently synthesised Barbital receptor containing a ferrocene unit,[9] though smaller than those previously reported by Hamilton and co-workers.[10] Thus, the preparation of receptors *via* light-induced capture of supramolecular assemblies can lead to functional receptors, of similar binding affinity as those obtained by conventional synthetic methodologies.

The rigid structure of **5d** is the basis for the observed selectivity in the binding of uracil *vs*. thymine or adenine. NMR titration ($CDCl_3$) of **5d** by 5-(4-*tert*-butylbenzyl)uracil (**7**) results in a binding isotherm indicating the formation of a 1:1 complex with a binding constant of 960 ± 120 M^{-1}.§ Molecular modelling using semi-empirical PM3 calculations (Fig. 3) reveals that uracil can bind within the diaminotriazine cleft with formation of 4 hydrogen bonds. In contrast, the presence of the methyl substituent in thymine is expected to prevent it from entering the binding cleft, and should therefore result in a lower binding affinity. This is indeed the case, and the binding of 5-(4-*tert*-butylbenzyl)thymine (**8**) to dimer **5d** can only be fitted to a model comprised of sequential 1:1 and 1:2 complex formation. This is rationalised by the binding of a thymine molecule to **5d** following partial rotation about the C–C bond connecting the diaminotriazine unit to the cyclobutane scaffold. The binding constants (K_1 = 1980 ± 65 M^{-1}, K_2 = 150 ± 5 M^{-1}) reflect a more favourable statistical weighting for binding the first thymine molecule, and a modest anticoopertive effect towards binding of the second thymine, presumably due to steric interactions. To adequately compare the binding of **7** or **8** to **5d**, one must take into consideration that whereas in the case of thymine four distinct 1:1 complexes may be formed, only one complex can be formed between **5d** and uracil. Thus, the microscopic binding constant of thymine is actually only one half that of uracil (500 *vs*. 960 M^{-1}). An upper limit of 50 M^{-1} was estimated for the association constant between **5d** and 9-ethyladenine, suggesting the formation of a rather labile complex. This is consistent with the binding of adenine in a fashion similar to that of thymine, but involving only two hydrogen bonds.

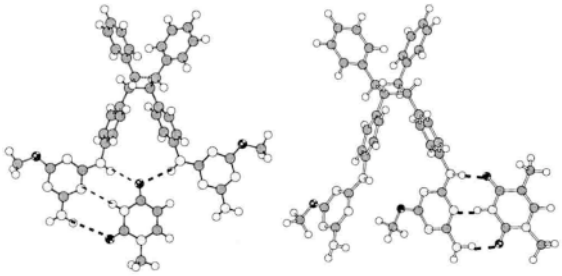

Fig. 3 Energy minimised (PM3) structures of complexes formed between **5d** and uracil (left) and thymine (right).

The methyl group in thymine has been recently recognized to play an important role in the recognition and suppression of DNA sequences by certain bacteria,[11] and receptors capable of mimicking this form of recognition would be of interest. The ability to differentiate between uracil and thymine may be further enhanced by preventing rotation of the binding site in **5d**, and this may open new possibilities for the selective recognition of RNA *vs*. DNA fragments.

We are indebted to Professor M. J. Hynes for making his program EQNMR available to us, and to the Conseil Régional Aquitaine and the MRT for supporting this work.

The first ^{17}O solid state NMR study of a low barrier hydrogen bond (LBHB) is reported which shows that very strong hydrogen bonds strongly affect both the quadrupole interaction and the isotropic chemical shift reducing both.

Hydrogen bonding plays a vital role in both chemical and biological systems. Non-covalent forces are important in determining the secondary, tertiary and quaternary structures of proteins. Changes in hydrogen bonding interactions between ground and transition states can also make an important contribution to enzyme catalysis.[1] The proposal that short strong hydrogen bonds (SSHBs) can contribute up to 20 kcal mol^{-1} stabilisation energy to transition states[1–3] has provoked a vigorous debate in which the validity of this concept has been challenged.[4–6] SSHBs have been taken as synonymous with low barrier hydrogen bonds (LBHBs).[7] In such bonds, the potential energy barrier between the two possible states of a hydrogen bond, in which the hydrogen atom is associated with either one or other of the donor or acceptor atoms, is lowered so that a single well potential energy system results. The monoanions of carboxylic acids have been the focus of most studies of LBHBs with examples reported of both centred and non-centred hydrogen atoms.[8] In these systems the O–O bond is short (~ 2.4 Å) but the concept that such short bonds should be associated with exceptional hydrogen bond strength has been disputed.[4,6,9]

Solid state ^{17}O NMR can be used, in principle, to study hydrogen bonding since oxygen is directly involved in the bonds of interest. The ^{17}O isotropic chemical shift (δ_{iso}), the quadrupole coupling constant (C_Q)[10] and the asymmetry parameter (η) are very sensitive to the bonding state.[11] Despite the low natural abundance (0.037%) and consequent necessity for enrichment in ^{17}O the number of solid state NMR studies in recent years has increased rapidly because of the high sensitivity of the ^{17}O NMR parameters to local structural details and its ability to probe directly structurally significant environments.[12,13] Most work to date concerning application of ^{17}O NMR to study hydrogen bonding has been in solution. In recent solution work the relaxation times of the ^{17}O have been used to determine the quadrupole interaction which has subsequently been related, *via ab initio* calculations, to the bonding state.[11] There have recently been some preliminary solid state ^{17}O measurements in a hydrogen bonded environment,[14] however the current study is the first report of ^{17}O in a SSHB. Solid state NMR spectra are presented from ^{17}O-labelled phthalic acid[15] and three alkali metal mono- and di-anion phthalates.[16–18]

^{17}O solid state NMR spectra were accumulated at a resonance frequency of 81.35 MHz on a Varian-Chemagnetics Infinity 600 spectrometer. Fast magic angle spinning (MAS) of ~ 20 kHz was used in a Chemagnetics 3.2 mm probe. Short excitation pulses were applied of 0.6 μs (corresponding to a tip angle of π/6) and 1.2 μs in a spin-echo sequence. The echo spacing was approximately an integral number of rotation periods. Typically 100–500k acquisitions were co-added using a recycle delay of ~ 1 s. Spectra were referenced to H_2O at 0 ppm. The MAS NMR spectra together with simulations are shown in Fig. 1.

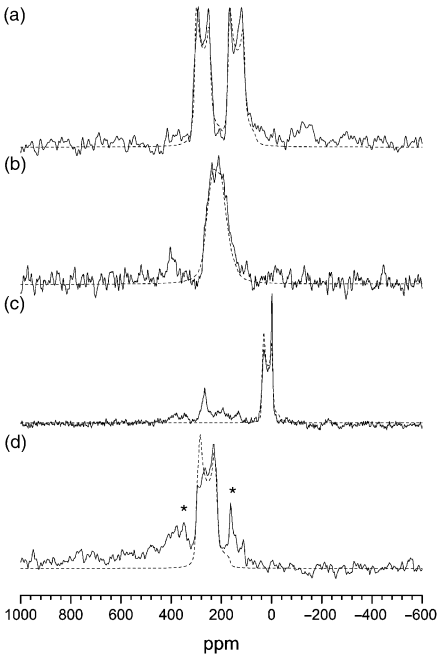

Fig. 1 ^{17}O 14.1 T MAS NMR spectra of (a) phthalic acid, (b) dilithium phthalate hemihydrate, (c) lithium hydrogen phthalate dihydrate and (d) potassium hydrogen phthalate dihydrate. [Note that the spinning speed in (d) was lower so that the spinning sidebands (*) are more prominent.]

Phthalic acid shows two completely resolved well defined second-order quadrupolar lineshapes[10] [Fig. 1(a)] with similar C_Q values but with δ_{iso} values that differ by ~ 130 ppm (Table 1). The dilithium salt gives a broader line intermediate in position to the two resonances of phthalic acid [Fig. 1(b)]. A single set of parameters provides a good simulation of both the MAS and static spectra (latter not shown) and this was confirmed by repeating the experiment at a different applied magnetic field. The monolithium salt has a well defined second-order quadrupolar lineshape with a large decrease in the isotropic chemical shift [Fig. 1(c), Table 1]. (The very sharp feature on this line at ~ 0 ppm is due to a small amount of fluid-like water in the sample.) There is also some weak intensity in the region 200–300 ppm. The monopotassium salt shows a

Table 1 ^{17}O NMR parameters from simulation of the MAS NMR spectra

Sample	δ_{iso}(ppm) ± 5	C_Q/MHz ± 0.1	η ± 0.05
Phthalic acid

Site 2	180	7.4	0
Lithium hydrogen phthalate dihydrate	46	5.9	0.21
Dilithium phthalate hemihydrate	272	7.6	0.44
Potassium hydrogen phthalate dihydrate	305	8.4	0.2

 DOI: 10.1039/b104308k

quadrupolar lineshape [Fig. 1(d)] with NMR parameters that are similar (Table 1) to the dilithium salt and phthalic acid, but are very different from the monolithium salt.

The ^{17}O NMR parameters observed in these four compounds show a very wide variation compared to previous studies, covering a chemical shift range $\geqslant$250 ppm with C_Q differences of ~40%. Recently there have been the first reports of high resolution ^{17}O NMR studies of solid organic materials. In poly(L-alanine) the α-helix and β-sheet show a difference in δ_{iso} for ^{17}O of 33 ppm, which is related to the different hydrogen bonding of these different units.[19] In potassium hydrogen benzoate the distinct oxygen sites show a difference in parameters of C_Q = 8.5 MHz, δ_{iso} = 290 ppm for the carbonyl group oxygen atom, and C_Q = 6.3 MHz and δ_{iso} = 230 ppm for the hydroxy group oxygen atom.[20] The limited data that currently exist for such materials indicate that as the hydrogen bond strength increases the shielding increases, so that both the chemical shift and C_Q decrease. Phthalic acid has two oxygen sites in the ratio 1 : 1. From comparison with solution ^{17}O NMR studies, the peak with a shift of 312 ppm can be assigned to the carbonyl group oxygen atom. The shift difference between the two observed peaks results from the different chemical nature of these species. However the similarity of C_Q indicates that the degree of hydrogen bonding is similar and this is confirmed by the similar O–O distance[21] of these sites. The equality of the signal intensity indicates that the two sites were equally enriched, as expected. The dilithium salt showed a chemical shift of ~280 ppm, comparable with phthalic acid. A single set of parameters simulates the line well, hence either the notionally different sites are in fact very similar, or on the NMR timescale there is some averaging of the environments. Neutron diffraction studies of lithium hydrogen phthalate monohydrate[17] have revealed that it exhibits a very short hydrogen bond with the structural properties associated with LBHBs (O–O distances of 2.4 Å). The oxygen resonance observed in the spectrum of lithium hydrogen phthalate hemihydrate in the present study provides strong evidence for a LBHB since it has a low isotropic chemical shift (the *lowest* yet reported for such a compound) and a much smaller C_Q than the other salts. The NMR spectrum reveals only one site with some additional minor intensity. Observation of a single site could indicate that locally the sites are structurally the same or alternatively there is some averaging for the NMR that is not seen by diffraction, highlighting the caution needed when the term equivalence is invoked since it depends on the timescale. This is likely to be especially true when small, mobile atoms such as hydrogen and lithium are present. The single line implies that in lithium hydrogen phthalate hemihydrate all the oxygen sites are equivalent on the NMR timescale, a result that may be attributable to electronic equivalence. Alternatively, it may be attributed to dynamic proton disorder, as has been proposed to explain an analogous equivalence in the ^{17}O solid state NMR spectrum of the benzoic acid dimer.[20] The monopotassium salt of phthalic acid contains an intermolecular hydrogen bond according to an X-ray determination and not a strong symmetric intramolecular hydrogen bond.[22] A single site simulation consistent with the MAS data is shown (and is also consistent with static and multiple field data). The ^{17}O NMR interaction parameters are similar to the dilithium salt with an isotropic chemical shift of ~305 ppm and C_Q = 8.4 MHz. There is *no* evidence of a second environment with a smaller quadrupole interaction and there is certainly no intensity at the shift seen in the monolithium salt. Hence as expected from the crystal structure there is no ^{17}O resonance characteristic of an SSHB environment. The contrast between the ^{17}O NMR spectra of these monoanionic salts is striking since the resonance of the lithium with the SSHB salt is shifted by a large amount compared to the potassium salt where the hydrogen bonding is weaker. As more data is collected it will become important to establish the exact nature of the correlation between the NMR parameters and the hydrogen bond strength.

This communication shows that ^{17}O NMR is a direct and sensitive probe of the hydrogen bonding state in solid organic compounds, easily identifying low barrier hydrogen bonds. The data indicates that the quadrupole interaction and in particular the chemical shift are strongly affected by hydrogen bonding. ^{17}O NMR should find widespread application as a probe of hydrogen bonding state, identifying other SSHBs, and determining the protonation states of proteins.

RD, APH and MES thank EPSRC for funding the solid state NMR equipment within the Physics Department at Warwick. MES thanks the Royal Society for funding work on ^{17}O NMR of hydrogen bonding. Dr C. Gervais and D. Padro are thanked for help in simulating the spectra.

Received (in Cambridge, UK) 4th May 2001, Accepted 25th June 2001
First published as an Advance Article on the web 11th July 2001

A new polyaniline/multi-wall carbon nanotube (PANI/MWNT) composite has been successfully synthesized by an "*in-situ*" polymerisation process; Raman studies indicate a site-selective interaction between the quinoid ring of the polymer and the MWNTs opening the way for charge transfer processes; transport measurements clearly reveal drastic changes in the electronic behaviour confirming the formation of a true composite material with enhanced electronic properties.

Carbon nanotubes have unique electronic[1] and mechanical[2] properties and are of great interest for the fabrication of new classes of advanced materials. Here, composites based on polymers and nanotubes especially offer the possibility of obtaining materials with superior characteristics.[3] Polyaniline (PANI), a particular conducting polymer[4] with a high application potential,[5] is a promising candidate for the synthesis of such nanotube composites suitable for improved structural or functional applications. In this article we report, for the first time, the synthesis of this new material by an "*in-situ*" polymerisation process.

The composites were synthesized by polymerisation of aniline with MWNTs. The MWNTs are prepared in an arc discharge experiment by sublimation of pure graphite rods under an helium atmosphere of 660 mbar, using a current of 100 A and a voltage of 25 V. After the experiment, MWNTs were collected from the inner core of the formed cathodic deposit. A solution of HCl 1 M, containing MWNTs, was sonicated at room temperature to disperse the carbon nanotubes. The aniline monomer, in HCl 1 M, was added to the MWNTs suspension. A solution of HCl 1 M containing the oxidant $(NH_4)_2S_2O_8$ was slowly added with a constant sonication at a temperature of about −3 °C. After a few minutes, the dark suspension became green indicating good polymerisation of aniline, and then was sonicated in an ice bath for 2 h. The composite is obtained by filtering and rinsing the suspension with HCl 1 M followed by drying of the remaining powder under vacuum at room temperature for 24 h. In this process, the PANI exists in its primary doped form called the "emeraldine salt"[4] in which coexist two structures: the polaronic form and the bipolaronic structure[6] (Fig. 1).

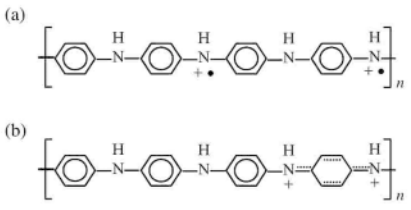

Fig. 1 Schematic structure of the emeraldine salt: (a) the polaronic form, (b) the bipolaronic structure.

† Electronic supplementary information (ESI) available: electron micrographs of PANI/MWNT composites. See http://www.rsc.org/suppdata/cc/b1/b104009j/

Different composites were synthesised by this process, using 10, 20, 30 and 50 wt% of MWNTs (in weight of monomer). In order to compare with the *in-situ* polymerised material, additionally, an "*ex-situ*" polymerised composite has been prepared by only mixing the doped PANI with 30 wt% of MWNTs by two hours of sonication.

The structural characteristics of the composites and its constituents have been analysed by X-ray powder diffraction measurements and is shown in Fig. 2. While the diffractogram of the pure MWNTs exhibits the typical peaks at 3.42, 2.13, 2.05, 1.71 and 1.23 Å corresponding to the graphite (002), (100), (101), (004) and (110) reflections, respectively, the one of PANI shows the highly pronounced oscillation structure characteristic of the doped form (emeraldine salt) with an oxidation degree of 0.5.[7] On the other hand, the diffractograms of the composites (10 and 30 wt%) display the typical peaks of the emeraldine salt as well as the strong peaks of MWNTs which are superposed and whose heights increase proportionally to their weight percentage. Therefore, it is clear that, from a structural point of view, no additional order has been introduced. This observation has also been confirmed by microscopy studies.†

On the other hand, Raman spectroscopy (Fig. 3) reveals that the electronic behaviour of the composites varies significantly from the one of its constituents. The Raman spectrum of the PANI shows the typical bands of the doped polymer in good agreement with a previous paper.[8] The spectra of pure nanotubes exhibit the three usual bands of MWNTs: the D-line at 1350 cm^{-1} (amorphous carbon and disorder induced line), the G-line at 1580 cm^{-1} (in-plane stretching E_{2g} mode) and a shoulder around 1600 cm^{-1} assigned to the D′-line (disorder line).[9] While the spectrum of the 10 wt% composite (not shown) is still identical to that of PANI, from 20 wt% on, the composite spectra clearly display different characteristics. Here, it is worth noting the remarkable decrease of the intensity of the PANI 1485 cm^{-1} band with respect to the 1161 cm^{-1} band. This band at 1485 cm^{-1} has been assigned to an in-plane deformation of

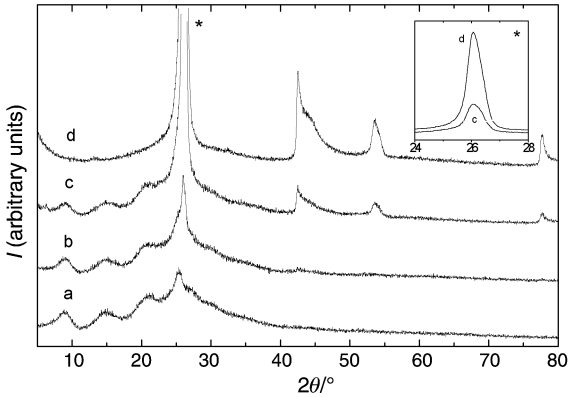

Fig. 2 X-Ray diffractograms (Cu-K_α) of doped PANI (a), composites containing 10 wt% (b) and 30 wt% (c) of MWNTs, and MWNTs (d).

 DOI: 10.1039/b104009j

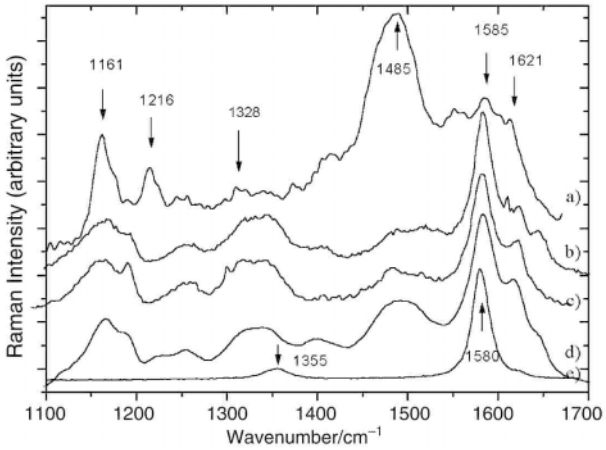

Fig. 3 Raman spectra (λ_{exc} = 514.5 nm) of doped polyaniline (a), composite using 20 (b), 30 (c) and 50 wt% (d) of MWNTs, and pure MWNTs (e).

the C–C bond of the quinoid ring of the doped PANI.[8] Therefore this pronounced decrease gives evidence that a site-selective interaction between the quinoid ring of the doped polymer and the nanotubes occurs as a consequence of the *in-situ* polymerisation. This interaction then may facilitate charge-transfer processes between the two components of the system and thus influence the transport properties of the composite.

Consequently, the transport behaviour (4 point-measurements between 300 and 1.25 K) has been studied on the MWNTs, the PANI, the *in-situ* polymerised composites (10, 20, 30 and 50 wt%) as well as on the *ex-situ* 30 wt% composite (Fig. 4). PANI shows a typical room temperature resistivity of 0.3 Ω cm.[10] It increases by 7 orders of magnitude following a $T^{-1/4}$-hopping law upon cooling to 1.7 K. The MWNTs resistivity is 2 Ω cm at room temperature and increases up to 15 Ω cm at low temperature.

The transport properties of the highly filled composites obtained by *in-situ* polymerisation exhibit the following remarkable facts. i) The room temperature resistivity is decreased by one order of magnitude as compared to PANI. ii) The low temperature resistivity is much smaller than both that of PANI as well as MWNTs (1.1 Ω cm for both the 50 and the 30 wt%, 2 Ω cm for the 20 wt% composites). iii) The temperature dependence of the resistivity is weaker than that of PANI. Regarding point iii), we can propose the following explanation. In this composite system, both the matrix and the filler (MWNTs) are conducting. At high temperatures, the conductivity is dominated by the polymer. Decreasing the temperature, the matrix becomes more and more resistive. On the other hand, the filler network which shows a very weak temperature dependence becomes more conducting than the matrix at low temperature. This means that the low temperature conductivity is due to the MWNTs. Actually this consideration is supported by the *ex-situ* polymerised 30 wt% composite (curve f) for which the low temperature resistivity shows the characteristic plateau due to MWNTs conduction.

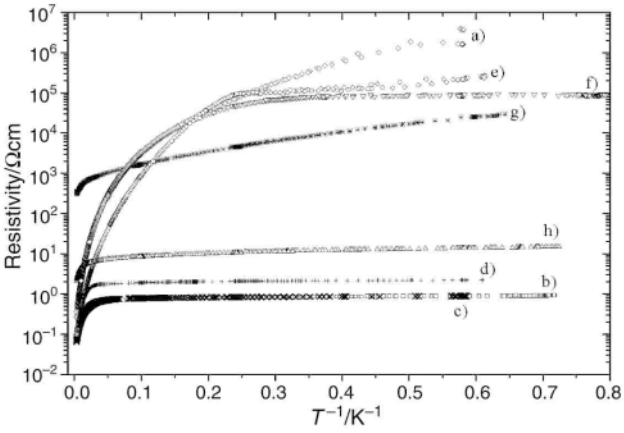

Fig. 4 Temperature dependence of the resistivity in polymer/MWNTs composite: PANI (a), *in-situ* PANI/MWNTs composites with 50 (b), 30 (c), 20 (d) and 10 wt% (e) of MWNTs, the *ex-situ* 30 wt% PANI/MWNTs composite (f), the *ex-situ* 30 wt% PMMA/MWNTs composite (g) and MWNTs (h).

Looking in more detail at the *in-situ* polymerised samples (curves b to d), the points i) and ii) further show that both the conductivity of PANI and of MWNTs has increased during the *in-situ* polymerisation process. This behaviour indicates that the electrical contacts between the MWNTs and the PANI grains have been improved. In accordance with the Raman observations, this suggests that *in-situ* polymerisation favours the charge transfer between PANI and MWNTs resulting in an overall material which is more conducting than the starting components. On the other hand, the apparent saturation of the resistivity decrease as well as of the increase of Raman intensity at 1485 cm^{-1} between the 30 and 50 wt% samples may be related to both the problems of achieving a homogeneous dispersion of large quantities of MWNTs in a matrix and the use of a microprobe in Raman spectroscopy. For the sake of comparison, additionally, a poly(methyl methacrylate) PMMA/MWNTs composite was prepared by mixing the insulating PMMA polymer with 30 wt% of MWNTs. In contrast to the PANI composites, the electronic behaviour of this material is completely different, especially in what concerns the temperature dependence of the resistivity, which is much stronger. Therefore, this observation further underlines the existence of a particular behaviour in case of the PANI/MWNTs composites. Further enhancement of the observed effects may be expected by using purified MWNTs, provided that the conducting path would include polyhedral particles as well.

Summarising, we have demonstrated the synthesis of a new PANI/MWNTs composite with enhanced electronic properties. Here, Raman and transport measurements show that the synthesis by an *in-situ* process leads to effective site-selective interactions between the quinoid ring of the PANI and the MWNTs facilitating charge-transfer processes between the two components. More detailed studies on the electronic behaviour along with the exploitation of the mechanical properties are currently carried out.

Received (in Cambridge, UK) 18th April 2001, Accepted 26th June 2001
First published as an Advance Article on the web 19th July 2001

The first enantioselective synthesis of 12-*tert*-butyl substituted 7,8-dihydrobenzo[*c*]phenanthrene-1,4-quinones having helical chirality is achieved with good chemical and optical yields through a domino Diels–Alder reaction–sulfoxide elimination–oxidation process starting from enantiopure (*S*)-2-(*p*-tolylsulfinyl)-1,4-benzoquinone and 5-*tert*-butyl substituted 3-vinyl-1,2-dihydronaphthalenes as dienes.

Compounds with the benzo[*c*]phenanthrene framework, [4]-helicenes, posess helical chirality due to the distortion of the planarity caused by overcrowding of the substituents at 1 and 12 positions of the terminal rings.[1] When such substituents are large enough, these molecules can be resolved into their corresponding enantiomers. The first configurationally stable 1,12-dimethyl substituted [4]-helicene was prepared and resolved by Newman[2] in 1956. Since then, only a few derivatives have been resolved into their optical isomers either by chemical[3–6] or chromatographic[4,7] methods. Some of them have shown interesting properties in chiral catalysis,[5] chiral recognition in complexation with cyclodextrins,[8] chiral Langmuir Blodgett film formation,[9] charge-transfer complexation,[10] chiral macrocyclic anhydride and amide formation,[11] and as a part of the first rationally designed chemically powered molecular motor.[12] Moreover, a recent report has shown that a high non-planarity of helical benzo[*c*]phenanthrenes induced by a methyl group at C-12 lowers their DNA-damaging effects compared with the unsubstituted derivative.[13] Although the interest in synthesizing these helicenes in optically active form is evident, to the best of our knowledge, only a single asymmetric approach has been described so far for the enantioselective construction of a lactone-type chiral tetrahelicene.[14]

In connection with a program devoted to asymmetric synthesis mediated by sulfoxides,[15] we have recently described the first asymmetric approach to [5]-helicenediquinones[16] based on the domino cycloaddition–sulfoxide elimination–oxidation process between enantiopure (*S*)-2-(*p*-tolylsulfinyl)-1,4-benzoquinone and vinyl phenanthrenes. Nevertheless, due to the poor reactivity of these aromatic derivatives as dienes, Diels–Alder reactions took place only in reflux of solvents with high boiling points or under high pressure conditions, with low chemical and optical yields. Taking into account the low racemization barriers of [4]-helicenes (< 16 kJ mol^{-1} for tetrahelicene),[17] such an asymmetric approach would not be applicable unless milder conditions conducive to the formation of the tetracyclic skeleton could be found. Thus, we thought of using more reactive non-aromatic dienes such as vinyldihydronaphthalenes which would probably allow the cycloaddition step to proceed under milder conditions, thus avoiding the racemization processes. We also reasoned that the introduction of a bulky substituent such as the *tert*-butyl group at C-1 or C-12 positions of the [4]-helicene could notably increase the racemization barrier as well as induce a higher non-planarity of these helical molecules. In this communication, we report the first enantioselective approach to configurationally stable helically chiral 12-*tert*-butyl substituted 7,8-dihydrobenzo[*c*]-phenanthrene-1,4-quinones based on this strategy.

As outlined in Scheme 1, the synthesis of vinyldihydronaphthalene **5** started with the addition of *tert*-butyl magnesium chloride to commercially available 7-methoxy-1-tetralone (**1**),‡ followed by dehydration of the resulting tertiary carbinol with 10% H_2SO_4 (48% yield for the two steps). The dihydronaphthalene **2** obtained was fully aromatized to naphthalene **3** with DDQ in 99% yield. Birch reduction of **3** with Na in refluxing EtOH followed by acid hydrolysis of the resulting

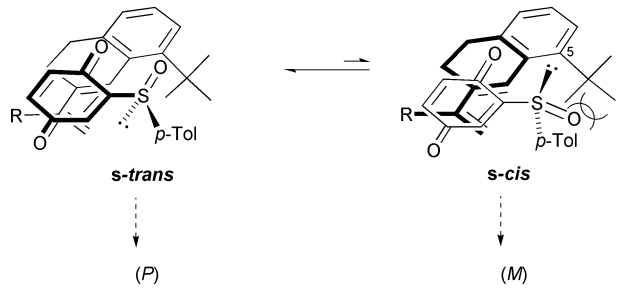

Fig. 1 *Endo* approaches of vinyldihydronaphthalenes on the s-*trans* and s-*cis* conformations of (*S*)-**6**.

vinyl ether gave 8-*tert*-butyl-2-tetralone (**4**) in 99% yield. Transformation of **4** into the corresponding enol triflate and Stille coupling with tributylvinylstannane afforded 5-*tert*-butyl-3-vinyl-1,2-dihydronaphthalene (**5**) in 40% yield for the two last steps.

The cycloaddition between diene **5** and enantiopure (*S*)-2-(*p*-tolylsulfinyl)-1,4-benzoquinone (**6**)[18] at room temperature afforded a 25:15:60 mixture of **7**, **8** and **9** which could be separated by flash chromatography (54% overall yield). Compound **7** was formed by *endo*-cycloaddition of **5** to the sulfinyl substituted C-2=C-3 double bond of **6** followed by elimination of the sulfoxide. This derivative, having a stereogenic center at C-12b, showed a 72% ee§ {$[\alpha]_D^{20} = -240$ (*c* 0.024, $CHCl_3$)}. Compound **8**, resulting from full aromatization of the B ring of **7**, was isolated in optically active form {$[\alpha]_D^{20} = +371$ (*c* 0.017, $CHCl_3$)} with a 72% ee,§ confirming the expected helical chirality for this type of quinone. Although the dienophile **6** was used in excess (2 equiv.) to achieve the aromatization of the B ring of **7**, only a small amount of the desired derivative **8** was formed under these conditions. The major component of the crude reaction mixture was characterized as a mixture of regio- and diastereoisomers **9**, resulting from the cycloaddition of diene **5** to the unsubstituted C-5=C-6 double bond of **6**.¶

In accordance with our previous findings,[19] the increasing electron donating effects of diene substituents favored cycloadditions through the more polarized sulfinyl substituted C-2=C-3 double bond of **6**. We thus thought of using a more reactive diene such as **10**, bearing an oxygenated substituent at the vinylic moiety, with the aim of increasing the yield of the desired [4]-helicenequinone. Compound **10** was prepared in a similar way as derivative **5**, by using 1-ethoxyvinyltributylstannane for the Stille coupling step (46% yield for two steps from **4**, Scheme 1). Cycloaddition between **10** and **6** could be conducted at –20 °C, affording in 57% yield helically chiral derivative **11** showing an optical rotation value of $[\alpha]_D^{20} = +1077$ (*c* 0.019, $CHCl_3$) and 88% ee.§ Compound **11** resulted from the exclusive attack of **10** on the sulfinyl substituted C-2=C-3 double bond of **6**, elimination of the sulfoxide and full aromatization of the B ring. This result evidenced that the use of the electron rich diene **10** not only completely reversed the chemoselectivity of the process, but also facilitated the aromatization of the B ring of the non-isolated intermediate, the 6-EtO derivative of (*R*)-**7**. Moreover, the lower temperature used in the cycloaddition step improved the diastereoselectivity of the whole process.[20]

The (*R*) absolute configuration at C-12b, the only stereogenic center of **7**, as well as the (*P*) absolute configuration of helical quinones **8** and **11** were initially established considering the preferred formation of a Diels–Alder adduct resulting from the *endo*-approach of **5** and **10** to the lower face of (*S*)-**6** adopting the s-*trans* conformation (Fig. 1). This should be the most favoured situation from the steric point of view since, when the dienophile reacts through the most stable s-*cis* rotamer, the approach of the diene from the less encumbered upper face gives rise to a transition state where a severe unfavourable interaction between the bulky *tert*-butyl group at C-5 of dienes and the sulfinylic oxygen of (*S*)-**6** appears. This configurational assignment was confirmed for **11** by applying, for the first time for a [4]-helicene, the methodology described by Katz[21] based on the different O=C–C–O conformations of (*M*)- and (*P*)-helicenyl camphanates‖ which bring about a different polarity and NMR behaviour of each diastereoisomer. Thus, we prepared di-(−)-camphanates (*P*)-**12** and (*M*)-**13** from racemic **11** and diastereoisomer (*P*)-**12** from enantiomerically enriched (+)-**11** (Scheme 1). The lower R_f (0.34) shown by diastereoisomer (*P*)-**12** on silica gel (eluent EtOAc–hexane 1:2) with respect to that of (*M*)-**13** (R_f = 0.42), as well as the existence of differentiated NOESY enhancements between H-2 and the methyl groups *a* and *b* of the inside camphanates (OR* at C-1, Scheme 1) in (*M*) and (*P*) isomers are consistent with the data reported[21] for determining the absolute configuration of these derivatives.

In summary, we have synthesized for the first time helically chiral 12-*tert*-butyl-substituted tetrahelicenequinones under very mild conditions from enantiopure (*S*)-2-(*p*-tolylsulfinyl)-1,4-benzoquinone and vinyldihydronaphthalenes. The presence of the bulky *tert*-butyl group at C-12 makes the system stable enough to be isolated in optically active form.

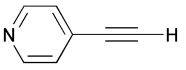
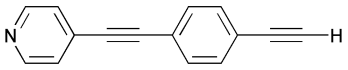
Received (in Cambridge, UK) 24th April 2001, Accepted 26th June 2001
First published as an Advance Article on the web 19th July 2001

The crystallization of 4-ethynylpyridine (1) and 4-(4-ethynylphenyl)ethynylpyridine (2) leads to C(sp)-H···N hydrogen bonded straight tapes that further assemble into polar crystals, in the case of 2, and show intense powder SHG response, 8 times more efficient than crystalline urea.

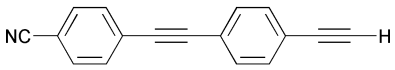
The aims of crystal engineering are to design crystal structures of molecular solids with specific topological features, chemical function, or physical properties.[1] One area of particular endeavor in this field is the design of non-centrosymmetric polar crystals[2] because of their importance for physical properties of bulk assemblies such as non-linear optical (NLO) activity.[3] In this study we introduce a new class of polar crystals in which the molecules are directed in a completely parallel orientation through C(sp)–H···N hydrogen bonds. Here we



1



2



3

report the X-ray crystal structures of 4-ethynylpyridine (**1**) and 4-(4-ethynylphenyl)ethynylpyridine (**2**) as well as NLO properties of the polar crystals of **2**.

The crystal structural analysis† for **1**[4] revealed the formation of a linear tape structure formed by very short and linear C(sp)–H···N contacts (Fig. 1); the H···N distance (2.33 Å) found in the structure is about 0.4 Å shorter than the sum of their van der Waals (vdW) radii (2.75 Å) and is one of the shortest C–H···N contacts reported.[5] The C(sp)–H–N angle is 180° and the molecules in the tape are located on a crystallographic two-fold axis. The head-to-tail polar tapes of **1** are arranged in antiparallel fashion in the crystal, resulting in a centrosymmetric packing with space group *C*2/*c*.

The crystal structure analysis‡ for **2**§ also shows the formation of a tape structure through very short and linear C(sp)–H···N contacts (Fig. 2). Molecule **2** is almost planar in the crystal with the largest deviation of 0.21 Å from the least-square plane; the dihedral angle between the two aromatic rings is 19.0°. Interestingly, further packing analysis reveals that the unit cell of the crystal contains eight molecules of **2** in a non-centrosymmetric packing with space group *Fdd*2. Since the majority of achiral organic compounds tend to pack into centrosymmetric crystals,[3] this observation is rather unusual. Moreover, the dipole moments of the molecules are arranged perfectly in a parallel orientation in the crystal and, therefore, the vector parts of the first hyperpolarizabilities of the molecules are directed in a completely parallel orientation, which make this compound attractive for second-order NLO materials. In fact, the crystals of **2** show a strong second-harmonic generation (SHG) signal, 8 times more intense than that of crystalline urea, in the Kurtz powder test at 1907 nm. With this finding, we explored the SHG response in related compounds and found that the crystals of 4-(4-ethynylphenyl)-ethynylbenzonitrile (**3**)¶ also exhibit an intense SHG signal, 16 times more efficient than crystalline urea, in the Kurtz powder test at 1907 nm. We surmise that molecules of **3** are also arranged linearly in the crystal, in a head-to-tail fashion directed by the C(sp)–H···N hydrogen bond.[6] Although it is not clear at present what factors are responsible for the polar organization of **2** and **3**, it can be pointed out that the *p*-phenylene units in **2** and **3**, which is absent in **1**, should play an important role in the polar assembly process.‖

In conclusion, we have found a unique assembly of directed polar crystals based on the C(sp)–H···N hydrogen bond, which has been little exploited in crystal engineering so far. The present results clearly demonstrate that the C–H···N weak

hydrogen bond is capable of not only constructing well-defined crystal structures but also inducing functional properties (SHG response) to the resulting bulk assemblies.

A squaramide fluorescent ensemble for monitoring sulfate in water

Rafel Prohens, Gabriel Martorell, Pablo Ballester and Antoni Costa*

Departament de Química, Universitat de les Illes Balears 07071. Palma de Mallorca, Illes Balears, Spain. E-mail: antoni.costa@uib.es; Fax: +34 971 173426; Tel: +34 971 173266

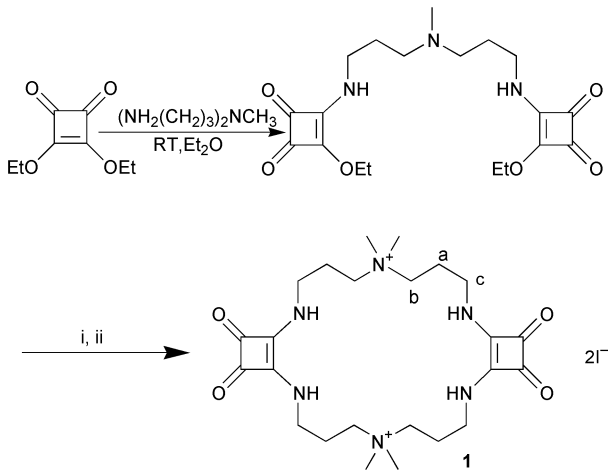
Received (in Cambridge, UK) 11th May 2001, Accepted 18th June 2001
First published as an Advance Article on the web 20th July 2001

A simple molecular sensor that uses the exclusive quenching and binding abilities of two squaramide units included within an anionic recognition site is proposed for monitoring sulfate in water.

Squaramides are ideal components for molecular sensing devices due to their quenching and binding abilities. We recently described a fluorescent molecular probe,[1] showing the classical covalent arrangement of a fluorophore close to the recognition site that takes advantage of the quenching ability of squaramides. In addition, squaramides feature two hydrogen bond donor atoms that, in extended conformation, bind carboxylate anions tighly.[2] Furthermore, it is possible to achieve strong and selective binding of oxoanions by combining electrostatics together with more directional hydrogen bonding interactions, as in a related streptavidin-2-iminobiotin sulfate complex.[3] On this basis, using the hydrogen bond donor capabilities of squaramides, we describe herein a competitive strategy for sensing sulfate based on a simple macrocyclic charge-assisted squaramide receptor.

In contrast to the usual high dilution conditions required for macrocyclization, receptor **1** was obtained on a gram scale, in 60% overall yield after three steps (Scheme 1). Despite its apparent flexibility, the rigidifying effect provided by the two squaramide rings and a charge repulsion avoid the collapse of **1** and, at the same time, generates a concave cavity lined with two quaternary ammonium groups and four hydrogen bond donors useful for binding. The resulting bowl-shaped receptor is well suited for recognising tetrahedral anions as it matches the spatial and charge requirements of a target guest like sulfate placed at the centre of the cavity.

The formation of a **1**–SO_4^{2-} association complex was evidenced from the observation of characteristic association-induced shifts (CIS) on both, the squaramide and cyclophane hydrogens of **1**. Additional support was obtained from HOESY experiments performed in methanol on a related **1**–$^{13}C_2O_4^{2-}$ complex. In this case, diagnostic ^1H to ^{13}C NOE intermolecular contacts between the oxalate carboxylate at 176.8 ppm and H_a, H_b hydrogens in **1**, were observed, in accordance with the proposed localisation of the anion in **1**.



Scheme 1 Synthesis of **1**, (i) 3,3′-diamino-*N*-methyldipropylamine (1.0 equiv.) EtOH, 7 h, rt; (ii) MeI (7 equiv.), DMF, 70 °C, 12 h.

Host–guest association was fully characterized by isothermal titration calorimetry (ITC).[4] This technique is a valuable resource for investigating the energetics of host–guest processes[5] as it allows the determination of association constants larger than 10^5 M^{-1} that are clearly out of the possibilities of the standard NMR direct titration methods. In the present case, for the complexes with SO_4^{2-}, $PhOPO_3^{2-}$, $C_2O_4^{2-}$ and **1**, respectively, the value of the experimental stoichiometry parameter "n" was always in the range $0.95 < n < 1.05$ in good agreement with a 1 : 1 mode of binding.

The results obtained with selected oxodianions, show that the association is endothermic and entropically driven in all cases. The binding model emerging from the calorimetric data is consistent with an exchange equilibrium between **1** and the anionic guests. Upon formation of the complex both, **1** and the guest, must break their bonds with methanol and the release of solvent bound molecules to the bulk solvent would outweigh the entropic cost of the association.[6] Remarkably, the binding of monoanions such as halides, nitrate, acetate, and others is negligible owing to the electroselectivity imposed by the tetraalkylammonium groups. On the other hand, the preference for tetrahedral sulfate is accounted for by the structural constraints of the hydrogen bond donor array of the squaramide units in **1**, favouring the binding of sulfate over other divalent anions.

Addition of **1** to a solution of fluorescein disodium salt (FNa_2)† in MeOH–H_2O mixtures (9 : 1 v/v) produced a non-fluorescent self-assembled ensemble as a consequence of the effective quenching of the fluorescein emission band in the complex. The observed fluorescence quenching is probably due to photo-induced electron transfer (PET) from the donor squaramide rings of **1** to the fluorescein excited singlet state. This effect, namely an increase of fluorescence on binding the anion due to the suppression of PET that occur when the **1**–FNa_2 complex dissociates, is formally equivalent to the well-known cation promoted suppression of PET widely used for cation recognition. In the present case, the system is not a fluorescent chemosensor, defined as an integrated fluorophore–receptor species,[7] but merely a mixture of a receptor and a fluorophore in which the latter competes with the target ion in complexation.

Table 1 Thermodynamic parameters for the interaction of **1** with key dianions[a]

Guest	K_a/M^{-1}	$\Delta G°$/ kJ mol^{-1}	$\Delta H°$/ kJ mol^{-1}	$T\Delta S°$/ kJ mol^{-1}
$C_2O_4^{2-}$	$(3.2 \pm 0.3) \times 10^5$	−31.0	+12.2	+43.2
$PhOPO_3^{2-}$	$(1.5 \pm 0.2) \times 10^4$	−23.5	+12.5	+36.0
SO_4^{2-}	$(4.6 \pm 1.0) \times 10^6$	−37.5	+11.3	+48.7

[a] Titration conditions: 30–40 injections (5 μL each) of a 5–10 mM solution of the anion, as sodium or tetramethylammonium salt, were introduced into a sample cell at 294 K containing 1.5 mL of a 0.8 mM solution of **1** in methanol. The heats of dilution were subtracted prior to data analysis by Origin MicroCal software. In all cases the c parameter,[4] defined as $c = K_a$ [**1**]$_t n$, was kept between 10 and 1000. Errors were calculated at a confidence level of 95%.

 DOI: 10.1039/b104172j

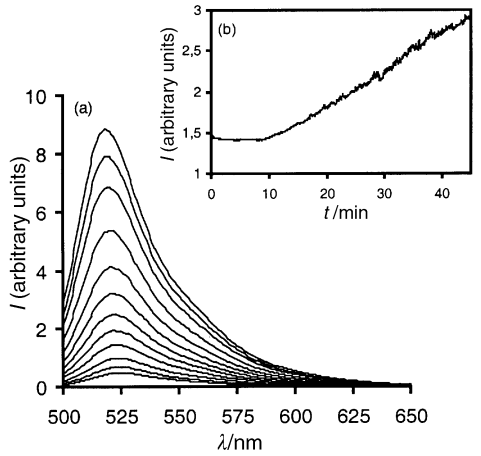


Fig. 1 (a) Fluorescence emission band ($\lambda_{exc.}$ 490 nm) of fluorescein, [FNa_2] = 1.4×10^{-5} M before (upper band) and after addition of **1**, [**1**] = 2.0×10^{-4} M (lowest band). Fluorogenic emission response with several concentrations of sulfate, [SO_4^{2-}] = 4.6, 6.5, 8.4, 10.0, 11.7, 13.3, 14.8, 15.9×10^{-5} M. The subset reflects the response of the **1**–FNa_2 ensemble to sulfate addition. (b) In this experiment, after an approximate 10 min period, the sulfate concentration of a water solution was continuously increased from 0 to 200 ppm and mixed at 0.10 mL min^{-1} together with a stream of [**1**] = 2.6×10^{-4} M and [FNa_2] = 7.4×10^{-4} M in MeOH–H_2O (90 : 10 v/v) at a flow rate 0.90 mL min^{-1}. Fluorescence was measured at 2 s intervals.

The association constant of the measuring **1**–FNa_2 ensemble (K_{ass} = $4.7 \pm 0.6 \times 10^4$ M^{-1}) was obtained by measuring the change in the fluorescence intensity of FNa_2 in the presence of an increasing amount of **1**.[8] In the same solvent system, the association constant for SO_4^{2-} (K_{ass} = $5.2 \pm 1.2 \times 10^6$ M^{-1}) estimated by competitive spectrophotometry[9] was clearly higher. In accordance, upon competitive addition of SO_4^{2-}, fluorescein was displaced[10] restoring the original fluorescence of FNa_2 (Fig. 1) and effectively signalling the presence of sulfate anion. This ensemble is also adequate for real time on-line determination of sulfate in water (pH ≥ 10). To this end, a stock solution of the sensing ensemble **1**–FNa_2 is mixed together at a 9 : 1 v/v ratio with an incoming water stream that contains an increasing concentration of sulfate. The result, shown in Fig. 1(b), shows a linear response within a wide range of sulfate concentration.

In conclusion, we have developed a squaramide-based receptor useful for sensing sulfate. In this ensemble the effective fluorescence quenching of the squaramides combined with an adequate hydrogen bond pattern are valuable resources that will be exploited in the future for sensing other targets.

Financial support from the Spanish DGESIC (PB98-0129) is gratefully acknowledged. R. P. thanks the Spanish Ministry of Education for a fellowship.

First published as an Advance Article on the web 19th July 2001

A first example of electroassisted activation of molecular oxygen by Jacobsen's epoxidation catalyst in an ionic liquid at room temperature has been achieved and showed the formation of the postulated high-valent manganese–oxo active intermediate.

Over the past few years, room temperature ionic liquids have re-attracted a wide range of sections of chemistry and generated much excitement and interest for various applications.[1] This renewed vigour is principally linked to the fact that these liquids have simple physical properties making them 'green friendly solvents' (easy to recycle, non-volatile and non-flammable). Thus, they offer potential alternatives for a large variety of disciplines, especially organic and inorganic chemistries. Recently, the discovery of enzyme activity in these media[1c] extends their potential use to bioinorganic applications. This context fits well with the desire to mimic enzymatic systems involving synthetic models (porphyrins and Schiff bases), especially for monooxygenases of the cytochrome P-450 family.[2]

Indeed, analysis of comparative studies dealing with the selectivity, efficiency, stability and recovery for both synthetic models and natural systems have shown that efficiency arises from the control of the environment of the enzyme active site and the development of practical immobilisation methods for catalysts, such as clay-intercalation,[3] zeolite-encapsulation,[4] covalent attachment to an organic polymeric matrix[5] and the use of two-phase systems.[6] Although relatively few efficient examples have been reported they constitute an important contribution to the development of efficient chemical systems operating according the catalytic cycle of substrate oxidation by cytochrome P-450, which involves a supposed high valent metal–oxo intermediate.[7] In the last decade, we have shown the first and rare examples involving electroassisted activation of molecular oxygen to generate metal–oxo active species for biomimetic oxidation of various hydrocarbons by immobilised enzyme models.[8,9]

Recently, Song and Roh[10] reported on the use of ionic liquids as practical recycling media for Jacobsen's catalyst {[*N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-cyclohexanediamine)]-manganese(III) chloride, the so-called chiral (salen)Mn epoxidation catalyst and denoted here **[Mn(III)]$^+$**, Fig. 1}, for the asymmetric epoxidation of alkenes by aqueous NaOCl (as the oxidant) in the air-and moisture-stable ionic liquid [bmim][PF_6] at 0 °C, ([bmim]$^+$ = 1-butyl-3-methylimidazolium cation, Fig. 1). Our interest in electroassisted biomimetic reactions encourages us to explore a further extension of our clean chemistry concept, involving molecular oxygen and electrochemistry, into the field of a non-aqueous and polar two-phase process alternative, to provide not only simple recycling of the catalyst without modification of its structure, but also an increase in its activity. Herein, we report for the first time the electrochemical analysis of the biomimetic activation of molecular oxygen with the electrochemically reduced catalyst **[Mn(III)]$^+$** (in the presence of benzoic anhydride and 1-methylimidazole) in the ionic liquid [bmim][PF_6]. This study constitutes the first approach demonstrating the possible existence of the key steps responsible for the electroassisted formation, from molecular oxygen, of the highly reactive [Mn(V)=O]$^+$ manganese–oxo intermediate in these conditions.

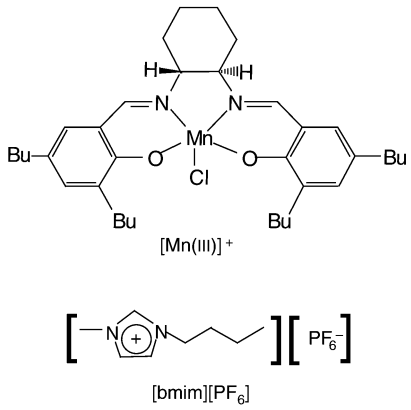

Fig. 1 Structures of **[Mn(III)]$^+$** and [bmim][PF_6].

Electrochemical experiments were carried out at a vitreous carbon electrode of area 0.07 cm^2 in [bmim][PF_6], conveniently prepared,[11] in the presence of **[Mn(III)]$^+$** catalyst and 1-methylimidazole (in the presence/absence of benzoic anhydride and molecular oxygen).† Fig. 2(a) shows the cyclic voltammogram of **[Mn(III)]$^+$** in a deaerated solution of the ionic liquid [bmim][PF_6] containing 1-methylimidazole. It exhibits a pair of well-defined peaks at $E \approx -0.460$ V *vs.* SCE corresponding to

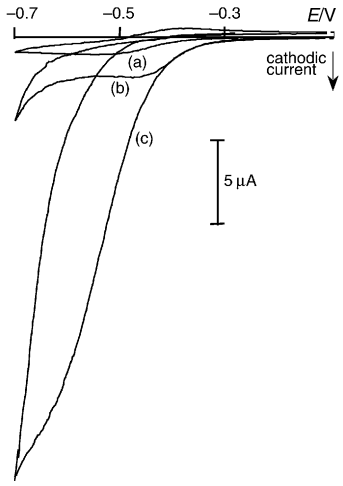

Fig. 2 Cyclic voltammograms of **[M(III)]$^+$** catalyst (2 mM) in [bmim][PF_6] ionic liquid in presence of 1-methylimidazole (10 mM) at room temperature (potential scan rate = 50 mV s^{-1}): (a): deaerated solution; (b) in the presence of molecular oxygen (saturated solution); (c) in the presence of benzoic anhydride (0.1 M) and molecular oxygen.

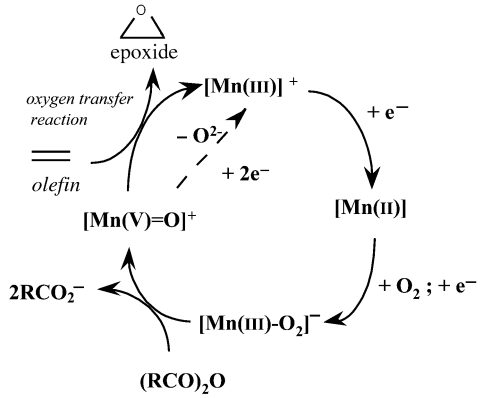
 DOI: 10.1039/b102526k

the reversible Mn^{III}/Mn^{II} redox process, by reference to the electrochemical behaviour of similar models in several organic solvents.[9,12,13] This was confirmed by rotating disk electrode voltammetry (data not shown). In presence of molecular oxygen, three main features related to the Mn^{III}/Mn^{II} reduction peak appear [Fig. 2(b)]: (i) its potential shifts to a higher potential value, *(ii)* its intensity is enhanced and *(iii)* its associated re-oxidation peak disappears. Such modification of the cyclic voltammogram is similar to that previously reported with related manganese catalysts under various conditions (dissolved or immobilised on solid supports and in organic solvents).[8,9,12,13] and is consistent with the first two steps of the catalytic cycle shown in Scheme 1.[12] Indeed, the reductive peak observed in Fig. 2(b) is representative of the reaction between the catalyst **[Mn(III)]**$^+$ (in the presence of 1-methylimidazole as an axial coordinating ligand, not shown in the cycle of Scheme 1) and molecular oxygen O_2, leading to a doubly reduced complex–oxygen adduct $[Mn–O_2]^-$, that can be interpreted as an 'electron transfer–chemical step–electron transfer' process.[9,12,13]

Fig. 2(c) shows the cyclic voltammogram of **[Mn(III)]**$^+$ in $[bmim][PF_6]$ containing both 1-methylimidazole and benzoic anhydride upon addition of molecular oxygen. A very large enhancement of the Mn^{III}/Mn^{II} reduction current peak is clearly observed. By reference to previously reported studies of similar complexes in several organic solvents, the modification of the cyclic voltammogram shows the occurrence of the expected reaction of the above mentioned $[Mn–O_2]^-$ adduct with anhydride $[(RCO)_2O]$ to give the high-valent manganese–oxo $[Mn(V)=O]^+$ intermediate, followed by its reduction and the steady state electrocatalytic regeneration of **[Mn(III)]**$^+$ (Scheme 1).[8,9,12,13] It is important to note that this reduction occurs competitively with the reaction of transfer of an oxygen to hydrocarbon in solution. However, we observed that the inclusion of olefin (*cis*-cyclooctene) did not produce a significant modification of the voltammograms, implying that the reaction is fast enough to be competitive with the rate of formation of the oxo complex.[9a,12] Finally, we have verified that the direct reduction of molecular oxygen takes place at *ca.*−0.8 V *vs.* SCE, outside the potential range investigated in this study, and that the presence of benzoic anhydride does not induce any electrochemical interference. Rotating disk voltammetry confirms all the above observations (data not shown).

In summary, this result shows for the first time the electroassisted biomimetic activation of molecular oxygen by Jacobsen's epoxidation catalyst in an ionic liquid and clearly demonstrates the possible existence of the key steps responsible for the formation of the highly reactive $[Mn(V)=O]^+$ manganese–oxo intermediate in the ionic liquid $[bmim][PF_6]$. This unique observation, combined with the immobilisation of the catalyst by using the ionic liquid, allows us to confidently explore this clean chemistry concept involving molecular oxygen and electrochemistry. Detailed studies are now in progress to extend this investigation to the preparative scale, for the epoxidation of selected olefins which may offer, for the first time to our knowledge, a possible extension of electrocatalysis and electrosynthesis to ionic liquid solvents.



Scheme 1 Proposed scheme for the electroassisted activation of molecular oxygen by **[M(III)]**$^+$ catalyst for olefin epoxidation reaction.

We are grateful to Prof. P. Letellier and Dr J. Devynck for helpful discussion and interest in this work.

† *Representative procedure* for the electrochemical study: all electrochemical studies were performed with a standard three-electrode potentiostatic system (Taccussel). The potentials are referred to an aqueous saturated Calomel electrode, (SCE), placed in a separate compartment. All the experiments were performed under atmospheric pressure and at ambient temperature. Jacobsen's catalyst was purchased from Aldrich and used as received while the ionic liquid $[bmim][PF_6]$ was prepared and purified as previously reported.[11]

First published as an Advance Article on the web 20th July 2001

***Ab initio* crystal structure determination of the peptide Piv-Pro-Gly-NHMe directly from powder X-ray diffraction data, using the genetic algorithm technique for structure solution, has allowed the complete structural characterization of the Type II β-turn conformation and the intermolecular interactions in this structure, and highlights the opportunities that now exist for structure determination of peptide systems when single crystals appropriate for single crystal X-ray diffraction experiments cannot be prepared.**

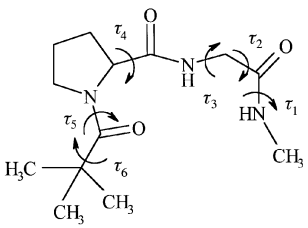
Knowledge of the conformational properties and interactions in model peptide systems can yield important insights concerning the structural properties of polypeptide sequences in proteins. An example concerns β-turns, which are structural elements that permit polypeptide chain reversals in proteins.[1] Tight turns in proteins and peptides, involving two residues as folding nuclei, have been very widely investigated,[2–5] and the understanding of β-turn stereochemistry that now exists has been facilitated by extensive high resolution structure determination of peptides[4] and proteins[2,3] from *single crystal* X-ray diffraction data. However, an intrinsic limitation of this technique is the requirement to prepare a crystal of sufficient size, quality and stability to allow single crystal diffraction data of appropriate quality to be measured. To circumvent this problem, progress has been made recently[6–10] in the development of new techniques for determining crystal structures directly from *powder* diffraction data, particularly with regard to the structure solution stage of the structure determination process. In the field of molecular crystals, the direct-space strategy[10,11] for powder structure solution has been a particularly important development. This paper reports the application of a genetic algorithm (GA) technique for *ab initio* structure determination of the peptide *N*-pivaloyl-L-prolyl-glycyl-*N*′-methylamide (Piv-Pro-Gly-NHMe) from powder X-ray diffraction data.

In the direct-space strategy for powder structure solution, trial structures are generated in direct space, with the quality of each trial structure assessed by comparing the powder diffraction pattern calculated for the trial structure and the experimental powder diffraction pattern (this comparison is made here using the powder profile R-factor R_{wp}, which implicitly takes peak overlap into consideration). In this work, direct-space structure solution was carried out using our GA method[12–19] to locate the trial structure corresponding to the global minimum in R_{wp}. In the GA method,[12–21] a population of trial structures is allowed to evolve subject to rules and operations (mating, mutation and natural selection) analogous to those that govern evolution in biological systems. Each structure is specified by its 'genetic code', which represents, for each molecule in the asymmetric unit, the position $\{x, y, z\}$ and orientation $\{\theta, \phi, \psi\}$ of the molecule, and the molecular conformation (defined by variable torsion angles $\{\tau_1, \tau_2, ..., \tau_n\}$). New structures are generated by the mating and mutation operations, and in our implementation used here,[16] each new structure is subjected to local minimization of R_{wp}. In natural selection, only the structures of highest 'fitness' (*i.e.* lowest R_{wp}) are allowed to pass from one generation to the next generation. Details of our GA methodology for powder structure solution[12–16] and examples of its application[17–19] are given in the cited refs.

The peptide Piv-Pro-Gly-NHMe was prepared by standard procedures,[22] purified by reverse phase HPLC on a C_{18} column and fully characterized by ^{1}H NMR (500 MHz) and electrospray mass spectrometry. The powder X-ray diffraction pattern of a lightly ground sample was recorded at ambient temperature on a Siemens D5000 diffractometer [transmission; $CuK_{\alpha 1}$ (Ge-monochromated); linear position-sensitive detector covering 8° in 2θ]. The 2θ range was 5 to 60°, measured in steps of 0.02° over 12 hours. The powder diffraction pattern was indexed by the program ITO,[23] giving a triclinic unit cell [final refined unit cell parameters following Rietveld refinement: a = 7.9747(3); b = 9.1814(3); c = 5.8456(2) Å; α = 97.020(2); β = 99.429(2); γ = 114.801(2)°]. Density considerations suggested that there is one molecule in the unit cell, and the space group was assigned as $P1$. Lineshape and linewidth parameters were determined using the POWDERFIT program,[24] which uses a modified Pawley fitting procedure.[25]

The GA structure solution calculation was carried out using the program EAGER.[26] The structural fragment (Scheme 1) comprised all non-hydrogen atoms of the molecule (with standard bond lengths and angles). For each structure, the genetic code comprised 9 variables $\{\theta, \phi, \psi, \tau_1, \tau_2, ..., \tau_6\}$, with the variable torsion angles allowed to take any value, except τ_5 which was allowed to take only the values 0 or 180°. We note that the position of the structural fragment $\{x, y, z\}$ is fixed arbitrarily in space group $P1$. The O–C–N–H torsion angle between τ_3 and τ_4 was fixed[27] at 180°. The population comprised 100 structures, and in each generation 100 offspring (50 pairs of parents) and 20 mutants were produced. The calculation was carried out for 50 generations.

The best structure solution (*i.e.* with lowest R_{wp} in the final generation) was taken as the starting structure for Rietveld refinement,[28] which was carried out using the GSAS program.[29] Standard restraints were applied to bond lengths and angles, and hydrogen atoms were inserted in calculated positions. Three common isotropic displacement parameters were refined, for



Scheme 1 Structural fragment used in the GA structure solution calculation for Piv-Pro-Gly-NHMe, with variable torsion angles indicated by arrows.

† Electronic supplementary information (ESI) available: fractional coordinates and isotropic displacement parameters for atoms in the final refined crystal structure. See http://www.rsc.org/suppdata/cc/b1/b103876c/

 DOI: 10.1039/b103876c

atoms of the main peptide chain, atoms of the ring system and oxygen atoms, respectively. For hydrogen atoms, a fixed common isotropic displacement parameter was used. In the final stages of refinement, a preferred orientation parameter was refined. The final Rietveld refinement (Fig. 1; supplementary information) gave R_{wp} = 4.14, R_p = 5.78 and R_F = 8.97% (75 variables; 269 reflections; 2857 data points).

Fig. 2 shows the final refined structure of Piv-Pro-Gly-NHMe. As shown in Fig. 2a, the molecule adopts a Type II β-turn conformation[30] (ϕ_{Pro} = −58.3; ψ_{Pro} = 127.2; ϕ_{Gly} = 71.4; ψ_{Gly} = 26.1°) stabilized by an intramolecular 4 → 1 hydrogen bond between the C=O group of the Piv residue and the methylamide N–H group (N···O, 2.99 Å; N···O–C, 140.6°). The conformation found here for Piv-Pro-Gly-NHMe is similar to those in other structures containing Type II β-turns, determined previously from single crystal X-ray diffraction data.[31] We note that Pro-Gly sequences in proteins and peptides

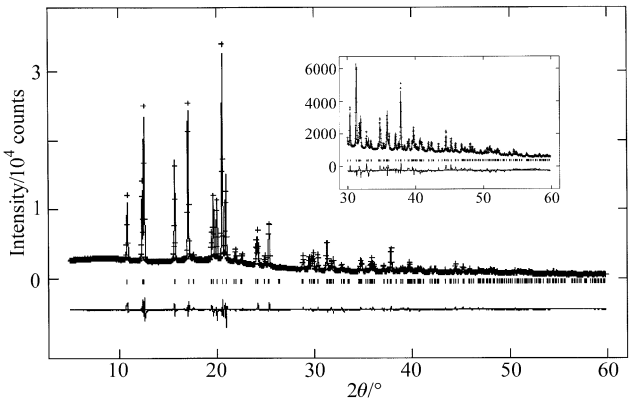


Fig. 1 Experimental (+ marks), calculated (solid line) and difference (lower line) powder X-ray diffraction profiles for the final Rietveld refinement of Piv-Pro-Gly-NHMe. The inset shows an expanded plot for 2θ = 30–60°.

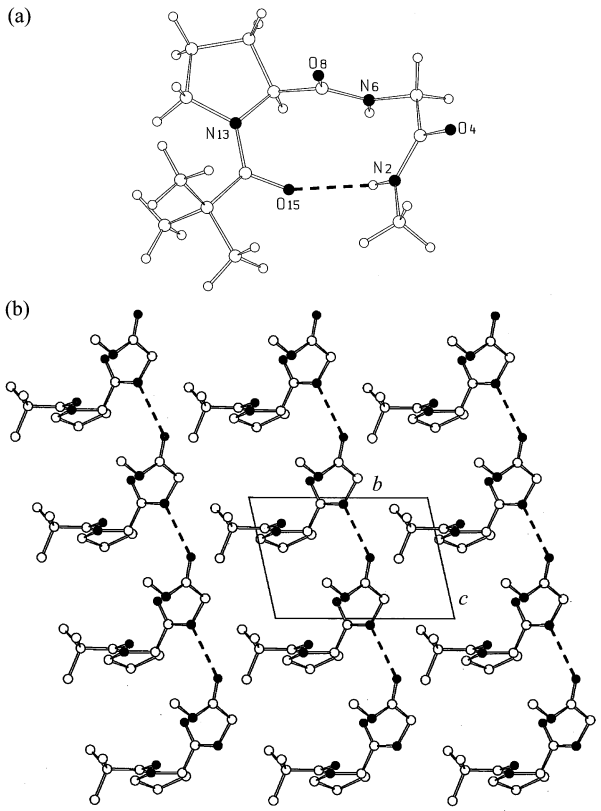

Fig. 2 (a) Molecular geometry of Piv-Pro-Gly-NHMe in the crystal structure, with the intramolecular hydrogen bond shown as a dashed line. (b) Crystal structure of Piv-Pro-Gly-NHMe viewed along the *a*-axis, with N–H···O hydrogen bonds shown as a dashed lines. Hydrogen atoms are omitted for clarity.

may alternatively adopt a Type I β-turn conformation, which is related to the Type II β-turn by a flip of the central peptide unit without disrupting the 4 → 1 hydrogen bond.[5] As shown in Fig. 2b, adjacent molecules in the crystal structure of Piv-Pro-Gly-NHMe are linked along the *c*-axis by intermolecular N–H···O hydrogen bonds (N···O, 2.87 Å; N···O–C, 135.3°).

Our *ab initio* determination of the crystal structure of Piv-Pro-Gly-NHMe from powder X-ray diffraction data has allowed the complete structural characterization of the Type II β-turn conformation as well as the intermolecular interactions in this structure, demonstrating that the direct-space approach for powder structure solution, with the molecular conformation treated as almost completely flexible, is well suited to applications in the field of polypeptides. The potential for applying powder diffraction techniques in this field is clearly important in cases that do not yield single crystals of suitable size and quality for single crystal diffraction studies.

We thank EPSRC, University of Birmingham, Wyeth-Ayerst plc and Ciba Specialty Chemicals for financial support.

First published as an Advance Article on the web 20th July 2001

We report the first molecular charge transfer salt containing channels of H_3O^+/H_2O within its lattice; it is formulated β″-(BEDT-TTF)$_4$[$(H_3O)Cr(C_2O_4)_3$]$_2$[$(H_3O)_2$(18-crown-6)]·5H_2O [BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene], deduced from the crystal structure and C=C and C–S bond lengths and Raman stretching frequencies.

Molecular charge transfer salts based on organo-chalcogen donors, especially those containing bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF) have provided examples of most of the collective electronic ground states known to condensed matter science, such as semiconductors, metals, superconductors, antiferromagnets, spin-Peierls systems *etc*.[1] Because of their layered structures, in which organic donor cations and inorganic anions are segregated from one another (what we have called 'organic–inorganic composites' or 'chemically constructed multilayers'[2]), they are also a fruitful source of compounds combining two different types of functionality, like paramagnetic superconductors[3] or ferromagnetic metals.[4] However, with one exception,[5] there have been no reports of efforts to combine electronic with ionic conductivity in this class of compound. In that context we now report the first BEDT-TTF salt containing crown ether molecules and both H_3O^+ and H_2O in the lattice, organised in such a way as to suggest the possibility of easy proton migration.

100 mg $(NH_4)_3[Cr(C_2O_4)_3]\cdot 3H_2O$, 200 mg 18-crown-6 ether, and 1 g pyrazine in a mixture of freshly distilled 25 ml of dichloromethane and 25 ml acetonitrile was stirred overnight, and filtered into an electrochemical cell. On applying a current of 1 μA across the cell, crystals first began to appear after 5 days and were harvested after 4 weeks. Two phases were obtained, long thin rectangular needles, whose structure was not resolved, and a small quantity of very thin dark brown plates. The structure of the latter was determined as β″-(BEDT-TTF)$_4$[$Cr(C_2O_4)_3$]$_2\cdot C_{12}O_6H_{24}\cdot 9H_xO$ **1** (where x = 2, 3). Single crystal X-ray diffraction data were collected using an Enraf Nonius Kappa CCD diffractometer mounted at the window of an Mo rotating anode generator with an Oxford Cryosystems N_2 open flow cryostat. The structure was solved by direct methods and refined anisotropically on F^2 using the SHELX97 program. H atoms were placed in idealised positions and refined using a riding model. Raman spectra were measured at room temperature with a Renishaw Ramascope System 1000 microscope equipped with a He–Ne laser (632.8 nm), using a slitwidth of 10 μm and a 10% neutral density filter.

Compound **1** crystallises in the triclinic space group $P\bar{1}$.† The structure consists of alternating layers of BEDT-TTF, and layers comprising $[Cr(C_2O_4)_3]^{3-}$, 18-crown-6 and water molecules. The packing of the layers follows the sequence ABCDABCDA, where A contains only BEDT-TTF, B contains $[Cr(C_2O_4)_3]^{3-}$ in either Δ or Λ configuration and an H_3O^+ molecule, as in the superconducting compound β″-(BEDT-TTF)$_4$[$(H_3O)Cr(C_2O_4)_3$]·PhCN,[6] while layer C contains the 18-crown-6 molecule and the remainder of the H_xO molecules (where x = 2, 3); layer D is a further $[(H_3O)Cr(C_2O_4)_3]^{2-}$ layer with the anions having opposite stereo-configuration to those in the B layer. Fig. 1 shows the packing of the successive layers projected onto the *bc* plane.

The BEDT-TTF molecules are arranged parallel to each other, in the β packing motif. There are two crystallographically independent BEDT-TTF molecules with similar charges of +0.4 ± 0.1 and +0.5 ± 0.1, as estimated from the C=C and C–S bond lengths,[7] which are close to those found in the β"-(BEDT-TTF)$_4$[$(H_3O)M(C_2O_4)_3$]·solv superconductors (solv being a solvent molecule). Since the $[Cr(C_2O_4)_3]^{3-}$ ions contribute a total charge of −6, this implies that four of the H_xO molecules must be H_3O^+ to maintain charge neutrality. By analogy with the superconductors two of these may be located in layers B and D. The terminal CH_2–CH_2 groups of the BEDT-TTF are both twisted, with one of the C atoms above the plane of the TTF

 DOI: 10.1039/b103877j

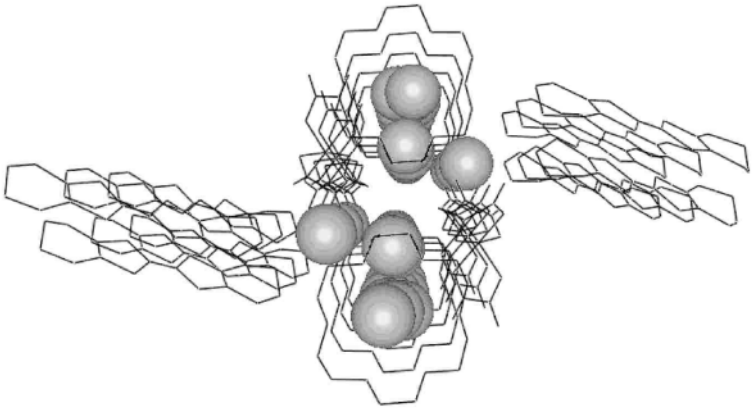

Fig. 2 The crystal structure of **1** showing the channels formed by the 18-crown-6 molecules and H_3O^+/H_2O.

moiety and the other below, but eclipsed with respect to the other end of the donor molecule. The two shortest S···S contacts between the crystallographically independent BEDT-TTF molecules average to 3.70 Å, although these are longer than the S···S van der Waals distance of 3.6 Å. The torsion angles of the CH_2–CH_2 groups of the BEDT-TTF indicate that one of the groups on one of the molecules is under more strain than the others, and the thermal ellipsoids show that this CH_2–CH_2 group is disordered. In fact it is the one located directly next to the Cr^{3+} centre of a tris(oxalato)Cr(III) ion. The other CH_2–CH_2 group, which has a more normal conformation, is closest to the 18-crown-6 ether.

Fig. 1 shows that, in contrast to the superconducting β″-BEDT-TTF tris(oxalato)metallate(III) salts,[8] the anion layer in **1** is almost as thick as two $[Cr(C_2O_4)_3]^{3-}$ and a molecule of 18-crown-6 ether. The latter separates the Δ and Λ forms of $[Cr(C_2O_4)_3]^{3-}$, between each of which there is one H_3O^+ cation, as in the superconducting phases. Thus there are two $[(H_3O)Cr(C_2O_4)_3]^{2-}$ layers, with crown ether and H_xO layers between them. One water molecule resides within each molecule of crown ether, the other forming a H-bonded chain to the next crown ether molecule along the *a* axis. The O···O contacts between these four water molecules are 1.84, 1.97 and 1.47 Å, the latter appearing short because one of the O atoms is disordered over two sites. In this way the 18-crown-6 ether molecules form an ion channel within the inorganic layer, as shown in Fig. 2. In this figure the O atoms of H_3O^+/H_2O are emphasised in space filling format, those on either side of the central chains being the H_3O^+ that form part of the $[(H_3O)Cr(C_2O_4)_3]^{2-}$ layers.

The Raman spectrum of **1** contains two peaks in the region of the totally symmetrical C=C vibrations at 1492 ± 2 and 1467 ± 2 cm^{-1} corresponding to ν_3 and ν_4 of BEDT-TTF. From the established correlation between stretching frequency and cation charge,[9] charges of +0.54 and +0.46 are indicated, in close agreement with the charges indicated by the BEDT-TTF bond lengths in the crystal structure. On the assumption that the two anion layers B and D are formulated as $[(H_3O)Cr(C_2O_4)_3]^{2-}$ as in the superconducting phases, charge neutrality requires that two of the remaining seven H_xO in the formula unit must be H_3O^+, the remaining five being H_2O. In the absence of evidence to the contrary, it can be assumed that the two H_3O^+ correspond to the water molecules closest to the rings of the crown ether molecules, with the remaining H_2O forming a H-bonded channel between neighbouring crown ether rings as described above.

In conclusion, we have found a new kind of organic–inorganic layer architecture in a molecular charge transfer salt, in which layers of $BEDT\text{-}TTF^{0.5+}$ with the classical β″-stacking arrangement, are interleaved with two layers of $[(H_3O)Cr(C_2O_4)_3]^{2-}$ honeycomb layers. The latter have the same topology as in the paramagnetic superconductors β″-$(BEDT\text{-}TTF)_4[(H_3O)M(C_2O_4)_3]\cdot solv$[2,6,8,10] but in the present case, instead of alternate anion layers consisting exclusively either of Δ or Λ-$[Cr(C_2O_4)_3]^{3-}$ separated by BEDT-TTF layers, we find alternate $[(H_3O)Cr(C_2O_4)_3]^{2-}$, again with exclusively Δ or Λ stereo-configurations, but separated by crown ether/H_3O^+/H_2O layers. The present small size and fragility of the crystals has inhibited detailed variable temperature transport measurements. However, a preliminary two-probe room temperature measurement gave a conductivity of 0.95 S cm^{-1} parallel to the plate long axis, which is in the range expected for a semiconductor. We could expect that four-probe measurements, where the contact resistances are discounted, would be higher and even metallic in nature like other β″-BEDT-TTF salts. Therefore, the possibility exists to combine both electronic and ionic conductivity in a molecular lattice which is important in fields as diverse as solid-state batteries[11] and electroluminescent displays.[12]

This work has been supported by the U.K. Engineering and Physical Sciences Research Council and the European Commission TMR Network on Molecular Magnets.

DNA recognition by the first *tail-to-tail* linked distamycin-like oligopeptide dimers†

Santanu Bhattacharya*‡ and Mini Thomas

Department of Organic Chemistry, Indian Institute of Science, Bangalore, India-560 012. E-mail: sb@orgchem.iisc.ernet.in; Fax: +91-80-360-0529

Received (in Cambridge, UK) 1st February 2001, Accepted 24th May 2001
First published as an Advance Article on the web 20th July 2001

Sequence-specific bidentate binding to double-stranded (*ds*)-DNA by '*tail-to-tail*' linked dimeric distamycin analogues is described; compared to their monomeric analogues, these dimers exhibit greater affinity and longer binding site size and open up a novel avenue in the design of minor groove binders that overcome the phasing problem.

Design of molecules with low molecular mass (M_w *ca.* 10^3) that bind with high affinity and specificity to pre-determined DNA sequences that are 10–16 base pairs long is a key issue in chemical biology. For instance, a unique site within the 3 billion base pair human genome is defined by a minimum of 15–16 contiguous base pairs.[1] Natural products such as distamycin and netropsin which exert their biological activity by competing with the TATA box binding protein (TBP) for the target site on DNA serve as the 'lead compounds' for the design of such 'lexitropsins' (information reading oligopeptides).[2] Some of the compounds developed on the basis of these principles have indeed exhibited interesting biological properties.[3]

Distamycin (Dst)-type polyamides with $(n - 1)$ *N*-methylpyrrole rings and n amide groups bind preferentially to the minor groove sites containing $(n + 1)$ successive AT base pairs of *ds*-DNA. The repeating *N*-methylpyrrole-2-carboxamide unit, however, is ~20% longer than is required to match the base pair rise along the minor groove of the DNA helix. As a result longer polyamides ($n > 6$) are out of phase with DNA.[4,5] An over-wound curvature of longer polyamides is an added disadvantage. These factors result in a sub-optimal contact between DNA and the ligand leading to the manifestation of lower binding affinities. To reset an optimum fit of long polyamides with the DNA double-helix, flexible β-alanine or glycine residues have in fact been inserted.[4]

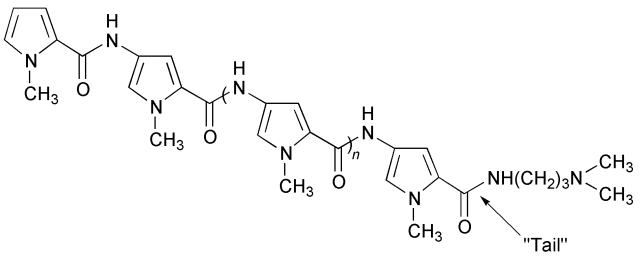
In an alternative strategy, two netropsin-like or distamycin-like cationic peptides have been connected in a 'head-to-head' (*N*-terminus-to-*N*-terminus) fashion using flexible or rigid linkers.[5] These bis(lexitropsins) were shown to adopt monodentate or bidentate modes of DNA binding depending upon the nature of the linker unit. Importantly those bound to DNA in a dimeric fashion also exhibited higher affinities.[1,6]

† Dedicated to the memory of Dr D. Ranganathan.

‡ Corresponding author and Swannajayanti Fellow (DST, Government of India); also at the Chemical Biology Unit, JNCASR, Bangalore 560012, India.

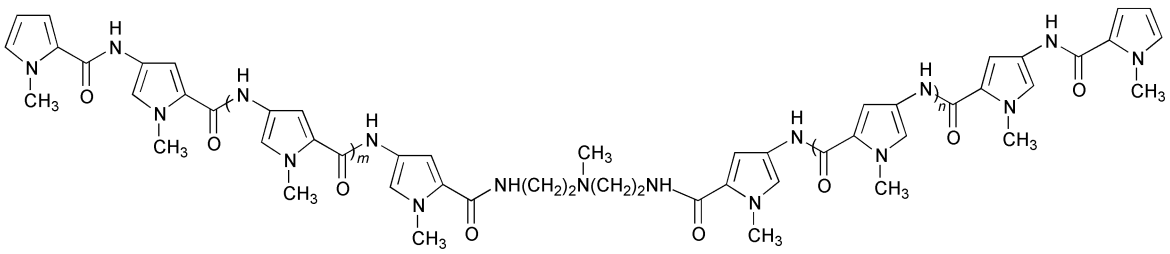
Herein we report a new approach to the design of dimeric lexitropsins such that optimum contacts between the successive amide units and the DNA helix are allowed. The following notable features characterize the present design. Firstly the dimers were constructed by linking the C-terminus of the individual monomers ('*tail-to-tail*' linkage). Secondly the positive charge necessary for optimizing the DNA affinity and water solubility is provided by the presence of a tertiary amine based linker which remains protonated at physiological pH.§ Significantly, these tail-to-tail linked *bis-Dst*s (**3**–**5**) bear only a single positive charge unlike the previously reported 'head-to-head' linked dimers which carry two positive charges. These bis-Dsts also lack the leading formamide unit at the *N*-termini.[7]

DNA binding abilities of the Dsts [**1**(**D3**) and **2**(**D4**)] and the corresponding bis-Dsts [**3**(**D33**), **4**(**D34**) and **5**(**D44**)] were examined for their ability to modify duplex DNA helix-to-coil transition temperature (T_m), induced circular dichroism (ICD) measurements, salt-dependence of ICD and fluorescence probe displacement assay.



1: n = 0 (**D3**); **2**: n = 1 (**D4**)

Dst and related minor groove binders are known to enhance the T_m of *ds*-DNA. This has been attributed to the stabilization of the double-helix.[8] Table 1 summarizes the results of the T_m measurements of DNA with the dimers **D33**, **D34** and **D44** along with those for the corresponding monomers, **D3** and **D4**. The ΔT_m is higher in the case of poly d(A.T) compared to calf thymus DNA (CT DNA, ~50% AT rich) indicating that these bis-Dsts have retained the AT-specific mode of DNA binding. The ΔT_m values are significantly higher for the complexes of the bis-Dsts compared to those of the corresponding monomers. This is notable, since the positive charge is not 'doubled' for the dimers compared with the monomers. The observed enhance-



3: m = 0, n = 0 (**D33**); **4**: m = 0, n = 1 (**D34**); **5**: m = 1; n = 1 (**D44**)

 DOI: 10.1039/b101105g

Table 1 Summary of melting temperature measurements[a]

Oligopeptide	ΔT_m/°C	
	Poly d(A.T)	CT-DNA
D3	0.5	0
D4	11.0	1.6
D33	12.5	1.6
D34	21.5	5.0
D44	27.5	6.5

[a] 40 mM NaCl, 10 mM Tris·HCl (pH = 7.4), [D]/[P] = 0.2.

ment in T_m could be entirely due to specific H-bonding and van der Waals interactions. The ΔT_m was also found to increase as a function of the length of the oligopeptides. For instance, the $\Delta(\Delta T_m)$ between the complexes of **D34** and **D33** with poly d(A.T) was ~9 °C and that between the complexes of **D44** and **D34** was ~6 °C. These results would be possible only if both the 'arms' of the dimeric distamycins are in contact with *ds*-DNA implying the effectiveness of the bidentate mode of binding.

The induced Cotton effect (ICD) produced at 25 °C upon the binding of Dst and its analogues to DNA that appear in the 280–380 nm region is distinct from the intrinsic CD spectrum of DNA.[8] The intensity of the ICD signal is proportional to the strength of binding and also on the number of the *N*-methylpyrrolecarboxamide units present in the oligopeptides. All the three bis-Dsts produced intense ICD signals upon binding to poly d(A.T) and CT-DNA (not shown). The ICD was higher in the case of poly d(A.T) compared to CT-DNA and the ICD intensity increased in the order **D33** < **D34** < **D44**.

Monotonous increase was observed in the ICD signal with [ligand] until saturation at [D]/[P] ratios {ratio of [ligand] *vs.* [DNA] (in base molarity)} characteristic of each ligand/duplex type. Importantly, a single set of isodichroic points was seen in each case (not shown) implying the existence of equilibrium between the bound and the free forms of the ligand. Molar ellipticity (θ) observed in the case of the dimers was found to be at least twice as high as that for the monomers. Taken together these results suggest that both the 'arms' of the dimeric Dsts bind to DNA at all [D]/[P] ratios.

Salt-induced complex dissociation experiments are often used for comparing the relative binding affinities of ligands towards DNA.[8] The higher the binding affinity, the lower should be the complex dissociation with increasing salt concentration. Plots of the relative intensities of the positive ICD bands at the respective ICD λ_{max} as a function of [NaCl] are presented in Fig. 1. It is seen that the ICD spectra of the bis-Dsts are less susceptible to high [NaCl] compared to their respective monomers. The most dramatic difference was observed in the case of **D33**. These results clearly show that the dimers bind to AT-rich DNA stronger than their monomeric

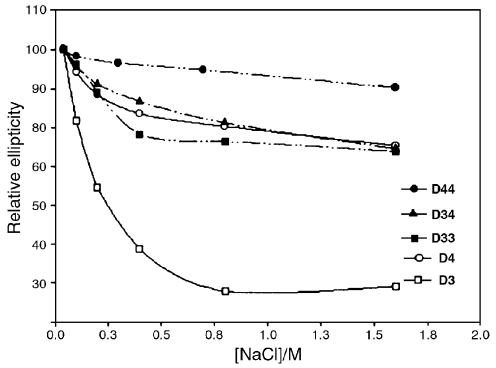


Fig. 1 Effect of NaCl on the ICD spectra of the complexes of **D33**, **D34**, **D44** and the monomers **D3** and **D4**.

counterparts, which would be possible only if the bidentate mode of binding is operational.

The binding site sizes of **1–5** were assessed from the saturation [D]/[P] values obtained from the CD titration plots. It was inferred that during DNA binding, each of the dimer arms overlap in a head-to-tail dimeric fashion with an equivalent arm from two neighboring dimers that lie on either side. The above arrangement is repeated throughout the DNA leading to 'multimeric' arrangement on the polymer. The *actual* number of bp covered by individual molecules of **3–5** may be assumed to be *ca*. 8–10 bp.

Finally, to estimate the relative binding constants (K_{app}) of these bis-Dsts and the corresponding monomers we also studied the competition between compounds **D3**, **D4**, **D33**, **D34**, **D44** and the well known AT specific DNA minor groove binder Hoechst-33258 for binding sites on poly d(A.T).[9] Displacement of Hoechst from poly d(A.T) was accompanied by a decrease in the fluorescence intensity measured at 460 nM (λ_{ex} = 355 nm). The apparent binding constants (K_{app}) were calculated from the concentration of the compounds required for 50% quenching of Hoechst fluorescence and the known values of [Hoechst] and binding constant[9] {[Hoechst-33258] = 230.4 nM, [poly d(AT)] = 4.6×10^{-6} M, $K_a = 5 \times 10^7$ M^{-1} (base molarity), 50 mM Tris·HCl buffer containing 100 mM NaCl)}. The K_{app} values for **D3**, **D4**, **D33**, **D34** and **D44** calculated this way were 6×10^5, 9.3×10^6, 2.0×10^7, 4.1×10^7 and 4.9×10^7 M^{-1} respectively. The highest enhancement in K_{app} compared to the corresponding monomer was observed in the case of **D33** (33-fold). The value of K_{app} for **D44** was 5 times that for the corresponding monomer **D4**.

In summary the present systems, which represent the first examples of 'tail-to-tail' linked dimeric lexitropsins, form a novel class of minor groove binders that bind to *ds*-DNA in a bidentate fashion and exhibit significantly greater affinity for *ds*-DNA compared to the respective monomers. These bind poly d(A.T) in a nearly 2:1 overlapped fashion and individual molecules seem to cover 8–10 bp and provide a significant step forward in the design of minor groove binders towards overcoming the phasing problem.

New room-temperature ionic liquids with C_2-symmetrical imidazolium cations†

Sergei V. Dzyuba and Richard A. Bartsch*

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409-1061, USA. E-mail: richard.bartsch@ttu.edu; Fax: +1(806) 742 1289; Tel: +1(806) 742 3069

Received (in Corvallis, OR, USA) 16th May 2001, Accepted 18th June 2001
First published as an Advance Article on the web 23rd July 2001

New 1,3-dialkylimidazolium hexafluorophosphates with two butyl, pentyl, octyl, nonyl or decyl groups are room temperature ionic liquids.

Room-temperature ionic liquids (RTILs),[1] such as 1-alkyl-3-methylimidazolium hexafluorophosphates, are finding ever-expanding applications as alternative reaction media for organic synthesis[2,3] and separation science.[4–6] Although our understanding of why these salts have such low melting points is incomplete, the unsymmetrical nature of the cation is believed to play a major role.[1,7] Thus, the 100 °C lower melting points of 1-ethyl-3-methylimidazolium salts than their *N*-butylpyridinium analogues have been attributed to the C_2 symmetry of the latter.[1]

By extension of such reasoning, 1,3-dialkylimidazolium salts that also have C_2 symmetry would seem to be poor candidates as RTILs. In agreement, 1,3-dialkylimidazolium hexafluorophosphates are reported to be solids at room temperature when the two alkyl groups are hexadecyl.[8] The salts with elongated alkyl groups are of interest because they exhibit liquid crystalline behavior above their melting points.[8,9]

We now report the synthesis of ten 1,3-dialkylimidazolium hexafluorophosphates $[(C_n)_2\text{-Im}]PF_6$ with dialkyl moieties ranging from dimethyl to didecyl and their phase transition behavior. Surprisingly, 1,3-dialkylimidazolium hexafluorophosphates with dibutyl, dipentyl, dioctyl, dinonyl, and didecyl substituents are found to be RTILs.

The $[(C_1)_2\text{-Im}]PF_6$ was prepared by reaction of commercially available 1-methylimidazole with iodomethane to form $[(C_1)_2\text{-Im}]I$[10] followed by its metathesis with potassium hexafluorophosphate in water.‡ Since higher homologues of 1-methylimidazole are not available commercially, a method was sought to convert imidazole directly into a 1,3-dialkylimidazolium halide. (Reported methods for the preparation of 1,3-dialkylimidazolium halides require multiple steps, long reactions times, and/or special precautions.[8,9,11,12]) We have found that reaction of imidazole with one equivalent of sodium hydride in THF followed by addition of two equivalents of a 1-bromoalkane and refluxing (Scheme 1) gives high yields (75–89%) of $[(C_n)_2\text{-Im}]Br$ with n = 2–10. Metathesis of the imidazolium bromide salts with potassium hexafluorophosphate in water gave high yields (89–95%) of $[(C_n)_2\text{-Im}]PF_6$ with n = 2–10.†‡

The phase transition temperatures (mid-points of glass transitions and/or melting points) for $[(C_n)_2\text{-Im}]PF_6$ with n = 1–10 as determined by differential scanning calorimetry (DSC)§ are presented in Table 1. As the alkyl groups are changed from methyl to ethyl to propyl, the melting point drops from 89 to 70 to 43 °C. This suggests poorer packing into the crystal lattice as the alkyl group is elongated. With dibutyl and dipentyl substituents, the salts are RTILs with glass transitions, but no melting points. In sharp contrast when the alkyl groups are elongated to hexyl, a melting point of 73 °C, but no glass transition, is observed. There is a remarkable, greater than 140 °C difference between the phase transition temperatures for $[(C_5)_2\text{-Im}]PF_6$ and $[(C_6)_2\text{-Im}]PF_6$. Apparently the hexyl groups pack into the crystal lattice almost as well as methyl and ethyl groups. As the alkyl groups are lengthened from hexyl to heptyl, the 73 °C melting point for the former diminishes to 47 °C. For octyl and nonyl groups, both glass transitions and melting points are observed. When the alkyl groups are decyl, there are two melting points. Since their melting points are below room temperature, $[(C_8)_2\text{-Im}]PF_6$, $[(C_9)_2\text{-Im}]PF_6$, and $[(C_{10})_2\text{-Im}]PF_6$ are also RTILs. Studies are currently underway to compare the other physical properties of these readily accessible $[(C_n)_2\text{-Im}]PF_6$ RTILs with the more common 1-alkyl-3-methylimidazolium hexafluorophosphates.

† Electronic supplementary information (ESI) available: ^{1}H NMR and IR spectra and elemental analysis results consistent with the indicated structures for all of the $[(C_n)_2\text{-Im}]Br$ and $[(C_n)_2\text{-Im}]PF_6$ compounds. See http://www.rsc.org/suppdata/cc/b1/b104512c/

‡ Representative procedures for the preparation of $[(C_n)_2\text{-Im}]Br$ and $[(C_n)_2\text{-Im}]PF_6$. *Synthesis of 1,3-dinonylimidazolium bromide*. A flask containing a magnetically stirred mixture of 95% sodium hydride powder (0.75 g, 29.4 mmol) in THF (20 ml) was cooled in an ice bath and a solution of imidazole (2.00 g, 29.4 mmol) in THF (20 ml) was added dropwise. The ice bath was removed and the mixture was stirred for 2 h at room temperature. Following dropwise addition of 1-bromononane (11.23 ml, 58.8 mmol) at room temperature, the mixture was refluxed for 7 h and filtered. The precipitate was thoroughly rinsed with THF. The filtrate was evaporated *in vacuo* and the residue was dissolved in dichloromethane. The mixture was filtered and the filtrate was evaporated *in vacuo*. The residue was rinsed with diethyl ether (20 ml) and dried *in vacuo* to give 10.40 g (82% yield) of the product as a waxy-like solid. *Synthesis of 1,3-dinonylimidazolium hexafluor-*

 DOI: 10.1039/b104512c

ophosphate. To a magnetically stirred solution of the imidazolium bromide prepared above (1.17 g, 3.69 mmol) in water (20 ml) was added potassium hexafluorophosphate (0.68 g, 3.39 mmol). After 30 min, the lower ionic liquid layer was separated and dissolved in dichloromethane (20 ml). The dichloromethane solution was washed with water (2 × 40 mL) and evaporated *in vacuo*. Benzene was added to the residue and the solution was dried using a Dean–Stark apparatus. After removal of the benzene *in vacuo*, the residue was dried *in vacuo* (0.5 Torr) at 100 °C overnight to give 1.27 g (90%) of $[(C_9)_2\text{-Im}]PF_6$.

For the synthesis of $[(C_2)_2\text{-Im}]Br$ and $[(C_3)_2\text{-Im}]Br$, 3.0 and 1.5 molar excess of ethyl bromide and propyl bromide were used, respectively.

§ Phase transition measurements. A Shimadzu DSC-50 differential scanning calorimeter with a LTC low temperature assembly was utilized. The sample (5–25 mg), that had been stored at room temperature before analysis, was sealed in an aluminum pan under air and cooled to about −130 °C by pouring liquid nitrogen into the LTC unit under helium (30 ml min^{-1}). Cooling to this temperature usually took 20–25 min. As soon as all of the liquid nitrogen had evaporated from the LTC unit and the temperature started to rise spontaneously, heating was initiated at 30 °C min^{-1}. Heating was continued to 70 °C for liquid samples and to 130 °C for solid samples.

Received (in Cambridge, UK) 24th April 2001, Accepted 15th June 2001
First published as an Advance Article on the web 23rd July 2001

This communication describes the use of nanofiltration (NF) membranes for efficient separation and recycling of phase-transfer catalysts, using the conversion of bromoheptane into iodoheptane with tetraoctylammonium bromide as the PT catalyst, as an example; a solvent flux of > 10 L m^{-2} h^{-1} was achieved with > 99% catalyst recycle and no loss in PT catalyst activity over a cycle of three consecutive reactions.

Phase-transfer (PT) catalysis, introduced by Starks,[1] is an alternative to the use of polar aprotic solvents (DMF, DMSO) for reactions involving a water-soluble nucleophilic reagent and an organic soluble electrophilic reagent (*e.g.* anions and organic substrates). However, one of the major technical problems inhibiting the use of phase-transfer catalysis in industrial applications is the need to separate the product and the phase-transfer catalyst.[2]

NF is a relatively new membrane process with a nominal molecular weight cut-off[3] (MWCO) in the range from 200–1000 Da. Recently NF membranes capable of performing separations in organic solvents have become available.[4] The molecular weight of many phase-transfer catalyts is in the range of 300–1000 Da. Therefore, it is of interest to investigate the potential application of NF membranes to separation of lipophilic phase-transfer catalysts from reaction mixtures, and subsequent recycling of the catalysts. We demonstrate the successful recycle and re-use of a catalyst in consecutive reactions using a solvent resistant NF membrane.

The model phase-transfer catalytic reaction employed in this study is given in eqn. (1), where PTC stands for phase-transfer

$$Br - C_7H_{15org} + KI_{aq} \xrightarrow{PTC} I - C_7H_{15org} + KBr_{aq} \quad (1)$$

catalyst. The model reaction involves the conversion of bromoheptane into iodoheptane using an aqueous phase containing potassium iodide[5] and is a classic example of a nucleophilic, aliphatic substitution reaction. Toluene, a common solvent in industry and a typical solvent used in phase-transfer catalysis, was used as the organic solvent. The PTC used was tetraoctylammonium bromide (TOABr). At the conclusion of the reaction, the lipophilic TOABr and the iodoheptane product both partition entirely into the organic phase.

Firstly, separation of PTC from a synthetic 'post-reaction' solution containing 0.1 M bromoheptane, 0.1 M iodoheptane and 0.01 M TOABr in toluene was studied using two polyimide solvent resistant NF membranes (142A and 142C, nominal MWCO of 220 and 400 Da respectively; W. R. Grace, USA).[6] The retention of the PTC, and the passage of the product molecule through the membrane, is necessary in order for the separation of product and catalyst to occur. Results are summarised in Table 1 and show that any residual reactant and the product pass through both membranes, which retain the catalyst for re-use. The 20–22% rejection[7] of reactant and product by 142A does not constitute a significant fraction of product being retained, and so 142A was chosen for further experiments involving repeated reactions. The flux in the presence of the reaction mixture is lower than for pure toluene, suggesting some degree of membrane fouling.

Two series of reactions were carried out, which differed only in the details of the process used to separate and recycle the PTC. In Case 1[8] a new membrane disc was used for each separation. In Case 2,[9] the same membrane disc was used for the series of separations. This latter procedure, with multiple membrane use, mimics more closely the likely procedure which would be used industrially. The time profiles for reactant (bromoheptane) and product (iodoheptane) during the Case 1 series of reactions, is shown in Fig. 1. After 5 h at 50 °C, with vigorous stirring, the yield was 97%. The phases were then separated, and the organic phase was filtered using 142A. After 35 mL of the original 40 mL of organic liquid had passed through the membrane, the residual 5 mL containing the PTC was recycled to the next reaction.

At the conclusion of the second reaction, this cycle was repeated, giving a total of three reactions and three catalyst separations. With pleasure we observed that the conversions of bromoheptane after 5 h in the second and third reactions were 90 and 96% respectively, indicating that the catalyst was recycled without any loss of activity.[10] Similar data were obtained in a second reaction cycle with catalyst recovery as per Case 2. A control confirmed no conversion of bromoheptane was observed in 6 hours in the absence of TOABr.

Flux data for filtrations from the two reaction cycles is summarised in Table 2. The permeate flux of the reaction mixture decreased to between 7 and 15 L m^{-2} h^{-1} by the end of the nanofiltration step, where a film of viscous material, assumed to be TOABr, was observed attached to the membrane surface. The solubility of TOABr in toluene is 380 g L^{-1}, and the starting concentration in the reaction mixture is 27 g L^{-1}, so it is expected that after 35 mL of organic phase has been removed, a maximum concentration of 218 g L^{-1} will result. This should be below the solubility limit of TOABr in toluene. However, it is possible that effects of the counter ion and the

Reaction 1	5	97	98	12	9.1	>99	>99	12	11	10	11
Reaction 2	5	90	97	14	8.5	>99	>99	18	15	14	18
Reaction 3	5	96	96	15	7.0	>99	>99	5	8	13	7

[a] Case 1: the 5 ml of retentate was washed out with pure toluene and then recovered by toluene evaporation; each filtration was carried out with a fresh membrane disc. Case 2: the retentate was washed out each time with fresh organic reactant solution containing no catalyst, and consecutive filtrations were carried out with the same membrane disc.

reactant/product in the system lower the TOABr solubility, causing the catalyst to come out of solution at the membrane surface.

For both reaction and filtration, Case 1 and Case 2 gave similar results with no noticeable difference. In Case 2, (in which the same membrane disc is used for all filtrations) the membrane is effectively 'washed' at the end of each filtration with the reaction mixture going into the next batch. In Case 1, the membrane is washed with pure toluene at the end of each filtration. Subsequently, prior to each separation, the pure toluene flux was measured and found to be between 50 and 60 L m^{-2} h^{-1}. Mass balances on the PTC over each separation cycle showed that effectively all of the PTC was recovered during separation and subsequent membrane washing. We conjecture that the decrease in flux during a post-reaction filtration is due to PTC which precipitates out on the surface of the membrane, as described above possibly due to concentration effects. Apparently this flux can be restored, and the catalyst reclaimed, by simple washing with the reaction solvent. This is likely to be an important factor in making catalyst recovery by NF a viable process.

Using the polyimide solvent resistant nanofiltration membranes, it is possible to retain essentially all the PTC and to repeat reactions in a cycle of at least 3 reactions, without adding any further catalyst. Membrane fouling occurs during filtration of the catalyst, but appears to be reversible when the membrane is washed with the reaction solvent. Finally, we conclude that the membrane retention of homogenous phase-transfer catalysts is feasible and offers exciting opportunities for further work in coupling of NF membrane separators with phase-transfer catalysis reactors.

This work was supported by the UK Engineering and Physical Sciences Research Council grant No. GR/M 50751, and support in kind from W. R. Grace, Colombia, USA, and GlaxoSmithKline, Tonbridge, UK, is gratefully acknowledged.

5 Reaction details: the reaction was carried out in a glass vessel of 100 mL with 40 mL aqueous phase (2 M KI) and 40 mL organic phase (0.5 M bromoheptane + 0.05 M TOABr in toluene). The temperature was kept at 50 ± 1 °C using an oil bath and stirring speed was 400 rpm. After the reaction was completed, the organic phase (40 mL) was transferred into a SEPA filtration cell and the cell was pressurized to 30 bar at room temperature. The SEPA cell was stirred at 300 rpm.
6 Values stated are supplied by W. R. Grace, Colombia, Maryland, USA, using various alkane solutes in toluene.
7 R_x defines the rejection of component x, this can be obtained from the following eqn. $1 - (C_{p,x}/C_{r,x})$ where $C_{p,x}$ is the concentration of x in the permeate and $C_{r,x}$ is the concentration of x in the retentate.
8 Case 1: the 5 ml of retentate left in the cell was washed out with pure toluene and the toluene was evaporated at 50 ± 1 °C (overnight in fume cupboard). This catalyst was then added to 35 mL 0.5 M bromoheptane in toluene (no fresh TOABr added) and mixed with 40 mL of 2 M KI aqueous phase. The reaction and nanofiltration were carried out as the above.
9 Case 2: the 5 ml of retentate left in the cell was washed out with 35 mL of 0.5 M bromoheptane in toluene to form the organic phase for the subsequent reaction. This organic phase was then mixed with 40 mL of 2 M KI aqueous phase. The reaction and nanofiltration were carried out as for the first reaction.
10 Reactants, products and catalyst were analysed using GC.

First published as an Advance Article on the web 23rd July 2001

The first complex-bridged cyano–rhenium cluster framework material $[Mn(salen)]_{4n}[Re_6Te_8(CN)_6]_n$, with a two-dimensional layered structure is prepared by the reaction of a methanol solution of $[Mn(salen)]ClO_4$ with an aqueous solution of $Na_4[Re_6Te_8(CN)_6]$.

The design of extended structures based on molecular complexes has received much attention. Recently, there have been many studies on developing engineered-supramolecular networks in an effective manner and designing highly dimensional molecular systems with adjustable structures.[1,2] One way to obtain an extended structure is to utilize a molecular precursor that consists of multi-binding sites such as hexacyanoiron(III). For example, in MnL^+ (L = 3-MeO-salen,[3] 5-Cl-salen[4,5] or acacen[6]) linkage occurs *via* hexacyanoiron(III) to form two-dimensional layers. These cyano-bridged mixed-metal compounds with ferromagnetic and antiferromagnetic interactions are two-dimensional network structures. There have also been extensive studies on the face-capped octahedral rhenium cluster, $[Re_6Te_8(CN)_6]^{4-}$, which is analogous to hexacyanoiron(III). Cluster-expanded materials such as $Fe_4[Re_6Te_8(CN)_6]_3{\cdot}27H_2O$, $Ga_4[Re_6Se_8(CN)_6]_3{\cdot}38H_2O$, $[Cd_2(H_2O)_4][Re_6S_8(CN)_6]{\cdot}14H_2O$, and Cs_2[*trans*-$Fe(H_2O)_2]_3[Re_6Se_8(CN)_6]_2{\cdot}18H_2O$, where simple metal ions link the Re clusters to form bigger cavities, resemble the Prussian Blue $Fe_4[Fe(CN)_6]_3{\cdot}14H_2O$.[7–9] These three-dimensional frameworks include plenty of water molecules as well as metal ions within their cavities. $[Re_6S_8(CN)_6]^{4-}$ also coordinates to Mn(II) centers to form a neutral three-dimensional framework with isopropyl alcohol molecules.[10] In order to develop new framework materials with a potential to create new spatial or chemical functions, we designed a new extended solid system based on the Re cluster. For our linking material, we chose the $[Mn(salen)]^+$ complex instead of a simple metal ion since $[Mn(salen)]^+$ is paramagnetic with a high-spin d^4 electronic configuration of Mn(III). Futhermore, it also has axial sites to which the cyano–rhenium clusters can link up. We report here the preparation of the first cyano–rhenium cluster which is linked to an Mn complex to provide an extended framework with a unique layered structure.

The face-capped octahedral rhenium cluster $Na_4[Re_6Te_8(CN)_6]$ was prepared by a previous procedure.[11] The orange-red solid $Na_4[Re_6Te_8(CN)_6]$ was purified by recrystallization using methanol–diethyl ether. After an aqueous solution of $Na_4[Re_6Te_8(CN)_6]$ was carefully layered with a methanol solution of $[Mn(salen)]ClO_4$, black crystals of $[Mn(salen)]_{4n}[Re_6Te_8(CN)_6]_n$ **1** formed directly at the interface. A quantitative yield[12] of **1** was obtained by mixing an aqueous solution of $Na_4[Re_6Te_8(CN)_6]$ with a methanol solution of $[Mn(salen)]ClO_4$. Compound **1** was not soluble in common solvents such as methanol, ethanol, water, diethyl ether, acetone, acetonitrile, or THF. The structure of **1** was determined by X-ray crystallography.[13]

The asymmetric unit contains half of an Re cluster, a bridged $[Mn(salen)]^+$ unit, and a dangling $[Mn(salen)]^+$ unit. The complete two-dimensional layered structure is generated by the symmetry operations, $(-x + 3/2, y - 1/2, -z + 1/2)$, $(-x + 2, -y + 2, -z + 1)$, and $(-x + 3/2, y + 1/2, -z + 1/2)$. Four cyano groups of the Re cluster with C–N distances of 1.17(2)–1.18(2) Å are linked to $[Mn(salen)]^+$ units, forming a two-dimensional layer. The remaining two cyano groups with C–N distance of 1.13(2) Å are bound to a $[Mn(salen)]^+$ unit dangling outside the layer. The IR spectrum (KBr) of this compound showed two CN stretching peaks at 2073 and 2090 cm^{-1}, whereas the starting Re cluster had only one CN stretching peak at 2081 cm^{-1}. This result is consistent with the X-ray crystallographic data which shows two different types of cyano groups. Fig. 1(a) shows the rhenium cluster $[Re_6Te_8(CN)_6]^{4-}$, surrounded by six $[Mn(salen)]^+$ units. The Re–Re and Re–Te bonds range from 2.6842(7) to 2.7004(7) Å and from 2.685(1) to 2.703(1) Å, respectively. These are not significantly different from the starting rhenium cluster [The mean values of the Re–Re and Re–Te distances of the cyano–rhenium cluster are 2.681(3) and 2.694(2) Å, respectively]. The Mn(bridging

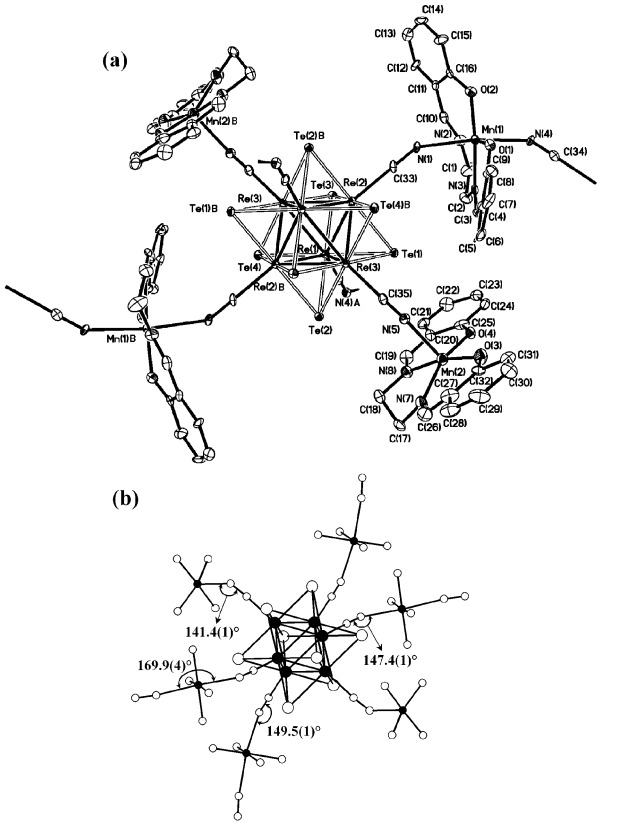

Fig. 1 (a) ORTEP drawing of the rhenium cluster $[Re_6Te_8(CN)_6]^{4-}$ surrounded by six $Mn(salen)^+$ units. Among the six $Mn(salen)^+$ units bound to six rhenium atoms, only four are shown. (b) A simplified drawing with some bond angles around the rhenium cluster. All carbon atoms of the salen molecules have been omitted for clarity. Symmery operations: A $(-x + 3/2, y - 1/2, -z + 1/2)$, B $(-x + 2, -y + 2, -z + 1)$.

 DOI: 10.1039/b104276a

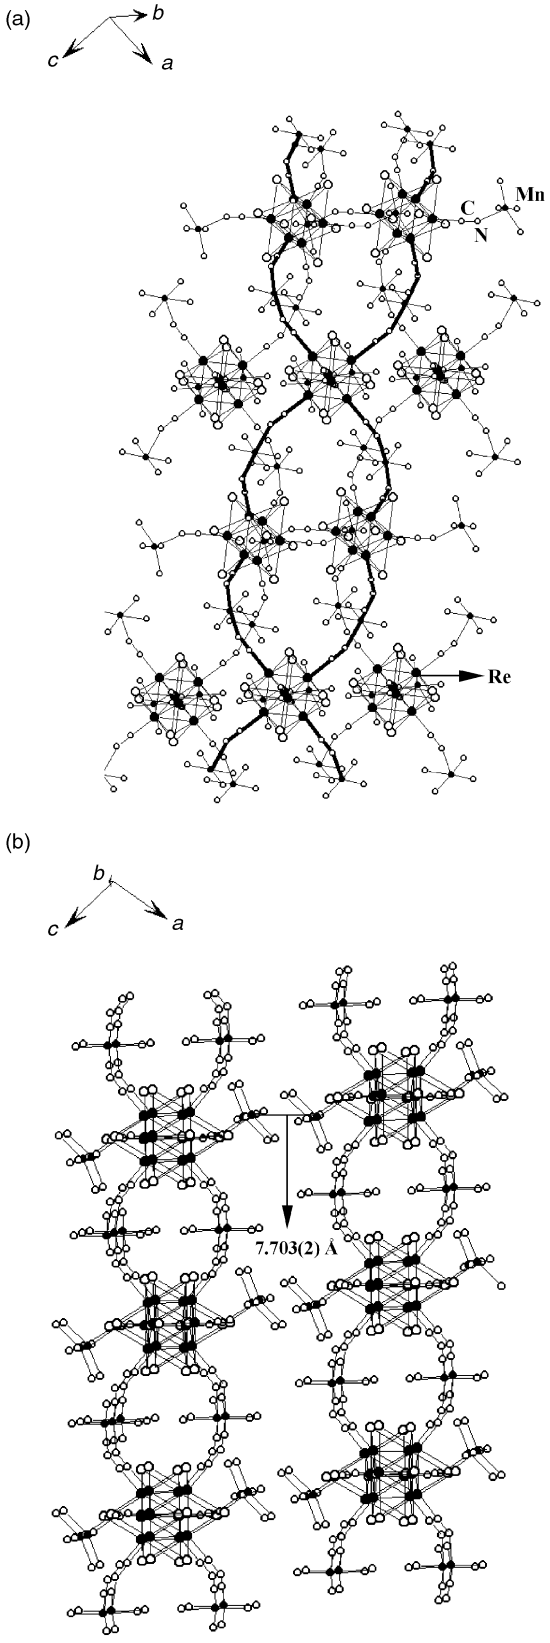

Fig. 2 (a) A two-dimensional layer containing [Mn(salen)]$^+$ units linked by cyano–rhenium clusters. The twisted ropes interconnected by Re_6Te_8 clusters are shown. (b) Side view of two layers. All carbon atoms of the salen molecules are omitted for clarity.

Mn unit)–N(cyano group) distances are 2.27(1) and 2.28(1) Å, while the Mn(dangling Mn unit)–N(cyano group) distance is 2.14(1) Å. Fig. 2(a) shows a two-dimensional layer containing [Mn(salen)]$^+$ units linked by cyano–rhenium clusters, while Fig. 2(b) shows a side view of two layers stacked perpendicular to the (1 0 1) direction. This layer is not a flat sheet, since the angle of the bridging elements N(cyano group)–Mn–N(cyano group) is 169.9(4)° and the angles C(cyano group)–N(cyano group)–Mn are 147.4(1) and 149.5(1)°. The unlinked dangling [Mn(salen)]$^+$ units are directed toward the outside of the layers, and the C(cyano group)–N(cyano group)–Mn(dangling Mn unit) angle is 141.4(1)° [Fig. 1(b)]. Two neighboring chains of –Mn(salen)–NC–Re_6Te_8–CN–Mn(salen)– run akin to a twisted rope, such ropes being interconnected by Re_6Te_8 clusters forming two-dimensional sheets. The intermolecular distances between the Mn units *via* the Re cluster are 14.490(9) and 14.38(1) Å, while the distance between the dangling Mn units *via* the Re cluster is 13.788(8) Å. The interlayer distance between the neighboring Mn (dangling Mn unit) atoms is 7.703(2) Å.

This system with cyano–rhenium clusters linked by Mn(salen) complexes is the first complex-bridged cyano–rhenium cluster framework material. Remarkably, this compound shows a unique thick-layered structure which opens the possibility of developing a new class of materials through crystal engineering of appropriate molecular complexes. We are currently investigating other transition metal complexes with high-spin systems which could provide extended network structures with cyano–rhenium clusters.

Folding and dimerization of resorcarene tetrasulfonates†

Alexander Shivanyuk‡

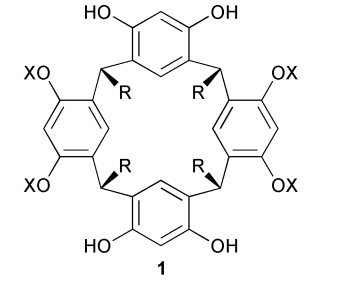
Department of Chemistry, University of Jyväskylä, P.O. Box 35, FIN-40351, Jyväskylä, Finland

Received (in Columbia, MO, USA) 1st May 2001, Accepted 25th May 2001
First published as an Advance Article on the web 23rd July 2001

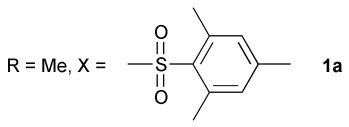
In the solid state and in $CDCl_3$ resorcarene tetramesitylsulfonates fold by intramolecular S=O···H–O hydrogen bonds and dimerise *via* intermolecular O–H···OH hydrogen bonding.

Intramolecular folding and intermolecular association of several sub-units are key properties of biologically important macromolecules.[1] A few synthetic compounds also exhibit these features. For instance, the bowl shaped crown conformers of resorcarene octols[2] formed by intramolecular hydrogen bonds lead to hydrogen bonded dimeric and hexameric aggregates.[3] A seam of intramolecular hydrogen bonds in the calix[4]arene tetraurea derivatives was shown to change considerably the stability and binding properties of self-assembled dimeric capsules.[4] The dimer of an artificial β-sheet[5] is also an example of self-assembly involving both intra- and inter-molecular hydrogen bonds.

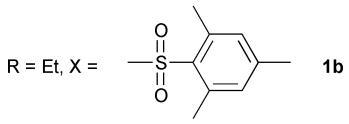
Novel hydrogen bonded self-assembly of tetramesityl sulfonates **1a, b**[6] is reported here which is a combination of folding and dimerization.



1



1a



1b

In the crystalline state§ the molecule of **1a** adopts a strongly pinched and twisted boat conformation with almost parallel unsubstituted resorcinol rings (Fig. 1). Two of mesitylsulfonyl fragments oriented clock- or counter-clockwise form short intramolecular S=O···H–O hydrogen bonds to the neighboring hydroxy groups making the whole conformation inherently chiral. The asymmetric unit contains two crystallographically independent molecules (A and B) which are different mainly in the arrangement of one *non*-hydrogen bonded mesitylsulfonyl residue (Fig. 1).

Two molecules of **1a** form a cross-shaped dimer linked by four intermolecular O–H···OH hydrogen bonds (Fig. 2). Short intra- and inter-molecular contacts between hydroxy and *ortho*-methyl groups of the mesityl residues (O···C 3.2–3.4 Å) clearly indicate the C–H···O interactions which may additionally stabilize the assembly. The unsubstituted resorcinol rings of

molecule A are nearly perpendicular both to diacylated and unsubstituted resorcinol rings of molecule B. Such a geometry leaves no space for the encapsulation of guest species within the dimer so that the solvent molecules are included in voids of the crystal.

In the dimer the molecules of **1a** have an opposite orientation of hydrogen bonded mesitylsulfonyl groups obviously owing to the requirements of complementarity. A simple consideration reveals that the molecules of **1a** having the same sense of inherent chirality cannot form the dimer.

The ^{1}H NMR spectrum of **1a**, **b** measured in $CDCl_3$ at 303 K contains four singlets for the protons of resorcinol rings, one singlet for the protons of hydroxy groups (δ 7.0) and one set of signals for other protons in accordance with C_{2v}-symmetric structure. 2D NOESY (t_m = 300 ms) and long range COSY ($CDCl_3$, 500 MHz) techniques showed that the molecules of **1** exist in the boat conformation with *parallel* unsubstituted resorcinol rings.[7] At 223 K a double set of ^{1}H NMR signals corresponds to the protons of the methyne bridges [Fig. 3(a), (b)], hydroxy groups and the aromatic protons of the mesitylene residues while the protons of the resorcinol rings emerge again as four singlets. This pattern can be ascribed to the slow exchange between two enantiomeric C_2-symmetric conformations having clock- or counter-clockwise orientation of two hydrogen bonded mesitylsulfonyl groups similar to that found in the solid state (Fig. 1). The signals of methyne bridges undergo a clear coalescence at 247 K corresponding to ΔG^* of 11.7 kcal mol^{-1}. The mixing of **1a** and **1b** in 1 : 1 molar ratio results in additional set of ^{1}H NMR signals for both resorcarenes [Fig. 3(c)]. This can be explained only by the formation of hetero-associate **1a** · **1b** which co-exists with **1a** · **1a** and **1b** · **1b** in a statistical 2 : 1 : 1 ratio. This is in accordance with the MALDI-TOF mass spectra of **1a** and **1b** which showed the peaks of both the monomer and the dimer.

The ^{1}H NMR spectrum of **1a** measured at 223 K in a 1 : 1 mixture of **1a**, **b** in CD_3OD–$CDCl_3$ (1 : 1) exhibits a sharp C_{2v}-symmetric pattern which presumably corresponds to the monomer. Furthermore, in less competing mixtures of $CDCl_3$ and acetonitrile-d_3 both C_{2v}- and C_2-symmetrical pattern are observed simultaneously, in a ratio proportional to the polarity of the medium. Since no signals of the monomer were observed at 223 K in $CDCl_3$ the dimerization constant should be $> 10^5$ M^{-1}.

The NOESY (t_m = 300 ms) spectrum of **1a** in $CDCl_3$ at 223 K reveals close proximity of the protons in 5-positions of diacylated resorcinol rings to the protons in 2-positions of unsubstituted resorcinol rings as found in the solid state dimer [Fig. 2(a)]. The singlet of hydroxy groups at δ 7.5 shows intense cross-peaks to the signal of the protons in 2-positions of unsubstituted resorcinol rings and to the OH resonance at δ 7.0. This is in accordance with the geometry of *intermolecular* O–H···O–H hydrogen bonding in the solid state dimer (Figs. 1 and 2). On the other hand, the correlation between *one* signal of the methyne bridges (δ 4.5) and the OH resonance at δ 7.0 is in keeping with the *intramolecular* S=O···H–O hydrogen bonds (Fig. 1).

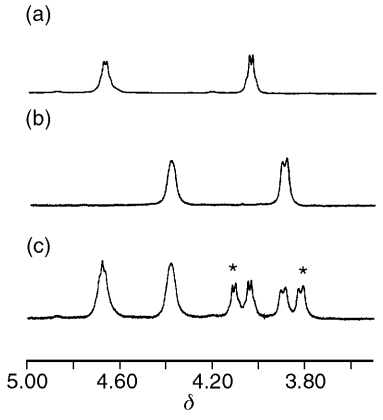

Fig. 3 The ^{1}H NMR signals of the methyne protons of the bridges at 223 K ([**1a**] = [**1b**] = 10 mM, 500 MHz, $CDCl_3$): (a) **1a**, (b) **1b**, (c) **1a** + **1b**. Signals of the heterodimer are indicated by an asterisk.

The above results strongly suggest the structural similarity of $\mathbf{1a}_2$ in $CDCl_3$ and in the solid state. The fact that only one C_2-symmetrical pattern is observed in the NMR spectra of $\mathbf{1a}_2$, $\mathbf{1b}_2$ and **1a**·**1b** reflects, most probably, the regioselective formation of one dimer—a feature predicted from the crystal structure of $\mathbf{1a}_2$.

In conclusion, the dimerization described above provides a novel structural motif for molecular self-assembly which is based on the interplay of intra- and inter-molecular hydrogen bonds. Obviously, the aggregation of resorcarene tetramesityl sulfonates characterized by cation and anion binding sites, hydrogen bonding, photochemically and/or electrochemically active groups could give novel polyfunctional molecular assemblies. Such systems are being investigated and will be reported in due course.

Professor Kari Rissanen (University of Jyväskylä) and Professor Dmitry Rudkevich (TSRI) are acknowledged for helpful discussions and Mr R. Kauppinen (University of Jyväskylä) for assistance with the NMR measurements. This work was supported by the Finnish Academy.

Received (in Cambridge, UK) 26th April 2001, Accepted 28th June 2001
First published as an Advance Article on the web 23rd July 2001

Platinum nanoparticles accomodating bifunctional thiolate ligands self-assemble into regular superstructures or organize around a large gold particle; the shape of the superstructures can be modulated by addition of water.

There is presently a substantial interest for the study and the use of the novel properties of metal nanoparticles.[1] Complexation of ligands at the surface of the nanoparticles may allow a good control of both their physical and chemical properties.[2] Furthermore, the use of polyfunctional ligands may lead to connection between particles, to their self-assembly and the formation of monolayers on surfaces, as recently described.[1g,3,4] However, the coordination chemistry of the surface of nanoparticles has been relatively little developed, probably because of the lack of adequate methods for synthesizing particles of controlled surface state. CO coordination at the surface of metal particles has often been used as a probe of the surface state[5] whereas thiol or amine coordination has been used to stabilize metal particles.

In our group, we have been interested for some time in the synthesis of metal nanoparticles from organometallic precursors.[6] Two main reasons for this interest were the possibilities to access to monodisperse particles of very small size (1–2 nm) and to perform coordination chemistry at their surface. In this respect, we have been able to prepare platinum particles of small size (*ca.* 1.5 nm) protected by various ligands such as CO, THF, PPh_3, TOPO (trioctylphosphine oxide), thiols and amines. In the presence of thiols, we have shown the absence of ligand exchange at the NMR time scale between free and complexed thiol.[6c–f]

Having demonstrated the possibility to control the growth and the stability of nanoparticles with ligands, the next step is the organization of the particles in two or three dimensions. This can be achieved by self-organization (In/TOPO[6e]) or by connection of the particles in a way similar to that used in molecular techtonics.[7] We report in this communication our first attempts in this direction using both the coordination ability of dithiols and the formation of hydrogen bonded networks.

The reaction of $Pt_2(dba)_3$ with CO (1 bar) in THF leads to the formation of platinum nanoparticles of uniform size centered near 1.2 nm (colloid **1**). Addition of alkanedithiol ligands proceeds similarly as previously described for octanethiol,[6c] and leads to new platinum particles (alkane = propane, colloid **2a**; octane, colloid **2b**). The reaction can be followed by IR spectroscopy in which a shift to lower frequency of surface CO stretches is observed from 2050, 1808 cm^{-1} to 2046, *ca.* 1800 cm^{-1} upon addition of 0.1 eq./Pt dithiol. The particles have been characterized by HREM and, for some samples, by WAXS (wide angle X-ray scattering) which both demonstrate their fcc structure. Their mean size is *ca.* 1.6 nm, similar to octanethiol stabilized particles.[6c] However, in contrast to the results observed with octanethiol, the particles agglomerate into large superstructures which do not evidence any crystalline arrangement but in which the inter-particle distances is regular (Scheme 1; experimental and characterization details are given as ESI†).

In order to determine whether this aggregation was due to the presence of coordination links between the particles, a solution of colloid **2b** was reacted with large gold particles prepared by the Turkevich method.[8] According to the density of platinum particles, the organization observed around gold particles [concentric circles, Fig. 1(b)] may lead to long range ordering. In each case, a regular inter-particle distance of *ca.* 1 nm can be measured. This result therefore demonstrates the possibility to use a linker for connecting two particles, of different or of same nature.

Another approach for connecting nanoparticles consists in trying to organize them through hydrogen bonds.[9] In our case, we chose to organize platinum nanoparticles by employing bifunctional thiophenol derivatives. As the thiolate groups display high affinity for platinum, the anchoring of the ligands at the surface of the particles occurs through the thiolate functions leaving free the *para* substituents for hydrogen bonding. This leads to a new series of platinum particles accommodating respectively *p*-hydroxythiophenol (colloid **3a**), *p*-aminothiophenol (colloid **3b**), and *p*-mercaptobenzoic acid (colloid **3c**). The addition of each ligand to compound **1** can be followed as before by IR spectroscopy. The terminal CO stretch shifts upon addition of 0.15 eq./Pt substituted thiophenol to a value of *ca.* 2040 cm^{-1}. The compounds were characterized by microanalysis, TEM and HREM. In all cases, the products were found to consist of severely agglomerated nanoparticles, the

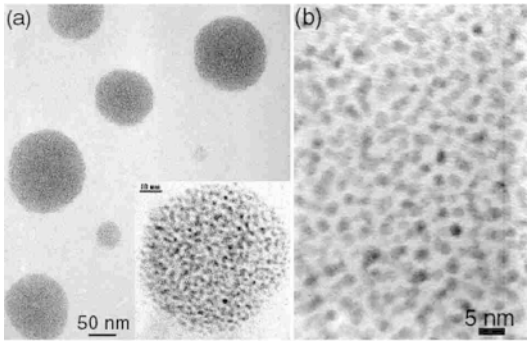

Fig 2 TEM (a) and HREM (b) micrographs of disks resulting from the condensation of **3a** and **3b** in the presence of water.

distance between which appears regular (near 1.5 nm). In most cases (Fig. 4, ESI†), the agglomerates adopt a compact shape, spherical or distorted spherical as also observed by Boal *et al.*[9] Since water may modify the hydrogen bonding network, the reaction was also carried out in the presence of water. In this case, disks composed of a monolayer of platinum particles were observed [Fig. 2(a)]. HREM analysis of these agglomerates [Fig. 2(b)] shows the presence of well-crystallized fcc platinum particles of uniform size near 1.6 nm, indicating the absence of modification of the particles upon complexation and reaction with water. Similar results were found with compounds **3b** and **3c**. In the latter case, the distance between the particles seems to be slightly shorter (1 nm) which may arise from strong hydrogen bonds between carboxylic groups.

In order to favour the organization of the particles, we mixed together fresh solutions of **3a** and **3b** containing hydroxy and amino pendent groups, respectively. XRD analysis of the samples is in accord with the presence of small fcc platinum with additional peaks at small angles possibly resulting from organization of the particles. TEM micrographs of **3a**/**3b** evidence the organization of the particles into systems showing an unidirectional anisotropy and resembling nanocrystals (Fig. 3, graphical abstract). Moreover in several cases we observe the formation of nanotubes which are hollow and may accommodate some 'pseudocrystals'. However, HREM analysis demonstrates that the 'pseudocrystals' or the walls of the tubes consist of fcc Pt nanoparticles of intact mean size and structure. As for the superstructures observed with **3a** alone, the addition of water to the system releases the hydrogen bonded network, leading to a monolayer organization.

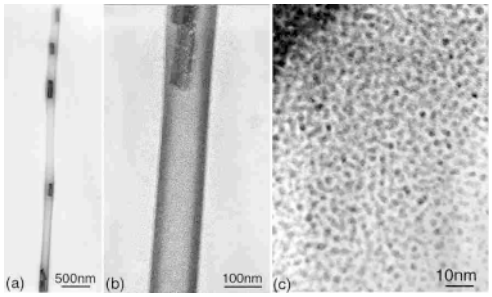

Fig 3 TEM and HREM micrographs of platinum nanotubes at different magnifications (a) ×15000 (b) ×100000 (c) ×600000.

In conclusion, functionalised platinum nanoparticles may be used as individual blocks for the growth of 2D or 3D superstructures through coordination bonds or hydrogen bonding networks. Although the chosen systems are very simple, several points appear nevertheless of interest : (1) the fact that water can control the shape of the hydrogen bonded agglomerates and favours the formation of monolayers is promising as far as the deposition of nanoparticles exhibiting controlled interparticle distance is concerned and may lead to selected electronic measurements or applications; (2) the shape of the obtained agglomerates are not yet predictable but some systems reproducibly display a preferred axis of growth to form 'pseudo-crystals' or nanotubes leading to possible access of nanowires comprised of nanoparticles; (3) connecting nanoparticles appears easy and may lead to interesting chemical and physical properties which will be studied in the future.

We thank CNRS and EC (TMR network CLUPOS) for support, and the TEMSCAN service of the 'Université Paul Sabatier' for electron microscopy facilities.

Tandem isomerisation–carbonylation catalysis: highly active palladium(II) catalysts for the selective methoxycarbonylation of internal alkenes to linear esters

Robert I. Pugh,[a] Eite Drent*[b] and Paul G. Pringle*[a]

[a] *School of Chemistry, University of Bristol, Cantocks Close, Bristol, UK, BS8 1TS. E-mail: paul.pringle@bristol.ac.uk*

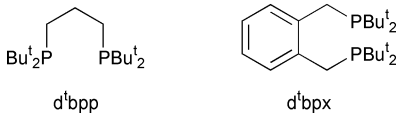
Received (in Cambridge, UK) 25th April 2001, Accepted 11th June 2001
First published as an Advance Article on the web 23rd July 2001

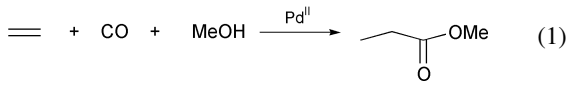
Fast, selective conversion of internal olefins to linear esters is catalysed by Pd(II) complexes of chelating bis(phospha-adamantyl)diphosphines and the catalysis is acutely sensitive to the ligand backbone and even to the diastereomer used; the results are compared with those for the PBu^t_2 analogue.

The palladium(II) catalysed methoxycarbonylation of olefins to esters has attracted much attention.[1] Recently, complexes of bulky alkyl diphosphines such as d^tbpp[2] and d^tbpx[3] have been



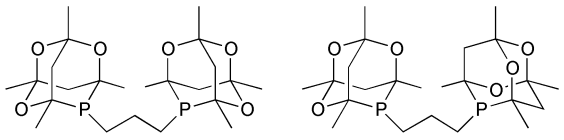
d^tbpp d^tbpx

reported to give excellent catalysts for the carbonylation of ethene to methyl propanoate (MeP) [eqn. (1)].

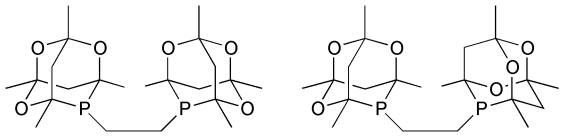


(1)

We have previously shown that adamantyl cage diphosphines *meso*/*rac*-**1** and *meso*/*rac*-**2** and their complexes are readily



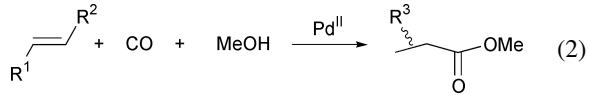
meso-**1** *rac*-**1**



meso-**2** *rac*-**2**

prepared.[4] We report here that *in situ* generated palladium(II) complexes of *meso*/*rac*-**1** and **2** catalyse the carbonylation of ethene and terminal olefins with comparable activity and selectivity to their PBu^t_2 substituted analogues; more importantly internal alkenes are selectively converted to linear esters, a discovery of potential application in the synthesis of detergents and nylon intermediates.[5]

Diastereomerically enriched *meso*-**1** (80%) and *rac*-**1** (96%) were separated by recrystallisation from MeOH of the *ca.* 1:1 diastereomeric mixture. Selected results from the carbonylation catalysis [eqn. (2)] are shown in Table 1.



(2)

Entry 1 shows that the catalyst from *meso*/*rac*-**1** and $Pd(OAc)_2$ quantitatively forms MEP at a slightly lower rate than its d^tbpp analogue.[2,3,5] The effect of the diphosphine backbone is beautifully illustrated by comparison of entries 1 and 2; the C_2-bridged *meso*/*rac*-**2** affords a catalyst for alternating CO/C_2H_4 polymerisation, yielding polyketone of a relatively low molecular weight. Normally the most active catalysts for polyketone formation are based on C_3-diphosphines,[7] but the sterically demanding phosphaadamantyl moiety renders the C_2-diphosphine more capable of copolymerision of ethene and CO.[8]

The most significant results were obtained with the carbonylation of 1-tetradecene (entry 3) and internal isomers of tetradecene (entry 4). The catalyst derived from *meso*/*rac*-**1** gave similar selectivities to linear esters for *both* substrates; the activity for the isomerisation/carbonylation of the internal olefins is *ca.* 0.4 that of the linear olefins, indicating that isomerisation is rate limiting and the high product linearity is a consequence of the increased rate of carbonylation at the terminal olefinic position. The analogous catalyst with d^tbpp (entry 5) showed hardly any activity for this isomerisation/carbonylation reaction. Our results on methoxycarbonylation of internal olefins also compare favourably with traditional cobalt[9] and more recent phosphorus(III)–rhodium systems for related hydroformylation catalysis, which suffer from relatively poor isomerisation activity[10] or low product linearity.[11]

The most unexpected result was the factor of two difference in activity between enriched catalysts from *meso*-**1** and *rac*-**1** for methoxycarbonylation of propene (entries 6 and 7). A similar difference in activity is observed in the conversion of internal C_{11}/C_{12} olefins to linear C_{12}/C_{13} esters (entries 8 and 9). Our results demonstrate that very subtle changes in the structure of the palladium catalyst can have a large influence on catalytic activity. Activity differences between diastereomeric Pd catalysts for CO/olefin copolymerisation have been reported recently.[12]

The difference in performance between the catalysts derived from the ostensibly similar bulky alkyl diphosphines *meso*/*rac*-**1** and d^tbpp, may be associated with the unusual stereoelectronic characteristics of the cage ligand. We have previously shown that the Tolman cone angle[13] for *meso*/*rac*-**1** (θ = 173°) is even larger than that of d^tbpp (θ = 155°).[14] The σ/π-bonding ability of *meso*/*rac*-**1** can be assessed from the ν(CO) of the A_1 band for the $[Ni(CO)_2(diphos)]$ chelates. When diphos = *meso*/*rac*-**1**, ν(CO) is 2002 cm^{-1} which is much higher than its PBu^t_2 analogue (1976 cm^{-1}) and even higher than its PPh_2 analogue (1997 cm^{-1}). The inference from these IR data is that the P-atom in the phosphatrioxaadamantane cage is electronically more akin to that in a $P(aryl)_2$ than a $P(alkyl)_2$ moiety. The low σ-basicity/high π-acidity of ligands *meso*/*rac*-**1** may be

traced to a combination of the effect of the electronegative oxygen atoms α to phosphorus and, perhaps more importantly, the effect of the acute (*ca*. 90°) C–P–C angle imposed by the cage.[15] Palladium–dppp isomerisation–carbonylation catalysts are known,[16] but the rate of hydroformylation of internal octenes was shown to be a factor of eight lower than the initial rate observed with 1-octene[17] and thus we cannot rationalise the observed catalysis on a purely electronic basis.

We thank Jan-Karel Buijink and Guido Batema for their contributions and Shell for financial support.

Direct functionalisation of σ-aryl ligands: preparation of homoleptic functionalised aryls of osmium(IV)†

Man-Kit Lau,[a] Qian-Feng Zhang,[a] Joyce L. C. Chim,[a] Wing-Tak Wong[b] and Wa-Hung Leung*[a]

[a] *Department of Chemistry, The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong, P. R. China. E-mail: chleung@ust.hk*
[b] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, P. R. China*

Received (in Cambridge, UK) 9th May 2001, Accepted 26th June 2001
First published as an Advance Article on the web 23rd July 2001

The osmium(IV) tetraaryl complex $[Os(C_8H_9)_4]$ (C_8H_9 = 2,5-dimethylphenyl) reacts with pyridinium tribromide in the presence of Fe powder to give $[Os(C_8H_8Br)_4]$, which undergoes Suzuki coupling with arylboronic acids to afford a series of homoleptic functionalised aryls of osmium(IV).

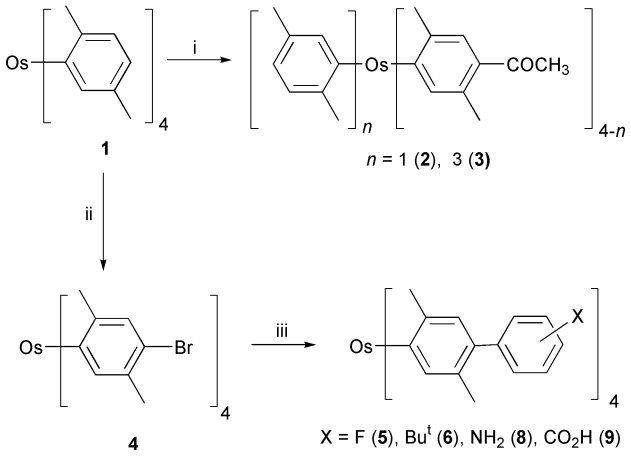
Transition metal complexes of σ-aryl ligands bearing reactive functional groups are of interest because they may serve as structure building units for organometallic polymers that exhibit interesting electrical, magnetic or catalytic properties.[1] There are, however, relatively few reports on chemical functionalisation of σ-aryl ligands. Functionalised arylmetal complexes have been previously prepared by using mercury transmetallation reagents[2] or oxidative addition of aryl halides to low-valent metal centres.[3] Recently Roper and Wright and their coworkers reported the direct functionalisation of aryl[4] and 2-(2′-pyridyl)phenyl[5] groups σ-bound to ruthenium and osmium, demonstrating that these metal aryls are sufficiently inert to undergo a wide range of transformations. This prompted us to investigate the functionalisation of homoleptic aryls of osmium(IV), which are known to be remarkably stable.[6] The use of homoleptic functionalised aryls of osmium as metalloligands is of interest because of their tetrahedrally directing property, and the fact that they can be readily oxidised to paramagnetic Os^V species.[7] We here report on the acylation and bromination of an osmium tetraaryl, and the Suzuki cross-coupling reactions of the resulting osmium bromoaryl complex.

The osmium tetraaryl complex $[Os(C_8H_9)_4]$ **1** (C_8H_9 = 2,5-dimethylphenyl) was synthesised by alkylation of $[OsO_4]$ with C_8H_9MgBr in diethyl ether, as described elsewhere.[6,8] Scheme 1 summarises the reactions that lead to functionalisation of the aryl groups in **1**.

As reported previously, the electron-rich σ-aryl groups in osmium tetraaryls are prone to electrophilic attack, *e.g.* Friedel–Crafts acylation.[9] Thus, treatment of **1** with MeCOCl in the presence of Al_2Cl_6 afforded a mixture of $[Os(C_8H_8COMe)_3(C_8H_9)]$ **2** and $[Os(C_8H_8COMe)(C_8H_9)_3]$ **3** in 40 and 30% yield, respectively. The solid-state structure of complex **2** is shown in Fig. 1.‡ The geometry around Os in **2** is approximately tetrahedral (average C–Os–C′ angle of 109.5°) and the average Os–C distance is 1.99(1) Å. The MeCO group in each aryl ligand is situated at the *para* position relative to Os, indicative of the *para*-directing property of the Os centre. Bromination of **1** by pyridinium tribromide in the presence of Fe powder afforded the tetrabromide compound $[Os(C_8H_8Br)_4]$ **4** in 52% yield. Fig. 2 shows the molecular structure of **4**.‡ The geometry around Os in **4** is approximately tetrahedral [average C–Os–C′ angle of 109.5°] and the average Os–C distance of 2.00(2) Å. Complex **4** in CH_2Cl_2 exhibits a reversible Os^V–Os^{IV} couple at 0.45 V *vs.*. the ferrocenium–ferrocene couple, which is about 0.21 V more anodic than that for complex **1**[7] due to the inductive effect of the bromo substitutents.

† Electronic supplementary information (ESI) available: preparations of osmium tetraaryl complexes. See http://www.rsc.org/suppdata/cc/b1/b104075h/

The tetrabromide **4** has proved to be a good starting material for metal-catalysed cross-coupling reactions. For example, complex **4** underwent Suzuki coupling with 4-$XC_6H_4B(OH)_2$ in



Scheme 1 *Reagents and conditions*: i, MeCOCl, Al_2Cl_6, CH_2Cl_2, −40 °C; ii, pyridinium tribromide, Fe powder, CH_2Cl_2, room temp; iii, 6 equivalents of arylboronic acids, $[Pd(PPh_3)_4]$, K_2CO_3, dmf, 110 °C.

Selected bond lengths (Å) and angles (°): Os(1)–C(1) 1.98(2), Os(1)–C(9) 2.01(2), Os(1)–C(17) 2.03(2), Os(1)–C(25) 1.98(1); C(1)–Os(1)–C(9) 107.3(6), C(1)–Os(1)–C(17) 111.6(6), C(1)–Os(1)–C(25) 109.5(6), C(9)–Os(1)–C(17) 110.8(6), C(9)–Os–C(25) 110.3(6), C(17)–Os(1)–C(25) 107.4(6).

the presence of $[Pd(PPh_3)_4]$ and K_2CO_3 to afford the respective homoleptic osmium biaryl $[Os(C_8H_8–C_6H_4X)_4]$ (X = F **5**, Bu^t **6**).§ Complexes **5** and **6** are highly soluble, lipophilic materials, which could be obtained as analytically pure dark solids after chromatography and recrystallisation. Oxidation of **5** with $AgBF_4$ gave a blue species, presumably $[Os(C_8H_8–C_6H_4F)_4]^+$, which exhibits an isotropic EPR signal at 77 K at g = 2.025 characteristic of Os^V species.[7] It appears that the Pd-catalysed cross coupling reaction involved oxidative addition of the aryl bromide ligand with Pd(0) followed by reductive elimination of the biaryl. The stoichiometric reaction between **4** and $[Pd(PPh_3)_4]$ afforded a blue solid analysed as $[Os(C_8H_8Br)_3\{C_8H_8PdBr(PPh_3)_2\}]$ **7**. Similarly, Pd-catalysed coupling of **4** with 3-$H_2NC_6H_4B(OH)_2$ and 4-$HO_2CC_6H_4$-$B(OH)_2$ afforded the tetraamine $[Os(C_8H_8–C_6H_4NH_2)_4]$ **8**, which seems to contain a very small amount of unknown impurity since the N analysis is not satisfactory at the moment, and the tetracarboxylic acid $[Os(C_8H_8–C_6H_4CO_2H)_4]$ **9**, respectively. Complex **9** is soluble both in organic solvents and in aqueous medium (pH $\geqslant$ 10), indicative of the inertness of the Os–C σ bonds. The homoleptic functionalised aryls of osmium can be used as starting materials for preparations of organometallic oligomers/polymers. For example, cyclic voltammetry indicated that complex **8** could be polymerised on a graphite electrode by anodic oxidation. A preliminary result showed that homo-coupling of the tetrabromide **4** by $[Ni(cod)_2]$ (cod = cycloocta-1,5-diene) yielded oligomers of **1**.[10]

In summary, we have demonstrated that the aryl groups in osmium tetraaryl complex **1** could be functionalised by electrophilic attack, *e.g.* acylation and bromination, without cleavage of the Os–C σ bonds. Suzuki coupling of the osmium bromoaryl complex with arylboronic acids provides convenient access to a wide range of homoleptic functionalized aryls of osmium, which can be used as starting materials for organoosmium oligomers/polymers.

First published as an Advance Article on the web 23rd July 2001

Linear, single stranded probes incorporating a fluorophore and an acridine moiety are weakly fluorescent until hybridised to a complementary target nucleic acid whereupon fluorescence increases due to reduced quenching.

In recent years interest in the detection of nucleic acid sequences in homogeneous solution has soared due to major developments in molecular genetics. Fluorescent moieties are the reporter groups of choice in these applications. Typically, an oligonucleotide probe is labelled with a fluorophore and a quencher. A reduction in quenching is caused by hybridisation of the probe to its target nucleic acid, leading to signal generation. Examples of such methods are scorpion primers,[1] TaqMan™ probes[2] and molecular beacons.[3]

These methods rely upon changes in secondary structure upon hybridisation, or subsequent enzymatic degradation of the probe for signal generation. Here, we describe a novel linear dual-labelled fluorescent probe capable of detecting specific nucleic acids in homogeneous solution that is not reliant on either of these mechanisms. The unhybridised linear probe is essentially non-fluorescent due to energy transfer between the fluorophore and the acridine quencher. However, formation of a probe–target duplex allows the acridine moiety to interact with the double strand—it can no longer act as an efficient quencher and a fluorescent signal is generated (Fig. 1). An acridine derivative has been used previously in an oligonucleotide probe as the donor in a fluorescence resonance energy transfer (FRET) system.[4] The mechanism of action leads to a *decrease* in fluorescent signal upon hybridisation. In contrast, the system we describe utilises the acridine moiety as a quencher – leading to an *increase* in fluorescence.

The probe is synthesised with the fluorophore 6-carboxy fluorescein (FAM), (Fig. 2i) at the 5′-end† linked to the intercalator 9-amino-6-chloro-2-methoxyacridine[5] (Fig. 2ii).

The advantages of the method lie in its simplicity: the probes are free of secondary structure, relatively short and inexpensive to synthesise (commercially available phosphoramidite monomers are used, Fig. 2), and the acridine stabilises probe–target hybrids.

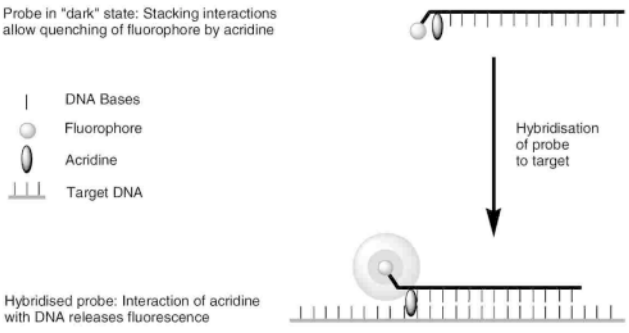

Fig. 1 Mechanism of action of the dual-labelled probe.

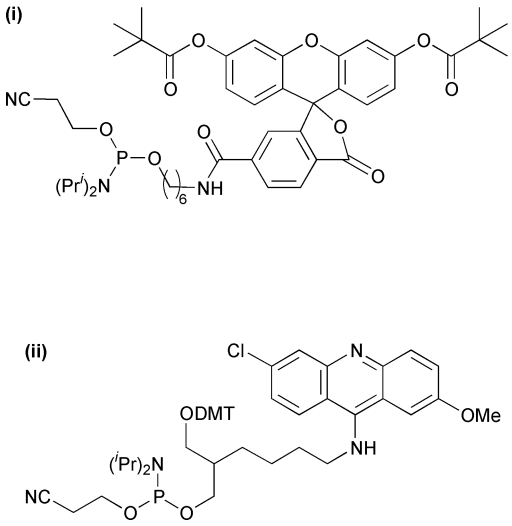

Fig. 2 Monomers used in probe synthesis (i) *O*-[(3′,6′-dipivaloyl-fluorescein-6-ylcarboxamidohexyl] *O*′-(2-cyanoethyl) (*N*,*N*-diisopropyl) phosphoramidite (PE Biosystems) (ii) *O*-[1-dimethoxytrityloxy-2-(*N*-acridin-1-yl-4-aminobutyl)propyl] *O*′-(2-cyanoethyl) (*N*,*N*,-diisopropyl)phosphoramidite (Glen Research).

The 14-mer probe (P1) used in this study was designed to hybridise to the wild type N1303K locus[6]‡ of the ABCC7 gene on chromosome 7 that produces the cystic fibrosis transmembrane conductance regulator (CFTR) protein. The probe sequence is:

5′-FAM-acridine-AAAAACTTGGATCC-octanediol-3′ (P1)

In the current studies we used a synthetic oligodeoxynucleotide version of a 24-nucleotide section of the target locus:

5′- TAGGGATCCAAGTTTTTTCTAAAT-3′ (T1)

The probe was synthesised as a 2′-*O*-methyl oligoribonucleotide. 2′-*O*-Methyl oligoribonucleotides are not generally substrates for hydrolysis by DNase enzymes, and the probes were assembled from 2′-*O*-methyl RNA phosphoramidites (Glen Research) to avoid a TaqMan-like cleavage[2] in any subsequent PCR assay. Octanediol (phosphoramidite was a gift from Oswel Research Products Ltd.) was incorporated at the 3′ end of the probe to avoid extension of the probe by *Taq* polymerase during PCR. In preliminary studies we have shown that the observed effect (Fig. 1) also occurs with oligodeoxynucleotide probes with unmodified sugars, and that the optimum position for attachment of the acridine is directly adjacent to the fluorophore.

The dual-labelled probe (210 nM) P1 was added to a suitable hybridisation buffer (100 mM sodium phosphate, 1 mM EDTA, 100 mM NaCl, pH 7.0) at room temperature, and the emission spectrum recorded on an LS 50B Luminescence Spectrometer

 DOI: 10.1039/b104421b

Table 1 T_m results of UV melting experiments

T_m of P1 with T1/ °C	T_m of C1 with T1/°C	ΔT_m °C
54.0[a]	52.3[a]	+1.7

[a] All experiments were run in triplicate, and the average reading reported.

(Perkin Elmer), from excitation at 495 nm. The synthetic target (T1, 1050 nM) was then added and the emission spectrum re-recorded with excitation at 495 nm.

On addition of T1 and excitation at 495 nm the fluorescence intensity at 520 nm rose from 61.6 units to 250.3 units (a 4.5-fold increase).

In order to investigate the mechanism of fluorescence enhancement we performed UV melting experiments to determine the T_m value of probe–target hybrids. Intercalators such as acridine are known to stabilise duplexes by participating in π-stacking and electrostatic interactions with the nucleobases.[7] A control unlabelled 2′-*O*-methyl oligoribonucleotide was synthesised with a sequence analogous to the probe:

5′-AAAAACTTGGATCC-octanediol-3′ (C1)

The probe P1 (963 nM) and the synthetic target (T1, 1260 nM) were added to the hybridisation buffer (100 mM sodium phosphate, 1 mM EDTA, 100 mM NaCl, pH 7.0). The sample was heated (75 °C, 1 min), cooled (15 °C, 1 min), then melted by heating for 3880 s, at 1 °C min^{-1}. The ultraviolet absorbance was continuously monitored at 260 nm on a Perkin Elmer Lambda 15 UV/VIS Spectrophotometer. T_m values were calculated using the PECSS 2 software (Perkin Elmer). The experiment was repeated, with unlabelled probe C1 (963 nM) in place of P1. The results are shown in Table 1.

The labelled probe–target hybrid exhibited a higher T_m than the analogous unlabelled probe–target hybrid suggesting that the acridine moiety intercalates into, or stacks on the end of the duplex upon hybridisation. Further experiments are necessary to confirm the precise interaction.

The lack of any probe secondary structure simplifies design, and enables the use of very short probes, since hybridisation to the target does not have to compete with any intramolecular structures. This can be a problem with molecular beacons.

To investigate the ability of the probes to discriminate between fully matched targets and those containing a single mismatch we prepared a further three oligodeoxynucleotides designed to form duplexes with a single base pair mismatch in the highlighted position:

5′-TAGGGATCCAA**C**TTTTTTCTAAAT-3′ (T2)

5′-TAGGGATCCAA**T**TTTTTTCTAAAT-3′ (T3)

5′-TAGGGATCCAAA**A**TTTTTTCTAAAT-3′ (T4)

P1 (0.5 μM) and the complement (5 μM T1, T2, T3, T4 or water) were added to a Roche LightCycler™ capillary containing a buffer (20 mM $(NH_4)_2SO_4$, 75 mM tris–HCl, 0.01% Tween, 4 mM $MgCl_2$, 250 ng μL^{-1} bovine serum albumin). Each tube was subjected to denaturation (95 °C, 30 s), cooled (25 °C), and then immediately heated (95 °C, 0.2 °C s^{-1}), whilst monitoring fluorescence in Channel 1 ($\lambda_{em} \approx 520$ nm) of the LightCycler™ (Roche). T_m values were calculated using the LightCycler™ software (Roche). The results are shown in Table 2.

In samples containing the synthetic targets (T1, T2, T3 or T4), the fluorescence intensity decreased with melting of the probe–target hybrid (Fig. 3). The first derivative of the melting curves allowed calculation of the T_m of probe–target hybrids (Table 2). Analysis of this data shows excellent discrimination between matched and mismatched probe–target hybrids, with the T_m values differing by up to 18.3 °C.

Table 2 T_m results of fluorescent melting experiments

Complement	Description of complement	T_m/°C	ΔT_m/°C
T1	Matched	56.8[a]	—
T2	C:C mismatch	38.5[a]	−18.3
T3	C:T mismatch	40.6[a]	−16.2
T4	C:A mismatch	40.9[a]	−14.9

[a] All experiments were run in triplicate, and the average reading reported.

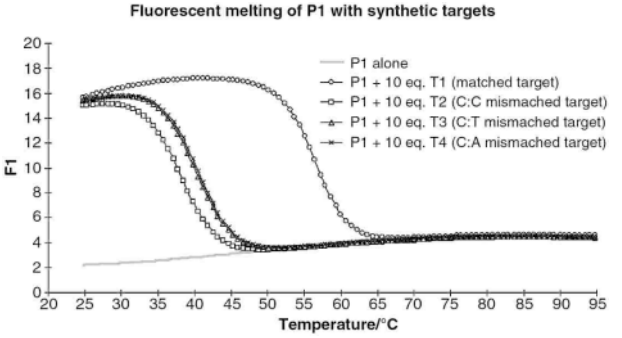

Fig. 3 Melting curves obtained from melting P1 with T1–T4.

We attribute the small rise of fluorescence with increasing temperature to thermal disruption of the fluorophore–quencher pair; in particular by increased molecular motion of the fluorescein moiety, although we have not investigated the phenomenon further.

In summary, we have developed a novel technique for detecting nucleic acid sequences that has advantages over existing methods.[8] The lack of probe secondary structure in this system allows the use of shorter probes with enhanced mismatch discrimination. At present, we are investigating the use of probes of this type in real time PCR and have shown that in this context P1 is capable of detecting a 103 base pair amplicon of the N1303K locus. We also expect the low activation barrier to probe hybridisation in this type of system to be advantageous in microarray technology.

Beyond Fe-only hydrogenases: *N*-functionalized 2-aza-1,3-dithiolates $Fe_2[(SCH_2)_2NR](CO)_x$ (x = 5, 6)

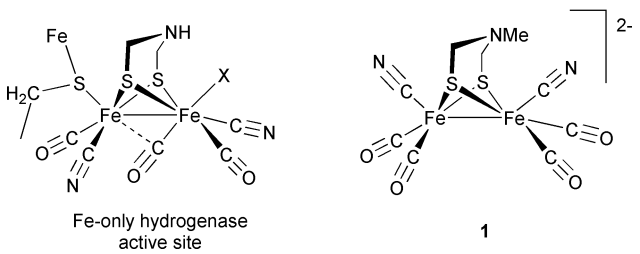
Joshua D. Lawrence, Hongxiang Li and Thomas B. Rauchfuss*

Department of Chemistry, University of Illinois, 601 S. Goodwin Ave., Urbana, IL 61801, USA. E-mail: rauchfuz@uiuc.edu

Received (in Cambridge, UK) 14th May 2001, Accepted 26th June 2001
First published as an Advance Article on the web 23rd July 2001

Primary amines undergo chloromethylation with CH_2O/$SOCl_2$ to give $RN(CH_2Cl)_2$, which in turn react with $Li_2[Fe_2S_2(CO)_6]$ to give $Fe_2[(SCH_2)_2NR](CO)_6$; in the case of R = $CH_2CH{=}CH_2$ and CH_2CH_2SMe, Me_3NO-induced decarbonylation afforded pentacarbonyl derivatives wherein the pendant functionality is coordinated to Fe.

The Fe-only hydrogenases are a topical class of proteins with organometallic reaction centers of the formula $[Fe_2(SR)_2(CN)_2(CO)_3\{Fe_4S_4(\mu\text{-}SR)(SR)_3\}(X)]$ (X = H_2O, CO, H^-/H_2).[1,2] Significant progress has been achieved in characterizing the first coordination shell of the diiron core,[3–5] including high quality crystal structures of the dicyanides $[Fe_2(SR)_2(CN)_2(CO)_4]^{2-}$ **1**.[3] It has recently been proposed that the dithiolate ligand is an azadithiolate $SCH_2NH_xCH_2S$,[6] and we have used $(ClCH_2)_2NMe$ to introduce this novel functionality (Scheme 1).[7]



Fe-only hydrogenase active site

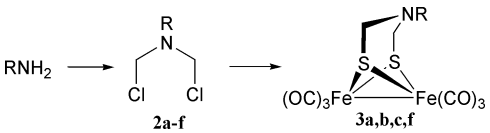
1

Scheme 1

Because the azadithiolate cofactor defines an unprecedented coordination motif, we sought to explore its scope. The only known bis(chloromethyl)amine, $(ClCH_2)_2NMe$, is however prepared *via* an uninviting degradation of triazine $[CH_2NMe]_3$ using PCl_5.[8]

We have found that many primary amines undergo efficient chloromethylation upon treatment with a solution of paraformaldehyde followed by 2× excess of $SOCl_2$ (Scheme 2). The reactions occur under mild conditions, and the chloromethylated amines are isolated as the free bases. In some cases the amines were further purified by vacuum distillation, but usually evaporation of ether extracts provided the targeted species. These compounds were identified by ^1H NMR spectroscopy (characteristic NCH_2Cl singlet at δ 5.5–5.2) as well as elemental analysis or high resolution mass spectrometry. The following derivatives were prepared: allyl (**2a**), *tert*-butyl (**2b**), methylcarboxylethyl (**2c**), benzyl (**2d**), 4-nitroaniline (**2e**), and 2-(methylthio)ethyl (**2f**).† Compounds **2a–f** are stable under anhydrous conditions at 0 °C.

Iron thiolate carbonyl dimers were prepared from bis(chloromethyl)amines **2a**, **2b**, **2c**, **2f** by treatment with $Li_2[Fe_2(S)_2(CO)_6]$ (Scheme 2), as for the synthesis of **1**.[7] Recrystallization from hexanes gave analytically pure samples with isolated yields of *ca.* 50% for $Fe_2[(SCH_2)_2NR](CO)_6$, **3a**, **3b**, **3c**, (**3f** was generated *in situ* and used immediately, see below).‡ We found that these alkylations proceeded more efficiently when the crude product mixture is treated with Et_3N at −78 °C to complex the BEt_3 coproduct.[9]



2a-f **3a,b,c,f**

Scheme 2

Suitable substituents on the amine nitrogen should be capable of coordinating to one of the two Fe centers. Decarbonylation of **3a** with Me_3NO afforded a single new derivative. Recrystallization afforded *ca.* 50% yield of the deep red pentacarbonyl $Fe_2[(SCH_2)_2N\text{-}\eta^2\text{-}CH_2CH{=}CH_2](CO)_5$ **4a**.§ ^1H NMR measurements indicate that the alkene is coordinated, *e.g.*, the $CH_2CH{=}CH_2$ signals show greatly increased coupling and chemical shift range (2.5 ppm) relative to the hexacarbonyl **3a**. Furthermore the 2-D ^1H NMR spectrum demonstrated that all methylene hydrogen atoms are diastereotopic indicative of lowered symmetry. The IR spectrum for **4a** was characteristic of a $Fe_2(SR)_2(CO)_5L$ species.[10]

Crystallographic characterization¶ shows that **4a** adopts a cage-like structure with one Fe center bound to a pair of S atoms and the alkene (Fig. 1). The alkene is approximately *trans* to the Fe–Fe bond. The remaining Fe–Fe and Fe–C and Fe–S distances are normal, indicating that the chelation does not impose strain on the Fe_2S_2 core. Alkene adducts of iron thiolates are not widely known, the closest examples being (1) $Fe_2(SMe)_2(CO)_6C_2F_4$, which results from the oxidative addition of tetrafluoroethene across the Fe–Fe bond,[11] and (2) $Fe_2(SPh)(CH_2{=}CHCHCHCH_2)(CO)_5$, which contains both alkene and allyl ligands.[12]

Analogously to the preparation of **4a**, MeCN solutions of **3c** and **3f** were subjected to Me_3NO-induced decarbonylation. We were unable to effect coordination of the ester group in **3c**, but the thioether did cyclise to give $Fe_2[(SCH_2)_2NCH_2CH_2SMe](CO)_5$ **4f** (Scheme 3). Crystallographic

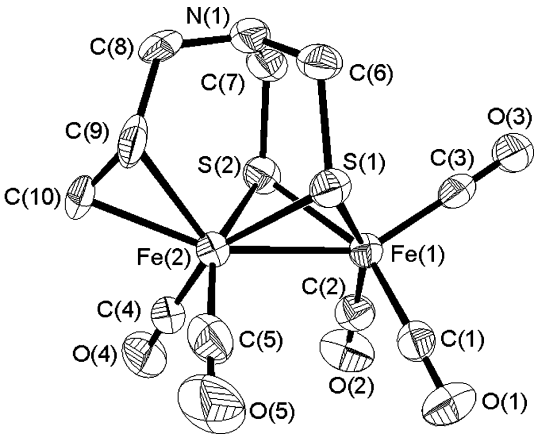


Fig. 1 Structure of $Fe_2[(SCH_2)_2NCH_2CH{=}CH_2](CO)_5$ **4a** with thermal ellipsoids set at the 50% probability level. Scheme 3

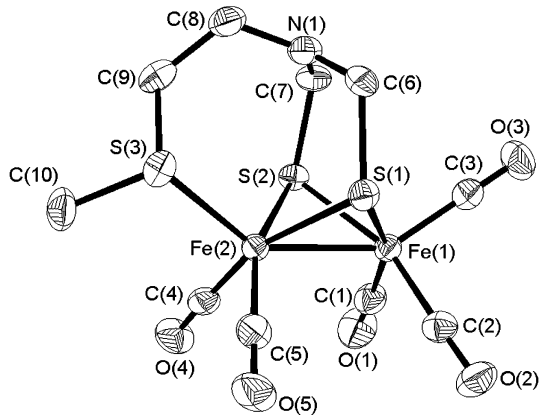

Fig. 2 Structure of $Fe_2[(SCH_2)_2NCH_2CH_2SMe](CO)_5$ **4f** with thermal ellipsoids set at the 50% probability level. Selected distances (Å) and angles (°): Fe(1)–Fe(2), 2.5144(14); Fe(2)–S(3), 2.2703(15); S(1)–C(6), 1.870(3); S(2)–C(7), 1.865(3); C(6)–N1–C(7), 115.4(3); C(7)–N(1)–C(8), 121.3(3); C(6)–N(1)–C(8), 118.3(3).

characterization showed that the thioether is coordinated in **4f** (Fig. 2). Pickett and coworkers have recently reported a similar complex $Fe_2[(SCH_2)_2CHCH_2SMe](CO)_5$.[13] For **4a**, and to an even greater extent, **4f**, C–S distances are lengthened and C–N–C angles are increased due to the anomeric effect.[7]

In summary, a new route to bis(chloromethyl)amines allows general access to a broad class of *N*-functionalized azadithiolato complexes. Independent of any biological relevance, azadithiolates could be applied more generally, especially as bridging ligands with functionality.[14]

This research was supported by the U.S. National Institute of Health.

Highly efficient copper-catalysed oxidation of ascorbic acid by peroxynitrite

Yurii V. Geletti, Alan J. Bailey, Eric A. Boring and Craig L. Hill*

First published as an Advance Article on the web 26th July 2001

The simple salt $CuCl_2{\cdot}2H_2O$, and the new Cu-substituted polyoxometalate (POM), $Na_7[CuCoW_{11}O_{39}]{\cdot}5H_2O$ 1 are highly efficient catalysts for the oxidation of ascorbic acid by peroxynitrite.

The chemistry and reactivity of the biologically important inorganic toxin peroxynitrite† is not yet fully understood.[1,2] Antioxidants are believed to reduce the toxic effects of peroxynitrite[3] and ascorbic acid is the most common antioxidant *in vivo*. The reaction between ascorbic acid and peroxynitrite is relatively slow (k = 42–47 M^{-1} s^{-1} at 25 °C, pH 7.4).[4,5] Transition metals are known to catalyse the decomposition of peroxynitrite and other peroxo species.[1,2,6] There are a number of reports in the literature of copper complexes that catalyse the oxidation of ascorbic acid using dioxygen[7] and peroxo species.[8] We report here the highly efficient catalytic oxidation of ascorbic acid by peroxynitrite in the presence of the simple aqueous cupric ion (henceforth Cu^{2+}), formed by dissolution of $CuCl_2{\cdot}2H_2O$, and the new Cu-substituted Co-centred polyoxometalate (POM), $Na_7[CuCoW_{11}O_{39}]{\cdot}5H_2O$ **1**.

Peroxynitrite was prepared by the reaction of nitrite and acidified hydrogen peroxide solution followed by quenching with NaOH in a simple flow reactor.[9] The concentrations of these solutions were determined by UV–VIS spectroscopy [ε_{302} = 1.7 × 10^3 M^{-1} cm^{-1}].[10] The new POM, **1**, was prepared by the slow addition of $K_9[CoW_{11}O_{39}]{\cdot}14H_2O$[11] to a solution containing an excess of $CuCl_2$.‡

Phosphate buffer solutions (pH 7.4) of Cu^{2+} show highly efficient catalysis of ascorbic acid oxidation by peroxynitrite. We also prepared and characterised **1**, a new type of mixed-metal POM, and compared its catalytic properties to those of Cu^{2+}. The kinetics of peroxynitrite decay are exponential§ and follow the rate law in eqn. (1) where k_{obs} increases linearly with [Cu^{2+}] (Fig. 1).

$$-d[ONOO^-]/dt = k_{obs}[ONOO^-] \quad (1)$$

The addition of EDTA completely inhibits the catalytic activity of Cu^{2+} and even results in a decrease of the reaction rate in the blank reaction (due to chelation of residual Cu^{2+}). The rate remains constant until [Cu^{2+}] ≈ 1.5 μM (in the presence of EDTA, Fig. 1) and then increases linearly with [Cu^{2+}]. The slope of k_{obs} *vs.* [Cu^{2+}] is the same in the presence and absence of EDTA (Fig. 1). The amount of residual Cu^{2+} in the solutions can be estimated from the interception of the straight lines (shown by the arrow in Fig. 1) at negative [Cu^{2+}]. The intercept of the plot with EDTA and the *y*-axis is linearly proportional to [ascorbic acid]. From this value the reaction rate constant for the bimolecular reaction of peroxynitrite and ascorbic acid is (51 ± 5) M^{-1} s^{-1} and is in good agreement with the literature value of 42–47 M^{-1} s^{-1}.[4,5] Thus, the reaction rate law can be written [eqn. (2)]:

$$-d[ONOO^-]/dt = (k_o + k_a[\text{ascorbic acid}] + k_{cat}[Cu^{2+}])[ONOO^-] \quad (2)$$

where k_o = the rate constant of unimolecular peroxynitrite self-decay (k_o = 0.4 s^{-1} [1,2]), k_a = the rate constant for the bimolecular reaction of ascorbic acid with peroxynitrite (k_a = 51 M^{-1} s^{-1}), and k_{cat} = the rate constant for the catalytic pathway. k_{cat} values for both Cu^{2+} and **1** depend on [ascorbic acid] (Fig. 2). This dependence is complex, and the activities of the two Cu species are very similar.¶

Similar reactions using other transition metal-containing species ($CoCl_2{\cdot}6H_2O$, $K_7[CoAlW_{11}O_{39}]{\cdot}13H_2O$,[12] $Fe(NO_3)_2{\cdot}6H_2O$, $MnCl_2{\cdot}4H_2O$ and $NiNO_3{\cdot}6H_2O$) in aqueous solution at pH 7.4 (25 °C, 75 mM phosphate buffer, 12 mM ascorbic acid and 0.1 mM initial peroxynitrite) were investigated, and the reaction rates (k_{cat}) compared to those catalysed by Cu^{2+} and **1**. While Fe^{2+} and Ni^{2+} are inactive, Mn^{2+} exhibits slight activity ($k_{cat} \leqslant 0.05 \times 10^6$ M^{-1} s^{-1}). Both Co^{2+} and $K_7[CoAlW_{11}O_{39}]$ showed significant catalytic activity[12] (k_{cat} = 0.13 ± 0.03 × 10^6 and 0.15 ± 0.03 M^{-1} s^{-1}, respectively) but were still over 30 times slower than either Cu^{2+} or **1** (k_{cat} = 3.65 ± 0.2 × 10^6 and 3.15 ± 0.2 × 10^6 M^{-1} s^{-1}, respectively). This catalytic system is one of the most efficient reported thus far. At physiological concentrations of ascorbic acid (1 mM), Cu^{2+} catalysis of peroxynitrite-based oxidation proceeds with k_{cat}

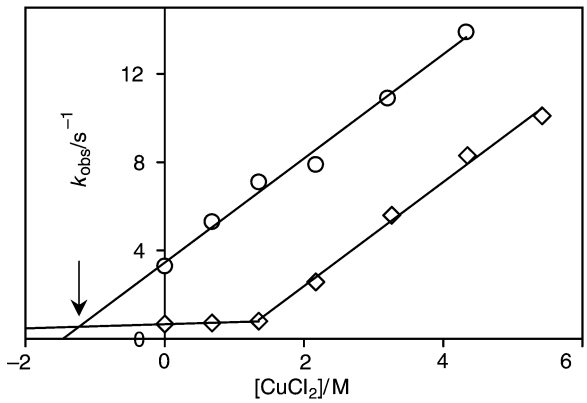

Fig. 1 Dependence of k_{obs} [eqn. (1)] *vs.* [Cu^{2+}]. *Reagents and conditions*: 25 °C, pH 7.4, 75 mM phosphate buffer, 12 mM ascorbic acid and 0.1 mM initial [peroxynitrite]. (○) No EDTA added. (◇) 2.5 μM EDTA added.

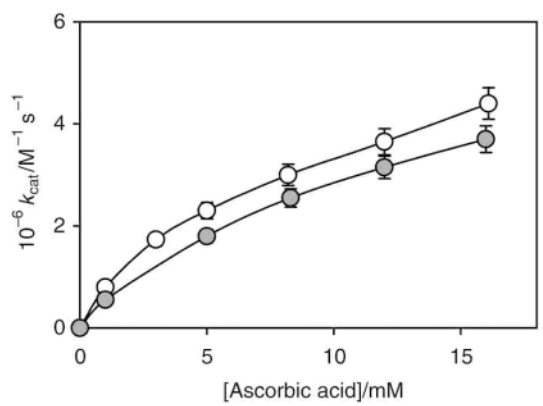

Fig 2 Dependence of k_{cat} [eqn. (2)] *vs.* [ascorbic acid]. *Reagents and conditions*: 25 °C, pH 7.4, 75 mM phosphate buffer and 0.1 mM initial [peroxynitrite]. (○): k_{cat} data for Cu^{2+}. (●): k_{cat} data for **1**.

 DOI: 10.1039/b104159m

values of 0.8×10^6 or 1.6×10^6 M^{-1} s^{-1} (at 25 and 37 °C, respectively), which is slightly slower than for Mn porphyrins (1.6×10^6 M^{-1} s^{-1} for MnTMPyP at 23 °C).[13]

In order to assess the possible relevance of Cu-catalysed ascorbic acid oxidation by peroxynitrite *in vivo*, the activity of Cu^{2+} was evaluated in the presence of biologically important Cu-binding chelates, Gly-Gly-His (GGH), bovine serum albumin (BSA), cysteine and ceruloplasmin. The effect of the abiological chelates *o*-phenanthroline and nitrilotriacetic acid was also evaluated. At a 2:1 GGH:Cu ratio ([ascorbic acid] = 12 mM), $k_{cat} = 3.0 \pm 0.2 \times 10^6$ M^{-1} s^{-1}, which is slightly lower than that for the reaction catalysed by Cu^{2+} and similar to that exhibited by **1**. Further increases in the GGH:Cu ratio decreased the rate until rate was that of the background reaction at a ratio higher than 6:1. BSA also decreased the rate. At a BSA:Cu ratio = 0.5 (the molecular weight of BSA was taken as 66429),[14] the reaction rate dropped to 60% of that in the absence of the chelate. However, at a BSA:Cu ratio >10 the activity decreased to 10% that of Cu^{2+}. Pure Cu-loaded ceruloplasmin purified from non-specifically bound Cu^{2+} was catalytically inactive. However, addition of up to 8 μM Cu^{2+} to this ceruloplasmin is a catalytic system with 50% of the activity of free Cu^{2+}. Cysteine strongly inhibits the catalytic activity of Cu^{2+} at a cysteine:Cu ratio >1.0, but the kinetics are more complex than eqn. (1). The non-biological chelates *o*-phenanthroline and nitrilotriacetic acid substantially inhibit the reaction (to approximately the background level) when they are added in a chelate:Cu ratio of 2 and 3, respectively. Most of the biologically important Cu-chelates do not greatly affect the catalytic activity. It is evident that at least one coordination site of the Cu^{2+} is required for catalytic activity. Significantly, the data suggest that Cu-catalysed peroxynitrite oxidation of ascorbic acid may constitute a minor but probable pathway for ascorbic acid depletion *in vivo*.

Detailed kinetic studies showed the oxidation of $Cu^{I}(GGH)_n$ to $Cu^{II}(GGH)_n$ (soluble models of Cu^+/Cu^{2+} suitable for kinetic studies) and subsequent reduction by ascorbic acid are both too slow under our experimental conditions to account for the observed overall reaction rate. The mechanism therefore may involve the formation of copper-peroxynitrito intermediate complex [eqn. (3)] which is subsequently trapped by ascorbic acid [eqn. (4)]:

$$Cu^{II}(H_2O) + ONOO^- \rightleftharpoons Cu^{II}(OONO^-) + H_2O \quad (3)$$

$$Cu^{II}(OONO^-) + H^+ + HA^- \rightarrow Cu^{II}(H_2O) + NO_2^- + A \quad (4)$$

where HA^- is the ascorbate anion and A is dehydroascorbic acid (the product of ascorbic acid oxidation). An alternative mechanism [eqns. (5) and (6)] may involve the formation of a complex between ascorbate and Cu(II) which is then oxidised by peroxynitrite:

$$Cu^{II}(H_2O) + HA^- \rightleftharpoons Cu^{II}(HA^-) + H_2O \quad (5)$$

$$Cu^{II}(HA^-) + H^+ + ONOO^- \rightarrow Cu^{II}(H_2O) + NO_2^- + A \quad (6)$$

Either of these mechanisms results in the rectangular hyperbolic rate law (7):

$$-d[ONOO^-]/dt = a[Cu(II)][ONOO^-][HA^-]/(b + c[HA^-]) \quad (7)$$

where $a = k_3k_4$, $b = k_{-3}$, $c = k_4$ for eqns. (3) and (4), or $a = k_6K_5$, $b = 1$, $c = K_5$ for eqns. (5) and (6). Eqns. (3) and (4) are likely to operate at low [ascorbic acid], while eqns. (5) and (6) are likely to operate at high [ascorbic acid] which is consistent with the data in Fig. 2.

We gratefully acknowledge funding by the NSF (C. L. H.) and INTAS (grant 99-209, to Y. V. G.).

Notes and references

† The term peroxynitrite is used to refer to the peroxynitrite anion O=NOO$^-$, and peroxynitrous acid, ONOOH, unless otherwise indicated. The IUPAC recommended names are oxoperoxonitrate(−1) and hydrogen oxoperoxonitrate, respectively.

‡ *Synthesis* of $Na_7[CuCoW_{11}O_{39}]\cdot 5H_2O$ **1**: $CuCl_2\cdot 2H_2O$ (0.12 g, 0.7 mmol) was dissolved in H_2O (20 mL) and $K_9[CoW_{11}O_{39}]\cdot 14H_2O$[11] (2.0 g, 0.6 mmol) was added over 30 min in small aliquots with each being allowed to dissolve before further POM was added. The resulting brown solution was stirred for a further 20 min, and KCl (10 g, 0.13 mol) was added. The solution was cooled at 5 °C overnight and the resulting brown precipitate filtered off, washed with cold H_2O (3 × 25 mL) and purified by dissolving in warm H_2O and passing a 0.1 M solution 3 times through an Amberlite® resin ion-exchange column charged with 1 M NaCl. The solution was concentrated and cooled overnight at 5 °C and the resulting solid was filtered and dried *in vacuo*. Analytical data: Calc. (found) for $Na_7CuCoW_{11}O_{44}H_{10}$: Na, 5.3 (5.2); Cu, 2.1 (2.1); Co 2.0 (2.0); W 67.0 (66.8%); IR data (cm^{-1}): 942m, 878s, 773vs, 750s, 697m, 530w, 450m.

§ Kinetics were monitored at 302 nm using a SF-61 stop flow instrument (Hi-Tech Scientific, UK). A deviation from exponential decay for the first 5–10% conversion of peroxynitrite was observed. The reaction proceeded more slowly than expected. In consequence, the first 10–15% of the kinetic curve was omitted for fitting the data. There are three possible explanations for this rate retardation. First, Cu^{2+} could be reduced by ascorbic acid to Cu^+ (in the stock solution), and subsequent reoxidation to the catalytically active Cu^{2+} is slow. Second, at high [peroxynitrite] the equilibrium in eqn. (3) can be shifted to the right and thus all the Cu^{2+} is in the form of the peroxynitrite complex. In this case, the reaction rate is zero-order with respect to peroxynitrite and proceeds slower than the projected first-order reaction. Third, at high [peroxynitrite], eqn. (5) can be rate-limiting again resulting in zero-order with respect to peroxynitrite.

¶ In aqueous solution **1** may dissociate to Cu^{2+} and lacunary POM (POM_{lac}). However, the observed activity of **1** is *not* due to this dissociation. The catalytic activities of mixtures of Cu^{2+} and POM_{lac} were investigated. The addition of POM_{lac} to Cu^{2+} slightly decreased the reaction rate. However, at a $[POM_{lac}] : [Cu^{2+}] > 1$ the catalytic activity was the same as for solutions of **1**. Moreover, the addition of POM_{lac} to **1** did not inhibit its activity.

Synthesis of pure polymorph C of Beta zeolite in a fluoride-free system

Avelino Corma,* Mª Teresa Navarro, Fernando Rey and Susana Valencia

Instituto de Tecnología Química, UPV-CSIC, Universidad Politécnica de Valencia, Avda. de los Naranjos s/n, 46022 Valencia, Spain. E-mail: acorma@itq.upv.es; Fax: +34(96)3877809; Tel: +34(96)3877800

Received (in Cambridge, UK) 10th May 2001, Accepted 28th June 2001
First published as an Advance Article on the web 18th July 2001

Pure polymorph C (denoted ITQ-17) resulting from the intergrowth of zeolite Beta has been synthesized in the presence of Ge from a fluoride-free synthesis mixture; this shows that fluoride is not necessary to obtain structures containing D4MR units that were believed to be stabilised by fluoride; on the other hand, the presence of Ge directs the synthesis towards the formation of pure polymorph C.

Zeolites are porous crystalline aluminosilicates that have found important applications in catalysis, adsorption and as ion exchangers. For many of these applications, it would be interesting to carry out an *a priori* design of zeolites. Unfortunately, despite the efforts made by several groups,[1,2] the existing knowledge on nucleation and crystallization mechanisms at the molecular level is limited, and the synthesis of new structures has advanced mainly by accumulated experience using different structure directing agents (SDAs) and synthesis conditions. More specifically, in the case of high silica/alumina large pore three-dimensional zeolites, the number of existing structures is quite limited[3] and up to now only Beta zeolite has found commercial applications.[4] Zeolite Beta is a highly faulted intergrowth of two polymorphs A and B. Newsam *et al.*[5] described a hypothetical framework, denoted as polymorph C, which is related to polymorphs A and B of zeolite Beta, and could be generated from polymorph A simply by the recurrent application to the building layers of a shear operation along both *a* and *b* axes. The structure of polymorph C has a three-dimensional system of 12MR channels that intersect perpendicularly, and in contrast with polymorphs A and B, all the channels in the structure C are linear.[5] Furthermore, polymorph C contains double four-membered ring (D4MR) cages as secondary building units [two D4MR cages per unit cell (u.c.)], while polymorphs A and B do not contain such secondary building units.

It has been reported[6] that, among a large number of pure silica structures, those that contain mainly triple 4-MRs are the least stable frameworks with enthalpies of transition for quartz $\rightarrow$ molecular sieve (ΔH^{298}_{trans}) $\geq$ 10.8 kJ mol^{-1}, indicating that the presence of large fractions of multiple 4-MRs seems to lead to a destabilization of the framework, at least for less dense structures such as CHA, ISV, FAU and AST. It is apparent from this point of view that structure C which presents D4MRs should be less stable than zeolite Beta formed by polymorphs A and B. Then, while it is true that purely thermodynamic data cannot answer questions about the kinetics of zeolite synthesis, they can nevertheless help to rationalize driving forces for synthesis.[6] On this basis it is not surprising that the polymorph C has been elusive, whereas zeolite Beta has been synthesized with several SDAs.[7–9] However, it has been shown[10] that fluoride ions can stabilize D4MR small cages and, consequently, a synthesis procedure in fluoride media, in principle, could favour the synthesis of polymorph C. Very recently, Liu *et al.*[11] have found polymorph C as an impurity of the pure silica Beta zeolite, when this was synthesized in fluoride media using tetramethylenebisquinuclidinium diquaternary cation (M_4BQ^{2+}) as structure directing agent. It was suggested that the presence of fluoride ions was required for the formation of the observed impurity. However, pure polymorph C (ITQ-17) was not obtained until Corma *et al.*[12] showed that in the presence of fluoride ions this structure is formed when Ge is also introduced in the synthesis media. Then, it appears that both F^- and Ge stabilise the presence of double four-membered rings in the structure and then it is possible to prepare the pure polymorph C of Beta with a large number of organic structure directing agents.

Unfortunately, the presence of F^- in the synthesis media is not desirable from an industrial point of view and, therefore, it is of interest to find a fluoride-free synthesis of the pure polymorph C, not only for practical reasons but also from a conceptual point of view in order to establish whether the presence of F^- anions is mandatory for the stabilization of D4MR units, which are present in that structure.

Here, we will show that the synthesis of pure polymorph C (ITQ-17) of the intergrowth of Beta zeolite has now been achieved in the absence of fluoride ions.

The synthesis was carried out in OH^- media, using 1-methyl-4-aza-1-azoniabicyclo[2,2,2]octane hydroxide (DABMe(OH)) as the structure directing agent. The 1-methyl-4-aza-1-azoniabicyclo[2,2,2]octane cation ($DABMe^+$) was synthesised in its iodide form in the following way: a solution of iodomethane (Aldrich) (3.7 g) in tetrahydrofuran (THF, 15 ml) was added dropwise to a solution of 1,4-diazabicyclo[2,2,2]octane (DABCO) (Aldrich) (5.6 g) in THF (200 ml) at room temperature, and the mixture was stirred for 20 h. The resulting solid was filtered off and washed with diethyl ether. Finally the salt, DABMeI, was exchanged into its hydroxide form using an anion-exchange resin (Amberlite IRN-78, Supelco). More specifically, a synthesis gel with the following composition was prepared:

$$0.666\ SiO_2 : 0.333\ GeO_2 : 0.5\ DABMe(OH) : 3.5\ H_2O.$$

This was obtained by adding GeO_2 (powder) and TEOS (tetraethylorthosilicate) to an aqueous solution of DABMe(OH). The homogenized mixture was stirred vigorously at room temperature in order to eliminate the ethanol produced during the hydrolysis of TEOS and to adjust the water content to that of the gel composition. The resulting gel was introduced

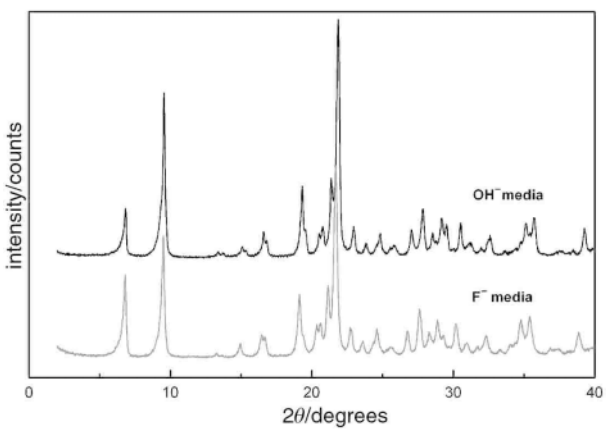

Fig. 1 X-Ray diffraction patterns of as-synthesized ITQ-17 zeolites prepared in fluoride-free media (top) and in the presence of fluoride[12] (bottom).

 DOI: 10.1039/b104114m

into new, Teflon-lined autoclaves that had never been in contact with a solution containing F^-, and were heated at 150 °C under static conditions. The fluoride-free gel after 12 days gives a sample, the X-ray diffractogram of which is given in Fig. 1. This is compared with a sample of ITQ-17 obtained in a fluoride system and whose structure was found to correspond to that of the pure polymorph C of zeolite Beta.[12] From the comparison, it becomes evident that well crystallized pure polymorph C has been obtained in OH^- media and in the absence of F^-. Elemental analysis of this sample gives a C/N atomic ratio of 3.5, as would be expected, which indicates that the SDA must be intact inside of the pores of the zeolite. A Si/Ge ratio of 2.5 was found for this sample when analysed whereas F^- anions were not detected by chemical analysis or by ^{19}F MAS NMR spectroscopy. Pure ITQ-17 samples with higher Si/Ge ratios have been obtained by this procedure. It should be remarked that even if pure polymorph C can be synthesized in the absence of F^- when Ge is introduced, the combination of both F^- and Ge accelerates the synthesis of this zeolite (Fig. 2).

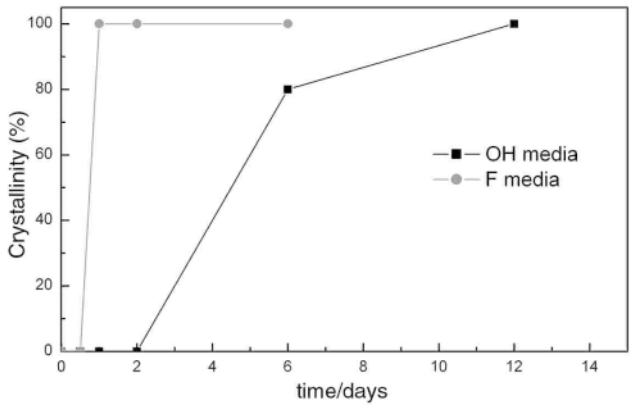

Fig. 2 Crystallization curves of ITQ-17 zeolite synthesized in fluoride-free media (■) and in the presence of fluoride (◍).

The results presented here clearly prove that pure polymorph C of Beta intergrowth can be obtained in the absence of F^- anions. Ge seems to direct the synthesis towards the formation of this structure due to the stabilization effect of D4MR units present in ITQ-17 materials. These results are in line with the fact that the presence of Ge in the synthesis media strongly accelerates the nucleation of Ti-ITQ-7[13] and Al-ITQ-7[14] zeolites that also contain D4MRs in the structure.

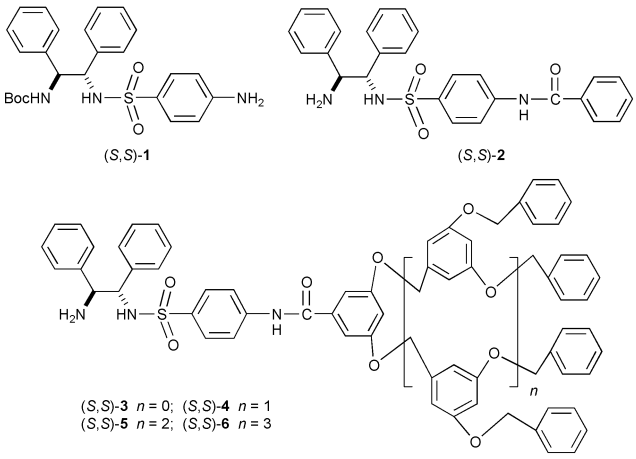
The synthesis of chiral diamine based dendritic ligands and their ruthenium complex catalysed asymmetric transfer hydrogenation is described.

Since the pioneer works reported in 1994,[1] dendritic catalysts with well-defined nanostructures have triggered increasing attention because in principle they have the potential to combine the advantages of homogeneous and heterogeneous catalysts in one system.[2] Although a number of dendritic catalysts have been described,[3] so far, relatively few reports on catalytic asymmetric synthesis are available.[4] Also, chiral ligands and metal catalysts are very expensive and the finding of the recyclable catalysts becomes increasingly important.

Noyori *et al*. discovered an excellent ligand, (*S*,*S*)-*N*-(*p*-tolylsulfonyl)-1,2-diphenylethylenediamine [(*S*,*S*)-TsDPEN], for the ruthenium catalysed transfer hydrogenation reactions.[5] The chiral DPEN is available in our laboratory on the kilogram scale. Moreover, the polymeric catalysts, in which the chiral TsDPEN was incorporated in a polymeric matrix or bound to the insoluble polymers, were reported to be detrimental to the catalytic activity and selectivity in varying degrees.[6] Herein we report the first use of soluble and recyclable dendritic catalysts for the enantioselective transfer hydrogenation of prochiral ketones. The amino-functionalised chiral ligand (*S*,*S*)-**1** was synthesized in three steps from (*S*,*S*)-DPEN, and subsequent condensation with Fréchet's polyether dendritic wedges[7] and the final deprotection of the Boc-group readily gave the dendritic chiral ligands.‡

Asymmetric transfer hydrogenation reactions were studied using acetophenone as the model substrate.§ Compared to the monomer Ru[(*S*,*S*)-**2**] complex, a slightly enhanced reactivity was observed for the dendritic catalysts with the high enantioselectivity (>96% ee), in which the first and third generation catalysts possess higher reactivity (Table 1).

Another unique feature of these dendritic catalysts was that they completely maintained the enantioselectivity with only slight loss of activity in successive use. Using the third and fourth generation catalysts Ru[(*S*,*S*)-**5**] and Ru[(*S*,*S*)-**6**], (*S*)-1-phenylethanol was formed after ~30 h for the fourth use with 88, 85% conversions and 96.4, 96.7% ee, respectively (entries 8 and 12), and high enantioseletivities (>95% ee) remained even for the fifth use (entries 9 and 13). Further addition of $[RuCl_2(cymene)]_2$ into the Ru[(*S*,*S*)-**6**] complex could not regain the reactivity and selectivity (entry 14), and subsequent TLC analysis of the recovered catalyst confirmed that this mostly resulted from the decomposition of the dendritic ligand. For the heterogeneous polymer immobilised catalysts,[6] the reactivity has been mostly lost after the third use. Moreover, the fourth generation catalyst was more active than the third one for the fifth use with 73 *vs*. 52% conversions, respectively (entries 13 and 9), although it is less active than the third generation



catalyst (entries 5 and 4). Thus, we refer the relatively robust activity of the dendritic catalysts to the "dendrimer effects" on stability of the catalytically active complex on the dendron, which had been observed in bis(μ-oxo)dicopper species toward oxidative self-decomposition.[8]

In conclusion, various generations of chiral diamine based dendritic catalysts encapsulated within the matrix have been synthesized and demonstrated good recyclable catalytic activity and enantioselectivity in transfer hydrogenation of an aromatic ketone. Current work is aiming at a detailed insight of the nature

Highly specific oxidative damage of double-strand DNA by copper aminoglycosides†

Anjali Patwardhan and J. A. Cowan*

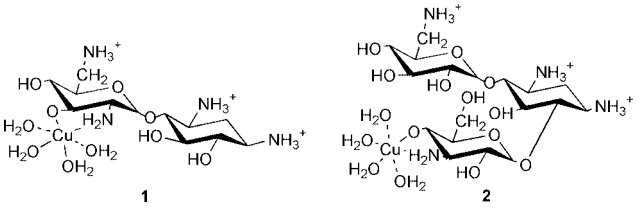
Evans Laboratory of Chemistry, The Ohio State University, 100 West 18th Avenue, Columbus, Ohio 43210, USA. E-mail: cowan@chemistry.ohio-state.edu

Received (in Cambridge, UK) 26th April 2001, Accepted 22nd June 2001
First published as an Advance Article on the web 23rd July 2001

Oxidative cleavage of double-strand DNA, mediated by either Cu^{2+}-neamine 1 or Cu^{2+}-kanamycin A 2, is shown to follow a highly specific C-4′ H mediated pathway and suggests a mechanism for efficient double-strand scission of duplex DNA.

Oxidative degradation of DNA has been demonstrated to follow a number of pathways, depending on the cleavage agent.[1] Proton abstraction from one of the C-1′, C-2′, C-3′, C-4′ or C-5′ ribose carbons is followed by a series of elimination reactions that afford a variety of small molecule products characteristic of the specific cleavage pathway. Fe–bleomycin mediated cleavage shows evidence of both a major C-4′H cleavage path and for C-1′H abstraction.[2,3] While copper phenanthroline and copper desferal had previously been assigned a major C-1′H cleavage path,[4–8] more recent work has indicated that C-4′H and C-5′H abstractions are the only routes that lead to backbone scission.[9] Enediynes, oxochromium reagents and manganese porphyrin derivatives have also been shown to mediate C-1′H, C-4′H, and C-5′H abstraction.[10,11] An example of C-2′H abstraction has been reported for 5-iodouracil.[12] With the exception of Barton's rhodium complexes, which mediate photocleavage *via* C-3′H abstraction,[13] most cleavage agents typically yield a mixture of products, indicative of relatively non-specific cleavage pathways.

Previously we have synthesized and characterized copper derivatives of aminoglycosides (**1** and **2**) and have demonstrated these compounds to be highly efficient catalysts for cleavage of both RNA and DNA under physiological conditions.[14,15] Here we characterize the mechanism for oxidative cleavage of DNA mediated by **1** or **2**, and demonstrate a highly specific C-4′H mediated pathway (Fig. 1). This observation provides an explanation for the efficient conversion of closed circular to linear plasmid DNA, following the double-strand cleavage path identified in our earlier work.[14]



1 **2**

The HPLC profile for Cu^{2+}–kan cleaved plasmid DNA (Fig. 2A) shows the release of cytosine (C), guanine (G), thymine (T), and adenine (A) following residual DNA and larger product fragments. An additional peak corresponding to 5-methylene furanone (5-MF) (Fig. 2) appears when the reaction mixture is heated at 85 °C for 20 min following incubation. C-1′H abstraction generates a C-1′ radical that is further oxidized to a carbocation and forms either a 2′-deoxyribonolactone[6] or a 1′,2′-dehydronucleotide intermediate after subsequent attack by H_2O.[8] Both intermediates are stable at pH 7.4 and 37 °C, the conditions of our cleavage reaction, and the HPLC elution profile corroborates heat treatment to be a prerequisite for the release of 5-MF (Fig. 2). Thus C-1′H abstraction leads to the formation of abasic sites with no apparent strand cleavage, confirming the recent observation by Sugiyama *et al.*[12]

C-4′H abstraction yields distinct reaction products, depending on the attacking species following formation of the radical intermediate. In the presence of dioxygen, base propenals (detected by the TBA assay, ESI†) and 3′-phosphoglycolate terminae are generated (Fig. 1; products C and D, respectively). When water is the attacking species the pathway again does not give rise to direct strand cleavage, but base release is observed. Under anaerobic conditions the TBA assay was negative,

† Electronic supplementary information (ESI) available: experimental section and complete HPLC trace for the truncated version shown in Fig. 2B. See http://www.rsc.org/suppdata/cc/b1/b103789g/

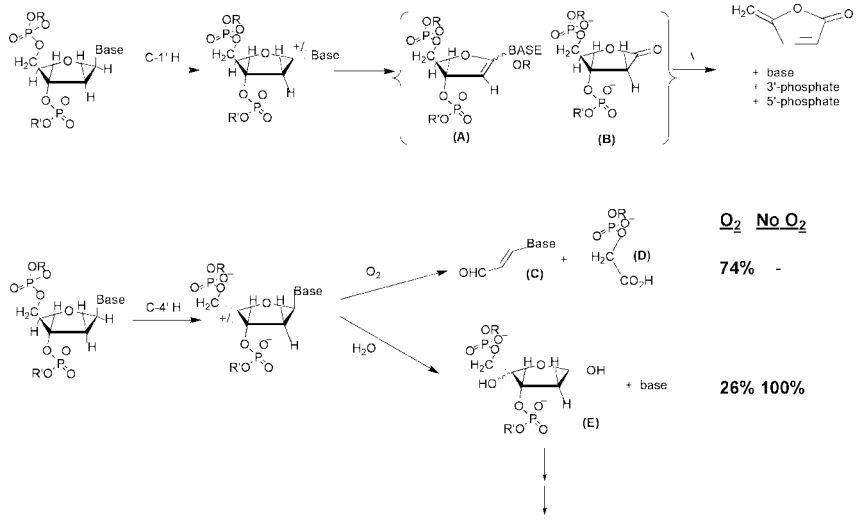


Fig. 1 Porposed radical mediated cleavage mechanisms for oxidative degradation of DNA. (A) 1′,2′-dehydronucleotide; (B) 2′-deoxyribonolactone; (C) base propenal; (D) 3′-phosphoglycolate; (E) hydroxyabasic site.

 DOI: 10.1039/b103789g

indicating the absence of a C-4′H (O_2) path. None of the expected products for C-2′H, C-3′H and C-5′H degradation paths were observed,[10–13] consistent with C-4′H abstraction paths as the only route leading to plasmid cleavage.

A C-1′H path was observed only in the case of supercoiled plasmid with peroxide as coreactant and the fraction of C-1′H abstraction was never found to be more than 12% of the C-4′H path, based on quantitation of the 5-MF released (ESI†). Reaction with ascorbate/O_2 appears to proceed *via* an intermediate copper species that does not mediate C-1′H abstraction. Neither linear plasmid, nor general polynucleotide duplex DNA (discussed below) show evidence for C-1′H loss, whereas C-4′H chemistry is observed with both substrates, and also using either H_2O_2 or ascorbate/O_2 as coreactants. This difference most likely reflects structural perturbations of the supercoiled strands that make C-1′H accessible for abstraction (Fig. 3 illustrates the close proximity of the C-1′ and C-4′ H's).

The reactivity of Cu^{2+}–kan A and Cu^{2+}–neamine toward two DNA duplexes, poly(dA)–poly(dT) and poly(dG)–poly(dC), was also examined in the presence of either hydrogen peroxide or ascorbate, under reaction conditions that were similar to those used for plasmid DNA. Base release was observed and quantitated by HPLC analysis (ESI†), and the occurrence of base propenals was confirmed with the thiobarbituric acid assay. Neither 5-MF (following heat treatment), nor products for other decay paths were observed, and so again the duplexes exhibit exclusive C-4′H abstraction chemistry in the presence of copper neamine or copper kanamycin in the presence of either H_2O_2 or ascorbate/O_2. C-4′H abstraction is normally associated with minor groove binding, and such a binding mode is consistent with our studies conducted in the presence of netropsin or Hoechst 33258 (minor groove binding drugs) which inhibit the cleavage of DNA duplexes (ESI†). Quantitation of the ratio of C-4′H (O_2) to C-4′H (H_2O) paths (ESI†) revealed a preference for the C-4′H (O_2) path, both for the polynucleotide duplexes (74 *vs.* 26%), and for a plasmid DNA (59 *vs.* 41%). These two pathways have previously been observed for $Cu(phen)_2^+$ cleavage of plasmid and duplex sequences,[6] although the factors that favor one path over another are not clear. Base release following peroxide mediated cleavage of either plasmid or duplex DNA by 1 or 2 also shows no obvious trend, other than a variable tendency for release of pyrimidine over purine.

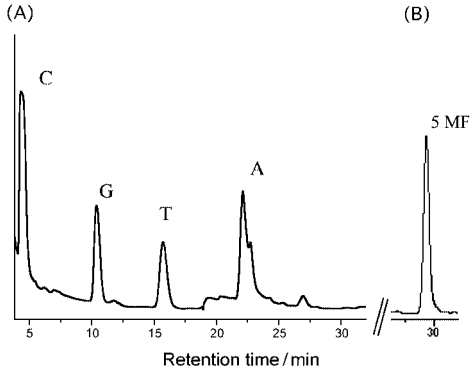

Fig. 2 HPLC profile for the reaction, 100 μg plasmid + 0.5 mM Cu–kan + 5 mM H_2O_2, incubated at 37 °C for 1 h (A) and 100 μg plasmid + 0.5 mM Cu–kan + 5 mM H_2O_2, incubated at 37 °C for 1 h followed by 20 min at 85 °C (B). Excess complex was used to promote rapid reaction, but multiturnover cleavage with sub-stoichiometric complex has been documented.[16]

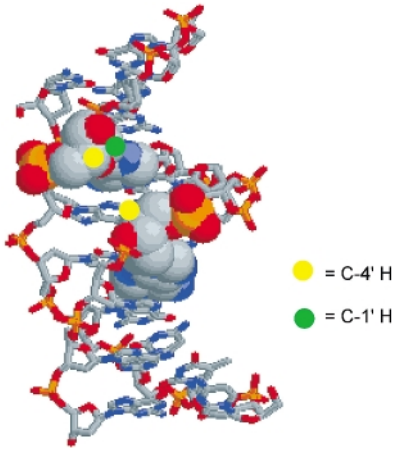

Fig. 3 The proximity of the ribose C-4′H's on opposing strands (*x*, *x* + 3 base positions) in the minor groove of B-conformer DNA suggests a pathway for double-strand scission of duplex DNA by formation of reactive oxygen intermediates in the vicinity of proximal ribose hydrogens. CPK coloring has been used and the two nucleotides on opposing strands are highlighted.

Under hydrolytic conditions,[16] in the absence of added H_2O_2 or ascorbate, treatment of DNA with either 0.5 mM $CuSO_4$ or 0.5 mM aminglycoside, under otherwise similar reaction conditions, produced neither free base, nor 5-MF, nor other products normally observed for the oxidative degradation of duplex or plasmid DNA. Reaction of $CuSO_4$ and a ten-fold excess of either H_2O_2 or ascorbate, again all other conditions being maintained, showed minimal (< 10%) base release, as compared to treatment with either **1** or **2**, but without the production of base propenals. The latter observation suggests an alternative path for production of nucleotide base. With increasing amounts of free Cu^{2+} (maintaining ten times excess of ascorbate or H_2O_2) the concentration of released bases increased. However, base release was found to be random with free Cu^{2+} and coreactant, and did not show any preference for either pyrimidines or purines, consistent with a distinct reaction path. No reaction was observed with H_2O_2 or ascorbate (with or without added neamine or kanamycin A) in the absence of Cu^{2+} (aq), **1** or **2**.

In contrast to other DNA cleavage agents that follow an oxidative path (cited earlier), copper aminoglycosides (**1** and **2**) follow a highly specific route mediated by abstraction of the C-4′H. Close proximity of C-4′H's on opposing strands separated by two additional base-paired nucleotides (Fig. 3) also provides a rational explanation for the observed linearization of plasmid (or double-strand cleavage of duplex DNA). A reactive copper moiety placed in the minor groove would be well placed to execute a double-strand scission with minor structural rearrangement between cleavage reactions. Taken with the unique enzyme-like character of these reagents,[16] these results demonstrate copper aminoglycosides to possess several valuable traits for a metallonuclease mimetic.

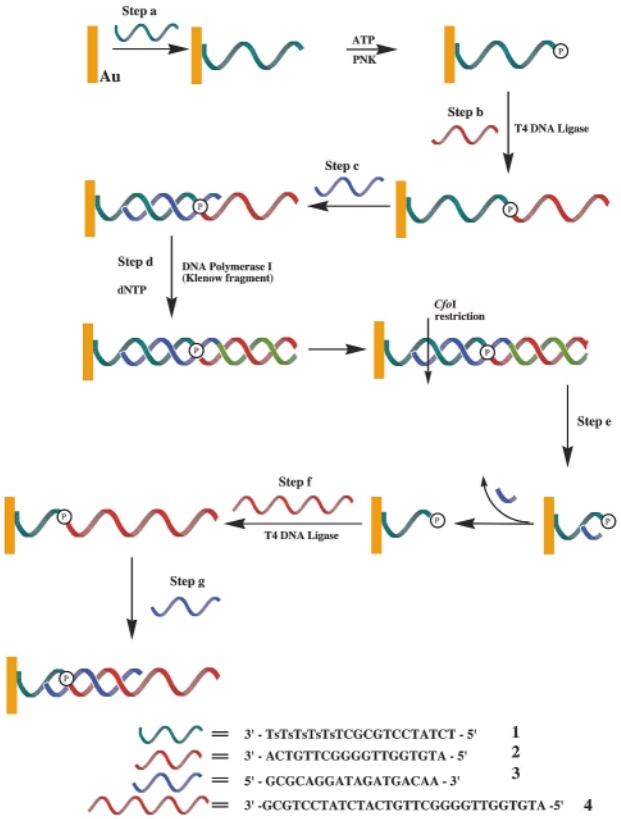
Electronic transduction of enzyme-catalyzed transformations on nucleic acids associated with surfaces such as ligation, polymerization or restriction, is accomplished.

The use of nucleic acid interactions to construct organized nanostructures,[1,2] circuits[3] and nanomachines,[4] the use of the encoded information in nucleic acids for the assembly of DNA-based computers,[5,6] and the electronic transduction of DNA detection processes[7,8] represent major research efforts in the rapidly developing area of DNA bioelectronics. The hybridization of nucleic acids, and the biocatalyzed ligation, replication and scission of DNA are basic tools to detect nucleic acid interactions and to generate DNA structures. Recently, Faradaic impedance spectroscopy[9] and microgravimetric quartz-crystal-microbalance (QCM) measurements[10] were used as electronic transduction means for the nucleic acid recognition events on conductive supports. Here we report on the novel electronic transduction of a series of biocatalyzed transformations involving nucleic acids that include the surface-stimulated ligation, replication and the specific scission of nucleic acids by a restriction enzyme.

The 18-mer oligonucleotide, **1**, was assembled on an Au-electrode or on an Au/quartz piezoelectric crystal (9 MHz, AT-cut) by the association of the thymine thiophosphate-tag to the gold supports.[11] The surface coverage of the oligonucleotide **1** was estimated by QCM to be $(5.0 \pm 0.7) \times 10^{-11}$ mol cm^{-2}. The resulting **1**-functionalized surfaces were reacted with polynucleotide kinase, PNK, in the presence of ATP to phosphorylate the 5′ termini of the oligonucleotide-monolayer.† The resulting interface was reacted with **2** in the presence of ligase,† Scheme 1, to induce the ligation of **2** to the base oligonucleotide associated with the surface. Fig. 1(A) shows the Faradaic impedance spectra observed upon performing the biocatalyzed transformations on the nucleic acids associated with the electrode, whereas Fig. 1(B) shows the respective frequency changes occurring on the piezoelectric crystal as a result of the chemical transformations occurring on the crystal.† The ligation of **2** results in an increase in the interfacial electron transfer resistance from $R_{et} = 0.44$ kΩ to $R_{et} = 1.33$ kΩ (Fig. 1(A), curve (b)). This is consistent with the fact that the increase of the negative charge associated with the electrode, as a result of ligation, enhances the electrostatic repulsion of the redox-label, $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$, thus increasing the interfacial electron transfer resistance. The frequency of the Au/quartz crystal changes upon ligation by $\Delta f = -100$ Hz, a value that translates to a surface coverage of the ligated product corresponding to $(5.1 \pm 0.8) \times 10^{-11}$ mol cm^{-2}.† No frequency changes of the Au/quartz crystal were observed upon an attempt to ligate **2** to the **1**-functionalized crystal without the primary phosphorylation of the interface by PNK. Also no frequency changes of the crystal were observed upon interacting the phosphorylated functionalized crystal with **2** in the absence of ligase. The resulting nucleic acid associated with the interface was hybridized with **3**, that is complementary to a part of the nucleic acid associated with the solid supports. The interfacial electron transfer resistance increases as a result of the hybridization of **3**, $R_{et} = 1.9$ kΩ, Fig. 1(A), curve (c), consistent with the increase of the negative charge associated with the electrode. The frequency of the quartz crystal changes by $\Delta f = -31$ Hz, that corresponds to a surface coverage of the hybridized assembly of $(2.2 \pm 0.4) \times 10^{-11}$ mol cm^{-2}. The incomplete hybridization is attributed to steric constraints on the electrode support that eliminate the formation of dsDNA with all of the nucleic acid components.

The resulting assembly was then reacted with the mixture of nucleotides, dNTP, in the presence of polymerase (Klenow fragment, DNA polymerase I).† This yields an increase in the interfacial electron transfer resistance, $R_{et} = 3.1$ kΩ, as a result of the higher negative charge associated with the interface, Fig. 1(A), curve (d). The change in the frequency of the piezoelectric crystal as a result of polymerization is $\Delta f = -26$ Hz, indicates a surface coverage of $(2.6 \pm 0.4) \times 10^{-11}$ mol cm^{-2} for the replicated product.† Reaction of the assembly with the endonuclease restriction enzyme *Dra*I that stimulates the



Scheme 1 Biocatalyzed ligation, replication and scission of single and double stranded DNA on electronic transducers (Ts = thymine thiophosphate).

† Electronic supplementary information (ESI) available: details of the experimental conditions for the biocatalytic transformations on the electrodes and a histogram of the frequency changes observed in a series of different experiments. See http://www.rsc.org/suppdata/cc/b1/b104335h/

 DOI: 10.1039/b104335h

specific scission of 5′TTT/AAA3′ sequence does not yield any change in the impedance spectrum of the assembly. Reaction of the resulting assembly with the endonuclease restriction enzyme *Cfo*I (*Hha*I) that induces the specific scission of the 5′GCG/C3′ sequence results, however, in the cleavage of the ds-assembly,† *cf.* Scheme 1. The resulting Faradaic impedance spectrum is shown in Fig. 1(A), curve (e). The interfacial electron transfer resistance decreases to R_e = 0.9 kΩ. This is consistent with the fact that removal of a major part of the ds-assembly and the negative charge associated with it, by the endonuclease activity, reduces the barrier for electron transfer between the redox-label and the electrode. The frequency change in the Au/quartz crystal as a result of the endonuclease activity is Δf = +75 Hz, implying a decrease in the mass associated with the crystal, Fig. 1(B). From the frequency change we estimate that *ca.* $(1.5 \pm 0.2) \times 10^{-11}$ mol cm^{-2} of the hybridized nucleic acid underwent scission. The scission of the double-stranded DNA yields a 5′-phosphorylated primer on the electrode. Note that the interfacial electron transfer resistance of the resulting electrode is higher than the electron transfer resistance of the **1**-functionalized electrode despite the fact that the endonuclease cleavage generates a shorter oligonucleotide than **1** on the electrode. This is explained by the fact that the *Cfo*I cleavage proceeds with partial efficiency, thus leaving a substantial surface coverage of the ds-replicated DNA on the electrode support (*ca.* 1.1×10^{-11} mol cm^{-2}). The resulting interface was then reacted with the oligonucleotide **4** in the presence of ligase to yield the original surface, Fig. 1(A), curve (f), exhibiting an electron transfer resistance of R_{et} = 2.2 kΩ. Further hybridization of **3** with the ligated interface results in an additional increase in the electron transfer resistance to R_{et} = 2.6 kΩ, Fig. 1(A), curve (g).‡ The ligation of **4** to the interface, and the hybridization of **3** with the interface yield, however, higher interfacial electron transfer resistances than those observed for the originally functionalized electrodes, curves (b) and (c), respectively. This is consistent with the fact that endonuclease-induced scission proceeds with partial efficiency, and thus the secondary ligation and hybridization occurs on an interface that includes a partial coverage of the polymerase-induced replicated double-stranded DNA. The negative charge associated with these latter components introduces the higher interfacial electron transfer resistances observed in the second cycle of the biocatalytic transformations. The QCM analyses, Fig. 1(B) confirm this explanation. Ligation of **4** to the interface results in a frequency change of $\Delta f = -42$ Hz, corresponding to a surface coverage of *ca.* $(1.4 \pm 0.3) \times 10^{-11}$ mol cm^{-2} of the coupled product. It should be noted that no significant changes in the interfacial electron transfer resistances, upon the performance of the set of biocatalyzed transformations outlined in Scheme 1, are observed in the presence of the neutral ferrocene methanol redox-label. This supports the conclusion that the changes in the impedance spectra originate from the electrostatic repulsions of the redox-label $Fe(CN)_6^{3-/4-}$. Also, it should be noted that the Faradaic impedance spectra results reveal an excellent reproducibility (±5%) whereas the QCM results reveal a larger experimental diversity due to a different roughness of the Au/quartz crystals.

In conclusion, the electronic transduction of different biocatalytic transformations that include nucleic acids on surfaces was accomplished. This enables the quantitative assay of DNA building blocks on surfaces, and the characterization of nanoengineered DNA structures on surfaces.

This research is supported by the Israel Ministry of Science as an Israel-Japan Binational Cooperation. The support of the Eshkol Fellowship, Israel Ministry of Science (L. A.) is acknowledged. We thank A. Lichtenstein for his assistance in the [γ-^{32}P]ATP labeling experiments.

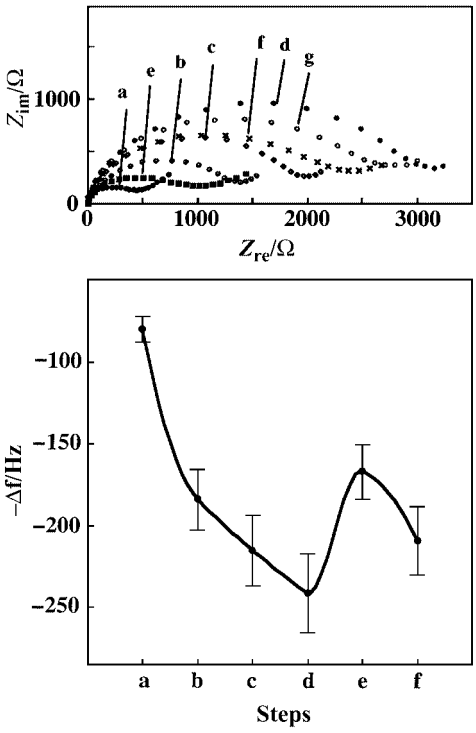


Fig. 1 (A) Faradaic impedance spectra corresponding to the biocatalytic transformation of nucleic acid-functionalized electrode: (a) **1**-functionalized electrode; (b) after ligation of **2**, 3×10^{-5} M, with the **1**-functionalized electrode in the presence of ligase, 20 units, 37 °C, 30 min; (c) after hybridization of the resulting electrode with **3**, 2.5×10^{-5} M, 2 h; (d) after replication of the double-stranded assembly in the presence of dNTP, 1×10^{-3} M, and DNA polymerase, 3 units, 37 °C, 30 min; (e) after scission of the resulting assembly with endonuclease, *Cfo*I, 10 units, 37 °C 1 h; (f) after ligation of the resulting interface with **4**, 6.5×10^{-5} M, in the presence of ligase, 20 units, 37 °C, 30 min; (g) after hybridization of the assembly with **3**, 1×10^{-4} M, for 2 h. (B) Frequency changes of an Au/quartz crystal (9 MHz, AT-cut) upon the assembly of the **1**-functionalized interface and as a result of the biocatalyzed transformations/processes occurring on the surface. Steps (a)–(f) correspond to the steps and preparation protocols outlined in (A).

Notes and references

‡ The different Faradaic impedance spectra of the DNA assemblies on the electrodes can be theoretically fitted with an equivalent circuit composed of a block of an electron transfer resistor element that is linked in series to the Warburg element in parallel to a capacitor element.

New, efficient electroluminescent materials based on organometallic Ir complexes†‡

Vladimir V. Grushin,* Norman Herron, Daniel D. LeCloux, William J. Marshall, Viacheslav A. Petrov* and Ying Wang*

Central Research and Development, E. I. DuPont de Nemours and Co., Inc., Experimental Station, Wilmington, DE 19880-0328, USA. E-mail: vlad.grushin-1@usa.dupont.com

Received (in Cambridge, UK) 18th April 2001, Accepted 26th June 2001
First published as an Advance Article on the web 23rd July 2001

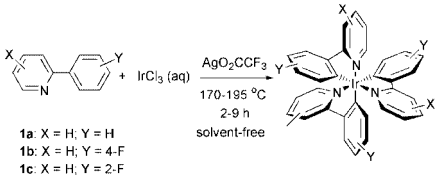
Reaction of $IrCl_3$ with fluorinated 2-arylpyridines in the presence of AgO_2CCF_3 affords *fac*-tris-cyclometalated arylpyridine Ir complexes exhibiting excellent processing and electroluminescent properties which can be fine-tuned *via* systematic control of the nature and position of the substituents on the aromatic rings.

Low cost, lightweight, flexible, ultra-thin flat panel display devices with miserly power consumption are being fabricated using a new generation of materials' chemistry aimed at exploiting the phenomenon of electroluminescence (EL). Molecule-based 'organic' light-emitting diodes (OLEDs) represent a promising approach for just these applications.[1–4] Suitable materials for OLEDs still need to be developed. A key goal of materials' research in this area is achieving very high power efficiency, which translates into enhanced operating lifetimes and longer battery life.

An important breakthrough was reported recently[5] with the use of materials displaying phosphorescence-like EL and having theoretical efficiency four times that of devices based on fluorescence (assuming electron–hole recombination is statistically controlled). Initial reports of electroluminescence from the Ir complex of 2-phenylpyridine ($[Ir(ppy)_3]$)[6] doped into a charge-transporting matrix, 4,4′-bis(carbazol-9-yl)biphenyl,[6–8] emphasized its dramatically increased power efficiency, 19 lm W^{-1} (26 cd A^{-1}) with a Mg/Ag cathode.

We now report on the synthesis and characterization of a series of highly efficient LED materials based on fluorinated organometallic iridium compounds.[9] Fluorinated substituents in the aromatic ligand result in markedly reduced concentration-quenching of luminescence, and in excellent volatility which aids device processing.

New tris-cyclometalated arylpyridine complexes were prepared by a novel one-step method [eqn. (1)]. Reaction (1) is run



(1)

1a: X = H; Y = H
1b: X = H; Y = 4-F
1c: X = H; Y = 2-F
1d: X = H; Y = 3-CF_3
1e: X = 5-NO_2; Y = 3-CF_3
1f: X = 5-CF_3; Y = H
1g: X = 5-CF_3; Y = 3-CF_3
1h: X = 5-CF_3; Y = 4-F
1i: X = 5-CF_3; Y = 3-F
1j: X = 5-CF_3; Y = 2-F
1k: X = 5-CF_3; Y = 4-CH_3O
1l: X = 5-CF_3; Y = 3-CH_3O
1m: X = 5-CF_3; Y = 4-CF_3O
1n: X = 3-Cl, 5-CF_3; Y = H
1o: X = 3-(N), 5-CF_3; Y = 4-F

in excess arylpyridine[10] which is easily recovered and reused. Complexes **2a–o** were characterized by elemental analysis, ^1H and ^{19}F NMR data, and cyclic voltammetry (CV). Nearly all of the complexes exhibited fully reversible reduction and oxidation waves (Table 1). Single-crystal X-ray structures were obtained for **2g**, **h**, **j**, and **l**.†§ Only *fac* configuration was observed in all cases,[11] as exemplified by the structure of **2h** (Fig. 1). Importantly, trifluoromethylated complexes **2d–o** sublime more easily than **2a** and thus exhibit processing properties superior to those of $[Ir(ppy)_3]$ (Table 1).

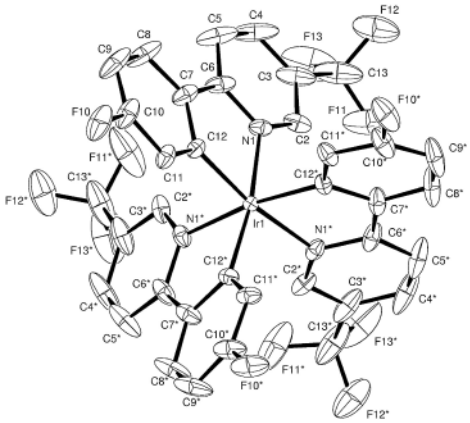


Fig. 1 An ORTEP drawing of **2h**

OLED devices were fabricated with **2a–o** by the thermal evaporation technique, and characterized by measuring current–voltage (*I–V*) curves, EL radiance *vs.* voltage, and EL spectra *vs.* voltage. A typical five-layer device employed ITO (indium doped tin oxide) as the anode, bis[4-(*N*,*N*-diethylamino)-2-methylphenyl](4-methylphenyl)methane (MPMP) as the hole transport material, **2a–o** as the luminescent material, 4,7-diphenyl-1,10-phenanthroline (DPA) or 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (DDPA) as the electron transport material, and Al as the cathode (Table 1).

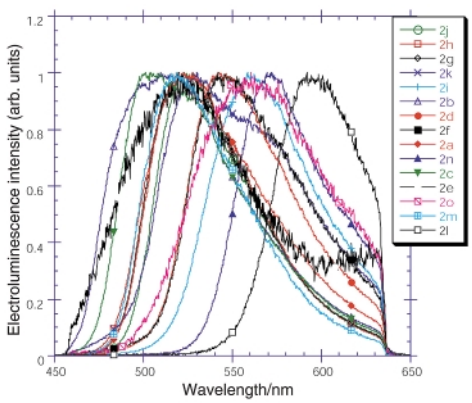

Fig. 2 Normalized EL spectra of Ir compounds shown in Table 1.

[a] Most yields are not optimized. [b] See ESI† for details. [c] LED device efficiency is dependent on the ITO substrate used and emitter purity; **2a** and **2h** received more purification effort. [d] At point of 50% weight loss (1 atm, N_2, 10 °C min^{-1}). [e] In THF, *vs.* Cp_2Fe/Cp_2Fe^+. Only fully reversible 2nd and 3rd reduction waves are listed. [f] In CH_2Cl_2, *vs.* Cp_2Fe/Cp_2Fe^+. [g] Substituent on the Ph ring *para* to Ir. [h] No return wave observed. [i] Mixture of isomers containing F *ortho* or *para* to Ir. [j] Multiple oxidation waves were only observed for **2l**; the second and third waves are tentatively assigned to ligand-based redox processes. [k] E_{pc}.

Most complexes **2a–o** show good EL efficiency on the order of a few cd A^{-1} (Table 1). A non-optimized device based on **2h** with an Al cathode yields a peak radiance of *ca.* 4800 cd m^{-2} and a peak external efficiency of 20 cd A^{-1} (*ca.* 16 lm W^{-1}). Improvement in the device is expected with a low work function cathode (*e.g.*, Mg/Ag or LiF/Mg) and further optimization.

Forrest and coworkers[6] used $[Ir(ppy)_3]$ as a 6% dopant in a charge-transporting host, in order to achieve highest efficiency. This is presumably due to the self-quenching effect in pure **2a**.[6] Measuring the relative luminescence quantum yield of **2h** *vs.* **2a** in the form of a solid state thin film under N_2 showed that the photoluminescence efficiency of pure **2h** was 10 times that of **2a**. Preliminary studies demonstrated comparable photoluminescence quantum yields of *ca.* 0.5–0.6 for **2a** and **2h** in toluene solution. The marked reduction of the self-quenching effect for some of the fluorinated iridium complexes (compare **2a** with **2b–d**, **f–o** in Table 1) obviates the need to dope them into a host material.

By changing the substituents and their position, the peak wavelength of the LED can be tuned from *ca.* 500 to 595 nm (Fig. 2). The peak wavelength is sensitive not only to the nature but also to the position of the substituent. Thus, **2l** with a MeO group *para* to Ir exhibits yellow–orange EL at 595 nm, whereas its *meta* isomer **2k** is green electroluminescent (530 and 565 nm). With fluorine *meta* to Ir (**2h** and **2j**) EL is at 525 nm, while the *ortho*/*para* isomers (**2i**) show EL at 560 nm. These changes are likely due to the strong π-donating effect of both F and MeO.[12] The F and MeO groups may π-interact with either Ir (**2i**, **2l**) or the pyridine ring (**2h**, **2j**, **2k**), leading to destabilization of the HOMO (Ir) and stabilization of the LUMO (Py). These findings raise the exciting possibility of color tuning all the way from blue to red *via* systematic control of the nature and position of the substituents. If material efficiencies can be maintained as this tuning occurs (as intimated by unoptimized results in Table 1) then these materials will provide a unique platform for full color display devices of the future.

First published as an Advance Article on the web 26th July 2001

Three-dimensional metal complexes synthesized from copper dicarboxylates and triethylenediamine (TED), which have an ideal pore size for methane adsorption, have higher methane adsorption capacity than the theoretical maximum for activated carbons.

Methane is a primary component of natural gas, which is an important candidate for clean transportation fuels. The storage of methane on adsorbents has been pursued actively as an alternative to high pressure compressed gas storage. However, it was concluded that none of the conventional adsorbents tested showed sufficient methane storage to meet that required for commercial viability.[1–5] The analysis of pore structure of adsorbents indicated that for even carbons as the best methane adsorbent, there is a large percentage of mesopores and macropores where methane adsorption does not occur sufficiently.[2] Therefore, to achieve higher adsorption capacity, it is essentially necessary that the micropore volume must be maximized, while the mesopore and macropore volume must be minimized as far as possible.

Recently, a great deal of attention has been directed toward the use of metal complexes in the design and synthesis of new porous materials.[6–11] Because of their structural controllability, these porous materials will be attractive adsorbents for methane storage. However previously reported complexes are not suitable owing to low adsorption capacities. Herein, a new type of methane adsorbent with ideal pore structure and sufficient adsorption capacity is reported.

Novel metal complexes $[\{Cu(O_2CRCO_2)\cdot 1/2TED\}_n]$ (R = 4,4′-$C_6H_4C_6H_4$ **1** or *trans*-$C_6H_4CH{=}CH$ **2**) were synthesized by a heterogeneous reaction between porous copper dicarboxylates[6] and TED.† The temperature dependence of the magnetic susceptibilities for the metal complexes obtained indicates that the existence of the same dinuclear structure as that of copper(II) acetate monohydrate and porous copper(II) dicarboxylates *i.e.* a two-dimensional structure of dicarboxylic acids bridging central copper ions. Based on these results and elemental analysis, it is suggested that the two-dimensional layer bridging the copper(II) ions with dicarboxylate ions are linked with TED as pillar ligands to give a three-dimensional structure (Fig. 1).

The stability of this network structure was studied by X-ray powder diffraction (XRPD) and thermal gravimetric (TG) analysis. The TG curve of **1** illustrates the release of the adsorbed molecules up to *ca.* 373 K, followed by thermal decomposition of the structure at 513 K. No chemical decomposition was observed between 373 and 513 K. The structure of this stable phase was studied by measuring the XRPD pattern at room temp., 473 K and 513 K. These results demonstrate that the porous network structure is retained up to 513 K in the absence of the included guest molecules. Similarly the network structure of **2** is retained up to 473 K in the absence of the included guest molecules.

Fig. 2 shows that the observed XRPD pattern of **1** is in very good accordance with a simulated pattern of the optimized plausible structure generated using Cerius2, indicating that the structure of **1** is similar to that shown in Fig. 1.

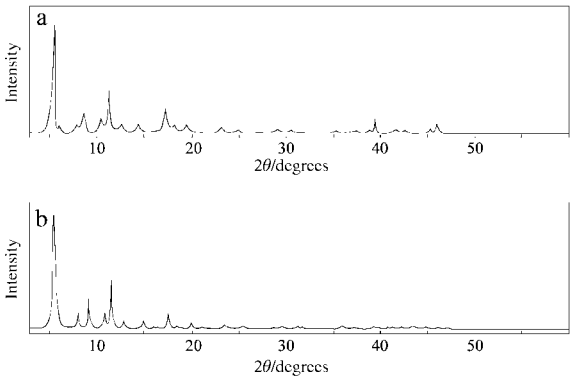

Fig. 2 X-Ray diffraction patterns of **1**. (a) Experimental X-ray powder diffraction after removal of the included guest molecules. (b) Simulated X-ray powder diffraction of the optimized structure using Cerius2.

To examine the porosity of **1** and **2**, high-resolution adsorption isotherms of Ar at 87.3 K were measured in a relative pressure (P/P_0) range from 10^{-6} to 1 using ASAP 2000M volumetric adsorption equipment from Micromeritics. These adsorption isotherms of **1** and **2** (Fig. 3) show typical isotherms of Langmuir type, confirming the presence of micropores without mesopores. Analyses of these isotherms yielded BET surface areas of 3265 and 3129 $m^2\ g^{-1}$, micropore volumes of 1.18 and 1.07 $cm^3\ g^{-1}$ and effective pore sizes of 10.8 and 9.5 Å for **1** and **2**, respectively (using Dubinin–Radushkevitch methods[12] and Horvath–Kawazoe methods[13]).

The pore size distributions are sharp with one sharp peak at 9.5 Å for **2**, indicating that the obtained metal complexes have uniform micropores. On the other hand, for **1**, the pore size distributions exhibit two peaks. This result does not indicate the existence of two kinds of pores, but rather the existence of two adsorption sites having different values of adsorption potential

 DOI: 10.1039/b104204c

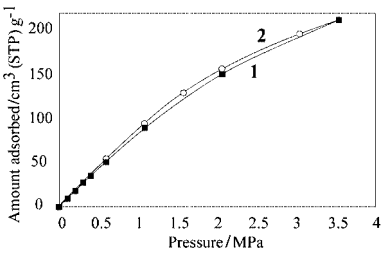

Fig. 4 High-pressure adsorption isotherms of methane at 298 K on metal complexes.

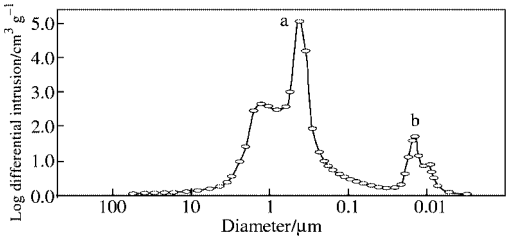

Fig. 6 Mercury penetration curve for **2** (differential intrusion *vs.* pore diameter).

in one pore. These sites are the corner and the edge of the square pore. HK methods can not be used to calculate the pore size distributions for pores of the more than >8 Å width.[14] To compare experimental values of the pore size with calculated values, the plausible structures were optimized by molecular mechanic (MM) and molecular dynamics (MD) of Cerius2 and the pore sizes were calculated. The effective pore size calculated from the optimized structure of **2** was *ca.* 9.4 Å (Fig. 1). This calculated value is in good agreement with the experimental HK value indicating the structure of the obtained complexes is as suggested. The bigger the size of dicarboxylic acid as a ligand, the larger the porosity and pore size, indicating that the porosity and pore size can be controlled by the starting materials. These surface areas and pore volumes are much larger compared with those of other coordination polymers, zeolites and commercial activated carbons already reported, and are the same as those of special high surface area activated carbons. These coordination polymers have adequate porosity to adsorb methane as well as a suitable pore size distribution which is nearly ideal for methane adsorption.

The adsorption isotherms of methane were measured gravimetrically up to 3.5 MPa. Fig. 4 shows methane adsorption isotherms of **1** and **2** at 298 K. The adsorption isotherms are of Langmuir type. Approximately 212 cm^3 (STP) and 213 cm^3 (STP) of methane were adsorbed per g of dried samples of **1** and **2** at 3.5 MPa. These values are much higher than that of zeolite 5A [*ca.* 83 cm^3 (STP) g^{-1} at 3.5 MPa] and nearly the same as that of the high surface area activated carbon AX-21, a methane adsorbent with the highest capacity among conventional materials.[2]

The samples were characterized by scanning electron microscopy (SEM) and atomic force microscopy (AFM). Fig. 5(a) and (b) show SEM image of particles of **2**, indicating that the particles are plate forms of *ca.* 0.2 μm in width, these particles aggregate and particles of *ca.* 7 μm in size are formed. Fig. 5(c) shows a surface AMF image of **2**. Nanocrystallites of *ca.* 100 nm in size were observed on the surface, considered to be the primary particles.

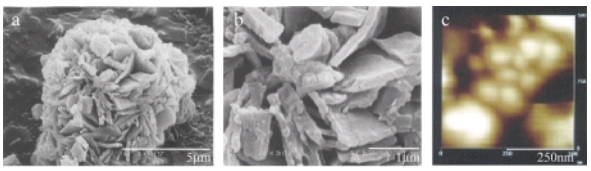

Fig. 5 SEM and AFM images of coordination polymer **2**.

Moreover, in order to characterize pore structures and material density, mercury intrusion penetration was measured from 1 to 60 000 psia with a Micromeritics instrument. Fig. 6 shows the result of mercury porosimetry for **2**, which is in good accordance with those of SEM and AFM, with regard to voids between particles, *i.e.* the voids between the secondary particles (plate forms) correspond to peak a of 0.1–5 μm and the voids between the primary particles correspond to peak b of 6–20 nm. The apparent density (0.983 g cm^{-3}) of the primary particles is calculated from the result of mercury porosimetry by assuming that peaks a and b are derived from voids between particles. The practical parameter, v/v, expressing the gas storage capacity [v/v is the volume of gas (at 298 K and 0.1013 MPa) divided by the volume of the tank] was estimated to be 225 from the density and the amount of adsorbed methane per weight of dried sample. On the other hand, adsorption simulations predict that the theoretical maximum for methane storage capacity of carbon, the structure of which consists of parallel planes of graphite with an optimum slit width 11.4 Å, is v/v = 198, for void-free monolithic carbon.[15] Thus the amount of adsorbed methane for **2** surpasses the theoretical maximum storage capacity of carbon calculated under the same conditions due to the high density of the complex.

The results of the present work have important implications since practical utilization of the coordination polymer for new adsorptive gas storage may be feasible.

I thank Dr Y. Yokomichi for simulation of structures, and Professor W. Mori and Professor S. Kitagawa for guidance and advice in the synthesis.

Diastereospecific synthesis of amino-acid substituted 2,2′-bipyridyl complexes

Shane G. Telfer,[a] Gérald Bernardinelli[b] and Alan F. Williams*[a]

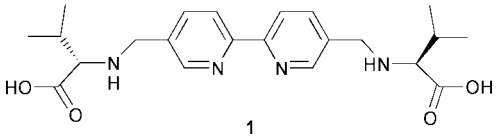
Received (in Cambridge, UK) 22nd May 2001, Accepted 4th July 2001
First published as an Advance Article on the web 26th July 2001

The L-valine substituted 2,2′-bipyridyl ligand 1 forms Δ-M(1)$_3$ (M = Fe^{II}, Co^{II}, Co^{III}) complexes diastereospecifically, with the L-valinate arms forming a chiral anion-binding pocket in the solid state.

Tris(2,2′-bipyridyl) metal complexes are among the most studied in coordination chemistry. Although the complexes are inherently chiral, simple bipyridines invariably lead to mixtures of enantiomers. To achieve stereoselectivity at the metal centre, the ligands must be modified to introduce an element of chirality as discussed recently by Knof and von Zelewsky.[1] For some years we have been interested in the synthesis of triple helicates using octahedral metal ions binding to multibidentate ligands, and the stereoselective synthesis of such complexes is an obvious challenge. With a view to combining stereoselectivity and the synthesis of heteronuclear helicates we conceived the ligand valabipy, **1**, comprising three bidentate



1

sites, one bipyridyl and two amino acids. The amino acid moiety could induce stereoselectivity in the coordination of metal ions, as demonstrated by Bernauer's group for mononuclear complexes of pyridine-amino acid ligands,[2] and the different ligating powers of bipyridyl and amino acids should allow the binding of different metal ions in the two sites. Ligand **1** is a rare example of a chiral 5,5′-substituted bipyridyl ligand and here we report the surprising observation of diastereospecificity when *only* the achiral bipyridyl chelating unit is occupied, and the observation of anion binding at the amino acid site in the solid state.

Valabipy **1** is prepared in three steps from diethyl-2,2′-dipyridyl-5,5′-dicarboxylate[3] by reduction of this ester to the corresponding alcohol, formation of the chloro derivative, and substitution of the chloride by L-valine in basic methanol.† The neutral ligand is sparingly soluble in water, but dissolves readily in slightly acid solution. If a solution of three equivalents of **1** in dilute HCl is treated with one equivalent of iron(II) perchlorate, a red–violet solution is obtained, indicating complexation of low spin iron(II) in the bipyridyl site. The composition [Fe(**1**)$_3$]$^{2+}$ was confirmed by electrospray mass spectrometry. The ^{1}H NMR spectrum of the diamagnetic complex showed it to be a mixture of diastereomers, most clearly revealed by the signals due to the α proton of the amino acid and the 6,6′-protons of the bipyridyl moiety. The initial ratio of diastereomers was 2:1, but on warming to 60 °C or on standing overnight, the weaker set of signals completely disappeared, indicating a thermodynamically controlled diastereospecificity. On the basis of the sign of the CD bands arising from the exciton coupling of the π–π* transitions, we can assign the Δ configuration to the thermodynamically stable diastereomer (Fig. 1).[4,5]

If the labile cobalt(II) ion was used instead of iron(II), the complex was less stable in acid solution than [Fe(**1**)$_3$]$^{2+}$ but in the pH range 4–5 the paramagnetic ^{1}H NMR spectrum showed a set of 9 peaks corresponding to [Co(**1**)$_3$]$^{2+}$. The sign of the exciton couplet in the CD spectrum again indicated a Δ-configuration at the metal centre (Fig. 1). [Co(**1**)$_3$]$^{2+}$ could be oxidised by hydrogen peroxide to give the corresponding cobalt(III) complex. The ^{1}H NMR spectrum of the crude product showed predominantly one diastereomer, with traces of some minor products easily removed by crystallisation. The CD spectrum indicated that the oxidation reaction was stereoretentive, yielding Δ-[Co(**1**)$_3$]$^{3+}$ (Fig. 1).[4,6]

If valabipy is synthesised using D-valine, instead of natural L-valine, the enantiomeric ligand **2** is obtained. As expected, the CD spectrum of [Co(**2**)$_3$]$^{2+}$ was the mirror image of that seen for [Co(**1**)$_3$]$^{2+}$, indicating that the Λ configuration is favoured for [Co(**2**)$_3$]$^{2+}$. Interestingly, when three equivalents of **1**, three equivalents of **2** and two equivalents of cobalt(II) were mixed, the ^{1}H NMR spectrum was identical to that of [Co(**1**)$_3$]$^{2+}$. This demonstrates that the ligands undergo a homochiral self-recognition process, preferentially forming Δ-[Co(**1**)$_3$]$^{2+}$ and Λ-[Co(**2**)$_3$]$^{2+}$ over any mixed ligand species.

Crystals suitable for an X-ray structure determination were obtained from a solution of [Fe(**1**)$_3$]$^{2+}$ in 1 M HCl with added sodium perchlorate.‡ The crystal structure of [Fe(**1**H)$_2$(**1**H)Cl$_2$](ClO$_4$)$_4$Cl·14H$_2$O confirmed the Δ-configuration for the [Fe(bipy)$_3$] unit, and revealed, to our surprise, the binding of two chloride ions by the complex. The cation may be regarded as a helicate in which the helical axis is defined by the Cl–Fe–Cl direction [angle Cl–Fe–Cl 179.50(6)] and the **1** ligands twist around the axis (Fig. 2 and 3).

The structure is held together by coordinate bonds between the iron and the bipyridyls, and hydrogen bonds and electro-

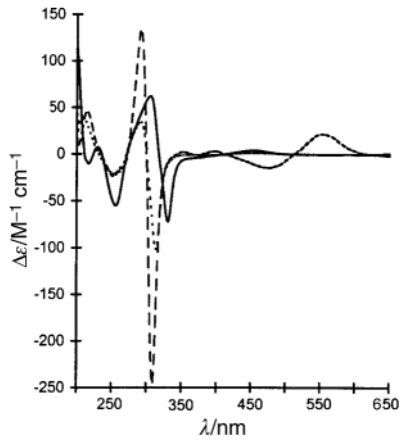


Fig. 1 CD spectra of [Fe(**1**)$_3$]$^{2+}$ (-----), [Co(**1**)$_3$]$^{2+}$ (pH 4.2) (·····), and [Co(**1**)$_3$]$^{3+}$ (—) in aqueous solution.

 DOI: 10.1039/b104520m

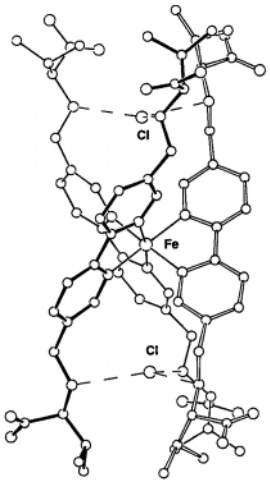

Fig. 2 View of the solid state structure of the $[Fe(\mathbf{1}H)(\mathbf{1}H_2)_2Cl_2]^{5+}$ cation showing the threefold hydrogen bonding of the chloride ions.

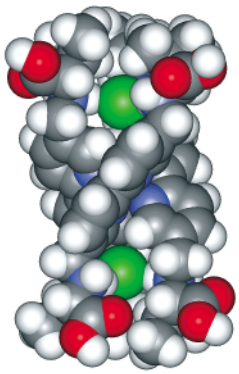

Fig. 3 Space filling view of the structure of the $[Fe(\mathbf{1}H)(\mathbf{1}H_2)_2Cl_2]^{5+}$ cation perpendicular to the pseudo-threefold axis. The iron atom is hidden by the bipyridyl unit; the chloride ions are shown in green and the carboxylate oxygens in red.

static interactions between the chlorides and the protonated amino residues of the ligand. The geometry of the $Fe(bipy)_3$ unit is normal[7] with an average Fe–N distance of 1.968 Å, interplane torsional angles for the bipyridyl units between 4 and 8°, and approximate D_3 symmetry. The isopropyl side chains of **1** are oriented so that they are clustered together around the helical axis, while the carboxylates are directed away from the axis to form a hydrophilic surface. The crystal packing of the cations shows an ABCABC packing of layers with the pseudo-threefold axis of the cation perpendicular to the layers and parallel to the [1 1 1] direction. The amino acid moieties are protonated on all the amino groups, and on five of the carboxylates, although the deprotonated carboxylate is delocalised between two sites. One of the N–H protons of each amino group is directed towards the helical axis and is available to hydrogen bond the chloride ions, with average N···Cl distances of 3.16 Å, typical of N–H···Cl hydrogen bonding. Each chloride forms three hydrogen bonds in an approximately trigonal arrangement, but is displaced slightly out of the N_3 plane towards the iron atom which is 4.98 Å away.

Whilst this manuscript was in preparation, a ruthenium(II) complex with amide-substituted 2,2′-bipyridyl ligands was shown by Beer and coworkers to encapsulate chloride ions in both the solid state and in solution ($MeOH–CH_2Cl_2$).[8] The anion binding site is very similar, though in the case of **1** the cationic ammonium units form significantly shorter N–H···Cl bonds, and both the chloride ions form three hydrogen bonds in the solid state, whereas in ref. 8 one chloride ion formed two hydrogen bonds and the other three hydrogen bonds.

It is interesting that for $[M(\mathbf{1})_3]^{n+}$, the stereoselective organisation of **1** around the metal ion leads to the generation of a chiral receptor site at each end of the complex. The nature of this site may be modified by changes in the chelating side arms used to construct the ligand and thus these complexes have promise as tunable selective chiral anion sensors—an area of much current interest.[9]

The diastereospecific formation of Δ-$[Fe(\mathbf{1})_3]^{2+}$ is initially surprising when the distance of the chiral centres of the ligand from the iron atom is considered. The fact that the complex may be crystallised from strongly acid (1 M HCl) solution implies that an additional stabilising element is present since α-diimine complexes such as $[Fe(phen)_3]^{2+}$ or [Fe(diethyl-2,2′-dipyridyl-5,5′-dicarboxylate)$_3$]$^{2+}$ are rapidly decomposed under these conditions. The observation that the labile Co^{II} ion shows immediate diastereoselectivity, whereas the kinetically more inert Fe^{II} ion takes longer for the ^1H NMR and CD spectra to stabilise indicates that the selectivity is thermodynamic rather than kinetic. Current investigations in this laboratory are focussing on the precise origins of the observed diastereoselectivity and the behaviour of the anion receptor site in solution.

Notes and references

† Ligand **1** was fully characterised by ^1H NMR, ^{13}C NMR, mass spectrometry and elemental analysis.

‡ *Crystal data*: $[Fe(C_{22}H_{31.667}N_4O_4)_3Cl_2](ClO_4)_4Cl{\cdot}14H_2O$: triclinic, space group $P1$, a = 12.2214(9), b = 13.0213(10), c = 15.5397 Å , V = 2361.3(2) Å^3, α = 85.007(9), β = 79.818(9), γ = 76.218(9)°, Z = 1, D_c 1.449 g cm^{-3}. 32169 reflections were collected using a STOE IPDS system at 200 K with Mo-Kα radiation. 17362 unique reflections (R_{int} = 0.041), Data correction for Lorentzian polarisation and absorption (μ = 0.45 mm^{-1}, T_{min} = 0.9289, T_{max} = 0.9539). The structure was solved by direct methods,[10] and refined against $|F|$ using anisotropic atomic displacement parameters for all non-hydrogen atoms. Ligand hydrogen atoms were calculated, and OH groups were attributed on the basis of the associated C–O distances. Inclusion and refinement of the water hydrogen atoms gave no improvement. The final R factor for 11445 reflections ($|F_o| > 4\sigma(F_o)$) with 1151 variables was 0.039 (R_w = 0.040) and the absolute structure parameter −0.04(2). Residual electron density peaks: min. −0.67, max. 0.52 e Å^{-3}. Calculation used the XTAL[11] programs.

A systematic series of structural studies has led to an understanding of how to use hydrogen-bonding and steric interactions to control two aromatic rings to interact in a well-defined and predictable manner in the solid state.

The study of non-covalent interactions in the solid state can be a rather hit or miss pursuit, as subtle changes in molecular structure can have dramatic effects on the way in which molecules organise in the crystal.[1] Indeed, the arrangement of molecules observed in a crystal structure is governed by maximising favourable intermolecular interactions and minimising unfavourable intermolecular interactions throughout the whole crystal, and the fact that the molecular packing arrangement arises from the interplay of several different factors calls for considerable caution in attempting to interpret, to rationalize and even to identify specific intermolecular interactions simply on the basis of inspecting known crystal structures. For example, there is an unfortunate tendency to attribute as a favourable interaction any situation in which two functionalities happen to be found close to each other in a crystal structure—however, the two groups involved may be unwillingly forced into close contact as the result of a stronger interaction involving neighbouring groups. To make progress in understanding and controlling specific interactions in the solid state requires investigations on families of materials designed such that the effects of different factors on the resultant structural properties may be systematically delineated. In this communication, we describe systematic studies of this type, which have led to an understanding of how to use hydrogen-bonding and steric interactions to control two aromatic rings to interact in a well-defined and predictable manner.[2]†

Using a combination of edge-to-face aromatic interactions and H-bonds to assemble double-stranded 'zipper' complexes from oligomeric amides, we have been able to quantify the magnitudes of a range of aromatic interactions in solution.[3] The key non-covalent structural motif is shown in Fig. 1(a). Simple aromatic amides of this general structure are self-complementary on both faces and should therefore self-assemble to give linear hydrogen bonded chains in the solid state (Fig. 1(b)).[3a,4] This system provides an interesting framework for probing the properties of aromatic interactions in the solid state, and so we have investigated the degree of control that can be achieved over the geometry of the interactions between the aromatic rings and the sensitivity of these interactions to the nature of the substituents on these rings.[5]

We synthesised the fifteen compounds shown in Fig. 2(a).[6] This series allows us to probe the influence of the size of the aniline *ortho* substituents (R^1 and R^2) and the effects of strongly polarising substituents (X and Y) on the edge-to-face aromatic interaction. For all but one of these compounds, crystals of appropriate size and quality for single crystal X-ray diffraction studies were obtained. It is found that, when there are no aniline *ortho* substituents (*i.e.* $R^1 = R^2 = H$), the molecules are more planar, and although linear H-bonded chains are formed, the molecules are arranged in a head-to-head fashion with stacking interactions between like aromatic rings (not shown). All of the other compounds except **12** adopt a conformation in which the benzoyl and aniline groups are orthogonal (in an intramolecular sense), and the crystal structures contain H-bonded chains with head-to-tail dimers of the type depicted in Fig. 1(a)—*i.e.* with

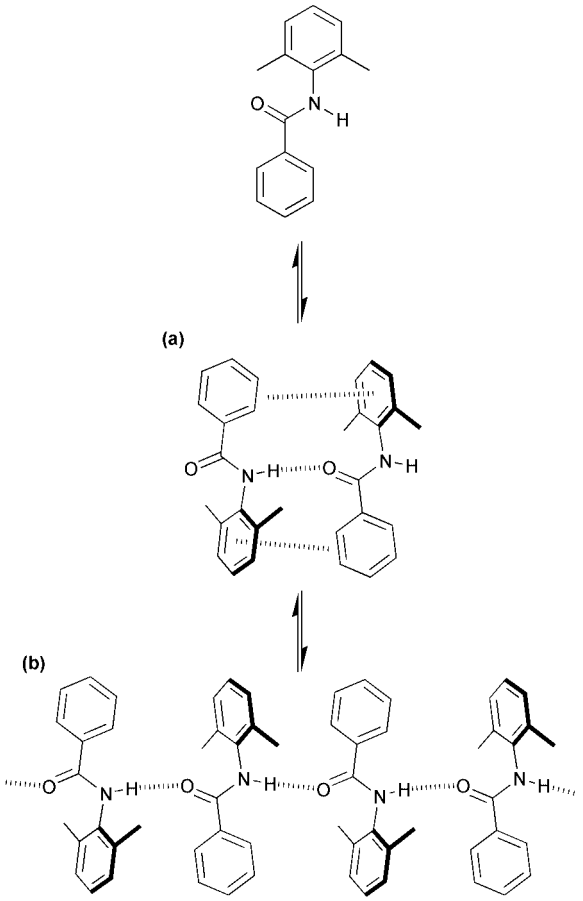

Fig. 1 (a) The key non-covalent structural motif used to assemble oligomeric zipper complexes in solution. (b) Extending this motif yields linear H-bonded chains for aromatic amides of the general structure shown. The term 'head-to-tail dimer' is used to refer to the situation shown, in which the aniline ring of one molecule is adjacent to the benzoyl ring of the neighbouring molecule along the chain (and *vice versa*). In the alternative situation (not shown), the aniline ring of one molecule is adjacent to the aniline ring of the neighbouring molecule along the chain, which is described as a 'head-to-head dimer'.

 DOI: 10.1039/b101575n

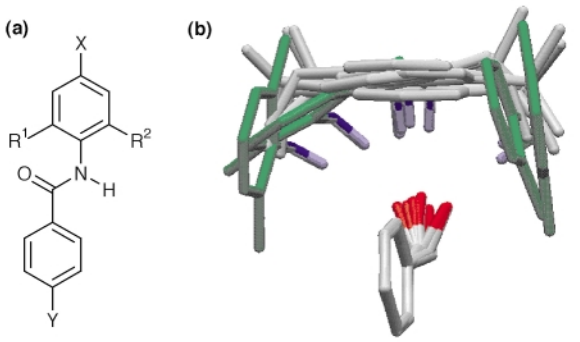

Fig. 2 (a) Compounds used to probe the influence of the aniline *ortho* substituents on the geometry of the aromatic interactions in the solid state.

X	Y	R^1 = R^2 =	H H	H Me	Me Me	Et Et	iPr iPr
H	^{t}Bu		**1**	**2**	**3**	**4**	**5**
H	NO_2		**6**	**7**	**8**	**9**	**10**
NO_2	^{t}Bu		**11**	**12**	**13**	**14**	**15**

(b) The aromatic interactions in the head-to-tail dimers found in the crystal structures of **2**–**5**, **8**–**10**, **13**–**15** are shown, with the benzoyl rings superimposed and the *para* substituents deleted for clarity.[5] Aniline rings with ethyl and isopropyl substituents are coloured grey, and anilines with methyl substituents are coloured green. The H-bonded chains in the crystal structures of **1**, **6**, **11** and **12** contain head-to-head dimers and are not shown. We have not yet been able to obtain a crystal structure of **7**.

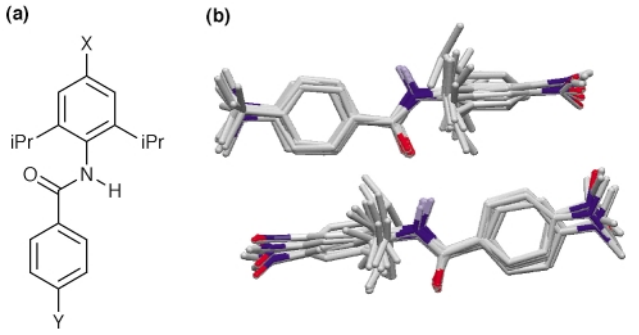

Fig. 3 (a) Compounds used to probe the influence of the polarising substituents on the geometry of the aromatic interactions in the solid state.

X	Y =	NMe_2	^{t}Bu	NO_2

(b) The head-to-tail dimers found in the crystal structures of **16**, **17**, **19**, **5**, **10**, **20**, and **15** are shown as a least squares overlay of the amide group (C, N and O), the aniline ring (six C atoms) and benzoyl ring (six C atoms).[5] We have not yet been able to obtain the crystal structures of **18** and **21**.

interactions between the benzoyl and aniline rings of adjacent molecules.

Fig. 2(b) shows an overlay of the aromatic interactions in all of the crystal structures that contain head-to-tail dimers. The behaviour of the aniline rings with *ortho* methyl groups is clearly different from those with *ortho* ethyl and *ortho* isopropyl groups. The bulkier substituents strictly enforce edge-to-face interactions between the two π-systems, such that the geometry of these interactions is essentially identical for all of the structures with ethyl and isopropyl groups. As shown in Fig. 2(b) (grey structures), the benzoyl group fits into a groove which runs along the face of the aniline ring, sandwiched between the two alkyl substituents which project above the plane of the aniline π-system.

For the smaller *ortho* methyl groups, the molecules still adopt a conformation in which the benzoyl and aniline rings are orthogonal to each other, but the intermolecular interactions are significantly different. Now the geometric relation between adjacent molecules is distorted such that intermolecular aromatic stacking interactions are observed (Fig. 2(b), green structures). The major distortion concerns the geometry of the H-bonding interaction which allows the two π-systems to become parallel, improving the packing efficiency of the dimer.

For X = NO_2, alternating head-to-tail and head-to-head dimers are found within the H-bonded chain for the dimethyl and diethyl aniline derivatives, and for the mono-methyl derivative only head-to-head dimers are found. There appears to be a strong driving force for the nitroanilines to stack with themselves, and this is only prevented in the presence of bulky isopropyl groups which disrupt stacking of the aniline groups.

These results suggest that we can rigorously control the geometry of the aromatic interactions in this system by using isopropyl aniline derivatives, and that the packing, at least within a chain, is insensitive to the nature of the terminal substituents (X and Y). It should therefore be possible to use this system as a scaffold to set up geometrically well-defined intermolecular aromatic interactions with a variety of different substituents. To explore this potential, we have synthesised the wider series of compounds containing isopropyl substituents shown in Fig. 3(a), and crystal structures have been obtained for seven of these compounds (three structures were available from our studies of the series shown in Fig. 2(a) and four additional structures were obtained). In all cases, the crystals contain H-bonded chains containing the expected head-to-tail dimers of the type shown in Fig. 1(a).[7] Fig. 3(b) shows an overlay of the aromatic interactions in the head-to-tail dimers found in these crystal structures. These structures are essentially identical, supporting the view that the H-bonded motif in Fig. 1 represents a robust framework for the study of edge-to-face aromatic interactions in the solid state.

We thank SmithKline Beecham (JFM), BBRSC (GAH), the Lister Institute (CAH) and EPSRC (BMK) for funding.

5 We emphasize that some of the measured diffraction data were of intrinsically poor quality as a consequence of comparatively poor crystal quality. In spite of this fact, significant new structural insights have been obtained, and the structural results are discussed at a level compatible with the quality of the data. Disorder is a factor in structures **12**, **13**, **15** and **16**, and a serious factor in the latter two, where it leads to alternative orientations for the H-bonded chains. These factors do not affect the overall findings reported here and will be fully discussed in a full paper on this topic.
6 All new compounds gave satisfactory spectroscopic data.
7 For compound **16** (X = Y = NMe_2), head-to-head dimers were also found within the H-bonded chain.

A cross-shaped Ag_5Ti_4 molecule based on a $[Ag(C{\equiv}N)_4]^{3-}$ core

Thomas Stein and Heinrich Lang*

Technische Universität Chemnitz, Fakultät für Naturwissenschaften, Institut für Chemie, Lehrstuhl für Anorganische Chemie, Straße der Nationen 62, D-09111 Chemnitz, Germany. E-mail: heinrich.lang@chemie.tu-chemnitz.de

Received (in Cambridge, UK) 4th June 2001, Accepted 29th June 2001
First published as an Advance Article on the web 26th July 2001

$K_3[Ag(C{\equiv}N)_4]$ (2) reacts with $\{[Ti](C{\equiv}CR)_2\}AgOClO_3$ {R = $SiMe_3$, 1a; R = Ph, 1b; [Ti] = $(\eta^5\text{-}C_5H_4SiMe_3)_2Ti$} in a 1 : 4 molar ratio to produce the nonametallic Ag_5Ti_4 species $[Ag(C{\equiv}N{\rightarrow}Ag\{(RC{\equiv}C)_2[Ti]\})_4](ClO_4)$ (R = $SiMe_3$, 3a; R = Ph, 3b) in which four heterobimetallic titanium(IV)–silver(I) tweezer units, $[\{[Ti](C{\equiv}CR)_2\}Ag]^+$, are bridged by a $[Ag(C{\equiv}N)_4]^{3-}$ core; the reaction chemistry of 3 is reported.

Recently, oligonuclear cyanide bridged transition metal complexes have attracted much attention, since they possess interesting chemical as well as physical properties.[1,2]

In this context, we here describe a straightforward method for the preparation of, *e.g.* the cross-shaped structured Ag_5Ti_4 species $[Ag(C{\equiv}N{\rightarrow}Ag\{(RC{\equiv}C)_2[Ti]\})_4](ClO_4)$ by introduction of a group-11 metal cyanide core, $[Ag(C{\equiv}N)_4]^{3-}$, as linking component for heterobimetallic early–late organometallic building blocks, *e.g.* $[\{[Ti](C{\equiv}CR)_2\}Ag]^+$.

Treatment of orange $\{[Ti](C{\equiv}CR)_2\}AgOClO_3$ {R = $SiMe_3$, **1a**;[3] R = Ph, **1b**;[4] [Ti] = $(\eta^5\text{-}C_5H_4SiMe_3)_2Ti$} with $K_3[Ag(C{\equiv}N)_4]$[5] in a 4 : 1 molar ratio in tetrahydrofuran as solvent affords nonametallic orange-brown (**3a**) or red (**3b**) $[Ag(C{\equiv}N{\rightarrow}Ag\{(RC{\equiv}C)_2[Ti]\})_4](ClO_4)$ (R = $SiMe_3$, **3a**; R = Ph, **3b**) in excellent yields (Scheme 1).†

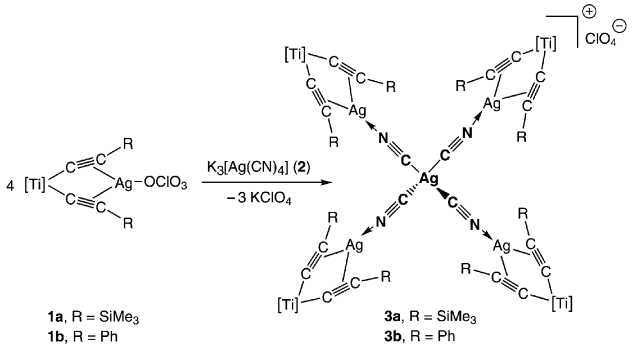
The most striking feature of **3a** and **3b** is the bridging cyano–argentate core $[Ag(C{\equiv}N)_4]^{3-}$, which links the four heterobimetallic early–late transition metal units $[\{[Ti](C{\equiv}CR)_2\}Ag]^+$, giving rise to the formation of the novel nonametallic Ag_5Ti_4 species **3a** or **3b**, respectively.

In **3** each cyano ligand of the $[Ag(C{\equiv}N)_4]^{3-}$ core is datively bonded to the silver(I) center of the respective end-grafted titanium–silver tweezer fragment $[\{[Ti](C{\equiv}CR)_2\}Ag]^+$. While, the core silver(I) center possesses a tetrahedral environment, the silver atoms of the corresponding tweezer moieties are trigonal-planar coordinated.[6]

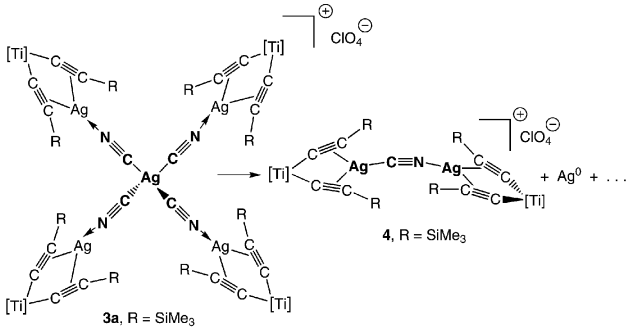
Although $[Fe(C{\equiv}N)_6]^{4-}$ can successfully be used for the preparation of, *e.g.* heptametallic cationic $\{Fe[C{\equiv}N{\rightarrow}Cu(tpa)]_6\}^{8+}$ [tpa = tris(2-pyridylmethyl)amine],[7] surprisingly no reaction seems to take place when $K_4[Fe(C{\equiv}N)_6]$ is reacted with **1a** or **1b**, even though various reaction conditions were applied.

Complexes **3a** and **3b** are readily soluble in polar organic solvents, such as acetone and tetrahydrofuran.

However, **3a** and **3b** decompose, even in the dark, in solution within several days. Besides the formation of elemental silver,



Scheme 1



Scheme 2

the tetranuclear Ag_2Ti_2 complex **4** along with other undefined products is produced (Scheme 2).

A further possibility for the preparation of **4** is *via* reacting equimolar amounts of $\{[Ti](C{\equiv}CSiMe_3)_2\}AgOClO_3$ **1a** and $\{[Ti](C{\equiv}CSiMe_3)_2\}AgC{\equiv}N$ **6**.[4] In this reaction the cyano moiety in the latter molecule replaces the $OClO_3$ group in **1a**, thus yielding **4**.[4]

Tetranuclear **4** features a bent Ag–C≡N→Ag array as was demonstrated by single X-ray structure analysis (Fig. 1).‡

The molecular structure of **4** in the solid state shows that each of the two silver(I) centers possesses a trigonal-planar surrounding, caused by two η^2-coordinated alkynyl moieties [Ag(1): Ti(1)–C(1)–C(2)–Si(1), Ti(1)–C(6)–C(7)–Si(2); Ag(2): Ti(2)–C(27)–C(28)–Si(5); Ti(2)–C(32)–C(33)–Si(6)] and the μ-bridging C≡N unit C(53)–N(1) (Fig. 1). A *cis*-bending of the central Ag(1)–N(1)–C(53)–Ag(2) assembly is observed [Ag(1)–N(1)–

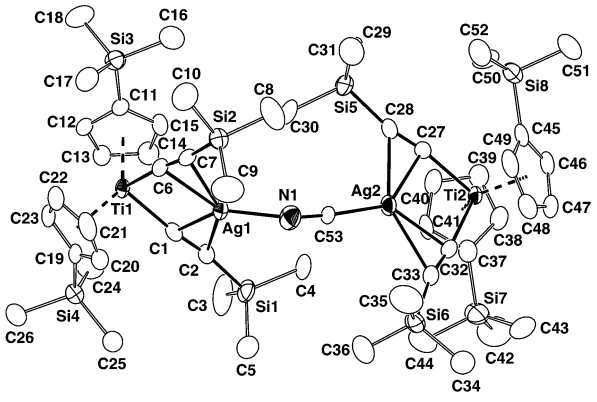


Fig. 1 ZORTEP drawing (50% probability level) of **4**. Selected interatomic bond distances (Å) and angles (°): Ti(1)···Ag(1) 3.1585(10), Ti(2)···Ag(2) 3.1705(9), Ag(1)–N(1) 2.152(5), Ag(1)–C(1) 2.279(5), Ag(1)–C(2) 2.445(5), Ag(1)–C(6) 2.313(5), Ag(1)–C(7) 2.442(5), Ag(2)–C(53) 2.106(5), Ag(2)–C(27) 2.290(5), Ag(2)–C(28) 2.443(5), Ag(2)–C(32) 2.309(5), Ag(2)–C(33) 2.434(5), Ti(1)–C(1) 2.133(5), Ti(1)–C(6) 2.112(5), Ti(2)–C(27) 2.135(5), Ti(2)–C(32) 2.124(5), C(1)–C(2) 1.216(6), C(6)–C(7) 1.248(6), C(27)–C(28) 1.223(7), C(32)–C(33) 1.236(6); Ag(1)–N(1)–C(53) 156.3(4), Ag(2)–C(53)–N(1) 158.5(5), C(1)–Ti(1)–C(6) 93.14(18), C(27)–Ti(2)–C(32) 92.85(18), Ti(1)–C(1)–C(2) 173.6(4), Ti(1)–C(6)–C(7) 171.3(4), Ti(2)–C(27)–C(28) 171.9(4), Ti(2)–C(32)–C(33) 171.2(4), C(1)–C(2)–Si(1) 164.9(4), C(6)–C(7)–Si(2) 169.5(4), C(27)–C(28)–Si(5) 163.3(5), C(32)–C(33)–Si(6) 167.4(5).

 DOI: 10.1039/b104841b

C(53) 156.3(4)°, Ag(2)–C(53)–N(1) 158.5(5)°; Fig. 1]. The planes, comprised of the atoms Ti(1), C(1), C(2), Si(1), C(6), C(7), Si(2) and Ag(1) (rms deviation of fitted atoms 0.02 Å) as well as Ti(2), C(27), C(28), Si(5), C(32), C(33), Si(6) and Ag(2) (rms deviation of fitted atoms 0.04 Å), respectively, are at 87.3°, almost perpendicularly orientated to each other.

The structural features of the organometallic π-tweezer part {[Ti](C≡CSiMe$_3$)$_2$}Ag are in accordance with this type of molecule: (i) the lengthening of the C≡C triple bonds, (ii) *trans*-bending of the Ti–C≡C–Si units and (iii) decreasing of the bite angle $_{C\equiv C}$C–Ti–C$_{C\equiv C}$, as a result of the η^2-coordination of both C≡C triple bonds of the [Ti](C≡CSiMe$_3$)$_2$ moieties to the corresponding silver centers.[6]

IR spectroscopy is a suitable method to prove the formation of **3a** and **3b**. While, in the starting material K$_3$[Ag(C≡N)$_4$] **2**, the $\nu_{C\equiv N}$ frequency is found at 2097 cm^{-1}, it is shifted to 2152 cm^{-1} in **3a** and **3b**. This behaviour is common for cyanide complexes in which the C≡N moiety bridges two transition metal atoms.[8,9b] The counter-ion ClO$_4^-$ in **3a** and **3b** is non-coordinated, since only one absorption band is found for the ν_{Cl-O} stretching vibrations at 1097 cm^{-1} (**3a**) or 1100 cm^{-1} (**3b**) which differs from the starting materials **1a** and **1b** in which the perchlorate entities OClO$_3$ are σ-bonded *via* the formation of a Ag–O bond to the corresponding silver(I) center, giving rise to two (**1a**: 1122, 1032 cm^{-1})[4] or three (**1b**: 1120, 1107, 1067 cm^{-1})[4] bands.[9]

^{13}C{^{1}H} NMR studies on **3a** and **3b** show only minor changes with respect to the chemical shifts of **1a** and **1b**, however, ^{1}H NMR measurements reveal conspicious differences for the protons of the cyclopentadienyl ligands. While **1a** and **1b** display the characteristic AA′XX′ pattern with two pseudo-triplets at δ 6.38 and 6.68 for **1a**[3,4] or δ 6.49 and 6.63 for **1b**,[4] in **3b** two singlets at δ 6.77 and 6.87 and in **3a** only one singlet at δ 6.56 are observed, probably due to the fact that dynamic processes are involved. However, variable temperature ^{1}H NMR measurements could not be carried out, since **3a** and **3b** start to precipitate on cooling during the measurements.

This work was supported in part by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

Notes and references

† *Experimental details*: as an example, the synthesis of **3a** is presented: to a tetrahydrofuran solution (80 mL) containing 500 mg (0.69 mmol) of {[Ti](C≡CSiMe$_3$)$_2$}AgOClO$_3$ **1a**,[3] 57 mg (0.17 mmol) of K$_3$[Ag(C≡N)$_4$][5] was added in one portion at 25 °C. The reaction mixture was stirred in the dark for 8 h. After filtration through a pad of Celite all volatiles were removed *in vacuo* (oil-pump) and the orange–brown residue washed twice with 20 mL of *n*-pentane (yield: 435 mg, 91%). **CAUTION**: Perchlorates of silver(I) can be explosive. Care has to be taken with all safety precautions followed.

Anal. Calc. for C$_{108}$H$_{176}$Ag$_5$ClN$_4$O$_4$Si$_{16}$Ti$_4$ (2810.28): C, 46.16; H, 6.31; N, 1.99. Found: C, 45.78; H, 6.44; N, 1.69%. Mp: 147 °C (decomp.). IR (KBr, cm^{-1}): [$\nu_{C\equiv N}$] 2152w; [$\nu_{C\equiv C}$] 1949w; [ν_{Cl-O}] 1099s. ^{1}H NMR (d$_6$-acetone), 250.130 MHz, δ 0.29 (s, 72 H, SiMe$_3$), 0.37 (s, 72 H, SiMe$_3$), 6.56 (br s, 32 H, C$_5$H$_4$). ^{13}C{^{1}H} NMR (d$_6$-acetone, 62.902 MHz), δ 0.4 (SiMe$_3$), 1.1 (SiMe$_3$), 118.0 (CH/C$_5$H$_4$), 120.6 (CH/C$_5$H$_4$), 128.0 (^{i}C/C$_5$H$_4$), 138.8 (C≡*C*Si), 156.3 (Ti*C*≡C); owing to the low solubility of **3a** in acetone the ^{13}C{^{1}H} NMR signals for the C≡N units could not be assigned.

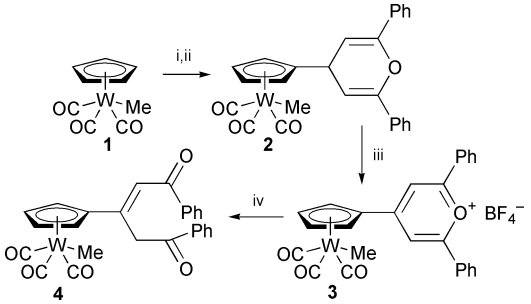
First published as an Advance Article on the web 18th July 2001

The first example of an organo-tungsten pyrylium complex (4-cyclopentadienyl-2,6-diphenylpyrylium)$W(CO)_3CH_3$ has been prepared, fully characterized and transformed in an aqueous basic medium to the corresponding pseudobase (3-cyclopentadienyl-1,5-diphenylpent-2-ene-1,5-dione)W-$(CO)_3CH_3$ which is the first X-ray structure analysed organometallic pseudobase.

It has been shown recently[1–3] that pyrylium salts bearing an organometallic fragment are very promising candidates for the labeling of biological molecules. Due to their electrophilicity, this family of compounds could be attractive for the selective introduction of heavy atoms into protein crystals by means of covalent bond formation with protein side chains carrying a primary amine. Since such heavy metal protein derivatives are required for crystallographic phase determination when using, for example, the multiple isomorphous replacement method (MIR),[4] organometallic pyrylium salts could potentially be of great use for three-dimensional protein structure determination by X-ray crystallography. Several synthetic approaches have been suggested for the preparation of organometallic pyrylium salts bearing benchrotrenyl,[1,5] ferrocenyl,[6] cyclopentadienyl-tricarbonyl-manganese[1,7] or -rhenium[1] fragments at the 4-position of the heterocyclic ring. Reactivity studies using benchrotrenyl pyrylium salts with primary amines, amino acids or proteins have shown that labeling was observed even using crystalline protein.[8] Nevertheless, X-ray diffraction experiments indicated the need for heavier atoms with larger electronic densities. We therefore sought to develop derivatives of the $CpW(CO)_3CH_3$ system which are both air and light stable and provide a heavy metal in a suitable organometallic environment.

We now report the synthesis of the first pyrylium salt containing a tungsten organometallic moiety and the X-ray structural analysis of the pseudobase obtained from its hydrolysis under basic conditions.

The tungsten pyrylium complex **3** was obtained by reaction of deprotonated starting material **1** with preformed 2,6-diphenylpyrylium salt followed by hydride abstraction from the resulting pyran derivative with trityl cation (Scheme 1).†



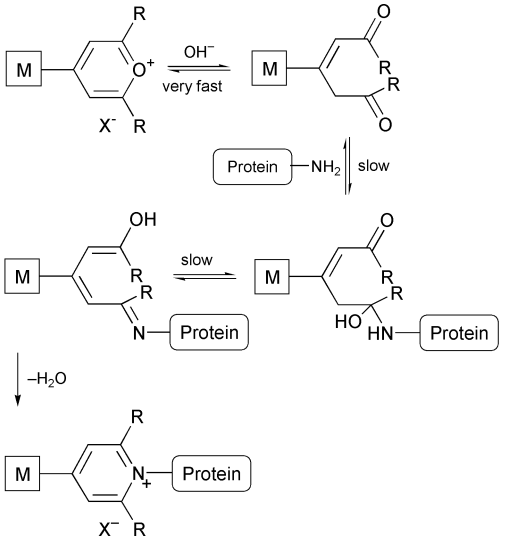
Scheme 1 *Reagents and conditions*: i, Bu^nLi, THF, −78 °C; ii, 2,6-diphenylpyrylium salt, THF, −78 °C to RT; iii, $Ph_3C^+BF_4^-$, CH_3CN, RT; iv, Na_2CO_3, acetone/H_2O/ether, RT.

Complex **3** was isolated as a deep purple air stable solid in 30% overall yield and characterized by elemental analysis, IR and ^1H and $^{13}C\{^1H\}$ NMR spectroscopies. In the ^1H NMR spectrum, a characteristic resonance at 8.79 (s) ppm was assigned to the two pyrylium protons. The $^{13}C\{^1H\}$ NMR spectrum exhibited three signals at 113.5, 164.1 and 171.2 ppm assignable to C^β, C^γ and C^α, respectively, of the heterocycle. These data are very similar to those of 2,4,6-triphenylpyrylium salt[9] and show no significant influence of the organometallic fragment on the heterocycle carbon chemical shifts.

The mechanism of pyrylium to pyridinium conversion has been thoroughly studied.[10] Kinetic measurements using UV–visible spectroscopy performed on a series of 4-benchrotrenyl pyrylium salts indicated that in aqueous media, and especially at basic pH, the hydrolysis of the pyrylium salt is very fast and that the pseudobase form (open chain diketone form) resulting from the addition of OH^- to the pyrylium salt is in fact the reactive species that undergoes the nucleophilic addition by the protein amino group (Scheme 2).[3] Thus, knowledge of the structure and reactivity of the pseudobase form of pyrylium complex **3** is important for the understanding of the mechanism of protein labelling by these species.

Treatment of the tungsten pyrylium salt **3** with Na_2CO_3 in an acetone–water mixture and subsequent extraction with diethyl ether led to the corresponding pseudobase ((3-cyclopentadienyl-1,5-diphenylpent-2-ene-1,5-dione)$W(CO)_3CH_3$) **4** in 92% yield (Scheme 1) as a moderately air stable yellow solid.†

The structure of **4** was established by ^1H NMR analysis which revealed the presence of methylenic and vinylic protons at 4.51 and 7.24 ppm, respectively. The carbon atoms of the pent-2-ene-1,5-dione chain gave signals at 195.7 (C=O), 190.3 (conjugated C=O), 144.4 and 121.2 (C=C) and 41.7 (CH_2) ppm



Scheme 2 Reaction of a protein with a pyrylium salt in basic aqueous medium.

 DOI: 10.1039/b104419m

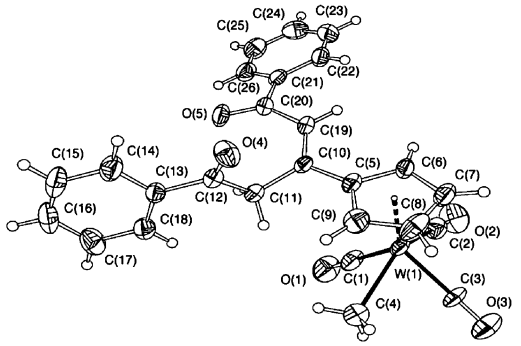


Fig. 1 The molecular structure of **4**. Selected bond lengths (Å) and angles (°); C(5)–C(10) 1.424(9), C(10)–C(19) 1.325(10), C(19)–C(20) 1.473(9), C(20)–O(5) 1.227(9), C(20)–C(21) 1.484(10); C(6)–C(5)–C(10) 126.5(7), C(5)–C(10)–C(19) 119.3(6), C(10)–C(19)–C(20) 124.7(6), C(19)–C(20)–O(5) 122.4(7), C(19)–C(20)–C(21) 118.1(6), C(5)–C(10)–C(11) 117.0(6), C(10)–C(11)–C(12) 112.6(6), C(11)–C(12)–O(4) 120.8(8), C(11)–C(12)–C(13) 118.4(6).

in the $^{13}C\{^{1}H\}$ NMR spectrum. These spectroscopic data are very similar to those of the corresponding compound bearing a phenyl group instead of the organo-tungsten fragment[11] except for the carbon C^3 signal which is shifted 8 ppm upfield.

The structure of pseudobase **4** was confirmed by X-ray crystallography (Fig. 1).‡ The complex exhibits a four-legged piano stool geometry with the methyl group on tungsten and the substituent on the Cp in perpendicular vertical planes. Bond distances within the diketone chain are in agreement with those reported for the only structurally characterized pseudobase $PhC(O)CH{=}C(CF_3)CH_2C(O)Ph$[12] which bears a CF_3 substituent in place of the Cp-tungsten fragment. The dihedral angles along the conjugated chain (C(6)–C(5)–C(10)–C(19) 18.6°; C(10)–C(19)–C(20)–O(5) 21.2°; O(5)–C(20)–C(21)–C(26) 18.7°) show significant deviation from planarity and the two phenyl end groups are almost perpendicular to each other.

The kinetics of reaction of complex **3** with *n*-butylamine in acetonitrile was studied spectrophotometrically. Conversion to the *N*-butylpyridinium salt followed a pseudo-first order reaction rate with $k_{obs} = 5.4 \times 10^{-4}$ s^{-1}. The structure of the final product was confirmed by ^{1}H NMR. For comparison, in the same experimental conditions, a k_{obs} of 0.58×10^{-4} s^{-1} and 0.32×10^{-4} s^{-1} was measured for 4-benchrotrenyl-2,6-diphenylpyrylium tetrafluoroborate and 2,4,6-triphenylpyrylium tetrafluoroborate, respectively.[3,13]

This synthesis may help provide a new approach in X-ray structural determination of proteins.

This work was supported by the European COST D8/0016 action.

Carbon–sulfur bond activation of thiophenes by [W(NPh){*o*-$(Me_3SiN)_2C_6H_4$}$(pyridine)_2$]†

R. C. Mills, K. A. Abboud and J. M. Boncella*

Department of Chemistry and Center for Catalysis, University of Florida, Gainesville, FL 32611-7200, USA. E-mail: boncella@chem.ufl.edu

Received (in Irvine, CA, USA) 1st March 2001, Revised version received 20th June 2001, Accepted 26th June 2001
First published as an Advance Article on the web 26th July 2001

Addition of thiophene, 2-methylthiophene, benzothiophene or 3-methylthiophene to [W(NPh){*o*-$(Me_3SiN)_2C_6H_4$}-$(C_5H_5N)_2$] 1 affords the metallathiacycle complexes [{*o*-$(Me_3SiN)_2C_6H_4$}(NPh)W(SC_4H_4)] 2, [{*o*-$(Me_3SiN)_2C_6H_4$}-(NPh)W(SC_5H_6)] 3, [{*o*-$(Me_3SiN)_2C_6H_4$}(NPh)W(SC_8H_6)] 4 and [{*o*-$(Me_3SiN)_2C_6H_4$}(NPh)W(SC_5H_6)] 5a and 5b, providing the first example of thiophene C–S bond activation by a W(IV) metal complex.

Hydrodesulfurization (HDS), the process by which sulfur is removed from petroleum feedstocks, represents one of the largest-scale industrial processes that utilizes transition metal catalysts. The process involves treatment of crude oil with a high pressure of hydrogen gas (up to 200 atm) in the presence of an alumina-supported catalyst, typically Mo/Co, at elevated temperatures (300–450 °C).[1–5] Of the sulfur containing impurities present in petroleum feedstocks, thiophene and its derivatives are among the most difficult to desulfurize. In order to improve the efficiency of the HDS process, a better understanding of the interaction of thiophenes with transition metal complexes is necessary. As a result, homogeneous modeling of HDS has become an active area of research during the past decade.[4]

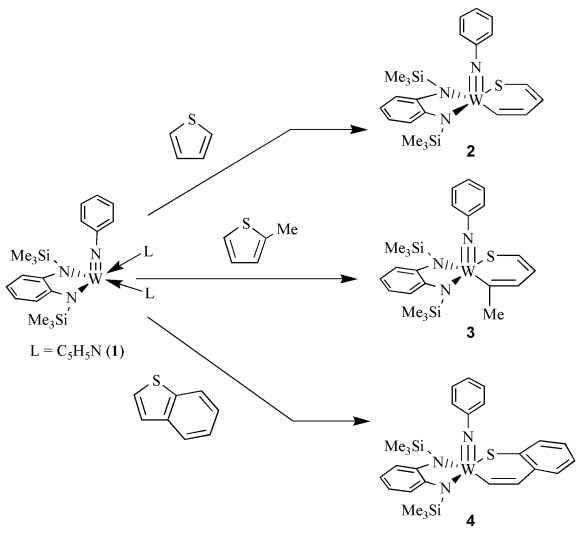
Many research groups have studied the coordination and activation of thiophenes, which are believed to be the initial steps in HDS. A variety of thiophene complexes have been prepared and studied possessing, η^1(S)-coordinated, η^4 and η^5 bound thiophenes.[6–10] In addition, several metal complexes have been found to promote direct C–S bond activation of thiophenes.[4] Surprisingly, thiophene complexes of group 6 metals (Mo and W), an integral component of an industrial HDS catalyst, have been almost non-existent. A recent report by Parkin and coworkers[11] of thiophene and benzothiophene C–S bond activation by the molybdocene complexes $[Me_2Si(C_5Me_4)_2]MoH_2$ and $[Me_2Si(C_5Me_4)_2]Mo(Ph)H$ represents the first homogeneous example of such chemistry with molybdenum. The analogous tungsten system has also been shown to facilitate the C–S bond activation of thiophene.[12]

Recently, we have prepared a series of coordinatively unsaturated [W(NPh){*o*-$(Me_3SiN)_2C_6H_4$}L_2] (L = pyridine, 4-picoline or quinoline) complexes.[13] Our investigation of ligand substitution reactions of the W(IV)L_2 complexes with unsaturated substrates has demonstrated the propensity of the W metal center to reduce the coordinated substrate ligand, thereby increasing the W(VI) character of the resulting compounds. These results have prompted us to examine the activity of these W(IV)L_2 complexes towards substrate oxidative addition, specifically the activation of the C–S bonds of thiophene and its derivatives.

Thermolysis (65 °C, 8–12 h) of a toluene solution containing [W(NPh){*o*-$(Me_3SiN)_2C_6H_4$}$(C_5H_5N)_2$] **1** and 2 equivalents of thiophene, 2-methylthiophene or benzothiophene afforded the carbon–sulfur bond activation products [{*o*-$(Me_3SiN)_2C_6H_4$}(NPh)W(SC_4H_4)] **2**, [{*o*-$(Me_3SiN)_2C_6H_4$}(NPh)-W(SC_5H_6)] **3** and [{*o*-$(Me_3SiN)_2C_6H_4$}(NPh)W(SC_8H_6)] **4**, respectively, as a dark red solid in 60–80% isolated yield for **2** and **3**, Scheme 1.‡ Isolation of a pure sample of compound **4** has proved difficult because the complex slowly decomposes during the work-up procedure. As determined by ^{1}H NMR spectroscopy, compound **4** is formed in *ca.* 50% yield.

Characterization of the reaction products by ^{1}H NMR spectroscopy was straightforward due to the distinct resonances and coupling constants associated with the thiophene ring protons, which are similar for all three compounds. For example, the ^{1}H NMR spectrum of **2** displays two resonances (δ 0.39 and 0.50), which correspond to the inequivalent Me_3Si groups. The metallathiacycle protons are shifted downfield with respect to free thiophene and appear as a doublet of doublets (δ 6.70, $^3J_{HH}$ 7, 9 Hz) corresponding to the β-CH, a doublet (δ 8.01, $^3J_{HH}$ 9 Hz) with ^{183}W satellites ($^2J_{WH}$ 8 Hz) for the α-CH, a doublet of doublets (δ 8.20, $^3J_{HH}$ 13, 7 Hz) for the γ-CH, and a doublet (δ 9.00, $^3J_{HH}$ 13 Hz) for the δ-CH adjacent to the S atom.

Compound **4** displays two doublet resonances corresponding to the α (δ 8.50, $^3J_{HH}$ 13 Hz) and β (δ 8.65, $^3J_{HH}$ 13 Hz) protons, respectively. The resonance at δ 8.50 has ^{183}W satellites ($^2J_{WH}$ 10 Hz), confirming the suggested C(vinyl)–S insertion product. The absence of a proton resonance in the ^{1}H NMR spectrum of **3** with ^{183}W satellites or in the vicinity of that observed for the α-CH proton of compound **2** suggests preferential activation of the (Me)C–S bond in the reaction of **1** with 2-methylthiophene. The observed downfield shift of the metallathiacycle protons for compounds **2**, **3** and **4** contrasts with the reported upfield shift with respect to free thiophene found for the complex $(C_5H_5)_2W(SC_4H_4)$.[12] This is presumably due to the increased electron deficiency of the d^0 W(VI) center in compounds **2**, **3** and **4** relative to the d^2, Cp_2W(IV) system.



Scheme 1 C–S bond activation products.

 DOI: 10.1039/b101955b

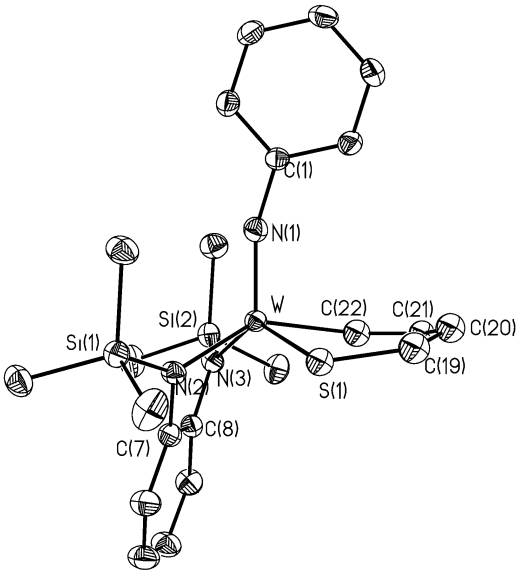

Fig. 1 Molecular structure of **2**, showing 50% thermal ellipsoids and the atom labeling scheme. The H atoms and the minor part of the disordered metallathiacycle are removed for clarity. Selected bond distances (Å) and angles (°): W–N(1) 1.734(3), W–N(2) 2.016(3), W–N(3) 2.008(3), W–S(1) 2.371(3), W–C(22) 2.196(9), S(1)–C(19) 1.722(12), C(19)–C(20) 1.192(16), C(20)–C(21), 1.600(16), C(21)–C(22) 1.289(14); W–N(1)–C(1) 162.4(3), N(1)–W–N(2) 116.06(13), N(1)–W–N(3) 117.02(14), N(1)–W–S(1) 104.49(13), N(1)–W–C(22) 98.0(3), C(22)–W–S(1) 83.7(3).

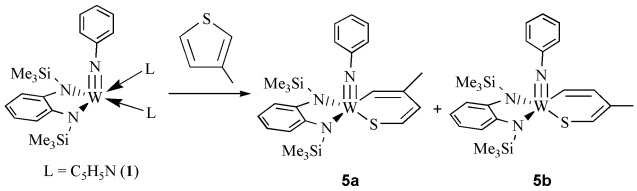
An X-ray diffraction study of a single crystal of **2** grown from a concentrated pentane solution at −40 °C confirmed the nature of the C–S bond activation product. Due to disorder in S1 and C22, the positions of the metallathiacycle atoms were solved independently in two parts. A molecular drawing of **2** with selected bond lengths and angles for the major part are shown in Fig. 1.§ Compound **2** adopts a five-coordinate, distorted square pyramidal geometry with the imido ligand occupying the apical position. The short W–N(imido) bond length of 1.734(3) Å, consistent with a W–N triple bond and the W–N(amido) bond lengths of 2.016(3) and 2.008(3) Å are similar to that observed for other W(VI) complexes.[14] The average bond lengths for the thiophene fragment of the complex suggest localized bonding within the metallathiacycle.

Thiophenes are known to interact with a metal center in a number of different modes however; a η^1-S-bound thiophene[6–10] is believed to be a prerequisite for C–S bond activation. Although the initial interaction of thiophene and its derivatives with compound **1** has not been directly observed, the ability of **1** to accommodate additional ligands has been demonstrated.[13] Compound **1** rapidly forms octahedral complexes with the addition ligands such as CO and PMe_3. For the reaction of the σ-donor ligand PMe_3 with **1**, the complex $[W(NPh)\{o\text{-}(Me_3SiN)_2C_6H_4\}(C_5H_5N)(PMe_3)_2]$ is the preferred product, suggesting labilization of one of the pyridine ligands upon coordination of the first PMe_3 ligands. Although thiophenes are weaker donor ligands than PMe_3, under the thermolysis conditions for the reaction of thiophenes with **1**, labilization of a pyridine ligand would generate the open coordination site necessary for C–S bond activation. Although no direct evidence for such a mechanism has been observed, it must be considered given the reactions of **1** with PMe_3.

Compound **1** also reacts with 2 equivalents of 3-methylthiophene. Unlike the previously described examples, 3-methylthiophene generates a mixture of the two possible C–S bond activation products, $[\{o\text{-}(Me_3SiN)_2C_6H_4\}(NPh)W(SC_5H_6)]$ **5a** and **5b**, Scheme 2.‡ As determined by ^{1}H NMR spectroscopy, the products are formed in a 60:40 ratio with **5a** as the major component. A similar product mixture was observed for the reaction of $Cp^*Rh(Ph)(H)(PMe_3)$ with 3-methylthiophene.[15] The observed product selectivity in the reaction of **1** with benzothiophene arises from steric congestion on one side of the thiophene ring, whereby C–S bond activation opposite the substituent is preferred. For the reaction of 3-methylthiophene with **1**, both C–S bonds are accessible as demonstrated by the formation of both **5a** and **b**.



Scheme 2 Product mixture generated from 3–methylthiophene C–S bond activation.

In summary, we have demonstrated that the chelate stabilized W(IV)L_2 complex $[W(NPh)\{o\text{-}(Me_3SiN)_2C_6H_4\}(C_5H_5N)_2]$ **1** facilitates the C–S bond activation of both thiophene and substituted thiophenes. To our knowledge, this reactivity is the first example of thiophene C–S bond activation by a W(IV) species. Currently we are investigating other substrates, such as more highly substituted thiophenes and nitrogen and oxygen containing heterocycles, to determine the scope of this reactivity.

We thank the National Science Foundation (CHE 9523279 and CHE 0094404) for funding of this work and the NSF and the University of Florida for funding X-ray equipment purchases.

Notes and references

‡ All reactions and manipulations were carried out using standard Schlenk techniques or in a dry box under atmospheres of argon or nitrogen. *Synthesis* of compounds **2**–**5a**,**b**: to a purple toluene solution of **1** were added 2 equivalents of the appropriate thiophene. Thermolysis (65 °C) of the reaction mixtures for 8–12 h resulted in a color change from purple to red. After removal of the reaction solvent *in vacuo*, the crude products were extracted with cyclohexane and dried *in vacuo*.

§ *Crystal data* for **2**: $C_{22}H_{31}N_3SSi_2W$, M = 609.59, triclinic, space group $P\bar{1}$, a = 9.4647(4), b = 11.7141(5), c = 12.4830(5) Å, α = 101.246(1), β = 111.655(1), γ = 93.904(1)°, V = 1246.64(9) Å^3, Z = 2, T = 173(2) K, final $R1$ = 0.0264, $wR2$ = 0.0647, GOF (on F^2) = 1.024.

The structure was solved by the Direct Methods in SHELXTL5, and refined using full-matrix least squares.[16] The non-H atoms, except the disordered, were treated anisotropically, whereas the methyl hydrogen atoms were calculated in ideal positions and were riding on their respective carbon atoms. The S1–C22 chain is found to be disordered by a 180° rotation and was refined in two parts; the major part is represented by the S1–C22 chain and the minor part by S1′–C22′. Their site occupation factors were dependently refined to 0.55(1) for the major part and, consequently, 0.45(1) for the minor part. All atoms of the disorder were refined with isotropic thermal parameters. The W–S1 and W–S1′ bonds were constrained to be equivalent during refinement. Similarly, W–C22 and W–C22′ were also constrained to remain equivalent.

Received (in Cambridge, UK) 4th June 2001, Accepted 4th July 2001
First published as an Advance Article on the web 26th July 2001

Interesting molecular architectures are obtained by self-assembly from silver(I) trifluoroacetate with a combination of the diphosphine ligands [$Ph_2P(CH_2)_nPPh_2$, n = 1–6] and *trans*-1,2-bis(4-pyridyl)ethylene (bipyen); in complexes with stoichiometry $Ag_2(O_2CCF_3)_2\{Ph_2P(CH_2)_nPPh_2\}$(bipyen), the complexes crystallize in the form of macrocyclic rings $[Ag_4(O_2CCF_3)_4\{\mu\text{-}Ph_2P(CH_2)_nPPh_2\}_2(\mu\text{-bipyen})_2]$ when n = 1 or 5, but as a one-dimensional polymer $[\{Ag_2(O_2CCF_3)_2\{\mu\text{-}Ph_2P(CH_2)_nPPh_2\}(\mu\text{-bipyen})\}_x]$ when n = 6. The complex $[\{Ag\{\mu\text{-}Ph_2P(CH_2)_3PPh_2\}(\mu\text{-bipyen})\}_x](CF_3CO_2)_x$ has a novel network structure.

There is intense current interest in polymeric coordination networks,[1] but there are surprisingly few examples containing silver(I) or phosphine ligands, and very few architectures with mixed bridging ligands.[2,3] Given the interesting electronic,[4] medicinal,[5] and structural[4–6] properties of silver(I) phosphine complexes, the synthesis of polymeric diphosphine bridged silver(I) complexes was attempted. The strategy was to form mixed ligand complexes, using the rigid linear dipyridyl ligand *trans*-1,2-bis(4-pyridyl)ethylene (bipyen) in conjunction with the more flexible diphosphine ligands $Ph_2P(CH_2)_nPPh_2$, since the diphosphines alone tend to give chelate complexes or other ring structures with silver(I).[4–6] This article shows that linear and network polymers, as well as ring complexes, can be formed by this strategy and that the variable coordination number of silver(I) is a key feature in allowing formation of a particularly interesting series of compounds.[7]

The new silver(I) complexes were prepared by reaction of silver(I) trifluoroacetate with the appropriate ligand $Ph_2P(CH_2)_nPPh_2$ (n = 1–6) followed by reaction with *trans*-1,2-bis(4-pyridyl)ethylene (bipyen).† Studies of the reaction solutions by ^1H or ^{31}P NMR spectroscopy indicated that mixtures of products were formed but, in favourable cases, it was possible to crystallize pure products for structure determination and these are representative of major components of the equilibrium system.‡

Three complexes were crystallized having the formula $Ag_2(O_2CCF_3)_2\{Ph_2P(CH_2)_nPPh_2\}$(bipyen) of which two formed macrocyclic ring structures (**1**, n = 1; **2**, n = 5) and one formed a one-dimensional polymer (**3**, n = 6). The structures are shown in Figs. 1 and 2. In the 30-membered ring complex **1** two of the trifluoroacetate ions bridge silver atoms in the ring while two are not coordinated, so the complex is formulated as $[Ag_4(\mu\text{-}O_2CCF_3)_2(\mu\text{-}Ph_2PCH_2PPh_2)_2(\mu\text{-bipyen})_2]^{2+}$, with each silver(I) ion having distorted trigonal planar stereochemistry. There is a short intramolecular silver–silver distance Ag(1)–Ag(2) 3.0479(8) Å, which is about equal to the distance P(1)–P(2) 3.051(2) Å but significantly shorter than N(11)–N(21) 3.507(4) Å, so indicating the presence of a secondary Ag···Ag bond.[4,8] In the related 38-membered ring structure **2**, all trifluoroacetate ions are close enough to silver(I) to influence the stereochemistry so **2** is formulated as $[Ag_4(\mu\text{-}O_2CCF_3)_4\{\mu\text{-}Ph_2P(CH_2)_5PPh_2\}_2(\mu\text{-bipyen})_2]$. The longer Ag···O bonds are shown in Fig. 1 as broken lines; if all are considered bonds, then each silver(I) ion is four-coordinate. The transannular distance Ag(1)–Ag(4) 3.936(1) Å is too long for a bonding interaction

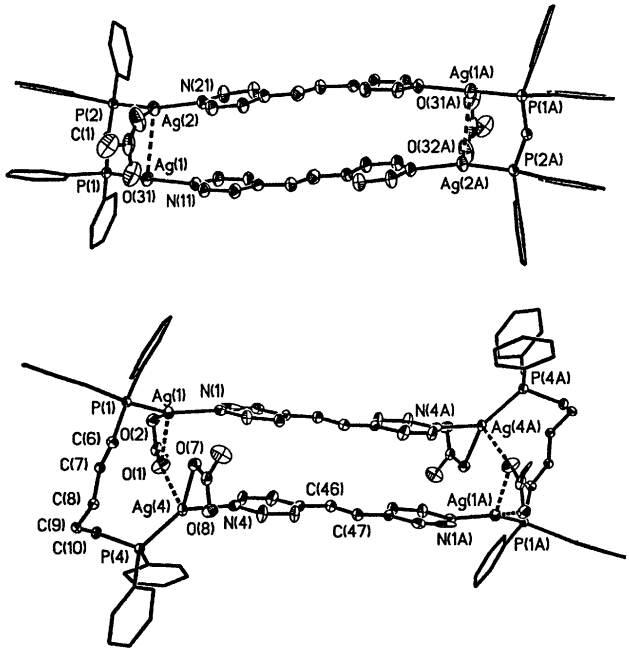

Fig. 1 Views of the structures of the macrocyclic ring complexes **1** (above) and **2** (below). Thermal ellipsoids for phenyl carbon atoms, and fluorine atoms of the trifluoroacetate groups, are not shown for clarity. Selected geometrical parameters (Å, °) for **1**: Ag(1)–P(1) 2.360(1), Ag(2)–P(2) 2.366(1), Ag(1)–N(11) 2.199(4), Ag(2)–N(21) 2.217(5), Ag(1)–O(31) 2.506(7), Ag(2)–O(32) 2.496(7); N(11)–Ag(1)–P(1) 157.5(1), N(21)–Ag(2)–P(2) 155.3(1). For **2**: Ag(1)–P(1) 2.348(3), Ag(4)–P(4) 2.363(3), Ag(1)–N(1) 2.20(1), Ag(4)–N(4) 2.23(1), Ag(1)–O(1) 2.63(1), Ag(1)–O(2) 2.63(1), Ag(4)–O(7) 2.379(9), Ag(4)–O(1) 2.63(1); N(1)–Ag(1)–P(1) 149.5(3), N(4)–Ag(4)–P(4) 130.1(3).

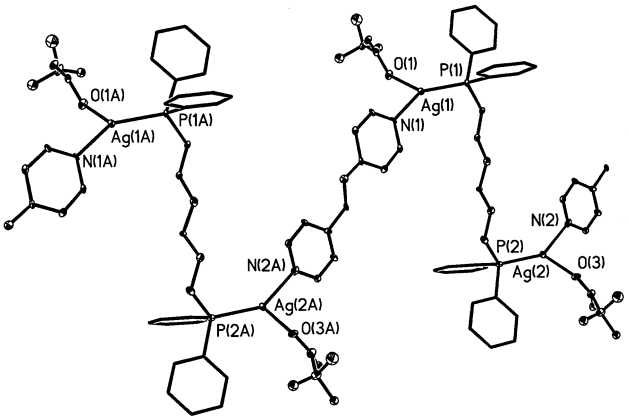

Fig. 2 A view of the structure of the polymeric complex **3**. Thermal ellipsoids for phenyl carbon atoms are not shown for clarity. Selected geometrical parameters (Å, °): Ag(1)–P(1) 2.377(6), Ag(2)–P(2) 2.367(7), Ag(1)–N(1) 2.18(2), Ag(2)–N(2) 2.31(3), Ag(1)–O(1) 2.38(2), Ag(2)–O(3) 2.46(2); N(1)–Ag(1)–P(1) 143.5(6), N(2)–Ag(2)–P(2) 143.4(6).

 DOI: 10.1039/b104857k

and the conformation may be controlled by the weakly bridging trifluoroacetate ligand and by π-stacking of the bipyen groups (the transannular distance between centroids of pyridyl rings in **2** is 3.86 Å).

Part of the polymeric chain structure of complex **3** is shown in Fig. 2. All trifluoroacetate ions are coordinated so the complex is formulated as $[Ag_2(O_2CCF_3)_2\{\mu\text{-}Ph_2P(CH_2)_6PPh_2\}(\mu\text{-bipyen})]_x$. The change in structure is attributed to the preference for the *syn* or *anti* conformation of the phosphorus donors when there is an odd or even number of methylene bridges in $Ph_2P(CH_2)_nPPh_2$,[7] leading naturally to ring structures **1** and **2**, when $n = 1$ and 5, but a polymer **3** when $n = 6$. This conformational change is clear from a comparison of Fig. 1 and 2. The polymer could be considered to be formed by ring-opening polymerization of the corresponding ring complex.

With higher ligand:silver ratios, more complex product mixtures were formed and only in one case ($n = 3$) was a pure complex crystallized. The complex **4** is formulated as $[\{Ag\{\mu\text{-}Ph_2P(CH_2)_3PPh_2\}(\mu\text{-bipyen})\}_x]^{x+}$, isolated as the trifluoroacetate salt, and its network structure is shown in Fig. 3, illustrating the presence of channels that are occupied by the anions and by solvent molecules. Each silver(I) ion is roughly tetrahedral with AgP_2N_2 coordination, and all silver centres are identical, but the overall structure is more complex. One view would be to consider the structure as spiral chains $[\{Ag(\mu\text{-dppp})\}_x]^{x+}$ [dppp = $Ph_2P(CH_2)_3PPh_2$], running roughly perpendicular to the plane in Fig. 3 crosslinked by μ-bipyen ligands. The smallest rings incorporated into these units are 46-membered $\{-Ag(\mu\text{-dppp})Ag(\mu\text{-dppp})Ag(\mu\text{-bipyen})\}_2$. Another view is to consider the structure to be formed from crossing zigzag polymers $[\{Ag(\mu\text{-bipyen})\}_x]^{x+}$ crosslinked by μ-dppp ligands. The conformation of the diphosphine is neither *syn* nor *anti* but intermediate such that the diphosphine links chains that are roughly orthogonal. The smallest ring structure is 56-membered $\{-Ag(\mu\text{-bipyen})Ag(\mu\text{-bipyen})Ag(\mu\text{-dppp})\}_2$ and they lie roughly in the plane of Fig. 3.

This work shows that combination of flexible diphosphine and linear dipyridyl ligands with silver(I) can give interesting new molecular architectures that are significantly different from those obtained with only nitrogen-donor ligands,[1,2] and that factors such as the preferred conformation of the diphosphine ligand[7] and the variable coordination number of silver(I)[1–6] can determine the preferred structure. There is clear potential for design of still more complex molecular topologies by application of these principles.

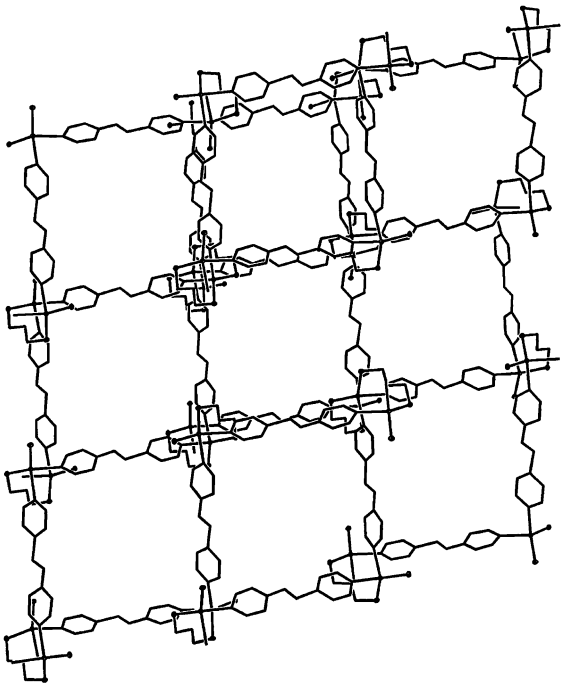

Fig. 3 A view of the structure of the network polymeric complex **4**. Phenyl carbon atoms are not shown for clarity. Selected geometrical parameters (Å, °): Ag–P(1) 2.444(3), Ag–P(2) 2.448(3), Ag–N(1) 2.425(8), Ag–N(2) 2.370(7); N(1)–Ag–N(2) 90.4(2), P(1)–Ag–P(2) 123.36(5), N(1)–Ag–P(1) 121.6(2), N(1)–Ag–P(2) 98.4(2), N(2)–Ag–P(1) 98.0(2), N(2)–Ag–P(2) 121.9(2).

MCM-41 can be used in the same way as amorphous silica for the preparation of supported titanium catalysts; MCM-41 does not show clear advantages over silica in epoxidation reactions with either TBHP or H_2O_2; only in one case is a positive effect observed and this involves the recycled catalyst with H_2O_2.

Catalysts based on mesoporous crystalline silicas, especially MCM-41, have been widely applied in recent years.[1] Among the advantages proposed for this type of solid are the presence of a regular porous system, and the large pore size. In many cases comparisons have only been made regarding the behaviour of zeolites and MCM-41, and comparisons with amorphous silica are generally ignored.

Titanium catalysts are among the most important oxidation catalysts[2] and titanium centres can be incorporated in MCM-41[3,4] or amorphous silica[6–9] either within the framework, by substitution of silicon atoms,[3] or by grafting titanium species onto the surface. Several of these catalysts have been used in the epoxidation of alkenes with dilute hydrogen peroxide.[10–12] In the case of MCM-41, grafting has been described as being more efficient than framework substitution.[10,13,14] However, no direct comparison has been made between amorphous and crystalline mesoporous silicas. In this communication we report the behaviour of MCM-41 as a support for $Ti(OPr^i)_4$ using the same methodology employed for amorphous silica.

The synthesis of pure siliceous MCM-41[15] and titanium grafting[7] were carried out as previously described. The titanium loading onto MCM-41 (Table 1) is in good agreement with the surface area of the support (802 $m^2\ g^{-1}$) and the reported density of hydroxy groups[16] (*ca.* 2 OH nm^{-2}). In the case of amorphous silica, this agreement (1.07 mmol g^{-1}, 475 $m^2\ g^{-1}$, 3.7 hydrogen-bridged OH nm^{-2}) is also observed. Treatment of the catalyst with tartaric acid was carried out as described for silica.[12] The Ti content of MCM-Ti(TA) was found to be very similar to that found in the silica counterpart (Table 1).

Si-Ti(OPr^i) has previously been characterised by MAS-NMR,[7] EXAFS[18] and IR.[12] The similarity of the IR spectra of the solids (ESI†), together with the agreement observed in the titanium loading, seem to indicate that the surface species' are similar irrespective of the structure of the silica. The exclusion of water in the preparation method prevents the formation of titania (anatase) on the silica surface, as demonstrated by the absence of a UV absorption above 300 nm.

All the catalysts were tested in the epoxidation of cyclohexene with 30% hydrogen peroxide in *tert*-butyl alcohol at 353 K (Scheme 1). The active hydroperoxotitanium species is able to epoxidise directly cyclohexene with hydrogen peroxide and also to produce free radicals, which give rise to an allylic hydroperoxide. This compound can also be involved in titanium-catalysed epoxidation of cyclohexene, leading to cyclohex-2-en-1-ol as a by-product. Finally, the acidity of the catalyst promotes the hydrolysis of cyclohexene oxide to the corresponding diol. The results of this study are gathered in Table 1.

As far as catalysts prepared with $Ti(OPr^i)_4$ are concerned, MCM-41 leads to a solid that is less active than the silica-based one in terms of both hydrogen peroxide conversion and turnover number to epoxidation products. Moreover, the epoxidation/allylic oxidation selectivity is also slightly lower, indicating a lower contribution of the direct epoxidation. The main advantage of MCM-41 comes from the reusability of the catalyst, in fact the turnover number for epoxidation products is nearly constant up to the third run. However, the epoxidation/allylic oxidation selectivity is almost 50/50, which indicates that only

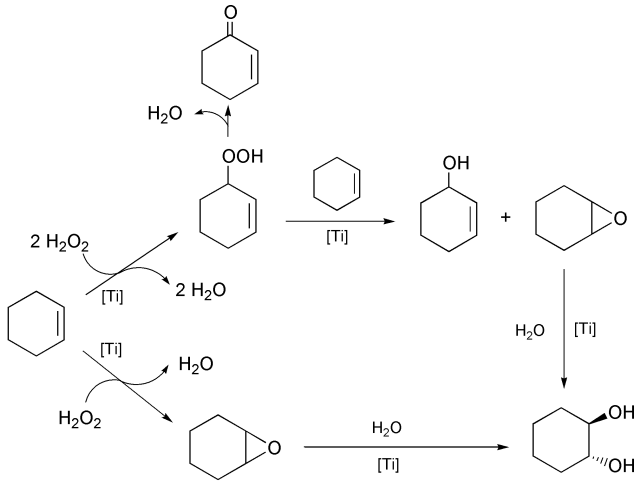

Scheme 1

the radical mechanism takes place with the recovered catalyst. The presence of different titanium species, with either two or three bonds to the surface, or the higher titanium dispersion due to the larger surface area of MCM-41 could be responsible for these differences in behaviour.

Treatment with tartaric acid improves the activity of the silica-based catalyst without causing a modification in the epoxidation/allylic oxidation selectivity. This higher activity is reflected in the higher hydrogen peroxide conversion and the higher turnover number for epoxidation products. It has been shown that some of the titanium species generated in the treatment with tartaric acid are able to pass into solution.[12] However, some other more active species remain on the solid, as shown by the higher turnover number attained with the recovered catalyst. Even with this recovered catalyst the epoxidation/allylic oxidation selectivity is > 50/50, signifying a contribution of the direct epoxidation with hydrogen peroxide. Similar treatment with tartaric acid does not cause the same beneficial effect in the case of the MCM-41 catalyst. This solid is much less active in terms of the productive conversion of hydrogen peroxide and turnover numbers and, in addition, the selectivities are very similar to those obtained with the parent MCM-Ti(OPr^i) catalyst. In this case the species are more strongly bonded to the surface, as demonstrated by the lower degree of titanium leaching.

A particularly interesting point concerns the stability of these catalysts in comparison to other similar systems described in the literature. One of the few studies regarding the stability of grafted titanium species on MCM-41 describes a titanium loss of 50–61% after two reactions, with a total H_2O_2/Ti ratio in the range 228–686.[10] However, this leaching does not seem to be proportional to either the H_2O_2/Ti ratio or the catalytic activity. In our case, titanium loss is 7–19% for MCM catalysts after three runs, with a total H_2O_2/Ti ratio in the range 150–200. These values indicate that the solids described here have a higher stability. The solids described here also show a higher stability in comparison with related silica-based catalysts.[8] This stability is demonstrated by the the fact that catalysts prepared with TiF_4 or tetraneopentyltitanium cannot be used with dilute hydrogen peroxide.

The IR spectra of the recovered catalysts (ESI†) show that some by-products remain adsorbed on the surface.

Another interesting feature of these systmes is the lower content of cyclohexenyl hydroperoxide (chhp) in the final reaction mixture when MCM-41-based catalysts are used. This may be due to a higher activity of these catalysts in the epoxidation with alkyl hydroperoxides or to a more rapid deactivation of the silica-based catalysts. In order to clarify this point, the four catalysts were compared in the epoxidation of cyclohexene with *tert*-butyl hydroperoxide (TBHP). The results (ESI†) show that the catalysts with isopropoxy groups have nearly the same catalytic activity and selectivity. Treatment with tartaric acid noticeably reduces the activity, irrespective of the type of support, but Si-Ti(TA) is clearly more active than MCM-Ti(TA). Thus, the hypothesis regarding the higher activity of MCM-catalysts is not confirmed.

In conclusion, the three factors studied (support, titanium environment and nature of the oxidant) have a significant influence on both the results of the reaction and the stability of the catalyst. Furthermore, the three factors are not completely independent and a careful selection of each parameter is necessary to optimise the behaviour of this kind of catalyst.

Treatment of MCM-41 with tartaric acid has a detrimental effect with both oxidants used (H_2O_2 and TBHP) in such a way that silica-grafted systems become far more active. On using amorphous silica, treatment with tartaric acid leads to a catalyst that is more active in the epoxidation with dilute hydrogen peroxide but is less active with TBHP. Ti(OPr^i) species immobilised on amorphous silica are only slightly more active than those grafted onto MCM-41. However, the use of the crystalline MCM-41 leads to more stable catalysts.

It is clear that none of the supports are particularly advantageous over the others and that the choice of one or other is influenced by other factors concerning the titanium environment and the reaction conditions.

This work was made possible by the generous financial support of the CICYT (project MAT99-1176).

Selective complexation of uranium(III) over cerium(III) by 2,6-bis(5,6-dialkyl-1,2,4-triazin-3-yl)pyridines: ^{1}H NMR and X-ray crystallography studies

First published as an Advance Article on the web 26th July 2001

Addition of 2,6-bis(5,6-dialkyl-1,2,4-triazin-3-yl)pyridines (btp) to UI_3 and CeI_3 in anhydrous pyridine gave the 1:3 complexes $[M(btp)_3]I_3$, the terdentate nitrogen ligand being completely selective for U^{III} over Ce^{III}, as shown by ^{1}H NMR competition experiments; crystal structures of analogous btp complexes of U^{III} and Ce^{III} revealed that the U–N bond distances are significantly shorter than the corresponding Ce–N distances.

Much attention is currently paid to the separation of trivalent minor actinides (americium and curium) from trivalent lanthanides, which represents a challenging goal for the definition of new methods in the management of nuclear wastes.[1] A number of multidentate nitrogen extractants have been designed for the selective complexation of the actinides, and the recently discovered 2,6-bis(5,6-dialkyl-1,2,4-triazin-3-yl)pyridines (btp) are the most effective so far.[2] The high separation factors have been attributed to the very weakly basic nature of these ligands which results in the formation of stronger actinide–nitrogen bonds with increased covalent character. However, no actinide complex with btp ligands has been isolated and characterized. We have studied the complexation of the triiodides UI_3 and CeI_3 with two btp molecules, Mebtp and Pr^{n}btp (Fig. 1) in anhydrous pyridine; U^{III} was used as an actinide analogue of the highly radiotoxic Am^{III} and Cm^{III}, and the similarly sized Ce^{III} was chosen as representative of the lanthanides. For the first time, btp complexes of 4f and 5f elements have been studied both in solution and in the solid state, and the remarkably better affinity of actinides(III) *vs.* lanthanides(III) for such multidentate ligands has been revealed by ^{1}H NMR competition experiments and also by X-ray crystallography, with the direct comparison of the crystal structures of the analogous complexes $[M(Pr^nbtp)_3]I_3$ (M = U, Ce).

A 2×10^{-2} M solution of UI_3 in [$^2H_5$]pyridine was titrated with Mebtp in the presence of cyclohexane as internal standard. The ^{1}H NMR spectra† showed that, whatever the number n of ligand equivalents, only the 1:3 complex $U^{III}(Mebtp)_3$ was formed in an immediate and quantitative manner. For $n > 3$, free Mebtp was observed in solution, without exchanging with coordinated ligands. The four resonances in the intensity ratio of 18:18:6:3 indicate that the three Mebtp ligands are equivalent in a D_3 symmetrical arrangement. Complexation of CeI_3 with Mebtp exhibited some differences since for $n < 3$, the 1:2 and 1:3 complexes $Ce^{III}(Mebtp)_2$ and $Ce^{III}(Mebtp)_3$ were formed together. This result is a first indication that Ce^{III} has a lesser affinity for Mebtp than U^{III}. However, the 1:3 complex was the major species for $n > 2$ and the sole present in solution for $n \geqslant 3$. It is also interesting to note that addition of Pr^{n}btp to $Ln(NO_3)_3$ in a 1:1 ratio in ethanol resulted in the crystallization of 1:3 complexes containing the $[Ln(Pr^nbtp)_3]^{3+}$ cations (Ln = Sm, Tm and Yb) with a variety of anions.[3] However, this work did not demonstrate, in contrast to the present study, that the 1:3 complexes were actually the dominant species in solution, while crystallization alone implies exceptional stability of the 1:3 complexes. The strong preference for the formation of the 1:3 complexes with respect to the 1:1 and 1:2 complexes is quite exceptional in coordination chemistry,[4] but some 1:3 complexes between lanthanide ions and terdentate nitrogen ligands have been reported.[5]

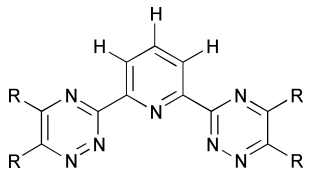

Fig. 1 The Rbtp ligands (R = Me and Pr^n).

Even more striking was the competition reaction of U^{III} and Ce^{III} with Mebtp. Only the 1:3 complex $U^{III}(Mebtp)_3$ was observed in pyridine solution on addition of 1–3 mol equivalents of Mebtp to 1 mol equivalent of both UI_3 and CeI_3; no cerium complex could be detected. The two Ce^{III} complexes $Ce^{III}(Mebtp)_2$ and $Ce^{III}(Mebtp)_3$ then appeared as more ligand was added (3–6 mol equivalents) and finally, only $U^{III}(Mebtp)_3$ and $Ce^{III}(Mebtp)_3$ were observed with an excess of ligand. Similar observations were made when Mebtp was replaced with Pr^{n}btp, and these results clearly demonstrate that these very efficient complexants are completely selective for uranium(III) over cerium(III). By considering that 5% of the cerium complex could be easily detected in solution by ^{1}H NMR, the selectivity factor is certainly higher than 20. This value can be compared with those obtained for the actinide(III)–lanthanide(III) separation (Am^{III}/Eu^{III}) with btp ligands from aqueous nitric acid solutions, which lie between 50 and 150 and are ten times greater than those observed with other terdentate nitrogen ligands such as 2,2′:6′,2″-terpyridine or 2,4,6-tri(2-pyridyl)-1,3,5-triazine.[2]

Single crystals of $[Ce(Mebtp)_3]I_3 \cdot 9C_5H_5N$ (red), $[Ce(Pr^nbtp)_3]I_3 \cdot 3C_5H_5N$ (orange) and $[U(Pr^nbtp)_3]I_3 \cdot 4C_5H_5N$ (brown) were obtained by slow diffusion of pentane into pyridine solutions and their structures were determined.‡ The crystals are composed of discrete $[M(btp)_3]^{3+}$ cations, iodide anions and pyridine molecules. The structures of the cations are very similar; those of $[Ce(Mebtp)_3]^{3+}$ and $[U(Pr^nbtp)_3]^{3+}$ are shown in Figs. 2 and 3, respectively, together with selected data. The metal centres are nine coordinate in a slightly distorted tricapped trigonal prismatic configuration, each btp ligand being attached *via* the nitrogen atom of the pyridine fragment (N_p or N1 in Figures) which occupies the capping position and the nitrogen atoms at the 2 position of the triazine rings (N_t or N3 and N6 in Figures). These structures are equivalent to those found in the lanthanide cations $[Ln(Pr^nbtp)_3]^{3+}$ (Ln = Sm, Tm, Yb).[3] Of special interest is the comparison of the metal–nitrogen bond distances in these cations. The Ce–N_p distances

 DOI: 10.1039/b103606h

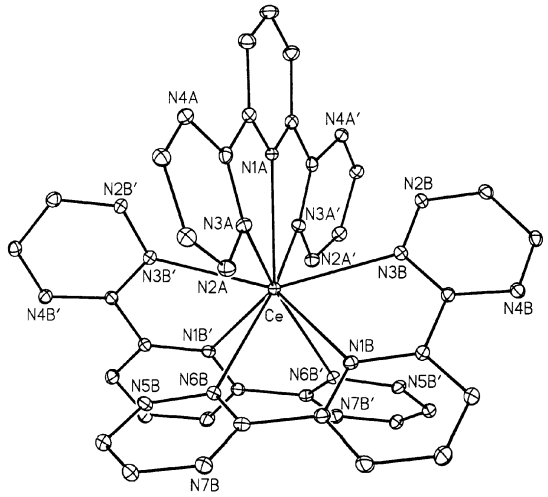

Fig. 2 Crystal structure of the cation $[Ce(Mebtp)_3]^{3+}$. Methyl groups and hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Ce–N1A 2.641(6), Ce–N1B 2.624(4), Ce–N3A 2.613(5), Ce–N3B 2.598(5), Ce–N6B 2.625(5); N1A–Ce–N1B 120.7(1), N1B–Ce–N1B′ 118.7(2). Primed atoms are related to unlabelled atoms by the two-fold axis.

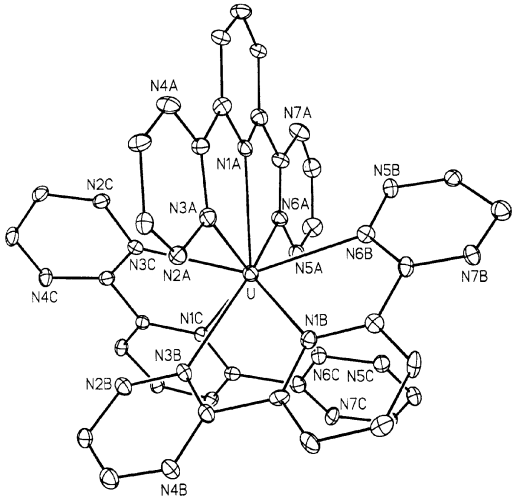

Fig. 3 Crystal structure of the cation $[U(Pr^nbtp)_3]^{3+}$. Propyl groups and hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°); the corresponding values in the analogous cerium cation are given in square brackets: U–N1A 2.56(2) [2.63(2)], U–N1B 2.53(2) [2.65(2)], U–N1C 2.56(2) [2.65(2)], U–N3A 2.54(2) [2.57(2)], U–N6A 2.57(3) [2.64(2)], U–N3B 2.56(2) [2.66(2)], U–N6B 2.53(3) [2.61(2)], U–N3C 2.52(3) [2.54(2)], U–N6C 2.53(3) [2.59(2)]; N1A–U–N1B 122.1(8) [116.9(7)], N1A–U–N1C 118.6(8) [121.9(5)], N1B–U–N1C 119.4(8) [121.2(6)].

in $[Ce(Mebtp)_3]^{3+}$ are equal to 2.624(4) and 2.641(6) Å with an average value of 2.63(1) Å whereas the Ce–N_t bond lengths range from 2.598(5) to 2.625(5) Å with a mean value of 2.61(2) Å. Very similar distances are found in $[Ce(Pr^nbtp)_3]^{3+}$ [$<$Ce–$N_p$$>$ = 2.64(1) Å and $<$Ce–$N_t$$>$ = 2.60(4) Å], indicating that the different alkyl groups at the 5 and 6 positions of the triazine moiety have no significant effect on the metal coordination sphere. These average Ce–N_p and Ce–N_t distances appear longer than the corresponding distances in the other $[Ln(Pr^nbtp)_3]^{3+}$ cations: 2.57(3) and 2.57(3) Å (Sm), 2.49(2) and 2.50(2) Å (Tm), 2.46(2) and 2.48(2) Å (Yb); this order is in agreement with the variation of the ionic radii of the metals.[6] In the cation $[U(Pr^nbtp)_3]^{3+}$, the U–N_p bond lengths vary from 2.53(2) to 2.56(2) Å and the U–N_t distances range from 2.52(3) to 2.57(3) Å. These metal–nitrogen distances are shorter than those found in the cerium analogue, by 0.09 and 0.06 Å, if the average values are considered, while U^{III} and Ce^{III} have similar ionic radii.[6] Such a difference, which has never been observed in other pairs of analogous uranium and lanthanide complexes with neutral N-donor ligands,[4,7] could reflect some uranium to nitrogen π-back bonding[8] and some degree of covalency in the U–N bond. The distinctive structural features of the $[U(Pr^nbtp)_3]^{3+}$ cation, in comparison with its Ce^{III} counterpart, should be related to the outstanding capacity of btp molecules to coordinate trivalent actinides in preference to trivalent lanthanides, and can be attributed to the much softer character of the N atoms in this weakly basic ligand.

The coupling constants are equal to 6–8 Hz; 4-py and 3,5-py denote the H atoms at the 4 and 3,5 positions of the pyridine ring, respectively.

‡ *Crystal data*: for $[Ce(Mebtp)_3]I_3{\cdot}9C_5H_5N$: $C_{90}H_{90}I_3N_{30}Ce$, M = 2112.74, monoclinic, space group $P2/n$, a = 14.078(3), b = 13.889(3), c = 24.741(5) Å, β = 101.94(3)°, V = 4732.9(16) Å^3, Z = 2, D_c = 1.483 g cm^{-3}, μ = 1.520 mm^{-1}, $F(000)$ = 2114. R_1 = 0.052, wR_2 = 0.117, S = 1.026 for 7635 observed reflections with $I > 2\sigma(I)$ (R_{int} = 0.075) and 508 parameters.

For $[Ce(Pr^nbtp)_3]I_3{\cdot}3C_5H_5N$: $C_{84}H_{108}I_3N_{24}Ce$, M = 1974.76, monoclinic, space group Pc, a = 13.576(2), b = 19.695(2), c = 16.643(2) Å, β = 95.095(4)°, V = 4432.4(8) Å^3, Z = 2, D_c = 1.480 g cm^{-3}, μ = 1.615 mm^{-1}, $F(000)$ = 1994. R_1 = 0.093, wR_2 = 0.158, S = 0.956 for 12500 observed reflections with $I > 2\sigma(I)$ (R_{int} = 0.117) and 974 parameters. The structure was refined as corresponding to a racemic twin with x = 0.25(4).

For $[U(Pr^nbtp)_3]I_3{\cdot}4C_5H_5N$: $C_{89}H_{113}I_3N_{25}U$, M = 2151.77, triclinic, space group $P\bar{1}$, a = 13.431(1), b = 16.509(1), c = 21.140(2) Å, α = 80.601(4), β = 88.755(4), γ = 83.588 (5)°, V = 4595.4(6) Å^3, Z = 2, D_c = 1.555 g cm^{-3}, μ = 2.832 mm^{-1}, $F(000)$ = 2146. R_1 = 0.084, wR_2 = 0.174, S = 0.990 for 15377 observed reflections with $I > 2\sigma(I)$ (R_{int} = 0.093) and 1011 parameters.

The data were collected at 123 K on a Nonius Kappa-CCD area detector diffractometer using graphite monochromated Mo-Kα radiation (λ = 0.71073 Å). The structures were solved by direct methods. Absorption effects were empirically corrected, except in $[Ce(Mebtp)_3]I_3{\cdot}9C_5H_5N$, with the program DELABS from PLATON.[9] Some pyridine molecules in all three compounds were found to be disordered as well as the propyl groups and two iodide ions in $[U(Pr^nbtp)_3]I_3{\cdot}4C_5H_5N$. Hydrogen atoms were included at calculated positions as riding atoms, except those of the disordered fragments or molecules. All non-hydrogen atoms were refined anisotropically, except those of the disordered fragments and some pyridine molecules. The structures were refined by full-matrix least-squares on F^2 with SHELXTL.[10]

Synthesis of a linear-shaped tetramer and trimers of rhenium(I) diimine complexes†

Osamu Ishitani,* Keiko Kanai, Yoshinori Yamada and Kazuhiko Sakamoto

Graduate School of Science and Engineering, Saitama University, 255 Shimo-Okubo, Saitama 338-8570, Japan. E-mail: ishitani@apc.saitama-u.ac.jp

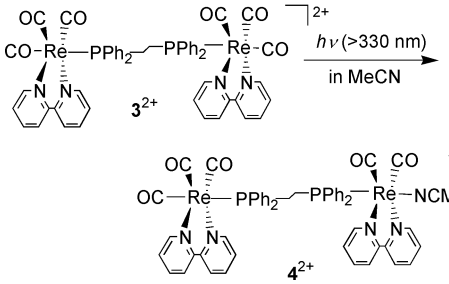
Received (in Cambridge, UK) 15th May 2001, Accepted 25th June 2001
First published as an Advance Article on the web 18th July 2001

First examples of a linear-shaped tetramer and non-symmetrical trimers of rhenium(I) diimine complexes have been synthesized in good yields, and their UV–vis absorption and emission spectra are reported.

Linear-shaped multinuclear complexes have excited much interest as electron or photon relays.[1,2] However, only certain kinds of metal complexes, for example, ruthenium(II) bisterpyridine derivatives[3] and *meso*-linked metalloporphyrins,[4,5] can be used as building blocks.[6] Also, rhenium(I) diimine complexes *fac*-[Re(LL)(CO)$_3$X]$^{n+}$ (LL = diimine ligand, X = monodentate ligand), for which the photophysics and photochemistry have been intensively studied,[7,8] have been used only as 'L-shaped' bent building blocks for supramolecules, such as molecular squares,[9–11] since only the ligands LL and X in positions *cis* to one another are easily modified.[12] In fact, only two 'linear-shaped' rhenium(I) diimine trimers, both having a symmetrical structure [{[Re(bpy)(CO)$_3$](dppene)}$_2$Re(LL)(CO)$_2$]$^{3+}$, have been reported so far because of the lack of general synthetic methods.[13]

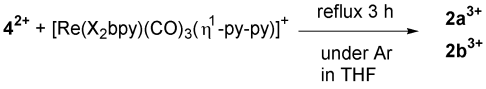
We report here new synthetic routes for 'linear-shaped' but non-symmetrical trimers of rhenium(I) diimine complexes. This new synthesis strategy is also successfully applied to obtain for the first time a 'linear-shaped' rhenium(I) tetrameter [{Re(bpy)(CO)$_3$(dppe)Re(bpy)(CO)$_2$}$_2$(py–py)]$^{4+}$ **1**$^{4+}$ (Scheme 1).

As a typical example, the synthetic procedure for [Re(bpy)(CO)$_3$(dppe)Re(bpy)(CO)$_2$(py–py)Re{(CF$_3$)$_2$bpy}(CO)$_3$]$^{3+}$ **2a**$^{3+}$, where bpy = 2,2′-bipyridine, dppe = 1,2-bis(diphenylphosphino)ethane, py–py = 4,4′-bipyridine, and X$_2$bpy = 4,4′-X$_2$-2,2′-bipyridine, is now reported. An acetonitrile (MeCN) solution (50 dm^3) of the PF_6^- salts of [{Re(bpy)(CO)$_3$}$_2$(dppe)]$^{2+}$ **3**$^{2+}$ (0.04 mmol) was irradiated under an argon atmosphere using a high-pressure mercury lamp with a glass filter (> 330 nm) for 40 min, giving [Re(bpy)(CO)$_3$(dppe)Re(bpy)(CO)$_2$(MeCN)]$^{2+}$ **4**$^{2+}$ [eqn. (1)].



(1)

After evaporation of the MeCN solvent, [Re{(CF$_3$)$_2$bpy}(CO)$_3$(py–py)]$^+$(PF_6^-) and tetrahydrofuran (5 dm^3) were added and the solution was refluxed under an argon atmosphere for 3 h. A red–orange solid consisting of (**2a**$^{3+}$)(PF_6^-)$_3$ was precipitated in 72% yield [eqn. (2)]



(2)

The further trimer [Re(bpy)(CO)$_3$(dppe)Re(bpy)(CO)$_2$(py–py)Re(bpy)(CO)$_3$]$^{3+}$ **2b**$^{3+}$ was also synthesized by a similar procedure in 78% yield. This photochemical method should be applicable for the synthesis of various rhenium(I) trimers [Re(X$_2$bpy)(CO)$_3$(PP)Re(X$_2$bpy)(CO)$_2$(BL)Re(LL)(CO)$_3$]$^{3+}$ (PP = diphosphorus ligand; BL = bridge ligand), because photoexcitation of rhenium(I) diimine complexes with a phosphorus ligand generally gives a good yield of the *cis*,*trans*-[Re$^{\mathrm{I}}$(LL)(CO)$_2$(PR$_3$)(L′)]$^{n+}$ type complexes.[14]

The tetranuclear complex **1**$^{4+}$ was also synthesized using the same photochemical product **4**$^{2+}$. This product was dissolved in THF containing half molar concentration of py–py. The solution was refluxed for 3 h to give (**1**$^{4+}$)(PF_6^-)$_4$ at 60% yield, based on **3**$^{2+}$ used [eqn. (3)]

(3)

The symmetrical dimers [{Re(LL)(CO)$_2$(MeCN)}$_2$(dppe)]$^{2+}$ are good candidates for synthetic building blocks for longer rhenium diimine oligomers because they have thermally-active acetonitrile ligands at both ends. Photochemical ligand substitution of **4**$^{2+}$ was much slower than for **3**$^{2+}$ because of the efficient energy transfer reaction from the excited state of the [Re(bpy)(CO)$_3$(dppe)–] group to the other group (specified below), but then proceeded to give [{Re(bpy)(CO)$_2$(MeCN)}$_2$(dppe)]$^{2+}$. Attempts to synthesize longer rhenium diimine oligomers are in progress.

The electrospray ionization mass spectra of the complexes essentially show just a parent peak, and the elemental analysis

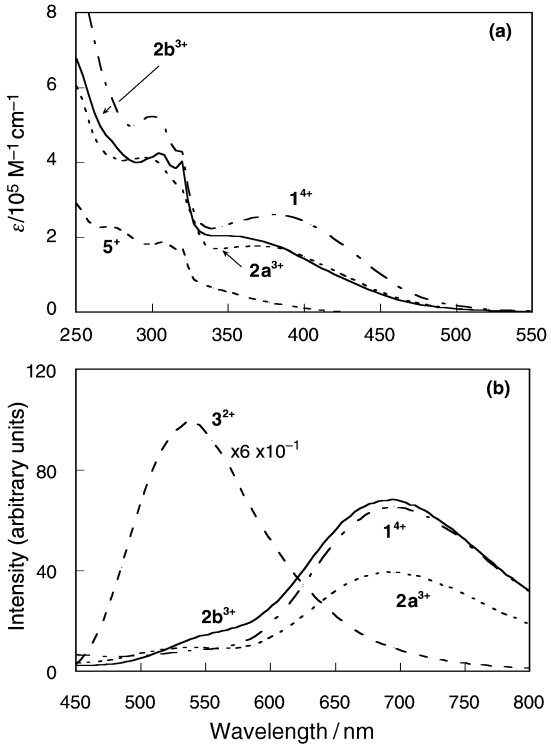

Fig. 1 (a) UV–vis absorption and (b) emission spectra (350 nm excitation) of $\mathbf{1}^{4+}$, $\mathbf{2b}^{3+}$, $\mathbf{3}^{2+}$ and $\mathbf{5}^{+}$ in acetonitrile.

data were in good agreement with the calculated values. The ^{1}H NMR spectra clearly indicate that the two pyridine rings of all the bpy and $(CF_3)_2$bpy ligands are magnetically equivalent and that the bridged ligands are in positions *trans* to one another, so that all the synthesized trimers and the tetrameter are linear-shaped.

We report preliminary spectroscopic data for the complexes synthesized. The UV–vis absorption spectra are shown in Fig. 1(a). The difference in the absorption maxima at 360–390 nm, due to metal-to-ligand charge transfer (MLCT), arises mainly from the differences in the constituent groups and their number. We chose two excitation wavelengths for emission measurements, at 350 and 440 nm: the higher energy photons can excite all the rhenium–complex groups in the oligomers while the other light is absorbed mainly by the central biscarbonyl group(s) [–{(dppe)Re^{I}(bpy)(CO)$_2$}$_2$(py–py)–] and one of the terminal tricarbonyl groups [Re^{I}{(CF$_3$)$_2$bpy}(CO)$_3$ (py–py)–].

Fig. 1(b) illustrates the emission spectra of both the tetramer $\mathbf{1}^{4+}$ and the corresponding dimer $\mathbf{3}^{2+}$ under 350 nm excitation; these differ greatly even though both complexes have the same emissive group, [Re^{I}(bpy)(CO)$_3$(dppe)–]. The strong emission of $\mathbf{3}^{2+}$, which arises from the triplet MLCT excited state (^{3}MLCT) of the [Re^{I}(bpy)(CO)$_3$(dppe)–] groups, was observed at 540 nm. The emission of $\mathbf{1}^{4+}$ at the same wavelength was much weaker, whereas another emission was observed at 695 nm, arising from ^{3}MLCT on the central groups [–(dppe)-Re^{I}(bpy)(CO)$_2$]$_2$(py–py)–]. This assignment is supported by the following experimental results: excitation of $\mathbf{1}^{4+}$ using 440 nm light absorbed mostly by the central groups gave emission only at 695 nm, and a model complex of the central groups [Re^{I}(bpy)(CO)$_2$(PPh$_2$Pr)(η^1-py–py)]$^+$ emits at 710 nm. The strength of the 695 nm emission stimulated by the 440 nm excitation, normalized using the absorbance, was only 1.3 times greater than that stimulated by the 350 nm excitation. These results clearly show that efficient energy transfer occurs from the excited state of the terminal [Re^{I}(bpy)(CO)$_3$(dppe)–] groups to the central [–{(dppe)Re^{I}(bpy)(CO)$_2$}$_2$(py–py)–] groups in $\mathbf{1}^{4+}$ as shown in Scheme 1.

The trimer $\mathbf{2b}^{3+}$ has a different emission property: excitation using 350 nm light causes dual emission, at 540 and 670 nm [Fig. 1(b)], whereas 690 nm emission alone was observed with 440 nm excitation. The emission at 540 nm arises from ^{3}MLCT of the [Re^{I}(bpy)(CO)$_3$(py–py)–] group, because the corresponding mononuclear complex [Re^{I}(bpy)(CO)$_3$(η^1-py–py)]$^+$ $\mathbf{5}^{+}$ emits at 570 nm and the excitation of another terminal [Re^{I}(bpy)(CO)$_3$(dppe)–] group should cause efficient energy transfer to the central group, as described above. Energy transfer from the excited [Re^{I}(bpy)(CO)$_3$(py–py)–] group to the central group is expected to occur (Scheme 1) because the emission strength from the [Re^{I}(bpy)(CO)$_3$(py–py)–] group was much less than that of the model complex.

Emission from $\mathbf{2a}^{3+}$ using either 350 or 440 nm light was weaker than that from $\mathbf{2b}^{3+}$. It follows that the ^{3}MLCT state of the central [–{(dppe)Re^{I}(bpy)(CO)$_2$}$_2$(py–py)–] group should be quenched by the terminal [Re^{I}{(CF$_3$)$_2$bpy}(CO)$_3$(py–py)–] group. There are two possible quenching mechanisms: energy transfer and electron transfer. Energy transfer might not occur because the ^{3}MLCT energy of the central group is lower than that of the [Re^{I}{(CF$_3$)$_2$bpy}(CO)$_3$(py–py)–] group, of which the model complex [Re^{I}{(CF$_3$)$_2$bpy}(CO)$_3$(η^1-py–py)]$^+$ emits at 660 nm.

Further study of the intramolecular electron- and/or energy-transfer processes of rhenium(I) oligomers is in progress using laser flash photolysis.

Biodegradable thermoreversible gelling PLGA-g-PEG copolymers†

Byeongmoon Jeong,* Li-Qiong Wang and Anna Gutowska*

Pacific Northwest National Laboratory (PNNL), 902 Battelle Boulevard, P.O. Box 999, K2-44, Richland, WA 99352, USA. E-mail: byeong.jeong@pnl.gov; Anna.Gutowska@pnl.gov

Received (in Columbia, MO, USA) 14th March 2001, Accepted 11th May 2001
First published as an Advance Article on the web 26th July 2001

The thermogelling aqueous solution of poly(DL-lactic acid-*co*-glycolic acid) grafted with poly(ethylene glycol)s is developed, and the elegant instrumental methods to determine sol–gel transition temperature and the method to control gel duration are reported.

Self-assembly of polymers by external stimuli has been studied extensively over the past decade.[1,2] *In situ* gelling systems have recently generated attention as promising biomaterials.[3–6] To apply *in situ* gelling systems for drug delivery and tissue engineering, the aqueous polymer solution should be free flowing at a certain temperature and form a gel at the physiological temperature. The resultant gel must have reasonable mechanical strength to persist as a drug-releasing depot over the designed lifetime.

The synthesis of thermogelling poly(ethylene glycol-*b*-(DL-lactic acid-*co*-glycolic acid)-*b*-ethylene glycol) (PEG-PLGA-PEG) triblock copolymers by Jeong *et al*. required two steps.[7,8] The ring-opening polymerization of DL-lactide and glycolide on methoxy poly(ethylene glycol), followed by the coupling of the PEG-PLGA diblock with hexamethylene diisocyanate (HMDI) requires strict anhydrous conditions. The resulting triblock copolymer contains two urethane linkages, which might affect the degradation profile of the polymer. However, there is a limitation of molecular weight for PEG-PLGA-PEG copolymers by a triblock topology. Because the sol–gel transition temperature strongly depends on the PEG length, the total molecular weight of PEG-PLGA-PEG triblock copolymers should be 4000–5000, if aqueous solutions are to show a sol–gel transition below 37 °C.[7]

In this paper, thermogelling aqueous solutions of biodegradable graft copolymers, poly(DL-lactic acid-*co*-glycolic acid) grafted with poly(ethylene glycol)s (PLGA-g-PEG) are reported and we will show that such a molecular weight limitation can be overcome by graft copolymer systems.

PLGA-g-PEG copolymers were synthesized by one-step ring opening polymerization of DL-lactide, glycolide, and epoxy terminated poly(ethylene glycol) (PEG; M = 600) using stannous octanoate, as a catalyst.[9] The final DL-lactic acid/glycolic acid/ethylene glycol mol ratio of 3.2/1/2.8 was determined by ^{1}H NMR spectroscopy. Therefore, the grafting frequency of PEG is 4.7 mol%. Gel permeation chromatography (GPC) using light scattering and refractive index detectors in series has been used to determine the absolute molecular weight of polymers.[10] GPC results found a unimodal distribution for our polymers. The number average molecular weight (M_n) and polydispersity (M_w/M_n) of the polymers determined by GPC using tetrahydrofuran (THF) as an eluting solvent were 9300 Daltons and 1.5, respectively. Therefore, the 4–5 PEGs are grafted onto the PLGA backbone.

At 23 °C, the viscosity of the aqueous solution (25 wt%) was *ca*. 0.3 P (g m^{-1} s^{-1}). This viscosity is suitable for injecting the solution through a 25-gauge syringe needle. With increasing temperature, the aqueous solution (25 wt%) of PLGA-g-PEG undergoes a sol–gel transition at 30 °C. In the practical application, the gel should keep its equilibrium-swollen state in an excess amount of water. Further increase in temperature above 50 °C of the PLGA-g-PEG aqueous solution results in a macroscopic phase separation between gel and water. The entire phase diagram will be reported elsewhere.[11] The gel state has been traditionally defined as a non-flowing semisolid in a test-tube inversion test. The method is controversial in its simplicity and lack of scientific rigidity.

To address this issue, the sol–gel transition of the graft copolymer aqueous solution was investigated using dynamic rheometry (Rheometric Scientific: SR 2000).[12] The polymer solution was placed between parallel plates of 25 mm diameter and a gap of 0.5 mm. The data were collected under a controlled stress (4.0 dyn cm^{-2}) and a frequency of 1.0 radian s^{-1}. The heating and cooling rate was 0.2 °C min^{-1}. According to dynamic rheometry, the sol–gel transition was identified in a more reproducible and quantitative manner than by the test-tube inversion method.

The storage moduli (G') of PLGA-g-PEG aqueous solutions varying from 22 to 29 wt% were measured at a heating rate of 0.2 °C min^{-1}. As the temperature increased, the storage modulus increased abruptly at the sol–gel transition temperature. The gels have a modulus of *ca*. 50 dyn cm^{-2} and are slightly affected by concentration in the range of 22–29 wt%. The sol–gel transitions occur at *ca*. 30 °C, suggesting easy formulation at room temperature.

To confirm the reversibility of the sol–gel transition, a 25 wt% PLGA-g-PEG aqueous solution was studied. The real part (η') of complex viscosity of the polymer solution, which is a measure of dissipated energy when cyclic deformation is applied to a material, is shown as a function of temperature in Fig. 1(a). During the first heating cycle (H1), η' increased 1000 times upon the sol–gel transition. The cooling curve (C1) shows that the gel phase persisted over the temperature range of 43–20 °C during the experiment. This fact results from the difficulty in molecular motion to occur in the gel phase; once the solution forms a gel, the gel resists rehydration. η' abruptly decreased at 15 °C due to the gel–sol transition during the cooling of the system. The second heating curve (H2) shows the sol–gel transition at practically the same temperature as the first heating curve (H1).

The storage modulus (G') of the PLGA-g-PEG aqueous solution (25 wt%), which is a measure of stored energy when a cyclic deformation is applied to a material, approaches zero in the sol state and is not shown in the heating curve [Fig. 1(b); H1]. G' sharply increased during the sol–gel transition at 32 °C as shown in the heating curves. The maximum value for G' was observed in the temperature range 35–39 °C, indicating a promising material for *in vivo* (37 °C) applications. During the cooling cycle (C1), the gel modulus increased over the temperature range 43–20 °C, exhibiting similar behavior to typical elastic materials, and dropped abruptly at 15 °C due to the gel–sol transition. During the first (H1) and second (H2) heating cycle, practically the same transition curve was measured for G', indicating reversible gelation. The decrease in G' at temperatures above 40–45 °C can be expected due to an increase in thermal motion. This trend was also observed in the ^{13}C NMR spectra (see ESI†).

† Electronic supplementary information (ESI) available: ^{1}H NMR spectrum of PLGA-g-PEG in $CDCl_3$. ^{13}C NMR (75 MHz) spectra of 25 wt% PLGA-g-PEG copolymer in D_2O as a function of T. See http://www.rsc.org/suppdata/cc/b1/b102819g/

 DOI: 10.1039/b102819g

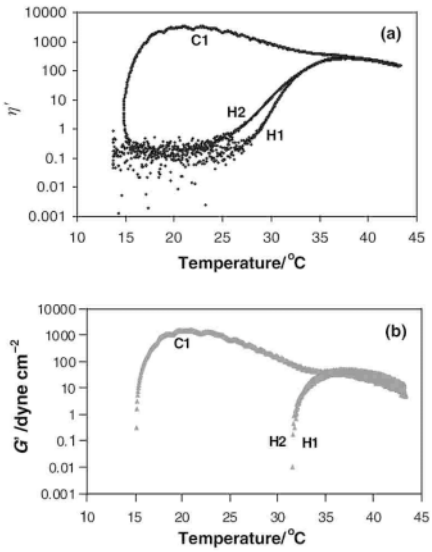

Fig. 1 Rheological study of PLGA-g-PEG copolymer aqueous solutions (25 wt%). The thermogram was obtained while heating and cooling with a rate of 0.2 °C min^{-1}. Temperature programming sequence was heating → cooling → heating. H1, C1 and H2 indicate the first heating cycle, cooling cycle and the second heating cycle, respectively. The real part (η') of complex viscosity, (a), and the storage modulus (G'), (b), of the copolymer solution were measured as a function of temperature.

The ^{13}C NMR spectra of a 25 wt% copolymer solution in D_2O were recorded with increasing temperatures. In the sol state (20 °C), the methyl peak of the hydrophobic PLGA (δ 18) is collapsed and broadened compared with PEG peak (δ 72) whereas that in $CDCl_3$ appears as a sharp peak, indicating a core–shell structure of this polymer in water. The core–shell structure of these amphiphilic copolymers was also confirmed by micelle formation in dilute aqueous solutions. The critical micelle concentration (CMC) determined by a dye solubilization method was 0.03 wt% at 20 °C.[13]

Just above the sol–gel transition temperature (33 °C) of an aqueous PLGA-g-PEG solution (25 wt%), the ^{13}C NMR peak shapes of both the hydrophobic PLGA methyl peak and the hydrophilic PEG peak are preserved except that the PEG peak is shifted down field about 0.3 ppm. With a further increase in temperature, the peak height of the PLGA methyl peak increases, and the PEG peak is split into two peaks, a sharp one at δ 72.4 and a broad one at δ 72.7. These behaviors are thought to be caused by an increase in molecular motion of the hydrophobic backbone and phase mixing between PEG and PLGA. Phase mixing between PEG and PLGA or PLLA has been previously reported.[14] A further increase in temperature resulted in macrophase separation between water and the polymer.

The reversibility of the sol–gel transition is also confirmed by deuterium NMR spectroscopy (Fig. 2). The peak at δ 4.8 at 20 °C (sol state) shifted to δ 4.6 at 33 °C (just above sol–gel transition), δ 4.58 at 37 °C (gel state), δ 4.56 at 40 °C, and δ 4.5 at 50 °C (syneresis). The change in chemical shift was most pronounced during the sol–gel transition (δ 0.2). When the system is cooled to 20 °C, the deuterium peak reappears at δ 4.8, indicating the reversibility of the transition. In a sol state, water moves more freely than in a gel state. During the sol–gel transition, PEG becomes more hydrophobic due to dehydration and the extent of hydrogen bonding between water molecules and polymers changes. Therefore, the time average environment around deuterium nuclei will be affected, leading to the changes in chemical shift of water during the sol–gel transition. This finding suggests that the deuterium NMR can be a good method for the determination of the sol–gel transition.

The sol–gel transition temperature could be controlled from 20 to 40 °C by changing PEG length and composition. When the PEG molecular weight of PLGA-g-PEG was increased from 600 to 1000 the sol–gel transition occurred at 40 °C, whereas the sol–gel transition occurred at 20 °C when the PEG composition was decreased by 20 mol%.[11]

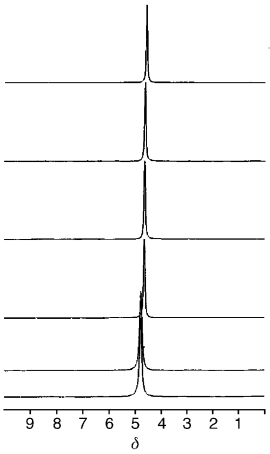

Fig. 2 Deuterium NMR showing reversibility of the sol–gel transition. The deuterium NMR spectra of PLGA-g-PEG in D_2O (25 wt%) were recorded at 20 (5th row from the top), 33 (4th row), 37 (3rd row), 40 (2nd row), 50 (1st row) °C, and after cooling to 20 °C (6th row). The sample was held at each temperature for 30 min.

To conclude, an aqueous PLGA-g-PEG system showing a reversible sol–gel transition at slightly elevated temperatures is developed and a dynamic mechanical test and deuterium NMR confirm the reversibility of this process. These tools can be suggested as standard methods to determine the sol–gel transition temperature than the more empirical test-tube inverting method reported most often.

The system developed in this study is very promising for injectable local delivery of pharmaceutical agents. *In vitro* study shows that the duration of gels could be controlled from one week to three months by mixing slow degrading PLGA-g-PEG and fast degrading PEG-g-PLGA in different ratios.[15] Both polymer aqueous solutions undergo a sol–gel transition around 30 °C. This is very important for applications in drug delivery and tissue engineering, which need the control of gel duration as a matrix or carrier.

First published as an Advance Article on the web 26th July 2001

Hollow clay microspheres of high thermal stability were easily fabricated by the adsorption of colloidal clay layers onto the surfaces of a spherical anion exchange resin and calcination of the resulting resin–clay composite.

Hollow spheres of nanometer to micrometer dimensions define an important class of shape-fabricated materials in which the shell of the hollow sphere can be constructed by a variety of materials of high scientific interest and technological importance; magnetic, semiconducting, ceramic, metallic, polymer, composite *etc*.[1–3] Owing to their low density, large specific area, stability and surface permeability, hollow spheres are widely used as controlled release capsules for drugs, dyes, cosmetics and inks, artificial cells, catalysts and fillers. Engineering hollow spheres from porous solids, such as mesoporous silica[4–6] and zeolites,[7] constitutes an important advance in materials, because of the unique properties of these well organized superstructures. Recently, the fabrication of hollow laponite submicrometer spheres (laponite is a synthetic smectite clay) based on the layer-by-layer self-assembly technique, was reported.[8] In this communication we report another approach for easy construction of hollow inorganic spheres, and in particular, describe the synthesis and characterization of thermally stable hollow smectite clay spheres in the micrometer range. In general, the production of clay spheres is expected to be of great value since smectite clays define a known class of layered aluminosilicate minerals that possess unique swelling, intercalative and cation exchange properties.[9] In addition, their thermal stability and chemical inertness make them suitable materials for particle engineering (clay ceramics) and for use as fillers in many industrial applications.[10,11] The method proposed for the morphogenesis of hollow clay microspheres, simply comprises the adsorption of colloidal acid clay layers onto the surfaces of a spherical anion exchange resin (carbonated form), followed by removal of the resin's organic backbone by calcination in air. In principle, our synthetic strategy resembles that of the sacrificial core–shell technique in which hollow spheres are assembled by a controlled adsorption, involving precipitation reactions, sol–gel condensations and layer-by-layer depositions of the desirable material onto the surfaces of an appropriately modified colloidal template (usually a polymer) and subsequent removal of the template by thermal or chemical treatment.[12–15]

In this work, a strongly basic anion exchange resin of a quaternary ammonium chloride type and spherical morphology (Dowex 2, x8 100/200 mesh) was used. The resin was initially treated with 1 M Na_2CO_3 aqueous solutions in order to obtain its carbonated form. Two sources of clay were used. The first, was a naturally occurring montmorillonite from the island of Milos, Greece, denoted Zenith-N. The montmorillonite was fractionated to <2 μm by gravity sedimentation and purified by standard methods to obtain its sodium saturated form with a CEC of 0.8 meq. g^{-1}. The second was a synthetic sodium hectorite (laponite, monovalent cation exchange capacity: CEC = 0.74 meq. g^{-1}) supplied by Laporte Industries Ltd. The resin–clay products were obtained as follows: 1 g of each clay sample was dispersed in 100 ml of deionized water. To each colloidal dispersion, 1–2 drops of concentrated HCl (37%) were added (pH of the mixture *ca*. 3) and the gelatinous mixtures were vigorously stirred for 1 min. After centrifugation of the solids, the supernatant liquids were discarded and the same procedure was repeated twice. Finally, the acid clays were washed once with water, centrifuged and redispersed in 100 ml of deionized water. Each acid clay colloidal dispersion was then slowly added to 4 g of carbonated resin in 20 ml of deionized water and the mixture was heated under vigorous stirring at 80 °C for 30–45 min. During the addition of the acid clay dispersions to the carbonated resin and the thermal treatment, evolution of gas (CO_2) was observed, indicating the binding of the negatively charged clay layers to the positively charged resin surfaces according to eqn. (1) where $Resin^+]$

$$Resin^+]CO_3^{2-} + 2H^+[^-Clay \rightarrow Resin^+][^-Clay + CO_2 + H_2O \quad (1)$$

denotes the positively charged surfaces of the resin and $[^-Clay$ denotes the negatively charged clay layers. After the thermal treatment, the resin–clay mixtures were centrifuged (4000 rpm, 1 min), washed twice with commercial acetone and dried at 60 °C for 20 min in an oven. Observation of the resin–clay samples under an optical microscope did not reveal the presence of any discrete clay phase but only the presence of transparent resin spheres, suggesting a homogeneous coverage of the resin surfaces by a thin clay coating. The as obtained resin–clay samples were finally calcined in air at 600 °C for 7 h *via* steps of 1 °C min^{-1} to give pure hollow clay microspheres as evidenced by the lack of organic absorptions in IR spectra. The final samples were studied by optical microscopy, SEM and XRD techniques.

Optical microscopy images of the parent anion exchange resin as well as the Zenith-N and laponite clay samples derived after calcination of the corresponding resin–clay composites are shown in Fig. 1. The XRD patterns of the clay samples are also included as inset photos. The parent amorphous resin particles possess a spherical morphology with a non-uniform size distribution of small and large spheres in the range 100–200 μm. On the other hand, both clay samples also consist of spherical particles (Zenith-N spheres: opaque and with rough surfaces, laponite spheres: transparent and with smooth surfaces) with a non-uniform size distribution in the range 20–50 μm. Therefore, the clay samples inherit the shape morphology and size non-uniformity of the parent resin throughout the synthetic process. Accordingly, by controlling the size distribution of the starting resin particles, *e.g*. by sieving the resin, the problem of the size non-uniformity can be eliminated. As far as the observed size shrinkage of the clay samples is concerned, this can be attributed to the removal of the large resin core (at least 100 μm) after calcination of the resin–clay composites. The spheres based on Zenith-N show a weak (001) XRD reflection with a basal spacing (d_{001} = 9.8 Å) characteristic for the collapsed state of the layers in the prime clay particles. In contrast to Zenith-N, the laponite based spheres do not exhibit any (001) reflection that may be attributed to a turbostatic stacking of the

 DOI: 10.1039/b104922b

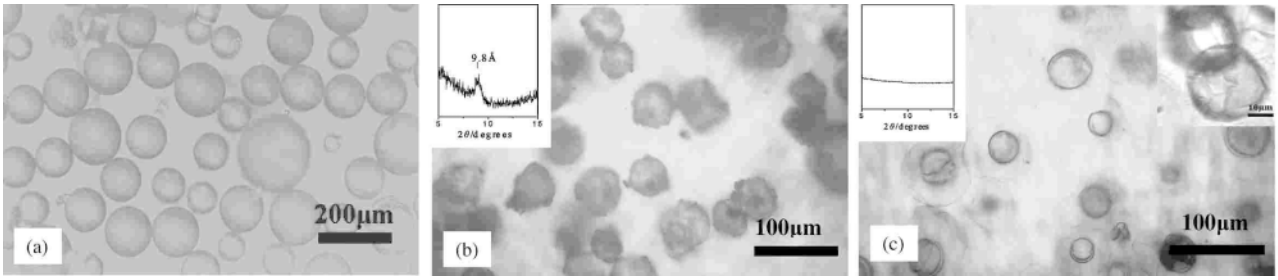

Fig. 1 Optical microscopy pictures of (a) parent resin spheres, (b) Zenith-N clay spheres and (c) laponite clay spheres (the inset photos show XRD patterns of the given clay samples).

layers in the clay particles due to their very small size (*ca.* 0.1 μm *cf. ca.* 1 μm for Zenith-N).

The SEM examination of Zenith-N and laponite samples reveals the presence of compact and intact spheres which are smoother in the latter, Fig. 2. The inset photo, Fig. 2(a), shows a broken sphere that reveals the hollow structure of the spheres. The wall thickness of the spherical cells is rather uniform and varies between 3 and 5 μm for both clay samples. Note that the large majority of the hollow clay spheres are intact at their surfaces. In contrast to this observation, when the clay samples were prepared using the sodium form of Zenith-N and laponite instead of the acid forms, and the chloride form of the resin instead of carbonated form, clay samples consisting primarily of broken specimens with irregular shape and morphology were obtained, features that were more pronounced for the laponite sample. It seems that the resin surfaces are not sufficiently covered by clay layers to form a thick enough coating that remains intact after calcination. This probably arises from the strong electrostatic binding of chloride ions by the positively charged surface of the resin thus making their efficient replacement by the negatively charged clay layers difficult.

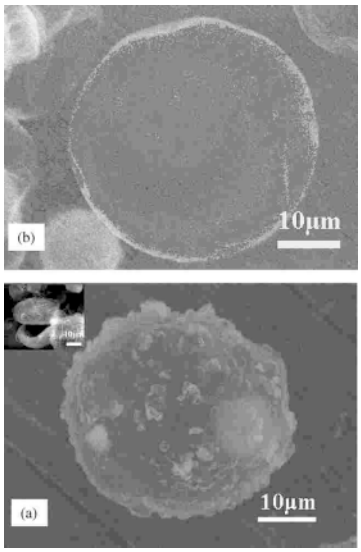

Fig. 2 SEM micrographs of a Zenith-N (a) and laponite (b) hollow clay sphere (the inset photo shows a broken Zenith-N hollow specimen).

Fig. 3 shows XRD patterns of Zenith-N clay spheres before (a) and after (b) treatment with trimethylamine vapor at 80 °C for 3 h. After vapor treatment, the basal spacing of the collapsed clay (d_{001} = 9.8 Å) increased to 12.8 Å due to the insertion of trimethylamine molecules into the gallery space of the clay layers *via* interlayer protonation of the base. The results show that the hollow clay spheres can be easily reconstructed to other clay derivatives *via* intercalative patterning of their interlayer space. For laponite, insertion of trimethylamine into the galleries does not alter the amorphous state of the clay shell, even after prolonged exposure. In this case, the lack of layer re-stacking may be attributed to some chemical sintering occurring after calcination, between laponite layers through cross-linking of adjacent broken sites (much greater in number than for

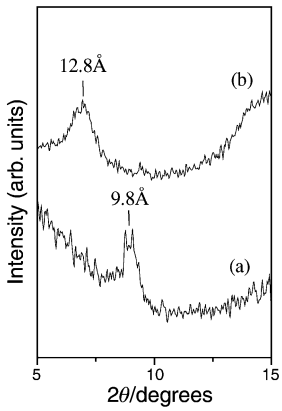

Fig. 3 XRD patterns of Zenith-N hollow spheres (a) before and (b) after trimethylamine vapor treatment.

Zenith-N due to the smaller size of the layers) near their edges.[8] It should be noted that the morphology of the clay samples was preserved after the above mentioned treatments.

In conclusion, thermally stable hollow microspheres (size: 20–50 μm, wall thickness: 3–5 μm) of a naturally occurring and of a synthetic clay were prepared using the sacrificial core–shell technique, in which an anion exchange resin played the role of the core/template and the clay particles the role of the building units of the shell. Intact hollow spheres were obtained only when a carbonated resin and an acid clay were used, as this combination provides an efficient way to sufficiently cover the resin surfaces with the clay layers without screening effects from the counter ions of the resin. The template approach described here can also apply to fabrication of micrometer sized analogues of clay colloidal systems, *e.g.* zeolites and magnetic particles. In a forthcoming publication the ability to synthesize a variety of hollow inorganic microspheres by simply exploiting the exchange properties of the resin will be described.

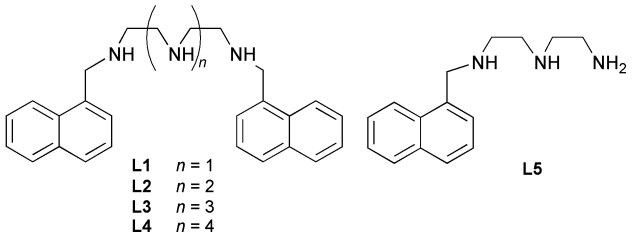
Received (in Cambridge, UK) 16th May 2001, Accepted 27th June 2001
First published as an Advance Article on the web 26th July 2001

A series of compounds made up by linking methylnaphthalene fragments at both ends of different polyamine chains have shown to behave as pH-regulated molecular machines driven by light and fluorescence emission studies have proved the formation of an excimer between the two naphthalene units whose appearance, fluorescence intensity and decay times depend on the pH value of the media.

Many biological systems can be considered as more or less complex molecular machines operated by chemical or physical stimuli. Examples of this behaviour are found in the triggering effect of many calcium binding proteins or in the astonishing ATP synthase molecular rotor.[1,2] Therefore, in the last few years a lot of research effort has been devoted to identifying systems able to perform molecular motions following chemical or physical inputs.[1–9] Herewith, we communicate on a family of very simple compounds whose molecular movements driven by light can be controlled and even modulated by inputs like the concentration of hydrogen ions and/or metal ions. Compounds L1–L5 have been prepared in good yields by reaction of the



elected polyamine with naphthalene-1-carbaldehyde in ethanol followed by reduction with sodium borohydride.[10]

While the absorption spectra of these compounds do not change significantly with pH, the fluorescence emission intensity dramatically depends on their protonation state (see Fig. 1A for L1). As described for related compounds,[10] the fully protonated forms of L1–L5 exhibit the most intense fluorescence emission. Unprotonated amines are efficient electron transfer quenchers of the aromatic excited state and depending on the distance to the fluorophore can produce a partial or complete quenching. This trend is illustrated in Fig. 1B, where the fluorescence emission intensity monitored at 334 nm is plotted together with the mole fraction distribution of the different protonated species calculated from the protonation constants determined potentiometrically.[11] In order to have a full picture of the situation, the protonation sequence established for L1 by means of the ^{1}H and ^{13}C NMR data has to be taken into account. As shown in Fig. 1B, the first deprotonation that occurs on the central nitrogen atom leads to a partial quenching, *ca.* 80% of the emission of the fully protonated form. Total quenching takes place only upon removing the second proton from one of the side nitrogens. However, the most remarkable feature in the emission spectra of these compounds is the presence of a red-shifted and non-structured band attributable to excimer formation (Fig. 1A). This red shitted band does not appear in the case of the compound containing a single terminal naphthalene (L5), or in the case of an analogue receptor possessing a reinforcing piperazine ring (L6, see ESI). This absence in L5 excludes the possibility of a charge transfer (CT) state involving the deprotonated amine and the fluorophore.[12]

Excimer formation is only observed for the H_2L1^{2+} species. Neither the fully protonated species H_3L1^{3+} nor the species with lower protonation degrees yield such association. In the case of H_3L1^{3+}, this can be ascribed to the large electrostatic repulsion at this stage which prevents the required bending movement while the total quenching of the emission produced in the low protonated species would avoid observing any excimer formation.

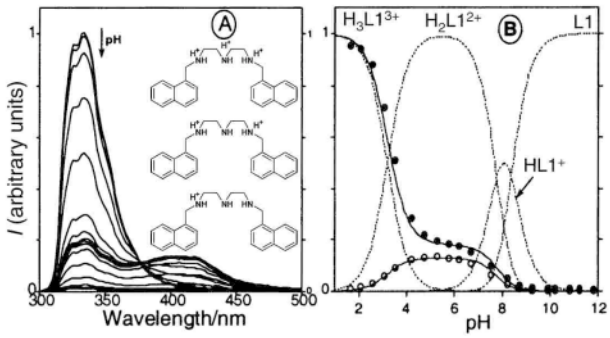


Fig. 1 A—pH dependence of the fluorescence emission of compound L1 at λ_{exc} = 287 nm. Protonation sequence determined by ^{1}H NMR is shown in the inset. B—Mole fraction distribution of the protonation states of compound L1 (-----); fluorescence emission at λ_{exc} = 287 nm and λ_{em} = 334 nm (●); fluorescence emission at λ_{exc} = 287 nm and λ_{em} = 418 nm (○).

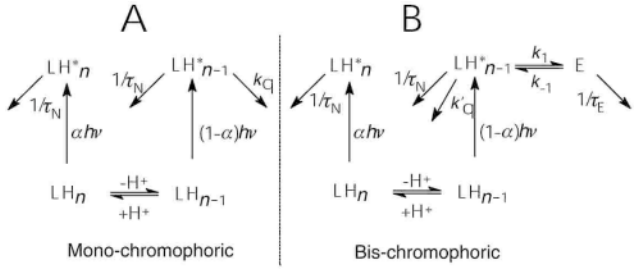
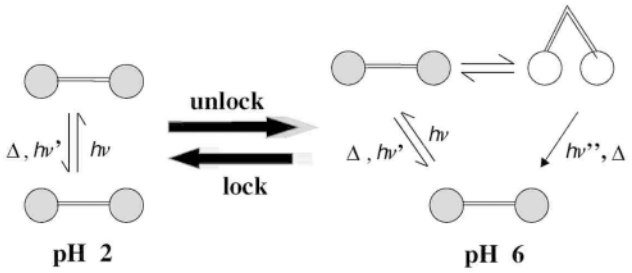
† Electronic supplementary information (ESI) available: synthesis and characterisation data for L1–L4, protonation constants and spectra. See http://www.rsc.org/suppdata/cc/b1/b104311k/

 DOI: 10.1039/b104311k



Scheme 1



Scheme 2

Intramolecular excimer formation was studied by nanosecond time-resolved fluorescence. Fluorescence decays were monitored at λ_{em} = 315 nm, where the fluorescence emission is essentially due to the excited monomer, and at λ_{em} = 418 nm, where the excimer emits. Global analysis of the decays can only be properly fitted with sums of two or three exponentials. The fluorescence emission behaviour of the mono-chromophoric and bis-chromophoric systems can be interpreted as depicted in Schemes 1A and 1B for the triaza receptors L5 and L1, respectively. In both cases, a ground-state equilibrium exists between the fully protonated species (H_3L^{3+}) and the mono-unprotonated one (H_2L^{2+}). Simultaneous excitation of both H_3L^{3+} and H_2L^{2+}, leads to H_3L^{3+*} and H_2L^{2+*} excited species; the relative proportion of these species will depend on the pH (Fig. 1B). While H_3L^{3+*} decays with a rate constant equal to the reciprocal of τ_N, H_2L^{2+*} presents an additional direct quenching to the ground-state by the CT state with k_q (rate constant due to amine quenching); the overall decay for the H_2L^{2+*} species is equal to $1/\tau_N + k_q$.

The question arising now is the correct attribution of the observed components of the decay times to the species shown in Fig. 1B for L1. At pH = 4.6, the H_3L1^{3+} and H_2L1^{2+} species coexist with the excimer. At pH = 2.3, where practically no excimer is observed, we have obtained a double-exponential decay with decay times equal to 29.6 and 2.9 ns, and pre-exponential factors, a_i, of respectively 0.93 for H_3L1^{2+} and 0.07 for the small amount of the H_2L1^{2+} species present at this pH. At pH = 3.2 the two monomers coexist with the excimer. While H_2L1^{2+*} with a decay time of 3.4 ns gives rise to the excimer (τ_E = 15.8 ns), the more protonated monomer is found uncoupled with the other emissive species and must unequivocally be attributed to the H_3L1^{3+} species. Also it is worth noting that the negative pre-exponential at λ_{em} = 418 nm is associated with the shorter lifetime (H_2L1^{2+}) and that no negative amplitude is associated with the longer lifetime (H_3L1^{3+}). This once more shows that the H_3L^{3+} species decays with a lifetime identical to the one obtained at pH = 2.3 and to the one of L5 (where no intramolecular excimer formation occurred).[10] For pH = 6.1 the system is now reduced to a bi-exponential decay law since the H_3Ll^{3+} species is absent (see ESI). The H_2L1^{2+*} species will have at this pH two additional deactivation channels: i) electron quenching promoted by unprotonated amino groups, k_q, and ii) excimer formation, k_1. This situation does not apply to the case of H_3L1^{3+*} because excimer formation is forbidden and the only possible deactivation route occurs *via* its natural fluorescence lifetime ($\approx$31 ns). Comparison with the excited state behaviour of L5, where only a double-exponential fit is required, clearly supports the above considerations.

Another interesting aspect is the existence of excited state reversibility of the excimer leading to delayed fluorescence emission because, as reported above, the intermediate lifetime emission can also be detected at 315 nm.

Although the behaviour of L2, L3 and L4 is analogous to that of L1, several aspects deserve comment. The quenching processes and the efficiency of excimer formation are strongly affected by the length of the chain and the protonation states of the molecules. Indeed, the protonation degree for which the ratio excimer–monomer emission is maximum increases proton by proton from one receptor to the following in size; for L2 it is H_2L2^{2+}, for L3 it would be H_3L3^{3+} and for L4, H_4L4^{4+}. In all these species the central nitrogens are unprotonated facilitating the delocalisation of the positive charges along the chain.

All these data clearly point out that the compounds here described are examples of elementary molecular movements driven by light and switched on/off by pH. Scheme 2 for compound L1 illustrates this concept. At pH values below 2, the system is rigid and no bending movement occurs upon light absorption; in this state the system is locked. The unlock step takes place following a pH jump to 6. For this pH value, light absorption by the monomer leads to excimer formation as well as to the back reaction responsible for the delayed fluorescence.

First published as an Advance Article on the web 15th August 2001

The epothilones have occupied center stage on the scenes of total synthesis, chemical biology and medicine for the last five years, no doubt because of their intriguing mode of action and unusually high potency against tumor cells, including multi-drug-resistant cell lines. This article highlights the most recent advances within this exciting field. Thus, an overview of recent synthetic endeavors culminating in a new generation of total syntheses and analogues, some with higher potencies than the naturally occurring substances, will be given, and the chemical biology, in particular the current understanding of structure–activity relationships of the epothilones, will also be discussed in light of the latest biological results. In addition, the recently elucidated biosynthetic machinery of the natural epothilone-producing myxobacterium *Sorangium cellulosum*, as it is now understood, will be described. Finally, some preclinical and clinical studies will be summarized.

† Dedicated to Drs Margaret Harris and Muriel Hall of Bedford College, London, for their dedicated and inspiring teachings and research contributions in celebration of their retirement.

K. C. Nicolaou, born in Cyprus and educated in England and the US, is currently Chairman of the Department of Chemistry at The Scripps Research Institute where he holds the Darlene Shiley Chair in Chemistry and the Aline W. and L. S. Skaggs Professorship in Chemical Biology as well as Professor of Chemistry at the University of California, San Diego. His impact on chemistry, biology and medicine flows from his works in organic synthesis described in over 500 publications and 65 patents and his dedication to chemical education resulted in the training of over 300 graduate students and postdoctoral fellows. His recent book titled Classics in Total Synthesis, *which he co-authored with Erik J. Sorensen, is used around the world as a teaching tool and source of inspiration for students and practitioners of the art of organic synthesis.*

Andreas Ritzén was born in Nicosia, Cyprus, in 1973. After completing a BSc in Organic Chemistry with Professor Rolf Carlson at Umeå University, Sweden, in 1994, he received his PhD degree in Organic Chemistry under the supervision of Professor Torbjörn Frejd at Lund University, Sweden, in 2000. He is currently a Research Associate at The Scripps Research Institute with Professor K. C. Nicolaou.

Kenji Namoto was born in 1973 in Chiba, Japan, and received his BSc in 1997 from Waseda University, Tokyo. In the same year, he joined a PhD program in chemistry at the Scripps Research Institute, La Jolla, California, where he currently conducts graduate research under the guidance of Professor K. C. Nicolaou. His major research interest is design and synthesis of biologically active compounds.

Introduction

Cancer claims approximately one death per minute in the United States alone. As such, this dreaded disease has stimulated enormous efforts directed at curative and preventive strategies to combat its menacing effects on society. Chemistry and biology provide most unique platforms for addressing this problem as evidenced by the several chemotherapeutic agents discovered and developed through endeavors in these disciplines. Prominent among them are Taxol® and Taxotere™, two tubulin binding anticancer drugs[1] whose combined sales exceed the 2 billion dollar mark. As a new class of potent tubulin polymerizing and microtubule stabilizing compounds, the epothilones[2] have received a great deal of attention over the last few years from chemists, biologists and clinicians. Research activities in this area span from isolation of natural products to genetic engineering of new producing organisms for fermentation purposes, from total synthesis to chemical synthesis of designed analogues, and from chemical biology to clinical studies. Despite the several reviews[3–6] covering the great strides made in the epothilone area, the fast pace of research surrounding these molecules necessitates this update which aims at summarizing and placing in perspective the latest developments in the field.

Recent total syntheses of epothilones and analogues thereof

Many groups have reported the total or partial syntheses of epothilone family members (Fig. 1) during the past years, and

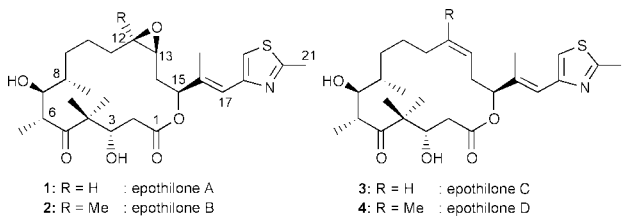

Fig. 1 The epothilones.

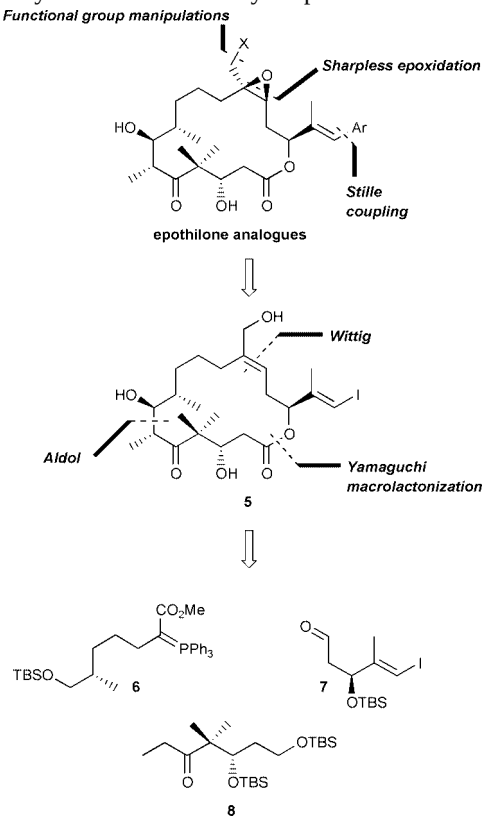
this subject has been extensively reviewed.[3–6] Within this section we will highlight the most recent developments with particular emphasis on the new generation total syntheses in the field of epothilones and analogues thereof.

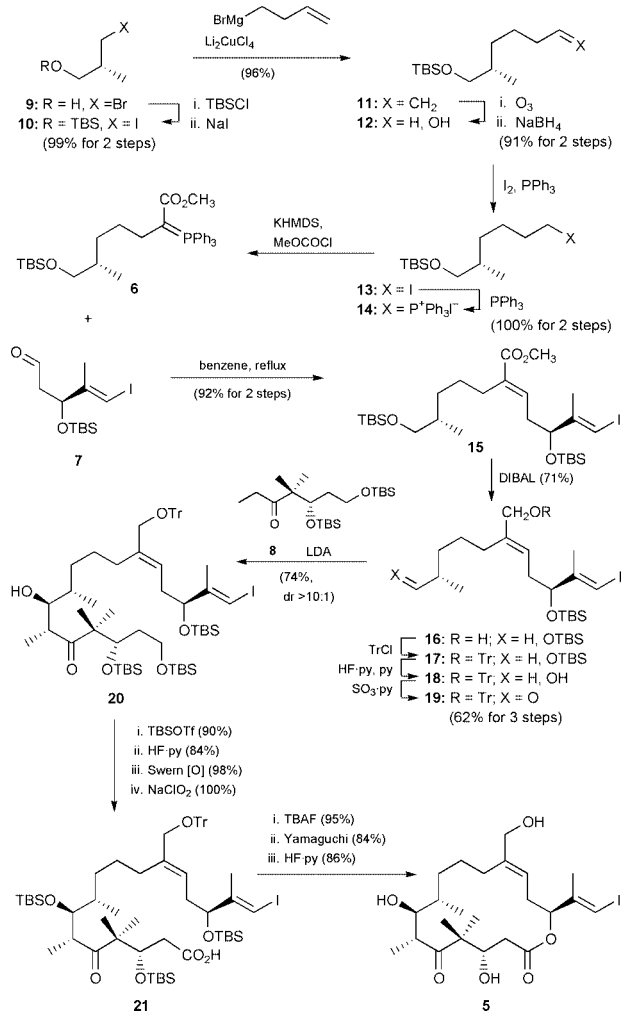
Although we had previously reported two different total synthesis strategies leading to epothilones and a large number of

analogues,[3] there was still room for improvements, particularly with regards to the stereoselectivity at some key points. Through our most recent work, these deficiencies have now been corrected, for the most part, so that a highly efficient, stereoselective, and flexible approach towards the epothilones has been established. Our general strategy is outlined retrosynthetically in Scheme 1. Key improvements include the introduction of the C12–C13 epoxide *via* a Sharpless asymmetric epoxidation directed by a C26 hydroxy group, and a highly efficient and reproducible protocol for the aldol coupling which creates the C6–C7 bond and simultaneously sets the stereochemistry at these centers with > 10 : 1 diastereoselectivity. A high degree of convergence was achieved, as the synthesis proceeds through the union of three fragments (**6**–**8**) of similar size and complexity, to afford the advanced intermediate **5**. This vinyl iodide (**5**) had already been proved to be highly versatile, as it allowed the synthesis of a large number of epothilones with aromatic side chains through our Stille coupling methodology,[7,8] and, in addition, enabled the synthesis of various C26-modified analogues.[7a]

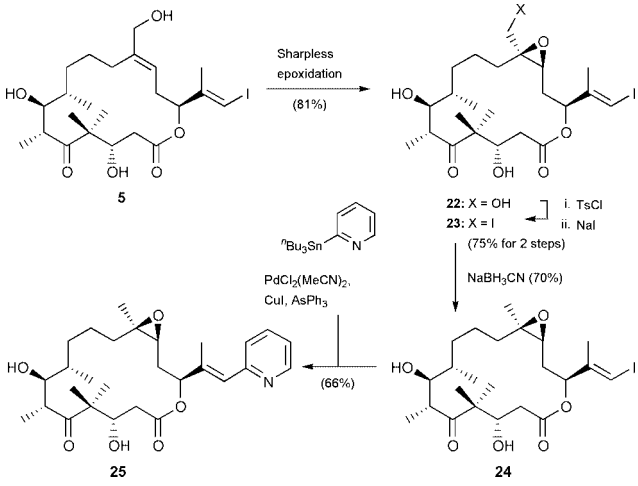


Scheme 1 Nicolaou's retrosynthetic analysis of epothilones.

The synthesis of vinyl iodide **5**[7b] is summarized in Scheme 2. Starting from the commercially available bromoalcohol **9** (optically active), protection and conversion to the iodide **10** was followed by an alkylation with but-4-enylmagnesium bromide to yield terminal olefin **11**. Through standard methodology, this was converted to the ylide **6**, which participated in a Wittig coupling with iodoaldehyde **7** to yield fragment **15**, which corresponds to the C7–C17 region of the epothilones. Functional group manipulations furnished aldehyde **19** in short order. When this derivative was subjected to our optimized aldol coupling protocol (enolate generation at −78 °C, then −40 °C for 1 h, then rapid addition of aldehyde at −78 °C followed by rapid quenching after 5 min with HOAc in THF)[7b,9] with ketone **8**,[10] a 74% yield of the desired aldol diastereomer **20** was realized. Moreover, the diastereoselectivity before purification was better than 10 : 1. With all the carbon atoms in place in **20**, straight-forward functional group manipulations and a Yamaguchi macrolactonization[10] afforded the desired vinyl iodide **5**.



Scheme 2 Nicolaou's synthesis of the advanced intermediate **5**.



Scheme 3 Nicolaou's synthesis of side chain-modified analogues.

The vinyl iodide **5** was converted into the epothilone B precursor **24** by a Sharpless epoxidation, followed by a mild deoxygenation protocol (Scheme 3). This vinyl iodide (**24**) was used to construct a series of aromatic side chain-modified epothilones (see Fig. 2). Notable among them are several pyridine derivatives (**25**–**28**, Fig. 2), some of which proved to possess remarkable biological activities (*vide infra*). Using analogous chemistry, 26-fluoroepothilone B (**37**)[11] and 16-desmethylepothilone B (**38**)[7b,9] were also constructed (see Fig. 2).

In order to probe the significance of the epoxide oxygen atom, a novel class of epothilones in which the epoxide was replaced by a cyclopropyl or cyclobutyl moiety was targeted for

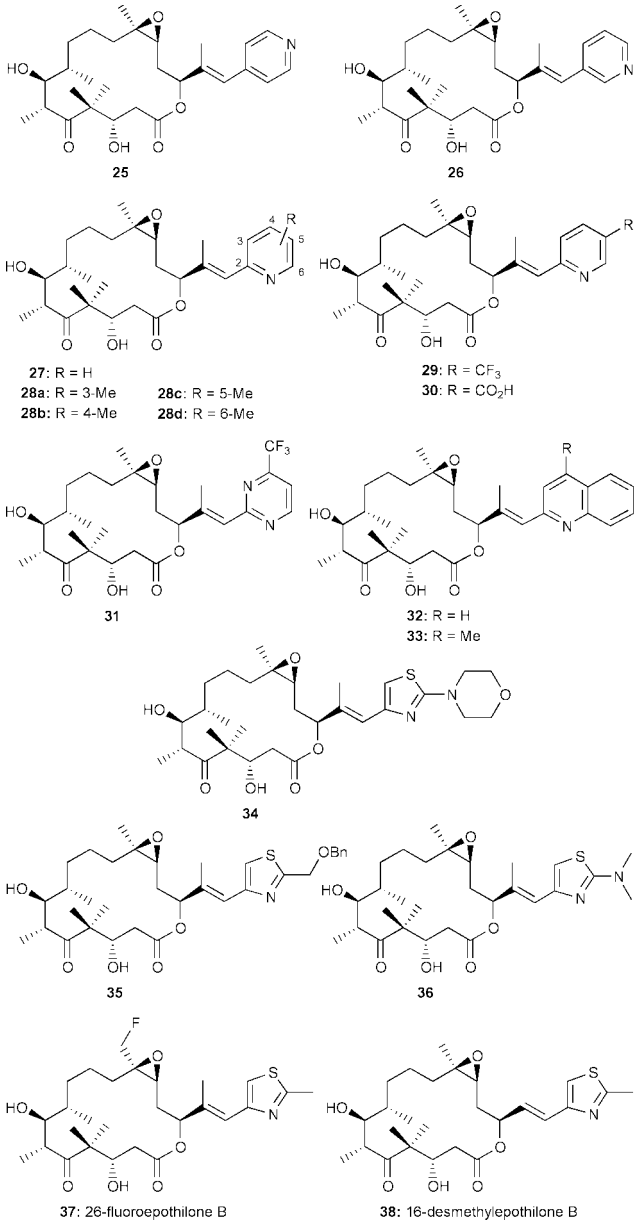


Fig. 2 Selected epothilone analogues.

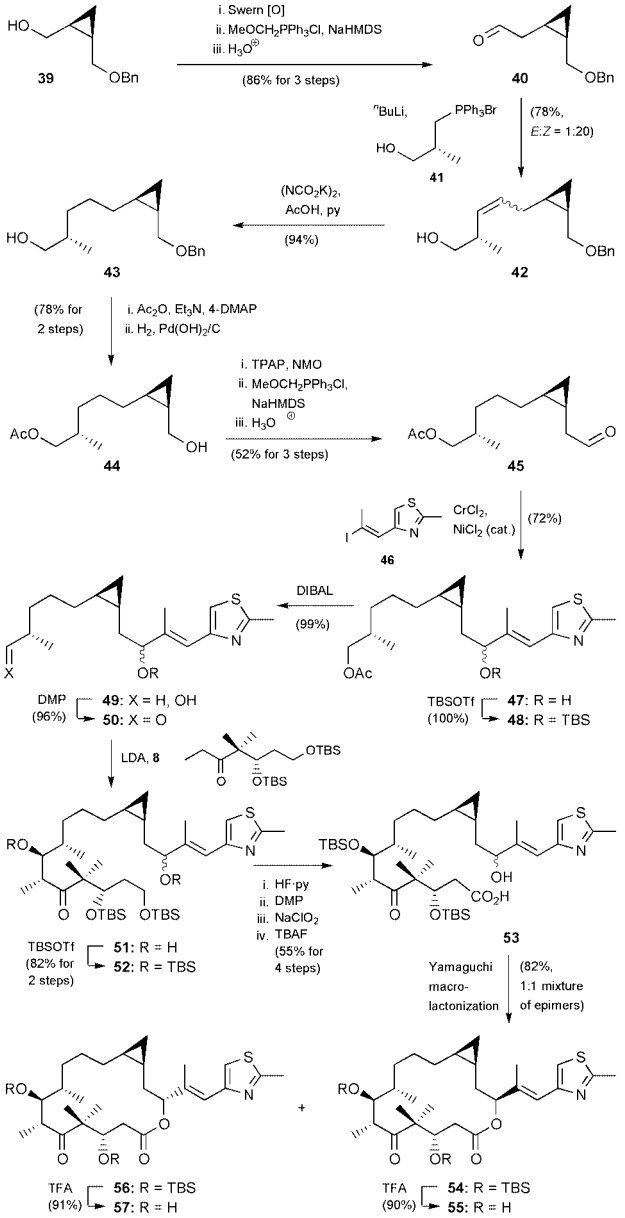

Scheme 4 Nicolaou's synthesis of cyclopropylepothilone A (**55**).

synthesis. Our original studies[12] with cyclopropyl epothilones probing this question were plagued by stereochemical ambiguities. Specifically, our original assignments[12] of the C12–C13 stereochemistries of cyclopropyl epothilones A were proven incorrect[13,14*a*] (the correct structures of these compounds are shown in Fig. 3, structures **58** and **59**). We therefore embarked on a new program directed at clarifying this issue. To this end, a new total synthesis had to be developed, which allowed for the incorporation of the requisite cycloalkyl moieties in a stereoselective manner at an early stage, in order to assure that no stereochemical ambiguity would exist in the final products.

The total synthesis of 12,13-cyclopropylepothilone A (**55**) serves to exemplify the approach to these compounds (Scheme 4).[14] This synthesis starts from the known cyclopropyl alcohol **39**, readily obtained by enantioselective Charette cyclopropanation[15] of *cis*-4-benzyloxybut-2-enol in 94% ee. Homologation and Wittig olefination with the commercially available chiral phosphonium bromide **41** afforded alkene **42**, predominantly as the *cis* isomer. Diimide reduction followed by hydrogenolysis of the benzyl ether and a second homologation yielded aldehyde **45**. At this point, a Nozaki-Kishi coupling with vinyl iodide **46**[14] afforded a 1:1 mixture of C15 epimers of the C7–C21 fragment **47**. Standard manipulations afforded aldehyde **50**, which smoothly underwent aldol coupling with ketone **8** to yield open-chain derivative **52** as a single diastereomer after TBS protection of the secondary alcohol. The same sequence of operations, *i.e.* protecting group manipulations, oxidation at C1 and Yamaguchi macrolactonization, as was described in Scheme 2, was then applied to complete the synthesis. After macrolactonization, the C15 epimers were separated and individually desilylated to afford the desired *cis*-12,13-cyclopropylepothilones **55** and **57**. This synthetic route also allowed the preparation of several other cycloalkylepothilone derivatives (**60**–**67**, Fig. 3) of various stereochemistries.[14*b*]

The Danishefsky group has made major contributions in the epothilone field, not only with regards to their total synthesis and their analogues, but also by extensive *in vitro* and *in vivo* studies.[4] A recent development from this camp is a new and highly efficient synthesis of epothilone D (**4**, Schemes 5 and 6),[16] and a closely related total synthesis of 12,13-desoxyepothilone F (**90**, Scheme 7),[17] which promise to secure sufficient quantities of these interesting compounds for ongoing biological and clinical investigations.

Danishefsky's 'new-generation synthesis' of epothilone D (**4**) is summarized in Scheme 6.[16,18] This new venture into the epothilone class features a newly developed *anti*-Felkin–Ahn selective aldol coupling of the (*Z*)-lithium enolate of **72**, an

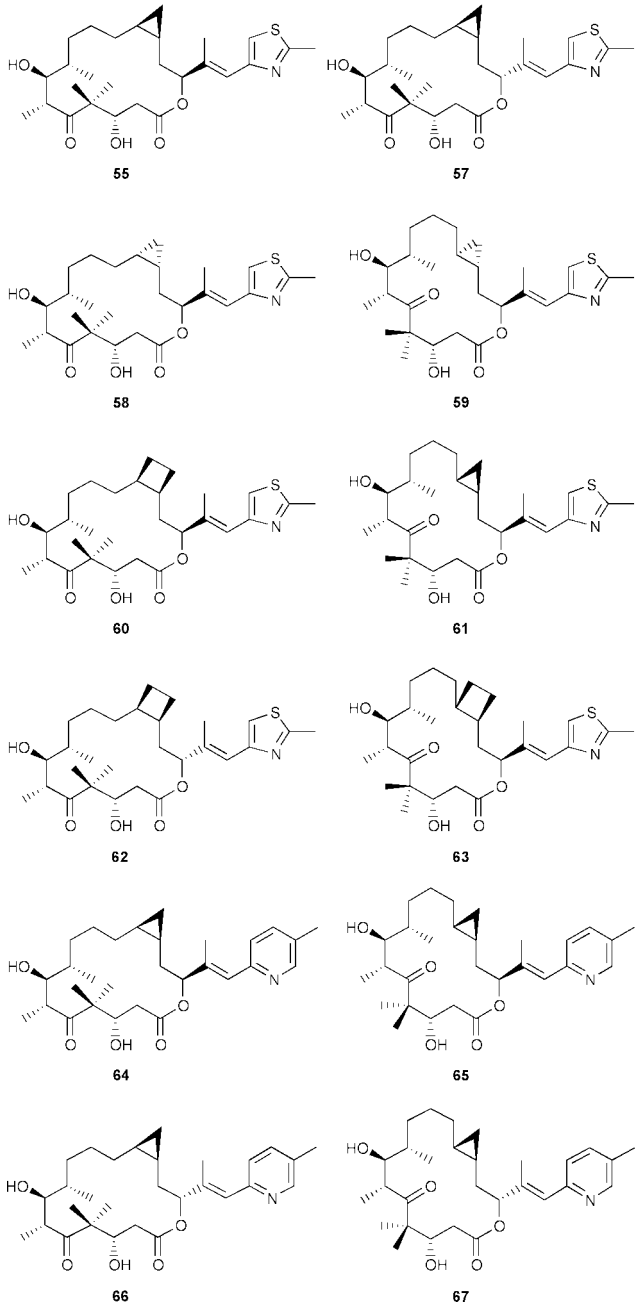

Fig. 3 Cyclopropyl and cyclobutylepothilones.

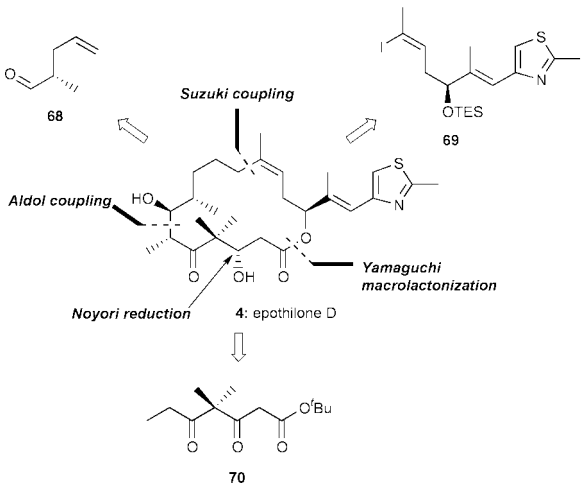
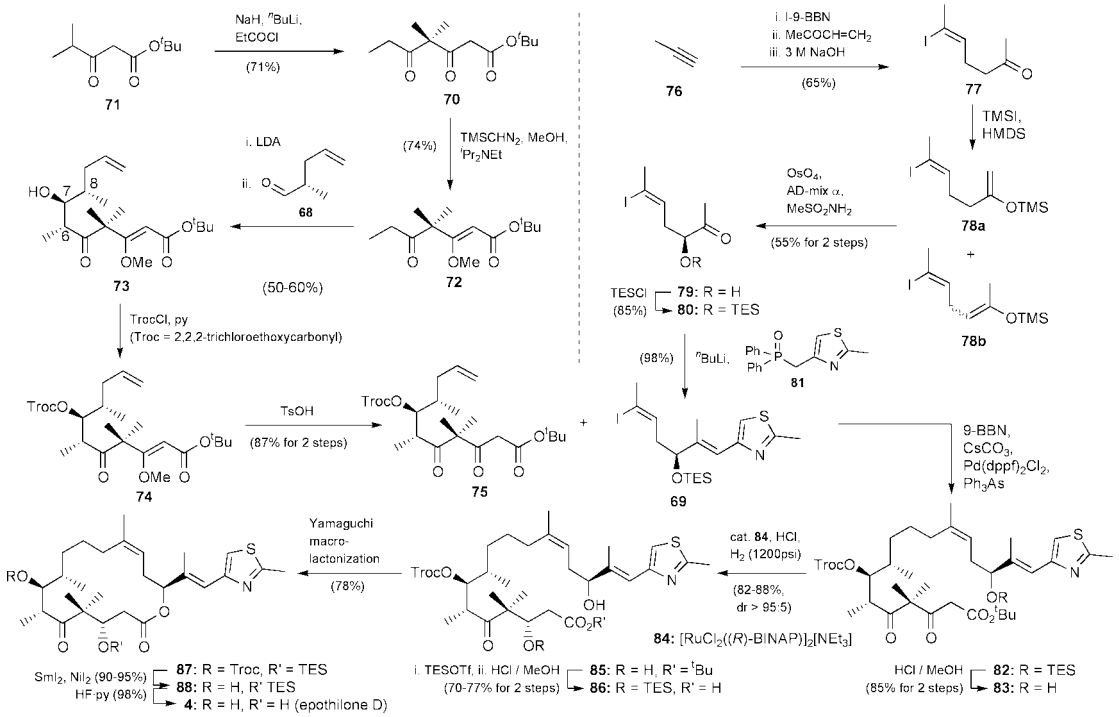


Scheme 5 Danishefsky's new retrosynthetic analysis of epothilones.

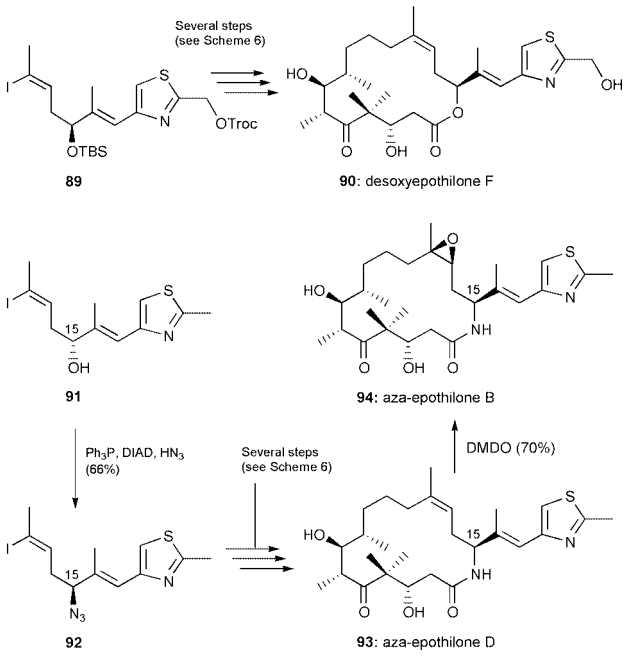
alkylborane Suzuki coupling of advanced intermediates **75** and **69**, and a stereoselective Noyori reduction of the C3 carbonyl group at a late stage of the synthesis. To this end, the requisite aldol coupling precursor **72** was assembled from the known β-ketoester **71** in two steps, and the chiral aldehyde **68** was derived from isoprene *via* asymmetric epoxidation. After extensive experimentation, good diastereoselectivity, 5–6 : 1 with the *syn*-(C6,C7)/*anti*-(C7,C8) compound **73** as the major isomer, was achieved in the aldol coupling between **68** and **72**. This outcome was rationalized by postulating neighboring-group participation by the olefinic moiety of **68**. Straightforward manipulations converted aldol **73** into olefin **75**. The vinyl iodide **69**, derived from propyne (**76**) *via* vinyl iodide **77** by an efficient protocol,[18] was joined with alkene **75** *via* the alkylborane Suzuki coupling, which proceeded smoothly to afford the open-chain ester **82**. After deprotection leading to alcohol **83**, the crucial Noyori reduction afforded the C3 alcohol **85** in > 95 : 5 diastereoselectivity, and in 82–88% yield. Protecting group manipulations and Yamaguchi macrolactonization, followed by global deprotection, finally afforded the desired epothilone D (**4**). By closely analogous routes, see Scheme 7, the Danishefsky group also prepared 12,13-deoxyepothilone F (**90**),[17] aza-epothilone D (**93**)[19] (both C15 epimers of **93** were prepared), and aza-epothilone B (**94**),[19b] the latter of which had previously been synthesized and shown to be very promising by the Bristol-Myers Squibb company (BMS), *vide infra*.

Using their reactive immunization technology,[20] the Lerner–Sinha group set out to devise a new synthesis of epothilones, where key intermediates would be generated by aldolase-like antibody catalysts. These efforts culminated in the syntheses of epothilones A–F,[21–23] as shown in Scheme 8. Thus, monoclonal antibodies, generated by reactive immunization against a β-diketone hapten, were used to prepare enantiomerically enriched key intermediates for epothilone A synthesis, either by kinetic resolution of racemic substrates through a retro-aldol reaction, or by enantioselective aldol reactions with prochiral substrates. The so obtained building blocks were elaborated to the target molecules, epothilones A–F. Remarkably, in their most recent work,[22,23] these authors report aldolase-type antibodies capable of resolving racemic aldols with 95–99% ee at 50% conversion, and with as little as 0.003 mol % of the antibody catalyst.

The C15 stereocenter of epothilones is arguably one of the most challenging to install, and many different solutions to this problem have been reported. In their first-generation synthesis,[21] the Lerner–Sinha group used their 38C2 antibody to catalyze the addition of acetone to aldehyde **95** (see Scheme 8a). At 51% conversion, an ee of 75% for **96** was realized for this tranformation. Using a new hapten, more efficient aldolase antibodies were raised, which allowed a retro-aldol kinetic resolution of (±)-**96**, affording **96** in > 97% ee and 45% isolated yield.[22,23] Moreover, the aldehyde **95** could be recovered and recycled back to (±)-**96**. Furthermore, it was possible to generate a host of closely related thiazoles, including **97**, which was subsequently elaborated into epothilone E. The team's total synthesis of epothilones started with a retro-aldol kinetic resolution of (±)-**98** to afford (–)-**98** in 98% ee. This operation set the stereocenters at C6 and C7 of epothilones. Hydrogenation afforded a 1:1 mixture of C8 epimers (**99**), and the desired epimer **99b** was taken on to the aldols **101a** and **101b**, obtained as a 1:2 mixture of diastereomers favoring the desired isomer **101b**. Further standard manipulations afforded acid **102**, which was esterified with alcohol **104**, obtained from **96** *via* a seven-step sequence. Ring-closing metathesis and deprotection afforded epothilone C (**3**) which was epoxidized to epothilone A (**1**) using a sequence of steps analogous to those previously reported in related works.[3–5] The Lerner-Sinha group also reported a related synthesis of epothilones A (**1**) and C (**3**)[21] *via* the macrolactonization approach,[10] as well as syntheses of epothilones B (**2**), D (**4**), E (**184** in Scheme 16) and F (**185** in Scheme 16).[21–23]



Scheme 6 Danishefsky's synthesis of epothilone D (**4**).

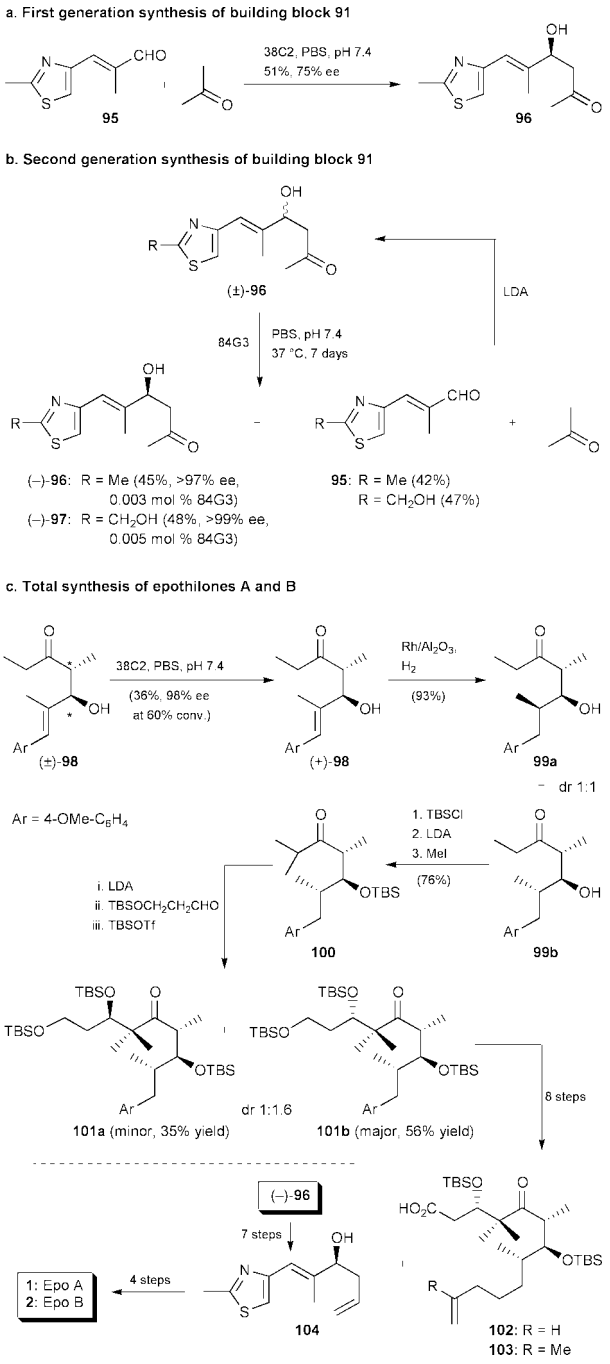


Scheme 7 Danishefsky's synthesis of selected epothilone analogues.

The Shibasaki group's syntheses of epothilones A and B addressed the stereochemical challenges posed by these target molecules by employing their recently developed Lewis acid–Lewis base bifunctional asymmetric polyheterometallic catalysts for cyanosilylation, aldol coupling and asymmetric protonation.[24,25] Thus, in their preparation of the C12–C21 fragment **111** (see Scheme 9), a catalytic asymmetric cyanosilylation using a bis(phosphine oxide)binaphthol–aluminum complex (**106**) as a chiral Lewis acid–Lewis base catalyst was successfully applied to the α,β-unsaturated aldehyde **105** to furnish, after acidic workup, the corresponding chiral cyanohydrin **107** in 97% yield and 99% ee. Straight-forward manipulations, including homologation, Wittig olefination and iodination, afforded the desired vinyl iodide **111**.

Two other multifunctional asymmetric catalysts, previously developed by the Shibasaki group, were applied to the preparation of the C1–C11 fragment **120** (see Scheme 10). In the first-generation approach,[24] the oxime ether epoxide **114** was constructed by a short sequence of steps from diol **112** using standard methodology. A cyanocuprate-based addition of a methyl group to **114** yielded the racemic *anti*-aldol **115**, by a process representing a new general approach to *anti*-aldols. Reductive cleavage of the O–N bond followed by regioselective alkylation of the resulting ketone furnished ketone **116**. The latter compound was reduced with good diastereoselectivity, and the resulting 1,3-diol was subjected to acetonide formation and other manipulations, ultimately leading to racemic aldehyde **118**. At this point, resolution by enantioselective aldol addition of acetophenone, catalyzed by the heteropolymetallic catalyst (*R*)-$LaLi_3$tris(binaphthoxide), afforded the desired aldol **119a** in 30% yield and 89% ee, together with its diastereomer **119b** (29%, 88% ee), which could be removed chromatographically. Standard transformations eventually afforded the desired fragment **120**. Noting the low efficiency of their resolution-based scheme, the Shibasaki group proceeded to develop a second generation synthesis,[25] starting with a catalytic asymmetric protonation of the enolate of thioester **121** (Scheme 10b). In the event, treatment of **121** with 5 mol % of $SmNa_3$tris(binaphthoxide) in the presence of 4-*tert*-butylthiophenol afforded the Michael adduct **122** in 92% yield and 88% ee. This intermediate was then elaborated into aldehyde **123**, which smoothly underwent an aldol coupling with the required ketone **124** to afford aldol **125** (dr = 4:1). Standard chemistry finally furnished the advanced intermediate **120** *via* **126**. The total synthesis of epothilone B (**2**) was completed by the joining of fragments **111** and **120** through a Suzuki coupling, macrolactonization and protecting group removal. The Shibasaki group also completed the synthesis of epothilone A (**1**) using closely related chemistry.[25]

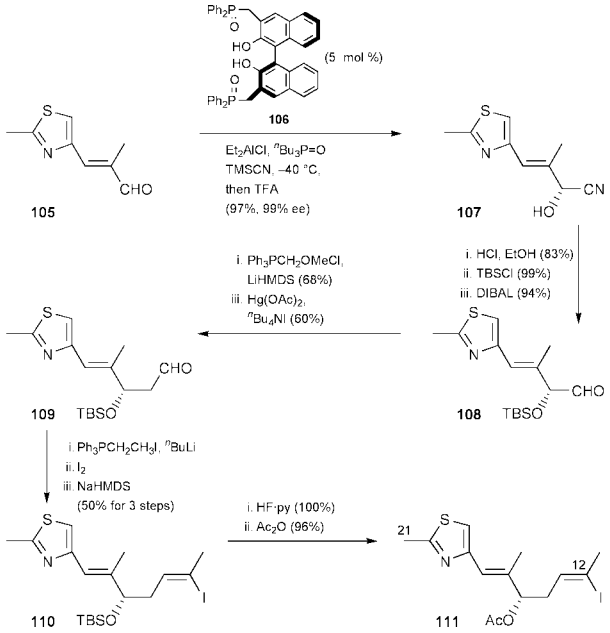
Although several of the reported epothilone syntheses form the macrocycle by ring-closing metathesis, poor *E/Z* selectivities are generally observed.[3–5] To circumvent this problem, the Kalesse group's formal total synthesis[26] of epothilone A (**1**) employed the metathesis ring closure to form a smaller, 10-membered lactone, which would be expected to favor the *Z* geometry on the basis of lower ring strain as opposed to the *E* arrangement. To this end (see Scheme 11), chiral aldehyde **127** was allylated and the product was esterified with hept-6-enoic acid to afford the cyclization precursor **129**. Ring-closing



Scheme 8 Lerner–Sinha's synthesis of epothilones A (**1**) and B (**2**).

metathesis of this diene system yielded 63% of the desired lactone **130**, with an *E*:*Z* ratio of 1 : 12; and furthermore, the *E* isomer could be separated and recycled, in 60% yield, to afford additional amounts of the desired *Z* lactone (*Z*)-**130** (see Scheme 11). Alkylation of the lactone enolate derived from (*Z*)-**130** with methyl iodide then afforded methylated lactone **131** (as a single diastereomer), the configuration of which was confirmed by independent synthesis using Evans' oxazilidinone technology. Elaboration of this intermediate (**131**), including installation of the thiazole side chain, ultimately yielded the aldehyde **136**. Since this aldehyde had previously been converted to epothilone A (**1**) by Nicolaou *et al.*[10] *via* coupling to ketoacid **137**, the formal total synthesis was complete. The Kalesse group also reported an independent synthesis of carboxylic acid **137**.[26]

The Panek group's synthesis of epothilone A (see Scheme 12) utilizes a lipase resolution to establish the stereochemistry at C15 of key fragment **111**, a Suzuki coupling between **111** and olefin **138** to form the C11–C12 carbon–carbon bond, a



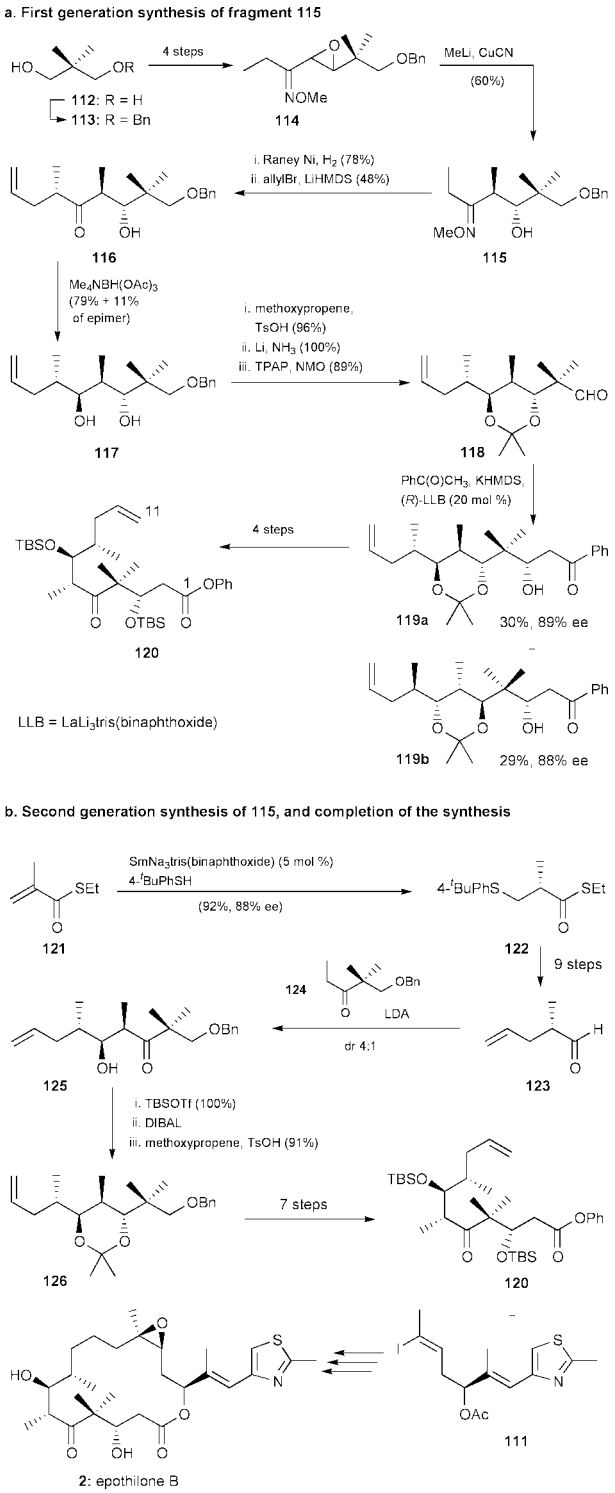
Scheme 9 Shibasaki's synthesis of vinyl iodide **111**.

Mukaiyama–type aldol coupling with **139** to construct the C2–C3 bond, and finally Yamaguchi macrolactonization and epoxidation.[27]

The Carreira group's synthesis of epothilones A (**1**) and B (**2**) features a unique nitrile oxide cycloaddition approach to the solution of the stereochemical problems at C12, C13 and C15 (see Scheme 13).[28] The highly diastereoselective cycloaddition of allylic alcohol **141** or **143** and nitrile oxide **145**, generated from phosphonate **140**, gave a single isoxazoline diastereomer (**142** and **146**, respectively), thus creating the C14–C15 bond while simultaneously establishing the correct stereochemistry at C12 and C13. A Horner–Emmons olefination with aldehyde **147** next installed the side chain, while reduction of the isoxazoline moiety of the resulting compound **148** yielded diol **149** stereoselectively. This intermediate was then conveniently converted to the key epoxide **150** *via* 1,3-cyclic sulfite formation and TBAF-mediated C12 desilylation. The latter compound (**150**) was then elaborated into epothilone A (**1**) following Mulzer's general strategy.[5] In a similar manner, the isoxazoline **142** was employed to synthesize epothilone B (**2**).

The Fürstner group's total synthesis of epothilone C (**3**), and formal total synthesis of epothilone A (**1**), features a novel ring-closing alkyne metathesis reaction as the key step (see Scheme 14).[29] The C1–C6 fragment **154** was prepared from ketone **151** through a Noyori asymmetric hydrogenation, protection and Grignard addition of an ethyl group to ester **153**. An aldol coupling was then employed to join the ketone **154** with the aldehyde **155** in a stereoselective manner to yield intermediate **156**. Straight-forward manipulations yielded carboxylic acid **157**, which was esterified with the side chain alcohol **158**, derived from the aldehyde **95** *via* a Brown asymmetric allylboration. The so obtained cyclisation precursor **159** was treated with 10 mol % of the metathesis catalyst **161** to afford the desired macrocycle **160**. Lindlar reduction and deprotection finally afforded the desired epothilone C (**3**).

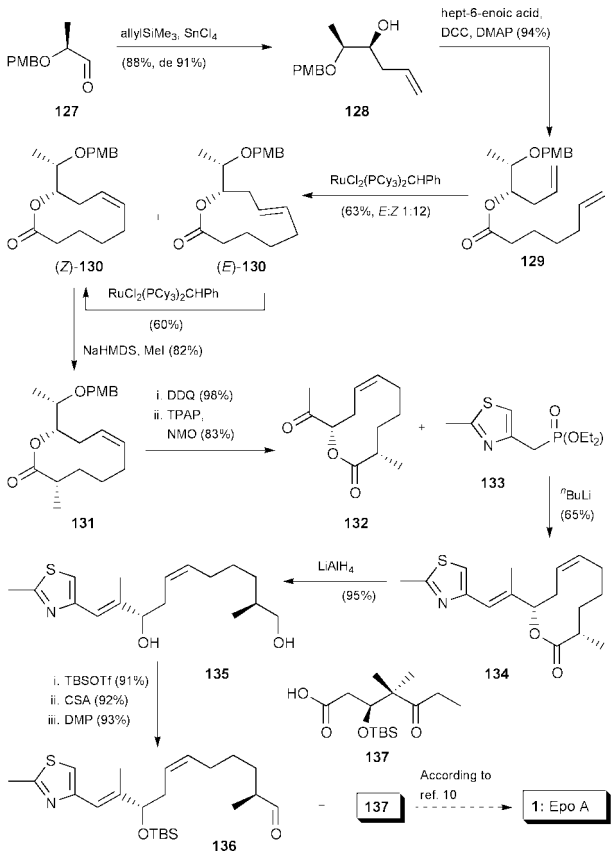
An ongoing research program at Novartis Pharma AG, led by Altmann, has resulted in a number of highly potent epothilone derivatives.[30,31] Thus, following a convergent route, several heterocyclic epothilone derivatives were prepared (see Scheme 15).[31] The required C1–C11 fragment **165** was reached by a short sequence of steps from **162** and **163**. This olefin was coupled to a series of vinyl iodides (**169**), which were synthesized using the Oppolzer sultam aldol reaction starting with sultam **166** and aldehyde **167**. Stille coupling of **169** with **165** followed by straight-forward manipulations and macro-



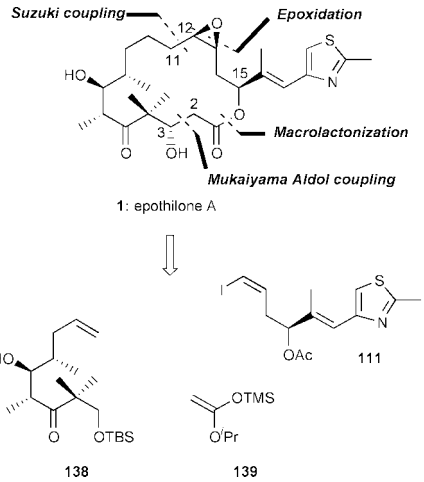
Scheme 10 Shibasaki's synthesis of epothilone B (**2**).

cyclization yielded the epothilone D derivatives **170**–**173**. Epoxidation of the latter compounds afforded epothilone B analogues **174**–**177**. Using similar methodology, a number of C12–C13 modified epothilones were also prepared.[30]

Many other groups, in particular those of Grieco,[32] Schinzer,[33] Mulzer[34] and White,[35] also made significant contributions to the epothilone field, and these efforts have been reviewed recently.[3,5] The Schinzer group, together with Altmann's group at Novartis, also reported a total synthesis of two 'aza-epothilone C' derivatives (epothilone lactams) using a ring-closing metathesis strategy.[36] An interesting biocatalytic method for the generation of intermediates for epothilone synthesis has been reported by Wong.[37]



Scheme 11 Kalesse's formal synthesis of epothilone A (**1**).

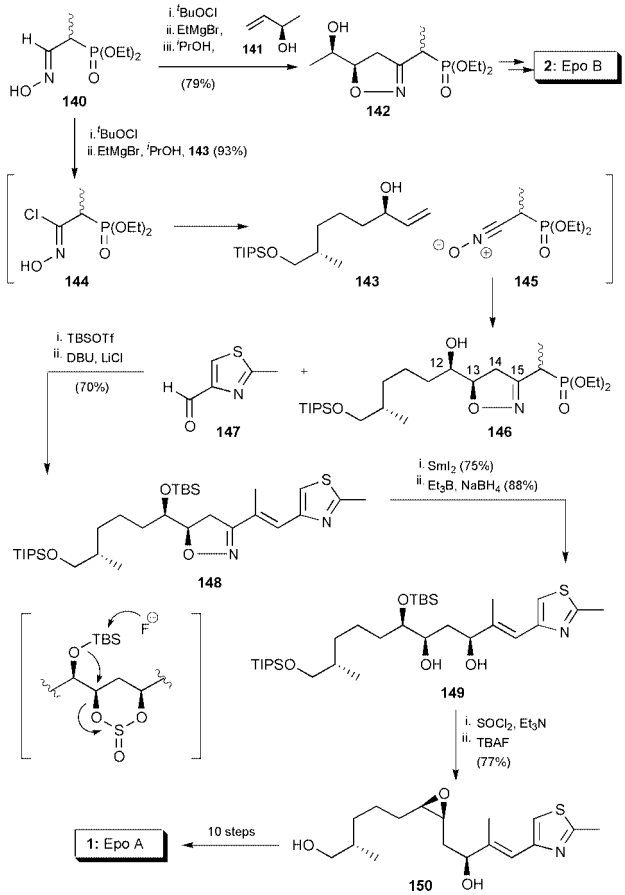


Scheme 12 Panek's retrosynthetic analysis of epothilone A (**1**).

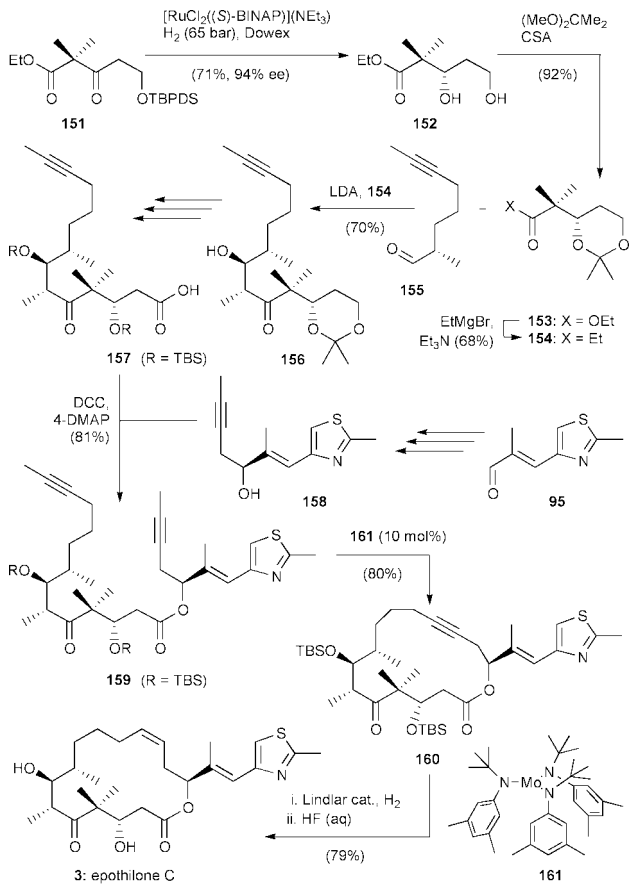
Partial syntheses of epothilone analogues

From an industrial standpoint, and despite the progress outlined above, fermentation followed by partial synthesis may still hold certain advantages over total synthesis. With such advantages in mind, a number of groups initiated programs directed at semisynthesis of epothilone analogues. Particularly notable are the reports from the Höfle[38] and Bristol-Myers Squibb[13,39] groups.

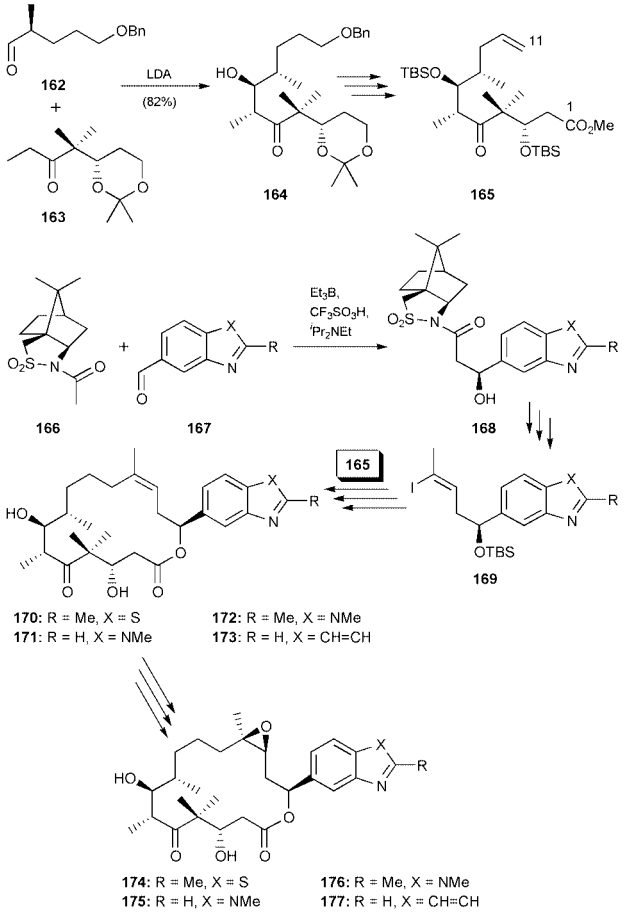
Thus, several interesting epothilone tranformations have been carried out by Höfle (see Scheme 16).[38] Ozonolysis and silylation of epothilone A (**1**) or B (**2**) afforded the versatile methyl ketone **178** (R = H, Me). Although Wittig-type reactions with this substrate were largely unsuccessful, probably due to enolization of the methyl ketone, aldol condensations with aromatic aldehydes produced the side chain modified epothilones **179**, none of which, however, exhibited any tubulin polymerization activity or cytotoxicity. Alternatively, ketone **178** could be converted into the vinyl boronic acid **180** (*E*:*Z* =



Scheme 13 Carreira's synthesis of epothilones A (**1**) and B (**2**).



Scheme 14 Fürstner's synthesis of epothilone C (**3**).



Scheme 15 Altmann's synthesis of side chain-modified analogues.

7:3), the *E* isomer of which could be transformed into vinyl iodide **181**, which bears considerable similarity to the highly versatile intermediate **24** (see Scheme 3) used by the Nicolaou group to generate a number of analogues *via* Stille coupling methodology.[3] Höfle also discovered that epothilones could be *N*-oxidized in fair yields by MCPBA. Upon acetylation, the *N*-oxides underwent a Polonovsky-type rearrangement to yield, after hydrolysis, the side chain oxidized epothilones E (**184**) and F (**185**) (see Scheme 16).[38]

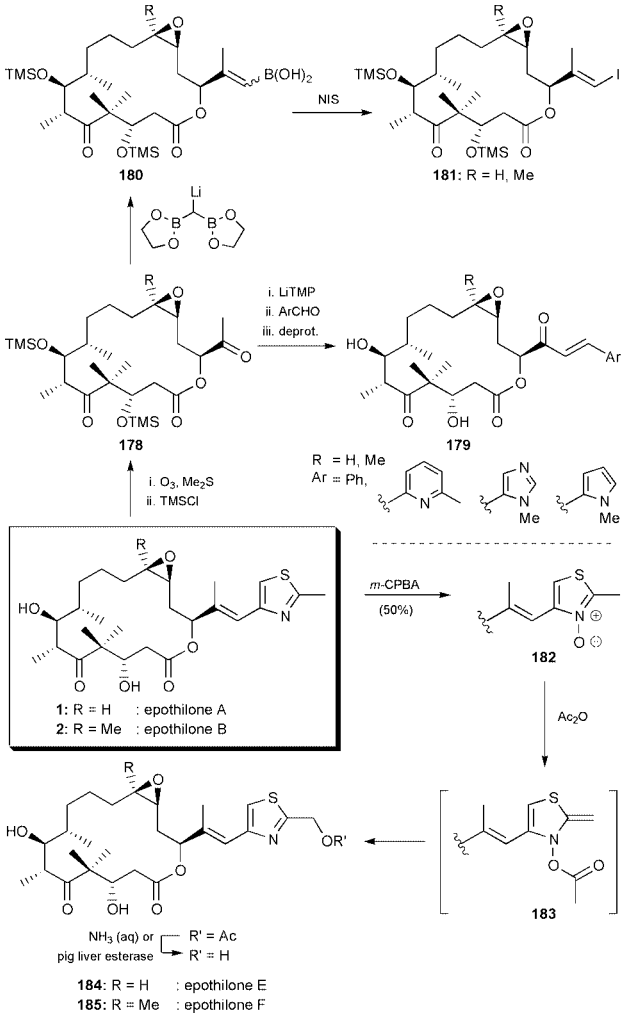
A partial synthesis of a number of cyclopropylepothilones has been disclosed by a Bristol-Myers Squibb group[13] (see Scheme 17). Thus, deoxygenation protocols to convert epothilones A (**1**) and B (**2**) into the C12–C13 olefinic epothilones C (**3**) and D (**4**) were developed. Epothilone C (**3**) could be cyclopropanated in 12% yield using dibromocarbene, generated from bromoform and aqueous base under phase-transfer conditions, to form the protected derivative **186**. Dehalogenation with $^{n}Bu_3SnH$ afforded silyl ether **187** which was deprotected to yield cyclopropylepothilone A (**55**). Using similar chemistry, cyclopropylepothilones **188**, **189** and **190** were also prepared (Scheme 17).

The Bristol-Myers Squibb (BMS) group developed a very convenient three-step, one-pot procedure for the conversion of epothilones into the corresponding macrolactams (aza-epothilones)[39] (see Scheme 17). To this end, treatment of epothilone B (**1**) with $Pd(PPh_3)_4$ in the presence of NaN_3 afforded the corresponding azide (**192**) with complete retention of stereochemistry at C15. Reduction of this azide with PMe_3 followed by macrolactamization afforded aza-epothilone B (**94**, BMS-247550) in moderate yield, and without the need to isolate any intermediates.

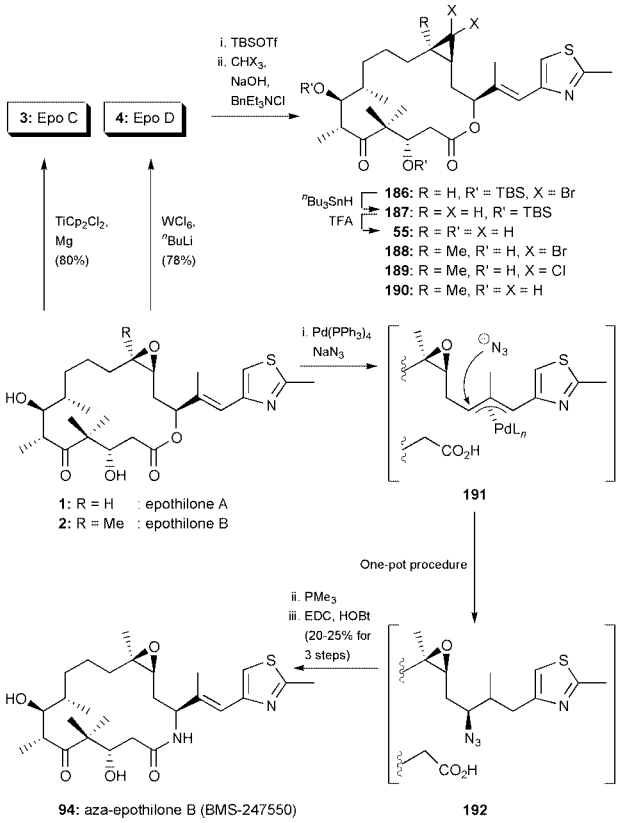
Chemical biology of epothilones

Biological evaluation

As more and more experimental data have accumulated, a fairly good understanding of what modifications to the epothilone



Scheme 16 Höfle's partial syntheses of side chain-modified analogues.



Scheme 17 BMS's partial syntheses of cyclopropyl and aza analogues.

structure might produce active analogues has developed. This section aims to survey some of the most recent progress in this area. Several excellent reviews have appeared,[3–6] and most of the data published in these works will not be repeated here.

Some difficulty in evaluating the results from different studies do arise as a result of the use of many different cell lines, and even differences in experimental protocols may lead to considerable variability between seemingly identical experiments. The *in vitro* experimental data generally fall into two categories, namely tubulin polymerization assays using purified tubulin, and cytotoxicity assays employing various cancer cell lines. Although there is generally some degree of correlation between the results from these two assays, factors such as uptake into and retention by cells obviously play a part in determining the observed effect on cell proliferation, in addition to the effects caused by the tubulin polymerization properties of a given agent. In fact, the concentrations needed to induce tubulin polymerization are two to three orders of magnitude higher than the medium concentrations which will induce cell death. This observation is rationalized by the fact that epothilones, like Taxol®, readily accumulate in cells, so that the relatively high concentrations necessary for tubulin polymerization are finally reached.[6] Because of differences in protocols and cell lines, it will be convenient to first discuss the contributions from the different research groups separately, and then compare the results in order to draw some general conclusions.

We have recently reported two new classes of epothilone analogues with potent biological activities, namely epothilones with pyridine or related side chains (Fig. 2, Table 1),[8] and derivatives of epothilone A (**1**) where the epoxide group has been replaced by a cyclopropyl or a cyclobutyl moiety (Fig. 3, Table 2).[14] A systematic substitution study[8] of pyridine epothilones where the nitrogen atom was "walked" around the ring (**25**–**27**) revealed its crucial position adjacent to the macrocycle attachment site in **27** (Fig. 2, Table 1). A second study "walked" a methyl group around the most active pyridine epothilone analogue (**27**) revealing the C4 and C5 methyl derivatives (**28b**, **28c**, Fig. 2, Table 1) as the most active. Interestingly, the latter compounds (**28b**,**c)** are more active than natural epothilone B (**2**) itself (see Table 1), and they are in fact among the most active derivatives reported to date, with IC_{50} values on the order of 10^{-10} M.

Remarkably, some of the prepared epothilone A cyclopropanes and cyclobutanes (**55**, **57**–**67**) were also active (Fig. 3, Table 1), in some cases even more active than the parent epoxide epothilone A (**1**).[14] In particular, the hybrid epothilones **64** and **65** with pyridine side chains and cyclopropyl moieties at C12–C13 (Fig. 3) were found to be highly active. On the other hand, all derivatives with the unnatural C15 (*R*) configuration (**57**, **62**, **66**, **67**, Fig. 3, Table 1) were essentially inactive. In addition, we have previously reported that *cis*- and *trans*-cyclopropyl epothilones **58** and **59** (Fig. 3, Table 1), with the configuration at C13 opposite to that of the natural series, were inactive.[12,14] From these results, it became clear that in the epothilone A series the stereochemistry at C13 and C15 is critical to the activity. Specifically, the configurations at these centers must match those of the natural compound. On the other hand, the C12 stereocenter appears to play a minor role, as both *cis*- and *trans*-cyclopropanes exhibited similar activity. Several other epothilone B derivatives with heteroaromatic side chains were also prepared (Fig. 2, Table 2; unpublished results). For example, the quinoline derivatives **32a** and **32b** retain significant activity, indicative of the fact that relatively large side chains are tolerated, as long as the basic nitrogen atom is present at the right position.

The Novartis group has also made major contributions to the field, and an excellent review on the biology of epothilones reporting up to the end of 1999 has been published by Altmann.[6] Notable among the many analogues reported by the Novartis group are a series of bicyclic aromatic side chain analogues of epothilones D (**170**–**173**) and B (**174**–**177**) where the aromatic moiety replaces the C16–C17 double bond in the native

epothilones, while retaining the overall shape and, most importantly, the position of the crucial nitrogen atom (see Scheme 15).[31] These compounds are also among the most active analogues reported to date (see Table 2), and they are indeed of comparable activity to our pyridine analogues **28b** and **28c** (*vide supra*).

The BMS group has reported an interesting, one-pot transformation which converts epothilones into their potentially more metabolically stable lactam congeners (*vide supra*).[39] While most of these lactams were found to be significantly less active than their parent lactones,[19,36,39] one compound, 'aza-epothilone B' (**94**: BMS-247550), with good activity was selected as a drug candidate and is currently in clinical trials (see Table 3).[39] The BMS group also reported the partial synthesis of cyclopropyl epothilones A (**55**) and B (**190**) and their potent biological activities (see Table 3).[13]

[a] Tubulin $EC_{0.01}$ (effective concentration) is defined as the interpolated concentration of compound capable of inducing an initial slope of 0.01 OD min^{-1} rate of polymerization.

The Danishefsky group has pursued an extensive synthesis and screening program, which led to a number of interesting results.[4] These authors reported that initial animal studies using the highly potent epothilone B (**2**) were plagued by the high toxicity of this compound. Specifically, it was difficult to achieve high enough doses to effect tumor regression in mice with human tumor xenografts without simultaneously causing lethal toxicity. This led the group to propose epothilone D (**4**), and later desoxyepothilone F (**90**),[17] as more viable drug candidates. Treatment efficacy of these compounds was demonstrated *in vivo*, again using mouse xenograft models.[17,40] The potency of these epothilones is about one order of

magnitude less than that of epothilone B (**2**), but this is apparently more than compensated for by their much lower toxicities to the animals used. Table 4 summarizes the observed

cytotoxicities for these compounds against some sensitive and multidrug-resistant human leukemia cell lines.

Structure–activity relationships

As a result of the extensive chemical synthesis–chemical biology studies of hundreds of epothilone analogues, structure–activity relationships could be established quite rapidly.[3] An electron crystallographic structure of the tubulin αβ dimer with bound Taxotere™ at 3.7 Å resolution has been disclosed, and although the resolution is too low to pinpoint the exact conformation of bound ligand, it clearly identifies its binding site.[41] The solution conformations of epothilones have been investigated by NMR methods,[42] and by purely computational techniques.[43] Several pharmacophore models have been advanced,[44–48] generally incorporating not only epothilones, but also taxoids and other tubulin binding molecules, under the assumption that they all bind to a common binding site on the tubulin dimer. This assumption was based on the similar biological effects of these various substances, the competitive and mutually exclusive binding of different compounds to tubulin, and the partial cross-resistance acquired by tubulin mutants with amino acid replacements at the proposed binding site. Although there are many differences between these studies, particularly as to the proposed binding conformations, there seems to be some level of consensus as to what features are of importance to binding (see Fig. 4).

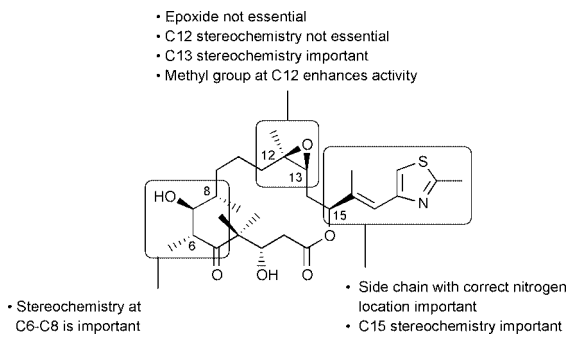

Fig. 4 Structure–activity relationships for the epothilones.

The configurations at C6–C8 are vital for the biological activity, probably because this region strongly influences the overall conformation of the macrocycle through steric and/or stereoelectronic effects.[42] There was initially some speculation that the epoxide oxygen of epothilone played a role as a hydrogen bond acceptor, but after independent reports by several groups[13,14,40*b*] it became clear that the epoxide moiety is not essential for biological activity. However, a substituent at C12, particularly a methyl group, consistently enhances the activity. Interestingly, both *cis*- and *trans*-epoxides and cyclopropanes are of comparable activity, so that as long as the configuration at C13 agrees with that of the native epothilones, the C12 stereochemistry is of relatively little importance. This is most probably due to the flexible C9–C11 trimethylene element, which allows both stereoisomers to be accomodated within the binding site. The side chain is also highly important for biological activity, with 4- or 5-methylpyridine or related derivatives being the optimum choice so far, about two-fold more active than the native 2-methylthiazole analogues.[8] Even quinoline side chains resulted in very active analogues, indicative of the fact that considerable steric bulk is tolerated in the side chain. Finally, the stereochemistry at C15 is very important, with C15 epimers being largely devoid of any biological activity.[14,19]

Biosynthesis

The biosynthetic pathway leading to the epothilones has been elucidated in some detail (Fig 5). Two independent reports, originating from Novartis[49] and KOSAN Biosciences,[50] on the gene cluster responsible for epothilone production in different *Sorangium cellulosum* strains have appeared with essentially identical results and conclusions. Both epothilones A and B are produced by the same polyketide synthase (PKS), which includes a non-ribosomal peptide synthase (NRPS) domain for the formation of the thiazole side chain from cysteine. One of the C4 gem-dimethyl groups is introduced by an (*S*)-adenosylmethionine-dependent methyltranferase domain which is also part of the PKS. It appears that the acyltransferase domain responsible for the installation of the C11–C12 fragment is rather unselective for malonyl-CoA *vs.* methylmalonyl-CoA, and can incorporate either of these units, ultimately giving rise to epothilones C and D, respectively. Both of these latter compounds are the end products of the same PKS, and the epothilones A and B are formed by post-PKS oxidation by a cytochrome P450 oxygenase, which is also part of the epothilone gene cluster. Additional biosynthetic studies have been performed by the Höfle group, and their results confirm the findings discussed above.[51,52] Using labeling techniques, it was confirmed that the epothilones are indeed synthesized from acetate and propionate units, one cysteine unit (C17–C19 of the thiazole side chain), and the methyl group of methionine (incorporated as one of the C4 methyls). It was further shown that epothilones C and D are the final products of the same PKS, and these are oxidized by a separate enzyme to epothilones A and B. Although only trace amounts of epothilones C and D are produced by the native strain of *S. cellulosum*, mutants with defects which render the oxygenase enzyme inactive have been created and shown to produce only epothilones C and D.[52] It has also been suggested that by replacing the C11–C12 acyltransferase domain with a methylmalonyl-CoA-specific one should lead to a PKS specific for epothilone D.[50] Impressively, it has already been possible to produce a mixture of epothilones A (**1**) and B (**2**) by cloning of the entire epothilone gene cluster and expressing it in *Streptomyces coelicolor*, a much better understood organism, and with a ten-fold faster rate of growth as compared to *S. cellulosum*.[50]

Preclinical and clinical studies

In contrast to the extensive chemistry and *in vitro* biological studies discussed above, relatively scarce data have been disclosed on the *in vivo* efficacy of the epothilones. To date, published results only exist for natural epothilones B (**2**)[6,40] and D (**4**),[40] aza-epothilone B (**94**: BMS-247550, Scheme 7),[19*b*,53] desoxyepothilone F (**90**, Scheme 7),[17] and 26-fluoroepothilone B (**37**, Fig. 2).[54] Danishefsky's group initially reported promising activity against subcutaneously implanted tumors in SCID mice for epothilone B (**2**),[40*a*] but they later encountered severe toxicity problems with this compound.[40*b*] On the other hand, it was claimed that epothilone D (**4**) was much less toxic, and this compound was found to be superior to both epothilone B (**2**) and Taxol® in a variety of mouse tumor models.[40*b*,40*c*] In some cases, epothilone D (**4**) was found to be curative against

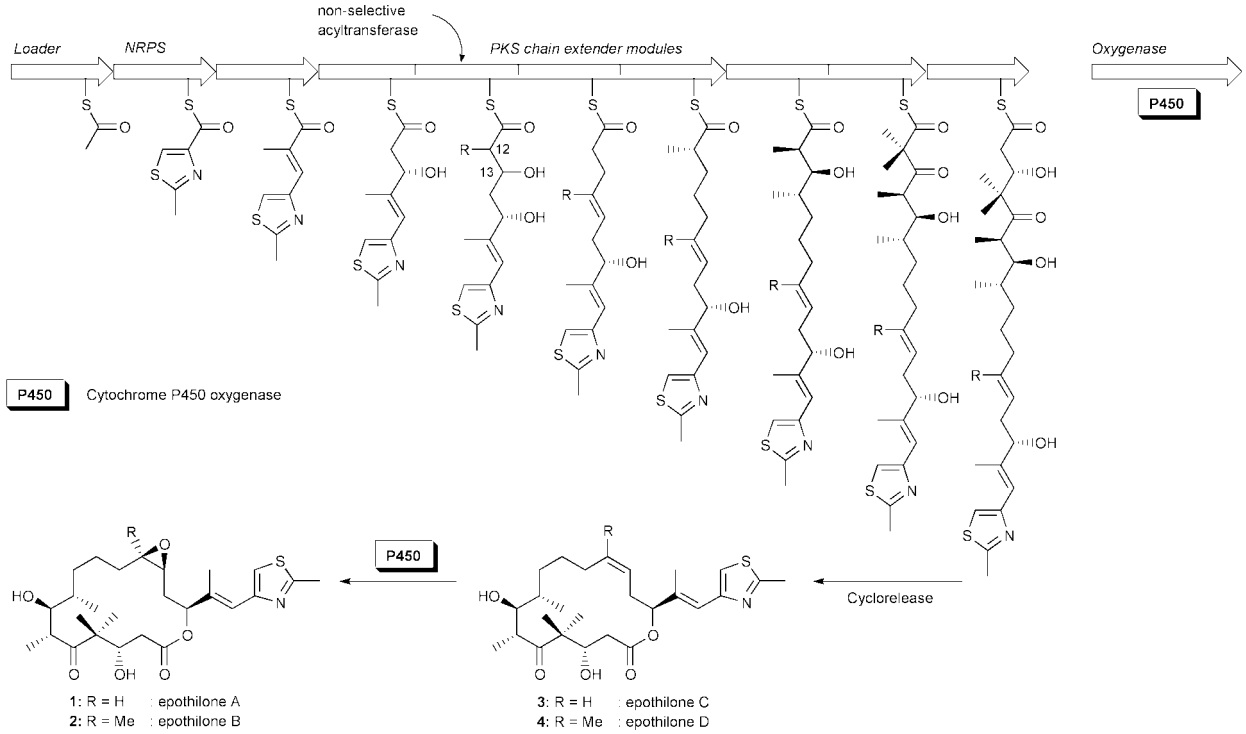

Fig. 5 Structure of the epothilone biosynthetic gene cluster from *Sorangium cellulosum*. NRPS = non-ribosomal peptide synthase, PKS = polyketide synthase.

human tumor xenografts, even when these were unresponsive to Taxol®.[40c] Preliminary results for desoxyepothilone F (**90**)[17] showed that this compound is highly potent in the mouse tumor models employed, while preliminary data for aza-epothilone B (**94**) showed that this compound appeared to be less effective in reducing tumor growth.

The BMS team also encountered difficulties with natural epothilone B (**2**) not only due to its toxicity in mice and lower primates, but also because of its low metabolic stability towards various esterases. To ameliorate these problems, aza-epothilone B (**94**: BMS-247550) was targeted and it was found to possess a very promising pharmacological profile, despite its lower *in vitro* activity compared to epothilone B (**2**).[53] In fact, even when orally administered, **94** was found to be highly effective against a range of human tumor xenografts in mice and rats, including taxol-resistant tumors.[53]

Phase I clinical trials with this compound have been conducted by BMS, and the results are so far very promising.[55] It was found that although the toxicity of **94** was similar to that of Taxol®, **94** did show evidence of being effective in patients with taxane-resistant tumors. Clinical trials with this compound are currently entering phase II.

Contrary to the results above, through tumor graft studies in mice, the Novartis group found epothilone B (**2**) itself to be a viable drug candidate,[6] and this compound is also currently in phase II clinical trials, having successfully been evaluated in clinical phase I trials.[56] The Novartis group has also carried out extensive preclinical studies with a number of our designed epothilone analogues. In collaboration with the Logothesis–Navone group, we have also carried out comparative *in vivo* studies with Taxol®, epothilone B (**2**) and 26-fluoroepothilone B (**37**),[54] and we found that the latter compound was more active than Taxol® in inhibiting growth of human prostate cancer xenografts in mice, and the tolerated dose of this agent was higher than that for either Taxol® or epothilone B (**2**). These observations were attributed to lower overall toxicity of the fluoroepothilone analogue **37**.

Conclusion

With a number of epothilones (from both the natural and designed categories) in clinical trials as potential anticancer agents, the anticipation regarding this class of compounds is climaxing. Indeed their emergence as top candidates for cancer chemotherapy was rapid, being greatly facilitated by chemical synthesis and chemical biology studies. Carried out by many groups around the world, these investigations ensured the availability of not only the naturally occurring substances, but also of thousands of analogues which allowed elucidation of structure–activity relationships. While more results from the clinical trials of this first generation epothilone drug candidates are eagerly awaited, the basic research efforts that brought these molecules thus far will no doubt continue unabated for some time to come.

Addendum

Since the submission of this manuscript relevant publications have appeared in the literature.[57–65]

Acknowledgements

It is with great pride and pleasure that we wish to thank our collaborators whose names appear in the references and whose contributions made the described work possible and enjoyable. We also wish to express our many thanks to our collaborators Dr Karl-Heinz Altmann (Novartis) and Dr Paraskevi Giannakakou (Emory University) for their contributions and for valuable discussions. We gratefully acknowledge the National Institutes of Health (USA), Merck & Co., DuPont, Schering Plough, Pfizer, Hoffmann-La Roche, GlaxoWellcome, Rhone-Poulenc Rorer, Amgen, Novartis, Abbott Laboratories, Bristol-Myers Squibb, Boehringer Ingelheim, Zeneca, CaPCURE, the George E. Hewitt Foundation, and the Skaggs Institute for Chemical Biology for supporting our research programs. This work was also supported by a fellowship to A. Ritzén (STINT).

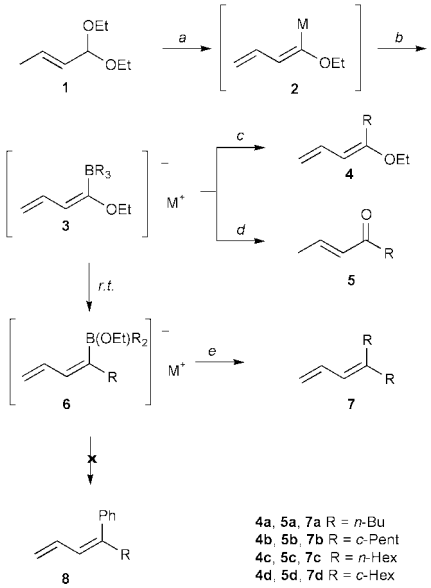
First published as an Advance Article on the web 31st July 2001

Iodobenzene and tetrakis(triphenylphosphine)palladium(0) $[(C_6H_5)_3P]_4Pd$ catalyse a new synthesis of 1,1-dialkylbuta-1,3-dienes, starting from 1,1-diethoxybut-2-ene and trialkylboranes, in the presence of Schlosser's superbase LIC–KOR.

The synthesis of polienic structures has been of great interest to organic chemistry owing not only to their presence in natural products,[1] but also to their importance as useful chemicals in the perfume industry and other fields.[2] Our interest in the synthesis of stereodefined substituted dienes required the development of diverse organometallic reagents and protocol for the preparation of key building blocks.[3] In the course of these studies we have set up a new synthesis of 1,1-dialkyl substituted buta-1,3-dienes, resorting to the reactivity of organoboron compounds.[4] Treatment of crotonaldehyde diethyl acetal (**1**) at −95 °C with LIC–KOR base (LIC: butyllithium, KOR: potassium *tert*-butoxide)[5] readily gives α-metalated 1-ethoxybuta-1,3-diene (**2**). Subsequent reaction with trialkylboranes leads to the immediate disappearance of the deeply red colour of the metalated diene. An intermediate 'ate' complex **3**[6] (Scheme 1) is probably formed that undergoes different reactions according to experimental conditions.

Treatment of complex **3** at −95 °C with H_2O–THF leads to the corresponding 1-alkoxy-1-alkylbuta-1,3-dienes **4**, that can be, like all enol ethers, smoothly converted to the corresponding



Scheme 1 *Reagents and conditions*: *a*: LIC–KOR, THF, −95 °C; *b*: BR_3, THF, −95 °C; *c*: −95 °C, H_2O; *d*: $BF_3{\cdot}OEt_2$, H_2O_2, −95 °C; *e*: C_6H_5I, $[(C_6H_5)_3P]_4Pd$, THF, 25 °C.

† Dedicated to Professor Iacopo Degani on the occasion of his 70th birthday.

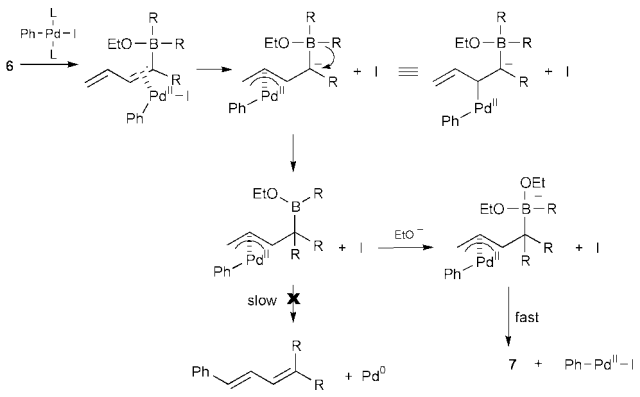
α,β-unsaturated ketones **5** (Scheme 1: path *c*). Moreover, derivatives **5** can be directly obtained from **3** upon treatment with a Lewis acid ($F_3B{\cdot}OEt_2$) in an oxidative milieu (Scheme 1: path *d*). More interestingly, a new and intriguing result comes from the reaction with iodobenzene in the presence of catalytic amounts of $[P(C_6H_5)_3]_4Pd$, according to the procedure of the Suzuki–Miyura cross-coupling reaction. Thus, when intermediate **3** was warmed to room temperature and treated with a THF solution of iodobenzene and $[P(C_6H_5)_3]_4Pd$ no coupling product **8** was detected, while the *gem*-dialkyl substituted buta-1,3-diene **7** was isolated in good yield (Scheme 1: path *e*).[7,8] In contrast, treatment of **3** with $[P(C_6H_5)_3]_4Pd$ in the absence of iodobenzene afforded only traces of product **7**.[9] Moreover, also when intermediate **3** undergoes the iodination reaction[6] or treatment with iodobenzene in the absence of a palladium complex no trace of product **7** was detected and only ketone **5** was recovered. The results obtained with different alkylboranes are reported in Table 1.

Table 1 Synthesis of 1-alkyl-1-ethoxybuta-1,3-dienes and 1,1-dialkylbuta-1,3-dienes[a]

1-Alkyl-1-ethoxybuta-1,3-dienes			1,1-Dialkylbuta-1,3-dienes		
R	Product	Yield (%)	R	Product	Yield (%)
n-C_4H_9	**4a**	86	*n*-C_4H_9	**7a**	79
c-C_5H_{11}	**4b**	87	*c*-C_5H_{11}	**7b**	86
n-C_6H_{13}	**4c**	82	*n*-C_6H_{13}	**7c**	68
c-C_6H_{11}	**4d**	71	*c*-C_6H_{11}	**7d**	77

[a] For experimental details, see note 7. The spectral data for new compounds **4a–4d** and **7a–7d** are consistent with the structures proposed.

The formation of compound **7** suggests the intermediate formation of the rearranged borate complex **6**, and in Scheme 2 a possible reaction mechanism is reported that may account for the formation of a *gem* substituted diene. According to this hypothesis vinylborate interacts with the Pd catalyst and undergoes transfer of an alkyl group, which promotes the



Scheme 2 Proposed reaction mechanism.

 DOI: 10.1039/b104449b

formation of a new π allyl complex. At this stage a new 'ate' complex forms that undergoes the elimination reaction much faster than the phenyl transfer process.

In conclusion, these results indicate that depending on the experimental conditions 1,1-dialkyl substituted buta-1,3-dienes, 1-ethoxy-1-alkylbuta-1,3-dienes and α,β-unsaturated ketones can be selectively prepared. Extension to other organoboron intermediates (asymmetric ones, in particular) and synthetic applications for these functionalized synthons, as well as mechanistic studies to check the role of the palladium complex and iodobenzene, are currently in progress in our group.[10]

This work was supported by grants from Italian MURST. We thank Dr Arnaud Gauthier and Dr Jacques Maddaluno (Université de Rouen) for helpful criticism, and CNR-CNRS for a grant for cultural exchange.

7 Typical run: to a cooled solution (−95 °C) of *t*-BuOK (1.4 g, 12.5 mmol) in anhydrous THF (10 ml) acetal **1** (0.72 g, 5.0 mmol) and BuLi (7.8 ml, 12.5 mmol) were consecutively added dropwise under stirring. After 2 h the purple–red solution was treated with tributylborane (5.0 mmol, 5 ml, 1.0 M in THF). The solution was allowed to warm to 25 °C and then added to a THF solution of C_6H_5I (4.0 mmol)–$[(C_6H_5)_3P]_4Pd$ (0.058 g, 1 mol%). The reaction mixture was allowed to react for 8 h. After standard work up the crude product was purified by column chromatography to afford pure **7a**. δ_H (400 MHz; $CDCl_3$) 0.87 (t, *J* 6.5, 3 H), 0.90 (t, *J* 6.5, 3 H), 1.2–1.5 (m, 8 H), 2.05 (t, *J* 6.2, 2 H), 2.15 (t, *J* 6.2, 2 H), 4.95 (dd, *J* 10.0, 1.0, 1 H), 5.10 (dd, *J* 16.0, 10.0, 1 H), 5.85 (d, *J* 10.0, 1 H), 6.60 (dt, *J* 16.0, 10.0, 1 H); δ_C (100.4 MHz; $CDCl_3$) 14.1, 22.7, 22.9, 29.8, 30.4, 30.5, 31.1, 37.0, 114.4, 125.3, 128.3, 133.4, 144.6.

8 Organoboron reagents have been used in the preparation of alkylidenecycloalkanes and *trans* disubstituted alkenes. See, G. Zweifel and R. P. Fisher, *Synthesis*, 1972, 557, and E. Negishi, J.-J. Katz and R. C. Brown, *Synthesis*, 1972, 555, respectively. Moreover, to our knowledge substituted and *gem*-dibutyl substituted buta-1,3-dienes have only been prepared in aqueous medium by the reaction of aldehydes and ketones with 1-chloro-3-iodopropene in the presence of zinc powder. See, T.-H. Chan and C.-J. Li, *Organometallics*, 1990, **9**, 2649.

9 We have carried out some control reactions (R = *n*-C_4H_9 and R = *c*-C_6H_{11}) in the presence of catalytic amounts (ranging from 5 to 10% with respect to acetal **1**) of PhI. The reactions proceed in good yields, but longer reaction times are needed.

10 In order to assess the role of the catalyst, in accordance with the suggestion of one of the referees, we have carried out a reaction in the presence of a Pd(II) complex. In particular we have repeated the synthesis of compound **7d** (R = *c*-C_6H_{11}) using $Pd(AcO)_2$ as a catalyst. The reaction takes place, but the product was obtained with a quite lower yield (by GC).

Direct observation of light induced spin transitions in new 3,5-bis(2-pyridyl)pyrazolato bridged thiocyanato diirion(II) complexes by monitoring variable temperature laser Raman spectra†

Naohiko Suemura, Mitsuo Ohama and Sumio Kaizaki*

Department of Chemistry, Graduate School of Science, Osaka University, Toyonaka, Osaka, 560-0043, Japan. E-mail: kaizaki@chem.sci.osaka-u.ac.jp

Received (in Cambridge, UK) 10th May 2001, Accepted 4th July 2001
First published as an Advance Article on the web 31st July 2001

The light induced excited spin state trapping LIESST and the reverse LIESST-like phenomena are observed below and above the spin transition temperature, respectively, for new dinuclear diirion(II) complexes and familiar Fe(II) complexes with thiocyanate ligands by monitoring the Raman spectra where only excitation light of various wavelengths for the spectroscopy was used without extra excitation light sources.

There have been a number of investigations concerning spin-crossover phenomena accompanying the spin state transition between the high-spin quintet and the low-spin singlet states of iron(II) complexes.[1] Among them, much attention has recently been paid to light induced excited spin state trapping (LIESST)[2] in relation with molecular switching or information storage from a viewpoint of molecular devices.[3] The thermal spin-crossover and LIESST by temperature variation and irradiation into the d–d or charge transfer transition regions are mainly observed by monitoring magnetic susceptibilities, optical spectra and Mössbauer spectroscopy.[2] On the other hand, there have been several studies of the spin-crossover on the basis of temperature variable vibrational spectroscopy. The Fe–N(NCS) or –N(phen) stretching bands for far IR[4] and the NC(NCS) band for IR[5] and FTIR[6] could be monitored to reveal the spin transitions for *cis*-$[Fe(NCS)_2(phen)_2]$ or related complexes. By monitoring the imine stretching band for Raman spectra, the Schiff base complexes were found to exhibit spin equilibrium. Meanwhile, the LIESST of *cis*-$[Fe(NCS)_2(phen)_2]$ has been detected by variable temperature FTIR measurement for the NC(NCS) stretching bands.[6] This occurs by irradiation of a low power 632.8 nm He–Ne laser for the calibration of the FTIR spectrophotometer. However, this method utilizes a limited radiation source with a low power and only one wavelength. Much advance in this field is expected to be made by overcoming this disadvantage of limited excitation sources. One of the candidates for easy access to LIESST could be laser Raman spectroscopy with excitation radiation of various wavelengths and variable powers for the spectroscopy itself, but without using any extra light source. Raman spectroscopy has been applied only to differentiating between high- and low-spin Fe(II) complexes[7,8] or estimating the entropy contributions.[8]

This paper reports a successful attempt to observe light induced spin transitions by measuring Raman spectra as a convenient and easily accessible probe. The complexes concerned are new dinuclear diiron(II) complexes bridged by two 3,5-bis(2-pyridyl)pyrazolates (bpypz) ligands with thiocyanate and pyridine derivatives in the Fe(II) unit, *trans*-(NCS, py-x)-$[Fe_2(NCS)_2(\mu\text{-bpypz})_2(py\text{-}x)_2]$ [py complex (**1**) and 3-Br-py complex (**2**)]‡ together with *cis*-$[Fe(NCS)_2(phen)_2]$ **3**§ and *cis*-$[Fe(NCS)_2(picen)]$ (picen = bis(2-pyridylmethyl)ethylenediamine) **4**.§ For complexes **1**–**4**, one or two Raman bands are observed around 2070 and 2100 cm^{-1} due to the C–N stretching of the NCS^- ligand. The lower and higher frequency bands correspond to the high- and low-spin complexes **1**–**4**, respectively, and their intensities vary with temperature [Fig. 1 (Figs. S1 and S2†)].¶ The high-spin fractions are approximated as $n_{HS} = I_{HS}/(I_{HS} + I_{LS})$ where I_{HS} of the high-spin species around 2070 cm^{-1} and I_{LS} of the low-spin one around 2100 cm^{-1} are Raman integrated band intensities at the observed temperatures. Plots of the high-spin fraction from the Raman band intensities *vs. T* do not always behave in a similar manner to those obtained from the magnetic susceptibility ($\chi_M T$) as seen in Figs. 2 and 3 (Fig. S3†). At temperatures just below T_c for complexes **1**–**3**, almost only the low-spin complexes exist as is evident from the $\chi_M T$ values; *ca.* 140–80 K for **1**, *ca.* 120–100

 DOI: 10.1039/b104121p

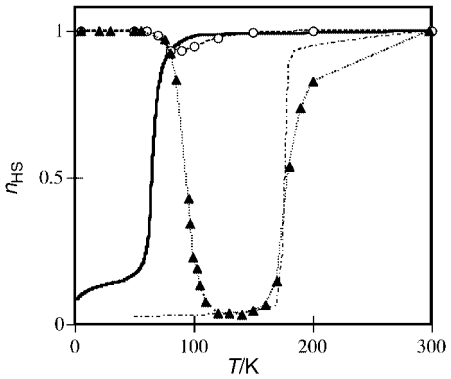

Fig. 3 Plots of the mole fraction of the high-spin state (n_{HS}) obtained from magnetic susceptibility measurements: **3** (-·-·-·-) and **4** (—) and from Raman intensities *vs.* *T*: **3** (···▲···) and **4** (---○---). The magnetic susceptibility and Raman measurements for complex **4** were conducted at a cooling rate of 0.06 K min^{-1}.

K for **2** and *ca*. 170–120 K for **3**. On further cooling, the low-spin fraction decreases and the high-spin state increases as shown in Figs. 2 and 3 (Fig. S3†). This observation of the spin transition from low- to high-spin demonstrates the LIESST. The LIESST occurs at the higher temperature with use of shorter wavelength irradiation light (Fig. 2 and Fig. S4†). In contrast to a deep drop to 100% of the low-spin fraction between the transition temperatures for **1**–**3**, complex **4** exhibits a shallow dip below T_c as shown in Fig. 3. This shallow dip might result from a slow relaxation from high- to low-spin[9b] or could be related to the anomalous spin-crossover phenomenon with hysteresis depending on cooling and heating rates.[9a] This observation suggests that the Raman spectra provide information on the spin-crossover dynamics. For the LIESST of complex **4**, the high-spin fraction was found to be *ca.* 40% by Mössbauer spectroscopy using broad-band (350–650 nm) excitation with a Xe arc lamp at 10 K,[9b] whereas the high-spin population is 100% according to Raman spectroscopy with a 632.8 nm He–Ne laser around 60 K.

It is noted that the low-spin complexes **1**–**4** exist even at temperatures above T_c. This phenomenon is more clearly recognized for the complexes **1** and **2** on measuring the Raman spectra with 514.5 nm Ar laser excitation (Fig. 1 and Fig. S2†). The low spin fraction for **1** is *ca.* 30% around 200 K (Fig. 2), and that for **2** is 15 and 50% at 300 and 118 K, respectively, (Fig. S3†). In contrast, almost 100% of the high-spin fraction is found to remain unchanged from the FT-IR[6] of **3** as well as the Raman measurements of **1** and **2** with 632.8 nm He–Ne laser irradiation at this temperature range. This light induced spin transition appears to be a kind of reverse LIESST.[10] However, the experimental conditions of temperature and radiation wavelength are definitely different from each other; the reverse LIESST occurs below T_c with 820 nm irradiation,[10] whereas the present phenomenon (reverse LIESST-like) is observed above T_c with 514.5 nm irradiation. This anomalous phenomenon is not clearly elucidated so far. Since both the Raman spectra and LIESST occur for a finite number of molecules[7] or a single molecule,[6c,11] the present Raman measurement may not be associated with light induced thermal hysteresis (LITH)[11] where the cooperative character affects the relaxation rate.[11b] To our knowledge, this is the first observation of LIESST and reverse LIESST-like phenomena in such a way that the high- and low-spin complexes are spontaneously trapped, respectively, below and above T_c by irradiation with a Raman spectral excitation laser. These discoveries by Raman spectroscopy will confer advantages to reveal new aspects of the light induced spin transitions by only one radiation source without an extra one.

We acknowledge support of this research by a Grant-in-Aid for Scientific Research on Priority Areas 'Metal-assembled Complexes' (No. 11136228) from the Ministry of Education, Science and Culture.

Highly active catalysts for the Suzuki coupling of aryl chlorides

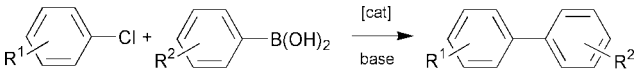
Robin B. Bedford* and Catherine S. J. Cazin

School of Chemistry, University of Exeter, Exeter, UK EX4 4QD. E-mail: r.bedford@ex.ac.uk

Received (in Cambridge, UK) 20th June 2001, Accepted 6th July 2001
First published as an Advance Article on the web 20th July 2001

Simple tricyclohexylphosphine adducts of palladium complexes with orthometallated *N*-donor ligands show by far the highest activity yet reported in the Suzuki coupling of aryl chlorides, even under aerobic conditions.

The ability to use aryl chlorides as substrates in Suzuki biaryl coupling reactions (Scheme 1), rather than the far more commonly employed aryl bromides, is advantageous for two reasons. Firstly there are many more commercially available aryl chlorides than bromides and secondly they are much cheaper. These considerations are particularly important for industrial applications. Consequently the search for catalysts that can activate these substrates is a highly topical field of study. Recent notable advances in the use of aryl chlorides in Suzuki reactions have been made by the groups of Buchwald,[1] Guram[2] and Nolan.[3] Most of these catalyst systems rely on the use of complexes derived from di- or tri-alkyl substituted phosphine ligands which are either laborious to synthesise or are commercially available but comparatively expensive. The expense is compounded by the fact that the catalysts have to be used in relatively high loadings. These factors coupled with the current high cost of palladium detract from the appeal of using aryl chloride substrates when far cheaper ligands can be used in ultra-high dilutions for the activation of aryl bromides.[4]

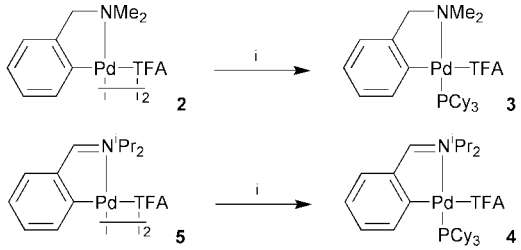


Scheme 1 The Suzuki biaryl coupling reaction.

By comparison with other phosphine ligands currently used in the activation of aryl chlorides, tricyclohexylphosphine is relatively cheap, readily available and easily handled. Littke and Fu have shown that palladium catalysts formed *in situ* with tricyclohexylphosphine show reasonable activity,[5] whilst Beller and coworkers have demonstrated that pre-formed Pd(0) complexes of the type [Pd(diene)(PCy_3)], **1**, are far more active.[6] Unfortunately, the synthesis and handling of the pre-formed complexes **1** are not particularly facile. It can be envisaged that an ideal catalyst for the Suzuki coupling of aryl chlorides would be one that: contains tricyclohexylphosphine; is easy to synthesise from cheap, commercially available materials; is easy to handle and shows good activity at low loadings.

We have previously obtained results that suggest that triphenylphosphine adducts of palladium complexes with orthometallated *N*-donor ligands act as precursors for low coordinate 'Pd–PPh_3' species in the Suzuki coupling of aryl bromides and that it is these low coordinate species that are the true active catalysts.[7] We were therefore interested to see whether analogous tricyclohexylphosphine adducts would show good activity in the Suzuki coupling of aryl chlorides. The preliminary findings of this study are reported below.[8]

The orthometallated amine complex **2** was used as a precursor as it is readily accessible from *N*,*N*-dimethylbenzylamine, which is commercially available and inexpensive and because we and later others have shown that the chloride-bridged analogue of **2** can be used in C–C bond forming processes.[9] Complex **2** readily reacts with tricyclohexylphosphine in dichloromethane to generate the adduct **3** in 60% yield after recrystallisation from dichloromethane–ethanol (Scheme 2). Complex **3** shows good air- and moisture-stability: ^{31}P NMR spectroscopy of a $CDCl_3$ solution shows only **3** and trace amounts of a second species after one month under aerobic conditions. For comparison purposes we also synthesised complex **4** by an analogous route from the metallated imine complex **5**. Complexes related to the precursor **5** have been found to give good activity in C–C coupling reactions with aryl bromides and iodides.[10]



Scheme 2 *Reagents and conditions*: i, PCy_3, CH_2Cl_2, r.t., 30 min.

4-Chloroanisole was chosen as the main test substrate for the optimisation studies as it is electronically deactivated and thus resistant to oxidative addition and consequently very reluctant to enter a catalytic manifold. Therefore any catalyst that can activate this challenging substrate would be expected to be active with a broad spectrum of aryl chlorides. The results of the coupling of 4-chloroanisole with phenylboronic acid are summarised in Table 1. A brief optimisation of solvents and bases (entries 1–8) showed that the activity of the catalyst was profoundly affected by reaction conditions and demonstrated that dioxane/Cs_2CO_3 mixtures gave the highest activity, although good activity was seen when K_3PO_4 was used as a base. We were delighted to see that complex **3** gave essentially complete conversion at 0.1 mol% catalyst loading and very high turnover numbers (TONs) of up to 8000 at 0.01 mol% loading. Astonishingly, no loss in activity was observed when coupling reactions were performed under air. The observed activity is over seven times higher than that of the catalysts **1** which give a maximum TON of 1120 for this reaction under similar conditions and an inert atmosphere.[6] To the best of our knowledge, the highest reported TON for any aryl chloride in the Suzuki reaction is 4600 for the comparatively easy to couple substrate 4-chloroacetophenone.[1*b*] Even at 60 °C catalyst **3** shows excellent conversion in the coupling of 4-chloroanisole at 1.0 mol% loading.

Whilst the parent dimer **2** shows virtually no activity in the coupling of 4-chloroanisole, catalysts prepared *in situ* from **2** and one equivalent of PCy_3 show essentially identical activity to **3**. However in this case the dilute solutions of the phosphine need to be made up under nitrogen whereas no special precautions are required with **3**. Increasing the amount of PCy_3 in *in situ* formed catalysts appears to have a deleterious effect on the activity. The complex **4** shows somewhat lower activity than **3**, in addition the need to pre-synthesise the imine ligand detracts from its appeal.

Encouraged by these results we investigated the use of **3** in the Suzuki coupling reactions of a range of aryl chlorides (entries 17–23). The reactions with the electron deficient substrates 4-chloroacetophenone, 4-chloronitrobenzene and

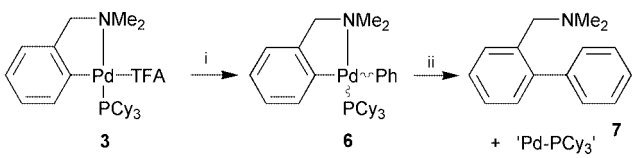
[a] Approximate internal temperature. [b] Determined by GC against hexadecane internal standard, based on aryl chloride. [c] Under air.

4-chlorobenzaldehyde all showed quantitative conversions at 0.01 mol% catalyst loading. Further reducing the catalyst loading gave a TON of at least 99 000 in the coupling of 4-chlorobenzaldehyde—over twenty times higher activity than observed previously in any aryl chloride coupling reaction.[1b] In order to evaluate the performance of **3** with more sterically demanding substrates, the reactions of 2-chlorotoluene and 2-chloroanisole were investigated. Both substrates were coupled with ease, the catalyst **3** again showing considerably higher activity than any other reported previously.

With respect to the mechanism, it seems highly unlikely that a Pd(II)/Pd(IV) catalytic cycle operates when complex **3** is used as a pre-catalyst, particularly when 4-chloroanisole, which is relatively resistant to oxidative addition reactions, is used as the substrate. It is far more likely that the active catalyst is a low-coordinate palladium(0) species. Such a species may conceivably be formed by a process involving nucleophilic attack of the phenylboronic acid at the metal centre followed by reductive elimination of the phenyl and metallated *N*,*N*-dimethylbenzylamine functions from the putative intermediate **6** (Scheme 3). Indeed GC and GC-MS analysis of the reaction mixture for the coupling of 4-chloroanisole at 60 °C showed the presence of substantial amounts of **7** (~63%) indicating that such a process almost certainly occurs under catalytic conditions. Mono-coordinate phosphine complexes have been implicated previously as catalysts in coupling reactions and it seems likely that they are the active species here.[6,11] This may help explain why doubling the concentration of PCy_3 in catalysts formed *in situ* drastically reduces the catalytic activity—effectively the Pd becomes over-ligated.



Scheme 3 *Reagents and conditions*: i, $PhB(OH)_2$, base; ii, reductive elimination.

Interestingly, regardless of the precise nature of the active catalyst species derived from **3** or from mixtures of **2** and PCy_3, they show far greater activity than preformed palladium(0) complexes of the type **1** or complexes formed *in situ* from PCy_3 and either $[Pd_2(dba)_3]$ or palladium acetate.[5,6] This demonstrates that the choice of palladium precursor can have a profound influence on the activity of the catalyst and that the orthopalladated *N*,*N*-dimethylbenzylamine moiety represents the most efficient source of active palladium species yet reported.

In summary we have found that the very easily synthesised, comparatively inexpensive complex **3** shows by far the highest activity yet reported in the Suzuki coupling of aryl chlorides, regardless of whether the substrates are electron rich or poor. Additionally this high activity is observed with catalysts formed *in situ* and when the reactions are performed under air.

We thank the University of Exeter for the provision of a student bursary (for C. S. J. C.).

Tuning metal coordination number by ancillary ligand steric effects: synthesis of a three-coordinate iron(II) complex

Jeremy M. Smith, Rene J. Lachicotte and Patrick L. Holland*

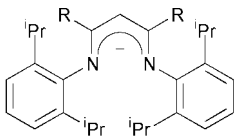
Department of Chemistry, University of Rochester, Rochester NY 14627, USA.
E-mail: holland@chem.rochester.edu

Received (in Cambridge, UK) 24th April 2001, Accepted 9th July 2001
First published as an Advance Article on the web 31st July 2001

The coordination number of the metal in iron(II) β-diketiminate complexes can be tuned through the size of the alkyl substituents on the ligand backbone.

Low coordinate transition metal complexes are of much interest for their ability to achieve unusual and difficult transformations.[1] Biological interest stems from the low coordinate iron centres found in the iron–molybdenum cofactor of nitrogenase.[2] The high reactivity of coordinatively unsaturated sites on iron surfaces may also be imitated by these complexes.[3]

The chelating β-diketiminate ligands (Fig. 1) have experienced a renaissance in interest recently, in part for their ability to stabilise low-coordinate metal complexes.[4] Here we show how a simple modification of these ligands at a position away from the immediate site of coordination results in dramatic changes to the geometry of the metal atom.



L R = Me
L′ R = ^{t}Bu

Fig. 1 β-Diketiminate ligands used in this study.

Reaction of equimolar amounts of the lithium salt of 2,4-bis(2,6-diisopropylphenylimido)pentane[5] (LiL) and $FeCl_2(THF)_{1.5}$[6] in THF results in the formation of a yellow solution, from which a yellow air-sensitive solid **1a** can be isolated by crystallisation from THF.† The molecular structure of crystals grown from pentane solution was determined by X-ray diffraction, revealing the product to be the 'ate' complex, $LFe(\mu\text{-}Cl)_2Li(THF)_2$ **1a**.‡ The complex crystallises with two molecules in the asymmetric unit (Fig. 2, only one molecule shown). The iron atom is four-coordinate, and distorted from ideal tetrahedral geometry. Thus, for example, the N(11)–Fe(1)–N(21) bond angle is relatively acute at 93.21(14)°, while the N(11)–Fe(1)–Cl(11) bond angle is relatively obtuse at 114.00(10)°. The bond lengths to iron do not significantly differ from typical values.[7] Interestingly, a second crystal form **1b**‡§ can be grown from THF at −35 °C; it crystallises with 3 molecules in the asymmetric unit. The gross structural features of all the unique molecules in both polymorphs are similar. The analogous diethyl ether solvated complex, $LFe(\mu\text{-}Cl)_2Li(Et_2O)_2$ **1c** can be obtained by crystallisation from diethyl ether at −35 °C.

The solid state magnetic moment is 5.4 μ_B, consistent with tetrahedral high spin iron(II).[8] More complicated behaviour is observed in solution. An unexpectedly large number of signals are observed in the ^{1}H NMR spectrum of **1a** in C_6D_6, although the correct number of resonances are observed in THF-d_8 solution. The solution magnetic moment[9] in either solvent is 4.4 μ_B. No changes in the spectrum or magnetic moment are observed in either solvent on addition of excess LiCl. Complexes **1a** and **1b** give identical ^{1}H NMR spectra in C_6D_6.

To determine the effect of the source of the β-diketiminate ligand on the coordination environment at iron, we used the magnesium complex LMg(Cl)(THF),¶ prepared from L and MeMgCl in THF. Reaction of this complex with $FeCl_2(THF)_{1.5}$ in THF solution results in the yellow complex $Mg(THF)_4[LFeCl(\mu\text{-}Cl)]_2$ **2** (Fig. 3).‖ The complex, which is insoluble in less polar solvents, can be isolated in moderate yield by multiple crystallisations from THF at −35 °C. An X-ray diffraction study‡ revealed the product to have an unusual structure, with the two iron centres bridged by a magnesium atom lying on a crystallographic inversion centre. Once again the iron is approximately tetrahedral, with bond lengths and angles similar to those in **1**.

Use of a slightly modified ligand resulted in a completely different product. Thus, refluxing a mixture of toluene, $FeCl_2(THF)_{1.5}$, and one molar equivalent of LiL′,[10] in which the ligand backbone methyls have been replaced by *tert*-butyl groups, results in the formation of a red solution from which a

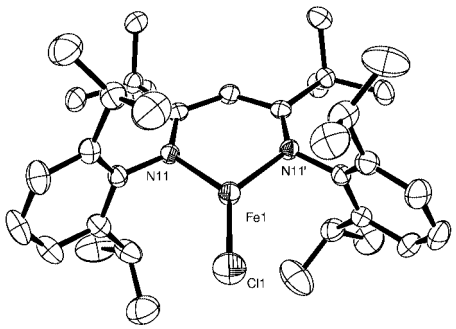

Fig. 4 Molecular structure of L′FeCl **3**. Hydrogen atoms not shown, thermal ellipsoids at 50% probability. Selected bond lengths (Å) and angles (°): Fe(1)–N(11) 1.948(2), Fe(1)–Cl(1) 2.172(1); N(11)–Fe(1)–N(11)′ 96.35(11), N(11)–Fe(1)–Cl(1) 131.83(5).

highly air-sensitive red solid **3** can be isolated.** The molecular structure of the product L′FeCl **3** was determined by X-ray crystallography (Fig. 4).‡ The iron and chlorine atoms are on a crystallographic mirror plane. The iron atom lies in a planar ring formed with the ligand; the bond angles around the metal reveal a planar geometry (sum of angles = 360°). The N(11)–Fe(1)–N(11)′ bond angle is compressed to 96.35(11)°, while the N(11)–Fe(1)–Cl(1) angle opens up to 131.83(5)°. As expected, the lower coordination number of the iron atom in **3** causes the bond lengths to the metal to decrease as compared to **1** and **2**. Both the solution (μ_{eff} = 5.5 μ_B) and solid state (μ_{eff} = 5.9 μ_B) magnetic moments confirm the high-spin iron(II) oxidation state. The ^{1}H NMR spectrum is relatively simple, consisting of seven paramagnetically shifted resonances.

While the effect of the ligand backbone groups on the coordination number of iron may not be immediately obvious, it can be understood by examining the C–N–C bond angles in the three complexes. In **1** they are in the range 118.6–120.3°, while in **3** they are 128.4(2)°. Thus, the *tert*-butyl groups on the ligand backbone in L′ force the aryl rings to close in on the metal, limiting the space available at the iron centre for more ligands.

In most three-coordinate complexes of Fe(II),[1,11] functionalisation, if it is achieved, is usually at the expense of the low coordination number. In contrast, complex **3** presents many viable pathways for further functionalisation by reactions with the chloride ligand while maintaining the low coordination number.

The University of Rochester is gratefully acknowledged for funding of this work. We would like to thank Kevin Mooney (University at Buffalo) for recording the SQUID data.

First published as an Advance Article on the web 1st August 2001

Heck reaction proceeds at ambient temperature (30 °C) with considerably enhanced reaction rate (1.5–3 h) through the formation of Pd–biscarbene complexes and stabilized clusters of zero-valent Pd nanoparticles in ionic liquids under ultrasonic irradiation.

The palladium catalyzed Heck reaction involving the coupling of alkenes/alkynes with aryl and vinyl halides is one of the most powerful tools in synthetic organic chemistry.[1] The reactions which are carried out in polar solvents such as DMF and NMP generally involve long reaction times (8–72 h) at temperatures ranging from 80–140 °C.[2] In recent times, ionic liquids have gained prominence as attractive alternatives to volatile organic solvents for catalytic reactions and separation processes.[3] Heck reaction in ionic liquids, in particular those involving dialkylimidazolium salts, have been reported very recently.[4] However, even in such media, wherein the ionic liquid anion and cation can exert a marked effect on the rate of the reaction, the reaction times involved are 24–72 h at temperatures ranging from 80–100 °C. This communication reports for the first time an ultrasound promoted Heck reaction in ionic liquids at ambient temperature (30 °C) with considerably enhanced reaction rates (reaction times 1.5–3 h) than those reported so far.

The sonochemical reactions were carried out in a thermostated ultrasonic cleaning bath of frequency 50 KHz (Branson 5200). Iodobenzene and substituted iodobenzenes were reacted with various alkenes/phenylacetylene in ionic liquids 1,3-di-*n*-butylimidazolium bromide [(bbim)$^+$Br$^-$] and 1,3-di-*n*-butylimidazolium tetrafluoroborate [(bbim)$^+$BF$_4^-$][5] using $Pd(OAc)_2$ as well as $PdCl_2$ as catalyst and sodium acetate as base under ultrasonic irradiation as shown in Fig. 1.

The products could be easily separated from the catalyst by extraction with 10% ethyl acetate in petroleum ether leaving behind the palladium catalyst in the dissolved state in the immiscible ionic liquid. The catalyst thus recovered as a solution in the ionic liquid could be reused at least three times without any loss of activity. Pure products were isolated by column chromatography.

The results are summarized in Table 1. As is evident, the ultrasound assisted Heck reaction of the iodobenzenes with alkenes/alkynes proceeded smoothly at ambient temperature (30 °C) with complete conversion of iodobenzenes in just 1.5–3 h to afford the *trans* products in excellent isolated yields (73–87%). No reaction under similar sonication conditions was observed when the ionic liquid was replaced by molecular solvents such as DMF and NMP even in the presence of a ligand such as PPh_3. The reaction also did not proceed with the less reactive aryl chlorides (chlorobenzene, *p*-nitrochlorobenzene and 2,4-dinitrochlorobenzene) and aryl bromides (bromobenzene) under the sonochemical conditions of the present work. Obviously, no reaction even in traces could be observed under ambient conditions in the absence of ultrasound.

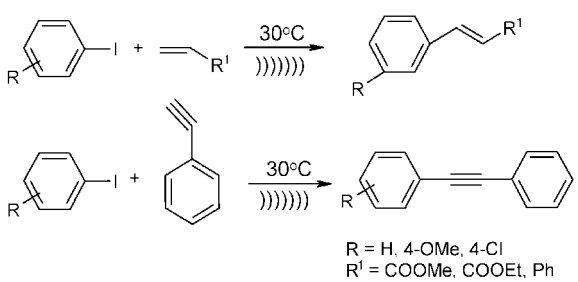

Fig. 1

Phosphine ligands, ammonium and phosphonium halides and quarternary ammonium salts have been found to stabilize the Pd-catalysts probably *via* formation of zero-valent Pd species and accelerate the olefination reaction.[6,7] In particular, Pd–carbene complexes with alkylimidazol-2-ylidenes have been reported very recently to be active in the Heck reaction.[4b] In the present work, the formation of such a complex was studied by subjecting a mixture of $Pd(OAc)_2$ or $PdCl_2$ and NaOAc in [bbim] + Br$^-$ and [bbim] + BF$_4^-$ respectively to ultrasound irradiation for 1 h. The complex was extracted into chloroform from the ionic liquid, the chloroform evaporated and the resulting crude product purified by column chromatography [petroleum ether–EtOAc, 1 : 1]. Indeed, the formation of the complex A was established and characterized by ^{1}H-NMR by the appearance of N–CH vinylic protons at δ 6.85 as a multiplet in the complex similar to the value reported by Xiao *et al.*[4b] and by the conspicuous absence of the N_2CH protons which appears as a singlet at δ 8.82 in the parent ionic liquid. The complexes were also characterized by MS which showed the respective molecular ion peaks. It is highly probable that complex A could be the immediate precursor for the likely active catalyst which could lead to a zero-valent Pd-species whose *in situ* generation by reduction of the divalent Pd–carbene complex is accelerated by electron transfer reactions under the sonochemical conditions primarily through the phenomenon of cavitation. It is well known that sonochemical processes proceed through SET mechanistic pathway by means of formation and adiabatic collapse of transient cavitation bubbles.[8,9] It is also highly probable that the Pd complexes formed *in situ* will experience secondary reactions in the liquid phase after the bubble collapses. Moreover, such Pd carbene complexes have been shown to be the precursors for active catalysts for the Heck and related C–C bond forming reactions in both molecular solvents and ionic liquids.[10–12] Detailed investigation of the mechanistic pathways as regards the formation/decomposition of the Pd–carbene complex under the sonochemical conditions is in progress and will form part of a full paper.

It has long been known that chemical or electrochemical reduction of transition metal salts in the presence of ammonium salts leads to $R_4N^+X^-$ stabilized colloids.[13] A recent study points to the involvement of intermediary colloidal Pd-nanoparticles generated under thermolytic conditions for the catalysis of the Heck reaction.[14] The formation of such Pd-nanoparticles was investigated in the present work by subjecting the reaction mixture, after successful Heck reaction of iodobenzene with ethyl acrylate in [bbim]$^+$BF$_4^-$ under sonochemical conditions, for '*in situ*' TEM analysis.

TEM analysis was carried out in Transmission Electron Microscope Model JEOL-1200 EX operated at 100 kV with a magnification of 200 K. The sample after appropriate dilution with isopropyl alcohol was directly deposited on carbon film

R = n-butyl
Y = Br, BF_4

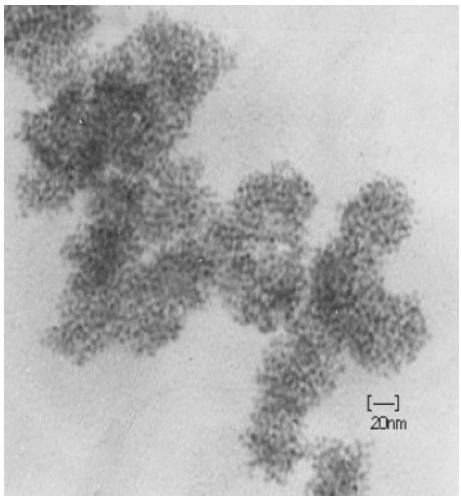

Fig. 2 TEM image of palladium clusters formed in the sonolytic Heck reaction.

coated TEM grids forming a thin film of colloidon. The TEM image (Fig. 2) shows the presence of monodispersed grains nearly spherical in shape. The average size of the grains obtained from the TEM picture is about 20 nm. The porous grains show that they are composed of dispersed particles of approximately 1 nm size. The clusters of Pd^0 nanoparticles in ionic liquids were found to be stable even after storage for a week since no change in the TEM picture was observed after this period, the ionic liquid obviously contributing to the stability. Further work is in progress in investigating the structural details of the nano-assembly of metallic palladium and its dispersion in ionic liquids under sonolytic conditions.

In conclusion, the Heck reaction has been performed at ambient temperature with considerably enhanced reaction rates by the combined use of ultrasonic irradiation and ionic liquids as solvent. Under the sonochemical conditions, the formation of Pd–biscarbene complex as a precursor and its subsequent sonolytic conversion to a highly stabilized cluster of zero-valent Pd nanoparticles has been established by NMR/MS and *in situ* TEM analyses respectively. Further work is in progress to elaborate these findings to other C–C bond formations such as Suzuki and Stille coupling reactions.[6]

Asymmetric trialkylaluminium addition to aldehydes catalyzed by titanium complexes of *N*-sulfonylated amino alcohols with two stereogenic centers

Jing-Song You,† Sheng-Hsiang Hsieh and Han-Mou Gau*

Department of Chemistry, National Chung-Hsing University, Taichung, Taiwan 402. E-mail: hmgau@dragon.nchu.edu.tw

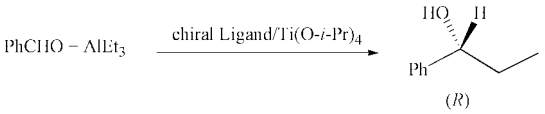
Received (in Cambridge, UK) 23rd April 2001, Accepted 20th June 2001
First published as an Advance Article on the web 1st August 2001

The asymmetric methylation, ethylation and allylation of aldehydes using trialkylaluminium reagents catalyzed by titanium(IV) complexes of *N*-sulfonylated amino alcohols gave excellent enantioselectivities of up to 99% ee.

Catalytic asymmetric carbon–carbon bond formation has been one of the most studied subjects in the past 10 years.[1] In these studies, the enantioselective additions of organozinc to aldehydes are one of the most reliable processes and thus gain much attention from chemists.[2–6] For alkylation reagents, trialkylaluminium reagents are more interesting since they are economically obtained in industrial scale.[7] Therefore the successful alkylation of aldehydes by trialkylaluminium should have great potential for practical applications. Unlike the diethylzinc addition to aldehydes which is extremely slow in the absence of a catalyst, trialkylaluminium reagents themselves are known to add to aldehydes at room temperature within hours. Due to competing reactions, the development of enantioselective catalysts for trialkylaluminium addition becomes much more challenging. Recently, Chan *et al.* reported the first example of asymmetric $AlEt_3$ addition to aldehydes employing titanium–BINOL systems with excellent ee's.[8] Subsequently, two papers dealing with the asymmetric methylation[9] and ethylation[10] of aldehydes by trialkylaluminium reagents were also reported.

Following our recent interest in titanium chemistry,[11] we herein report the synthesis of a family of amino alcohol derivatives **1**–**4** with one or two stereogenic centers. For *N*-sulfonylated amino alcohol derivative (*S*)-**1a** or (*S*)-**1b** as a chiral ligand, the asymmetric triethylaluminium addition to benzaldehyde was examined to afford low ee values of 29% (*R*) and 2% (*S*), respectively. The above results prompted us to synthesize a series of amino alcohols with two stereogenic centers, hoping to learn more about the structural factors that influence the enantioselectivity. Based on the route described by Reetz *et al.*,[12] amino alcohols **2** with two stereogenic centers starting from (*S*)-amino acids were synthesized. Compound **2** further reacted with arylsulfonyl chloride to give *N*-sulfonylated amino alcohol derivatives (*R*,*S*)-**3a**, (*R*,*S*)-**4a**–**c**, and (*S*,*S*)-**4a**.

Asymmetric triethylaluminium additions to benzaldehyde catalyzed by titanium(IV) complexes were conducted [eqn. (1)],



(1)

and the results are listed in Table 1.‡ While using 10 mol% of *N*-sulfonylated β-amino alcohol (*S*)-**1a** or (*S*)-**1b**, the reaction gave low ee values (entries 1 and 2). In using bidentate (*R*,*S*)-**3a** with two stereogenic centers, the ee value dramatically improved to 70% (entry 3). From entries 4–6, the tridentate ligands (*R*,*S*)-**4a** were examined with variation of the amount of $Ti(O\text{-}i\text{-}Pr)_4$ added. Without the addition of $Ti(O\text{-}i\text{-}Pr)_4$, the yield of 1-phenylpropanol is 44% with ee value of only 4% (*R*) (entry 4). With the addition of 0.05 mmol $Ti(O\text{-}i\text{-}Pr)_4$ (10 mol%), which gives a molar ratio of 1 : 1 of $Ti(O\text{-}i\text{-}Pr)_4$–(*R*,*S*)-**4a**, the ee value improves to 45% (*R*) (entry 5). Similar to previous studies of asymmetric diethylzinc addition to aldehydes, excess $Ti(O\text{-}i\text{-}Pr)_4$ is required in order to obtain the best enantioselectivity and, in this study, the best ee value of 96% was obtained for a catalytic system with a $Ti(O\text{-}i\text{-}Pr)_4$–(*R*,*S*)-**4a** ratio of 18 (entry

12	2-Naphthaldehyde	(Allyl)$AlEt_2$	0.9	100	96 (*R*)

[a] Aldehyde, 0.5 mmol; trialkylaluminium, 1.25 mmol; Ti(O-*i*-Pr)$_4$, 0.9 mmol; reaction temperature, 0 °C; reaction time, 12 h. [b] The ee values were determined by HPLC with a chiral OD column. [c] Determined by HPLC with a chiralcel AS column after protecting as a benzoyl ester.

6). Even with the use of as little as 5 mol% of (*R*,*S*)-**4a**, 95% ee was still obtained (entry 7). For chiral ligand (*S*,*S*)-**4a** which is a diastereomer of (*R*,*S*)-**4a**, a much lower ee value of 26% was obtained (entry 8). When the substituent on the amino carbon was replaced with a phenyl group ((*R*,*S*)-**4b**), the ee value decreases to only 75% (entry 9). For (*R*,*S*)-**4c** with a *tert*-butyl substituent instead of a phenyl group on the chiral alcoholic carbon in (*R*,*S*)-**4a**, an ee value of 8% of *S*-configuration was observed (entry 10). In the initial study of triethylaluminium addition to benzaldehyde, a profound solvent effect was observed, and only a coordinating solvent such as THF prompted high enantioselectivities.

The enhanced unique reactivity of the *N*-sulfonylated amino alcohol (*R*,*S*)-**4a** is suggested to arise from the following two factors: (1) phenoxides are known to form strong bonds to group 4 transition metals, and with electron withdrawing halogen groups, the phenoxide moiety may lead to enhance Lewis acidity at the metal centre; (2) the phenolic ring provides conformational rigidity which may be an important factor in the transfer of asymmetry.

For examining the substrate generality, the best performing (*R*,*S*)-**4a**–Ti(O-*i*-Pr)$_4$ catalytic system was used (Table 2). Ee values ranging from 92–96% (*R*) (entries 1–4) were recorded for aromatic aldehydes with the best result observed for benzaldehyde as a substrate. For the (*E*)-cinnamaldehyde, the ee value is somewhat lower at 88% (entry 5). Interestingly, the catalytic system catalyzed the ethylation of the aliphatic cyclohexanecarboxaldehyde with an ee value of 91% (entry 6). Though not many aldehydes were examined, the catalytic system generally seems to work well for both aromatic and aliphatic aldehydes.

In addition, other trialkylaluminium reagents such as $AlMe_3$ and $AlEt_2$(allyl)[13] were also examined. $AlMe_3$ was added to aldehydes, to give exceptional ee values from 91 to 99% (entries 7–10). More interestingly, when allyldiethylaluminium was used as an alkylation reagent, the allyl group rather than the ethyl group selectively added to aldehydes to give the secondary homoallyl alcohol with excellent ee values of 90% for benzaldehyde (entry 11) and 96% for 2-naphthaldehyde (entry 12). For catalytic allylation reactions, this is the first example of catalytically enantioselective allylation of aldehydes employing the allyldialkylaluminium reagent, to the best of our knowledge.

In summary, a family of *N*-sulfonylated amino alcohols have been developed for asymmetric alkylation reactions. The (*R*,*S*)-**4a**–Ti(O-*i*-Pr)$_4$ system is an excellent catalyst for trialkylaluminium addition to aldehydes at a convenient temperature of 0 °C. Furthermore, the (*R*,*S*)-**4a**/Ti(O-*i*-Pr)$_4$ catalytic system shows a wide generality of trialkylaluminum reagents such as $AlEt_3$, $AlMe_3$, or even (allyl)$AlEt_2$.

Notes and references

‡ *General procedures for the addition of trialkylaluminium reagents to aldehydes*. Under a dry dinitrogen atmosphere, the ligand and Ti(O-*i*-Pr)$_4$ were mixed in 1.5 mL of dry THF at room temperature. After 1 hour, 1.25 mmol of $AlEt_3$, $AlMe_3$ or allyldiethylaluminum was added at 0 °C. After the mixture was stirred for 30 min, the orange-colored solution was treated with aldehyde (0.5 mmol) at 0 °C, kept at this temperature for 10 h, and quenched with 1 M HCl. The aqueous phase was extracted with ethyl acetate (3 × 5 mL), dried over $MgSO_4$, filtered and concentrated. Chromatography of the residue on silica gel (elution with 5:1 hexane–ethyl acetate) gave the alcohol. The enantiomeric purity of the product was determined by HPLC.

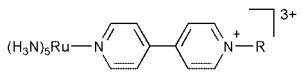
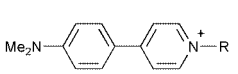
Hyper-Rayleigh scattering and Stark spectroscopic studies show that the complex salts [1–4]PF_6 have larger static first hyperpolarizabilities β_0 than [5–8]PF_6, because the higher HOMO energy of a $\{Ru^{II}(NH_3)_5\}^{2+}$ centre more than offsets the superior π-orbital overlap in the purely organic chromophores.

Recent years have witnessed great interest in molecular materials having non-linear optical (NLO) properties, due to their potential for applications in nascent optoelectronic/photonic technologies.[1] Most such materials are purely organic, but organotransition metal complexes also exhibit NLO effects.[2] Our contribution to this field has focused on the quadratic NLO properties of dipolar Ru^{II} ammine complexes.[3]

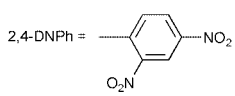
Molecules with large quadratic NLO activities contain electron donor and acceptor groups connected via polarisable π-systems. Molecular quadratic NLO behaviour arises from first hyperpolarizabilities β, and static first hyperpolarizabilities β_0 are used for comparison purposes. Perhaps surprisingly, quantitative, systematic comparisons of the electron donor/acceptor properties of metal centres with those of more traditional organic groups are very scarce. Indeed, the only such study appears to be a ZINDO analysis of β values which showed that the ferrocenyl and 4-(methoxy)phenyl donor groups are essentially interchangeable.[4] Here we report an experimental study of the complex salts [**1**–**4**]PF_6 and the organics [**5**–**8**]PF_6 which allows a comparison of the $\{Ru^{II}(NH_3)_5(py)\}^{2+}$ (py = pyridyl) and 4-(dimethylamino)phenyl π-electron donors.



R = Me (**1**), Ph (**2**), 2,4-DNPh (**3**), 2-Pym (**4**)



R = Me (**5**), Ph (**6**), 2,4-DNPh (**7**), 2-Pym (**8**)



[**1**–**4**]PF_6[3b,c] and [**5**–**7**]Cl[5] were synthesized as described previously, and [**5**–**7**]Cl were metathesised to [**5**–**7**]PF_6 by precipitation from H_2O–NH_4PF_6.† [**8**]PF_6 was prepared from 4-(dimethylaminophenyl)pyridine[6] and 2-chloropyrimidine, followed by precipitation from H_2O–NH_4PF_6.†

Selected spectroscopic and electrochemical data for [**1**–**8**]PF_6 are given in Table 1. The visible absorptions of [**1**–**4**]PF_6 are due to $d_\pi(Ru^{II}) \rightarrow p_{\pi^*}$(pyridinium) charge-transfer (CT) excitations,[3b,c] whilst those of [**5**-**8**]PF_6 arise from $p_\pi(NMe_2) \rightarrow p_{\pi^*}$(pyridinium) CTs. The CT energies E_{max} of [**5**–**8**]PF_6 are higher than those of [**1**–**4**]PF_6, but the organic *vs.* complex energy difference decreases from 0.85 to 0.72 eV as R changes in the order Me > Ph > 2,4-DNPh > 2-Pym. Also, the molar extinction coefficients of the CT bands of [**5**–**8**]PF_6 are *ca.* 2–3 times larger than those of [**1**–**4**]PF_6. Within both series, E_{max} decreases as R changes in the order Me > Ph > 2,4-DNPh > 2-Pym, the differences between the extremes being 0.26 eV for [**1**–**4**]PF_6 and 0.39 eV for [**5**–**8**]PF_6.

The cyclic voltammetric data show that the $\{Ru^{II}(NH_3)_5\}^{2+}$ moiety is much easier to oxidise than the $–NMe_2$ group, and the pyridinium groups in the complexes are easier to reduce than those in the organics. These observations are consistent with the lower E_{max} values, due to smaller HOMO–LUMO gaps, for [**1**–**4**]PF_6 compared with [**5**–**8**]PF_6. Furthermore, the E_{red} values show that the $–C_6H_4NMe_2$-4 group exerts a greater electron-donating influence on the acceptors than does the $\{Ru^{II}(NH_3)_5(py)\}^{2+}$ moiety, despite the fact that the $\{Ru^{II}(NH_3)_5\}^{2+}$ centre is more electron-rich than the $–NMe_2$ group. E_{ox} does not change greatly within each series, but E_{red} becomes less negative as R changes in the order Me < Ph < 2-Pym < 2,4-DNPh. This trend almost parallels the decreasing CT energies and reflects the increasing electron-deficiency of the acceptor group. The NMR data show that the protons *ortho* to the pyridinium N atoms are more shielded in [**5**–**8**]PF_6, consistent with the greater net electron-donating effect of the $–C_6H_4NMe_2$-4 group *vs.* $\{Ru^{II}(NH_3)_5(py)\}^{2+}$.

The greater electron-donating influence of a $–C_6H_4NMe_2$-4 group compared with $\{Ru^{II}(NH_3)_5(py)\}^{2+}$ can be traced to two

[a] Butyronitrile glasses at 77 K (*ca*). 10^{-5} mol dm^{-3}). [b] Oscillator strength determined by numerical integration of the digitized absorption spectra. [c] Static first hyperpolarizability calculated from eqn. (1). [d] First hyperpolarizability measured in acetonitrile at 298 K using a ns 1064 nm laser for [**1**–**4**]PF_6 and a fs 1300 nm laser for [**5**–**8**]PF_6. [e] Static first hyperpolarizability estimated from β *via* the two-state model.[9] [f] Ref. 3(*b*). [g] Ref. 3(*c*).

factors. Firstly, the latter is a σ-electron acceptor, as well as a π-donor, whilst the former is only a π-donor. The second, and perhaps more important, factor is more effective p(N)–p(C) compared with p(N)–d(Ru) π-orbital overlap. Such an effect also explains differences between mixed-valence ions containing $–C_6H_4NMe_2$-4 or $\{Ru^{II}(NH_3)_5(py)\}^{2+}$ groups.[7]

We have obtained β values for [**1**–**8**]PF_6 by using hyper-Rayleigh scattering (HRS) studies;[8] β_0 values were derived *via* the two-state model[9] and results are shown in Table 2. The previously reported β_0 values of [**1**-**4**]PF_6 were derived from nanosecond 1064 nm HRS,[3b,c] whilst [**5**-**8**]PF_6 were studied using femtosecond 1300 nm HRS,[10] incorporating fluorescence demodulation.[11] Unfortunately, the 650 nm HRS signal from [**5**]PF_6 was too weak to allow determination of β. Two conclusions can be drawn from the HRS data: *(i)* the β_0 values of the complexes appear to be much larger than those of their organic counterparts (but note that comparison of HRS β_0 values obtained under different experimental conditions may be of limited validity),[12] and (*ii*) decreasing E_{max} generally corresponds with increasing β_0 within both series.

Stark spectroscopy affords dipole moment changes upon CT excitation $\Delta\mu_{12}$.[13] According to the two-state model, $\Delta\mu_{12}$ can be used to calculate β_0 by using eqn. (1)[9]

$$\beta_0 = \frac{3\Delta\mu_{12}(\mu_{12})^2}{2(E_{max})^2} \quad (1)$$

where μ_{12} is the transition dipole moment. The results of Stark studies on [**1**–**8**]PF_6, carried out at 77 K as previously described,[14] are given in Table 2. Unfortunately, the data fits for [**4**]PF_6 and [**7**]PF_6 were unsatisfactory. The μ_{12} values, diabatic dipole moment changes $\Delta\mu_{ab}$, mixing coefficients c_b^2 and electronic coupling matrix elements H_{ab} for the diabatic states were calculated as previously described.[14]

The CT f_{os} and μ_{12} values of [**5**–**8**]PF_6 are larger than those of [**1**–**4**]PF_6. Furthermore, μ_{12} generally increases as E_{max} decreases within each series. [**1**–**8**]PF_6 show relatively large $\Delta\mu_{12}$ values, with [**1**]PF_6 and [**2**]PF_6 having larger values than [**5**]PF_6 and [**6**]PF_6, respectively. For the complexes, $\Delta\mu_{12}$ increases as R changes in the order Me < Ph < 2,4-DNPh, but a similar trend is not shown by the organics. The values of c_b^2 and H_{ab} for the organics are about twice those for the complexes, consistent with the less effective d(Ru)–p(N) *vs.* p(N)–p(C) π-orbital overlap indicated by the electrochemical and NMR data. The β_0 values derived from eqn. (1) are in agreement with the HRS results in as much as they increase as E_{max} decreases within each series. However, in contrast with HRS, the Stark data indicate that the β_0 values of [**1**]PF_6 and [**2**]PF_6 are only slightly larger than those of their organic counterparts. This is because the β_0-enhancing effects of decreasing E_{max} and increasing $\Delta\mu_{12}$ are largely offset by decreasing μ_{12} when moving from organic to complex.

In conclusion, a $\{Ru^{II}(NH_3)_5(py)\}^{2+}$ centre is more electron-rich than a $–C_6H_4NMe_2$-4 group, but the latter exerts a greater electron-donating effect on pyridinium units due in part to more effective π-orbital overlap. HRS data show that [**1**–**4**]PF_6 have much larger β_0 values than their organic counterparts, but Stark spectroscopy indicates that the increase in β_0 between the complexes and organics is much smaller. Nevertheless, the complexes do have the added attraction that their CT absorption and NLO responses are redox-switchable.[15]

We thank the EPSRC for a PhD studentship (J. A. H.). Studies at Brookhaven National Laboratory were carried out under contract DE-AC02-98CH10886 with the US Department of Energy and supported by its Division of Chemical Sciences, Office of Basic Energy Sciences. K. W. is a research assistant with the Fund for Scientific Research-Flanders.

A new stabilised form of isobenzofuran, rack-mounted on an alicyclophane

Ronald N. Warrener,* Muhong Shang and Douglas N. Butler

Centre for Molecular Architecture, Central Queensland University, Rockhampton, Queensland, 4702, Australia. E-mail: r.warrener@cqu.edu.au; Fax: +61 7 4930 9919; Tel: +61 7 4930 9917

Received (in Cambridge, UK) 18th May 2001, Accepted 20th June 2001
First published as an Advance Article on the web 1st August 2001

New stable, crystalline isobenzofurans 9a and 9b linked through the 1,3-positions and incorporated into alicyclophanes have been prepared from the related furano-alicyclophane 5 in three steps (i) addition of benzyne or 4,5-bis(trimethylsilyl)benzyne (ii) hydrogenation of the π-bond (iii) ejection of ethylene by flash vacuum pyrolysis, and shown to yet retain high 1,3-diene character and form adducts with dienophiles, *e.g.* dimethyl acetylenedicarboxylate or *N*-methyl maleimide; the corresponding off-rack 1,3-dimethylisobenzofurans were too unstable for isolation.

Many cyclic polyene compounds that resist isolation in monomeric form, do so because of their propensity to react with themselves, *e.g.* dimerisation of cyclobutadiene[1] or polymerisation of isobenzofuran.[2] Specialised techniques to generate the monomer species in a controlled environment have been reported, *e.g.* flash vacuum pyrolysis or matrix isolation at liquid helium temperatures. The most ingenious way to isolate such a highly reactive monomer, however, was reported by Cram and co-workers who were able to corral cyclobutadiene inside a hemicarcerand (**1**, Fig. 1), study its chemistry and even record its NMR spectrum.[3] This method succeeded since it kept the cyclobutadiene molecules separated from each other, and confirmed the inherent stability of cyclobutadiene itself. In principle, this technique should be suitable for the study of isobenzo-systems, a class of unstable monomeric compounds characterised by the presence of the *o*-xylylidene chromophore.[4] In practice, our efforts to achieve this goal using the Cram technique have been unrewarding because of the difficulty in preparing hemicarcerand hosts large enough to encase photosubstrates currently required for such isobenzo-system generation.[5]† Accordingly, we have sought ways to stabilise these highly reactive monomers other than having them so heavily substituted that their natural chemistry could be compromised.[6]

We report herein a new technique for stabilising isobenzofurans (rack-IBFs) by incorporating them into an alicyclophane macrocycle (**2**, Fig. 1).[7] The concept depends on the rack section of the alicyclophane acting as a steric shield (6.65 × 6.81 Å in rack **3**, X-ray data[8]) that by its presence in rack-IBFs **9a** and **9b** inhibits intermolecular self-dimerisation or polymerisation processes. This motif should be applicable to other isobenzo-systems (isoindoles, isoindenes and isobenzofulvenes) as well as elusive monomers such as cyclobutadiene and cyclopentadienones. The new rack-IBFs **9a** and **9b** are stable, high melting solids that could be isolated, handled as regular compounds and stored in solution for several days at 5 °C and for many months in the solid state.

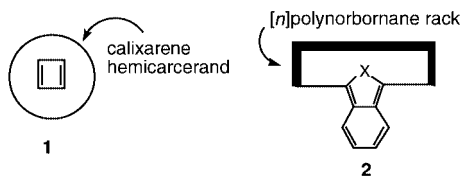

Fig. 1

The synthesis of the parent rack-IBF **9a** commenced from the bis(succinimide) rack **3**[7] which was reacted with 2,5-bis-(bromomethyl)furan **4** in dimethylformamide containing solid potassium carbonate to produce the furano-alicyclophane **5**[9] in 84% yield (Scheme 1). Reaction of rack-furan **5** with benzyne **6a**, generated by diazotisation of anthranilic acid, gave the 1,4-epoxy-1,4-dihydronaphthalene derivative **7a** which was hydrogenated (Pd/C, H_2, 50 psi, 3 days) to the 2,3-dihydro compound **8a** and this subjected to flash vacuum pyrolysis (FVP, 500 °C, 0.001 mbar) to afford the rack-IBF **9a**, mp 199–201 °C, in 98% yield.[10]‡ The stability of rack-IBF **9a** contrasted strikingly with the structurally similar 1,3-dimethylisobenzofuran **12a** which, when generated under the same FVP conditions from **11a**, was found to form a polymer upon attempted isolation.§

The ^{1}H NMR spectrum of rack-IBF **9a** revealed that the rack *endo*-protons Ha, Hb were equivalent (δ 1.70) and upfield-shifted relative to those in rack-IBF **3** (δ 2.30) owing to the ring-current of the 10π-isobenzofuran while the other rack protons occurred as overlapping resonances at δ 3.01 (bridgehead, succinimide) and an AB doublet (δ 2.19, δ 1.33 J = 11 Hz) for the methano bridges. Also, the aromatic protons appeared as an AA′BB′ pattern at δ 6.99 and 7.59 while the *N*-methylene protons displayed a singlet resonance at δ 4.93 indicative of a rapid, pendulum motion of the IBF ring about the long σ-plane of the molecule.¶

While the isobenzofuran component of rack-IBF **9a** was stabilised against polymerisation (or homocycloadditions) by incorporation into the rack, it still retained the ability to react as a 4π-diene with small 2π-dienophiles to form [4π + 2π] Diels–Alder cycloadducts, *e.g.* reaction with *N*-methylmaleimide **13** was complete in 2 minutes (quantitative yield) and gave exclusively the *endo*-adduct (*N*-Me δ 2.25). In contrast, *N*-methylmaleimide **13** reacted more slowly (1 hour, RT) with the unstable 1,3-Me_2IBF **12a** and produced a 1:5 mixture of *exo*-(*N*-Me δ 3.03) and *endo*- (*N*-Me δ 2.23) isomers of **14** in 55% yield.

This rack-mounting strategy was general and FVP (500 °C, 0.001 mbar) of **8b** yielded rack-$(TMS)_2$IBF **9b**‖ [^{1}H NMR δ 7.93 (s, 2H), 4.93, (s, 4H), 3.02, (s, 8H), 2.19 (d, J = 11 Hz, 2H), 1.73 (s, 4H), 1.56 (s, 4H), 1.28 (d, J = 11 Hz, 2H), 0.42 (s, 18H)], isolated as a stable crystalline product (96% yield), mp 312–314 °C. In a model study, 5,6-$(TMS)_2$-1,3-Me_2IBF **12b** was prepared by FVP (620 °C, 0.001 mbar) of the 1,4-epoxy-1,2,3,4-tetrahydro $(TMS)_2$ naphthalene **11b**. The non-crystalline product **12b** [^{1}H NMR δ 7.55 (s, 2H), 2.57 (s, 6H), 0.35 (s, 18H)] rapidly decomposed in $CDCl_3$ solution but could be characterised by treating the pyrolysate immediately after deposition with a solution of *N*-methyl maleimide **13** in $CDCl_3$ as its *endo*-adduct **14b** (67% yield).

In conclusion, we have demonstrated that incorporation of isobenzofurans into alicyclophanes to produce rack-IBFs dramatically increases their stability, yet achieves this without compromising the Diels–Alder capacity of the IBF component. This strategy should be applicable to other reactive monomers with a propensity for self-dimerisation, and experiments to test

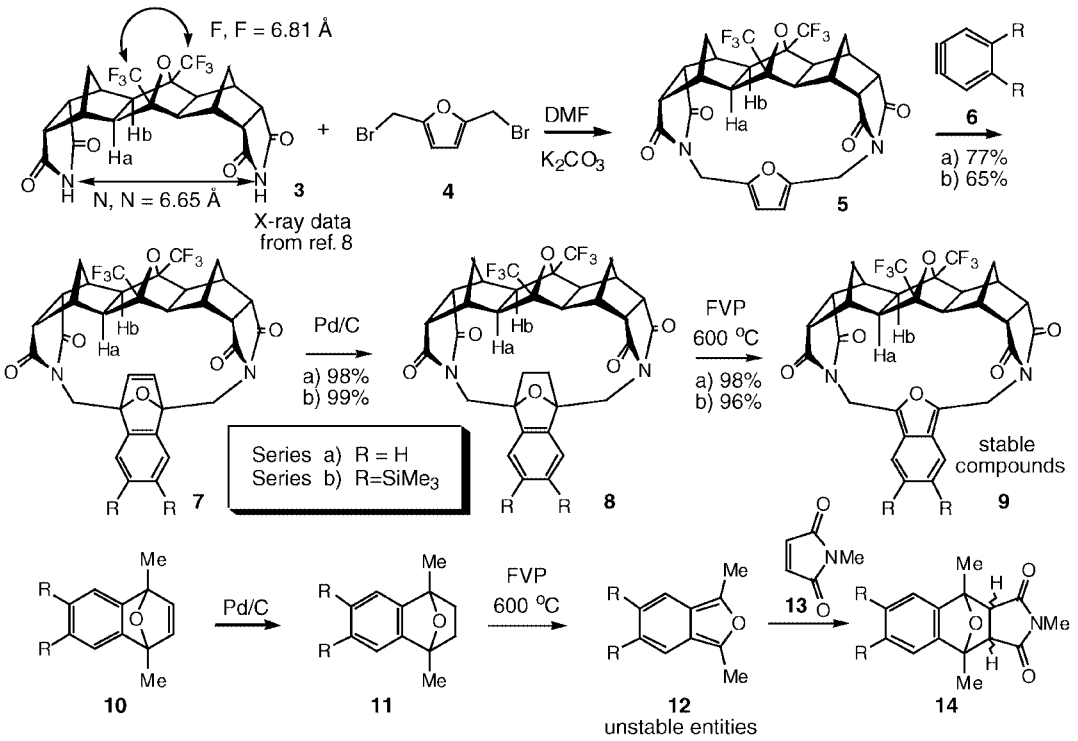

Scheme 1

this proposal are currently being undertaken and results will be reported in due course.

Notes and references

† We have conducted a theoretical study (AM1) on the size compatibility of guests with Cram-type hemicarcerands as an aid to selecting hemicarcerands for photosubstrate incorporation (ref. 7).

‡ The incorporation of trifluoromethyl substituents into the alicyclophane improved their volatility and thermal stability, key factors required for application of this FVP technique.

§ Substituents at the 1,4-positions of 1,4-epoxy-1,4-dihydronaphthalene are known to restrict access of 3,6-di-2-pyridyl-s-tetrazine (ref. 11) to the π-bond and often preclude the use of this route to produce the corresponding IBF (ref. 12) in this study, attempts to prepare rack-IBF **9a** from **7** failed (too crowded), yet it is known that 1,3-Me_2IBF **12a** can be formed from **10a**. Removal of one or both 1,4-substituents allows the reaction to proceed, *e.g.* Wong and co-workers used the method successfully for the preparation of 5,6-$(TMS)_2$IBF and trapped it with *N*-phenylmaleimide (ref. 13).

¶ Protons Ha, Hb are non-equivalent in **7** and **8**, but are equivalent in **5** and **9**. The significance of these observations will be discussed elsewhere, (ref. 14).

‖ The 4,5-bis(trimethylsilyl)benzyne **6b** required for the formation of **7b** from **5b** was generated from 1,2,3,4-tetra(trimethylsilyl)benzene by treatment with diacetoxyiodobenzene (ref. 15).

Synthetic study of phomoidride B (CP-263,114); utilization of the oxidopyrylium [5 + 2] cycloaddition

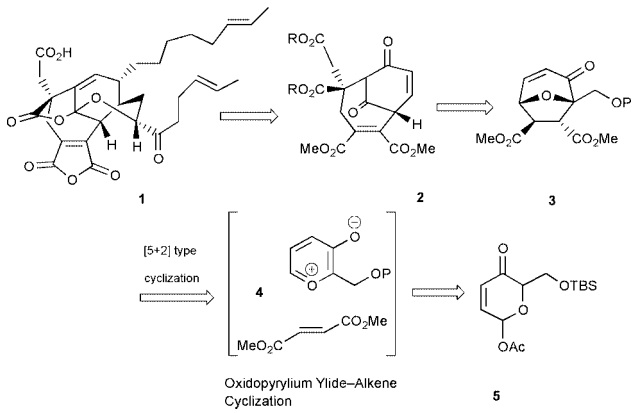
Naoki Ohmori

Department of Chemistry, Graduate School of Science, Hiroshima University, 1-3-1 Kagamiyama, Higashi-Hiroshima 739-8526, Japan. E-mail: d1174001@hiroshima.u.ac.jp

Received (in Cambridge, UK) 15th May 2001, Accepted 28th June 2001
First published as an Advance Article on the web 1st August 2001

The highly functionalized core structure of phomoidride B (CP-263,114) was pursued by using intermolecular oxidopyrylium–alkene cyclization as one of the key steps.

In 1997, the group of Kaneko reported the structure of phomoidride B (**1**) and its hydrolysed derivatives, both showing inhibitory activity towards farnesyl transferase[1] with IC_{50} values in the micromolar range.[2] A great many synthetic organic chemists have been attracted by its fascinating structural features and so far four groups have achieved elegant complete total syntheses.[3] Retrosynthetic analysis suggested that **1** could be accessed from **2** by introducing side chains followed by minimal functional group manipulations. Bicyclic **2** in turn could be constructed from modestly functionalized seven-membered ring **3**, which could easily be obtained by treating the oxidopyrylium ylide[4] **4** with fumarate ester or its variants thus providing easy access to the maleic anhydride moiety of the CP-core (Scheme 1).



Scheme 1 Strategy for the total synthesis of phomoidride B (**1**).

The synthesis began with the protection of but-2-ene-1,4-diol with TBSCl (Scheme 2). Oxidopyrylium precursor **8** was easily prepared in 5 steps (39% from but-2-ene-1,4-diol). When using dimethyl fumarate as the alkene, cyclization took place quite efficiently in the presence of Et_3N to deliver oxabicycles **9a** and **9b** (13 : 1) in 77% combined yield. Hydrogenation of **9a** followed by the removal of the silyl protecting group and iodination gave **12** (Scheme 3). Of several attempts to cleave the ether bridge in reductive fashion, Zn proved to be the most suitable, yielding *exo*-enone **13** in 96% yield. Homologation of the *exo* olefin seemed reasonable for introducing the lacking two carbon unit required for construction of the bicyclo-[4.3.1]decene core. To this end, **13** was treated with TBSOTf in the presence of 2,6-lutidine to give a separable mixture of TBS-protected acetal **14** (49%) and enone **15** (5%). Acetal **14** was next converted to **16**† in two steps by allylation in the presence of $TiCl_4$ followed by reprotection of the liberated alcohol with TBSOTf. Ketone **16** was subjected to ozonolysis to yield a keto-aldehyde, which was subsequently treated with DBU to promote the intramolecular aldol reaction.[6] The crude aldol adduct was oxidized with PCC to deliver diketones **17a** and **17b** (4 : 1, 82% yield over 2 steps). Oxidation of **17a** to enone **18** under Saegusa's conditions[7] proceeded in 35% yield. Improved yields were obtained using the recently reported Nicolaou method using IBX (IBX = 2-iodylbenzoic acid),[8] giving enone **18** in 30% yield along with recovery of the starting material (42%). Repeated oxidation of recovered **17a** resulted in a combined yield of 42% (52%, based on recovered **17a**). Lewis acid catalyzed allylation of **18** gave a 1,4-adduct as a single stereoisomer. Further allylation utilizing palladium chemistry

delivered **19**‡ (19% yield from **18**) a highly advanced bicyclic intermediate with the required relative stereochemistry between the bridging carbonyl group and the hydrophobic side-chain at C9 along with **20** (10% yield from **18**).

Having established a method for the construction of the bicyclic framework, we then focussed upon the quaternary carbon centre adjacent to the bridgehead. To this end **9a** was first converted to **21** in 2 steps (96%) (Scheme 4). Various attempts to produce directly the desired quaternary centre with organometal reagents were unsuccessful, probably due to the highly functionalized nature of **21**. Only by using a sulfonium ylide did the reaction take place without any problems, furnishing a cyclopropane product **22**. Reductive cleavage of **22** with SmI_2 proceeded with complete regioselectivity to generate the required quaternary centre.§ Compound **23** was next deprotected under acidic conditions followed by iodination to give **25**. Zinc reduction and protection of the resultant hydroxy group with an acetyl group gave **26**.¶

We are currently exploring methods to complete the fully functionalized core and modify the side chains *en route* to phomoidride B.

I am grateful to Professor K. Ohkata for his valuable advice and to Dr S. Kojima for prereading of the manuscript. I am also grateful to Drs Y. Hiraga and R. Takagi for assistance in NMR.

Notes and references

† In this reaction **16** was obtained stereoselectively at the C2 centre. While the reason for this selectivity is unclear, it may be due to the proton delivering effect of the hydroxy group in the intermediate silyl enol ether during work-up (ref. 5).

‡ Although the C8 stereochemistry of **19** is not certain, **19** was obtained as the sole stereoisomer.

§ Although SmI_2 has previously been used for cyclopropane opening (ref. 10), to our knowledge, regioselective opening of cyclopropane bearing electron stabilizing groups on all three carbons with SmI_2 is unprecedented.

Self-assembled nanoscale capsules between resorcin[4]arene derivatives and Pd(II) or Pt(II) complexes

Seong Jin Park and Jong-In Hong*

School of Chemistry and Molecular Engineering, Seoul National University, Seoul 151-747, Korea. E-mail: jihong@plaza.snu.ac.kr

Received (in Cambridge, UK) 4th June 2001, Accepted 5th July 2001
First published as an Advance Article on the web 1st August 2001

Nanoscale molecular capsules have been prepared by self-assembly of resorcin[4]arene derivatives and Pd(II) or Pt(II) complexes; the positively charged *N*-alkylpyridinium derivatives are encapsulated inside capsules due to strong cation–π interactions.

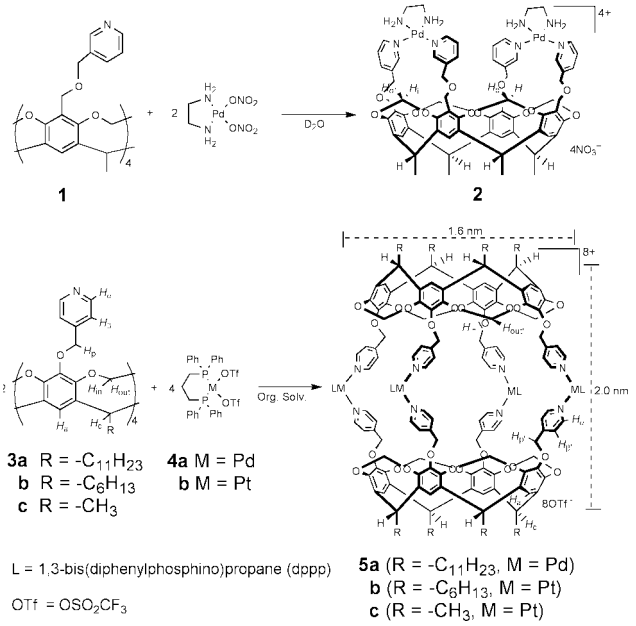
The formation of self-assembled superstructures has received a great deal of attention in recent years. Two main approaches have been widely used to construct supermolecules using intermolecular interactions between building blocks. One involves using hydrogen bonding interactions between the complementary binding sites.[1] The other approach is to employ metal–ligand interactions. Metal-induced self-assembly is a flourishing area of study in the field of host–guest and supramolecular chemistry. There are many examples of metal-mediated self-assembly to form squares,[2] helices,[3] grids,[4] catenanes,[5] cylinders,[6] circular helicates[7] and cages.[8]

Recently we reported that an intramolecularly assembled structure **2** was constructed by addition of two equivalents of $(en)Pd(NO_3)_2$ to a suspension of **1** in aqueous solution (Scheme 1).[9] Molecular models show that pyridyl groups of **3** with one fewer carbon compared to **1**, however, cannot easily get close enough to form an intramolecularly organized structure *via* Pd(II) or Pt(II) complexation. Herein we describe the formation of nanoscale cage-like complexes composed of two resorcin[4]arene derivatives and four Pd^{II} or Pt^{II} square planar precursors, and the complexation of *N*-alkylpyridinium derivatives in the organic phase.

Capsules are instantly formed by simple addition of two equivalents of $Pd(dppp)(OTf)_2$ to acetone, CH_2Cl_2 or $CHCl_3$ solutions of resorcin[4]arene derivatives **3a–c**† having four pyridine units as pendent groups (Scheme 1). For **2**, the bridge methylene protons split into two sets of signals in the ^1H NMR spectrum since $H_{i'}$ and $H_{o'}$ exist in the shielding region between two pyridine ligands interacting with a Pd(II) ion and move far upfield compared to H_i and H_o.[9] In the present case, however, the bridge methylene protons ($H_{in'}$ and $H_{out'}$) do not divide into two sets [Fig. 1(e)]. Both ^1H and ^{13}C NMR spectra are in accord with the D_{4h} symmetric structure of **5** and the assignments are fully supported by two-dimensional NMR measurements. In particular, a ^1H NMR titration study clearly shows capsule formation. When **3a** and **4a** are mixed in a 1 : 1 molar ratio, a mixture of the capsule **5a**† and free **3a** is obtained. Moreover, when an excess amount of **4a** is added, **5a** and unreacted **4a** are present (Fig. 1). This means that a 1 : 2 adduct is formed as the sole product.

The molecular weight estimated by vapor pressure osmometry (VPO) of a CH_2Cl_2 solution containing **3a** and **4a** in a 2 : 4 molar ratio (6230 ± 590) is consistent with the molecular weight for the dimer **5a** (6426). Moreover, electrospray ionization mass spectrometry (ESI-MS) clearly shows the formation of **5b** when a $CHCl_3$ solution containing **2b** and **3b** in a 2 : 4 molar ratio was examined: $[M - 2CF_3SO_3^-]^{2+}$ (2961.99), $[M - 3CF_3SO_3^-]^{3+}$ (1928.83) and $[M - 4CF_3SO_3^-]^{4+}$ (1406.44).‡ Molecular modeling shows that the cavity of **5** has nanoscale dimensions of 16 × 20 Å.[10]

Several neutral guest molecules such as adamantane, anthracene, phenanthrene and pyrene show no ^1H NMR spectroscopic signs of encapsulation within the capsule. This indicates either that there is no driving force for the guest encapsulation or the guests are too small to be encapsulated due to the large portals of the capsule through which these guests can permeate. However, addition of a positively charged guest such as 1-methyl-4-phenylpyridinium (OTf^- salt) **6** and methylviologen ($2OTf^-$ salt) **7** to an acetone-d_6 solution of **3a** followed by addition of 2 equivalents of **4a** to the resulting mixture gave two sets of separate ^1H NMR peaks for the free and bound



Scheme 1

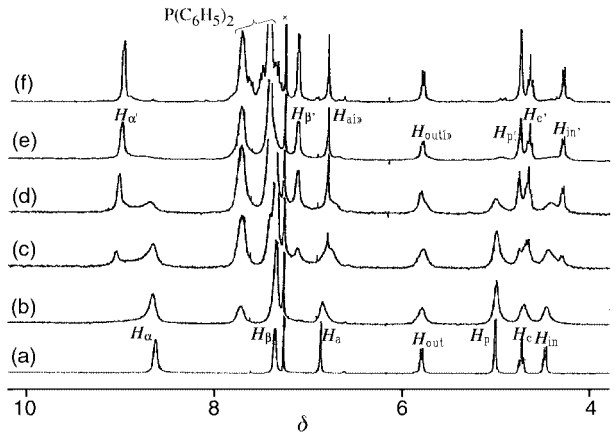


Fig. 1 Monitoring capsule formation by ^1H NMR spectroscopy (300 MHz, $CDCl_3$, 300 K). (a) free **3a**; (b) **3a**:**4a** = 2:1; (c) **3a**:**4a** = 2:2; (d) **3a**:**4a** = 2:3; (e) **3a**:**4a** = 2:4; (f) **3a**:**4a** = 2:5 molar ratio. A signal at δ 7.28 from $CDCl_3$ is marked by an asterisk.

 DOI: 10.1039/b104897j

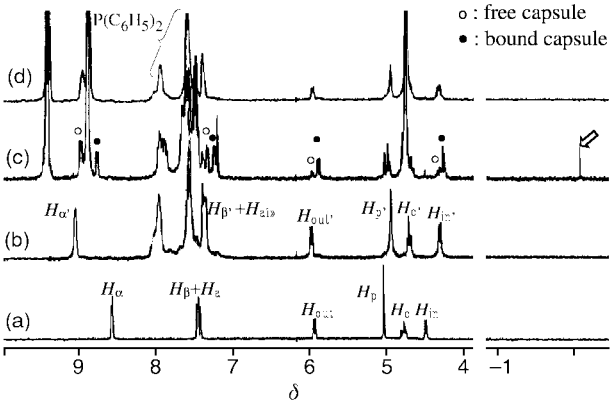

Fig. 2 Portion of the ^{1}H NMR spectra (300 MHz, acetone-d_6, 300 K); (a) free **3a**; (b) capsule **5a** formed from **3a**:**4a** = 2:4; (c) *ca.* 10 equiv. **7** added to **3a** and then 2 equiv. **4a** was added; (d) *ca.* 10 equiv. **7** was added to **5a**. The methyl group of the encapsulated guest is indicated by an arrow.

capsules.[11] This peak separation indicates that the decomplexation or guest-exchange rate is slow with respect to the ^{1}H NMR time scale. In addition, the integration ratio of the bound capsule and encapsulated guest resonances indicated a highly symmetric 1:1 complex. Particularly, NCH_3 protons of **7** move *ca.* 6.8 ppm upfield, appearing at δ −2.08,§ which presumably indicates that **7** is encapsulated such that the methyl group points towards the shielding region of the aromatic cavity at the end of the long axis of the capsule. As expected from the nearly irreversible Pd–pyridine bond formation in organic solvents, when **7** was added after the capsule formation, no spectroscopic signs of encapsulation were detected except that the pyridine's α-proton shifted slightly in the upfield direction (Fig. 2).¶ In order to investigate the behavior of the counter ions, the ^{19}F NMR spectrum was examined and showed only one signal at δ −77 in the spectra of **5a** and **5a** containing **7**; this indicates that there is not a slow exchange between triflate ions inside and outside of the cage. We also observed the release of the encapsulated **7** from the capsule in acetone-d_6 upon heating at 35 °C in the sealed NMR tube. The first-order approximation gives a guest-releasing rate constant of 4.5×10^{-6} s^{-1}. This means that guest release occurs slowly with a half-life of 43 h at 308 K. These phenomena indicate that **7** was complexed inside **3a**, most probably due to the cation–π interaction, and then if **4a** was added, properly positioned **7** was entrapped in the forming capsule **5a**.¶

In summary, we have constructed nanoscale self-assembled molecular capsules instead of an intramolecularly organized structure between properly designed resorcin[4]arene derivatives having relatively rigid pendent pyridine groups and square planar metal complexes. The positively charged *N*-methylpyridinium derivatives turn out to be encapsulated by cation–π interactions. Further studies will explore the potential for the use of nanoscale capsules as selective reaction chambers for chemical reaction catalysis.¶

We are grateful to the CMDS (KOSEF) for support of this work. S. J. P. thanks the Ministry of Education for the BK 21 fellowship.

‡ When **5c** formed from gentle heating of a $CHCl_3$–MeOH (10:1, v/v solution of **3c** and **4b** in 1:2 molar ratio was examined by ESI-MS, [M − *n*$CF_3SO_3^-$]$^{n+}$ (*n* = 2,3,4) ion peaks were also clearly observed at *m*/*z* 2682.21, 1739.52 and 1266.74, respectively.

§ NCH_3 protons of the encapsulated guest **6** appear at δ −2.09.

¶ Addition of 1,4-dimethylpyridinium triflate, which is small enough to freely pass in and out of the cavity, either before or after capsule formation, results in two sets of separate ^{1}H NMR peaks for the free and bound capsules. NCH_3 protons of the encapsulated 1,4-dimethylpyridinium triflate also appear at δ −2.08. This constitutes strong evidence for cation–π interactions in the encapsulation process. According to molecular modeling[10] and ^{1}H NMR integration, the interior of **5a** can accommodate two molecules of 1,4-dimethylpyridinium triflate. The association constant (K_a) can be estimated from the ratio of peak intensity of free and bound to be 1180 dm^6 mol^{-2}.

Self-assembled organogels formed by mono-chain L-alanine derivatives

Xuzhong Luo, Bin Liu and Yingqiu Liang*

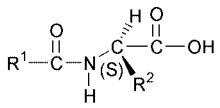
Lab of Mesoscopic Materials and Chemistry and State Key Lab of Coordination Chemistry, Nanjing University, Nanjing 210093, P. R. China. E-mail: yqliang@netra.nju.edu.cn

Received (in Cambridge, UK) 18th May 2001, Accepted 26th June 2001
First published as an Advance Article on the web 1st August 2001

The mono-chain L-alanine derivatives self-assemble into bilayer aggregates in a number of organic liquids and gelatinize the liquids.

Recent discoveries of low molecular weight gelators have stimulated considerable interest not only in academic investigations but also technological applications.[1–9] Although dozens of different categories of gelators have so far been identified, it is difficult to select a molecule that will definitely gel a selected liquid. Previous reports reveal that some oligomers of α-amino acids[2a,b,8] and bolaform amides derived from amino acids[2c] can gel a number of organic liquids, while the reports relating mono-amino acid derivatives are relatively few.[2d,e] Bhattacharya and co-workers reported recently that mono-amino acid derivatives can gelate selectively oil from oil–water mixtures.[9] Herein, we report simple compounds, mono-chain L-alanine derivatives, which form bilayer aggregates in a number of organic liquids and gelate the liquids.

The L-alanine derivatives, **1**–**8**,† used here were prepared in our laboratory. A typical procedure for studying gel formation



1 $R^1 = C_9H_{19}$, $R^2 = CH_3$ **2** $R^1 = C_{11}H_{23}$, $R^2 = CH_3$
3 $R^1 = C_{13}H_{27}$, $R^2 = CH_3$ **4** $R^1 = C_{17}H_{35}$, $R^2 = CH_3$
5 $R^1 = (CH_3)_3COCO$, $R^2 = CH_3$ **6** $R^1 = C_6H_5$, $R^2 = CH_3$
7 $R^1 = C_{11}H_{23}$, $R^2 = H$ **8** $R^1 = C_{11}H_{23}$, $R^2 = C_6H_5CH_2$

ability is as follows: a weighed sample was mixed with an organic liquid (1 mL) in a sealed test tube and the mixture was heated until the solid dissolved. The resulting solution was cooled at 20 °C for 2 h and then the gelation was studied. Upon formation the organogel is stable and the tube can be inverted without any change of shape of the organogel.

The results of gelation tests of **1**–**3** are summarized in Table 1,‡ in which the values denote the minimum gel concentrations (g L^{-1}) necessary for gelation. From Table 1, it is clear that compounds **1**–**3** can form a stable physical organogel and gelatinize a number of organic fluids even at a very low concentration. For example, the amounts of **2** necessary to gel 1 L of CCl_4, PhH, PhMe, *o*-xylene and mesitylene are 7, 4, 5, 5 and 4 g, respectively. Weiss and co-workers' studies reveal that the size of organogel colloids depends upon the nature of the liquid.[1c] The amphiphiles **1**–**3**, which form transparent or translucent organogels in different liquids, may be due to the different size of their colloids.

Table 1 Gelation test of **1**–**3** and minimum gel concentration necessary for gelation at 20 °C. Values refer to the minimum gel concentration in g L^{-1} (gelator/liquid)

	Gel concentration/g L^{-1}		
Organic liquids	**1**	**2**	**3**
Carbon tetrachloride	6 (translucent)	7 (translucent)	6 (translucent)
Benzene	5 (transparent)	4 (transparent)	4 (transparent)
Toluene	5 (transparent)	5 (transparent)	4 (transparent)
o-Xylene	6 (transparent)	5 (transparent)	5 (transparent)
Mesitylene	5 (transparent)	4 (transparent)	4 (transparent)
1,1,2,2-Tetrachloroethane	6 (translucent)	6 (translucent)	5 (translucent)
Tetrachloroethylene	6 (transparent)	6 (transparent)	5 (transparent)
Tetralin	6 (translucent)	5 (translucent)	5 (translucent)
n-Octane	4 (translucent)	4 (translucent)	4 (translucent)
1,1,2-Trichloroethane	7 (translucent)	7 (translucent)	6 (translucent)
Cyclohexane	5 (transparent)	5 (transparent)	5 (transparent)

Fig. 1 shows the FT-IR spectra for the CCl_4 gel and the $CHCl_3$ solution of **2**. The FT-IR spectrum of the translucent CCl_4 gel of **2** is characterized by bands attributed to intermolecular hydrogen bonding, *i.e.* 3349 (νN–H of amide), 1704 (νC=O of −COOH), and 1640 cm^{-1} (νC=O of amide), whereas the isotropic solution of **2** in $CHCl_3$ affords bands at 3450 (νN–H), 1740 (νC=O of carboxylic acid), and 1660 cm^{-1} (νC=O of amide), indicative of non-hydrogen bonding stretching vibrations. The FT-IR spectrum of the KBr pellet of **2** is similar to that of the CCl_4 gel of **2,** suggesting that the pattern of hydrogen bonding in the gel is close to that in the crystal. The sharp peak near 1704 cm^{-1} is ascribed to the C=O stretching mode of CO_2H groups, characteristic of the formation of carboxylic acid dimers.[10] These results imply that in the gel the intermolecular hydrogen bonds have been formed between the neighboring molecules of **2** and thus they form a hydrogen bond network.

The TEM image of a CCl_4 gel of **2** is shown in Fig. 2. It reveals a number of fibers, juxtaposed and intertwined by several long slender aggregations with width of *ca*. 30–100 nm. The X-ray diffraction pattern (Fig. 3) of the gel cast film from the CCl_4 gel of **2** show periodical diffraction peaks, indicating

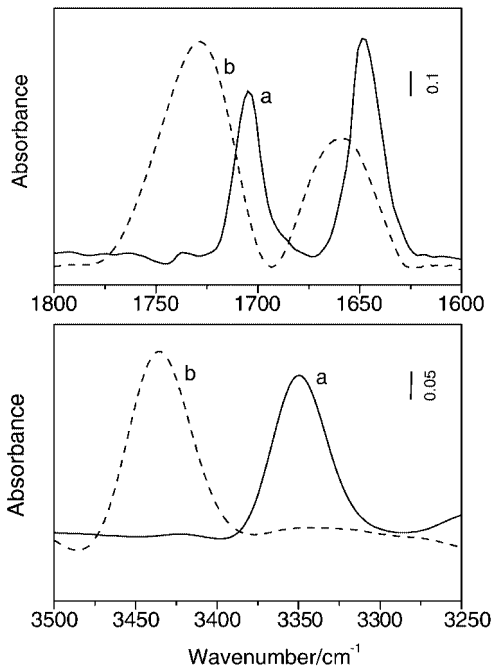


Fig. 1 FTIR spectra of **2** a) as a CCl_4 gel, b) in $CHCl_3$ solution (dashed line).

 DOI: 10.1039/b104428c

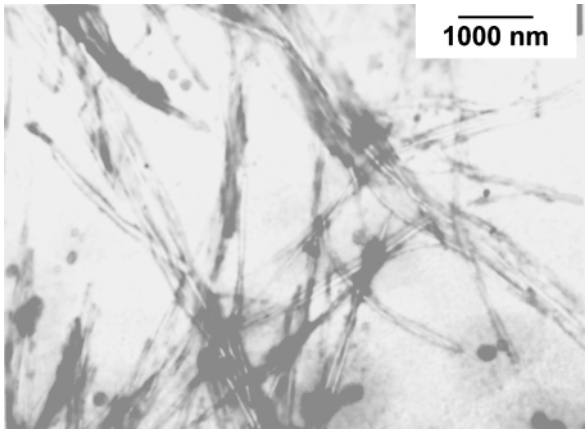

Fig. 2 TEM image of a CCl_4 gel of **2** (7 g L^{-1}). The sample was prepared by picking up the gel on a carbon grid and post-stained by uranyl acetate.

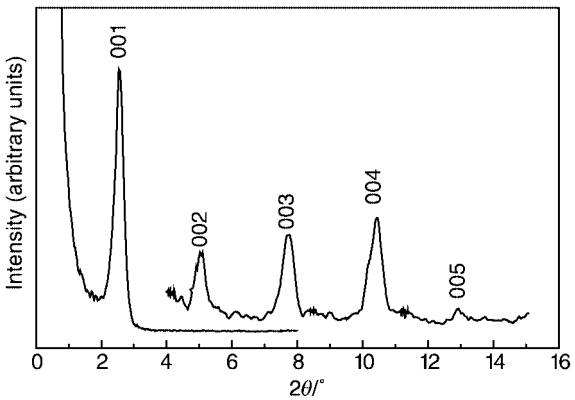

Fig. 3 X-ray diffraction patterns of a cast film from CCl_4 gel of **2**.

that **2** indeed assembles into an ordered structure. The long spacing (*D*) of the aggregate obtained by the XRD method is about 3.43 nm, which is much smaller than twice the evaluated molecular length of **2** (2.14 nm, by the CPK model), but much larger than the length of one molecule of **2**. From the XRD and FT-IR results, it can be deduced that that the gel aggregates consist of a repeating bilayer unit, which bears the head-to-head packing model with highly tilted alkyl chains relative to the bilayer normal. Within the bilayer unit, the amphiphiles are connected by intra- and inter-layer hydrogen bonds to form a hydrogen bond network and then develop the superstructure that is schematically shown in Fig. 4.

The gelling abilities of some structurally related compounds **4**–**8** (non-gel-forming) have been inspected. Comparing the molecular structure of **4**–**6** with **1**–**3**, it can be inferred that suitable length of the tail chain is essential for gelation since organogels fail to form when the tail chain is lengthened to 18 C atoms (**4**) or is substituted by *tert*-butoxycarbonylcarbonyl (**5**) and benzoyl (**6**). In experiment, we also find that the racemes of *N*-dodecanoylalanine do not induce any gelation, which is similar to that for *N*-dodecanoylglycine (**7**). The findings imply that the homochiral effect plays an important role in the gel formation. *N*-Dodecanoyl-L-phenylalanine (**8**), a compound containing a chiral center, does not exhibit gelling ability, which may be due to the relatively large steric hindrance effect of the benzyl group of the L-phenylalanine which weakens the intermolecular hydrogen bonding between neighboring molecules. Therefore the intermolecular hydrogen bonding is unable to meet the need for gelation. From these observations and analyses, it can be concluded that (i) gelling ability strongly depends on the L-alanine group, (ii) the hydrophile–lypophile balance is a significant factor for gelation, the suitable length of the tail chain is in the range of 8 to 14 C atoms, (iii) the formation of the bilayer aggregates and the homochiral effect play important roles in gel-forming.

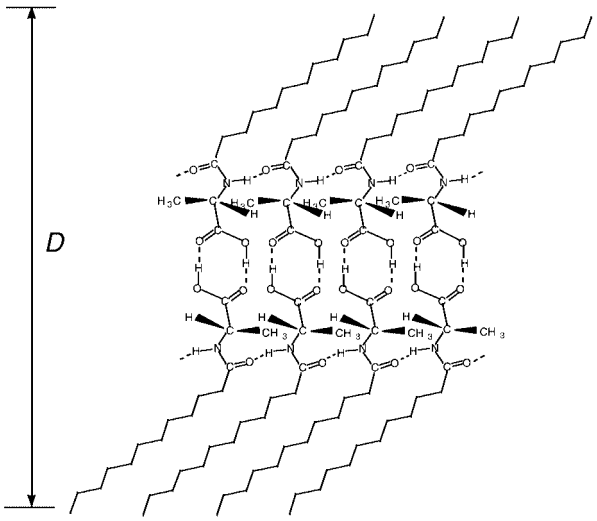

Fig. 4 Local microstructure of the bilayer aggregates of **2** in organogel.

In conclusion, this paper has shown that simple mono-chain L-alanine derivatives can self-assemble into bilayer aggregates through intermolecular hydrogen bonding and the homochiral effect in a number of organic liquids, which are juxtaposed and interlocked by van der Waals interaction, and finally gelate the organic liquids.

† Amino acid (0.05 mol) is placed in a three-necked round-bottomed flask, filled with an efficient stirrer, and dissolved in 50 mL of 1 M NaOH. The flask is then almost completely immersed in a bath of ice and water (*T ca.* +3 °C) and the stirrer is now set in very rapid motion. To the solution are added, dropwise, 0.10 mol of pure acyl chloride and 80 mL of 1 M NaOH at the same rate. When the reaction is complete, the suspension is acidified carefully with 2 M HCl. The residue obtained after filtration is extracted with petroleum ether to remove the fatty acid. The final amino acid derivative is chromatographed on a silica gel column empolying appropriate solvent. Satisfactory ^{1}H NMR, IR, element analysis and optically activity data were obtained for the corresponding amino acid derivatives.

‡ The minimum gel concentration was calculated as described in the literature.[8] The gels were stable in a sealed tube for over two weeks. On re-heating, the physical gelation is reversible.

A regioselective cycloaddition route to isoxazoleboronic esters†

First published as an Advance Article on the web 1st August 2001

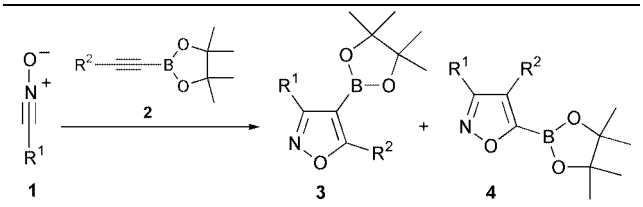
Alkynylboronates participate in 1,3-dipolar cycloaddition reactions with nitrile oxides to provide isoxazoleboronic esters with excellent levels of regiocontrol; additionally, these potentially valuable synthetic intermediates have been shown to participate efficiently in Suzuki coupling reactions.

Aromatic boronic esters are amongst the most valuable and widely used synthetic intermediates in modern organic chemistry due to their ability to participate in functional group transformations and carbon–carbon bond forming reactions.[1] These compounds are generally accessed *via* a functional group interconversion strategy from a starting aryl halide or triflate.[2] However, the requirement of these precursors can prove problematic when more highly substituted or heavily functionalised boronic ester products are required. Accordingly, in an effort to develop novel and efficient routes to complex arylboronates, we have recently been exploring the possibility of employing cycloaddition/benzannulation reactions of boron containing alkynes.[3] In connection with this study, we wish to report herein our recent findings on the [3+2] cycloaddition reaction of alkynylboronates with nitrile oxides towards the assembly of highly substituted isoxazoleboronic esters.

The cycloaddition reaction of nitrile oxides with alkynylboronates has received scant attention in the literature to-date. Indeed, we are aware of only a single report whereby dibutyl ethynylboronate provided the corresponding isoxazole as a single regioisomer.[4] However and importantly, only this terminal alkynylboronate was examined and the effect of acetylenic alkyl substituents on regioselectivity was not described. In contrast, the employment of alkynylstannanes is well documented.[5] However, this approach suffers from ready protodestannylation of the heterocyclic product, as well as the associated problems of handling toxic organotin species. In an effort to further clarify the effectiveness of alkynylboronates as precursors to isoxazoleboronic esters, to examine the regiochemistry of substituted boron containing alkynes and to establish the utility of isoxazoleboronic esters in carbon–carbon bond forming processes, we undertook a study of the scope of the cycloaddition reaction as outlined in Table 1.

We decided to initiate our studies on the scope of alkynylboronate [3+2] cycloaddition reactions with mesitylenecarbonitrile oxide **1** (R^1 = Mes), which is known to be stable towards dimerisation.[6] As outlined in Entry 1, we were pleased to find that 2-ethynyl-4,4,5,5-tetramethyl-1,3,2-dioxaborolane[7] **2** (R^2 = H), underwent a smooth cycloaddition reaction to provide the isoxazole **4a** bearing the boronic ester unit in the 5-position in 59% yield, with only 23% of the alternative regioisomer **3a**. On changing the alkyne substituent R^2 = H to R^2 = Me (Entry 2) the reaction proceeded cleanly to provide a *single regioisomer* of **3b**, remarkably, with complete reversal in regiochemistry. Finally, the use of longer chain alkyl and phenyl substituents also provided the 4-substituted boronic esters as single regioisomers in good yield.[8] We briefly examined the scope of nitrile oxides in the cycloaddition process and were pleased to find that this technique was applicable to phenyl and alkyl substituted 1,3-dipole substrates (Entries 5–7), the isoxazole

Table 1 1,3-Dipolar cycloadditions[a]



Entry[b]	R^1	R^2	Product	Yield (%)
1	Mes	H	**4a**	59%[c]
2	Mes	Me	**3b**	90%
3	Mes	Bu	**3c**	73%
4	Mes	Ph	**3d**	64%
5	Ph	H	**4e**	53%[c]
6	Ph	Me	**3f**	54%
7	*t*-Bu	Me	**3g**	27%[e]

[a] Regiochemical assignments made on the basis of diagnostic ^{13}C resonances. Additionally, these assignments have been supported by X-ray data for compounds **3b** and **3c**, which will be the subject of a future disclosure. [b] For experimental conditions, see ref. 8. [c] 23% of **3a** was isolated. [d] 6% of **3e** was islolated. [e] Estimated by ^1H NMR.[9]

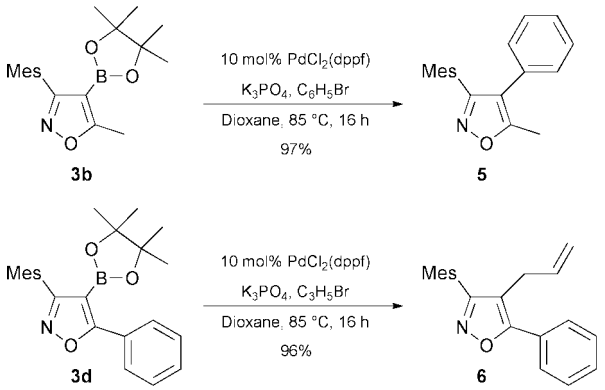
 DOI: 10.1039/b103319k

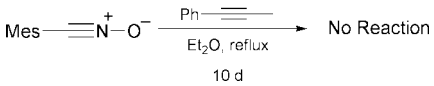
products **4e**, **3f–g**, were again formed with excellent levels of regioselectivity and followed the same insertion pattern established with the mesitylenecarbonitrile oxide in Entries 1–4. Notably, and in contrast to the stannylated isoxazoles, boronic esters **3** and **4** were isolated as white crystalline solids which could be readily purified by standard chromatographic techniques without problematic protodeboronation side reactions.

The regiochemical outcomes outlined in Table 1 are consistent with literature reports of electron deficient alkyne [3+2] cycloaddition reactions with nitrile oxides. Specifically, whereas terminal propiolates generally give a mixture of regioisomers which favours that bearing the ester moiety in the 5-position,[10] substituted propiolates and alkynyl ketones provide the regioisomeric products with the electron withdrawing group in the 4-position with high levels of selectivity.[11] Nonetheless, from a synthetic standpoint, this methodology provides a quick and direct method for the assembly of isoxazoleboronic esters which avoids problematic metallation of the heterocyclic nucleus.[12]

With a rapid and efficient entry into isoxazoleboronic esters in hand, we decided to confirm their effectiveness as synthetic intermediates for Suzuki coupling reactions. As outlined in Scheme 1, isoxazoles **3b** and **3d** were found to undergo smooth and efficient Pd-catalysed coupling with bromobenzene and allyl bromide to give **5** and **6** respectively in excellent yields. We therefore anticipate that this efficient two step procedure holds great promise for the regioselective assembly of a range of functionalised highly substituted isoxazole products.[13] Additionally, as exemplified in Scheme 2, attempts to prepare **5** by direct [3+2] cycloaddition of prop-1-ynylbenzene failed to produce any of the cycloaddition product, even after prolonged reaction times. Therefore, not only does the cycloaddition–coupling technique permit the regioselective formation of highly substituted isoxazole products, it also circumvents limitations associated with preparing 4,5-dialkyl or -diaryl substituted isoxazoles through the employment of unactivated alkyne substrates.



Scheme 1 Suzuki coupling reactions.



Scheme 2

In conclusion, we report a novel and flexible approach to highly substituted isoxazoles through a key [3+2] cycloaddition reaction of nitrile oxides with alkynylboronates. The investigation of related cycloaddition reactions is currently underway in our laboratories and will be reported in due course.

The authors are grateful to the EPSRC for a studentship (M. W. D.) and to GlaxoSmithKline and the University of Sheffield for generous financial support.

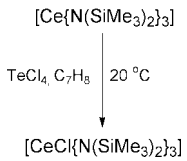
Received (in Cambridge, UK) 24th April 2001, Accepted 28th June 2001
First published as an Advance Article on the web 2nd August 2001

Oxidation of the three-coordinate cerium amide [Ce{N(SiMe$_3$)$_2$}$_3$] with TeCl$_4$ in toluene solution yields purple, diamagnetic [CeCl{N(SiMe$_3$)$_2$}$_3$], whose structure has been examined by X-ray crystallographic and computational methods.

Cerium occupies an unusual position in the periodic table, providing a bridge between Group 3 and the lanthanides, but rather than combining the useful characteristics of both families it often fails to fulfil expectations. Were it not for the fact that at atomic number 58 electrons begin to occupy the 4f shell,[1] cerium would behave more like a member of Group 4, and would presumably warrant study as intensive as that devoted to titanium, zirconium and hafnium.[2] Nature is, however, not that accommodating, and while cerium is abundant, cheap and readily available, it is very much a lanthanide element, is commonly encountered as Ce^{III}, and is thus often consigned to the backwaters of the Periodic Table.

When seen from the point of view of the other lanthanides, its standing is reversed, and it becomes potentially the most interesting of those elements as it is the only one so far proven to have chemically accessible (II),[3] (III) and (IV)[4] oxidation states. High-valent cerium chemistry (excluding *O*-donor complexes, where there is a more obvious convergence in behaviour between cerium and Group 4) is still very much under-developed, but an important contribution has been made in this area by Scott and co-workers,[5] who have reported the oxidation of the trisamidoamine complex [Ce(NN′$_3$)] [NN′$_3$ = N(CH$_2$CH$_2$NSiMe$_2$Bu^t)$_3$] with molecular halogens, which in the case of iodine produces the mononuclear Ce^{IV} amide [CeI(NN′$_3$)].

We wish to report that it is possible to oxidise the prototypical cerium amide [Ce(NR$_2$)$_3$] (R = SiMe$_3$)[6] **1** (eqn. 1), and to



(1)

isolate a well-defined cerium(IV) compound from the reaction. Notwithstanding the fact that the Ce^{III} amide is known to be unreactive towards Cl$_2$,[5] we find that the addition of 0.25 equivalents of TeCl$_4$[7] to a toluene solution of **1** results in an immediate change in colour from yellow to deep purple.‡ Very dark, almost black, needles, which are characterised as [CeCl(NR$_2$)$_3$] **2** by ^{1}H NMR, EI-MS, microanalysis and an X-ray crystallographic study,§ are isolable in—admittedly low—yields of 24–30%. The diamagnetic nature of the complex (and by implication the cerium(IV) oxidation state) is apparent from the proton NMR spectrum in C$_6$D$_6$ which shows a sharp singlet at δ 0.42. The haloamide **2** has marginal stability in solvents other than thf, decomposing over a few hours into small amounts of [Ce(NR$_2$)$_3$] **1**, and other, unidentified, products. This instability is reflected in the absence of a parent ion and the paucity of chlorine-containing fragments in its mass spectrum, the highest *m/z* peak being assigned as [M − Me]$^+$. A representation of the molecular structure is shown in Fig. 1.

The molecule is C_3 symmetric about the Ce–Cl axis, while the geometry at the metal is intermediate between tetrahedral and trigonal pyramidal (although closer to the latter) the angles Cl–Ce–N and N–Ce–N′ being 99.48(7) and 117.34(4)° respectively. The cerium ion protrudes 0.36 Å out of the plane formed by the three nitrogen atoms, which is around 0.05 Å further than is the case for the parent Ce^{III} species **1**.[8] These features may be contrasted with those of the superficially similar Group 4 complexes [MCl(NR$_2$)$_3$] (M = Ti, Zr, Hf)[9] which are tetrahedral (despite their shorter M–N bonds) although distorted significantly from the ideal. The Ce–N and Ce–Cl bonds of 2.217(3) and 2.597(2) Å in **2** are all relatively short, as a consequence both of the presence of a contracted metal ion and the adoption of a lower coordination number than is normally found for Ce^{IV} species; we estimate from our data that Ce^{IV} has a radius of *ca*. 0.77 Å in four-coordination. There

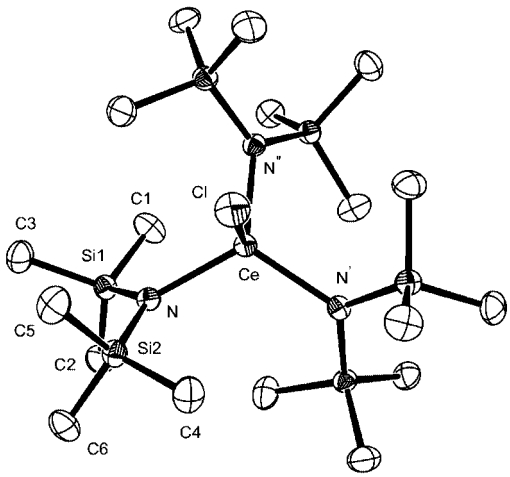


Fig. 1 Molecular structure of [CeCl{N(SiMe$_3$)$_2$}$_3$] **2**. Ce–N 2.217(3), Ce–Cl 2.597(2), Si(1)–N 1.752(3), Si(2)–N 1.750(3) Å, N–Ce–N′ 117.34(4), Cl–Ce–N 99.48(7), Si(1)–N–Si(2) 120.13(16)°.

† Electronic supplementary information (ESI) available: further details of calculations relating to **3**. See http://www.rsc.org/suppdata/cc/b1/b103634n/

 DOI: 10.1039/b103634n

is a notable elongation of the N–Si bonds to around 1.751 Å, 0.05 Å longer than those found in **1** (see below).

In order to investigate the factors which determine the overall geometry of **2**, we have undertaken a computational study, using methods previously described,[10] on the hypothetical complex [CeCl{N(SiH$_3$)$_2$}$_3$] **3**. The optimised model has C_3 symmetry, with the Ce–Cl bond coincident with the C_3 axis, and in general its geometrical features are very close to those of the experimental complex **2**, although the Ce–L separations are slightly longer (Ce–Cl 2.589; Ce–N 2.246 Å) than those determined by X-ray methods, all L–Ce–L′ bond angles are around 109°, and the dihedral angle Cl–Ce–N–Si is smaller in **2** (40°) than it is in **3** (55°). These latter, more substantial, angular differences may be ascribed to imperfect modelling of steric bulk in the periphery of the amide ligands; however, even in their absence the lengthening of the N–Si bond is reproduced very well (1.762 Å *vs*. 1.75 Å experimental) indicating that the effect is electronic in origin.

The calculated structure **3** may in turn be compared to that of the model cation [Ce{N(SiH$_3$)$_2$}$_3$]$^+$ **4**.[11] It is apparent that the N–Si bonds are significantly elongated in those complexes containing an additional chloride ligand, apparently irrespective of the metal oxidation state,¶ unperturbed bonds being 1.70 Å by our initial calculations on the Ce^{IV} centre **4** and 1.702(2) Å by X-ray analysis on the parent Ce^{III} amide **1**,[8] both of which are nominally three-coordinate. It is surprising to find that the presence of an additional ligand appears to exert a greater influence on the geometry within the amido ligand than on the Ce–N distances themselves (Ce–N in **4** is calculated to be 2.22 Å, similar to equivalent bonds in **2** and **3**).

In summary, we have accomplished the isolation of [CeCl(NR$_2$)$_3$] **2**, a cerium analogue of the familiar [M(anion)(amido)$_3$] family of complexes perhaps best known for M = Ti, Zr and Hf. Its structural characterisation has revealed an elongation of the N–Si bonds in the hexamethyldisilylamido ligands, which, when the continued uncertainty over the existence or otherwise of N(p_π)–Si(d_π) bonding is considered, invites further study of its origin. Preliminary steps towards this end have been taken in the computational characterisation of [CeCl{N(SiH$_3$)$_2$}$_3$] **3**, which reproduces the effect very well even in the absence of significant steric crowding.

We wish to thank the EPSRC (M. F. L., A. G. H.) and CNRS (O. E., L. M.) for support.

¶ We have been unable to synthesise the [CeCl(NR$_2$)$_3$]$^-$ anion to test this hypothesis further.

1 It should be noted that like Ti^{4+} and Zr^{4+}, but in contrast to Hf^{4+}, the Ce^{4+} ion has no 4f electrons, and so in one way deserves to be associated with Group 4. While a re-ordering of the Periodic Table is clearly not appropriate in this case, see W. B. Jensen, *J. Chem. Educ.*, 1982, **59**, 634 for an interesting and persuasive discussion of the relative positioning of La and Lu.

2 Notably absent from the literature of cerium chemistry, but pivotal in Group 4, are the metallocene dihalides [MCl$_2$Cp$_2$]. With respect to claims on their synthesis: see B. L. Kalsotra, R. K. Multani and B. D. Jain, *J. Inorg. Nucl. Chem.*, 1972, **34**, 2679 and references therein, see also ref. 4 and references herein.

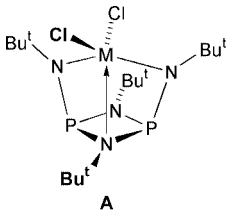
First published as an Advance Article on the web 3rd August 2001

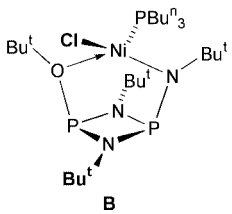
The syntheses and solid-state structures of the first three-membered nickel–phosphorus–nitrogen ring compounds, having anionic four-electron P=N moieties are reported.

Most modern homogeneous catalysts, which polymerize olefins to macromolecules with predictable properties, are mixtures of early-transition metal compounds and Lewis-acidic Group 13 cocatalysts.[1] Recently Brookhart and Gibson demonstrated that similar mixtures of late-transition metal complexes, particularly those with chelating bis(imino) ligands, also polymerize olefins with excellent activities.[2] Even more promising are single-component, late transition-metal alkyls, because they are both active in the absence of the expensive cocatalyst and they polymerize polar olefins.[3] The unusual properties of these neutral compounds and their polymers have rekindled interest in transition metals, especially iron, cobalt and nickel, that were once considered unlikely candidates for polyolefin catalysis.

We previously reported bis(amido)cyclodiphosph(III)azane complexes **A** of group 4 metals, which form polyethylene, but



A

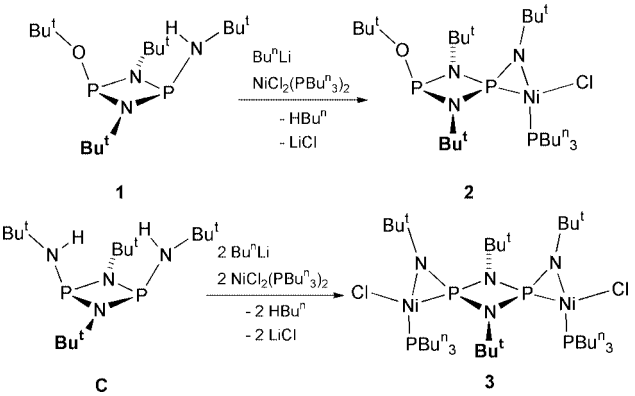


B

have comparatively short lifetimes.[4] Follow-up studies showed that the Lewis-acidic medium deactivates the catalyst by the ring opening of the cyclodiphosph(III)azane. This caused us to test the suitability of these heterocycles as ligands for neutral late-transition metal catalysts. To synthesize such complexes we modified the cyclodiphosph(III)azane to a monoanionic version, because one chloride ligand is required for polymer-chain growth.

By treating $NiCl_2(PBu^n_3)_2$ with *cis*-[$Bu^tOP(\mu\text{-}NBu^t)_2PN\text{-}Bu^t$]$^-$ (Scheme 1) we hoped to obtain precatalyst **B** and activate it by alkylation. Although both, tetrahedral and planar, coordination geometries were conceivable, the diamagnetism of the orange–red product **2**‡ indicated that the nickel atom was planar or almost planar. The uncommon chemical shift of one of the heterocycle's phosphorus atoms (−53.1 ppm and *ca*. 170 ppm upfield of that of pristine ligand), however, suggested an unusual ligand coordination.

This suspicion was confirmed by an X-ray analysis, Fig. 1, which showed that in **2**§ the amidocyclodiphosph(III)azane is not the expected *N,O*-chelate, but an η^2-*P,N* ligand, instead. Compound **2** is a spirocycle of three- and four-membered rings, whose crystallographic *m* symmetry implies a perfectly-planar



Scheme 1

nickel environment, although some of the bond angles [*e.g.* P1–Ni–N1 45.62(9)°] are far from ideal square planar. The Ni–Cl [2.2175(10) Å] and Ni–P3 [2.1522(12) Å] bond lengths, however, are quite similar to those in related nickel–chloro–amido–phosphine complexes.[5]

To test the generality of the reaction we repeated it with the bifunctional bis(amino)cyclodiphosph(III)azane **C** (Scheme 1), for which *N,N* chelation seemed a distinct plausibility. Treatment of {$NiCl_2[P(Bu^n)_3]_2$} with dianionic **C** afforded again a dark-red, diamagnetic complex **3**.‡ The X-ray analysis, Fig. 2,§ confirmed that **3** was an almost C_2-symmetric, dinuclear analogue of **2**, whose nickel atoms exhibited bond parameters that are isometric with each other and those of **2**.

A survey of the bond lengths of **2** and **3** reveals that the amidocyclodiphosph(III)azanes are not simple amido ligands with auxiliary nickel–phosphorus interactions. Thus, the metal-

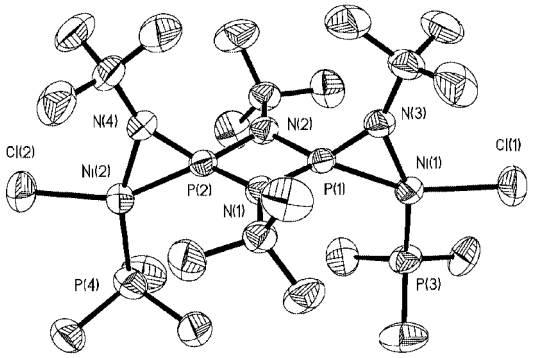

Fig. 2 Thermal ellipsoid (35% probability) plot of **3**. The *n*-butyl substituents of both PBu^n_3 ligands have been truncated to the first methylene carbons. Selected bond lengths (Å) and angles (°): Ni(1)–Cl(1) 2.2001(16), Ni(2)–Cl(2) 2.1996(17), Ni(1)–P(1) 2.0759(13), Ni(2)–P(2) 2.0739(14), Ni(1)–N(3) 1.939(4), Ni(2)–N(4) 1.944(4), Ni(1)–P(3) 2.1551(16), Ni(2)–P(4) 2.1584(18), P(1)–N(3) 1.556(4), P(2)–N(4) 1.551(4); P(3)–Ni(1)–Cl(1) 95.64(7), N(3)–Ni(1)–Cl(1) 105.27(13), P(1)–Ni(1)–N(3) 45.44(12), P(1)–Ni(1)–P(3) 113.76(6), P(4)–Ni(2)–Cl(2) 95.24(7), N(4)–Ni(2)–Cl(2) 105.72(13), P(2)–Ni(2)–N(4) 45.27(12), P(2)–Ni(2)–P(4) 113.91(6).

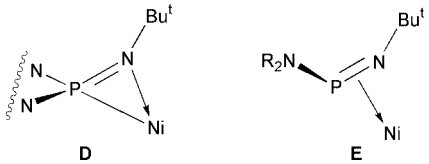
lacyclic P–N bonds [av. 1.555(5) Å] are substantially shorter than in pristine **C** [1.664(3) Å],[6] and consistent with P=N double bonds. This electron distribution places a formal negative charge on the phosphorus atoms, thereby reversing the polarity in the phosphorus–nitrogen bonds. The very short Ni–P [av. 2.0796(9) Å] and normal Ni–N [av. 1.925(3) Å] bonds reflect this as well, suggesting that canonical form **D** best describes the bonding in these mono- and di-nuclear species. The title compounds are thus planar, 16-electron nickel(II) complexes with anionic four-electron P=N ligands.



Only two nickellaazaphosphiranes have previously been structurally characterized, but in these nickel(0) species (**E**) the iminophosphine is a neutral π-donor ligand.[7] Diagnostic for this type of coordination is the lengthening of the P=N bond from 1.544(4) Å[8] in the free iminophosphine to 1.646(2) Å in the complexes, as would be expected from the removal of π-bonding electron density. The nickel–phosphorus bonds in such compounds are also substantially longer [2.23(1)–2.409(3) Å] than those in **2** and **3**.

Nickellaazaphosphiranes with anionic P=N moieties have, to our knowledge, not been fully characterized, although their existence has been confirmed by NMR spectroscopy.[9] The closest crystallographically characterized analogue of the title compounds is a zirconium phosphinomethanide complex with a three-membered P–Zr–C ring, the $P{=}CR_2$ unit being isoelectronic with P=NR.[10]

The easy syntheses and remarkable stabilities of these three-membered metallacycles suggest that it may be possible to extend these metallations to related heterocyclic and perhaps even acyclic primary aminophosphines. Despite their unexpected structures, **2** and **3** exhibit the expected reactivity and are readily alkylated. They may thus still serve as the targeted neutral, single-component catalysts. Our investigations into the generality of these metallaazaphosphirane formations and potential uses of the title compounds in olefin catalysis are continuing.

We thank the Chevron Phillips Chemical Company for financial support.

Received (in Cambridge, UK) 30th May 2001, Accepted 2nd July 2001
First published as an Advance Article on the web 3rd August 2001

Silicon-29 NMR spectra of a neutral, dilute aqueous silicic acid solution, with a pH and Si concentration typical of soil solutions, reveal that a significant fraction of the silicon is incorporated in two five-coordinated organosilicon complexes when sodium gluconate is present.

The solubility of silica in aqueous solution is markedly pH dependent above pH 8.0, although it is nearly constant across the pH range typical of groundwater and soil solutions, varying from *ca.* 5 ppm for α-quartz to 130 ppm for amorphous silica at pH 7.[1] At these concentrations, silica exists primarily as tetravalent monosilicic acid, $Si(OH)_4$, although some also occurs as disilicic acid, $(OH)_3SiOSi(OH)_3$.[2] Indeed, small quantities of higher oligomers are also expected since the speciation of aqueous silicates is governed by the rules of polymer chemistry, and monomeric silicic acid is always in dynamic equilibrium with more condensed species.[3–5] No other silicon containing species have ever been identified in neutral aqueous solutions, and there has never been any evidence to suggest that silicic acid reacts with organic species at these pH values and concentrations. Although it has often been proposed that organosilicon compounds are key to molecular level processes underpinning the weathering of minerals and biosilicification in plants, such claims have always been speculative.

We have shown elsewhere,[6,7] however, that silicon–carbohydrate compounds readily form in aqueous solution, although at pH values and silica concentrations much greater than are generally found in nature. Surprisingly, the Si centres in such complexes are not tetravalent, but instead exist with either pentaoxo or hexaoxo coordination, or both.[6] Such hypervalent species only form when the carbohydrate ligand contains four or more adjacent hydroxy groups, with two in *threo* configuration, and are especially stable if the ligand also contains a carboxylic acid end group.[7] Accordingly, simple sugar acids like gluconic, saccharic and glucoheptonic acid show great affinity for aqueous silicate anions at high pH.

Here we present evidence for the existence of stable silicon–carbohydrate compounds in *neutral* solution. This represents the first observation of an organosilicon compound forming at biologically relevant Si concentrations and pH. Indeed, with the exception of the well attested monosilicic and disilicic acid species, no other Si-containing molecule has ever been observed in neutral aqueous solution.

Fig. 1 shows the ^{29}Si-{^{1}H} NMR spectrum of an aqueous sodium gluconate solution which has been tumbled with amorphous silica (enriched to 75 atom% in the NMR active ^{29}Si nuclide) for 4 weeks at 311 K. The solution has a measured pH of 7.0† and a silicon concentration of 1.4×10^{-3} mol kg^{-1}, a figure that is consistent with Si levels in soil solutions. As expected, most of the silicon is present as monosilicic and disilicic acid, and the corresponding signals at −71.0 and −80.2 ppm, respectively, are labeled in the figure. Two additional signals are seen at −101.3 and −102.0 ppm, in the region characteristic of five-coordinated Si,[8] and account for 31% of the silicon in solution. Analogous signals appear in the ^{29}Si spectra of high pH silicate solutions that contain gluconic acid or other aliphatic carbohydrate molecules having the requisite hydroxy group configuration.[6,7] Analysis of ^{29}Si–^{1}H scalar coupling and the corresponding ^{13}C NMR spectra for those solutions showed unequivocally that the ^{29}Si signals originate from Si centres coordinated to two or more carbohydrate –OC≡ linkages.[6,7] Since a –OC≡ group is significantly less shielding than –OSi≡, the peaks at −101.3 and −102.0 ppm almost

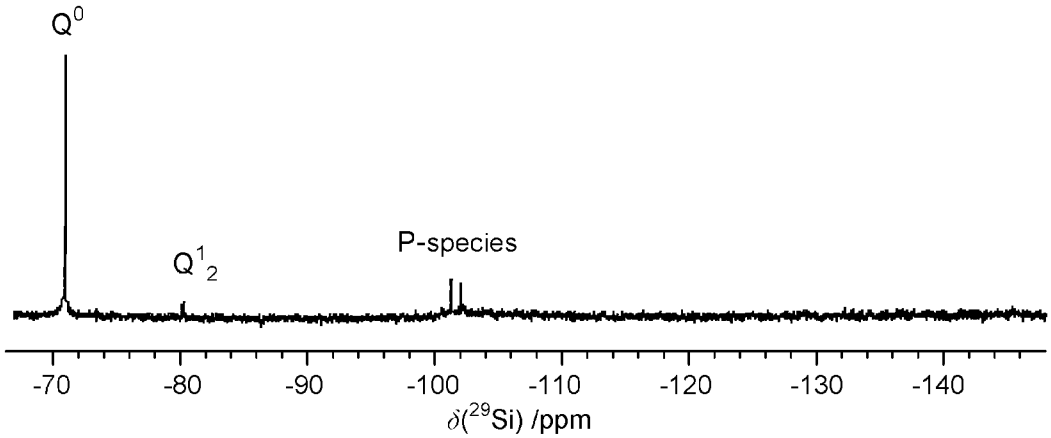

Fig. 1 Silicon-29 NMR ^{1}H-decoupled spectrum (99.36 MHz) at 270 K of a 3.35 mol kg^{-1} sodium D-gluconate solution in which amorphous SiO_2 (75% ^{29}Si-enriched) was tumbled for 4 weeks at 311 K, followed by 0.1 μm filtration. The final solution composition was 1.4×10^{-3} mol kg^{-1} Si (by ICAP), with a measured pH of 7.0 (298 K). The spectrum was recorded using 8414 π/2 pulses with an interpulse delay of 47 s, and processed using 2 Hz artificial line broadening. Spectral integration shows that 66 ± 2% of the dissolved silicon exists as the four-coordinated silicate monomer [$Si(OH)_4$, Q^0; −71.0 ppm, $\Delta\nu_{\frac{1}{2}}$ = 2.5 Hz], 3 ± 1% as the dimer [$(OH)_3SiOSi(OH)_3$, $Q^1{}_2$; –80.2 ppm, $\Delta\nu_{\frac{1}{2}}$ = 2.5 Hz], and 31 ± 2% as one of two five-coordinated silicon (denoted 'P' for pentafunctional[6]) complexes that correspond to the signals at −101.3 ($\Delta\nu_{\frac{1}{2}}$ = 8.2 Hz) and −102.0 ppm ($\Delta\nu_{\frac{1}{2}}$ = 3.7 Hz).

 DOI: 10.1039/b104713m

certainly arise from pentaoxosilicon complexes rather than from those containing either tetrahedral $Si(OSi\equiv)_4$ or $(\equiv CO)_nSi(O\text{-}Si\equiv)_{4-n}$ sites.

The spectrum remains unchanged over time, indicating that the complexes are thermodynamically stable. Indeed, the complexes are so energetically favoured that they re-assemble within the time required to obtain an NMR spectrum if the sample constituents are broken down by heating the sample to boiling.

The actual molecular structure of these complexes cannot be deduced with certainty from our spectra. The low Si concentrations involved place these experiments at the very edge of the spectrometer detection limits, even using isotopically enriched materials. The spectrum shown in Fig. 1 required 8 days to acquire. Nevertheless, our work on concentrated alkaline samples[7] would suggest that pentavalent organosilicon complexes **1**, **2** and **3** occur when silicate anions combine with gluconate ligands. Based then on the chemical shifts of signals identified at higher pH, we tentatively assign the peak at −101.3 ppm in Fig. 1 to species **2** and that at −102.0 ppm to species **3**.

3

Evidence that gluconic acid is effective at sequestering silicate anions in dilute neutral solution suggests that simple sugar acids, or molecules containing structurally related subunits, could indeed play a role in isolating and trapping silicate anions in groundwater and biofluids, thus contributing to the functionality of silicon in nature.

Notes and references

† pH measurements were performed on two non-isotopically enriched solutions prepared under conditions identical to those used for the ^{29}Si enriched sample in Fig. 1 (also yielding the same 1.4×10^{-3} mol kg^{-1} Si concentration), using an Orion ROSS glass pH electrode. The calculated pH for a 3.35 mol kg^{-1} gluconate ($K_b = 4.0 \times 10^{-11}$) solution is 9.0, which indicates that 4 weeks exposure to atmospheric CO_2 and amorphous silica had an appreciable neutralizing effect.

Phenol can be alkylated with propan-2-ol without catalyst in supercritical water at 673 K with mainly *ortho* substituted alkylphenols being obtained and alkylation reaction rate increasing with increasing water density.

The Friedel–Crafts reaction is the most widely used in chemistry and industry for the alkylation of aromatics. This reaction is promoted by strong acid catalysts such as Lewis acids ($AlCl_3$ and BF_3) and mineral acids (HF, H_2SO_4),[1] and is frequently conducted in organic solvents, which requires considerable waste treatment. Because of increased awareness towards our environment, research has been directed towards alternative solvents and non-catalytic pathways.

The reactivity of the hydroxy group of phenol strongly activates the ring substituents, especially at the *ortho* and *para* positions. Thus, in the alkylation of phenol through the Friedel–Crafts reaction, it is difficult to alkylate only one position. If the alkylating agents are propan-1-ol or propan-2-ol, the condensation between alcohol and hydroxy group yields isopropyl phenoxy ether, in addition to the alkylation.[2] Solid catalysts have been used for *ortho*-selective alkylation of phenol.[3,4] Gray *et al.* reported that the etherification and alkylation of phenol could be controlled and the *ortho* alkylphenol obtained was over 3 times larger than that for *para* substituents in supercritical CO_2 with a solid catalyst.[4]

High temperature water can possibly provide an alternative pathway for formation of C–C bonds.[5,6] In the alkylation of phenol, Chandler *et al.*[7,8] studied non-catalytic alkylation of phenol with several alcohols in high temperature water at 523–573 K. They reported that alkylation of phenol with propan-2-ol occurred almost only at the *ortho* position of phenol. However, the reaction rate and alkylphenol yield obtained were low being about 20% after 120 hours reaction time.

Supercritical water (T_c = 647 K, P_c = 22.1 MPa) shows some unique properties and has been considered for the decomposition of organics.[5] It is completely miscible with many organics and can provide a homogeneous reaction field. Solvent properties such as density and relative permittivity can be varied by manipulating temperature and pressure. The reaction rate in supercritical water is expected to be much higher than that in sub-critical water due to not only the higher temperature but also to the homogeneous reaction environment[9] and the chemical effects caused by the relative permittivity.[10] In this study, we conducted non-catalytic alkylation of phenol with propan-2-ol in supercritical water at 673 K and water densities ranging from 0 to 0.5 g cm^{-3} and determined the reaction pathway. We show that high reaction rate, high alkylphenol yields and *ortho* selectivity are possible in high temperature dense water.

Reactions were conducted with 6 cm^3 stainless 316 tube bomb reactors. Phenol (99.0% purity, Wako Pure Chemical Industries, Ltd.) and propan-2-ol (99.5% purity, Wako Pure Chemical Industries, Ltd.) were loaded into the reactors and then a given amount of water was added. The air in the reactor was exchanged with argon gas by successive purgings and the reactor was sealed. The molar ratio of propan-2-ol to phenol was 1 : 5, which corresponded to a concentration of 0.33 mol L^{-1} for propan-2-ol and 1.65 mol L^{-1} for phenol. Water was loaded from 0 to 0.5 g cm^{-3} of water density corresponding to a range of concentration from 0 to 27.7 mol L^{-1}. The reactors were submerged into a sand bath controlled at 673 K. After 10–60 minutes, the reactors were quenched. Products were identified by GC-MS and by comparison of the GC retention time with standards. Quantitative analysis of products was conducted with GC-FID. For some cases, we conducted experiments for the analysis of gas products using a reactor that was connected to a valve. For these cases, the gas compositions were analyzed by GC-TCD. The product yield was defined on a propan-2-ol basis, as: yield (%) = (moles of carbon atom of the alkyl chain except benzene ring) / (moles of carbon atom in propan-2-ol loaded) × 100.

Fig. 1 shows the yield of main products for the alkylation of phenol with propan-2-ol in supercritical water at 0.5 g cm^{-3} of water density and 673 K. The main liquid products were 2-isopropylphenol, 2-propylphenol and 2,6-diisopropylphenol, and their maximal yields were 57.9, 6.9 and 5.9%, respectively. Other liquid products obtained were 2-isopropyl-6-propylphenol and 4-isopropylphenol, and their maximal yields were 1.7 and 2.4%, respectively. From 10 to 60 minutes reaction time, the gas product was almost all propylene, whose molar proportion to all gases was always above 90%. In particular, the proportion of propylene was above 95.9% before 30 minutes reaction time. After that, the proportion of hydrogen, methane and propane slightly increased up to 4.7, 1.5 and 3.4%, respectively. Propylene yields shown in Fig. 1 were obtained by the carbon balance and so include other gas products as well. The yield of propan-2-ol rapidly decreased and the conversion of propan-2-ol was above 90% at 20 minutes of reaction time. The yield of propylene was 52.1% at 10 minutes of reaction time and decreased with reaction time down to 25.8%. The yield of 2-isopropylphenol increased with time up to 57.9% and that of 2-propylphenol increased up to 6.9%. The yield of 2,6-diisopropylphenol increased up to 5.9% at 45 minutes and subsequently decreased to 5.2% at 60 minutes reaction time. After 45 minutes, the reaction appeared to be at equilibrium. In contrast, Chandler *et al.*[7] reported that the reaction did not reach equilibrium even after 120 hours of reaction time at 548 K.

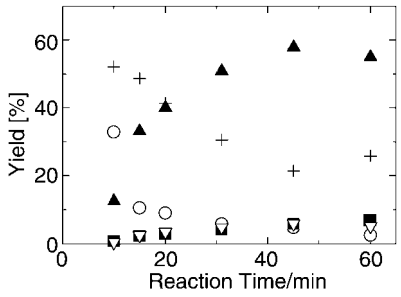

Fig. 1 Yield of (+) propylene, (▲) 2-isopropylphenol, (■) 2-propylphenol and (▽) 2,6-diisopropylphenol for reaction of phenol with propan-2-ol (○) at 0.5 g cm^{-3} of water density and 673 K.

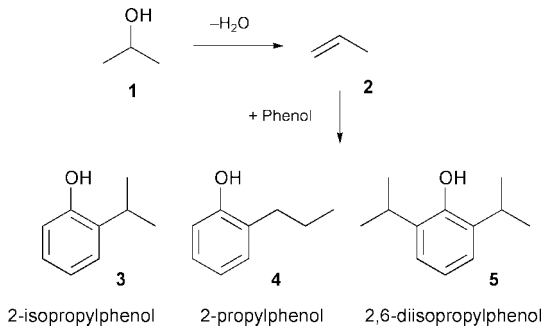
 DOI: 10.1039/b104184n

The dehydration of propan-2-ol yielded propylene at the early reaction times. Alkylphenols dissociate in its aqueous solution, as shown by Xiang *et al.*[11] who reported that β-naphthol dissociates even in supercritical water. For example, the dissociation constant of β-naphthol is 1.26×10^{-11} mol kg^{-1} at 673 K and 0.5 g cm^{-3} of water density. At room temperature and pressure, the dissociation constant of phenol (pK_a = 9.89) at 293 K and 0.1 MPa was similar to that of β-naphthol (pK_a = 9.51) at 298 K and 0.1 MPa.[12] Phenol probably dissociates in supercritical water. Antal *et al.*[13] reported that the acid-catalyzed dehydration of propan-2-ol yielded propylene in high temperature water at 593 K.

Considering these experimental findings, the reaction pathway shown in Scheme 1 was developed. The dehydration of propan-2-ol (**1**) probably yields propylene (**2**), following alkylation of phenol with propylene to 2-isopropylphenol (**3**), 2-propylphenol (**4**) and 2,6-diisopropylphenol (**5**). It is probable that phenol acts as an acid catalyst and promotes the dehydration of propan-2-ol at supercritical conditions.



Scheme 1

The alkylation of phenol with propylene yielded 2-isopropylphenol, 2-propylphenol and 2,6-diisopropylphenol and this reaction was the rate-determining step. Phenoxyether was not produced, probably because hydrolysis of ethers occurs readily in supercritical water.[5] Phenol was alkylated almost solely at the *ortho* position of the hydroxy group even in the homogeneous system as obtained in high temperature water by Chandler *et al.*[7] The hydroxy group of phenol and several water molecules can construct a ring structure formed by hydrogen-bonds[14] and the distance between hydroxy oxygen and hydrogen increases with increasing the number of water molecules in a ring structure.[15] In supercritical carbon dioxide, specific solvation around the hydroxy group of phenol can occur.[16] Taking these results into account, water molecules probably locate around the hydroxy group of phenol at supercritical conditions and construct a ring structure with the hydroxy group of phenol. Then, the dissociation of the hydroxy group is promoted locally around it. This makes the reaction field limited only around the hydroxy group, which results in mainly the *ortho* position being alkylated.

The data reported above were measured at 0.5 g cm^{-3} of water density. At these conditions, the phase in the reactor was probably homogeneous and phenol was dissociated to a certain extent as discussed previously. In order to determine the effect of phase behavior and the dissociation of phenol, we conducted the experiment at various water densities from 0 g cm^{-3} (in Ar atmosphere) to 0.5 g cm^{-3} and at reaction times of 60 minutes. The sum of the yield of alkylphenol was less than 2.4% below 0.3 g cm^{-3} of water density. Table 1 shows the yield of propan-2-ol (**1**), 2-isopropylphenol (**3**), 2-propylphenol (**4**) and 2,6-diisopropylphenol (**5**) at 673 K and more than 0.3 g cm^{-3} of water density. The yields of all alkylphenols increased with increasing water density at more than 0.4 g cm^{-3} of water density, compared with the yield of propan-2-ol. This result clearly shows that alkylation was accelerated with increasing water density. We consider that phase behavior and the concentration of protons can affect the reaction. At low water density, the reactants were separated into two phases. Phenol would probably be mainly distributed in the liquid phase while the propan-2-ol would be distributed in the gas phase. With increasing water density, the phase in the reactor probably became homogeneous. In addition, the dissociation constant of β-naphthol increases with increasing water density in supercritical water.[11] This trend seems to be applicable to the dissociation of phenol. If the dissociation constant of phenol increased with increasing water density, the concentration of protons also increased. Then, dehydration and alkylation was promoted with increasing water density, because the proton catalyzed both reactions.

Table 1 Yield of propan-2-ol and alkylphenols with water density for 60 minutes of reaction time at 673 K, [propan-2-ol]$_0$ = 0.33 mol L^{-1}, [phenol]$_0$ = 1.65 mol L^{-1}

Water density/ g cm^{-3}	Yield (%)			
	1	**3**	**4**	**5**
0.3	75.9	3.1	0.3	0
0.4	58.5	18.0	2.2	0.6
0.42	13.7	45.5	5.8	3.7
0.46	4.5	55.1	7.1	5.1
0.48	3.6	58.8	7.5	5.4
0.5	2.6	55.0	6.9	5.1

In summary, phenol was alkylated with propan-2-ol without catalyst in supercritical water at 673 K. The alkylphenols obtained were mainly *ortho* substituted compounds and the maximum yield of 2-isopropylphenol was 58.8%. The sum of *ortho* alkylphenols yield was 71.7%. Further, alkylation was enhanced with increasing water density. Our results show that supercritical water can provide a unique reaction field for the alkylation, which is non-catalytic and highly selective.

The authors thank a Grant-in-Aid for Scientific Research on Priority Areas (09450281, 10555270, 11450295 and 11694921) the Ministry of Education, Culture, Sports, Science and Technology, for support of this research.

Rhodizonate and croconate dianions as divergent hydrogen-bond acceptors in the self-assembly of supramolecular structures†

Chi-Keung Lam and Thomas C. W. Mak*

Received (in Cambridge, UK) 18th May 2001, Accepted 9th June 2001
First published as an Advance Article on the web 9th August 2001

The $C_5O_5^{2-}$ and relatively unstable $C_6O_6^{2-}$ dianions, each serving as a hub for binding with a set of convergent NH donor groups of four phenylurea molecules, have been generated *in situ* and stabilized in nearly isostructural hydrogen-bonded host lattices.

Recently we initiated a program to explore the use of the non-benzenoid aromatic oxocarbons $C_nO_n^{2-}$ (n = 3, deltate; n = 4, squarate; n = 5, croconate; n = 6, rhodizonate),[1] each bearing a planar set of divergent hydrogen-bond acceptor sites, in combination with urea or thiourea, for the construction of anionic host frameworks that accommodate quaternary ammonium cations. In the series of inclusion complexes $[Et_4N^+]_2C_4O_4^{2-}\cdot 2Et_4N^+\cdot HCO_3^-\cdot 4(NH_2)_2CO\cdot 6H_2O$,[2] $[Pr^n{}_4N^+]_2C_4O_4^{2-}\cdot 6(NH_2)_2CO\cdot 2H_2O$,[3] $[Et_4N^+]_2C_4O_4^{2-}\cdot 4(NH_2)_2CS\cdot 2H_2O$,[4] $[Et_4N^+]_2C_4O_4^{2-}\cdot 6(NH_2)_2CS$[6] and $[Et_4N^+]_2C_4O_4^{2-}\cdot 2(NH_2)_2CS\cdot 2H_2O$,[6] direct linkages between squarate and urea/thiourea exhibit the hydrogen bonding patterns I–IV shown in Fig. 1, which are further connected with the commonly occurring infinite urea/thiourea chains or ribbons[5] to generate two- or three-dimensional host networks.

Attempts to obtain analogous croconate and rhodizonate inclusion complexes with urea (and thiourea) have so far been unsuccessful. We then proceeded on the hypothesis that an oxocarbon dianion could be stabilized by surrounding it with the maximum number of convergent NH donor sites, and to do so it would be necessary to disrupt the intermolecular association between urea molecules. We therefore decided to replace urea with phenylurea, whose bulky and hydrophobic substituent is expected to prevent, or at least suppress, the formation of urea ribbons. Furthermore, the rhodizonate dianion readily undergoes oxidative ring contraction through an α-oxo alcohol rearrangement,[6] which is related to the well known benzil–benzylic acid rearrangement,[7] to produce the croconate ion. Accordingly we developed a simple method to generate the rhodizonate ion *in situ* and incorporate it and its ring-contracted croconate product into the host lattices of new inclusion compounds $[Bu^n{}_4N^+]_2C_6O_6^{2-}\cdot 4PhNHCONH_2$ **1** and $[Bu^n{}_4N^+]_2C_5O_5^{2-}\cdot 4PhNHCONH_2$ **2**, respectively.‡

In the crystal structure of **1**,§ four crystallographically independent phenylurea molecules are directly connected to the rhodizonate ion *via* separate pairs of strong N–H$_{anti}$···O hydrogen bonds in the range of 2.834–2.933 Å [ring motifs **A**, **B**, **C** and **D**; graph set $N_2 = R_2^2(9)$][8] to form a pseudo-centrosymmetric, slightly twisted X-shaped pentamer (Fig. 2). One pair of opposite phenylurea molecules (designated as type A) are nearly coplanar with the rhodizonate ion, as shown by the relevant torsion angles C46–N5···O3–C3 0.6°, C46–N6···O4–C4 18.9°, C60–N9···O6–C6 23.5° and C60–N10···O1–C1 −8.2°, while the other pair (type B) are inclined to it at about 45°. Adjacent pentamers are joined together by pairs of strong N–H$_{syn}$···O hydrogen bonds between urea fragments (N5···O10 2.913 Å and N9···O8 2.969 Å) in a complementary manner [**E**, $N_2 = R_2^2(8)$] to generate a wide rhodizonate–phenylurea ribbon, which is further strengthened by additional strong N–H$_{anti}$···O hydrogen bonds (N3···O10 3.063 Å and N7···O8 3.083 Å) to produce two other ring motifs [**F** and **G**, $N_2 = R_4^2(8)$]. This wide ribbon runs parallel to the [110] direction, and the hydrophilic amido fragment of the type A phenylurea molecule participates in the construction of its zigzag 'pseudo rhodizonate–urea' backbone in a 'chain of rings' pattern $C_3^3(12)[R_2^2(9)R_2^2(8)\ R_2^2(9)]$. The phenyl rings of type A urea molecules and whole urea molecules of type B protrude outward from the backbone, and stacking of the wide ribbons leads to a system of grated, broken-walled channels each accommodating two parallel columns of well ordered tetra-*n*-butylammonium cations (Fig. 3).

The hydrogen bonding pattern in the crystal structure of **2**§ (Fig. 4) is very similar to that in **1** (Fig. 2), and the cyclic pentameric structural unit with an oxocarbon core is basically retained, so that the pair of inclusion compounds exhibit an interesting isostructurality relationship.[9] However, the croconate ion is disordered about an inversion center, and it adopts two equally populated orientations. Consequently, there are only two independent phenylurea molecules in the asymmetric unit of **2**, and the length of the *c*-axis is about half of that in **1**. In addition to the conventional N–H···O hydrogen bonds, the croconate-based pentamers are consolidated by the charged-assisted C–H···O hydrogen bonds, whose metric parameters (C19···O5 3.282 Å, H19···O5 2.497 Å, C19–H19···O5 142.3°, H19···O5–C5 135.6°; C8···O2 3.341 Å, H8···O2 2.568 Å, C8–

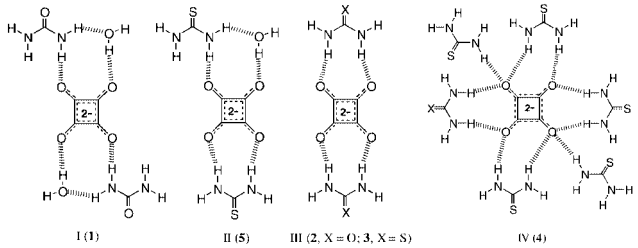

Fig. 1 Hydrogen bonding interaction between squarate ions and urea/thiourea molecules in some inclusion complexes.

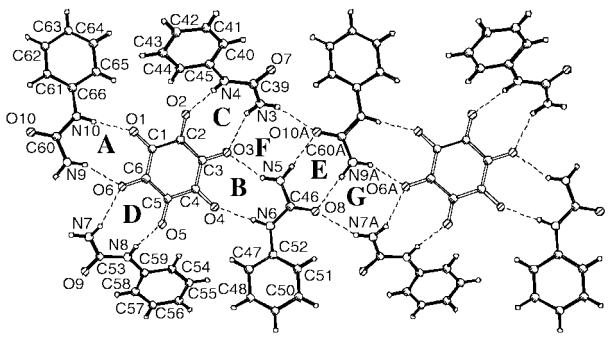

Fig. 2 Hydrogen bonding scheme of **1** showing a portion of the rhodizonate–phenylurea wide ribbon consolidated by strong N–H···O hydrogen bonds. The phenyl rings lie on opposite sides of the zigzag ribbon; half of them are nearly co-planar with the ribbon, and the other half are inclined at 45°. The orientation of these two kinds of phenyl rings is further illustrated in Fig. 2. Symmetry transformation: A ($-x$, $-y$, $-z$).

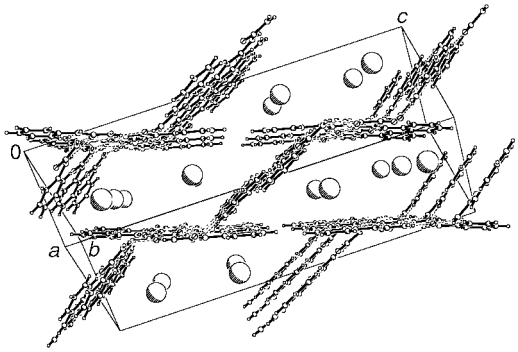

Fig. 3 The crystal structure of **1** showing the one-dimensional 'broken-walled' channel system. The well ordered tetra-*n*-butylammonium cations (represented by large shaded circles for clarity) are arranged in two parallel columns in the [1$\bar{1}$0] direction. Half of the phenylurea molecules reach out of the plane of each rhodizonate–phenylurea ribbon, functioning as spacers which effectively separate the double cationic columns. The cross-section of the parallelogram-shaped channel is *ca.* 11.6 × 19.2 Å.

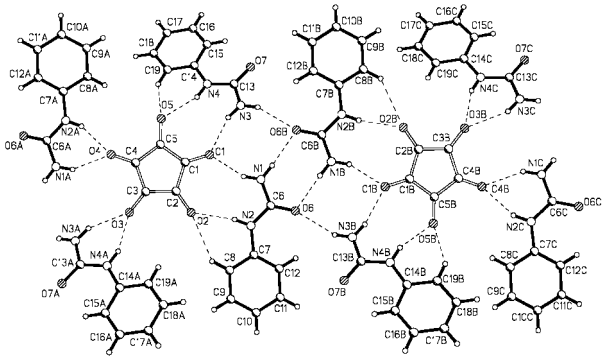

Fig. 4 Hydrogen bonding scheme of **2**, showing a wide croconate–phenylurea ribbon running parallel to the *b*-axis. The disordered croconate dianion lies at an inversion center; for clarity, one orientation is shown on the left and the other on the right. Symmetry transformations: A ($1 - x$, $-y$, $1 - z$), B ($1 - x$, $1 - y$, $1 - z$) and C (x, $1 + y$, z).

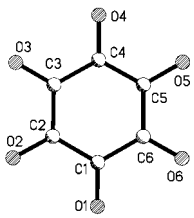

Fig. 5 Structure of $C_6O_6^{2-}$ in **1**. Bond lengths (Å) and angles (°) with esds in parentheses: O(1)–C(1) 1.234(4), O(2)–C(2) 1.247(4), O(3)–C(3) 1.252(4), O(4)–C(4) 1.251(4), O(5)–C(5) 1.258(4), O(6)–C(6) 1.250(4), C(1)–C(2) 1.449(5), C(1)–C(6) 1.458(5), C(2)–C(3) 1.443(5), C(3)–C(4) 1.421(5), C(4)–C(5) 1.424(5), C(5)–C(6) 1.447(5); O(1)–C(1)–C(2) 120.1(4), O(1)–C(1)–C(6) 120.5(4), C(2)–C(1)–C(6) 119.4(4), O(2)–C(2)–C(3) 120.0(4), O(2)–C(2)–C(1) 120.8(4), C(3)–C(2)–C(1) 119.2(4), O(3)–C(3)–C(4) 120.4(4), O(3)–C(3)–C(2) 119.2(4), C(4)–C(3)–C(2) 120.5(4), O(4)–C(4)–C(3) 119.7(4), O(4)–C(4)–C(5) 118.9(4), C(3)–C(4)–C(5) 121.4(4), O(5)–C(5)–C(4) 120.8(4), O(5)–C(5)–C(6) 120.1(3), C(4)–C(5)–C(6) 119.1(4), O(6)–C(6)–C(5) 119.5(4), O(6)–C(6)–C(1) 120.4(4), C(5)–C(6)–C(1) 120.1(4).

H8···O2 140.9°, H8···O2–C2 164.4°) are comparable to those in the most probable ranges (C···O 3.3–3.4 Å, H···O 2.2–2.6 Å, C–H···O 150–160° and H···O–C *ca.* 120°).[10]

The present study provides the first reasonably precise molecular dimensions of the rhodizonate dianion, which lends support to the aromaticity of this non-benzenoid cyclic oxocarbon. Notably, the measured C–C bond lengths [1.421(5)–1.458(5) Å; see Fig. 5] of the rhodizonate in **1**, which exhibits approximate D_{6h} molecular symmetry, are significantly shorter than the corresponding values (1.488 and 1.501 Å) in $Rb_2C_6O_6$[11] and the calculated values (1.500 and 1.501 Å) for the C_2 structure of this dianion.[12] Compound **1** provides yet another example of the use of urea and its derivatives for stabilizing elusive molecular anions such as allophanate[13] and dihydrogen borate[14] in a hydrogen-bonded host lattice.

In summary, we have shown that the supramolecular approach to the synthesis of solids may lead to the stabilization, by way of crystal engineering, of a reactive covalent species, and this strategy holds good promise for further development.

‡ *Synthesis*: phenylurea[15a] and tetrahydroxy-1,4-quinone hydrate[15b] were prepared according to literature procedures. For **1**, tetrahydroxy-1,4-quinone hydrate was dissolved in a small amount of absolute ethanol (E-Merck, 99.8%) in a stoppered flask, to which two molar equivalents of aqueous tetra-*n*-butylammonium hydroxide solution (40 wt% in water, Aldrich) were added. The solution was stirred until all solid material had completely dissolved. Five molar equivalent of phenylurea was then added and stirred for a while. The solution was concentrated under vacuum to yield a brownish orange solid. The solid was next re-dissolved in a minimum amount of absolute ethanol. After filtration, the deep orange red solution was evaporated in a dessicator charged with anhydrous calcium chloride. Rose-red polyhedral crystals of **1** (yield *ca.* 50%) were obtained after about one week. Mp 125.4–130.6 °C. IR (KBr): 3390, 3338, 3271, 3205, 3075, 2956, 2871, 1696, 1652, 1598, 1545, 1500, 1444, 1343, 1247, 756, 696 cm^{-1}. It was found that when **1** was exposed in air, its reddish color gradually faded and completely turned to pale yellow in *ca.* 3 h, therefore, a selected crystal from a freshly prepared sample was sealed in a 0.5 mm glass capillary for X-ray analysis. For **2**, having noticed the color change of **1** in air, a small amount of warm absolute ethanol was added to re-dissolve the immersed crystals. After the solution was kept inside a locker for another three weeks, a crop of brownish yellow rectangular prisms of **2** was deposited in *ca.* 60% yield. Compound **2** proved to be stable in air for an indefinite period. Mp 128.3–134.5 °C. IR (KBr): 3339, 3271, 3201, 3076, 2957, 2874, 1695, 1595, 1545, 1509, 1445, 1343, 1250, 755, 698 cm^{-1}.

A remarkable temperature-dependent, accidental degeneracy of ^{31}P NMR chemical shifts in Ru(II) diphosphine/diimine complexes

Paul W. Cyr, Brian O. Patrick and Brian R. James*

Department of Chemistry, The University of British Columbia, Vancouver, British Columbia V6T 1Z1, Canada. E-mail: brj@chem.ubc.ca

Received (in Cambridge, UK) 18th April 2001, Accepted 28th June 2001
First published as an Advance Article on the web 2nd August 2001

Several *cis*-RuX_2((*R*)-BINAP)(diimine) complexes have been prepared, and many of these exhibit an unusual temperature-dependent, accidental degeneracy of the ^{31}P shifts in their solution NMR spectra.

There is on-going research in this laboratory on Ru(II) complexes possessing one chelating, ditertiary phosphine (P–P) per Ru atom, because of their proven ability as hydrogenation catalysts,[1] especially for enantioselective catalysis when P–P is a chiral diphosphine ligand;[2] of such ligands, the C_2-symmetric BINAP (2,2′-bis(diphenylphosphino)-1,1′-binaphthyl) and its derivatives have been employed very successfully in asymmetric catalysis.[3,4] We have also studied Ru(II) complexes with mixed P- and N-donor ligand sets, where the N-donor is either incorporated into the phosphine ligand,[5] or with separate P- and N-donor ligands,[6] and the use of Ru(II) systems with tetradentate 'P_2N_2' ligands for catalytic hydrogenation[7] and epoxidation[8] reactions has been explored recently. Of particular note, spectacular success has been achieved in the use of chiral Ru(II) complexes with phosphine (either mono- or bidentate) and diamine ligands in catalytic enantioselective hydrogenation.[4] We report here a warning concerning interpretation of the ^{31}P NMR spectra of such systems: 'apparent complications' can result from a remarkable temperature-dependent degeneracy of ^{31}P NMR chemical shifts. More specifically, some systems, where two P atoms are *trans* to different ligands (an N-donor, and a halogen), generate a singlet ^{31}P{^{1}H} signal resulting from an authentic, accidental degeneracy.

Complexes of formula *cis*-RuCl_2((*R*)-BINAP)(L_2), where L_2 = a bidentate (N–N) ligand,† were prepared by reaction of L_2 with RuCl_2((*R*)-BINAP)(PPh_3),‡ and halide metathesis using NaX (X = Br, I) in acetone afforded the corresponding *cis*-RuX_2((*R*)-BINAP)(L_2) complexes. The structure of *cis*-RuBr_2((*R*)-BINAP)(bipy) (**1b**) is shown in Fig. 1.§ The crystallographic and solution ^{31}P{^{1}H} NMR data (Table 1) indicate that these complexes are formed stereoselectively. For example, the pseudo-octahedral structure of **1b** has the expected[3b] λ-conformation of the (*R*)-BINAP chelate ring, and only the *R*,Λ diastereomer is seen (where Λ refers to the chirality about the Ru atom; a parallel structural refinement was carried out for both Λ and Δ isomers, but only the Λ structure refined to convergence). Further, the solution ^{31}P spectra reveal the presence of only one set of signals at any given temperature, while diastereomeric Ru(II) BINAP complexes have been differentiated by ^{31}P NMR data.[6b,9] *Cis*-**3a** is seen solely as the *R*,Δ diastereomer; whether the halide metathesis reaction occurs with retention or inversion of stereochemistry at Ru remains to be established.[10] The solution ^{31}P NMR behaviour is

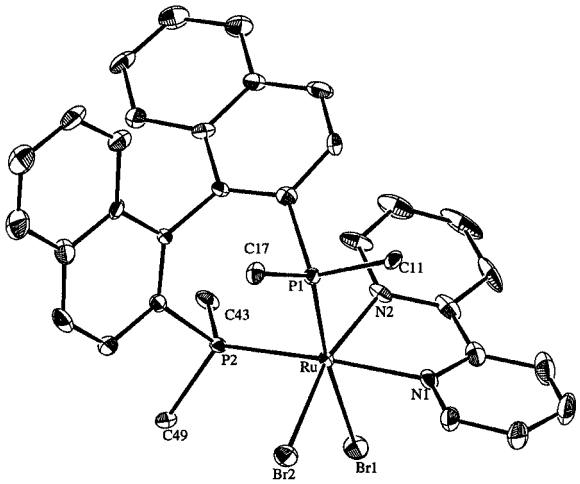

Fig. 1 ORTEP representation (50% probability ellipsoids) of *cis*-RuBr_2((*R*)-BINAP)(bipy) (**1b**). Solvates and H-atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Ru–Br(1), 2.6175(6); Ru–Br(2), 2.5476(7); Ru–P(1), 2.305(1); Ru–P(2), 2.317(2); Ru–N(1), 2.128(4); Ru–N(2), 2.091(4); Br(1)–Ru–Br(2), 89.42(2); P(1)–Ru–P(2), 93.13(5); N(1)–Ru–N(2), 77.7(2). Only the *ipso* carbon atoms (C(11), C(17), C(43) and C(49)) of the phenyl groups are shown.

Table 1 ^{31}P{^{1}H} NMR spectroscopic data for *cis*-RuX_2((*R*)-BINAP)(L_2)[a]

	δ_A, δ_B [$^2J_{AB}$/Hz][b]		
Complex	C_6D_6	$CDCl_3$	CD_2Cl_2

[a] Satisfactory elemental analyses were obtained for all the complexes listed.[10] [b] At room temperature (~20 °C) except where noted (121 MHz spectrometer frequency). [c] At 50 °C: δ 47.2 (s). [d] At −30 °C: δ_A = 47.8, δ_B = 47.4 [33.8]; at 35 °C: δ_A = 47.4, δ_B = 47.0 [34.5]. [e] At −60 °C: δ 47.3 (s). [f] At 10 °C: δ 47.2 (s); at −20 °C: δ_A = 47.6, δ_B = 47.2 [32.9]. [g] At 25 °C: δ 47.3 (s); at 40 °C: δ_A = 47.4, δ_B = 47.0 [33.6]. [h] At −30 °C: δ_A = 47.8, δ_B = 47.2 [34.4]; at 60 °C: δ_A = 47.2, δ_B = 46.9 [33.9]. [i] At 0 °C: δ 47.9 (s); at −90 °C: δ_A = 48.4, δ_B = 48.1 [34.9]. [j] At −40 °C: δ 47.7 (s). [k] At −10 °C: δ 47.6 (s); at −20 °C: δ_A = 47.6, δ_B = 47.2 [32.9]. [l] At 25 °C: δ 47.2 (s).

 DOI: 10.1039/b103473c

remarkable in that the expected AB pattern is sometimes 'lost' (Table 1). Thus, **3a** in $CDCl_3$ shows a singlet (δ47.2) in its room temperature spectrum, while in CD_2Cl_2 an AB pattern (δ_A = 47.9, δ_B = 47.5, $^2J_{AB}$ = 34.4 Hz) is present; **1a** demonstrates the opposite behaviour (an AB pattern in the $CDCl_3$ spectrum and a singlet in CD_2Cl_2).

Variable temperature (VT) NMR studies, conducted on all the complexes, are exemplified by the data shown in Fig. 2. From 0 to 10 °C, the spectrum of **1b** consists of a sharp singlet, while an AB pattern is observed either side of this range with increasing separation of the signals; there is clearly no dynamic exchange process between, for example, two species giving a time-averaged singlet. A temperature-dependent, accidental degeneracy of the two signals of the 4-line AB pattern gives rise to the singlet. At a specific solvent and temperature combination, an A_2 pattern is observed, the ^{31}P nuclei having become isochronous. This degeneracy occurs in at least one solvent studied (usually chlorinated) for most of the *cis*-RuX_2((*R*)-BINAP)(L_2) complexes, while *cis*-$RuCl_2$((*R*)-BINAP)(dmbipy) (**2**) is the only complex exhibiting degeneracy in C_6D_6 and not in $CDCl_3$ or CD_2Cl_2. The dibromo complexes **1b** and **3b** exhibit degeneracy at lower temperatures than the corresponding dichloro analogues (**1a** and **3a**); the diiodo complexes (**1c** and **3c**) show no degeneracy from −90 to 60 °C. Changing from the planar bipy- or phen-based ligand systems (**1**–**4**) to that with bis(*o*-pyridyl)amine (**5**) sufficiently separates the two ^{31}P shifts that degeneracy is not seen (Table 1). The related *cis*-$RuCl_2$(DPPB)(L_2) complexes (DPPB = 1,4-bis(diphenylphosphino)butane) possess well separated ($\Delta\delta$ > 10) signals in their ^{31}P NMR spectra.[6c]

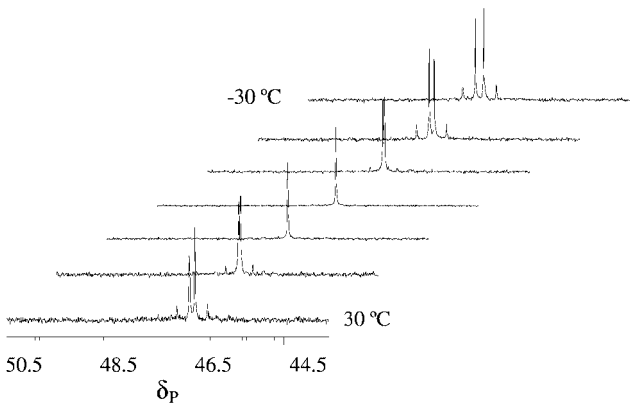

Fig. 2 VT ^{31}P{^{1}H} NMR spectra (CD_2Cl_2, 121 MHz) of *cis*-$RuBr_2$((*R*)-BINAP)(bipy) (**1b**) from 30 to −30 °C. Spectra are plotted in 10 °C increments.

Such accidental degeneracy is likely involved in some 'anomalies' in earlier work from this laboratory. Within the L(DPPB)Ru(μ-Cl)$_3$*Ru*Cl(DPPB) complexes (L = nitrile), a ^{31}P{^{1}H} singlet, rather than the expected AB (or AX) pattern, is seen for the two P atoms at *Ru* at 20 °C in CD_2Cl_2 (*i.e.* a singlet and 2 doublets are observed), while the expected 4 doublets are seen in C_6D_6 or $CDCl_3$;[6b] at −40 °C in CD_2Cl_2 the 2 sets of AB patterns are seen.[11] When L is Me_2S, the AB pattern is seen at 20 °C in C_6D_6, but not in $CDCl_3$, while the reverse holds true when L is tetrahydrothiophene, although VT NMR experiments were not performed.[12]

The temperature-dependence of ^{31}P NMR shifts is well documented, and indeed has been used for measuring sample temperature in VT work; *e.g.* the δ_P values for PPh_3 and O=PPh_3 change linearly with temperature (~1.3 Hz °C).[13] Further, the temperature-dependence of the δ_P values for the dimetallic, mixed-halide ClPd(μ-DPPM)$_2$PdI species (DPPM = bis(diphenylphosphino)methane) formed *in situ* varies with solvent, and the A_2B_2 pattern observed in $CDCl_3$ at −20 °C 'collapses' to a singlet at 35 °C, and reemerges above 45 °C,[14] behaviour similar to that of our Ru complexes.

To our knowledge, the *cis*-RuX_2((*R*)-BINAP)(L_2) complexes are the first isolated complexes to exhibit temperature-dependent degeneracy of ^{31}P NMR shifts. These data, particularly the observance of the degeneracy at room temperature in common NMR solvents, indicate that caution should be taken in the analysis of ^{31}P NMR data, especially for the widely studied chiral P–P systems, where such spectra remain a major characterization technique. The 'impossible' observation of a singlet NMR signal *must* be interrogated further by variation of temperature *and* variation of solvent.

We thank Colonial Metals Inc. for a loan of $RuCl_3 \cdot 3H_2O$, Dr S. King (formerly of Merck Research) for a gift of (*R*)-BINAP, and NSERC of Canada for financial support.

Assembling the biosynthetic puzzle of crucifer metabolites: indole-3-acetaldoxime† is incorporated efficiently into phytoalexins but glucobrassicin is not

M. Soledade C. Pedras,* Sabine Montaut, Yiming Xu, Abdul Q. Khan and Ali Loukaci

Received (in Cambridge, UK) 18th April 2001, Accepted 27th June 2001
First published as an Advance Article on the web 9th August 2001

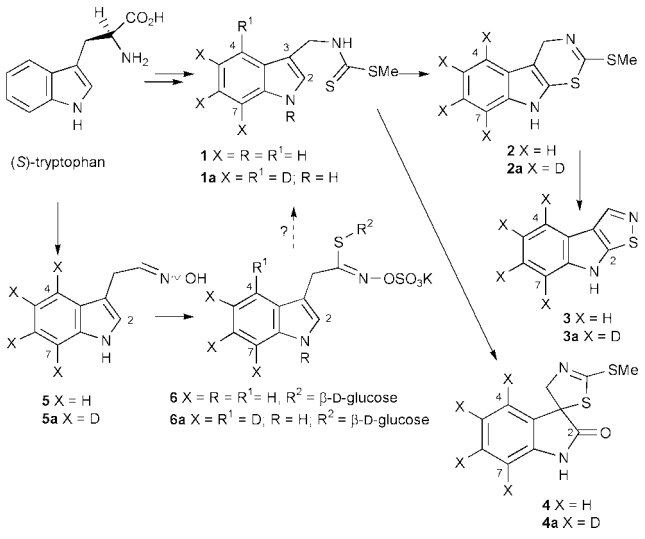
First biosynthetic studies utilizing tetradeuterated precursors indicate that the indole glucosinolate glucobrassicin is not a precursor of the phytoalexin brassinin, and that indole-3-acetaldoxime is an efficient precursor.

Plants have a complex arsenal of defense mechanisms to fight pathogen attack. A significant aspect of these defense mechanisms involves secondary metabolites, which may be either constitutive or biosynthesized *de novo* in response to diverse forms of stress, *i.e.* phytoalexins.[1] The plant family Cruciferae comprises a large number of economically important oilseed crops as well as vegetables. Besides their economic importance, crucifers are also interesting plant model-systems, containing the first and only example to date of a completely sequenced plant genome.[2] Chemical characterization of secondary metabolites from crucifers has unraveled a remarkable array of phytoalexins (*e.g.* **1**–**4**),[3] and a group of structurally related secondary metabolites known as glucosinolates (*e.g.* **6**).[4] This structural connection becomes more transparent considering that methoxy derivatives of brassinin **1** (*e.g.* R = OMe, R^1 = H) and glucobrassicin **6** (*e.g.* R = OMe, R^1 = H, R^2 = β–D–glucosyl) are naturally occurring within the same species and that their levels increase simultaneously in plants subjected to stress.[5] Furthermore, unambiguous biosynthetic studies have demonstrated that (*S*)-tryptophan is the precursor of both metabolites **1** and **6**.[3,6] In this connection a number of suggestions and attempts to establish a biogenetic relationship between indole glucosinolates such as glucobrassicin **6** and cruciferous phytoalexins have been reported.[3,7] Furthermore, a number of studies[8] have demonstrated that (*S*)-tryptophan is converted to **6** *via* indole-3-acetaldoxime **5** (Scheme 1).

Paradoxically, because glucosinolates are considered an undesirable group of metabolites in brassicas,[8] a large number of oilseed breeding programs are directed at obtaining plants containing low levels of glucosinolates. However, if indole glucosinolates such as glucobrassicin **6** are precursors of phytoalexins **1**–**4** (Scheme 1), then lowering glucosinolate contents in these oilseeds may pose a substantial ecological risk from a plant defense perspective. Nonetheless, despite a number of biosynthetic studies in crucifers, this biogenetic relationship has not been demonstrated.[3] Thus we became interested in establishing the possible biogenetic relationship between indole glucosinolate **6** and brassinin **1**, as well as the biosynthetic pathway to the phytoalexin brassilexin **3**.[9] Here we establish for the first time a biosynthetic relationship between indole-3-acetaldoxime **5** and phytoalexins **1**–**4** which, contrary to previous speculations,[3] do not appear to be derived from indole glucosinolate **6**.

To investigate the possible biogenetic relationship between phytoalexins and indole glucosinolates, [4,5,6,7-$^2H_4$]-compounds **1a**–**3a** were synthesized as previously reported;[9] [4,5,6,7-$^2H_4$]glucobrassicin **6a** was synthesized according to the previously reported route[10] but utilizing **7a**[9] as the starting material.[11] Initially, the cruciferous brown mustard (*Brassica juncea*) was selected to determine the proposed biosynthetic relationship because it produces phytoalexins **1**–**4** and indole glucosinolate **6**. Thus, [4,5,6,7-$^2H_4$]glucobrassicin **6a** was administered to leaves of brown mustard; after solution uptake the leaves were elicited with a spore suspension of the fungus *Phoma lingam* (perfect stage *Leptosphaeria maculans*), were incubated, and extracted.[9,12] HPLC analysis of the extracts indicated the presence of phytoalexins **2**–**4**; the extracts were fractionated by HPLC and the identity of each phytoalexin was confirmed by ^{1}H NMR and HRMS-EI. Deuterium incorporation in **2**–**4** (≤0.1% relative to a natural abundance control sample by HRMS-EI) was too small to establish **6a** as a precursor. Similar results were obtained when leaves were elicited with UV light instead of the fungal spores. This lack of deuterium incorporation was thought to be partly due to the substrate not reaching the appropriate cell site.

Subsequently, it was thought that a different plant tissue where precursors could be in contact with the tissue for a longer period (*i.e.* no uptake of the substrate solution *via* the plant vascular system) might lead to higher deuterium incorporation levels. Thus, [4,5,6,7-$^2H_4$]glucobrassicin **6a** was administered to UV-irradiated turnip root slices (*B. rapa*)[6] followed by incubation. Similar experiments were conducted with non-irradiated turnip roots. Extraction of the turnip tissue, fractionation, and HPLC analysis of extracts and fractions indicated the presence of phytoalexins **1**–**4**. Once again HRMS-EI analysis indicated that deuterium incorporation in **1**–**4** was too low to allow a reliable conclusion (≤0.1%). However, two additional compounds containing deuterium were separated and identified unambiguously as indole-3-carbaldehyde **7a** (34% ^{2}H incorporation) and methyl indole-3-carboxylate **8a** (26% ^{2}H



Scheme 1 Biosynthetic pathway from (*S*)-tryptophan to phytoalexins **1**–**4** and indole glucosinolate **6**.

† The IUPAC name for an acetaldoxime is acetaldehyde oxime.

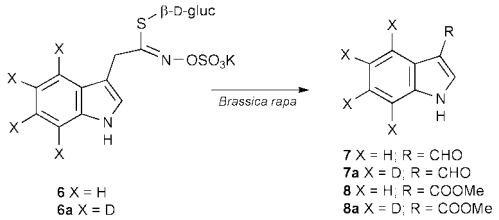
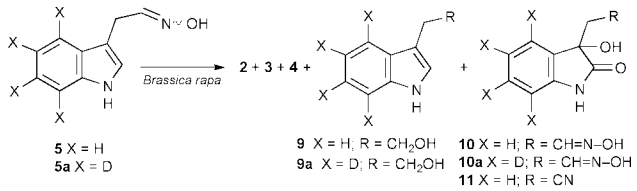
incorporation**)**. These results indicated that metabolism of **6a** to **7a** and **8a** occurred in turnip roots and that the metabolism was unrelated to phytoalexin biosynthesis (Scheme 2).[13] These results also revealed for the first time that **3** was produced in turnip roots.[14]



Scheme 2 Metabolism of [4,5,6,7-$^2H_4$]glucobrassicin (**6a**) in turnip roots (*B. rapa*).

Next, to confirm that turnip root was an appropriate tissue to study phytoalexin pathways, [4,5,6,7-$^2H_4$]brassinin **1a** was added to roots, the tissues were incubated, extracted, analyzed, and the extracts fractionated to yield phytoalexins **3** and **4**. HRMS-EI and ^{1}H NMR analysis indicated substantial deuterium incorporation into both spirobrassinin **4a** (15% ^{2}H incorporation) and **3a** (9% ^{2}H incorporation).[13] The incorporation level of deuterium into brassilexin was substantially higher than our early work utilizing *B. carinata* leaves,[9] thus demonstrating for the first time that in turnip, **1a** is also a precursor of **3a** and confirming that turnip root tissue is an adequate system for biosynthetic studies.[6]

Because of our unsuccessful attempt to demonstrate that **6a** is a precursor of **1a** or related phytoalexins **2a**–**4a**, we investigated the potential biogenetic relationship between **5a** and **1a**. Thus, tetradeuterated **5a** was administered to UV-irradiated turnip roots;[15] after incubation of the tissues, extraction, and fractionation of the extracts, **2**–**4** were obtained. HRMS-EI analysis indicated significant deuterium incorporation into **2a** (10% ^{2}H incorporation), **4a** (14% ^{2}H incorporation) and **3a** (2% ^{2}H incorporation). Furthermore, three additional compounds, subsequently established to be tryptophol **9a** and oxindoles **10a** and **11a**, were isolated and analyzed by HRMS-EI. Deuterium incorporation levels suggested that metabolites **9a**–**11a** were fully derived from metabolism of **5a** (Scheme 3, deuterium incorporation ⩽98%). This conclusion was consistent with the absence of compounds **9a**–**11a** in elicited control tissues. Additional studies indicated that oxime **10a** dehydrated upon standing to yield nitrile **11a**, suggesting that turnip tissue contained the enzyme system required to oxidize oxime **5a** to **10a**, and that **11a** might be an artifact of the isolation process.[16] Note that **11** was previously isolated from *B. oleracea*,[17] however its precursor oxindole oxime **10** has not been described to date.



Scheme 3 Metabolism of [4,5,6,7-$^2H_4$]indole-3-acetaldoxime (**5a**) in turnip roots (*B. rapa*).

In conclusion, our results established a most important biogenetic relation between phytoalexins **1**/**1a**–**4**/**4a** and aldoxime **5**/**5a**, whereas the postulated relationship between indole glucosinolate **6**/**6a** and these phytoalexins was not demonstrated. Thus, considering that **5** is also a precursor of **6**,[8] it is likely that the pathway to phytoalexins follows the tryptophan–aldoxime route and will branch out from the indole glucosinolate pathway a step(s) earlier than previously proposed.[3] Nonetheless, our results have strong implications on plant breeding to produce low glucosinolate content oilseed brassicas, *i.e.* it is essential not to delete the indole acetaldoxime formation steps, as aldoxime **5** is a close precursor of important cruciferous phytoalexins (*e.g.* **1**–**4**). Otherwise, ecologically unfit plants with higher disease susceptibility may be produced. Further work is necessary to find additional intermediates between aldoxime **5** and brassinin **1** as well as the branch point between the tryptophan pathway to indole glucosinolates and to phytoalexins.

Support for the authors' work was obtained from the Natural Sciences and Engineering Research Council of Canada (Individual Research grant and NRC-NSERC Research Partnership grant to M. S. C. P.) and the University of Saskatchewan. We would like to acknowledge the technical assistance of Ken Thoms, Department of Chemistry, for mass spectroscopic determinations.

11 All compounds gave satisfactory spectroscopic data; in each case the percentage of tetradeuterated synthetic compound was ⩾99%.
12 Experiments were carried out as reported in ref. 9; each incorporation experiment was repeated at least twice. All compounds administered to plant tissues were tetradeuterated at concentrations of 6×10^{-4}–10^{-3} M.
13 Indole glucosinolate **6**/**6a** was stable on standing in solution. The % of deuterium incorporation was determined by HRMS-EI using the expression: $[M + 4]^+/([M]^+ + [M + 4]^+) \times 100$ (HRMS data indicated that $[M + 4]^+$ is not present in natural abundance samples).
14 In previous work we attributed lower incorporation of deuterated **2a** into **3a** to factors such as the low solubility and high phytotoxicity of **2a**,[9] however these factors are not likely to account for the absence of incorporation of **6a** into any of the phytoalexins **2a**–**4a**; **6**/**6a** was soluble in aqueous solution and did not show phytotoxicity to leaves of *B. juncea*.
15 Spectroscopic data of **5a**: δ_H (300 MHz, CD_3OD): 7.08 (s, 1H, H-2), 6.80 (t, *J* 5.3, 1H, CH_2-CH=N-OH), 3.80 (d, *J* 5.4, 2H, CH_2-CH=N-OH). δ_C (75.5 MHz, CD_3OD): 152.2, 138.3, 128.7, 123.8, 122.2 (t, $^1J_{C\text{-}D}$ 24), 119.4 (t, $^1J_{C\text{-}D}$ 24), 118.9 (t, $^1J_{C\text{-}D}$ 24), 112.4 (t, $^1J_{C\text{-}D}$ 24 Hz), 111.2, 22.5. HRMS-EI *m/z*: calcd. for $C_{10}H_6D_4N_2O$ 178.1044, found 178.1040. Synthesis to be published elsewhere.
16 In the absence of turnip cells acetaldoxime **5**/**5a** was stable in solution for the duration of the experiments.

First published as an Advance Article on the web 3rd August 2001

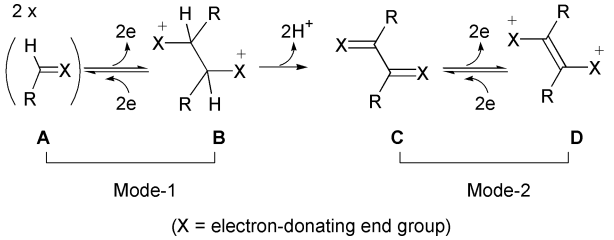
Upon oxidative dimerization of pale yellow Ar_2C=CHPh 1 (Ar = 4-$Me_2NC_6H_4$), deep blue 1,4-dication 2^{2+} was obtained as a stable salt, which was transformed into 1 by reductive C–C bond fission; deprotonation of 2^{2+} gave intense yellow diene 3, which was interconvertible with violet dication 4^{2+} by two-electron transfer, thus exhibiting two distinct modes of electrochromism before and after proton transfer.

Recently, much attention has been focused on electrochromic dyes[1,2] for use as optical memories or electrochemical switches.[3] The representative examples are a series of open-chain violenes[4] shown by the redox couple of **C** and **D** in Scheme 1. Diene **C** can be prepared by oxidative dimerization of olefin **A**,[2a] and the similar procedure has been widely used to synthesize novel TTF vinylogues.[5,6] Although the oxidation reactions are believed to proceed *via* unconjugated 1,4-dication **B**, this intermediate has never been isolated nor even detected spectroscopically probably due to its instability by rapid deprotonation to **C** under the reaction conditions.

In our continuing efforts to develop new electrochromic systems endowed with bistability by reversible C–C bond making/breaking[7] or drastic structural changes[8] upon electron transfer (dynamic redox properties), we have found here that the dication **B** possessing two dye chromophores [X = $(4\text{-}Me_2NC_6H_4)_2C$] and two aryl groups (R = aryl) can be isolated as stable salts. By the selective transformation of **B** to **A** by reduction and **B** to **C** by deprotonation, novel dual-mode electrochromism shown in Scheme 1 could be realized, where proton transfer alters the mode from one to another.

The voltammetric analysis‡ indicated that olefin **1**§ undergoes irreversible oxidation at +0.55 V *vs.* SCE in MeCN. The corresponding reduction wave appeared in the far cathodic region (−0.38 V), which is rather close to the reduction potential of $(4\text{-}Me_2NC_6H_4)_2CH^+$ (−0.54 V). Such a large shift of redox peaks can be accounted for by assuming oxidative dimerization of **1** (Scheme 2).

In fact, dication $\mathbf{2}^{2+}$ was isolated as deep blue I_3^- salt§ in 97% yield by the reaction of yellow olefin **1**§ with 1.5 eq. of I_2 in CH_2Cl_2. Mechanistically, there can be two pathways to produce $\mathbf{2}^{2+}$ from **1**: (a) dimerization of $\mathbf{1}^{+\cdot}$ to $\mathbf{2}^{2+}$, and (b) reaction of $\mathbf{1}^{+\cdot}$ with neutral **1** to form $\mathbf{2}^{+\cdot}$ followed by further one-electron



Scheme 1

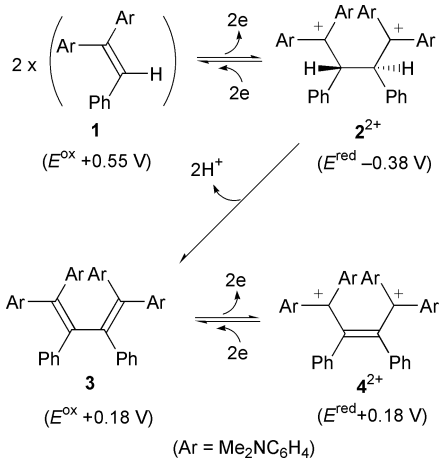

Scheme 2

oxidation. In the present case, path (a) is plausible because $\mathbf{2}^{2+}$ $(I_3^-)_2$ was obtained in 92% yield by the reaction of **1** with 1.5 eq. I_2 under the presence of Ph_2C=CHPh (2 eq.) which remained intact and was recovered quantitatively.

The 1,4-dication $\mathbf{2}^{2+}$ is surprisingly stable with no sign of spontaneous deprotonation; its methine proton appears at 6.02 ppm as a sharp singlet in the ^{1}H NMR spectrum measured in CD_3CN. Upon reduction of this salt with Zn powder in MeCN, olefin **1** was regenerated in 100% yield. Such high-yield interconversion indicates that **1** and $\mathbf{2}^{2+}$ can be considered as a 'reversible' redox pair even though C–C bond making and breaking are accompanied by two-electron transfer.[7,10]

When $\mathbf{2}^{2+}$ $(I_3^-)_2$ was treated with $Bu^n{}_4NF$ in THF–MeCN, deprotonation proceeded smoothly to give intense yellow diene **3**§ in 75% yield, which is a stronger donor [E^{ox} +0.18 V (2e, rev.)]‡ than **1**. Attempted deprotonation of $\mathbf{2}^{2+}$ $(I_3^-)_2$ with Et_3N [E^{ox} +0.85 V (irrev.)] resulted in formation of olefin **1** in quantitative yield by electron transfer, and deprotonation with pyridine was very slow.

Upon treatment of **3** with 3 eq. of I_2 in CH_2Cl_2, deep violet dication salt $\mathbf{4}^{2+}$ $(I_3^-)_2$§ was obtained in 98% yield, which regenerated diene **3** in 100% yield upon reduction with Zn in MeCN. According to the X-ray analyses,¶ the diene unit in **3** adopts a nonplanar geometry with a large torsion angle of 59.1° around the C^2–C^3 bond (Fig. 1a), which is undoubtedly due to steric congestion among six aryl groups. It is likely that lack of effective conjugation in diene **3** as well as steric shielding against the base in the hindered C–H acid $\mathbf{2}^{2+}$ are the reasons for reluctant deprotonation of $\mathbf{2}^{2+}$ to **3**. On the other hand, all of the diene carbons lie nearly on the same plane in $\mathbf{4}^{2+}$ (Fig. 1b), thus confirming drastic geometrical changes by twisting motions[2,6,8] during interconversion between **3** and $\mathbf{4}^{2+}$.

In this way, two types of dynamic structural changes are presented by the redox couples of **1**–$\mathbf{2}^{2+}$ and **3**–$\mathbf{4}^{2+}$, which can be switched by proton transfer. Furthermore, the novel dual-mode electrochromism can be realized by these couples since each pair exhibits distinct spectral changes upon electrolyses

 DOI: 10.1039/b104742f

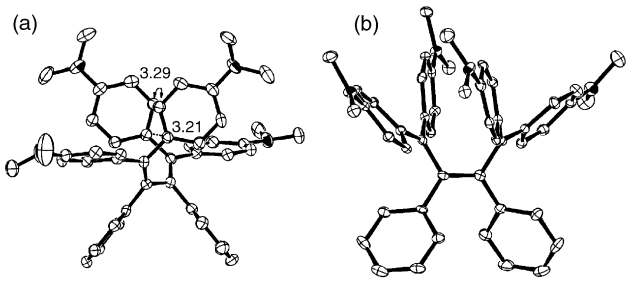

Fig. 1 (a) ORTEP drawing of diene **3** determined by X-ray at −163 °C. Torsion angle of diene unit is 59.1°. Two aryl groups are arranged in a face-to-face manner (dihedral angle 7.9°). Short intramolecular C···C contacts (3.21 and 3.29 Å) are shown by dotted line. (b) ORTEP drawing of dication $\mathbf{4}^{2+}$ determined by X-ray at −176 °C on I_3^- salt. The four carbon atoms of C^+–C=C–C^+ lie nearly on the same plane (the largest deviation from the least-squares plane, 0.09 Å).

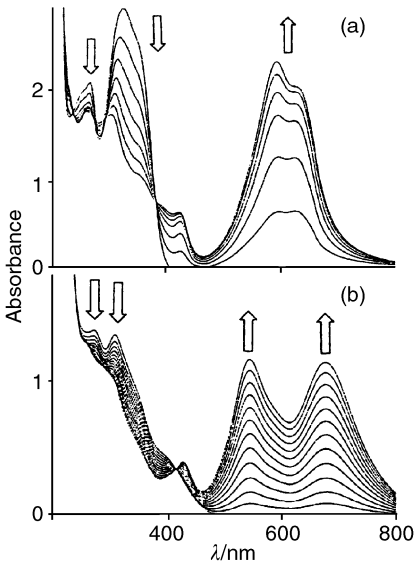

Fig. 2 Two modes of electrochromism. a) Mode-1; changes in the UV-VIS spectrum of **1** (3.5 mL, 1.1×10^{-4} mol dm^{-3} in MeCN) upon constant-current electrochemical oxidation (32 μA, 4 min interval) to $\mathbf{2}^{2+}$. (b) Mode-2; changes in the UV-VIS spectrum of **3** (3.5 mL, 2.6×10^{-5} mol dm^{-3} in MeCN) upon constant-current electrochemical oxidation (31 μA, 2 min interval) to $\mathbf{4}^{2+}$. Note the presence of isosbestic points in both transformation.

(Fig. 2), which opens up a way to construct a molecular device where two independent inputs (e^- and H^+) are transduced into a unified two-dimensional output (ε *vs.* λ in UV-VIS).

This work has revealed that the 1,4-dication **B** in Scheme 1 can exist as stable species (as in $\mathbf{2}^{2+}$)‖ when deprotonation is not feasible due to steric shielding in **B** and/or prohibited full-conjugation in diene **C** by twisted geometry. In such an appropriate case, all of the species of **A**–**D** (as in **1**–$\mathbf{4}^{2+}$) are stable enough to realize the dual-mode optical response. The present electrochromism modulated by proton transfer provides a new successful entry into the proton–electron cooperating functions.[11]

This work was supported by the Ministry of Education, Science, and Culture, Japan (No. 13440184). Financial support from the Iwatani Naoji Foundation is gratefully acknowledged. We thank Professor Tamotsu Inabe (Hokkaido University) for use of the X-ray structure analysis system.

Efficient radical addition of tertiary amines to electron-deficient alkenes using semiconductors as photochemical sensitisers

Siniša Marinković and Norbert Hoffmann*

Laboratoire des Réactions Sélectives et Applications, UMR CNRS et Université de Reims Champagne-Ardenne, UFR Sciences, B.P. 1039, F-51687 Reims, Cedex 02, France.

Received (in Cambridge, UK) 18th May 2001, Accepted 9th July 2001
First published as an Advance Article on the web 3rd August 2001

Tertiary amines can be added to electron-deficient alkenes with yields up to 98% in a radical chain reaction initiated by a photochemical electron transfer using inorganic semiconductors like TiO_2 as sensitiser.

Radical reactions have become a valuable tool in preparative organic chemistry.[1] Among radicals having a nucleophilic character which can be considered for addition reactions with electron deficient alkenes, α-aminoalkyl radicals seem very attractive.[2] Recently, we described an efficient procedure involving a photochemical electron transfer to initiate the intermolecular radical addition of tertiary amines to electron deficient alkenes.[3] Under the same conditions, radical tandem reactions could also be carried out efficiently.[4]

In principle, photochemical excited semiconductors like TiO_2 could initiate the radical addition of tertiary amines. Photochemical reactions with TiO_2 were studied, for instance, for detoxification of waste water,[5] oxidations and reductions,[6] solar energy havesting[7] or in the context of organic synthesis.[8] Metal sulfides like ZnS and CdS have been used for the formation of dehydrodimers of olefins or enol/allyl ethers and for the addition of allyl radicals to imines or diazo compounds.[9]

During photochemical excitation, an electron is transferred from the valence band into the conduction band.[10] The resulting electron hole h^+ of the valence band can be filled by electron transfer from a reductive species such as a tertiary amine (Scheme 1) with the formation of a radical cation and of nucleophilic α-aminoalkyl radicals by deprotonation.

We started our investigations by irradiating a suspension of SiC, TiO_2 (anatase) or ZnS in a solution containing (5*R*)-menthyloxy-2[5*H*]furanone **1a** and *N*-methylpyrrolidine **2a** in acetonitrile (Table 1, entries 1–3). Low conversion rates were observed for TiO_2 and ZnS while no transformation could be detected for SiC. The yields based on conversion were rather low. Much faster conversions was observed when the reaction was carried out in **2a** as solvent (Table 1, entries 4–7) and yields increased under these conditions. The concentration of **1a** was changed and it turned out that 5×10^{-2} mol L^{-1} with a corresponding quantity of TiO_2 is the optimal concentration (Table 1, entries 4, 6 and 7). Under these reaction conditions, *N*-*tert*-butylpyrrolidine **2b** was added to **1a** with the same efficiency (entry 8). As mentioned previously, the addition of the amine took place exclusively from the less-hindered side of the furanone **1a**.[3] Unfortunately, little selectivity was observed for the asymmetric carbon in the α-position of the nitrogen.

Under the optimised conditions,† the reaction of various α,β-unsaturated lactones with methylpyrrolidine **2a** was examined (Table 2). Generally, high conversion rates and high yields were observed. However, in the case of lactone **1e** possessing two substituents in the 4-position, the conversion rate was low. A low reactivity for β-disubstituted enones is also observed when homogeneous reaction conditions were applied.[3]

When TiO_2 was used as sensitiser for the addition of *N*-methylpiperidine **2c**, only a slow reaction was observed and

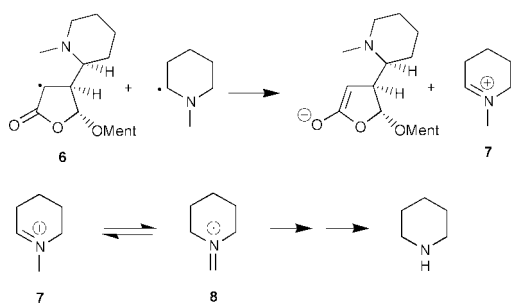
product **5** resulting from a Michael addition of piperidine to **1a** was isolated (Table 3, entry 1). Due to their lower reactivity of α-aminoalkyl radicals derived from *N*-methylpiperidine, the oxidation of these radicals became competitive and demethylation occurred.[11] Even under strictly anhydrous conditions, this side reaction took place (entry 2). However, when the concentration of compound **1a** was reduced, the radical addition could be observed and product **4g** was isolated with moderate yield (entry 3). This result indicates that **1** or, more likely, the oxoallyl radical **6** might participate in the demethylation process *via* an electron transfer from the radical cation to **7** (Scheme 2). It should be noted that the radical addition always takes place on the ring of **2a**,**c** and never at the methyl group. Therefore, we propose a tautomeric equilibrium of the iminium ions **7** and **8**.[11] As described previously, only one diastereomer was isolated.[3] Such a bimolecular reaction between two reactive intermediates appears more realistic if the overall reaction takes place near the surface of the semiconductor.



Scheme 2 Possible mechanism of the oxidation of an α-aminoalkyl radical by an oxoallyl radical introducing the demethylation of **2c**.

Oxidation of an α-aminoalkyl radical by excited TiO_2 is also possible. Therefore, we searched to diminish the two-electron oxidation by changing the semiconductor (Table 3, entry 4). When ZnS was used as sensitiser, only product **4g** could be isolated. Despite the more rapid conversion, the yield of the desired product **4g** remained low. Probably, this semiconductor is less oxidative due to the higher energy level of its valence band edge[12] and its surface properties.

The most apparent difference between the reaction conditions of the homogeneous and the heterogeneous catalysis is the concentration of the tertiary amine. In the case of homogeneous catalysis, acetonitrile must be used as solvent to obtain the best results[3] and the reaction is slower and less chemoselective when the tertiary amine is used as solvent. These results might be explained by the higher polarity of acetonitrile solutions which stabilise the radical ion pairs formed by electron transfer and decrease the rate of the back electron transfer. In the case of heterogeneous catalysis, the electron transfer from the amine to the sensitiser takes place at the surface of the semiconductor. Molecules at interfaces are less mobile than the same molecules in solution. Therefore, the back electron transfer can be slowed down only by enhancement of the subsequent deprotonation step. This acid–base reaction is facilitated by the presence of a large excess of tertiary amine. A higher concentration of the tertiary amine favours also the hydrogen abstraction of the oxoallyl radical **6** in the chain propagation.

We thank Professor J. P. Pete for his support and for helpful discussions. S. M. thanks the Ministère de la Recherche for a doctoral fellowship.

First published as an Advance Article on the web 6th August 2001

The 1-(4-mercaptobutyl)-4-(2-ferrocenylvinyl)pyridinium bromide {1-HS$(CH_2)_4$-4-[(*E*)-FcCH=CH]C_5H_4N}$^+Br^-$ and its hydrogenated product [1-HS$(CH_2)_4$-4-(-FcCH_2CH_2)C_5H_4N]$^+Br^-$ were synthesized and assembled on an Au electrode to form self-assembled monolayers which showed a structure-dependent electrochemical-response in phosphate buffer aqueous solutions (pH = 7).

Self-assembled monolayers (SAMs) of alkanethiols and their derivatives with functionalized terminal groups have been studied intensively on gold electrodes due to their stability, organization, and potential application in many fields such as surface chemistry, biochemistry, electroanalytical chemistry, *etc.*[1] Motivated by Chidsey's novel work,[2] many research groups have investigated SAMs of ω-ferrocenylalkanethiols on gold because the ferrocenyl group is expected to exchange electrons readily with gold in the monolayer and the system can be considered as a model for the formation of electronic devices by self-assembly.[3–6] The advantage of electrochemically-active (*e.g.* ferrocene) monolayers is that the redox signal can be used as an internal readout. A linear porphyrin–ferrocene–alkanethiol was recently shown to be both sensitive and electrochemically-active.[7] A mixed acid–ferrocene self-assembled sulfide monolayer on gold shows a pH-dependent electrochemical-response by through-space communication between the receptor and ferrocene readout unit.[8] In addition, Marder reported that the compound incorporating a ferrocenyl moiety as a donor and a pyridinium as an acceptor connected by a CH=CH bridge, which is similar to our compound **1**, has excellent NLO properties.[9]

Here we primarily discuss a novel kind of 1-(4-mercaptobutyl)-4-(2-ferrocenylvinyl)pyridinium bromide and its structure-dependent electrochemical-response in phosphate buffer solution.

Compounds **1** and **2** can be conveniently prepared following the steps shown in Scheme 1.[10,11] Electrochemical measurement was conducted in a three-electrode cell with a CHI660A electrochemical workstation (Covarda, USA). Ag/AgCl and Pt foil were used as reference and counter electrodes, respectively. A gold disk electrode (CHI101) was employed as the working electrode (its apparent area S = 0.0314 cm^2), which was subjected to the same pre-treatment procedure before each experiment. The polished gold electrode (with 0.05 μm Al_2O_3) was rinsed with water. Thereafter, it was cleaned thoroughly in an ultrasonic cleaner with 1:1 nitric acid, 1:1 alcohol and distilled water, respectively. The cleaned gold electrode was washed with ethanol, dried by N_2 stream, then put into 0.1 mmol **1** or **2** ethanol solution and self-assembled in 12 h. After assembling, the monolayers were rinsed with ethanol and dried under a stream of purified N_2. The electrochemistry of the SAMs modified Au electrodes was tested by cyclic voltammetry in 0.1 mol L^{-1} phosphate buffer aqueous solution. The scan rates were 50, 100, 200, 300 and 400 mV s^{-1}, respectively.

Fig. 1(A) and (B) show a typical cyclic voltammogram obtained from the SAMs of **1** and **2** modified gold electrodes in 0.1 mol L^{-1} phosphate aqueous solution (pH = 7.0).

In each voltammogram, the electrode potential was cycled between −0.1 and 0.7 V. One electron reversible oxidation of the surface-confined ferrocenyl tail group was observed. The peak currents (i_{pa}, i_{pc}) were found to increase linearly with scan rate (v) as expected for a surface-confined redox system. The currents do not show decrease after repeated cycling in buffer solution, indicating that the ferrocene SAMs are very stable. Hence, it can be considered that the redox centers of these SAMs are fully solvated by aqueous electrolyte and the local environment around each redox center is quite uniform. The surface coverage of each thiolate was estimated from the charge passed for the oxidation of the ferrocene redox center during the anodic sweep. Values of Q_{Fc} were obtained by integration of the area under the anodic wave and were corrected for any charging-current contributions. The surface coverage of **1** was 6.4×10^{-11} mol cm^{-2}, and **2** was 7.1×10^{-11} mol cm^{-2}. This coverage is somewhat lower than the value of *ca.* 4.5×10^{-10} mol cm^{-2}, which is typically reported for a complete monolayer of uncharged ferrocenylalkanethiolates.[2] However, a decrease in packing efficiency is to be expected in this case, considering the steric effects of the pyridinium ion, ethylene band and the cationic charge on the nitrogen. The electrostatic repulsion of the adjacent cationic charges and the need to accommodate a counterion at each positively charged site would necessarily prevent the formation of a tightly packed monolayer. In a study carried out by Creager and co-workers a low monolayer coverage was reported for a charged thiol on gold, and this was

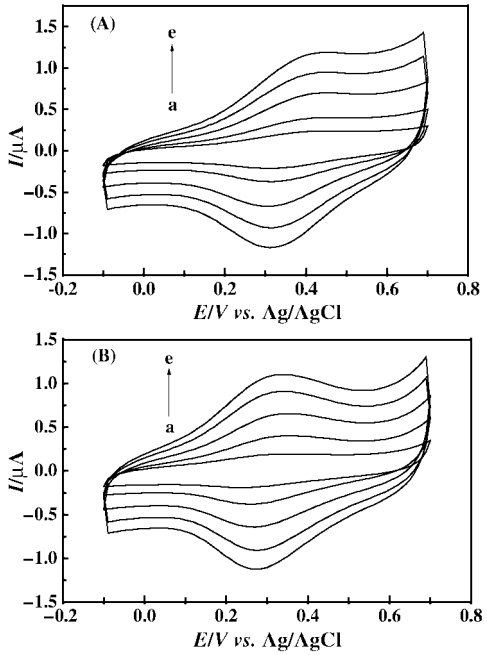

Fig. 1 The cyclic voltammograms of **1** and **2** SAMs modified Au electrode in 0.1 mol L^{-1} phosphate buffer electrolyte (pH = 7). (A) **1**; (B) **2**. The scan rate from **a** to **e** was 50, 100, 200, 300, 400 mV s^{-1}.

attributed to the strength and nature of the coulombic forces relative to dipolar and dispersion of forces within the monolayer.[12]

The location of the electron-withdrawing ethylene band and the electron-donating pyridinum group had a pronounced effect on the formal potential of the modified electrodes. The formal potential for the surface-bound ferrocenyl species was estimated from the average of the anodic (E_{pa}) and cathodic (E_{pc}) peak potentials, $E^{0\prime} = 1/2(E_{pa} + E_{pc})$. Monolayers of **1** displayed the more positive formal potential of 0.37 V, whereas monolayers of **2** exhibited the less positive potential of 0.30 V. This can be expected because the electroactive ferrocenyl moiety is located adjacent to the strong electron-withdrawing ethylene band in **1**, thus making it more stable and slightly harder for the ferrocene to undergo oxidation. It is well known that ferrocene monolayers are pH-independent. Fig. 2 shows the redox signal for **1** at pH 5.0, 6.0 and 7.0. The electrochemical response of the **1** monolayer is influenced by the pH of the electrolyte solution.

The electron transfer rate of these SAMs can be estimated from the peak separation ΔE_p. A surface-confined species participating in a reversible electron transfer process would be expected to exhibit a value of $\Delta E_p = 0$ mV. The experimental ΔE_p values obtained from the voltammograms show that the peak potential separation is independent of the scan rate, which implies that the electron transfer is relatively fast. However, the nonzero ΔE_p values (for **1** $\Delta E_p = 120$ mV, for **2** $\Delta E_p = 60$ mV) for separation between the oxidation and reduction peak

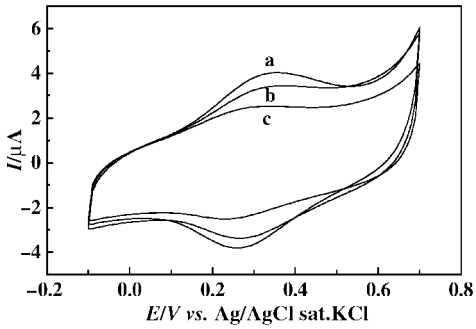

Fig. 2 Electrochemical response of **1** in phosphate electrolyte: (a). pH = 7.0; (b). pH = 6.0; (c). pH = 5.0.

potentials of Fc/Fc^+ indicated that the presence of the pyridinium ion with positive charge and the ethylene band slowed the electron transfer rate to some extent. The apparent electrochemical reversibility of the monolayers of ferrocene derivatives of the alkanethiolate has been tentatively attributed to the rapid lateral transport of the electrons from one ferrocene unit to an adjacent ferrocene unit, following electron shuttling from the conducting gold surface to the ferrocene plane.[2]. Here, the electron may be entrapped by the pyridinium ion, so the ΔE_p values became large.

The authors are grateful to the NSF (QT program) and the foundation of the University Key Teacher by the Ministry of Education of China for suport.

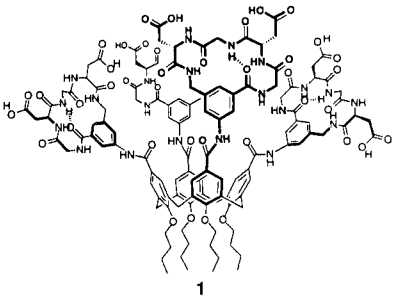
Received (in Cambridge, UK) 1st May 2001, Accepted 14th June 2001
First published as an Advance Article on the web 6th August 2001

Synthetic receptor 1 has been found *via* fluorescence titration to compete effectively with cytochrome *c* peroxidase for binding cytochrome *c* (Cc), forming 1:1 Cc:1 complex with a binding constant of (3 ± 1) × 10^8 M^{-1}, and to disrupt Cc:Apaf-1 complex, a key adduct in apoptosis.

Protein–protein recognition is critical to virtually all cellular processes. Consequently, molecules which could specifically disrupt the high affinity natural protein complexes found physiologically could provide an important route to modulate cellular processes. However, there are few examples of such a modulation.[1] Since high affinity protein–protein complexes generally involve large surface areas,[2] it has been argued that small synthetic molecules which bind at the interaction surface are unlikely to compete with high affinity natural protein partners. Here, we show that a synthetic receptor molecule of structure **1** can bind cytochrome *c* (Cc) with a sufficiently high



1

affinity to displace a natural high affinity protein partner, cytochrome *c* peroxidase (CcP). Cytochrome *c* provides an important model for such studies for several reasons. First, the structure of Cc is well characterized.[3] Second, the Cc:CcP complex is unusually well characterized, both from structural and thermodynamic viewpoints.[4,5] Finally, the key role of Cc in mediating apoptosis[6–8] makes it a particularly interesting target.

Several previous studies have explored the binding of small molecules to Cc.[3,9] However, in few previous cases was the binding sufficiently strong and specific to be shown to compete with the binding of natural partner proteins at relevant concentrations ($< 10^{-6}$ M). Preliminary data on Cc binding by **1** suggested the possibility of specific and high affinity binding.[10] To test this possibility, we have carried out a series of spectroscopic studies and established that the synthetic receptor **1** is indeed capable of disrupting the physiological complex of Cc with CcP by binding competitively to Cc. From the concentration of **1** needed to disrupt the Cc:CcP binding, we can estimate that the dissociation constant (K_d) for the Cc:**1** complex is near the nanomolar level ($\sim 10^{-8}$ M) in a phosphate buffer (10 mM, pH 6.0). Furthermore, the competitive displacement of CcP from its natural protein partner by **1** suggests that they share a similar binding site on the surface of Cc.

The competitive binding experiments were based on the quenching of strong fluorescence of magnesium(II) CcP (MgCcP) by Cc and the reversal of that quenching by addition of receptor **1**. The reaction schemes are illustrated in eqns. (1) and (2). It has been demonstrated that the magnesium substitution of iron in the native CcP does not alter the binding characteristics of CcP with Cc.[5] The use of MgCcP is advantageous because of its strong, interference-free fluorescence signals. In a typical experimental procedure, 3.0 mL of 0.077 μM solution of MgCcP[5] in 10 mM degassed potassium phosphate buffer (KPhos, pH 6.0) was prepared in a quartz cuvette of 1 cm pathlength equipped with magnetic stirrer. The fluorescence spectrum of the solution was recorded on a PTI fluorimeter (Photon Technology International, NJ) with an excitation wavelength of 556 nm and a scan rate of 1 nm s^{-1} at 15.0 °C (Fig. 1a). The solution was titrated *in situ* with a 3.5 μM solution of yeast Cc (Sigma) to an equivalent point [CcP]:[Cc] = 1. Upon Cc:CcP complex formation, the fluorescence signals of MgCcP at 598 and 653 nm were quenched by resonant energy transfer (Fig. 1b). Then a 4.48 μM solution of receptor **1**[10] in 10 mM KPhos (pH 6.0) was added in aliquots of 10 to 20 μL. The fluorescence spectrum was measured after each addition until the [**1**]:[Cc] molar ratio reached 5 or higher (Figs. 1c and 1d). Upon addition of receptor **1**, the intensity of the fluorescence signals of MgCcP increased, indicating that CcP is gradually freed from the Cc:CcP complex.

$$\mathrm{Cc} + \mathrm{CcP} \leftrightharpoons \mathrm{Cc{:}CcP} \quad (1)$$

$$\mathrm{Cc{:}CcP} + \mathbf{1} \leftrightharpoons \mathrm{Cc{:}}\mathbf{1} + \mathrm{CcP} \quad (2)$$

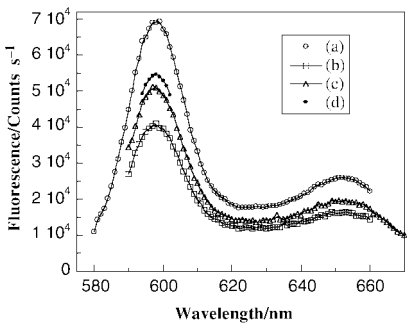


Fig. 1 Representative fluorescence spectra of (a) MgCcP (0.075 μM), (b) MgCcP (0.075 μM) with 0.077 μM of Cc, and the MgCcP:Cc complex titrated with (c) 0.11 and (d) 0.28 μM of **1**. Excitation at 556 nm at 15.0 °C in 10 mM KPhos buffer (pH 6.0).

 DOI: 10.1039/b104142h

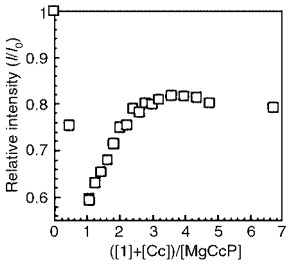

Fig. 2 Plots of the relative fluorescence intensity (I/I_o) at 598 nm against the normalized concentration ([Cc] + [**1**])/[CcP] (ex. 556 nm). [Cc] = 0.077 μM, [MgCcP] = 0.075 μM in 10 mM KPhos buffer (pH 6.0) at 15.0 °C.

Fig. 2 shows the plots of relative intensity of the fluorescence at 598 nm against the normalized concentration, ([Cc] + [**1**])/[CcP]. At [Cc]/[CcP] = 1 and before addition of **1**, the fluorescence intensity (I) of MgCcP was reduced to ~57% of the initial value (I_o), which is in agreement with that reported in the literature.[5] Addition of **1** resulted in a sharp increase in the relative intensity (I/I_o) until ([Cc] + [**1**])/[CcP] reached about 2, *i.e.* [**1**]/[Cc] ≈ 1, after which the intensity levelled off, suggesting the formation of 1:1 Cc:**1** complex. The intensity does not increase to the original level because of partial photodegradation of MgCcP. The recovery of fluorescence suggests that receptor **1** effectively disrupts the Cc:CcP complex at nanomolar concentrations (*i.e.* ~0.08 μM), and releases CcP free into solution. Under these conditions, the interaction between **1** and Cc appears stronger than that between CcP and Cc, with a K_d value < 100 nM.

The binding constant (K_b) for Cc:**1** complex can be estimated from the competitive titration results using a standard nonlinear curve-fitting. The competition equilibrium constant K_c for eqn. (2) can be expressed [eqn. (4)] in terms of the K_b's for eqn. (1) ($K_{b1} = 2 \times 10^7$ M^{-1})[5] and for eqn. (3) (K_{b2}). Assuming that the concentration of free Cc in eqn. (3) at equilibrium is negligible, a quadratic equation can be derived as shown in eqn. (5), where $A = [Cc]_{Total}$, $B = [CcP]_{Total}$, $x = [\mathbf{1}]_{Total}$, and $y = (I_{obs} - I_f)/(I_i - I_f)$ with I_i and I_f being the fluorescence intensities at ([Cc] + [**1**])/[CcP] of 1 and of ⩾2, respectively. From the solution for y in eqn. (5), K_c was obtained. A set of typical results are shown in Fig. 3, from which K_{b2} was estimated to be $(3 \pm 1) \times 10^8$ M^{-1}.

$$Cc + \mathbf{1} \leftrightharpoons Cc{:}\mathbf{1} \quad (3)$$

$$K_c = K_{b2}/K_{b1} \quad (4)$$

$$(B^2K_c - B^2)y^2 + (K_cBx - ABK_c + AB + B^2)y - AB = 0 \quad (5)$$

The titration of the MgCcP solution with **1** in the absence of Cc showed little change in the fluorescence of MgCcP in the range of [**1**]/[MgCcP] from 0 to 5, indicating that there is no significant interaction between **1** and CcP. The region of Cc

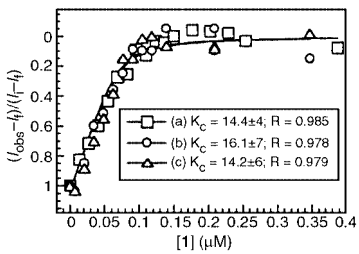

Fig. 3 Typical curve-fitting results for the fluorescence titration of 1:1 Cc:CcP complex with the receptor **1**. The values of $y = (I_{obs} - I_f)/(I_i - I_f)$ for emissions at (a) 598 nm at 15.0 °C, (b) 598 nm at 25.0 °C and (c) 653 nm at 25.0 °C are plotted against the concentration of **1**. The experimental data are fitted according eqn. (5) to estimate K_c values. Excitation at 556 nm, [MgCcP] = 0.076 μM, [Cc] = 0.077 μM in 10 mM KPhos buffer (pH 6.0).

involved in binding to CcP contains an array of positively charged residues that interacts with a complementary patch of negative residues on CcP.[4] The polyanionic receptor **1** competes successfully with CcP, presumably by binding to a similar site on the surface of Cc. The CcP molecules are freed from the interactions with Cc, leading to the observed recovery of fluorescence.

The binding of **1** with Cc has been independently confirmed by direct fluorescence titration of **1**. Receptor **1** exhibits a broad fluorescence peak at ~432–443 nm with excitation wavelength of 298 nm. Addition of Cc results in a rapid decrease in the fluorescence intensity, which levels off as Cc concentration increases. Further quantitative interpretations of such data are precluded at the present time, since the receptor molecules (**1**), due to their surfactant-like structure, tend to aggregate, which interferes with the determination of binding stoichiometry. Reducing the concentration of **1** prevents the aggregation but the decrease in fluorescence signal to noise ratio impedes quantitative analysis.

The ability to bind to Cc with high affinity is of great interest, given the major role of Cc as a signal protein for activating Apaf-1 (the apoptosis protease activating factor-1) protein in apoptosis.[6–8] The binding constant for the 2:1 Cc:Apaf-1 complex was estimated to be ~10^{11} M^{-1} from the fluorescence polarization titration measurements, in which Apaf-1 was added to nanomolar concentrations of horse heart zinc(II) Cc and the increase in polarization was monitored.[8] Upon formation of the Cc:Apaf-1 complex, receptor **1** was added to the system. At a [**1**]/[Cc:Apaf-1] molar ratio of ~200, the relative fluorescence polarization decreased significantly from 1.9 to 1.3. The preliminary data indeed suggest that **1** can disrupt the Cc:Apaf-1 interactions. More detailed results of further studies will be reported in due course.

In conclusion, we have demonstrated that the physiological complex of Cc with CcP can be disrupted by a synthetic receptor (**1**). Receptor **1** competes effectively with CcP for binding Cc, forming 1:1 Cc:**1** complex with a binding constant of ~10^8 M^{-1}. Investigation is in progress to evaluate the effects of the structure of synthetic receptors on their competitive binding with various proteins, including Apaf-1, and protein–protein complexes.

Y. Wei thanks Drexel University for granting him a sabbatical leave at Princeton University and Drs V. Lai, S. Springs and S. Hatch for many helpful discussions.

First published as an Advance Article on the web 6th August 2001

Bidimensional hexagonal or centred-rectangular mesoporous zirconia thin films have been reproducibly prepared by evaporation-induced self-assembly (EISA), which are stable up to 300 °C, with pore size around 35 Å; the films can be post-functionalised with organic ligands presenting different functions, opening a land of opportunities for the design of new hybrid mesostructured materials, based on the synergy of a transition metal oxide network and organic groups.

Since Beck and coworkers[1] demonstrated the use of arrays of amphiphilic species as 'supramolecular templates', mesoporous materials have been receiving increasing attention.[2,3] However, the hydrothermal treatment usually applied in the synthesis procedures is not adequate for the processing of mesoporous films, fibres or monoliths. The evaporation-induced self-assembly (EISA)[4] process represents an alternative way to design mesostructured organic–inorganic hybrids, which are precursors for mesoporous solids. By this process, silica based mesoporous materials have been prepared as powders, fibres, monoliths and thin films in a variety of structural arrangements (2D- and 3D-hexagonal, cubic and lamellar phases).[1,5] This same process has been applied to obtain transition metal oxide-based materials, such as mesoporous TiO_2,[6] ZrO_2, Nb_2O_5, Al_2O_3, SnO_2, WO_3, Ta_2O_5 and many mixed metal oxides.[7] For these systems, this approach has been applied mainly to the preparation of powders, or even titania mesoporous films.[8]

Here, we report for the first time to the best of our knowledge, the preparation of oriented mesostructured zirconium oxide-based hybrids and mesoporous oxide films. The post-functionalisation of the zirconia mesoporous films is also reported. Zirconia mesoporous films are particularly interesting because of the high chemical stability of this oxide, being potentially applicable as catalyst support, adsorbent, heavy duty membranes and chemical sensors.

Films were prepared by dip-coating glass or silicon substrates at a constant withdrawal speed ranging from 0.08 to 0.4 cm s^{-1} at room temperature (20–23 °C). The dipping solutions contain 1 $ZrCl_4$: 0.05 Brij-58 [$C_{16}H_{33}(CH_2CH_2O)_{20}OH$] : 40 EtOH : 0–20 H_2O.[9] The relative humidity (RH) inside the dip-coater chamber is a parameter of paramount importance, and was thus controlled between 10 and 80%. After drying, the as-prepared films were submitted to a sequence of treatments in order to stabilise the structure and remove the surfactant: drying overnight at low humidity (< 10%), 12 h at 60 °C, ammonia atmosphere (30 min), and calcination in air at temperatures ranging from 150 to 500 °C for 2 h (ramp of 1 °C min^{-1}).

Two-dimensional XRD patterns in transmission mode demonstrate that a hexagonal (*p*6*m*) mesophase is obtained upon dip-coating, the organised domains are mono-oriented, as previously observed in silica and titania mesoporous films.[8,10] Fig. 1(a)–(c) shows representative 2D-XRD patterns of films treated at 60, 220 and 300 °C, respectively. The observed spots can be indexed in all cases in a 2D-centred-rectangular cell

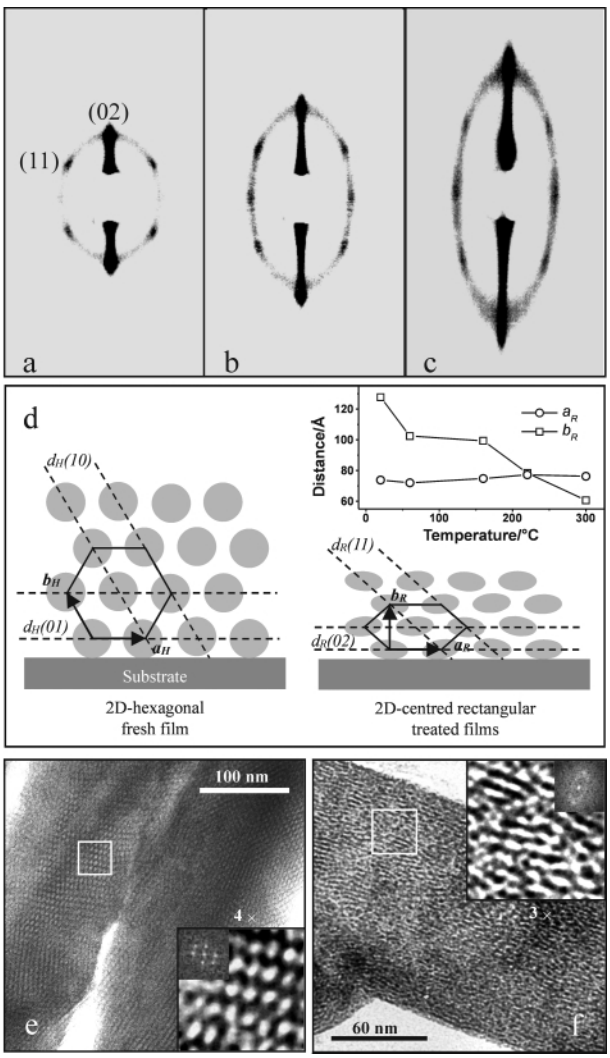

Fig. 1 Two-dimensional XRD patterns obtained by transmission for films treated at (a) 60, (b) 220 and (c) 300 °C. Schematic representation of the relationship between 2D-hexagonal (*p*6*m*) and 2D-centred rectangular (*c*2*m*) cells (d), the inset showing the observed variation of the parameters a_R and b_R of the 2D-centred rectangular cell with temperature. TEM images along the [001] zone axis of Brij 58-templated mesostructured zirconia films treated at (e) 60, and (f) 300 °C. Inset in parts (e) and (f) are reconstructed images and moduli of the Fourier transform of the indicated regions.

† Electronic supplementary information (ESI) available: XRD and SEM data showing the influence of water content in solution and atmospheric relative humidity in the organisation and optical quality of the films, and details about the post-functionalisation.  DOI: 10.1039/b104623n

(space group *c*2*m*), resulting from a preferential contraction of the hexagonal mesophase in the direction normal to the substrate.[8,10] Low-angle XRD analysis in θ–2θ mode (graphite-monochromated Cu-Kα_1 radiation, λ = 1.5406 Å) of the as-prepared films only showed the presence of a single peak at d = 63.9 Å, corresponding to the d_{02} spot of the bidimensional rectangular (*c*2*m*) lattice [equivalent to the d_{01} distance of the hexagonal (*p*6*m*) structure, see Fig. 1(d)]. The uniaxial contraction in the direction normal to the substrate upon thermal treatment is clearly observed by θ–2θ and 2D-XRD [see inset in Fig. 1(d)], the a_R parameter remaining almost constant (*ca*. 76 Å).

TEM images of films (detached from the substrate, embedded in epoxy resin and ultramicrotomed) support the XRD data, showing almost circular pores for films treated between 60 and 160 °C, and elliptical pores for films treated between 200 and 300 °C, clearly a consequence of the uniaxial contraction. Representative examples are shown in Fig. 1(e) and 1(f). Moreover, images obtained for films treated at low temperatures (60–160 °C) display regular long-range ordered patterns, in accord with XRD data that showed narrow, intense diffraction peaks (or spots, in the 2D-XRD pattern). The partial degradation of the structure can be clearly visualised from Fig. 1(e), that shows broad diffractions for films treated at temperatures > 200 °C, and the presence of an ellipse (characteristic of entangled worm-like channels[10]), the intensity of which increases with temperature. The wall thickness was estimated from TEM to be *ca*. 37 Å for the film treated at 60 °C, decreasing to *ca*. 20 Å upon treatment at 300 °C, probably as a consequence of further condensation, as showed by TGA–DSC analysis. The pore diameter was estimated to be *ca*. 35 Å for films treated between 60 and 160 °C; thermal treatment at 300 °C results in *ca*. 14 × 36 Å pores. N_2 adsorption data (scratched films treated at 220 °C followed by UV/O_3 treatment) showed an average pore diameter of 28 Å (BJH) and specific surface (BET) of 192 $m^2\ g^{-1}$.

Films were prepared in different conditions by varying the water contents in the solution ($h = H_2O/Zr = 0$–20) and the relative humidity (RH 10–80%) (ESI†). In general, 'dry' conditions (low h and RH) lead to non-organised coatings, confirming the essential role of water in solution and evaporation rate.[6] The organisation increases for higher h values, and in most cases, with increasing relative humidity. However, the highest degree of organisation was observed with h = 20 and 10% RH. This result confirms the importance of the evaporation rate, relatively fast (drying within 1 min) at 10% RH and very slow at high humidity conditions.

Despite the high degree of organisation attained for high water contents, the optical quality of the coatings is poor, due to a phase segregation (observed by SEM) (ESI†). In order to obtain transparent films, a two-step process was developed. Submitting fresh films (h = 20; RH% = 10) to a high humidity atmosphere (RH > 80%) for a short time (5–10 s) resulted in the incorporation of water. A second drying process led to transparent and homogeneous films. A SEM image of a film submitted to this treatment shows a completely smooth surface, and the corresponding XRD diagram presents a narrow, intense peak with a *d*-spacing of 63.9 Å. These results indicate that the as-prepared films are quasi-liquid, showing a liquid crystal behaviour, as shown before by Brinker *et al.* for silica films.[4,11] The post-processing (submission to high humidity for few seconds) facilitates homogeneous texture, and leads to better organised domains in the mesostructure, indicated by the narrowing and increasing in intensity of the XRD peak. The thickness of such films as estimated by SEM was 700 nm, and can be tailored by varying the withdrawal speed and the ethanol content in the solution without any noticeable variation in the structure or optical quality.

Following drying overnight at low humidity and room temperature, the *d*-spacing slightly contracted from 63.9 to 63.0 Å while subsequent ammonia vapour treatment resulted in a *d*-spacing of 57.3 Å, indicating further condensation of the zirconium oxide network. From this point on, the films were submitted to thermal treatment, in order to increase the stability of the inorganic network and to remove the surfactant. TGA–DSC analysis of detached films (1 °C min^{-1}, air flow) shows that surfactant decomposition occurs from 150 to 350 °C (26.5 mass%). A crossed XRD-FTIR analysis showed that contraction is small [$(d_0 - d)/d_0 < 22\%$] up to 200 °C; in this range, the surfactant is not removed. From 200 °C on, a strong contraction was observed (40–52% in the range 200–300 °C) coinciding with the decomposition of the surfactant. By 350 °C the mesostructure is lost. However, organic or carboxylate species (detected by FT-IR bands at *ca*. 1618 and 1378 cm^{-1}) cannot be removed, even at 400 °C. An alternative combination of UV light and ozone at room temperature was thus performed,[12] giving rise to pure zirconia mesoporous films.

In order to tailor the nature of the pore surfaces, organic molecules were grafted on the mesoporous zirconia films. Three grafting functions were selected, known by their ability of complexing Zr(IV): β-diketonate, carboxylate and phosphonate. The probe molecules were chosen because of their different properties: dibenzoylmethane, (DBM) and phenylphosphonic acid, (PPA) carrying hydrophobic groups, can be used to impart hydrophobic properties to the pore surface. Methyl red dye, (MTR) is well known as a pH indicator. Finally, ferrocenecarboxylic acid (FCA), is interesting due to its redox properties. FT-IR and UV–VIS data clearly show the grafting of the probes (ESI†). The possibility of ready post-functionalisation of the film, leading to pores with a tailored surface, is a very interesting result, since functionalised films can be applied in many fields, depending on the nature of the grafted species.

Synthesis and structure of the novel mixed anion–dianion lithium cage compound $[(6\text{-}LiCH_2Py\text{-}2\text{-}OLi)_4(6\text{-}CH_3Py\text{-}2\text{-}OLi)_2(THF)_9]$

Received (in Cambridge, UK) 30th May 2001, Accepted 9th July 2001
First published as an Advance Article on the web 6th August 2001

The title compound crystallises as a novel homometallic mixed anion–dianion cage incorporating two four-coordinate diorgano lithiate centres, in addition to eight lithium centres coordinated only by oxygen and nitrogen atoms.

The past two decades have witnessed considerable interest in organolithium chemistry. Within this realm the formation of complexes containing 'ate' centres is still comparatively rare, despite the overwhelming number of organolithium complexes reported to date. The first example was reported by Eaborn *et al.*,[1] and some closely related complexes subsequently followed.[2] There are only a handful of other examples,[3] including the recently reported dibenzyl lithiate complex by Bildmann and Müller, which contains the first example of a four-coordinate diorganolithiate.[3c] Examples of ate complexes with nitrogen donors have also been reported.[4]

We are currently interested in aspects of the structural chemistry of 2-hydroxy-6-methylpyridine (Hhmp) and other substituted 2-pyridones. Hhmp has been employed extensively in transition metal chemistry where the similarity of its anion hmp^- to the carboxylate group has been exploited to probe the nature of multiple metal–metal bonds in dinuclear complexes.[5] Such complexes are frequently synthesised *via* an alkali metal salt; these are notable by their relative lack of structural characterisation. Indeed, a search of the Cambridge Structural Database[6] reveals, with the exception of some heterobimetallic alkali metal–transition metal complexes,[7] only two related compounds, both produced in aqueous media, namely the monohydrated potassium salt of 2-pyridone $[2\text{-}KOPy\cdot H_2O]$[8] and the caesium salt of the more highly substituted 2-pyridone $[2\text{-}CsO\text{-}3\text{-}CN\text{-}4\text{-}CF_3\text{-}6\text{-}Ph\text{-}Py\cdot H_2O]$.[9] Consequently we have sought to characterise alkali metal complexes of hmp, as they promise to be more structurally diverse than 'pure' alkoxides or aryloxides due to the additional coordination possibilities provided by the pyridyl nitrogen. Although our principal goal has been to synthesise monometallated complexes, we find that subsequent lithiation at the methyl site occurs readily, thus allowing facile access to the synthesis of mixed anion–dianion complexes. Indeed, it is possible to control precisely the extent of metallation from monometallated through to dimetallated by addition of the appropriate amount of butyllithium. It is consequently possible to synthesise aggregates with varying degrees of anion/dianion character and we have synthesised a range of such complexes, which will be elaborated on in a full account of this work. As revealed herein, we describe the synthesis and solid state structure of the title compound **1**, which is notable for being a rare example of a Group I mixed anion–dianion complex containing two four-coordinate organolithiate centres.

In a Schlenk tube under dry nitrogen, Hhmp (10 mmol) in dry THF (50 mL) was lithiated by Bu^nLi (10 mmol) to afford a dark orange solution. Addition of an additional 2/3 equivalent of Bu^nLi (6.67 mmol) affords a dark red solution with evolution of gas clearly visible [eqn. (1)]. Concentration and layering with *n*-hexane at −30 °C affords highly air-sensitive orange crystals of

$$6\text{-}CH_3Py\text{-}2\text{-}OH + 10\ Bu^nLi \xrightarrow{THF} [(6\text{-}LiCH_2Py\text{-}2\text{-}OLi)_4(6\text{-}MePy\text{-}2\text{-}OLi)_2(THF)_9] + 10\ Bu^nH \quad (1)$$

the title compound **1** in 82.4% isolated yield, which rapidly degrade to a yellow powder when removed from solvent or exposed to vacuum. Despite repeated attempts, it was not possible to obtain satisfactory microanalysis for **1**, due to the extremely air- and moisture-sensitive nature of this complex and loss of coordinated THF. Analyses obtained were consistent with variable loss of non-integral amounts of coordinated THF (typically between two and four molecules).

The structure of **1** (Fig. 1)† consists of an alkoxo cage with two diorgano lithiate centres. There are ten lithium centres, two anionic and four dianionic hmp ligands (deprotonated at the hydroxy *and* methyl sites), and nine THF molecules. Each lithium centre, with the exception of the three-coordinate Li(2), which is distinctly pyramidal [sum of angles 343.5(6)°], displays a distorted tetrahedral environment. Setting aside the C–Li bonds, four of the hmp ligands are tetra-coordinating [N(1), N(2), N(4) and N(6)] (with μ_3-oxygen atoms) and two [N(3) and N(5)] are penta-coordinating (with μ_4-oxygen atoms).

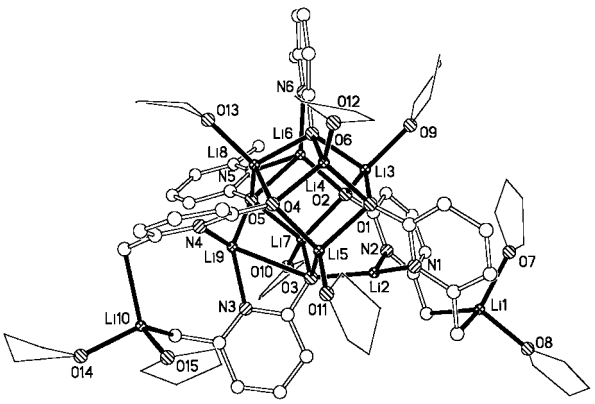

Fig. 1 Molecular structure of **1**. Hydrogen atoms and parentheses in atom labels have been omitted for clarity. Both these bonding modes are, to the best of our knowledge, unprecedented with this ligand; only mono-, di- and tri-coordination modes are known. The core of the cage may be thought of as a stack of two six-membered $(LiO)_3$ rings [ring 1: Li(3)–O(1)–Li(5)–O(3)–Li(7)–O(2); ring 2: O(6)–Li(4)–O(4)–Li(9)–O(5)–Li(6)], of similar architecture to the hexameric complex $[\{Li(OPh)(THF)\}_6]$,[10] which has been distorted by the presence of the four extra lithium centres [Li(1), Li(2), Li(8) and Li(10)]. The chiral cage crystallises in the non-centrosymmetric space group *P*1.

Turning to bond lengths, excluding the four long Li–O contacts of 2.267(15), 2.580(16), 2.613(15) and 2.655(17) Å [Li(6)–O(5), Li(9)–O(3), Li(6)–O(6) and Li(9)–O(4) respectively], the $Li–O_{hmp}$ bond lengths span the range 1.898(15)–2.063(15) Å. This compares with a range of 1.856–2.063 Å in the heterometallic cluster $[(Bu^tOLi)_6(Bu^tOK)_2(Li_2O)(TMEDA)_2]$,[11] and a range of 1.830–2.101 Å in the heterometallic cluster $[\{(Bu^tOLi)_5(Bu^tORb)_4(Li_2O_2)(TMEDA)_2\}_\infty]$,[12] and agrees well with a recently reported series of lithium phenoxides.[13] The overall larger range observed in **1** reflects the various coordination modes adopted by the hmp ligands. The $Li–O_{THF}$ bond lengths span the range 1.933(16)–2.010(15) Å, which is in good agreement with previously reported values for neutral oxygen donor co-ordinated organolithium complexes.[14] The Li–N bond lengths span the range 1.996(15)–2.678(16) Å, reflecting the distorted nature of the cage and, discounting the longest Li(9)–N(4) contact of 2.678(16) Å, compare well with values previously reported for tertiary amine coordinated organolithium complexes.[15] The Li–C bond lengths are distinctly longer than the Li–O and Li–N average bond lengths in accord with periodic considerations, spanning the range 2.198(16)–2.300(20) Å; this is in good agreement with Li–C bond lengths reported previously.[3c,14] The bond angles around the benzylic carbons span the range 99.9(7)–108.3(8)°, indicating geometries more in keeping with sp^3 hybridised centres. This relatively wide range of bonding angles implies a complicated situation in terms of the electronic environment of the hmp dianion ligand, and is in keeping with the highly polar nature of bonding exhibited by Group I metals. This is also indicated by inspection of the $O–C_{ipso}$ bond lengths, which span the range 1.284(9)–1.343(9) Å; this range is in between values generally quoted for C–O (1.43 Å) and C=O (1.20 Å) bond lengths, and indicates a bond order greater than one.

Recorded in $[^2H]_8$THF solution at 298 K, the ^1H NMR (200 MHz) spectrum consists of multiplets at 1.40 and 3.61 ppm characteristic of THF, a broad multiplet at 2.35–2.85 ppm attributed to the methyl and benzylic protons, and three broad multiplets centred at 5.47, 6.43 and 7.46 ppm attributed to the three pyridyl protons. Integration indicated an average loss of approximately three THF. The broad appearance of these signals implies that a dynamic process is operating in solution. Dynamic exchange in solution is a process for which alkoxides are notorious, and alkali metal complexes are also well known for their partial to full deaggregation in solution. However, no coalescence was observed in a variable temperature study over the range 200–323 K, indicating that this dynamic process continues to operate over that temperature range. The ^7Li NMR (116.6 MHz) spectrum in $[^2H]_8$THF at 298 K exhibits six identifiable signals at 1.92, 1.67, 0.66, −0.04, −1.02 and −1.17 ppm. No further signals were apparent from a variable temperature study over the range 200–323 K.

In conclusion, we have demonstrated that 2-hydroxy-6-methylpyridine can be deprotonated not only at the hydroxy site, but also subsequently at the methyl site. This allows the possibility of preparing structurally diverse alkoxo clusters with varying degrees of alkyl character, and thus the possibility of tuning the properties such clusters may display. Further work will explore such avenues and will also investigate hetero-bimetallic complexes of hmp with higher alkali metals. These should prove to be interesting as it is likely that the lithiate centres will be the first to be substituted by higher alkali metals.

We thank EPSRC for equipment funding.

Novel octahedral tungsten sulfidocyanide cluster anion $[W_6S_8(CN)_6]^{6-}$†

Song Jin and Francis J. DiSalvo*

Baker Laboratories, Department of Chemistry and Chemical Biology, Cornell University, Ithaca, NY 14853, USA. E-mail: fjd3@cornell.edu

Received (in Cambridge, UK) 10th May 2001, Accepted 13th July 2001
First published as an Advance Article on the web 6th August 2001

Novel tungsten octahedral sulfidocyanide cluster compounds $Na_6[W_6S_8(CN)_6]\cdot18DMSO$ 1 and $K_6[W_6S_8(CN)_6]$ 2 have been synthesized and characterized by X-ray crystallography and NMR spectroscopy.

Chevrel phases,[1] $M_xMo_6Q_8$, (M = metal, Q = chalcogen) are a class of cluster compounds extensively studied for their superconductivity,[2] fast ion conductivity[3] and catalytic activity.[4] The building block of the Chevrel phases is an octahedral molybdenum cluster face-capped by eight chalcogenide atoms (Q). Although no tungsten analogues of the Chevrel phases are known, the molecular tungsten clusters $W_6Q_8L_6$ (L = neutral Lewis base ligand) have been synthesized in solution,[5–10] as have the $Mo_6S_8L_6$ clusters.[11,12] Our investigation of $W_6S_8L_6$ clusters,[10,13–15] particularly the finding of strong bonding to the W_6S_8 cluster by isocyanide,[15] suggested cyanide might also be a good ligand. It would be interesting to explore such chemistry, given the diverse structural chemistry of cyanides,[16] in particular, $[Re_6Q_8(CN)_6]^{4-}$ clusters have been exploited to prepare a number of extended structure coordination compounds.[17,18] It was reported recently that molecular $[Mo_6Se_8(CN)_6]^{7-/6-}$ clusters could be synthesized through 'excision' of clusters from the Chevrel phase with molten KCN,[19] however, such synthesis could be achieved from simple non-cluster starting materials as well.[20] We report here the synthesis and characterization of the first W_6S_8 cluster compounds with anionic cyanide ligand: $Na_6[W_6S_8(CN)_6]\cdot18DMSO$ **1** and $K_6[W_6S_8(CN)_6]$ **2**. Our preliminary study indicates that $[W_6S_8(CN)_6]^{6-}$ have different redox behavior from $[Mo_6Se_8(CN)_6]^{6-}$.

Reaction of $W_6S_8(4\text{-Bu}^t\text{py})_6$[10] with NaCN (slightly more than 1:6 equiv.) in DMSO at 100 °C for 1 day resulted in a brown-red crystalline precipitate which was filtered off as product **1**‡ from a brown–red solution (yield of the product: 84%). Slow cooling of a hot DMSO solution of **1** yielded suitable single crystals for X-ray structural analysis.§ The identity of the cluster anion is apparent and shown in Fig. 1(a). The W_6S_8 cluster core is a quite regular octahedron with an average W–W distance of 2.685(3) Å, similar to that found in $W_6S_8(C{\equiv}NBu^t)_6$ [2.681(3) Å].[15] The N terminal of each CN^- ligand is coordinated to a Na^+ ion in a roughly collinear fashion and each Na^+ ion is also coordinated by 3 O atoms from DMSO solvent molecules [Fig. 1(b)]. The overall crystal structure can be described as approximately "ABC" close packing of the cluster complexes including Na^+ ions and DMSO [Fig. 1(c)]. Based on the stoichiometry, the charge of the cluster anion is −6 and the metal electron count (MEC) of the cluster is 20.

Reaction of $W_6S_8(4\text{-Bu}^t\text{py})_6$ with $K^{13}CN$ (slightly more than 1:6 equiv.) in DMSO at 100 °C for 1 day resulted in a lustrous crystalline precipitate which was filtered off as product **2**¶ from a nearly colorless solution (yield of the product: 91%). Insoluble in any organic solvents, **2** is apparently not isostructural to **1** as the PXRDs are different. Layering deoxygenated water solutions of **2** with methanol yielded dark red single crystals suitable for X-ray structural analysis.§ Shown in Fig. 2, the refined cubic structure of $K_6[W_6S_8(CN)_6]\cdot10H_2O$ (**2**·$10H_2O$) shows *fcc* packing of the $[W_6S_8(CN)_6]^{6-}$ cluster anion. The K^+ ions and solvent water molecules reside, often with partial occupancies, in octahedral, tetrahedral and other interstitial sites. The cluster has the ideal O_h symmetry with a slightly shorter W–W distance [2.6772(7) Å] than that of **1**.

These syntheses are facilitated by the sparing solubility of both $W_6S_8(4\text{-Bu}^t\text{py})_6$ and NaCN (or KCN) in DMSO and simplified by the insolubility of product **2** or the low solubility of **1** at RT. Cyanide can replace the more weakly bonded ligands (L) on $W_6S_8L_6$ clusters, such as *n*-butylamine,[13] more readily, but phosphine ligands on $W_6S_8(PEt_3)_6$[10] can not be completely replaced by cyanide even in considerable excess. Therefore, the binding free energy of CN^- is estimated to be, not surprisingly, close to that of *tert*-butyl isocyanide.[15]

The PXRD of the bulk sample of **1** is identical to the simulated pattern from the single crystal structure (both

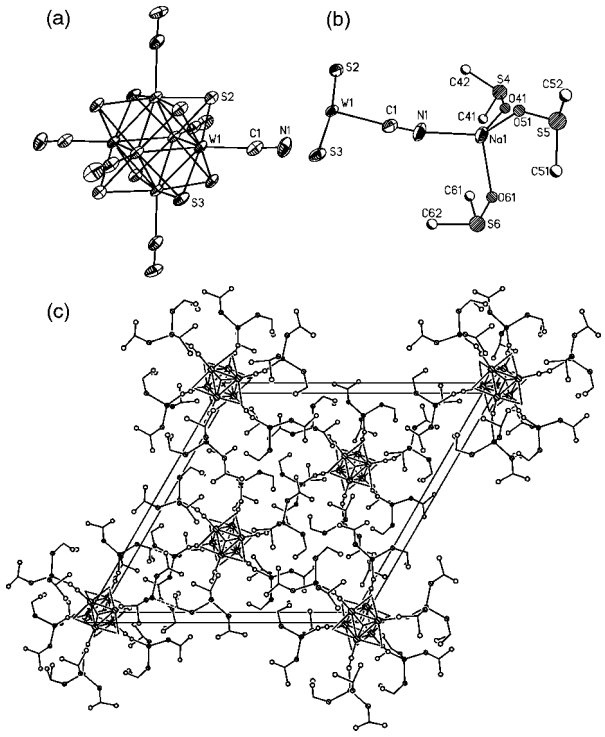

Fig 1 (a) ORTEP drawing of the $[W_6S_8(CN)_6]^{6-}$ cluster anion in **1** at 50% probability level; (b) asymmetric unit in **1** emphasizing the tetrahedral environment around the Na^+ cation (DMSO molecules are disordered, but not shown for clarity); (c) packing diagram of $Na_6[W_6S_8(CN)_6]\cdot18DMSO$ **1** along the *c* axis. Selected bond lengths (Å) and angles (°): W1–W1A 2.6875(4), W1–W1C 2.6818(4), W1–S2 2.4518(15), W1–S3 2.4571(12), W1–S3A 2.4587(11), W1–S3B 2.4667(11), W1–C1 2.196(5), C1–N1 1.158(6), N1–Na1 2.327(4), Na1–O range 2.118(13)–2.378(8); W1–C1–N1 176.6(4), C1–N1–Na1 164.2(4). Symmetry transformations used to generate equivalent atoms: A *y*, $-x+y$, $-z+2$; B $x-y$, *x*, $-z+2$; C $-y$, $x-y$, *z*.

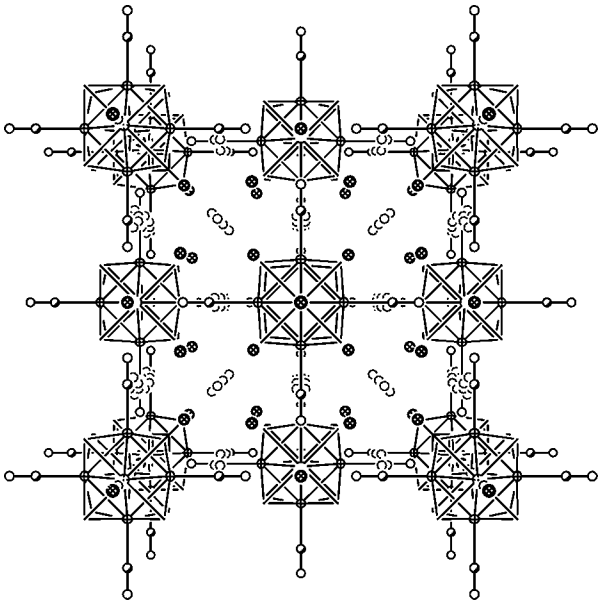

Fig 2 Unit cell (*fcc*) packing structure of $K_6[W_6S_8(CN)_6]\cdot 10H_2O$ (**2**·$10H_2O$). The circles of S atoms are omitted for clarity, K^+ ions are shown as cross-hatched circles, oxygen atoms of solvent water are shown as open circles with dotted boundaries. Selected bond lengths (Å): W–W 2.6772(7), W–S 2.452(2), W–C 2.152(16), C–N 1.162(19), N–K 2.447(13), 3.139(5).

available as ESI†). The stoichiometry was also confirmed by elemental analysis‡ and TGA analysis in which all of the DMSO solvent molecules (46 wt%) were lost upon heating. For **2**, the crystallographic refinements alone can not determine the stoichiometry or cluster oxidation state since K^+ and H_2O are disordered. Interestingly, the reported *blue* crystal of $K_7[Mo_6Se_8(CN)_6]\cdot 8H_2O$[19] is isotypic to this structure. However, elemental analysis¶ and ^{13}C NMR (*vide infra*) of the as prepared compound **2** establishes the 6− charge for the cluster anion.

It proved to be extremely difficult to observe the ^{13}C NMR signal from $[W_6S_8(CN)_6]^{6-}$ anions due to the low receptivity and tertiary nature of ^{13}C in CN^-.[21] Using ^{13}C labeled KCN enabled such observation and thus provides convenient means to monitor the chemistry in solution. A ^{13}C NMR spectrum of cluster **2** in D_2O is shown in Fig. 3. The chemical shift, δ 146.8, is different from that of free CN^- in water (δ 165) and falls into the general range for C-bonded cyanide ligands.[21] Satellite peaks with $J_{W\text{-}C}$ 107 Hz caused by coupling to ^{183}W isotope (14.3%)[21] confirms C terminal bonding to the W atom in the cyanide. The *sharp* NMR signal indicates a closed shell electron configuration. *If* the cluster was oxidized or reduced, the paramagnetic cluster would have severely broadened the NMR peak(s).[14]

In deoxygenated D_2O, the NMR spectrum of the clear brown–red solution of **2** does not change for at least a week. Upon exposure to air, the solution becomes darker and the ^{13}C NMR peak diminishes to half of the original intensity within 20 days accompanied by some new upfield peaks, suggesting that the cluster has been oxidized. This behavior is different from that of $[Mo_6Se_8(CN)_6]^{7-/6-}$ anions: the *reduced* cluster $[Mo_6Se_8(CN)_6]^{7-}$ (MEC = 21) was found to be the product of

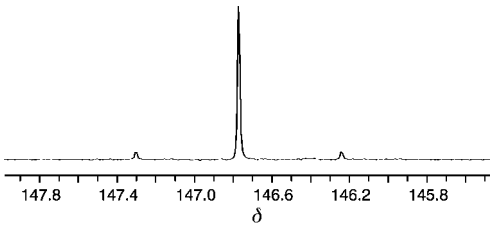

Fig 3 ^{31}C NMR spectrum of $K_6[W_6S_8(CN)_6]$ **2** in deoxygenated D_2O with dioxane as internal reference.

reactions with molten KCN (though the reducing agent has yet to be identified) and this cluster is oxidized in air to the *'normal'* closed shell cluster $[Mo_6Se_8(CN)_6]^{6-}$.[19,20] The stability of the $[W_6S_8(CN)_6]^{6-}$ cluster in deoxygenated water should allow the exploration of its aqueous solution chemistry.

When excess NaCN is present in the DMSO solutions, the $[W_6S_8(CN)_6]^{6-}$ cluster anion is stable at least up to 180 °C. This suggests that $[W_6S_8(CN)_6]^{6-}$ might be synthesized by direct reaction of NaCN, W and S.

We thank the Department of Energy (Grant No. DE-FG02-87ER45298) for support of this work. This study made use of the Polymer Characterization Facility of the Cornell Center for Materials Research supported through the NSF Material Research Science and Engineering Centers program (grant DMR-0079992).

First published as an Advance Article on the web 6th August 2001

Irradiation of H-ETS-10 in the presence of adsorbed methanol or ethene causes photoreduction of Ti(IV) to Ti(III); photoreduction does not occur for Na, K-ETS-10, but a photoinduced polymerization of ethene is observed.

ETS-10 is a titanosilicate zeolite with a novel structure comprising one-dimensional chains of corner-linked TiO_6 octahedra surrounded by tetrahedral silicate units, generating a three-dimensional 12-ring pore system.[1] There is particular interest in the O–Ti–O–Ti–O chains, which have been described as semiconductor nanowires within an insulating sheath.[2] Titanium in ETS-10 can be chemically reduced by adsorbing sodium vapour into ETS-10,[3] suggesting that electronic communication can occur between the semiconductor chains and species in the pores. There is also an early report of photocatalytic activity of ETS-10 in the oxidation of organic alcohols,[4] which likewise implies that electron transfer can occur through the silicate 'insulation'. The photoreactivity of conventional anatase photocatalysts has been extensively studied; band gap irradiation of anatase in the presence of adsorbed organic compounds causes photoreduction of Ti(IV) to Ti(III), due to trapping of holes by the adsorbed organic and consequent trapping of electrons at Ti(IV) sites.[5] We have begun a study comparing the photoreactivity of anatase with that of ETS-10, and report here that the photoreduction of ETS-10 depends on the presence of defects in the structure.

Two ETS-10 samples were studied: a hydrogen exchanged material provided by Engelhard,[6] and a sample synthesized in-house following established procedures[7] which contains sodium and potassium as the charge balancing cations. Both samples gave X-ray powder diffraction patterns characteristic of ETS-10;[1] the higher angle peaks of the H-ETS-10 sample were however substantially broadened relative to Na,K-ETS-10, indicating a higher degree of disorder in the proton exchanged sample (chemical analysis of this sample showed the extent of proton exchange to be H/(H + Na + K) = 0.78). SEM showed average crystallite sizes to be around 2 μm for Na,K-ETS-10, but 0.3 μm for H-ETS-10. Indications of greater disorder in the O–Ti–O–Ti–O chains in the proton exchanged material came from the absence of the intense Raman band at 732 cm^{-1} attributed to Ti–O stretching vibrations in the chains[8] which is present in the Na,K-ETS-10, and substantially increased Debye–Waller factors in the Ti K-edge EXAFS of H-ETS-10 compared with Na,K-ETS-10.[9] ^{29}Si NMR spectra of the H-ETS-10 were similar to those previously reported,[6] showing retention of Si–O–Ti bonds. A commercial (Degussa P25) anatase sample was used for comparison with ETS-10.

Photoreduction experiments were performed in a vacuum EPR cell; samples were outgassed *in vacuo* at 573 K, then exposed to either methanol or ethene vapour and irradiated at room temperature with a 125 W mercury arc lamp. Irradiation of anatase in the presence of methanol or ethene produces a dark blue colour and an intense broad EPR signal of Ti(III), with parameters $g_\perp$ = 1.973, $g_\parallel$ = 1.949 (measured at 77 K). This signal could not be detected at room temperature. Similar signals have been previously attributed to Ti(III) cations on lattice sites distributed through the bulk of anatase, or to surface Ti(III) cations, in both cases with distorted octahedral coordination.[10] The Ti(III) signal was removed when the sample was evacuated then exposed to oxygen, but no new signals were formed.

Fig. 1 shows EPR signals recorded at room temperature following irradiation of H-ETS-10 in the presence of ethene. The sample turns grey and the new signal which appears is shifted significantly to higher field relative to that obtained with anatase ($g_{av} \approx 1.95$). The other important difference from anatase is that this signal could be observed at room temperature. Subsequent exposure to oxygen (5 Torr) gave weak new signals in the vicinity of g = 2.010, but evacuation followed by exposure to 5 Torr of oxygen totally removed the Ti(III) signal (and the grey colour) and enhanced the new signals [Fig. 1(c)]. Closer examination of the new signals reveals that one component is the superoxide ion O_2^- adsorbed on Ti(IV) sites (g_{zz} = 2.022, g_{yy} = 2.011, g_{xx} = 2.004).[11] Identification of the other species is less certain, but the lower field shoulders may be the g_{zz} components of superoxide species adsorbed on sites of lower formal charge.[12] Similar spectra were obtained when H-ETS-10 was irradiated in the presence of adsorbed methanol and subsequently exposed to oxygen.

The Ti(III) signal formed on irradiation of H-ETS-10 in the presence of the adsorbed ethene or methanol differs from that formed in anatase under the same conditions. This is not unexpected if the Ti(III) is in a one-dimensional O–Ti–O–Ti–O chain rather than the three-dimensional anatase lattice. However it is clear from the reactivity of this species towards oxygen, and in particular from the observation of O_2^- adsorbed on Ti(IV)

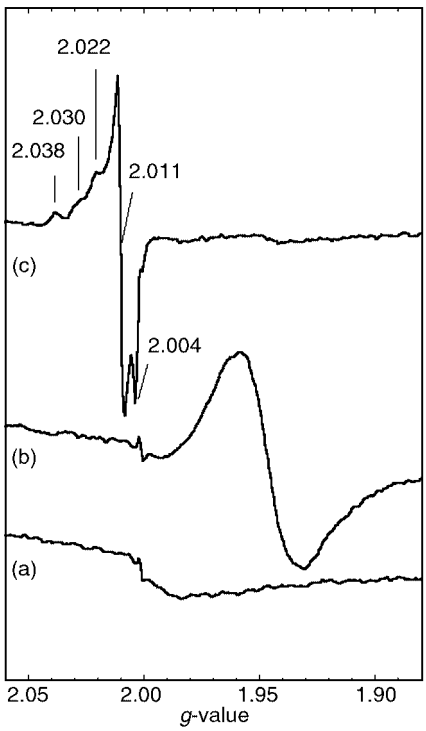

Fig. 1 EPR signals from H-ETS-10: (a), exposed to ethene prior to irradiation; (b), irradiated for 2 h; (c), evacuated at room temperature then exposed to 5 Torr of oxygen.

 DOI: 10.1039/b104870h

sites, that H-ETS-10 contains exposed titanium sites which should not be present in a defect free ETS-10 structure.

This conclusion is supported by the observation that when the same experiments were conducted with Na,K-ETS-10 in which the spectroscopic evidence indicates that the O–Ti–O–Ti–O chains are relatively defect free, no photoreduction was observed; *i.e.* no colour changes occurred on irradiation in the presence of methanol or ethene, and no Ti(III) signals were detected by EPR.

Nevertheless, *in situ* FTIR studies of Na,K-ETS-10 in the presence of adsorbed ethene show that a photoinduced reaction of ethene with the ETS-10 does occur. Fig. 2 shows IR spectra recorded in an *in situ* cell of Na,K-ETS-10 following adsorption of ethene and subsequent irradiation (these are difference spectra from which the spectrum of the dehydrated ETS-10 prior to admission of ethene has been subtracted, and ratioed against a background containing the gas phase ethene to remove gas phase contributions to the spectra).

On irradiation bands due to adsorbed ethene (*e.g.* 3083, 1613, 1445 and 1338 cm^{-1}) are reduced in intensity, and new bands appear and grow in the ν(OH) region (3660, 3580 cm^{-1}), in the ν(CH) region (2926 and 2856 cm^{-1}), at 1632 cm^{-1} and at 1468 cm^{-1}. Evacuation at room temperature removes the adsorbed ethene bands but leaves the new bands unchanged.

The bands appearing at 2926, 2856 and 1468 cm^{-1} are characteristic of saturated CH_2 groups,[13] suggesting that polymerization of ethene has occurred to form $(CH_2)_n$ chains. On the other hand, the bands at 3660, 3580 and 1632 cm^{-1} are close to those expected for isolated (non-hydrogen bonded) water molecules.[14] This experiment thus suggests that in Na,K-ETS-10 holes and electrons formed on irradiation both react with adsorbed ethene. A free radical polymerization of ethene may be initiated by electrons generated in the O–Ti–O–Ti–O chains, while the formation of adsorbed water may occur as a result of oxidation of adsorbed ethene by positive holes (involving reaction of lattice oxide ions). The sharpness of the bands due to adsorbed water indicates that these are isolated water molecules. It is important to note also that no reaction occurred in the absence of irradiation.

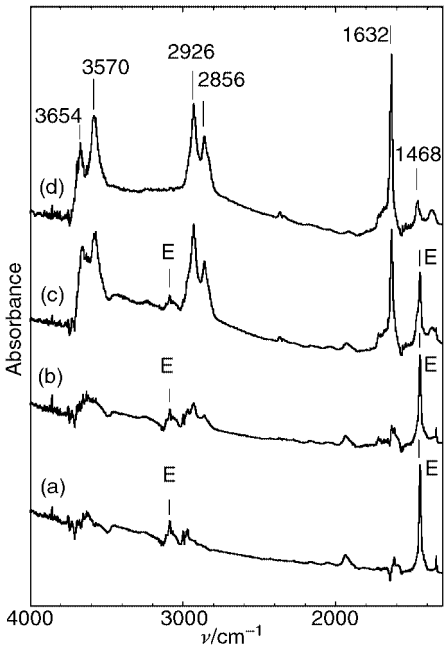

Fig. 2 *In situ* FTIR spectra of ethene in Na,K-ETS-10 (gas phase and background spectrum of ETS-10 subtracted): (a) exposed to ethene (70 Torr) at room temperature; (b), irradiated 90 min; (c), irradiated 300 min; (d), evacuated at room temperature. (E denotes bands due to physisorbed ethene).

This chemistry is different from that occurring in H-ETS-10, where electron trapping occurs preferentially at Ti(IV) sites associated with defects. An IR experiment similar to that described above was performed on ethene adsorbed in H-ETS-10. In this case irradiation caused a similar reduction in intensity of the bands due to physisorbed ethene, but the only new bands appearing were broad bands due to hydrogen bonded adsorbed water, at *ca.* 3300 and 1630 cm^{-1}. In particular, no new bands due to polyethene were detected in H-ETS-10.

Further work is needed to establish details of the photoreduction and photoinduced polymerization mechanisms. Further characterization of the defect sites in H-ETS-10 is also in progress. It is clear however that the defect sites are important in the photoreactivity of these novel materials. Our observation of photoinduced ethene polymerization in Na,K-ETS-10 also confirms that electron transfer can occur between the semiconductor chains and molecules adsorbed in the ETS-10 pores. This has important consequences for the potential use of ETS-10 as a photocatalyst.

This work was carried out in the School of Chemistry, University of New South Wales, and supported by a grant from the Australian Research Council. Y. K. acknowledges an AUSAID postgraduate scholarship.

The synthesis of a new Gly-Pro turn mimetic and the computational study of its ability to induce β-turn is reported.

In recent years several strategies have been adopted to limit the conformational space of peptide chains[1] and many efforts have been made to develop β-turn mimetics.[2]

It is known that a *cis* peptide moiety is geometrically suited for inducing the peptide chain to bend and that β-turns of type VI are characterized by a *cis*-Pro in the *i* + 2 position.[3] The control of the *cis*-prolyl amide geometry has been effectively achieved by tethering the α-carbon of the *N*-terminal amino acid residue to the proline 2-position.[4] Particularly, the bicyclic dipeptide analogues **1**, in which the α positions are joined by a two (X = $–CH_2CH_2–$) or three (X = $–CH_2NHCO–$) atom bridge, have been synthesized[4] to serve as mimetics of dipeptide *cis*-Xxx-Pro (Fig. 1). To reduce the conformational freedom of dipeptide mimetics like **1**, a shorter link could be introduced. In this way the pyrrolizidine amino acids **1** (X = $–CH_2–$), containing the *cis*-Xxx-Pro residue, would result (Fig. 1).

In this communication we report the synthesis of the GPTM (Gly-Pro Turn Mimetic) **2** (Fig. 1) either in racemic or enantiomerically pure form and its successful coupling with L-Boc-Phe-OH.

The 1,3-dipolar cycloaddition (1,3-DC) of nitrone **3**[5] and an acrylic acid derivative, followed by reductive opening of the isoxazolidine ring and intramolecular cyclization was envisaged as a rapid route to afford the bicyclic lactam **9**.

The 1,3-DC reaction was performed under different conditions and the best results were obtained from **3** and acrylamide (**4**) in water at 60 °C (Scheme 1) which afforded the 2-aminocarbonylhexahydropyrrolo[1,2-*b*]isoxazoles **5** and **6** and their 3-aminocarbonyl isomers **7** in 4 : 1 ratio and excellent yield (98%). Although the *endo–exo* selectivity of the cycloaddition was very low (6% de) this approach was synthetically convenient because both the diastereomeric adducts **5** and **6** could be transformed into **9**.

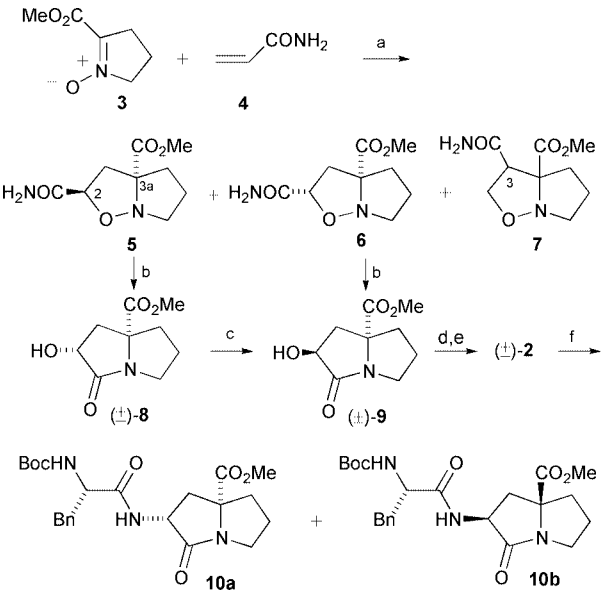
The pyrrolizidine **9** was obtained from **6** through the domino process N–O bond hydrogenolysis/intramolecular trans-amidation. Moreover, the *cis* substituted pyrrolizidine **8**, analogously derived from **5**, could be quantitatively isomerized to the corresponding *trans* hydroxy ester **9** by treatment with NaOH–MeOH at 70 °C followed by methylation with CH_2N_2. Therefore, the intermediate **9**, possessing the bicyclic skeleton of the GPTM **2**, was achieved in 55% overall yield starting from **3** and **4** (Scheme 1).

The *trans* alcohol **9** was easily transformed into the corresponding *cis* amine **2** by mesylation followed by a nucleophilic displacement with NaN_3 and reduction of the azido group with Ni-Raney (Scheme 1). The lactam **2**, was immediately coupled with an amino acid such as Boc-L-Phe, to test the reactivity of the amino group towards the peptide synthesis and to avoid the possible epimerization to the thermodynamically more stable *trans* isomer. The two diastereomeric tripeptides **10a** and **10b** were separated by chromatography on silica gel and fully characterized.

To assign the absolute configuration of **10a** and **10b**, a sample of the racemic *cis* alcohol **8** was resolved through the formation of the corresponding diastereomeric esters of *R*-Mosher acid, and one of the separated esters was analyzed by single crystal X-ray crystallography.† Consequently, both the diastereomeric esters were assigned their absolute configuration. After hydrolysis and treatment with CH_2N_2 the enantiomerically pure alcohols (2*R*,7a*R*)-**8** and (2*S*,7a*S*)-**8** were obtained, and transformed into **10a** and **10b**, respectively, through the previously described procedure.

The investigation of the turn-inducing potential of both the enantiomers (2*R*,7a*R*)-**2** and (2*S*,7a*S*)-**2** has been carried out through a simulation procedure run on model hexapeptides according to the criteria recently proposed by Müller *et al.*[6]

The model hexapeptides Ac-Ala-Ala-GPTM-Ala-Ala-NHMe **11** and **12** (Fig. 2), containing in the central position *RR*-GPTM and *SS*-GPTM respectively, were examined for their conformational freedom by Monte Carlo (global search



Scheme 1 a: H_2O, 60 °C, 14 h (**5**: 37%, **6:** 42%, **7**: 19%). b: $Pd(OH)_2$ (cat), MeOH, AcOH, H_2, 12 h (98%). c: (i) NaOH, MeOH, 70 °C, 2 h; (ii) Dowex 50; (iii) CH_2N_2; (60%). d: (i) MsCl, py; (ii) NaN_3, DMF; (87%). e: Ni-Raney (80%). f: L-Boc-Phe-OH, PyBroP, DiPEA, CH_2Cl_2 (55%).

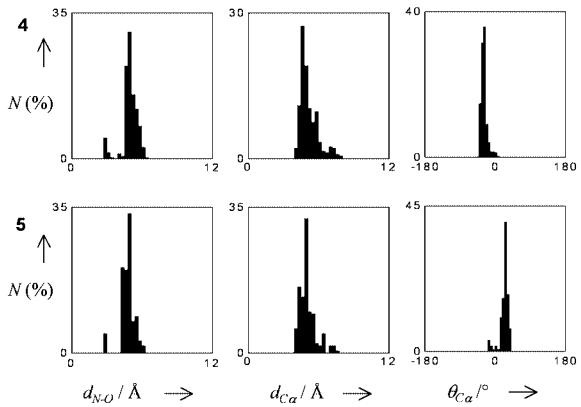

Fig. 3 Percentage distribution N of $d_{N\text{-}O}$, $d_{C\alpha}$ and $\theta_{C\alpha}$ values in the conformers of **4** and **5** within 6 kcal mol^{-1} of the global minimum. (Each column spans 0.3 Å or 6°.)

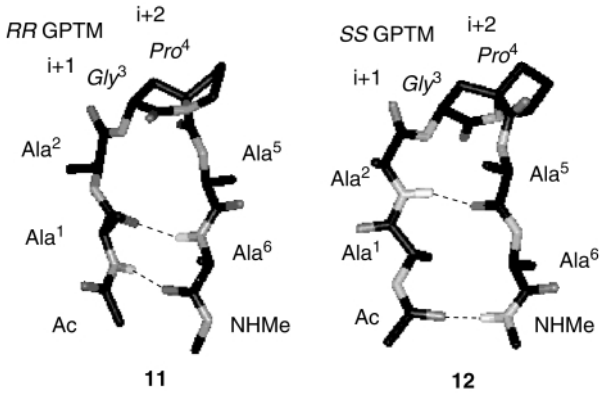

Fig. 4 Structures of two low energy conformers of **11** and **12**. Legend: C: black, N: pale grey, O: grey, H: white. For reasons of clarity only the H atoms involved in hydrogen bondings (--) were depicted.

MCMM) procedure.[7] The following parameters were used to establish the presence of a reverse turn: the donor–acceptor NH_{Ala5}–CO_{Ala2} distance $d_{N\text{-}O}$, the $C\alpha_{Ala2}$–$C\alpha_{Ala5}$ distance $d_{C\alpha}$ and the virtual torsion angle $\theta_{C\alpha}$ (defined by $C\alpha_{Ala2}$–$C\alpha_{Gly3}$–$C\alpha_{Pro4}$–$C\alpha_{Ala5}$).[3,6] The percentage distribution of $d_{N\text{-}O}$, $d_{C\alpha}$ and $\theta_{C\alpha}$ values in the calculated conformations within 6 kcal mol^{-1} of the global minimum of **11** and **12** (318 and 170 conformers respectively) were reported in Fig. 3. The histograms showed a substantial restriction of the occupied conformational space of hexapeptides incorporating GPTMs **2**. Moreover, a very good portion of conformers possessed the $d_{C\alpha}$ and $\theta_{C\alpha}$ values characteristic of β-turn. In particular the percentages of conformers of **11** and **12** with $d_{C\alpha}$ less than 5 Å (one definition of a tight β-turn) were 55 and 58%, respectively, while almost all structures showed $d_{C\alpha}$ less than 7 Å (**11**: 94%, **12**: 96%).[3] All conformers had $|\theta_{C\alpha}|$ under 50°, and $|\theta_{C\alpha}|$ under 30° present in 54 and 75% conformers of **11** and **12**, respectively.

On the contrary, the presence of the hydrogen bonding characteristic of classical β-turn ($d_{N\text{-}O}$ < 3.5 Å) was found in a small fraction of conformers (**11**: 7%; **12**: 5%). However, the intramolecular hydrogen bond was not found critical for the stability of a β-turn,[3] and seems not to be necessary in peptides incorporating mimics **2**, because the three torsion angles (ψ_{Gly3}, ω_{Pro4} and φ_{Pro4}) embedded in the 5,5-bicyclic structure and the spatial orientation of the terminal amino and carboxylic groups (on the same face of the bicyclic ring system) force the peptide chain to fold back upon itself.

The whole set of computational data clearly showed that bicyclic lactams like (2*R*,7a*R*)-**2** and (2*S*,7a*S*)-**2** were effective turn restraints when incorporated in the hexapeptides **11** and **12**.

The spatial arrangement of side chains is generally critical to recognition and bioactivity of peptides and its control is one of the goals of peptidomimetics. GPTMs (2*R*,7a*R*)-**2** and (2*S*,7a*S*)-**2** were shown to promote complementary relative orientation of the side chains of the residues near the reverse-turn.

As shown in Fig. 3, the $\theta_{C\alpha}$ values were prevalently negative in the conformers of **11**, but positive in those of **12** because of the enantiomeric relationship between the incorporated GPTMs. The presence of opposite reverse turns resulted also in an opposite orientation of the amino acid side chains as illustrated by a structural comparison of two representative low energy conformers of **11** and **12** (Fig. 4).

Both the selected structures were characterized by the presence of two intramolecular hydrogen bonds which indicated the initiation of an antiparallel β-sheet interaction between the two half-strands. In **11** the β-sheet hydrogen bonds were contiguous (between NH_{Ala6}–CO_{Ala1} and NH_{Ala1}–CO_{Ala6}) while in **12** were more distant (between NH_{Ala2}–CO_{Ala5} and NH_{NHMe}–CO_{Ac}). In **11** the methyl groups of Ala^2 and Ala^5 were situated under the back-bone plane (when the peptide chain was oriented as shown in Fig. 4) and those of Ala^1 and Ala^6 over the plane, while in **12** the opposite orientations occurred.

In conclusion both the enantiomers of GPTMs **2** were shown to be potentially useful reverse turn mimics. Attractive features of these new dipeptide surrogates were the reduced flexibility compared to analogous bicyclic systems, the complementary behavior of the two enantiomers in controlling the side-chain orientation, the rapid access to these systems starting from easily available compounds, the possibility of extending the process to the synthesis of other Xxx-Pro analogues (XPTMs) through the cycloaddition of nitrone **3** to 2-substituted acrylic acid derivatives.

Some structural modifications of GPTMs **2** for their use in solid phase syntheses and their incorporation into selected bioactive peptides for structure–activity relationship studies are currently under investigation in our laboratories.

Self-assembly of a bis-urea macrocycle into a columnar nanotube

Linda S. Shimizu,* Mark D. Smith, Andrew D. Hughes and Ken D. Shimizu

University of South Carolina, Department of Chemistry and Biochemistry, Columbia, SC 29208, USA. E-mail: shimizul@mail.chem.sc.edu

Received (in Columbia, MO, USA) 20th December 2000, Accepted 30th April 2001
First published as an Advance Article on the web 7th August 2001

A bis-urea macrocycle 1 was synthesized and shown to form extended nanotubular columns by X-ray crystallography.

There has been great interest in the development of new molecular building blocks that predictably self-assemble into three-dimensional nanoscale structures.[1] In particular, columnar or tube shaped structures have been sought for applications as sensors, templates for directed reactions, and in ion and small molecule transport systems.[2] A common design motif has been to identify macrocyclic building blocks that stack to form cylindrical assemblies (Fig. 1). The interior cavity size and integrity of the columns are ensured by the rigidity of the macrocyclic building blocks. Excellent examples in this regard are Ghadiri's cyclic peptides, Stang's molecular squares, and Moore's macrocyclic polyphenylenethynylenes.[3] We have designed a series of bis-urea macrocycles that are readily synthetically accessible and similarly self-assemble into columnar nanotubes. We report, herein, the synthesis and assembly of the first and smallest member of this family.

The guiding interaction in macrocycle **1** is the urea self-association. The topology of urea assembly is well understood. The ureas commonly form head-to-tail arrays based on 3-center hydrogen bonds from the NH's of the urea in one molecule to the carbonyl of the urea in the adjacent molecule which position the ureas 4.6 Å apart.[4] This strong hydrogen-bonding interaction has been used in self-assembled materials,[5] supramolecular assemblies,[6] and organic gelators.[7] Most of these have been acyclic systems and only a single demonstration of a macrocyclic assembly has been reported in which the ureas are part of the cyclic framework.[8]

In macrocycle **1**,† two *meta*-xylenes serve as rigid spacers. The macrocycle **1** was readily synthesized (Scheme 1). First the urea functionality was protected as a triazinanone **2**, inhibiting over-alkylation and premature self-assembly. Reaction of 5-*tert*-butyl-1,3,5-triazinan-2-one **2** with *meta*-dibromoxylene yielded the protected bis-urea **3**.[9] The enhanced solubility of the protected bis-urea **3** enabled facile isolation and purification. Deprotection with diethanolamine in methanol yielded bis-urea macrocycle **1**. Proton NMR analysis in DMSO of the deprotected **1** showed two broad peaks for the benzyl CH_2 groups centered at 4.6 and 3.8 ppm, consistent with slow flipping of the 16-membered ring. This dynamic conformational behavior is consistent with studies of the protected macrocyclic precursor **3** by Dave *et al.*[10]

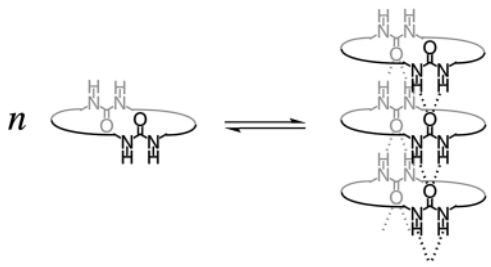

Fig. 1 Schematic representation of the self-assembly of rigid macrocyclic bis-ureas.

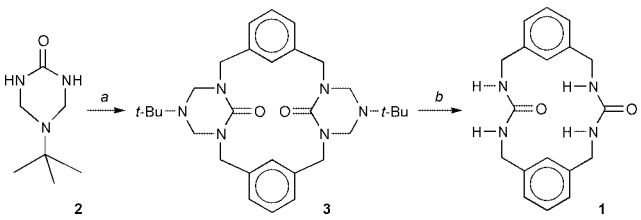

Scheme 1 Synthesis of bis-urea macrocycle **1**. *Reagents and conditions*: (a) *meta*-dibromoxylene, NaH, THF, 20%, (b) 20% diethanolamine, MeOH, reflux, 66%.

The solid-state molecular and assembled structures of bis-urea **1**‡ were examined by X-ray crystallographic analysis. The self-association of **1** was immediately apparent by its poor solubility characteristics. Single crystals suitable for X-ray diffraction were ultimately obtained upon slow cooling of **1** (135 °C to 25 °C) in a sealed tube of glacial acetic acid (100 mg/15 mL). The crystal structure of **1** reveals the expected bis-urea macrocycle (Fig. 2). The opposing urea functionalities are parallel but oriented oppositely, presumably to minimize the dipole moment. Most importantly, the ureas are not intramolecularly hydrogen-bonded and thus are free to form the designed macrocyclic stacks. The phenyl rings are tilted slightly out of the plane of the macrocycle, one pointing above and the other pointing below the plane of the macrocycle. The protons on C4 point inward, with an intramolecular H···H distance of 3.5 Å, filling most of the interior cavity.

The extended structure reveals that bis-urea units **1**§ stack on top of each other to form the desired supramolecular tubular structure. The bis-urea monomers are held together by the head-to-tail urea hydrogen-bonding motif extending along on both sides of the tube (Fig. 3). The three-centered hydrogen bonds have an N···O distance of between 2.82 and 3.01 Å and an H···O distance of 1.98 to 2.21 Å. This generates a spacing of 4.614 Å between the urea groups, consistent with other urea hydrogen-bonding systems. The urea monomers are aligned parallel but off-centered. The stacks are tilted 26° off of perpendicular as measured by the tilt in the ureas with respect to the macrocycle. This brings the aryl rings in adjacent macrocycles closer together within π-stacking distance (3.568 Å) while maintaining the longer urea–urea distance of 4.614 Å. The tilt also serves to orient the adjacent aryl rings in the more favorable offset aryl π-stacking geometry.[11]

In conclusion, the simple, symmetric bis-urea macrocycle **1**, assembles as designed into columnar structures. These extended

tubes are held together by the urea–urea 3-centered hydrogen bonds and by aryl stacking interactions. Fig. 4 highlights the potential channels that may form with larger bis-urea macrocycles. We are currently focused on the synthesis and crystallization studies of larger analogues that would contain channels upon nanotubular assembly.

A multi-component coupling approach to benzo[*b*]furans and indoles†

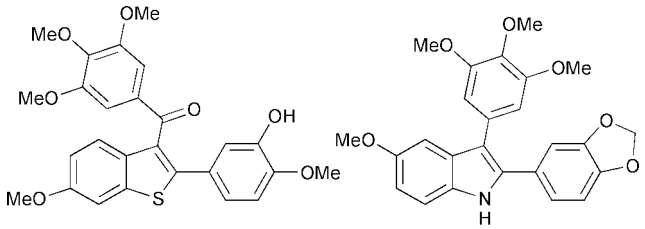
Jason H. Chaplin and Bernard L. Flynn*

Department of Chemistry, The Faculties, Australian National University, Canberra ACT, 0200, Australia. E-mail: flynn@rsc.anu.edu.au

Received (in Cambridge, UK) 25th May 2001, Accepted 28th June 2001
First published as an Advance Article on the web 6th August 2001

A single step access to multiply substituted benzo[*b*]furans and indoles has been developed.

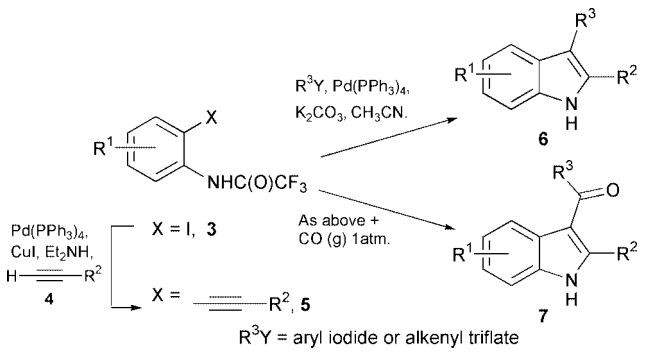
Indoles, benzo[*b*]furans and benzo[*b*]thiophenes are structural cores to a host of bioactive compounds in pharmaceutical use or development. Recently, we described a novel, concise approach to benzo[*b*]thiophenes.[1] This synthesis was used to prepare the tubulin polymerisation inhibitor (TPI) **1**.[1,2] TPIs are valued for



1 **2**

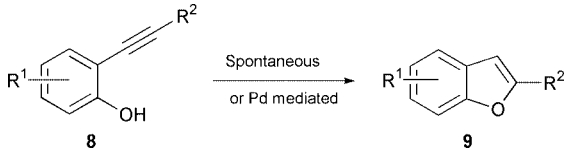
their capacity to inhibit the proliferation of cancer cells and to target tumour vascular endothelial cells.[2c] Medarde *et al.* recently described some cytotoxic 2,3-diarylindole systems, *e.g.* **2**, that were also believed to be TPIs.[3] In our ongoing examination of the structure–activity relationship (SAR) of TPIs such as **1** and **2**,[1,4] we required a concise, flexible access to 2,3-diaryl (and aroyl) benzo[*b*]furans and indoles to complement our access to benzo[*b*]thiophenes. Here we describe a palladium mediated, one-pot, multi-component coupling process that gives direct access to 2,3-disubstituted benzo[*b*]furans and indoles.

Cacchi and co-workers previously reported a two step synthesis of 2,3-disubstituted indoles from *o*-iodotrifluoroacetanilides **3** (Scheme 1).[5] This involves initial Sonogashira coupling of **3** to a terminal alkyne **4** to give an *o*-alkynyltrifluoroacetanilide **5**, which undergoes heteroannulative coupling to aryl iodides and alkenyl triflates to give indoles **6** (R^3 = aryl or alkenyl respectively). The trifluoroacyl group is lost during the coupling process. When performed under an atmosphere of CO gas, heteroannulation proceeds in a carbonylative fashion to provide the corresponding 3-acylindoles **7**.



Scheme 1

This access to indoles **6** and **7** was generally quite efficient. However, extending this approach to the synthesis of 2,3-disubstituted benzo[*b*]furans from *o*-iodophenols proved problematic.[6] The propensity of intermediate *o*-alkynylphenols **8** to undergo cyclisation to simple 2-substituted benzo[*b*]furans **9**, particularly in the presence of palladium, required that the phenolic hydroxy be protected during the initial coupling of the alkyne to the *o*-iodophenol [eqn. (1)].[6] Cyclisation of **8** to **9** was



(1)

also a problem during deprotection and attempted heteroannulative coupling. As a result the overall yield of 2,3-disubstituted benzo[*b*]furan obtained from this multi-step sequence was generally very low. The process was also quite specific to the use of alkenyl triflates as substrates in the heteroannulative coupling reaction and for electron withdrawing groups in the *o*-alkynylphenol.[6]

We sought to improve this access to benzo[*b*]furans by removing any possibility of cyclisation of the *o*-alkynylphenols **8** to 2-substituted benzo[*b*]furans **9** and by reducing the number of steps required. This led to our development of a one-pot, multi-component coupling procedure (Scheme 2). This involves initial deprotonation of a mixture of *o*-iodophenol **10** and terminal alkyne **4** with MeMgCl to give the corresponding magnesium phenolate and magnesium acetylide respectively (not shown). Addition of $Pd(PPh_3)_2Cl_2$ (3 mol%) and heating leads to a coupling to give *o*-alkynylphenoxy magnesium chloride **12** (X = O). Dilution with an equal volume of DMSO and addition of a suitable coupling partner R^3Y (**13**) then gives the heteroannulatively coupled product **14** (X = O) or **15** (X = O) (under carbonylative conditions).

Alkenyl bromides, alkenyl iodides, and aryl iodides all proved to be effective coupling partners in heteroannulation (Table 1, entries 1–5).† The low yield of the product involving

Table 1 Multi-component coupling reaction for the formation of benzo[*b*]furans and indoles (see also Scheme 1)[a]

	Components					Components			
Entry	**10**	**4**	**13**	Product (yield (%))	Entry	**10/11**	**4**	**13**	Product (yield (%))
1	 **10a**	 **4a**	 **13a**	 **14a** (78%)	6	**10a**	 **4d**	 **13d**	 **14f** (70%)
2	 **10b**	 **4b**	 **13b**	 **14b** (45%)	7[b]	**10a**	**4a**	 **13e**	 **14g** (64%)
3	**10b**	 **4c**	 **13c**	 **14c** (88%)	8[c]	**10b**	**4c**	**13c** + CO(g)	 **15a** (64%)
4	 **10c**	**4b**	**13c**	 **14d** (81%)	9[c]	**10c**	**4b**	**13b** + CO(g)	 **16** (46%)
5	 **10d**	**4b**	**13c**	 **14e** (70%)	10	 **11a**	**4c**	**13c**	 **14h** (85%)

[a] All reactions were performed as follows (unless otherwise stated): (i) **10** (or **11**), **4**, 2 × MeMgCl in THF, 0 °C; (ii) $Pd(PPh_3)_2Cl_2$ 3 mol%, 65 °C, 1–2 h; (iii) cool to 18 °C, add **13**, dilute with an equal volume of DMSO and heat to 80–95 °C, 4–19 h. [b] CH_3CN was used as a solvent in place of DMSO and a further 1.3 equiv. of **12e** was added after 2 h. [c] CO (g) 1 atm was introduced upon addition of **13** and DMSO and the reaction heated to 80–95 °C for 20 h.

the styrenyl iodide **13b** is expected to have resulted from the instability of this iodide under the reaction conditions, that is, in the presence of palladium at elevated temperatures. Good yields were also obtained when allyl acetate **13d** and propargyl tosylate **13e** (gives an allenic product) were used as coupling partners (entries 6 and 7).

When the coupling reaction that gave rise to **14c** was repeated, using a carbon monoxide atmosphere at the point of introduction of **13c**, the heteroannulative coupling proceeded in a carbonylative fashion to give **15a** in good yield (entry 8). There were no signs of formation of significant quantities of ester (esterification of the *o*-alkynylphenol) or the simple 2-substituted benzo[*b*]furan **9**, which dominated under the reaction conditions employed by Cacchi and co-workers.[6] Heteroannulative coupling involving the styrenyl iodide **13b** under such carbonylative conditions gave rise to the 3-alkylidenebenzo[*b*]furan-2-one **16** as the major product (entry 9). Benzo[*b*]furanone **16** has clearly resulted from an alternative coupling pathway. Arcadi *et al*. recently described a similar reaction involving vinyl triflates with *o*-ethynylphenols and proposed a mechanism of formation of the benzo[*b*]furanones.[7]

Although the two step process developed by Cacchi for the synthesis of indoles was quite efficient we were gratified to find that our approach to benzo[*b*]furans could also be extended to a one-pot access to indoles as is exemplified by our efficient preparation of **14h** (entry 10).

Enantioselective Michael addition of β-keto esters to methyl vinyl ketone employing a chiral *N,N′*-dioxide–scandium trifluoromethanesulfonate complex as a catalyst

Makoto Nakajima,* Yukiko Yamaguchi and Shunichi Hashimoto

Graduate School of Pharmaceutical Sciences, Hokkaido University, Sapporo 060–0812, Japan. E-mail: nakajima@pharm.hokudai.ac.jp

Received (in Cambridge, UK) 4th June 2001, Accepted 16th July 2001
First published as an Advance Article on the web 6th August 2001

An enantioselective Michael addition of β-keto esters to methyl vinyl ketone exploiting a chiral *N,N′*-dioxide–scandium trifluoromethanesulfonate complex as a catalyst affords the corresponding Michael adducts in high yields and with enantioselectivities of up to 80% ee.

Enantioselective catalytic Michael additions are one of the most important carbon–carbon bond formation reactions because of the versatility of the products as chiral building blocks.[1] Various chiral catalysts have been reported for the Michael addition of prochiral β-keto esters to α,β-unsaturated carbonyl compounds including cinchona alkaloids,[2a–c] chiral crown ether–metal alkoxide complexes,[2d] chiral amine–transition metal complexes,[2e–g] chiral alkoxide complexes,[2h] and chiral bimetallic lanthanoid complexes[1b].

The *N*-oxide functional group is known to form complexes with a variety of metals[3] due to its strong electron donating ability, and as such could be considered useful in potential catalysts. However, only a limited number of attempts to employ *N*-oxides in chiral catalysts have been reported.[4] As part of our program of developing *N*-oxide-mediated reactions,[5] herein we describe an enantioselective Michael addition of β-keto esters to methyl vinyl ketone catalyzed by a chiral *N,N′*-dioxide–scandium trifluoromethanesulfonate complex.

We have recently reported enantioselective conjugate addition of thiols to cyclic enones and acyclic enals catalyzed by the complex between **1** and cadmium iodide.[6] This prompted an investigation of the Michael addition of dimethyl malonate to cyclohexenone employing the **1**–cadmium complex, however, no Michael adduct was obtained with the cadmium complex. A study of the Michael addition of methyl 1-oxoindan-2-carboxylate (**2a**) to methyl vinyl ketone, a reaction frequently investigated as a probe for enantioselective Michael addition, was then undertaken. The reaction proceeded smoothly with the **1**–cadmium iodide complex, but the observed enantiomeric excess of the adduct was low (75% yield, 13% ee). After screening complexes prepared *in situ* from **1** and various metal salts, we found that 5 mol % of a 1:1 complex of **1** and scandium trifluoromethanesulfonate in dichloromethane at room temperature catalyzed the Michael addition to generate the adduct **3a** in quantitative yield with moderate enantioselectivity of 39% ee (Table 1, entry 1).

Introduced by Kobayashi *et al.*, scandium trifluoromethanesulfonate[7] is known as a versatile Lewis acid, yet only a few chiral scandium complexes as catalysts for enantioselective reactions have been reported, scandium trifluoromethanesulfonate–BINOL–amine complexes[8,9] and bimetallic complexes.[1b] Scandium trifluoromethanesulfonate is not soluble in dichloromethane, while its complex with **1** and **2a** dissolves in dichloromethane to give a yellow solution. Other solvents examined in the Michael addition were found to generate products in lower enantiomeric excess than dichloromethane (toluene: 99% yield, 8% ee; propionitrile: 99% yield, 19% ee, tetrahydrofuran: 99% yield, 10% ee). Lower selectivities were obtained at both higher and lower temperatures (0 °C: 91% yield, 5% ee; 40 °C: 98% yield, 20% ee). The enantioselectivity also strongly depended on the ratio of *N*-oxide to scandium (2.5; 99% yield, 19% ee, 1.0: 99% yield, 39% ee, 0.5: 94% yield, 30% ee with 0.5 mM scandium trifluoromethanesulfonate), as well as the catalyst concentration (0.1 mM: 85% yield, 35% ee; 0.5 mM: 99% yield, 39% ee; 2.5 mM: 93% yield, 6% ee with the ratio of *N*-oxide to scandium 1.0). These results suggest a variety of aggregation states for the complexes of scandium and *N*-oxide, though the details of these complexes are beyond the scope of this work.

As a Michael acceptor, acrolein generates a product with similar enantioselectivity (rt, 2 h, 75% yield, 30% ee after conversion of aldehyde into methyl ester), while chalcone

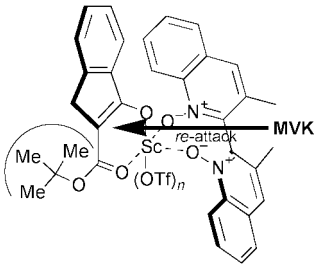

Fig. 1

generates a complex mixture of products. No reaction was observed using methyl acrylate as an acceptor. A variety of β-keto esters were then evaluated as Michael donors employing methyl vinyl ketone as an acceptor. Benzyl 2-oxocyclopentanecarboxylate, methyl 1-oxo-1,2,3,4-tetrahydronaphthalene-2-carboxylate, and methyl 2-methyl-3-oxopropanoate produced racemic mixtures, which suggests the importance of the indan skeleton in directing the enantiocontrol.

Enantioselective Michael additions of various esters of 1-oxoindan-2-carboxylic acid to methyl vinyl ketone were then investigated. The bulkiness of the ester substituent was found to have a pronounced effect on the observed enantioselectivity. As shown in Table 1, the enantioselectivities increased with the bulkiness of the ester. *tert*-Butyl ester **2e** exhibits the highest enantioselectivity of 80% ee (entry 5), while the Michael addition of *tert*-butyl ester **2e** to acrolein also produces notably better enantioselectivity (entry 6) than that of methyl ester **2a**.

The predominant formation of (*R*)-**3e** may be explained by the transition state model shown in Fig. 1. The bulky *tert*-butyl ester moiety should be located on the *si*-face of the keto ester plane in order to avoid steric repulsion with the quinoline moiety, which leads the attack of methyl vinyl ketone at the *re*-face preferentially.

A representative procedure for the enantioselective Michael addition catalyzed by the scandium trifluoromethanesulfonate–**1** complex is as follows. A mixture of *N*,*N*′-dioxide **1** (8.0 mg, 0.026 mmol), scandium trifluoromethanesulfonate (15 mg, 0.026 mmol) and β-keto ester **2e** (120 mg, 0.52 mmol) in dichloromethane (5 ml) was sonicated for 5 min to generate a yellow solution. Methyl vinyl ketone (0.2 mL, 2.6 mmol) was added to the solution and the mixture was stirred at room temperature for 0.5 h. After standard work-up followed by silica gel chromatography, **3e** (145 mg, 93%) was isolated as needles. *N*,*N*′-Dioxide **1** was recovered by elution with 10% ethanol in dichloromethane without a loss of optical purity. The enantiomeric excess of the adduct was determined by chiral HPLC.

In conclusion, we have demonstrated the potentiality of a chiral *N*,*N*′-dioxide–scandium trifluoromethanesulfonate complex to act as a catalyst for enantioselective Michael additions of β-keto esters to methyl vinyl ketone. The present reaction provides the first example of a chiral *N*-oxide–scandium complex acting as a catalyst in an enantioselective reaction. Studies into design modifications of chiral *N*,*N*′-oxides to further enhance enantioselectivity, and into the refinement of the mechanism of the reaction are currently in progress.

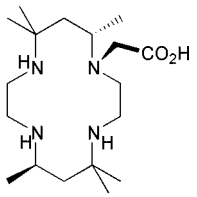
First published as an Advance Article on the web 31st July 2001

A novel macrocycle-MoS_2 nanocomposite has been synthesized and characterized using the exfoliation/restacking properties of $LiMoS_2$, providing the first of a new family of intercalation compounds.

There is significant interest in the properties of polyazamacrocycles bearing pendant-arms, particularly those having arms attached at the nitrogen atoms of the macrocycles. Interest in these complexes has focussed on applications to catalysis, ion-selectivity[1] and their use as radioimmunotherapy agents.[2] Transition metal macrocycles find utility as electrocatalysts in fuel cells,[3] or as catalysts for decomposition of environmentally important small molecules (NO_x, SO_x and CO_2).[4] Cobalt macrocycles will bond sulfur directly to the metal[5] and these complexes, which are also extremely stable in aggressive environments, provide excellent candidates for both fundamental and applied studies of hydrodesulfurization (HDS) of fossil fuels. Thus macrocycles may provide a portal to a completely unique class of intercalation compounds, that may prove to be robust, efficient HDS catalysts.

While the synthesis of nanocomposite materials is an important area of research and there have been a number of reports of intercalation of, for example, crown ethers into phyllosilicates[6] and inorganic hosts,[7] there have been no reports to date of intercalation of tetraazamacrocyclic compounds, particularly of the pendant-arm variety. This class of compound is particularly interesting, given its ability to form extremely stable redox active transition metal complexes. Molybdenum disulfide is a very attractive host material for nanocomposites and has already been shown in its own right to be an effective catalyst in the hydrodesulfurization (HDS) process.[8] It also finds application as a solid lubricant[9] and as a cathode material in high energy density lithium batteries.[10] Despite the importance of MoS_2 in industrial applications, formation of its intercalation compounds using redox techniques is usually limited to those of alkali and alkaline earth metals dissolved in liquid ammonia,[11] or to organolithium reagents such as *n*-butyllithium.[12] However, intercalation compounds of MoS_2 may be produced by utilizing the exfoliation and restacking properties of $LiMoS_2$. Complete exfoliation of $LiMoS_2$ occurs upon reaction with water. Addition of guest species such as organic molecules and polymers to the de-laminated layers can afford a wide range of intercalation compounds of MoS_2.[13] These include the intercalation of crown ethers and polyethylene oxides.[14] In this case, however, washing the intercalation compounds containing alkali metal complexes of the guest ethers caused progressive elimination of the intercalated compounds, giving solids of variable stoichiometry. We have chosen to exploit the $LiMoS_2$ exfoliation technique to attempt to prepare a series of intercalation compounds containing tetraazamacrocycles that should provide new, stable intercalation compounds with novel, useful properties.

We report here the formation and characterization of the first MoS_2 intercalation compound containing a pendant-arm tetraazamacrocycle, 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-1-acetic acid, (L).



The macrocycle L was prepared by following the literature procedure.[15] $LiMoS_2$ was prepared by reacting MoS_2 with 3 equivalents of Bu^nLi[12] and was exfoliated by reaction with water. Addition of an ethanol solution of L to the delaminated layers resulted in its encapsulation in between the disulfide sheets.

Evidence for the intercalation of L into MoS_2 was obtained by powder X-ray diffraction (XRD)† which clearly shows the first eight (00*l*) reflections, indicative of a lamellar structure (Fig. 1). The observed *d*-spacing of the intercalated compound is 11.48 Å, showing an interlayer expansion of 5.3 Å with respect to pristine MoS_2, which has a *d*-spacing value of 6.15 Å. This expansion is consistent with a monolayer of L lying virtually co-planar with the MoS_2 sheets.

The stoichiometry of the sandwiched compound was determined by thermogravimetric analysis under air. This method has been shown previously[13] to give reliable results that agree closely with elemental analysis data. Examination of the thermogram showed that the inclusion compound is stable up to 308 °C. Thereafter, a major weight loss was observed up to 450 °C, followed by the formation of MoO_3, which was stable up to 650 °C. The identity of the MoO_3 phase was confirmed by XRD. From the thermogram, the composition of the intercalated material was found to be $L_{0.11}MoS_2$. It was also found that 0.11 is the maximum loading of L into MoS_2. Increasing the molar ratio of L : MoS_2 from 0.11 to 1.0 during the intercalation process had no effect. The average particle size of $L_{0.11}MoS_2$ was calculated from its powder pattern by using the Scherrer formula[16] and was found to be 80 Å, which may be compared

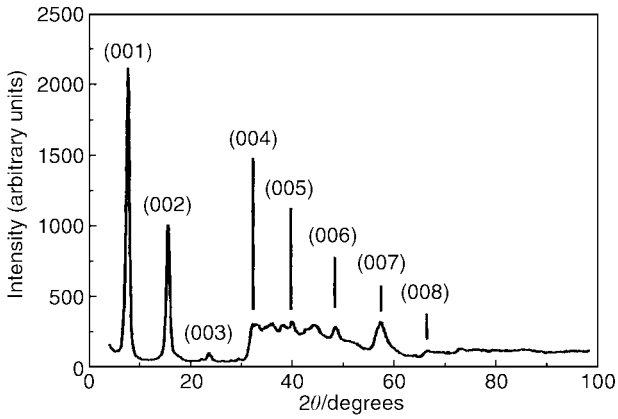


Fig. 1 Powder X-ray diffraction pattern for $L_{0.11}MoS_2$.

 DOI: 10.1039/b103965m

with an average particle size of 129 Å for the pristine MoS_2 used in this study. The decrease in particle size of MoS_2 upon intercalation corresponds to a significant loss in crystallinity of the material since upon exfoliation it does not restack quite as well as in its initial state.

The room temperature electronic conductivity of $L_{0.11}MoS_2$ was assessed by the two-probe technique on a pressed pellet of the sample. The measured conductivity value is 2.5×10^{-3} S cm^{-1}, which shows a 250-fold increase with respect to pristine MoS_2. The latter, which is in the 2H form, is a semiconductor with a room temperature electrical conductivity of 10^{-5} S cm^{-1}. This increase in electrical conductivity is explained by a structural transformation of the MoS_2 which takes place during the intercalation process. In 2H-MoS_2, the molybdenum atoms are bonded to the sulfur atoms in a trigonal prismatic arrangement. Upon treatment of 2H-MoS_2 with Bu^nLi, reduction of the layers takes place forming $LiMoS_2$ that contains molybdenum atoms octahedrally coordinated to six sulfurs. The reaction of $LiMoS_2$ with water is fast, where oxidation of the layers results in the formation of single layers trapped in the octahedral geometry. When the single layers restack with L sandwiched in between, the octahedral geometry of the MoS_2 is retained. Band structure calculations by Matthesis showed that MoS_2 in the octahedral (O_h) form is metallic.[17] However, this form is metastable and reverts to the thermodynamically more stable 2H state. This is consistent with the observed continuous decrease in conductivity of our samples over a period of time. This effect is currently being examined as well as the effect of temperature and pressure on the conductivity of $L_{0.11}MoS_2$, and will be the subject of a future paper. The structural conversion of MoS_2 in $L_{0.11}MoS_2$ has also been probed by differential scanning calorimetry which shows a broad exothermic peak with a peak maximum at 200 °C. This is consistent with the structural transformation of MoS_2 from the O_h to the 2H form. The observed transition was found to be irreversible. restacked MoS_2 (*d*-spacing 6.15 Å) has been reported to show a similar transition at 100 °C.[18] It seems that an increase in *d*-spacing leads to an increase in the transition temperature and we are currently exploring this effect by using macrocycles of different sizes and with differing number and bulk of substituents. A detailed study of the steric effects of pendant-arm macrocycles on the properties of their MoS_2 intercalation compounds is currently underway. This work provides the first evidence that pendant-arm macrocycles are viable guests in intercalation compounds hosted by MoS_2, which may lead to materials with unique and useful properties.

We are grateful to the Natural Sciences and Engineering Research Council (NSERC) of Canada, and the UPEI Senate Committee on Research for financial support. Thanks go to Dr J. Dahn, Physics Department, Dalhousie University for the thermogravimetric measurements.

Tandem anionic Michael addition/radical cyclizations: a new and efficient strategy for the synthesis of functionalized cyclopentanes†

Ullrich Jahn

Received (in Cambridge, UK) 18th May 2001, Accepted 2nd July 2001
First published as an Advance Article on the web 1st August 2001

The combination of anionic Michael addition of lithium ester enolates with radical 5-*exo* cyclizations through SET oxidation gives highly functionalized cyclopentanes.

Radical reactions have developed into a valuable tool in organic synthesis. Especially radical cyclizations are widely used since one of their advantages is the versatility to design tandem processes.[1] However, this advantage is offset by tedious precursor preparation. Radical addition/cyclization sequences are conceptually attractive since the gain in complexity from simple precursors is high. However, this strategy suffers from drawbacks: 1) radical additions (Giese reactions) obey complex kinetics, requiring an excess of one precursor (often a α,β-unsaturated carbonyl compound).[2] This excess, however, may interfere with the following reaction steps in the tandem processes thus limiting overall efficiency. 2) The radical acceptor should be unsubstituted in the β-position to achieve useful addition rates.[2,3]

A promising alternative to radical addition/cyclization cascades should be one in which the addition step is performed on the anionic oxidation stage allowing better reactivity/selectivity control. An attractive approach is the anionic Michael addition[4] proceeding with stoichiometric amounts of reagents, but the resulting enolate is normally not able to undergo anionic cyclization to unpolar functionalities.[5] However, by oxidizing the adduct enolate, radical cyclizations may be induced.[6]

Here, efficient tandem Michael addition/radical cyclizations[7] are reported. Cyclopentane derivatives with up to five stereocenters can be created from simple precursors.

An initial study of the Michael addition revealed that (*Z*)-enolates **1a**–**e** generated by deprotonation of the ester with LDA–THF–HMPA underwent a useful *anti*-selective addition to Michael acceptors **2a**–**c** providing good yields of **3** [Scheme 1, dr > 6.6 : 1 except for **1e**/**2b** (4.6 : 1), see Table 2 in the ESI†]. Enolates (*E*)-**1a**,**d** (generated with LDA–THF) gave *syn*-**3** with a very moderate selectivity. Additions of **1** to **2a**,**b** provided **3** directly while those of **1** to **2c** formed the aldol adduct at −78 °C that rearranged to **3** on warming to 0 °C.[4a,b]

With these results in hand, the Michael addition/radical cyclizations were studied (Scheme 2, Table 1). Addition of **2a** or **2c** to (*Z*)-**1** in THF–HMPA at −78 °C followed by warming to 0 °C generated the enolates **4** that were treated with a thoroughly homogenized solid mixture of SET oxidant ferrocenium hexafluorophosphate **5**–TEMPO **6** as oxygenation/termination reagent at −40 °C (Scheme 2, Table 1). For 5-unsubstituted **1a** and **2a**,**c** oxygenated cyclopentane derivatives **7aa**‡ and **7ac** were formed with good to excellent diastereoselectivity (entries 1,2). 5-Monosubstituted **1b** gave an inseparable 1.6 : 1 diastereomeric mixture of **7ba**‡ and **8ba** in 87% yield with good control of the exocyclic stereocenter (entry 3). More bulky ester **1c** improved the cyclization diastereoselectivity **7ca**/**8ca** only slightly, but induced excellent diastereoselectivity at the exocyclic stereocenter (entry 4). Even a fifth stereocenter can be controlled with reasonable efficiency. Applying **1c** and **2c** provided 61% (75% based on **1c**) of a partly separable 13.5:3.3:1 mixture of **7cc**/**8cc**/**9cc** (entry 5). The *cis*/*trans*-cyclization diastereoselectivity for *anti*-**4** amounted to 4.1 : 1. Michael addition/radical cyclization of **1d**/**2a** gave a 2 : 1 diastereomeric mixture of **7da** and **8da** in good yield (entry 6).

The protected alcohol function in **7** can be regenerated by reductive N–O bond cleavage[6,8] as exemplified for **7aa** providing **11aa** in 63% yield (Scheme 3).

The sequences are not limited to TEMPO trapping of the cyclized radical (Scheme 4). If Michael donors **1d**,**e** were coupled with **2a,b** followed by addition of 2.5–3 equiv. of **5**, isopropenylcyclopentanes **12** were formed as the major products together with minor amounts of **13**–**18**. The sequence of methyl ester **1d**/**2a** in the absence of additives gave **12da** in 51% yield as a 3:1 diastereomeric mixture accompanied by **14da**–**16da**. Alcohol α-**15da** lactonized to **17da** during purification. The more bulky ester **1e** and addition of 3 equiv. of KO*t*Bu

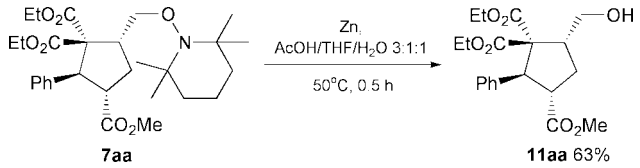
Table 1 Tandem Michael addition/radical cyclizations of **1**/**2**

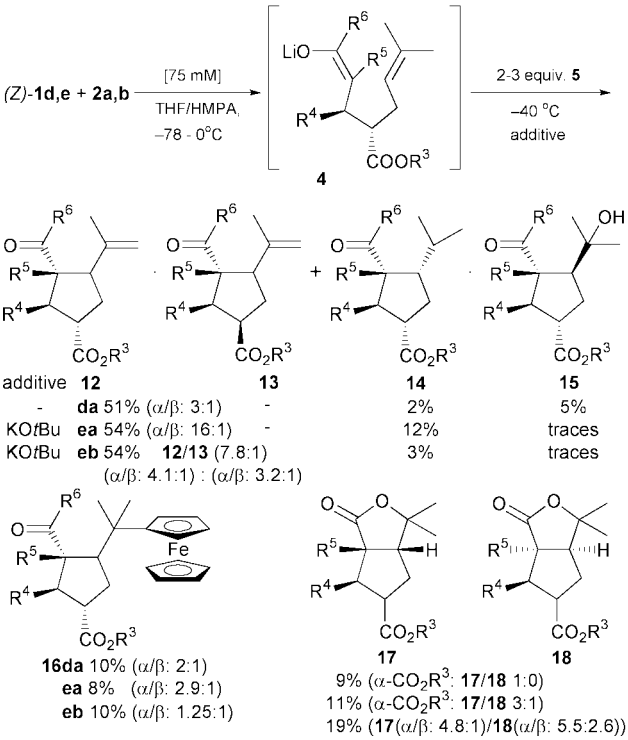
Entry	1	2	Yield (%) 7+8+9	dr: 7 : 8 : 9 7(βR¹:αR¹)[a]	8(αR¹:βR)[a]	9	10 (%)
1	**a**	**a**	71	100(−)	0	0	—
2	**a**	**c**	53[b]	7.5(−)	1(−)	0	25[c]
3	**b**	**a**	87	1.6(6:1)	1(>20:1)	0	—
4	**c**	**a**	86	2.3(22:1)	1(>20:1)	0	—
5	**c**	**c**	61(75)[d]	13.5(5.4:1)	3.3(2:1)	1	—
6	**d**	**a**	82	1.8(−)	1(−)	0	—

[a] Configuration at exocyclic stereocenter. [b] A cyclized dimer was also formed in 4.7% yield. [c] Mixture of four diastereomers (not assigned). [d] Yield in parentheses represents yield based on recovered **1c**.



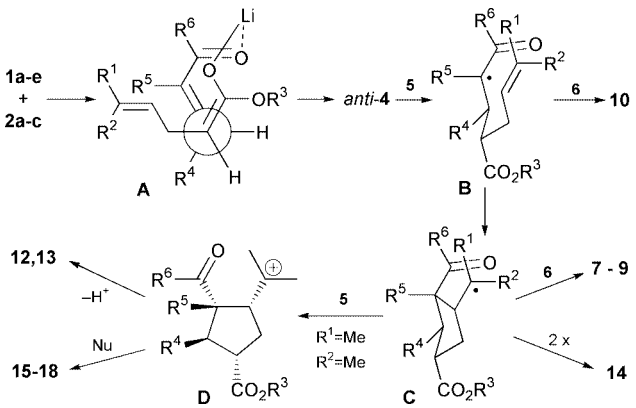
Scheme 3

improved the product distribution and the diastereoselectivity of the sequence to **12ea**. Some **14ea**, **16ea**, **17ea** and **18ea**, but almost no **15ea**, were formed. From ethylidenemalonate **2b** and **1e**, all four diastereomers of **12eb**/**13eb** were isolated in 54% yield in a 26:6:3:1 ratio due to the lower *anti*-selectivity of the Michael addition (4.6:1). Although not that interesting from the synthetic point of view, this example strengthened the configuration assignment to all products and indicated that *syn*-**4** may cyclize as efficiently as *anti*-**4**.



Scheme 4

The tandem processes can be rationalized by assuming a chelation controlled Michael addition step *via* **A** to *anti*-**4**[9] (Scheme 5). SET oxidation of **4** by **5** occurs predictably to radicals **B**. The cyclization diastereoselectivity to **C** can be explained by a preferred Beckwith–Houk chair transition state **B**[10] depending on the substitution pattern of the alkene in **1** followed by combination with TEMPO **6** to the major diastereomer **7**. TEMPO trapping of radical **B** does not play a significant role except for the **1a**/**2c** combination. Tertiary radicals **C** are predominately oxidized to carbenium ions **D**



Scheme 5

giving **12**(**13**) and **15**–**18** *via* deprotonation and nucleophilic trapping, respectively, while **14** and **16** may be formed from **C** *via* disproportionation or ligand transfer with ferrocenium/ferrocene, respectively.

In summary, it was shown that Michael addition/radical cyclization cascades are a convenient strategy to overcome limitations of purely radical or anionic addition/cyclization sequences. The results may have many implications for the design of heterointermediate strategies since other enolate generating reactions such as conjugate additions or anionic rearrangements can be envisaged to be coupled with radical reactions thus expanding the opportunities of organic synthesis.

I thank Deutsche Forschungsgemeinschaft and Dr Otto Röhm-Gedächtnisstiftung for generous financial support. Professor H. Hopf's support is gratefully acknowledged.

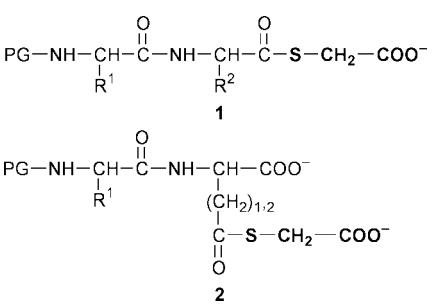
A biocatalytic route to the 'post-synthesis' formation of Asp/Glu-derived isopeptides is illustrated on the basis of the *Staphylococcus aureus* V8 protease used as the biocatalyst, a new type of substrate mimetics as the donor peptides, and several acceptor peptides varying in length and sequence.

The trifunctional structure of Asp and Glu allows both amino acids to be incorporated in the backbone of polypeptides by the side-chain and the C^{α}-carboxyl moiety as well. While the latter results in the formation of normal linear peptides, the involvement of the side-chain carboxyl group in the peptide backbone leads to the corresponding isopeptides. Isopeptides are ubiquitously found in nature and are considered to be one of the most common forms of non-enzymatic degradation of linear polypeptides under physiological conditions.[1] Rearrangement of normal peptides into isopeptides is catalysed by bases as well as acids, and starts with the formation of cyclic succinimide intermediates following dehydration. Re-opening of the ring finally leads to a mixture of normal peptides and isopeptides in a typical ratio that ranges from 40 : 60 to 15 : 85 along with small amounts of D-isopeptides.[2] Since isopeptide formation involves the addition of extra carbon atoms to the polypeptide backbone, its presence in a functional protein domain has profound effects on biological activity and its susceptibility to proteolytic degradation.[3] Recent findings have demonstrated that widespread accumulation of isopeptide linkages in cellular proteins greatly increases the immunogenicity and disrupts a wide range of important biochemical pathways by competitively displacing normal proteins in protein–protein or protein–ligand interactions.[4] Because of this function, isopeptides were found to be highly useful to study complex biological phenomena and for the development of therapeutic agents resulting in a great interest in their synthesis.

Although isopeptide bond formation is often an undesired side reaction during the chemical synthesis of normal linear peptides due to the need for strong bases and acids for deprotection steps and peptide release,[5] the directed synthesis of isopeptides is difficult and strictly limited by competitive cyclisation reactions. Like bases and acids, the use of coupling reagents to yield side-chain activation of Glu- and Asp-containing peptides further reinforces the formation of unwanted cyclic products and finally leads to a crude synthesis product with substantial amounts of undesired material. A few enzymes, *i.e.* protein carboxyl methyltransferases,[6] isopeptidases,[7] and transglutaminases,[8] are known to be active on the side-chain of Glu and Asp and, therefore, may be interesting biocatalysts for the synthesis of isopeptide bonds. However, due to the highly restricted substrate and reaction specificity, none of these enzymes is capable of catalysing the synthesis of isoAsp- or isoGlu-Xaa bonds. Therefore, the development of alternative catalytic and mild approaches to improve the current synthesis methods of isopeptides is a challenging task.

This account reports on the use of a normal peptidase, *i.e.* the Glu-specific endopeptidase from *Staphylococcus aureus* strain V8 (V8 protease), that acts as an efficient biocatalyst for the formation of isopeptides. The key feature of this approach is the use of a novel type of substrate mimetics that directs the synthesis activity of the protease to the side-chain carboxyl moiety of Asp and Glu (Scheme 1). Similar to classical substrate mimetics, the novel type donors bear a site-specific ester leaving group that mediates the acceptance of non-specific acyl moieties by the protease.[9] To direct the activity of the enzyme to the side-chain, the specific ester group, however, is linked to the ω-carboxyl moiety of Asp and Glu instead of being at the C-terminus of the peptide donor. This different architecture was shown to lead to a shift in the synthetic activity of the protease from the C^{α}-carboxyl group towards the side-chain moiety of the two amino acids finally resulting in the synthesis of isopeptides.

The general function of this biocatalytic approach was proved by the use of several Asp- and Glu-containing peptides that were esterified by carboxymethylthiol at their side-chain carboxylates. The carboxymethyl thioester functionality (SCm, *cf.* Scheme 1) itself was selected due to its function as a mimic which was already shown to mediate the acceptance of non-specific (non-Asp- and Glu-containing) linear donor peptides by V8 protease and other highly Glu-specific peptidases as well.[10] The influence of the length of the donor peptide on the synthesis reaction was investigated by using donor esters derived from single amino acids up to pentapeptides. Furthermore, the effect of the position of the Asp and Glu moieties within the donor peptide on the acceptance by the enzyme was studied by using peptides with either N-/C-terminal or endogenous Glu/Asp-residues. The resulting 14 peptide esters have served as donor components in V8 protease-catalysed isopeptide syntheses using amino acid amides, dipeptide amides, and



Scheme 1 General structures of classical linear (**1**) and new type (**2**) substrate mimetics. The site-specific carboxymethyl thioester group is emphasized by bold letters. PG, protecting group; R^1, R^2, individual side chains.

pentapeptides as the amino components. The reactions themselves were performed under identical conditions at pH and temperature optimal to the enzyme.[11] As a control for spontaneous hydrolysis and aminolysis of the peptide esters that may interfere with the enzymatic syntheses, parallel reactions without enzyme were analysed. On the basis of these control experiments, non-enzymatic aminolysis could be ruled out and the extent of spontaneous hydrolysis was found to be less than 5%. The results observed for the enzyme-catalysed syntheses are summarised in Table 1. Generally, the data document that all donor peptides show productive binding at the active site of the biocatalyst resulting in isopeptide bond formation. In contrast, model reactions using donor components lacking the specific ester moiety, *i.e.* Z-Glu(SMe)-OH and Z-Asp(SMe)-OH (SMe, methylthiol), gave no reaction. This finding indicates that the negative charge of the SCm-leaving group is essential to mediate the acceptance by V8 protease. Accordingly, the lack of this charge causes a complete loss of specificity that inevitably leads to a loss of synthesis activity of the enzyme. On analysis of the efficiency of syntheses, yields of isopeptide products within a range of about 40–70% were obtained that roughly correspond with those of comparable reactions using normal linear substrate mimetics.[10] Interestingly, apart from the formation of the respective hydrolysed donor peptides no further side products could be detected. Addressing the moderate variations in the yields, the Asp- and Glu-residue itself appears to affect the efficiency of synthesis to the highest extent. While the use of Z-Glu(SCm)-OH and Z-Asp(SCm)-OH led to practically the same yields, the chain elongation of the Asp ester either in the C- or N-terminal direction resulted in an increase in the product yields of around approximately 10–20%. This increase makes the Asp-containing peptides more efficient donor components than those derived from glutamic acid. Interestingly, the individual position of both the Asp and Glu residue within the donor peptide does not affect the course of isopeptide synthesis significantly. In the same way, there is only a minor influence of the length of the donor peptide on the reaction. Surprisingly, this also holds for the acceptor peptide as it is reflected by the similar product yields which are less affected by the sequence and the chain length of the respective peptide. This atypical behaviour is in contrast to reactions using classical linear substrate mimetics as the donor peptides that generally displayed a more pronounced influence of the acceptor peptide on the course of synthesis.[10] Accordingly, in particular, N-terminal Gly and Met residues usually led to a decrease in product yield; an effect that can not be found for the synthesis of isopeptides. The synthesis of glutathione (γ-glutamylcyteinylglycine) starting from Z-Glu(SCm)-OH and Cys-Gly, which proceeds with a yield of about 62%, gave a further hint to the small influence of the acceptor peptide on the efficiency of catalysis. From a synthetic point of view, this broad tolerance towards the sequence and chain length of both the acceptor and donor peptide should make the approach presented a rather general one for the synthesis of a wide variety of isoaspartyl- and isoglutamyl-containing peptides. Furthermore, due to the mild reaction conditions, the weak carboxyl activation, and abandoning the use of additional bases and acids, the risk of undesired cyclisation reactions is reduced to a minimum. The synthetic utility of the method is even not narrowed by proteolytic side reactions. Model syntheses with elongated reaction times up to several days do not gave any hints to an undesired cleavage activity of V8 protease towards the formed isoGlu- and isoAsp-bonds indicating an irreversible course of the enzymatic ligation reaction (data not shown). Only the presence of further Glu and Asp residues additional to those that are to be modified may lead to undesired peptide cleavages. In such cases, freezing of the reaction mixture, which was shown to repress the proteolytic activity of enzymes closely related to V8 protease while retaining their synthesis activity,[12] may represent an efficient resource. From a biocatalytic point of view, the approach presented broadens the scope of proteases in organic synthesis and opens up a new field of synthetic applications of these enzymes for the synthesis of isopeptides. Finally, because of the universal applicability of substrate mimetics it can be further expected that other proteases may also be useful biocatalysts for isopeptide synthesis. Studies in this direction are presently under investigation.

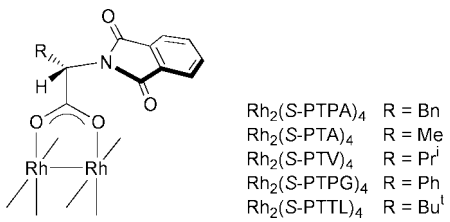
Received (in Cambridge, UK) 25th April 2001, Accepted 12th July 2001
First published as an Advance Article on the web 9th August 2001

A highly efficient one-pot construction of optically active 1,1′-spirobi[indan-3,3′-dione] derivative (up to 80% ee) has been achieved by exploiting the double intramolecular C–H insertion reaction of dimethyl 2,2′-methylenebis(α-diazo-β-oxobenzenepropanoate) under the influence of dirhodium (II) tetrakis[*N*-phthaloyl-(*R* or *S*)-*tert*-leucinate] as a catalyst.

The development of efficient chiral metal complexes in the field of asymmetric synthesis has focused mainly on the design and synthesis of novel chiral ligands. BINAP, BINOL and related ligands based on the axially chiral 1,1′-binaphthyl skeleton have achieved significant success in asymmetric catalysis.[1] In this context, certain bifunctional chiral spirans with C_2-symmetry may be regarded as promising ligands, as they contain a totally rigid spiro backbone which creates an effective asymmetric environment. Although chiral *cis*,*cis*-spiro[4.4]nonane-1,6-diol has recently shown potential either as a chiral ligand itself[2] or as a precursor to other useful chiral ligands,[3] the widespread application of this class of spiran ligands has received relatively little attention.[4] Clearly, a major obstacle is the difficulty in obtaining enantiomerically pure spiran molecules, which generally involves a tedious resolution of racemates *via* fractional crystallization[5] or chromatography[6] of the diastereomeric mixtures. Thus, the development of a catalytic asymmetric synthesis of C_2-symmetrical chiral spirans would represent significant improvement over current methodologies for obtaining these ligands.[7,8]

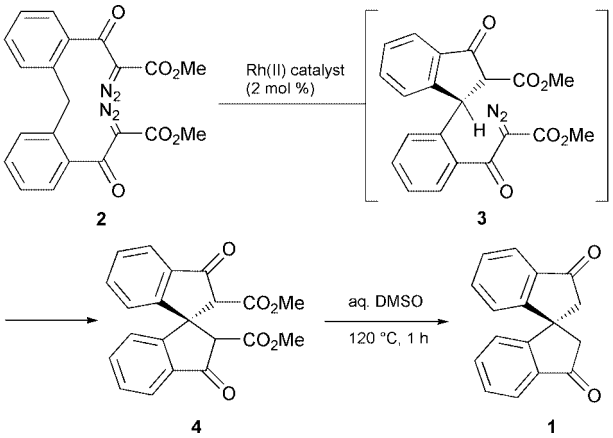
Recently, Aburel and Undheim reported a new synthetic approach to generate racemic spiro[4.4]nonane-2,7-dione derivatives from acyclic bis(α-diazoketone) using a $Rh_2(OAc)_4$-catalyzed double intramolecular C–H insertion reaction, though the product yields are found to be only 27–35%.[9] Inspired by their pioneering work, and taking advantage of our continuing research in this field,[10] we turned our attention to the feasibility of a high-yielding and enantioselective synthesis of C_2-symmetrical chiral 1,1′-spirobiindan systems. Herein we report



Rh_2(*S*-PTPA)$_4$ R = Bn
Rh_2(*S*-PTA)$_4$ R = Me
Rh_2(*S*-PTV)$_4$ R = Pr^i
Rh_2(*S*-PTPG)$_4$ R = Ph
Rh_2(*S*-PTTL)$_4$ R = Bu^t

a facile path to optically pure 1,1′-spirobi[indan-3,3′-dione] **1**,[5b] a potential intermediate in the synthesis of the hitherto unknown *cis*,*cis*-1,1′-spirobi[indan-2,2′-diol], *via* an enantioselective double intramolecular C–H insertion process with up to 80% ee.

At the outset of this work, we explored the double cyclization of bis(α-diazo-β-keto ester) **2** in the presence of 2 mol % of $Rh_2(OAc)_4$.† While the use of DCM as solvent gave a complex mixture of products, the catalysis of **2** in toluene was found to proceed sluggishly at rt to produce spirobiindanone derivative



4, which, without purification, was transformed by demethoxycarbonylation to give spirobiindanone **1**. As might be expected from the results of Undheim,[9] a product yield of only 29% was found. The use of $Rh_2(O_2CC_7H_{15})_4$, $Rh_2(O_2CCPh_3)_4$[12] or $Rh_2(O_2CC_3F_7)_4$ also resulted in low yields.‡ Thus, we were gratified to find that the reaction proceeded smoothly at 0 °C with the aid of chiral dirhodium(II) carboxylates, Rh_2(*S*-PTPA)$_4$, Rh_2(*S*-PTA)$_4$, Rh_2(*S*-PTV)$_4$, Rh_2(*S*-PTPG)$_4$, and Rh_2(*S*-PTTL)$_4$, derived from *N*-phthaloyl-(*S*)-phenylalanine, -alanine, -valine, -phenylglycine, and -*tert*-leucine, respectively,[10] to give synthetically useful product yields (Table 1). Although no explanation for the striking contrast between the achiral and chiral dirhodium(II) carboxylates can be offered at present, the advantage of our catalysts extends beyond stereocontrol in this system.§ While the formation of (*R*)-1,1′-spirobi[indan-3,3′-dione] (*R*)-**1** was favored in all cases, Rh_2(*S*-PTTL)$_4$ characterized by an exceptionally bulky *tert*-butyl group proved to be the catalyst of choice for displaying a reasonable degree of enantioselectivity (68% ee, entry 5).¶ Further screening of solvents confirmed that the use of toluene was the superior choice for allowing smooth insertion at −10 °C to provide (*R*)-**1** in 78% yield with 80% ee (entry 6), which, upon a single recrystallization from ethanol, produced the optically pure sample, mp 212–213 °C, $[\alpha]_D^{25}$ −237.0 (*c* 0.69, $CHCl_3$) [lit.,[5b] $[\alpha]_D^{24}$ +238.7 (*c* 0.64, $CHCl_3$) for (*S*)-**1**], in 67% yield. The use of Rh_2(*R*-PTTL)$_4$ also generated (*S*)-**1** with 79% ee (entry 7). Thus, both enantiomers of **1** are equally available. The use of DCM provided (*R*)-**1** with 60% ee (entry 8), however, 0 °C was found to be the temperature limit for allowing smooth cyclization. It is of particular interest that the use of benzotrifluoride (α,α,α-trifluorotoluene)[14] greatly accelerated the insertion rate, though the largest ee was found to be 72% at −23 °C (entry 9).

The stereochemical outcome observed here suggests that the chiral rhodium(II) carbene intermediate generated *via* Rh_2(*S*-PTTL)$_4$-catalyzed decomposition of **2** preferentially inserts into a methylene C–H*s* bond to give (3*S*)-indan-1-one derivative **3**, which undergoes a second C–H insertion at the methine C–H bond with well-established retention of configuration[15] to

[a] Reactions were carried out as follows: 2 mol % of catalyst was added to a stirred solution of diazo compound **2** (0.20 mmol) in the indicated solvent (2 ml) at the indicated temperature under argon. After the reaction proceeded to completion, the solvent was evaporated *in vacuo* and the residue was treated with 90% aqueous DMSO (1.5 ml) at 120 °C for 1 h. Standard workup followed by chromatography provided (*R*)-**1**. [b] Overall isolated yield. [c] Determined by HPLC (column, Daicel chiralcel OD; 4.6 × 250 mm × 2; eluent, 15% propan-2-ol in hexane; flow rate, 1.0 ml min^{-1}; retention time, 31.2 min [(*R*)-**1**] and 35.1 min [(*S*)-**1**]). [d] (*S*)-**1** was preferentially formed.

provide (*R*)-**1** after demethoxycarbonylation. Thus, the sense and magnitude of enantioselection indicates the level of differentiation between methylene C–H bonds during the first C–H insertion. In accordance with the order of reactivity of the target C–H bond (methine C–H > methylene C–H),[16] we could not observe the first insertion product **3**,[9] which makes it possible to conduct this one-pot reaction under the constant conditions.

In summary, we have achieved the first catalytic, enantioselective synthesis of 1,1′-spirobi[indan-3,3′-dione] (**1**) of up to 80% ee, in which the use of Rh_2(*R* or *S*-PTTL)$_4$ as a catalyst is crucial to the success of the double C–H insertion process. The present protocol has the advantages of operational simplicity as well as a facile entry to optically pure **1** *via* a single recrystallization, thus providing great potential for large-scale preparation. Elaboration of (*R*)- or (*S*)-**1** to hitherto unexplored chiral ligands such as 1,1′-spirobi[indan-2,2′-diol] for metal catalyzed enantioselective reactions is currently in progress.

This research was supported in part by a Grant-in-Aid (No.11470465) from the Ministry of Education, Science, Sports and Culture, Japan. We thank Ms S. Oka of the Center for Instrumental Analysis at Hokkaido University, for mass measurements.

Notes and references

† Bis(α-diazo-β-keto ester) **2** was prepared from diphenylmethane-2,2′-dicarboxylic acid[11] in 70% yield by the following three-step sequence: i, $SOCl_2$, toluene, reflux; ii, $LiCH_2CO_2Me$, THF, −78 °C; iii, MsN_3, Et_3N, MeCN.

‡ Overall isolated yield: $Rh_2(O_2CC_7H_{15})_4$, 28%; $Rh_2(O_2CCPh_3)_4$, 13%; $Rh_2(O_2CC_3F_7)_4$, 17%.

§ While reaction of the corresponding bis(α-diazoketone) with $Rh_2(OAc)_4$ in CH_2Cl_2 provided 52% yield of **1**, Rh_2(*S*-PTTL)$_4$ gave a complex mixture of products under the same conditions.

¶ Rh_2(*S*-DOSP)$_4$ developed by Davies[13] was found to be less reactive than our catalysts; catalysis of **2** with 2 mol % of Rh_2(*S*-DOSP)$_4$ in toluene proceeded at rt sluggishly to afford, after demethoxycarbonylation, (*S*)-**1** in 48% yield with 8.3% ee.

A tandem allylsilane–vinylsilane difunctionalization by silylcupration of allene followed by reaction with α,β-unsaturated nitriles

Asunción Barbero, Yolanda Blanco and Francisco J. Pulido*

First published as an Advance Article on the web 9th August 2001

Silylcupration of allene using phenyldimethylsilylcopper 1 followed by BF_3-mediated reaction with α,β-unsaturated nitriles at −40 °C affords allylsilane–vinylsilane-containing ketones resulting from consecutive addition (1,2 and 1,4) of the intermediate allyl- and vinylcopper species formed in the silylcupration of allene.

We recently reported[1–3] that addition of phenyldimethylsilylcopper ($PhMe_2SiCu{\cdot}LiCN$, **1**) to propa-1,2-diene leads to a silylated copper intermediate, which can be imprecisely formulated as a mixture of the allylsilane–vinylcopper species **2** and the vinylsilane–allylcopper species **3**. The reversibility of the reaction is one of its features. Quenching of the intermediate copper species with different electrophiles results in formation of compounds of type **4** or **5** (Scheme 1).

The reaction is temperature dependent and the presence of species **2** and **3** can be demonstrated by protonation of the reaction mixture at different temperatures. Thus, at −40 °C (or lower temperature) only formation of **4** (E = H) was observed, whereas **5** (E = H) was the major product obtained near to 0 °C.

In general, for most of the reported work[1] the reactive species at low temperature is **2**. Thus, at −40 °C, α,β-unsaturated ketones or aldehydes react with **2** giving exclusively 1,4-addition. However, at temperatures around −40 °C, simple ketones are unreactive toward species **2**, but they are readily attacked by **3** as the temperature increases to 0 °C, giving hydroxymethyls bearing the vinylsilane moiety.[1] In this case, conversion of species **2** into species **3** seems to occur rapidly as the temperature increases, which probably accounts for the observed result.

We now report an interesting and unusual tandem diaddition-hydrolysis process by successive addition (1,2 and 1,4) of species **3** and **2** to α,β-unsaturated nitriles. Protonation of the intermediate adduct, gives products that have both allylsilane and vinylsilane functionality.

Reaction of α,β-unsaturated nitriles with organocopper compounds has not been widely explored. Yamamoto[4] reported that the reaction of α,β-unsaturated nitriles with $RCu{\cdot}BF_3$ was not satisfactory; yields were low, and mixtures of monoalkylated and dialkylated products were obtained. Alexakis *et al.*[5] showed that introduction of an additive like TMSCl in the reaction of Me_2CuLi with some α,β-unsaturated nitriles gave the dialkylated ketone, whereas Lipshutz *et al.*[6] found that $Me_2CuCNLi_2$ slowly produced a poor yield of the methyl ketone resulting from 1,2 addition.

Silylcupration of allene (2 eq., following our usual protocol[1]) followed by addition of $BF_3{\cdot}Et_2O$ (2 equiv.) and subsequent slow addition of nitriles **6**–**9** (1 eq., THF, −40 to 0 °C) afforded, after hydrolysis at 0 °C, the ketones **10**–**13**, which seem to be produced by addition of the vinylsilane–allylcopper species **3** to the nitrile group and conjugate addition of the allylsilane–vinylcopper species **2** to the β position (Table 1).[7] The reaction (one pot) is clean and high yielding. Monoaddition products were not found. Remarkably, when this reaction is carried out with one equivalent each of allene and **1**, BF_3 and nitrile, the same diaddition products were formed, and almost half of the nitrile was wasted, which suggests that the second stage of the overall addition occurs quickly. It should be also noted that silylcupration of allene and further reaction with **8**, **9** (nitrile–organocopper; 1:2) at 0 °C, in the absence of BF_3, gives exclusively the 1,2-adducts **14** and **15** (Table 1).

The order in which the two steps (1,2 and 1,4) of addition take place and the mechanistic pathway are not certain. Weiberth and Hall[8] have proposed the intervention of Cu(III) intermediates in the copper-activated reaction of benzonitriles with Grignard reagents. Although we defer any definitive statement about the mechanism, it seems feasible—in view of the absence of 1,4-monoaddition products—that the reaction proceeds by initial addition of species **3** to the nitrile group followed by BF_3-catalyzed conjugate addition of species **2** to the intermediate α,β-unsaturated ketimine (Scheme 2). The chemoselectivity observed and the preference for the attack of **3** to the nitrile and of **2** to the conjugate position can be related to the different hardness of the nucleophilic species.

A completely different pattern of reaction is observed when the bulky *tert*-butyldiphenysilyl group is used instead of $PhMe_2Si$. Silylcupration of propa-1,2-diene with *tert*-$BuPh_2Si$-$Cu{\cdot}LiCN$[9] followed by addition of BF_3 and reaction with **6** and **8**—under the same conditions used before—affords selectively the 1,4-adducts **16** and **17** as the only products (Table 1). We have noted before[1] that species of type **2**, but carrying the bulky *tert*-butyldiphenysilyl group, are regiochemically stable at any temperature between −40 °C and 0 °C.

The one-pot tandem diaddition-hydrolysis process reported here could be of importance in synthetic work since the allylsilane and vinylsilane moieties are versatile synthons for organic synthesis. Thus, the diadducts undergo selective intramolecular allylsilane terminated cyclization,[1] while the vinylsilane unit remains unchanged, as shown in Scheme 3 with the conversion of **10**–**12** into **18**–**20**.

In summary, silylated organocopper reagents, like those used in this work, react well with α,β-unsaturated nitriles, giving

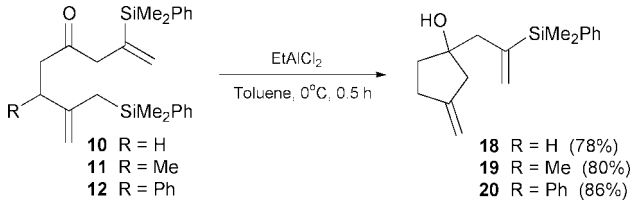

Scheme 3

1,2-adducts, 1,4-adducts or diaddition adducts, depending on the reaction conditions and on the nature of the silyl group.† We are not totally clear why we succeeded where others did not, but most probably it is connected with the nature of the equilibrium mixture of species and with the fact that a Lewis acid (BF_3)-activated organocopper is used. The effects of Lewis acid on cuprates have been examined recently, and they show that a strong chemoselectivity enhancement is frequently observed when Lewis acid-modified organocopper reagents are used.[10]

7 *Typical procedure*: a solution of 6 mmol of $PhMe_2SiCu{\cdot}LiCN$ (see ref. 1) in THF (16 ml) was cooled to −40 °C and a slight excess of propa-1,2-diene was added from a balloon. The mixture was stirred for 1 h at this temperature, then $BF_3{\cdot}Et_2O$ (6 mmol) was added at −40 °C and the solution stirred for an additional period of 10 min. The nitrile (3 mmol) in THF (3 ml) was slowly dropped in at −49 °C, and the resulting mixture stirred at this temperature for 1 h. The reaction mixture was left to warm to 0 °C and was quenched with saturated ammonium chloride solution. Purification by flash-chromatography gave the ketones **10**–**13** (Table 1).

Alizarin Red S. as a general optical reporter for studying the binding of boronic acids with carbohydrates

Greg Springsteen and Binghe Wang*

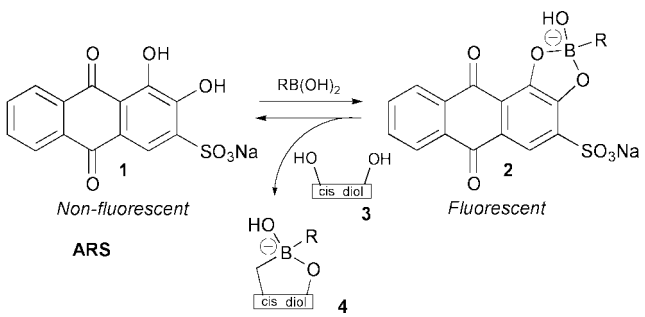
Department of Chemistry, North Carolina State University, Raleigh, NC 27695-8204, USA. E-mail: binghe-wang@ncsu.edu

Received (in Cambridge, UK) 4th June 2001, Accepted 16th July 2001
First published as an Advance Article on the web 9th August 2001

Alizarin Red S. displays a dramatic change in fluorescence intensity and color in response to the binding of a boronic acid and can be used as a general reporter for studying carbohydrate–boronic acid interactions, both quantitatively and qualitatively.

Boronic acids are known to bind diol moieties with high affinities through reversible boronate formation.[1] Consequently, boronic acid compounds have been widely used for the synthesis of artificial receptors for sugars with great success.[2–4] In addition, boronic acid compounds have been used for the development of protease inhibitors and other biologically important agents.[5,6] However, the examination of the binding of boronic acids to the target compounds is often difficult. Detection of boronate ester formation can sometimes be achieved by appending a fluorophore directly to the boronic acid.[4,7] In cases without a readily detectable and sensitive signal associated with the binding events, nuclear magnetic resonance, circular dichroism, and pH titration have been used for the examination of the binding.[1,8] In our research, we are interested in the design and synthesis of boronic acid compounds with highly selective affinities for saccharides,[9] especially certain cell surface carbohydrates. In such studies, the incorporation of fluorophores onto the boronic acid could greatly affect the binding affinity of the artificial receptor for the target sugar in a negative fashion, and could significantly increase the difficulty of the synthesis. Non-fluorescent assays using NMR and absorbance techniques often lack the desired sensitivity. Therefore, we wish to develop a general fluorescence assay method that allows us to monitor the binding of an unmodified boronic acid compound with its target carbohydrate.

Conceivably, the binding between boronic acids and their target carbohydrates can be monitored with the inclusion of a separate reporter fluorophore whose fluorescence is sensitive to the binding event. This type of fluorescence assay system requires two competing equilibria (Scheme 1). The first equilibrium, between the boronic acid and a fluorescent reporter compound (**1**), will be directly measured. To this end, we have worked on the synthesis of sensors that detect free boronic acids.[10] Alizarin Red S. (ARS) (**1**, Scheme 1) has been used as a reagent for the fluorimetric determination of boric acid concentrations.[11] Although the mechanism of the fluorescence increase was not elucidated, it is known that the active protons of hydroxyanthraquinones are responsible for a large fluorescence quenching.[12] Conceivably, binding of a boronic acid to the catechol diol of ARS would remove the active protons and, therefore, abolish the fluorescence quenching (**2**, Scheme 1). The addition of a carbohydrate (**3**) sets up a second equilibrium between the boronic acid and the diol moiety of the carbohydrate to give complex (**4**). This perturbs the reporter–boronic acid equilibrium, resulting in a change in fluorescence intensity. The fluorescence intensity changes in a three-component system can be used for the determination of binding constants using well-known literature procedures.[3,13,14]



Scheme 1 Competitive binding of a boronic acid with Alizarin Red S. and a *cis*-diol.

To test the feasibility of this assay method, we first examined the effect of added boronic acid on the spectroscopic and fluorescence properties of ARS in aqueous solution at physiological pH. ARS shows a color change, from deep red to yellow, and an increase in fluorescence intensity by 20–80 fold in the presence of a wide variety of arylboronic acids in aqueous solution at pH 7.4 (data not shown). All of the boronic/boric acids tested induced significant fluorescence increases, indicating the general applicability of this method. It should also be noted that ARS has reasonable water solubility, up to 10^{-3} M, which makes it a good candidate as a reporter compound in an aqueous assay.

In order to determine the applicability of using ARS for the determination of the binding between a boronic acid and a carbohydrate in a three-component system, we used fructose as a model compound. D-Fructose is known to bind to phenylboronic acid (PBA) with high affinity.[1] When D-fructose was added to the mixture of PBA and ARS, significant fluorescence intensity changes were observed. Titrating fructose into an aqueous solution of 10^{-4} M ARS and 10^{-3} M PBA caused an eight-fold drop in fluorescence intensity (at 100 mM), and a measurable change down to the 100 μM level (Fig. 1). The fructose–PBA complex forms immediately upon mixing, and can also be monitored by UV absorption and a corresponding change in solution color from yellow to red (Fig. 2).

The ARS system also allows the quantitative determination of association constants (K_a) of diol–boronic acid complexes.

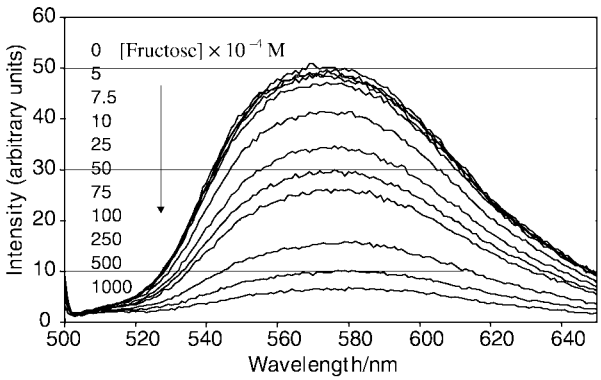


Fig. 1 Titration of fructose into a solution of ARS (10^{-4} M) and PBA (10^{-3} M). Fluorescence decreases with added fructose (0 through 0.1 M), aqueous 0.1 M phosphate buffer, pH 7.4, Exc. λ = 495 nm.

 DOI: 10.1039/b104895n

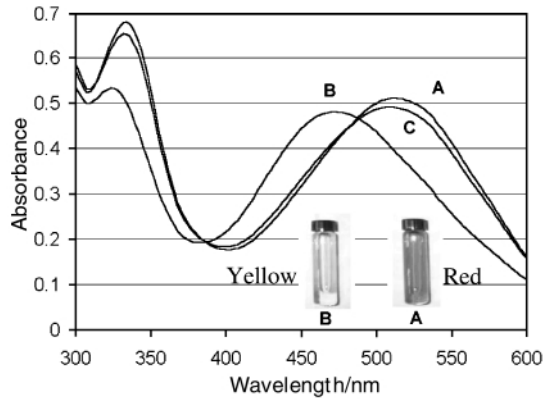

Fig. 2 A, Absorbance of ARS at 10^{-4} M in pH 7.4, 0.1 M phosphate buffer. B, ARS at 10^{-4} M with PBA at 10^{-3} M. C, Alizarin Red S. at 10^{-4} M with PBA at 10^{-3} M and fructose at 10^{-1} M.

Monitoring the fluorescence of ARS at different concentrations of boronic acid allows the calculation of the K_a of the boronic acid–ARS complex by the Benesi–Hildebrand method.[15] The boronic acid–diol association constant can then be measured in a separate titration with all three components using well-established literature procedures.[14] Using the ARS system, we have determined the binding constant between PBA and sialic acid (K_a, 21; pH 7.4 in 0.1 M phosphate buffer), one of the carbohydrates that we are interested in making a specific sensor for because of its important roles in biological systems.

In order to gain a greater understanding of the causes of the fluorescence change, the pH profile of the PBA–ARS complex was studied (Fig. 3). The profile shows that the largest response to PBA is centered on pH 7. The shape of the profile is likely a result of both the stability of the ARS–PBA complex, and the intrinsic fluorescence of the three ionic forms of ARS (pK_a = 5.3 and 10.9 by UV titration). It is well known that boronate ester complexes have decreased stability under acidic conditions.[16] This results in a high concentration of the quenched, free form of the dye at low pH (< 5). At medium pH (5–9), the boronate ester becomes stable, and therefore the quenching

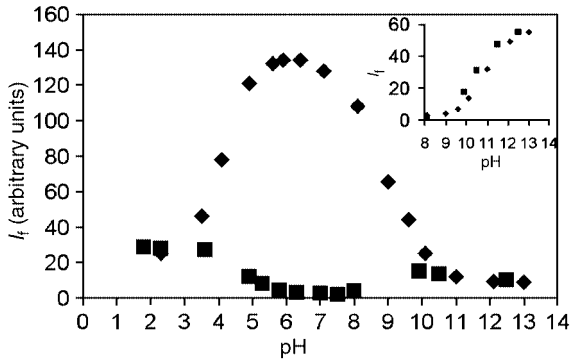

Fig. 3 (■)–pH titration of the fluorescence intensity (I_f) of ARS (10^{-4} M). (◆)–ARS (10^{-4} M) in the presence of PBA (10^{-2} M). Em. λ = 565 nm, Exc., λ = 495 nm, 0.1 M phosphate buffer. Inset–Em. λ = 633 nm, Exc. λ = 600 nm.

active protons are removed from the system. Association constants determined using the Benesi–Hildebrand method support this view (K_a = 190 at pH 4.6, and 1100 at pH 7.4). At high pH, there is also a considerable drop-off in the stability of the ester (K_a = 274 at pH 9.1). Although the uncomplexed dianion form has no active protons, there is a shift in fluorescence to longer wavelength (Fig. 3 inset), resulting in a sharp decrease in intensity at the shorter excitation and emission wavelengths (Fig. 3). Methylation of the 2′-hydroxyl of ARS causes an increase in the intrinsic fluorescence of the molecule, but removes virtually all response to phenylboronic acid at neutral pH (data not shown).

The absorption shift to lower wavelength upon complexation with phenylboronic acid (Fig. 2) is likely due to a decreased electron density on the ARS oxygens caused by the electron deficient boron. Acetyl and benzoyl substitution on hydroxy-anthraquinones results in similar shifts.[17]

ARS can be used as a general fluorescent reporter for studying the binding events between boronic acids and carbohydrates. It needs to be emphasized that there is no intrinsic specificity to the ARS system, and this is vital for its application as a general fluorescent reporter. There are many examples in the literature of boronic acids designed to specifically bind a particular analyte.[18,19] The ARS system will allow researchers a general and sensitive method to study the binding events of any boronic acid–diol interaction both quantitatively and qualitatively. This will aid in the further development of carbohydrate sensors and other biologically important boronic acid compounds.

Financial support by the National Institutes of Health (DK55062 and CA88343) is gratefully acknowledged.

Received (in Cambridge, UK) 16th May 2001, Accepted 13th July 2001
First published as an Advance Article on the web 9th August 2001

The electrochemical properties of the title compound reveal electronic interactions between two dicobalt–dicarbon clusters *via* a 1,12-*para*-carborane cage.

Conjugated molecular and polymeric compounds with delocalised π-electron frameworks and rigid-rod geometries are a source of immense contemporary interest, with potential for application in the construction of photonic and molecular electronic devices.[1] The unusual electronic properties of *closo*-carborane cages, which display three-dimensional aromaticity,[2] and the abilities of *para*-carboranes to form rod-like structures have raised considerable interest in the synthesis of novel conjugated materials that contain this motif.[3–7] The capacity for polyhedral transition metal clusters to act as 'electron sinks', accepting or releasing electrons in response to the demands of the environment (*i.e.* an electrode) or pendant groups, suggests molecular assemblies which feature these moieties may be of use in molecular electronics applications.[8]

However, compounds which feature both carborane and transition metal clusters are rare,[9] and the transmission of electronic effects between these different types of polyhedra has not yet been demonstrated. We have taken advantage of the availability of 1,12-bis(trimethylsilylethynyl)-*para*-carborane **1**[10] and the redox properties of Co_2(alkyne) complexes[11,12] to demonstrate, using electrochemical methods, the capacity for the 12-vertex *para*-carborane fragment to transmit electronic information between two transition metal clusters. Aryl, alkynyl and ferrocenyl based spacing groups have already been shown to permit such interactions between cobalt-containing tetrahedral clusters.[12]

The reaction of **1** with $[Co_2(CO)_6(dppm)]$[13] in refluxing benzene afforded a dark red solution from which the novel tricluster compound **2** was isolated as the major product (60 mg, 40%) by preparative TLC and crystallisation (CH_2Cl_2–MeOH) (Scheme 1). The composition of the complex was established from the spectroscopic data,† and confirmed by X-ray analysis.‡ The structure (Fig. 1) clearly shows the *para*-C_2B_{10} icosahedron and the two Co_2C_2 tetrahedra, which are related by a crystallographic inversion centre at the centre of the carborane cage. The carborane cage in **2** is the most spherical example of a *para*-carborane structurally characterised to date, with a cage C···C separation of 3.176 Å and an average tropical B–B bond length of 1.776 Å. This contrasts sharply with the distorted cage geometry found in 1,12-bis(ethynyl)-*para*-carborane [C···C 3.104(2) Å, tropical B–B 1.793(3) Å].[10] These variations in the geometry of the carborane cage are probably a consequence of the different interactions between the carborane C_{sp} atom and the carbon centre of the pendant ethynyl group [C_{sp}, C–C 1.451(2) Å] or cobalt cluster [**2**, C_{sp^3}, C(1)–C(2) 1.497(2) Å]. The parameters associated with the cobalt(alkyne) cluster cores fall in the range established for aryl substituted clusters.[14] While the description of carborane clusters as analogues of benzene is not intended to be literal, we note here that the C(1)–C(2) bond in **2** is longer than the C(aryl)–C(cluster) separations in conjugated $Co_2(\mu\text{-}\eta^2\text{-}RC_2C_6H_4\text{-}X\text{-}p)(CO)_4(dppm)$ systems [1.458(3)–1.463(3) Å],[14] due to the high coordination number of the carborane cage carbon atoms.

The Co_2C_2 tetrahedral cluster core offers a filled a_2-type fragment orbital suitable for interaction with π-systems of adjacent groups bonded at a carbon vertex of the tetrahedron.[15] The carbon atoms of the carborane cage offer tangential fragment orbitals with considerable p-character suitable for such an interaction.[16] Of course, good orbital overlap requires matching of fragment orbital energy as well as symmetry. The concept of a degree of π-bonding between the cobalt/carbon and boron/carbon cluster cores in the neutral tricluster **2** is supported, although by no means proven, by the geometry adopted by the complex in the solid state. Semi-empirical MO calculations (LANL2MB)[17] revealed the frontier orbitals (HOMO and LUMO) of **2** to be largely centred on the cobalt clusters.

The cyclic voltammogram of complex **2** revealed both oxidation and reduction processes which were better resolved using semi-derivative[18] and square wave voltammetry (SWV) (Fig. 2). Digital simulation of the CV and SWV responses was employed to confirm the four redox potentials [+0.87, +0.77, −1.58, −1.66 V (*vs.* decamethylferrocene, Fc*/Fc*$^+$ 0.084 V); ΔE^0(ox) *ca.* 105 mV, $K_C = e^{\Delta E^\circ F/RT} = 60$; ΔE^0(red) *ca.* 80

 DOI: 10.1039/b104307m

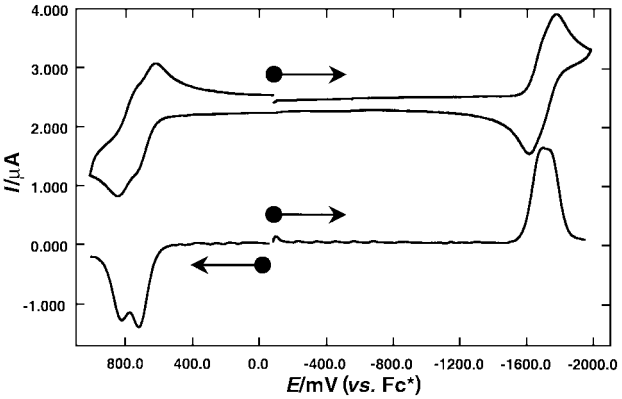

Fig. 2 Cyclic voltammogram (upper trace) and corresponding semi-derivative voltammogram of a THF solution of **2** (0.5 mM), containing 0.1 M $[NBu_4]PF_6$ as supporting electrolyte, at 0.2 V s^{-1}. Data obtained at 298 K, glassy carbon working electrode *vs.* SCE reference electrode.

mV, K_C = 5].[19] No redox processes were found within the accessible potential window when **1** was subjected to a similar electrochemical study. For comparison, the phenyl-bridged complex $[\{Co_2C_2(H)(CO)_4(dppm)\}_2(\mu\text{-}1,4\text{-}C_6H_4)]$ gave also gave two oxidation and reduction processes with ΔE^0(ox) 110 mV, ΔE^0(red) 80 mV.[12c]

The splitting of redox waves associated with otherwise chemically identical redox sites contained within a single molecular unit is often cited as evidence of electronic interaction (or communication) between these sites.[11,12,20] These interactions may be transmitted between the bonding framework or through-space.[21] While ion-pairing effects may be expected to play a role in the magnitude of the coulombic interaction between remote intramolecular sites, a through-space interaction should affect both oxidation and reduction processes more or less equally. In the present example, the difference in oxidation potentials observed is significantly large, especially given the > 6 Å separation of the cobalt cluster cores, and is indicative of a moderate degree of extended electronic communication between the cobalt clusters in the radical cation $\mathbf{2}^{\cdot+}$. The separation of the reduction events is somewhat smaller, but is still larger than the statistical limit (*ca.* 36 mV at 298 K) predicted for non-interacting redox centres.[20] The voltammetric studies reported here therefore suggest that the unpaired electron in both the radical cation $\mathbf{2}^{\cdot+}$ and the radical anion $\mathbf{2}^{\cdot-}$ is delocalised through the bonding framework. These studies clearly indicate that the bonding framework of the *para*-carborane cage can offer an efficient conduit for electronic effects, and may participate in π-type delocalised bonding with substituents in the 1 and 12 positions. Further studies on the scope of these interactions and a thorough molecular orbital description of assemblies derived from *para*-carboranes, including $\mathbf{2}^{\cdot+}$ and $\mathbf{2}^{\cdot-}$ are in progress.

First published as an Advance Article on the web 9th August 2001

Treatment of α-naphthyl acrylate with both aliphatic and aromatic aldehydes in the presence of DABCO (30 mol%) afforded the desired (α-methylene-β-hydroxy)esters with reasonable chemical yields (51–88%) within 20 min.

Increasing interest has been focused on the coupling of an aldehyde with acrylate in the presence of DABCO (Baylis–Hillman reaction).[1] The resulting (α-methylene-β-hydroxy)-esters are versatile intermediates that allow for further functional group manipulation. One of the major drawbacks of this transformation is the poor reaction rates which limits the range of substrates that are tolerated.[2] Many aromatic aldehydes and branched aliphatic aldehydes are reluctant to serve as substrates. It is not surprisingly that numerous methods including physical as well as chemical attempts have been made to increase the reaction rate.[3] Modest increases in rates have been obtained under modified reaction conditions. No practical methods have been developed so far. We wish to report here that an extremely rapid rate can be achieved using α-naphthyl acrylate as the Michael acceptor for the Baylis–Hillman reaction.

A plausible mechanism for the Baylis–Hillman reaction is proposed and the addition of ammonium enolate with an aldehyde is believed to be the rate-determining step.[4] Stabilization of the enolate species would shift the equilibrium forward and therefore to accelerate the rates. The use of Lewis acid to catalyze this transformation is a common strategy. The use of lanthanides and group III metal triflates to accelerate the Baylis–Hillman reaction have been studied.[3e–g] However structural variants of acrylates for this transformation have not been studied systematically.[5] This promoted us to screen a range of substituted acrylates **1a**–**g** as Michael acceptor. The substituted acrylates may provide stereo- and/or stereoelectronic effects to stabilize the oxy anion intermediate and subsequently accelerate the following aldol reaction. To test this hypothesis various acrylates **1a**–**g** with diverse steric, geometric and electronic properties were prepared and benzaldehyde was used as a probe electrophile (Table 1). Reaction of methyl acrylate (1.0 equiv.) with benzaldehyde (1.0 equiv.) in CH_3CN in the presence of DABCO (50 mol%) at room temperature gave the corresponding product **2a** in 62% yield for 48 h (entry 1). The use of *tert*-butyl acrylate affords a similar result (entry 2). The use of phenyl acrylate **1c** gave the desired product **2c** with 86% yield in 2 h (entry 3). Treatment of benzyl acrylate with benzaldehyde under the same reaction conditions provided **2d** with 80% yield in 15 h (entry 4). The desired product **2e** was isolated in 34% yield when the commercial available 1,1,1,3,3,3-hexafluoroisopropyl acrylate[6] **1e** was used (entry 5). The use of β-naphthyl acrylate **1f** gave **2f** with 70% yield in 5 h (entry 6). A significant rate acceleration was observed when α-naphthyl acrylate **1g** was employed. Thus, treatment of **1g** with benzaldehyde in the presence of DABCO affords the desired product with 88% yield in 20 min (entry 7). The unexpected rate acceleration using α-naphthyl acrylate for the Baylis–Hillman reaction is amazing and was studied in more detail.

To further determine the feasibility of this system, various aldehydes were then studied using α-naphthyl acrylate under the optimum conditions and the results are tabulated in Table 2. Thus, treatment of **1g** with acetaldehyde affords **3a** with 70% yield at room temperature in 20 min (entry 1). Similar results were observed with different chain aldehydes (entries 2–4). The reaction was slightly less effective when α-branched aldehyde was used (entry 5). *trans*-Cinnamaldehyde was employed to give the desired product with 60% yield in 20 min (entry 6). Next, substituted aromatic aldehydes were subjected to the same reaction conditions. Reaction of *p*-nitrobenzaldehyde and *p*-fluorobenzaldehyde with **1g** under the same conditions

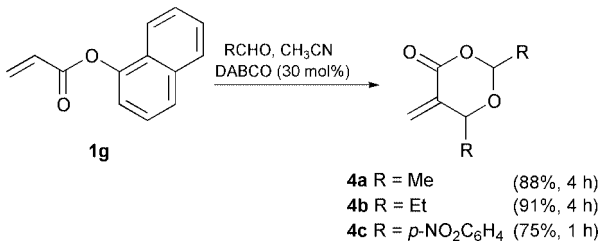
12	3-Pyridyl	20	72

[a] All reactions were conducted using 1:1 molar ratio of acrylate and aldehyde in CH_3CN at room temperature. The amounts of DABCO used was reduced to 30 mol% to minimize the formation of the cyclic acetates **4**. [b] Isolated yield.

 DOI: 10.1039/b103644k



Scheme 1 The synthesis of 1,3-dioxan-4-ones **4a**–**c**.

provide the desired products with 82 and 65% yield, respectively (entries 7 and 8). Although the use of *p*-methylbenzaldehyde gave a similar result, the use of *p*-methoxybenzaldehyde requires 96 h to obtain comparable yield (entries 9 and 11). This may be due to the relatively strong electron donating ability of the methoxy group that deaccelerates the reaction rate. The detailed mechanistic speculation is premature at this stage and work is underway to study this phenomenon in more detail.

The reaction of various aldehydes with α-naphthyl acrylate **1g** was very fast as mentioned above. In addition to the conventional Baylis–Hillman products isolated, small quantities (3–10%) of cyclic acetates were identified dependent upon the substrates used. The minor product may come from the addition of the initial product with the unreacted aldehyde followed by elimination of α-naphthol anion.[5] The cyclic acetal products are of great synthetic interest.[7] The preparation of various 1,3-dioxan-4-ones under several different reaction systems have been reported.[3k,5,6] In this study, the use of excess amounts of aldehydes (4.0 equiv.) under prolonged reaction time gave 1,3-dioxan-4-ones **4a**–**c** with good to high chemical yields (Scheme 1).

In summary, we have developed an efficient method for the synthesis of highly functionalized acrylates. Reaction of α-naphthyl acrylate **1g** with both aliphatic and aromatic aldehydes in the presence of DABCO (30 mol%) provided the corresponding α-methylene β-hydroxy carbonyl derivatives with reasonable material yields within 20 min. *This represents, to the best of our knowledge, one of the best rate acceleration systems for wide ranges of aldehydes in Baylis–Hillman reactions under atmospheric pressure*. The pronounced acceleration of this reaction further extends the Baylis–Hillman reaction into a viable transformation. The asymmetric version of the Baylis–Hillman reaction using this reaction system is underway in our laboratory.

We thank the National Science Council (NSC) for financial support of this work.

Positive and negative photopatterning of metal oxides on silicon *via* bipolar electrochemical deposition†

Hee Cheul Choi and Jillian M. Buriak*

Department of Chemistry, 1393 Brown Laboratories, Purdue University, West Lafayette, IN 47907-1393, USA. E-mail: buriak@purdue.edu

Received (in Cambridge, UK) 24th May 2001, Accepted 13th July 2001
First published as an Advance Article on the web 9th August 2001

Negative and positive microscale patterning of metal oxides is efficiently and rapidly carried out on flat Si(100) surfaces *via* a simple white light assisted bipolar electrochemical process.

The importance of transparent or semi-transparent thin films of high band gap metal oxide semiconductors is rapidly increasing due to a wide range of applications,[1] such as inexpensive photovoltaic cells,[2,3] electrochromic smart windows,[4] ultrafast color displays,[5] and as a base material for room temperature dilute magnetic oxides (DMO).[6] Various techniques such as simple sol–gel preparation followed by dip or spin coating,[7] radio frequency magnetron sputtering,[8] chemical vapor deposition,[9] or laser ablation[10] have been used for many years to prepare metal oxide thin films. Electrochemical deposition has, however, been the focus of much recent interest due its comparable simplicity of required apparatus, and the possibility for either kinetic or thermodynamic control of products *via* galvanostatic or potentiostatic modes.[11] Since Switzer introduced an electrosynthetic technique for preparation of metal oxides in 1987,[12] there have been many reports outlining electrochemical deposition of different metal oxides on various types of conducting substrates.[11] Generally, metal oxide deposition can be accomplished by either anodic or cathodic bias, depending on the desired oxide.[11,13–17] Patterning of metal oxide thin films is central to their application in technological devices to allow for spatial definition.[18] Here we describe a general white light promoted electrochemical metal oxide photopatterning procedure on n- or p-type Si(100) that allows, in a very straightforward and efficient manner, both negative and positive masking, as shown in Fig. 1.

A number of electrochemical deposition parameters were systematically varied to determine the requirements for positive and negative pattern formation on Si(100) substrates, as summarized in Table 1. In addition, the influence of different procedures on the metal oxide structures was determined by X-ray diffraction (XRD) and scanning electron microscopy (SEM). The first four processes, 1P–4P, are illuminated through a grid mask with white light, and the second four, processes 1–4, do not involve photopatterning and are used as reference samples. Only processes 3P and 4P lead to positive and negative photopatterning, depending upon the doping of the silicon. Processes 1P and 2P, on the other hand, lead to homogeneous deposition of metal oxides across the entire face of the exposed silicon surface. Fig. 2 shows the results of positive and negative photopatterning experiments formed *via* process 3P with zinc nitrate on n-type (left) and p-type (right) silicon substrates as visualized by optical microscopy (similar patterns of CeO_2 and Cr_2O_3 are shown in the ESI†). The dark areas in Fig. 2 are underivatized Si, and the light areas the metal oxide, as determined by XRD (*vide infra*). The metal oxides deposit in the shaded region when the substrate is n-type Si, and exclusively in the illuminated area on p-type Si. Process 4P, involving *in situ* heating and elimination of the secondary sintering step, yields similar results and indicates that metal oxides can be successfully patterned regardless of the heating process. Earlier work has shown that in the case of metal oxides

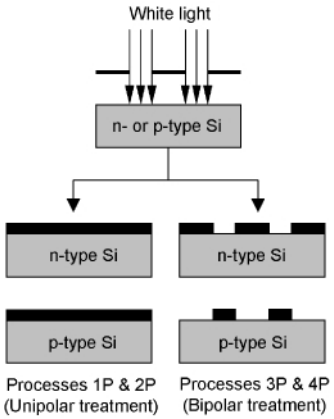

Fig. 1 Schematic view of electrochemical patterning of ZnO on Si(100) substrates with white light illumination through a photomask. Positive and negative patterning can be achieved through bipolar electrochemical treatment.

Table 1 Outline of the 8 different metal oxide deposition approaches for synthesis of ZnO, CeO_2 and Cr_2O_3 on Si(100). Processes 1–4 do not involve patterning, while processes 1P–4P differ only in that they are patterned *via* simultaneous white light illumination with a photomask

Method	Treatment
Photopatterning of metal oxides on Si	
Process 1P	Unipolar (cathodic) → *ex situ* sintering at 350 °C
Process 2P	Unipolar (cathodic) → *in situ* heating at 60 °C
Process 3P	Bipolar (anodic followed by cathodic) → *ex situ* sintering at 350 °C
Process 4P	Bipolar (anodic followed by cathodic) → *in situ* heating at 60 °C
Non-photopatterned deposition of metal oxides on Si	
Process 1	Unipolar (cathodic) → *ex situ* sintering at 350 °C
Process 2	Unipolar (cathodic) → *in situ* heating at 60 °C
Process 3	Bipolar (anodic followed by cathodic) → *ex situ* sintering at 350 °C
Process 4	Bipolar (anodic followed by cathodic) → *in situ* heating at 60 °C

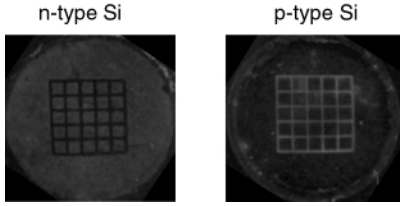

Fig. 2 Optical micrographs of the patterned ZnO films on n- and p-type Si. The diameter of the circular area is 1.0 cm. The light areas correspond to the metal oxide deposits while the dark areas correspond to underivatized Si surfaces.

 DOI: 10.1039/b104586p

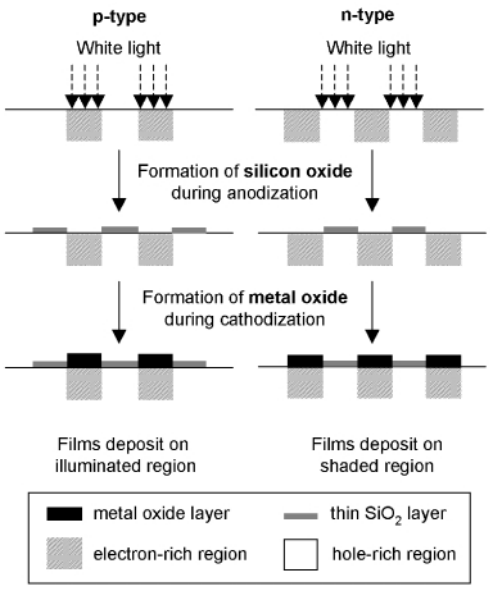

Fig. 3 Schematic illustration of the effect of light illumination, allowing selective photopatterning of various metal oxides on n- and p-type silicon, outlining the importance of doping type. Illumination coupled with application of an anodic bias induces holes to localize in the illuminated areas for n-type Si, and in the shaded areas for p-type Si. Therefore, silicon oxide formation occurs in positive and negative areas, relative to the photomask. The insulating characteristics of the SiO_2 layer prevent metal oxide deposition during the subsequent cathodic step.

which can be formed *via* anodic oxidation on silicon (Tl_2O_3 for example), photopatterning occurs only in the illluminated area of n-type silicon.[14] The bipolar electrochemical deposition approach therefore demonstrates excellent and unique selectivity for both negative and positive photopatterning of different metal oxides on silicon substrates.

While unipolar cathodic metal oxide deposition with either *ex situ* sintering[19] or *in situ* heating[15] is known in the literature, bipolar deposition, on the other hand, is not. Processes 1–4 were examined to prepare large areas of metal oxide for characterization, and to ensure that the same material is produced under photopatterning conditions (processes 1P–4P). XRD experiments reveal that the ZnO film deposited by cathodic unipolar treatment (processes 1 and 2), with or without illumination, is of a wurtzite crystal structure (JCPDS table 35–1451).[20] The XRD patterns of ZnO deposited through processes 3 and 4 on n-type Si are identical to processes 1 and 2, also of a wurtzite structure, and little difference in the crystal structure between *in situ* (process 3) and *ex situ* heating (process 4) is noted. The XRD spectra of the photopatterned metal oxides indicate that the crystal structures formed under these conditions (processes 3P and 4P) are the same as processes 1–4, and thus the photopatterning process does not have a major influence on the nature of the metal oxide. The details of XRD studies of all the metal oxides studied here are included in the ESI†. SEM studies revealed that a porous granular thin film is formed *via* all of these electrodeposition procedures ESI†. The mechanism for cathodic metal oxide formation is most likely nitrate reduction, forming OH^- which precipitates the metal hydroxide/oxide.[15]

The bipolar electrochemical deposition technique that leads to patterning requires application of a short period of anodic current to the silicon surface (+ 5 mA cm^{-2}) for 5 s, prior to cathodization (−5 mA cm^{-2}) for 5 min. As a control experiment, the silicon surface (both n- and p-type) was illuminated through a photomask during application of a cathodic current for 5 min, without the preceding short anodic pulse. Under these conditions, only homogeneous deposition of metal oxides occurs over the entire substrate surface; no patterning is observed, confirming the importance of the short anodic pretreatment for patterning ZnO, CeO_2 and Cr_2O_3. Another control experiment involved cathodic treatment after light illumination on n- or p-type Si in the deposition solution for 10–60 s without any applied current. Again, only a homogeneous thin film was achieved, as observed under cathodic unipolar treatment. These results clearly show that the deposition of metal oxides and their patterning is not controlled by the generation of excess holes during the electrochemical metal oxide deposition process.

On the n-type Si electrode, hole migration under positive bias to the illuminated area takes place, leading to patterned silicon oxide formation which requires holes at the surface; the holes are provided by electron tunneling from the valence band to the conduction band. Therefore, the applied current will flow preferentially through the illuminated areas, giving rise to selective silicon oxide growth in these regions. The silicon oxide formed is expected to act as an electronic barrier. Thus, upon application of cathodic current, metal oxide deposition will take place only in the dark areas because the SiO_2 layer blocks current in the illuminated regions, as shown schematically in Fig. 3. On the p-type Si electrode, on the other hand, holes are the majority charge carriers and thus charge separation upon the illumination is not expected at a low bias of +5 mA cm^{-2}, *i.e.* the whole area should be oxidized. In this case, however, the onset of the photocurrent may be at a more positive potential than the breakdown potential of the bulk silicon band gap (electron tunneling from the valence band to the conduction band at the surface), leading to metal oxide deposition only in the illuminated areas. Further investigation is presently being performed in order to elucidate these mechanisms more clearly.

The effect of the primary structure of the polypeptide catalyst on the enantioselectivity of the Juliá–Colonna asymmetric epoxidation of enones

Paul A. Bentley,[a] Robert W. Flood,[a] Stanley M. Roberts,*[a] John Skidmore,[a] Corina B. Smith[a] and John A. Smith[b]

Received (in Cambridge, UK) 10th May 2001, Accepted 13th July 2001
First published as an Advance Article on the web 1st August 2001

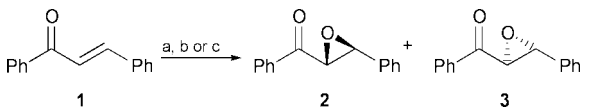
Epoxidation of chalcone (1), using basic hydrogen peroxide, catalysed by polypeptides with defined primary structures demonstrates that the residues in the chain near to the *N*-terminus determine the stereochemical outcome of the reaction.

In recent years there has been an increase in the application of peptides as catalysts for asymmetric reactions.[1] One of the first reported examples was the asymmetric epoxidation of chalcones, catalysed by polyamino acids in a triphasic system, discovered and developed by Juliá and Colonna.[2] Advances in this field have been made through the introduction of biphasic protocols, leading to an expansion in the range of enones which can be epoxidised with good stereoselectivity.[3] These methodologies have been successfully applied to reach various synthetic targets.[4]

For such synthetic work, the preferred catalyst is polyleucine prepared by the polymerisation of leucine *N*-carboxyanhydride (Leu-NCA), in an organic solvent, using a nucleophilic initiator (typically 1,3-diaminopropane or cross-linked aminomethyl polystyrene).[5] This polymerisation generates a mixture of oligomers with a distribution of chain lengths. Epoxidation of chalcone (**1**) using a catalyst prepared from L-Leu-NCA (15 equivalents compared to the initiator) at the start of the process followed by D-Leu-NCA (5 equivalents) provided the first indication that the *N*-terminal region of the chain has a disproportionately large influence on the stereochemical outcome of the reaction.[6]

In order to investigate more thoroughly the influence of the primary structure of a given polypeptide on its activity as an epoxidation catalyst, selected oligoleucines were prepared using an automated peptide synthesiser. It was shown that H-(L-Leu)$_{20}$-R† catalyses the epoxidation of chalcone (**1**), to afford the (2*R*, 3*S*)-epoxide **2**, in a similar manner to the NCA-derived polymer having an *average* chain length of twenty residues.[7] A peptide was then prepared in which the five *N*-terminal L-Leu residues were replaced by D-Leu: H-(D-Leu)$_5$-(L-Leu)$_{15}$-R. This material catalysed the epoxidation of chalcone (**1**) to give the antipodal (2*S*, 3*R*)-epoxide **3** with 85% conversion and 45% ee after 32 hours under the Juliá–Colonna triphasic conditions (Scheme 1).[8] In this last catalyst, the D-Leu residues make up only 25% of the total polyamino acid, however they dictate the stereochemical outcome of the reaction.

In this paper the use of other polypeptides as epoxidation catalysts is reported, in order to investigate in detail which residues in the *N*-terminal region are responsible for determining the origin of the stereocontrol exhibited by these catalysts.



Scheme 1 *Reagents and conditions*: (a) aq. NaOH, aq. H_2O_2, catalyst, toluene; (b) DBU, urea–H_2O_2, catalyst, THF; (c) $Na_2CO_3{\cdot}1.5H_2O_2$, catalyst, DME, water.

First, in order to determine whether the terminal amine group plays a defining role in the action of the peptide catalyst, three derivatives of H-(L-Leu)$_{20}$-R were prepared. In the first, one of the terminal amine hydrogens was substituted by an acetyl group [Ac-(L-Leu)$_{20}$-R]. The second oligomer had the same hydrogen replaced by a methyl group [Me-(L-Leu)$_{20}$-R] while the third had both amine hydrogens replaced by methyl groups [Me$_2$-(L-Leu)$_{20}$-R].‡ The peptides were tested as catalysts for the epoxidation of chalcone (**1**) under mild reaction conditions in order to minimise the possible cleavage of the sterically unhindered acetyl moiety (Table 1). The biphasic conditions[3a] utilise urea–H_2O_2 and DBU in THF, whilst the percarbonate conditions[3b] employ sodium percarbonate as both base and oxidant, in a DME–water solvent mixture.

Table 1 Epoxidation of chalcone (**1**) using selected catalysts

Catalyst[a]	Conditions[b]	Time/h	Conversion[c] (%)	Ee[d] (%)
H-(L-Leu)$_{20}$-R	Percarbonate	7	94	88
Ac-(L-Leu)$_{20}$-R	Percarbonate	5	96	50
Me-(L-Leu)$_{20}$-R	Percarbonate	5	98	67
Me$_2$-(L-Leu)$_{20}$-R	Percarbonate	6	82	58
H-(L-Leu)$_{20}$-R	Biphasic	1.07	100	92
Me$_2$-(L-Leu)$_{20}$-R	Biphasic	1.5	78	78

[a] For the reactions under the biphasic conditions the catalyst was activated before use by stirring with toluene–aq. NaOH for 18 h, filtered and then washed with water, acetone and hexane. [b] Ref. 3. [c] Determined by HPLC. [d] Determined by chiral HPLC.

All three polymers gave significant enantioselectivities (50–78% ee). The polymer Ac-(L-Leu)$_{20}$-R gave the lowest ee but clearly this modification (which markedly reduces the basicity and nucleophilicity of the terminal nitrogen atom) does not render the catalyst wholly inactive. This result is in agreement with the observation by Ohkata[9] that a 20-mer of L-Leu, protected at the amino-terminus with a Boc group and at the carboxylate end as a benzyl ester, when used as an epoxidation catalyst, affords chalcone epoxide **2** in 41% ee.

Next, a series of five peptides, H-(L-Leu)$_n$-(D-Leu)$_5$-(L-Leu)$_{15-n}$-R where n = 1–5 was prepared (these are referred to as *n*L/5D/(15 − *n*)L). These peptides were used to catalyse the epoxidation of chalcone (**1**) under the triphasic conditions[2] and the results are summarised in Table 2. On using the peptide L/5D/14L as a catalyst, the major product was epoxide **3** (*i.e.* that normally generated under poly-D-leucine catalysis), with an ee somewhat greater than that observed for the 5D/15L polymer.[8] In contrast, utilisation of the polymer 2L/5D/13L led to a sharp drop in the ee of the product; however the major enantiomer was still the epoxide **3**. Moving the block of five D-Leu residues one step further away from the amino terminus had another dramatic effect on the outcome of the epoxidation. Thus the 3L/5D/12L catalyst provided the epoxide **2** (normally generated using the

 DOI: 10.1039/b104123c

Table 2 Epoxidation of chalcone (**1**) using mixed D- and L-Leu catalysts under triphasic[a] conditions over 32 h

Catalyst	Major product	Conversion[b] (%)	Ee[c] (%)
1L/5D/14L	**3**	99	67
2L/5D/13L	**3**	96	11
3L/5D/12L	**2**	100	89
4L/5D/11L	**2**	99	86
5L/5D/10L	**2**	99	88

[a] Ref. 2. [b] Determined by HPLC. [c] Determined by chiral HPLC.

poly-L-leucine catalyst) in 89% ee; the oligomers 4L/5D/11L and 5L/5D/10L gave very similar results. From this study it appears that the penultimate and antepenultimate residues from the *N*-terminus play a dominant role in determining the stereoselectivity of the Juliá–Colonna reaction.

We reasoned that, given the above results, the inclusion of glycine residues close to the *N*-terminus might have a significant effect on the catalytic activity of the peptide. Three catalysts H-(L-Leu)-Gly-(L-Leu)$_{18}$-R, H-(L-Leu)-Gly$_2$-(L-Leu)$_{17}$-R and H-(L-Leu)-Gly$_3$-(L-Leu)$_{17}$-R were prepared. Inclusion of three glycine residues reduces the ee of the epoxide **2** significantly; the effect of incorporating two glycine residues is more modest and the substitution of Gly for L-Leu in the penultimate position has relatively little effect, when compared to the polymer containing only L-Leu residues (Table 3). Interestingly, incorporation of the glycine residues results in a reduced conversion to the epoxide as well as diminishing the enantioselectivity.

Table 3 Epoxidation of chalcone (**1**) using selected catalysts under triphasic[a] conditions over 24 h

Catalyst	Conversion[b] (%)	Ee[c] (%)
H-(L-Leu)$_{20}$-R	97	88
H-(L-Leu)-Gly-(L-Leu)$_{18}$-R	90	70
H-(L-Leu)-Gly$_2$-(L-Leu)$_{17}$-R	79	52
H-(L-Leu)-Gly$_3$-(L-Leu)$_{17}$-R	60	29

[a] Ref. 2. [b] Determined by HPLC. [c] Determined by chiral HPLC, in each case epoxide **2** was the major enantiomer.

Finally, on the evidence that the residues close to the amino terminus of the polypeptide chain have the primary influence on the stereochemistry of the oxidation reaction, the peptides H-(L-Leu)$_n$-(D-Leu- L-Leu)$_8$-R, where n = 3–6, were prepared. These have an equal mixture of the two enantiomers of leucine in the bulk of the peptide chain and a different number of residues of the L-enantiomer at the amino terminus.

Table 4 shows that the polymers with five or six consecutive L-Leu residues at the amino terminus are excellent catalysts. Surprisingly, even the polymer with just three L-Leu residues at the amino terminus generates **2** with significant ee. It is noteworthy that this polymer has only one change (D- to L-Leu) from a polymer with residues of alternating stereochemistry, adding a little more weight to the postulate that polyamino acids could potentially have been prebiotic catalysts,[10] in as much as these results show that even a small excess of one enantiomer in an oligomeric structure, when correctly assembled, can lead to an amplification and a diversification of chirality.

Overall, it appears that the enone substrate and/or the peroxide reagent binds to the polyleucine near the *N*-terminus. It may well be pertinent that the final four N–H groups of an α-helical peptide are not able to act as hydrogen bond donors to carbonyl groups within the helix, thus providing a possible explanation for the differentiation between the terminal region and the bulk of the peptide. Kinetics and spectroscopy experiments are being undertaken (using PEG-bound polyamino acids that are soluble in organic solvents[11]) to ascertain which species is complexed to the chiral environment of the polymer. Such experimentation seems prudent before more detailed modelling can commence.

Table 4 Epoxidation of chalcone (**1**) using selected catalysts under triphasic[a] conditions over 18 h

Catalyst	Conversion[b] (%)	Ee[c] (%)
H-(L-Leu)$_3$-(D-Leu-L -Leu)$_8$-R	55	64
H-(L-Leu)$_4$-(D-Leu-L -Leu)$_8$-R	52	64
H-(L-Leu)$_5$-(D-Leu-L -Leu)$_8$-R	95	92
H-(L-Leu)$_6$-(D-Leu-L -Leu)$_8$-R	98	91

[a] Ref. 2. [b] Determined by HPLC. [c] Determined by chiral HPLC, in each case epoxide **2** was the major enantiomer.

A novel precipitating auxiliary approach to the purification of Baylis–Hillman adducts†

Todd Bosanac and Craig S. Wilcox*

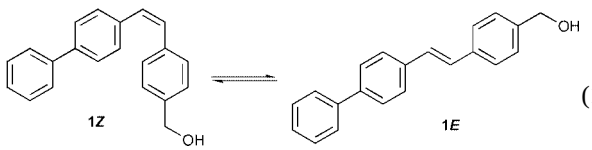
Department of Chemistry and The Combinatorial Chemistry Center, University of Pittsburgh, Pittsburgh, PA 15260, USA. E-mail: daylite@pitt.edu

Received (in Cambridge, UK) 3rd May 2001, Accepted 27th June 2001
First published as an Advance Article on the web 9th August 2001

Diaryl alkene alcohol 1 is a 'precipiton', a precipitating auxiliary that is used to aid the isolation of Baylis–Hillman adducts.

There is a need for new methods of product isolation which rely on simple purification procedures, eliminate the need for distillation or chromatography, and can be easily automated and used for parallel chemical syntheses.[1] While solid-phase organic synthesis (SPOS) remains the most popular method, there are several disadvantages associated with SPOS: the supports can be expensive; loading capacities can be low (0.1–1.0 mmol g^{-1}); solid-phase reactions often require extensive optimization of reaction conditions; and monitoring of reaction progress is difficult. To address the shortcomings of SPOS, molecules can be attached to 'phase-tags'. Fluorous synthesis,[2] soluble polymer-supported organic synthesis (SPSOS),[3] dendrimer-supported organic synthesis,[4] and acid/base tags[5] are examples of this approach. With these methods, tagged compounds can be easily separated from untagged compounds by a phase-transfer event (precipitation or liquid–liquid partition).

We recently introduced an approach to product isolation based on a solubility switch activated by structural isomerization.[6] Diaryl alcohol **1** is a 'precipiton', a group of atoms



(1)

(molecular fragment) that is purposefully attached to a reactant molecule and that can be activated {in this case isomerized [equilibrium (1)]} after the reaction in order to cause precipitation of the attached product. Our method has been applied to the synthesis and isolation of isoxazolines[6] and α-substituted β-ketoesters.[7] In this communication, we describe the precipiton approach for the synthesis of pure Baylis–Hillman adducts.

The Baylis–Hillman reaction[8] is a C–C bond forming reaction between an activated alkene and an aldehyde in the presence of a tertiary amine, tertiary phosphine, or chalcogenide.[9] This reaction provides useful multifunctional intermediates that can be used for subsequent transformations. One of the drawbacks associated with the Baylis–Hillman reaction is that one of the components must be used in an excess to drive the reaction to completion.[10] This often leads to a need to use chromatography to separate the desired product from the excess reactant. In order to avoid chromatography we sought to use our methodology to isolate pure Baylis–Hillman adducts.

Alcohol **1*Z*** was prepared as previously described from 4-biphenylcarbaldehyde and *p*-bromobenzyl alcohol *via* a Negishi coupling.[7] Acrylate **2*Z*** was then readily prepared by treatment of **1*Z*** with acryloyl chloride in the presence of NEt_3.[6]

† Electronic supplementary information (ESI) available: full experimental details. See http://www.rsc.org/suppdata/cc/b1/b103969p/

The precipiton Baylis–Hillman reactions were performed on a 0.52 to 2.43 mmol scale with respect to the acrylate. The acrylate **2*Z*** was treated with a catalytic amount of DABCO and an excess of aldehyde at room temperature.[11] Upon completion of the reaction (depending upon the nature of the aldehyde, reactions were complete in 1 to 10 days) the crude mixture was diluted with a suitable solvent and treated with I_2 and dibenzoyl peroxide or PhSSPh.[12] The isomerization process was monitored by ^{1}H NMR (isomerizations were complete in 4–24 h). Upon completion of the isomerization event, the crude reaction mixture was diluted with $CHCl_3$. Aqueous work-up with bisulfite, followed by evaporation of the organic layer, gave a crude product, that was then purified simply by trituration with hexanes, ether, or MeOH, followed by filtration. This protocol afforded Baylis–Hillman adducts in good yields and with purities of ≥95% (Table 1).[13]

The precipiton-bound products were cleaved from the precipiton by hydrolysis (LiOH in THF–H_2O).[14] These reactions were performed on a 22 to 188 μmol scale. The acids were isolated by filtration of the insoluble precipiton, acidification of the solution, followed by extraction with EtOAc. Removal of the EtOAc furnished the desired acids in good yields and with purities of ≥95% (Table 2).[13] Several other conditions,

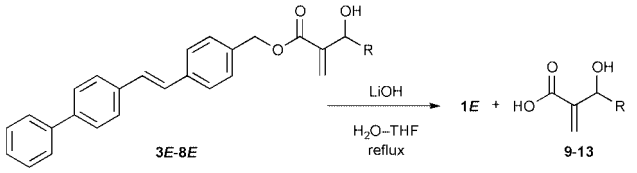
Table 2 Hydrolytic removal of product from the precipiton



Entry	Starting material	R	Product	Yield (%)
1	**3*E***		9	72
2	**4*E***		10	74
3	**5*E***		11	85
4	**6*E***		12	83
5	**7*E***		13	72

methanolysis and the Weinreib aminolysis, were examined for cleavage of the precipiton but were found ineffective. The acid derived from compound **8*E*** is a zwitterionic compound which could not be conveniently isolated.

These experiments demonstrate an application of the precipiton approach to product isolation. This method does not require chromatography, which is often a necessity in the Baylis–Hillman reaction. This process can be automated and has been successfully applied to very small scale reactions. It therefore may be found useful for preparing small quantities of pure compound for biological screening. We expect the method will be equally useful for large-scale preparations of compounds.

Attenuation of Hofmeister bias in ion-pair extraction by a disulfonamide anion host used in strikingly effective synergistic combination with a calix-crown Cs^+ host

Konstantinos Kavallieratos† and Bruce A. Moyer*

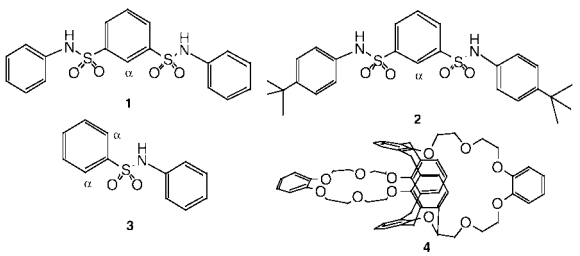
Chemical Separations Group, Chemical and Analytical Sciences Division, Oak Ridge National Laboratory, Bldg. 4500S/MS-6119, P.O. Box 2008, Oak Ridge, TN 37831-6119 USA. E-mail: moyerba@ornl.gov

Received (in Columbia, MO, USA) 11th February 2001, Accepted 13th July 2001
First published as an Advance Article on the web 9th August 2001

A calix-crown/disulfonamide dual-host combination in 1,2-dichloroethane exhibits markedly enhanced ion-pair extraction of caesium salts, with the observed synergism following an anti-Hofmeister order.

Ion-pair recognition and extraction by synthetic hosts is an area of intense interest. Design of early prototype ion receptors has mainly focused on cation complexation, the co-extracted anion selectivity being determined by non-specific solvation effects. Consequently, salt extractability generally increases in the direction of larger, more charge-diffuse anions, consistent with the well-known Hofmeister selectivity.[1] Hence arises the question as to the extent to which one may perturb this bias-type *vs*. recognition-type of selectivity.[2] This question has gained particular relevance in connection with the need to separate radiocaesium from nuclear waste,[3] where recent attention has been focusing on certain calix-crowns.[4] Although elegant heteroditopic hosts which are able to complex both the anion and the Cs cation have been reported,[5] the use of dual-host systems remains rare, despite their apparent simplicity and versatility.[6,7] We recently demonstrated that simple carboxamides enhance extraction of the $CsNO_3$ ion pair *via* binding of the co-extracted anion, when used together with a crown-ether cation host.[6a,b] These encouraging results prompted us to examine the question of anion selectivity in such systems.[6c] Herein, we report that synergism in the dual-host system involving disulfonamides **1** or **2** as anion hosts,[8] and the Cs^+ selective calix-crown **4** as cation host[4b] is strongly biased toward small anions, with remarkably uniform dependence on the standard Gibbs energies of partitioning for the anions OAc^-, Cl^-, Br^-, I^-, NO_3^- and ClO_4^-. In addition, this particular dual-host system is shown to be strikingly effective, generating the largest synergistic effects yet observed.

The anion-binding properties of disulfonamide **1**, the di(*tert*-butyl) disulfonamide **2**, and the monosulfonamide **3** (Scheme 1) were initially investigated in 1,2-dichloroethane-d_4 by ^{1}H NMR titrations of receptor solutions with ^{n}Bu$_4$NX salts (X = Cl^-, Br^-, I^-, OAc^-, NO_3^-, ClO_4^-). The observed large downfield chemical shift changes for the sulfonamide N–H protons, as well as for the α-C–H protons (Scheme 1) were analyzed *via* non-linear regression methods.[8a,9,10] The results confirm the observations of Crabtree and coworkers indicating a predominant 1:1 complex formation in CD_2Cl_2 for all anions plus a weaker 1:2 complexation mode for OAc^-, Cl^-, Br^- and NO_3^-.[8a] The association constants (Table 1) are generally higher for the more charge-dense Cl^- and OAc^- and much smaller for the large and more hydrophobic, NO_3^-, ClO_4^- and I^-. This general order is what one would expect for a strong non-specific hydrogen-bond receptor.[2,8a] It follows that synergistic enhancements on combining **1** or **2** with a cation receptor should also follow this general order.



Scheme 1 Ion receptors used in this study.

Table 1 Association constants K (M^{-1}) for the formation of 1:1 and 1:2 complexes of **1**, **2** and **3** with anions in 1,2-dichloroethane-d_4 at 295 K. Tetrabutylammonium salts were used as anion sources

Anion X^-		**1**	**2**	**3**
OAc^-	K_{11}	19 500 (± 1400)	13 500 (± 400)	750 (± 80)
	K_{12}	73 (± 1)	70 (± 1)	
Cl^-	K_{11}	50 000 (± 4000)	32 500 (± 2000)	410 (± 9)
	K_{12}	5.8 (± 0.2)	3.6 (± 0.1)	
Br^-	K_{11}	10 600 (± 500)	8 900 (± 600)	150 (± 5)
	K_{12}	1.7 (± 0.7)	1.2 (± 0.3)	
NO_3^-	K_{11}	4 300 (± 100)	1 800 (± 20)	55 (± 5)
	K_{12}	2 (± 0.2)	1.2 (± 0.7)	
I^-	K_{11}	1 400 (± 13)	690 (± 27)	19 (± 2.5)
ClO_4^-	K_{11}	81 (± 1)	48 (± 1)	< 3

The ^{137}Cs tracer distribution experiments were performed by methodology described earlier,[4b] using aqueous phases containing 0.10 M NaX (inextractable)[11] and 5×10^{-6} M CsX (X = Cl^-, Br^-, I^-, OAc^-, NO_3^-, ClO_4^-) and organic phases containing 0.010 M of calix[4]arene-bis(benzo-18-crown-6) **4** with 0.035 M of **1**, **2** or **3**. Based on previous results[4b] and ion-pairing theory,[12] these experimental conditions are expected to minimize ion-pairing and its role in anion selectivity. In particular, at the low maximum concentration of CsX that could be extracted, estimated ion-pairing in the organic phase would at most be 5%. Control experiments were also performed with organic phases containing (1) no sulfonamide, (2) no crown ether, and (3) solvent only. The results summarized in Table 2

Table 2 Caesium distribution ratios for calixarene **4** only (D_4) and for calixarene **4** plus sulfonamides **1**–**3** (D_{4+R}, R = **1**–**3**). Last column shows the synergistic factors observed for **1**, expressed as the ratio D_{4+1}/D_4[a]

Anion	D_4	D_{4+1}	D_{4+2}	D_{4+3}	D_{4+1}/D_4
OAc^-	0.471	291	62.3	1.45	618
Cl^-	0.357	42.2	11.8	0.88	118
Br^-	2.64	125	48.5	6.32	47.3
NO_3^-	8.44	180	73.0	17.0	21.3
I^-	77.6	644	284	113	8.3
ClO_4^-	850	1770	1070	1020	2.1

[a] D_1 is negligible in relation to D_4.

 DOI: 10.1039/b102152b

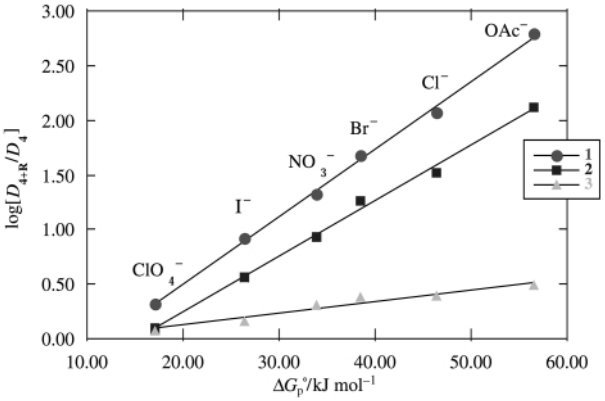

Fig. 1 Plot of the logarithm of the synergistic factor (D_{4+R}/D_4) for sulfonamides (**R** = **1**–**3**) *vs*. the standard Gibbs energy of partitioning $\Delta G°_p$ for various anions.

and Fig. 1 show that receptors **1** and **2** dramatically enhance Cs^+ ion extraction by the calix-crown. The synergism is stronger for the more charge-dense OAc^- and Cl^-, and weaker for the more hydrophobic I^- and ClO_4^-, as expected by the corresponding anion-receptor binding affinities. It is noteworthy that the extraction selectivity is higher for OAc^-, while K_{11} is higher for Cl^-, possibly reflecting a contribution of 1:2 complexation or anion-hydration effects.[13] For NO_3^- the observed synergism is in good agreement with data previously obtained using tetrabenzo-24-crown-8 as a cation receptor.[13] This observation implies weak if any ion-pairing effects and no significant role of the nature of the cation hosts.

One of the remarkable and unexpected aspects of this system is the excellent correlation between the synergistic effect and the standard Gibbs energy of anion partitioning $\Delta G_p°$.[11,14] Plotting the logarithm of the synergistic factor *vs*. $\Delta G_p°$ gave straight lines (Fig. 1) with a higher slope for the stronger anion receptor **1**. This correlation reveals that, whereas the bidentate nature of the disulfonamide receptor confers a strong interaction, the extraction enhancement is remarkably non-specific in breaking the simple bias-type dependence on anion size. Since the magnitude of enhancement reflects the strength of anion complexation in the organic phase,[7a,b] the strict correlation with $\Delta G_p°$ suggests that the anion receptor functions by non-specific solvation in a manner fundamentally resembling the partitioning process.

In conclusion, a potent disulfonamide anion receptor strongly synergizes the extraction of Cs salts when used together with a calix-crown cation host. The synergistic effects, as well as the anion binding affinities, are anti-Hofmeister, and thus these compounds and derivatives represent a new, valuable tool for tuning selectivity for anions in ion-pair extraction.

We thank Drs Jeffrey C. Bryan and Richard A. Sachleben for useful discussions. This research was sponsored by the Division of Chemical Sciences, Geosciences, and Biosciences, Office of Basic Energy Sciences, U.S. Department of Energy under contract DEAC0500OR22725 with Oak Ridge National Laboratory, managed and operated by UT-Battelle, LLC. The participation of K. K. was made possible through a appointment to the U.S. Department of Energy Postgraduate Research Program, administered by Oak Ridge Associated Universities.

Selective recovery of solutes from ionic liquids by pervaporation—a novel approach for purification and green processing

Thomas Schäfer, Carla M. Rodrigues, Carlos A. M. Afonso and João G. Crespo*

Department of Chemistry-CQFB, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, 2825-114 Caparica, Portugal. E-mail: jgc@dq.fct.unl.pt

Received (in Cambridge, UK) 14th May 2001, Accepted 18th July 2001
First published as an Advance Article on the web 9th August 2001

Non-porous membranes with the selective layer consisting of hydrophilic or hydrophobic polymers have been applied for the quantitative and selective recovery of solutes with different physico-chemical properties from a room-temperature ionic liquid, ([bmim][PF_6]).

Room-temperature ionic liquids are fluids that consist entirely of organic cations and inorganic or organic anions and, as a consequence, they lack a measurable partial pressure.[1] This feature of ionic liquids permits their repeated use as benign solvents for green chemical syntheses without solvent loss to the environment due to evaporation.[2] The challenge for the equally benign recovery of solutes from ionic liquids remains and has been identified.[3] Conventional separation techniques for solute recovery either apply energy non-specifically to the bulk (distillation), or employ volatile organic solvents for extraction, thus cancelling out one of the ionic liquid's major advantages. 'Cleaner' and energy-efficient technologies for solute recovery from ionic liquids have recently been summarised to comprise supercritical carbon dioxide extraction and liquid–liquid extraction using aqueous systems or crown ether extractants.[4] Although supercritical carbon dioxide extraction is an efficient separation technique applicable to a wide range of separation problems, it remains technically demanding.[5] Here we demonstrate that pervaporation, as a highly selective and versatile membrane separation process, is capable of quantitatively recovering volatile solutes directly from ionic liquids, more effectively and under milder operating conditions than distillation. Choosing the appropriate membrane for the individual separation problem, pervaporation may prove more versatile than solvent extraction processes as well as more efficient and energetically more advantageous than evaporative techniques.

The separation principle of pervaporation is based on the preferential partitioning of a solute from a liquid feed phase into a dense, non-porous membrane through which it diffuses according to its chemical potential gradient.[6] This gradient is the driving force for the solute transport across the membrane. It is in general established by maintaining a low vacuum on the membrane downstream side, while keeping the membrane upstream side, which is in contact with the liquid feed, at ambient pressure. According to the solution-diffusion model, the partial flux J_i of a solute i across the membrane is given by eqn. (1):

$$J_i = \frac{S_i D_i}{z_m} \Delta\mu_i = \frac{S_i D_i}{z_m} (\mu_i^{\mathrm{f}} - \mu_i^{\mathrm{p}}) \qquad (1)$$

with S_i the partitioning coefficient of solute i between the feed liquid phase and the membrane; D_i the diffusion coefficient of i in the membrane; z_m the membrane thickness; $\Delta\mu_i$ the chemical potential gradient of i over the membrane; μ_i^{f} and μ_i^{p} are the chemical potential of i in the liquid feed phase and the permeate, respectively.

Any compound partitioning between the bulk solvent and the membrane can be recovered by pervaporation once there exists a chemical potential gradient over the membrane. For the same chemical potential gradient, pervaporation can be more effective than distillation for solute recovery.[7] The solute partitions from the bulk solvent into the membrane polymer where it sorbs. Due to the chemical potential gradient it then diffuses through the membrane polymer and subsequently desorbs on the membrane downstream side into the vacuum. This explains why pervaporation can also be applied to the recovery of low-volatile, high-boiling compounds at relatively moderate temperature: unlike distillation, pervaporation is not governed by the vapour–liquid equilibrium, but by solute–polymer interactions.[8] For an individual separation problem, it is therefore crucial to choose or develop the membrane polymer such that it exhibits a high selectivity for the target compounds under the separation process operating conditions. Otherwise, the process is not efficient.[9]

Energy consumption in pervaporation stems mainly from establishing the vacuum and condensing the solutes permeated. Specific to coupling pervaporation to ionic liquids is the fact that energy is spent very efficiently on the permeating solute only because no bulk solvent permeates the membrane. In contrast, during distillation energy is spent non-specifically on heating both the non-volatile bulk solvent and the solutes, with the latter often being present in minor concentrations.

Four case studies were chosen to test the promising concept of removing volatile solutes from ionic liquids by pervaporation: (1) water as a possible reaction product during, for example, condensations or esterifications, whose removal shifts the reaction equilibrium toward higher product yields; (2) ethyl hexanoate as a possible product of low volatility from a heat sensitive biotransformation; (3) chlorobutane as a possible residue stemming from the synthesis of the ionic liquid, whose removal increases significantly the purity of the latter; (4) naphthalene as a low-boiling compound.

Laboratory-scale pervaporation experiments were carried out using a range of binary solutions of the ionic liquid, 1-butyl-3-methylimidazolium hexafluorophosphate [bmim][PF_6], and model solutes all of which differ strongly in their physico-chemical properties. The ionic liquid was synthesised in our laboratory using a procedure reported.[10] The model solutes used were naphthalene, ethyl hexanoate, chlorobutane and water with initial feed concentrations of 15, 3.5, 20 and 17 kg m^{-3}, respectively. Different dense hydrophilic and hydrophobic polymeric membranes, namely poly(octylmethylsiloxane) (POMS) polyether block amide (PEBA) and poly(vinyl alcohol) (PVA) were chosen for the solute recovery based on their selectivity for the individual model solute. All experiments with results depicted in Figs. 1 and 2 were carried out at 323.15 K and a permeate pressure of 10 Pa, using a standard laboratory pervaporation set-up with an effective membrane area of 0.01 m^2.[11] The feed volume used was 110 cm^3 throughout all experiments. No ionic liquid was detected in any of the permeates, with the detection limit being 74 μg kg^{-1} using inductively coupled plasma (ICP) spectroscopy and phosphorus as the reference atom for the hexafluorophosphate anion of [bmim][PF_6]. Organic model solute concentrations in the feed and the permeate were determined by gas chromatography after extraction from the ionic liquid with diethyl ether. Water

 DOI: 10.1039/b104191f

concentration in the ionic liquid was determined using an automated Karl–Fischer titrator.

Fig. 1 depicts the successful, quantitative recovery (> 99.2%) of all solutes tested by pervaporation. It should be noted that recovery rates apply for the small membrane area used in the laboratory and therefore appear uneconomically long. Because membrane area is relatively inexpensive, large-scale pervaporation units will employ larger membrane area/feed volume ratios, thus diminishing the time for quantitative solute recovery manifold, as can be simulated on the basis of the partial fluxes presented in Fig. 2.

Water exhibited the highest flux, using a hydrophilic PVA-composite membrane. Because of their hydrophilicity, PVA-membranes are highly permeable for water, while hindering the permeation of hydrophobic molecules.[12] This is particularly interesting for reversible condensation reactions or biocatalytic esterifications carried out in ionic liquids, during which the selective and continuous removal of the water formed shifts the equilibrium to higher yields of the target product.[12] The target product, such as esters formed by esterification, can then be recovered using an appropriate hydrophobic membrane, with an example being the pervaporation of ethyl hexanoate utilising a POMS-composite membrane (Figs. 1 and 2). It should be pointed out that especially with regard to biotransformations carried out in ionic liquids, pervaporation is the only separation technique that can be applied without either degrading the biocatalyst or interfering with the bioconversion: it can be efficiently operated at a moderate temperature, and does not require any extraction aid detrimental to the performance of the biocatalyst that, in turn, can be reused without loss of activity.[13]

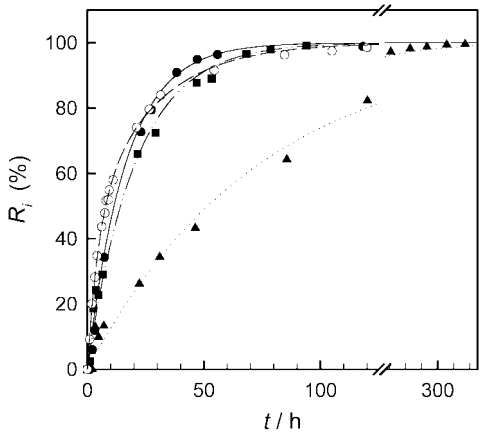

Fig. 1 Recovery of water by a PVA (4 μm)-composite membrane (○); chlorobutane (●) and ethyl hexanoate (■) by POMS (25 μm)-composite membrane; naphthalene by a homogeneous PEBA (30 μm)-membrane (▲). All solutes were recovered to a degree > 99.2% (limit of the analytical sensitivity) of their initial feed concentration.

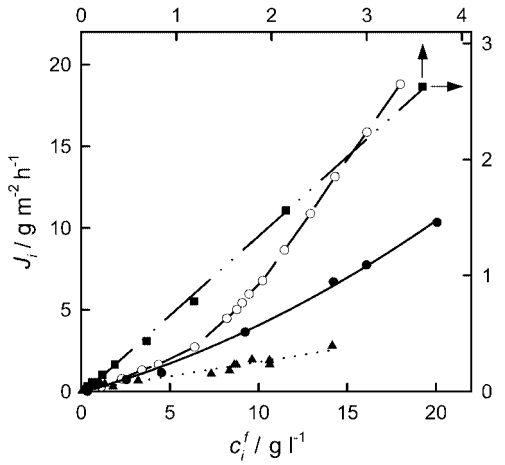

Fig. 2 Partial fluxes of the solutes recovered from [bmim][PF_6] as a function of their respective feed concentration. Experimental conditions and symbol legend are as reported in Fig. 1; for graphical reasons, the *x*- and *y*-axes for ethyl hexanoate are depicted on the top and on the right of the plot (indicated by arrows).

Once prepared, ionic liquids still contain solvent/reactant originating from their synthesis or the subsequent purification procedure. Commonly, these solvent residues are removed using evaporative techniques under high vacuum and/or an elevated temperature.[10] Utilising a POMS-composite membrane, chlorobutane as a solvent/reactant during synthesis of [bmim][PF_6] was recovered as depicted in Figs. 1 and 2, respectively. Pervaporation can hence be integrated in the production and purification process of ionic solvents for the recovery of volatile solvent residues, enabling a closed-loop production process for obtaining a pure ionic liquid at mild operating conditions.

The low-volatile model solute, naphthalene, was recovered quantitatively at 323 K, 168 K below its boiling point of 491 K (Figs. 1 and 2) using a homogenous PEBA-membrane. A homogenous membrane was chosen for this separation because in composite membranes the pressure loss in the porous support can be sufficient to cause undesired condensation of the low-volatile solute on the membrane downstream face. Although the rate of recovery was lower than that of the other solutes, owing to a smaller driving force, this example illustrates the potential pervaporation has for the recovery of high-boiling compounds.

In conclusion, pervaporation is a non-evaporative process that can be integrated in the production and purification process of ionic solvents for the selective recovery of volatile solvent residues at mild, and therefore energetically favourable, operating conditions. For the recovery of volatile solutes from heat sensitive reactions carried out in ionic liquids, such as bioconversions, pervaporation may be superior to other techniques.

We thank Elf Atochem, Portugal, and GKSS, Germany, for the kind donations of membranes, and João N. Rosa and Luis C. Branco for the preparation of the ionic liquid. T. S. gratefully acknowledges financial support from FCT, Portugal.

The first examples of hetero Diels–Alder reaction of masked *o*-benzoquinones with nitroso dienophiles leading to novel and highly functionalized heterocycles, which are potential intermediates for nitrogenous natural products are reported.

The hetero Diels–Alder reaction represents a powerful strategy for the stereoselective construction of highly functionalized heterocyclic systems.[1] A nitroso function that is directly linked with an electron-withdrawing group acts as an efficient dienophile as a result of extremely low LUMO energy and weak π-bond.[2] Acyl nitroso compounds have been used as dienophiles in both intermolecular and intramolecular versions of hetero Diels–Alder reactions to produce highly functionalized cycloadducts that provide valuable synthetic intermediates to a variety of biologically interesting molecules.[1,3]

Masked *o*-benzoquinones (MOBs),[4] a highly reactive class of 2,4-cyclohexadienones with extensive utility can be generated by the oxidation of easily available 2-methoxyphenols using hypervalent iodine reagents such as diacetoxyiodobenzene (DAIB) and phenyliodonium(III) bis(trifluoroacetate) (PIFA) in MeOH. In the course of our investigations on MOB chemistry, we have developed methods for their *in situ* generation and studied their inter-[5] and intramolecular[6] carbo-Diels–Alder reactions. The synthetic potential of this methodology has been demonstrated in the total/formal syntheses of several natural products by us[7] and others.[8] Very recently, MOBs were shown to drive heteroaromatics such as furans,[9] pyrroles[10] and indoles[11] as 2π-components in the carbo-Diels–Alder reaction. In continuation of our efforts to broaden the versatility of MOBs, we contemplated their hetero Diels–Alder reaction with nitroso dienophiles to generate functionalized bicyclo[2.2.2]octenone derivatives that are possible intermediates for several biologically active natural products such as aminocyclitols,[12] pancratistatin[13] and tetrodotoxin[14] (Scheme 1).

Owing to their highly reactive nature, both MOB (diene) and nitroso dienophile were transiently generated in the reaction medium. Thus, at the outset of our study, we examined the reaction of MOB **1a**, obtained from the parent 2-methoxyphenol *i.e.* guaiacol (**2a**), with nitroso compound **3a**. The oxidation of **2a** with DAIB in MeOH produced MOB **1a** and the periodate oxidation of *tert*-butyl *N*-hydroxycarbamate (**4a**) produced **3a**. When the reaction was performed with an equimolar ratio of **2a** and **4a**, the two transient intermediates reacted very efficiently at 0 °C to furnish the Diels–Alder adduct **5a** in 80% yield. However, use of two equivalents of **4a** under the same conditions increased the yield to 90%. This overwhelming result prompted us to extend this reaction to other 2-methoxyphenols. Thus, a variety of phenols **2b–j** in the reaction with **4a** were examined as summarized in Scheme 2 and Table 1.† The MOBs **1b–g** reacted very smoothly with nitroso compound **3a** at 0 °C resulting in the formation of adducts **5b–g** in good to excellent yields (entries 1, 3, 5, 7, 9, 11 and 13). However, the reactions of phenols **2h–j** bearing electron-releasing substituents at C-4 did not proceed at 0 °C. A workable solution was found by the slow addition of hydroxamic acid **4a** to a mixture of phenol **2h** and oxidants in MeOH–CH_2Cl_2 at 50 °C and continuing the reaction at the same temperature. Under these

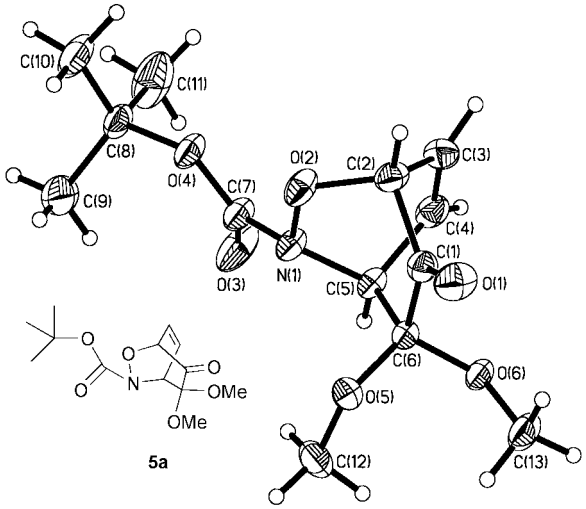

Fig. 1 ORTEP plot of the crystal structure of cycloadduct **5a** (numbering is arbitrary).

conditions, phenols **2h**–**j** afforded the cycloadducts **5h**–**j** in high to excellent yields (entries 15, 17 and 19).

In an effort to ascertain whether the *N*-substitution of nitroso compound has influenced the reaction, we have evaluated the Diels–Alder reaction of MOBs **1a**–**j** with (*N*-carbobenzyloxy)nitroso compound **3b** (Scheme 2). These cycloadditions were found to be quite efficient and the adducts **6a**–**j** were obtained in very good to excellent yields. These results are summarized in Table 1.

The structures of all the cycloadducts were based on the IR, ^{1}H (400 MHz) and ^{13}C (100 MHz) NMR, DEPT, low-, and high-resolution mass spectral analyses. The regiochemistry of the adduct **5a** was confirmed by its single crystal X-ray structure (Fig. 1)‡ and that of the adducts **5b**–**j** and **6a**–**j** is derived by comparing the chemical shifts of their ^{1}H NMR spectra with that of **5a**.

The excellent regioselectivity of this Diels–Alder reaction is in full agreement with our earlier studies on Diels–Alder reactions of MOBs.[5,9–11] The moderately stable MOBs such as **1i**,**j** require higher temperature and prolonged reaction times for the reaction as reflected by the reaction conditions employed for phenols **2i**,**j** (entries 17–20), which is in accordance with our earlier findings.[15]

In conclusion, bicyclo[2.2.2]octenone derivatives embedded with heteroatoms—types of substrate that are useful in the total syntheses of natural products possessing an aminopolyhydroxycyclohexane or cyclohexene moiety—are accessed in a highly regioselective manner from simple 2-methoxyphenols. The simplicity of the experimental procedure and the ready accessibility of masked *o*-benzoquinones and nitroso dienophiles thus renders this an experimentally attractive method for the preparation of nitrogenous heterocycles. Currently, we are actively pursuing the transformation of such cycloadducts to pertinent targets including conduramines and natural products such as pancratistatin and tetrodotoxin.

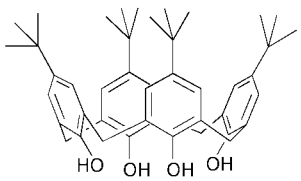
First published as an Advance Article on the web 9th August 2001

We report the first quantum mechanical calculations of *p-tert*-butylcalix[4]arene inclusion complexes in the crystalline state with geometrical aspects demonstrating good agreement with experiment, while comparison of the configurations calculated for an isolated complex and in the crystal, illustrate that crystal packing forces contribute to the observed structure of the host–guest assembly.

The solid-state structures of calix[*n*]arene host–guest complexes have been studied intensively since the archetypal *p-tert*-butylcalix[4]arene·toluene structure was reported.[1] The structural and dynamic features of this particular system have been studied using a range of experimental methods revealing a remarkably complex structure.[2,3] To complement experimental studies of this and other host–guest complexes, we have used *ab initio* methods, within the framework of density functional theory, to calculate the structures and energetics of calixarene complexes in the crystalline state. Through the use of an appropriate method it has been possible to treat both the periodic crystal structure and gas phase molecular systems at the same level. This allows the influence of crystal packing on the host–guest chemistry of calixarenes to be assessed. To this end, geometry optimisations for *p-tert*-butylcalix[4]arene **1** with the guests toluene and carbon disulfide have been performed.



1

All calculations were performed using the *ab initio* program SIESTA[4] which is capable of determining the electronic structure and properties of molecules, surfaces and bulk materials based on density functional theory. For this work, all runs were performed using the non-local density functional of Perdew, Burke and Ernzerhoff.[5] The core electrons for all elements were represented by norm-conserving non-local pseudopotentials, while the valence orbitals were described using a double-zeta basis set, with polarisation functions included for non-hydrogens. Here the basis set is a numerical one, consisting of the exact solutions of the pseudopotential for the atomic state, except that a radial confinement is included to localise the orbital corresponding to an energy shift of 0.001 Rydberg.[4,6] The energy shift used in the present work is smaller than typical values used in many studies. This is necessary to reduce the basis set superposition error (BSSE) that arises due to the radial confinement. Residual BSSE present in binding energies was accounted for using the counterpoise correction. Selected calculations with lower energy shift values verified that the binding configurations are not significantly influenced by further reduction in orbital confinement. A real space mesh equivalent to a planewave cut-off of 150 Rydberg was used for the evaluation of the Hartree and exchange-correlation energies. Optimisations performed on the solid-state structures were constrained at the experimental unit cell dimensions, while all other degrees of freedom were free to relax with no symmetry restrictions.

The results for *p-tert*-butylcalix[4]arene·CS_2 (Fig. 1 and Table 1) show that the guest is less deeply included in the calixarene cavity in the calculated crystal structure as compared to experiment,[7] although other structural parameters are in reasonable agreement (the two complexes in the calculated unit cell were essentially identical). For comparison, results for the previously reported *ab initio* RHF/6-31G* calculation[8] of the gas phase complex are given in Table 1. In this case, the host–guest intermolecular forces are underestimated to a greater extent, although some parameters, such as the C–S bond length are in better agreement with experiment than the present DFT study due to the tendency of the Hartree–Fock calculations to yield shorter bonds. A key finding is that the binding of the guest is weaker in the gas phase (3.2 kJ mol^{-1}) than in the solid

state (7.7 kJ mol^{-1}), consistent with the fact that the cavity in the crystal is defined and influenced by neighbouring calixarene molecules, as well as the main host. However, the absolute binding energies will be underestimated due to the absence of dispersion forces.

Experimental data suggest that the *p-tert*-butylcalix[4]arene·toluene complex has a C_2-elliptical calixarene cavity that is dynamically disordered to give an average 4-fold symmetry.[2] This disorder is associated with rotational disorder of the toluene guest molecule. While inclusion of statistical sampling, typically *via* dynamical calculations, will be required to study these processes, geometry optimisation gives preliminary results consistent with some aspects of the experimental data. In this case, the two complexes in the calculated crystal structure were slightly different (Table 2). The most striking difference between the calculated structures of the complex in the crystal and the isolated system is the orientation of the guest toluene molecule, along the *pseudo* 4-fold axis of the host calixarene (Fig. 2). In the isolated assembly, the toluene molecule lies on the *pseudo* mirror plane intersecting two of the methylene C atoms (the interplanar angle is 1.5°). In the calculated crystal structure, the same interplanar angle is 19.9 and 24.8°, in good agreement with the experimental crystal structure (22.5°). It is likely that the *tert*-butyl groups of neighbouring calixarenes, which lie 'above' the host calixarene, are inducing this change in orientation. It is also noteworthy that experimental data suggest that the toluene molecule is tilted relative to the calixarene 4-fold axis by 7°; the calculated results are 1.1 and 3.8° in the crystal, and 3.5° in the isolated complex. As observed for the CS_2 guest, the toluene is more deeply included in the calculated crystal structure than in the isolated complex (Table 2).

The results presented here clearly demonstrate that crystal packing can have a significant effect on the geometries of host–guest assemblies and that periodic density functional calculations can accurately reproduce this effect. Molecular dynamics calculations will be the next step in studying the disorder observed in the experimental crystal structures.

An efficient synthesis of 3,3′-diphenyl-2,2′-bithiophene based bis(triarylamines) and their physical properties are reported.

Amorphous triarylamines with high glass transition temperatures (T_g) are widely used as hole-transporting materials in organic light-emitting devices (OLED).[1] Thiophene and oligothiophene-linked triarylamines and bis(triarylamines), with phenyl rings separating the thiophene system from the terminal diarylamino groups were first introduced by Shirota *et al.*[2] These amorphous materials form thin films with high morphological stability and also show interesting hole-transporting properties, resulting in their successful use as colour-tunable emitting materials for OLED devices. Triarylamines with diarylamino group(s) directly attached to thiophene are one of the least exploited class of hole-transporting materials.[3,4] Recently, Watanabe and co-workers[5] have accomplished a systematical study on Pd-catalysed amination for the synthesis of 2-diarylaminothiophenes and 2,5-bis(diarylamino)thiophenes. In addition to this, a new synthetic strategy involving transition-metal free cyclization followed by thermal decarboxylation has also been introduced for the synthesis of triarylamines bearing a thiophene moiety.[6] However, the physical properties of thiophene based triarylamines are still limited.[5,6] In this communication, we report the synthesis and physical properties of a new class of bis(triarylamines) based on 3,3′-diphenyl-2,2′-bithiophene as a central linkage. It is well documented that the physical properties of oligothiophenes and polythiophenes strongly depend on the nature of the substituents. However, the similar oxidation potential and absorption λ_{max} of bithiophene and 3,3′-diphenyl-2,2′-bithiophene have been attributed to counterbalancing the resonance effect of phenyl substituents by the steric effect.[7] Interestingly, polythiophenes with phenyl substituent(s) at its 3- and 4-position exhibit higher thermal stability and lower oxidation potentials.[8] Accordingly, the resulting new class of bis(triarylamines) based on 3,3′-diphenyl-2,2′-bithiophene could enhance the thermal and morphological stability, which are crucial for their application in optoelectronic devices.

Cu-promoted Ullman reaction for the synthesis of 3,3′-diphenyl-2,2′-bithiophene was first reported by Johnson in 1976.[9] Further synthetic efforts based on the Ni-catalysed Kumada coupling reaction of 2-halo-3-phenylthiophene with 2-magnesium-3-phenylthiophene gave 3,3′-diphenyl-2,2′-bithiophene in poor yields.[7,8] We report herein a more efficient synthetic pathway (Scheme 1). In the presence of a catalytic amount of $Pd(PPh_3)_4$, 3,3′-dibromo-2,2′-bithiophene **1**[10] was treated with phenylboronic acid in DME to afford 3,3′-diphenyl-2,2′-bithiophene (**2**) in 86% yield. Regioselective bromination[11] of **2** was accomplished by treating **2** with bromine in AcOH–$CHCl_3$ (1:2) solution, which afforded 5,5′-dibromo-3,3′-diphenyl-2,2′-bithiophene **3** in 95% yield. Six different diarylamines were screened to react with **3** respectively in the presence of a catalytic amount of $Pd(OAc)_2$ and PBu^t_3 in toluene[12] at reflux temperature, resulting in compounds **4a**–**4f** as bright yellow solids in moderate yields (Table 1). For a comparative study of the influences of phenyl

substituents on the physical properties, model compound **5** was also synthesized by the Pd-catalysed amination of 5,5′-dibromo-2,2′-bithiophene.

The absorption spectra of **4a**–**4f** in ethyl acetate showed similar behaviour, displaying two absorption maxima (Table 1). The second bands of **4e** and **4f** were slightly red-shifted compared to that of **4a**–**4d**. Compound **4a**–**4d** were highly fluorescent. These results indicate that the absorption λ_{max} is relatively insensitive to the nature of the diarylamino substitutents. However, the photoluminescence efficiency and emission maxima are strongly dependent on the structural feature of the terminal diarylamino groups. Thus, bis(triarylamines) (**4a**–**4d**) with less conjugated diarylamino substituents showed more efficient photoluminescence than when compared with those bearing more conjugated terminal diarylamino groups (**4e**–**4f**). The significant Stokes shift (*ca*. 170 nm for **4a**–**4d**) reveals that the 3,3′-diphenyl-2,2′-bithiophene linkage may be highly twisted in the ground state. The emission maxima with relatively long wavelength could be attributed to the relaxation from an excited state with a more coplanar conformation. The influence of phenyl substituents of the bithiophene linkage on the photophysical properties are demonstrated by a comparison of the UV-Vis and photoluminescent spectra of **4b**, **4e**, and **5** (Fig. 1). Bis(triarylamine) **5** exhibited a sharper, red-shifted absorption and a blue-shifted emission compared to that of **4b**. The longer emission wavelength of **4b** further confirms a more conjugated excited state.

Compounds **4a**–**4f** exhibited only quasi-reversible anodic oxidation (Table 1). The onset of oxidation and E_{pa} (V *vs*. Ag/AgCl) varied with the nature of the terminal diarylamino groups. Differing from the conventional bis(triarylamines),[13] only one redox couple (E_{pa} 550 mV, E_{pc} 430 mV *vs*. Ag/AgCl) was detected for **4a** and **4c**. Coulometry in a thin layer cell showed the redox process of **4a** to be a two-electron oxidation. The lack of co-planarity of the central 3,3′-diphenyl-2,2′-bithiophene linkage prevents the extension of π-conjugation along the molecular axis. The rate of second oxidation in **4a** may be faster than the conformational change reaching a more coplanar conformation. Therefore, the first radical cation can not efficiently delocalise in the whole molecule, the two triarylamine systems behave independently but are oxidized simultaneously without any communication. Fig. 2 shows a comparison of the cyclic voltammogram of **4b, 4e**, and **5**. Two partially resolved redox processes (E_{pa} 545 mV, E_{pc} 455 mV and E_{pa} 650 mV, E_{pc} 570 mV *vs*. Ag/AgCl) of **4e** were detected, which were assigned to be a two-step one-electron redox couple corresponding to removal of an electron from each triarylamine system. The redox potential difference (110 mV) of **4e** indicates that the second oxidation could occur *via* a radical cation with more coplanar conformation. **4b**, **4d**, and **4f** showed similar redox behaviour but were less resolved when compared with that of **4e**. The model compound **5** exhibited two well-resolved redox couples (E_{pa} 460 mV, E_{pc} 385 mV and E_{pa} 695 mV, E_{pc} 610 mV *vs*. Ag/AgCl). The lower oxidation onset and larger potential difference (230 mV) reveal that the the central bithiophene linkage is in a coplanar conformation.

All the compounds in this study exhibited an amorphous nature evidenced by the presence of the glass transition temperature (Table 1). The asymmetric diarylamino substituent and the diphenyl substituted central bithiophene linkage significantly contribute to the high T_gs. Compounds (**4d**, **4e**, **4f**) with higher molecular weight aryl groups showed higher T_gs compared to that of **4a**, **4b** and **4c** bearing a lower molecular weight aryl group in the terminal diarylamino substituents.

In summary, we have successfully established an efficient method for the synthesis of a new class of bis(triarylamines) bearing 3,3′-diphenyl-2,2′-bithiophene as a central linkage. The introduction of phenyl substituents on the central linkage apart from improving the morphological stability, twists the conformation of the central bithiophene linkage in the ground state, which results in interesting photophysical and electrochemical properties. Further studies on the modification of the central bithiophene linkage by introducing bulkier aryl groups and their applications in OLED are under way and will be reported in due course.

We thank the National Science Council of Taiwan for providing financial support (NSC-89-2113-M002-053).

Highly diastereoselective dihydride formation by activation of methanol with IrCl{(*S*)-binap}(PPh_3)

Kazuhide Tani,* Kouji Nakajima, Aika Iseki and Tsuneaki Yamagata

Department of Chemistry, Graduate School of Engineering Science, Osaka University, Toyonaka, Osaka 560-8351, Japan. E-mail: tani@chem.es.osaka-u.ac.jp; Fax: +81-6-6850-6245

Received (in Cambridge, UK) 13th March 2001, Accepted 13th July 2001
First published as an Advance Article on the web 3rd August 2001

Reaction of [IrCl{(*S*)-binap}(PPh_3)] {(*S*)-3} with methanol gave one of the diastereomers of the *cis,mer*-dihydride, *cis,mer-OC*-6-44-*A*-[$IrCl(H_2)$\{(*S*)-binap}(PPh_3)] {(*S*)-4a} stereoselectively, the structure of which was determined crystallographically, whereas the reaction of (*S*)-3 with H_2 produced a 1:1 mixture of the diastereomers of the *cis,mer*-dihydride, (*S*)-4a and *cis,mer-OC*-6-44-*C*-[$IrCl(H_2)$\{(*S*)-binap}(PPh_3)] {(*S*)-4b}.

Although the stereochemistry for the formation of the dihydrides of rhodium and iridium carrying chiral ligands is of great interest in connection with their potential as asymmetric hydrogenation and its mechanism,[1] only very rare cases of detection of diastereoselective formation of dihydrides have been reported.[2–6] Even in such cases the absolute configuration of the hydride was only estimated based on spectroscopic results. Here we report a highly diastereoselective formation of the dihydride (*S*)-**4a** by reaction of [IrCl{(*S*)-binap}(PPh_3)] {(*S*)-**3**}[7] with methanol, the absolute configuration of which was determined by X-ray analysis. Oxidative addition of dihydrogen to (*S*)-**3** gave also the same *cis,mer*-dihydrides **4** but as a 1:1 mixture of the diastereomers **4a** and **4b**.

Recently we have reported that iridium(I) complexes bearing peraryldiphosphines [IrCl(diphosphine)]$_2$ (**1**) can activate O–H bonds easily at room temperature. For example, [IrCl(binap)]$_2$ (**1a**) reacted easily with methanol at room temperature to give the hydrido(methoxo) complex, [{Ir(H)(binap)}$_2$(μ-OMe)$_2$(μ-Cl)]Cl (**2**) in good yield,[8] which becomes an efficient catalyst precursor for transfer hydrogenation of alkynes using methanol as a hydrogen source.[9] During the studies on the reactivity of complex **1**, we have found that [IrCl(binap)]$_2$ (**1a**) reacted with 2 equiv. of PPh_3 to give a square-planar complex, [IrCl(binap)(PPh_3)] (**3**) selectively as a red solid.[7] The molecular structure of (*R*)-**3** is shown in Fig. 1.† In contrast to complex **1a**, complex **3** was fairly stable in the solid state. Heating a toluene solution of complex (*S*)-**3** with large excess of methanol at 70 °C during 6 h, however, gave pale-red precipitates (67% yield) of the dihydride (*S*)-**4a**[10] as a single diastereomer. The crude reaction mixture obtained after removal of the all solvents showed almost quantitative and selective formation of the dihydride **4** containing a small amount of the other diastereomer (*S*)-**4b**[11] {(*S*)-**4a**:(*S*)-**4b** = 92:8}. The reaction of (*S*)-**3** with methanol proceeded even at room temperature in toluene and after 45 h gave selectively the *cis,mer*-dihydride (*S*)-**4a** in about 90% yield {(*S*)-**4a** : (*S*)-**4b** = 96:4} (Scheme 1). The reaction, however, is very much suppressed when excess triphenylphosphine is present. Complex (*S*)-**4a** was fully characterized by elemental analyses and spectroscopic studies. The ^{1}H NMR spectrum showed two characteristic hydride signals at δ −19.56 and –9.97; the latter signal showed one large P–H coupling indicating that the hydride is situated *trans* to one phosphorus atom while the former signal does not show any couplings larger than *ca.* 20 Hz, indicating the hydride situates *cis* to all the phosphorus atoms. The ^{31}P NMR spectrum measured at 35 °C showed three phosphorus signals at δ −4.7 (br m), 14.9 (dd, J = 16, 358 Hz) and 19.6 (dd, J = 11, 358 Hz) in a 1:1:1 ratio; the signal pattern indicates that the three phosphorus atoms

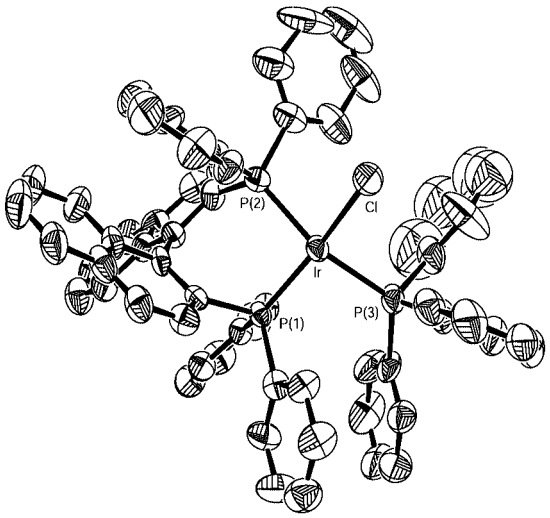

Fig. 1 View of (*R*)-**3** showing the labeling of the heteroatoms. Displacement ellipsoids are drawn at the 50% probability level. Selected bond distances (Å) and angles (°): Ir–P(1) 2.1998(19), Ir–P(2) 2.277(2), Ir–P(3) 2.305(2), Ir–Cl 2.394(2); P(1)–Ir–P(2) 91.58(7), P(1)–Ir–P(3) 99.20(8), P(2)–Ir–P(3) 157.11(8), P(1)–Ir–Cl 159.23(10), P(2)–Ir–Cl 87.76(9), P(3)–Ir–Cl 89.09(9).

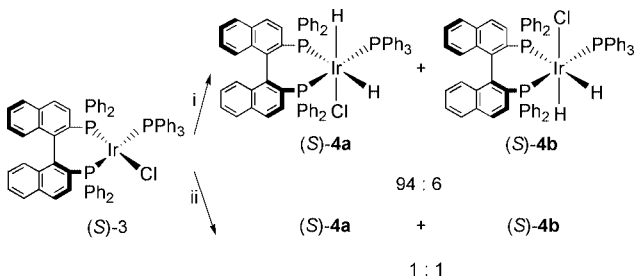
coordinate to the central atom in a *mer* configuration. The dihydride complex showed two Ir–H stretchings (Nujol) at 2207 (*trans* to Cl) and 2083 cm^{-1} (*trans* to P). Suitable crystals for X-ray analysis were obtained by recrystallization from toluene-methanol. The absolute configuration of the dihydride was concretely determined by X-ray crystallography.† The ORTEP drawing is depicted in Fig. 2. The predominant diastereomer (*S*)-**4a** obtained by the reaction of (*S*)-**3** with methanol was revealed to be the (*S*)-*OC*-6-44-*A* isomer. The long bond distance (2.363(2) Å) of Ir–P(2) indicates a strong *trans* influence of the hydride ligand. Similarly, the Ir(III)–Cl bond distance (2.505(3) Å) is long and even longer than the Ir(I)–Cl distance (2.394(2) Å) in the Ir(I) complex (*R*)-**3**. The acute P(1)–Ir–P(3) angle (167.30(9)°) reflects also the small hydride ligand. The same diastereomeric dihydride (*S*)-**4a** was also obtained selectively by the reaction of (*S*)-**2** with 2 equiv. of PPh_3 in a mixed solvent of methanol and toluene under reflux



Scheme 1 *Reagents and conditions*: i, MeOH–toluene, room temp.; ii, H_2 (1 atm)/toluene, room temp.

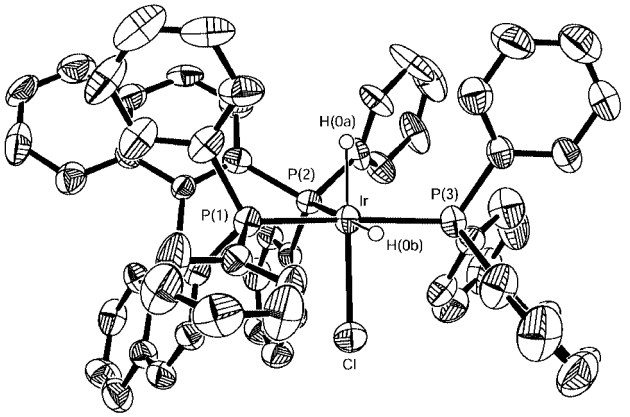

Fig. 2 View of (*S*)-**4a** showing the labeling of the heteroatoms and the hydride hydrogen atoms. Displacement ellipsoids are drawn at the 50% probability level. Selected bond distances (Å) and angles (°): Ir–P(1) 2.299(3), Ir–P(3) 2.326(3), Ir–P(2) 2.363(2), Ir–Cl 2.505(3); P(1)–Ir–P(3) 167.30(9), P(1)–Ir–P(2) 92.70(16), P(3)–Ir–P(2) 100.00(16), P(1)–Ir–Cl 88.81(10), P(3)–Ir–Cl 88.38(10), P(2)–Ir–Cl 102.98(10).

but accompanied by small amounts of several unidentified hydrides [eqn. (1)]. Hydrogenation of complex (*S*)-**3** with dihydrogen in toluene at room temperature also yielded the same *cis*,*mer*-dihydride **4** but as an almost 1 : 1 mixture of the two diastereomers (*S*)-**4a** and (*S*)-**4b**. These dihydrides are obtained by a concerted *cis* addition of H_2 along the P–Ir–Cl axis of the square planar complex (*S*)-**3**. In the reaction products obtained by oxidative addition of H_2 to (*S*)-**3** substantial amounts of *cis*,*fac*-isomer **5** resulted from *cis* addition of H_2 along the P–Ir–P axis of complex (*S*)-**3** and the other possible dihydride **6** could not be detected.

$$[(\text{ir(H)}\{(S)\text{-binap}\})_2(\mu\text{-OMe})_2(\mu\text{-Cl})]\text{Cl} + 2\text{PPh}_3 \xrightarrow[\text{MeOH/toluene (v/v = 1/1)}]{\text{reflux, 39 h}} (S)\text{-}\mathbf{4a} \quad (1)$$

(*S*)-**5a** (*S*)-**5b** (*S*)-**6**

Although the detailed mechanism for diastereoselective formation of (*S*)-**4a** by the reaction of (*S*)-**3** with methanol is not clear at present, the large difference of the selectivity between methanol and hydrogen may be explained as follows. Dihydride formation from the reaction of **3** with methanol could be explained by β-hydrogen elimination from the Ir–OMe group of the initial oxidative addition product of methanol, a hydrido-(methoxo) complex, 'IrCl(H)(OMe)(binap)(PPh_3)', which is not detected in the reaction mixture. Such iridium dihydride formation from the H–Ir–OMe species has been reported.[12] Because methanol is much larger than dihydrogen, methanol approaches also only along the P–Ir–Cl axis to complex (*S*)-**3** and in addition can discriminate efficiently between the two diastereotopic planes of (*S*)-**3**, above and below the Ir(I) square plane. By inspection of a CPK model, approach of methanol from above the square plane of (*S*)-**3** described in Scheme 1 is more preferable and leads to the highly stereoselective formation of dihydride (*S*)-**4a**.[13] In contrast, the small dihydrogen molecule can not efficiently discriminate between the diastereotopic planes.

First published as an Advance Article on the web 14th August 2001

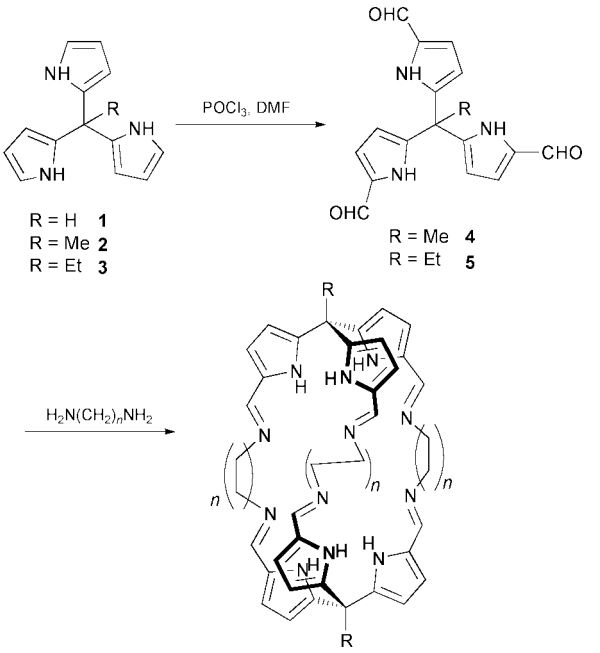
Bis(tripyrrolyl) cryptands are prepared *via* a [2 + 3] Schiff base condensation of formyltripyrrolyls with diamines; an ethyl-spaced hexapyrrole cryptand is shown to bind strongly ethane-1,2-diamine and ethane-1,2-diol in chloroform solution.

Cryptand ligands and carcerand hosts display fascinating coordination and host–guest chemistry due to their ability to wholly encapsulate their guest atoms or molecules.[1,2] Novel and versatile building blocks possessing multiple and convergent donor atoms from which to prepare these cage-like molecular hosts are currently in particular demand. From a practical perspective, the ease with which a building block can be prepared and modified contributes significantly to its degree of future exploitation. Recent developments in calixarene-[3] and more recently porphyrinogen/calixpyrrole-[4] chemistry are prime examples of how simple-to-prepare and robust macrocycles can be skilfully exploited for the coordination of cations[5] and anions.[6]

We were quite surprised therefore that given the recent attention accorded to the chemistry of cyclic, oligomeric pyrrole compounds that the coordination and supramolecular chemistry of tripyrrolylmethane **1** appears to have been sparsely studied.[7] In addition, three-dimensional cryptand-like pyrrole compounds have also remained largely unexplored.[8,9] Herein we report our initial findings on the synthesis of substituted tripyrrolyls and demonstrate the ease with which such molecules can be incorporated into cryptand-like ligands *via* a Schiff base condensation reaction. An ethyl-spaced bis(tripyrrolyl) host **6** is shown to bind strongly ethane-1,2-diamine and ethane-1,2-diol in chloroform solution.

Attempts to formylate tripyrrolylmethane[10] **1** employing a variety of modifications to the Vilsmeier–Haack reaction were unsuccessful. However, adaptation of Bruce's method[11] employing triethyl orthoacetate or triethyl orthopropanoate yielded the methyl and ethyl tripyrrolyls **2** (59%) and **3** (60%) respectively (see Scheme 1). These were easily formylated employing standard Vilsmeier–Haack conditions ($POCl_3$ and DMF) to give the triformylpyrrolyls **4** (84%) and **5** (70%) in good yields. The use of two different triethyl orthoalkanoates demonstrates the generality of this reaction and also illustrates a convenient route to the preparation of further apically-substituted tripyrrolyls.

Treatment of **5** with 1.5 eq. of ethane-1,2-diamine (**en**) or butane-1,4-diamine (**bn**) in THF afforded the cryptand-like Schiff base pyrrole cages **6** and **7**. Recrystallisation from DCM–hexane afforded large, yellow, prismatic crystals of the butyl-spaced cage **7**. Confirmation of the structure was provided by X-ray crystallography‡ (Fig. 1) and also showed the fortuitous inclusion of a molecule of butane-1,4-diamine (**bn**) within **7**. The diaminobutane guest is encapsulated within the cavity *via* 7 hydrogen bonds between the two nitrogen atoms in the guest and 7 different nitrogen atoms in the host. Each nitrogen head of the **bn** molecule is held in place by host hydrogen-bonding



Scheme 1

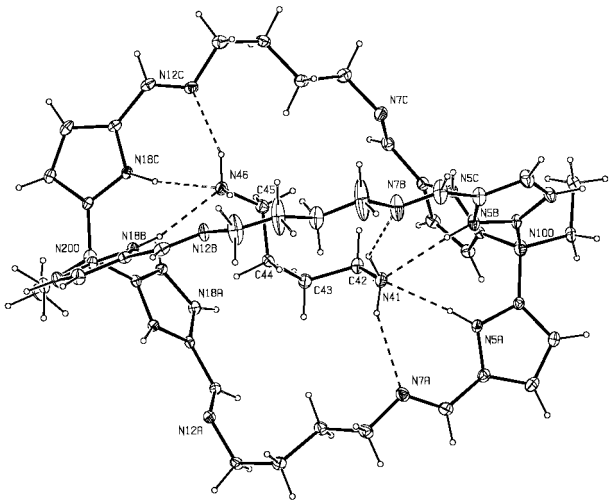


Fig. 1 The structure of **7**·**bn**. Ellipsoids are shown at 10% probability. The 7 hydrogen bonds are shown as dotted lines. Distances for donor hydrogen bonds from the guest are N(46)···N(12C), 3.19; N(41)···N(7A) 2.99; N(41)···N(7B) 3.01 and acceptor hydrogen bonds are N(46)–N(18B) 3.00; N(46)–N(18C) 3.09; N(41)–N(5A) 3.16 and N(41)–N(5B) 3.22 Å.

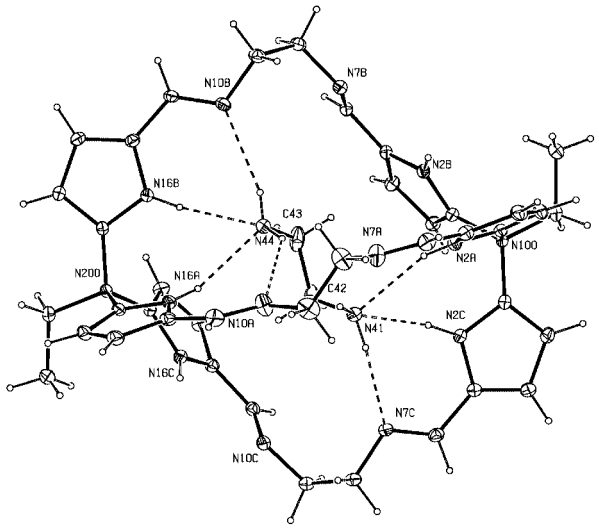

Fig. 2 The structure of **6·en**. Ellipsoids are shown at 10% probability. The 7 hydrogen bonds are shown as dotted lines. Distances for donor hydrogen bonds from the guest are N(41)···N(7c), 3.20; N(44)···N(10b), 3.17; N(44)···N(10a), 3.29 and acceptor hydrogen bonds are N(41)–N(2C), 3.05; N(41)–N(2a), 3.06; N(44)–N(16a), 3.04 and N(44)–N(16b), 3.06 Å.

acceptor interactions to the pyrrole nitrogen atoms and donor interactions to the Schiff base nitrogens. There are seven typical hydrogen bonding N···N distances which range between 2.99 and 3.22 Å (see Fig. 1). In the crystal structure of **7·bn** only two of the three pyrrole moieties at each end of the macrocycle are orientated with their NHs towards the guest **bn**. The remaining two pyrroles are both turned away and only participate in the binding interaction with the **bn** through weak $C–H_{bn}\cdots\pi_{pyrrole}$ contacts at 2.97 and 2.66 Å. Interestingly, in order to fit into the cavity the guest molecule **bn** takes up a *gauche, gauche, trans* conformation rather than the more energetically favourable *trans, trans, trans* conformation. Overall, inspection of the **7·bn** complex illustrates the excellent complementarity of the host's shape and hydrogen bonding capabilities which hold the guest in place through multiple co-operative binding interactions.

Further evidence for the binding of **bn** by **7** was provided by ^{1}H and ^{13}C NMR in $CDCl_3$ solution.[12] In the ^{1}H NMR spectrum of **7·bn** the two resonances for the methylene chain of the coordinated **bn** were observed to be shifted upfield, at δ 2.24 and 0.92 compared to their unbound values, 2.72 and 1.42 ppm. Peaks at δ 40.2 and 29.9 ppm in the ^{13}C of **7·bn** are assigned to the methylene carbons of the guest **bn**. The inclusion and identity of the guest was further qualified by ^{1}H COSY and ^{1}H–^{13}C HETCOR experiments. A very broad resonance at approximately δ 5 is attributed to both the pyrrolic and **bn** amine protons; this peak is lost upon addition of D_2O.

In a similar manner the preparation of **6** in THF produced the ethane-1,2-diamine (**en**) included complex **6·en**. The crystal structure of which was also determined and is shown in Fig. 2. The structure of **6·en** closely resembles that of **7·bn** with very similar hydrogen-bonding distances from the host's donor pyrrole and acceptor Schiff base nitrogen atoms to the guest **en**. Notably, the bound guest **en** adopts the *gauche* conformation. Weak contacts attributable to $C–H_{en}\cdots\pi_{pyrrole}$ interactions are again observed. The identity of the guest was supported by ^{1}H, ^{13}C and 2D NMR experiments with the incarcerated **en** molecule assigned to resonances at δ 2.12 (^{1}H), and 43.6 ppm (^{13}C).

The inclusion of the reactant diamine inside the Schiff base suggests that the formation of the tripyrrolyl cages is templated by the diamine. The preparation of **6** and **7** was performed in acetonitrile using 2 eq. but again yielded **6·en** (81%) and **7·bn** (73%). It is noteworthy that using 2 eq. of diamine does significantly improve the yield of tripyrrolyl cryptands. Considering the high yields of cages **6** and **7** it is quite likely that the guest diamine is involved, in some shape or form, in templating the formation of the bis(tripyrrolyl) cryptands.

The guest **en** could be simply removed from **6·en** by stirring with MeOH. ^{1}H NMR titration experiments in $CDCl_3$ of the diamine-free bis(tripyrrolyl) cryptand **6** were performed to confirm diamine binding and determine a stability constant. Titration of **en** with **6** produced identical ^{1}H, ^{13}C and 2D NMR spectra as for **6·en** and a binding constant, *K*, of 1500 ± 140 M^{-1} was calculated using EQNMR.[13]† Titration experiments showed **6** binds ethane-1,2-diol (**eg**) strongly, K = 1060 ± 29 M^{-1}; the resonance attributed to the **eg** methylene protons being shifted upfield from 3.74 to 3.32 ppm. However, no significant shift in the resonance of the methylene protons of 1,2-ethanedithiol (**es**) was observed under the same titration conditions. That no binding was observed for **es** can be attributed to a number of factors such as the reduced hydrogen bonding abilities of thiols, the larger size of the dithiol guest and the significantly lower stability of the *gauche* conformation in **es** compared to **en** and **eg**. Macrocyclic calix[4]pyrroles have been shown to bind neutral guest molecules in d_6-benzene solution.[12] The large binding constants for the binding of difunctional neutral guest molecules by the pyrrole cryptands reported here demonstrates the enhancement in molecular recognition that can be achieved by the use of three dimensional host molecules that encompass their guest. Further studies with neutral guest molecules are in progress.

In summary, bis(tripyrrolyl) cryptand-like cages have been prepared in excellent yields and preliminary studies demonstrate neutral guest molecule binding. The ease and scale with which the formylated tripyrrolylalkanes can be prepared offers plenty of opportunity for the future exploitation of these building blocks in the construction of new cryptands. We are currently exploring the cation and anion coordination chemistry of these bis(tripyrrolyl) cryptands and routes to further cages based on metal-assembled strategies.[14]

We thank the EPSRC for a post-doctoral fellowship (O. D. F.) and the University of Reading and EPSRC for funds for the Image Plate diffractometer.

Formation of the monoanion $[Ar^*P(BH_3)(\mu\text{-}BH_2)_2H]^-$ with a symmetrically bridging hydride from the attempted synthesis of the dianion $[Ar^*P(BH_3)_3]^{2-}$†

Valentyn L. Rudzevich, Heinz Gornitzka, Vadim D. Romanenko* and Guy Bertrand

Received (in Cambridge, UK) 7th June 2001, Accepted 23rd July 2001
First published as an Advance Article on the web 14th August 2001

Addition of an excess of Bu^nLi to the bis(borano)phosphide complex $[Ar^*PH(BH_3)_2]^-Li^+$ 1 (Ar^* = 2,4,6-tri-*tert*-butylphenyl) and subsequent treatment with BH_3, gives the anionic complex $[Ar^*P(BH_3)(\mu\text{-}BH_2)_2H]^-Li^+$ 2 instead of the expected tris(borano)phosphide dilithium, $[Ar^*P(BH_3)_3]^{2-}2Li^+$ 3.

Borane complexes of trivalent organophosphorus derivatives have been extensively used in organic synthesis.[1] In particular, borane-stabilized phosphide anions of the type $[R^1R^2PBH_3]^-$, which are readily available by deprotonation of the corresponding secondary phosphine– or phosphinite–borane adducts, have been found to be valuable intermediates for the preparation of enantiomerically pure phosphines with chiral carbon skeletons or stereogenic phosphorus centres.[2] It may be assumed that application of a conceptually similar approach (P–H deprotonation/P–B complexation) to primary phosphines and PH_3 would lead to a series of reactive anions $[R_nH_{3-n-m}P(BH_3)_{m+1}]^{m-}$ (n = 1, m = 1, 2 or n = 0, m = 1–3). However, surprisingly, few investigations of borane-stabilized RP^{2-} and P^{3-} anions have been reported to date. An early ^1H NMR spectroscopic study claimed that stepwise removal of protons from $[H_2P(BH_3)_2]^-$ followed by complexation of intermediates with BH_3 afforded $[HP(BH_3)_3]^{2-}$ and $[P(BH_3)_4]^{3-}$ anions. Yet, the observed formation of $LiBH_4$ leaves some doubts as to the true structure of the anionic products.[3]

The Cambridge Structural Database reveals that trivalent phosphorus derivatives in which the phosphorus is bonded to two or three boron atoms have rarely been characterized in the solid state, and those identified are limited to polyhedral compounds,[4] neutral diborylphosphines[5] and various heterocyclic systems.[6] No poly(borane)phosphide anions have so far been characterized by X-ray crystallography. Here we report the synthesis of the $[Ar^*PH(BH_3)_2]^-$ anion (Ar^* = 2,4,6-tri-*tert*-butylphenyl) and its subsequent deprotonation and complexation with BH_3.

The $[Ar^*HP(BH_3)_2Li]$ complex **1** was prepared in 95% yield by metallation of Ar^*PH_2 with an equimolar amount of Bu^nLi in thf solution and subsequent addition of BH_3 (2 equiv.).‡ An alternative route to **1**, based on the preparation of the $Ar^*PH_2{\cdot}BH_3$ adduct and its subsequent deprotonation, led to the formation of a complex mixture of products. The ^{31}P NMR spectrum of **1** in C_6D_6 displays a broad doublet at δ −53 [^1J(PH) 340 Hz]. The resonance is considerably shifted toward low field compared to that of $Ar^*P(H)Li$ [δ −108, ^1J(PH) 172 Hz]. The signal observed by ^{11}B NMR spectroscopy (δ −30.6) was very broad ($W_{1/2}$ ~ 350 Hz) in both the ^{11}B proton-coupled and decoupled spectra, with no observable ^{11}B–^{31}P coupling. Furthermore, the signal attributable to BH_3 units in ^1H-{^{11}B} and ^1H-{^{31}P} spectra is not resolved and appeared as a broad singlet at δ 1.54.

The molecular structure of **1** is depicted in Fig. 1.§ The compound crystallizes with three molecules of thf and can be described by the formula $[Ar^*HP(BH_3)_2Li(thf)_3]$. Two different BH_3 units are found in the crystal: one shows contacts of two hydridic hydrogen atoms with Li through a μ_2-type interaction, while the hydridic hydrogen atoms of the other are not involved in the Li–H bonding. The bond distance between phosphorus and boron engaged in B–H···Li coordination [P(1)–B(1), 1.955 Å] is shorter than that found for the 'free' BH_3 group [P(1)–B(2) 1.984 Å]. It is apparent that the sterically demanding Ar* group has no significant influence on the molecular geometry of **1** since the Li(1)–B(1) distance (2.430 Å) is quite similar to those found in $Li\cdots(H)_2BH_2$ complexes in which the BH_4^- group acts as a μ_2 donor.[7]

In marked contrast to the PH-acid type behaviour generally shown by secondary phosphine–borane complexes, $R^1R^2(H)PBH_3$, compound **1** does not react with KH at room temperature in thf. The reaction with Bu^nLi in a 1 : 1 molar ratio only proceeds partially; complete deprotonation of **1** requires an excess of Bu^nLi (*ca.* 2.0 equiv., toluene, −50 °C), according to ^{31}P NMR spectroscopy. Removal of the solvent and extraction of the residue with pentane gave a pale yellow moisture-sensitive oil that exhibits strong, basic properties (on addition of $CHCl_3$ the complex **1** is regenerated immediately). Both ^{11}B– and ^{31}P–^1H coupled NMR spectra show a single broad resonance (δ_P −143.9 , δ_B −27.8), indicating the absence of a PH bond. Addition of excess borane to a toluene solution of the deprotonated product at −50 °C results in the formation of a mixture of the complex **2**‡ (δ_P −161.8 , δ_B −28.4) and $LiBH_4$ (δ_B −42.1) (Scheme 1). After crystallization from toluene–pentane solution, single colourless crystals of the phosphorus-containing complex were obtained, suitable for the determination of its molecular structure in the solid state.§ Compound **2** crystallizes as a dimer and can be described by the formula $[Ar^*P(BH_3)(\mu\text{-}BH_2)_2HLi(thf)_2]_2$ (Fig. 2). The most prominent feature of **2** is the presence of both a four-membered heterocyclic ring with a symmetrically bridging hydride P(μ-

The molecule of toluene has been omitted for clarity.

$BH_2)_2H$, and a BH_3 unit. The P(1)–B(2) and P(1)–B(3) bonds in the four-membered ring are slightly shorter than the exocyclic P(1)–B(1) bond distances, indicating that, as expected, B(2) and B(3) are stronger electron acceptors than B(1). The B(2)–B(3) distance in **2** is 2.00 Å, approximately 0.1 Å larger than in neutral μ-aminodiboranes $[R_2N(\mu\text{-}BH_2)_2H]$.[8] Two H atoms of the BH_3 group coordinate through a μ_1-interaction to two different Li cations forming an eight-membered ring. The Li···B(1) distances (2.548–2.563 Å) compare well with those found in other H_3B–H···Li interactions.[7] The coordination sphere of each Li atom is completed by two molecules of thf. In solution, no evidence for or against the dimeric structure can be found, but the presence of the hydride bridging two boron atoms is strongly suggested by the presence of an upfield broad doublet at δ −0.65 [^2J(PH) 36 Hz] in the ^{1}H NMR spectrum.

In conclusion, we have demonstrated that accumulation of negative charge on phosphorus by H^+/Li^+ replacement in complex **1** resulted in a considerable increase in the reduction properties of BH_3 groups. This results in the formation of the monoanionic bridging complex **2** observed along with $LiBH_4$, instead of the expected dianionic tris(borano)phosphide complex **3**. Compound **2** does not react with KH in the presence of 18-crown-6 (thf, 20 °C, 24 h), despite the presence of the electron deficient 3c–2e B–H–B bond. Thus, it appears that the anionic μ-(boratophosphino)diboranes are considerably more stable than previously described neutral μ-phosphinodiboranes, $[R_2P(\mu\text{-}BH_2)_2H]$.[9]

Received (in Cambridge, UK) 15th May 2001, Accepted 19th July 2001
First published as an Advance Article on the web 14th August 2001

A bimetallic cluster complex, $[(2,2'\text{-}Py_2NH)_2Co]_3V_8O_{23}$ ($2,2'\text{-}Py_2NH$ = 2,2′-dipyridylamine) 1, has been hydrothermally synthesized; X-ray crystallography reveals that 1 possesses a novel cage topology structure in which the metal cluster core is constructed from six V_4Co pentatomic rings.

The hydrothermal synthesis of organic–inorganic hybrid vanadium oxides and polyvanadate clusters is of great interest due to their intriguing structural diversity and their potential functions as microporous solids for molecular adsorption, ion exchange and heterogeneous catalysis,[1–3] and as anode candidates in secondary lithium batteries and electrochromic devices.[4,5] Besides acting as a charge-compensating and space-filling constituent, the organic structure-directing component of such hybrid materials may also function as a ligand, the resulting transition metal complexes or fragments are then covalently bonded to metal framework or polyanion clusters.[6] Up to now, the study of vanadium solid state complexes has largely focused on infinite chains and layer structures.[7–10] Only a few discrete clusters have been reported, they are limited to $V_4O_{12}^{4-}$, [11] and $V_{10}O_{29}^{8-}$,[12] the latter formed through combination of two $V_4O_{12}^{4-}$ and one $V_2O_7^{4-}$ building unit by sharing oxygen atoms. Herein, we report the structure of a novel bimetallic cage complex, $[(2,2'\text{-}Py_2NH)_2Co]_3V_8O_{23}$ ($2,2'\text{-}Py_2NH$ = 2,2′-dipyridylamine**) 1**, which is based upon a new vanadium cluster $V_8O_{23}^{6-}$. To our knowledge, **1** is the first heterometallic cage complex composed of six pentatomic rings.

Complex **1** was obtained as red blocks in 20% yield by a hydrothermal reaction. A mixture of V_2O_5, 2,2′-dipyridylamine, $Co(OAc)_2{\cdot}4H_2O$ and H_2O in the mol ratio of 1 : 2 : 1 : 889 was stirred for 20 min, then transferred to a 25 ml Teflon-lined stainless steel bomb, which was kept at 140 °C under autogenous pressure for three days.‡ The IR spectrum of **1** exhibits characteristic bands at 922vs cm^{-1} for the terminal V=O stretch and at 800–770 cm^{-1} for the V–O–V stretch.

As shown in Fig. 1, the crystal structure§ of **1** consists of isolated neutral undecanuclear heterometallic clusters $[(2,2'\text{-}Py_2NH)_2Co]_3V_8O_{23}$ which are built up from a $V_8O_{23}^{6-}$ cluster and three $[(2,2'\text{-}Py_2NH)_2Co]^{2+}$ fragments. The cobalt atom has a distorted octahedral environment. It coordinates to four N atoms from two 2,2′-dipyridylamine ligands and two oxygen atoms from vanadium oxides, which adopt *cis*-orientation.

The core of **1** is $V_8O_{23}^{6-}$, which can be regarded as a pseudo-cube octanuclear vanadium cluster though there are three V–O–V edges replaced with three V–O–Co–O–V long edges (Fig. 2). The anionic vanadium cluster is composed of corner-sharing VO_4 tetrahedra, all VO_4 tetrahedra have one terminal oxygen atom. There are two crystallographically independent vanadium atoms: the V1 atom shares oxygen atoms with one CoN_4O_2 octahedron and two VO_4 tetrahedra while the V2 atom only shares oxygen atoms with three VO_4 tetrahedra. The cobalt atoms connect with neighboring vanadium atoms *via* O1 and its symmetry equivalents to finish the empty 'edges' of the pseudo-cube, thus a unique cage topology structure is formed, which is constructed from six V_4Co pentatomic rings. This cage topology feature has not been described in other heterometallic clusters to date.[11,12]

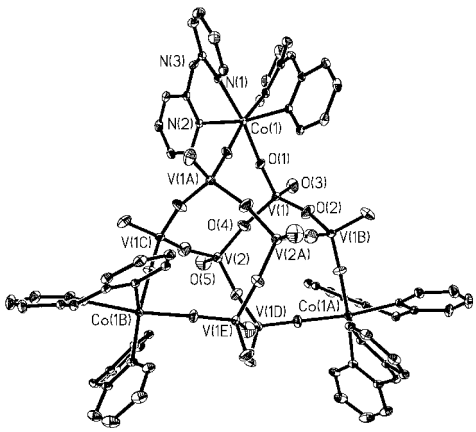

Fig. 1 A diagram showing the molecular structure of **1** with 10% thermal ellipsoids.

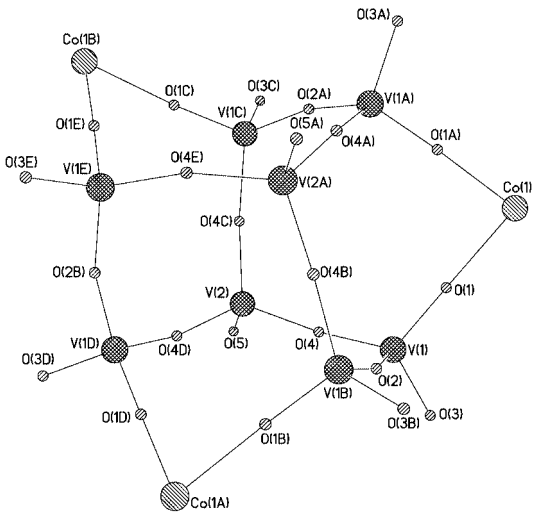

Fig. 2 The metal cluster core in **1**.

† Electronic supplementary information (ESI) available: rotatable 3-D crystal structure diagrams of **1** in CHIME format. Fig. S1: another view of the packing of cage **1** in three-dimensional space. See http://www.rsc.org/suppdata/cc/b1/b104273b/

 DOI: 10.1039/b104273b

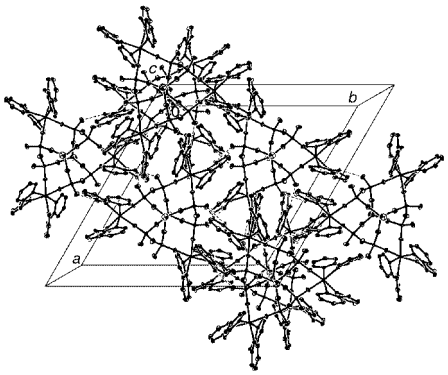

Fig. 3 The three-dimensional supramolecular array formed through intermolecular hydrogen bonding interactions in the solid state of **1**.

It is noteworthy that there is a C_3 symmetry axis along the O5=V2···V2A=O5A vector, the cluster, therefore, looks like a paddle with six 2,2′-dipyridylamine ligands corresponding to the paddles. The Co···Co separation along the edge of the cobalt triangle is 8.832 Å while the V2···V2A separation is 5.765 Å. The intermolecular hydrogen bonds play a significant role in stabilization of the structure of **1**. Each uncoordinated amino group of the 2,2′-dipyridylamine ligand links to O3 or its symmetry equivalents of the neighboring $V_8O_{23}^{6-}$ clusters *via* hydrogen bonding with a corresponding N···O distance of 2.787 Å. These hydrogen bonding interactions force the undecanuclear cages $[(2,2'\text{-}Py_2NH)_2Co]_3V_8O_{23}$ into an interesting three-dimensional supermolecular array, as shown in Fig. 3.

The cube-based cage compounds related to silsesquioxanes have been studied extensively for modeling framework metal zeolite centers.[13,14] This work demonstrates that a hydrothermal method is another optional route for obtaining new metal oxide cage materials. The formation of this type of heterometallic cage suggests that there will be many potential implications of such materials as new candidates for models of zeolites or catalyst.

Bidentate carbenoid ester coordination in ruthenium(II) Schiff-base complexes leading to excellent levels of diastereo- and enantioselectivity in catalytic alkene cyclopropanation†

Ian J. Munslow, Kevin M. Gillespie, Robert J. Deeth and Peter Scott*

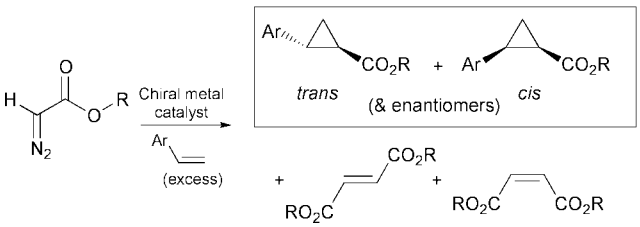
Received (in Cambridge, UK) 5th June 2001, Accepted 12th July 2001
First published as an Advance Article on the web 14th August 2001

Exceptionally high stereoselectivity (ee ⩽ 98%, dr ⩽ 99 : 1) in the cyclopropanation of alkenes with ethyl diazoacetate using a non-planar ruthenium(II) Schiff-base precatalyst is a result of η^2*C,O* binding of the carbenoid ester intermediate, according to DFT calculations.

The design of selective methods for the catalytic enantioselective synthesis of cyclopropanes remains of great interest to organic chemists, not least because of the importance of the compounds in biological and medicinal chemistry.[1] The asymmetric addition of carbenes to electron rich alkenes[2] (alkene cyclopropanation) represents a conceptually simple approach,[3] but typical reactions, such as that of styrenes with α–diazoacetates in the presence of a chiral metal catalyst, give a total of six organic products (Scheme 1).

Chemoselectivity for cyclopropanes over carbene dimerisation products (diethyl malonate and fumarate) is achieved through use of an excess of alkene and slow addition of the carbene source *e.g.* ethyl diazoacetate (EDA) to the reaction mixture.[4,5] For *trans*-selective catalysts, excellent enantiomeric excesses have been obtained,[6] but most exhibit only moderate *trans*/*cis*- *i.e.* diastereoselectivity. For example, Evans' bis(oxazoline) copper system gave 99% ee in the *trans* product which was formed with a dr of 73 : 27.[6] This and other results are consistent with Pfaltz's analysis that the *cis/trans* selectivity for a given metal depends almost exclusively on the structure of the alkene and diazo compound; the effect of the ligand is relatively unimportant.[7] Correspondingly, the use of bulkier diazo ester substituents such as *tert*-butyl and 2,6-di-*tert*-butyl-4-methylphenol leads to much higher diastereoselectivities.[6,8,9] An exception here is found in Che's D_4-symmetric Ru porphyrin system (dr 97 : 3, ee 98% at −40 °C) where the four sterically-demanding chiral substituents strongly orient alkene approach.[10] Highly *cis* selective catalysts based on Co and Ru using *tert*-butyl diazoacetate have recently been reported (*e.g.* dr 7 : 93 and ee 99%).[11]

We have been interested in the use of biaryldiimine complexes in enantioselective catalysis,[12] and have discovered



Scheme 1 Products typically formed in metal catalysed cyclopropanation *via* intermolecular carbene transfer to alkene.

R = R' = Cl **H_2L^3**

that unlike salen-derived ligands, the system L in its early transition metal complexes gives the α-*cis* topology **I** or occasionally the β-*cis* structure **II**;[13] both arrangements dictate that the co-ligands X are placed in mutually *cis* coordination sites. This has important consequences for alkene cyclopropanation by the complexes M = Ru as described herein.

The reaction of Na_2L^n with [{RuCl(μ-Cl)(η-C$_6$H$_6$)}$_2$] in acetonitrile gave the Ru^{II} complexes of ligands L^n in high yield.

The molecular structure of one example β-*cis*-[RuL^1(CH$_3$CN)$_2$] is shown in Fig. 1.† This, and analogous complexes of L^2 and L^3 retain the β-*cis* structure **II** in solution as evidenced by NMR spectroscopy.

Table 1 Enantioselective cyclopropanation catalysed by (*R*)-β-*cis*-[RuL^1(CH$_3$CN)$_2$][a]

Entry	Product	Yield/(%)[b]	dr/(%)	ee/(%)[c]
1		92	99:1	98
2		88	99:1	97
3		94	98:2	95
4		90	96:4	86
5		89	96:4	86
6		80	—	91
7		98	—	85

[a] Entries 1–5; 5 mol% of (*R*)-β-*cis*-[RuL^n(CH$_3$CN)$_2$] in toluene, 4/5 equiv. of styrene, 2 h at rt. [b] Isolated yield after flash chromatography (yield based on EDA for entries 1–5). [c] Absolute configuration of *trans* isomer (1*R*,2*R*) by comparison of optical rotations with literature values (ref. 15) for entries 1–5.

The results of addition of EDA over 2 h to solutions of styrenes at rt in the presence of pure precatalyst (*R*)-β-*cis*-[RuL^1(CH$_3$CN)$_2$] are summarised in Table 1 (entries 1–5).‡ The chemoselectivity (yield), *trans*:*cis* ratios (dr) and ee are arguably the best yet attained.[10,11] The ligand L^1 appears to be close to optimal for the cyclopropanation of styrenes; preliminary experiments with the bulky system L^2 and the electron withdrawing L^3 gave significantly lower selectivities. Mechanistic details for the catalytic reaction are currently under investigation.§

The selectivity determining step in alkene cyclopropanation involves the transfer of a metal bound carbene to the substrate,[14] and we set out to investigate this crucial step for the current system using Density Functional Theory (DFT) calculations. A fully optimised DFT structure of the precatalyst β-*cis*-[RuL^1(CH$_3$CN)$_2$] was found to be virtually superimposable on the molecular structure shown in Fig. 1. Minimisation of a structure arising from the removal of the CH$_3$CN groups and addition of the carbene derived from EDA (*i.e.* :CH-CO$_2$Et) led spontaneously to formation of a chelate, reminiscent of η^2-carboxylate, with both carbene C atom and carbonyl oxygen atom bound to Ru (Fig. 2). This structure with the carbene C atom *trans* to phenolate is *ca.* 30 kJ mol^{-1} more stable than that with the carbene *trans* to imine; an observation in accord with the expected order of *trans* influence of the two groups (N > O).

Hence the electronically controlled placement of the carbene *trans* to phenolate and the subsequent ester binding determines which diastereomeric face of the carbenoid is presented to the incoming alkene. The sense of asymmetric induction is as predicted by this model.¶ Also as a result of tight binding of the carbenoid ester, the orientation of approach of the alkene toward the reaction centre is exceptionally well directed by the chiral biaryldiimine ligand (Fig. 2); this leads to the high diastereoselectivity observed.

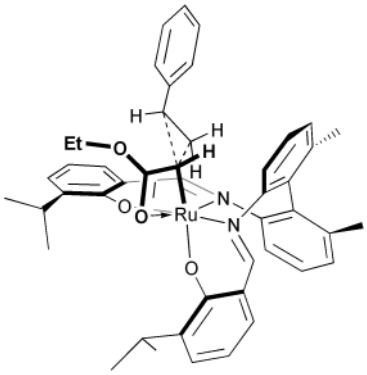

Fig. 2 Calculated structure of the carbene catalyst [RuL^1(η^2-CHCO$_2$Et)] showing the preferred orientation of approach of styrene.

P. S. wishes to thank EPSRC for a postdoctoral fellowship (K. M. G.) and Pfizer Ltd for a CASE award (I. J. M.). R. J. D. acknowledges the use of the EPSRC UK Computational Chemistry Facility.

Notes and references

‡ This complex also efficiently catalyses the intramolecular cyclopropanation/cylisation of a range of allylic diazoacetates. For example, *trans*-hex-2-enyl and geranyl diazoacetates were converted to the corresponding oxabicyclohexanones (entries 6 and 7) in a similar manner to Doyle *et al.*,[3] with the exception that *slow addition of substrate was not required* and the reaction proceeded at rt in under 2 h.

§ Attenuated selectivity in polar solvents, particularly for more electron rich alkenes, suggests significant polarity in the transition state. This will be investigated by Hammett methods. Preliminary kinetic experiments have indicated that the reaction is first order in catalyst.

¶ The (*S*)-catalyst shown in Fig. 2 gives rise to 1*S*-2*S* cyclopropanes, hence (*S*)-β-*cis*-[RuL^1(CH$_3$CN)$_2$] used in the experimental study is predicted to yield 1*R*-2*R* isomers (Table 1).
