Zr–O(2)–Zr/°	146.50	146.35

[a] Ref. 15.

The starting point for this study, prior to the introduction of the proton, was the simulation of the equilibrium bulk structure. The perovskite structure of $CaZrO_3$ is built upon a framework of corner-linked ZrO_6 octahedra with the calcium ion in a 12-coordinate site. The orthorhombic structure (space group *Pcnm*) exhibits significant tilting of the octahedra from the ideal cubic configuration.[15] The calculated and experimental lattice parameters, bond lengths and bond angles are listed in Table 1. Examination of the values shows good agreement between experimental and simulated structures, with $< 0.5\%$ deviation in the cell parameters and bond lengths. In addition, the appreciable tilting of the ZrO_6 octahedra (and the corresponding Zr–O–Zr bending) are correctly reproduced.

Of primary interest here is the information on the microscopic mechanism revealed by the MD calculations. Graphical analysis of the evolution of the system with time shows a number of proton 'hopping' events during the simulation run. Fig. 1 presents 'snapshots' of one of these proton hops between neighbouring oxygen ions of connecting octahedra, illustrating initial and barrier (transition) states. This confirms that proton conduction occurs *via* a simple transfer of a lone proton from one oxygen ion to the next (Grötthuss mechanism), with no evidence for the migration of hydroxyl ions ('vehicle' mechanism) on the present timescale.

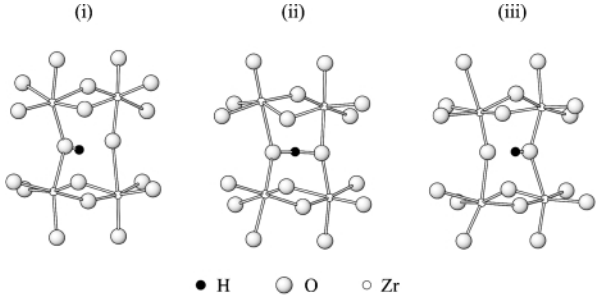

Fig. 1 Sequence of three snapshots from *ab initio* MD simulations showing inter-octahedra proton hopping in orthorhombic $CaZrO_3$ (the Ca ions are omitted for clarity).

We also find rapid rotational and stretching motion of the O–H group, which allows the reorientation of the proton towards the next oxygen ion before the transfer process. However, the simulations reveal predominantly inter-octahedra proton hopping, rather than within octahedra. This diffusion path is influenced by the ZrO_6 tilting within the orthorhombic structure which leads to short oxygen–oxygen separations between the vertices of adjacent octahedra (shown in Fig. 1). These results are consistent with the observation that proton mobility is lower in perovskite structures deviating strongly from cubic.[1,2] There is also considerable lattice vibrational dynamics with large amplitudes of vibration of the oxygen ions. In particular, for each hopping event the O(H)–O distance shortens from equilibrium values (of *ca*. 2.7–2.9 Å) to <2.4 Å so as to facilitate proton transfer; this suggests that migration is 'phonon-assisted'. We note that recent simulations of zeolites have found similar coupling between proton motion and framework dynamics.[16]

The interaction between oxygen ions and the proton is probed further by analysis of the electron density distribution (illustrated in Fig. 2 as a contour map for the inter-octahedra path). The barrier state displays a symmetric density distribution, in which there is equal hydrogen bonding to the two adjacent oxygen ions (leading to a shorter oxygen–oxygen distance). This confirms that the proton is not transferred through a totally 'free' state, so that all the OH bonds are never completely broken. Although additional analysis of the wavefunction would be useful, it is apparent that the host lattice exhibits localised spherical-like density about the nuclei indicative of the largely ionic character.

In an attempt to probe the question of proton–dopant association, we have undertaken a series of calculations on defect pairs ($OH_O^{\bullet}M'_{Zr}$) comprised of a hydroxyl ion and a neighbouring dopant substitutional; here we employed a slightly larger periodically-repeated system corresponding to $Ca_8Zr_7MO_{24}H$ in order to achieve a lower dopant content. Attention was focused on three commonly used dopants in $CaZrO_3$, namely Sc^{3+}, Ga^{3+} and In^{3+}. The binding energies were derived with respect to the two isolated defects where a negative value indicates the system is bound.

The resulting energies (reported in Table 2) predict that all the hydroxyl–dopant pairs are favourable configurations, with the lowest value for Ga^{3+}. Although there are no experimental data on $CaZrO_3$ for direct comparison, the calculated values are in accord with proton 'trapping' energies of *ca*. -0.2 and -0.4 eV for Sc-doped $SrZrO_3$ and Yb-doped $SrCeO_3$ respectively, derived from recent muon spin relaxation (μSR) and quasi-elastic neutron scattering (QENS) experiments.[17] These studies postulate that in the course of their diffusion, protons are temporarily trapped at single dopant ions. The present calculations therefore predict possible trapping effects and the presence of proton–dopant pairs in the $CaZrO_3$ material. It is noted, however, that defect pairs do not necessarily preclude the presence of isolated protons and dopant ions, since clusters will be in equilibrium with single defects. This picture can be viewed as analogous to oxygen ion conductivity in fluorite oxides and the well-known importance of dopant–vacancy interactions.[18]

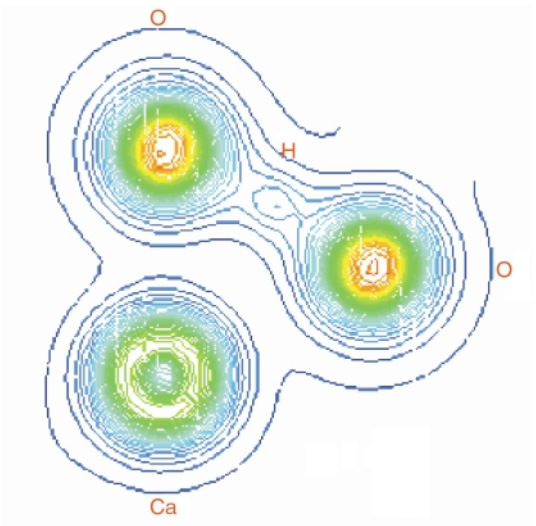

Fig. 2 Electronic charge density of the barrier (transition) state for inter-octahedra proton transfer in the plane defined by Ca, O and H (colour scale: high to low density is red to blue).

Table 2 Binding energies of hydroxyl–dopant pairs ($OH_O^{\bullet}M'_{Zr}$) at nearest-neighbour sites

Dopant	E_{bind}/eV[a]
Sc^{3+}	−0.31
Ga^{3+}	−0.18
In^{3+}	−0.30

[a] 1 eV ≡ 96.486 kJ mol^{-1}.

In summary, our *ab initio* simulation study has allowed us to gain significant insight as to the proton migration mechanism and proton–dopant binding in the $CaZrO_3$ orthorhombic perovskite at the microscopic level. This forms part of the continuing effort to improve our understanding of proton transport, a key phenomenon in a variety of systems that range from inorganic solids to biomolecules. Further simulation work is in progress and it is hoped that the present study prompts new experimental investigations in this area using, for example, neutron scattering or muon spin techniques.

We wish to thank the EPSRC for funding this work, the Royal Society for a University Research Fellowship (J. D. G.) and the Computational Chemistry Working Party for the use of the supercomputer facilities at the Rutherford Appleton Laboratory, UK.

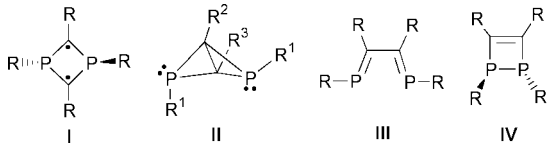
First published as an Advance Article on the web 16th March 2001

The reaction of $PbCl_2$ with *Z*-[CyP=C(Bu^t)MgCl(OEt$_2$)] (Cy = cyclohexyl) affords the first example of an *endo*:*endo*-2,4-diphosphabicyclo[1.1.0]butane, $Cy_2P_2C_2Bu^t_2$, which displays unusual spectroscopic and geometric properties, the origins of which have been explored by theoretical calculations.

Because of their unusual properties and application to organic transformations, strained hydrocarbon rings and cages have been the subject of intense investigation.[1] In recent years this attention has extended to the phosphorus substituted analogues of these systems, often with remarkable results.[2] For example, Niecke *et al.* have succeeded in preparing several stable, crystalline, diradical 1,3-diphosphacyclobutanediyls **I**.[3] Thermal valence isomerisations of these have yielded 1,2-dihydro-



I II III IV

1,2-diphosphetes **IV**[4] whilst a photolytic isomerisation has yielded the only example of a 2,4-disphosphabicyclo[1.1.0]butane **II** (R^1 = Mes* ($C_6H_2Bu^t_3$-2,4,6), R^2 = $SiMe_3$, R^3 = H, **1**) which has *exo*:*endo*-phosphorus substituents.[3] Indeed, compound **1** can itself thermally valence isomerise to the corresponding 1,4-diphosphabutadiene **III**. The relative stabilities of these isomers have been calculated to be in the order **I** < **II** < **III** < **IV**.[3–5] Compounds of the general type **III** and **IV** are now relatively common and have found a number of applications as building blocks in organophosphorus and organometallic chemistry, and as ligands in the formation of novel coordination compounds.[2,6] Despite this, examples of **I** and **II** are very rare and their preparation can be challenging. We have developed a high yielding stereospecific route to a range of phosphavinyl Grignard reagents, *e.g. Z*-[CyP=C(Bu^t)MgCl(OEt$_2$)] (Cy = cyclohexyl) **2**,[7] which we saw as potential precursors to $P_2C_2R_4$ heterocycles such as **I** and **II** *via* oxidative coupling reactions. The results of our endeavours in this area are reported herein.

† Electronic supplementary information (ESI) available: calculation data and atomic coordinates for compounds **4**–**6**. See http://www.rsc.org/suppdata/cc/b1/b100993l/

Treatment of an ethereal solution of $PbCl_2$ with 2 equivalents of **2** at −78 °C led to the deposition of lead metal and the stereoselective formation of the diphosphabicyclo[1.1.0]butane **3** in 60% yield (Scheme 1). The reaction also occurs with $SnCl_2$ though in lower (30%) yield. The mechanism of this reaction presumably involves an organolead intermediate, *Z,Z*-[Pb{C(Bu^t)=PCy}$_2$], though this could not be detected when the reaction was followed by ^{31}P NMR spectroscopy. The formation of **3** contrasts with the reaction between **2** and Me_2SnCl_2 which does not lead to an oxidative coupling but to *Z,Z*-[Me_2Sn{C(Bu^t)=PCy}$_2$] as the major product.[8] Interestingly, **3** was found to be remarkably stable (mp 118 °C) and did not valence isomerise in refluxing toluene over 10 h or when treated with UV light (*cf.* the facile thermal isomerisation of **1**).

Most of the spectroscopic data‡ for **3** are consistent with its proposed structure. However, its ^{31}P{^{1}H} NMR spectrum displays a singlet at δ 12 ppm which is far removed from the expected region (upfield of δ −80 ppm, *e.g.* δ −83 and −84 ppm for **1**) for three-membered phosphirane rings[2,9] but close to values normally observed for examples of **I**.[3,4] In addition, the signal for the framework carbon atoms appears as a triplet at δ 60.3 ppm, $^1J_{PC}$ 52 Hz, which is significantly downfield of the values for **1**, δ 28.3 ppm, and phosphirane rings in general.[9] We hoped to shed light on these apparent inconsistencies by carrying out density functional studies[10] on the three possible stereoisomers of tetramethyl-2,4-disphosphabicyclo[1.1.0]butane. A summary of the results of this preliminary investigation is shown in Table 1.

It is clear that the *endo*:*endo* isomer is the thermodynamically least favourable of the three isomers but probably forms in the case of **3** due to stereochemical constraints on the coupling reaction. The calculated ^{31}P NMR shift for **4** is close to the experimental value for **3** and more than 100 ppm downfield of the values for **5**, **6** and the experimentally observed compound **1**.[3] Unfortunately there are no known examples of *exo*:*exo* diphosphabicyclobutanes for purpose of comparison. An explanation for the low field ^{31}P and ^{13}C NMR shifts for **3**

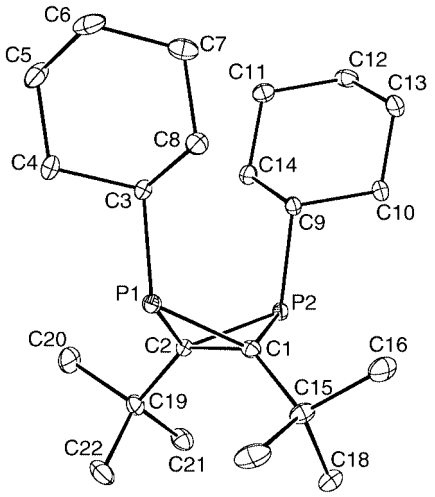

Fig. 1 Molecular structure of **3**. Selected bond lengths (Å) and angles (°): P(1)–C(1) 1.833(3), P(1)–C(2) 1.826(3), P(1)–C(3) 1.875(3), P(2)–C(1) 1.819(3), P(2)–C(2) 1.832(3), P(2)–C(9) 1.859(3), C(1)–C(2) 1.543(4); C(2)–P(1)–C(1) 49.89(13), C(2)–P(1)–C(3) 113.03(13), C(1)–P(1)–C(3) 117.25(13), C(1)–P(2)–C(2) 50.01(13), C(1)–P(2)–C(9) 112.39(13), C(2)–P(2)–C(9) 116.47(13), C(15)–C(1)–C(2) 138.0(3), C(19)–C(2)–C(1) 138.0(3).

may be drawn from its geometry (Fig. 1).§ The fold angle between its two PCC rings is in good agreement with theoretical calculations on **4** and markedly greater than in **1**,[3] **5** and **6**. There is a concomitant loss of pyramidalisation of its P- and framework C-centres relative to **1** and **6** and a lengthening of the transannular bond. Thus it is possible that the bonding in the P_2C_2 frameworks of the *endo*:*endo* isomers, **3** and **4**, lies closer to that reported for partially delocalised 1,3-diphosphacyclobutanediyls than does the bonding in the *endo*:*exo* isomers, **1** and **6**. In this context it is noteworthy that the two general valence isomers **I** and **II** have been described as bond stretch or orbital isomers.[3,4]

We are currently carrying out more extensive calculations to determine the nature of any bonding differences in **4**–**6**. We are also further investigating valence isomerisations of **3** and related compounds, in addition to exploring the versatility of **2** as a synthon in the formation of other strained organophosphorus heterocycles and cages. The results of these studies will appear in forthcoming publications.

We gratefully acknowledge financial support from the EPSRC (studentship for A. F. R) and for access to the UK Computational Chemistry Facility.

Polarity and hydrogen-bonding of ambient to near-critical water: Kamlet–Taft solvent parameters

Jie Lu, James S. Brown, Charles L. Liotta and Charles A. Eckert*

Schools of Chemical Engineering, Chemistry and Biochemistry, and Specialty Separations Center, Georgia Institute of Technology, Atlanta, GA 30332-0100, USA. E-mail: cae@che.gatech.edu

Received (in Corvallis, OR, USA) 9th January 2001, Accepted 20th February 2001
First published as an Advance Article on the web 16th March 2001

The Kamlet–Taft solvent parameters π^*, α, and β of saturated liquid water have been determined from 25 to 275 °C based on solvatochromic measurements and indicate that the polarity and hydrogen-bonding of water are highly tunable properties with temperature.

Nearcritical water (NCW) is an environmentally benign solvent and alternative reaction medium, which can simultaneously solubilize organics and ionics[1] because the dielectric constant of water decreases significantly at elevated temperatures (for example, ε = 23.5 at 275 °C).[2] In addition, the ionization constant of water increases several orders of magnitude from ambient to nearcritical conditions,[3] providing hydronium and hydroxide ions that can act as modest acid or base catalysts in chemical reactions.[4,5] Interest in NCW as a reaction medium has prompted study of the solvent properties of water at elevated temperature.[6,7] However, to date our understanding of the solvent properties of NCW has been inadequate for correlating and predicting chemical reactions and other physicochemical processes.

Kamlet–Taft solvent parameters π^*, α, and β have been related to a variety of configurational properties in solution: solubilities, partition coefficients, thermodynamic and kinetic properties of chemical reactions, *etc.*, based on successful treatments of solvent effects by linear solvation energy relationship (LSER) theory,[8]

$$XYZ = (XYZ)_0 + s\pi^* + a\alpha + b\beta$$

where π^*, α and β are the parameters for dipolarity/polarizability, hydrogen bond donating ability and hydrogen bond accepting ability, respectively. XYZ and $(XYZ)_0$ are the solvent-dependent physicochemical properties in a given solvent and in a reference solvent (gas or inert solvent). *s*, *a*, and *b* are solvent-independent coefficients indicating the susceptibility of the corresponding parameters to the solvent property. Based on the LSER theory, the π^*, α, and β solvent parameters of water can be used to correlate and predict processes occurring in NCW. In this work, we report the solvatochromic parameters of saturated liquid water in the temperature range 25–275 °C.

A high-pressure titanium optical cell equipped with sapphire windows (Insaco Inc., PA, 0.50 inches diameter, 0.25 inches thick) sealed with gold gaskets (Aldrich, 99.99%) was constructed to measure the solvatochromic parameters of NCW from ambient to nearcritical conditions. The path length of the cell is 10.5 mm at rt and the internal volume is 17.7 cm^3.

Some of the indicators used decompose in water at elevated temperatures. When decomposition products contain similar chromophores to those of indicators, an undesirable spectral shift can result. In order to avoid errors associated with decomposition of solvatochromic indicators, the cell was first loaded with water (Aldrich, HPLC grade, deoxygenated with N_2 before being used) and heated to the desired temperature. Then a small amount of concentrated indicator solution was injected into the cell through a sample loop. Temperature equilibrium was restored within 10 s. Multiple spectra were measured in less than five minutes before significant decomposition could take place. A Hewlett-Packard 8450 UV-Vis spectrophotometer was used to perform the spectroscopic measurements and data processing.

The π^* parameters were determined based on the UV-Vis spectral shift of 4-nitroanisole (Aldrich, 97%). Cyclohexane and dimethyl sulfoxide at ambient conditions were used as reference solvents, the π^*s of which are 0.0 and 1.0, respectively.

The spectral shift of the dichloro-substituted betaine dye (2,6-dichloro-4-(2,4,6-triphenyl-1-pyridinio)phenolate, Fluka, HPLC grade) was measured to obtain α parameters instead of commonly used betaine dye. To function as an effective solvatochromic indicator, a betaine dye must remain deprotonated. The p*K*a of the betaine dye (E_T(30) dye) is 8.6,[9] while that of dichloro-substituted betaine dye (E_T(33) dye) is 4.8. The latter is less basic and a more suitable indicator for this study due to the increased ionization constant of water at nearcritical conditions. The E_T(30) values of water were obtained from the established correlation between E_T(30) and E_T(33).[9] The calculation of α is based on the correlation with E_T(30) and π^*, which is deduced from the correlation of literature data of 16 compounds.[10] 4-nitroaniline (Aldrich, 99+%) and *N*,*N*-dimethyl-4-nitroaniline (Acros) were used to obtain the β based on the solvatochromic comparison method.[11]

The π^* values of water are shown at different temperatures from 25 to 275 °C in Fig. 1. The dipolarity/polarizability of water decreases continuously with increasing temperature. At 275 °C, water has a polarity comparable to that of acetic acid at rt. This trend is consistent with the decrease in the dielectric constant of water with temperature as observed by Uematsu and Franck.[2]

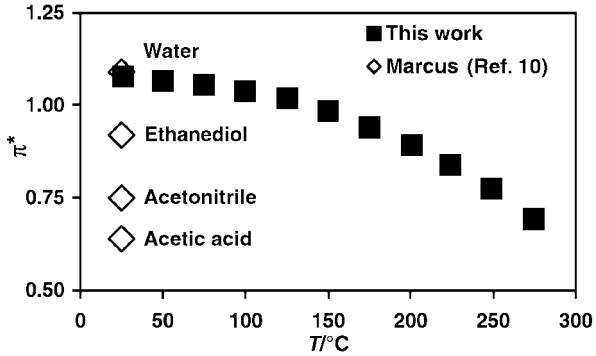

Fig. 1 π^* for nearcritical water as a function of temperature.

α indicates the hydrogen bond donating ability of a solvent. The α values of saturated liquid water as a function of temperature are shown in Fig. 2. The hydrogen bond donating ability of water decreases at elevated temperature and changes from that of ambient water to ambient methanol-like and then to ambient ethanol-like when we raise the temperature from 25 to 275 °C.

β indicates the hydrogen bond accepting ability of a solvent. The β values of water are shown in Fig. 3. Although various values of β are reported in the literature, this result at rt is consistent with that of Taft *et al.*, who attributed it to water-

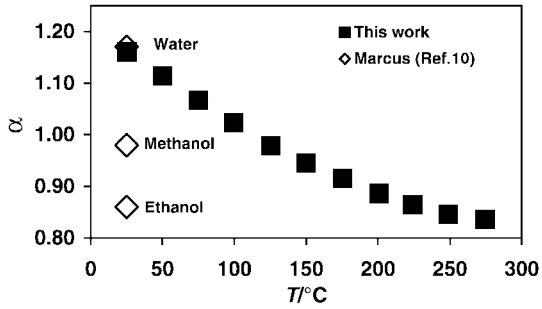

Fig. 2 α for nearcritical water as a function of temperature.

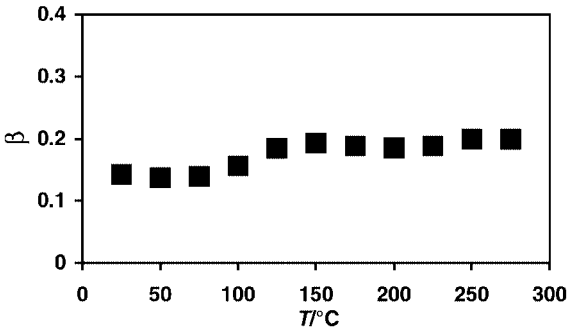

Fig. 3 β for nearcritical water as a function of temperature.

solvent clusters.[12] In contrast to the π^* and α of water, the β actually increases slightly with increasing temperature. The slight increase of β may be brought about by the breakdown of the hydrogen-bonding network of water at elevated temperature, which makes the oxygen atom of the water molecule more accessible as a hydrogen bond acceptor.[13] Bennett and Johnston measured the solvatochromism behavior of organic probes in near- and supercritical water, and observed similar large changes in polar and hydrogen-bonding interactions as the temperature was increased from ambient to 250 °C.[6]

In summary, the large dipolarity/polarizability, π^*, and hydrogen bond donating ability, α, of ambient water decrease significantly with increasing temperature. The hydrogen bond accepting ability, β, remains low and relatively constant throughout the entire temperature range studied. NCW is a benign and promising reaction medium for the replacement of organic solvents. The Kamlet–Taft parameters we report in this work provide a powerful tool for describing varied physicochemical processes in NCW.

The authors are grateful for the financial support of the National Science Foundation (CTS-9613063) and the Environmental Protection Agency (R-825325 and R-82813001-0). We would like to thank Brandon Eason, Kevin West, and David Bush for valuable suggestions and discussions.

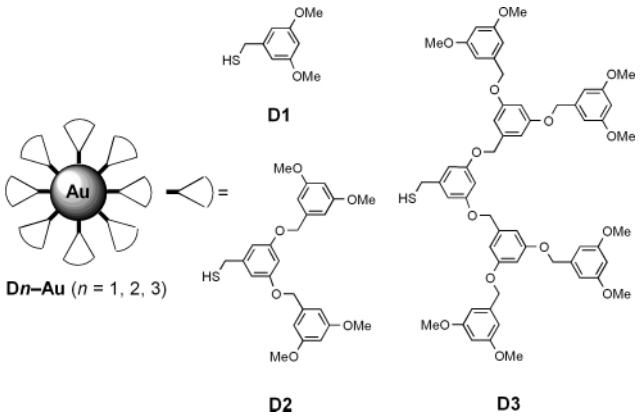
Received (in Cambridge, UK) 16th January 2001, Accepted 28th February 2001
First published as an Advance Article on the web 21st March 2001

Dendron-stabilized gold nanoparticles synthesized with Fréchet-type dendrons possessing a single thiol group at the focal point have small cores (average diameters of 2.4–3.1 nm) with narrow size distribution and remarkably high stability; in particular, the nanoparticles synthesized with the second generation dendron has an almost monodisperse core (2.4 ± 0.2 nm).

The chemistry of metal nanoparticles is one of the rapidly emerging research fields because of their potential applications to sensor devices, catalysis, nanoelectronics and many other area.[1] In particular, synthesis of large quantities of monodisperse nanoparticles of diameter < 10 nm is important for many of their applications. Following the seminal work of Schiffrin and coworkers[2] on stable gold clusters coated with alkanethiolate monolayers, many monolayer-stabilized gold nanoparticles have been reported.[3] Among them, dendrimer-stabilized gold nanoparticles, in which dendrimers play dual roles as a stabilizer and a permselective organic shell, have drawn considerable attention: early examples include gold colloids coated with poly(amidoamine) (PAMAM) dendrimers containing terminal amines.[4,5] However, they are only stable in solution and in the presence of excess of free dendrimers owing to the low affinity of the terminal amine groups for gold. Subsequently, PAMAM dendrimers partially functionalized with thiol groups have been used to enhance the stability of the dendrimer-stabilized gold nanoparticles.[6] Despite the enhanced stability, however, the resulting gold nanoparticles exhibit a rather broad size distribution because the degree of functionalization of the dendrimers is difficult to control precisely. Herein we report a new strategy where dendrons with a single thiol group at the focal point are used as a stabilizer and a permselective organic shell is employed to produce Au nanoparticles. This affords highly stable Au nanoparticles with smaller cores (ave. diam., 2.4–3.1 nm) and narrower size distribution. In fact, the nanoparticles synthesized with the second generation dendron has an almost monodisperse core (2.4 ± 0.2 nm). To our knowledge, this is the first set of examples of dendron-stabilized metal nanoparticles.[7]

First, second and third generation dendron-thiols (**D1**, **D2**, and **D3**, respectively; Scheme 1)[8] were prepared from the reaction of the corresponding Fréchet-type dendron-bromides[9] with thioacetic acid, followed by reduction with $LiAlH_4$.† Dendron-stabilized gold nanoparticles (**D1–Au**, **D2–Au**, and **D3–Au**) were synthesized by the two-phase method reported by Schiffrin with some modification.[2] More specifically, a two-phase mixture containing $HAuCl_4$ in water and tetraoctylammonium bromide in toluene was stirred, the organic layer separated and treated with dendron-thiol (dendron-thiol : Au = 2 : 1) and finally allowed to stir vigorously with an aqueous solution of $NaBH_4$ which afforded the crude product. Purification of the crude products by several cycles of precipitation–filtration–dissolution from toluene–ethanol solution yields **D1–Au** and **D2–Au** as black powders, and **D3–Au** as a black waxy powder. All of the nanoparticles are soluble in common organic solvents such as toluene, acetone, dichloromethane, chloroform or THF. They are remarkably stable both in solution, as well as in the solid state. Little decomposition or aggregation occurs even after several months in solution, as judged by their solubilities and UV–VIS spectra. Furthermore, these nanoparticles remain unchanged after standing overnight at elevated temperatures (at 50 °C in solution and at 160 °C in the solid state). The origin of the remarkable stabilities of these dendron-stabilized Au nanoparticles remains to be established.



Scheme 1 Schematic illustration of dendron-stabilized Au nanoparticles.

The core size and size distribution of the dendron-stabilized Au nanoparticles were examined by high resolution transmission electron microscopy (HR-TEM) (Fig. 1). In general, the present Au nanoparticles have a narrower size distribution than most of the previously known alkanethiolate-,[3a] arylthiolate-,[3b] or dendrimer-stabilized gold nanoparticles.[4–6] For example, **D1–Au**, having an average core size of 2.8 ± 0.3 nm, shows a narrower size distribution compared with the gold nanoparticles prepared with arylthiols of similar sizes.[3b] Most remarkably, **D2–Au** is nearly monodisperse with an average core size of 2.4 ± 0.2 nm. The core size and dispersity are not significantly affected by use of different molar ratios of **D2** : $HAuCl_4$ such as 0.5 and 6. Such monodispersity is seldom observed in unfractionated metal nanoparticles.[10] On the other hand, **D3–Au** has a larger and less narrow-disperse core (3.1 ± 0.6 nm) compared with **D1–Au** and **D2–Au**. The larger core size of **D3–Au** over those of **D1–Au** and **D2–Au** is in contrast to the earlier observation that the cores of dendrimer-stabilized Au nanoparticles decrease in size and dispersity with increasing dendrimer generation.[4,5] At present, we do not understand why

† Electronic supplementary information (ESI) available: synthetic procedures and characterization data for dendron-thiols (**D1**–**D3**) and their gold nanoparticles. See http://www.rsc.org/suppdata/cc/b1/b100575h/

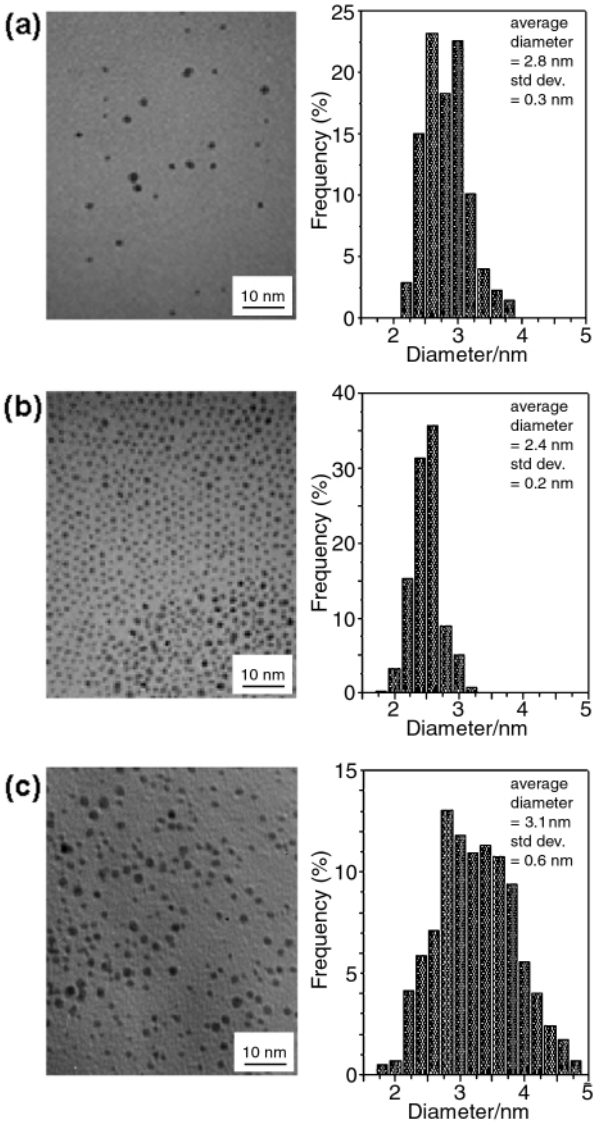


Fig. 1 TEM micrographs and histograms of size distribution for the dendron-stabilized Au nanoparticles: (a) **D1–Au**, (b) **D2–Au** and (c) **D3–Au**. The average core sizes and distribution were determined by counting 345 (**D1–Au**), 598 (**D2–Au**) and 819 (**D3–Au**) particles.

there is apparently no correlation between dendron generation and particle size. However, we suspect that the second generation dendron **D2** may have a 'magic' size to protect Au particles with the particular size leading to monodispersity. We are currently investigating in depth the effect of dendron size on the size and dispersity of Au nanoparticles. As seen in Fig. 2, **D1–Au** and **D3–Au** exhibit a typical surface plasmon (sp) band at 530–540 nm in their UV–Vis spectra, whereas **D2–Au** displays a very weak sp band, which is consistent with its smaller particle size and narrower distribution.[11] Further characterization of the dendron-stabilized Au nanoparticles is in progress.

In summary, we present the first dendron-stabilized Au nanoparticles synthesized with Fréchet-type dendrons possessing a single thiol group at the focal point, which have remarkably high stability and narrow size distribution. Particularly, the results on **D2–Au** suggest that this method may

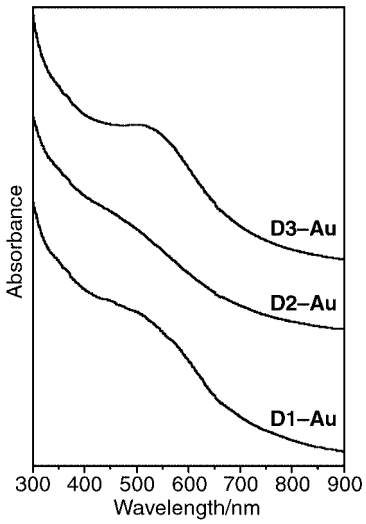

Fig. 2 UV–Vis spectra of the dendron-stabilized Au nanoparticles in THF.

provide a convenient way to synthesize stable, monodisperse Au nanoparticles with small cores. Furthermore, this work should be easily expanded to the synthesis of other dendron-stabilized metal nanoparticles which may find useful applications in many areas including chemical sensing and catalysis.

Received (in Cambridge, UK) 23rd January 2001, Accepted 22nd February 2001
First published as an Advance Article on the web 21st March 2001

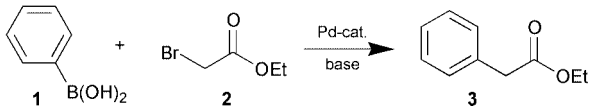
A palladium(0)-catalyzed cross-coupling reaction between arylboronic acids or esters and α-bromoacetic acid derivatives is described which allows the synthesis of various functionalized arylacetic acid derivatives under mild conditions.

Methylenecarboxy groups are key functionalities in many biologically active compounds such as the antiinflammatory and analgesic drugs Indomethacin or Aclofenac.[1] A mild and efficient procedure for the introduction of the methylenecarboxy group into functionalized molecules is thus of great interest. Traditional syntheses involve multistep procedures that are often incompatible with sensitive functionalities.[2] Alternatively, transition metal-catalyzed cross-coupling reactions between aryl halides and Reformatsky reagents,[3] tin,[4] copper,[5] and other enolates,[6] or ketene acetals have been employed.[7] Some electrochemical syntheses have also been reported.[8] However, especially for applications in combinatorial chemistry, most of these syntheses are quite inconvenient due to the instability or toxicity of the reagents or the required bases.

We imagined that the inverse approach of combining an arylmetal species with an α-halocarbonyl derivative might be an interesting alternative, especially for substrates containing sensitive functions such as enolizable keto-groups. Due to their easy handling and long shelf life, arylboronic acid derivatives would be the starting materials of choice, particularly for small-scale reactions. Arylboronic esters have recently become widely accessible from aryl halides by *in situ* coupling reactions that tolerate many functional groups.[9,10] In order to permit an application of the outlined coupling reaction in drug discovery, it is of utmost importance to overcome the necessity of using highly toxic reagents such as thallium carbonate.[11] Initial studies were carried out with phenylboronic acid and ethyl bromoacetate (Scheme 1).

Under standard Suzuki conditions using tetrakis(triphenylphosphine)palladium and potassium carbonate in DMF,[12] only trace amounts of the expected product **3** were detected. Instead, redox reactions between the arylboronic acid and ethyl bromoacetate predominated, leading to large amounts of biphenyl **4** and benzene **5**. This is not surprising since similar systems have purposely been used in the synthesis of symmetrical biaryls.[13] We have now discovered that the selectivity of the reaction can be completely inverted when bulky, moderately electron-donating phosphines are employed as ligands on palladium. Selected results are shown in Table 1.

Changing the ligand from triphenylphosphine to tri(*o*-tolyl)phosphine significantly improves the selectivity towards the desired coupling product and allows smooth conversions even at room temperature. In order to determine the origin of this effect, we varied both the steric and the electronic properties of the ligand (entries 1–9). Tri(*m*-tolyl)phosphine gives only poor selectivities, which led us to conclude that the steric bulk of the tri(*o*-tolyl)phosphine is responsible for the good selectivities. Additionally, the lower selectivities observed for tri(*o*-ethylphenyl)-, tri(*m*-xylyl)-, tri(mesityl)-, and di-*tert*-butylbiphenyl-2-ylphosphine indicate that the ligand must not be too electron-rich. These combined requirements are best fulfilled with tri(1-naphthyl)phosphine, and indeed, this ligand leads to enhanced product selectivity. Chelating phosphines such as (±)-BINAP totally inhibited the reaction, suggesting that the catalytic cycle proceeds through mono-ligated palladium complexes.



Scheme 1 Coupling of benzeneboronic acid and ethyl bromoacetate.

† Dedicated to Professor K. B. Sharpless on the occasion of his 60th birthday.

Both palladium(II) acetate and tris(dibenzylideneacetone) dipalladium(0) can be used as palladium(0) precursors and show no significant differences in activity (entries 3, 14). However, the amount of biaryl formed is slightly higher when palladium(II) acetate is used. This suggests that the boronic acid initially acts as a reducing agent for the palladium(II). Since a slight excess of boronic acid is usually added, this reaction has no influence on the isolated yields.

The choice of the base also affects the product selectivity (entries 3, 10, 11 and 8, 15). Both K_2CO_3 and K_3PO_4 are equally suitable as bases. However, at room temperature, shorter reaction times were often observed with potassium phosphate. KF was inferior for most substrates since larger amounts of the reduction products were formed. Only in the case of some electron-poor boronic acids did KF become the base of choice (see also Table 2). Other bases, for instance triethylamine, were significantly less active. Best results were obtained with excess amounts of base.

THF proved to be by far the most effective solvent. In acetonitrile, the reaction was much slower and the use of more polar solvents, *e.g.* DMF, drastically decreased the amount of isolable products. This could indicate that hydrolysis of the ester occurs. In THF, however, the presence of small quantities of

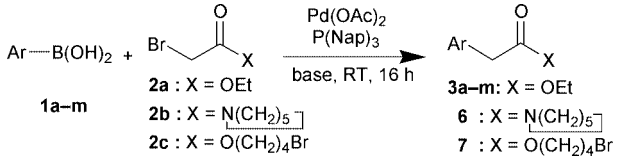
Conditions: (A) 1.2 equiv. arylboronic acid, 3 mol% $Pd(OAc)_2$, 9 mol% $P(Nap)_3$, 5 equiv. K_3PO_4, 2 equiv. H_2O, 20 °C, THF; (B) 1.2 equiv. pinacol boronate, 3 mol% $Pd(OAc)_2$, 9 mol% $P(Nap)_3$, 5 equiv. K_3PO_4, 2 equiv. H_2O, 20 °C, THF. [a] Isolated yields (GC-determined yields in parentheses). [b] KF instead of K_3PO_4. [c] K_2CO_3 instead of K_3PO_4

water had no adverse effect on the reaction outcome so that special drying of the solvent and the reagents is not required.

The generality and selectivity of the reaction were investigated using a number of arylboronic acids **1a**–**m** in combination with several alkyl halides (Scheme 2).

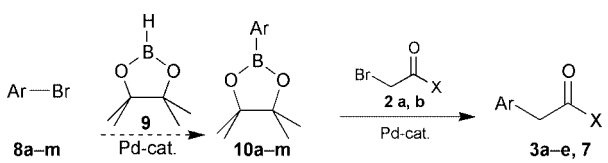


Scheme 2 Pd-catalyzed synthesis of arylacetic acid derivatives.

As can be seen in Table 2 (Method A), most substrates give good yields. Electron-poor and electron-rich compounds are equally suitable for the transformation. Even sterically hindered compounds (*o*-tolylboronic acid) or substrates that are sometimes problematic in palladium-catalyzed reactions (nitro- or heteroarenes) were successfully employed. Moreover, products containing enolizable keto-groups are readily formed without any signs of side products arising from undesired aldol condensations.

Besides ethyl bromoacetate (**2a**), other bromoacetates (**2c**) or -amides (**2b**) can be used. The high selectivity of the transformation is demonstrated by the formation of compound **7**‡ (Table 2): the arylation of 4-bromobutyl bromoacetate (**2c**) takes place exclusively α to the carbonyl group even though a primary alkyl bromide functionality is present.

Many functionalized pinacol boronates§ (**10**) are conveniently accessible from aryl halides (**8**) and bispinacol diboron[9] or pinacol borane (**9**).[10] We thus considered it to be important to extend our reaction to this substrate class (Scheme 3).



Scheme 3

We were pleased to find that the best conditions for the conversion of the boronic acids turned out also to be optimum conditions for pinacol boronate and that the reaction usually gives similar yields for both starting materials (Table 2, 'method B').

In summary, the disclosed palladium-catalyzed cross-coupling reaction between arylboronic acids or esters and α-bromoacetic esters or α-bromoacetic amides represents a mild and general approach to arylacetic acid derivatives. The simple reaction protocol which involves only air-stable chemicals and does not require absolutely dry solvents makes this reaction a valuable alternative to the existing protocols, especially for applications in combinatorial chemistry and drug discovery.

I thank M. Rössig and A. Söthe for technical assistance and Professor Dr M. T. Reetz for generous support and constant encouragement.

‡ *Synthesis of 4-bromobutyl phenylacetate* (**7**): A 100 mL flask was charged with palladium acetate (67.3 mg, 0.30 mmol), tri-1-naphthylphosphine (371 mg, 0.90 mmol), 4-bromobutyl bromoacetate (**2b**) (2.74 g, 10.0 mmol) and an excess of potassium phosphate (10.61 g, 50.0 mmol). The reaction vessel was purged with argon, a solution of benzeneboronic acid (1.46 g, 12.0 mmol) in THF (40 ml) was added and the reaction mixture was stirred at 20 °C overnight. The reaction slurry was then poured into water (300 mL) and extracted 3× with 100 mL portions of dichloromethane. The combined organic layers were dried over $MgSO_4$, filtered, and the volatiles were removed *in vacuo*. The residue was purified by fractional distillation. A colorless oil (2.41 g, 89%) boiling at 91 °C/0.01 mbar was collected and identified as the desired product. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 7.33–7.26 (m, 5H), 4.12 (t, ^3J (H,H) = 6 Hz, 2H), 3.62 (s, 2H), 3.38 (t, ^3J (H,H) = 6 Hz, 2H), 1.87 (m, 2H), 1.79 (m, 2H) ppm; ^{13}C NMR (75 MHz, $CDCl_3$, 25°C, TMS): δ = 171.5, 134.0, 129.2, 128.6, 127.1, 63.8, 41.4, 32.9, 29.2, 27.2 ppm; MS (70 eV): *m/z* (%): 270(6) [M^+], 191(4), 179(4), 136(23), 91(100); HRMS: calcd. for $C_{12}H_{15}BrO_2$ [M^+]: 270.02555; found: 270.02546; anal. calcd. for $C_{12}H_{15}BrO_2$ (271.16): C, 53.16; H, 5.58; N, 0.0; found: C, 52.96; H, 5.65; N, 0.0. The reactions in Table 1 and Table 2 were performed at least twice on 1 mmol scale using 0.05 mL tetradecane as an internal GC standard. The products were isolated by column chromatography (SiO_2, hexane–ethyl acetate 10 : 1) and characterized by means of ^{1}H and ^{13}C NMR as well as by GC-MS.

§ The IUPAC name for pinacol boronates and pinacol borane is 2,3-boranediyldioxy-2,3-dimethylbutane.

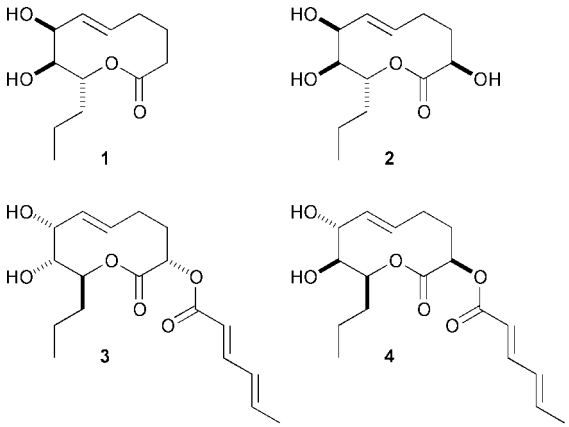
First published as an Advance Article on the web 21st March 2001

A concise total synthesis of the potent herbicide herbarumin I (1) is presented based on an (*E*)-selective RCM reaction forging the 10-membered ring of this macrolide.

Bioassay guided fractionation of a culture broth of the fungus *Phoma herbarum* recently led to the discovery of two novel nonenolides. Named herbarumin I (**1**) and herbarumin II (**2**), these lactones were found to exhibit significant phytotoxic

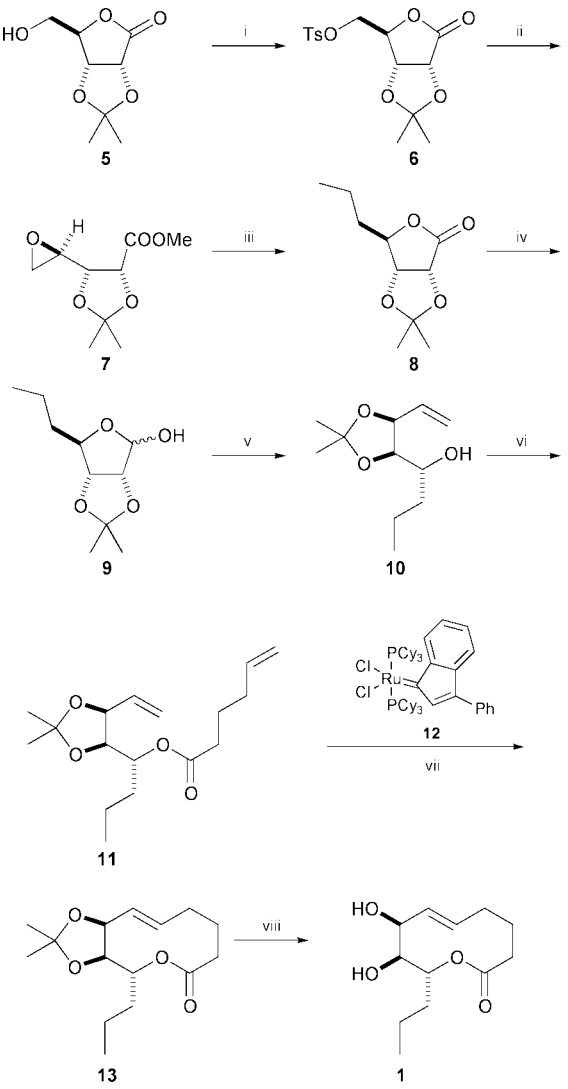


effects in an assay monitoring the radicle elongation of *Amaranthus hypochondriacus* seedlings, with IC_{50} values being as low as 5.43×10^{-5} for compound **1**.[1] This level of activity together with the fact that closely related compounds such as pinolidoxin (**3**)[2] and lethaloxin (**4**)[3] also exert significant phytotoxicity renders this class of compounds promising new lead structures in the search for novel herbicidal agents. Described below is the first total synthesis of a member of this family of natural products.

Our approach to herbarumin I (**1**) as the most active compound of this series is guided by the perception that the stereochemistry of its three contiguous chiral centers is matched by the pattern displayed by D-ribose. Therefore, the D-ribonolactone acetonide derivative **5** was chosen as a well accessible starting material which is converted on a multigram scale into tosylate **6** (Scheme 1).[4] Subsequent treatment with NaOMe in THF leads to product **7** *via* transesterification followed by spontaneous closure of the epoxide ring once the alkoxide at O-4 is liberated.[5] This compound is then exposed to the cuprate reagent formed from EtMgBr and CuBr·Me_2S in THF,[6] thus providing lactone **8** in 60% yield.† DIBAL-H reduction followed by reaction of the resulting lactol **9** with methylenetriphenylphosphorane in the presence of catalytic amounts of quinuclidine[7] delivers alcohol **10** in good yield, which is esterified with hex-5-enoic acid in the presence of DCC and DMAP to afford diene **11**. This sets the stage for the crucial macrocyclization reaction *via* ring closing olefin metathesis (RCM).

During the last decade, olefin metathesis has evolved into a versatile and practical tool for advanced organic chemistry.[8] Despite the impressive number of applications of this reaction to the synthesis of structurally diverse carbo- and heterocycles, it must be kept in mind that the formation of medium sized rings by this method still poses considerable challenges.[9,10] Because of the inherent ring strain, eight- to eleven-membered cycloalkenes are particularly prone to the reverse process, *i.e.* to ring opening metathesis (ROM) or ring opening metathesis polymerization (ROMP).

It has been shown, however, that this problem can be circumvented in many cases by incorporating suitable conformational control elements forcing the substrate to adopt a suitable conformation for ring closure. This facilitates RCM and stabilizes the product formed against the competing ROMP



Scheme 1 *Reagents and conditions*: i, tosyl chloride, pyridine, −20 °C, 16 h, 77%; ii, NaOMe, THF, 0 °C → rt, 16 h, 62%; iii, EtMgBr (3 eq.), CuBr·Me_2S (3 eq.), THF, −78 °C → rt, 16 h, 60%; iv, DIBAL-H, CH_2Cl_2, −78 °C, 2 h, 97%; v, $Ph_3P{=}CH_2$ (2 eq.), quinuclidine (0.2 eq.), THF, reflux, 30 min, 77%; vi, hex-5-enoic acid, DCC, DMAP, CH_2Cl_2, rt, 4 d, 84%; vii, catalyst **12** (10 mol%), CH_2Cl_2, reflux, 7 h, 69%; viii, aq. HCl (1 M), THF, 50 °C, 16 h, 90%.

DOI: 10.1039/b101148k

pathway. The isopropylidene acetal of compound **11** may act as such a temporary constraint which adequately shapes this particular diene and simultaneously confers bias upon the stereochemistry of the newly formed double bond.[11]

We were pleased to find that this is indeed the case. Treatment of compound **11** with catalytic amounts of the ruthenium indenylidene complex **12**[12] in refluxing CH_2Cl_2 affords the desired ten-membered lactone **13** as the only product in 69% isolated yield. Although applications of RCM to the synthesis of medium-sized and macrocyclic cycloalkenes are frequently plagued by the formation of *E*/*Z*-mixtures,[8,13] compound **13** was obtained as a single diastereoisomer which was assigned the *E*-configuration based on detailed NMR investigations.‡ This particular example also nicely features the excellent application profile of the ruthenium complex **12** which is equipotent or even superior to the more popular Grubbs carbene $(Cy_3P)_2(Cl)_2Ru{=}CHPh$[14] yet easier to make from stable and commercially available precursors.[12]

Final cleavage of the acetal group with dilute aq. HCl occurs uneventfully and provides herbarumin I **1** in 90% yield as a low melting solid. Although the $[\alpha]_D$ value of the synthetic sample deviates from the reported one to some extent,§ there is no doubt as to the constitution and configuration of this compound since the high resolution NMR spectra (Bruker DMX 600) as well as the IR and MS data are in excellent agreement with the proposed structure and perfectly match those reported in the literature.§

In summary, a concise total synthesis of the potent phytopathogenic macrolide herbarumin I is presented. The approach using D-ribonolactone as a convenient source of chirality is based on a highly efficient and diastereoselective RCM reaction for the formation of the ten-membered ring of the target, which is delivered in enantiomerically pure form in only 8 steps starting from **5** in ~11% overall yield. Extensions of this methodology to other members of this series of herbicidal agents are underway and will be disclosed in the near future.

Generous financial support by the Deutsche Forschungsgemeinschaft (Leibniz award) and the Fonds der Chemischen Industrie is gratefully acknowledged. We thank Dr R. Mynott and C. Wirtz for their help with the interpretation of the NMR spectra of compound **13**.

Notes and references

† Competitive attack of bromide ions on epoxide **7** could not be fully supressed; small amounts of 5-bromo-2,3-isopropylidene-D-ribono-1,4-lactone thus formed are separated by flash chromatography. In this context it should also be noted that all attempts to prepare compound **8** more directly by reaction of tosylate **6** with various ethyl donors (Et_2CuLi or EtMgBr + $CuBr{\cdot}Me_2S$) turned out to be low yielding and could not compete with the route depicted in Scheme 1.

‡ NMR investigations at this stage are hampered by the fact that compound **13** exists in two slowly interconverting conformers in solution. The assignment of the stereochemistry of the double bond, however, is unambiguous and is ultimately corroborated by the successful completion of the synthesis, providing synthetic **1** which exhibits a coupling constant of ^3J = 15.8 Hz for the vicinal olefinic protons. Details on the structural assignment of **13** will be reported in a forthcoming full paper.

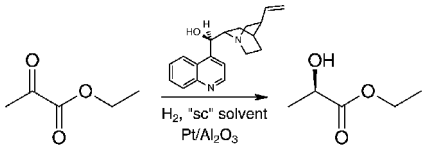
Laboratory of Technical Chemistry, Swiss Federal Institute of Technology, ETH-Zentrum, CH-8092 Zürich, Switzerland. E-mail: E-mail:baiker@tech.chem.ethz.ch; Fax: +41 1 6321163; Tel: +41 1 6323153

Received (in Cambridge, UK) 15th January 2001, Accepted 6th March 2001
First published as an Advance Article on the web 21st March 2001

Hydrogenation of ethyl pyruvate in 'supercritical' ethane in a fixed bed reactor over cinchona-modified Pt/Al_2O_3 affords good ee at an exceptionally high rate, whereas in carbon dioxide the catalytic performance under similar conditions is inferior.

Application of supercritical (sc) fluids as solvents and reactants has great potential for optimizing chemical reactions.[1–3] The continuous hydrogenation of organic compounds in sc CO_2 or propane has recently been reported by Poliakoff and co-workers.[4] Here we show the first example of a continuous asymmetric hydrogenation in a 'sc' fluid. The well studied enantioselective hydrogenation of ethyl pyruvate (EP)[5] over cinchonidine (CD)-modified Pt/Al_2O_3 has been chosen as a model reaction (Scheme 1) to demonstrate the feasibility of the process. A crucial point is that trace amounts of the chiral modifier have to be fed continuously to the reactor in order to maintain a good ee with time-on-stream.[6] We show that the application of 'sc'ethane as a solvent affords a remarkable increase in reaction rate compared to the best conventional solvent, toluene. Note that the widely used term supercritical is deprived of any meaning in multi-component systems since phase separation is still possible at conditions beyond the mixture critical point or the critical point of the pure components.[7] For convenience, 'sc' is used here in quotes for the solvent-rich phase at temperatures exceeding its mixture critical point, irrespective of further liquid phases present.



Scheme 1

Catalytic studies were carried out in a continuous stainless steel tubular fixed-bed reactor with 12.5 mm inner diameter.[6] A mechanical mixture of 100 mg 5 wt% Pt/Al_2O_3 (Engelhard 4759, metal dispersion: 0.27) and 900 mg Al_2O_3 (110 m^2 g^{-1} surface area) as diluent was employed, resulting in a catalyst bed length of 15 mm. The catalyst was prereduced *in situ* at 400 °C in H_2. A flow of 1.0 ml min^{-1} EP (Fluka, 97%) was mixed with ethane (99.5%) or CO_2 (99.995%) and H_2 (99.999%) in a static mixer before entering the reactor. CD (Fluka, > 98%) was fed together with EP (Fluka, 97%) at a molar ratio EP : CD of 2500 : 1. The corresponding solution was prepared immediately before the reaction and kept cool and in the dark to minimize side-reactions. Conversion and ee were determined by GC analysis without derivatization. Chemoselectivity to ethyl lactate was always 100%. Enantiomeric excess is defined as $([R] - [S])/([R] + [S])$.†

Preliminary studies using CO_2 and ethane as solvents indicated that the latter is a better solvent for EP hydrogenation. Fig. 1 shows the changes in conversion and ee induced during continuous hydrogenation of EP when the solvent is changed from dense CO_2 to ethane. Note the prominent increase in reaction rate and enantioselectivity with ethane. A similar but

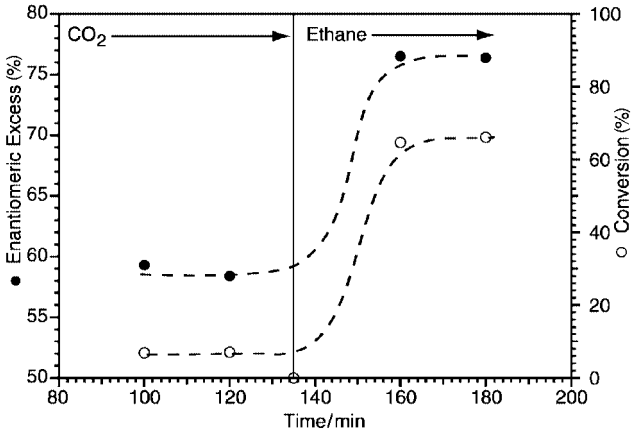


Fig. 1 Conversion (○) and ee (●) of EP hydrogenation in dense CO_2 and ethane at 30 °C and 100 bar. Molar ratio of solvent : EP : H_2 = 500 : 1 : 10. EP-flow was 4.3 mmol min^{-1}.

reversed behaviour was observed when the sequence of solvents was changed. The poor performance in CO_2 is not completely understood yet. A possible explanation is partial poisoning of the platinum catalyst due to the formation of CO *via* the reverse water gas shift reaction ($CO_2 + H_2 \rightleftharpoons CO + H_2O$).[8] As a consequence of these comparative studies further investigations were performed in ethane.

Careful consideration of the phase behavior under reaction conditions is critical for understanding the outcome of the reaction. The phase behavior of the system under reaction conditions was investigated in a computer controlled high-pressure view cell of variable volume (23–63 ml), equipped with on-line digital video imaging and recording. The magnetically stirred cell consisted of a horizontal cylinder equipped with a sapphire window covering the entire diameter and an opposite, horizontally moving piston equipped with another sapphire window for illumination of the system. The basic setup of the computer-based approach and video imaging has been described before.[9]

The reaction mixture ethane–EP–H_2 exhibited a three-phase LLV equilibrium (EP–rich liquid, ethane-rich liquid and ethane–H_2-rich gaseous phase) at 30 and 40 °C. The upper two ethane-rich phases critically merged at around 40 °C and 70 bar. Beyond this upper critical endpoint of the coexistence of the ethane-rich phases, the system exhibited a two-phase equilibrium of a liquid EP-rich phase and a dense fluid ('sc') ethane-rich phase, continuously blending to one phase with increasing pressure. The pressure required for this transition depended strongly on temperature (20–50 °C) and H_2 concentration (1–9%) in the system. A similar phase behavior was found in the system ethane–ethyl lactate–H_2 as well as in the system ethane–ethyl pyruvate–ethyl lactate–H_2. On this basis we assume that the whole conversion range can be well modelled by the ethane–EP–H_2 system discussed above.

At low H_2 concentration, the transition from a multiphase to a homogeneous fluid phase (single phase) was accompanied by a pronounced increase in EP conversion (Fig. 2, k = 2). In

DOI: 10.1039/b100511l

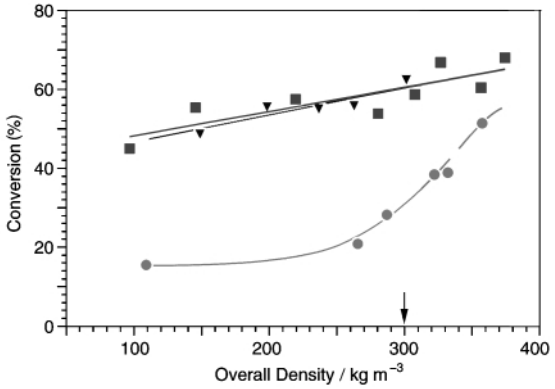

Fig. 2 Conversion of EP at 40 °C as a function of overall density at various H_2 concentrations. Ethane : EP : H_2 molar ratio = 200 : 1 : *k*, (○) *k* = 2, (■) *k* = 10, (▼) *k* = 20. Arrow marks density required for merging of fluid phases to homogeneous phase.

contrast, at higher H_2 concentration the conversion changed continuously with density, irrespective of changes in phase behavior. This behavior clearly corroborates the often made assumption that a homogeneous fluid phase affords remarkably higher reaction rates, which only holds true under conditions where mass transfer of the limiting reactant is enhanced due to elimination of phase boundaries. Enantiomeric excess to (*R*)-ethyl lactate was in the range 55–75%, depending on the temperature and H_2 concentration. Representative results illustrating the influence of pressure and reactant ratio (H_2 : EP) at 40 °C are listed in Table 1. Note that full conversion could easily be attained by increasing the contact time. Lower conversions are shown here to illustrate the effect of reaction conditions on reaction rate (conversion).

The continuous enantioselective hydrogenation in 'sc' ethane afforded a remarkably fast reaction with good ee. At best, a TOF of 15 s^{-1} was obtained at 70% conversion and ambient temperature. Using toluene as solvent provided the highest TOF of 1.8 s^{-1} under otherwise comparable conditions and optimal H_2 concentration. The process in 'sc' ethane furthermore facilitated an easy and complete separation of the solvent from the reactants by simple expansion of the reaction mixture.

Table 1 Conversion, ee and number of phases present at different pressures and feed compositions, for the enantioselective hydrogenation of EP in dense ethane at 40°C

Feed ratio	*p*/bar	Number of phases	ee (%)	Conv. (%)
	62	3	66	49
H_2 : EP = 20	88	2	65	55
	114	1	63	59
	62	3	68	20
H_2 : EP = 2	88	1	71	37
	114	1	72	50

The phase behavior of the system can be understood in terms of immiscibility of the EP-rich and ethane-rich dense phases at intermediate temperature. The solubility of EP in the ethane-rich dense phase depends mainly on the density of this phase in the temperature range investigated.[10] In fact, complete solvation of EP occurred at a density of around 300 kg m^{-3} (indicated in Fig. 2) for all temperatures and H_2 concentrations, resulting in a saturated ethane-rich dense phase under these conditions. The higher the H_2 concentration in the system, the higher was the pressure required to achieve a density of 300 kg m^{-3} and thus complete solubility of EP in the dense ethane-rich phase. Note that coexistence of two phases was observed at values well above the critical parameters of ethane (ethane, T_c = 32.2 °C, p_c = 48.8 bar). This observation illustrates the danger of assuming that the phase behavior of a multi-component system is similar to that of the pure solvent.

In conclusion, we have shown the feasibility of continuous enantioselective hydrogenation of an α-ketoester in dense ('sc') ethane by continuous dosing of a minute quantity of the chiral modifier CD. High reaction rates combined with good enantioselectivity and easy separation of products are beneficial features of this process.

Financial support by the 'Bundesamt fuer Energie' and by the 'Kommission für Technologie und Innovation' (KTI) is gratefully acknowledged.

Received (in Cambridge, UK) 9th January 2001, Accepted 15th February 2001
First published as an Advance Article on the web 29th March 2001

Active centres have been designed on high-area, molecular sieve catalysts which, *inter alia*, can convert n-alkanes to n-alkanols and n-alkanoic acids, cyclohexane to cyclohexanol, cyclohexanone and adipic acid, and n-hexane to adipic acid all using either oxygen or air as oxidants. A number of one-step processes and solvent-free chemical conversions, of paramount importance in the development of clean technology, are also described with catalysts designed (i) to oxidise *p*-xylene to terephthalic acid aerobically, (ii) to effect Baeyer–Villiger reactions with oxygen, and (iii) for the conversion of cyclohexanone to ε-caprolactam under mild conditions. The inner surfaces of mesoporous silicas may also be atomically engineered so as to yield high-performance epoxidation of alkenes at Ti^{IV}-centred active sites, as well as enantioselective hydrogenations of organic species using constrained chiral catalysts.

John Meurig Thomas began his academic career at the University of Wales, first at Bangor then at Aberystwyth where he was Head of Chemistry from 1969 to 1978. He then became Head of the Department of Physical Chemistry, University of Cambridge and Professorial Fellow at Kings College. He succeeded George Porter as Director of the Royal Institution and the Davy Faraday Research Laboratory (1986–1991), where he still does most of his experimental work. His researches have covered wide areas of solid state, surface and materials chemistry, and heterogeneous catalysis and he has received numerous medals and awards for his various contributions. Ten years ago he was knighted for services to chemistry and the popularisation of science. In 1993 he became Master of the oldest college in Cambridge, Peterhouse. In 1999, he was the (first) recipient of the American Chemical Society award for creative research in homogeneous and heterogeneous catalysis.

Robert Raja received his Masters degree in Chemistry at the Birla Institute of Technology and Science and completed his Ph.D. on zeolite mimics of enzymes with Paul Ratnasamy at the National Chemical Laboratory, Pune, India (1997). He was Royal Commission of 1851 Exhibitioner at the Davy Faraday Research Laboratory of the Royal Institution of Great Britain (1997–1999) and is currently a Peterhouse Senior Research Associate at the Department of Chemistry, Cambridge University, working jointly with Brian F. G. Johnson and John Meurig Thomas. His research interest focuses on designing novel microporous and mesoporous catalysts for environmentally benign selective oxidation and hydrogenation processes. He is the author of 30 research publications and is the co-inventor of five International Patents.

1 Introduction

Important milestones in our understanding of catalytically active centres were reached in the mid-1960s with Phillips's determination, by X-ray crystallography, of the structure of lysozyme,[1] and Blow's elucidation, also by X-ray diffraction, of the structure of chymotrypsin,[2] and in particular of the precise environment of the catalytic pockets within these solid enzymes. Not only did knowledge of the structure of the active centres suggest a convincing mechanism for the mode of action of these two catalysts, it transformed the world of enzymology. Ever since that time, protein engineers[3] have become increasingly expert at designing new biological catalysts principally because they know (a) what the precise, atomically-resolved structure of the active centre is in many wild enzymes, and (b) the atomic changes that should be made in the vicinity of the active centre so as to enhance either the enzyme's activity, its selectivity, or both.

It is not possible to use the X-ray approach of protein crystallographers in the study of solid (low surface-area) inorganic heterogeneous catalysts, principally because the bulk of the catalyst contributes vastly more to the diffraction of the X-rays than do the minute numbers of active centres distributed in a random manner at the exterior surface of the solid. When, however, highly microporous or mesoporous solids such as those that possess channels, cavities or cages with diameters in the ranges 4–14 Å (micro) and 15–250 Å (meso) are used as catalyst supports, the atomic structures of the implanted active centres may be retrieved by X-ray-based methods but this time by the use of X-ray absorption fine-structure spectroscopy (XAFS) rather than by X-ray diffraction.[4–8] XAFS as a technique yields detailed local structural information even when the catalyst is non-crystalline.[7–9]

Microporous and mesoporous hosts (see below) may have internal surface areas that are so large—in excess of 1000 $m^2\ g^{-1}$—that, effectively, these solids are best envisaged as possessing three-dimensional surfaces. Either by heterogenizing well-defined organometallic precursors on mesoporous hosts, or by preparing microporous hosts that contain within them adroitly placed potentially active centres, advantage may be taken of special *in situ* methods, described fully elsewhere,[5–9] to determine in atomic detail the nature of the catalytically active sites prior to and during the course of the chemical transformation. Armed with this knowledge, one is in a far better position chemically to modify variants of the original catalysts and thereby to enhance their performance. Knowledge of the atomic architecture of the active centre also facilitates interpretative mechanisms of the catalytic path, a task nowadays greatly aided by invoking reliable computational procedures either of the atomistic or electronic kind. Table 1

takes cognizance of all the above points, and also emphasizes other practical desiderata pertaining to porous (open-structure) oxide catalysts discussed herein.

Table 1 Desiderata for engineered porous oxide catalysts

High activity, high selectivity, longevity and durability
Freedom from restrictions imposed by diffusional considerations (reactants and products)
Capable of facilitating regio-selective, shape-selective and enantioselective processes
Should operate under mild conditions and be environmentally, economically and atom efficient
Should be able to facilitate an increasing number of solvent-free conversions
Possession of isolated, well-defined (single-site) active centres, the atomic architecture of which may be delicately modified
Capability of yielding detailed mechanistic understanding of catalytic action
Between them certain microporous (3.5–14.5 Å apertures) and mesoporous (15–250 Å) oxides satisfy all these desiderata

Close to a half of the elements of the Periodic Table are capable of being incorporated into the framework structures—generally in tetrahedral, but more frequently nowadays in six- or five-fold coordination—of the ever-growing families of microporous and mesoporous materials. In the case of microporous solids, the largest two sub-families are the aluminosilicates and **al**umino**p**h**o**sphates (AlPOs). These are essentially three-dimensional networks of corner-sharing SiO_4 and AlO_4 tetrahedra and of AlO_4 and PO_4 tetrahedra, respectively. Heteroatoms, especially those known to exhibit powerful catalytic properties such as Co^{III}, Mn^{III}, Fe^{III}, Ti^{IV}, may be incorporated substitutionally at regular framework sites. (They may, as in the case of cobalt or manganese, be easier to introduce during preparation as Co^{II} or Mn^{II} ions: they are later convertible, by calcination *in situ*, for example, into their higher-valent forms, Co^{III} and Mn^{III}.) Mesoporous solids, on the other hand, are generally easier to prepare in their pristine state (as SiO_2, GeO_2, TiO_2, *etc*.), and heteroatoms, which serve as the loci of catalytic action, are grafted onto the inner surfaces of the mesopores after synthesis, as described in Section 3 below.

2 Specific examples of designed, characterized and proven microporous catalysts

Although the main thrust of our work is to arrive at new solid inorganic catalysts by engineering appropriate active centres through the principles of solid-state and surface chemistry, we especially aim to produce those catalysts that are important in the context of *clean technology*. The intellectual challenge is to devise strategies for such environmentally desirable objectives as:

- the development of one-step processes and/or solvent-free chemical conversions; and
- to produce oxidation catalysts that use air or oxygen as the oxidant.

In describing below the progress that we have made towards these goals we also recall the salient features of those currently favoured, important processes that need to be replaced either because of their expense, and/or inconvenience, or because they are environmentally (or otherwise) unacceptable.

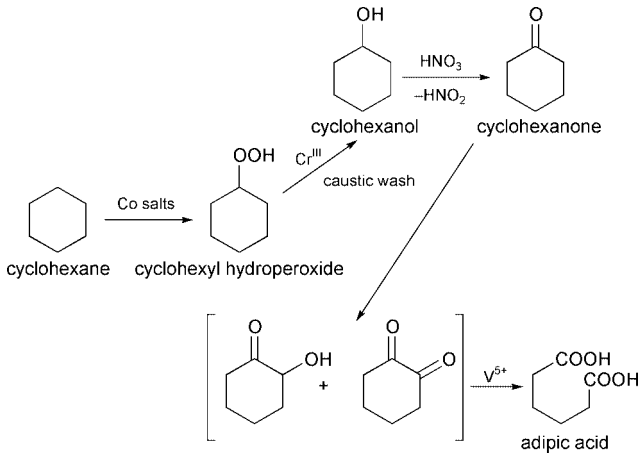
We now proceed to highlight our work on:

A the selective oxidation of cyclohexane in air to cyclohexanol, cyclohexanone and adipic acid;
B regio- and shape-selective oxyfunctionalization of n-alkanes in air to yield n-alkanols and n-alkanoic acids;
C conversion of n-hexane to adipic acid in air;
D aerobic oxidation of *p*-xylene to terephthalic acid;
E Baeyer–Villiger reactions using oxygen as the oxidant for conversion of (i) ketones to lactones and (ii) alkenes to epoxides;
F solid-acid-catalyzed dehydrations and oligomerizations, and
G ammoximation of cyclohexanone to yield the oxime and caprolactam.

For a majority of these conversions it has been shown[8,10,11] that free radicals participate in a crucial, spatially constrained manner. One of the key features of our approach[12,13] to the design of the necessary catalysts is to insert (implant) transition metal ions in high oxidation states into the framework of the microporous oxide. These serve as free radical initiators (see, for example, Section E below), but the mean-free path of the radicals is necessarily small (owing to the microporosity of the solid) so that only a limited number of reactions may ensue. Moreover, by astute choice of the dimensions of the pores of the molecular sieve oxide within which the transition metal ion active centres are placed, one may harness the advantages of shape selectivity, whereby only molecules of certain sizes and shapes may reach, or diffuse away from, the active centres. In some instances, where the siting of active centres and the access to them of reactant molecules are sharply defined, it becomes possible to effect regio-selective as well as shape-selective conversions.[10]

A The selective oxidation of cyclohexane to cyclohexanol, cyclohexanone and adipic acid

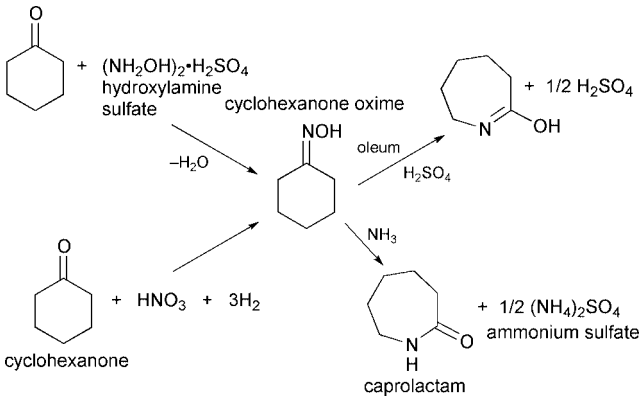
Apart from its intrinsic importance in the chemistry of C–H activation,[14] the selective oxidation of cyclohexane to yield cyclohexanol and cyclohexanone is the centre-piece of the commercial production of nylon. Many key precursors and products in the polymer industry are generated in costly and polluting processes that also involve the selective oxidation of cyclohexane (Scheme 1).[15] Intermediates such as cyclohexanol



Scheme 1

and cyclohexanone, which, together, are known as K-A oil, are the stepping stones for the production of caprolactam (Scheme 2), which is the monomer for nylon 6, and adipic acid (AA) which is the building block for a series of synthetic polyamide fibres such as nylon 66 and polyurethane resins. Alternate synthetic routes have been developed, such as the one-step oxidation of cyclohexane with either alkyl hydroperoxide as oxidant and a catalyst consisting of cobalt salts,[16,17] or dioxygen as oxidant and a cobalt acetate catalyst in acetic acid.[18] More recent industrial syntheses include homogeneously catalyzed hydrocarboxylation or carboalkoxylation of butadiene.

Because the free radicals generated in the autoxidation of cyclohexane are constrained in space within the interior of the



Scheme 2

high-area porous catalysts chosen by us, we opted to prepare three distinct kinds of MeAlPO molecular sieve catalysts for this oxidation: $Co^{III}(Mn^{III})$AlPO-36,[19] $Fe^{III}(Mn^{III})$AlPO-5,[20] and Fe^{III}AlPO-31[21] (see Fig. 1).

When a few percent of Al^{III} ions in AlPO-36 (pore aperture 6.5 × 7.5 Å) are replaced by Co^{III} (or Mn^{III}) ions it becomes[19] a good catalyst for cyclohexane oxidation in O_2, the principal products being cyclohexanol and cyclohexanone and small quantities of adipic acid (AA). XAFS measurements show that, in CoAlPO-36, only 50% of the Co^{II} ions present in the framework in the as-prepared state may be raised to the Co^{III} state by calcining in air. In FeAlPO-5, however, (pore aperture 7.3 × 7.3 Å) all of the iron ions are found (by XAFS) to be in the Fe^{III} state. Indeed, this active site (Fe^{III} in the framework) has an immediate environment almost indistinguishable from that of Fe^{III} in FeZSM-5 (Fig. 2) in which again the Fe^{III} resides in the framework.

We argued that there was merit in designing a MeAlPO molecular sieve catalyst in which the active sites (either Fe^{III} or Mn^{III}) are the same as, but the pores are significantly smaller than, those of MeAlPO-5 analogues. This would mean that, of the reaction intermediates formed within the pores of the catalyst, those that are more sinuous (like AA) would diffuse out readily. MeAlPO-31, in the form of Fe^{III}AlPO-31, was therefore selected by us.[21] In effect, we capitalize here on 'product shape-

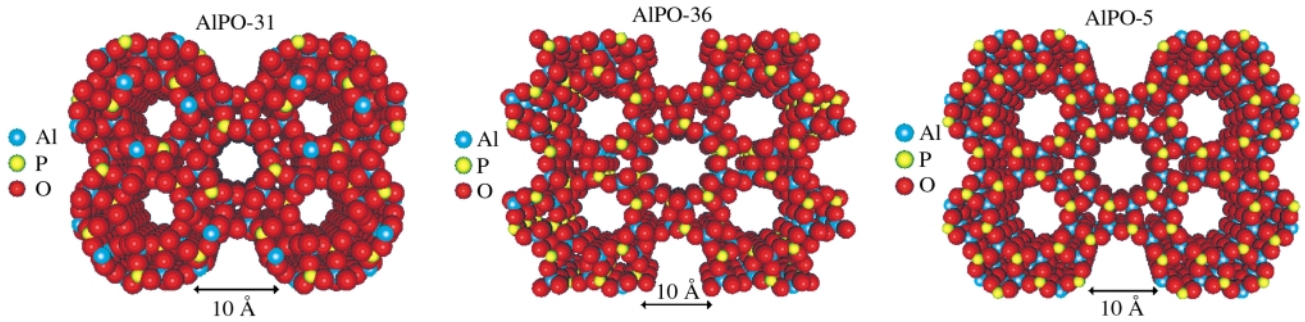


Fig. 1 Computer graphic representation of the framework structures of the three aluminophosphate molecular sieves used in this work. In the active microporous catalysts a small fraction of the Al^{III} framework ions is replaced by either Co^{III} or Mn^{III} or Fe^{III} ions, which function as the active centres (see text). Diameters of the apertures are: AlPO-31, 5.4 Å; AlPO-36, 6.5 × 7.5 Å; and AlPO-5, 7.3 Å.

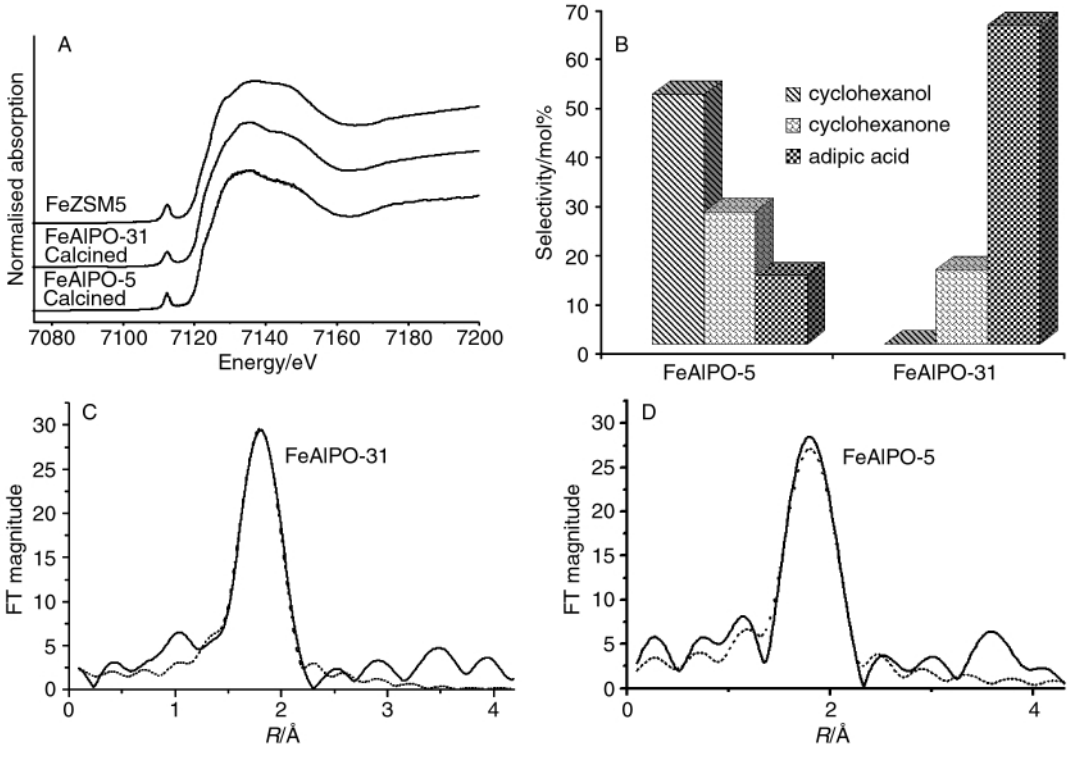

Fig. 2 (A) X-Ray absorption near-edge (XANES) spectra of as-synthesized FeZSM-5 (with framework-substituted Fe^{III} ions) and of calcined FeAlPO-31 and FeAlPO-5. Note the similarities in pre-edge intensities. (B) Bar chart contrasting the product selectivities (at T = 373 K, 24 h contact time) of the three principal, selective oxidation products with these two catalysts. (C) and (D) Associated Fourier transform of calcined FeAlPO-31 and FeAlPO-5, respectively (the solid and the dashed curves represent the experimental and calculated data, respectively.

selectivity' (in the same sense as described by Weisz[22] for acid-catalyzed dehydrations of alkanols)—only those products with appropriate molecular dimensions may diffuse easily out of the pores, whereas larger ones formed in the course of the reaction are trapped inside on account of their significantly retarded diffusion. Qualitatively, we may envisage the free radical and molecular intermediates cyclohexanol, cyclohexanone, formed from cyclohexyl hydroperoxide (cHHP) or 2-hydroxycyclohexanone and 1,2-cyclohexanedione, to be held in the vicinity of the active site until oxidation proceeds further to yield the more mobile and desired linear product AA (see Fig. 3). Because of the more puckered walls of AlPO-31 compared with AlPO-5, and the significantly reduced pore diameter (5.4 Å), we have the constrained environment required for the favoured production of AA (see Fig. 2).

B Regio- and shape-selective oxyfunctionalization of n-alkanes in air

Although linear alkanes are readily oxidized to completion (burnt) at elevated temperatures, they are among the most difficult to oxyfunctionalize at lower temperatures. It is widely acknowledged that the controlled oxyfunctionalization of linear alkanes is one of the major challenges of modern catalysis; and particularly desirable products are those that have been terminally oxidized (hexanoic acid, for example), since these serve as feedstocks for the chemical and pharmaceutical industries. A gleam in the eye of the expert catalyst scientist is to arrive at a catalyst that regiospecifically functionalizes n-alkanes using either air or dioxygen as the oxidant.[23] We have succeeded in doing this (for n-alkane C_nH_{2n+2}, n = 6–8, 10, 12) using a carefully designed MeAlPO molecular sieve.[8,10,11,24] Moreover, we have very recently demonstrated how, by judicious modification of the siting of single-site active centres within the same kind of catalyst Co^{III}AlPO-18, it also becomes possible to achieve double terminal oxyfunctionalization, thereby enabling n-hexane to be converted in air to AA (see below).

We are certain that Me^{III} ions (substituting for Al^{III} ones, in the MeAlPO-18) are a *sine qua non* for the catalytic oxidation of the hydrocarbon. If, for example, Mg^{II} or Zn^{II} ions (or Co^{II} or Mn^{II} ions) are present in place of Me^{III} ions in the MeAlPO, no oxidation ensues.

To achieve single, terminal methyl group attack, one harnesses the fact that the Me^{III} ion active site must, during reaction, be readily accessed in a preferential manner by the terminal methyl group of the alkane. One must also ensure that the alkane can gain entry into the interior of the MeAlPO catalyst only by an 'end-on' approach (Fig. 4), otherwise oxyfunctionalization of the CH_2 groups at C_2 and C_3 will occur. [It must be remembered that, all the while during the oxidation, the catalyst and alkanes are swathed in molecular oxygen (Fig. 4) as the latter is so small that it readily reaches the Me^{III} and other sites within the molecular sieve catalyst.)

CoAlPO-18 or MnAlPO-18 catalysts are very effective in the regioselective oxidation of n-alkanes. Apart from the qualitative arguments given above for facilitating terminal attack, the quantitative results of energy-minimization (see Fig. 5) yield further insights into, and a deeper understanding of, the regiospecificity.

The computation, which combines Monte Carlo, molecular dynamics and docking procedures,[25] reveals that the terminal methyl group is significantly closer to a tetrahedral framework site than either C_2 or C_3 carbons in the alkane chain. Moreover, the end of the alkane becomes slightly bent, and all this favours oxidation of the terminal (mainly) and penultimate carbon atoms, just as is seen in the experimental results (Fig. 6).

The so-called primary selectivity index (defined as the ratio of concentration of primary products to secondary/tertiary products normalized for the respective number of hydrogens in the alkane molecule) is superior for the Co^{III}AlPO-18 and Mn^{III}AlPO-18 catalysts than for all previously reported[14,26] inorganic heterogeneous catalysts, even though the latter use sacrificial oxidants such as iodosylbenzene[27] and not air or O_2. It is to be noted[10] that some 70% of the products of oxidation of n-octane after 24 h are the result of oxyfunctionalization of the terminal methyl group for Co^{III}AlPO-18 (60% for Mn^{III}AlPO-18). Octanoic acid, octan-1-al and octan-1-ol, in descending order, are the principal products of oxyfunctionalization of n-octane.

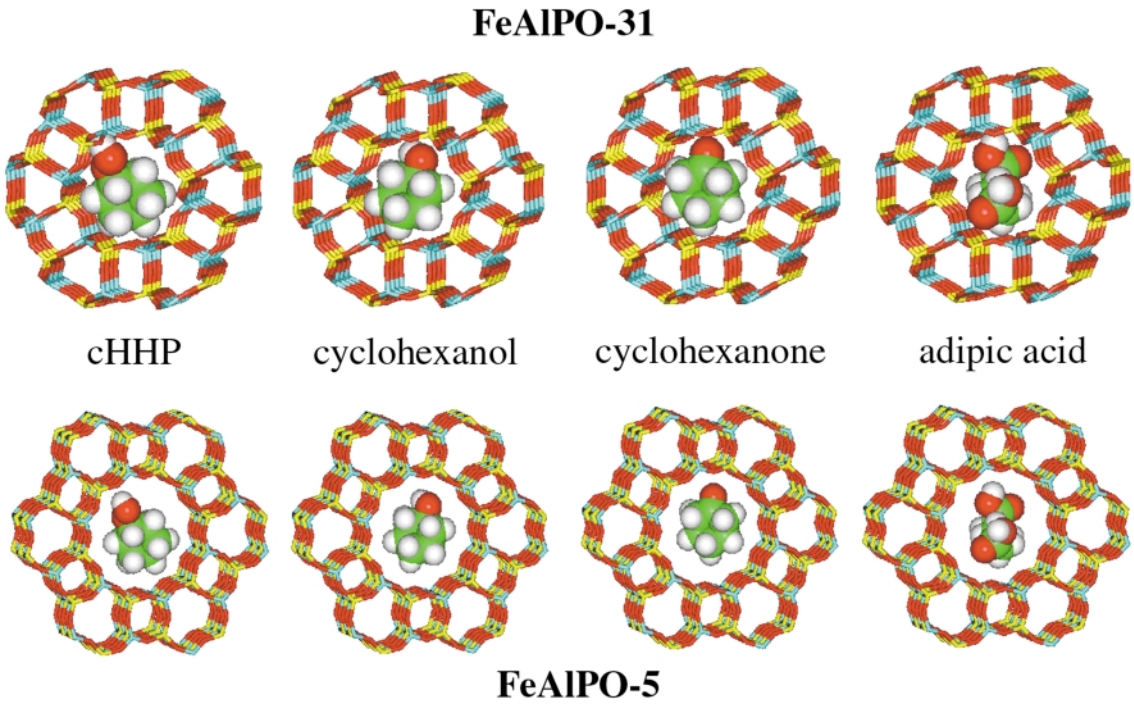

Fig. 3 In the autocatalytic oxidation of cyclohexane in air, the main products are cyclohexyl hydroperoxide (cHHP), cyclohexanol, cyclohexanone and adipic acid (AA). In the larger (7.3 Å) FeAlPO-5 catalyst, all products diffuse out freely, whereas in the smaller pore (5.4 Å) FeAlPO-31 catalyst, diffusion out of the solid is much easier for the sinuous adipic acid molecule than for the other three, which fit rather tightly within the pores. This product shape-selectivity explains the results shown in Fig. 2B.

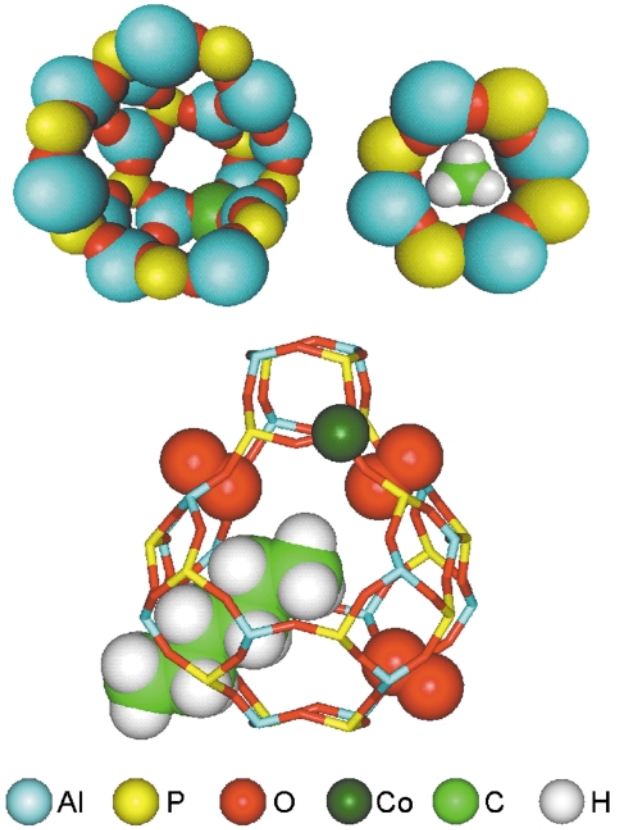

Fig. 4 Views of (left) interior of the chabazitic cage in the Co^{III}AlPO-18 catalyst, with the end-on approach of the alkane to the active site emphasized (top right). At the bottom is another view showing the approach to the Co^{III} active site of n-hexane into the chabazitic cage. Oxygen molecules freely enter the cage *via* the other openings.

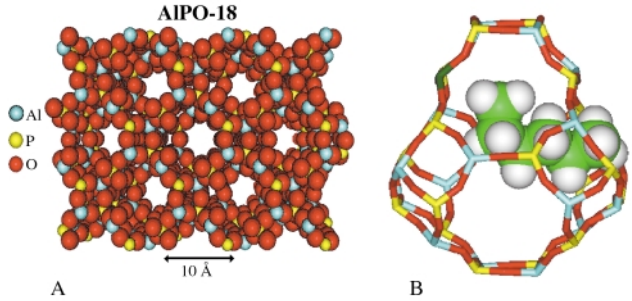

Fig. 5 (A) Computer graphic view of the framework structure of AlPO-18. Each of the intersecting pores, whose openings are shown here, has an array of side pockets possessing a so-called chabazitic structure shown in B. (B) Energy-minimized configuration adopted by n-hexane at 0 K inside the chabazitic cage of the AlPO-18 framework. This configuration was derived from a calculation that combines Monte Carlo, molecular dynamics and docking procedures as described in ref. 25. Note that the terminal methyl group (C_1) is significantly closer to a tetrahedral framework site (and hence to the Me^{III} active centre) than either C_2 or C_3.[10]

C Converting n-hexane to adipic acid (AA) in air

To achieve oxyfunctionalization at both (methyl) ends of n-hexane, a sufficiently large number of framework Co^{III} ions needs to be accommodated on the inner walls of the CoAlPO-18 catalyst in such a manner that two framework Co^{III} ions should be separated by *ca.* 7–8 Å from one another. With the composition $Co_{0.1}Al_{0.9}PO_4$ for the CoAlPO-18 structure (*i.e.* with a Co : P ratio of 0.1, instead of 0.04, as above) there is a high probability for there being two (separated) Co^{III} ions in each cage of the AlPO-18 structure, and for these two ions to be situated opposite one another as shown in Fig. 7.

Fig. 8 summarizes the results of the selective oxidation experiments and, in particular, highlights the contrast in catalytic performance—especially in regard to production of

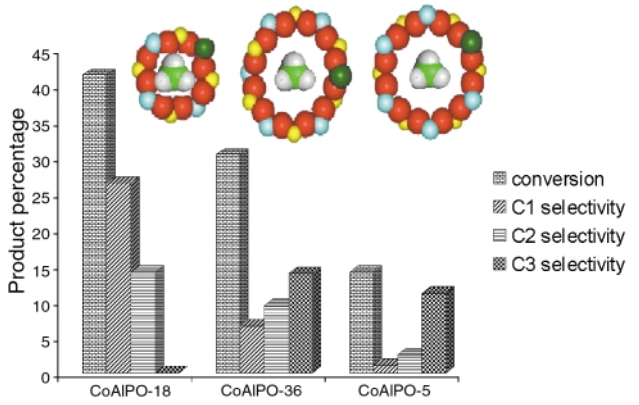

Fig. 6 Bar chart showing the regio-selective oxyfunctionalization of n-hexane when exposed to air and a Co^{III}AlPO-18 catalyst. 65% of the products are oxyfunctionalized at the terminal methyl (C_1), and 34% at the penultimate methylene (C_2) carbons, in marked contrast to what occurs under identical conditions (373 K, 1.5 MPa, 24 h) with CoAlPO-36 and CoAlPO-5 catalysts.

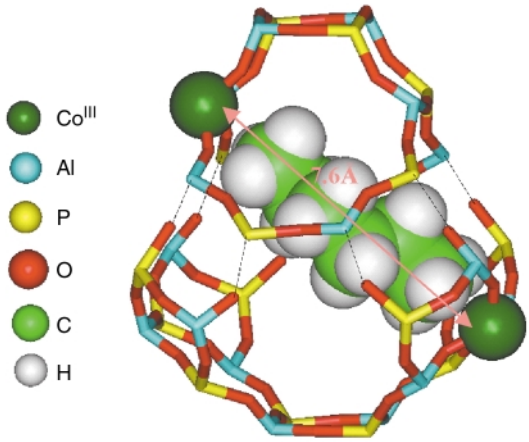

Fig. 7 With two Co^{III} ions at the opposite vertices of the chabazitic cage in CoAlPO-18 (as occurs when the composition is close to $Co_{0.1}Al_{0.9}PO_4$), their separation distance (*ca.* 7.6 Å) is similar to that which separates the two terminal methyl groups in n-hexane. This maximizes the occurrence of oxyfunctionalization of the alkane to form adipic acid (see text and Fig. 8)

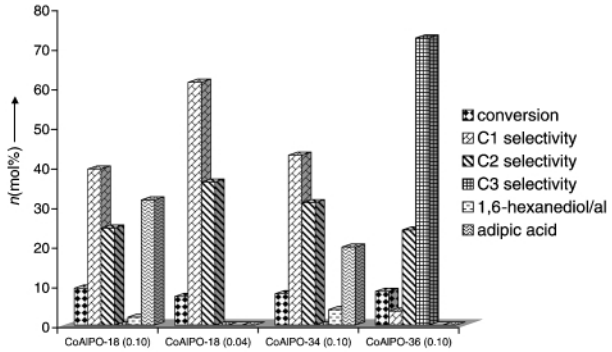

Fig. 8 A low ratio of Co : P (*e.g.* 0.04) in the CoAlPO-18 catalyst yields essentially no adipic acid, whereas a high one (*ca.* 0.10) yields substantial quantities. The closely similar CoAlPO-34 catalyst (which is structurally identical to CoAlPO-18 in its chabazitic cages and pore dimensions) also yields adipic acid with a high (0.10) Co : P ratio. CoAlPO-36, on the other hand, which has no chabazitic cages and has larger pores than CoAlPO-18 or CoAlPO-34, and which therefore exerts no shape selectivity, produces no adipic acid.

adipic acid—of low and high Co : P ratios for CoAlPO-18 (*i.e.* 0.04 and 0.10, respectively). It is to be noted that CoAlPO-34, which is very similar structurally to CoAlPO-18 (they each have chabazitic cages), exhibit broadly similar catalytic performance

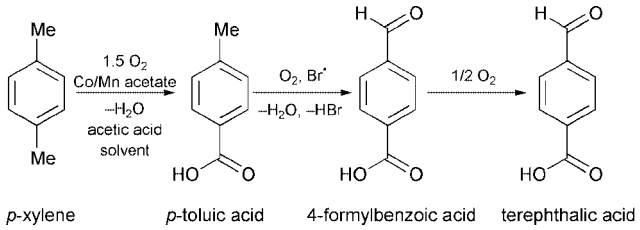
when the Co : P ratio is 0.10. But CoAlPO-36, which has a much larger pore aperture (6.5 × 7.5 Å) is markedly different from both CoAlPO-18 and CoAlPO-34.

Detailed kinetic studies (described elsewhere[10,28]) are also informative, especially when compared with those reported earlier for CoAlPO-18 with a Co : P ratio of 0.04. With a Co : P ratio of 0.10, for both CoAlPO-18 and CoAlPO-34 catalysts, hexan-1-ol is the major product during the initial stages of the reaction, but this is subsequently converted to hexan-1-al and hexanoic acid. After 5 h, hexane-1,6-diol, hexane-1,6-dial and traces of adipic acid appear in the reaction mixture as well as the three principal products (hexan-1-ol, hexan-1-al and hexanoic acid) observed earlier.[10]

It is noteworthy that there is no decrease in the hexanoic acid selectivity, but at prolonged contact times (10–24 h) there is a steady decrease in the concentration of both hexane-1,6-diol and hexane-1,6-dial, and a concomitant build-up in the production of AA. Evidently, the production of AA arises as a result of the further oxidation of the hexane-1,6-diol and hexane-1,6-dial. Further, when hexanoic acid was taken as the substrate (instead of n-hexane), using CoAlPO-18 (0.10) as catalyst, we did not observe any conversion to AA. With a Co : P ratio of 0.04, the CoAlPO-18 catalyst, under identical conditions, does not produce hexane-1,6-diol or hexane-1,6-dial or any detectable AA. This active adipic acid-producing CoAlPO-18 catalyst, with a Co : P ratio of 0.10, is remarkably stable and there is no leaching of the cobalt ions (see Section 4) during catalysis.

D Terephthalic acid from *p*-xylene

Textile and synthetic fibres such as saturated polyesters (Terylene) are made from terephthalic acid, which is currently produced commercially by the oxidation of *p*-xylene using aggressive reagents such as bromine, and acetic acid as solvent (Scheme 3).[15] In 1992, the worldwide demand for terephthalic



Scheme 3

acid was 12.6 × 10^6 tonnes and textile and industrial fibres accounted for 75% of this demand.[29] Various salts of cobalt and manganese can be used as homogeneous catalysts and the bromine source is usually HBr, NaBr or tetrabromoethane. The highly corrosive bromine–acetic acid environment requires the use of titanium-lined equipment.

Our approach to the design of suitable catalysts for this important reaction again relies on the use of a microporous molecular sieve in which the active sites are Co^{III} or Fe^{III} ions in framework sites substituting for Al^{III} ions. These catalysts operate under solvent-free conditions without the need for corrosive activators and solvents such as bromine or acetic acid. Their mode of operation also relies on shape-selective, free-radical processes of a spatially constrained kind. Moreover, all such oxidation catalysts designed by us require only benign oxidants (dioxygen or air), and consist of inexpensive, readily preparable, $Co^{III}(Fe^{III})$–AlPO-36 or $Co^{III}(Fe^{III})$–AlPO-5.

Our molecular sieve catalysts are effective for the aerobic oxidation of *p*-xylene, the main products being toluic acid, 4-formylbenzoic acid (4-carboxybenzaldehyde) and terephthalic acid, leaving the benzene ring virtually untouched. 4-Formylbenzoic acid is a troublesome impurity and, because of its structural similarity to terephthalic acid, it co-crystallizes with the latter and becomes trapped and inaccessible for completion of the oxidation.[30] We find that AlPO-36-based catalysts, containing up to 10 atom% of transition metal ions (Co^{III}, Mn^{III}, Fe^{III}, *etc*.), suppress the formation of 4-formylbenzoic acid and increase the selectivity for terephthalic acid. As in the case of Co^{III}AlPO-18, containing *ca*. 10 atom% of Co^{III} ions in the framework (see Section C), one might envisage oxyfunctionalization occurring simultaneously at both methyl ends of *p*-xylene, which could well be the reason for the higher selectivity of the Co^{III}AlPO-36 (0.10) catalyst for terephthalic acid (see Fig. 9) compared to Co^{III}AlPO-36 (0.04).[31] Owing to the low solubility of terephthalic acid in *p*-xylene (and since no co-solvents are used) most of it precipitates as it forms.[32]

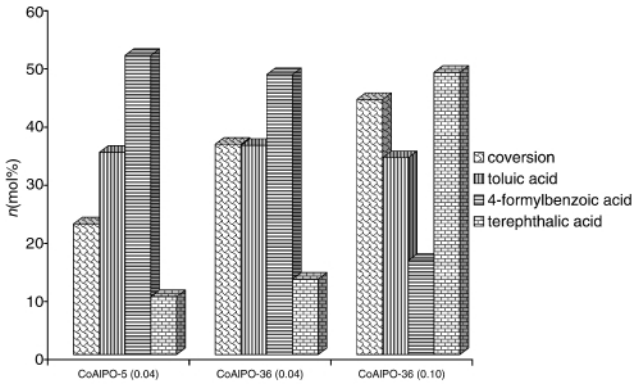


Fig. 9 CoAlPO-36, with a high Co : P ratio (*ca*. 0.10) is a good catalyst for the aerial oxidation of *p*-xylene to terephthalic acid (see text).

E Baeyer–Villiger reactions using oxygen as the oxidant

A reaction of great commercial importance is that devised more than a century ago by Baeyer and Villiger[33] who showed how cyclic ketones could be converted into lactones using a powerful oxidant, such as peroxomonosulfuric acid, H_2SO_5, otherwise known as Caro's acid. This reaction plays a central role in applications that span antibiotics, steroids and numerous aspects of agrochemistry. For environmental and other reasons the use of H_2SO_5, or alternatives such as (the potentially explosive) 90% H_2O_2, is frowned upon (where not banned); and some have turned to the use of milder forms of H_2O_2 in the presence of inorganic materials such as methyl-trioxorhenium.

Our approach (Fig. 10) relies[34] on Mn^{III} (or Co^{III})-framework-substituted MeAlPOs, in which air (or O_2) and a

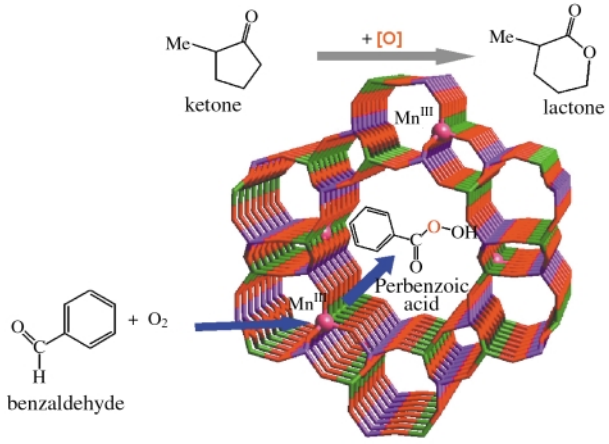

Fig. 10 Graphical representation of a Mn^{III}AlPO-36 molecular sieve catalyst showing the Baeyer–Villiger oxidation of a cyclic ketone to the corresponding lactone. In place of the conventional aggressive oxidants such as H_2SO_5, here, perbenzoic acid is formed *in situ* from benzaldehyde in the presence of O_2 assisted by the Mn^{III} active sites. (After Thomas *et al.*[15])

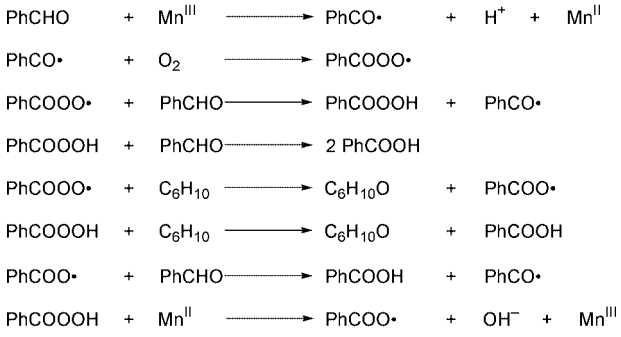
sacrificial aldehyde are used. These constituents produce *in situ*, a percarboxylic acid (*e.g*. perbenzoic acid), and this functions as

an environmentally successful oxygen donor to convert the ketone to the corresponding lactone. [A similar approach, again using a sacrificial aldehyde, serves to epoxidize a range of alkenes in O_2 (air), with the same kind of molecular sieve catalyst employing a Mn^{III} (or Co^{III}) active site in its framework.[35]]

Insofar as catalytic epoxidations are concerned, as with Baeyer–Villiger reactions with ketones, the centre-piece of our heterogeneous catalytic conversion is MeAlPO-36 (with Me ≡ Mn^{III} and Co^{III}). In both cases, we exploit the easy autoxidation of aldehydes to promote the *in situ* formation of peroxy acids.[36]

Benzaldehyde molecules may freely enter the large internal areas of MeAlPO-36 thereby generating[37] first PhCO· and then PhCOOO· radicals, which, from the sequence of steps shown below, lead to the formation of perbenzoic acid and the alkene



oxide—in our case[35] cyclohexene oxide. This free-radical-based epoxidation of cyclohexene [and other alkenes such as α-(+)-pinene, *R*-(+)-limonene and styrene] is mechanistically quite distinct from the radical-free epoxidation of alkenes using alkyl hydroperoxides and titanosilicate catalysts (which is described in Section 3A, below).

F Solid acid-catalyzed reactions

As described elsewhere,[38] solid acid catalysts are urgently required in the petrochemical and other industries to replace such environmentally aggressive and widely used liquid acids as HF, H_3PO_4 and H_2SO_4. Following the lead given by the Union Carbide group[39] on the use of metal-ion- and silicon (framework)-substituted AlPOs as Brønsted acid catalysts, our colleague Jiesheng Chen and one of us[40] found that many MeAlPO-18 molecular sieves (M ≡ Zn^{II}, Mg^{II}, Co^{II}, Ni^{II}, *etc.*) were extremely effective, shape-selective catalysts for the dehydration of methanol to olefins. Moreover, they could be readily prepared in a state of high phase purity.[40] Such are the dimensions of the cavities and locations of the active sites—loosely attached protons to framework oxygen atoms in the vicinity of the metal ions (Me) {or of the Si^{IV} ions that substitute for framework P^V ions}[41] as shown in Fig. 11—that there is room inside this molecular sieve acid catalyst for the production of only ethene, propene and traces of butene. Because of the spatial restrictions, no aromatic molecules, such as those produced using H^+-ZSM-5 catalysts, can be formed. This is an example of transition-state shape-selectivity.

Success in designing shape-selective, microporous solid-acid catalysts consists in building a molecular sieve, the pore apertures and cage dimensions of which function as spatial constraints for the production of bulky hydrocarbons, but which still favour the generation of the light olefins alluded to above. By careful choice of structure-directing agents (SDAs), a new, shape-selective, microporous MAlPO solid acid catalyst, known as DAF-4, having a framework structure essentially the same as that of the naturally occurring zeolitic mineral levyne was produced.[42] In its Co^{II}-substituted form, DAF-4 transforms methanol with greater than 75% conversion at 350 °C into

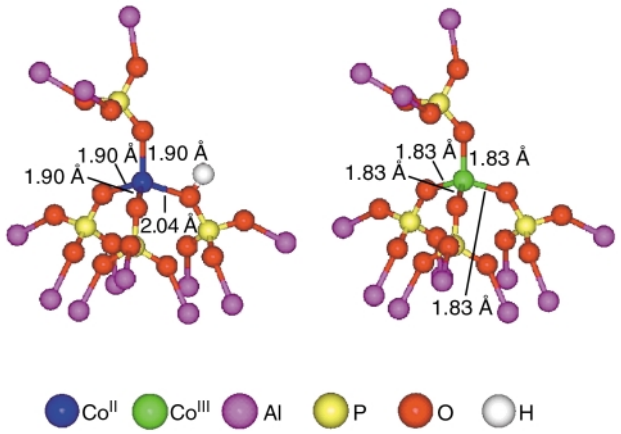


Fig. 11 The Brønsted acid active centre in Co^{II}AlPO-18 consists of the Co^{II} ion (shown in blue) together with its nearby proton (white) loosely bound to an adjacent framework oxygen. (When this acid catalyst is calcined in oxygen, the Co^{II} ion is converted to Co^{III} which is the redox active centre.[5])

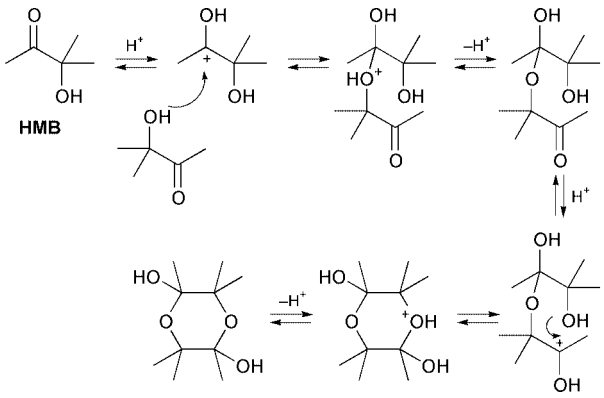
ethene and propene, with a selectivity of *ca.* 60% and *ca.* 20% for the two alkenes, respectively.

There are many points of similarity between catalytic reactions in microporous sieves on the one hand and enzymatic reactions on the other, shape-selectivity being the most prominent common feature. Further points of comparison have been made in a recent study[43] with Harris and his group involving the (solid)-acid-catalyzed oligomerization or cyclo-dimerisation of 3-hydroxy-3-methylbutan-2-one, hereafter abbreviated as HMB.

HMB is a stable liquid at ambient temperature. In acidic solutions, however, HMB readily undergoes reaction to generate a variety of products including the cyclic dimer (see Scheme 4) and the dehydrated reactant $MeCOC(Me)=CH_2$. The



Scheme 4

precise nature and distribution of the products varies significantly depending on the solvent and conditions used for the proton-catalyzed solution-state reaction. However, when HMB is incorporated within the channels of a synthetic zeolite, ferrierite, only one product (established by ^{13}C solid state MAS NMR) is observed together with some unreacted HMB. A plausible mechanism for the Brønsted acid-catalyzed cyclo-dimerisation is shown in Scheme 4. Harris and coworkers[43] have recently made a comparison of the proton-catalyzed bimolecular reaction observed in the cyclo-dimerization of HMB and other monomers with the mode of action of triosephosphate isomerase.

G Ammoximations: ε-caprolactam from cyclohexanone

For completeness, we should also mention the ability possessed by our designed Me^{III}AlPO-36 and Me^{III}AlPO-5 molecular sieve catalysts in effecting ammoximations. The reaction of

cyclohexanone with hydroxylamine (in its sulfate or phosphate form) is the best known method for the production of cyclohexanone oxime, and its subsequent Beckmann rearrangement to ε-caprolactam is an important, industrially used reaction. About 90% of ε-caprolactam world-wide is produced by using the above-mentioned conventional cyclohexanone process. However, large-scale industrial processes for the production of ε-caprolactam (monomer for nylon 6), employing cyclohexanone as the starting material, invariably produce large quantities of ammonium sulfate as by-products (see Scheme 2), which are undesirable. In 1990, the world-wide production of ε-caprolactam reached 3 million metric tons.

Fig. 12 summarizes the results of our ammoximation experiments using cyclohexanone in the presence of ammonia

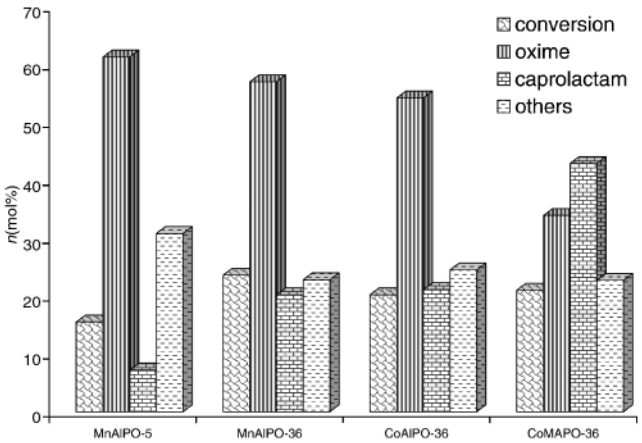


Fig. 12 Bar chart showing the relative performance of various transition metal ion (framework)-substituted molecular sieve catalysts in the conversion of cyclohexanone to its corresponding oxime and ε-caprolactam. The best catalyst is the bifunctional one (CoMAPO-36) which has both redox- and Brønsted acid-active sites.

and H_2O_2 [O_2 or *tert*-butyl hydroperoxide (TBHP) can also be used as oxidants], and MnAlPO-5 or Mn(Co)-AlPO-36 as catalysts, to produce the corresponding cyclohexanone oxime and ε-caprolactam. The ketone (cyclohexanone) is first oxidized in the presence of the 'redox' (Co^{III}, Mn^{III}) ions and ammonia to the oxime (cyclohexanone oxime). The Brønsted acid sites in the molecular sieves catalyze the subsequent Beckmann rearrangement of cyclohexanone oxime to ε-caprolactam. Interestingly, the (deliberate) introduction of acid centres (in the form of Mg^{II} or Zn^{II}, during synthesis, and typified by CoMAPO-36 in Fig. 12), further enhanced the selectivity for ε-caprolactam, thereby bringing out the bifunctional ability possessed by our catalysts.

3 Atomically engineered active sites in mesoporous solids

Here we demonstrate how to design and characterize high-performance catalysts for four distinct categories of reaction: the epoxidation of alkenes, solvent-free hydrogenations of unsaturated organic species, a novel kind of enantioselective hydrogenation, and selective oxidation (including oxidative dehydrogenation). Since these conversions employ mesoporous catalysts (with pore diameters upwards of 30 Å), quite bulky organic molecules (many of which could not gain access to the active centres inside the microporous catalysts discussed so far in this review) may be processed. Moreover, all the desiderata enumerated in Table 1, with the exception of regio- and shape-selective processes that are easier to effect with microporous, molecular sieve catalysts are achievable with mesoporous silicas onto the three-dimensional surface areas of which active sites have been grafted as described below.

A Titanosilicate epoxidation catalysts

The catalytic conversion of propylene to propylene oxide over Ti/SiO_2 catalysts in the presence of *tert*-butyl hydroperoxide (TBHP) is an industrially important epoxidation that accounts for an annual production of more than a million tons of propylene oxide worldwide.[23] From the outset,[44] there has been much speculation as to both the nature of the active site and the mechanism of this reaction and other selective oxidations effected by titanium-centred catalysts.[45] Five years ago, one of us and his colleagues set out[46] to prepare single-site, Ti^{IV}-centred, silica-based catalysts by reacting titanocene dichloride in the presence of triethylamine with the silanol groups that line (see Fig. 13) the inner walls of mesoporous silica. After

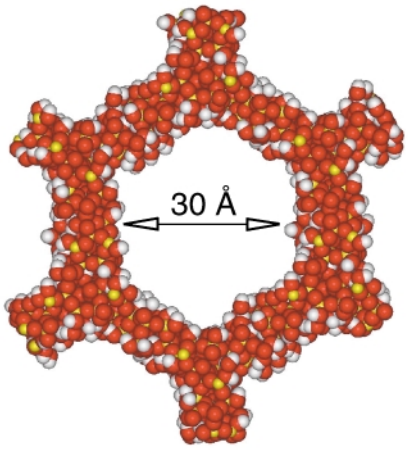

Fig. 13 Computer graphic representation of a single mesopore in MCM-41 silica (red, oxygen; yellow, silicon; white, hydrogen).

subsequent calcining in oxygen, all the organic residue in the silica-bound titanocene was driven off; and XAFS analysis showed that the structure of the active site is as shown in Fig. 14.

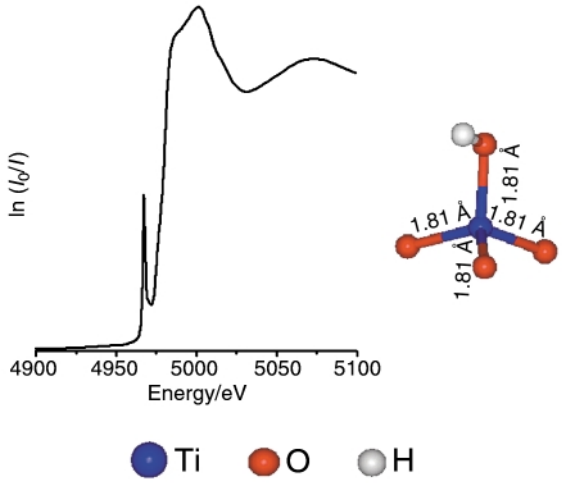

Fig. 14 Ti K-edge XANES of a Ti↑MCM-41 epoxidation catalyst after calcination. Both the XANES and EXAFS data (latter not shown) point to the tripodally attached titanyl group as the (Ti^{IV}-centred) active site.[47]

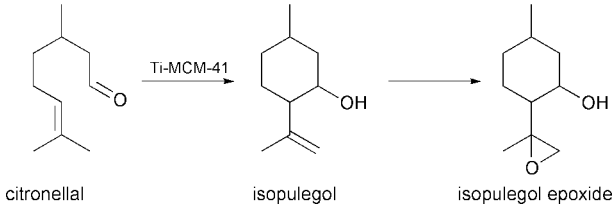
Both the XANES and EXAFS results for this catalyst revealed that isolated Ti^{IV}-centred active sites, composed of a tripodally-linked titanol groups, abound on the catalyst surface. There are no signs of Ti–O–Ti linkages, nor of any titanyl (T=O) groups of the kind proposed[44] earlier, either of a three- or five-coordinated kind. Detailed comparisons (of XAFS data) with several other local Ti^{IV}-centred oxygen environments leave no doubt[47–49] that the active sites in our highly active (so-called[48] Ti↑MCM-41) catalyst are four-coordinated. There are no 6-coordinated Ti^{IV}-centred sites present in the as-prepared catalyst. Thomas and Sankar also recorded[7,47,49] XAFS data

during the course of operation of the Ti ↑ MCM-41 catalyst in the epoxidation of cyclohexene to its epoxide with TBHP, a convenient test reaction. Significantly, the coordination shell of the original, 4-coordinated Ti^{IV} active sites expands to six during catalysis. And, whereas four of the surrounding oxygens are at distances strictly comparable to those in the pristine active site, in the reactive state there are two additional oxygens situated further away. This fact flatly contradicts the mechanism of epoxidation proposed earlier:[44] a more realistic picture is one in which, just prior to the act of epoxidation, the Ti^{IV}-centred active site is in six-fold coordination. This is compatible with the radical-free picture of epoxidation that we established previously.[48] Our method of preparing highly active titanosilicate catalysts from a titanocene precursor has been shown[50] recently to be ideally suited for the one-pot conversion of citronellal into isopulegol epoxide (see Scheme 5).



Scheme 5

Knowing the structure of the active site, we may set about boosting its catalytic activity by altering its immediate environment. This can be done by replacing[51] one of the silicons in the tripodally attached Ti^{IV} centre by germanium. The resulting catalyst, with a modified active site, exhibits an activity for the epoxidation of cyclohexene that surpasses that of the original catalyst, which, in turn, is superior to that of the catalyst prepared according to the procedure employed for the industrial preparation. There is clearly a favourable electronic influence in proceeding from ⩾$(SiO)_3$Ti–OH to ⩾$(SiO)_2$(GeO)Ti–OH.

It is a fortunate fact that titanosilsesquioxanes,[52] in which the Ti occupies one of the eight vertices of the cube formed by alkyl-substituted Si_7O_{11} moieties, are soluble in organic solvents, and that they also function as good, homogeneous epoxidation catalysts.[53] Moreover, the immediate environment of the Ti^{IV}-centred active sites in these soluble catalysts may also be readily probed using the XAFS technique.

Significantly, the performance of the heterogeneous and homogeneous Ti^{IV}-centred epoxidation catalysts are quantitatively very similar,[54] both in the un-enhanced and promoted states, caused by juxtaposing germanium in place of silicon. Furthermore, the fact that the turnover frequency in absolute terms (number of moles of the alkene epoxidized by the active site in unit time) is essentially the same for the heterogeneous as it is for the homogeneous (titanosilsesquioxane) catalyst lends independent proof (beyond the structural one based on EXAFS) that our designed titanosilicate catalysts are indeed 'single-site' ones.

B Engineered active centres for selective hydrogenations: encapsulated bimetallic nanocatalysts for solvent-free reactions

An inherent advantage possessed by mesoporous silicas, of the type exemplified in Fig. 13, is that it is readily possible to insert into such pores mixed-metal carbonylates that are quite bulky, or to graft onto their inner walls carefully constructed, chirally biased large metal complexes. In a collaboration with Johnson and his coworkers, we have capitalised upon this fact. In particular, we have inserted[55] cluster carbonylate salts such as $[Ru_6C(CO)_{16}CuCl]_2[PPN]_2$, where PPN stands for bis-(triphenylphosphino)iminium, into MCM-41 silica. These salts can be shown by *ex situ* HREM studies[55] to be encapsulated in a spatially uniform manner along the inner surfaces of the mesopores. (The Si–OH groups undergo hydrogen-bonding with the O–C–M bond of the carbonyls). *In situ* XAFS and FTIR studies are used to chart the progressive conversion, by gentle thermolysis, of the carbonylate salts into the denuded, bimetallic (carbided) nanoparticle catalysts. Separate Cu and Ru K-edge XAFS studies, for example, yield[55] a good picture of the active nanoparticle catalyst (*ca.* 15 Å diameter), which has a composition $Cu_4Ru_{12}C_2$. (They exhibit high turnover frequencies for hex-1-ene, diphenylacetylene, stilbene, *cis*-cyclooctene, D-limonene and 1,5,9-cyclododecatriene.)

In a further collaboration with Johnson and his group, a number of solvent-free selective hydrogenations of polyenes using a bimetallic Ru_6Sn nanoparticle catalyst have been highlighted[56] (see Fig. 15 and 16). The selective hydrogenation

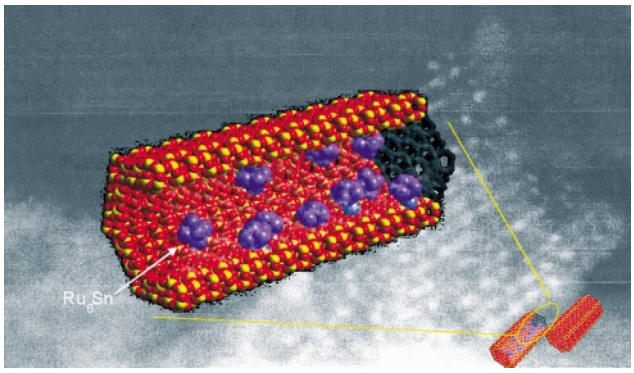


Fig. 15 Clusters of Ru_6Sn, anchored at the inner surfaces of mesoporous silica (MCM-41) function as powerful catalysts in the solvent-free selective hydrogenation of a variety of polyenes. In the background electron micrograph the linearly arranged white spots demarcate the anchored bimetallic clusters (diameter *ca.* 10 Å).[15]

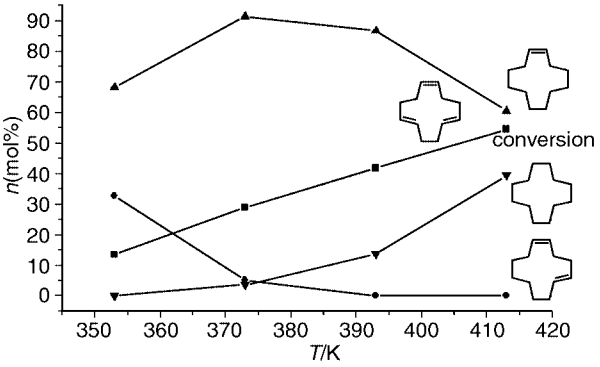

Fig. 16 The influence of temperature on the activity and selectivity of an anchored Ru_6Sn nanoparticle catalyst in the selective hydrogenation of 1,5,9-cyclododecatriene.[56]

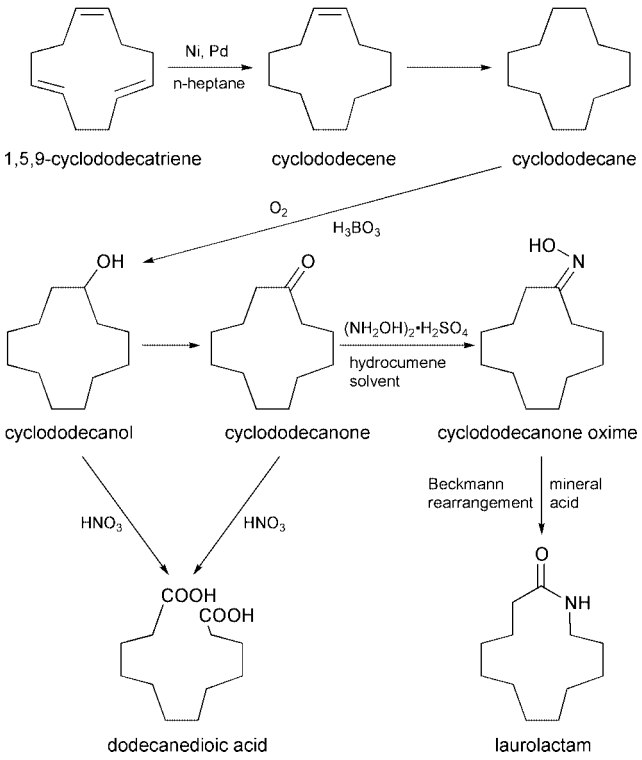
of polyenes such as 1,5,9-cyclododecatriene is quite an important procedure in the synthesis of organic and polymeric intermediates such as laurolactam, 12-aminododecanoic acid and dodecanedioic acid, which are important monomers for nylon 12, nylon 612, copolyamides, polyesters and for various materials used as coatings (see Scheme 6). Hitherto, Raney nickel, Pd, Pt, Co, and mixed transition metal complexes have been used for these hydrogenations, and all the reactions entail the use of organic solvents (such as n-heptane or benzonitrile) and often in the presence of efficient hydrogen donors (such as 9,10-dihydroanthracene). Our procedures emphasize that there are solvent-free routes available for such processes.

C Constrained chiral catalysts for enantioselective hydrogenation

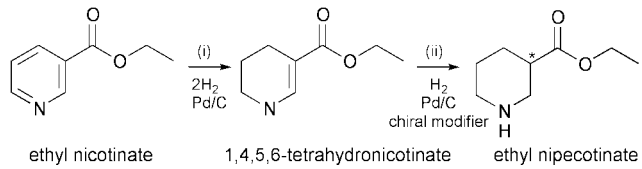
The large diameters of mesoporous silica permit the direct grafting of complete chiral metal complexes on to the inner walls by functionalizing the pendant surface silanols with organic groups such as alkyl halides, amines, carboxylates and



Scheme 6

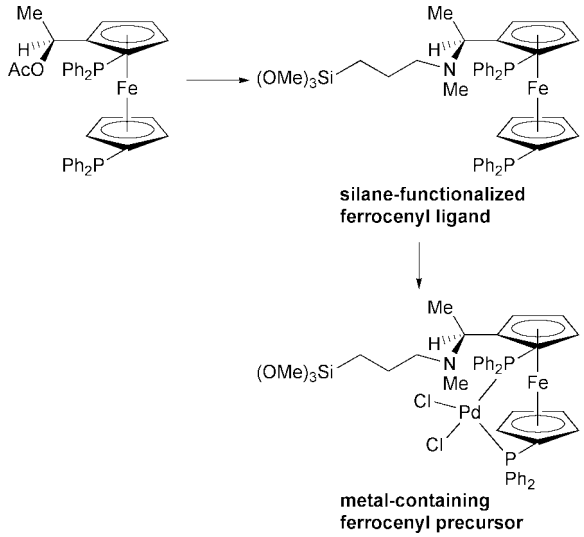
phosphanes. As pointed out by our colleague Maschmeyer,[57] this opens routes to the preparation of novel catalysts consisting of quite large concentrations of accessible, well-spaced and structurally well-defined active centres. As detailed elsewhere,[8,57,58] chiral chelate ligands based on 1,1′-bis(diphenylphosphino)ferrocene (dppf) are particularly attractive for tethering on to mesoporous silica; and the superior performance of the chiral, heterogenized catalyst compared with the unconfined homogeneous analogue in the allylic amination (Tsuji–Trost) reaction between cinnamyl acetate and benzylamine has been described.[58]

We have recently demonstrated[59] that this kind of confined dppf catalyst displays remarkable increases in both enantioselectivity and activity in the one-step hydrogenation of ethyl nicotinate to ethyl nipecotinate (see Scheme 7) when compared to an analogous homogeneous compound. Some of the key points to note here are as follows:



Scheme 7

- the previously available[60] procedure for producing the biologically relevant nipecotinate entailed a two-step process (Scheme 7) and the use of a chiral modifier, such as dihydrocinchonidine, in one of the steps;
- confinement is a crucial step in producing the enantioselective, anchored ferrocenyl precursor that is prepared as outlined in Scheme 8;
- when exactly the same ferrocenyl precursor is attached in a spatially unconstrained fashion to a silsesquioxane, thereby producing a homogeneous catalytic analogue of the chiral catalyst confined within mesoporous silica, no enantioselectivity results (Fig. 17);
- to maximize the efficiency of such confined chiral catalysts the exterior surfaces of the mesoporous silica are first reacted with dichlorodiphenylsilane, so as to ensure that anchoring of the dppf precursor occurs only at the interior faces of the siliceous support.[58]



Scheme 8

It is to be emphasized that the enantioselectivity that we achieve in this approach (with constrained chiral catalysts) is somewhat different from that which was introduced by Corma[61] but quite distinct from that used by Hutchings.[62]

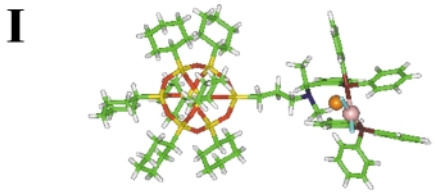
D Selective oxidations and oxidative dehydrogenations

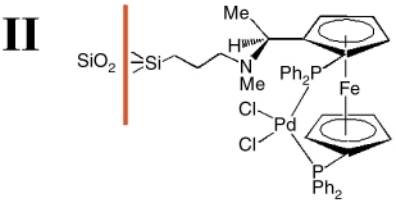
Here we illustrate briefly the merits of engineering well-defined active centres at mesoporous silica surfaces for the purposes of (i) oxidatively dehydrogenating methanol at Mo^{VI}-centred sites; and (ii) selectively oxidizing hydrocarbons grafted at vanadyl centres and an anchored oxo-centred Co^{III} acetate oligomer.

Just as $Ti(\eta^5\text{-}C_5H_5)_2Cl_2$ serves as an excellent means of introducing isolated Ti^{IV}-centred, catalytically active sites on a silica support (for epoxidation and other conversions[50]), so also does[63] $Mo(\eta^5\text{-}C_5H_5)_2Cl_2$ function as a similar precursor for the creation of Mo^{VI}-centred sites for the oxidative dehydrogenation of methanol to produce formaldehyde. Mo K-edge XAFS shows that, at low loadings, isolated, tetrahedrally-bound MoO_4 species are generated on the surface; however, these bipodally attached oxo–molybdenum species are held less strongly to the silica support than the tripodal Ti^{IV} centres described earlier.

Designed vanadium-centred active sites situated at the inner surface of mesoporous siliceous hosts (as well as at amorphous, microporous mixed-metal oxides of the types described by Maier *et al.*[64]) are catalysts, under mild conditions, for both the epoxidation of alkenes (typified by cyclohexene) and the selective oxidation of alkanes (typified by cyclohexane). XAFS studies proved invaluable in determining the nature of these active sites (see Fig. 18), the performance of which could be boosted[65] by juxtaposing methyl groups (to enhance the hydrophobicity) in the immediate vicinity of the vanadyl active centre.

In homogeneous mixtures of Co^{III} acetates rich in acetic acid, such as those used commercially in the selective oxidation of cyclohexane, many oligomers of the cobalt salt are present. By isolating and testing the catalytic activity of each separate oligomer it was found that the trimer displayed exceptional selectivity in oxidizing the CH groups of adamantane.[66] Specimens of the trimer were accordingly tethered to the inner walls of mesoporous silica, and the resulting uniform heterogeneous catalyst exhibited high activity in the solvent-free oxidation of cyclohexane to cyclohexanol and cyclohexanone using the sacrificial oxidant TBHP.[17] Moreover, *in situ* XAFS measurements showed that significant structural changes occurred in the tethered trimer during the initial period of induction prior to the onset of catalysis. There is reason to





Dppf–ferrocenyl–diamine–Pd catalyst	Substrate (reactant)	*t*/h	Conv. (%)	ee (%)
Homogeneous (**I**)	Ethyl	72	15.9	—

Tethered silica (**II**)	Ethyl	72	12.6	2
	nicotinate	120	19.2	2
Tethered to MCM-41 and confined inside mesopore (**III**)	Ethyl	48	35.5	17
	nicotinate	72	53.7	20

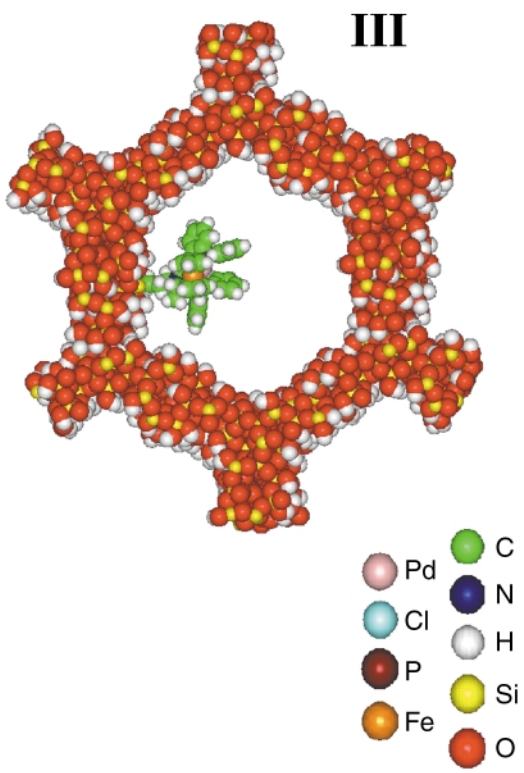

Fig. 17 Depiction of the catalytically active centre attached to a soluble silsesquioxane moiety **I** (top left) to a non-porous silica particle **II**, and bound in a constrained manner inside mesoporous silica **III** (right). The table (bottom left) shows that a significant measure of enantiomeric excess (ee) and substantial conversions are obtained only when the dppf–ferrocenyl–Pd-catalyst is in a constrained environment within the mesopore.

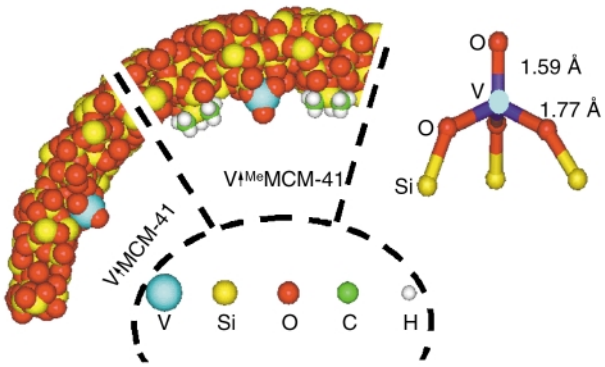

Fig. 18 A vanadyl active centre: (left) grafted onto a mesoporous silica; (centre) surrounded by nearby surface methyl groups to boost hydrophobicity; and (right) model, with bond distances derived from XAFS spectra (not shown), of the four-coordinated vanadium ion.[65]

believe[67] that certain metal complexes anchored to the inner walls of mesoporous silica may function as effective oxidation catalysts.

E Other related reactions

The atomic engineering of active centres on silica surfaces described above is part of a widely-applicable approach used previously by us[17,38,66,68] and others, especially by Basset and his group in their pioneering work[69] on surface organometallic chemistry. Basset *et al.*[70–73] have, for example, shown how various kinds of C–C bond cleavage and formation (involving hydrogenolysis or metathesis of alkanes) may proceed smoothly at tantalum hydride centres that are either monopodally or bipodally anchored to silica surfaces.

Among the principles that we seek to emphasize in this review are the twin advantages in using (a) synchrotron radiation for the *in situ* and *ex situ* characterisation[47] of the precise nature of the engineered active centres, and (b) well-defined mesoporous silicas with their high internal surface areas and adjustable pore diameters.

4 The stability of our catalysts

When we began our studies of MeAlPO selective oxidation catalysts, many practitioners who had earlier studied such solids predicted that we would run into insurmountable obstacles largely because of the tendency for the framework ions that constitute the active sites to be leached out of the molecular sieves during reaction. It is undoubtedly true that such solids do tend to suffer leaching if aggressive solvents (such as acetic acid) are used. But, from the outset, our aim was to achieve desirable chemical conversions in a solvent-free manner. By simply using the reactants (such as n-alkanes and oxygen as oxidant) we found that our microporous, molecular sieve catalysts ($Me^{III}AlPO$-*n* with $Me \equiv Fe^{III}$, Co^{III} or Mn^{III}) remained intact even after repeated use, provided that the overall conversion in the oxidations was kept relatively low (*ca.* 10–12%). This level of conversion avoids leaching by the polar products of the reaction (such as the n-alkanoic acids).

One recommended experimental test designed to ascertain whether the catalysis is truly heterogeneous or merely apparently so entails filtering off the 'active' solid catalyst from the reaction mixture (when hot) and then determining whether the reactants are still catalytically converted (by leached out active entities) in the residual liquid. Whenever we have carried out such tests they have always been negative: no reaction ensues in the absence of the solid molecular sieve catalyst [a striking example is shown in Fig. 2b of ref. 10(a)].

There is another incontrovertible procedure[20] to test whether the catalysis is truly heterogeneous or only apparently so because leached out ions are retained within the liquid phase that closely adheres to the molecular sieve. This is the one which involves taking an equimolar mixture of n-hexane and cyclohexane and subjecting it to aerobic oxidation over a $Co^{III}AlPO$-18 (or $Mn^{III}AlPO$-18) catalyst. There is, unsurprisingly, no conversion whatsoever of the cyclohexane molecule

as it is too large to gain access into the interior of the MeAlPO-18 where the vast majority of the active sites are located. The conversion of the n-hexane, however, is, as expected, to be quite substantial (there being good selectivity for terminally oxy-functionalised products). However, when the same reactant mixture is dissolved in acetic acid, the Co^{III}AlPO-18 catalyst gives rise to considerable oxidation of both cyclohexane and n-hexane. Moreover, C_2 and C_3 alcohols and ketones are now the main products (not the C_1 alcohols or acids) from n-hexane. Clearly, acetic acid as a solvent results in homogeneous as well as heterogeneous catalysis.

Other work (as yet unpublished) using CrAlPO-5 as a molecular sieve catalyst has likewise been found to facilitate genuine heterogeneous conversions (such as the decomposition of cyclohexyl hydroperoxide) of organic chemical compounds.

Leaching has to be considered as a factor also in the epoxidation and other oxidative reactions catalyzed by mesoporous silica on to which Ti^{IV} or Mo^{VI} centres have been grafted. Whereas tripodally attached Ti^{IV} ions stand up well to continued use as epoxidation catalysts with reagents such as TBHP,[54] detailed investigations[52c,53a] with model silsesquioxanes show that bipodally or monopodally attached Ti^{IV} ions are less securely held and tend to be leached out during reaction. Moreover, in the case of dipodally attached Mo^{VI} ions, leaching is quite appreciable, making the molybdenocene-derived Mo/SiO_2 catalyst[63] analogue of Ti/SiO_2 less effective in oxidative dehydrogenation reactions.

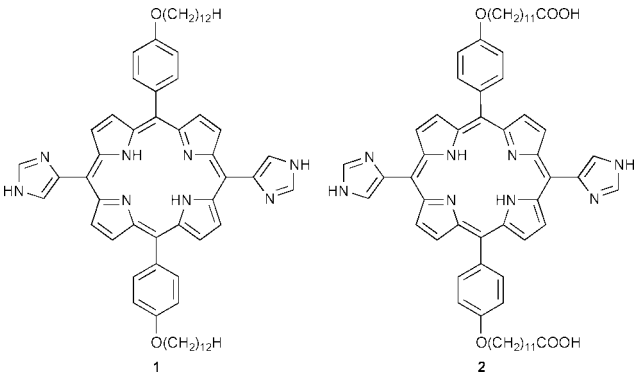
First published as an Advance Article on the web 29th March 2001

5,15-Bis(imidazol-4-yl)-10,20-bis(ω-carboxyalkyloxyphenyl)porphyrin 2 was assembled in water to form liposomal dispersions, whose structure were confirmed by DLS, AFM, TEM measurements as well as entrapment of a hydrophilic fluorescent probe.

Solar energy conversion is undertaken efficiently in chloroplasts or photosynthetic bacterial membranes, where chlorophylls or bacteriochlorophylls are arranged in well-organized structures of fixed distances and orientations. Examples are found in photosynthetic bacterial light-harvesting complexes where a large number of bacteriochlorophylls are arranged in a macro-ring form by coordination of imidazolyl side chains from transmembrane α-helices.[1] We have been interested in constructing light harvesting systems from chromophore assemblies without use of peptides.[2] Recently, we found that 5,15-bis(4-dodecyloxyphenyl)-10,20-bis(imidazol-4-yl)porphyrin **1** was assembled through imidazolyl–imidazolyl hydrogen bonds in non-polar media and that the assembly could perform more or less antenna functions.[3] Following on from this, large porphyrin assemblies were planned, to be organized into the form of liposomes by their own combined intermolecular interactions. For this purpose, a bis(imidazolyl)porphyrin **2** having two meso-ω-carboxyalkoxyphenyl substituents was designed and prepared according to Lindsey's procedure[4] from imidazol-4(5)-yl-2,2′-dipyrrylmethane and ethyl 12-(4-formylphenoxy)dodecanoate, followed by hydrolysis.[5]



1 2

Compound **2** was dispersed in water by sonication and subjected to gel filtration column separation to isolate the fraction corresponding to small unilamellar vesicles.[6] Dynamic light scattering (DLS) measurement[7] of the dispersion of **2** elucidated a mean diameter of 27 ± 8 nm. The aqueous sample was then applied on a smooth mica plate and dried in air. Fig. 1(a) shows a top view of atomic force microscope (AFM) measurement and 1(b) the side view along the line in 1(a). The observed full widths at the baseline level were 36, 32 and 38 nm for (A), (B) and (C), respectively. These values are larger than those estimated from DLS measurements because of the geometrical tip/sample convolution effect.[8] Fig. 1(c) shows a TEM image of the liposome dispersions. Many particles with diameters in the range 20–30 nm are observed, along with some aggregates that may have formed through drying under vacuum. These images confirm the size distribution obtained by the DLS measurement.

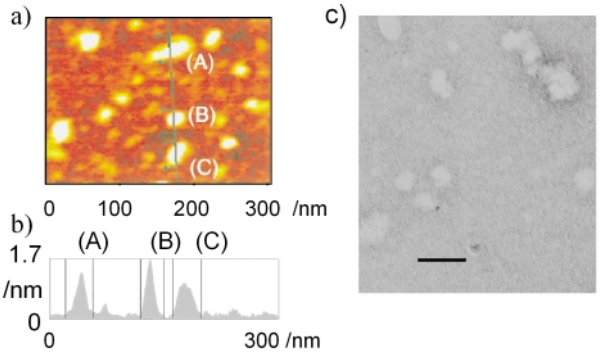


Fig. 1 AFM image of dispersion prepared from **2** developed on mica. a) A top view and b) a cross-section along the line in a). c) TEM image of negatively stained samples of dispersion from **2** with uranyl acetate. (bar = 50 nm).

The size of the system is apparently larger than that of spherical micellar aggregates in the range 2–4 nm[9] and coincides with the typical range for small unilamellar vesicles, 20–30 nm. Definitive evidence of vesicle formation, however, would be obtained by proving the presence of an interior aqueous phase and showing it to be capable of keeping polar solutes inside the vesicle. Therefore, a hydrophilic fluorescent probe, pyranine, was co-sonicated with **2** and the dispersion was isolated by Sephadex G-50 gel filtration.[10] Because of the strong absorption of porphyrin **2** and diffraction from the dispersion, no absorption of pyranine was detected in the UV-Vis spectrum. However, the presence of pyranine in the fraction from a gel filtration column was detected by its fluorescence spectra as shown in Fig. 2(a). The fluorescence intensity was low, due to self-quenching at the relatively high initial concentration of 0.3 mM. Fig. 2(b) and (c) show the emission from pyranine after 24 h and 40 h, respectively, from the gel filtration. The intensity gradually increased in a slow time-course and reached a saturation value only after 40 h. In a separate experiment, the fluorescence intensity of pyranine was increased 3× by the addition of 0.1 ml of a 0.1% aqueous solution of Triton X-100. Adsorption of pyranine on the liposomal membrane surface is unfavorable because both components are negatively charged, but in order to safely exclude that possibility the liposome was prepared without the

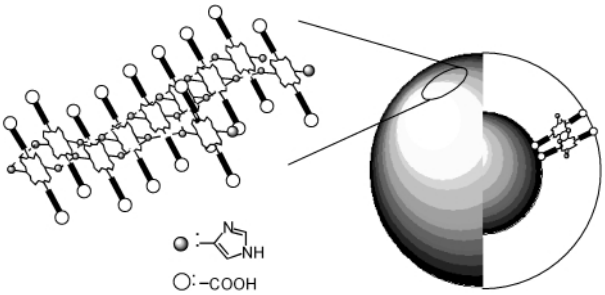

Fig. 3 Schematic representation of the liposome structure of **2** in aqueous solution.

addition of pyranine and than subjected to gel filtration. The resulting liposome fraction was immersed in a 0.3 mM pyranine solution. The liposome fraction, gel-filtered again, gave no fluorescence emission of pyranine (Fig. 2(d)). These results clearly indicate that the membrane can hold the entrapped pyranine and release it slowly to the exterior, when the fluorescence intensity is increased by liberation from the concentration quenching.

Based on these observations, the dispersions are concluded to be liposomes that contain an interior aqueous phase and provide a barrier toward the release of the hydrophilic solute entrapped. Their size corresponds to small unilamellar vesicles. A schematic representation of liposome formation from **2** is shown in Fig. 3. The liposomes we report on here are made only of bis(imidazolyl)porphyrin **2** without any phospholipid such as lecithin. To the best of our knowledge, Fuhrhop and coworkers reported only one example of liposome formation from porphyrins in the literature.[11] In their report, tetrakis[(bixinylamino)-*o*-phenyl]porphyrin was stabilized by side chain polymerization. In our system, the primary driving force for the formation of membrane aggregates comes from hydrophobic and ionic interactions of the amphiphilic compound in water.

The absorption spectrum of **2** dispersed in water (λ_{max} = 426 nm with the bandwidth at the half-height(hbw) of 91 nm resembled that of **1** in cyclohexane (λ_{max} = 432.5 nm and hbw_{Soret} = 86 nm). Both Soret bands were significantly broadened compared to that of **1** in methanol (λ_{max} = 417 nm and hbw_{Soret} = 40 nm). Analysis of ^{1}H-NMR and UV spectral studies shows bisimidazolylporphyrin **1** to assemble into primarily a slipped cofacial orientation through imidazole–imidazole hydrogen bonds in non-polar solvents such as cyclohexane, toluene or $CDCl_3$, but not methanol.[3] Similar structure formation is expected for the dispersion of **2** in water by hydrogen bond networks in the aggregate assembled by hydrophobic interactions. A further stabilization may be provided by hydrogen bond networks by imidazolyl substituents and π–π interactions of porphyrins assembled in the central belt part of the membrane and therefore favoured by an entropy term. The low permeability of entrapped pyranine across the liposomal membrane suggests that a strong hydrogen bond network has been constructed in the central region of the membrane. The liposomal membrane seems rather stiff as judged from AFM and TEM images since the liposomes maintained convex structures even under dry or vacuum conditions, respectively. The symmetrical structure of two carboalkoxyphenyl-substituted porphyrins may not be ideal for the formation of liposomes of small curvatures. However, a membrane-penetrating lipid, glycerol dialkylglycerol tetraether from thermophilic archaebacteria,[12] provides a convincing example of stable liposome formation from such symmetrical transmembrane lipids.

Porphyrins assembled in liposomal membranes are interesting materials in view of testing functions of light harvesting, light-induced charge separation and electron transfer across the membrane. Research targets along these lines are currently under active investigation.

The authors thank Dr M. Iwano (NAIST) and Mr N. Ohkubo (Seiko Instruments Co.) for the measurement of TEM images and AFM images, respectively.

6 Preparation of liposomes: bis(imidazolyl)porphyrin **2** (0.5 mg, 0.48 μmol) was dissolved in MeOH (5 mL). After evaporation of the solvent, the sample was dried under vacuum at rt for 6 h. The thin porphyrin film thus obtained was dispersed in a solution of pyranine (0.5 mg) dissolved in 3 mL of distilled water. The dispersion was sonicated in a cold room at 4 °C using a horn-type sonicator (TOMY SEIKO, UR-200) for 5 min (level 4) and left at 4 °C for 10 min cooling. This procedure was repeated 4×. The dispersions free from external pyranine were isolated through a Sephadex G-50 gel filtration column (ø 2 × 20 cm).

7 Dynamic light scattering (DLS) measurement was carried out by DLS-6000 (Photal, Co.). The atomic force microscope (AFM) image of the dispersion of **2** on a mica plate was obtained on a SPI 3800N (Seiko Instruments Co.) according to a dynamic force mode with a Si cantilever (a spring constant of 56 N m^{-1}, tip curvature radius of 10 nm).

Is ferrocene more aromatic than benzene?†

Matthew Laskoski, Winfried Steffen, Mark D. Smith and Uwe H. F. Bunz*

Department of Chemistry and Biochemistry, The University of South Carolina, Columbia, SC 29208, USA. E-mail: bunz@mail.chem.sc.edu

Received (in Columbia, MO, USA) 30th November 2000, Accepted 30th January 2001
First published as an Advance Article on the web 22nd March 2001

A combination of Pd-catalyzed arene–alkynyl couplings and $Cu(OAc)_2$-promoted internal alkyne dimerization furnishes novel ferrocene-based dehydroannulenes in high yield.

The notion of aromaticity in sandwich and half-sandwich complexes dates back to their observed Friedel–Crafts reactivity and was computationally explored by Bursten and Fenske, leading to the concept of metalloaromaticity,[1] reinforced both by Mitchell's[2] fundamental experiments utilizing chromotrene, cymantrene, and ruthenocene-fused dimethyldihydropyrenes and Schleyer's recent NICS calculations on organometallic π-complexes.[3] While there is little doubt that ferrocene is aromatic, its *degree* of aromaticity is less clear (more or less aromatic than benzene?), and experimental measures are lacking, due to the specific problem of *making* suitable ferroceno-fused dehydroannulenes or dehydrobenzoannulenes.[2] We present herein the synthesis and characterization of ferrocene-based benzodehydro[14]annulenes (**8**,**9**), a ferrocene-based dehydro[14]annulene (**10**), as well as the hitherto unknown 1,2-benzo-3,4,7,8,9,10,13,14-hexadehydro[14]annulene **13**.

The fusion of a [14]dehydroannulene to any π-system offers the unique opportunity to elucidate the (relative) aromaticity of the latter by examining (a) the ^{1}H NMR chemical shifts and b) the coupling constants of the vinylic H-5,6 protons in the dehydroannulene. According to both Mitchell[2] as well as to Günther and Scott,[4] the disruption of aromaticity under increasing bond fixation can lead to an increase in the observed $^3J_{HH}$ values of the coupling constants[4] and an upfield shift of the vinylic protons.[5] Dehydroannulenes **10** and **13** allow to directly compare the effects of benzo-*vs*. ferroceno-annelation onto an aromatic [14]dehydroannulene, which should be a measure of the relative aromaticity of ferrocene *vs*. that of the epitome of aromaticity, benzene.

Vollhardt and coworkers and others[6,7] developed a powerful route to hexadehydro[14]annulenes. Pd-catalyzed coupling of two C_4-fragments to an unsaturated 2,5-hexadiyne, a C_6-fragement (**1**, **11**) is followed by an internal Glaser[8] type cyclization, which leads to dehydro[14]annulene-derivatives. While originally reported for the synthesis of *benzo*dehydroannulenes we have exploited this concept to make **8**–**10** and **13** (Scheme 1).[9] Starting from 1,2-diethynylferrocene[10] (**1**), Pd/Cu-catalyzed coupling with **2**–**4** furnishes the open tetraynes **5**–**7** in yields of 30–96% (ESI)†. The relatively low yield of **5** is probably due to the electron-donating character of the iodide **2**. The coupling products **5**–**7** are stable oils, which were purified by column chromatography. Removal of the trimethylsilyl groups by potassium carbonate or NBu_4F proceeds smoothly and in high yields. Efficient, copper-catalyzed ring closure by $Cu(OAc)_2$ in acetonitrile[8] furnishes the cycles **8**–**10** in 50–62%

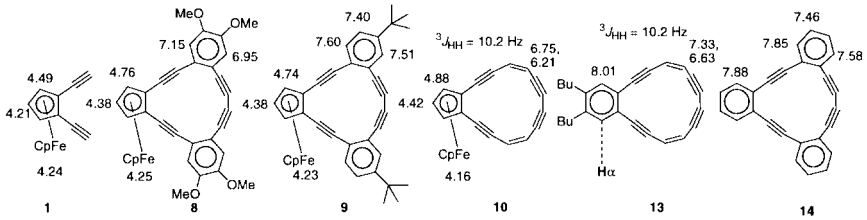

Scheme 2

yield as sole isolable products. The remainder of these reactions is black, insoluble, and intractable, a consequence of the partial oxidative decomposition of the ferrocene nuclei by the Cu^{II} salts, and low yields in the copper-catalyzed homocoupling reactions of ethynylated ferrocene derivatives have been observed earlier.[10,11] If instead of **1**, 1,2-diethynyl-4,5-dibutylbenzene **11** is coupled to **4**, we obtain the novel hexadehydrobenzo[14]annulene **13** in an overall yield of 53% after Cu-catalyzed coupling.[8] The material is orange–yellow and stable in dilute solution, but unstable as a solid at ambient temperature. Surprisingly, this is the first reported hexadehydrobenzo[14]annulene.

The cycles **8** and **9** are stable in the solid state and crystallize well from hexane–dichloromethane mixtures to give a specimen suited for single-crystal X-ray analysis.‡ Fig. 1 shows the ORTEPs of **8** and **9**. The bond angles and bond lengths are in excellent agreement with the expected values showing distinct bond alternation between triple, double and single bonds. The large hydrocarbon ligand is planar, as expected for a [14]-dehydroannulene. In the solid state, the diyne units of the cycles do not show unusual contacts, and we did not observe solid-state polymerization of these dehydroannulenes.

Most interesting with respect to ferrocene's aromaticity are the ^{1}H NMR spectra of **8**–**10**. Comparison of the ^{1}H NMR spectrum of Vollhardt's cyclyne (**14**)[5,6] and that of the benzo–fused dehydro[14]annulene **13** allows extraction of the relative aromaticity of ferrocene with respect to benzene. When the ^{1}H NMR spectrum of **14** is compared to that of **9**, a small upfield shift is observed for H_α (the protons adjacent to the dehydro[14]annulene), suggesting that, if no other effects are present, ferrocene has a similar, or bigger localizing influence on the dehydroannulenic core than benzene (Scheme 2). This measure is clear but relatively indirect. A proton attached to the reporter annulene would increase the effect, and thus the compounds **10** and **13** offer a much more direct comparison. The ^{1}H NMR spectrum of the benzo compound **13** shows two doublets at δ 7.33 and 6.63, while in the ^{1}H NMR spectrum of **10** the *same* vinylic protons appear at δ 6.75 and 6.21, respectively. In the same wake we can compare the ^{1}H NMR spectrum of **7** (open, non-aromatic) to that of **10** (closed) and the ^{1}H NMR spectrum of **12** to that of **13**. Upon conversion of **7** $\rightarrow$**10** the annulenic vinyl protons experience a modest downfield shift ($\Delta\delta_{\text{vinyl-H}}$ = 0.40 and 0.77) and the vinylic $^3J_{HH}$ coupling decreases slightly by ΔJ_{HH} = 0.7 Hz, while for the conversion of **12** $\rightarrow$ **13** the shift of the vinyl protons is much bigger ($\Delta\delta_{\text{vinyl-H}}$ = 0.78 and 1.32 respectively). Here the coupling constant decreases by ΔJ_{HH} = 0.8 Hz. These data show that upon ring closure to **10** the downfield shift of the vinyl protons is relatively small, while the downfield shift in the ^{1}H NMR spectra, when closing the benzo-fused ring (**12** $\rightarrow$ **13**), is almost twice of these values. Consequently a benzene ring disturbs the aromaticity of the fused dehydro[14]annulene *less* than a ferrocene ring. Both sets of data suggest, that in the ferrocene case there is a stronger localization of the dehydro[14]annulene than for benzo-fused **13**, and thus ferrocene is *more* aromatic than benzene by this measure. These arguments are in line with Mitchell's findings.[2] In future we will report the electrochemistry, Bergman rearrangement and the products of the pyrolysis of the ferrocene-fused dehydroannulenes **8**–**10**.

Isomorphous substitution of Fe in the MFI framework and extraction by steaming leads to a highly active and stable catalyst for N_2O decomposition in tail-gas from nitric acid plants.

Nitrous oxide (N_2O) has been identified as a greenhouse gas and a contributor to the destruction of ozone in the stratosphere.[1,2] At present, emission from nitric acid plants is the most important environmentally harmful source of N_2O in the chemical industry, since abatement technologies for the other major industrial source, *i.e.* adipic acid plants, have been successfully developed.[2] The direct catalytic decomposition of N_2O into N_2 and O_2 is an attractive *end-of-pipe* solution to reduce N_2O emissions, but none of the catalysts proposed in the literature show a good activity and stability in N_2O decomposition in the presence of high concentrations of O_2, NO_x and H_2O.[2,3] FeZSM-5 is an interesting system because N_2O conversion shows anomalous behaviour in the presence of these tail-gas components.[4] Different preparation methods have been reported to optimize the catalytic performance of FeZSM-5, not only in N_2O decomposition,[5,6] but also in de-NO_x HC-SCR and selective oxidations.[7–9] In this study, an *ex*-framework FeZSM-5 catalyst is shown to be very active and stable in direct N_2O decomposition in simulated tail-gas from nitric acid plants, compared to FeZSM-5 catalysts prepared by sublimation and (aqueous and solid) ion-exchange methods.

Isomorphously substituted FeZSM-5 was synthesized hydrothermally using TPAOH as the template.[10] The as-synthesized sample was calcined in air at 823 K for 10 h and was converted into the H-form by three consecutive exchanges with a NH_4NO_3 solution (0.1 M) for 12 h and subsequent air calcination at 823 K for 5 h (FeZSM-5*c*). Finally, the catalyst was activated in flowing steam at ambient pressure (water partial pressure of 300 mbar and 30 ml min^{-1} of N_2 flow) at 873 K during 5 h (*ex*-FeZSM-5). Other FeZSM-5 catalysts were prepared by liquid (aqueous) ion-exchange with $Fe(NO_3)_3{\cdot}9H_2O$ (*lie*-FeZSM-5) and solid-ion exchange with $FeCl_2{\cdot}4H_2O$ (*sie*-FeZSM-5), following standard procedures described in the literature.[5,8] NH_4-ZSM-5 (P&Q Corporation) was used as the support. *Sub*-FeZSM-5 was prepared by sublimation of $FeCl_3$ on H-ZSM-5 (Degussa).[7] The reaction was carried out in a six-flow reactor system,[11] by passing a mixture of N_2O (4.5 mbar), O_2 (70 mbar), NO (1 mbar) and H_2O (15 mbar) in He at a flow rate of 50–100 ml min^{-1} over 50 mg of catalyst (125–200 μm). Total pressure was 3 bar and space velocities (*GHSV*) of 36 000–120 000 h^{-1} were applied. Before reaction, the catalysts were pretreated in He at 723 K for 1 h. The product gases were analyzed with a chemiluminescence NO_x analyzer and by GC equipped with a thermal conductivity detector, using a PoraplotQ column and a Molsieve 5A column.

Table 1 shows the characterization results and the specific activity per mol of iron (turnover frequency, TOF) of the different catalysts. Fig. 1 shows that *sub*-FeZSM-5 and *ex*-FeZSM-5 induce similar absolute N_2O conversion levels in a N_2O–He feed and significantly higher levels than the exchanged catalysts. *sie*-FeZSM-5 is more active than *lie*-FeZSM-5. Calculation of the TOF at 700 K (Table 1) shows that the specific activity per mol of iron is more than 4, 7 and 10 times higher for *ex*-FeZSM-5 than for *sie*-FeZSM-5, *sub*-FeZSM-5 and *lie*-FeZSM-5, respectively. Electron microscopy reveals a very dispersed and homogeneous distribution of FeO_x clusters of 1–2 nm in *ex*-FeZSM-5 (see graphical abstract and Table 1), denoted as micro-aggregates here. The other preparation methods fail to lead to a homogeneous distribution of the iron species in the catalyst, as revealed by the broad FeO_x cluster size distribution indicated in Table 1. Activation of the calcined sample (FeZSM-5*c*) with steam at 873 K is crucial to create active Fe-species in *ex*-FeZSM-5, as can be concluded by comparison of the activity curves of both samples in Fig. 1. The steam treatment induces the migration of iron towards extra-framework positions by cleavage of Si-O-Fe bonds, as revealed by UV–VIS spectroscopy,[10] producing the FeO_x micro-aggregates. This treatment also leads to dealumination of the zeolite framework and formation of a secondary network of larger pores.

The performance of *ex*-FeZSM-5 in different feed mixtures containing N_2O and O_2, NO_x and/or H_2O is shown in Fig. 2. These gases are present in tail-gases from nitric acid plants. *ex*-FeZSM-5 shows a substantial N_2O conversion above 700 K in

Table 1 Data of catalysts used

Catalyst	Si/Al[a]	Fe[a]/wt%	ΔL[b]/nm	10^{-4} TOF[c]/s^{-1}
ex-FeZSM-5	31.3	0.64	1–2	48.6
sie-FeZSM-5	37.5	1.50	5–15	10.5
lie-FeZSM-5	37.5	1.46	7–25	4.7
sub-FeZSM-5	14.0	5.0	3–12	6.5

[a] Determined by ICP-OES and AAS. [b] FeO_x cluster size distribution (determined by TEM). [c] Mol of N_2O converted per mol of Fe ions s^{-1}, determined at 700 K after 1 h time on stream; feed composition: 4.5 mbar N_2O in He, total pressure 3 bar, GHSV = 36 000 h^{-1}.

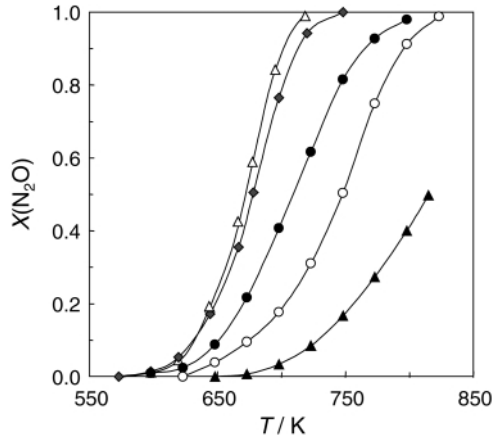

Fig. 1 N_2O conversion as a function of temperature over (◆) *ex*-FeZSM-5, (▲) calcined FeZSM-5*c*, (●) *sie*-FeZSM-5, (○) *lie*-FeZSM-5 and (△) *sub*-FeZSM-5. Feed composition: 4.5 mbarN_2O in He; total pressure 3 bar; GHSV = 36 000 h^{-1}.

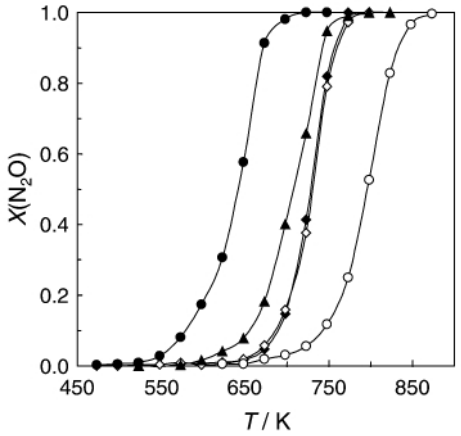

Fig. 2 N_2O conversion as a function of temperature in different feed compositions: (◆) 4.5 mbarN_2O, (◇) 4.5mbarN_2O + 70 mbarO_2, (●) 4.5 mbarN_2O + 1 mbarNO, (○) 4.5 mbarN_2O + 15 mbarH_2O, (▲) 4.5 mbarN_2O + 70 mbarO_2 + 1 mbarNO + 15 mbarH_2O; balance He; total pressure 3 bar; GHSV = 60 000 h^{-1}.

a N_2O–He feed. Addition of O_2 to the feed hardly affects the activity, while NO enhances the reaction rate considerably. Apparently, molecular oxygen does not dissociate over FeZSM-5 and does not compete with N_2O for active sites. NO scavenges adsorbed O* (deposited by N_2O decomposition), forming NO_2 and regenerates the active site. Water severely inhibits the reaction, probably by hydroxylation of the active sites and adsorption in the zeolite channels. Nevertheless, in the complete gas mixture (N_2O + O_2 + NO_x + H_2O), *ex*-FeZSM-5 still shows a significantly higher activity than in N_2O alone. The promoting effect of NO is thus stronger than the inhibition by H_2O. This extraordinary behaviour distinguishes FeZSM-5 from other N_2O decomposition catalysts (usually based on noble metals like Rh or Ru), since these are severely inhibited by NO_x (*via* surface nitrite/nitrate formation) and H_2O.[2,3,12,13] The remarkable behaviour of *ex*-FeZSM-5 is not limited to its activity, but also includes stability. N_2O conversion over *ex*-FeZSM-5 exhibits a remarkable stability in the complete feed mixture at different space velocities, ranging from 36 000 to 120 000 h^{-1} (Fig. 3). *sub*-FeZSM-5 shows slight deactivation at 36 000 h^{-1}. Significant deactivation was observed for the *sie*-FeZSM-5 and *lie*-FeZSM-5 catalysts, further increasing the differences in performance of the catalysts.

The differences in activity and stability of the different FeZSM-5 samples can be related to the preparation method, which lead to different constitutions of the catalysts with respect

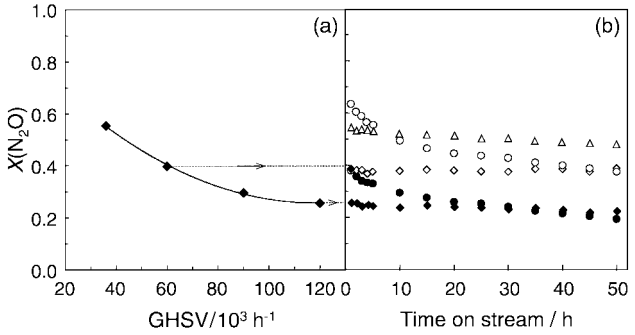

Fig. 3 N_2O conversion as a function of (a) the space velocity (GHSV) over *ex*-FeZSM-5 and (b) time-on-stream over (◇) *ex*-FeZSM-5 (60 000 h^{-1}, 700 K), (◆) *ex*-FeZSM-5 (120 000 h^{-1}, 700 K), (●) *sie*-FeZSM-5 (36 000 h^{-1}, 725 K) (○) *lie*-FeZSM-5 (36 000 h^{-1}, 775 K) and (△) *sub*-FeZSM-5 (36 000 h^{-1}, 700 K). Feed composition: 4.5 mbar N_2O + 70 mbar O_2 + 1 mbar NO + 15 mbar H_2O, balance He. Total pressure 3 bar.

to dispersion, morphology, and structure of the active sites. A comparison of the FeO_x cluster size and TOF suggests a correlation (Table 1): the TOF increases with decreasing average FeO_x cluster size. The FeO_x micro-aggregates observed by TEM in *ex*-FeZSM-5 represent a large fraction of the total amount of Fe in the sample (*ca*. 70%), as estimated by ^{57}Fe Mössbauer spectroscopy. Sublimation and ion-exchange lead to a significantly lower relative amount of small clusters than the *ex*-framework method. In general, for other FeZSM-5 catalysts, the identification of the active species is difficult, due to the inhomogeneous nature of the catalysts. Isolated Fe^{3+} ions, binuclear and multinuclear complexes, small iron–oxide clusters, and large iron-oxide particles have been identified.[5–10] Large FeO_x particles at the external surface of the zeolite are widely accepted to be inactive in the de-NO_x HC-SCR.[5,7,8] This could also explain the lower activity of ion-exchanged catalysts compared to *ex*-FeZSM-5 in N_2O decomposition. *sub*-FeZSM-5 possesses small FeO_x clusters (*ca*. 3 nm), which may account for the high activity observed, but this catalyst also contains a significant fraction of large FeO_x particles (*ca*. 12 nm). A contribution of other iron species in the zeolites to the N_2O decomposition activity can not be excluded. We are currently further investigating the structure of the active sites in the different samples and the reason for the high stability of the *ex*-framework catalyst. We are also addressing the effect of the pore size distribution and extra framework aluminum formed in the steaming procedure of *ex*-FeZSM-5 on the activity.

The temperature of the exhaust in nitric acid plants, which ranges from 500 to 773 K depending on the plant operation, is of utmost importance for the feasibility of an *end-of-pipe* catalytic solution. Large modern dual-pressure plants, with tail-gases in the range 723–773 K, contribute to *ca*. 75% of the total N_2O emission. Nitric acid production facilities in the Netherlands (high-temperature tail-gases) contribute to 25 kton y^{-1}, *i.e. ca*. 6% of the global N_2O emission related to nitric acid plants (*ca*. 400 kton y^{-1}).[14] The use of *ex*-FeZSM-5, which shows stable N_2O conversion (> 90%) at 725 K and 60 000 h^{-1}, appears quite viable. This technology can contribute to greenhouse gas abatement in a cost-attractive way, since *ex*-FeZSM-5 does not contain any expensive noble metal. For low temperature tail-gases (500–525 K), typical in low (single or dual)-pressure plants, *ex*-FeZSM-5 would additionally require extra-heat exchange to preheat the feed mixture, or the addition of hydrocarbon as reducing agent.

A general, two-directional synthesis of *C*-(1→6)-linked disaccharide mimetics: synthesis from non-carbohydrate based starting materials

Michael Harding and Adam Nelson*

School of Chemistry, University of Leeds, Leeds, UK LS2 9JT

Received (in Cambridge, UK) 6th February 2001, Accepted 1st March 2001
First published as an Advance Article on the web 26th March 2001

The enantiomerically enriched diol 1,4-di(furan-2-yl)butane-1,4-diol (*R*,*R*)-1, synthesised either by Sharpless kinetic resolution or asymmetric reduction of the corresponding diketone, was a key intermediate in the stereodivergent synthesis of diastereoisomeric *C*-(1→6)-linked disaccharides. Two-directional stereoselective functionalisation steps, for example *syn*- and/or *anti*-selective dihydroxylation reactions, were exploited in the stereoselective synthesis of five diastereoisomeric *C*-linked disaccharides.

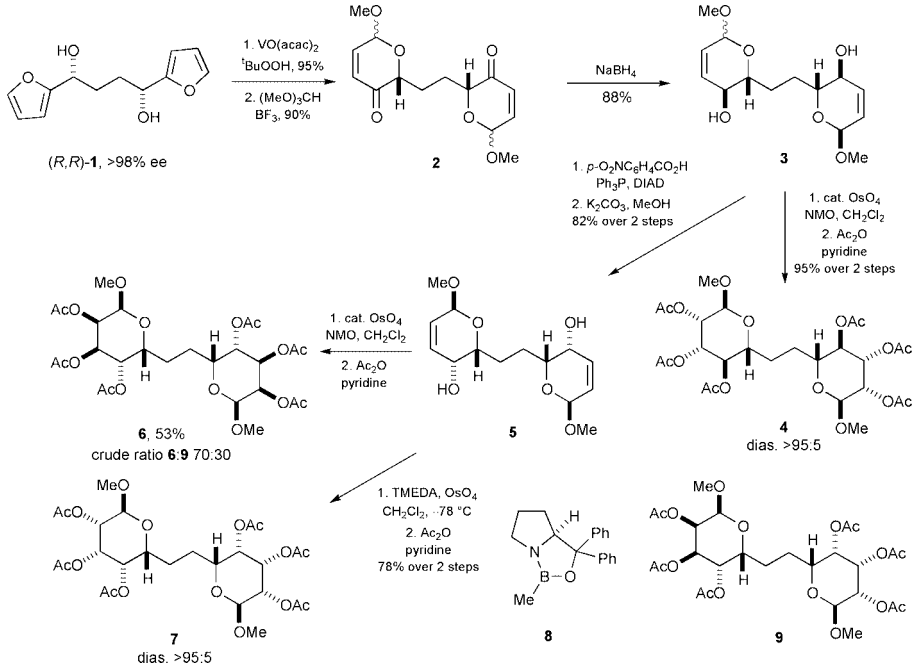
Libraries of stereo- and regioisomeric oligosaccharides and carbohydrate mimetics can probe large areas of conformational space, and can be used to identify unnatural ligands for carbohydrate receptors.[1] *C*-Linked glycosides are a particularly interesting class of carbohydrate mimetic which are resistant to enzymatic degradation, have potential as inhibitors of glycosidases and glycosyl transferases[2] and often have biological activity[3] and conformational properties[4] which are similar to natural oligosaccharides. Established methods for the preparation of stereoisomeric *C*-linked di- and trisaccharides often rely on the separation of the stereoisomers which result from unselective functionalisation reactions; this approach has been exploited in the synthesis of *C*-linked analogues of disaccharides formed from D- and L-hexoses, and *C*-linked trisaccharides which are potential ligands for cell surface proteins.[5]

In this communication, we describe the preparation of some *C*-linked analogues of some (1→6)-linked disaccharides from the racemic difuryl diol *rac*-**1**, prepared by unselective reduction of the corresponding diketone. Sharpless kinetic resolution[6] of *rac*-**1** returned (*R*,*R*)-**1** in 38% yield and 85% ee. An alternative approach[7] involved asymmetric reduction of the corresponding diketone using borane–dimethyl sulfide complex and 10 mol% of Corey's CBS catalyst **8** to give the diol **1** as a 85 : 15 mixture of diastereoisomers in 80% yield; (*R*,*R*)-**1** had > 98% ee. Oxidative ring expansion of the furan rings of (*R*,*R*)-**1**, using $VO(acac)_2$/^{t}BuOOH, and acetalisation, gave the dipyranone **2** as a 75 : 25 mixture of anomers (Scheme 1), which were reduced with $NaBH_4$ to give the separable diols **3**.

The C_2-symmetric diol **3** was a key intermediate in our divergent synthesis of *C*-linked disaccharides. For example, dihydroxylation of both of the alkenes of **3** under Upjohn conditions (cat. OsO_4–NMO) occurred opposite[8] to the adjacent hydroxy groups to give, after acetylation, the hexaacetate **4** as a > 95 : 5 mixture of diastereoisomers. This two-directional approach[9] is very efficient indeed: in just two steps, six new stereogenic centres have been introduced in the reaction sequence **2**→**4** with almost complete stereocontrol. The di-THP **4** is a protected *C*-linked disaccharide mimetic in which *C*-6 of the one of the rings has been replaced with a methoxy group.

In a similar manner, the diastereomeric diol **5**, synthesised by Mitsunobu inversion of **3** and hydrolysis, was converted into the protected *C*-linked disaccharides **6** and **7**. Hence, double dihydroxylation of **5** opposite to[8] the axial hydroxy groups gave, after acetylation, the protected *C*-linked disaccharides **6** and **9** in 53 and 23% yield respectively. Alternatively, directed[10] double dihydroxylation of **5** under Donohoe's reaction conditions gave, after acetylation, the hexaacetate **7** in 78% yield. The ability to choose at a late stage which diasteroisomer is synthesised is an exceptionally valuable feature of a general synthesis of stereoisomeric analogues.

A two-directional synthetic strategy[9] does not, of course, restrict our approach to the synthesis of C_2-symmetric mim-



Scheme 1

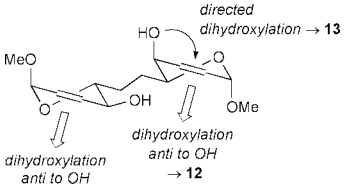


Fig. 1

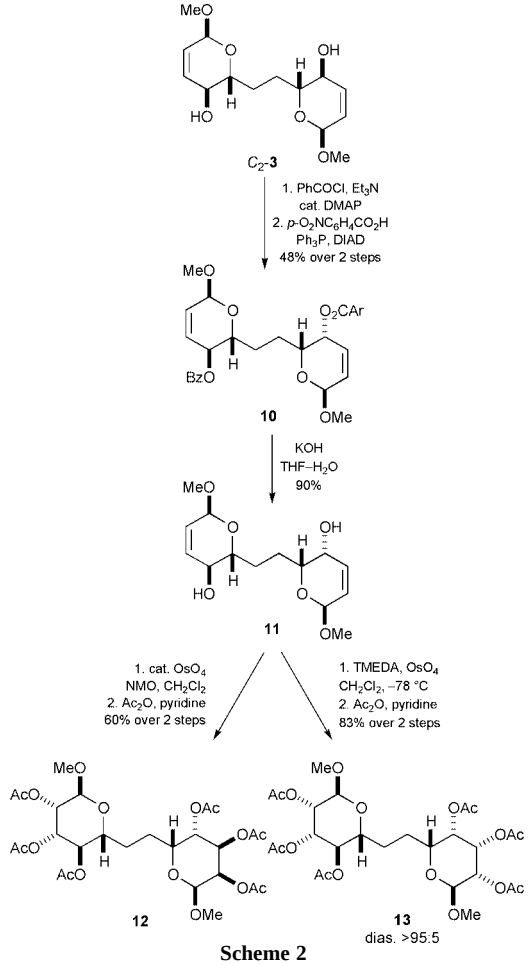

Scheme 2

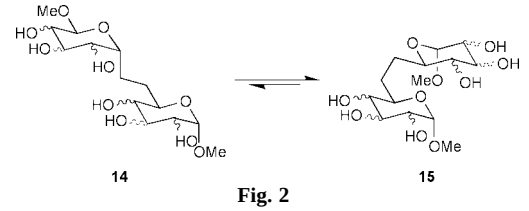

Fig. 2

etics. For example, benzoylation of one of the homotopic alcohols of **3**, inversion of the remaining alcohol and hydrolysis, gave **11** in which the dihydropyran rings had been stereochemically differentiated (Scheme 2). Dihydroxylation of **11**, *anti* to both of the hydroxy groups[8] (Fig. 1) gave the protected carbohydrate mimetic **12**.

More remarkably, the diol **11** could be elaborated in a two-directional fashion such that the stereochemical outcome of dihydroxylation was different in each of the rings. The diol **11** has both an axial and an equatorial hydroxy group; the dihydroxylation of **11** under Donohoe's conditions (TMEDA, OsO_4, CH_2Cl_2, −78 °C) was directed[10] by the axial alcohol but occurred *anti* to the equatorial alcohol (Fig. 1) to give, after acetylation, the protected disaccharide mimetic **13** in 83% yield.

The stereoisomeric compounds **4**, **6**, **7**, **9**, **12** and **13** can be considered to be protected versions of either *C*-α(1→6)- or *C*-β(1→6)-linked disaccharides (see Fig. 2). Although the free *C*-disaccharides are likely to predominantly populate the conformation **15** which resembles a β-linked disaccharide formed from a D and an L sugar (see Table 1), higher energy conformations can often be stabilised by complexation with a carbohydrate receptor.[4b] The conformations **14** mimic α(1→6)-linked disaccharides formed from two natural sugars (see Table 1).

Table 1 Classification of *C*-linked disaccharide mimetics

Compound	Parent α-linked disaccharide(s)	Parent β-linked disaccharide(s)
4	D-Alt-α(1→6)-D-Man	L-Gal-β(1→6)-D-Man
6	D-Gal-α(1→6)-D-Gul	L-Alt-β(1→6)-D-Gul
7	D-All-α(1→6)-D-Tal	L-Tal-β(1→6)-D-Tal
9	D-Gal-α(1→6)-D-Tal or D-All-α(1→6)-D-Gul	L-Alt-β(1→6)-D-Tal or L-Tal-β(1→6)-D-Gul
12	D-Gal-α(1→6)-D-Man or D-Alt-α(1→6)-D-Gul	L-Alt-β(1→6)-D-Man or L-Gal-β(1→6)-D-Gul
13	D-All-α(1→6)-D-Man or D-Alt-α(1→6)-D-Tal	L-Tal-β(1→6)-D-Man or L-Gal-β(1→6)-D-Tal

We believe that our work is the first synthesis of *C*-linked disaccharides entirely from non-carbohydrate based precursors, though Vogel has reported the use of a non-carbohydrate based template to introduce one of the sugar rings.[11] Most other syntheses rely on the coupling of sugar derivatives.[12–15] A particular merit of our approach, which makes it amenable to the synthesis of libraries of stereoisomeric carbohydrate mimetics, is that several diastereomeric *C*-linked disaccharides may be prepared by minor variation of a general reaction sequence. There are 136 possible stereoisomeric carbohydrate mimetics **14** (ignoring anomers); we have reported the stereoselective synthesis of five of these mimetics, and their enantiomers could have been synthesised by using the enantiomeric reagent in the enantioselective step.

We thank the Leverhulme Trust for a grant to the University of Leeds, the Royal Society for funds for chiral HPLC equipment, AstraZeneca and Pfizer for strategic research funding and Robert Hodgson for helpful discussions.

Solid phase chemistry can be used to prepare, in excellent yield and purity, a range of Fréchet-type aryl-ether dendrimers, for use in either dendrimer conjugation studies, resin loading enhancement or the wedge based synthesis of larger dendrimers.

Over the past few years we have shown that resin-bound polyamidoamine (PAMAM) dendrimers are readily synthesized[1,2] and are inert under a broad range of chemical conditions[3] such as coupling reactions, nucleophilic displacements or borohydride reductions. However, synthetic patterns requiring the use of strong reducing agents or strong bases have to be avoided. In the area of solution dendrimer synthesis Fréchet[4] has reported the construction of arylether dendrimers *via* the alkylation of bromobenzylic dendrimeric fragments with 3,5-dihydroxybenzyl alcohol, with which he also introduced the concept of convergent dendrimer synthesis. Since polyether dendrimers are substantially more chemically inert than the PAMAM dendrimers and because of the problems associated with solution dendrimer synthesis, the solid-phase synthesis of Fréchet-type aryl-ether dendrimers (Fig. 1) was targeted both as a means of resin loading enhancement as well as a convenient approach to dendrimer *wedge*[4] synthesis. Since the building blocks originally used by Fréchet were considered to be unsuitable for solid-phase synthesis, 3,5-bis(acetoxymethyl)-phenol (**1**) was used and was prepared by modification of the literature procedure.[5,6] The presence of a phenolic group and of two acetyl-protected primary alcohols allowed the synthesis of the dendrimer *via* a two-step iterative procedure, consisting of a Mitsunobu condensation followed by ester hydrolysis. The synthesis was first carried out using an analytical construct,[7] consisting of glycine attached to the TFA-cleavable Rink linker[8] allowing ready characterisation of the intermediates and optimisation of the Mitsunobu condensations and ester hydrolysis. Compound **2**, obtained in two steps from **1**, was coupled onto Gly-Rink-PS resin under standard conditions (Scheme 1) to give **3**.

Hydrolysis of **3** followed by Mitsunobu condensation with (**1**) afforded Generation 2.0 dendrimer after TFA cleavage. The most efficient conditions for the hydrolysis were found to be Bu_4NOH(aq)–THF 1:3, while the Mitsunobu reaction was performed with DIAD–PPh_3† in THF. Generation 3.0 and 4.0 dendrimers were synthesized using the same procedure and the crude HPLC trace of Generation 3.0 dendrimer is shown in Fig. 2.[9] Dendrimers were subsequently synthesized directly on hydroxymethylpolystyrene **4** (Scheme 2), which was obtained from commercial Merrifield resin (1% DVB, 0.93 mmol g^{-1}, 90–106 μm) *via* displacement of the chloride with caesium acetate in DMF and hydrolysis of the resulting ester with Bu_4NOH(aq) in THF. This was extended to give dendrimer resin **6** as shown in Scheme 2.

The loading of resin **4** was determined to be 0.82 mmol g^{-1} (0.44 nmol $bead^{-1}$). Synthesis of generation 3.0 dendrimer resin gave a resin with a loading of 2.85 mmol g^{-1} (3 nmol

DOI: 10.1039/b100003i

Table 1 Bead diameter (μm) in different solvents (average of 10 beads)

	Dry	DCM	DMF	MeOH	H_2O	THF
4	90	165	155	95	95	175
6	110	145	185	105	110	150
$(Ac)_8$-6	115	195	190	110	115	190

bead^{-1}) (7 times that of the initial resin). Since the synthesis of this dendrimer involved 7 distinct Mitsunobu condensations and 14 distinct ester hydrolyses and the final loading was 86% of that expected this implies that each reaction had proceeded to 99.3% completion. The swelling properties of this resin were analyzed and compared with those of hydroxymethylpolystyrene and are summarized in Table 1.

The diameter of the dry resin beads increased by about 25% after the dendrimerisation process. Acetyl-protected dendrimer resin had the same swelling trend as the hydroxymethylpolystyrene **4**, while resin **6** presented some interesting features with apolar solvents like DCM and THF. In these solvents the resin swelled much less than the parent acetyl-protected resin and also less than resin **4**, due to the high density of hydroxy groups. The two resins **4** and **6** were also compared in terms of reaction kinetics. Fmoc-Ala-OH was coupled onto the two resins and Fmoc and quantitative ninhydrin tests were carried out with samples removed over 2 h. Differences in reactivity were found to be negligible.

To prove the versatility of this new resin, methyl 4-hydroxybenzoate was coupled *via* a Mitsunobu condensation on to resin **6** and the resin-bound methyl ester was then reduced with $LiAlH_4$ (Scheme 2). This two-step procedure was found to be an efficient alternative method to introduce the Wang linker onto a polystyrene support. The polyether dendrimer resin was perfectly stable to $LiAlH_4$ reduction and the final loading of the dendrimer–Wang resin **7** was found to be 2.3 nmol bead^{-1}. The utility of resin **7** was demonstrated by synthesising the hexapeptide Leu-Enkephaline-Lys. Following cleavage with TFA–H_2O 95:5 and purification, the peptide was isolated in 66% yield, relative to the loading of resin **4**.

In conclusion, we have demonstrated that the polyether dendrimer resin can be conveniently and efficiently synthesised on hydroxymethyl polystyrene resins and that the final loading is sufficient for multiple single-bead screenings and is inert under severe chemical conditions. Moreover we have shown that polyether dendrimers can be conveniently synthesised on the solid phase. No purification of the intermediates (usually a non-trivial step, taking in account the molecular weight and character of these molecules) is required to obtain highly pure compounds. The *wedges* synthesised on solid phase could be used to assemble bigger fragments according to the convergent dendrimer methodology outlined by Fréchet.

We thank the BBSRC for funding (ROPA).

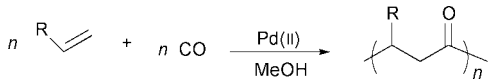
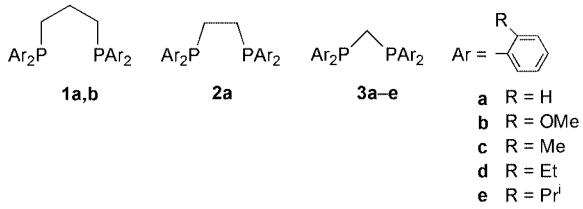
Palladium(II) complexes of ligands of the type $Ar_2PCH_2PAr_2$ and $Ar_2PN(Me)PAr_2$ (Ar = *ortho*-substituted phenyl group) are very efficient catalysts for copolymerisation of CO and C_2H_4.

The perfectly alternating polyketone made by palladium(II)-catalysed copolymerisation of CO and alkenes [eqn. (1)] has



(1)

numerous potential applications.[1] Several types of palladium(II) chelates have been reported to be catalysts[1,2] but diphosphine chelates outperform all others in terms of activity and selectivity. Drent *et al.*[1] have shown that the CO/C_2H_4 copolymerisation catalytic activity of palladium(II) complexes of diphosphines of the type $Ar_2P(CH_2)_nPAr_2$ is a sensitive function of the backbone chain length, *n*, and the aryl group, Ar.



Thus it was shown that the 6-membered chelate derived from **1a** was an order of magnitude more active than the 5-membered analogue from **2a** and that the 4-membered chelate from **3a** was essentially inactive. It was also disclosed that the complex of **1b**, containing *ortho*-methoxy substituents, gave a polymer of significantly greater molecular weight than that obtained with the complexes of unsubstituted ligand **1a**.[3] The catalyst sensitivity to chelate ring size might be rationalised in terms of bite angle effects.[4] However, we show here that the activity of 4-membered Pd–P–C–P chelates is dramatically increased by the presence of bulky *ortho* substituents on the aryl groups and that polymerisation rates comparable to, or even exceeding, the best commercial catalysts are obtained with 4-membered Pd–P–N–P chelates.[5,6]

The diphosphine ligands **3b–e** were made from bis(dichlorophosphino)methane[7] according to eqn. (2) and fully

(2)

characterised. The catalysts were tested for the production of ethene/propene/CO terpolymer over a 3 h period at 50 barg and 70 °C in dichloromethane using tris(pentafluorophenyl)borane promoter. In Table 1, the polymer yield is a measure of the productivity of the catalysts over 3 h. The polymerisation rate and catalyst half-life, as determined by fitting first order curves to the cumulative gas uptake profiles, are also given in Table 1. The borane activation method was reported recently and involves the transfer of a pentafluorophenyl group from boron to palladium to form a cationic $Pd–C_6F_5$ complex which is the catalytically active species.[6] The catalysts were formed by the reaction of palladium acetate and ligand *in situ* or using pre-formed palladium acetate complexes. The results obtained in terms of rate and productivity are the same (within the accuracy of our measurements) for both of these methods, indicating that the same catalytic species is formed in both cases (see Table 1, entries 3 and 4).

Polydispersities are consistently around the value of 2, as expected for a single site catalyst, and termonomer incorpora-

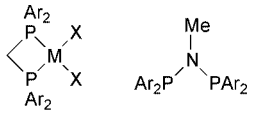
tion is largely unaffected by ligand structure. However, other aspects of the polymerisations are very sensitive to the structure of the ligand. Generally, polymerisation rate, catalyst stability and polymer molecular weight all increase with increasing steric bulk of the aryl *ortho* substituent (entries 1–6). These effects are very pronounced with the *o*-isopropylphenyl derivative **3e** (entry 6) where, compared with the *o*-ethylphenyl derivative **3d** (entry 5), the productivity has increased 5-fold and the molecular weight has doubled. Polymerisation under the methanolic conditions described by Drent[1] gave only a very low rate (entry 7), showing the importance of the activation method used. Indeed, even dppm (**3a**) produces polymer under our conditions, albeit in very low yield (entry 1). Derivative **3b** (entry 2), bearing polar methoxy substituents, gives some improvement over the performance of **3a**; however, productivity is less than one third that of the sterically similar *ortho* ethyl compound **3d**.

The correlation between the steric bulk of the *ortho* substituents and the catalytic performance of the 4-membered chelates led us to investigate further the source of this steric activation by carrying out solid state and solution structural studies of model chelates of general structure **4** (M = Pd, X = Cl, OAc; M = Pt, X = Cl). Most enlightening to the catalysis



4a–e **5a–e**

discussed here is the structure of the chelate complex **4e** (M = Pt, X = Cl), a model for the very active catalyst system derived from **3e**. The crystal structure of **4e** was determined (as its dichloromethane solvate) and is shown in Fig. 1.† It shows a flat 4-membered chelate ring with, as a consequence, isoclinal aryl groups, two of which have *ortho*-isopropyl groups orientated so as to block the axial sites at the metal. The NMR spectra for **4e** show that this species is fluxional. The ^{31}P NMR spectrum of **4e** in $CDCl_3$ at +20 °C is a singlet at −64.5 ppm [^1J(PtP), 3130 Hz] but this signal broadens as the temperature is lowered and at −60 °C, there appears to be a 1 : 1 mixture of two species which give rise to an AB pattern [δ_A −65.4, $^1J(PtP_A)$ 3045 Hz, δ_B −66.1, $^1J(PtP_B)$ 3337 Hz, $^1J(P_AP_B)$ 48 Hz] and a singlet [δ_C −68.4, ^1J(PtP) 3195 Hz]. The ^{1}H NMR signals for the isopropylgroups of **4e** are broad at ambient temperatures and at −60 °C this signal is resolved into overlapping complex multiplets. The ^{1}H and ^{31}P NMR spectra for the parent dppm complex **4a** (M = Pt, X = Cl) are invariant with temperature and therefore the changes in the NMR spectra with temperature

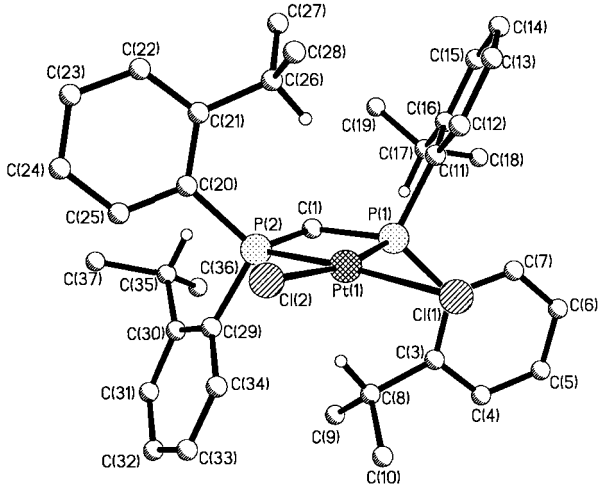


Fig. 1 Molecular structure and numbering scheme for **4b**. All but tertiary isopropyl hydrogen atoms have been omitted for clarity. Important molecular bond lengths (Å) and angles (°): Pt(1)–P(1) 2.2301(9), Pt(1)–P(2) 2.2202(9), Pt(1)–Cl(1) 2.3627(9), Pt(1)–Cl(2) 2.3465(9); P(1)–Pt(1)–P(2) 75.96(3), P(1)–C(1)–P(2) 94.54(13).

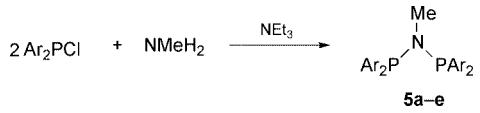
observed with **4e** are associated with the presence of the bulky *ortho* substituents. Thus we tentatively assign the fluxionality of **4e** to interconversion of symmetrical and unsymmetrical rotamers arising from restricted rotation around the aryl–P bond.

The success of bulky diarylphosphinomethane ligands prompted us to investigate other one-atom backbone diphosphines in which similar steric effects may be observed. Amino-bridged diphosphines offered such a suitably versatile ligand architecture. Although the chemistry of the simple ligands based on this structural motif has been studied,[8] the synthesis of bulky derivatives **5b–e** and their use in catalysis has not been explored. The methylamino-bridged diphosphines (**5a–e**) were made according to eqn. (3) and fully characterised.



(3)

5a–e

The palladium(II) complexes of ligands **5a–e** were tested for polymerisation activity as before (entries 8–13) and the results largely parallel those obtained with (**3a–e**). Thus, polymerisation rate, catalyst stability and polymer molecular weight all increase with increasing steric bulk of the aryl *ortho* substituent (entries 8–13) and methanolic conditions give only very low activity (entry 13). In this case, the *ortho*-methoxy derivative **5b** (entry 9) shows comparable productivity to the ethyl derivative **5d**, albeit to give a lower molecular weight material. The N_1-backbone chelates are consistently superior to their C_1-backbone analogues and the polymerisation rate of the most active catalyst in this family, **5e**, exceeds that of even dppp (**1a**) under our conditions.[6] The molecular weight of the polymer produced by this system is also extremely high compared with other polyketone catalysts.[1,3,6]

Our studies have shown that 4-membered palladium(II) diphosphine chelates, hitherto considered to be inefficient polyketone catalysts, are in fact very active when sterically demanding derivatives are used.

A novel reaction on a Mo_2N/γ-Al_2O_3 catalyst: low-temperature isomerization of but-1-ene

Zili Wu, Can Li,* Pinliang Ying, Zhaobin Wei and Qin Xin*

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, PO Box 110, Dalian 116023, China. E-mail: xinqin@ms.dicp.ac.cn; canli@ms.dicp.ac.cn

Received (in Cambridge, UK) 17th January 2001, Accepted 9th February 2001
First published as an Advance Article on the web 26th March 2001

An Mo_2N/γ-Al_2O_3 catalyst is found to catalyze the double-bond migration (DBM) of adsorbed but-1-ene below 201 K by *in situ* FT-IR spectroscopy, resembling the behavior of Group VIII metals in the isomerization of butenes.

Recently, molybdenum nitrides have attracted much attention because they show catalytic properties resembling Group VIII metals in a number of reactions involving hydrogen,[1] such as hydrotreating (HDS and HDN), hydrogenolysis, hydrogenation and NH_3 synthesis. However, these studies were concentrated on passivated nitride catalysts. It is known that the passivation procedure causes a dramatic change in the nitride surface, *i.e.* from nitride to oxygen-covered nitride. Therefore, the surface of the passivated catalyst has been modified by the oxygen and it does not reflect the case of the fresh nitride catalyst. Recent study[2] has shown that the reduced, passivated and nitrided Mo_2N/γ-Al_2O_3 catalysts show very different IR spectra of adsorbed CO, indicating quite different properties of the surface sites of the two catalysts. It is therefore reasonable to deduce that the fresh molybdenum nitride may show different catalytic behaviour in some reactions compared with the reduced, passivated one. Here, such an example is presented: the double-bond migration (DBM) of but-1-ene is found, by *in situ* FT-IR spectroscopy, to proceed on an Mo_2N/γ-Al_2O_3 catalyst below 201 K, but not on a reduced, passivated one even at room temperature (RT).

The preparation of the passivated Mo_2N/γ-Al_2O_3 (10 mass% Mo) catalyst is described elsewhere.[3,4] XPS data show that Mo^{6+}, Mo^{4+} and $Mo^{\delta+}$ ($0 < \delta < 4$) cations, with a binding energy of Mo $3d_{5/2}$ at 232.6, 230.7 and 229.0 eV, respectively, are present for the passivated sample. This is consistent with the unsupported Mo nitrides,[4] indicating the formation of the Mo_2N phase on the γ-Al_2O_3 support. Previous XRD results[5] also show that the Mo_2N phase is formed and well dispersed on the support of the Mo_2N/γ-Al_2O_3 catalysts with low Mo loading.

For the IR study, a passivated sample was renitrided in a quartz IR cell in flowing NH_3. The sample renitrided in the IR cell is denoted Mo_2N/γ-Al_2O_3 or nitrided sample, whereas the passivated sample treated with H_2 at 773 K for 2 h is denoted as reduced, passivated Mo_2N/γ-Al_2O_3. Haddix *et al.*[6] have reported that an air-exposed γ-Mo_2N sample can be renitrided by simply treating it in flowing NH_3 at 973 K, and that the procedure did not affect the BET surface area, the crystal structure and the H_2 uptake characteristics. So it can be deduced that the surface of our nitrided sample is in the Mo_2N form. IR spectra were collected on a Fourier transform infrared spectrometer (Nicolet Impact 410) with a resolution of 4 cm^{-1}.

Fig. 1(a)–(e) shows the IR spectra recorded from the adsorption and reaction of but-1-ene on the Mo_2N/γ-Al_2O_3 catalyst below RT. Shown in Fig. 1(a), the IR spectra of adsorbed but-1-ene at 150 K are characterized by bands of ν(CH) at 3070 cm^{-1}, ν(C=C) at 1631 cm^{-1} and CH vibrations in the 3000 and 1400 cm^{-1} regions. The band at 1631 cm^{-1} is attributed to weakly π-adsorbed but-1-ene on the support of the Mo_2N/γ-Al_2O_3 sample. Another band of ν(C=C) at 1597 cm^{-1} can be attributed to σ-bonded but-1-ene on the Mo sites,[7] indicating some chemical changes of adsorbed butenes on the surface of Mo_2N/γ-Al_2O_3 even at quite low temperature. With increased temperatures, the following spectra changes are observed.

(1) At 181 K, the decrease in the amount of adsorbed but-1-ene is evidenced by the decrease in the ν(CH) band at 3070 cm^{-1}, which is accompanied by the appearance of a new band at 3005 cm^{-1}. The change in the ν(C=C) region is also obvious. The intensity ratio of the two bands at 1631 and 1597 cm^{-1} is smaller than that in Fig. 1(a), namely, more σ-bonded but-1-ene is formed with the decrease of π-adsorbed but-1-ene on the surface. Meanwhile, an additional small band at 1619 cm^{-1} appears.

(2) Further increase of the temperature to 201 K causes substantial changes in the IR spectra, where all the characteristic bands of the adsorbed but-1-ene disappear: bands at 3070 and 1631 cm^{-1} disappear and the band at 1597 cm^{-1} decreases in intensity. Concomitantly, new bands appear and increase in intensity: one ν(CH) band at 3005 cm^{-1}, two bands in ν(C=C) region at 1619 and 1614 cm^{-1}, indicating the formation of new adsorbed species from but-1-ene.

(3) At 256 K, shown in Fig. 1(e), the band at 1619 cm^{-1} becomes dominant in the ν(C=C) region and the band at 1597 cm^{-1} is very weak. This IR spectrum is completely different from that of the adsorbed but-1-ene [Fig. 1(a)], suggesting that a reaction of but-1-ene on the Mo_2N/γ-Al_2O_3 catalyst occurs.

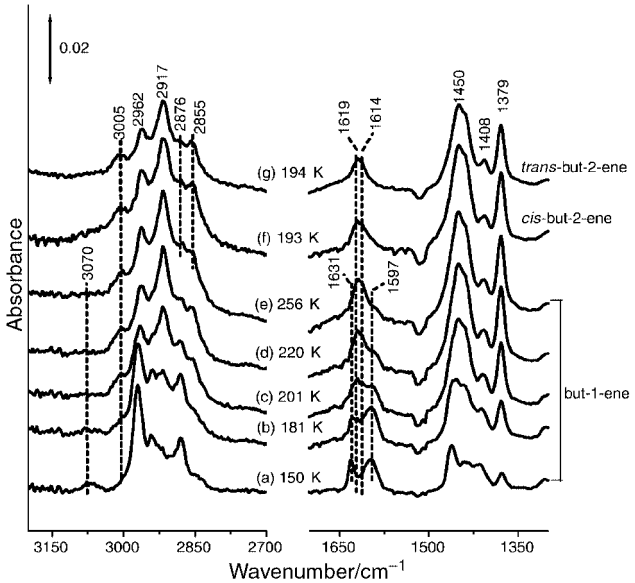

Fig. 1 IR spectra of but-1-enes and but-2-enes adsorbed on to a Mo_2N/γ-Al_2O_3 catalyst at 145 K and recorded at elevated temperatures: but-1-ene at (a) 150 K; (b) 181 K; (c) 201 K; (d) 220 K; (e) 256 K; *cis*-but-2-ene at (f) 193 K; *trans*-but-2-ene at (g) 194 K. In the IR study, the passivated sample was heated from RT to 623 K in 30 min, then to 723 K in 100 min, further from 723 K to 873 K in 75 min, and finally held for 60 min. The renitrided sample was then evacuated at 773 K for 60 min and subsequently cooled to 145 K, a small amount of but-1-ene (*ca.* 0.05 Torr) was introduced and then the temperature was gradually increased to RT.

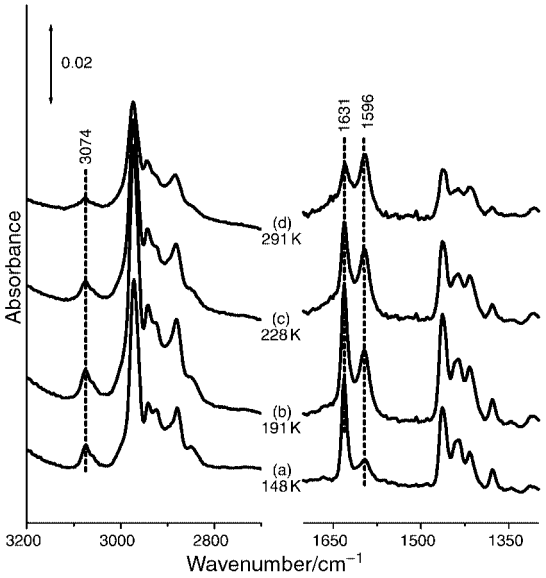

Fig. 2 IR spectra of but-1-ene adsorbed on to a reduced, passivated Mo_2N/γ-Al_2O_3 catalyst initially at (a) 145 K and then increased to (b) 192 K, (c) 231 K and (d) 291 K. The IR procedure for the reduced, passivated sample is similar to that of the nitrided sample.

A similar experiment of but-1-ene adsorption on nitrided γ-Al_2O_3 shows no evident changes in the IR spectra, confirming that the changes in but-1-ene adsorbed on the Mo_2N/γ-Al_2O_3 catalyst are mainly associated with the surface of Mo_2N.

The most likely products formed from the reaction of but-1-ene on the Mo_2N/γ-Al_2O_3 catalyst at such low temperatures are regarded as being the isomers *cis*- and *trans*-but-2-ene. IR spectra of the adsorbed *cis*- and *trans*-but-2-ene on the Mo_2N/γ-Al_2O_3 catalyst at about 193 K are shown respectively in Fig. 1(f) and 1(g) for a comparison with those of the reaction products from the adsorption of but-1-ene [Fig. 1(e)]. In the ν(CH), ν(C=C) and δ(CH) regions, the three spectra show similar contours to each other, implying similar surface species. Hence, it is clear that the adsorbed species produced from the reaction of but-1-ene on the Mo_2N/γ-Al_2O_3 catalyst are a mixture of *cis*- and *trans*-but-2-ene.

The adsorption of but-1-ene was also carried out on the reduced, passivated Mo_2N/γ-Al_2O_3 catalyst. As exhibited in Fig. 2, IR spectra of adsorbed but-1-ene at 145 K [Fig. 2(a)] presents similar contours to those from the Mo_2N/γ-Al_2O_3 catalyst at 150 K [Fig. 1(a)]. However, a further increase of temperatures does not cause changes in the spectra: IR bands at 3074, 1631 and 1596 cm^{-1}, characteristic bands of adsorbed but-1-ene, are still evident even at 291 K and no new bands appear. It is obvious that adsorbed but-1-ene does not convert to its isomers on the reduced, passivated Mo_2N/γ-Al_2O_3 catalyst.

The DBM of butenes has been widely investigated on a variety of catalysts, including solid acid catalysts,[8] base catalysts[9] and noble metal catalysts.[10,11] Only a few studies[12] reported the isomerization properties of reduced, passivated nitride catalysts, and there is no such study on fresh nitrides. Until now, this is the first study reporting the low-temperature isomerization of but-1-ene on a nitrided Mo catalyst. For the Mo_2N/γ-Al_2O_3 catalyst, the surface oxygen sites have been eliminated during the renitridation procedure and the surface Mo sites are in a low valence state (*ca*. 0–2).[2] It can be deduced[13] that the acidity of the nitrided Mo catalyst is quite weak. Therefore, the DBM of but-1-ene may not proceed *via* the same mechanism as that on reduced, passivated nitrides where the activity is attributed to the surface oxide sites as a consequence of the passivation procedure.[12]

A separate coadsorption experiment of CO with but-1-ene on the Mo_2N/γ-Al_2O_3 catalyst showed that preadsorbed CO greatly inhibits the isomerization of but-1-ene, and also that adsorbed but-1-ene significantly influences CO adsorption on Mo sites,[3] suggesting that the DBM of but-1-ene takes place on the same surface sites as for CO adsorption, mostly the $Mo^{\delta+}$ ($0 < \delta < 2$) cus (coordinatively unsaturated sites). Hence, it is likely that the Mo_2N/γ-Al_2O_3 catalyst behaves in a similar way to noble metal catalysts where but-1-ene isomerization also takes place on metal sites. The mechanism of the reaction can be referred from the literature[10] where the paths for an addition–abstraction (AD–AB) mechanism (alkyl–reversal) and an abstraction–addition (AB–AD) mechanism (π-allylic intermediate) are reported. Rooney and Webb[10] suggested that, in the isomerization of *n*-butenes on metal catalysts, the alkyl intermediates prevail at low temperatures whereas allylic intermediates participate to a greater extent in the surface processes as temperature is increased. Therefore, for low-temperature DBM of but-1-ene on the Mo_2N/γ-Al_2O_3 catalyst, it is reasonable to deduce that the mechanism of this reaction resembles one of the two mechanisms proposed on noble metal catalysts, most possibly the AD–AB mechanism (alkyl intermediate).

In conclusion, a novel reaction, low-temperature isomerization of but-1-ene, is found on the Mo_2N/γ-Al_2O_3 catalyst using IR spectroscopy. The reduced, passivated Mo_2N/γ-Al_2O_3 catalyst does not catalyze this reaction even at RT. The isomerization reaction is proposed to proceed *via* an alkyl intermediate on the surface $Mo^{\delta+}$ ($0 < \delta < 2$) cus on the nitrided Mo sample. This mechanism is quite different from that of the passivated nitride catalyst in isomerization reactions but is similar to that of Group VIII metals. The results manifest the unique catalytic properties of fresh nitride catalysts and urge more attention to be focussed on fresh nitrides, which may catalyze some new reactions.

First published as an Advance Article on the web 26th March 2001

Frequency distributions of hydrogen bond trajectories for X–H···Ph interactions (X = O, N, C) need to be corrected for the finite area of the acceptor moiety and once this correction has been performed, it is seen that the donor groups have a distinct tendency to interact with the centroid of the aromatic ring.

Statistical analysis of experimental and theoretical data is very important for a correct interpretation of several chemical phenomena. Hydrogen bonds are typically described in terms of various parameters (lengths, angles) obtained from crystal structure determinations. These parameters are most simply depicted as histograms. However, such simple methods of analysis can be sometimes misleading.[1] For example, it was found that a distribution of hydrogen bond angles, θ, in O–H···O hydrogen bonds is in the range 120–180° with a maximum at around 160°. Such an observation suggests that hydrogen bonds in crystals are non-linear.[2] This is, however, inconsistent with theoretical predictions in the gas phase, say for the water–water dimer. The reason for this seeming contradiction is the failure to take into account a geometrical factor that seriously influences the crystal statistics. The number of hydrogen bonds with angle θ is proportional to $\sin\theta$ for purely geometrical reasons, there being a greater probability of finding such interactions on the rims of cones of increasing solid angles. A simple procedure, namely the use of $N/\sin\theta$ instead of N (where N is the number of hydrogen bonds in the interval θ to $\theta + \Delta\theta$) in the histograms, effectively resolves this contradiction. This is known today as the *cone correction* and is illustrated in Fig. 1(a). This correction is used widely in the interpretation of hydrogen bonds and occurs as a standard procedure in the program VISTA that is a part of the Cambridge Structural Database (CSD).[3]

Recent work on weak X–H···Ph hydrogen bonds has led to only a limited consensus concerning the nature of these interactions.[4] Some authors have held that the donor group X–H interacts with the centroid of the aromatic ring.[5–8] Others have stated that donors interact with one or more of the ring carbon atoms.[9–11] However, neither of these conclusions has been unambiguously substantiated. During our own studies of X–H···Ph (X = O, N, C) interactions, we realised that the frequency distributions of these interactions must be corrected for the fact that the acceptor, being of a multiatom type, has a finite area. Therefore the numbers of observed trajectories of the

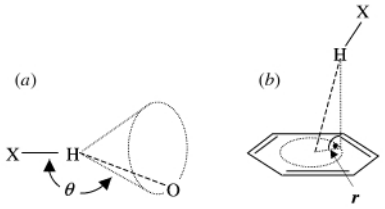

Fig. 1 Schematic diagrams for geometrical corrections of hydrogen bond metrics. (a) Cone correction for hydrogen bond angles θ. (b) Area correction for hydrogen bond offsets r.

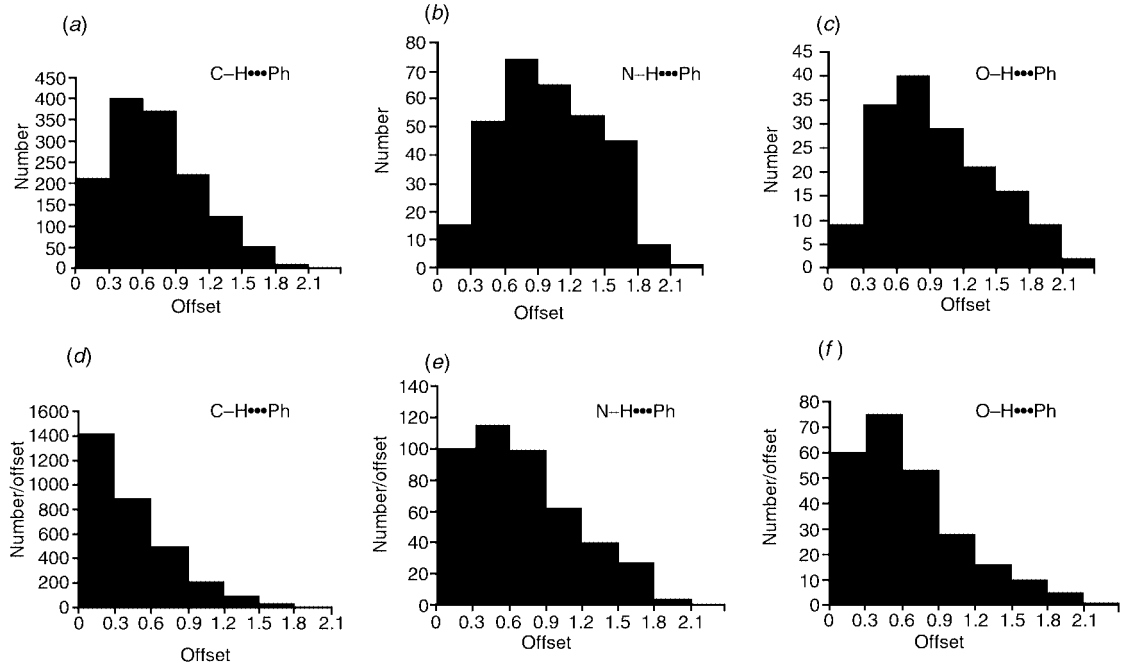

Fig. 2 Histograms of offsets r for X–H···Ph hydrogen bonds: Uncorrected (a) C–H···Ph, (b) N–H···Ph and (c) O–H···Ph; corrected (d) C–H···Ph, (e) N–H···Ph and (f) O–H···Ph. Offsets are in Å.

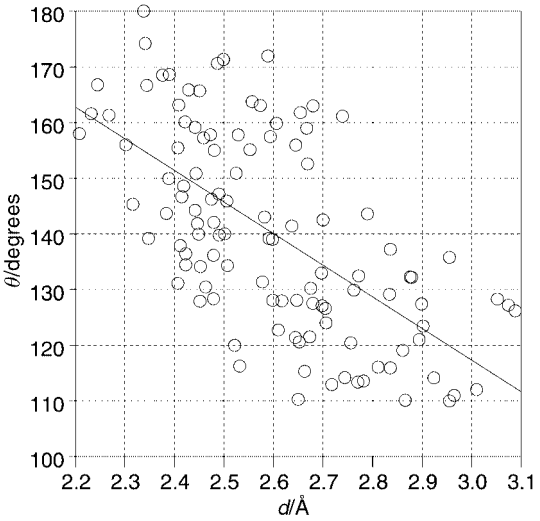

Fig 3 d–θ scatterplot for O–H···Ph hydrogen bonds with $r \leqslant 1.2$ Å, assuming that the ring centroid is the point acceptor. Notice the inverse correlation typical of hydrogen bonds.

donor onto the acceptor are a result of both chemical and geometrical factors. Simply put, an interaction X–H···Ph has an offset r which is the distance from the ring centroid to the projection of the H-atom position on the plane of the ring. This is shown in Fig. 1(b). The number of hydrogen bonds with offset r is proportional to $2\pi r$ for geometrical reasons and accordingly, histograms of N (where N is the number of offsets in the range r and $r+\Delta r$) must be replaced by N/r before they become chemically meaningful. So, we would like to term this procedure an *area correction* to match the term *cone correction* used in θ histograms.

Fig. 2(a), (b) and (c) are uncorrected histograms of X–H···Ph offsets for C–H···Ph, N–H···Ph and O–H···Ph hydrogen bonds ($d \leqslant 3.10$ Å, $\theta \geqslant 110°$) from 769, 649 and 431 appropriately retrieved crystal structure data in the CSD.† The histograms contain 1379, 314 and 160 hydrogen bonds respectively. Figs. 2(d), (e) and (f) are the respective corrected histograms.‡ The correction is carried out within ranges of 0.3 Å; the range from 0.0 to 0.3 Å is corrected by a factor of 1/(0.15), the range between 0.3 and 0.6 Å is corrected by a factor of 1/(0.45), and so on. The uncorrected histograms seem to indicate no particular offset preference. However, all three area corrected histograms show a preference for hydrogen bonds to a phenyl ring to be directed at or near the centre of the ring. For C–H···Ph interactions, this preference is clear. For N–H···Ph and O–H···Ph interactions, there is a maximum around 0.3 Å from the centroid. However, the number of observations in these latter cases is insufficient to draw fine distinctions.§ What *is* important is that the preference for a centroid or a close-to-centroid approach is seen in all cases.

To examine this matter further, we obtained the scatterplot of the hydrogen bond angle θ *vs.* the hydrogen bond distance d, assuming the centroid to be the point acceptor site for the 112 O–H···Ph hydrogen bonds with offsets < 1.20 Å (Fig. 3). This scatterplot (correlation coefficient -0.63) shows the typical inverse length–angle correlation that arises from the electrostatic nature of hydrogen bonds,[4] and indicates that the centroid may be reasonably approximated as the acceptor site in these interactions. The corresponding C–H···Ph scatterplot is fuzzier but this is not unexpected.

In summary, we conclude that this area correction for phenyl ring acceptors should be used in all relevant analyses of hydrogen bonds formed to such multiatom acceptors.

We thank the DST–KBN for travel support to Z. C. under Indo-Polish grant INT/POL/008.00 and Dr A. Nangia for helpful discussions and comments.

Notes and references

† CSD (release: April 2000, 215 403 hits). Data were retrieved using the following overall criteria for all structures: 'no polymers'; 'no disorder'; 'error free structures'; 'atom coordinates present'; H···Ph(centroid) distances shorter than 3.5 Å and $R \leqslant 0.05$. Two additional criteria were used: 'no ions' for the N–H···Ph contacts (to eliminate the $>$N–H$^+$ donors); $T \leqslant$ 120 K for the C–H···Ph contacts. For polynuclear ring acceptors, the offsets were calculated only with respect to the phenyl ring towards which the donor is oriented.

‡ Histograms were prepared using program Microsoft Excel.

§ Unsurprisingly, the exact profiles of the N–H···Ph and O–H···Ph histograms near the centroid depend on the range within which the area correction is performed (0.2, 0.3 Å). This is not the case for the C–H···Ph histogram, because the number of observations (1379) is satisfactorily large.

A structurally characterised, naked sp^3-hybridised carbanion in the zwitterionic imido complex [Ti(NBu^t){C(Me$_2$pz)$_3$}Cl(THF)] (HMe$_2$pz = 3,5-dimethylpyrazole)†

Received (in Cambridge, UK) 8th January 2001, Accepted 27th February 2001
First published as an Advance Article on the web 26th March 2001

Reaction of the tris(3,5-dimethylpyrazolyl)methane complex [Ti(NBu^t){HC(Me$_2$pz)$_3$}Cl$_2$] with MeLi or LiNPr$^i_2$ in tetrahydrofuran (THF) gives the zwitterionic titanium imido derivative [Ti(NBu^t){C(Me$_2$pz)$_3$}Cl(THF)] 2 which contains the first structurally authenticated, naked sp^3-hybridised carbanion; the molecular and electronic structures of 2 are described.

The tris(pyrazolyl)hydroborate ligands are important face-capping, anionic, six-electron donor ligands in inorganic and organometallic coordination chemistry.[1] Their neutral analogues, the tris(pyrazolyl)methanes are considerably less well developed.[2] We are interested in the use of tris(pyrazolyl)-methanes in our ongoing program in early transition metal imido chemistry.[3] Target complexes of the type [Ti(NR)-{tris(pyrazolyl)methane}Cl$_2$] are isolobal analogues of the group metallocenes [M(η-C$_5$R$_5$)$_2$Cl$_2$] (M = Ti, Zr) which are in turn a very important class of single-site olefin polymerisation catalysts;[4] no tris(pyrazolyl)methane-supported imido complexes have been described previously. As part of these studies we found a unique example of a stabilised, naked *sp*^{3}-hybridised carbanion as described below.

Reaction of [Ti(NBu^t)Cl$_2$(py)$_3$][5] with HC(Me$_2$pz)$_3$ (HMe$_2$pz = 3,5-dimethylpyrazole) in CH_2Cl_2 afforded the tris(3,5-dimethylpyrazolyl)methane complex [Ti(NBu^t){HC-(Me$_2$pz)$_3$}Cl$_2$] **1** in 80% yield after the addition of hexane (Scheme 1).‡ Reaction of **1** with one equivalent of MeLi (initially in a failed attempt to alkylate titanium) or LiN(Pr^i)$_2$ in THF leads to smooth removal of the apical proton of HC(Me$_2$pz)$_3$ and formation of the diamagnetic compound [Ti(NBu^t){C(Me$_2$pz)$_3$}Cl(THF)] **2** in *ca.* 60% yield. Reaction of **2** in benzene with HCl (1 equivalent) reforms **1**; the corresponding reaction of **2** with DCl forms [Ti(NBu^t){DC-(Me$_2$pz)$_3$}Cl$_2$] **1-d** with deuterium enrichment occuring exclusively at the apical carbon of the tridentate ligand.

Crystallization of **2** from toluene at 5 °C gave diffraction-quality crystals.§ The molecular structure of **2** is shown in Fig. 1 together with selected bond lengths and angles. Fourier difference syntheses revealed the positions of all hydrogen atoms of the {C(Me$_2$pz)$_3$}$^-$ ligand; none was located for the apical carbon C(24). A formal negative charge is assigned to this atom as illustrated in Scheme 1; the Ti centre thus has a formal charge of +4 in line with the observed diamagnetism. The N–C–N angles subtended at C(24) lie in the range 108.3(3)–109.6(3)°, consistent with this atom being formally sp^3 hybridised. In general, the distances and angles for **2** are comparable with those of previously reported titanium imido and tris(pyrazolyl)methane complexes.[2,3,6] The solution ^{1}H and ^{13}C NMR data for **2** support the solid state structure.

The {C(Me$_2$pz)$_3$}$^-$ ligand in [Ti(NBu^t){C-(Me$_2$pz)$_3$}Cl(THF)] **2** is analogous to the hydroborate relative {HB(Me$_2$pz)$_3$}$^-$. We have previously reported a series of titanium imido complexes with tris(pyrazolyl)hydroborate li-

Table 1 Comparison of selected bond distances (Å) for [Ti(NH){HC(pz)$_3$}Cl$_2$] **1a**, [Ti(NPBu^t){C(Me$_2$pz)$_3$}Cl(THF)] **2**, [Ti(NH){C(pz)$_3$}Cl(OH$_2$)] **2a** and [Ti(NH){HB(pz)$_3$}Cl(OH$_2$)] **4**. For the Ti–N$_{pyrazole}$ distances 'A', 'B' and 'C' refer to the nitrogens *trans* to imide, Cl and O (or Cl for **1a**), respectively

	1a	**2**	**2a**	**4**
Ti=N$_{imide}$	1.711	1.713(3)	1.71	1.70
Ti–O	—	2.152(3)	2.15	2.08
Ti–Cl	2.40	2.394(1)	2.41	2.37
Ti–N$_{pyrazole(A)}$	2.44	2.358(3)	2.36	2.30
Ti–N$_{pyrazole(B)}$	2.28	2.191(4)	2.22	2.17
Ti–N$_{pyrazole(C)}$	2.28	2.169(3)	2.16	2.11

gands. The Ti=N$_{imide}$, Ti–Cl and Ti–N$_{pyrazolyl}$ distances in **2** are comparable to those of tris(pyrazolyl)hydroborate analogues.

DFT (density functional theory) calculations[8] were used to optimise the geometry of [Ti(NH){C(pz)$_3$}Cl(OH$_2$)] **2a** as a model for [Ti(NBu^t){C(Me$_2$pz)$_3$}Cl(THF)] **2**, and to determine its electronic structure.¶ Comparative calculations were also carried out for the tris(pyrazolyl)hydroborate species [Ti(NH){HB(pz)$_3$}Cl(OH$_2$)] **4** and for C_s symmetric [Ti(NH){HC(pz)$_3$}Cl$_2$] **1a** (as a model for [Ti(NBu^t){HC(Me$_2$pz)$_3$}Cl$_2$] **1**). Table 1 compares selected bond distances for **1a**, **2**, **2a** and **4**. There is very good agreement between those of the real compound **2** and of its model **2a**. The N–C$_{apical}$–N angles in **1a** (110–111°) are comparable to those of **2a** (108–109°) in line with the sp^3 hybridisation of the apical carbon; in **4** the N–B–N angles lie in the range 107–109°.

The highest occupied molecular orbital (HOMO) for [Ti(NH){C(pz)$_3$}Cl(OH$_2$)] **2a** is based predominantly on the {C(pz)$_3$}$^-$ apical carbon and has a computed energy of −5.14 eV; the isosurface is shown in Fig. 2.† There is an energy separation of 2.00 eV between this MO and the lowest unoccupied molecular orbital (LUMO) which is Ti 3d in character. The calculations support our proposal that **2** and **3** are zwitterionic Ti(IV) complexes that contain naked, formally sp^3-hybridised apical carbanions; an alternative interpretation of **2** and **3** as antiferromagnetically coupled Ti(III) complexes with an apical carbon-based radical can be discounted. There is a net atomic charge (calculated from the Voronoi Deformation Density[8]) of −0.13 e for the apical carbon in **2a** whereas the corresponding atomic charge in **1a** is 0.11 e; the atomic charges for Ti in **1a**, **2a** and **4** are 0.29, 0.32 and 0.29 e, respectively. The molecular and electronic structures for [Ti(NH){C(pz)$_3$}Cl(OH$_2$)] **2a** and [Ti(NH){HB(pz)$_3$}Cl(OH$_2$)] **4** confirm the analogy between {C(R$_3$pz)$_3$}$^-$ and {HB(R$_3$pz)$_3$}$^-$.

The apical carbon in [Ti(NBu^t){C(Me$_2$pz)$_3$}Cl(THF)] **2** is the first example of any naked, sp^3-hybridised carbanion.[6] Formally sp^2-hybridised carbanions are very well-established in the literature and for such species the planar geometry around the carbanion assists resonance stabilization.[6,9] Previous reports have shown that the apical carbon of the free or complexed parent tris(pyrazolyl)methane can be deprotonated (and, in many instances, functionalised this way),[10] but no carbanionic species have been structurally characterised.

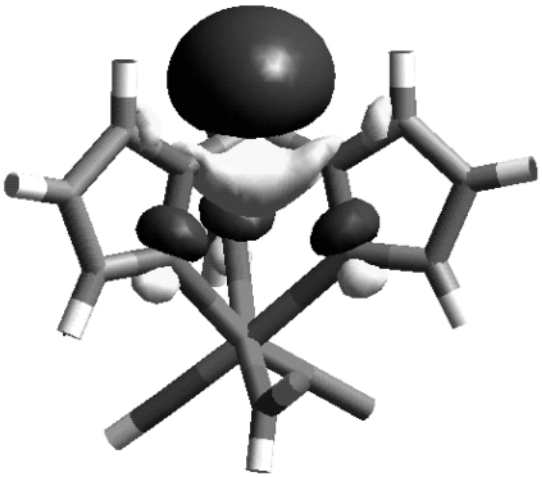

Fig. 2 Isosurface for the highest occupied molecular orbital of **2a**.

The anionic {C(Me$_2$pz)$_3$}$^-$ is potentially a new ligand in transition metal chemistry, not least because of the improved, multi-gram synthesis now available for HC(Me$_2$pz)$_3$.[2b] The methyl substituents in the 5-position of the pyrazolyl rings clearly offer significant protection of the carbanionic carbon in **2**. Moreover, it is possible to cleanly deprotonate HC(Me$_2$pz)$_3$ itself (*i.e.* without prior complexation to a metal centre) by reaction with MeLi in THF to form benzene-soluble LiC(Me$_2$pz)$_3$ **5** in quantitative isolated yield. The anionic apical carbon in **5** is confirmed by reaction with D$_2$O to generate DC(Me$_2$pz)$_3$ with deuterium enrichment exclusively in the apical position. We have established the potential use of LiC(Me$_2$pz)$_3$ **5** as a reagent (*via* salt-elimination type reactions) and source of anionic {C(Me$_2$pz)$_3$}$^-$. Thus, reaction of [Ti(NBu^t)Cl$_2$(py)$_3$] with LiC(Me$_2$pz)$_3$ **5** in THF forms [Ti(NBu^t){C(Me$_2$pz)$_3$}Cl(py)] **3** in good yield (Scheme 1). A survey of the syntheses and chemistry of a range of zwitterionic complexes with the anionic {C(Me$_2$pz)$_3$}$^-$ ligand and its homologues is currently underway.

This work was supported by the EPSRC and Royal Society. S. C. L. is the recipient of a European Scatcherd Scholarship. We thank Professor D. L Reger for his improved synthesis of HC(Me$_2$pz)$_3$ prior to publication, and Professor S. Trofimenko for helpful comments.

Variation of the energy gap in fullerene-based dendrons: competitive *versus* sequential energy and electron transfer events

First published as an Advance Article on the web 29th March 2001

Artificial molecular models, based on rigid dendrimeric *meta*-substituted phenylenevinylene moieties bearing different electron donating groups and the electron acceptor C_{60}, were probed in an effort to gain control over a sequential *versus* a competitive scenario in energy and electron transfer events.

The design of supramolecular ensembles for use in energy conservation and conversion is a long-standing objective.[1] Understanding the complexity of efficient energy migration and unidirectional electron transfer occurring, for example, in the photosynthetic reaction center[2] offers powerful guidelines for developing artificial devices. A particularly challenging aspect is to explore the role of a sequence *versus* a competition in energy/electron transfer reactions, especially upon altering the energy gaps.

The choice of the connecting spacer in donor–bridge–acceptor (D–B–A) assemblies is fundamental, since it ensures the control over distance, angle and coupling between the donor and acceptor. These parameters govern in large character, rate and efficiency of long distance energy and/or electron transfer processes.[3,4] Dendritic structures provide key criteria such as rigidity and conjugation, which, most importantly, can be chemically fine-tuned.[5] In turn, these unique molecular architectures emerged as versatile building blocks for the preparation of artificial systems.[6]

Previous work has focused mainly on encapsulating flexible dendron units.[7] The flexibility prohibits, however, a detailed comprehension of effects stemming from donor–acceptor separation and/or orientation, which drew our attention to the unique features of a stiff dendritic macromolecule.[8]

Here we report on the synthesis and photophysical studies of D–B–A systems in which four dibutylaniline (**8a**) or dodecyloxynaphthalene (**8b**) electron donors are located at the peripheral positions of well-defined phenylenevinylene-based dendrons and an acceptor fullerene at the focal point of the dendrimer.

Yu and coworkers[9a] and Meier and Lehman[9b] have reported synthetic routes towards formyl-substituted rigid poly(phenylenevinylene) dendrimers starting from different AB_2 type building blocks. A remarkable advantage of the convergent route, presented here is the use of a nitrile group in the readily available AB_2 starting material **1**.[10] This functionality remains unaffected during the Arbuzov and the Wittig–Horner reaction (*i.e.* with aldehydes **3a**,**b**) to yield bisphosphonate **2** and the first-generation dendrons **4a**,**b** with an *all-trans* configuration, respectively.

Subsequent treatment of the nitrile-substituted systems **4a,b** with DIBAL-H in dichloromethane transforms them in good yield to the corresponding formyl-substituted analogues **5a**,**b**. In the next step, a second Wittig–Horner reaction of **5a**,**b** with bisphosphonate **2** affords the nitrile-substituted second-generation dendrons **6a**,**b**. Additional DIBAL-H treatment allowed us to prepare the formyl functionalized dendrons **7a**,**b**. Dyads **8a,b** have been prepared in good yields (30%) by 1,3-dipolar cycloaddition of the respective rigid dendron (**7a**,**b**) to C_{60} in the presence of sarcosine in refluxing toluene (Fig. 1).[11]

The redox properties of the fullerene-containing dendrons **8a,b** were studied by cyclic voltammetry in toluene/acetonitrile (4 : 1 v/v) solutions and revealed several oxidation and reduction steps. In particular, anodic processes with peaks at 0.72 V (**8a**) and 1.30 V (**8b**) refer to the oxidation of the dibutylaniline and dodecyloxynaphthalene moieties, respectively. In the cathodic region three quasireversible reduction waves were recorded (**8a**: −0.65; −1.07, −1.70 V, **8b**: −0.64, −1.03; −1.62 V), which correspond to the stepwise reduction of the fullerene moiety and resemble those observed for a fulleropyrrolidine reference.

Replacement of the poly(arylenevinylene) cores (**8b**) with the analogous dibutylaniline functionalities (**8a**) imposes important consequences on the dendron's physico-chemical properties: red-shifted ground-state maxima in combination with better electron donor character create quite different energy gaps between the dendron's singlet excited state and that of the $C_{60}^{\bullet-}$–dendron$^{\bullet+}$ radical pair in **8a** and **8b**.

In general, the strongly fluorescing dendrons **7a** and **6b** with quantum yields as high as 0.47, give rise to an almost entirely quenched emission in dyads **8a** and **8b** (Table 1). For example, in non-polar toluene the dendrimer emission in the visible (400–450 nm) is reduced by more than two orders of magnitude.

From this observation we reach the conclusion that in toluene the dendrimer singlet excited state in **8a**,**b** undergoes a rapid singlet–singlet energy transfer to the energetically lower-lying

fullerene singlet (Fig. 2). Evidence that this energy transfer indeed takes place, comes from a set of decisive emission and excitation measurements.

The species evolving from energy transfer, namely, the fullerene singlet excited state (1.76 eV), has been identified *via* the characteristic fluorescence pattern[12] of a fulleropyrrolidine produced in nearly comparable quantum yields. Importantly, the complementary excitation spectrum of the fullerene emission in **8a**,**b** is virtually identical with the ground-state absorption and the excitation spectra of the reference compounds. To further test the above assignment, that is, a rapid singlet–singlet energy transfer, transient absorption spectroscopy was deemed necessary. Despite the unequivocal and nearly quantitative excitation (355 nm) of the dendrimer moieties no spectral evidence for the dendrimer's singlet–singlet absorption (*ca.* 650 nm) was found after the 18 ps laser pulse. Instead the spectral features are identical with the texture of the fullerene singlet excited state. Specifically, a characteristic maximum at 880 nm is a clear attribute of the fullerene singlet–singlet absorption. The rise time of the 880 nm absorption, representing the actual energy transfer event in **8a**,**b**, is, however, masked by the instrument response time and, therefore, prevents a meaningful kinetic analysis of the intramolecular reaction. On a longer time-scale the fate of the fullerene singlet excited state is identical to that known for a fulleropyrrolidine: intersystem crossing, driven by a strong spin-orbit coupling, governs the transformation (*ca.* 6.0×10^8 s^{-1}) of the singlet into the triplet excited state. The latter was identified by a long-lived (*ca.* 20 μs) and strongly absorbing triplet–triplet maximum (700 nm).

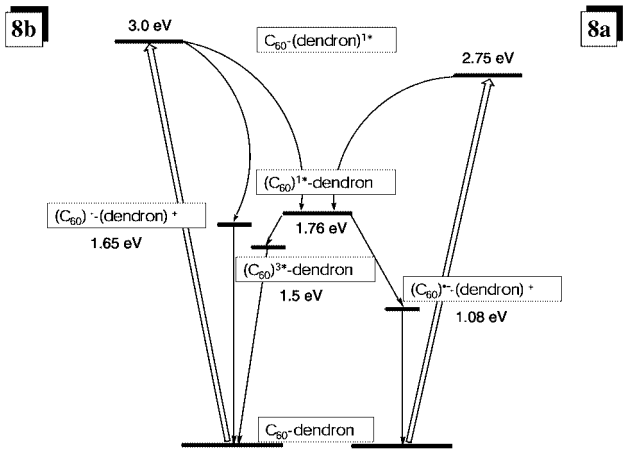

Fig. 2

Upon probing more polar THF and benzonitrile, the fullerene fluorescence in **8b** reveals a gradual decrease of up to 50%, while the dendron emission continued to be almost unchanged relative to that in toluene. This observation is consistent with an assumption that implies an energy transfer scenario, which is in competition with an activated electron transfer. Crucial support for this competitive synopsis evolves from the fullerene singlet lifetimes (Table 1), which are, despite the emission quenching, identical to those of a fulleropyrrolidine in all the solvents investigated.

8a, on the other hand, reveals much stronger reductions of the fullerene emission (up to 94%). Most importantly, much shorter lifetimes of the fullerene singlet excited state, the product of the initial energy transfer, were seen. This suggests, in sharp contrast to **8b**, a sequential energy and electron transfer starting from the initially excited dendron. In its final instance this sequence generates restrictively a radical pair, $C_{60}^{\cdot-}$–dendron$^{\cdot+}$.

Formation of the charge-separated state was established for both donor–acceptor systems by means of transient absorption spectroscopy. The fullerene π-radical anion displayed its typical near-IR absorption at 1000 nm, while the one-electron oxidized forms of the donors were evidenced through their absorption in the visible with λ_{max} *ca.* 480 nm (**8a**) and 540 nm (**8b**). It is important to note that for the dibutylaniline-containing dyad **8a** the radical pair, with lifetimes of 350 ns and 725 ns, in THF and benzonitrile, respectively is the sole product, corroborating the sequence of energy and electron transfer. Quite different is the situation for the poly(arylenevinylene) derivative **8b**: both energy transfer and electron transfer products were noted as superimposed spectral features.

Synthesis of a novel mesoporous iron phosphate

Xuefeng Guo, Weiping Ding,* Xueguang Wang and Qijie Yan*

Department of Chemistry, Nanjing University, Nanjing, 210093, P. R. China. E-mail: qyan@nju.edu.cn and dingwp@nju.edu.cn

Received (in Cambridge, UK) 17th January 2001, Accepted 2nd March 2001
First published as an Advance Article on the web 29th March 2001

A novel mesoporous iron phosphate, possessing a specific surface area of 254 m^2 g^{-1} and average pore diameter of 2.6 nm, is synthesized using a fluoride route.

Since the discovery of M41s silica molecular sieves in 1992,[1] mesoporous materials, possessing remarkably large internal surface areas and narrow pore size distributions, have attracted considerable attention for their great potential application as catalysts, absorbents, and host materials. Several supermolecular assembly pathways have also been developed and extended to synthesize a variety of mesoporous metal oxides[2] and aluminophosphates.[3–6] Compared to those successes, however, only a few preparative approaches have been reported for the preparation of mesoporous transition metal phosphates.[7–10]

Iron phosphate has been reported as a good catalyst for selective oxidation reactions, *e.g.* oxidative dehydrogenation of isobutyric acid to methacrylic acid, a versatile raw material for various polymers,[11] and partial oxidation of methane or ethane to oxygenates.[12] Iron phosphates with novel mesostructure would be interesting in terms of structure and catalytic performance. Huang *et al.*[13] have reported microporous iron phosphate with an open framework and a cell volume of 2957.5 Å^3 and expected it to be a novel catalyst. The preparation of mesoporous iron phosphate, however, has not been reported so far, although the preparation of mesoporous aluminium phosphate has been reported. Considering the similarity between iron and aluminium in their chemical properties, the preparation of mesoporous iron phosphate should be feasible. Unfortunately, despite substantial effort we failed to synthesize mesoporous iron phosphate using similar methods reported for the preparation of mesoporous aluminium phosphate.

Using a series of surfactants and different experimental conditions, we have finally prepared some mesostructural lamellar and porous iron phosphates. Here we report our successful synthesis and characterization of ordered mesoporous iron phosphate with an average pore size of 2.6 nm.

In a typical sample preparation route, 8.08 g $Fe(NO_3)_3$ was dissolved in 80 g distilled water and 7.16 g Na_2HPO_4, dissolved in 80 g distilled water, was added with stirring. The resulting $FePO_4$ precipitate was recovered by centrifugation and washed by distilled water. The precipitate was suspended in 20 g distilled water, followed by dropping 1.32 g HF (40 wt%) into the suspension with vigorous stirring. When a transparent solution was obtained, 2.88 g sodium dodecyl sulfate (surfactant), dissolved in 10 g water, was added to the solution with stirring at room temperature for 30 min. The resultant mixture was heated to 60 °C and held for 2.5 h. After cooling to room temperature, a light yellow precipitate was observed in the solution which was recovered by centrifugation, followed by repeated washing with water and acetone. The resultant solid was dried at room temperature.

Removal of the surfactant species from the as-synthesized solid was carried out by anion exchange in a manner similar to that reported by Holland *et al.*[14] for the preparation of mesoporous aluminophosphate. The as-synthesized solid (0.7 g) was mixed with a 0.05 M ethanol solution of sodium acetate (50 ml) with stirring at room temperature for 40 min. The solid was then recovered by centrifugation, washed thoroughly using ethanol and dried at room temperature. XRD (Rigaku D/Max-RA diffractometer), TEM (JEOL-200CX; 160 kV), FTIR (Nicolet 170SX FTIR spectrometer) and nitrogen sorption (Micromeritics ASAP 2000 sorption analyzer) were used to characterize the resultants.

A strong absorption peak at *ca.* 1252 cm^{-1}, characteristic of $(ROSO_3)^-$, was observed in the FTIR spectra of the surfactant containing sample which vanished after acetate-treatment, indicating no residual dodecyl sulfate species in the acetate-treated sample. This appears to suggest the complete removal of the surfactant in the sample. X-Ray diffraction patterns of as-synthesized sample and acetate-treated sample are shown in Fig. 1. Both patterns show a sharp diffraction peak (100) at low angle ($2\theta \approx 2.4$ and 2.3°, for the surfactant containing and acetate-treated samples, respectively). The low-angle diffraction peaks suggest a mesoporous structure of the obtained iron phosphate samples. The slight shift to higher angle for the acetate-treated sample reveals slight contraction of mesostructure of iron phosphate upon surfactant removal. A TEM photograph, (Fig. 2) confirms the mesoporous structure of the acetate-treated samples. The isothermal N_2 sorption data of the

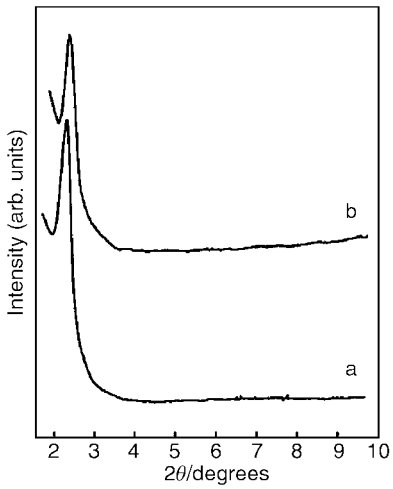

Fig. 1 XRD patterns of the as-synthesized sample (a) and acetate-treated sample (b).

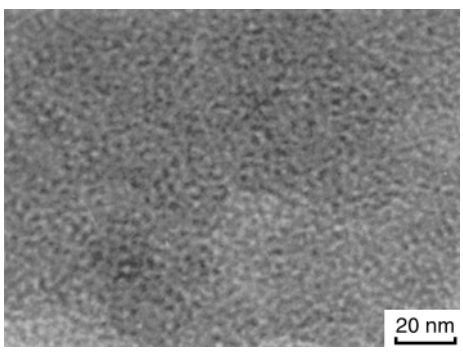

Fig. 2 TEM image of mesoporous iron phosphate after surfactant extraction.

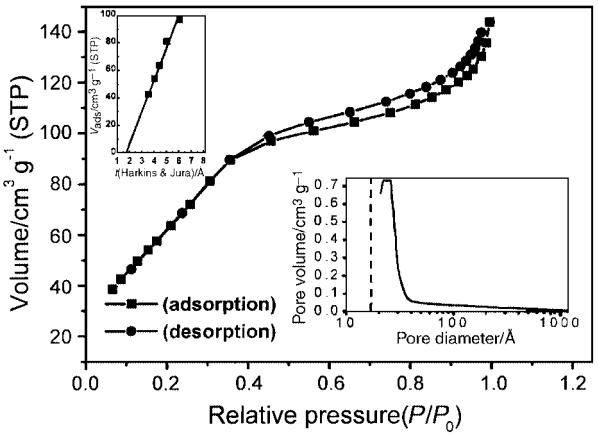

Fig. 3 Nitrogen adsorption–desorption isotherm of acetate-treated sample measured at 77 K, insets show pore diameter distribution of the sample (right) and *t*-plot (left).

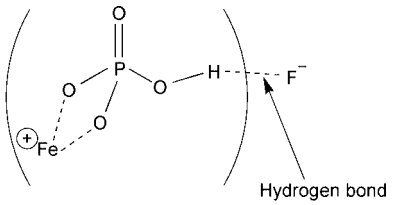
acetate-treated sample at 77 K are shown in Fig. 3. The type-IV isotherm with a small hysteresis loop is similar to that of mesoporous zirconium phosphate reported in ref. 7. Quantitative calculation shows the acetate-treated mesoporous iron phosphate possesses a BET surface area of *ca*. 254 m^2 g^{-1} and a pore volume of 0.21 cm^3 g^{-1}, similar to documented non-silicate mesoporous solids, and narrow a distribution of pore diameter centered at 2.6 nm (Fig. 3, right inset). The linear *t*-plot suggests the sample possess uniform pores (Fig. 3, left inset). With the unit cell dimension ($a_0 = 2d_{100}/\sqrt{3}$) and the pore diameter, the wall thickness can be calculated as *ca*. 1.6 nm, much thicker than that of typical siliceous MCM41 (*ca*. 1.0 nm). The greater molecular weight and much thicker walls of the pores should be responsible for the lower BET specific surface area on comparing the mesoporous iron phosphate to M41s mesoporous silica.

We have attempted many routes other than *via* HF but all gave layer structures rather than an ordered mesoporous structure. Fluorides other than HF, *e.g*., ammonium fluoride and sodium fluoride, were tested but failed to give mesoporous iron phosphate. It appears HF plays an important role in the mesoporous iron phosphate synthesis. Undissociated HF molecules (aqueous HF is a weak acid with p$K_a \approx 4$) may react with iron phosphate to form ion pairs, as shown in Scheme 1. F ions



Scheme 1 The effect of fluoride on the charge density of Fe–P–O clusters.

bonding to [Fe–P-O–H]$^+$ *via* hydrogen bonding so adjusting the charge density of [Fe–P-O–H]$^+$ allow matching of the surface charge of the surfactant micelles, resulting in the formation of hexagonal mesoporous iron phosphate.

In conclusion, a novel mesoporous iron phosphate has been synthesized for the first time using a fluoride route. After removal of surfactant by acetate-exchange, mesoporous iron phosphate with a surface area of 254 m^2 g^{-1} and average pore size of 2.6 nm was obtained.

A novel molecule, containing two photochromic dithienylethene moieties linked to a fluorescent bis(phenylethynyl)anthracene residue has been prepared, and shows a reversible change in its fluorescence quantum yield from 0.001 to 0.83, and a corresponding increase in laser emission intensity, on exposure to UV light.

Dithienylethenes are the most promising photochromic compounds among various photochromic compounds for the photoelectronic applications, such as optical memory media and photoswitching devices, because of their fatigue resistant and thermally irreversible properties.[1–4] Although several dithienylethene derivatives have been reported to exhibit reversible fluorescence intensity changes upon photoisomerization,[5–11] the fluorescence quantum yields (Φ_{fl}) of the molecules were relatively small. In the present work, a highly fluorescent dithienylethene was prepared and its photoresponsive laser emission was demonstrated.

9,10-Bis(2-phenylethynyl)anthracene was chosen as the fluorescence unit, because its Φ_{fl} is high (Φ_{fl} = 1) and its emission spectrum overlaps with the characteristic absorption band of the closed-ring isomer of 1,2-bis(2,5-dimethyl-3-thienyl)perfluorocyclopentene.[12] The two photochromic dithienylethene units, 1-(2,5-dimethyl-3-thienyl)-2-(2,4-dimethyl-5-bromo-3-thien-yl)perfluorocyclopentene, were connected to the fluorescent unit, 9,10-bis(4-bromo-phenylethynyl)anthracene by Pd(0) catalyzed cross-coupling reaction to obtain **1a** shown in Scheme 1. The molecular structure and purity of **1a** were confirmed by elemental analysis, ^{1}H-NMR and mass analysis.[13]

Fig. 1 shows optical absorption spectral change of **1a** in THF solution upon photoisomerization. By irradiation with 313 nm light the absorption bands at 340 nm decreased along with the increase of a new absorption band between 500 and 650 nm. The original absorption spectrum was recovered by irradiation with visible light (λ > 500 nm). Fig. 1 also shows the absorption spectrum of the isolated photo-product. It should be noted that there was only one photo-product in the HPLC analysis although **1** has two dithienylethene units. On the basis of the ^{1}H-NMR, the photo-product was assigned to the ring closed form **1b** in which one of the two dithienylethene units is in the closed-ring form.[13] Upon excitation of **1b**, excitation energy transfer from the excited open-ring unit to the closed-ring unit is considered to suppress further photo-cyclization of **1b**.

Fig. 1(b) shows the fluorescence emission spectrum of **1** in THF solution. The emission profile is similar to that of the bis(phenylethynyl)anthracene unit. The fluorescence intensity decreased upon irradiation with 313 nm light and almost disappeared in the isolated **1b**. The original emission spectrum

was recovered by visible light irradiation. The fluorescence quantum yields, ϕ_{fl}, of **1a** and **1b** were determined, by using 9,10-bis(phenylethynyl)anthracene as a reference, to be ϕ_{fl} = 0.83 and $\phi_{fl} < 0.001$, respectively.

The strong fluorescence quenching in **1b** is attributed to the efficient energy transfer from the excited bis(phenylethynyl)anthracene to the closed-ring dithienylethene unit. Because of spectral overlapping of the emission band of **1a** at about 530 nm and the absorption band of **1b**, the excited state of the bis(phenylethynyl)anthracene unit is quenched by the closed-ring unit. The residual weak emission observed in isolated **1b** was considered to be the emission from a small amount of **1a** which was formed from **1b** during the fluorescence measurement.

The laser emission experiment of **1a** was carried out as follows. THF solution of **1a** (0.1 mM) in a quartz cuvette (10 × 10 mm) was placed in the cavity of a dye laser system (Laser Photonics, DL2S), which is composed of a front highly reflective mirror, a back grating reflector and a cylindrical lens for focusing the pumping beam from a pulsed N_2 laser (Hamamatsu Photonics, LN-203). The excitation laser power, the pulse width, the wavelength and the repetition frequency were 0.1 mJ, 600 psec, 337.1 nm, and 10 Hz, respectively. The solution was stirred during the measurements. The emission was detected with a gated streak-scope system (Hamamatsu Photonics, C4334-01, C5094 and C4792). The emission from the laser cavity was detected by an analog integration mode, while its spontaneous emission was detected by a single-photon counting mode. Fig. 2(a) and (b) show emission spectra and the decay profile of **1a** placed inside and outside of the laser cavity, respectively. The emission of **1a** in the laser cavity showed a symmetrical narrow peak and any Stokes line typical for the spontaneous emission was not observed. The spontaneous emission decayed exponentially with a single lifetime of about 1.8 nsec, as shown in the inset of Fig. 2(b), while the emission from the laser cavity was dumped immediately with the excitation light pulse. The narrow and symmetrical emission profiles in the wavelength and the time domains are typical for the laser emission. Characteristic threshold of the laser emission was observed at about 0.08 mJ.

As shown in Fig. 2(c), the laser emission intensity dramatically decreased by irradiation with 313 nm light and it was recovered to the initial value by irradiation with visible light (λ > 500 nm). The reversible intensity change was observed for several tenth cycles. The emission power remained stable after standing in the absence of UV light.

In conclusion, a photochromic dithienylethene having bis(phenylethynyl)anthracene changed the fluorescence intensity by photoisomerization of the dithienylethene units (between ϕ_{fl} = 0.83 and < 0.001). The dye exhibited a laser emission and the emission intensity was reversibly switched by alternative irradiations with 313 nm light and λ > 500 nm light.

A new templating method using small, inexpensive non-surfactant chemicals has been developed facilitating the synthesis of hydrothermally stable foam-like mesopore networks with high surface areas.

Porous materials are of fundamental importance in science and technology.[1] Various templates are employed to direct the synthesis of uniform micro-, meso- and macro-pores. Principally, three types of templating have been reported thus far, *i.e* templating by individual molecules giving rise to micropores, by micelles giving rise to mesopores and by emulsions or latex particles giving rise to macropores.[2–5]

Here, we report a new templating method for well defined mesoporous (siliceous) oxides (denoted as TUD-1, Fig. 1),[6] in which small, non-surfactant templates direct the formation of mesosized structural features during the polycondensation of inorganic species upon temperature increase during synthesis. The key to a successful formation of mesopores is the careful control of the intermolecular interaction among organic templates and inorganic species, *i.e.* matching the type of template molecule with the temperature regime used. With a system initially composed of three different components, (*i.e.* water, silica source and template) taking account of the change in the nature of interactions between the different constituents with temperature, we were able to synthesize a new material that is characterized by well-defined pores with an easily tunable mesopore size distribution (25–250 Å in diameter), three-dimensional connectivities (foam-type structure), high surface areas (up to *ca*. 1000 m^2 g^{-1}), and high thermal and hydrothermal stability (negligible degradation at 650 °C for 12 h or boiling in water for 2 h, little degradation after heating to 1000 °C for 2 h or boiling in water for 17 h).

The starting point of our investigation was the desire to examine whether large pores in structured silicas might be templated, not by micelles or by very large and complex organic molecules, but by aggregates of simpler molecules. Following some preliminary investigations, triethanolamine was selected as a small, inexpensive and stable organic template with a high boiling point (*ca*. 340 °C) and good miscibility towards water, alkoxysilanes (Si-source) and the silica species generated by their hydrolysis. The new methodology also allows the facile introduction of catalytic sites (acid, base, redox) as well as micropores during the initial synthesis stage.

In the first step, a homogeneous mixture is obtained by mixing tetraethylorthosilicate (TEOS), triethanolamine (TEA) and water at room temperature.† After aging and drying in air, this mixture solidified and formed a homogeneous gel, the X-ray powder diffraction pattern of which showed no discernible peak. We interpret these data as deriving from a largely hydrogen-bonded siliceous composite polymer: the initial hydrolysis of TEOS was followed by the partial condensation of the resulting silanol species with each other and with some of the TEA, forming mixtures of mono- and oligomeric silatrane complexes and of various silica species (by ^{1}H, ^{13}C and ^{29}Si solution and MAS NMR). Hydrothermal treatment of this material changed its structure from amorphous to mesostructured. Finally, TUD-1 was obtained as a white mesoporous solid by the removal of the template either *via* Soxhlet extraction or *via* calcination. The circumstance that the mesopore range obtained is found to be directly proportional to the heating time (see Fig. 2) allowed for a very convenient, direct control of the mesopore size distributions of TUD-1. Interestingly, the porous structure can also be created without hydrothermal treatment, by employing careful calcination instead (for which a low ramp rate of *ca*. 1 °C min^{-1} is required). Hydrothermal treatment at moderately high temperature or thermal treatment (calcination) with a low ramp rate is necessary, because the condensation reactions of the various silica species are not completed after the gel formation.

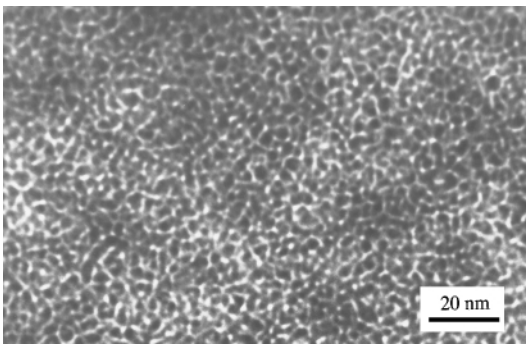

Fig. 1 High resolution transmission microscopy (HRTEM) image of the regular, mesoporous foam-like structure of TUD-1.

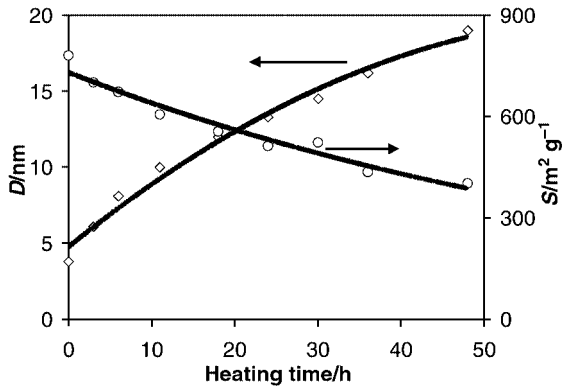

Fig. 2 Typical graph obtained when tuning the mesoporosity by variation of the heating time during hydrothermal treatment (in this case a homogeneous synthesis mixture with a molar composition of TEOS: 0.5TEA: 0.1TEAOH: $11H_2O$ was, after drying at 98 °C for 24 h, heated in an autoclave to 190 °C for different times). *D* is the mesopore diameter at maximum peak height calculated using the BJH model based on nitrogen desorption branch; *S* is the mesopore surface area calculated using the t-plot method.

At low temperatures (up to 100 °C) and after substantial loss of volatile components (water and ethanol, up to 70 wt%), the strengths of the various interactions between TEA, the various types of silatrane complexes and the silica oligomers are similar enough to form a homogeneous mixture without mesostructure. However, at elevated temperatures the silica oligomers condense extensively and the silatrane complexes partially or fully hydrolyze due to the more labile nature of Si–alkoxy bonds as compared to Si–siloxy bonds. The TEA is then largely expelled from the silica network and separate silica and template phases begin to form. The coalescence of the resulting silica particles further separates the phases on a mesoscale. This micro-syneresis (resulting in a solid–liquid mixture) gradually forces the TEA into meso-sized aggregates, templating the mesopores.

X-Ray diffraction patterns of TUD-1 show only one peak at low angle (scanning from 0.5–40° in 2θ), indicating it is a mesostructured material. Nitrogen adsorption isotherms revealed reproducible surface areas of between 500 and 1000 $m^2\ g^{-1}$ and pore volumes of between 0.6 and 1.7 $cm^3\ g^{-1}$, depending on the synthesis conditions. When employing hydrothermal treatment, the pore volume and wall thickness of TUD-1 increased with time, with a corresponding decrease in surface area, demonstrating that the pore formation is a dynamic process, consistent with the model proposed above.

We attempted to visualise the mesopore connectivity by HRTEM using Pt wires as a contrast agent.[7] The resulting images are consistent with a 3-D connectivity, but not sufficient to prove this. The synthesis of an inverse structure of TUD-1 out of carbon (using the methodology of Ryoo[8]) yielded a nanoscale carbonaceous network (surface area $>1000\ m^2\ g^{-1}$, tunable mesopore size),‡ showing a similar image of a foam-like mesopore structure (Fig. 3). This result excludes one- or two-dimensional pore connectivities in TUD-1, as otherwise the resultant carbonaceous mesopore network would collapse upon the removal of silica. Thus, we were able to show that TUD-1 contains three-dimensional pore networks.

Hence, siliceous TUD-1, with its inherent possibility of a bimodal pore distribution (*vide supra*), offers a wide scope for chemical applications as most procedures commonly employed to impart functionality on silica can be used. For example, it is very straightforward to prepare highly dispersed metal particles on TUD-1. Furthermore, ^{29}Si CP-MAS NMR measurements of a typical TUD-1 sample before and after calcination reveal the presence a substantial Q_3 signal, allowing for functionalization *via* grafting onto the pendant silanol groups lining the mesopore walls.[9]

In addition, metals such as, *e.g.* titanium, zirconium or vanadium can be grafted *via* complexation with the TEA onto the surface of the mesopore wall, providing a 'one-pot' grafting methodology.[10]

In a similar vein, functionalized surfaces are easily fashioned in a one-pot procedure by the inclusion of a certain amount of functional siloxy precursor (*e.g.* $NH_2(CH_2)_3Si(OEt)_3$) into the synthesis gel.[11] Moreover, strong acid sites (by NH_3-TPD) can be prepared that are located in the micropores, whereas the mesopores can be made mildly acidic, offering a wide scope for application in acid catalyzed reactions.

Full results on acid site functionalizations, one-pot surface functionalizations, metal particle and metal oxide impregnations/immobilizations and related catalytic tests will be published shortly.

This work was financially supported by ABB Lummus Global, IN, USA. We thank Mr J. Groen for the gas adsorption measurements.

Notes and references

† Tetraethyl orthosilicate (TEOS), triethanolamine (TEA) and water were combined at room temperature in ratios of 1:0.25–2:10–40 to obtain a homogeneous mixture. This mixture solidified after aging at room temperature for 6–24 h and subsequent heating to 96–100 °C for 12–24 h in air, forming a homogeneous gel. This gel was transferred into an autoclave and heated at *ca*. 150–200 °C for between 0 and 3 days. Finally it was calcined at 600 °C for 10 h with a ramp rate of *ca*. 1 °C min^{-1} in air, or extracted in a Soxhlet apparatus using ethanol for 3 days to obtain the final mesoprous materials. Micropores could also be introduced by addition of traditional zeolite templates, *e.g.* tetraethylammonium hydroxide, with a ratio of 0.1–0.3 with respect to Si in the final synthesis mixture.

‡ The carbonaceous network templated by TUD-1 shows a bimodal mesopore system due to structure transformation. The sizes of these two mesopores can be tuned in ranges of 3.5–5.0 and 15–25 nm, respectively, depending on the original TUD-1 sample. Full details will be published shortly.

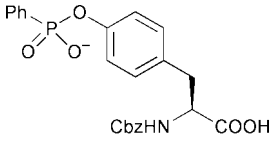
Received (in Cambridge, UK) 11th January 2001, Accepted 8th March 2001
First published as an Advance Article on the web 29th March 2001

Esterase antibody 522c2, the first example of a catalytic antibody specifically programmed to control the reactivity of functional groups on the side chain of tyrosine, accelerates the hydrolysis of benzoate esters of L-tyrosine and tyrosine-containing dipeptides by a factor of 10^4 and is moderately active against other benzoate esters.

The control of reactivity of functional groups on the side chains of amino acids and peptides is a potentially attractive field for applications of catalytic antibodies.[1] The selective modification of amino acid side chains in peptides and proteins is important for many areas of chemistry, from organic synthesis to the irreversible inhibition of enzymes and the improvement of pharmacokinetic properties of peptide drugs.[2] However, the high level of control over chemo- and regioselectivity which is required for these transformations is not easily obtained by chemical or enzymatic approaches.[3]

While a number of antibody catalyzed reactions taking place on amino acid substrates have been described, there are no examples to date dealing specifically with the reactivity of amino acid side-chains. In this communication we describe the activity of esterase antibody 522C2, the first catalytic antibody specifically designed to hydrolyze an ester group on the tyrosine phenolic side chain. As benzoate is a common modifier and protecting group in amino acid and peptide chemistry, we chose the hydrolysis of tyrosine benzoate **1** as the target reaction (Scheme 1).

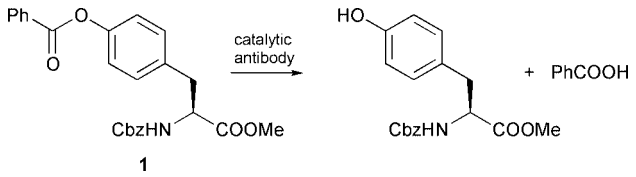
Hapten **2**, a classical phosphonate transition state analog, was synthesized by a conventional approach,[4] *via* the corresponding monoester monochloride.† The carboxylate group of tyrosine



2

was used to conjugate directly the phosphonate to cationised bovine serum albumin (cBSA)†. We reasoned that holding the hapten in close contact with the carrier protein surface would result in a relatively 'open' antigen binding site, able to recognize and hydrolize the substrate also when tyrosine is part of a peptide chain. For this reason the use of a linker between the hapten and the carrier was avoided.

The cBSA conjugate was used to immunize three Balb/c mice following a standard protocol.[5] Hybridomas obtained from the



1

Scheme 1

fusion of spleen cells were selected on the basis of the affinity of the antibodies for an ovalbumin (OVA) conjugate of **2** and cloned. Only three good binders for the hapten **2** were obtained, but two of the selected antibodies (517A41 and 522C2) exhibited catalytic activity for the hydrolysis of benzoate **1** after purification by protein G and ion exchange chromatography.† Antibody 517A41 was only a weak catalyst (k_{cat}/k_0 = 148), while 522C2 accelerated the hydrolysis of **1** by a factor of over 10^4 and was selected for further studies (Table 1). After the preliminary kinetic assay, carried out on the antibody isolated from hybridoma supernatants, 522C2 was subcloned and larger quantities of the antibody were obtained from ascitic fluids. A fully functional Fab fragment was also obtained by papain digestion and purification by gel exclusion and ion exchange chromatography. The observed catalytic activity was always reproducibile and did not depend on the antibody's preparation.

The kinetic parameters for the catalyzed hydrolysis of ester **1** were calculated at pH 8 in TRIS buffer at 25 °C (k_{cat} = 0.063), and at pH 7.5 in PBS at 30 °C (k_{cat} = 0.017), showing in both cases a rate enhancement factor in excess of 10^4 (Table 1).† This allows the observation of a net enhancement of more than 150-fold in the initial rates of hydrolysis under typical experimental conditions (5 μM antibody, 50 μM substrate **1**), in spite of the rather high value of K_M (370–500 μM), which does not allow the maximum rate to be reached within the solubility limit of this substrate.

The antibody is inhibited by an equimolar amount of the phosphonate **2**. The apparent dissociation constant of the antibody–hapten complex obtained by a competitive ELISA assay[6] ($K_{d,app}$ = 75 nM) is in reasonable agreement with the upper limit for the inhibition constant ($K_i \leq$ 100 nM) estimated from kinetic measurements. Inhibition by the hapten demonstrates that the catalyzed process takes place in the antibody combining site and is not due to interactions between the substrate and the protein surface. Nonspecific interactions of this type can indeed be observed when the hydrolysis of **1** is carried out in the presence of BSA or unrelated mouse IgGs, but result in a modest acceleration by a factor of less than 1.5 in the initial rates (at 5 μM protein and 50 μM substrate **1**).

For an antibody accelerating a reaction by simple transition state complementarity, it has been derived that $K_M/K_i = k_{cat}/k_0$.[7] In the case of 522C2, the values of k_{cat}/k_0 (11 000) and K_M/

† Electronic supplementary information (ESI) available: the synthesis and characterization of compound **2**, preparation of the immunogenic conjugate, preparation and purification of monoclonal antibodies, experimental details for kinetic studies and Lineweaver-Burk plots. [a] TRIS 10 mM, pH 8, dioxane 10%, 25 °C. [b] PBS, pH 7.5, 10% dioxane, 30 °C. [c] Fab fragment. [d] PBS, pH 7.5, 30% DMSO, 30 °C.

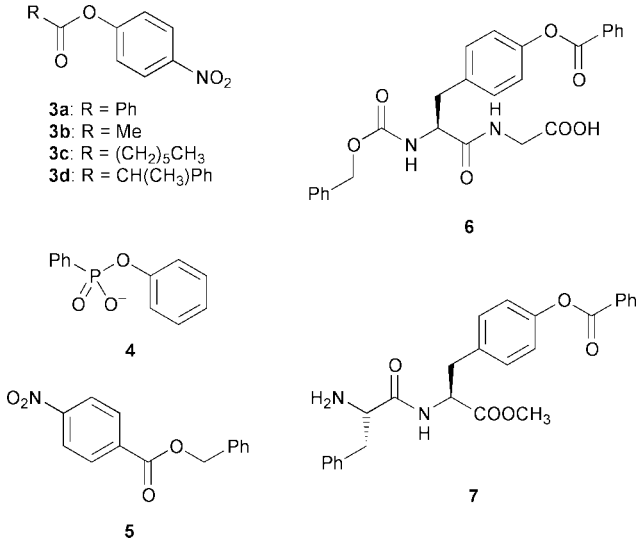
$K_{d,app}$ (4900) indicate that selective recognition of the transition state significantly contributes to the catalytic activity. Thus 522C2 behaves similarly to other ester hydrolyzing antibodies for which oxyanion stabilization has been recognized as the main source of catalytic activity.[8]

Antibody 522C2 is highly specific for the *S*-enantiomer of tyrosine benzoate, mirroring the configuration of the hapten, and no acceleration over background is observed in the hydrolysis of the corresponding *R*-ester. While displaying such a high enantiospecificity, antibody 522C2 is able to hydrolyze a number of simplified esters **3** in which tyrosine is replaced by *p*-nitrophenol. Solubility, and the high values of K_M for these substrates, restrict the accessible substrate concentrations to a range in which [*S*] << K_M. Therefore, second order rate constants, corresponding to k_{cat}/K_M ratios assuming Michaelis–Menten behaviour, were obtained for this set of esters and the ratio $k_{cat}/K_M \cdot k_0$ (catalytic proficiency) was chosen to compare the efficiency of the antibody on these substrates (Table 1).[9]

Data in Table 1 show that one order of magnitude in the catalytic proficiency is lost on going from *N*-Cbz-tyrosine benzoate **1** to *p*-nitrophenyl benzoate **3a**. This decrease in the catalytic activity of the antibody is paralleled by its affinity for the corresponding phosphonates. In fact, while the tyrosine phosphonate **2**, as we have seen, is a strong binder, the simple phenyl phenylphosphonate **4** does not inhibit 522C2. This



indicates that in the substrate **1** and hapten **2** the region of the molecule corresponding to the protected α-amino acid group plays a significant role in recognition by the antibody.

Replacing the benzoyl group by aliphatic residues, as in the hydrolysis of esters **3b** and **3c**, results in a further decrease of catalytic proficiency by one order of magnitude (Table 1). The catalytic activity is completely lost when branching is introduced in the ester **3d**. Surprisingly however, antibody 522C2 shows good efficiency in the hydrolysis of benzyl *p*-nitrobenzoate **5**.

It is noteworthy that the substrate selectivity exhibited by 522C2 is reversed with respect to that displayed by a hydrolytic enzyme such as α-chymotrypsin. This protease is known to hydrolyze esters with a broad specificity. However, under similar conditions, the acceleration in the hydrolysis of *p*-nitrophenyl ester **3a** is six times higher than the acceleration in the hydrolysis of tyrosine ester **1**. Another major difference between α-chymotrypsin and 522C2 is represented by the pre-steady state burst which is observed with the enzyme but not with 522C2, in agreement with the mechanism proposed for the antibody.

Finally, the activity of 522C2 was also tested on the dipeptides **6** and **7** (Table 1). 522C2 retains most of its catalytic activity on both the dipeptide benzoates even in the presence of 30% DMSO, which is necessary for solubility. Replacement in **7** of the *N*-Cbz protecting group with the somewhat isosteric residue of phenylalanine does not lead to a loss of activity.

In conclusion, 522C2 is an efficient and selective catalyst for the hydrolysis of (*S*)-tyrosine benzoate and retains its activity when the substrate is part of a simple dipeptide. This preliminary result is promising in view of a possible extension of this approach to the selective deprotection of tyrosine benzoate in more complex peptide structures, which would be a valuable application and is currently being investigated.

We are grateful to CNR (Progetto Finalizzato Biotecnologie) and to MURST (Programma PRIN) for financial support.

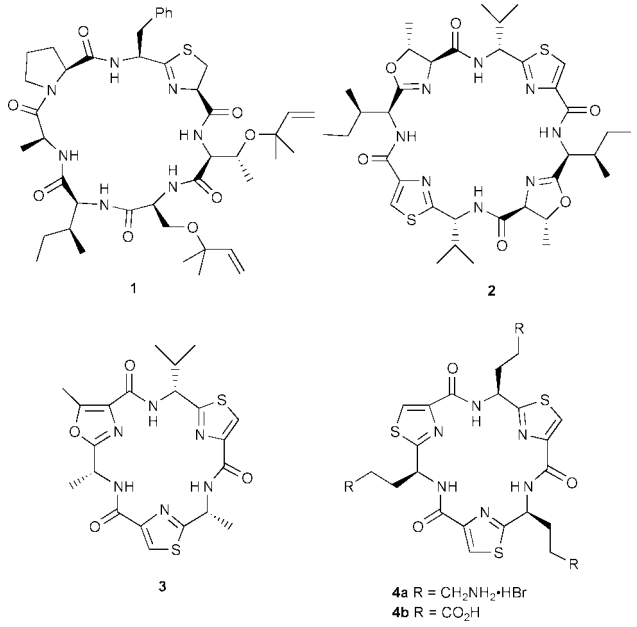
Received (in Cambridge, UK) 13th February 2001, Accepted 8th March 2001
First published as an Advance Article on the web 29th March 2001

Tubular and cage structures, *i.e.* 16 and 18, have been synthesised from modified cyclic peptides following selective cyclotrimerisations of L-ornithine and L-glutamic acid thiazole amino acids under high dilution conditions.

Marine organisms, especially sea-squirts, have delivered an astonishing variety of novel cyclopeptide alkaloids which accommodate thiazole and oxazole rings derived from unusual amino acids, *e.g.* trunkamide **1**,[1] ascidiacyclamide **2**.[2] The



sequence of alternating heterocyclic rings and amino acid units which characterise these structures has led to speculation that the metabolites may have a role to play *in vivo* as metal transport agents, and/or that metals may act as templates in their biological assembly from constituent amino acids/heterocyclic rings.[3] In previous studies we have examined the self assembly and metal-templated cyclooligomerisations of amino acid based thiazoles and oxazoles, culminating in the syntheses of novel cyclotetramers and cyclotrimers,[4] and also in the total synthesis of the natural cyclopeptide dendroamide A **3**.[5] In a continuation of this work we have now investigated the syntheses of the cyclopeptide scaffolds **4a** and **4b**, containing additional amino and carboxylic acid functionality respectively, with a view to examining their applications in the synthesis of 'cage-' and 'tube-' like structures for possible use as membrane ion channel mimics and for the development of macromolecular devices and scaffolds for protein mimics. Thus, in this *Communication* we describe concise syntheses of **4a** and **4b**[6] and their conversion into the tubular polyamide **16** and into the cage structure **18**.[7,8]

Each of the substituted thiazoles **4a** and **4b** was prepared by routes developed in our laboratories and based on well-established literature precedent. Thus, protection of the C-5 amino group of L-ornithine **5** as its *Z*-carbamate followed by Boc protection of the C-2 amino function first led to the carboxylic acid **6**. Amidation of **6** followed by treatment with Lawesson's reagent [2,4-bis(4-methoxyphenyl)-1,3,2,4-dithiaphosphetane-2,4-disulfate] next produced the thioamide **7**. A Hantzsch thiazole ring forming reaction between **7** and ethyl bromopyruvate[9] then gave the substituted thiazole **8** which, on saponification of the ethyl ester and removal of the Boc protection, gave the L-ornithine based thiazole amino acid **9** with ⩾95% ee (Scheme 1).[10]

The corresponding L-glutamic acid based thiazole **14** was prepared from L-glutamic acid 5-methyl ester **10** following Boc protection and coupling with DL-serine benzyl ester benzenesulfonate leading to the dipeptide **11**. After conversion of **11** into the thioamide **12**, cyclodehydration in the presence of Burgess' reagent [methyl(carboxysulfamoyl)triethylammonium hydroxide, inner salt][11] next produced the corresponding thiazoline which was immediately converted into the thiazole **13** upon treatment with $BrCCl_3$–DBU at 0 °C.[12] Debenzylation of **13** under catalytic transfer hydrogenation conditions[13] and Boc deprotection finally gave the free thiazole amino acid **14** with ⩾95% ee (Scheme 2).

When the L-ornithine amino acid thiazole **9** was treated with pentafluorophenyl diphenylphosphinate (FDPP) in the presence of *i*-Pr_2NEt in DMF under high dilution, selective cyclooligomerisation took place to give the cyclic trimer **15a** in 11% yield. In a similar manner, cyclooligomerisation of the L-glutamic acid based thiazole **14** under the same conditions led cleanly to the C_3-symmetric cyclic trimer **15b** in 41% yield (Scheme 3). After removal of the amine protection in **15a** and saponification of the methyl ester groups in **15b**, activation of the tris-carboxylic acid **4b** with FDPP and *i*-Pr_2NEt followed by treatment with the tris-amine **4a** under high dilution in DMF led to the formation of the tubular structure **16** as a powder in 30% yield (Scheme 4).† Mass spectometry indicated the presence of a monomeric product. This was reinforced by the NMR spectroscopic data for

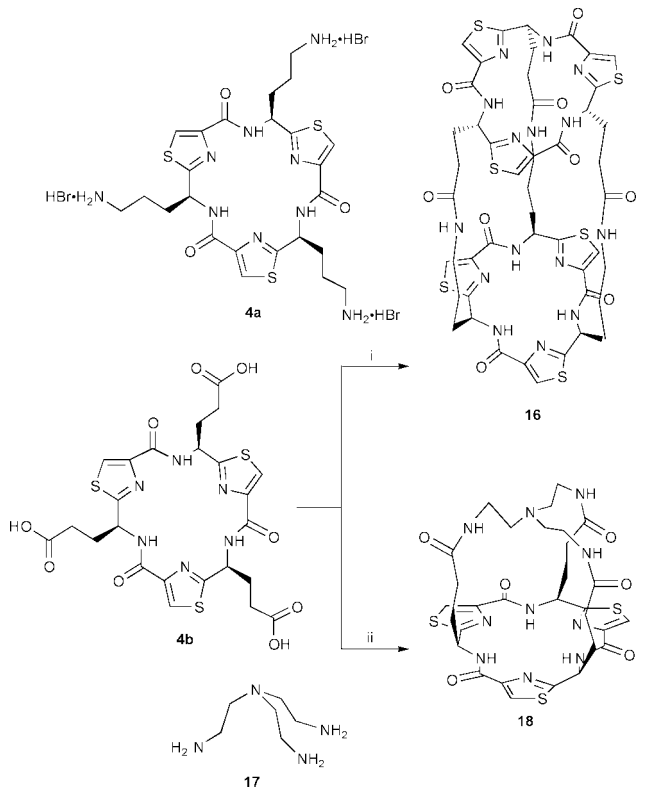

Scheme 4 *Reagents and conditions*: i, FDPP, *i*-Pr_2NEt, **4a**, DMF, 10 d, 30%; ii, FDPP, *i*-Pr_2NEt, **17**, DMF, 3 d, 40%.

16 which were consistent with those expected for a C_3-symmetric polymacrocycle. Most notably, two singlet peaks at δ 8.13 and δ 8.11 were observed in the ^{1}H NMR spectrum corresponding to the two sets of thiazole protons. Additionally, NMR signals were observed relating to the amide N–H (δ 8.47 and δ 8.43) and the α-carbon protons (δ 5.68 and δ 5.58) within the macrocyclic rings.

A corresponding condensation between the L-glutamic acid trimer **4b** and tris(aminoethyl)amine **17** in the presence of FDPP–Pr_2NEt led to isolation of the cage structure **18**, also as a solid, in 40% yield.‡ Again, mass spectrometry established that formation of the desired monomer had occurred. Additionally, the ^{1}H NMR spectrum confirmed the structure of **18** as C_3-symmetric with peaks at δ 8.89 and δ 8.11 relating to the ring N–H and thiazole protons with a signal at δ 6.26 corresponding to the three side-chain amide protons. The applications of the C_3-symmetric cyclic trimers **4a** and **4b** and their relatives in asymmetric and library synthesis, and also in molecular recognition phenomena, will be described in future publications.

We thank Dr Luis Castro for his interest in this study and Merck Sharp and Dohme for financial assistance. We also thank Dr Kate Jolliffe for preliminary work with the synthesis of the L-ornithine thiazole.

The effect of bulky substituents on the olefin polymerisation behaviour of nickel catalysts bearing [P,O] chelate ligands

Vernon C. Gibson,* Atanas Tomov, Andrew J. P. White and David J. Williams

Department of Chemistry, Imperial College of Science, Technology and Medicine, Exhibition Road, South Kensington, London, UK SW7 2AY. E-mail: v.gibson@ic.ac.uk

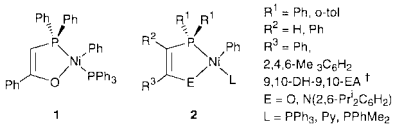
Received (in Cambridge, UK) 19th February 2001, Accepted 7th March 2001
First published as an Advance Article on the web 29th March 2001

Incorporation of bulky substituents adjacent to the oxygen donor site of [P,O]Ni catalysts affords dramatic increases in olefin polymerisation activities

Nickel catalysts have provided some of the most significant advances in late transition metal olefin polymerisation catalysis and have given some of the most promising results with regard to polar monomer incorporation into polyolefinic materials.[1–4] One of the earliest systems to be investigated was the nickel-ylide oligomerisation system (**1**) introduced by Keim *et al.*[5] and subsequently developed by the groups of Starzewski[6] and Klabunde[7] for olefin polymerisation and copolymerisation. However the intrinsic activities of these catalysts are not high.

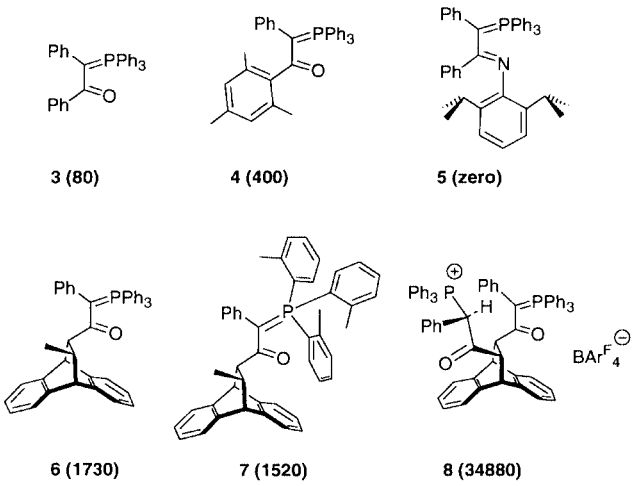
Bulky substituents have been shown to have a strong influence on the activities and selectivities of α-diimine[8] and salicylaldimine[9] nickel catalysts, yet the influence of sterically demanding groups has not been fully explored in the [P,O]Ni system. Several sites around the ligand are amenable to modification (see **2** below†): (i) the tertiary phosphine substituents (R^1), (ii) the backbone carbon substituent (R^2) adjacent to the phosphine donor, and (iii) the backbone carbon substituent (R^3) adjacent to the enolate oxygen. It was also recognised that an alternative approach to changing the steric influence at the enolate oxygen site is to exchange the oxo group for the isoelectronic [NR] unit. Here, we describe a series of new nickel catalysts containing [P,O] chelate ligands which reveal a dramatic enhancement in ethylene polymerisation activities, in some cases in excess of two orders of magnitude, on introduction of bulky substituents, especially at the site adjacent to the oxygen donor group.

The phosphorus ylide ligand precursors **3**–**5** (Scheme 1) were



synthesised *via* modified literature procedures.[10,11] The ligand precursors **6**–**8** were prepared *via* Diels–Alder addition of crotonic acid or fumaric acid to anthracene, followed by conversion to the acyl chloride and subsequent treatment with benzylidenetriphenylphosphorane. For **8**, the bis(acyl chloride) is used to introduce the pendant phosphonium group. The catalysts **3a**–**8a** were then generated *in situ* by treatment of $Ni(cod)_2$ with the phosphorus ylide ligand precursor. *In situ* $^{31}P\{^1H\}$ NMR studies show that oxidative addition of **3**–**8** to the Ni(0) species occurs very rapidly in the presence of an olefin to form [P,O]Ni chelates.

Complexes containing these chelate ligands were also synthesised and isolated‡ from the corresponding ligand precursors and $Ni(cod)_2$ in the presence of an auxiliary ligand, typically triphenyl- or dimethylphenyl-phosphine, or pyridine. A crystal structure of the complex **6b**§ containing the ligand from catalyst system **6a** and the stabilising triphenylphosphine ligand is shown in Fig. 1. Complex **6b** crystallises with two independent molecules **A** and **B** in the asymmetric unit both of which have very similar conformations, the differences being in the relative orientations of the phenyl substituents. The geometry at nickel is only very slightly distorted square planar, the nickel and the four coordinated atoms being coplanar to within *ca.* 0.028 Å in both molecules. The plane of the C(43) phenyl ring is, in both molecules, oriented almost orthogonally



Scheme 1 Ligand precursors (LP) used in the corresponding *in situ* catalyst systems LP/$Ni(cod)_2$/olefin, **3a**–**8a** (olefin = ethylene, propylene or hex-1-ene) and their catalytic activities (g $mmol^{-1}$ h^{-1}) for ethylene polymerisation; BAr^F_4 = $[3,5\text{-}(CF_3)_2C_6H_3]B$.

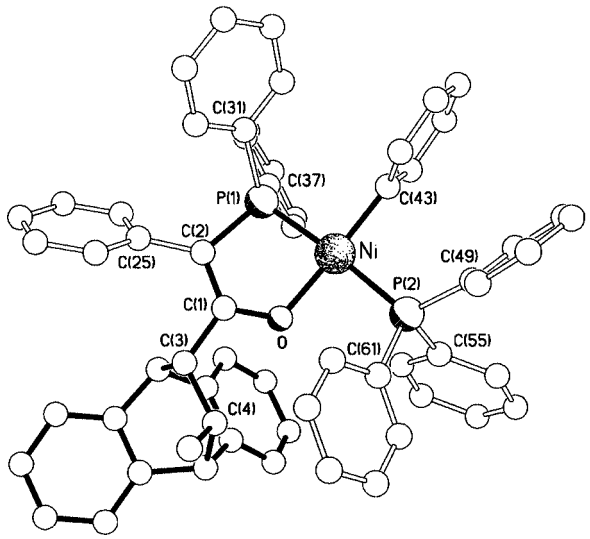


Fig. 1 One of the pair of crystallographically independent molecules present in the structure of **6b**. Selected bond lengths (Å) (data for molecule **B** are given in square brackets); Ni–O 1.901(2) [1.906(2)], Ni–P(1) 2.165(1) [2.174(1)], Ni–P(2) 2.212(1) [2.223(1)], Ni–C(43) 1.921(1) [1.928(1)], P(1)–C(2) 1.784(3) [1.775(3)], O–C(1) 1.309(4) [1.308(4)], C(1)–C(2) 1.374(4) [1.368(4)].

DOI: 10.1039/b101582f

to this plane. The *cis* angles at nickel are in the ranges 85.74(6)–93.03(7) and 85.43(6)–93.27(6)° in **A** and **B**, respectively, within each case the most acute angle being associated with the bite of the chelating ligand. The Ni–P(1) distance is, in both molecules, 0.05 Å shorter than that to P(2), indicating possibly an extension of the clear pattern of bond delocalisation, that extends from O through to P(1) *via* C(1) and C(2), to include the metal centre. The chelate ring has a slightly folded envelope conformation with the phosphorus atom lying 0.28 Å (molecule **A**) and 0.13 Å (molecule **B**) out of the plane of the remaining four atoms which are coplanar to within 0.007 Å (molecule **A**) and 0.009 Å (molecule **B**). The C(25) phenyl substituent is rotated by *ca.* 55° (**A**) and 68° (**B**) out of the plane of the chelate ring. The O–C(1)–C(3)–C(4) torsion angle is, in both molecules, small (*ca.* 6 and 15° in **A** and **B**, respectively), possibly as a consequence of a C(4)–H···O intramolecular hydrogen bond (the H···O distances are 2.24 and 2.26 Å in **A** and **B**, respectively).

The activities of these neutral catalysts for ethylene polymerisation and the results of product analyses are collected in Table 1. The ligand precursor **3**, and its triphenylphosphine stabilised nickel complex have been described earlier as precursors to ethylene polymerisation catalysts.[3,12] The catalytic performance of **3**/Ni(cod)$_2$ (**3a**) was used as a benchmark for the present study. Polymerisations were carried out both on *in situ* generated catalysts, which do not require the presence of a phosphine scavenger, and on the tertiary-phosphine stabilised pre-catalysts in the presence of Ni(cod)$_2$. Approximately the same activities are found in both cases and the resultant polymers also possess similar properties. In all cases, the polyethylene is essentially linear with number average molecular weights in the range 3000–10 000 and with molecular weight distributions in the range 2.0–3.7. It can be seen that there is an increase in activity upon introduction of a mesityl unit on the carbon adjacent to the enolate oxygen (**4a** *cf.* **3a**). Surprisingly, the activity falls to zero when the oxo group is exchanged for a N(diisopropylphenyl) unit (**5a**). A dramatic increase in activity is found upon introduction of the bulky anthracenyl-derived substituent (**6a**–**8a**), particularly for the phosphonium-containing catalyst **8a** which achieves an activity of almost 35 000 g mmol^{-1} h^{-1}. Comparison of **6a** with **7a** indicates that there is no beneficial effect on activity of increasing the size of the phosphorus substituents.

Another interesting feature of the neutral nickel complexes bearing bulky [P,O] ligands is their ability to oligomerise propylene and hex-1-ene. While co-polymerisations of ethylene with higher α-olefins by nickel phosphinoenolate complexes have been reported,[7] there have been no reports of propylene or hex-1-ene oligomerisations using these or related catalysts. Our attempts to oligomerise propylene with **3a** resulted in formation of only traces of propylene dimers. However **6a**, dissolved in toluene, oligomerised propylene at 4 bar and 70 °C with an activity of 1350 g mmol^{-1} h^{-1} to give a Schultz–Flory distribution (K = 0.64) of C_6–C_{48} olefins. Catalyst **8a** oligomerises propylene with a similar activity to give oligomers with a similar product distribution. Both catalysts homo-oligomerise hex-1-ene to C_{12}–C_{36} oligomers with relatively low activities. Thus, for example, catalyst **6a** shows an activity of 15 g mmol^{-1} h^{-1} for hex-1-ene oligomerisation.

The increase in activity is clearly linked to the introduction of the bulky anthracenyl-derived substituent next to the oxygen donor site. Possible effects of this are to protect the electrophilic nickel centre from binding potentially poisoning donor groups and/or to disfavour the coordination of Lewis acids at the oxygen site, especially another nickel centre which can result in ligand migration and formation of a catalytically inactive bis(chelate) species. Co-polymerisations of ethylene with hydrocarbon and polar co-monomers are presently under investigation.

BP Chemicals Ltd is thanked for financial support. Drs G. Audley and J. Boyle are thanked for GPC and NMR measurements, respectively.

Table 1 Results of ethylene polymerisation using catalytic systems **3a**–**8a** in toluene at 70 °C[a]

Two functionalized bipyrroles, 3,3′,5,5′-tetraethoxycarbonyl-4,4′-dipropyl-2,2′-bipyrrole 1 and 3,3′,5,5′-tetraethoxycarbonyl-4,4′-diphenyl-2,2′-bipyrrole 2, are highly luminescent materials at room conditions; they show UV emission at λ_{max} = 416 (1) and 414 nm (2) with quantum yields close to unity in the solid state; the molecular structure of 2 shows a coplanar structure stabilized by intramolecular hydrogen bonds, and the molecules are self-assembled along the crystallographic *c* axis by π-stacking interaction to form a one-dimensional chain; electroluminescence of 1 is evaluated.

The chemical, physical and electronic properties of conducting conjugated organic polymers such as poly(*p*-phenylenevinylenes)[1] and polythiophenes[2] have been widely exploited for the past decade, and recently some of these materials have been successfully developed for application in molecular electronics and light-emitting diode (LED) devices. However, among the numerous conducting polymers prepared to date, polypyrroles are the most extensively studied.[3] Apparently, polypyrroles possess a number of features that are attractive to materials science such as environmental stability, good redox properties and high electrical conductivity. Several applications based on polypyrroles including supercapacitors, electrochemical sensors, anti-static coating and drug delivery systems have been resulted.[4] Apart from these applications, to our knowledge, there are no reports describing highly luminescent poly/oligopyrroles at ambient conditions in the literature. Herein, we present the first report on UV photoluminescence of two functionalized bipyrrole compounds, namely 3,3′,5,5′-tetraethoxycarbonyl-4,4′-dipropyl-2,2′-bipyrrole **1** and 3,3′,5,5′-tetraethoxycarbonyl-4,4′-diphenyl-2,2′-bipyrrole **2** (Fig. 1). Blue luminous materials for application in blue-light emitting devices has recently been receiving widespread interest in materials science. We[5] and others[6] have reported that metal complexes of some *N*-heterocycles such as 7-azaindole, di-2-pyridylamine and 2,6-bis(2-pyridylamino)pyridine are strongly luminescent in the UV region; some of them have shown promising results as light-emitters for LED fabrication.[5b]

As reported by Nonell *et al.*,[7] **1** and **2** were prepared by the copper-mediated dehalogenated coupling of the iodopyrroles. The crude products were recrystallized by slow solvent evaporation of a CH_2Cl_2–MeOH mixture to afford colorless needle-shaped crystals.† As depicted in Fig. 2(a), the bipyrrole **2** adopts a near planar structure in a transcoid configuration, where the carbonyl functions of the carboxylate substituents are hydrogen bonded with the pyrrolic NH groups [N(1)···O(1A) 2.651 Å; N(1)···O(4) 2.486 Å]. It should be noted that the interannular torsion angle of unsubstituted 2,2′-bipyrrole for the most stable conformation is about 30° along the principal molecular axis according to theoretical models and some physical measurements.[8] In this work, we found that the coplanar conformation of **2** is essentially stabilized by intramolecular hydrogen bonding. Indeed, several studies by Brédas *et al.* have pointed out that coplanarity of the polyaromatic materials would permit better π-conjugation, thereby lowering the ionization potential and band gap of the compounds.[9] It is also suggested that coplanar conformation of polypyrroles

2	290 (21020) 346 (34950)	414, 431(sh)	401	0.87[c]	0.63, 3.39	0.3, 2.5
3	271 (16780)	—[d]	313	0.0016		
4	275 (16820)	—[d]	360	0.0175		

[a] In CH_2Cl_2 at 298 K. [b] In degassed CH_2Cl_2 [c] Excited at 345 nm. [d] Intensity too weak to measure. [e] Excited at 266 nm ps pulses (T = 300 K). [f] In degassed CH_2Cl_2 (1 mM).

could facilitate intrachain mobility of charge defects such as polarons or bipolarons.[9b,c] By comparing the absorption spectra with those of the mono-pyrrole analogues (2,4-diethoxycarbonyl-5-methyl-3-propylpyrrole **3** and 2,4-diethoxylcarbonyl-5-methyl-3-phenylpyrrole **4**),[10] the absorptions for the bipyrroles are significantly red-shifted (see Table 1) due to the extended π-conjugation of the molecules.

The phenyl rings are oriented perpendicular to the bipyrrole plane, and the four carboxylate groups are arranged in a spiral arrangement along the principal C_2 axis of the molecule. The respective O(1)–C(5) and O(3)–C(12) distances of 1.212(1) and 1.187(1) Å are consistent with a C=O formulation, and the C(1)–C(5) [1.457(1) Å], C(3)–C(12) [1.473(2) Å] and C(4)–C(4A) [1.462(2) Å] distances are slightly shorter than a typical C–C (sp^3-hybridized) single bond, suggesting the presence of a partial double bond character. The molecule appears to form a one-dimensional chain along the crystallographic *c* axis *via* intermolecular π-stacking interaction [see Fig. 2(b)], the interplanar separation is *ca.* 3.8 Å [N(1)–N(1′) 3.669 Å and C(1)–C(1′) 3.723 Å].

The absorption and emission data of the bipyrroles are shown in Table 1. Their absorption spectra are featured by two absorption bands (250 and 350 nm for **1**; 290 and 346 nm for **2**), presumably arisen from π–π* transitions. Importantly, both compounds are strongly luminous at around 400 nm. In CH_2Cl_2 solution, the emission quantum yields (Φ_{em}) of **1** and **2** are 0.56 and 0.87, respectively, and their solid state quantum yields are unity within the experimental error. We observed a large Stokes shift with a magnitude of *ca.* 4500 cm^{-1} for the emission from the lowest singlet π–π* transition of the bipyrroles, which suggests a significant structural distortion of the excited state from the ground state structure. For better understanding the nature of emission, we have examined the emission of the bipyrroles using picosecond laser spectrophotometer. The luminescent lifetimes are listed in Table 1. The short lifetimes suggest that the emissions are due to fluorescence arising from the singlet π–π* transitions. Upon cooling the solid sample of **1** to 15 K, a vibronically structured emission was identified with a peak splitting of *ca.* 1080 cm^{-1}, which corresponds to the skeletal vibration of the bipyrrole. The measured luminescence lifetime was found to be 5.9 ns.

The transient luminescence trace of **2** monitored at 420 nm revealed two decay processes with lifetimes being 0.63 and 3.39 ns in the solid state, and 0.3 and 2.5 ns in solution. For **1**, however, there is only a single exponential decay with lifetime being 2.0 and 2.7 ns in the solid state and CH_2Cl_2 solution, respectively. We propose that the short luminescence decay [*i.e.* lifetime = 0.3 ns (solution) and 0.63 ns (solid)] for **2** may have originated from the rapid excited state energy transfer between the bipyrrole ring(s) and the phenyl substituent(s).[11]

The electroluminescence (EL) of the bipyrrole **1** has been evaluated. A film of **1** (20 or 50 nm) was obtained by vapor deposition onto a glass substrate pre-coated with indium–tin oxide and 4,4′-bis[*N*-(1-naphthyl)-*N*-phenylamino)biphenyl (NPB; thickness = 80 nm). To achieve better contact between the emitter layer (*i.e.* **1**) and the Mg : Ag cathode, a layer of TPBI (40 or 20 nm, see Fig. 1 for structure) was evaporated on top of the bipyrrole layer. When the LED was forward biased with the ITO electrode at positive polarity, EL with a blue–green color was observed. The EL spectrum shows a prominent band at 440 nm, which is red–shifted from the solid state emission of **1** (blue color, λ_{max} = 415 nm). It should be noted that the PL spectrum of the bipyrrole film is essentially identical with the solid state emission of **1**. The reasons underlying the red-shift of the EL remain unclear. The maximum luminance of 750 cd m^{-2} with maximum efficiency being 0.9 cd A^{-1} was attained at 14 V.

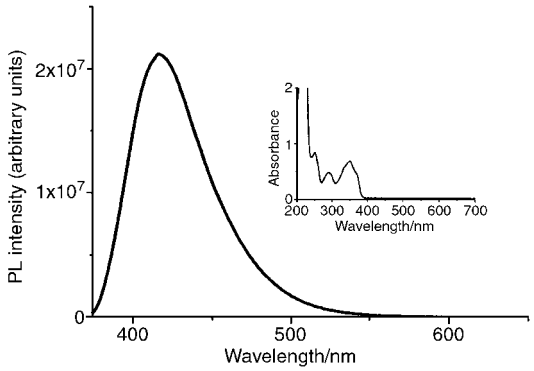

Fig. 3 Emission and absorption (inset) spectra of **1** in CH_2Cl_2 solution at 298 K.

Polymer site–site interactions: mechanistic implication in the solid-phase Zincke reaction

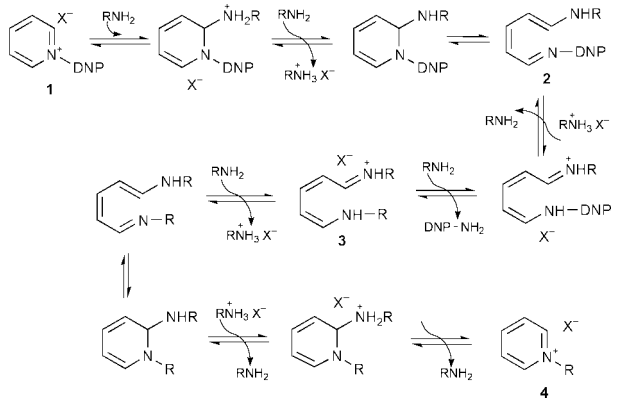
Received (in Corvallis, OR, USA) 8th December 2000, Accepted 30th January 2001
First published as an Advance Article on the web 29th March 2001

Mechanistic aspects of the solid-phase Zincke reaction have been investigated using Wang resins; a proton transfer mechanism is proposed which obviates the need for covalent bond site–site interactions.

In 1903, Zincke reported the ring opening-reaction of 2,4-dinitrophenylpyridinium chloride (**1**) with aniline to give 5-anilino-*N*-phenyl-2,4-pentadienylideniminium chloride (**3**, R = Ph; Scheme 1)[1] which underwent ring reclosure to give *N*-phenylpyridinium chloride (**4**, R = Ph).[1] This process, known as the Zincke reaction, is now the standard route to *N*-arylpyridinium salts which cannot be formed by direct reaction of electrophiles with pyridine.[2] The Zincke mechanism had previously been divided into ring-opening[3] (**1** → **3**) and ring-closing[4] (**3** → **4**) stages until Ise and co-workers determined the complete process for **1** → **4** as shown in Scheme 1.[5] In this mechanism, excess amine (RNH_2) assists in proton transfer and reacts twice with **1** to deliver intermediate **3**.



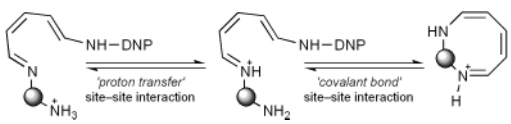
Scheme 1

We recently reported[6] a solid-phase (SP) variant of the Zincke reaction, which according to Ise's mechanism, would require two kinds of resin-bound amine interactions — 'proton transfer site–site interactions' and 'covalent bond site–site interactions' (Scheme 2). However, an intriguing question arises as to whether the SP Zincke reaction proceeds *via* **3** as formation of this intermediate requires covalent bond site–site interactions between two resin-bound amines. Since the amine moiety (RNH_2) is attached to resin in the SP system, formation of the SP aminopentadienylideniminium (**3′**; Scheme 3) and subsequent re-closure to the SP Zincke product (**4′**) would seem to be inefficient because each covalent bond site–site interaction generates a new crosslink which would reduce resin mobility[7] and hinder formation of SP intermediate **3′**. Moreover, most SP aminopentadienylideniminiums (**3′**) would not be able to negotiate the six membered transition-state required for electrocyclic ring closing.

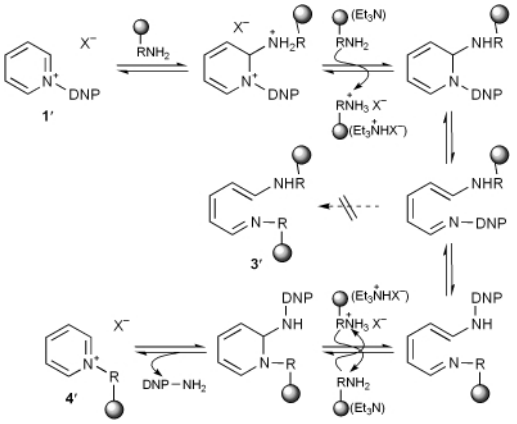
We reasoned that conversion of Zincke salt to Zincke product (**1′** → **4′**; Scheme 3) by a process which avoids the intermediacy of aminopentadienylideniminiums would be more likely in the SP reaction. To probe this, we have carried out more detailed studies of the SP Zincke reaction and report our findings here.

Three crucial factors mediate site–site interactions in SP reactions: (i) crosslinking density, (ii) functional group loading, and (iii) solvent properties.[8] Therefore, we have compared Zincke reactions using Wang resins (both 1%- and 2%-crosslinked; Novabiochem) at a variety of amine loading levels.[9] Wang resin (**5**) was loaded[10] with a mixture of Fmoc–amino alcohol and a suitable amount of *n*-propanol to provide resin **6** (Scheme 4). The actual amino loading of **7** was determined by UV spectrophotometric analysis of the Fmoc decomposition product.

Reaction of amino resin **7a** (100 mg) with Zincke salt **8a**[11] (5 eq. relative to **7a**'s amine loading) both with and without TEA (10 μL) or 2,4-dinitroaniline (DNP–NH_2, 13 mg) in solvent (toluene or *n*-butanol, 2 mL) at 80 °C for 35 h gave SP Zincke product **9a**. Cleavage of the Wang tether in **9a** using 10% TFA in CH_2Cl_2 solution gave Zincke product **10**. The overall yield of **7a** → **10** was determined by HPLC analysis [Symmetry® C_{18}, 4.6 × 150 mm, linear gradient elution of 10–100% MeOH–phosphoric acid buffer solution (pH 7.0) for 20 min; flow rate 1 mL min^{-1}; detection, 220 nm, **10**: t_R = 9.32 min]. Fig. 1 shows the relationship between resin **7a**'s amine loading and the yield of Zincke product **10**. Running SP reactions with TEA increases product yield at all loading levels for either degree of crosslinked resin. Addition of DNP–NH_2 causes no yield improvement (*i.e.* product yield with and without DNP–NH_2 were similar) suggesting that DNP–NH_2 (formed *in situ*) does not assist proton transfer in **7a** → **9a**. In contrast, TEA does play an important role in assisting proton transfer so that **7a** → **9a** proceeds primarily *via* the process outlined in Scheme 4.

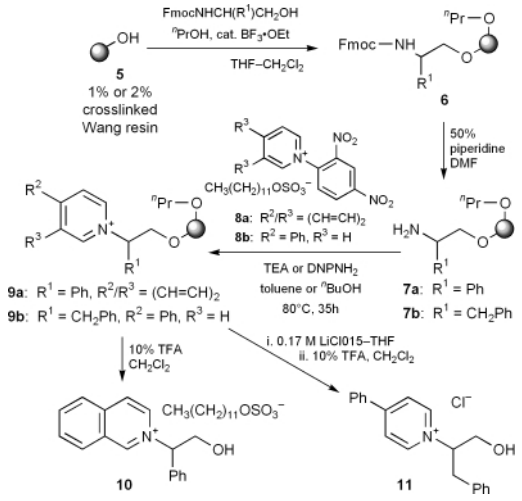


Scheme 2



Scheme 3

DOI: 10.1039/b009886h



Scheme 4

Relative to *n*-butanol (effective solution-phase solvent),[11] toluene is the solvent of choice for SP Zincke reactions due to its ability to swell the resin.[12] Unfortunately, these distinct solvent requirements make meaningful rate comparisons between solution (24 h, 118 °C)[2b,11] and SP (35 h, 80 °C) unworkable.

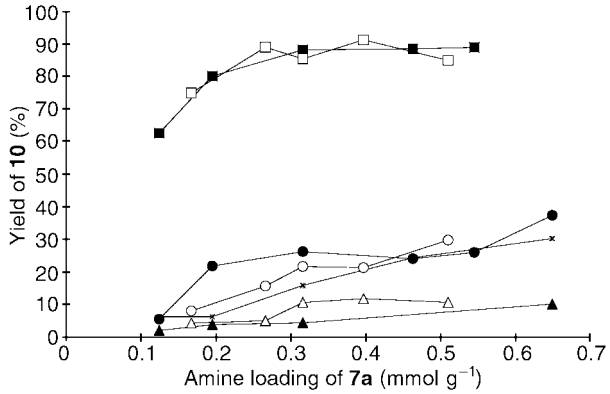


Fig. 1 Plotted yield of **10** *versus* the amine loading of **7a**: 1% crosslinked (●), 2% crosslinked (○), 1% crosslinked + TEA (■), and 2% crosslinked + TEA (□) in toluene, and 1% crosslinked (▲) and 2% crosslinked (△) in *n*-butanol; 1% crosslinked + DNP–NH_2 (⁎) in toluene.

We also studied the more reactive combination of SP amine **7b** condensing with Zincke salt **8b**[6] to give SP Zincke product **9b**. Subsequent treatment of **9b** with LiCl, followed by cleavage, liberated **11** as the chloride salt. The relationship between amine loading in starting resin **7b** and yield of **11** is shown in Fig. 2. Again, reactions in the presence of TEA resulted in good product yields. In reactions without TEA, yield improvement was observed with resin loadings for **7b** of >0.3 mmol g^{-1}. This result—namely, that effective site–site interactions occur at loadings >0.3 mmol g^{-1}—is in agreement with Patchornik's report that 0.1–0.3 mmol g^{-1} loadings can be employed successfully in syntheses requiring effective site-isolation.[13] The fact that SP Zincke reactions proceed in good yield at resin loadings of $\leqslant 0.3$ mmol g^{-1}—even at lower loading such as 0.09 mmol g^{-1}—in the presence of TEA indicates that this reaction can progress from Zincke salt **1′** to SP Zincke product **4′** without the formation of intermediate **3′**. No amine site–site interactions are required if TEA is present to negotiate proton transfer and direct conversion of **1′** to **4′**. However, reactions run without added TEA on resin with loadings of >0.3 mmol g^{-1} experience significant proton transfer site–site interaction as evidenced by the increased yield.

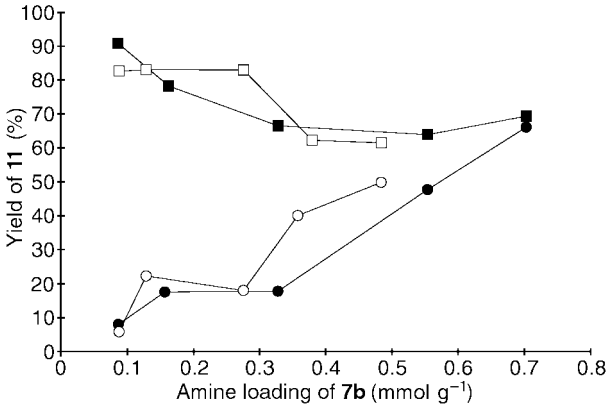

Fig. 2 Plotted yield of **11** *versus* the amine loading of **7b**: 1% crosslinked (●), 2% crosslinked (○), 1% crosslinked + TEA (■), and 2% crosslinked + TEA (□) in toluene.

The yields of Zincke product from 1%- and 2%-crosslinked Wang resin are generally equivalent (see Fig. 1). Indeed, solvent swelling ratios (*s*) for 1%- and 2%-DVB–styrene beads are quite similar (s = 5.13 and 4.52 in toluene, respectively)[14] which suggests that these crosslink densities are not sufficiently disparate to cause differential site–site interactions.

In summary, we have analyzed the SP Zincke mechanism under a variety of resin loadings and reaction conditions. We conclude that while **3′** may be involved to some limited extent in this SP Zincke transformation, a proton transfer mechanism provides the more likely reaction path for conversion of polymer-supported amine (●–RNH_2) to polymer-supported Zincke product (**4′**; Scheme 3). Addition of TEA greatly facilitates the SP Zincke reaction by involvement of Et_3N–$Et_3N{\cdot}HX$ in several key SP proton transfer steps.

The National Science Foundation and the Cystic Fibrosis Foundation supported this research; the NMR spectrometers used were funded in part by a grant from NSF (CHE-9808183).

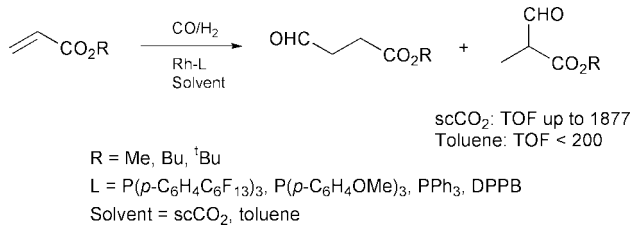
Received (in Cambridge, UK) 30th January 2001, Accepted 8th March 2001
First published as an Advance Article on the web 29th March 2001

Fast and regioselective hydroformylation of alkyl acrylates can readily be accomplished in supercritical CO_2 ($scCO_2$), which promotes the reaction probably *via* specific solvent–solute interactions.

The hydroformylation of acrylic esters produces bifunctional compounds, which can be converted into synthetically useful intermediates such as malonic acid and 1,4-dicarboxylic acid derivatives and butyrolactones. In the past three decades or so, a number of publications have appeared, directed towards effecting the reaction with acceptable rates and regioselectivities.[1–10] In this context, catalysts based on various rhodium-ligand combinations have been examined. However, in common organic solvents and regardless of the ligands that have been tested, the reaction is in general slow and high temperature and/or high pressure are often required.[1,6,7,9,10] For example, in the hydroformylation of ethyl acrylate in ethylbenzene, complete conversion, corresponding to an average turnover frequency (TOF) of 413 h^{-1}, of the olefin was only achieved in 5 h reaction time at 150 °C and *ca*. 100 bar syngas using $[RhCl(CO)_2]_2$ in the presence of bis(diphenylphosphino)butane (DPPB).[1] While milder reaction conditions are possible with phosphite[4] and phosphanobornadiene ligands,[2] the TOFs were very low. Much improved rates have recently been obtained when the reaction is run under organo-aquo biphasic conditions or when a 'supported aqueous phase' catalyst is used.[5,8] However, low solubilities of the less hydrophilic acrylates in water limit the applicability of the biphasic systems and, in the case of the latter, it was shown that even a slight alteration in the water content in the supported aqueous phase could sharply reduce the activity of the catalyst. We report herein that fast and selective hydroformylation of alkyl acrylates can readily be effected in $scCO_2$ in the presence of $[Rh(acac)(CO)_2]$ and the fluoroalkylated phosphine ligand P(*p*-$C_6H_4C_6F_{13})_3$ (Scheme 1).[11]

We first tested this ligand in the hydroformylation of butyl acrylate in toluene and compared the results obtained with three other ligands, PPh_3, DPPB and P(*p*-$C_6H_4OMe)_3$, of which the first two are frequently used and DPPB is one of the most effective ligands in liquid solvents.[1,5,7] The reaction was performed using a combination of $[Rh(acac)(CO)_2]$ and 10 equiv. of a phosphine ligand as catalyst precursor in an autoclave at 80 °C and 20 bar H_2–CO (1:1) with the initial olefin concentration being 0.28 M. All the reactions were run for 1 h and were homogeneous throughout. The results are summarized in Table 1. Consistent with previous findings, DPPB stands out as the most effective ligand in terms of the average TOF to aldehydes given in Table 1. With PPh_3 and the relatively electron-rich P(*p*-$C_6H_4OMe)_3$, the expected aldehydes could barely be detected. With the electron-deficient P(*p*-$C_6H_4C_6F_{13})_3$, a TOF of 85 was observed. Increasing the syngas pressure to 50 bar led to some increase in TOF to 122, which is still significantly lower than the value of 304 with DPPB. Judging from these values, it is clear that hydroformylation of acrylates in normal organic solvents by arylphosphines, including the most effective DPPB, will be of little practical value.



Scheme 1

Table 1 Hydroformylation of butyl acrylate by Rh-L in toluene[a]

L	Pressure/ bar	Conv. (%)[b]	Ald. (%)[c]	TOF/h^{-1}[d]
PPh_3	20	< 1		
P(*p*-$C_6H_4OMe)_3$	20	< 1		
P(*p*-$C_6H_4C_6F_{13})_3$	20	2.1	99.8	85
P(*p*-$C_6H_4C_6F_{13})_3$	50	2.7	99.8	122
DPPB	20	7.6	99.9	304

[a] Reactions were carried out at L–$[Rh(acac)(CO)_2]$ = 10, olefin–rhodium = 4000, olefin concentration = 0.28 mol dm^{-3}, 80 °C and indicated H_2–CO (1:1) pressure in 20 mL of toluene for 1 h, with product analysed by GC. [b] Conversion of the acrylates. [c] Selectivity to branched aldehydes. The linear aldehydes were not detected by GC. The hydrogenated product, propionates, accounts for the product balance. [d] Average turnover frequency: mole of aldehyde formed per mole of catalyst per hour.

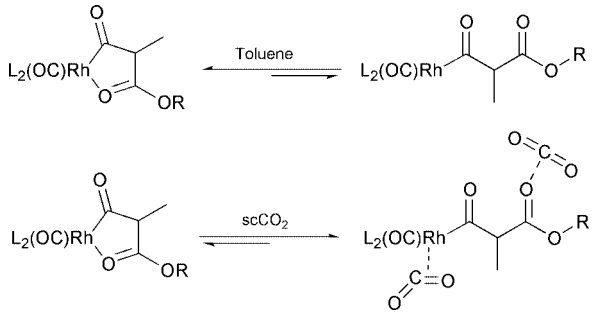
Having determined the activity of the Rh-P(*p*-$C_6H_4C_6F_{13})_3$ catalyst in toluene, we then applied the same catalyst to the hydroformylation of methyl, butyl and ^{t}butyl acrylates in $scCO_2$ (Scheme 1).† The reactions were carried out for 1 h and the detailed procedure has been described before.[11] Table 2 summarises the results obtained in $scCO_2$ and those in toluene under the same temperature, pressure and olefin concentrations. In all these reactions, the linear aldehydes could not be detected by GC, which is in line with the literature that the hydroformylation of acrylates usually affords branched aldehydes as the dominant product.[1–10] The ratio of the hydrogenated product, propionates, was somewhat higher in $scCO_2$ (*ca*. 2.5%) than in toluene (< 0.5%). However, of much more significant

Table 2 Hydroformylation of acrylates by Rh-P(*p*-$C_6H_4C_6F_{13})_3$ in $scCO_2$ and toluene[a]

Substrate	Solvent	[Olefin][b]	Conv. (%)[c]	Ald. (%)[d]	TOF/ h^{-1}[e]
Methyl acrylate	$scCO_2$	0.45	40.8	97.6	1593
Butyl acrylate	$scCO_2$	0.28	42.9	97.5	1671
^{t}Butyl acrylate	$scCO_2$	0.28	46.9	97.4	1827
Methyl acrylate	Toluene	0.45	2.3	99.6	92
Butyl acrylate	Toluene	0.28	2.1	99.8	84
^{t}Butyl acrylate	Toluene	0.28	4.8	99.6	191

[a] Reactions were carried out at P(*p*-$C_6H_4C_6F_{13})_3$–$[Rh(acac)(CO)_2]$ = 10, olefin–rhodium = 4000, 80 °C, 180 bar CO_2 and 20 bar H_2–CO (1:1) for 1 h. [b] Olefin concentration: mol dm^{-3}. [c] Conversion of the acrylates. [d] Selectivity to branched aldehydes. The linear aldehydes were not detected by GC. The hydrogenated product propionates accounts for the product balance. [e] Average turnover frequency.

DOI: 10.1039/b101043n



Scheme 2

interest is the observation that, in $scCO_2$, the average TOFs for the formation of aldehydes ranged from 1593 to 1827 h^{-1}, whereas in toluene the TOFs were less than 200 h^{-1}. In both solvents, the fastest rates were derived from the sterically most demanding ^{t}butyl acrylate. Thus, by simply changing the reaction medium from toluene to $scCO_2$, the TOF values increased *ca*. 10–20 fold. Such dramatic enhancement in reaction rates by $scCO_2$ has rarely been observed before,[11–14] although the high miscibility of various gases with CO_2 and its excellent transport properties have often been suggested to be impetus for fast reactions.[15] One of the best-known examples, where greatly improved rates were achieved, is the hydrogenation of CO_2 by a Ru-PMe_3 catalyst, the high rates being partly attributed to the high concentration of the gaseous reagents.[15] In the present study, the enhanced TOFs are less likely to be primarily due to a high concentration of syngas in $scCO_2$, since more than doubling the pressure for the hydroformylation of butyl acrylate in toluene led to a TOF of only 122 h^{-1} (Table 1), far less than that of 1671 h^{-1} obtained in $scCO_2$ at 20 bar.

A further demonstration of the rate enhancement aforesaid is the hydroformylation of a mixture of butyl acrylate and dec-1-ene in $scCO_2$. The reaction was run under identical conditions to those for butyl acrylate itself, except with the concentration of the olefin reduced by *ca*. half (0.12 M for both dec-1-ene and butyl acrylate). The TOFs observed for butyl acrylate and dec-1-ene were 1511 and 379 h^{-1}, respectively. This is remarkable, considering that in the absence of the acrylate the average TOF for dec-1-ene (0.22 M initial concentration) was 2794 h^{-1} under otherwise identical reaction conditions.[11] In a similar experiment in toluene, the TOF was found to be 56 for the acrylate and 24 h^{-1} for dec-1-ene, while in the absence of the acrylate the TOF for the latter olefin (0.28 M) rose to 901. Evidently, the Rh-P(*p*-$C_6H_4C_6F_{13})_3$ catalyst is considerably more chemoselective towards the less reactive acrylates, but it is only in $scCO_2$ where it becomes highly active as well.

The significant enhancement in hydroformylation rates for the acrylates in $scCO_2$ might be accounted for by specific solvent–solute interactions. The low rates observed in common organic solvents are generally believed to be a result of the formation of thermodynamically stable five or six-membered rings (Scheme 2, where only the intermediate leading to branched product is shown).[7,8] The rate determining step of the hydroformylation has therefore been suggested to be the dissociation of the chelated carbonyl species to give a coordinatively unsaturated intermediate that is active towards the oxidative addition of H_2.[8] We suggest that, in $scCO_2$, the equilibrium position is shifted in favour of the key unsaturated intermediate as a result of a carbonyl–CO_2 donor–acceptor interaction as shown in Scheme 2. Previous spectroscopic studies have already shown that carbonyl groups can act as Lewis bases and interact with CO_2 acting as a Lewis acid.[16] In addition, coordination of CO_2 to the rhodium atom of the unsaturated intermediate and other oxygen atoms is possible, which would further shift the equilibrium to the right.[17] A similar model involving H_2O and hydrogen bonding was earlier proposed to account for the increase in rates in the hydroformylation of acrylates in the presence of water.[5,8]

In summary, we have shown that the hydroformylation of alkyl acrylates, although sluggish in conventional organic solvents, can readily be effected in $scCO_2$. In such reactions, CO_2 acts not only as a solvent but may also function as an electron acceptor, interacting with and stabilizing key carbonyl intermediates and thus promoting the overall reaction. Such specific solvent–solute interactions have rarely been exploited in catalysis in $scCO_2$ but could provide a unique means for tuning chemical activity and selectivity in synthesis in $scCO_2$.

Received (in Cambridge, UK) 11th October 2000, Accepted 8th March 2001
First published as an Advance Article on the web 29th March 2001

A novel and simple one-step, solid-state reaction in the presence of a suitable surfactant has been developed to synthesize uniform copper oxide nanorods with average diameters of *ca.* 8 nm and lengths of up to 400 nm.

One-dimensional nanostructural materials are currently the focus of considerable interest. Many methods have been used for the preparation of nanorods or nanowires.[1–6] However, to our knowledge, complex process control, high reaction temperatures or long synthesis time may be required for these approaches. Here we report a novel and simple one-step, solid-state reaction in the presence of a suitable surfactant, polyethylene glycol (PEG) 400, for preparation of copper oxide nanorods. This method requires no complex apparatus and techniques. The process is carried out in air at room temperature and the synthetic time is very short.

Transition metal oxide-containing glasses are of interest due to their possible technological application in electrical and optical switching devices. Copper oxide is a p-type semiconductor and it is useful for the preparation of organic catalysts. Great attention has been devoted to metal–organic chemical vapor deposition (MOCVD) processes for the fabrication of copper oxides. Interest has been spurred on by the applications of these materials for the vapor phase deposition of high-T_c superconducting films.[7–10] Applications of copper oxides have recently been extended to gas sensors.[11–13]

The procedure employed by us for preparing copper oxide nanorods is as follows. In a typical synthesis, 5.045 g of $CuCl_2 \cdot 2H_2O$ and 3 g of NaOH were ground for 5 min each before mixing together, 6 ml of polyethylene glycol (PEG) 400 was then added to the mixture. After 30 min of grinding, the mixture was washed in an ultrasonic bath three times with distilled water and then with EtOH to remove the PEG. Finally, the product was dried in air at 60 °C for 3 h.

X-Ray powder diffraction (XRD) was carried out on a Rigaku D_{max} γ_A X-ray diffractometer with Cu-Kα radiation (λ = 0.154178 nm). Transmission electron microscopy (TEM) micrographs were taken using a JEM-200CX transmission electron microscope, with an accelerating voltage of 200 kV.

Fig. 1 shows the XRD pattern of a sample of the copper oxide nanorods prepared by the one-step, solid-state reaction in the presence of a suitable surfactant, PEG 400. Powder XRD peaks of the copper oxide are consistent with the data of the JCPDS file.[14] The peaks at 2θ values of 32.530, 35.408, 38.728, 45.200, 48.856, 53.525, 58.627, 60.266, 67.976, 74.940 and 81.273° correspond to the crystal planes of 110, 002, 111, 112, 202, 020, 202, 113, 220(312), 004, 313 of crystalline copper oxide, respectively.

The TEM image of the copper oxide sample of Fig. 1 is shown in Fig. 2, which reveals that the copper oxide powders consist of uniform nanorods. It can be seen that the nanorods have average diameters of *ca*. 8 nm and lengths of up to 400 nm. The formation of a rod shape of copper oxide is speculated to be due to the surfactant assemblage because PEG in water can form a chain structure.[15]

In summary, a novel and facile method has been developed to synthesize copper oxide nanorods. This relatively fast reaction gives nanorods or nanometric powders with potentially broad applications in the synthesis and in the shape control of nanometric powders.

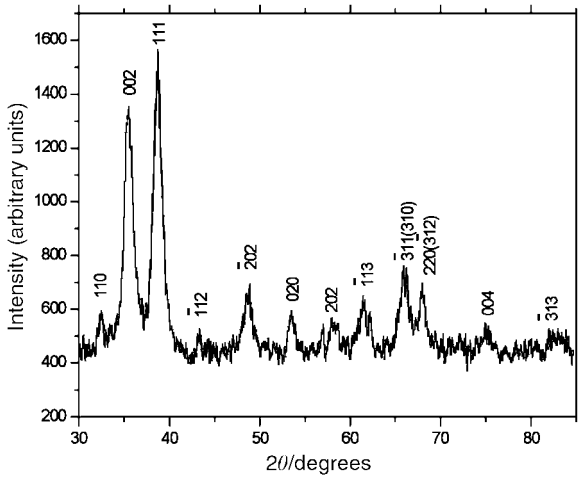

Fig. 1 XRD pattern of a copper oxide nanorod sample produced by a one-step, solid-state reaction in the presence of a suitable surfactant at room temperature.

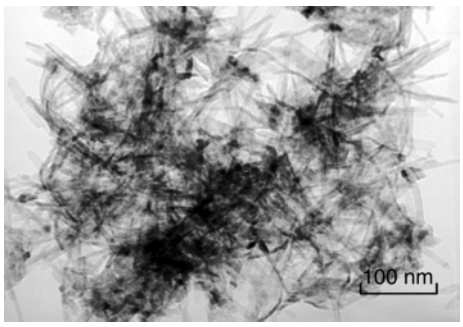

Fig. 2 TEM image of the copper oxide nanorod sample shown in Fig. 1.

Platinum(II) nicotinamide complexes as receptors for oxo-anions†

Chantelle R. Bondy,[a] Philip A. Gale*[b] and Stephen J. Loeb*[a]

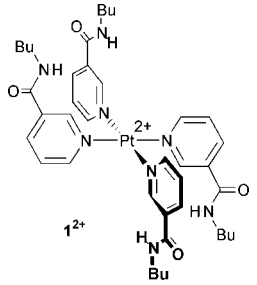
Received (in Cambridge, UK) 11th February 2001, Accepted 13th March 2001
First published as an Advance Article on the web 30th March 2001

The coordination of four *n*-butylnicotinamide ligands to a platinum(II) centre provides a facile method of organizing amide H-bond donors for anion binding; the PF_6^- complex is an effective receptor for a variety of oxo-anions.

The coordination of anionic guest species by hydrogen bond donating receptors is an area of supramolecular chemistry that continues to attract attention.[1] A large number of the anion receptors reported so far are 'built' upon organic scaffolds such as calixarenes.[2] However, the preparation of these types of receptors can often be synthetically challenging, a fact that prompted us to look for alternative means of arranging hydrogen bond donating groups. It occurred to us that some easy to prepare metal ligand complexes could be exploited as simple pieces of inorganic molecular scaffolding.[3] We initially chose to study square planar platinum(II) complexes due to their relative inertness towards ligand substitution and nicotinamide ligands due to their ease of synthesis. The homoleptic $[PtL_4]^{2+}$ complex cation is an ideal candidate to act as an anion receptor as it provides both hydrogen bond donating amides[4] and an electrostatic contribution from the metal centre. As a first test of this strategy, the complex $[Pt(L)_4]^{2+}$ (L = *n*-butylnicotinamide), **1**, has been synthesised as the PF_6^- salt and shown to act



as a polydentate anion receptor both in solution and in the solid state.†

The *n*-butylnicotinamide ligand was prepared from the nicotinamide ethylester and *n*-butylamine by standard methods.[5] The Pt^{II} complex was prepared by reacting 1 equiv. of $PtCl_2(EtCN)_2$ with 4 equiv. of ligand and 2 equiv. of $AgPF_6$ in MeCN solution.[6] After filtration to remove AgCl and evaporation of the solvent, crude $\mathbf{1}[PF_6]_2$ was recrystallized from $MeCN/Et_2O$ and isolated in 87% yield.‡ The material produced in this fashion was determined to be analytically pure and subsequently used in all anion receptor studies. Recrystallization of $\mathbf{1}[PF_6]_2$ from a CH_2Cl_2/Pr^i_2O solvent mixture produced crystals of $\mathbf{1}[PF_6]_2{\cdot}2CH_2Cl_2$ suitable for an X-ray structure determination.§

Fig. 1 shows a ball and stick representation of the X-ray structure of $\mathbf{1}[PF_6]_2{\cdot}2CH_2Cl_2$. By drawing an analogy to calix[4]arene nomenclature, there are four conformations (cone, partial cone, 1,3- and 1,2-alternate) possible for **1** due to facile

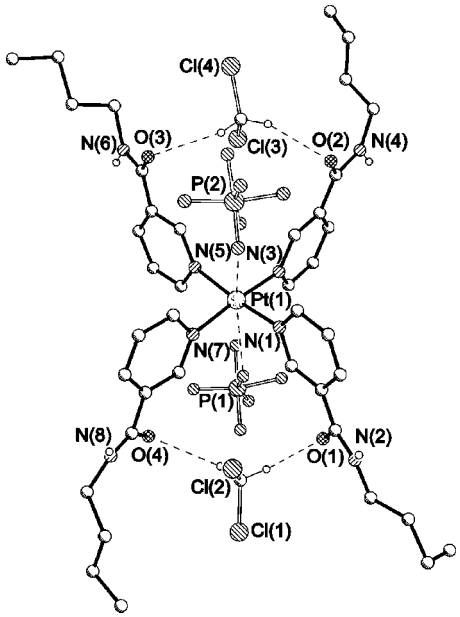


Fig. 1 X-Ray structure of $\mathbf{1}[PF_6]_2{\cdot}2CH_2Cl_2$ showing the basic numbering scheme. C–H···O distances (Å) and angles (°): H(50A)···O(4) 2.40, C(50)–H(50A)···O(4) 113; H(50B)···O(1) 2.43, C(50)–H(50B)···O(1) 118; H(60A)···O(2) 2.42, C(60)–H(60A)···O(2) 115; H(60B)···O(3) 2.47, C(60)–H(60B)···O(3) 125. Pt···F distances (Å) and angles (°): Pt(1)···F(1) 3.42, Pt(1)···F(1)–P(1) 147; Pt(1)···F(8) 3.28, Pt(1)···F(1)–P(1) 155.

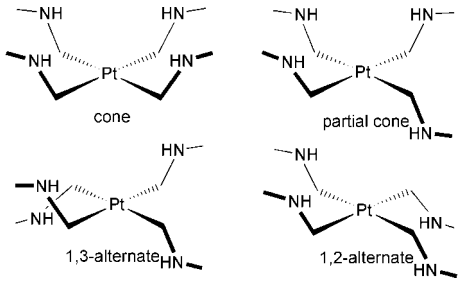

rotation about the Pt–N bonds.[7] In the solid state, the four nicotinamide ligands adopt a centrosymmetric 1,2-alternate conformation which places two amide hydrogen bonding sites in a *cis* orientation on each side of the metal square plane. Interestingly, the amide NH groups do not interact with the PF_6^- anions which are situated above and below the Pt^{II} metal centre presumably to maximize electrostatic interactions and cation–anion crystal packing. In fact, it is the amide C=O groups which are involved in hydrogen bonding to the methylene hydrogens of the CH_2Cl_2 solvent molecules. It was therefore assumed that (i) the PF_6^- anions would not be competitive for the binding of the oxo-anions used in this study[8] and (ii) a 2:1 anion:host ratio is certainly possible and may predominate.

The ability of $\mathbf{1}[PF_6]_2$ to function as a receptor for oxo-anions in solution was determined by measuring association constants, K_a, in various solvents by ^1H NMR spectroscopic titration

† Electronic supplementary information (ESI) available: titration plots for $[PtL_4][PF_6]_2$ with various oxo-anions. See: http://www.rsc.org/suppdata/cc/b1/b101440o/

Table 1 Association constants, K_a, for $\mathbf{1}^{2+}$ with various oxo-anions

Anion[a]	Solvent	K_a/M^{-1}
$CF_3SO_3^-$	CD_3CN	129
ReO_4^-	CD_3CN	150
NO_3^-	CD_3CN	K_1 = 562, K_2 = 132
HSO_4^-	CD_3CN/DMSO-d_6 3:1 *v/v*	149
$CH_3CO_2^-$	CD_3CN/DMSO-d_6 3:1 *v/v*	Precipitate[b]
$H_2PO_4^-$	CD_3CN/DMSO-d_6 1:9 *v/v*	Precipitate[b]
$CH_3CO_2^-$	CD_3CN/DMSO-d_6 1:9 *v/v*	K_1 = 230, K_2 = 491

[a] Anion added as the tetrabutylammonium salt. [b] Precipitation occurred during the titration. The precipitate re-dissolved upon further addition of anions, however the titration profile could not be fitted satisfactorily (see ESI†).

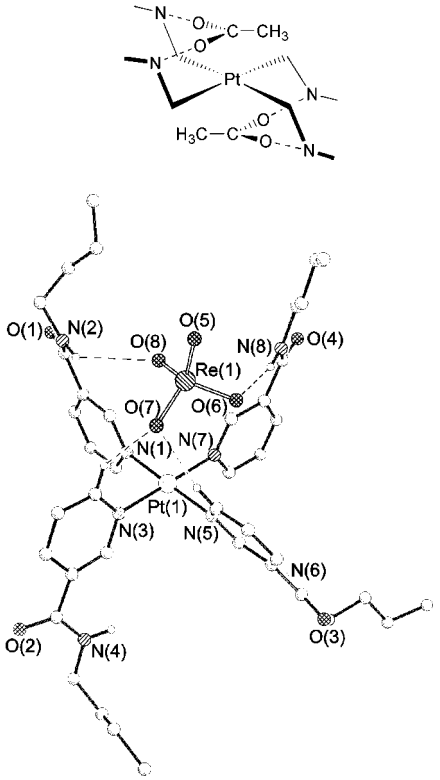

Fig. 2 X-Ray structure of the $[\mathbf{1}(ReO_4)]^+$ cation showing the basic numbering scheme. N–H···O distances (Å) and angles (°): H(2A)···O(8) 2.79, N(2)–H(2A)···O(8) 137; H(8A)···O(6) 2.13, N(8)–H(8A)···O(6) 168; H(11A)···O(7) 2.50, C(11)–H(11A)···O(7) 142; H(21A)···O(7) 2.37, C(21)–H(21A)···O(7) 171. Pt···O distances (Å) and angles (°): Pt(1)···O(6) 4.20, Pt(1)···O(6)–Re(1) 86; Pt(1)···O(7) 4.11, Pt(1)···O(7)–Re(1) 89; Pt(1)···O(8) 4.16, Pt(1)···O(8)–Re(1) 87. Pt(1)···Re(1) 4.42.

techniques. The results reported in Table 1 for $CF_3SO_3^-$, ReO_4^-, NO_3^-, HSO_4^-, $H_2PO_4^-$ and $CH_3CO_2^-$, show that receptor **1** is capable of acting as an effective host for oxo-anions. There appears a certain amount of selectivity towards planar bidentate anions such as NO_3^- and $CH_3CO_2^-$ and these are bound in a 1:2 receptor:anion ratio. This can be attributed to a shape specific match between two *cis* amido groups and a bidentate anion. In particular, the binding of acetate ion is relatively strong even in the very polar 9:1 DMSO/MeCN mixture. The fact that K_2 is greater than K_1 infers that binding of the first anion has a positive allosteric effect, which favours binding of the second.

The tetrahedral or pseudo-tetrahedral oxo-anions ReO_4^-, $CF_3SO_3^-$ and HSO_4^- are more weakly bound and solution evidence supports a simpler 1:1 receptor:anion ratio or at least a situation in which K_1 can be reliably obtained but K_2 is too small to be measurable. The 1:1 host:anion binding observed for the weakly coordinated ReO_4^-, $CF_3SO_3^-$ and HSO_4^- anions is supported by the X-ray structure§ of $\mathbf{1}[ReO_4]_2$ shown in Fig. 2. In particular, it can be seen that in order to try and maximise hydrogen bonding to a single ReO_4^- anion with 3-fold symmetry the relatively acidic nicotinamide CH's from the ligands on the opposite side of the square plane contribute to binding the anion. To do this, the complex must distort significantly from centrosymmetry, a fact that presumably disfavours the interaction with a second anion resulting in the observation of 1:1 binding in solution.

Although solubility problems and thus the need to vary solvent systems prohibited a direct comparison of all the available anions, there is sufficient evidence to suggest that this new type of anion receptor is worthy of further study. The results presented herein suggest that future re-design of this type of host might produce anion receptors with high selectivity and binding strength based on a simple inorganic scaffold.

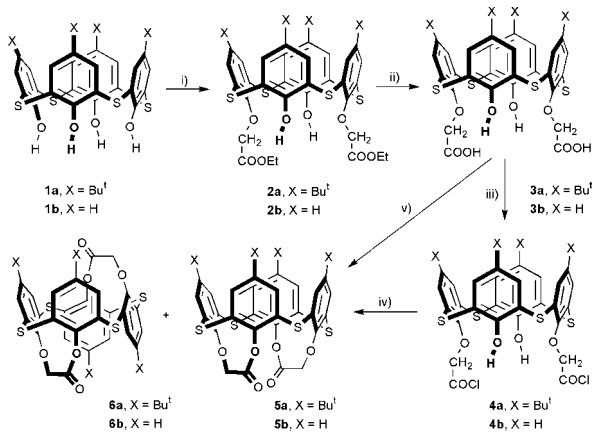
First published as an Advance Article on the web 30th March 2001

Distal bis(carboxymethyloxy) derivatives of thiacalix[4]arene were found to undergo an unprecedented intramolecular cyclisation to yield lactone compounds 5a or 5b, the structure of lactones possessing nine-membered ring was proved by X-ray crystallography; inherent chirality of new compounds was demonstrated using separation on a chiral HPLC column.

The well-established chemistry of calix[*n*]arene family[1,2] was recently 'rejuvenated' by the discovery of so called thiacalix-[4]arenes.[3] The presence of sulfur atoms instead of methylene groups makes thiacalix[4]arenes **1a** and **1b** very interesting molecules with some novel features compared with the chemistry of 'classical' calixarenes (Scheme 1). Thus, the preparation of appropriate tetrasulfoxide[4] or tetrasulfone[4a,5] derivatives proceed very easily by direct oxidation of sulfur. Unfortunately, the employment of thiacalix[4]arenes as building blocks or molecular scaffolds in supramolecular chemistry is still rather restricted by almost unknown chemistry of these compounds and the lack of general derivatization methods. As we found recently, simple tetraalkylated products[6] exhibit interesting conformational behaviour[7] that differ to a high degree from that of 'classical' calix[4]arene derivatives. In this paper we report on another example of different chemical behaviour of thiacalix[4]arene derivatives.

During our attempts at the preparation of diamides by the reaction of acyl chlorides **4a** or **4b** with various aromatic amines we isolated substantial amounts of unknown byproduct. Surprisingly, as we found, the same type of compounds can be prepared in high yields using the reaction of **4a** or **4b** in the presence of triethylamine in tetrahydrofuran. Thus, the stirring of **4a** (prepared from **3a** by the reaction with oxalyl chloride) with 6 eq. of Et_3N in THF at rt leads to the main product **5a** in 69% yield.[8] The ^{1}H NMR spectrum of this compound (see ESI†) exhibits two singlets of Bu^t groups (0.88 and 1.40 ppm) and four doublets with characteristic meta coupling (J ~ 2.2 to 2.7 Hz) in the aromatic region. Together with two doublets possessing typical geminal coupling constants (J ~ 12 Hz) at 4.63 and 5.52 ppm it reflects C_2 symmetry of the whole molecule. This was confirmed also by ^{13}C NMR where the expected 18 signals were recognised. The above-mentioned findings can be explained by structure **5a** formed by the intramolecular reaction of acyl chloride with the neighbouring hydroxy group.



Scheme 1 i) $BrCH_2COOEt$, acetone–K_2CO_3; ii) KOH, H_2O–EtOH; iii) $(COCl)_2$, CH_2Cl_2; iv) NEt_3, CH_2Cl_2; v) P_2O_5, CH_2Cl_2.

As we found, the same product can be prepared directly from diacid **3a** by reaction with a dehydration agent. Thus heating of **3a** with acetanhydride led to **5a** in 50% yield while stirring the same acid with P_2O_5 in DCM solution gave **5a** in 66% yield, in both cases accompanied by 10% of byproduct **6a**. The splitting pattern and the number of signals in the ^{1}H NMR spectrum of **6a** is identical with that of **5a**. On the other hand, there is a dramatic change in the chemical shifts of methylene groups where corresponding protons are shifted up-field by 1.5 and 1.1 ppm respectively if compared with **5a**. This indicates a strong anisotropic shielding effect of aromatic units in good agreement with the proposed *1,2-alternate* conformation. Albeit all our attempts to grow suitable crystals for X-ray analysis have failed, molecular modelling (MOPAC) confirmed the close proximity of C–H bonds and the plane of inverted aromatic units (see ESI). Interestingly, the corresponding derivative **6b** has not been observed in similar reactions of **3b**.

Bis(carboxymethyloxy) derivatives **3a** and **3b** adopt a *cone* conformation both in the solution (proved by NMR) and in the solid state (X-ray crystallography). On the other hand, the formation of the *1,2-alternate* product **6a** requires a previous rotation of the CH_2COOH substituent through the cavity which was never observed in the chemistry of 'classical' calixarenes. As we found very recently,[9] in contrast to 'classical' calix[4]arene the propyl groups are not bulky enough to fully prevent such a rotation in the thiacalixarene series. Because the steric requirements of the carboxymethyl groups are apparently comparable or even lower than those of propyl, anticipated rotation of this group seems to be feasible.

The above described behaviour, the formation of lactones **5** or **6**, was observed only in the case of thiacalix[4]arene derivatives. The same reactions carried out with 'classical' calix[4]arene never gave similar cyclic products, probably due to the better preorganisation of thiacalixarene moiety for intramolecular cyclisation (bigger cavity).

The structure of **5a** possessing nine-membered lactone rings was unequivocally demonstrated using a single crystal X-ray diffraction[10] (suitable single crystals were obtained by slow evaporation of EtOAc–CH_2Cl_2 solution). The presence of two bridges induces the distortion of the *cone* conformation and impresses an effective C_2 symmetry to the whole structure (Fig. 1). Four sulfur atoms are placed in the corners of a lozenge with shorter (S2–S4) and longer (S1–S3) diagonals being 6.9 and 8.3 Å, respectively. Two opposite aromatic rings are tilted outwards while the other two units are almost coplanar thus closing the cavity for potential inclusion of solvent molecule. As follows

DOI: 10.1039/b100906k

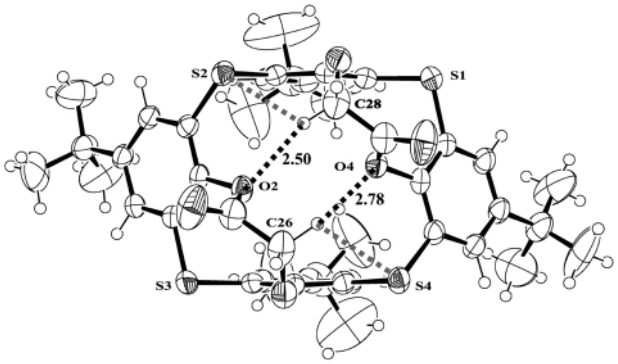


Fig. 1 X-ray structure (ORTEP drawing) of **5a** with indicated intramolecular hydrogen bonds.

from Fig. 1, the structure is supported by intramolecular hydrogen bonds (HBs) between lactone methylene hydrogens (H261, H282) and neighbour oxygen atoms O2, O4 with possible contribution of sulfur bridges S2, S4 (all distances shorter than 3 Å).

A very interesting feature of the derivative **5a** is represented by its molecular packing. The thiacalix[4]arene moieties are arranged along the *y* axis in such a way that they create an infinite network of molecules held together by the non-classical intermolecular hydrogen bonds. Every carbonyl oxygen is in a close contact with at least two hydrogen atoms of *tert*-butyl groups from a neighbouring thiacalix[4]arene unit (see ESI) with distances of 2.49 and 2.84 Å (two other hydrogens are slightly further than 3.0 Å). To the best of our knowledge such an arrangement has never been described in the calix[4]arene chemistry (Cambridge Structural Database).

Lactone **5b** also possesses very unusual crystal packing.[11] As is obvious from Fig. 2, derivative **5b** creates a kind of dimer with a net of close contacts between carbonyl oxygen and neighbour CH_2 groups of lactone functions (hydrogen bonds with the H···O=C distances 2.64–2.85 Å). These dimers are then interconnected by several additional HBs between carbonyl oxygens and aromatic hydrogens from neighbouring calixarene units (Ar–H···O=C distances ~2.70 Å). The network of molecules is held together by the intermolecular π–π interactions between the aromatic rings (upper rims) of thiacalix[4]arenes (Fig. 2). The average distance of the two coplanar rings (3.5 Å) is very similar to that in other thiacalixarene derivatives (3.41 Å) as described very recently.[14]

The inherent chirality of the new compounds was demonstrated using HPLC chromatography on a chiral column (*R*,*R*)-Wheelk-O 1, which is designed for the separation of systems possessing π–π and/or HB interactions. The column proved to be highly suitable for separating lactones **5a** and **5b**, especially because of the possibility of using chlorinated solvents which is important for the solubilization of the compounds. Thus, derivative **5b** exhibits base-line separation with retention times 24.9 and 26.5 min for appropriate enantiomers (see ESI).

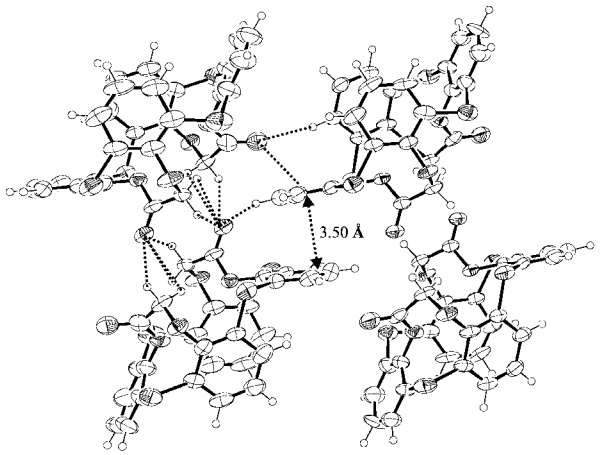

Fig. 2 Crystal packing of **5b** demonstrating intermolecular hydrogen bonding network, all indicated contacts are shorter than 3.00 Å.

In conclusion, bis(carboxymethyloxy) derivatives of thiacalix[4]arene were found to undergo an unprecedented intramolecular cyclisation to yield nine-membered lactone compounds **5a** or **5b**. The X-ray diffraction of these compounds revealed an interesting molecular packing, held together by the combination of π–π and HB interactions. The inherent chirality of the new compounds was demonstrated through separation on a chiral HPLC column.

The synthesis and both spectroscopic and electrochemical studies of a bis-porphyrinic tweezer are reported, as well as the insertion of Lewis base guests into the host bis-porphyrinic cavity, monitored through physico-chemical characteristics.

In natural photosynthetic systems, the energy contained in a single photon is transferred in a very short time and with minimal loss from the point where it is absorbed to where it is needed.[1]

Increased efforts have been developed towards understanding this great efficiency and many multi-porphyrinic devices have been synthesized as potential models of the natural system.[2] One possible approach for the preparation of such devices is to force the cofacial orientation of the porphyrins *via* the use of a rigid spacer.[3] With the aim of identifying an optimized spacer for the construction of photonic and electronic wires, we first focused on the study of a cofacial porphyrin dimer.[4] We now report how the insertion of a pyrazine molecule into the cavity of a Zn(II) porphyrin dimer through host–guest interactions causes an electronic coupling between the two porphyrin chromophores.

A 1,8-diethynylanthracenic spacer has been chosen for its expected ability to hold two chromophores in a cofacial orientation and for synthetic reasons as well. Indeed, the use of a Sonogashira coupling reaction between the diacetylene **1** and the iodoporphyrin **2**[5] allowed the efficient synthesis of dimer **3a** in four steps starting from commercially available compounds (Fig. 1).[6] The free-base dimer **3b** was obtained in 89% yield by demetallation of the two porphyrins under acidic conditions.[7]

UV-visible spectra of the reference porphyrins, the Zn(II) and free-base 5,10,15,20-tetra(3,5-di-*tert*-butylphenyl)porphyrins **4a**–**b**, and both dimers **3a** and **3b** were recorded in CH_2Cl_2 solutions. Only a small blue shift (2 nm for free-base compounds and 3 nm for metallated porphyrins) as well as a tiny broadening of the Soret band could be noticed from the monomer to the dimer, indicating that almost no coupling exists between the two porphyrins.

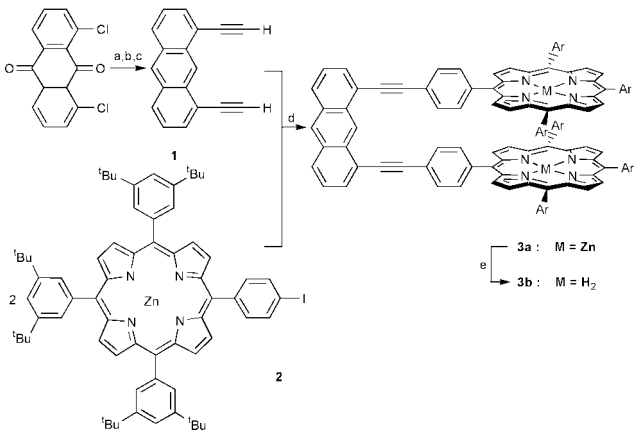

Fig. 1 (a) Zn, NH_3aq., then HCl, *i*-PrOH, 36%; (b) TMSCCMgBr, PPh_3, $Ni(acac)_2$, THF, reflux, 75%; (c)K_2CO_3, THF–CH_3OH 85:15, 61%; (d) $Pd(PPh_3)_2Cl_2$, CuI, NEt_3, 63%; (e) TFA in CH_2Cl_2, 89%. Ar = 3,5-di-*tert*-butylphenyl.

Fluorescence measurements were carried out in CH_2Cl_2 on both dimers **3a**–**b**, and also on the spacer **1** and on the reference porphyrins **4a**–**b**. Upon almost selective excitation of the anthracene moiety at 267 nm in the free-base dimer **3b**, only the fluorescence of the two porphyrins could be detected, indicating a total quenching of the emission from the anthracenic moiety. The assumption of an energy transfer from anthracene to the adjacent porphyrins was corroborated by the registration of the excitation spectrum of the dimer **3b**, which matches the absorption of the multicomponent system. A similar energy transfer from anthracene towards the adjacent chromophores was also observed upon irradiation of the Zn(II) dimer **3a** but the quantum yield was smaller and the fluorescence of the anthracenic sub-unit still remains the main deactivation pathway.

We investigated also the possible generation of host–guest complexes between the Zn(II) bis-porphyrin **3a** and small bidentate ligands bearing two nitrogen atoms.[4] Pyrazine and DABCO (1,4-diazabicyclo[2.2.2]octane) were chosen as first examples because of their fairly different p*K*a values (respectively 0.6 and 3). The coordination was monitored by ^{1}H NMR and UV-visible absorption spectroscopies in order to determine, in particular, the stoichiometry of the complexes, and the effects of such coordination on the characteristics of the porphyrin dimer.

The complexation was first studied by ^{1}H NMR (300 MHz) titration of dimer **3a** with pyrazine in $CDCl_3$. Upon addition of increasing amounts of pyrazine to a 2.10^{-3} M solution of porphyrin dimer **3a**, changes in the chemical shifts were observed up to a concentration of pyrazine equal to one equiv. of **3a** and no further changes beyond. This strongly suggests that a 1:1 complex was created between pyrazine and porphyrin dimer **3a**. Further indications on this complexation were obtained from UV-visible spectrophotometric titrations of a 2.10^{-5} M solution of dimer **3a** in CH_2Cl_2 with pyrazine (Fig. 2): such a titration of **3a** with pyrazine resulted in significant red-shift of the Soret and Q bands in the porphyrins,[8] and the titration curves obtained from absorption changes at 562 nm (Q band) exhibited a sharp saturation beyond the concentrations ratio 1:1 for pyrazine–**3a**. The titration data and the observed isosbestic points clearly indicated the existence of an equilibrium between two defined species, thus leading to the conclusion that a 1:1 complex was formed between dimer **3a** and pyrazine, with an association constant of $10^{5.6}$ M^{-1}.[9] In contrast, there was no experimental evidence of any appreciable complex formation between the reference porphyrin **4a** and pyrazine at such low concentrations by either UV-visible or ^{1}H NMR spectroscopies. These results clearly indicated that the pyrazine molecule was inserted into the cavity of the porphyrin dimer **3a**, yielding a 1:1 host–guest complex.

Titration of **3a** with DABCO and the absence of complexation between the latter and the reference porphyrin **4a** until a

DOI: 10.1039/b100423i

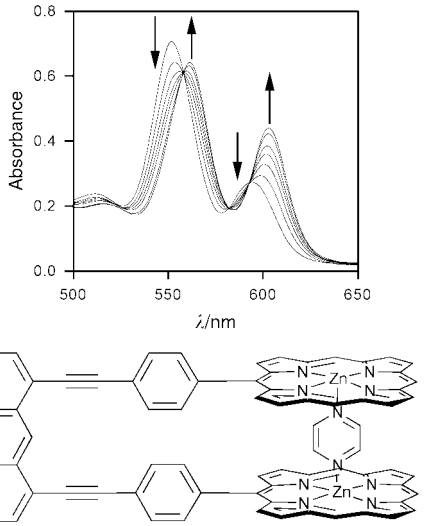

Fig. 2 UV-vis spectroscopic titration of **3a** with pyrazine in CH_2Cl_2 at rt. Spectral change of **3a** on addition of pyrazine at rt: [**3a**] $= 2.10^{-5}$ M, concentrations ratio = [pyrazine]:[**3a**] = 0; 0.2, 0.4, 0.6, 0.8, 1, 2. 3,5-Di-*tert*-butylphenyl substituents on the porphyrins have been omitted for clarity.

concentrations ratio of DABCO–**4a** = 10:1, produced similar conclusions as above with pyrazine. A 1:1 host–guest complex was created by insertion of one DABCO molecule into the cavity of each porphyrin dimer **3a**, with an association constant of 10^7 M^{-1}.[9]

Electrochemical studies were carried out on a glassy carbon working electrode in CH_2Cl_2 + 0.1 M Bu_4NPF_6. Cyclic voltammetry exhibited, for the porphyrin dimer **3a**, two reversible oxidation steps as well as a third, irreversible oxidation and three reversible reduction steps at respectively −2.30 (2e$^-$), −2.10 (1 e$^-$), −1.86 (2 e$^-$), +0.32 (2 e$^-$), +0.64 (2 e$^-$) and +0.95 V *vs.* Fc^+/Fc. Assignments of the different steps were made by comparison with the redox pattern of the building blocks, namely anthracene **1** and porphyrin **4a**, whose redox characteristics are summarised in Table 1.

Analysis of the electrochemical results revealed that the reversible one electron reduction of **3a** at −2.10 V and the irreversible oxidation at +0.95 V *vs.* Fc^+/Fc occur on the anthracene linker. The remaining four electron transfers each involve two one-electron reversible transfers occurring on the two porphyrin units. The peak shape and characteristics of the cyclic voltammograms indicated that the two porphyrins behave in **3a** as independent redox centers as expected from the large ring–ring distance (*ca.* 5.8 Å, according to molecular modelling). Such a distance makes unlikely any interaction between the two porphyrin rings.

In the presence of increasing amounts of pyrazine, the cyclic voltammograms of **3a** were modified up to a pyrazine–**3a** ratio of 1, in agreement with the UV-visible titrations. The resulting complex gave well resolved cyclic voltammograms where the first oxidation and the first reduction steps each became split into two distinct one-electron reversible steps at respectively −1.87 and −1.95 V *vs.* Fc^+/Fc and +0.28 and +0.40 V vs. Fc^+/Fc.[10] Such a behavior is characteristic of a porphyrin–porphyrin interaction. This experimental observation unambiguously indicated that it is possible to modify the electron transfer pattern of the dimer **3a** by host–guest interactions, as documented for instance in the present paper, by intercalating one pyrazine molecule into the cavity of the bis-porphyrinic tweezer **3a**. Both spectroscopic and electrochemical studies on the complexation of either pyrazine or DABCO Lewis bases by the porphyrin dimer **3a** revealed that no further spectral or voltamperogram changes occurred beyond a concentrations ratio Lewis base–**3a** = 1:1.

Table 1 Redox potentials in CH_2Cl_2 + 0.1 M Bu_4NPF_6 obtained by cyclic voltammetry on a glassy carbon working electrode. All potentials are given *vs.* ferrocene used as internal standard. Pyrazine is not electroactive in the available potential range

Species	Reduction *E* (V *vs.* Fc^+/Fc)				Oxidation *E* (V *vs.* Fc^+/Fc)		
1	−2.08 (1 e$^-$)						+0.97 (irrev.)
4a	−2.25 (1 e$^-$)		−1.85 (1 e$^-$)	+0.35 (1 e$^-$)		+0.67 (1 e$^-$)	
3a	−2.30 (2 e$^-$)	−2.10 (1 e$^-$)	−1.86 (2 e$^-$)	+0.32 (2 e$^-$)		+0.64 (2 e$^-$)	+0.96 (irrev.)
3a + **pyrazine**	−2.07 (1 e$^-$)	−1.95 (1 e$^-$)	−1.87 (1 e$^-$)	+0.28 (1 e$^-$)	+0.40 (1 e$^-$)	+0.75 (2 e$^-$)	+0.95 (irrev.)

The above results clearly indicated that each bidentate Lewis base (pyrazine and DABCO) was inserted into the cavity of the porphyrin dimer **3a**, generating a 1:1 host–guest complex. The enhanced stability observed in the complexation of the bidentate bases by the dimer **3a** (if compared with the complexation of the same bases by the reference porphryin **4a**) may be ascribed to the preorganization of the Zn(II) bis-porphyrin **3a**. The spectrometric and electrochemical results revealed that the 1:1 host–guest complex generated between **3a** and the pyrazine molecule enabled the two porphyrins to undergo an electronic coupling. Such changes in the spectroscopic and electrochemical properties of cofacial porphyrin dimers by host–guest interactions pave the way towards self-coordinated molecular systems with predictable spectral and redox characteristics. Work is in progress on this subject.

Enantioselective synthesis of bicyclic compounds *via* catalytic 1,4-addition-ring closing metathesis†

Robert Naasz, Leggy A. Arnold, Adriaan J. Minnaard and Ben L. Feringa*

Department of Organic and Molecular Inorganic Chemistry, Stratingh Institute, University of Groningen, Nijenborgh 4, NL-9747 AG Groningen, The Netherlands. E-mail: Feringa@chem.rug.nl; Fax: +(50)3634296

Received (in Cambridge, UK) 8th January 2001, Accepted 8th March 2001
First published as an Advance Article on the web 30th March 2001

A novel three step asymmetric annulation procedure comprises a tandem catalytic enantioselective 1,4-addition-allylic substitution, Grignard addition and ring closing metathesis (RCM) sequence to provide [6,6], [7,6], [8,6] and [6,7] bicyclic products with ee's of 93–97% in which the size of both rings can easily be varied independent of each other.

Novel routes to carbobicyclic compounds in enantiomerically pure form continue to offer a synthetic challenge since numerous products including terpenes and steroids show this structural feature. A classical example is found in the synthesis of (±)-D-homo-19-nortestosterone starting from the readily available Wieland–Miescher ketone for which an asymmetric synthesis proceeds *via* the Hajos–Parrish version of the Robinson annulation.[1,2] In the pursuit of novel catalytic asymmetric annulation strategies we focus on the construction of enantiomerically pure carbobicyclic products with various ring sizes.[3]

Since the pioneering work by the groups of Grubbs and Schrock, ring closing metathesis (RCM) has become a powerful tool for the synthesis of a variety of cyclic structures.[4] Especially for medium sized and macrocyclic ring systems, which are difficult or even impossible to make by other methods, RCM proved to be highly valuable.[5] As a result of the remarkable tolerance of the Grubbs catalyst towards various functional groups, RCM is increasingly applied in natural product synthesis.[6]

We envisioned that by making use of a combination of RCM and the copper–phosphoramidite based catalytic enantioselective 1,4-addition developed in our laboratories, a variety of enantiomerically pure bicyclic products would become readily accessible. In these bicyclic products both ring sizes can easily be varied, independent of each other. The following considerations were made: (i) cyclic enones with different ring sizes and substituents can be employed in the catalytic 1,4-addition with enantioselectivities generally exceeding 96% in the products. These products can subsequently act as templates onto which a second ring can be annulated.[7] (ii) The use of RCM for this annulation would make different ring sizes in the second ring possible.[8]

To examine the viability of this approach we synthesized 2-allyl-3-alkylcycloalkanones **2a–f** by a tandem 1,4-addition-allylic substitution reaction.[3,9]

As is shown in Scheme 1 the zinc enolate resulting from the catalytic 1,4-addition of dialkylzinc reagent to cycloalkenones in the presence of phosphoramidite ligand (*S*,*R*,*R*)-**3** (1 mol%) and $Cu(OTf)_2$ (0.5 mol%) was trapped stereo- and regioselectively by the Pd–allyl complex *in situ* generated from allyl acetate and a catalytic amount of $Pd(PPh_3)_4$, giving disubstituted cycloalkanones **2a–f** in good yields and with ee's ranging from 93 to 97% (Table 1). Furthermore a *trans–cis* ratio of 9 : 1 or higher is observed in all cases except for **2e** (entry 5).[10] In the case of **2b** and **2d** complete diastereoselectivity towards the *trans* isomer is found.

[a] Isolated yield as a mixture of diastereomers. [b] Determined by chiral GC (Chiraldex G-TA). [c] Not determined. [d] Isolated yield of all-*trans* isomer after column chromatography. [e] Determined by chiral HPLC after conversion into the *p*-nitrobenzoate ester. [f] Only a small amount (< 10%) of *cis*-fused **6g** was detected by GC.

of the Grignard reagents to **2a**–**f** in all cases and the major isomer results from the attack of the Grignard reagent *trans* to the allyl group leading to the all-*trans* isomer as the major product (Scheme 2). Addition of allylmagnesium chloride (*m* = 1, entry 1) to a 90 : 10 *trans–cis* mixture of **2a** yields three out of four possible diastereomers of **4a** in a ratio of 74:16:10 as judged by GC. This result is explained as follows: addition of the Grignard reagent to the *trans* compound (2*R*,3*S*)-**2a** proceeds preferably *trans* to the allyl group but not with complete selectivity accounting for 74% (1*R*,2*R*,3*S*)-1,2-diallyl-3-ethylcyclohexanol (**4a**) and 16% (1*S*,2*R*,3*S*)-**4a**. The relative configuration of the major isomer was determined by COSY, HSQC and NOESY NMR experiments on the *p*-nitrobenzoate ester of **6a**.† Addition to the minor *cis* compound (2*S*,3*S*)-**2a** accounts for the 10% of another isomer of **4a**, most probably (1*S*,2*S*,3*S*)-**4a**.

In the case of *trans*-**2b** the ratio of *trans* and *cis* addition is 80:20 and pure *trans*-**4b** (68%) could be isolated by column chromatography. The addition to *trans*-**2c** proceeds with a moderate selectivity giving a *trans*:*cis* ratio of 63 : 37. Addition of butenylmagnesium bromide (*m* = 2) to a 9 : 1 *trans–cis* mixture of **2a** in THF at 0 °C required transmetallation to the organocerium reagent to prevent enolization and to give complete conversion to **4h** as a mixture of 3 isomers (87 : 12 : 1) with (1*R*,2*R*,3*S*)-**4h** as the major product (entry 8).[11]

All dienes **4a**–**h** readily undergo ring closure in benzene in the presence of 7.5 mol% of Grubbs catalyst **5**, except for **4g**. In the latter case formation of only a small amount of **6g** was observed (entry 7). GC analysis revealed that only the *cis* isomer of **4g** had been converted. The *trans*-fused 5,6-ring system is not formed, most probably due to the strain in such a system.[12] Formation of a six membered ring (entries 1–6) proceeded well in all cases as 100% conversion was observed, indicating that both *cis*- and *trans*-fused ring systems are readily formed. Isomerically pure *trans*-diene **4b** provided the 7,6-bicyclic product in 100% isolated yield. In all other cases the major isomer of the resulting carbobicyclic products from this annulation protocol was isolated in moderate to good yield by simple chromatographic procedures with ee's ranging from 93 to 97%. For example, (1*S*,9*R*,9a*R*)-**6a** could be isolated in 60% yield. Annulation of a seven membered ring by RCM was also successful as (1*S*,4a*R*,9a*R*)-**6h** with an ee of 96% was isolated in 65% yield (entry 8).

In conclusion, new methodology for the synthesis of enantiomerically pure carbobicyclic compounds has been developed, based on an enantioselective tandem 1,4-addition–allylic substitution, Grignard addition and RCM three step sequence. In contrast to most methodologies for asymmetric annulations, which are restricted to specific ring sizes, the method presented here gives high enantioselectivities for the construction of a variety of bicyclic structures. Products with [6,6], [7,6], [8,6] and [6,7] carbobicyclic skeletons and different alkyl substituents have been prepared with ee's ranging from 93–97%.

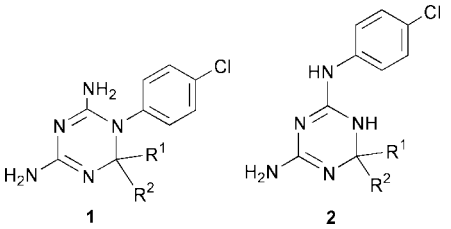
First published as an Advance Article on the web 30th March 2001

Chiral 1,2-diaryl-1,2-dihydro-4,6-diamino-1,3,5-triazines undergo facile racemisation by a reversible thermal electrocyclic reaction mechanism; the transient intermediate can lead, after tautomerisation, to rearranged racemic 2-aryl-1,2-dihydro-4-amino-6-anilino-1,3,5-triazines.

Cycloguanil **1a** (**1**, $R^1 = R^2 = Me$) is a potent inhibitor of *Plasmodium falciparum* dihydrofolate reductase (*pf*DHFR). It has been extensively employed (usually as the prodrug



1 **2**

proguanil) alone or in combination with other drugs, as a prophylactic agent and for the treatment of malaria. As a result, malaria parasites resistant to the drug have emerged and compromised its clinical utility.[1] Analysis of DHFR sequences of several resistant *P. falciparum* isolated from different geographical origins revealed that resistance to cycloguanil is associated with point mutations in the DHFR gene.[2,3] The importance of residue 16 in *pf*DHFR for binding cycloguanil has been investigated using mutants obtained *via* a synthetic gene.[1]

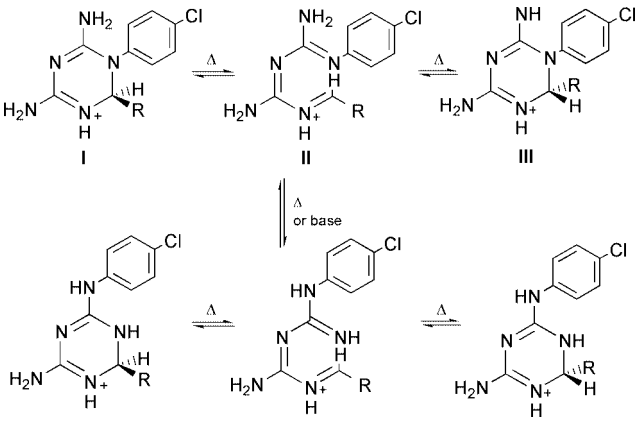
Recently, a three-dimensional homology model of *pf*DHFR was constructed to aid understanding of the structural basis of antifolate resistance in malaria.[4] This study led to the hypothesis that resistance of the A16V+S108T mutant of *pf*DHFR to cycloguanil is due to a steric clash between one of the methyl groups of cycloguanil and Val-16 of the mutant *pf*DHFR, and that mutation of residue 108 (S108T) reinforces this steric constraint. Support for this hypothesis was obtained by testing both the wild-type and A16V+S108T mutant *pf*DHFRs against cycloguanil analogues devoid of one or both methyl groups.[4] By replacing one of the C2 methyl groups in cycloguanil by hydrogen and the other by an aryl group **1b** (**1**, $R^1 = H$, $R^2 = Ph$) the inhibitory activity against the A16V+S108T mutant *pf*DHFR is restored to the level obtained with cycloguanil against the wild-type *pf*DHFR.[5] Unlike cycloguanil (**1a**), these analogues (**1b**) possess a chiral centre and only one of the enantiomers is likely to have significant inhibitory activity against the A16V+S108T mutant of *pf*DHFR.

Previous attempts to resolve racemates of **1c** (**1**, $R^1 = H$, $R^2 =$ alkyl) as diastereoisomeric salts using chiral acids have failed.[6] 1,2-Dihydro-1,3,5-triazines should be capable of thermal electrocyclic ring-opening by a disrotatory pathway; there are, however, two such pathways. Steric considerations normally determine the preferred pathway[7] and since N lacks configurational stability, enantiomer **I** will ring-open by an anticlockwise rotation about the C2–N1 bond, while enantiomer **III** will open by a clockwise rotation about the C2–N1 bond leading to the sterically least-hindered common intermediate **II** (Scheme 1). Since intermediate **II** can ring close by either a clockwise or anticlockwise disrotatory pathway at C2, the product will be racemic.

The temperature at which pericyclic reactions occur is influenced by steric factors and heteroatomic substitutents.[7,8] The electrocyclic ring closure of *trans*-2, *cis*-4, *trans*-6-octatriene to *cis*-5,6-dimethyl-1,3-cyclohexa-1,3-diene occurs at 132 °C with a $t_{0.5}$ = 4.3 h.[9] 1-Aryl-1,2-dihydro-4,6-diamino-1,3,5-triazines are synthesised from aryl biguanides and a carbonyl compound in refluxing ethanol under acidic conditions.[10] Since there is no accumulation of the Schiff base intermediate it may be reasonably assumed that the ring closure is not rate determining and could occur at or close to room temperature. If the ring-opening also occurs at or close to room temperature this would provide an explanation for the failure to resolve racemates of **1c** by the crystallisation of diastereoisomeric salts.

When α- or β-cyclodextrin was added to a solution of racemic **1d** (**1**, $R^1 = H$, $R^2 = p\text{-}ClC_6H_4$), resonances of the enantiomeric dihydrotriazines were seen to separate in the 500 MHz ^1H NMR spectrum. The effect of increasing the concentration of β-cyclodextrin on the ^1H NMR spectrum of racemic **1d** is shown in Fig. 1. This demonstrates that the enantiomers have sufficient lifetime at room temperature to be observed on the NMR time-scale and therefore in principle should be resolvable. The *p*-chlorophenyl groups are expected to bind within the β-cyclodextrin cavity and it is noticeable that their chemical shifts are most sensitive to the presence of β-cyclodextrin (Fig. 1). Only at a high molar ratio (17 : 1) of β-cyclodextrin to racemic **1d** are the enantiomeric C2–H resonances resolved.

In view of the ability of β-cyclodextrin to selectively shift the resonances of the enantiomers of **1d** in the NMR spectrum, we



Scheme 1 Proposed mechanism for the racemisation and rearrangement of 1,2-disubstituted-1,2-dihydro-4,6-diamino-1,3,5-triazines.

† Electronic supplementary information (ESI) available: Arrhenius plot for racemisation of enantiomers of **1d**. See http://www.rsc.org/suppdata/cc/b1/b101245m/

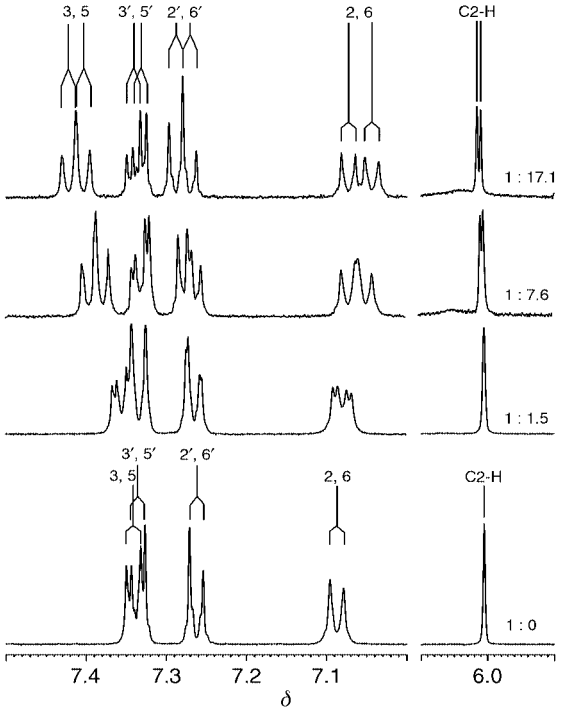


Fig. 1 ^{1}H NMR spectra of racemic **1d** hydrochloride (**1**, R^1 = H, R^2 = *p*-ClC_6H_4) in D_2O in the presence of an increasing concentration of β-cyclodextrin. The molar ratio of **1d** hydrochloride to β-cyclodextrin is shown on the right of each spectrum. 1- and 2-*p*-ClC_6H_4 substituents are designated unprimed and primed, respectively. The assignments were made by NOE experiments.

sought to separate the enantiomers of **1d** by HPLC on a column with β-cyclodextrin covalently attached to the silica support (Shodex Orpak CDBS-453; 4.6 × 150 mm). A solvent system was found[11] which would resolve the racemate and this system worked well at 10 °C. The CD spectra of the resolved enantiomers of **1d** were of similar shape but of opposite sign.

By incubating a solution of each enantiomer in a temperature controlled heating block and measuring the proportion of the two enantiomers (by HPLC on the β-cyclodextrin column) as a function of time, the rate of racemisation of the enantiomers of **1d** was determined. Racemisation of the enantiomers obeyed a first order rate law and the data were plotted using the equation $\ln x_e/(x_e - x) = 2kt$ where x is the amount of the initial enantiomer that was converted to the other enantiomer at time t, and x_e is the amount converted at equilibrium (*i.e.* $x_e = 0.5$).[12] The rate constants were determined between 40 and 60 °C at 5 °C intervals. The activation energy (E_a = 165 kJ mol^{-1}) was obtained from the slope of the Arrhenius plot (ESI†) from which the enthalpy of activation ($\Delta H^{\ddagger}$ = 162 kJ mol^{-1}) and the entropy of activation ($\Delta S^{\ddagger}$ = +176 J K^{-1} mol^{-1}) were calculated.

The relatively high enthalpy of activation is understandable since the stable 1,2-dihydro-4,6-diamino-1,3,5-triazine ring is being disrupted by breaking a single bond and forming a double bond. Moreover, the ring-opened intermediate **II** (Scheme 1) has more degrees of freedom than the cyclic 1,2-dihydro-1,3,5-triazine and hence the entropy of activation should be positive as observed. The balance of these two competing factors leads to a relatively small Gibbs function of activation and hence a fast ring-opening reaction. Thus, although it has now been possible to resolve a racemic 1,2-diaryl-1,2-dihydro-4,6-diamino-1,3,5-triazine, its half life is too short to make it worthwhile resolving these materials since as prophylactic agents they will circulate in the blood (at 37 °C) for several days.

Cycloguanil **1a** as its hydrochloride salt undergoes rearrangement to 2,2-dimethyl-4-amino-6-*p*-chloroanilino-1,2-dihydro-1,3,5-triazine **2a** (**2**, $R^1 = R^2$ = Me) on heating to its melting point (bath temperature 245 °C). As its free base in aqueous solution the rearrangement occurs at a much lower temperature (< 100 °C); the reaction is catalysed by base.[6,13] In dimethyl sulfoxide we observed rearrangement of the racemic **1d** hydrochloride (*ca.* 12 mM) at 60 °C with a half-life of *ca.* 10 days. Addition of an equimolar amount of KCl decreased the half-life to about 8 days. We propose that in dimethyl sulfoxide the chloride ion (which is essentially unsolvated in this solvent) acts as a general base and catalyses the tautomerisation of the acyclic intermediate **II** (Scheme 1). Support for this proposal was provided by the observation that addition of an equimolar amount of KF to a dimethyl sulfoxide solution of racemic **1d** hydrochloride (*ca.* 12 mM) markedly accelerates the rearrangement, the half-life at 60 °C now being about 14 min.[14] When an enantiomer of **1d** is treated under the same conditions the rearranged product **2b** (**2**, R^1 = H, R^2 = *p*-ClC_6H_4) is racemic. Thus the rearrangement and the racemisation of 1-aryl-2-substituted-1,2-dihydro-4,6-diamino-1,3,5-triazines can be envisaged as occurring by the common intermediate **II** (Scheme 1).

The reversible thermal electrocyclic reaction of 1,2-dihydro-1,3,5-triazines has not been recognised previously. Since 1,2-diaryl-1,2-dihydro-4,6-diamino-1,3,5-triazines are potent inhibitors of mutant *pf*DHFRs found in resistant strains of the malaria parasite *Plasmodium falciparum*,[5] binding to the target enzyme can be expected to perturb the enantiomer ratio in favour of the more effective inhibitor. Thus the facile reversible thermal electrocyclic reaction reported here renders unnecessary the resolution of these materials for therapeutic use.

Synthesis of a double-activated switchable molecule *via* ruthenium–acetylide barbituric derivatives

Jean-Luc Fillaut,* Matthew Price, Andrew L. Johnson and Johann Perruchon

Institut de Chimie de Rennes, Laboratoire 'Organométalliques et Catalyse', UMR 6509 CNRS - Université de Rennes 1, Campus de Beaulieu, 35042 Rennes, France. E-mail: jean-luc.fillaut@univ-rennes1.fr

Received (in Cambridge, UK) 19th October 2000, Accepted 8th March 2001
First published as an Advance Article on the web 30th March 2001

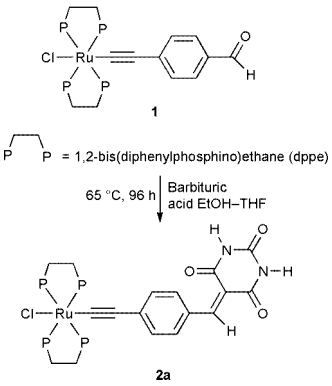
Ruthenium–σ-acetylide derivatives connected to barbituric acceptors through a π-conjugated bridge define a series of molecular systems presenting highly tunable properties.

Several molecular systems capable of performing elementary tasks on the molecular level have been synthesized in recent years.[1] In most cases, the molecular device obeys a binary rule; *i.e.* an input provides a positive or negative output response.[2] This ability to switch on/off a function through an external parameter (light, electron transfer, chemical reaction) defines the concept of a molecular switch. Another objective is the building of molecules which exhibit useful electronic/photonic functions that can be externally controlled.[3] With this in mind, organometallic and coordination compounds are currently the subject of considerable investigations.[4] Transition metal complexes with η^1-alkynyl ligands ($L_nMC{\equiv}CR$) attract particular interest, mostly as precursors of molecules containing a linear array of delocalized π-systems between two different functionalities.[5]

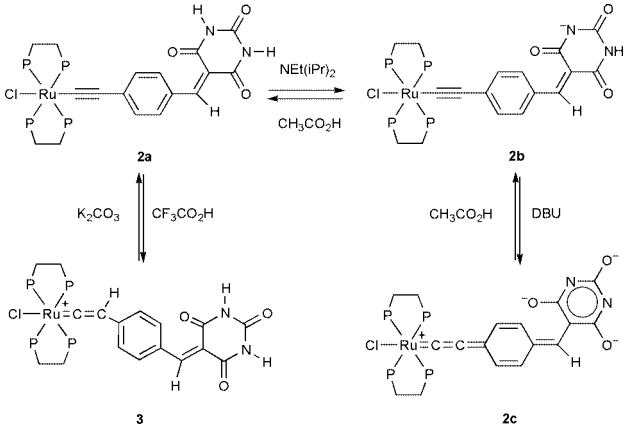
In this context, we set out to investigate metal–alkynyl donor–acceptor systems, as prototypes for molecular materials possessing switchable properties, through chemical or redox modifications. We now describe the design and synthesis of ruthenium(II)–alkynyl, connected to a barbituric acceptor, selected for its ability in stabilizing charge delocalized canonical structures through an heteroaromatic limit form, as a first example of this concept.

Knoevenagel condensation of **1**[6] (Scheme 1) with barbituric acid yields the target compound **2a** as an air-stable blue powder. Its structure was confirmed by spectrometric methods.† The UV–VIS spectra of complexes **1** and **2a**, characterized by intense ($\varepsilon \approx 1.2$–2×10^4 M^{-1} cm^{-1}) MLCTs at λ_{max} = 410 and 547 nm, respectively, in THF [Fig. 1(*a*)] proved the donor–acceptor nature of these systems.

Complex **2a** possesses three independant sites for successive protonation–deprotonation sequences (Scheme 2), which permit us to modulate the donor–acceptor coupling in **2a**, alternatively at the donor or at the acceptor head, as depicted through dramatic colour changes. The protonation on the β-carbon of transition metal acetylide complexes leading to their



Scheme 1 Synthesis of the barbituric derivative **2a**.



Scheme 2

corresponding vinylidene is a well-known process.[7,8] Addition of an excess of a strong acid (HCl, CF_3CO_2H) to **2a** was therefore monitored by ^{31}P NMR: a significant shift of the signal for the 4 equivalent phosphorus nuclei from 48.6 to 39.6 ppm was observed. This latter value is consistent with the formation of a *trans*-chlororuthenium–vinylidene cationic complex **3** (Scheme 2).[9] The presence of a quintuplet ($^4J_{[P,H]}$ = 3 Hz) at 3.96 ppm in the ^1H NMR spectrum of **3** is also in agreement with such a Ru=C=C*H* cationic fragment.

Simultaneously a rapid colour change from purple to red (λ_{max} = 495 nm, $\varepsilon = 1.7 \times 10^4$ M^{-1} cm^{-1}) [Fig. 1(*b*)] was observed. This reveals the weakening of the donor–acceptor electronic coupling arising from an alteration of the metal–acetylide moiety. This hypothesis was confirmed by electrochemical studies on the Ru^{2+}/Ru^{3+} redox couple. Complex **2a** presents a reversible oxidation wave in its cyclic voltammogram [Fig. 2(*a*)] at $E_{1/2}$ = 560 mV *vs.* SCE, in CH_2Cl_2,‡ assigned to the Ru(II)/(III) oxidation. The addition of a slight excess of trifluoroacetic acid to **2a** resulted in the total disappearance of the initial anodic wave, as expected for a vinylidene derivative [see Fig. 2(*a*,*b*)]. As the CV for **2a** reappears upon addition of K_2CO_3 to **3**, complete reversibility and high speed switching were observed for both the protonation (acetylide to vinylidene) and deprotonation (vinylidene to acetylide) reactions.

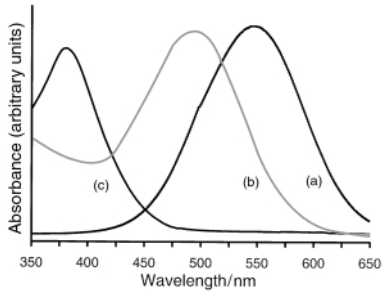


Fig. 1 Absorption spectra of **2** in THF: (*a*) pure **2a**; (*b*) after addition of 1 equiv. of CF_3CO_2H to **2a**; (*c*) after addition of 2 equiv. of DBU to **2a**.

DOI: 10.1039/b100384b

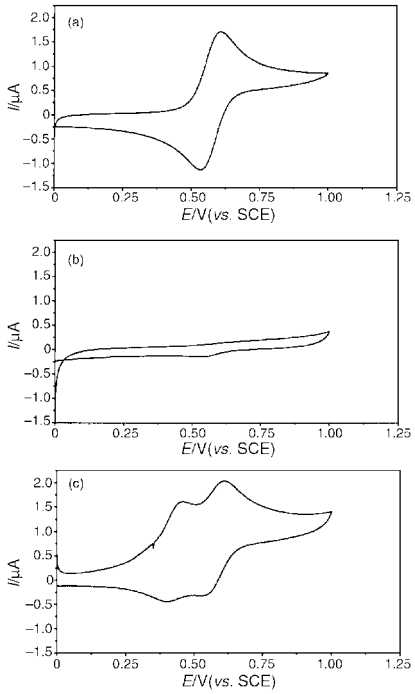

Fig. 2 Cyclic voltammograms‡ of **2a** in CH_2Cl_2, at a scan rate of 200 mV s^{-1}: (*a*) pure **2a**; (*b*) after addition of 1 equiv. of CF_3CO_2H on **2a**; (*c*) after addition of 1 equiv. of DBU on **2a** (see text).

On the other hand, the addition of a strong base (KOH, DBU (DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene)), to **2a** induces an immediate colour change from purple to pale yellow (λ_{max} = 380 nm, $\varepsilon = 1.5 \times 10^4$ M^{-1} cm^{-1}) [Fig. 1(*c*)]. A minor variation of the ^{31}P NMR shift for the phosphorus ligands, from 48.6 to 49.5 ppm, is observed. This process is perfectly reversible, upon addition of a weak acid (CH_3CO_2H). Both these observations are consistent with the weakening of the acceptor strength of the barbituric moiety as a result of its deprotonation. This hypothesis was ascertained by monitoring the modifications of the Ru(II)/(III) oxidation wave of **2a**, upon sequential addition of DBU. This resulted in the growth of a new anodic wave, at a less positive potential ($E_{1/2}$ = 460 mV *vs.* SCE, in CH_2Cl_2), in accord with the formation of a more electron rich species, whereas the initial wave ($E_{1/2}$ = 560 mV *vs.* SCE) was progressively disappearing [Fig. 2(*c*): for instance, these concomitant reversible waves were observed upon addition of 1 equiv. DBU].

Two equivalents of base were necessary to afford complete conversion from the purple compound **2a** to its yellow analogue. This process was therefore monitored by ^1H NMR spectroscopy. As expected, complete disappearance of both the NH (at 8.2 and 7.9 ppm) and a significant shift of the ethylenic CH signal (from 8.5 to 8.1 ppm) at the barbituric head resulted from the addition of 2 equiv. of DBU. Addition of 1 equiv. of base gave an unclear outcome (partial disappearance and broadening of the most significant signals of **2a**). At this stage, two ^{31}P NMR signals were observed at 48.6 and 49.5 ppm, which indicated that the deprotonation process was not complete. This process was monitored, by ^1H NMR, upon addition of a large excess of the less basic *N*-ethyldiisopropylamine. The initial signals for the NH groups disappeared, but only slight variations were observed for the ethylenic proton, at 8.5 ppm, and the aromatic system, at 8.2 and 6.4 ppm. Neither colour change (UV–VIS spectra) nor electrochemical potential shift for the oxidation of **2** were observed. Finally, complete conversion from **2a** into its yellow analogue were obtained when 1 equiv. of DBU was added to the solution containing the weaker base. We assume then that a double NH deprotonation at the barbituric head[9] is necessary to induce considerable electronic changes (Scheme 2: **2b** represents one of the ketoenolic forms of the monodeprotonated species whereas **2c** is a conceivable mesomeric form of the bi-deprotonated derivative).

This second mode of switching is different from the first one which acts more specifically on the metal–acetylide moiety. The synthesis of complex **2a** has therefore proven an effective strategy for designing highly sensitive derivatives, whose properties are adjustable alternatively at the donor or at the acceptor head. On the other hand, such a switching mode could permit us to control the hydrogen binding ability of the barbituric head, either by deprotonation on this residue or by protonation on the ruthenium moiety.

This research was supported by the CNRS, the MENRT, and the Socrates-Erasmus Program (financial support to M. P. from the University of Edinburgh).

Ligand exchange reactions of chloride ligands on a trinuclear palladium acetylide core with platinum acetylide dendrons having a 4-pyridyl group at a focal point result in the quantitative formation of novel organometallic dendrimers, which easily revert to the core and the dendrons by treatment with Bu_4NCl.

Dendrimers are three-dimensional macromolecules with regularly hyperbranched structures, and have a wide range of potential applicable to the development of new materials.[1] In recent years, attention has shifted towards dendritic molecules containing metal centers since they exhibit characteristic properties such as redox behavior and catalysis.[2] Previously we have synthesized novel organometallic dendrimers composed of platinum acetylide units.[3,4] On the other hand, configurational and constitutional changes in a dendritic molecule responding to simple external stimuli are of interest for the practical application of dendrimers.[5,6] Thus, we engaged in the construction of organometallic dendrimers containing switchable metal components by adopting coordination bonds. Herein we report the syntheses of novel organometallic dendrimers in which platinum–acetylide dendrons are reversibly bonded to a palladium acetylide core.

It is well known that halide ligands on transition metal atoms are reversibly substituted for neutral ligands such as phosphine and pyridine. We have therefore designed platinum–acetylide dendrons having a 4-pyridyl group at a focal point and have achieved successful preparation by a convergent method as shown in Scheme 1. Reaction of the platinum acetylide complex **1** with 1,3,5-triethynylbenzene derivative **2**, which has two terminal acetylenes and one pyridylethynyl group, in the presence of a Cu(I) catalyst gave the first generation dendron **GD1** in 74% yield. Similar reactions of diplatinum **3** and hexaplatinum complexes **5**, which were prepared as reported previously,[4] with **4** gave second and third generation dendrons **GD2** and **GD3** in 60 and 44% yield, respectively (Scheme 2). Trace analysis on these reactions by GPC showed that sharp peaks due to **GD2** with a higher molecular weight relative to those of **3** and **4** grew with consumption of the substrates. Purification by column chromatography on alumina followed by reprecipitation from CH_2Cl_2–hexane gave a single product which was confirmed by GPC analysis. Although no molecular ion peaks of these dendrons except for **GD1** were detected in the mass spectrum, full characterization was performed by means of NMR spectral analyses. For example, the ^{31}P NMR spectrum of **GD3** exhibited two singlet signals at δ 11.0 and 10.8 in a 4 : 3 integral ratio. The former was assignable to the phosphine on the platinum atoms bound to the *p*-methoxyphenylethynyl groups on the surface of the dendron, whereas the latter was due to the phosphines on inner platinum atoms. In the ^1H NMR spectrum, a sharp signal due to methoxy protons appeared at δ 3.78 with twelve-fold intensity of those of the signals due to α- and β-protons of pyridyl groups at the focal point.

We then examined the synthesis of dendrimers by the ligand exchange reaction of the trinuclear platinum–acetylide complex

6 with dendrons.[7] Although chloride ligands on complex **6** are easily replaced with pyridine in the presence of KPF_6, the reaction of complex **6** with **GD1** allowed only partial ligand exchange to give a mixture of the desired dendrimer and other complexes having one or two **GD1** in the molecule. Therefore, the core was changed to a palladium–acetylide complex **7** and it was found that the treatment with **GD1** in the presence of $NaBAr'_4$ (Ar′ = 3,5-$(CF_3)_2C_6H_3$) resulted in complete ligand exchange and produced the first generation dendrimer **G1** in a quantitative yield (Scheme 3). Similarly, the second generation dendrimer **G2** was also prepared by the reaction of **7** with **GD2** in quantitative yield. However, no exchange of chloride ligand with **GD3** took place and third generation dendrimer **G3** did not form at all. The difference in reactivity between **GD2** and **GD3** may arise from the steric effect of **GD3**.

The absence of structural defects in dendrimers **G1** and **G2** was confirmed by spectral analysis. A singlet signal assignable to PEt_3 on palladium was observed at δ 32.2 in the ^{31}P NMR spectrum of **G2** while the spectrum of **7** showed a signal at δ 32.7. The ^1H NMR spectrum of **G2** exhibited a sharp singlet at δ 2.87 due to the methyl protons of the central mesitylene moiety while the methyl signal of **7** was observed at δ 3.14. In the ^1H NMR spectrum of **G2** the integral ratio of the central methyl signal relative to that of the methoxy protons situated at the surface was 1 : 4. These data clearly suggest that all chloride ligands on palladium were replaced with the pyridyl groups of **GD2**, and are consistent with the structure of **G2**.

Treatment of dendrimer **G1** with excess Bu_4NCl in benzene led to the quantitative formation of core **7** and dendron **GD1** (Scheme 4). Similar treatment of dendrimer **G2** regenerated **7** and **GD2** in quantitative yield. These results suggest that the bonding of dendrons **GD1** and **GD2** to core **7** can be reversibly controlled by the ligand exchange reaction. Quantitative formation of **G1** and dissociation into **7** and **GD1** were repeated up to three times by successive treatment of $NaBAr'_4$ and Bu_4NCl, respectively. These results show the first examples of morphology control in dendrimers by chemical stimuli other than light.[6]

Self-assembly of the racemic ligands, (*R*)- and (*S*)-1,1′-binaphthyl bis(isonicotinate) and Pt^{II} shows that the (*S*)-ligand stereospecifically recognises the (*R*)-ligand to give rise to an achiral heterodimeric complex.

Recently much progress has been achieved on the metal-assisted self-assembly of independent ligands.[1] A supramolecular assembly is manufactured from the information embedded in each preprogrammed molecular component.[2] The information stored in the rigid and chiral ligand systems can be used in the selective recognition of their partners in order to produce highly ordered supramolecular complexes from ligand mixtures in solution. In principle, the simplest situation arises from racemic ligands in which two extreme cases are possible. One is called ligand self-recognition, where each enantiomeric ligand selectively recognises itself to give a homochiral complex,[3] and the other is known as ligand self-discrimination, in which one enantiopure ligand specifically perceives its enantiomer to generate an achiral complex. There have been several examples of self-recognition of achiral and chiral ligands.[3,4] However, there exist few reports of ligand self-discrimination in which two different ligands form a heterodimeric complex.[5] Herein we report a system that exhibits ligand self-discrimination in which the complex of racemic ligands with metal ions produces only an achiral 2:2 complex.

The design of the ligand L (Fig. 1) satisfies three requirements needed for ligand self-discrimination: restricted rotational degrees of freedom, a divergent array of two pyridyl groups for preclusion of intramolecular ligation of a single metal, and ligand chirality. These requirements are fulfilled by the incorporation of chiral 1,1′-binaphthol into the ligand backbone. Both the racemic ligand (^{rac}L) and the enantiomerically pure ligands (^{S}L, ^{R}L) are readily prepared by ester condensation of the appropriate 1,1′-binaphthol and the acid chloride of isonicotinic acid. An equimolar mixture of $(dppp)M(OTf)_2$ (M = Pd^{II}, Pt^{II}) and L (^{S}L, ^{R}L, ^{rac}L) in acetone-d_6 was tested for the ligand chirality-induced self-discrimination process.†

^{1}H NMR titration spectra of ^{rac}L with $(dppp)Pd(OTf)_2$ in acetone-d_6 show a highly symmetric single set of signals at a 2:2 metal:ligand ratio. Addition of more $(dppp)Pd(OTf)_2$ to this 2:2 complex does not result in the generation of any new sets of signals, indicating the formation of a single metal complex. In contrast, ^{1}H NMR titrations of ^{S}L with $(dppp)Pd(OTf)_2$ show complicated sets of resonances. The differences between ^{1}H NMR titrations of ^{rac}L and ^{S}L, respectively, with $(dppp)Pd(OTf)_2$ imply that ^{S}L prefers to form an achiral, heterodimeric complex exclusively with ^{R}L, [(eqn. (1)] rather than a homochiral complex [eqn. (2)]. Interestingly, ^{1}H NMR titrations of L (^{rac}L or ^{S}L) with $(dppp)Pt(OTf)_2$ in acetone-d_6 do not produce any distinction between ^{rac}L and ^{S}L. It is reported that the Pt^{II} complex has the same coordination geometry as the Pd^{II} complex but the former cannot rapidly reach thermodynamic equilibrium at ambient temperature compared with the latter.[6] In fact, heating an equimolar mixture of ligand and $(dppp)Pt(OTf)_2$ results in the generation of a similar ^{1}H NMR pattern to that of the Pd^{II} complex. The single set of ^{1}H NMR resonances of the racemic complex compared with those of the enantiopure complex indicates that this system is an example of self-discrimination of the racemic ligands: ^{S}L stereospecifically recognises its counterpart, ^{R}L (Fig. 2).

$$^{S}L + {}^{R}L \xrightarrow{2\ (dppp)M^{2+}} [\{(dppp)M^{S}L\}\{(dppp)M^{R}L\}] \quad (1)$$

$$^{S}L \xrightarrow{(dppp)M^{2+}} [\{(dppp)M^{S}L\}_2]^{4+} + [\{(dppp)M^{S}L\}_3]^{6+} + \cdots \quad (2)$$

Careful interpretation of the HH-COSY of the achiral heterodimeric complex, $[\{(dppp)Pd\}_2(^{S}L)(^{R}L)]^{4+}$ reveals that

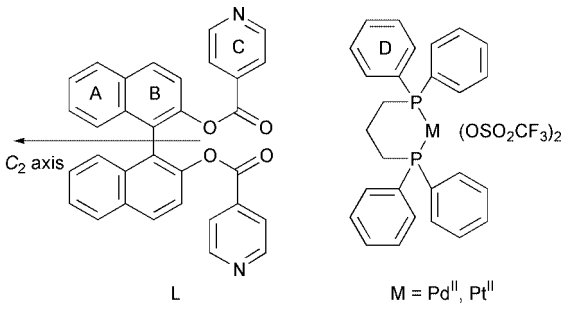

Fig. 1 Nomenclature of the ligands and metal complexes used in this work.

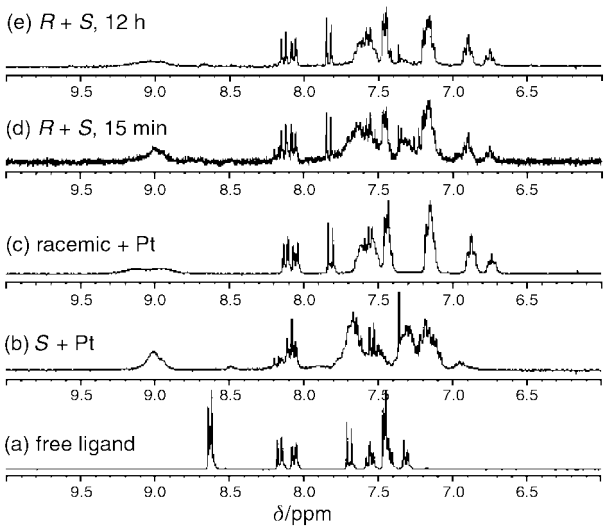

Fig. 2 Partial ^{1}H NMR spectra (300 MHz, acetone-d_6, aromatic protons) of (a) ligand L, (b) the complex of equimolar amounts of Pt^{II} and ^{S}L, (c) the complex of equimolar amounts of Pt^{II} and ^{rac}L. the signals for the four identical phenyl units of free dppp are split into two different sets. L has no symmetry plane due to its C_2 dissymmetry induced by 1,1′-binaphthol. Incorporation of the dissymmetric ^{S}L and ^{R}L into $[\{(dppp)Pd\}_2(^S L)(^R L)]^{4+}$ should break one symmetry plane of dppp which includes two P atoms and bisects two adjacent phenyl rings. This intriguing phenomenon constitutes strong evidence for the formation of $[\{(dppp)Pd\}_2(^S L)(^R L)]^{4+}$ in solution. In fact, the solubility of the enantiopure complex is different from that of the racemic complex: the enantiopure complex generally shows enhanced solubility in various solvent systems. In acetone solution, measurements of molecular weight by vapor pressure osmometry (VPO)[7] give M^N (number averaged molecular weight) = 4000 g mol^{-1} for an equimolar complex of ^{S}L and (dppp)Pd(OTf)$_2$, and M^N = 3400 g mol^{-1} for an equimolar complex of ^{S}L and (dppp)Pt(OTf)$_2$.‡ Calculated molecular weights of the 2:2 complex are 2627 and 2804 g mol^{-1} for $[\{(dppp)Pd\}_2(^S L)_2](OTf)_4$ and $[\{(dppp)Pt\}_2(^S L)_2](OTf)_4$, respectively. Thus, VPO measurements show that the formation of homodimeric structures is excluded in the enantiopure case.

The crystal structure of an equimolar complex of (dppp)Pt(OTf)$_2$ with ^{rac}L supports the interpretation of the solution behavior of the complex.§ As expected from the ^{1}H NMR titrations, the racemic ligands generate a heterodimeric species, $[\{dppp)Pt\}_2(^S L)(^R L)]$ (Fig. 3). A crystal structure shows two crystallographically independent but chemically identical complexes in the unit cell. Both of them have crystallographic inversion centers with a C_{2h} point group. There are many existing reports on the formation of planar rectangular boxes by metal-assisted self-assembly.[8] However, this complex has a particularly interesting structural variation from its predecessors. It forms a folded rectangular box: the two planes, N(2)–Pt(1)–N(1) and N(2A)–Pt(1A)–N(1A) are separated on the different spaces, making two steps of stairs. A rectangular cavity (6.8 × 7.2 Å) is in the center of the complex. Two triflate anions, captured in the center of the cavity, are in extensive van der Waals contact with the pyridyl groups of the ligand and are also in van der Waals contact with each other (F2A–F2A: 2.79, 2.91 Å). The remaining two triflate counter anions are in short contact with Pt(II) metal ions *via* an oxygen atom.

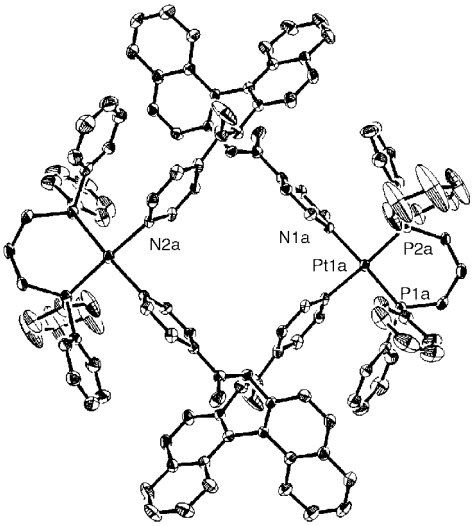

Fig. 3 An ORTEP representation of the structure of $[\{(dppp)Pt\}_2(^S L)(^R L)]^{4+}$ perpendicular to the Pt–Pt vector (30% probability thermal ellipsoids). Selected average distances (Å) and angles (°): Pt–P 2.260, Pt–N 2.098; P–Pt–P 90.76, N–Pt–N 85.14, *cis* P–Pt–N 92.02, *trans* P–Pt–N 176.61. (Because of two independent but chemically identical complexes in the unit cell, average values are reported.)

It turns out that the racemic ligands combine to generate an achiral 2:2 complex with Pd^{II} or Pt^{II}, whereas the enantiopure ligands are not assembled into an entropically favorable homodimer, presumably due to the unfavorable strain energy involved in the formation of a homodimer. The destabilization of the homochiral dimer will be reduced by reorganization to less strained oligomeric complexes. In order to identify the reorganisation behavior of the homochiral complex, the ^{1}H NMR signal changes of a 1:1 mixture of equimolar ^{R}L/(dppp)Pt(OTf)$_2$ and ^{S}L/(dppp)Pt(OTf)$_2$ complexes are monitored (Fig. 2). The convergence into the racemic complex suggests that the reorganisation process is reversible in dynamic equilibrium and that the heterodimeric complex represents a thermodynamically stable product.

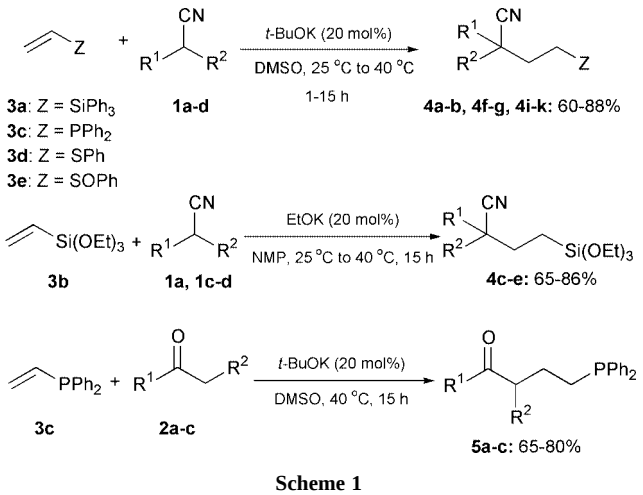
Received (in Cambridge, UK) 13th February 2001, Accepted 13th March 2001
First published as an Advance Article on the web 30th March 2001

Catalytic amounts of *t*-BuOK in DMSO allow the smooth addition of nitriles and in some cases of ketones to vinylsilanes, phosphines or thio derivatives in good yields.

The conjugate addition of metalated nitriles **1** or ketones **2** to activated alkenes of type **3** (Z = electron-withdrawing group) is a well-known reaction (Michael addition).[1] Stabilized nucleophiles like enolates usually do not add to moderately activated vinylic derivatives of type **3** (Z = SiR_3, SR or PR_2).

Only highly reactive organolithiums add to these moderately active Michael-acceptors.[2] Recently, we have found that potassium enolates of ketones or nitriles generated catalytically using *t*-BuOK in DMSO or *N*-methylpyrrolidinone (NMP) have a high nucleophilicity in these solvents and add readily to various styrenes in good yields, allowing a unique catalytic phenylethylation reaction.[3] Herein, we wish to report that a range of nitriles add to vinylic silanes **3a** and **3b**, diphenylvinylphosphine (**3c**), phenyl vinyl thioether (**3d**) and phenyl vinyl sulfoxide (**3e**) in the presence of a catalytic amount of *t*-BuOK (20 mol%) in DMSO leading to the corresponding Michael-adducts **4a–g** and **4i–4k** in 60–88% yield (Scheme 1, Table 1). Thus, 2-phenylbutyronitrile **1a** (entry 1 of Table 1) adds to triphenylvinylsilane (**3a**) within 12 h at 40 °C in the presence of *t*-BuOK (20 mol%) in DMSO leading to the addition product **4a** in 60% yield. The related cyclohexanecarbonitrile (**1b**) adds to **3a** even at rt (12 h) affording the adduct **4b** in 76% yield (entry 2). Triethoxyvinylsilane (**3b**) adds similarly valeronitrile (**1d**), secondary nitriles **1a** and α-tetralone (**2a**) at 40 °C. In this case potassium ethoxide (20 mol%) is used as a catalyst in NMP. This avoids alkoxide exchanges at silicon and leads to the functionalized alkyltriethoxysilanes **4c–e** and **5d** in 65–86% yield (entries 3–5 and entry 15). These products may be interesting precursors for the preparation of functionalized silicones. This result shows that a variety of potassium alkoxides can certainly be used in this catalytic addition reaction. Vinylic phosphines only reluctantly undergo the addition of nucleophiles[2g] and, usually, efficient additions only are observed to vinylic phosphine oxide derivatives or alkenylphosphonium salts.[4] Under our reaction conditions, various nitriles add to diphenylvinylphosphine (**3c**) very smoothly (25 °C, 1 h) leading to the expected products **4f–g** in 81–88% yield and the double addition product **4h** in 80% yield. Interestingly, ketones like α-tetralone (**2a**), camphor (**2b**) and cyclohexanone (**2c**) also undergo an efficient Michael addition at 40 °C (12 h) leading to the ketophosphines **5a**, **5b** and **5c** in respectively 80, 72 and 65% yields (entries 12, 13 and 14). In the case of **5b** only the *endo*-isomer is produced.[5] Finally, nitriles like **1a** or **1b** add also to phenyl vinyl thioether (**3d**) affording the Michael-adducts **4i–j** (entries 9 and 10) in 75–78% yield. The corresponding sulfoxide (**3e**) adds nitrile **1a** under similar conditions (40 °C, 1 h) furnishing the sulfoxide **4k** in 82% yield (entry 11).



Scheme 1

In summary, we have described a new *t*-BuOK-catalyzed addition of nitriles to various moderately active Michael-acceptors allowing the preparation of new functionalized silanes, phosphines and thioethers. In the case of diphenylvinylphosphine (**3c**) the addition of ketones also proceeds well. We are currently exploring the application of this reaction for the preparation of new chiral ligands for metal catalysis.[6]

We thank the Deutsche Forschungsgemeinschaft (Leibniz program) and the Humboldt Foundation for a scholarship to A. R. We also thank the BASF AG (Ludwigshafen), Chemetall GmbH (Frankfurt) and Degussa-Hüls AG (Hanau) for the generous gift of chemicals.

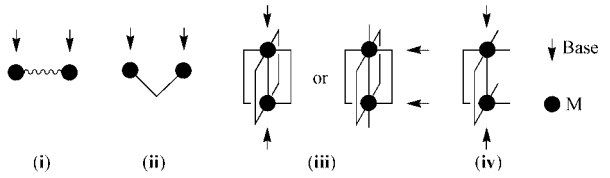
First published as an Advance Article on the web 30th March 2001

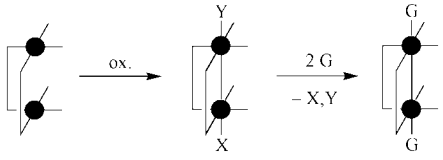
The preparation, crystal structure and NMR spectroscopic properties of a cisplatin-derived diplatinum(III) complex is reported which contains two bridging 1-methylcytosinato nucleobases in mutual *head–tail* orientation and in addition two axially bound 9-ethylguanine nucleobases.

Reactions of di-, rather than mononuclear metal antitumor complexes with nucleobases or DNA, in which the integrity of the dimetal core is retained, have recently attracted attention. Examples are nucleobase adducts of dinuclear Pt(II) complexes with flexible aliphatic (**i**)[1] or rigid heterocyclic linkers (**ii**),[2] and



'lantern' type dirhodium(II) tetracarboxylates (**iii**).[3] In the latter case nucleobase binding can occur both through the axial positions[4] or with replacement of two bridging ligands.[5] Here we report on a diplatinum(III) complex (**iv**) which binds two guanine nucleobases with high efficiency through the two axial positions of the dimetal core. The novelty of (**iv**) relates to Pt binding through guanine-N^7, a pattern ruled out in the case of dimetal tetracarboxylates (**iii**) because of repulsive interactions between O^6 of guanine and the four oxygen donor atoms in the metal plane.[6] In contrast, axial binding of adenine nucleobases (*via* N^7) was rationalized on the basis of favourable H bonding interactions with the MO_4 plane.[3–5] The observation by Aoki *et al.*[7] on axial theophylline-N^7 binding to a mixed-valence tetrakis(μ-acetamidato)rhodium(II)-rhodium(III) cation was a logical consequence of the partial replacement of O atoms by NH functions and the possibility of interligand H bond formation. Consistent with this view, the presence of three H donor sites (NH, two NH_3) in the MN_4 faces of the diplatinum(III) core applied in this study proved particularly advantageous for guanine binding.

The title compound was prepared as follows: The diplatinum(II) precursor *cis*-[{$Pt(NH_3)_2$(μ-mcyt-N^3-N^4)}$_2$]$^{2+}$ (**1**)[8] con-



taining two bridging 1-methylcytosinato (mcyt) model nucleobases in *head–tail* arrangement was oxidized to the diplatinum(III) complex *cis*-[X$Pt(NH_3)_2$(μ-mcyt-N^3-N^4)$_2$-$Pt(NH_3)_2$Y](Z)$_n$ (**2**).[9] Subsequently, the axial ligands X and Y were replaced by 9-ethylguanine (Hetgua) by adding this nucleobase to an aqueous solution of **2** (pH ≃ 2) to give *cis*-[{$Pt(NH_3)_2$(Hetgua-N^7)(mcyt-N^3-N^4)}$_2$]$^{4+}$ (**3**). The cation of the title compound **3** $[ClO_4]_4 \cdot 5H_2O$[10,11] is depicted in Fig. 1. Salient structural features are as follows: the Pt–Pt bond length of 2.5868(8) Å is in the typical range for single bonds of diplatinum(III) complexes derived from cisplatin.[12] The two Pt planes form an angle of 20.3(1)°, and the torsional angle about the Pt–Pt vector is 26.9(2)° (N(3C)–Pt–Pt–N(4C)) and 33.2(2)° (N2–Pt–Pt–N1). Pt–N distances in the Pt plane are normal [Pt–N(4C), 2.002(5); Pt–N(3C), 2.043(5); Pt–N(2), 2.056(5) Å] or only slightly elongated [Pt–N(1), 2.070(5) Å]. However, the Pt–N^7 bond [2.189(6) Å] is markedly longer than those typically seen in Pt(II)[13] and Pt(IV)[14] complexes of guanine. The guanine ligand is oriented in such a way, that O^6 escapes any steric clash with O^2 of the mcyt ligand by H bond formation with the two NH_3 groups (N1···O6G, 2.854(8); N2···O6G, 3.101(7) Å; angles: N1–H1A···O6G, 159.8(4); N2–H2B···O6G, 144.2(4)°].

Compound **3** is stable in aqueous solution for at least 7 d. The ^{195}Pt NMR signal at −816 ppm is consistent with a Pt(III) oxidation state and the singlet indicates that the two Pt centers have identical environments. A ^{195}Pt ^{1}H HMQC experiment reveals ^4J coupling between ^{195}Pt and H5 of mcyt (9.2 Hz), ^5J coupling between ^{195}Pt and H6 of mcyt (8.3 Hz), as well as ^3J coupling between ^{195}Pt and H8 of Hetgua (5.2 Hz). While coupling with the cytosine protons are in the expected range,[15] it is noted that ^3J coupling to guanine H8 is rather small as compared to guanine bases bonded to Pt(II) (20–32 Hz[16]) and even to Pt(IV) (12 Hz[14]). It is a consequence of the apparent weak binding of the axial guanine ligands. This situation contrasts the strong binding of a single, C^5 bonded 1-methyluracilyl entity to a diplatinum(III) core,[17] which has some

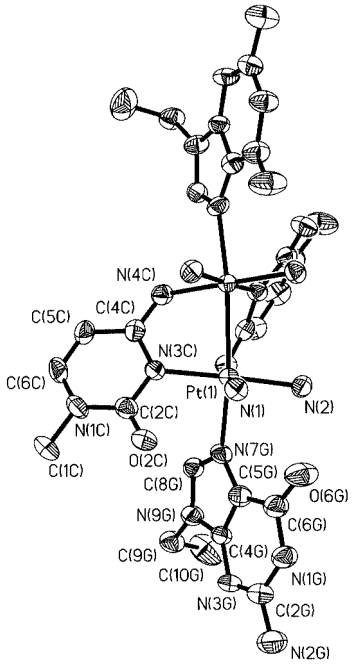


Fig. 1 Crystal structure of cation of *cis*-[{$Pt(NH_3)_2$(Hetgua-N^7)(mcyt-N^3-N^4)}$_2$][$ClO_4]_4 \cdot 5H_2O$(**3**).

structural similarity with the present case as it is another example of a diplatinum(III) complex carrying a nucleobase in an axial position.

The affinity of **2** for the guanine model nucleobase is retained in reactions with the corresponding nucleoside 2′-deoxyguanosine and the nucleotide 5′-dGMP. Binding occurs rapidly, as evident from ^{1}H NMR spectroscopy. Doubling of most resonances is consistent with formation of diastereomers upon combination of the chiral *head–tail* species **2** with the chiral nucleoside/nucleotide.[15] The guanosine adduct is stable in aqueous solution for approximately 1 d, whereas the 5′-GMP compound is stable for at least one week (*e.g.* ^{195}Pt NMR resonance at δ −804 ppm for 5′-dGMP complex). Afterwards the ^{1}H NMR spectra of both species become quite complicated. It is unclear at present whether oxidative degradation processes of either the purine skeleton and/or the sugar moieties take place similarly to the situations encountered with Au(III)[21] and high valent Mn,[22] Ni,[23] or Ru[24] species.

Attempts to bind model nucleobases other than guanine, *e.g.* 1-methylcytosine, 1-methyluracil or 9-methyladenine to **2** under comparable conditions, failed. Thus **2** appears to be highly selective for guanine nucleobases. Whether this feature may be exploited to generate a chemical probe for guanine in nucleic acids remains to be seen.

First published as an Advance Article on the web 30th March 2001

1,5-Dinitrenonaphthalene was prepared in two cryogenic matrices by photolysis of 1,5-diazidonaphthalene; the cryogenic matrices were an argon matrix at 11 K and a glassy 2-methyltetrahydrofuran matrix at 77 K; the photolysis was analyzed by UV-VIS, FT-IR, and ESR matrix isolation spectroscopies.

Dinitrenes have been intensively studied to examine the magnetic properties of the building blocks in molecule-based magnetic materials.[1] The two nitreno groups in dinitrenes are triplet centers and provide important insight into intramolecular interelectronic exchange interaction. Some dinitrenes exist in the quinonoidal form, where, for each nitreno group, one of the unpaired electrons of the nitrogen atom forms a π bond with a π electron of the adjacent carbon atom.[2,3] Hence, these dinitrenes are not high-spin molecules but diradicals with two localized electrons in a singlet ground state. Even though they are not very attractive as organic magnetic materials for technical applications, these dinitrenes are important species for the study of interelectronic interaction in organic diradicals.[4] In these quinonoidal dinitrenes, electronic interaction between the radical centers is explained by spin polarization,[2] an important interelectronic exchange mechanism. The quinonoidal dinitrenes have been studied to understand the relationship between their interelectronic exchange interaction and their chemical structure.[1] However, frequently there are complicating structural ambiguities, such as twisting of the aromatic system in biphenyl[5,6] or *E–Z* iosmerization in stilbene.[2] Connecting two nitreno groups to a condensed polycyclic aromatic hydrocarbon, where structural ambiguity is excluded, should make it easier to study the relationship between structure and interelectronic interaction and could lead to a clearer understanding of this relationship, Here, we studied 1,5-dinitrenonaphthalene, where two nitreno groups were connected to a rigid naphthalene structure, by low temperature matrix isolation spectroscopies.

Crystallites of 1,5-diazidonaphthalene **1** were vaporized at 45 °C and codeposited with argon (99.9999%) onto a CsI plate at 11 K. Matrix-isolated **1**, which showed structured UV-VIS absorption bands in the 300–340 nm region (Fig. 1) and major IR bands at 2116, 1409, 1294, 781, and 707 cm^{-1}, was photolyzed by XeCl excimer laser pulses (λ = 308 nm, 1 Hz, 1.2 mJ cm^{-2} $pulse^{-1}$, τ = 20 ns). The photolysis was simultaneously monitored by FT-IR and UV-VIS spectroscopies.[7] Upon irradiation at 308 nm, the UV-VIS and IR absorption bands ascribed to **1** decreased rapidly, while some new bands appeared. These new bands behaved differently during irradiation: in the UV-VIS absorption spectra, the weak absorption bands at 581, 565, 541, 535, 391, and 372 nm disappeared after prolonged irradiation, while the absorption bands at 470, 442, and 415 nm increased continuously during the irradiation (Fig. 1). A similar behavior was observed in the FT-IR spectra, with some new bands disappearing and others growing continuously during irradiation. The former bands were ascribed to mononitrene **2** in the triplet state, showing good agreement with the theoretical IR spectrum calculated at the UB3LYP/6-31G* level.† Meanwhile, the FT-IR spectrum obtained upon irradiation with 330 shots (Fig. 2(a)) did not contain the characteristic IR band of the azido group (2116 cm^{-1}). Thus, the resulting product was formed by elimination of two nitrogen molecules from **1** (Scheme 1). This product (**3**) showed a prominent IR band at 750 cm^{-1} and others at 507, 1033, 1161, 1212, 1279, 1393, 1466, and 1506 cm^{-1}. These bands were ascribed to a single photoproduct from the dynamic behavior in intensity during irradiation.[8] Moreover, the dynamic behavior of the IR spectra corresponded to that of the

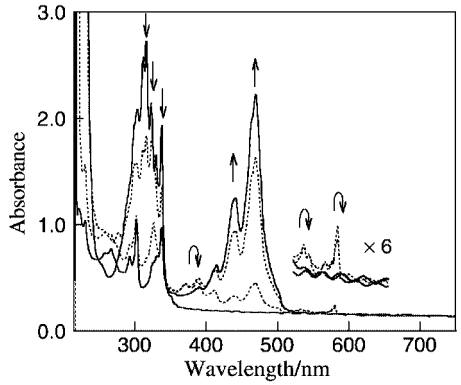

Fig. 1 UV-VIS absorption spectra of **1** photolyzed by XeCl excimer laser pulses (0, 30, 140, and 3440 shots) in an argon matrix. Arrows show the dynamic behavior in intensity of peaks during irradiation.

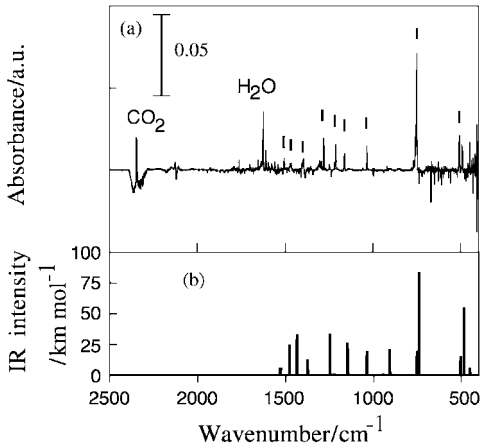

Fig. 2 (a) FT-IR spectrum observed upon irradiation with 330 shots and (b) theoretical IR spectrum of **3** (open-shell singlet state).

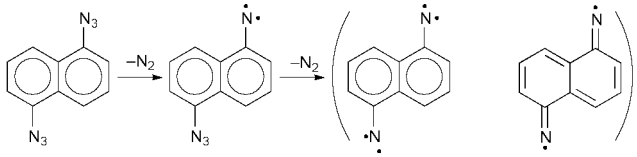

Scheme 1

† Electronic supplementary information (ESI) available: experimental details and computational study of the dinitrenes. See http://www.rsc.org/suppdata/cc/b0/b008560j/

DOI: 10.1039/b008560j

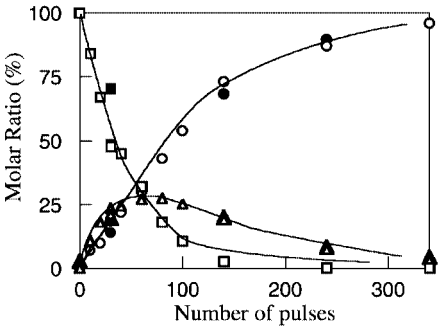

Fig. 3 Dynamic behavior of the intensities in the UV-VIS and FT-IR bands ascribed to **1** (solid squares, 339 nm; open squares, 1409 cm^{-1}), **2** (solid triangles, 581 nm; open triangles, 769 cm^{-1}), and **3** (solid circles, 470 nm; open circles: 750 cm^{-1}).

UV-VIS spectra during the whole irradiation as shown in Fig. 3. This behavior of the UV-VIS and IR bands ascribed to **1**, **2**, and **3** revealed a typical consecutive reaction, that is, consecutive elimination of two nitrogen molecules from **1**.[9] No IR bands ascribable to other species were observed under the present conditions. The observed FT-IR spectrum was compared with the theoretical IR spectrum of 1,5-dinitrenonaphthalene. For the quinonoidal dinitrenes reported as far, the ground state is the singlet diradical state which lies slightly below the triplet state: their energy gaps between singlet and triplet states ($\Delta E_{S\text{-}T}$) are rather small (< 1 kcal mol^{-1}).[2,3] The state order of the dinitrene with different spin multiplicities was often difficult to reproduce in the computational study,[10] since the theoretical calculations for singlet-diradicals show much difficulty because of their multireference character. It has recently been reported that calculations using the symmetry-broken spin-unrestricted DFT method give reasonable solutions for such diradicals.[10–12] Moreover, this method can afford reasonable solutions even for larger molecules. Therefore, preliminary calculations for the singlet, triplet, and quintet states of **3** were carried out at the UB3LYP/6-31G* level. Fig. 2(b) shows the theoretical IR spectrum of the singlet state. The theoretical calculation underestimated the wavenumbers of the IR bands by ~125 cm^{-1}. The deviation was larger than that shown normally in the calculations at this computational level. The deviations would be due to the spin contamination: the results on **3** showed the spin squared expectation ($< S^2 >$) value of 1.78, indicating the admixture of the triplet and quintet states. In the symmetry-broken spin-unrestricted calculations, the $< S^2 >$ value of the singlet diradical should be 1.0.[11] Although deviations in wavenumber were shown, the observed spectral feature was well described by comparison of those with other spin multiplicities (see ESI†). Moreover, the observed UV-VIS spectra indicated the quinonoidal structure as followed. (1) The UV-VIS bands (470, 442, and 415 nm) of **3** corresponded to that of the 1,5-naphthoquinone derivative (475 and 458 nm) which should have a similar electronic structure to the quinonoidal dinitrene.[13] (2) The INDO/S computation[14] based on the quinonidal geometry of singlet diradical predicts major UV-VIS bands at 468 and 460 nm, that are in agreement with the experimental results. Thus, it is concluded that the photoproduct prepared from **1** was 1,5-dinitrenonaphthalene, which was the quinonoidal singlet diradical in the ground state. The dinitrene **3** was formed by elimination of two nitrogen molecules from **1** without the rearrangement observed for 1- or 2-azidonaphthalenes.[15]

UV-VIS spectroscopy revealed that a similar photolysis occurred for **1** in a glassy 2-methyltetrahydrofuran (MTHF) matrix at 77 K upon a Xe lamp irradiation through a band-pass glass filter ($350 < \lambda < 380$ nm). Under these conditions, ESR spectroscopy (X band) was used to analyze the photolysis of a MTHF solution of **1** (4.6 mM). Upon irradiation, ESR signals at 622 and 611 mT, ascribed to triplet mononitrenes,[16] were observed in addition to the typical impurity signal in the $g = 2$ region. Signals ascribable to a dinitrene with higher spin multiplicity were not observed. The absence of the signals indicated that the ground state of **3** was a singlet diradical. Minato and Lahti[2] and Nimura and others[3] report that 1,4-dinitrenobenzene **4** and several other quinonoidal dinitrenes show ESR signals ascribable to thermally populated excited triplet states. The reason for the absence of such signals can be explained as follows: since 1,5-dinitrenonaphthalene has a larger $\Delta E_{S\text{-}T}$ than **4** and the other quinonoidal dinitrenes, the population of the thermally-excited triplet state is too low to detect. The DFT calculations support our interpretation of the reason why the quinonoidal triplet ESR signals are difficult to detect.† Moreover, theoretical calculations with higher levels by Serwinski *et al.* also support our interpretation.[17]

In conclusion, 1,5-dinitrenonaphthalene was formed by the consecutive elimination of nitrogen molecules from 1,5-diazidonaphthalene upon irradiation at 308 nm in low-temperature matrices. On the basis of matrix isolation spectroscopies and theoretical calculations, we confirmed that the dinitrene formed was a quinonoidal singlet diradical with a relatively large $\Delta E_{S\text{-}T}$. Further study on other dinitrenonaphthalenes is in progress.

We are grateful to Professor Paul M. Lahti (University of Massachusetts) and Professor Hideo Tomioka (Mie University) for helpful discussions.

7 The sample chamber has two pairs of windows: KBr windows for IR measurement and quartz windows for UV-VIS measurement. Therefore, UV-VIS and FT-IR spectra of the same sample matrix can be simultaneously observed.
8 The photoproduct **3** was generated upon irradiation at 308 nm and photolyzed at 248 nm. The dynamic behavior of these bands was analyzed for its generation and decomposition. All of these bands showed similar dynamic behavior.
9 The dynamic behavior in absorbance was scaled to express the molar ratio in the matrix. The molar ratios (%) of **1** and **2** to initial **1** were estimated from the absorbance of the IR bands due to the azido groups in each compound on the basis of their theoretical IR intensities (1929 and 923 km mol^{-1} for **1** and **2**, respectively). The residual portion was allocated to **3** because no other species was detected under the present conditions. The absorbance of the UV-VIS bands are scaled to fit the dynamics in absorbance of the IR bands.

Pillar-shaped structures and patterns of three-dimensional carbon nanotube alignments

Xianbao Wang, Yunqi Liu* and Daoben Zhu*

Center for Molecular Science, Institute of Chemistry, Chinese Academy of Sciences, Beijing 100080, P. R. China. E-mail: liuyq@infoc3.icas.ac.cn

Received (in Cambridge, UK) 8th January 2001, Accepted 16th March 2001
First published as an Advance Article on the web 30th March 2001

Pillar-shaped structures and patterns of three-dimensional multi-walled carbon nanotube arrays have been synthesized by pyrolysis of iron(II) phthalocyanine.

Alignments of carbon nanotubes (CNTs) are particularly important for fabricating functional devices such as field emitters[1–4] and nanoelectronics[5,6] as well as ultrahydrophobic materials.[7] Two-dimensional (2D) aligned nanotubes were obtained previously by using chemical vapor deposition (CVD) over catalyst embedded in mesoporous silica[4,8] or on quartz substrate[9] and over laser-patterned catalysts.[10] Recently, Ren *et al.*[11,12] have reported the synthesis of self-aligned 2D nanotubes on glass substrates by using plasma-enhanced CVD, although this method suffered from complex pre-synthesis manipulations. However, to our knowledge, preparation of three-dimensional (3D) CNT alignments has not been reported. Here, we have developed a simple method for a large-scale synthesis of 3D aligned CNTs normal to the quartz substrate surface without any pre- or post-synthesis manipulations.

A typical experimental procedure was as follows:[13] a clean quartz glass plate ($4 \times 2 \times 0.1$ cm) was placed in a flow reactor consisting of a quartz tube and a furnace fitted with an independent temperature controller. A flow of Ar–H_2 (1 : 1, v/v, 20 cm^3 min^{-1}) was then introduced into the quartz tube during heating. After the central region of the furnace reached 950 °C, a quartz boat with 0.5 g of iron(II) phthalocyanine was placed in the region where the temperature was 550 °C. After 5 min heating, CNTs grew in a direction normal to the substrate surface. The CNT samples were examined by scanning electron microscopy (SEM, JEOL JSM-6301F) to characterize their profile, alignment and uniformity. Transmission electron microscopy (TEM, Hitachi H-800, 100 kV) was used to determine the diameters and microstructure of the CNTs. X-Ray photoelectron spectroscopy (XPS) analyses of the samples were performed on a VG ESCALAB 220-IXL spectrometer using an Al-Kα X-ray source (1486.6 eV).

Fig. 1 shows SEM images of 3D regular arrays of nanotubes aligned along the direction perpendecular to the substrate surface. As can be seen in Fig. 1(a), a few pillar-shaped structures of CNTs grow out from the 2D alignments in a well distributed mode. At high magnification, the SEM image [Fig. 1(b)] clearly shows that the pillar-shaped structures dispersed in the middle of the 2D CNT alignments. The CNT posts with a diameter of *ca*. 3.4 μm are 7.8 μm higher than the 2D nanotube alignments, whose height is typically 6 μm from the quartz substrate. The structure is reminiscent of papillose epidermal cells of lotus leaf surfaces that provide very effective water-repellent and anti-adhesive properties against particulate contamination, denoted self-cleaning ability.

A high magnification SEM image (Fig. 2) of an individual nanotube post shows that it is a tubular bundle with a diameter of 2.8 μm and a height of 5.5 μm. A TEM investigation (inset) reveals that the nanotubes composing 3D alignments are bamboo-like multiwalled nanotubes[15] with a diameter of *ca*. 50 nm. The alignment is partially preserved despite the sonication of the raw material in ethanol before deposition of the nanotubes onto the holey carbon film TEM grid. This clearly indicates that the nanotubes of 3D alignments are densely packed and held together by van der Waals interactions.

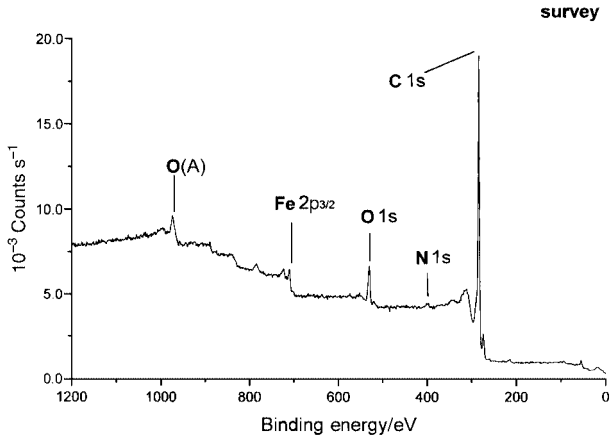

Fig. 3 A wide survey XPS spectrum of the carbon nanotubes.

Fig. 3 shows a wide survey XPS spectrum of the nanotubes. A sharp peak at 284.5 eV corresponds to a π* feature associated with sp^2 hybridized carbon. This observation confirms that the nanotubes mainly contain carbon. Besides carbon (93.30 atom%), nitrogen (0.96 atom%) and iron (0.74 atom%), oxygen (5.00 atom%) is also present in the surface of the nanotubes, which may arise from air absorbed on the nanotubes. A split in the π*-type peak of the N 1s spectrum (not shown) reveals the presence of two peaks at 399.3 and 401.1 eV, corresponding to sp^2 pyridine-like N and sp^3 bridgehead-type N incorporated into the graphitic network, respectively.[16] The 399.3 eV feature is due to pyridinic nitrogen present at the nanotube end, while the peak centered at 401.1 eV corresponds to trivalent nitrogen replacing the carbon in the hexagonal structure.[17] The substitutional N in a graphite sheet strongly favours the formation of pentagons and heptagons, which is responsible for the bamboo-like morphologies.[15]

In addition to the pillar-shaped 3D nanotube alignments, most interesting patterns made of nanotubes arrays, such as ring-like castles [Fig. 4(a)] and a 490 μm long crucian carp without a tail and fins [Fig. 4(b)], were observed under similar experimental conditions. Although the growth mechanism for these patterns is not clear at the present stage, we think that the substrate should be responsible for their formation. Apart from this, both the strong van der Waals interactions between the tubes and the high surface density of the growing nanotubes serve as additional factors for the constituent nanotube to be "uncoiled" and allow the aligned nanotubes to develop on the quartz substrate.

In conclusion, we report the pillar-shaped fabrication and the most interesting patterns of 3D CNT alignments by pyrolysis of iron(II) phthalocyanine. The nanotube alignments have been identified as promising candidates for field emitters in applications such as flat panel displays. Moreover, we can find innumerable technical applications in the field of biomimetic materials if the ultrahydrophobic property of the pillar-shaped 3D alignments of CNTs can be transferred to artificial surfaces (*e.g.* cars, facades, foils). Further efforts should concentrate on the understanding the growth mechanism and controlled synthesis of the 3D regular arrays of the nanotubes.

We gratefully acknowledge financial support from the National Nature Science Foundation of China (NSFC) and the Chinese Academy of Sciences.

cis-Fused γ-lactones from simple precursors *via* β-lactone rearrangements

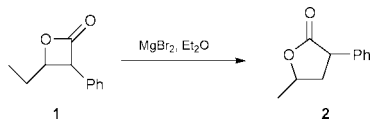
T. Howard Black,*† Douglas C. Smith,‡ Shane A. Eisenbeis, Karen A. Peterson and Mark S. Harmon

Department of Chemistry, Eastern Illinois University, Charleston, IL 61920 USA. E-mail: thblack@eiu.edu

Received (in Corvallis, OR, USA) 2nd January 2001, Accepted 3rd March 2001
First published as an Advance Article on the web 3rd April 2001

***cis*-Fused bicyclic γ-lactones were prepared in a three step sequence, featuring the stereospecific rearrangement of spiro bicyclic β-lactones; the dependence of the β- to γ-lactone ring expansion on the relative stabilities of the intermediate carbocations was also investigated.**

We have previously demonstrated that β-lactones, such as **1**, undergo ring expansion towards more highly or equally substituted carbon atoms, *via* carbocation rearrangements, to afford γ-lactones **2** (Scheme 1).[1] Moreover, it has also been determined that this ring expansion requires that both migrating bonds bear an antiperiplanar relationship with respect to one another to effect γ-lactone formation.

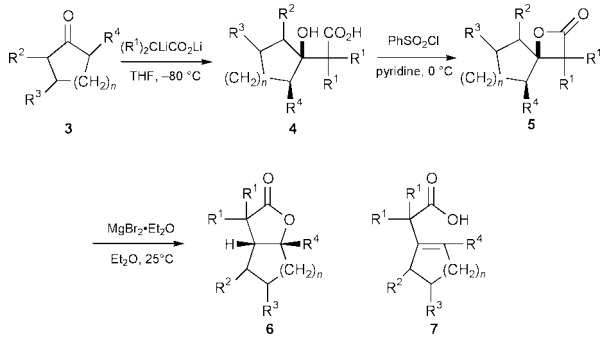


Scheme 1

In an effort to further explore the scope and limitations of this very useful transformation, we examined the rearrangement of β-lactones derived from cyclic ketones, carefully selected in order to most accurately ascertain how structural variations within the spiro-bound carbocycle would affect β- to γ-lactone ring expansion reactions.

Scheme 2 depicts the method by which butyrolactones were prepared from simple carbonyl precursors.[2] In this study, the dianion of either isobutyric acid or acetic acid was condensed with cyclic ketones **3** to afford the corresponding β-hydroxy acids **4** in fair to good yields.[3] These acids were subsequently treated with $PhSO_2Cl$ in pyridine for 12 h at 0 °C to provide, in good to excellent yields, spiro bicyclic β-lactones **5**. Treatment of **5** with freshly prepared $MgBr_2$[4] in anhydrous diethyl ether initiated their rearrangement to the fused γ-lactones **6** or, in one case, the corresponding β,γ-unsaturated carboxylic acid **7**.[5] These results are summarized in Table 1.

The pivotal event in this transformation is the rearrangement of one intermediate tertiary carbocation to another tertiary carbocation; this is followed by annulation to form the γ-lactone ring. The *cis* fusion of these systems, although predicted on



Scheme 2

‡ Camille and Henry Dreyfus Fellow, 1993–1995.

Table 1 Structural and yield data for Scheme 2

						Isolated yield (%)			
Suffix	**3***n*	R^1	R^2	R^3	R^4	**4**	**5**	**6**	**7**
a	1	CH_3	H	H	CH_3	67	85	88	0
b	2	CH_3	H	H	CH_3	63	93	73	0
c	2	H	H	H	CH_3	78	82	84	0
d	2	CH_3	H	H	OCH_3	89	73	85	0
e	2	CH_3	Benzo fused		H	79	67	0	57

mechanistic grounds, could not be determined spectroscopically *a priori*; thus, stereochemical assignment of these compounds was made by analogy to compounds previously reported in the literature. Accordingly, the known[6] γ-lactone **6c** was prepared from the dianion of acetic acid and 2-methylcyclohexanone, **3c**, in 54% overall yield (three steps). This compound was found to have physical and spectral characteristics identical to those previously reported for the *cis* isomer.[4] Moreover, this analog permitted unequivocal stereochemical determination spectroscopically through the use of NOE techniques; these results are summarized in Fig. 1. Irradiation of the methyl group in Fig. 1 led to an NOE enhancement of 7.2% for the adjacent bridgehead proton, while reciprocal irradiation of the bridgehead proton led to an NOE enhancement of 3.7% for the adjacent methyl group. Therefore, compounds **6a,b,d** were also assigned a *cis* ring fusion by analogy.

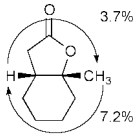

Fig. 1

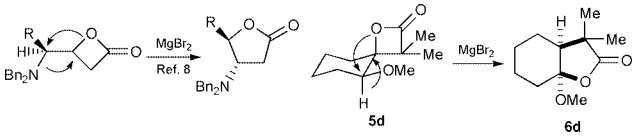
In only one instance was a fused bicyclic butyrolactone not produced. The rearrangement of spiro bicyclic β-lactone **5e**, derived from α-tetralone, to such an entity, would have required the rearrangement of a tertiary benzylic carbocation to a secondary homobenzylic species. As this is obviously a thermodynamically unfavorable process, elimination occurred instead to provide exclusively β,γ-unsaturated carboxylic acid **7e**.[7]

An interesting observation noted during this investigation was the migration of a hydride, in place of an available methoxy group, in the **5d** to **6d** transformation. Reetz has demonstrated heteroatom migration preferentially to hydride in β-lactone ring expansions, when single bond rotation allows for ready alignment of either.[8] However, in β-lactone **5d**, only the hydrogen is situated in the required antiperiplanar alignment with the lactone ring oxygen; thus, exclusive migration of the hydride occurs in high yield. These reactions are illustrated in Scheme 3. The success of the transformation of **5d** to **6d** bodes very well for future applications as an alternative route for the preparation of γ-*exo*-enol lactones,[9] which are common structural units in natural products possessing a variety of applications.[10] Moreover, this strategy also allows for an alternative preparation[11] of 1,4-dicarbonyl compounds, which are useful

DOI: 10.1039/b100261a



Scheme 3

synthons in natural products synthesis. Future studies of the generality of this procedure are planned, employing different heteroatom substituents in various conformations, to determine the scope and limitations of this potentially very useful new protocol.

In summary, the ability of β-lactones to rearrange to their corresponding butyrolactone derivatives depends upon both the relative stability of the two involved intermediate carbocations and the ability of the migrating bonds to achieve an anti-periplanar relationship. This method has also proved to be very efficient for the preparation of a variety of *cis* fused bicyclic lactones, and provides easy access to these important structural subunits.

We wish to thank Dr Ellen Keiter of Eastern Illinois University and Dr Dean Carlson of Purdue University for their assistance in determining the relative stereochemistry of the bicyclic γ-lactones. Additionally, we would like to thank the Petroleum Research Fund (administered by the ACS), the National Science Foundation (CHE-9203760), the Camille and Henry Dreyfus Foundation, and the National Institutes of Health (GM52677-01) for their financial support; as well as the NSF ILI program for funds with which to purchase a GCMS (USE-9251113) and a QE 300 NMR spectrometer (CHE-8815619).

3 These acids were routinely recrystallized (ethyl acetate) prior to lactonization, so that only the predominant (shown) stereoisomer was carried on. In early experiments, the *erythro*:*threo* isomer ratio was determined to be at least 95:5.
4 Note: it is important to use freshly prepared $MgBr_2$ to effect this rearrangement. This is most readily accomplished by treating 1,2-dibromoethane with magnesium metal in anhydrous ether for approximately 1 h prior to the addition of the β-lactone substrate. Employing either commercial $MgBr_2$ or its diethyl ether complex results in considerably lower yields of the γ-lactone.

Received (in Cambridge, UK) 6th December 2000, Accepted 13th March 2001
First published as an Advance Article on the web 3rd April 2001

An ultrasensitive microgravimetric biosensor has been developed incorporating Au nanoparticle-amplified sandwiched immunoassay and silver enhancement reaction; Au nanoparticle-promoted silver(I) reduction and silver metal deposition result in *ca.* two orders of magnitude improvement in human IgG quantification.

The use of gold nanoparticles as a signal amplifier has attracted increasing interest in biosensor development. For example, in surface plasmon resonance[1–3] and microgravimetric quartz crystal microbalance (QCM)[4] based protein binding assay and DNA hybridization assay, mass coupling of functional Au nanoparticles results in a tens- to hundreds-fold sensitivity increase. However, the use of primary Au nanoparticles is not the end of the amplification. Efforts have been made to realize ultrasensitive biosensing by means of sequent amplification routes of, for example, multilayered[5] or dendritic-type Au nanoparticles.[6] In the latter example (microgravimetric DNA sensor), the primary Au nanoparticle amplification (*ca.* 10-fold) is followed by a secondary dendritic-type Au nanoparticle interaction. A total of 30-fold signal enhancement is achieved through the stepwise amplification.

Immunogold silver staining (IGSS) has been widely used in histochemical microscopy studies,[7] where functional Au nanoparticles act as catalysts to reduce silver ions to metallic silver. The autometallographic silver deposition procedure enlarges the size and darkens the color of the particles, such that protein-, antibody- or DNA-conjugated Au particles become visible under electron- or light-microscope. Most recently, this amplification strategy has been adopted in a pioneering study of scanometric DNA array quantification.[8] The incorporation of Au nanoparticle labeling and silver staining amplification results in two orders of magnitude improvement in detection sensitivity when compared with a conventional fluorophore system. Based on the similar amplification routes, a silicon-based flexural plate wave sensor has been developed.[9] The mass loading caused by Au particle-catalyzed deposition of metallic silver leads to a five orders of magnitude improvement in cancer antigen detection. In addition to the Au conjugate-promoted silver staining reaction, enzyme conjugate-catalyzed precipitation processes have also been applied for signal amplification in QCM and electrochemical sensors.[10,11]

Using an Au conjugate as a biocatalytic probe, we present herein an ultrasensitive microgravimetric QCM biosensor, in which primary Au nanoparticle-amplified sandwiched-immunoassay is followed by a silver staining reaction. The sensor elements are 10 MHz AT-cut quartz crystals coated with silver electrodes. An immunochemical molecular recognition event between anti-human IgG (a-h IgG) and human IgG (h IgG) is chosen to illustrate the sandwich procedure and, sequentially, the silver enhancement reaction (Scheme 1). It can be seen the proposed assay starts from the shielding of the metal electrode by polystyrene treatment. As reported in our previous study,[12] deposition of a polystyrene film (from a 5 mg ml^{-1} toluene solution) shields the silver electrode from undesirable oxidation and, in addition, provides a substrate for biomolecular immobilization. In this study, to evaluate the coverage of the polymer film further, the silver enhancement reagent [a freshly prepared 1:1 mixture of the silver enhancement solution A

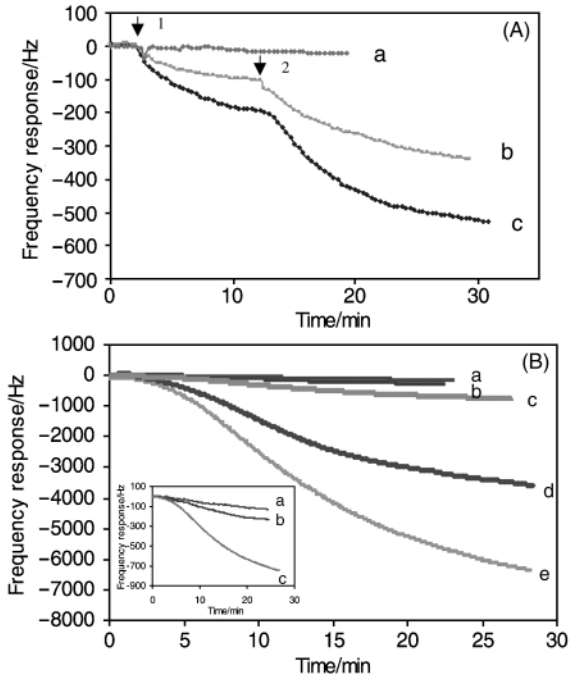

Fig. 1 (A) Frequency response of a-h IgG-modified sensors upon the application of h-IgG (10 μg ml^{-1}, curve b; 20 μg ml^{-1}, curve c) at arrow 1 and, sequentially, F_c specific a-h IgG:Au at arrow 2. Curve a is obtained when the modified sensor was exposed to the Au conjugate directly without h IgG application. (B) Frequency response of sandwiched complex coated sensors upon the exposure to silver enhancement reagent. Curves a and b are the background signals obtained in the absence of Au conjugate and h IgG incubation, respectively, in the sandwiched procedures; curves c, d and e represent h IgG concentrations of 0.5, 10 and 20 μg ml^{-1}, respectively.

DOI: 10.1039/b009768n

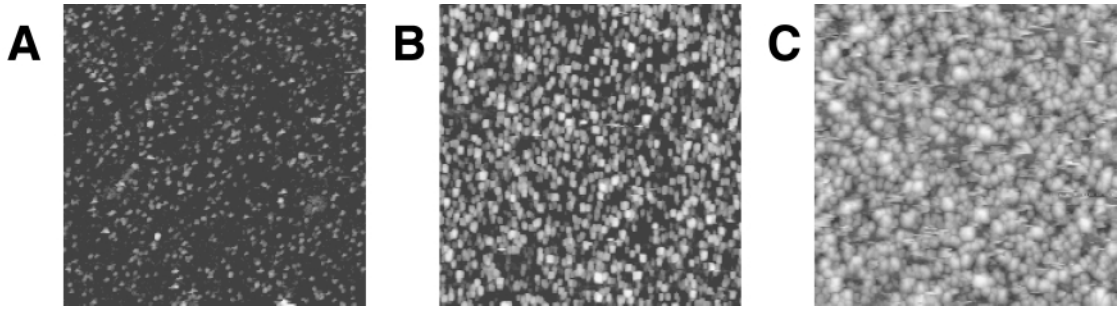

Fig. 2 AFM images (1 μm × 1 μm) of anti-h IgG/h-IgG (20 μg ml^{-1})/a-h IgG:Au coated surfaces before exposure (A), and after 10 min (B) and 30 min (C) exposure to silver enhancement solution.

(silver salt) and solution B (hydroquinone initiator) from Silver Enhancer Kit, SE-100 (Sigma)] was applied to the treated surface. After 30 min of reaction, no darkening of the surface was observed and the resonant frequency of the sensor remained unchanged. Thus it can be assumed that, after shielding by polystyrene, none of the metal electrode is exposed to serve as a nucleation site for silver ion reduction. This is essential for the proposed assay.

After polystyrene coating, the sensor surfaces were exposed to 0.5 mg ml^{-1} of a-h IgG (γ-chain specific, Sigma) in PBS buffer, pH 7.4. Through 1 h of incubation at 37 °C, the antibody molecules were firmly immobilized through passive adsorption and hydrophobic interaction. After blocking the non-occupied binding sites (2% BSA incubation for 15 min), the modified surfaces (with resonant frequency F_0) were exposed to h IgG (purified from serum, Sigma) and, when equilibrated, to 10 nm Au-conjugated a-h IgG (F_c-specific, Sigma). As a result, the analyte (h IgG) was sandwiched between bound antibodies and Au-conjugated antibodies. Fig. 1(A) shows the frequency responses of the sandwich procedures. The binding of h IgG with bound a-h IgG leads to a smooth frequency decrease to F_1. Complete binding is achieved within *ca*. 10 min. The following Au conjugate application results in further frequency response to F_2 after a longer duration of about 20 min. The total frequency changes caused by the sandwich procedures (F_0–F_2) are three- to four-fold greater than those obtained by direct analyte binding (F_0–F_1). The lower response of the Au conjugates may arise from steric inhibition of the huge molecules (it has been estimated that a 10 nm Au particle conjugates with seven IgG molecules). If the a-h IgG-modified sensor was exposed to Au-conjugated a-h IgG directly without analyte application, no frequency response was detectable [curve a in Fig. 1(A)]. This confirms that the binding of the Au-conjugate is attributable to the primary amplification for h IgG determination in the sandwich assay.

This is not the end of the amplification. Upon formation of the sandwiched immunocomplex, the sensor surfaces are coated with Au nanoparticles, which serve as nucleation sites to catalyze silver ion reduction. Fig. 1(B) shows the frequency responses of the sandwiched-immunocomplex-coated surfaces upon application of the silver enhancement solution. The deposition of metallic silver on the surface of the bound Au particle boosts the signal further to F_3 (Scheme 1). To optimize the signal and to reduce the silver staining background, after the sandwich reactions the sensors were rinsed thoroughly using deionized water to remove all salt content so as to avoid the auto-nucleation of silver. In addition, a five-fold diluted silver enhancement solution was optimal in reducing the staining background obtained in the absence of Au-conjugated antibodies [curve (a) in Fig. 1(B)] or h IgG [curve (b) in Fig. 1(B)]. These results confirm that neither significant nonspecific silver staining nor nonspecific Au particle binding occurs. Under the optimal conditions, the enormous frequency changes caused by silver metal deposition on a-h IgG/h IgG/a-h IgG:Au-coated sensors (F_2–F_3) are reflective of h IgG at different concentrations [curves c–e in Fig. 1(B)]. The incorporated primary and secondary amplified signals (F_0–F_3) are proportional to h IgG concentrations with ΔF(Hz) = $317C_{IgG}$(μg ml^{-1}) + 256, r^2 = 0.962. This is about two orders of magnitude more sensitive than that of direct assay.[12] It is also interesting to note that Fig. 2(B) reveals the mechanism of Au-promoted silver(I) reduction: within the first 5 min, the reduction is slow; after 5 min, significant reduction appears; and at *ca*. 30 min the reduction tends to be complete.[7]

The above observations are further proved by atomic force microscopy (AFM) studies. AFM images(1 μm × 1 μm) acquired for a-h IgG/h IgG/a-h IgG:Au-coated surfaces before [Fig. 2(A)] and after exposure to the silver enhancement solution [Fig. 2(B) and 2(C)] were obtained using a TMX 2000 Explorer System (TopoMetrix, Santa Clara, CA) operated under ambient conditions. Si_3N_4 cantilevers with V-shaped tips (20–50 nm radius of curvature) were used for measurement in contact mode. Although the observed particle size may deviate from the actual value because of the intrinsic curvature of the tip,[13] the deposition of metallic silver on the surface of the Au particles is still clearly evident.

In conclusion, we have developed an ultrasensitive QCM biosensor which combines metal electrode shielding, Au nanoparticle-amplified sandwiched-assay and a silver enhancement reaction. Based on this method, the detection sensitivity of the microgravimetric sensor is no longer subject to the mass of the analyte molecules. Since the proposed assay relies on the shielding of the metal electrode, the advanced electrode shielding technique remains a challenge. For example, functionalization of a polystyrene film may combine electrode protection with covalent DNA molecule immobilization in one preparation step, such that the proposed assay can be extended to ultrasensitive DNA analysis. In addition, this study suggests the possibility of utilizing the silver enhancement reaction for quantification in chip-based biosensing.

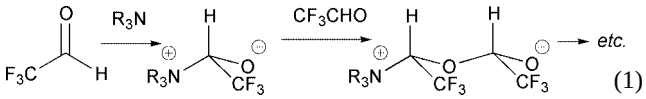
First published as an Advance Article on the web 4th April 2001

The product formation and yields for the Baylis–Hillman reaction of fluorine-containing carbonyl compounds depend on a balance between the reactivities of the carbonyl and olefin partners.

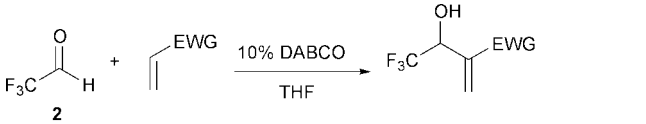
It is well established that the biological properties of medicinal compounds can often be influenced by fluorine substitution.[1] The physical properties of several electronic and optical devices also depend immensely on the structure of fluoroorganic molecules.[2] Fluorine substitution provides organic chemists with an opportunity to study an extreme case of electronic effect in reactions.[1,2] As part of our ongoing projects in fluoroorganic chemistry,[3] we examined the Baylis–Hillman (BH) reaction[4] of activated olefins with fluoro-aldehydes and -ketones in the



(1)

presence of 10 mol% of 1,4-diazabicyclo[2.2.2]octane (DABCO). Herein we report a fascinating relation between the reactivities of the carbonyl and olefin partners for the BH reaction of fluorocarbonyls; a match providing optimum yields of the products, whereas a mismatch resulting in the decomposition or side reaction of the faster reacting partner.

Acrolein (**1a**), methyl vinyl ketone (**1b**), ethyl acrylate (**1c**) and acrylonitrile (**1d**) were the olefins chosen for the reaction. Initially we studied the reaction of fluoral (**2**) with **1a**–**d**. Upon mixing **2** with **1a** at rt under neat conditions, in the presence of 10% DABCO, polymerization of both reactants occurred. Both of these are known to polymerize in the presence of amines [eqn. (1)].[5,6] We then carried out the reaction in THF and obtained a very low yield of the expected product along with the polymerized starting materials. With the hope of arresting the polymerization, we lowered the reaction temperature to −25 °C and obtained a 40% yield of the product, **3a** [eqn. (2)]. However,



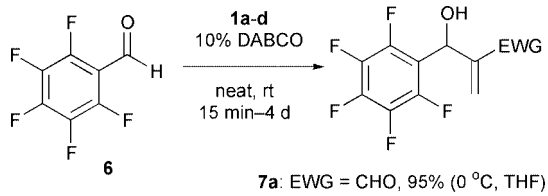
(2)

we could not suppress the polymerization completely. Further lowering the temperature had a deleterious effect since polymerization of both reactants was faster than the BH reaction at this temperature.

Reaction of **2** with **1b** provided the product **3b** in 35% yield under neat conditions, at rt, 1 h. Surprisingly, the yield in THF at −25 °C was 65%! [eqn. (2)]. However, the reaction of **1c** provided only a 20% yield of the product **3c** at rt under neat conditions [eqn. (2)]. Decreasing the reaction temperature suppressed the BH reaction completely and only the polymer of fluoral was obtained. Olefin **1d** did not yield any BH product **3d** at room or lower temperature.

Reaction of 2,2,3,3,4,4,4-heptafluorobutanal (**4**), the fluorinated homolog of **2**, showed identical reaction patterns with slightly improved yields of the products. Thus, while **1a** and **1b** provided 50 and 70% yield, respectively, of products at −25 °C, **1c** provided 22% yield of the product **5c** and **1d** failed to provide any product at rt.

The dissimilarity in product yields from activated olefins of differing reactivity captivated us. We considered a less reactive perfluorinated aldehyde that does not undergo polymerization in the presence of a 3°-amine and tested pentafluorobenzaldehyde (**6**) with **1a**–**d**. While the reactions of **1b**–**d** were complete under neat condition at rt within 2–4 d, **1a** polymerized. However, it reacted in THF at 0 °C within 15 min providing 95% yield of the product [eqn. (3)].



(3)

7a: EWG = CHO, 95% (0 °C, THF)
7b: EWG = COMe, 70%
7c: EWG = CO_2Et, 70%
7d: EWG = CN, 75%

Ordinary ketones undergo Baylis-Hillman reaction occasionally under high pressures[4] and activated carbonyls, such as α-keto esters and hexafluoroacetone undergo relatively fast reaction.[7,8] 1,1,1-Trifluoroacetone (**8**) is known to trimerize in the presence of amines.[9] However, our partial success with **2** persuaded us to carry out its reaction at low temperatures. In fact, we obtained only 10–12% yield of the products **9a** with **1a** in THF at −25 °C, and **9d** with **1d** at rt. Olefins **1b** and **1c** failed to provide any product with **8**. We isolated a polymeric material in both of these cases.

To avoid the polymerization initiated by abstraction of the α-hydrogen atom, we focused our attention on aromatic trifluoromethyl ketones. The treatment of 2,2,2-trifluoroacetophenone (**10**) with two equiv. of **1a**, under neat conditions, at rt did not provide any product. Decreasing the reaction temperature to −25 °C yielded 15% of acrolein dimer along with its polymer. Olefin **1b** also did not provide any of the expected BH products at rt, although we obtained a 30% yield of the dimer. Lowering the temperature resulted only in the suppression of the dimerization. In contrast, a slow reaction (7 d) between **10** and **1c** resulted in 70% yield of the expected allylic alcohol **11c**. The reaction with **1d** was faster, complete within 24 h, and provided 94% yield of the product **11d** [eqn. (4)].

2-(Trifluoroacetyl)thiophene (**12**) provided similar results. On testing with **1a**–**d**, it underwent reaction only with **1c** within 7 d providing the product **13c** in 65% yield, and with **1d**, within 24 h, providing the product allylic alcohol **13d** in 82% yield [eqn. (4)].

(4)

2,3,4,5,6-Pentafluoroacetophenone (**14**) behaved like an ordinary ketone, failing to react with any of the four activated olefins.

In conclusion, we have studied the effect of fluorine substitution in the Baylis–Hillman reaction. A series of novel functionalized fluorinated allyl alcohols have been synthesized during this study, enriching fluoroorganic chemistry.[10] We have successfully obtained products even from amine-sensitive carbonyls as well as olefins by controlling the reaction conditions. This is the first report of a Baylis–Hillman reaction at such low temperatures (−25 °C).

When the fluorocarbonyls are extremely reactive, capable of reacting with themselves in the presence of an amine (*e.g.* fluoral, heptafluorobutanal), the olefin has to be very reactive as well (*e.g.* acrolein, methyl vinyl ketone) to obtain the products. A mismatch as in the case of relatively less reactive ethyl acrylate and acrylonitrile results in the polymerization of these fluoroaldehydes. The reaction of a less reactive fluorocarbonyl, such as pentafluorobenzaldehyde, is effective with both highly reactive and moderately reactive olefins. Decreasing the reactivity of the fluorocarbonyl further (*e.g.* 2,2,2-trifluoroacetophenone) provides good yield of products only with the less reactive olefins (*e.g.* ethyl acrylate and acrylonitrile). Ring-fluorination of aromatic ketones does not sufficiently activate the carbonyl for the reaction. It appears that a match between the reactivities of the fluorocarbonyl and olefin partners is essential for obtaining reasonable yield of the products in the Baylis–Hillman reaction.[11]

11 The reaction of methyl vinyl ketone with fluoral is representative. 2,2,2-Trifluoroacetaldehyde (0.49 g, 5 mmol) was added, at −25 °C, to a stirred solution of methyl vinyl ketone (0.70 g, 10 mmol, 0.83 mL) in THF (5 mL). DABCO (0.056 g, 0.5 mmol) in 0.5 mL THF was added to this and was stirred at this temperature for an additional hour. The solvent was evaporated under vacuum, and the crude reaction mixture was purified by silica gel chromatography (hexanes–ethyl acetate 9:1) to yield 0.55 g (65%) of the pure product.

First published as an Advance Article on the web 3rd April 2001

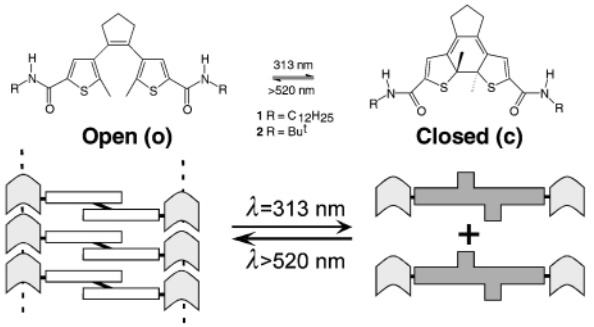
A new self-assembling system is developed, based on dithienylcyclopentene photochromic switches, which forms extended aggregates in solution and for which the viscosity can be changed by light.

The self-assembly of small functional molecules into supramolecular structures comprises a powerful approach towards the development of new materials and devices of nanoscale dimensions,[1,2] and the control of these organisational processes by chemical or physical elements is a major challenge. A promising approach towards such responsive or smart materials is the integration of an addressable function, *e.g.* photochromic moieties,[3] into the supramolecular building blocks, which would offer the possibility to alter the self-assembly process of the individual molecules or change the properties of the supramolecular arrays by means of light.[4]

Here we report on a new self-assembling system based on diarylethene photochromic switches,[3] which forms extended aggregates in solution, and the viscosity of which can be changed by light. Diarylethene and particularly dithienylcyclopentene molecular switches[3,5] are a distinct class of photochromic compounds that can undergo a reversible ring-closure reaction upon irradiation with UV- and visible-light, respectively, which is accompanied by a pronounced change of the electronic properties and conformational flexibility: in the open form (**1o**) the two thienyl moieties are not conjugated and can rotate around the bond connecting them with the cyclopentene ring, whereas in the ring-closed form (**1c**) the conjugation extends throughout the molecule and the rotational freedom is lost (Scheme 1). In this study, the geometrical change accompanying the photochemical transformation is exploited to change the self-assembling properties of **1**, and hence the macroscopic properties of the system. The dithienylcyclopentenes used here offer two distinct features when compared to the commonly used azostilbenes:[4] (i) the photochemically induced ring-closure reaction of dithienylcyclopentenes involves geometrical transformation which is clearly different from the *cis–trans* isomerization, and (ii) the activation energy for thermal interconversion between the open and closed form is large.[3] The use of dithienylcyclopentenes in switchable supramolecular systems will therefore expand the scope of available transformations and will lead to thermally bistable systems (Scheme 1).

In order to promote the formation of supramolecular assemblies in solution by hydrogen bonding, a dithienylcyclopentene-switch has been extended with amide groups (Scheme 1). The 1,2-bis(5′[(alkylamino)carbonyl]-2′-methylthien-3′-yl)cyclopentenes (**1o** and **2o**) were synthesised in a two-step procedure starting from 1,2-bis(5′-formyl-2′-methylthien-3′-yl)cyclopentene.[6] Oxidation with Ag_2O provided the corresponding diacid, which was next converted to amides **1o** and **2o** by first activating the carboxylic acid with 2-chloro-4,6-dimethoxytriazine, followed by a reaction of the activated ester with the corresponding amine. Compounds **1o** and **2o**† were obtained in 33 and 30% overall yield, respectively, after column chromatography starting from the dialdehyde.

The gelation behaviour of **1o** was studied in various solvents of different polarity.[7] It was found that **1o** did not form gels with any of the solvents investigated, but with apolar solvents, like cyclohexane, dodecane and benzene, clear viscous solutions were formed at concentrations well above 5 mM, indicating that aggregation of **1o** occurs.[8] The ^{1}H NMR spectra of **1o** in C_6D_6 show a gradual down field shift of δ_{NH} from 5.26 to 5.56 ppm, and an increase of the line width with increasing concentration, indicating that **1o** forms highly dynamic aggregates through hydrogen bonding between the amide groups at higher concentrations. Together with the observation that the results are not changed by prolonged aging of the samples, this also indicates that the aggregates formed by **1o** are equilibrium structures. Fitting of the data to a cooperative aggregation model[9] revealed that the dimerization constant K_2 = 81 ± 3 M^{-1}, and the association constant for the formation of higher order aggregates K_N = 787 ± 19 M^{-1}. Apparently, the formation of higher order aggregates by bisamide **1o** is highly favored over the formation of dimers in apolar solvents like benzene. Viscosity measurements‡ were performed with a 14.6 mM solution of **1o** in benzene at different shear rates. As is clear from the data shown in Fig. 1, the viscosity decreases with increasing shear rate, indicating that solutions of **1o** behave as a non-Newtonian liquid. Although the molecular interpretation of this phenomenon is not yet clear, similar shear-thinning effects have been observed in helical self-assembled polymers consisting of small hydrogen bonding subunits.[8] It should be noted that dissolution of **2o** does not result in gel formation, nor does it cause a significant increase of the viscosity of the solvent.[10] Moreover, the ^{1}H NMR spectra of **2o** in C_6D_6 show only minor



Scheme 1 Photoswitching of diarylethene **1o** and **2o** and thereby controlling the extent of self-assembly of **1** by photochemical switching.

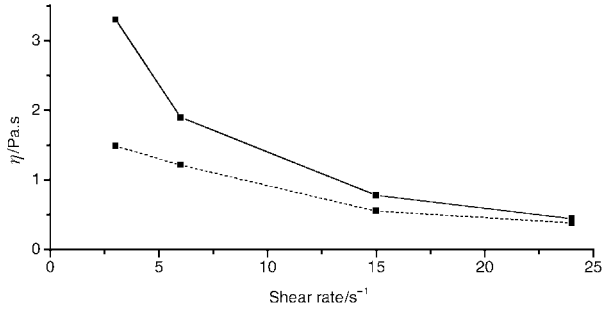


Fig. 1 Viscosity of 14.6 mM solution of **1o** in benzene before (—) and after irradiation (···) (**1o**/**1c** = 4).

DOI: 10.1039/b101231m

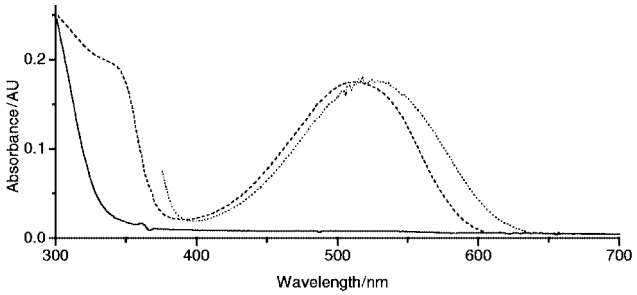

Fig. 2 UV–VIS spectra of a solution of **1o** in benzene (0.29 mM) before (—) and after irradiation (---) at 313 nm for 20 min and of a viscous solution of **1o** in benzene (11.7 mM) after irradiation (···) for 10 min at 313 nm.

shifts (< 0.05 ppm) upon increasing the concentration from 2 to 22 mM, indicating that the sterically more demanding *tert*-butyl groups effectively prevent aggregation of **2o** by intermolecular hydrogen bonding.

The photochromic behaviour§ of a dilute solution of **1o** in benzene (0.29 mM) was followed by UV spectroscopy as is depicted in Fig. 2. Upon irradiation of the solution of **1o** at 313 nm, a new absorption band at 514 nm appeared due to the formation of the conjugated closed form **1c**. From ^{1}H NMR data it was deduced that the photostationary state consists of a mixture of **1o** and **1c** in a molar ratio of **1o**/**1c** = 0.43. Irradiation at λ > 520 nm causes a complete conversion to the initial state consisting of pure **1o**, and this switching process between **1o** and **1c** could be repeated several times without showing any degradation. It is interesting to note that switching between **1o** and **1c** is not prohibited by formation of intra-molecular hydrogen bonds as has previously been reported for carboxylic acid derivatives of diarylethene switches,[11] although it cannot be excluded that such an intra-molecular hydrogen bond between the two amide groups is present. Also irradiation of a concentrated viscous solution of **1o** in benzene (11.7 mM) leads to the appearance of an absorption band at longer wavelength, characteristic for the formation of the closed form. The absorption maximum of **1c** shows a small red shift to 524 nm and is slightly broadened compared to the measurements at low concentrations, indicative of a weak exciton coupling between the chromophores in the aggregates. The switching process is also fully reversible in these concentrated solutions and can be repeated several times, although at very long irradiation times (> 20 h) some decomposition (< 5%) takes place.[12] The viscous solution needs, however, considerably longer irradiation times (6 h) to reach the photo-stationary state compared to monomeric solutions of **1o** (< 0.5 h), but quantitative analysis of the kinetics is not yet possible in our experimental set-up due to inner filter effects and an inhomogeneous optical field.

Most remarkably, even at relatively low conversions of **1o** to **1c** (**1o**/**1c** = 4) there is a clear decrease of the viscosity compared to benzene solutions of pure **1o**, demonstrating that the viscosity of solutions of **1** can be controlled by light (Fig. 1).[13] In order to determine whether this photo-induced viscosity change is due to a change of the aggregate properties like stiffness, or to a change of the extent of aggregation of **1**, the photoconversion of viscous benzene solutions of **1o** (7.32 mM in C_6D_6) was followed by ^{1}H NMR. Irradiation of a solution of **1o** at 313 nm caused the appearance of a second set of NH and CH_3 signals, which can be assigned to the closed form **1c**.§ After 50 min irradiation the NH signal of **1c** appears as a shoulder upfield from the NH signal of **1o**. After longer irradiation times both the NH signals of **1o** and **1c** are shifted upfield compared to the NH signal of pure **1o** (5.53 ppm) and after 6 h they have reached a constant position at 5.39 ppm. Although these results do not rule out any mesoscopic changes of the aggregates due to irradiation, they clearly indicate that photoconversion of **1o** to **1c** causes a decrease of the extent of aggregation. After 6 h irradiation a photostationary state was reached with the ratio **1o**/**1c** = 0.5 (determined from the integration of the CH_3 signals of **1o** and **1c** at, respectively, 1.76 and 2.16 ppm), which is comparable to the photostationary state of monomeric **1**. Irradiation at λ > 520 nm causes a complete conversion to **1o** with the NH signal again appearing at 5.53 ppm. Apparently, both the photoswitching and the aggregation of **1** are completely reversible. For comparison, similar experiments were carried out with C_6D_6 solutions of **2o**. Irradiation of 22 mM solutions of **2o** also resulted in two NH signals at 5.37 and 5.44 ppm, which can be assigned to **2o** and **2c** respectively, but for this compound the NH signals did not shift with increasing conversion of **2o** to **2c**. Also the viscosity measurements did not reveal a significant change of the viscosity due to photoswitching of **2**.

In conclusion, the bis-amide photochromic switch **1** self-assembles in apolar solvents through a cooperative association mechanism, and forms extented aggregates, resulting in highly viscous solutions. Most remarkably, the reversible photoswitching of **1** from the open form to the closed form causes a change of the extent of aggregation, which is accompanied by a decrease of the viscosity. These changes can be attributed to different molecular properties like shape and conformational freedom of the open and closed form of diarylethene switch **1**, and it is expected that this feature of diarylethene switches can be employed to control other macroscopic properties like gel formation by light as well.

We are grateful for a fellowship to J. van Esch from the Royal Academy of Science of the Netherlands (KNAW), and we thank ir. V. W. A. Verhoeven for this help with the viscosity measurements.

Notes and references

† Compounds **1o** and **2o** were fully characterised showing spectroscopic and analytical data in accordance with the structure shown.

‡ Viscosity measurements were performed on a Brabender Rheotron, with a cone/plate geometry (cone angle 3°), and ^{1}H NMR experiments were performed on a Varian VXR-300 spectrometer, using 0.15–22 mM benzene solutions of **1** or **2**. All measurements have been carried out at room temperature. For a more detailed survey about viscosity measurements the following reference is recommended: A. Dinsdale and F. Moore, *Viscosity and its Measurement*, Chapmann and Hall, London, 1962.

§ The samples were irradiated in a 1 mm quartz cuvet for UV–VIS measurements and in 5 mm pyrex tubes for NMR experiments, using a 200 W mercury lamp with a 313 nm band-pass or a 520 nm high-pass filter.

The first stereoselective synthesis of an axially chiral biscarbazole has been achieved, by application of the 'lactone concept'.

Axially chiral biaryl natural products are of increasing importance, but the phenomenon of atropisomerism is often neglected—even nowadays.[1] A typical example is, *e.g.* the class of biscarbazoles,[1,2] which consists of eleven *C,C*- and three *N,C*-coupled alkaloids. All of the *C,C*-bonded representatives should have a configurationally stable biaryl axis, which was, however, not recognized during structural elucidation. The first biscarbazole for which axial chirality was demonstrated, was bismurrayaquinone-A (**1**, Fig. 1):[3] after racemate resolution of synthetic **1**, the absolute configuration at the axis was attributed by quantum chemical circular dichroism (CD) calculations. Racemate resolutions succeeded also for murrastifoline-F[4] and for clausenamine-A (**2**, $R^1 = R^3 = OMe$, $R^2 = H$).[5]

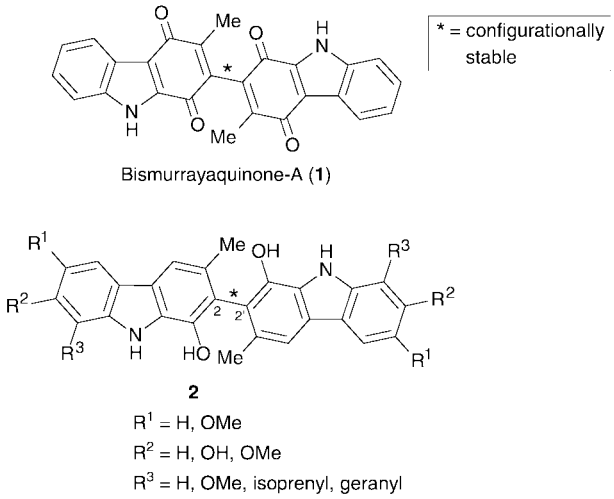

Fig. 1 Bismurrayaquinone-A (**1**) and the general structure of other 2,2′-coupled biscarbazole alkaloids.

No *stereoselective* approaches to biarylic biscarbazoles have so far been described. As a most rewarding synthetic target for a first atropo-enantioselective access we chose the 2,2′-coupled biscarbazole core **2** ($R^1 = R^2 = R^3 = H$, Fig. 1), since it constitutes the basic framework of five naturally occurring alkaloids, bismurrayaquinone-A (**1**), bismurrayafolines-B, -C, and -D, and clausenamine-A (all represented by the general structure **2**). Such a synthesis would also permit investigations on the (possibly divergent) bio-activities of the atropo-enantiomers of the respective natural products.[6] In this paper, we present the first stereoselective preparation of an axially chiral 2,2′-biscarbazole core related to **2**.

† Novel Concepts in Directed Biaryl Synthesis, part 95; for part 94, see G. Bringmann, A. Wuzik, J. Kümmel and W. A. Schenk, *Organometallics*, 2001, in press.

For the atropo-selective construction of the biaryl axis, we chose the 'lactone concept',[7] with biaryl lactone **9** (Scheme 1) as the crucial intermediate. Since it is configurationally unstable at the axis due to the ester bridge, it should permit an atroposelective ring cleavage with chiral nucleophiles in a dynamic kinetic resolution, giving rise to—then configurationally stable—atropisomers. The synthesis of lactone **9** required the preparation of the bromoacid **5** and the phenolic component **7**.

Exploratory work rapidly showed the necessity of protecting the base-sensitive and electron-pushing endocylic nitrogen, to avoid side reactions on the NH function or, due to its electronic impact, on the isocyclic ring. Such a protective group should, in the first instance, be robust to survive the scheduled reaction conditions, thus avoiding the need to establish different protective groups for each single step. For this purpose, the stable (and small) methyl group was chosen at this point, even though it bears the inherent problem of being cleavable only enzymically[8] or under extreme conditions,[9] which were not expected to be tolerated by the dimeric target structures of type **2**. For a first exploration of the synthetic concept, this disadvantage seemed acceptable.

The synthesis of the bromoacid **5** started from the phenolic carbazole ester **3**[10] (Scheme 1). Regioselective bromination at the 2-position was achieved by the DoM (= Directed *ortho*-Metalation)[11] strategy. The MOM (= methoxymethyl) function was introduced using MOMCl,[12] followed by *N*-methylation with dimethyl sulfate. $LiAlH_4$ reduction gave **4** as a DoM-suited substrate, which afforded 2-bromination in an excellent yield and with complete regioselectivity upon treatment with *n*BuLi and $(CBrCl_2)_2$. Conversion of this bromoalcohol into the corresponding acid **5** succeeded by Swern and $NaClO_2$ oxidation, giving the first coupling portion in as much as 52% overall yield from carbazole **3**.

The phenolic 'half' **7** was synthesized from murrayafoline-A (**6**),[10] by *N*-methylation with dimethyl sulfate and BBr_3-mediated *O*-demethylation. The crude 1-hydroxycarbazole **7** thus obtained was taken directly for esterification with bromoacid **5** with DCC and DMAP, giving ester **8** in 86% yield.

The intramolecular biaryl coupling of **8** was the most tricky and yield-limiting step of the synthesis. Among different reagents and conditions tested, the best result was obtained using 1.5 equiv. $Pd(OAc)_2$ and 3.0 equiv. PPh_3 for 1.5 h at 120 °C. The biscarbazole lactone **9** was isolated in 35% yield, along with 20–30% of the corresponding hydrodebromination product. This—compared to other lactone syntheses[7]—moderate coupling yield, which is in agreement with that for similar coupling substrates with an *ortho*-'OCH' unit next to the palladation site,[13] is disappointing at first sight; still, it opens up the first stereoselective access to an axially chiral biscarbazole core.

For the atroposelective ring cleavage of the configurationally unstable lactone **9**, a CBS reduction was attempted first, since it had given excellent chemical and optical yields in similar conversions.[7] In this case, however, apparently due to the significantly decreased reactivity of the ester group by the

MOMCl: chloromethyl methyl ether.

electron-donating carbazole nitrogen, the reduction took place in only up to 40% yield, leading to the (*M*)-enantiomer of diol **10** with a maximum er of 82 : 18. Slightly better chemical yields were attained with (*M*)-BINAL-H (58%), but with an er of only 67 : 33, again in favor of (*M*)-**10**. The best results with respect to chemical yields and 'asymmetric inductions' were achieved with lithium (1*R*)-mentholate as a chiral *O*-nucleophile,[7] giving **11** in 89% yield and a dr of 85 : 15.

The attribution of the newly created axial configurations of the ring cleavage products was achieved by a combination of CD spectroscopy and quantum chemical CD calculations.[14,15] The CD spectrum for the main enantiomer of diol **10** was measured on line by LC-CD analysis on a chiral phase (Chiralcel OD-H) and matched very well the CD spectrum quantum chemically calculated for the (*M*)-enantiomer—here based on a molecular dynamics (MD) simulation[15]—clearly showing it to be (*M*)-configured, in agreement with the stereochemical outcome of many other cleavage reactions on similar lactone substrates.[7]

The purification of the main atropo-diastereomeric product **11** of the mentholate ring opening, by preparative HPLC on a chiral phase (Chiralcel OD), gave the first atropisomerically pure biscarbazole stereoselectively synthesized. The phenolic part of this pure main isomer proved to be highly sensitive to autoxidation during removal of the HPLC solvent in the presence of air oxygen to yield the corresponding quinone. The CD spectrum of its $LiAlH_4$ reduction product showed strong similarities with that of (*M*)-**10**, revealing the main atropisomer of **11** to be likewise (*M*)-configured, as was to be expected in analogy to numerous related lactone cleavage reactions.[7]

Since first attempts to adopt this reaction sequence for the atroposelective biscarbazole synthesis to substrates with an *N*-benzyl group as an eventually removable protective group for the carbazole nitrogen gave promising results, the final steps for the synthesis of an—unnatural—*N*,*N*′-dimethyl analog of bismurrayaquinone-A were not performed for the *N*-methyl protected model biscarbazole **11**.

The presented pathway provides the first stereoselective synthetic access to atropisomerically pure axially chiral biscarbazoles and defines the strategy for the now scheduled synthesis of the corresponding genuine alkaloids. The electronically exceptional conditions within the carbazole core as compared to those of the other biaryl systems previously prepared, made the realization of the lactone concept much harder than expected. That these problems could be overcome, succeeding in the preparation of an enantiomerically pure biscarbazole, demonstrates the value of the applied method.

This work was funded by the Deutsche Forschungsgemeinschaft (SFB 347) and by the Fonds der Chemischen Industrie. The authors thank K. Messer for skillful help on LC-CD analyses and Dr A. Wuzik for inspiring discussions.

First published as an Advance Article on the web 3rd April 2001

Highly ordered hydrothermally stable SBA-15 mesoporous silica containing phosphonic acid groups are synthesised for the first time by using amphiphilic block copolymers as the structure-directing agents.

Surfactant-templated mesoporous hybrid materials constitute a very exciting field in materials chemistry.[1–8] This class of materials has numerous potential applications[9–12] due to their high surface areas and their narrow pore size distributions as well as the diversity of the functional groups which they can contain. Recently Stucky *et al.*[8] have published the preparation of ordered SBA-15 mesoporous silica containing sulfonic acid groups using the direct synthetic approach. That prompted us to report in this paper the results that we obtained by the same route concerning the preparation and the physicochemical characteristics of periodic hybrid mesoporous materials containing phosphonic acid groups based on the co-condensation of tetraethylorthosilicate (TEOS) and an appropriate organotrimethoxysilane in the presence of triblock copolymers as the structure-directing agent under acidic conditions.

First we prepared SBA-15 mesoporous silica containing phosphonic acid diethyl ester groups. In a typical experiment 4.0 g of $EO_{20}PO_{70}EO_{20}$ was dissolved in an aqueous HCl solution (160 ml, pH ≈ 1.5). This solution was added to a mixture of 8.4 g of TEOS and of 1.4 g of trimethoxysilylpropyldiethylphosphonate **1** at ambient temperature. The mixture was stirred for 3 h giving rise to a microemulsion. After heating this perfectly transparent solution at 60 °C, a small amount of NaF (75.4 mg) was added with stirring to induce hydrolysis and polycondensation. The mixture was stirred at 60 °C for 48 h. The resulting solid was filtered off and washed. The surfactant was then removed by hot ethanol extraction in a Soxhlet apparatus affording the $X[PO(OEt)_2]$ material in 95% yield. The molar composition of the reaction mixture was: 0.04 F^-: 1 TEOS: 0.11 **1**: 0.02 P 123: 0.12 HCl: 220 H_2O. Some relevant physicochemical data for $X[PO(OEt)_2]$ are given in Table 1. The CP MAS ^{31}P NMR spectrum of $X[PO(OEt)_2]$ displays one sharp signal ($\Delta\nu_{1/2}$ = 720 Hz) which was attributed to the phosphonic acid diethyl ester group. Further indication of the presence of diethyl ester group was given by CP MAS ^{13}C NMR spectroscopy with the signal at 63 ppm attributed to $PO(OCH_2)$ groups. From elemental analysis, the content of functional groups was found to be of 1.33 mmol g^{-1} while the theoretical value was 1.29. The powder X-ray pattern (Fig. 1*a*) exhibits an intense diffraction peak corresponding to d_{100} spacing and two weak peaks (d_{110} 61.5 Å and d_{200} 52.5 Å) which are characteristic of a 2D hexagonal structure. Interestingly, no significant change was observed for the XRD pattern recorded eight months later of the material which was stored in air (Fig. 1*b*), indicating a very stable structure. Further evidence for a highly ordered 2D hexagonal structure was provided by the transmission electron microscopy (TEM) images shown in Fig. 2. The N_2 adsorption–desorption isotherm for $X[PO(OEt)_2]$ is displayed in Fig. 3. The sample showed type IV isotherm, characteristic of mesoporous materials with a narrow pore size distribution.

Two routes gave rise to mesoporous silica containing phosphonic acid groups. In both cases, silylation of SiOH groups was first achieved by treating the mesoporous solid with Me_3SiCl in toluene heated under reflux for 12 h in order to avoid side reactions between the phosphonic acid groups and the surface SiOH. Acid catalysed hydrolytic desalkylation[13] was then accomplished by treating the resulting solid $X_{Si}[PO(OEt)_2]$ with a 12 M aqueous solution of HCl for 24 h under reflux (route

DOI: 10.1039/b100515o

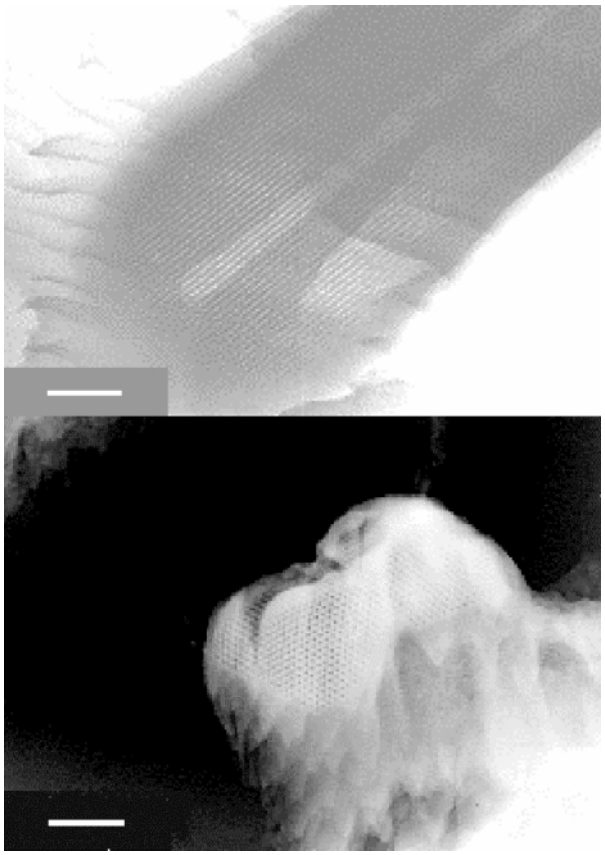

Fig. 2 TEM images of the X[PO(OEt)$_2$] material: (bottom) in the direction perpendicular to the pore axis; (top) in the direction of the pore axis. The images were recorded on a JEOL JEM 200CX transmission electron microscope. Scale bar = 100 nm.

a) giving rise to $X_{Si}a[PO(OH)_2]$. The second route (route b) consisted of the preparation of the bis(trimethylsilyl)phosphonate which can then be smoothly converted to phosphonic acid on contact with neutral H_2O at room temperature[14] thus avoiding the harsh reaction conditions of preparation of $X_{Si}a[PO(OH)_2]$. For this purpose, refluxing $X_{Si}[PO(OEt)_2]$ with 2 equiv. of Me_3SiBr in toluene for 24 h afforded $X_{Si}b[PO(OH)_2]$ after addition of H_2O. Some relevant physicochemical data for both materials are given in Table 1. It is worth noting that all the data are very similar. The CP MAS ^{31}P NMR spectra of both materials display only one sharp signal ($\Delta\nu_{1/2}$ = 640 Hz), indicating the absence of reaction between the phosphonic acid groups and the surface SiOH. Though the ^{31}P NMR chemical shift of the PO(OH)$_2$ groups is unfortunately very close to that of PO(OEt)$_2$ groups, evidence for the complete formation of phosphonic acid groups in both cases was given by CP MAS ^{13}C NMR spectroscopy with the disappearance of the signal attributed to the PO(OCH$_2$) groups. Furthermore, the exact amount of phosphonic acid groups was measured by acid–base titration. For this determination, the materials were first placed in an aqueous Li_2CO_3 solution (pH 8) in which an ion exchange occurred quantitatively (^{31}P NMR, δ 26 ppm ($\Delta\nu_{1/2}$ = 320 Hz), Li/P ratio, 1.95 from elem. anal.). The filtrate was then treated with an excess of an aqueous HCl solution. From the acid–base conductimetric titration, the amount of PO(OH)$_2$ groups per gram was found to be 1.08 mmol g^{-1} taking into account the same titration from $X_{Si}[PO(OEt)_2]$ as a blank. The N_2 adsorption–desorption isotherms are of type IV in both cases with a very similar narrow pore size distribution (Fig. 3). Figs. 1*c* and 1*d* show the powder X-ray patterns of respectively $X_{Si}a[PO(OH)_2]$ and $X_{Si}b[PO(OH)_2]$. They are very similar to

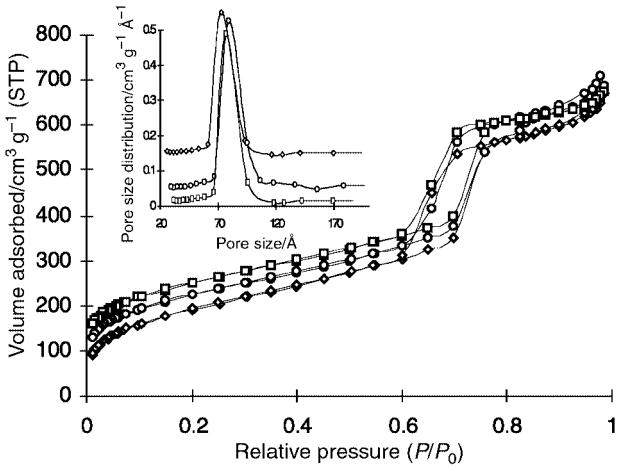

Fig. 3 Nitrogen adsorption–desorption isotherm and BJH pore size distribution plot (inset) of XPO(OEt)$_2$ (□), $X_{Si}aPO(OH)_2$ (○) and $X_{Si}bPO(OH)_2$ (◇). To allow a better comparison, the data for $X_{Si}aPO(OH)_2$ and XPO(OEt)$_2$ were shifted by 50 and 100 cm^3 g^{-1} respectively.

that of X[PO(OEt)$_2$] (Fig. 1*a*) indicating that the mesoscopic ordering completely survives both post syntheses. Thus, it can be concluded that the structures of these materials are hydrothermally stable as $X_{Si}a[PO(OH)_2]$ was treated with a 12 M HCl aqueous solution heated under reflux for 24 h. This is a specificity of SBA-15 materials.[8,15,16] They are also stable under basic conditions (pH 8). Finally, phosphonic acid groups are interesting in that they allow the incorporation of numerous transition metals which should have good potential in catalysis. As example, we show that treatment of $X_{Si}a[PO(OH)_2]$ with a THF solution of nickel acetylacetonate (2 equiv. per PO(OH)$_2$ group) heated under reflux for 12 h yielded quantitatively the nickel salts (one signal at 22 ppm in CP MAS ^{31}P NMR).

In summary, we have developed two routes in several steps giving rise to the same highly ordered mesoporous hybrid materials containing free phosphonic acid groups. This study constitutes, to the best of our knowledge, the first example of ordered mesoporous silica containing such a functional group.

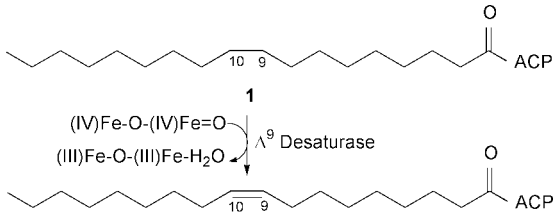
First published as an Advance Article on the web 3rd April 2001

Desaturation of (*S*)-9-fluorostearoyl-ACP using stearoyl-ACP Δ^9 desaturase yielded mainly (*E*)-9-fluoroalk-9-enic product, while desaturation of (*R*)-9-fluorostearoyl-ACP gave the novel (*Z*)-9-fluoroalk-9-ene and (*Z*)-9-fluoroalk-10-ene.

The O_2-dependent conversion of stearoyl acyl carrier protein (ACP) **1** to oleyl-ACP **2** is a remarkable example of a highly



chemo-, regio- and stereoselective enzymatic process.[1] The enzyme responsible for this fascinating reaction, stearoyl-ACP Δ^9 desaturase, has been isolated from castor seed and is the only protein of its type to be thoroughly characterized. The X-ray crystallographic structure of this protein confirmed the presence of a non-heme diiron oxidant which is strategically located at the centre of a narrow, hydrophobic pocket.[2] The amino acid co-ordination of the catalytic diiron centre and the fold of the protein are very similar to that found in methane mono-oxygenase—an enzyme which converts methane and other small alkanes to the corresponding alcohol.[3] It has long been suggested that desaturation and hydroxylation reactions are closely related[4a] and that precise control of substrate conformation and oxidant location may play an important role in determining reaction outcome.[1,4b] We decided to probe the catalytic versatility of the stearoyl-ACP Δ^9 desaturase by challenging this enzyme with a substrate bearing a potentially non-oxidizable, CHF-group at C-9. The availability of chiral 9-hydroxystearic acid derived from natural sources offered a convenient synthetic entry into this project. Here, we report the results of this study.

Each enantiomer† of methyl 9-fluorostearate, (9*S*)-**3** and (9*R*)-**3**, was incubated separately as the ACP derivative (200 nmol) with freshly prepared Δ^9 desaturase (14 nmol) and required cofactors in a total volume of 250 μl for 30 min.[6] The reaction was quenched by addition of THF and the thioester fraction was reduced ($NaBH_4$) to give the corresponding terminal alcohols. These products were analyzed directly by ^{1}H-decoupled ^{19}F NMR and by GC/MS (60 m SP-23 capillary column) as the tetramethylsilyl derivatives.

We were somewhat surprised to observe that very little starting material could be detected in the extracts of both incubations, indicating that both (*S*)- and (*R*)-9-fluorostearates could function as substrates under these conditions (Fig. 1). No obvious inhibitory effects were noted and the product profile did not appear to change as a function of % conversion. The major product formed in the desaturation of (9*S*)-**3** was, after reductive workup, (*E*)-9-fluorooctadec-9-en-1-ol **4** (Scheme 1 and Fig. 1a)‡—identical in all respects (MS, ^{1}H-decoupled ^{19}F NMR, GC rt of TMS derivative) to a sample derived by LAH reduction of previously identified, methyl (*E*)-9-fluorooctadec-9-enoate.[7] Interestingly, this material was accompanied by a small (4–7% of the total products) but reproducible amount of a *threo*-9,10-fluorohydrin **5** (MS: *m/z* 215 $(C_9H_{18}OTMS)^+$, ^{1}H-decoupled ^{19}F NMR: δ −195.25).§ Notably, no products attributable to 9,9-fluorohydrin formation (9-keto- or its reduction product, 9-hydroxystearoyl alcohol) were observed.

Desaturation of the ACP derivative of (9*R*)-**3**, yielded two major novel fluorinated olefinic products, **6** and **7** (Scheme 1 and Fig. 1b).‡ **6** was determined to be the geometric isomer of **4** on the basis of its GC retention time (*ca*. 0.2 min shorter than the corresponding (*E*)-product), similar mass spectrum (*m/z* 358 M^+, 343 $(M - CH_3)^+$, 338 $(M - HF)^+$, 323 $[(M - CH_3) - HF]^+$) and ^{1}H-decoupled ^{19}F NMR chemical shift (δ −110.45 ppm; lit. (*Z*)-7-fluorotetradec-7-ene (δ −110.37 ppm)).[8] The second novel product **7** was identified as (*Z*)-9-fluorooctadec-

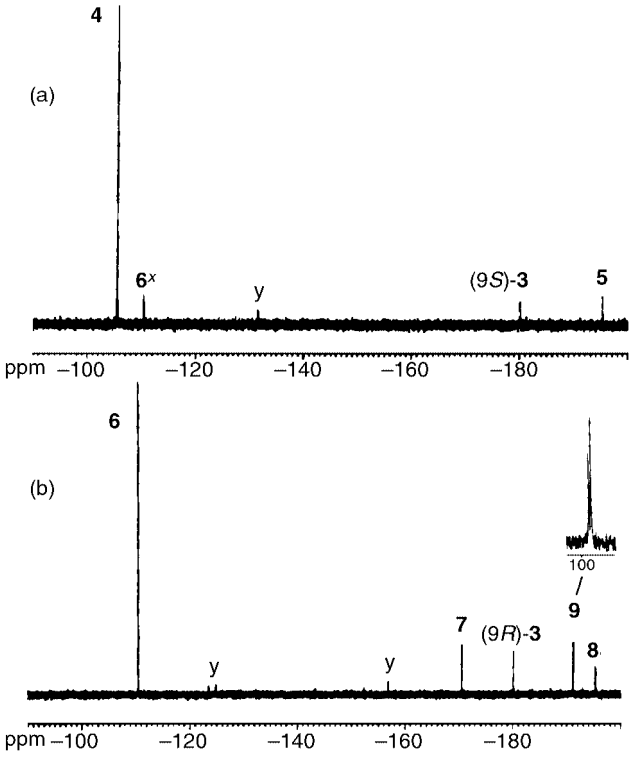


Fig. 1 ^{1}H-decoupled ^{19}F NMR (376.5 MHz) of products obtained from desaturation of (a), (9*S*)-**3**; (b), (9*R*)-**3**. Unidentified, minor peaks of variable intensity are marked with a 'y'. *x* Product derived from a minor amount of (*R*)-9-fluorostearoyl-ACP—the levels of this diastereomer appear to be enhanced relative to the (*S*)-9-fluoro-isomer in the ACP synthase-mediated acylation reaction as was previously noted in preliminary studies using racemic 9-fluorostearate as substrate.

DOI: 10.1039/b100035g

10-en-1-ol by comparison of its GC retention time and ^{1}H-decoupled ^{19}F NMR chemical shift (δ −170.54) with those of (*Z*)-8- and (*Z*)-11-fluorooctadec-9-en-1-ol (δ −170.61 and −170.34, respectively).¶ In addition, a mixture of stereoisomeric hydroxylated products (Scheme 1) was also observed in the product profile: *threo*- **8** (*m*/*z* 215 $(C_9H_{18}OTMS)^+$, ^{1}H-decoupled ^{19}F NMR: δ −195.27) and *erythro*-9,10-fluorohydrin **9** (*m*/*z* 215 $(C_9H_{18}OTMS)^+$; ^{1}H-decoupled ^{19}F NMR: δ −191.18 (.23)‖).

The formation of **4** with 'normal' regio- and stereochemistry *via* desaturation of (9*S*)-**3** indicates that this substrate can adopt the required gauche conformation for what is thought to be a diiron(IV)oxo-mediated, *syn*-dehydrogenation process.[7] However, when removal of the hydrogen occupying the '*pro-R*' position at C-9 is blocked by fluorine substitution as in (9*R*)-**3**, substantial reorientation of substrate occurs and two 'novel' olefinic products (**6**, **7**) are produced as depicted in Scheme 1. There is some precedent for a substrate-induced shift in the regiochemistry of desaturation,[6] but the observation of a switch in stereochemical outcome as displayed by the production of **6**, was completely unexpected. In a previous series of experiments, incubation of racemic 9-fluorostearoyl substrate with a structurally unrelated yeast Δ^9 desaturase produced only the anticipated methyl (*E*)-9-fluorooctadec-9-enoate.[7]

A small amount of hydroxylated materials *is* observed in the product profile of both fluorosubstrates (9*S*)-**3**, (9*R*)-**3**. These compounds do not appear to be formed by hydration of the corresponding fluoroolefins during the workup§ and thus it is tempting to attribute the formation of these products to an MMO-type hydroxylation reaction.[9] It is interesting to note that the stereochemistry of these compounds is dependent on the chirality of the fluorosubstrate: exclusively *threo*-product (**5**) was obtained from (9*S*)-**3**, while a mixture of *threo*- and *erythro*-fluorohydrins (**8**, **9**)‖ was formed from a conformationally distorted (9*R*)-**3** (Scheme 1). Experiments to further investigate the origin of these novel hydroxy products are in progress.

In summary, we have demonstrated a remarkably high preference for the catalysis of dehydrogenation rather than oxygen transfer by stearoyl-ACP Δ^9 desaturase. In addition, valuable new insights into the enantioselectivity of oxidative attack have been obtained.

The technical assistance of Jamie Cote, Christine Caputo and Christopher Savile (Carleton University) in the synthesis of substrate analogues is gratefully appreciated.

Notes and references

† Methyl (*S*)-9-fluorostearate was synthesized *via* extraction of dimorphecolic ((*R*)-9-hydroxyoctadec-10,12-enoic) acid from *Dimorphoteca* seeds[5a] followed by reduction of double bonds using H_2/Pt and fluorination of the resultant methyl (*R*)-9-hydroxystearate with diethylaminosulfur trifluoride (DAST).[5b] The corresponding (*R*)-9-fluoro-enantiomer was prepared by inverting the stereogenic center of methyl (*R*)-9-hydroxystearate using the Mitsunobu reaction[5c] followed by fluorination using DAST. The absolute configuration of the methyl (*R*)- and (*S*)-9-hydroxystearates was confirmed using standard methods;[5d] the % ee of the alcohols (and hence that of the final fluorinated products[7]) was estimated to be more than 98%.[5d] The ACP derivatives of each enantiomer were prepared according to established enzymatic methods.[5e]

‡ The position of the double bond in **4**, **6** and **7** was confirmed by the results of a labelling experiment in which [10,10-$^2H_2$]-(*R*,*S*)-9-fluorostearoyl-ACP was converted to olefinic products with the concomitant loss of one deuterium: *m*/*z* 359 M^+, 344 $(M - CH_3)^+$, 339 $(M - HF)^+$, 324 $[(M - CH_3) - HF]^+$). The deuterated substrate was prepared from [1,1-$^2H_2$]-bromononane *via* a modification of a published procedure.[7] Since the allylic fluoride **7** is partially hydrolyzed to a pair of corresponding isomeric allylic alcohols (*m*/*z* 329 $[C_{11}H_{19}(OTMS)_2]^+$, 227 $(C_{10}H_{18}OTMS)^+$) during the work-up procedure ($NaBH_4$), the ratio of **6**/**7** is highly variable and ranges from 1 to 3 as measured by GC/MS. The recovery of total products and remaining substrate was estimated to be *ca*. 70–90% of theoretical.

§ The structural assignments were consistent with data obtained using readily available synthetic 9(10),10(9)-fluorohydrins.[7] Control experiments showed that the observed fluorohydrin products did not arise by hydration of fluoroolefins and *vice versa*: (a) no olefinic products were detected when the workup conditions of desaturase assay were simulated using synthetic fluorohydrin; (b) no fluorohydrin was detected as by-products of (*R*,*S*)-8- and (*R*,*S*)-11-fluorostearoyl-ACP desaturation; (c) no fluorohydrin was detected when a typical desaturase assay spiked with (*Z*)-9-fluorooctadec-9-en-1-ol was worked up. Under the same conditions, 9-ketostearoyl alcohol was reduced to the corresponding alcohol. (The detection limits in these control experiments was *ca*. 0.1% of total products.)

¶ Prepared by desaturation of the corresponding (*R*,*S*)-8- and (*R*,*S*)-11-fluorostearoyl-ACP substrates using castor stearoyl-ACP Δ^9 desaturase. The substrates were prepared by standard methods.[7]

‖ The *erythro*-9,10-fluorohydrin fraction appeared to contain some regioisomeric *erythro*-10,9-fluorohydrin as determined by ^{19}F NMR and GC ret. time, the appearance of a diagnostic cleavage ion in the mass spectrum (*m*/*z* 303 $(C_9H_{17}(OTMS)_2)^+$ and use of samples spiked with a synthetic standard of regioisomers (see footnote §). This result does not appear to be an artifact of the workup; fluorine scrambling may be due to a reversible elimination/addition of HF or direct fluorine migration[10] in the unsolvated environment of the active site.

Polystyrene microspheres have been used as templating entities to fabricate thin macroporous silicate films with controllable porosity for catalysis and chemical sensing-related applications.

The fabrication of microporous and mesoporous silica has received considerable attention due to the need to develop more efficient and stable materials for applications in catalysis, separations, coatings and chemical sensing.[1,2] Among various strategies for the preparation of porous materials, template-based sol–gel processing has rapidly gained popularity.[1] In this approach, the silicate matrix is assembled around a suitable template. Upon removal of the template, cavities with a specific size and shape remain in the cross-linked host.[1]

A wide variety of templates has been used to prepare materials with pore sizes that range from a few nanometers to several microns.[1,2] Examples used in the fabrication of porous silica materials include organic molecules,[3,4] latex spheres,[5,6] organic ligands,[7,8] bridged template ligands,[9–11] emulsion droplets,[12] and surfactants.[13–18] To date, most investigations have focused on the formation of *micropores* ($d < 2$ nm) or *mesopores* ($2 < d < 50$ nm) into bulk silica solids or thick membranes with a specific focus on the preparation of 3D arrays. Relatively little attention has been focused on the generation of *macroporosity* ($d > 50$ nm) in thin films, particularly those that allow for easy transport through the film.

In chemical sensing, thin films (typically < 1 μm) prepared using sol–gel technology are most often utilized due to their short path length for diffusion that decreases response times and improves recovery rates.[19,20] Sol–gel-derived thin films, however, are inherently much less porous than corresponding silica monoliths as gelation and evaporation occur simultaneously.[21,22] The ability to engineer porosity into these materials will clearly improve their performance in analytical science.

In this work, a new approach is described for the preparation of macroporous thin silica films whose pores are open on both sides and enable efficient transport of reagents through the film. This approach utilizes polystyrene microspheres as the templating entities to fabricate thin *macroporous* sol–gel-derived films with controllable porosity. A mild chemical treatment is used to completely remove the polystyrene template without destruction of the film. The morphology and properties of the templated silica films have been examined using a combination of microscopic, spectroscopic and electrochemical methods.

In these experiments, the silica sol was prepared by mixing tetramethoxysilane (TMOS) with water and 0.1 M hydrochloric acid followed by stirring for 5–10 min. The mole ratio of $Si:H_2O:HCl$ was 1 : 9 : 0.003. The original aqueous suspension of polystyrene microspheres (PSMS, Interfacial Dynamics, 8% wt/v surfactant-free, sulfated) was sonicated for 5 min prior to use. The sample solutions of PSMS suspension were prepared by mixing the original suspension with water and 10 mM sodium dodecyl sulfate followed by sonication for 2 min. The aged (3 days) silica sol was then added to a PSMS suspension in a ratio of 1 : 2 (v/v). The final mixture was vigorously stirred and again sonicated for 1 min and the resultant suspension was cast on the surface of a glassy carbon electrode or on a silicon substrate at *ca.* 7000 rpm using an in-house built rotator. The thin films were allowed to dry overnight under room conditions (45–55% RH, ambient temperature). The polystyrene microspheres were removed from the dense silica framework by soaking the film in chloroform for two hours.

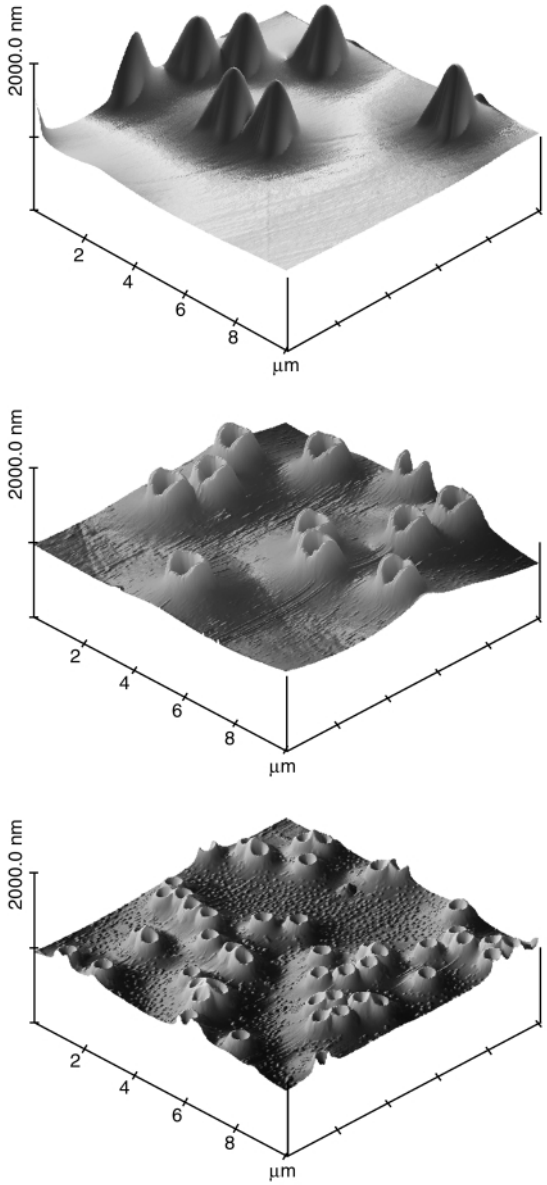

Fig. 1 10 μm × 10 μm AFM images of silicate films prepared from a sol containing 1.0 μm polystyrene microspheres, 1.3% wt/v before (top) and after (middle) chloroform treatment. (Bottom) macroporous silica film formed after removal of polystyrene microspheres from the composite film prepared with a sol containing 2.5% wt/v of 0.5 μm polystyrene microspheres.

DOI: 10.1039/b008035g

Fig. 1 (top and middle) shows AFM images of the composite silica films prepared with 1 μm diameter PSMS particles before and after chloroform treatment. As can be seen in the top panel of Fig. 1, the polystyrene particles embedded within the silicate film appear as the 'hills' randomly distributed through the topography of the film. Evaluation of the height of the embedded particles gives a value close to the diameter of the bare particle whereas the width is estimated to be approximately twice that of the particle. Upon formation of the film, the silica likely pulls away from the polystyrene microsphere exposing the top of the particle and building up around the sides.

After exposure to chloroform for two hours, the AFM images show craters that are visibly open with an inside top diameter close to the width of the polystyrene particle, Fig. 1 (middle). A blow up of the cross-section of a cavity formed from a 0.5 μm polystyrene microsphere is shown in Fig. 2. As can be seen, the shape of the cavity mimics the shape of the bottom half of the polystyrene particle. Part of the electrode underneath the polystyrene microsphere becomes exposed after removal of the particle. The size of the cavity can be changed by changing the diameter of the polystyrene microsphere template. Likewise, the number density of the cavities in the film can be increased *via* changes in the amount of polystyrene particles added to the sol. Fig. 1 (bottom) shows an AFM image of a templated film prepared from a sol containing 2.5% of 0.5 μm polystyrene microspheres. As can be seen, there are significantly more cavities in the films with an inner diameter close to the size of the polystyrene particle.

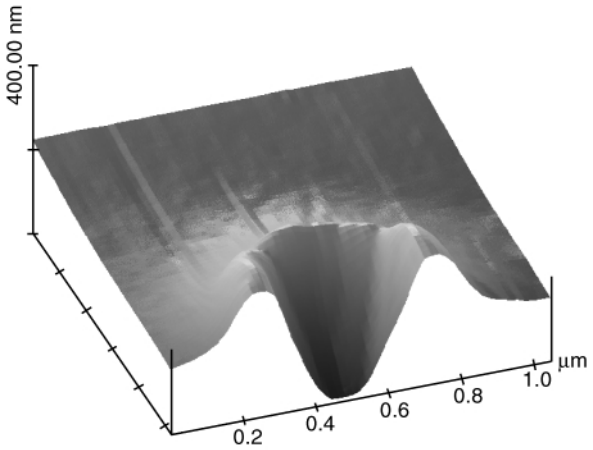

Fig. 2 Cross-section AFM image of an individual hole formed from a 0.5 μm polystyrene microsphere.

In order to verify that the films are open on both sides and allow for easy transport of reagents, electrochemical probe experiments were conducted. In these experiments, the silicate film cast on an electrode surface is placed in a solution containing an electroactive 'probe' molecule. If the probe molecule is able to reach the underlying electrode surface *via* diffusion through a defect site or a template induced cavity, Faradaic current will be observed. Fig. 3 shows the cyclic voltammograms of 1 mM ruthenium hexaammine $[Ru(NH_3)_6^{3+}]$ at the silicate film both before and after template removal. Prior to treatment in chloroform, no Faradaic current can be seen with any of the electroactive probes. This is consistent with our prior work that has shown that films fabricated with a silica sol prepared *via* the acid-catalyzed hydrolysis of tetramethoxysilane are compact and essentially defect-free.[23] After the polystyrene spheres are removed from the dense matrix, however, sigmoidal shaped CVs are obtained for $Ru(NH_3)_6^{3+}$ due to electron transfer at the electrode–solution interface produced by the template. The magnitude of the Faradaic current increases upon increasing the number density of cavities within the film.

In summary, a relatively simple approach is described to engineer porosity in otherwise dense silica films. The size and number density of the pores thus produced can be easily varied over a large range *via* judicious selection of the size of the polystyrene microsphere template and its concentration in the sol. The template is removed *via* chemical means, otherwise temperature sensitive reagents can also be entrapped within the silicate framework. It is envisioned that this approach can be utilized to prepare more porous sol–gel-derived materials for chemical sensing- and catalysis-related applications or serve as a unique way to fabricate ultra-small reaction vessels for small volume chemistry related applications.

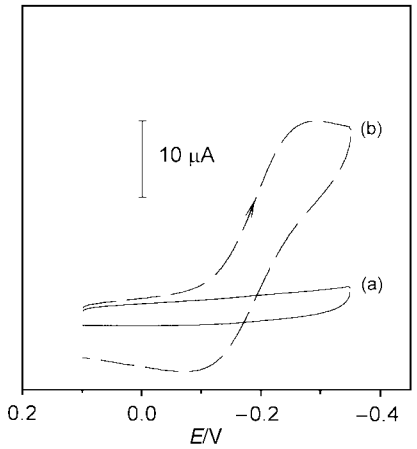

Fig. 3 Cyclic voltammograms of 1 mM ruthenium hexaammine in 0.1 M KNO_3 at a polystyrene templated film (a) before and (b) after chloroform treatment. Films were prepared from a silica sol containing 0.5 μm polystyrene microspheres, 1.3% wt/v. Scan rate 100 mV s^{-1}.

Phage display selection of peptides possessing aldolase activity

Fujie Tanaka and Carlos F. Barbas III*

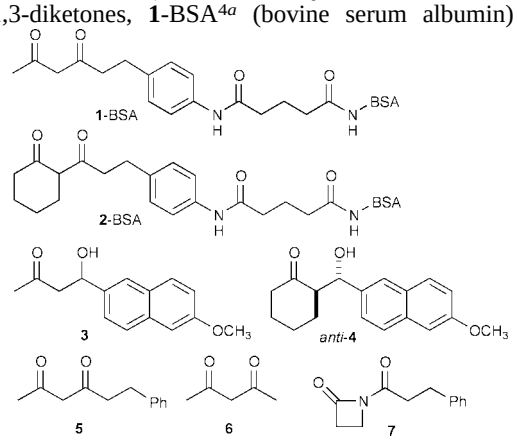
The Skaggs Institute for Chemical Biology and the Department of Molecular Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037, USA. E-mail: carlos@scripps.edu; Fax: +1-858-784-2583; Tel: +1-858-784-9098

Received (in Corvallis, OR, USA) 10th January 2001, Accepted 1st March 2001
First published as an Advance Article on the web 3rd April 2001

Peptides catalyzing retro-aldol reactions were selected from a phage display peptide library using 1,3-diketones designed for the covalent selection of an enamine-based reaction mechanism.

The folded states of enzymes are key to their catalytic activity since structure can be used productively to modify the chemical reactivity of amino acid side chains, for example with electrostatic or hydrophobic effects, to build isolated reaction vessels, and to stabilize transition states of reactions. Small peptides are limited in their potential to catalyze reactions since they typically do not adopt well-defined structures. While the design of folded peptides has advanced tremendously in recent years, design at the level of catalysis is a challenging task. Rationally designed small catalytic peptides (14–42 amino acid residues peptides) have been reported that catalyze the decarboxylation of oxaloacetic acid,[1] ester hydrolysis,[2] and transesterifications.[2] Rational design, however, is limited in throughput.[1b] The combination of rational design with library based methods may be an attractive approach to catalyst development. Phage display allows for libraries of greater than 10^9 peptides to be probed for function, but this approach has not been used to select for catalytic peptides.[3] Here we report the applicability of a mechanism-based covalent selection of catalytic peptides *in vitro*. Peptides possessing aldolase activity (aldolase peptides) that use an enamine-type mechanism were selected by reaction of peptide phage with 1,3-diketones that have been employed for the induction of aldolase antibodies[4] (Scheme 1).

Amine catalyzed decarboxylation and aldol reactions share imine and enamine intermediates on their reaction coordinates. Accordingly, enzyme and antibody catalysts of these reactions are generally bifunctional catalysts capable of accelerating both decarboxylation and aldol reactions.[5] In order to select aldolase peptides that use an imine–enamine reaction mechanism, we sought to exploit mechanistic homology by using as our starting point an 18-residues peptide (YLK-18-opt)[1b] that catalyzes the decarboxylation of oxaloacetic acid. This peptide contains multiple lysyl residues that are key to its activity. To evolve the catalytic activity of this peptide, a 6-amino acid residue library was appended to the C-terminus of the peptide and the library was displayed on phage.[6] The phage display peptide library YKLLKELLAKLKWLLRKLXXXXXX (X = any of the natural 20 amino acids) was selected by three rounds of reaction with 1,3-diketones, **1**-BSA[4a] (bovine serum albumin) and



2-BSA.[4c] Screening of selected phage by ELISA identified clones that bound to **1**- and **2**-BSA. The two most reactive peptides as judged by ELISA, FT-YLK-3 and FT-YLK-4, were chemically synthesized (C-terminal amide). Both peptides catalyzed the retro-aldol reactions of fluorogenic substrates (±)-**3**[4b] and (±)-*anti*-**4**[4c] in 5% CH_3CN–42.5 mM Na phosphate (pH 7.5). Since the solubility of the peptide FT-YLK-4 was low in buffer (around neutral pH) and prevented exact kinetic analyses, FT-YLK-3 was characterized in detail.

YLK-18-opt	YKLLKELLAKLKWLLRKL-NH_2
FT-YLK-3	YKLLKELLAKLKWLLRKLLGPTCL-NH_2
FT-YLK-4	YKLLKELLAKLKWLLRKLSDHLCL-NH_2
FT-YLK-3-R5	YRLLRELLARLRWLLRRLLGPTCL-NH_2
FT-YLK-3-23S	YKLLKELLAKLKWLLRKLLGPTSL-NH_2

The catalyzed reaction displayed saturation kinetics as described by the Michaelis–Menten equation. The parameters of FT-YLK-3 and of the template peptide YLK-18-opt are shown in Table 1.[7] The K_m values were in mM range. The rate acceleration above the buffer catalyzed background reaction (k_{cat}/k_{uncat}) of the selected peptide FT-YLK-3 was 1400 and 500 for (±)-**3** and (±)-*anti*-**4**, respectively, and was superior to the template peptide YLK-18-opt. FT-YLK-3 demonstrated moderate enantioselectivity in the retro-aldol reaction of **3**. Studies performed using FT-YLK-3 (100 μM) and each of the enantiomers of **3** (1 mM) in 10% CH_3CN–40 mM Na phosphate (pH 7.5), revealed that the ratio of the initial velocities of FT-YLK-3-catalyzed reactions of (*R*)-**3**:(*S*)-**3** was 1.8:1.0.[8]

In order to probe the catalytic mechanism of the peptide, reactivity and mutational studies were performed. The catalyzed reaction was inhibited by the addition of diketone **5**. When FT-YLK-3 (100 μM) was mixed with diketone **5** (2 mM) at pH 7.5 for 2.5 h at rt and the retro-aldol activity assessed with (±)-**3** (1.2 mM) in 5% CH_3CN–42.5 mM Na phosphate (pH 7.5), the velocity of the retro-aldol reaction was < 15% that observed in the absence of **5**. Further, FT-YLK-3 formed a UV-observable enaminone with pentane-2,4-dione (**6**) when FT-YLK-3 (100 μM) was mixed with **6** (5 mM) as indicated by the appearance of a new absorption at 318 nm.[4] The pH profile of the velocity of the enaminone formation indicates that FT-YLK-3 has a pK_a

Table 1 Kinetic parameters of the retro-aldol reactions[a]

	(±)-**3**			(±)-*anti*-**4**		
Peptide	K_m, mM	k_{cat}, min^{-1}	k_{cat}/k_{uncat}	K_m, mM	k_{cat}, min^{-1}	k_{cat}/k_{uncat}
YLK-18-opt	1.8	2.1×10^{-4}	540	0.9	4.1×10^{-4}	170
FT-YLK-3	1.8	5.6×10^{-4}	1400	1.1	1.2×10^{-3}	500

[a] Reaction conditions: [peptide] 100 μM, 5% CH_3CN–42.5 mM Na phosphate (pH 7.5) for (±)-**3** and, 5% DMSO–42.5 mM Na phosphate (pH 7.5) for (±)-*anti*-**4**, 25 °C. The first-order kinetic constant of the background reaction (k_{uncat}) was 3.9×10^{-7} for (±)-**3** and 2.4×10^{-6} min^{-1} for (±)-*anti*-**4**. The reaction was followed by monitoring the increase in fluorescence (λ_{ex} 330 nm, λ_{em} 452 nm).

lower than that typical of a lysine ε-amino group or a N-terminal amino group. The lowest pK_a is approximately 5.5. These results are consistent with peptide catalysis of the retro-aldol reaction using an enamine mechanism and chemically reactive amino group(s).

Since the low pK_a nucleophilic amino group of LysH93 of aldolase antibodies 38C2 and 33F12 can be specifically covalently modified with lactam **7**,[9] FT-YLK-3 was treated with **7** to further study amino group reactivity. FT-YLK-3 (100 μM) was mixed with **7** (1 mM) and analyzed by MALDI-mass at 30 min, 2 h, and 6 h. Analysis indicated a time-dependent modification at multiple sites. At 30 min, 0–4 additions of **7** per molecule of FT-YLK-3 were observed while 1–5 and 1–7 modifications were observed at 2 and 6 h, respectively. In addition to lysine and a free amino terminus, FT-YLK-3 contains tyrosine, threonine, and cysteine residues that can react with **7**. Even with consideration of labeling at these 3 additional potential modification sites, the results suggest that more than one reactive amino group is labeled.[10]

To examine the effect of the lysyl residues, all five lysyl residues in FT-YLK-3 were replaced by arginine residues. Peptide FT-YLK-3-R5 displayed less than 5% of the catalytic activity of FT-YLK-3 with (±)-**3**. This result is also consistent with catalytic role for the ε-amino groups of the lysine residues of FT-YLK-3. In addition, 1 mM of lysine, arginine, tyrosine, proline, and mixtures of these amino acids, or lysyl-lysine did not catalyze the retro-aldol reactions described above as assayed in 5% CH_3CN-42 mM Na phosphate (pH 7.5).

Since no additional amino functionalities were selected in FT-YLK-3, improvement of the catalytic activity of the peptide may originate from structural changes to the peptide and/or the addition of factors such as acid–base catalysis and transition state stabilization. The CD specta of FT-YLK-3 and YLK-18-opt (100 μM) in 45 mM Na phosphate buffer (pH 7.5) at 25 °C are shown in Fig. 1. For FT-YLK-3 the mean residue ellipticity at 208 and 222 nm were -3.04×10^4 and -2.47×10^4 deg cm^2 dmol^{-1}, respectively.[11] The CD spectra indicate that the peptide adopts an α-helical structure with an α-helical content of ~70%.[12] The template peptide YLK-18-opt showed a much reduced α-helical content under the same conditions, ~20%.[13] These results suggest that selection of the 6 amino acid residue C-terminal extension in FT-YLK-3 stabilizes the α-helical conformation of the peptide. MALDI mass analysis of FT-YLK-3 revealed the peptide forms a covalent dimer though a monomer was the main species detected after storage in the buffer used for kinetic studies. The dimer of FT-YLK-3 formed by a disulfide linkage did not preferentially form. The role of the Cys residue was assessed by synthesis of the Ser analog FT-YLK-3-23S. FT-YLK-3-23S catalyzed the retro-aldol reactions described above and the velocity of the catalyzed reaction of (±)-**3** (2 mM) was 75% that of FT-YLK-3. The ratio of the mean residue ellipticity of FT-YLK-3-23S at 208 and 222 nm were 0.8 and this ratio is the same as that observed in FT-YLK-3. The α-helix content of FT-YLK-3-23S was ~50%. The reduction in α-helical of FT-YLK-3-23S was correlated with a reduction in retro-aldolase activity. These results suggest that improved catalytic activity is intimately linked with stabilization of the conformation of the peptide.

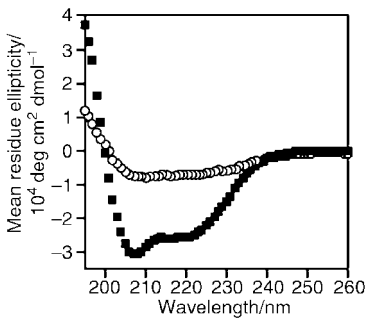

Fig. 1 CD spectra of peptides FT-YLK-3 (solid square) and YLK-18-opt (open circle). The CD spectra were recorded in 45 mM Na phosphate buffer (pH 7.5) at 25 °C at a peptide concentration of 100 μM.

In this study, we demonstrate that phage display and a compound designed to covalently trap catalysts that operate by a predefined mechanism can be used to directly select for small structured peptides that catalyze the aldol reaction. The coupling of phage display with this type of selection strategy provides a direct selection for peptide folding. For the aldolase peptide reported here, folding and catalytic activity were intimately linked.

This study was supported in part by the NIH (CA27489) and The Skaggs Institute for Chemical Biology.

First published as an Advance Article on the web 3rd April 2001

Triphenylphosphine selenide and its polymer-supported counterpart are found to be efficient selenium-transferring reagents for the conversion of H-phosphonate diesters and phosphite triesters into the corresponding phosphoroselenoate derivatives.

In the last two decades organoselenium chemistry became a rapidly expanding field of organic chemistry as various selenium-based reagents have enabled chemists to perform important synthetic transformations simply and in high yields.[1]

In 1957 Schwarz and Foltz[2] found that selenium is an essential nutrient for mammals (previously known as Factor 3 present in yeast) and prevents dietary necrotic degeneration of liver, heart and other organs. This unexpected nutritional role of selenium[3] has been a powerful incentive to study the biochemistry of organoselenium compounds.[4] Kindled by hopes of finding novel, useful theraputic properties, selenium has been incorporated into various biologically important compounds,† *e.g.* carbohydrates,[5] lipids,[6,7] nucleosides[8] and oligonucleotides.[9–11]

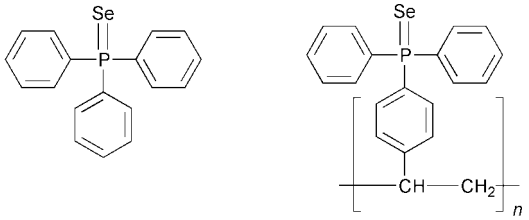
Organoselenophosphorus compounds are usually prepared[12] *via* P^{III} intermediates (*e.g.* phosphite triesters,[9,10,13] H-phosphonate-[6,11] or H-phosphonothioate[11] diesters), with a crucial step involving an oxidative transfer of selenium to phosphorus. As a source of electrophilic selenium in such transformations elemental selenium[6,14,15] and potassium selenocyanate,[10,13,16] are most commonly used. However, the low reactivity of these reagents and serious problems in their application in solid phase synthesis, led to the development of two selenizing agents soluble in organic solvents, 3*H*-1,2-benzothiaselenol-3-one (BTSe),[11] and bis(di-*O*,*O*-isopropyl phosphinothionyl)diselenide.[17]

To expand this short list of available selenizing reagents, we have embarked on investigations of a selenium exchange phenomenon between phosphine selenides and various P^{III} compounds as a viable route to selenophosphates. The rationale behind this was the observation that selenium-transfer from tertiary phosphine selenides to tertiary phosphines,[18] in contradistinction to phosphine sulfides, occurs readily at ambient temperature to produce an equilibrium mixture of the corresponding P^{III} and P^{V} species, as shown in Scheme 1.

Although established in a general sense, this reaction has not been recognised as a possible way of synthesising selenophosphorus compounds.

To find out if the selenium exchange process also occurs readily between phosphine selenides and other P^{III} compounds, we first investigated the reaction of triphenylphosphine selenide (TPPSe, **1**) with triethyl phosphite. Triphenylphosphine selenide **1**[14,16] seemed most attractive as a possible source of electrophilic selenium, since it is a stable, crystalline, inexpensive, commercial reagent, with good solubility in organic solvents.‡

Scheme 1

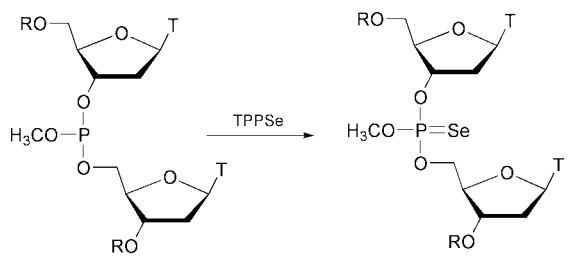


TPPSe **1** PS-TPPSe **2**

Thus, triethyl phosphite in chloroform was treated with selenide **1** (1.1 equiv.) and progress of the reaction was followed by ^{31}P NMR spectroscopy. It was rewarding to find that transfer of selenium from **1** (δ_P = 36.5, $^1J_{PSe}$ = 640 Hz) to triethyl phosphite (δ_P = 139.0) occurred rapidly (within 5 min) and quantitatively with the formation of triethyl phosphoroselenoate§ (δ_P = 72.0, $^1J_{PSe}$ = 938 Hz) and triphenylphosphine (δ_P = −4.2). Encouraged by this result we assessed TPPSe as a selenizing reagent for dinucleoside phosphite **3**¶ (Scheme 2). The reaction of **3** with 1.1 equiv. of selenide **1** was only slightly slower than that with triethyl phosphite (completion within 20 min) and produced the expected phosphoroselenoate triester **4** as a *ca.* 1 : 1 mixture of diastereomers (δ_P = 74.6 and 74.2, $^1J_{PSe}$ = 969 and 970 Hz). Compound **4** was isolated by silica gel chromatography (*ca.* 70% yield) and its structure was confirmed by NMR spectroscopy and MALDI data.

Somewhat surprisingly, attempted selenization of diethyl H-phosphonate with selenide **1** (2 equiv.) failed as no selenium-transfer occurred within 24 h (^{31}P NMR spectroscopy) in pyridine or in chloroform in the presence of triethylamine (5 equiv.). However, the conversion of diethyl H-phosphonate (δ_P = 7.6) into the corresponding silyl phosphite‖ (δ_P = 128.5) furnished rapid (< 10 min) and clean selenization upon addition of selenide **1** (1.1 equiv.) with the formation of diethyl phosphoroselenoate diester (δ_P = 56.2, $^1J_{PSe}$ = 934 Hz). We also found that selenization of diethyl H-phosphonate with **1** (2 equiv.) in pyridine could be effected without presilylation, when diazabicyclo[5.4.0]undec-7-ene (DBU, 5 equiv.) was used as base (completion within 25 min).

The efficacy of this approach for selenization of nucleoside H-phosphonate diesters was evaluated by reacting dinucleoside H-phosphonate **5a** with TPPSe (1.1 equiv.) in pyridine in the



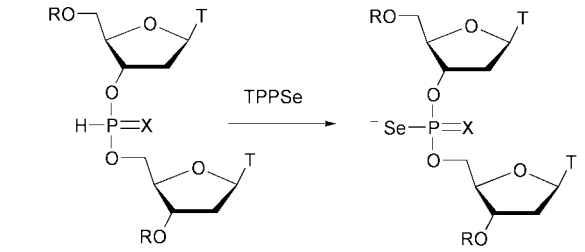
3 **4**

R = 4,4′-dimethoxytrityl
T = thymin-1-yl

Scheme 2

DOI: 10.1039/b101002f

presence of trimethylsilyl chloride (TMS-Cl, 6 equiv.) as a silylating agent (Scheme 3). The reaction was clean and went to completion within 15 min producing the silylated phosphoroselenoate **6a** (δ_P = 56.9 and 56.6) as the sole nucleotidic product. Similarly to diethyl H-phosphonate, selenization of H-phosphonate **5a** with **1** (1.1 equiv.) also occurred rapidly (< 5 min) and cleanly in pyridine in the presence of DBU (5 equiv.) as a base. The produced dinucleoside phosphoroselenoate **6a** was isolated from the reaction mixture by silica gel chromatography in *ca*. 90% yield and it was identical to **6a** prepared in another way.[11]



Scheme 3

The above conditions were also found to be most efficient for the preparation of phosphorothioselenoate **6b**[11] (δ_P = 104.2 and 103.8, $^1J_{PSe}$ 759.0 and 756.0 Hz) from the corresponding H-phosphonothioate **5a** (80% isolated yield).** Preliminary data from selenization of **5a** and **5b** containing different ratios of both diastereomers showed that selenide **1** furnished transfer of selenium to H-phosphonate and H-phosphonothioate diesters in a stereospecific manner (most likely with retention of configuration).

As the final part of these studies we also investigated the possibility of using a polymer-supported phosphine selenide **2** (PS-TPPSe) as a selenium-transferring reagent. Thus, a commercially available polystyryl diphenylphosphine resin was converted into selenide **2**†† and reacted with selected P^{III} derivatives. Preliminary ^{31}P NMR experiments showed that **2** can indeed act as an efficient selenium-transferring reagent. When triethyl phosphite was treated in dichloromethane with polymer-supported selenide **2** (4 equiv.), complete conversion to the corresponding phosphoroselenoate occurred within a few minutes. Also selenization of dinucleoside H-phosphonate **5a** with selenide **2** (3 equiv.) in the presence of DBU (5 equiv.) proceeded rapidly (> 5 min) producing the expected dinucleoside phosphoroselenoate **6a**.‡‡

In conclusion, we have developed a new and efficient method for the selenization of P^{III} compounds based on selenium exchange. Triphenylphosphine selenide **1**, which is proposed as a new source of electrophilic selenium in this method, is a stable, easy to handle, inexpensive and commercially available reagent, with good solubility in organic solvents. Efficiency of **1** as a selenium-transferring reagent was demonstrated by using it for the conversion of phosphite triesters and H-phosphonate diesters into the corresponding phosphoroselenoates, as well as in the transformation of H-phosphonothioate diesters into the phosphorothioselenoate derivatives. The reactions were fast and occurred under mild, homogeneous conditions. A polymer-supported counterpart of reagent **1**, triphenylphosphine selenide **2**, also showed favourable selenium-transferring properties. This reagent can be considered as an alternative to **1**, especially if separation problems arise.

We are indebted to Professor P. J Garegg for his interest in this work. Financial support from the Swedish Natural Science Research Council is gratefully acknowledged.

Notes and references

† Selenium compounds are generally toxic to animals. However, toxicity *per se* does not rule out a compound for drug use although it frequently prevents the administration of an effective dose that is also safe.

‡ Triphenylphosphine selenide **1** can also be easily prepared *via* selenization of triphenylphosphine in 1,4-dioxane with elemental selenium or according to the Nicpon and Meek procedure,[16] using KSeCN. Approximate solubility of **1** in organic solvents (solvent, mg mL^{-1}): acetonitrile, 6; THF, 80; pyridine 100; dichloromethane 130; chloroform, 230.

§ Identity of this and other phosphoroselenoates obtained in these studies (*e.g.* **4**, **6a**, **6b**) was confirmed by independent synthesis of these compounds *via* selenization of the corresponding P^{III} precursors with elemental selenium.

¶ Dinucleoside phosphite **4** was generated *in situ* from 5′-*O*-dimethoxytritylthymidin-3′-yl methyl *N*,*N*-bis(diisopropyl)phosphoramidite and 3′-*O*-dimethoxytritylthymidine in chloroform in the presence of tetrazole. Besides **4**, the reaction mixture contained *ca*. 10% hydrolysis products and *ca*. 5% of the unreacted phosphoramidite.

‖ Reaction in chloroform, using bis(trimethylsilyl)acetamide (BSA) and triethylamine.

** In a typical experiment, H-phosphonate **5a** or H-phosphonothioate **5b** (0.1 mmol) was dissolved in pyridine (4 mL) containing triphenylphosphine selenide **1** (2.0 equiv.), and DBU (5 equiv.) was added. After 5 min the reaction mixture was diluted with dichloromethane (20 mL), extracted with 0.5 M TEAB buffer (pH = 6.5, 4 × 50 mL) and the organic phase was subjected to silica gel chromatography using a stepwise gradient of methanol (0–2%) in chloroform containing 0.2% triethylamine. Yields: **6a** 90%, **6b** 80%.

†† Polymer-supported phosphine selenide **2** was synthesized by shaking in THF polystyryl diphenylphosphine resin with KSeCN (3 equiv.) for 4 h. After that time the ^{31}P NMR spectrum of the suspended polymer beads showed a complete disappearance of the broad signal at −5.4 ppm due to the phosphine and a new broad signal at 35.5 ppm due to phosphine selenide.

‡‡ *Ca*. 10% of the corresponding nucleoside 3′- and 5′-*H*-phosphonate monoesters were present in the reaction mixture, probably as a result of hydrolysis of **6a**.

Fundamental design aspects of amphiphilic shell-crosslinked nanoparticles for controlled release applications

K. Shanmugananda Murthy, Qinggao Ma, Christopher G. Clark, Jr., Edward E. Remsen and Karen L. Wooley*

Department of Chemistry, Washington University, One Brookings Drive, CB 1134, St. Louis, MO 63130, USA. E-mail: klwooley@artsci.wustl.edu; Fax: +1 (314) 935 9844; Tel: +1 (314) 935 7136

Received (in Corvallis, OR, USA) 19th January 2001, Accepted 15th March 2001
First published as an Advance Article on the web 3rd April 2001

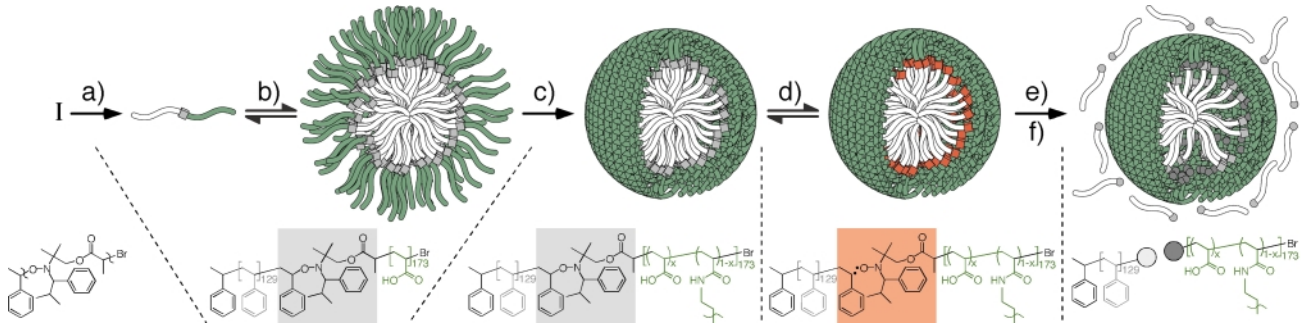
A unique method is developed for the controlled release of the hydrophobic polymer chains from the core of the shell crosslinked nanoparticles (SCKs) by selective cleavage of labile C–ON bonds present at the core–shell interface; this represents a methodology to probe the permeability of nanoscopic membranes and a means for applications in the controlled release of macromolecular species.

Polymeric nanoparticles, engineered with controlled composition, structure and dimensions, have attracted great interest in recent years for their potential applications in medicine and in nanotechnological devices, particularly as drug delivery vehicles.[1,2] Inspired by the nano-sized, amphiphilic core–shell structure of lipoproteins, shell crosslinked nanoparticles (SCKs) with a hydrophobic core, contained within a hydrogel network, were prepared by the self-assembly of amphiphilic block copolymers followed by intramicellar crosslinking between the polymeric chains located within the shell.[3] SCKs are characterized by their structural integrity and available functionality to attach receptor-recognizing ligands on the shell surface.[4] The control over size, shape and composition of these nanoparticles holds great potential in drug delivery applications.[5–7] The permeable crosslinked shell of the SCKs can act as a protective layer for the encapsulated guest molecules and determines the transport into and out of the core of these nanoparticles.[8] The polymer chains constituting the core can be selectively degraded and extracted to generate hollow nanospheres, which makes possible the loading of large quantities of guest molecules.[9]

SCKs with the core composed of bioactive polymeric chains, and covalently attached to the shell, through labile bonds at the core–shell interface, are expected to be of interest for the release of hydrophobic drugs, such as peptides.[2] Such SCKs may be useful as prodrugs with enhanced oral bioavailability for poorly absorbed drugs and may exhibit site-specificity and controlled release, the latter being controlled by the extent of crosslinking of the permeable shell membrane. Therefore, the porosity of these membrane networks, which are only a few nanometers in thickness, must be accurately evaluated. Herein, we report our preliminary results carried out on an SCK model system, based on poly(styrene)-*b*-poly(acrylic acid) (PS-*b*-PAA), possessing labile C–ON bonds present at the core–shell interface. The controlled release of the core PS chains is demonstrated, upon selective thermolytic cleavage of the C–ON bonds.

The synthetic approach for the preparation of the SCK nanoparticles from PS-*b*-PAA and the subsequent release of the PS chains from the core is presented in Scheme 1. SCKs possessing thermally labile C–ON bonds at the core-shell interface were prepared from the amphiphilic copolymer PS-*b*-PAA, which was designed to have a C–ON bond connecting the hydrophilic and hydrophobic blocks. The synthesis of PS-*b*-PAA utilized a combination of nitroxide mediated radical polymerization (NMRP) and atom transfer radical polymerization (ATRP)[10] from a bi-functional initiator, **1**.[11] The alkoxyamine group of **1** was utilized for polymerizing styrene by NMRP and the resulting PS with a terminal bromopropionyl ester group was then used as a macroinitiator for the ATRP of *tert*-butyl acrylate to obtain PS-*b*-P*t*BA.[12] The diblock was made amphiphilic by the hydrolysis of *tert*-butyl ester groups by reaction with TFA in CH_2Cl_2 at rt.[13]

Micellization of PS-*b*-PAA and subsequent shell crosslinking, using 2,2′-(ethylenedioxy)bis(ethylamine) as a crosslinker, were carried out according to the previously reported procedure.[3] To study the effect of shell crosslinking on the structure of the nanoparticles and, in particular, the shell permeability, polymeric micelles were crosslinked to different extents by adding stoichiometric ratios of diamine crosslinker to carboxylic acid moieties that would result in a maximum theoretical crosslinking of 20, 50 and 100%. Upon crosslinking, the C=O absorption band corresponding to free carboxylic acid groups (1710 cm^{-1}) decreased and the amide I and II bands (1650 and 1540 cm^{-1}) with intensity in proportion to the amount of added crosslinker appeared in the IR spectra of lyophilized samples of the SCKs. The effective Stokes, volume-weighted, mean hydrodynamic diameters (by dynamic light scattering (DLS) measurements) were 54 ± 3 nm for the micelles, and the SCKs were respectively, 55 ± 3, 28 ± 2 and 35 ± 3 nm for 20, 50 and 100% crosslinking.[14]



Scheme 1 The synthetic approach for the preparation of SCK nanoparticles by a combination of self-assembly and intramicellar crosslinking reactions followed by the subsequent release of core polymer chains upon the cleavage of C–ON bonds present at the core–shell interface. (a) *See* ref. 12 and 13; (b) and (c) *see* ref. 3; (d) thermolysis of C–ON bonds (125 °C, 24 h in water); (e) lyophilization and (f) resuspension in THF.

The irreversible termination of the PS· radicals, generated upon the thermal homolytic cleavage of the C–ON bonds at the core–shell interface[15] leads to the detachment of PS chains from the crosslinked shell. The addition of ascorbic acid during this process facilitates the irreversible termination of the carbon-centered radicals by reducing the aminoxyl counter radicals to the corresponding hydroxylamine.[16] Thermal decomposition studies were carried out first with the amphiphilic diblock copolymer PS-*b*-PAA, by heating at 125 °C for 24 h in a sealed Schlenk tube (in toluene–acetic acid, 80 : 20 v/v) in the presence and absence of ascorbic acid. The isolated PS (pure by ^{1}H NMR) accounted for 58.5% (ascorbic acid) and 20.7% (no ascorbic acid) of the theoretical amount of PS expected. The polydispersity index (PDI) decreased from 1.22 (for PS-*b*-PAA) to 1.10 (for the PS obtained upon decomposition). The GPC trace of the PS obtained was monomodal and the peak retention time coincided with that of the PS macroinitiator.

The amount of PS isolated (20.7% in 24 h) by the homolytic cleavage of C–ON bonds in PS-*b*-PAA was significant even in the absence of radical quencher, ascorbic acid. Hence, for simplicity, the cleavage of the C–ON bonds present at the core–shell interface of the SCKs were carried out by heating the aqueous solution of SCKs (125 °C in a sealed Schlenk tube for 24 h) in the absence of ascorbic acid. The kinetics of PS chains released from the core was followed by suspending the lyophilized SCKs in THF (at rt) with stirring and analyzing aliquots removed at different time intervals, after filtration through a 20 nm filter (Whatman), by GPC using a PS standard (M_n = 2450) of known weight as an internal reference. Representative GPC traces of PS released as a function of time, for SCKs with 20% crosslinking, are given in Fig. 1(a) and the data for % PS released as a function of time for SCKs with different extents of crosslinking are plotted in Fig. 1(b). In each case, the GPC retention time of the PS released and that of the PS macroinitiator was identical. Based on the nearly monodisperse GPC chromatograms of the released PS, it appears that bimolecular termination between the PS· radicals is not a major termination process. However, an alternative argument for the lack of observable PS dimer is that the molecular weight of the dimer may be sufficiently great as to prevent its permeation through the shell of the SCK. An inverse relationship was observed between the amount and rate of PS release with the extent of shell crosslinking. The amount of PS released (92 h) was 28.7, 6.8 and 3.5% for the SCKs with 20, 50 and 100% crosslinking, respectively.[17] The PS released during the initial period was rapid ('burst effect'), likely due to the increase in osmotic pressure with the addition of THF, followed by a decreasing rate of release, consistent with passive diffusion.

The amount of PS released from the nanoparticles was larger (28.7% in 92 h, 20% crosslinking) than that isolated (20.7%) from PS-*b*-PAA under similar decomposition conditions (125 °C, 24 h). A decreased efficiency of the recombination reactions between the PS· radicals in the core and the aminoxyl counter radicals located at the inner surface of the shell, leading to more dead PS chains, is consistent with the observed results for SCKs.

The experimental data reveal that the free PS chains, present in the core, can penetrate the hydrogel-like shell membrane. However, when the shell is highly crosslinked such penetration is inhibited. The controlled release of polymer chains from the core by adjusting the crosslink density of the shell opens the possibilities of designing polymeric nanoparticles with specific shell permeabilities, capable of delivery of large guests. This approach may provide a solution to some of the delivery problems posed by biologically active molecules, such as peptides and proteins, genes and oligonucleotides. The results of this study also provide a foundation for better understanding of the porosity of the crosslinked shell of SCKs.

Funding of this research, provided by National Science Foundation (DMR-9974457), is gratefully acknowledged.

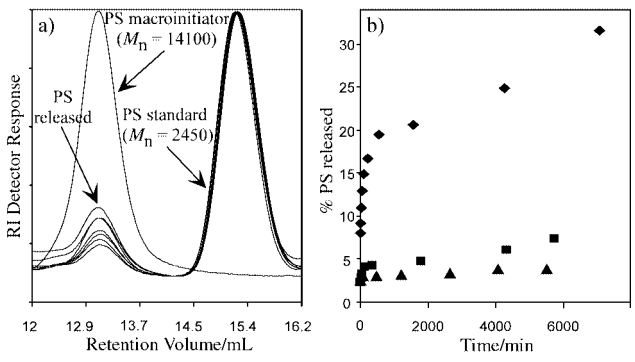


Fig. 1 (a) GPC traces of PS (M_n = 14100) released from the core of SCKs (20% crosslinking) as a function of time. The PS standard (M_n = 2450) provided concentration quantification. (b) Release kinetics of PS from the core of SCKs crosslinked to different extents (◆ 20%, ■ 50% and ▲ 100% crosslinking).

11 The initiator, **1**, was synthesized by reacting 1-hydroxy-2,2,5-trimethyl-3-(1-phenylethoxy)-4-phenyl-3-azahexane (HAA) with excess bromoisopropionyl bromide in the presence of triethylamine. The crude ester was purified by column chromatography eluting with hexane–ethylacetate (4 : 1). ^{1}H NMR ($CDCl_3$, 300 MHz, diastereomers) δ 7.5–7.1 (m, 20H), 5.0–4.8 (m, 2H), 4.5–2.3 (m, 8H), 2.0–1.8 (m, 8H), 1.66 (d, 3H, J = 6.6 Hz), 1.58 (d, 3H, J = 6.6 Hz), 1.37 (d, 3H, J = 6.3 Hz), 1.36 (d, 3H, J = 6.3 Hz), 1.26 (s, 3H,), 1.05 (s, 3H), 0.98 (d, 3H, J = 6.3 Hz), 0.61 (s, 3H,), 0.59 (d, 3H, J = 6.6 Hz), 0.26 (d, 3H, J = 6.6 Hz). HRMS mass calculated for $C_{25}H_{34}BrNO_3$ $[M + 1]^+$ 476.17, found 476.2. For the preparation of HAA *see* D. Benoit, V. Chaplinski, R. Braslau and C. J. Hawker, *J. Am. Chem. Soc.*, 1999, **121**, 3904.

12 Styrene (13.10 g, 0.126 mol), **1** (0.43 g, 9×10^{-4} mol) and acetic anhydride (0.19 g, 1.8×10^{-3} mol) were charged into a Schlenck tube and after three freeze–thaw cycles, the tube was sealed and the polymerization was carried out at 125 °C for 6 h. The bromopropionyl terminated PS (M_n (GPC) = 14100 g mol^{-1}, PDI = 1.11) was isolated by methanol precipitation and was then used as an initiator (4.00 g, 2.84 $\times 10^{-4}$ mol) for the ATRP of *tert*-butyl acrylate (8.75 g, 6.80×10^{-2} mol) in the presence of *N*,*N*′,*N*′,*N*″*N*″-pentamethyldiethylenetriamine (0.10 g, 5.80×10^{-4} mol) and CuBr (0.07 g, 4.70×10^{-4} mol) at 50 °C for 15 h.

13 To 6.05 g of PS-*b*-P*t*BA was added 150 mL of CH_2Cl_2 followed by 15.0 mL of TFA. The reaction mixture was stirred at 25 °C for 40 h, concentrated *in vacuo*, and precipitated (3×) in hexane from THF solution. The PS-*b*-PAA product was dried under vacuum.

14 The effect of shell crosslinking upon the hydrodynamic diameter is being studied in detail for these and other shell crosslinked nanostructures.

15 Model studies with ethyl 2-bromopropionate under similar reaction conditions gave no ester bond hydrolysis.

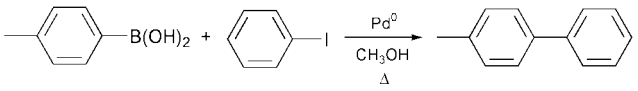
A ligandless palladium catalyzed Suzuki coupling reaction is described.

The palladium catalyzed carbon–carbon cross-couplings of organometallics with organoelectrophiles is an important synthetic reaction.[1] Most organometallic compounds are sensitive to air, moisture or are toxic and often will not tolerate functional groups which may be important in complex syntheses. Boronic acids constitute one of the few organometallic reagents that tolerate a wide range of functional groups, are available and generally environmentally benign. In addition, they are inert to air, resistant to heat, and can be recrystallized from water or alcohol.

The Suzuki reaction[2] which uses boron-containing precursors has gained considerable attention in recent years because a large number of functionally substituted boron-containing reagents are commercially available. The Suzuki reaction generally employs expensive organic solvents such as tetrahydrofuran as well as expensive complex palladium catalysts. These palladium reagents tend to be difficult to manipulate and recover. We recently reported an energy efficient modification of the Suzuki reaction using an alumina surface and palladium powder which solved some of these problems.[3,4]

Earlier studies revealed that potassium fluoride was an effective Suzuki base.[5] Therefore we selected KF as the base for the current study. We found that aromatic iodides readily couple with arylboronic acids in the presence of palladium powder when the reactions are carried out in methanol, Scheme 1. The initial results are summarized in Table 1. The reaction can be utilized to couple benzyl bromides with arylboronic acids but aryl bromides and aryl chlorides are ineffective substrates. Aliphatic boronic acids are also not reactive.



Scheme 1

Table 1 Suzuki coupling of tolylboronic acid with aryl iodides[a]

Boronic acid	Aryl iodide	Yield[b] (%)
4-Methylphenyl	1-Fluoro-2-iodobenzene	91
4-Methylphenyl	1-Iodo-4-nitrobenzene	94
4-Methylphenyl	2-Iodoaniline	77
4-Methylphenyl	4-Iodoacetophenone	93
4-Methylphenyl	4-Iodoanisole	83
4-Methylphenyl	2-Iodothiophene	93
4-Methylphenyl	2-Iodophenol	76
4-Methylphenyl	1-Fluoro-3-iodobenzene	98
4-Methylphenyl	4-Iodotoluene	89

[a] Reactions carried out utilizing 1.0 mmol of aryl iodide and 1.1 mmol of tolylboronic acid in refluxing methanol (5 mL) for 4 h in the presence of palladium powder. [b] Isolated yields.

Table 2 Suzuki coupling of arylboronic acids with aryl iodides[a]

Boronic acid	Aryl iodide	Yield[b] (%)
Naphthyl	Iodobenzene	90
Naphthyl	1-Iodo-4-nitrobenzene	89
Naphthyl	2-Iodoaniline	74
2-Methylphenyl	2-Iodothiophene	90
2-Methylphenyl	1-Iodo-4-nitrobenzene	93
2-Methylphenyl	Iodobenzene	97
3-Formylphenyl	2-Iodothiophene	98
3-Formylphenyl	1-Iodo-4-nitrobenzene	98

[a] Reactions carried out utilizing 1.0 mmol of aryl iodide and 1.1 mmol of arylboronic acid in refluxing methanol (5 mL) for 4 h in the presence of palladium powder. [b] Isolated yields.

From the data in Tables 1 and 2, it would appear that the reaction is relatively insensitive to the electronic nature of substituents on the aromatic ring.

The synthesis of 4-methylbiphenyl is representative: palladium black (0.050 g), KF (0.380 g), *p*-methylphenylboronic acid (0.150 g, 1.10 mmol) and iodobenzene (0.204 g, 1.0 mmol) were added to a clean, dry, 50 mL round bottomed flask. Methanol (5 mL) was added to the mixture and the solution was refluxed for 4 h in the open air. After decanting the solution, the product was isolated *via* flash chromatography to yield 4-methylbiphenyl (92.2%); m.p. 44.0–45.5 °C, ^{1}H NMR ($CDCl_3$; δ ppm): 7.40 (m, 9 H), 2.37 (s, 3H).

It is important to note that the palladium metal can be recovered and recycled by a simple decantation of the reaction solution. In one series of experiments, we carried out eight consecutive preparations of 4-methylbiphenyl with no significant loss in product yields. In each case, the palladium powder was recovered by decantation, washed with methanol, and the experiment repeated. We made no effort to rigorously exclude water from the reactions. In fact, successful syntheses were achieved in 20% aqueous methanol.

We wish to thank the U.S. Department of Energy and the Robert H. Cole Foundation for their support of this research.

First published as an Advance Article on the web 3rd April 2001

The neutral ligand [Bu^{t}NHP(μ-NBu^t)$_2$PNH(2-py)] and its dilithiate [{Bu^{t}NP(μ-NBu^t)$_2$PN(2-py)}Li$_2$] exhibit a parallel ability to coordinate cations and anions, as revealed in the structures of the tris-solvate [LiCl{Bu^{t}NHP(μ-NBu^t)$_2$PNH(2-py)}$_3$] 1 and the unusual co-complex [{Bu^{t}NP(μ-NBu^t)$_2$PN(2-py)}Li$_2$·{Li(Bu^{t}N)$_2$P}] 2.

In recent years the coordination chemistry of new ligand systems based on Group 15 element/nitrogen frameworks has been the focus of an increasing number of investigations.[1] The most intensively studied species of this class are $[E_2(NR)_4]^{2-}$ dianions, which have been prepared for all the Group 15 elements (E = P–Bi).[2–5] For the heavier congeners (As–Bi) the dianion frameworks are readily established by condensation reactions of the dimers $[Me_2NE(\mu\text{-}NR)]_2$ with primary amido lithium complexes ($[RNHLi]_n$).[3–5] However, the phosphorus analogues are obtained by metallation of the pre-formed acids $[RNHP(\mu\text{-}NR)]_2$ with organolithium reagents.[2] The structures of the resulting lithium cages are based on $[\{E_2(NR)_4\}Li_2]$ cubane units, generally being of the type $[\{E_2(NR)_4\}Li_2\cdot 2thf]$[2a,5] or $[\{E_2(NR)_4\}\ Li_2]_2$[2b,3,4] (depending on the presence or absence of thf solvation). We recently showed that the precursor [Bu^{t}NHP(μ-NBu^t)$_2$PCl] is useful in the synthesis of non-symmetrical dianions, the reaction of the former with [CyPHLi] (Cy = cyclohexyl)/Bu^{n}Li giving the bifunctional (hard/soft) dianion [Bu^{t}NP(μ-NBu^t)$_2$PPCy]$^{2-}$.[6]

Both NMR spectroscopic and analytical investigations revealed that the reaction of (2-py)NHLi with [Bu^{t}NHP(μ-NBU^t)PCl][6] does not yield the free ligand [Bu^{t}NHP(μ-NBu^t)PNH(2-py)] (py = pyridyl), rather the product is the lithium chloride complex [LiCl{Bu^{t}NHP(μ-NBu^t)PNH(2-py)}$_3$] (Scheme 1) (ESI†). Addition of Bu^{n}Li to a solution of **1** [prepared *in situ* from the 1:1 reaction of [Bu^{t}NHP(μ-NBu^t)PCl] with (2-py)NHLi] (1.6 equiv., respectively)] leads to precipitation of LiCl and the formation of [{BuNP(μ-NBu^t)$_2$PN(2-py)}Li$_2$·{Li(Bu^{t}N)$_2$P}] **2** (in 19% yield) (ESI†). A ^{31}P NMR study of the reaction mixture before and after the addition of Bu^{n}Li reveals that the production of **2** stems from the formation of $[Bu^tNHP(\mu\text{-}NBu^t)]_2$ as a significant byproduct in the synthesis of **1**. ^{31}P NMR studies also show that only the dilithiate $[\{Bu^tNP(\mu\text{-}NBu^t)_2PN(2\text{-}py)\}Li_2]_n$ is produced by lithiation of *pure* **1**. However, addition of $[\{P_2(NBu^t)_4\}_2Li_2]_2$ (the product of lithiation of $[Bu^tNHP(\mu\text{-}NBu^t)]_2$[2b]) to a solution of $[\{Bu^tNP(\mu\text{-}NBu^t)_2PN(2\text{-}py)\}Li_2]_n$ in the correct stoichiometric ratio gives **2**.‡ The formation of **2** can therefore be explained in both cases by symmetrical cleavage of the P_2N_2 ring units of $[\{P_2(NBu^t)_4\}_2Li_2]_2$ (Scheme 1). Of particular interest is the highly deshielded nature of the P centre of the $[(Bu^tN)_2P]^-$ anion in **2**, whose resonance is found at δ 395.3 (+25 °C). This value is considerably greater than observed for other $[(RP)_2N]^-$ anions (*ca.* δ 340–360).[2b,7] suggesting an even greater degree of charge separation within the anion backbone in **2** [*i.e.* N$^-$–P$^+$–N$^-$ rather than (N⋍P⋍N)$^-$]. The extent of this charge separation is probably related to the unusual coordination mode of the $[(Bu^tN)_2P]^-$ anion observed in the later structural characterisation of the complex (involving two N–Li bonds to each of the N centres of the anion, rather than only one as in all other previously characterised lithiates[2b,7]).

Confirmation of the structure proposed on the basis of spectroscopic and analytical studies is provided by a low-temperature X-ray crystallographic study of **1**.‡ This reveals that **1** is monomeric in the solid state, being composed of a lithium chloride unit which is coordinated by three neutral [Bu^{t}NHP(μ-NBu^t)PNH(2-py)] ligands (the molecules having exact C_{3v} symmetry about the Li–Cl bond axis) (Fig. 1). Although other tris-pyridine complexes of LiCl have been structurally characterised,[8] the 'cooperative' mode of coordination of the LiCl unit in **1** (by a combination of (pyridyl)N–Li bonding and H-bonding to the Cl$^-$ anion within the hydrophilic ligand cavity) is, to our knowledge, unprecedented for such an inorganic ligand system. This behaviour has closer parallels

with organic ligand frameworks such as the mode of coordination of HSO_4^- and $H_2PO_4^-$ ions by the tripodal naphthylurea receptor $N\{CH_2CH_2NHC(=O)NHC_{10}H_7\}_3$.[9] Judging by the lengths of the N–H···Cl interactions involved, the H-bonds with the NH(2-py) groups [Cl(1)···H(2N) 2.647(3) Å] are far more significant than those to the Bu^{t}NH groups [Cl(1)···H(3N) 3.177(3) Å]. This conclusion is confirmed by the variable-temperature ^{1}H NMR spectrum of the complex, in which the (2-py)NH proton resonance shifts from δ 6.40 at 20 °C to δ 5.60 at 40 °C with disruption of the N–H···Cl H-bonds. In comparison, the resonance for the Bu^{t}NH protons remains almost static (at δ 3.30).

The structure of **2**‡ consists of a co-complex of the anticipated pseudo-cubane [{Bu^{t}NP(μ-NBu^t)$_2$N(2-py)}Li$_2$] with a [(Bu^{t}N)$_2$P]Li monomer (Fig. 2). Alkali metal complexes containing [(RN)$_2$P]$^-$ anions have only been observed previously where sterically demanding organic substituents are present, which prevent dimerisation into [P$_2$(NR)$_4$]$^{2-}$ dianions (such as 2,4,6-Bu$^t_3$C$_6$H$_2$ or 1-adamantyl).[2b,7,10] Significantly, the steric demands of the Bu^t group alone are insufficient to prevent dimerisation in [{P$_2$(NBu^t)$_4$}Li]$_2$[2b] or its thf solvate [{P$_2$(NBu^t)$_4$}Li$_2$·2thf].[2a] Clearly, the disruption of this dimerisation and the 'trapping' of the [(Bu^{t}N)$_2$P]$^-$ anion in **2** stem from the ability of the supporting [{Bu^{t}NP(μ-NBu^t)$_2$PN(2-py)}Li$_2$] pseudo-cubane to coordinate cooperatively the cation and anion of the [(Bu^{t}N)$_2$P]Li monomer (behaviour which parallels that of the neutral [Bu^{t}NHP(μ-NBu^t)PNH(2-py)] ligand in **1**, *i.e.* the Li$^+$ cations now playing a similar role to the H atoms in anion coordination). A similar ability to form co-complexes of this type has also been observed for the Group 15 complex [{Sb(NCy)$_3$}$_2$Li$_6$][11] and the Group 16 complex [S(NBu^t)$_3$Li$_2$].[12]

Examination of the Li–N bond lengths found in the core of **2** reveals that chelation of Li(3) by the N(2-py) group plays a decisive role in stabilising the [(Bu^{t}N)$_2$P]Li monomer. In fact, bonding of the imido N centre of the N(2-py) group to the two Li$^+$ cations within the [{BuNP(μ-NBu^t)$_2$PN(2-py)}Li$_2$] fragment [N(2)–Li(1) 2.523(7), N(2)–Li(2) 2.823(7) Å] is almost completely sacrificed to allow effective coordination of Li(3) by the N(2-py) group [N(1)–Li(3) 2.003(6), N(2)–Li(3) 2.040(6) Å]. Thus, Li(1) and Li(2) only interact significantly with the terminal and μ-NBu^t groups of the [Bu^{t}NP(μ-NBu^t)$_2$PN(2-py)]$^{2-}$ dianion [N(3)–Li(1,2) mean 2.05, N(4,5)–Li(1,2) mean 2.16 Å], and these Li$^+$ cations are therefore primed (spacially and electronically) for coordination by the two N centres of the [(Bu^{t}N)$_2$P]$^-$ anion [Li(1,2)–N(7,6) 2.08 Å]. Although the P···N bond lengths within the [(Bu^{t}N)$_2$P]$^-$ anion [P(3)–N(6) 1.613(3), P(3)–N(7) 1.606(3) Å] are similar to those found in [(RN)$_2$P]Li complexes containing bulky substituents (*ca.* 1.58–1.60 Å),[2b,7] unlike the latter the PN$_2$Li ring in **2** is non-planar as a result of the interaction of the N atoms of the anion with Li(1) and Li(2). This is a unique coordination mode for any [(RN)$_2$P]$^-$ anion.[2b,7,10,13]

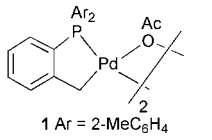
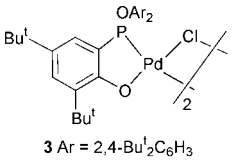
First published as an Advance Article on the web 3rd April 2001

Phosphapalladacyclic complexes synthesised from *ortho*-bromobenzylphosphine ligands are effective catalysts for carbon–carbon bond forming reactions, exhibiting activity that compares with, and in several examples exceeds, that of existing systems.

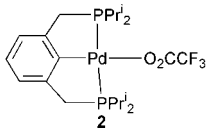
Outstandingly active catalysts for the Heck (Scheme 1) and Suzuki (Scheme 2) coupling reactions using palladacyclic compounds have been reported by Herrmann *et al.* (**1**, turnover numbers (TON, mol (mol Pd)$^{-1}$) for Heck reactions up to 1 M),[1,2] Milstein and coworkers (**2**)[3] and Bedford and coworkers (**3**, TON for Heck up to 5.75 M, but substantial formation of polystyrene occurred and TON to product was not reported).[4]



1 Ar = 2-MeC$_6$H$_4$



3 Ar = 2,4-Bu$^t_2$C$_6$H$_3$



2

We were interested in whether the nature of the Pd–C bond was important in determining catalyst efficiencies, so we attempted the synthesis of a complex similar to that of Herrmann *et al*., but with a metallated benzyl ligand.

† Current address: ICI Synetix, PO Box 1, Belasis Avenue, Billingham, Cleveland, UK TS23 1LB.

Tertiary *o*-bromobenzylphosphine ligands **4** undergo metallation with [Pd$_2$(dba)$_3$] (dba = dibenzylideneacetone) to yield the palladacycle complexes **5** (Scheme 3) which also exhibit efficient cross-coupling catalytic activity. In common with the studies of Herrmann *et al.*, we have found that aryl groups on the phosphine moiety of the palladacyclic complex give superior catalytic performance than electron-donating alkyl groups,[5] so we have concentrated on complex **5a** (Table 1).

The reaction of 4-bromoacetophenone with *n*-butyl acrylate consistently resulted in reasonable yields of 85–90% when 2×10^{-4} mol% of **5a** was used. As expected, longer reaction times were required to achieve the same yield when a lower reaction temperature was used (entry 2). It is noted that higher

[a] *Reaction conditions*: 50 mmol aryl halide, 75 mmol phenylboronic acid, 100 mmol K_2CO_3, 150 cm^3 *o*-xylene. [b] Determined by GC-MS. [c] Catalyst **5c**. [d] Conversion is 83.4%, other products are 1-(4-chlorophenyl)-1-phenylmethanol (37.4%) and 1-4-biphenyl-1-phenylmethanol (19%).

temperature (170 °C, entry 1) is required to achieve activity comparable to the Herrmann system (1000 000 TON in 24 h at 130 °C),[5] but no additive/promoting salts (*e.g.* NBu_4Br) are required. In fact we have not observed any increase in activity or catalyst stability when such salts are added to our system. As the catalyst concentration is decreased, higher turnover numbers, in excess of 3×10^6, are achieved at the expense of product selectivity (entries 3 and 4). Indeed, when bromoacetophenone was used as the substrate, Michael addition to the alkene was a competing side reaction, which predominated with higher temperatures and lower catalyst concentration. The Michael addition is reversible so that the selectivity to the coupled product increases with time (Fig. 1). Michael addition was not observed when 4-bromobenzaldehyde was used (entry 5), as the aldehyde proton is less acidic than the α protons of the acetophenone, and a TON of 3.7×10^6 was achieved with good selectivity. There is also evidence to suggest that complex **5a** is deactivated more quickly due to palladium metal aggregation when higher catalyst concentrations are used, resulting in incomplete reaction. Product decomposition at prolonged high reaction temperatures has also proven a problem with certain substrates.

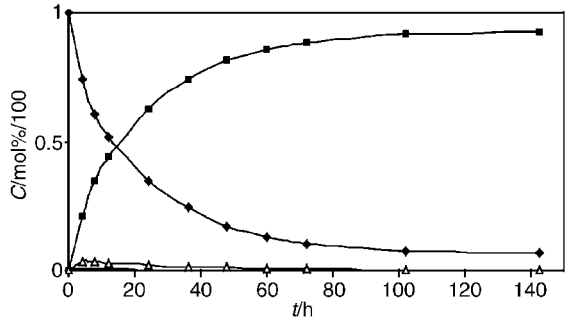

Fig. 1 Diagram of the concentration (*C* in mol%/100) *vs*. reaction time of the Heck reaction of 4-bromoacetophenone (◆) with *n*-butyl acrylate at 130 °C to form *n*-butyl (*E*)-4-acetylcinnamate (■): catalyst **5a** (0.0001 mol%, 0.0002 mol% Pd). Michael addition by-products (△) and (□) are also formed.

Non-activated and deactivated (electron donating) substrates, such as bromobenzene, 4-bromoanisole and 4-bromo-*N*,*N*-dimethylaniline (entries 6–8) require higher catalyst concentrations and reaction times to obtain reasonable yields, but the turnover numbers compare favourably with other palladacyclic systems.[5] Even 4-bromophenol reacted to give 20% of *n*-butyl-(*E*)-4-hydroxycinnamate, but 4-bromoaniline gave almost exclusively Michael addition products. The industrially important reaction of ethene with 2-bromo-6-methoxynaphthalene also occurs with excellent selectivity and good activity (entry 12).

Although the observations of Herrmann that aryl donating groups on the phosphino moiety give higher activity than alkyl groups have been confirmed, complex **5c** catalyses the coupling of 4-bromoacetophenone and *n*-butyl acrylate with excellent selectivity when 0.02 mol% Pd is used (entry 13).

In addition to being an effective Heck catalyst, complex **5a** also exhibits catalytic activity towards the Suzuki coupling, and, to a lesser extent, the Stille coupling (35% yield from 4-bromoacetophenone and Me_3PhSn in 6 h at 110 °C, 3528 turnovers) and the hydroarylation reaction[6] (57% conversion of norbornene to phenylnorbornane using **5a** and bromobenzene in 12 h at 130 °C, 9500 turnovers).

The Suzuki reaction is the coupling of aryl halides with arylboronic acids (Scheme 2). It is mechanistically similar to the Heck reaction, and both the Herrmann[1b] and Bedford[7] complexes have also been reported as active catalysts for this reaction. Some results for the coupling of alkyl halides with phenylboronic acid are displayed in Table 2.

Excellent conversions and selectivities are observed with catalyst concentrations down to 0.001 mol% Pd, after which longer reaction times are required. In contrast to the results of Bedford and coworkers, little activity is observed when toluene is used as the reaction solvent (Bedford obtains 1000 000 TON in toluene in 2.25 h).[7] No activity is observed with aryl chlorides when using complex **5a**, but using the more electron donating **5c** activities higher than those reported by Fu and coworkers[8] using Pd/PBu^t_3 complexes (maximum TON = 200) or than those recently reported by Beller and coworkers[9] using unmetallated monophosphine palladium complexes (maximum TON < 2000) are obtained in the coupling of 4-chlorobenzaldehyde with phenylboronic acid. The major side products of this reaction are 1-(4-chlorophenyl)-1-phenylmethanol and 1-(4-biphenyl)-1-phenylmethanol. Since the latter arises from coupling of the Suzuki product to the boronic acid, the overall turnovers to Suzuki products are *ca.* 4600, which is similar to the best results obtained by Buchwald using di-*tert*-butylphosphinobiphenyl.[10] Other highly active catalysts for Suzuki coupling, which have been reported since the submission of this communication, show very low activities for coupling of chloroaromatics with aryl boronic acids.[11,12]

In conclusion, we have developed an underligated palladium catalyst system that shows comparable activity to existing palladacycle systems but does not require promoting salts. By making the P atom strongly electron donating (Bu^t_2P groups), a catalyst which shows very high activity for coupling of Suzuki chloroaromatic compounds is obtained.

Continuous flow homogeneous catalysis: hydroformylation of alkenes in supercritical fluid–ionic liquid biphasic mixtures

Murielle F. Sellin, Paul B. Webb and David J. Cole-Hamilton*

School of Chemistry, University of St. Andrews, St. Andrews, Fife, Scotland, UK, KY16 9ST. E-mail: djc@st-and.ac.uk

Received (in Cambridge, UK) 30th January 2001, Accepted 13th March 2001
First published as an Advance Article on the web 3rd April 2001

Rhodium complexes of [1-propyl-3-methylimidazolium]$_2$ [PhP($C_6H_4SO_3$-3)$_2$] dissolved in the ionic liquid, 1-butyl-3-methylimidazolium hexafluorophosphate catalyse the hydroformylation of oct-1-ene at a constant rate for > 20 h in a continuous flow process in which the substrate, gases and products are transported in and out of the reactor dissolved in $scCO_2$; < 1 ppm rhodium is present in the collected product.

Rhodium catalysts show very high activity and good regioselectivity under mild operating conditions for the hydroformylation of long chain hydrocarbons, but have not yet been commercialised for linear alkenes with > 6 C atoms because of problems associated with the separation of the low volatility product aldehydes from the thermally sensitive catalyst.[1] Instead, the less efficient cobalt based catalysts are still in use for the synthesis of soap and detergent range alcohols.[2] Various new ways are being investigated to ovecome this separation problem but the ideal system would provide a continuous flow process in which the advantages of reactions in the homogeneous phase (all catalytic sites equally accessible, high activity and high selectivity) could be combined with transport of the substrate, CO and H_2 into the solution and transport of the product aldehyde from the solution. This would mimic the systems currently in use for hydroformylation of propene and ethene.[1] As part of our on going studies on the use of supercritical fluids in homogeneous catalysis,[3–5] we have recently reported such a system,[5] where the catalyst is dissolved in a triaryl phosphite and the reactants are introduced dissolved in $scCO_2$, which is also used to remove the products from the reaction; both the ligand and the catalyst have low solubility in $scCO_2$. The initially high activity and selectivity to the desired linear aldehyde are gradually lost because the phosphite slowly dissolves in the $scCO_2$ and is removed from the system; it is also degraded by water.[5]

For a continuous flow system, an involatile solvent, which is insoluble in $scCO_2$ and contains a polar (preferably ionic) catalyst would be ideal and these properties are met by ionic liquids.[6] Previous attempts to carry out hydroformylation in room temperature ionic liquids using rhodium complexes of sulfonated triphenylphosphine ligands, showed rather low conversions,[7] perhaps because of the low solubility of permanent gases in the ionic liquid. Somewhat improved conversions could be obtained if other solvents (THF, toluene or water) were added. Even so, conversions were only of the order of 30%.[7] More recently, such reactions have been successfully carried out in ionic liquids using rhodium complexes of cobaltocenium based diphosphine ligands.[8]

A recent report has shown that $scCO_2$ is highly soluble in certain ionic liquids (up to 0.6 mol fraction), whilst the ionic liquid is insoluble in $scCO_2$.[9] Since $scCO_2$ is fully miscible with permanent gases and is a good solvent for alkenes and aldehydes, we reasoned that $scCO_2$ might help transport the permanent gases into the ionic liquid and could then also act as the transport medium for a flow system. A very recent paper shows that $scCO_2$ can extract a wide range of organic compounds from ionic liquids of this type.[10] We now report results of a study of the hydroformylation of alkenes in supercritical fluid–ionic liquid biphasic mixtures.

Table 1 shows results obtained from the hydroformylation of hex-1-ene in the ionic liquid, 1-butyl-3-methylimidazolium hexafluorophosphate using triphenylphosphite as the rhodium based ligand.† As with other ligands,[7] the results obtained in the pure ionic liquid are poor with a selectivity to aldehyde of only 15.7%, and the linear : branched (l:b) ratio is low at 2.4 although all of the hex-1-ene is converted. The main products arise from aldol condensation of the product aldehydes. On adding $scCO_2$, the rate of reaction falls, but the selectivity to aldehyde increases to 82.3% and the l:b ratio to 6:1. Using toluene as solvent, the rate and selectivity to aldehydes are high, but the l:b ratio is low (2.5).

In view of the success of the reaction in the biphasic system, we carried out similar reactions of hex-1-ene or non-1-ene, flushing the products from the reactor with $scCO_2$ at the reaction temperature and pressure at the end of the reaction and decompressing into a second autoclave held at low temperature.[4,5] After all the product had been removed by this flushing process, the reactor was cooled, depressurised and recharged with fresh substrate, CO, H_2 and CO_2. Several repetitive uses of the same catalyst show that it retains activity and selectivity for 2–3 runs, but then loses both. Visual inspection shows that the catalyst solution has become black and ^{31}P NMR studies show the presence of $O_2PF_2^-$ and $P(OPh)_nF_{3n}$ (n = 1–2). These products arise from reaction of the PF_6^- with water, releasing HF, which then attacks the phosphite.

Because of the water sensitivity of the ligands in this system, we investigated sulfonated triphenylphosphines, for which both the ligands and the rhodium complexes are insoluble in $scCO_2$. Complexes derived from the sodium salts of mono- and trisulfonated triphenylfosphine show low activity, at least in the case of the trisulfonate because of low solubility in the ionic liquid. We, therefore, synthesised [$Ph_2PC_6H_4SO_3$]-[BMIM] and used it together with [$Rh_2(OAc)_4$] as the catalyst precursor for the hydroformylation of non-1-ene in the $scCO_2$–[BMIM]PF_6 biphasic system with flushing of the products from the reactor with $scCO_2$. Fig. 1 shows that the activity of a rhodium catalyst derived from this ligand remains high for 12 runs (tunrover number = 160–320 h^{-1}) and the l:b ratio is acceptable. Rhodium leaching is not observed (< 0.003%) for

[a] [$Rh_2(OAc)_4$] (10 mg, 4.5×10^{-5} mol), $P(OPh_3)$ (0.2 g, 6.7×10^{-3} mol), hex-1-ene (2 cm^3, 1.8×10^2 mol), 4 cm^3 of solvent, 70 bar CO/H_2, 100 °C, 1 h. [b] The majority of the product is condensed aldehydes. [c] Total pressure = 230 bar.

DOI: 10.1039/b101046h

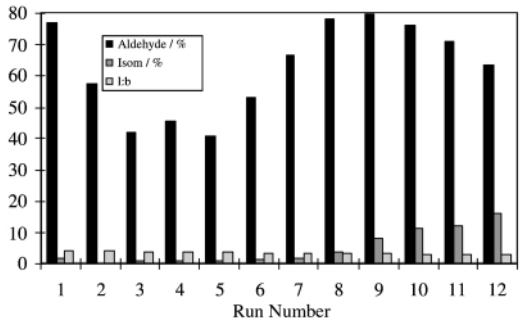

Fig. 1 Repetitive use of a catalyst synthesised *in situ* from $[Rh_2(OAc)_4]$ (10.3 mg, 4.7 $\times$ 10^{-5} mol Rh) and $[BMIM][Ph_2P(C_6H_4SO_3)]$ (0.33 g, 0.7 mmol) for the hydroformylation of non-1-ene (2 cm^3) in $[BMIM]PF_6$ (4 cm^3), CO/H_2 40 bar, total pressure 185 bar, 100 °C, 1 h. The products were flushed from the reactor using $scCO_2$ at the reaction temperature and pressure after each run. The reactor was then depressurised, recharged, repressurised and reheated.

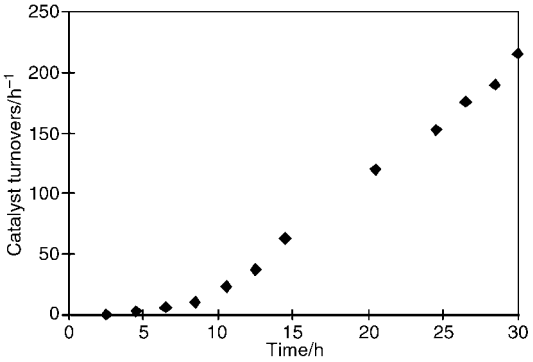

Fig. 3 Catalyst turnovers during the continuous flow hydroformylation of oct-1-ene (0.03 cm^3 min^{-1}, 1.91 $\times$ 10^{-4} mol min^{-1}) catalysed by $[Rh_2(OAc)_4]$ (10 mg, 4.5 $\times$ 10^{-5} mol Rh)/$[PMIM][PhP(C_6H_4SO_3)_2]$ (0.47 g, 7.1 $\times$ 10^{-4} mol) dissolved in the ionic liquid, $[BMIM]PF_6$ (6 cm^3). CO/H_2 (0.45 dm^3 min^{-1}), 200 bar total pressure, 100 °C.

the first 9 runs. Throughout the series of runs, the l:b ratio falls slowly (from 3.7 to 2.5), isomerisation increases and, after the ninth run, Rh leaching becomes significant. ^{31}P NMR studies of the organic phase show no P resonances confirming that the phosphine is not leaching, but the ^{31}P NMR spectrum of the ionic liquid after the 12th run shows only PF_6^- and $[Ph_2P(O)C_6H_4SO_3][BMIM]$. The rhodium leaching after run 9 can then be attributed to the ligand oxidation so that the active species is $[RhH(CO)_4]$, which is soluble in $scCO_2$ and which is known to give more isomerisation and lower l:b ratios than phosphine coordinated systems.[1] Isomerisation increases and l:b ratio decreases with increased recycling of the catalyst as a result of the increased ligand oxidation. The observed ligand oxidation may arise from contamination with air during the many openings of the reactor. However, the stability of the ligand framework towards degradation led us to select a similar ligand for continuous flow studies.

The apparatus used for the continuous flow reactions is shown in Fig. 2 and consists of separate feeds for the alkene, the CO and H_2 and the CO_2. These join above the reactor and pass through the ionic liquid before being removed from the reactor still in the $scCO_2$ undergoing a two stage decompression to recover the products, which are then analysed by GC. Fig. 3 shows the results of an experiment using $PhP(C_6H_4SO_3)_2]$-$[PMIM]_2$ (PMIM = 1-propyl-3-methylimidazolium) and $[Rh_2(OAc)_4]$ dissolved in $[BMIM]PF_6$, with the oct-1-ene substrate being transported into and the products being transported out of the reactor using $scCO_2$ as the transport vector. The experiment was carried out for 33 h and the linearity of the graph over 8–30 h shows that the catalyst is stable at least over this period of time.‡ The l:b ratio of the product aldehydes is 3.1 throughout the reaction, showing that ligand oxidation is not occurring. Rh analysis of the recovered products shows < 1 ppm of Rh in any of the samples (< 0.06% of the Rh loaded). GCMS and NMR analyses of the recovered liquid products show the presence only of the two aldehyde products and unreacted substrate, indicating that the continuous flow supercritical fluid–ionic liquid biphasic system provides a method for continuous flow homogeneous catalysis, with built in separation of the products from both the catalyst and the reaction solvent, and that this is possible even for relatively low volatility products. The only related system to have been reported uses a catalyst supported on a sol–gel silica operating as a heterogeneous catalyst again with the transporting agent being $scCO_2$.[11] Since submission of this paper, two other relevant papers have appeared. Asymmetric hydrogenation has been carried out in an ionic liquid, with the product being removed by flushing with $scCO_2$[12] and hydrogenation of alkenes or of CO_2, the latter in the presence of triethylamine, has been carried out in an ionic liquid–$scCO_2$ biphasic system with flushing of the products from the reactor with $scCO_2$ and reuse of the catalyst up to four times.[13]

Zeolite coated fibers with compact and full deposits have been fabricated by electrophoretic deposition of nanozeolites onto carbon fibers, whereafter hollow zeolite fibers have been obtained by calcination to remove the substrates.

Zeolites have been widely used in various fields as a class of crystalline materials with unique properties such as large microporosity, molecular sieving behavior and high hydrothermal stability. Construction of zeolite coated fibers and hollow zeolite fibers with designed structures has attracted considerable attention due to their fast diffusion and low pressure drop while maintaining high catalytic efficiency.[1–3] Although several methods have been put forward to prepare these materials, such as *in situ* soft solution process,[1] *in situ* zeolite deposition[2] and seed film method,[3] they all suffer from the drawback that the film thickness and the zeolite particle size are difficult to control. In addition, it is difficult for the last two methods to avoid the zeolites crystallizing concurrently in the synthesis solution. To overcome the limitations above, the layer-by-layer (LbL) technique has been utilized recently to prepare hollow zeolite fibers in our laboratory.[4] The products prepared by LbL are expected to be more favorable for mass transfer due to their solely nanozeolite composed walls whose thickness is convenient to control.

Electrophoretic deposition (EPD) is another effective and controllable method to assemble charged colloid particles.[5–13] The advantages of the EPD process are twofold: one is the fine uniformity of the deposition, the other is the easy manipulation and convenient control of the process.[7,8] The performance of the EPD method has made it an attractive route to effectively manufacture ordered structures of colloidal systems, such as micrometer-sized silica colloids, polystyrene latexes,[5,6,9,10] nanometer-sized gold colloids,[7,11] and submicron ceramic powders.[12,13] The EPD technique is also used to modify electrodes.[14–16] A Pt disk electrode modified with a large crystal zeolite/polymer coating of *ca.*11 micron thickness was obtained by the high-voltage (200 V) EPD technique in organic solution.[15,16] Recently, nanozeolites have proved to be efficient 'building blocks' to construct hierarchical structures for their colloidal character and surface charge.[4,17,18] Here, exploiting the characteristic properties of nanozeolites, the EPD technique has been used for the first time to fabricate zeolite coated carbon fibers (ZCFs) and hollow zeolite fibers (HZFs) with ultra-thin walls of nanozeolite under low voltage (1–3 V) in aqueous solution.

The preparation of ZCFs was operated in an electrophoretic cell, where a cathodic carbon fiber (*ca.* 7 μm diameter, 2 cm length) bundle was centered in a cylindrical platinum container (*ca.* 2.75 cm diameter) which served as the anode. In this arrangement, voltages were controlled by a CHI660 Electrochemical Workstation. Nanocrystals of silicalite-1 (95 ± 10 nm diameter, determined by DLS) were prepared and purified by a literature method.[19] Suspensions for EPD experiments were obtained by dispersing the nanosilicalite-1 in distilled water to a concentration of *ca.* 1.5 wt%. The pH of the suspension was adjusted with 0.1 M HCl. Prior to use, the carbon fibers were cleaned according to the literature.[3] To yield HZFs, ZCFs were heated to 873 K at a heating rate of 5 K min^{-1} in nitrogen and kept for 4 h, then calcined in air for 8 h at the same temperature to remove the substrates.

Dense and complete deposition of nanozeolites on carbon fibers is an essential requirement for the preparation of perfect ZCFs as well as intact HZFs by the EPD technique. The success of deposition relies on conditioning two sequential steps (i) the motion of particles towards the electrode and (ii) the formation of a coherent deposit on the electrode surface by overcoming the electrostatic repulsion arising from the similar charge of nanoparticles.[5,8] It has been suggested the latter step is induced by lateral interaction between the deposited particles caused by electrodynamic flows which result from distortions in the applied electric field and the passage of ionic current through the solution.[5,6,20] The modulation of the entire process thereby can be fulfilled by changing the particle charge and the field strength. Hence, the pH of the suspension and the voltage exerted on the electrophoretic cell are important variables.

At pH 6 the zeta potential of the nanosilicalite-1 particles was only +4.5 mV (DELSA 440SX), thus zeolite particles prefer to coalesce and form aggregates in solution during the EPD process. When the pH was adjusted to 4.5, there were largely uncoated areas on the carbon substrates. This can be explained by the electrical force driving nanoparticles towards the cathode being too weak to form complete and dense deposits although the zeta potential rose to +21.1 mV. The best result was obtained at pH 2.5 [Fig. 1(b)]. All longitudinal strips on the original carbon fibers [Fig. 1(a)] disappeared, implying that the deposits obtained at pH 2.5 [Fig. 1(b)] were compact and complete due to the high zeta potential of +46.8 mV. This result illustrates

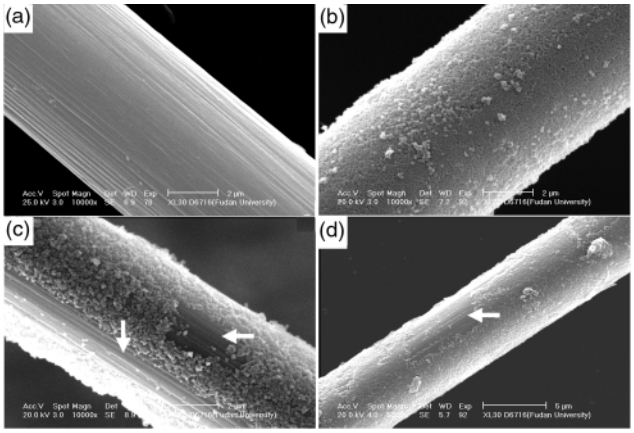

Fig. 1 SEM images of original carbon fibers (a) and zeolite coated fibers prepared under voltages of 2 V (b), 1 V (c) and 3 V (d) at pH 2.5 for 2 × 10 min.

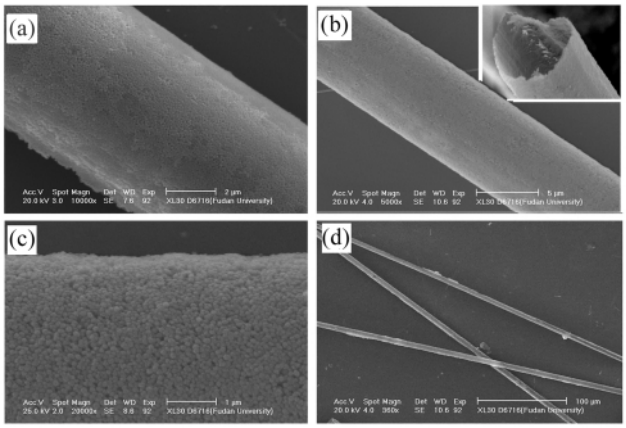

Fig. 2 SEM images of zeolite coated fibers (a) and hollow zeolite fibers (b, c, d) prepared at pH 2.5 and step voltage 1 V, 2 × 10 min; 2 V, 2 × 10 min; (c) and (d) are high and low magnification micrographs of (b), respectively.

how the particle mobility towards the cathode is largely enhanced as the zeta potential increases,[9] thereby facilitating the formation of complete deposits on the cathode. Upon applying different voltages, such as 1, 2 and 3 V, each for two cycles of 10 min (2 × 10 min), the deposit thickness increased with increased voltage. There were many bare areas when applying 1 V [see arrows in Fig. 1(c)] due to insufficient particles being deposited on the cathode. In addition, it is noticeable that most of the particles on the fibers assembled in large or small clusters, implying the existence of lateral motion of the particles on the electrode.[6] When 2 V was applied, the fibers were fully coated with nanozeolites as shown in Fig. 1(b), attributed to the improved rate of particle movement towards the cathode under increased electric field. At 3 V, although deposits on some areas of the fibers were thicker, some bare areas were found again [Fig. 1(d)]. The reason for this may be the production of hydrogen due to the electrolysis of water at the cathode which hinders the deposition or peels the deposited layer off the electrode.[21] Water electrolysis was also established by the current *vs.* time curve at 3 V. Unlike the monotonously decreasing current with time at 2 V this exhibited an increasing trend as well as fluctuation at 3 V. The EPD process at 2 V provides a feasible route to fabricate ZCFs with compact and complete deposits under appropriate conditions.

To fabricate ZCFs with denser and thicker coatings and further obtain intact HZFs, two improved processes have been adopted: (i) lengthening the deposition time from 2 V, 2 × 10 min to 2 V, 2 × 20 min, (ii) the application of a step voltage: 1 V, 2 × 10 min; 2 V, 2 × 10 min. Although both procedures improved the quality of deposits and produced intact HZFs after removal of the carbon substrates, the walls of fibers prepared by the latter method were more smooth and uniform. Fig. 2(a) shows that ZCFs prepared *via* the step voltage possessed even and dense zeolite films instead of the original texture of the carbon fibers [Fig. 1(a)]. After calcination the carbon substrates in the ZCFs were removed and hollow fibers with uniform walls were obtained [Fig. 2(b) and inset]. A micrograph of HZFs at high magnification [Fig. 2(c)] demonstrated the uniformity and compactness of the zeolite walls while a micrograph at low magnification [Fig. 2(d)] reveals the high fidelity of HZFs maintaining the original carbon fibrous morphology. The improvement under step voltage can be ascribed to better matching between the motion of nanozeolites towards the cathode and the lateral motion on the cathode.[5] The non-conducting nanozeolites deposited on the cathode under 1 V might reduce the voltage drop over the suspension,[8] so weakening the actual effect of the later application of 2 V so as to slow down the velocity towards the cathode.

The XRD spectrum of carbon substrates shows the pattern of an amorphous phase. However characteristic peaks of silicalite-1 occurred in patterns of ZCFs and only peaks ascribed to silicalite-1 appeared in patterns of HZFs. IR spectra of ZCFs and HZFs further confirm that the carbon fibers have been coated by nanozeolites and HZFs are solely composed of silicalite-1 particles.

Our research has shown that the EPD technique can be employed to assemble nanozeolite particles conveniently and effectively. Uniform zeolite coated fibers have been fabricated by this method and after removal of the substrates, hollow zeolite fibers with ultra-thin walls composed solely of nanozeolites can be obtained. Currently, the preparation of zeolite materials with other structures by electrophoretically assembling various nanozeolites and the applications of zeolite coated fibers as well as hollow zeolite fibers are under way in our laboratory.

First published as an Advance Article on the web 4th April 2001

The highly enantioselective (≤98%) aziridination of cinnamate esters is achieved using the title catalyst system *via* a concerted non-polar mechanism involving ancillary binding of carbonyl group to copper.

The addition of nitrenes RN: to alkenes is an attractive method for the synthesis of aziridines.[1] Evans' work[2] and particularly the asymmetric variant,[3] has inspired a number of groups to design chiral metal complex systems for this reaction.[4] The standard protocol uses an I^{III} iodinane such as PhINTs as the source of nitrene and a metal complex (most successfully of Cu) which acts as a transfer catalyst (Fig. 1). An early report provided powerful evidence for the presence of a discrete nitrenoid complex intermediate **I**.[5]

It has been noted that both Cu^{I} and Cu^{II} act as adequate precatalysts and that UV spectra of the Cu^{I} and Cu^{II}-derived reaction mixtures are indistinguishable in the Evans system.[2] Mechanistic evidence from Pérez relating to a tris(pyrazolyl)borate catalyst points clearly to Cu^{II}.[6] It is becoming clear, however, that the mechanism may be system-dependent; Norrby has very recently described detailed calculations on the Jacobsen system which indicate a route by which a Cu^{II} starting complex may enter the Cu^{I} manifold.[7] *In situ* UV spectra of our catalysts are consistent with operation in this lower oxidation state.

The Evans and Jacobsen systems appear to be complementary in that the former give excellent enantioselectivity for *trans* disubstituted alkenes,[3] while the latter are most efficient for *cis*.[5] We were thus rather surprised to find that [CuL(CH$_3$CN)$_2$] **1**, which is a very fast and selective precatalyst for *cis*-disubstituted alkenes,[8] also mediates the rapid aziridination of a range of *trans*-cinnamate esters with excellent enantioselectivity (Scheme 1, Table 1).

Data from competitive kinetic experiments based on eight cinnamate esters gave an excellent straight line Hammett plot, using simple σ_X constants, with slope $\rho = -0.65$ (Fig. 2). The low negative value of ρ indicates that the intermediate species is not dipolar, *i.e.* there is little build up of positive charge at the benzylic carbon in the rate- and selectivity-determining nitrene transfer step. Even so, we might expect a deviation from linearity in Fig. 2 for mesomerically electron-donating substituents (*e.g.* OMe), necessitating the use of σ^+ constants.[6,9] That this is *not* observed indicates that there is minimal through-conjugation between substituent X and the reaction centre. This is probably caused by disinclination of the system to become planar (*vide infra*). In any event, the behaviour is very different from that in the Pérez system for which a two-term Hammett-type equation incorporating σ^+ and Jackson's $\sigma\cdot$ constants[10] was required to fit the data.[6] Finally in this regard we note that the

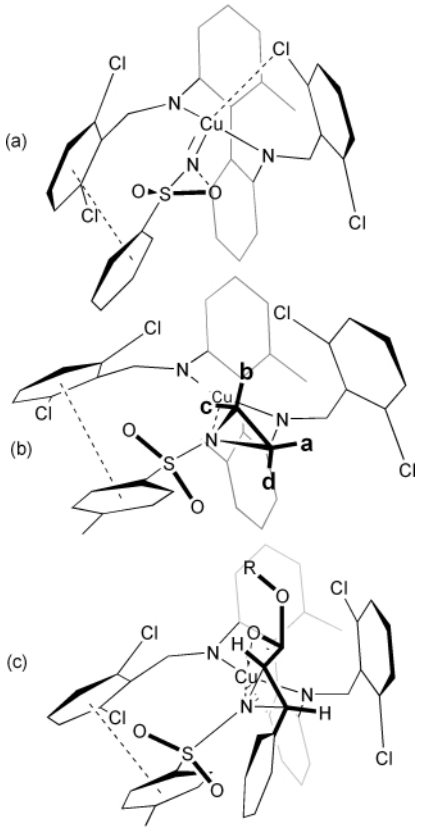

Fig. 3 Based on calculated (DFT) structures of (a) catalyst [CuL(NTs)] **2**, (b) aziridine complex **3** and (c) cinnamate ester aziridine complex.

presence of significant radical character in our rate- (and selectivity-) determining step is strongly opposed by the absence of detectable levels of *cis* cinnamate aziridines in the product mixtures. Our catalysts clearly operate *via* a concerted mechanism; both C–N bonds are formed at approximately the same time.

Armed with this experimental data we set out to investigate the structure of the relevant catalytic intermediates using Density Functional Theory (DFT).† A fully optimised DFT structure of the precatalyst **1** was found to be essentially superimposable on the molecular structure.[8] The proposed catalyst species arising from the removal of the CH_3CN groups and addition of the nitrene NTs *i.e.* [CuL(NTs)] **2** was minimised successfully. One of two similar structures located† is shown in Fig. 3(a). The tosyl group is oriented such that the arene forms what may be a planar π stacking interaction with one of the dichlorophenyl groups. Interestingly, coordination of one of the sulfonyl O atoms to the nitrene N has occurred, thus forming a three-membered ring.‡ Although we do not wish to assert that this interaction plays an important part in the catalysis, it does indicate that the N atom is highly electrophilic, as expected from the negative value of ρ above. The TsN–Cu distance of 1.80 Å in **2** indicates multiple metal–ligand bond character.

Insights into the interactions between the catalyst and alkene were obtained by computing the structure of a complex with ethylene bound to the nitrene N.[7] The aziridine complex [CuL($TsNC_2H_4$)] **3** thus obtained [Fig. 3(b)] has a TsN→Cu distance of 1.93 Å. The alignment of the alkene fragment in this species is controlled by the chiral ligand *via* the orientation of the tosyl group as described above.

The energetic consequences of adding substituents to the alkene were assessed by optimising the structures for three orientations of styrene bound to N; that with a phenyl group in site **a** was not considered viable since it is severely hindered by a dichlorophenyl group. The structures with phenyl in sites **b**–**d** have the same energies within *ca*. 10 kJ mol^{-1}, and this is consistent with the modest enantioselectivity for aziridination of this alkene (entry 9). The stereochemical preference for the cinnamate esters is more clear cut however. Placing a $–CO_2Me$ group in site **b** facilitates coordination of the carbonyl oxygen to the otherwise three-coordinate copper [Fig. 3(c)]; this is not feasible at sites **c** and **d**.§ The interaction contributes *ca*. 20 kJ mol^{-1} to the stability of the structure, and, assuming that this energetic preference is reflected at the transition state for alkene binding (which seems likely given the concerted mechanism) it readily explains the excellent selectivity observed. The absolute sense of asymmetric induction is as predicted by this model.

Two compelling pieces of circumstantial evidence further support our proposed mode of enantioselection. Firstly, the cinnamate phenyl group must be placed in site **d**, and our calculations indicate that its achievement of coplanarity with the alkene unit (and thus through-conjugation, *vide supra*) is hampered by steric effects [Fig. 3(c)]. Secondly, we note that while Evans' bis(oxazoline) system was highly selective for aziridination of both cinnamates *and trans*-β-methylstyrene, **1** performed very poorly with the latter (entry 10). With no suitable coordinating group, this alkene shows little preference for either of the two possible diastereomeric orientations, *viz*. Me and Ph at sites **b** and **d**.

Hence the observed enantioselectivity for aziridination of cinnamate esters with precatalyst **1** arises in two-centre binding of the substrate. While being somewhat unexpected, it is related to well documented examples of η^2 substrate binding at catalytic metal centres.[11]

P. S. wishes to thank EPSRC for a postdoctoral fellowship (to K. M. G). R. J. D. acknowledges the EPSRC UK Computational Chemistry Facility for computing resources.

Notes and references

‡ In contrast, Norrby[7] found that in calculations based on the Jacobsen system, η^2-*N,O* coordination at Cu of N–SO_2Me was found throughout. We were unable to locate such a structure here.

§ In the catalyst structure there is weak dative coordination of an aryl C atom at this site [see Fig. 3(a)].

Luminescent carbon-rich rhenium(I) complexes

Vivian Wing-Wah Yam

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, P. R. China. E-mail: wwyam@hku.hk

Received (in Cambridge, UK) 16th August 2000, Accepted 16th February 2001
First published as an Advance Article on the web 16th March 2001

The synthesis and luminescence behaviour of carbon-rich rhenium(I) complexes containing rigid-rod sp carbon chains are reported. Perturbation of the luminescence properties through structural variation of the ancillary ligands and the carbon chain length has been achieved. Utilization of the alkynylrhenium(I) system for mixed-metal complex formation is also described.

Introduction

The constant search for new advanced materials with new and improved properties has led to a variety of investigations into inorganic/organometallic molecular materials.[1] It is well known that the properties of materials may be modified dramatically by seemingly subtle changes in chemical structure, thus the possibility of using organometallic or metal-containing structural moieties to prepare molecular materials with interesting and possibly useful characteristics is an attractive option. With metal-containing materials, a wide variety of transition metals with different nature, coordination geometry, coordination number, and oxidation states, and hence the number of d electrons, can be employed. These together with the wide diversity of ligand systems and variation would provide an extremely important and rich area of research in the field of materials science. Recently, there has been a growing interest in the chemistry of carbon-rich metal-containing systems, in particlar those with long sp carbon chains.[1d–f] The alkynyl group, with its linear geometry, the rigidity of its structure, its extended π-electron delocalization and its ability to interact with metal centres *via* p_π–d_π overlap which can effectively strengthen the metal–carbon bonds, would render it an attractive building block for the construction of carbon-rich metal-containing materials which may possess potential applications as nonlinear optical materials, molecular wires, and molecular electronics. Despite the growing interest and extensive studies in metal acetylides, relatively less attention was focused on the luminescence behaviour of this class of compounds. In this context, we have directed our research efforts specifically to the design and synthesis of luminescent metal acetylides which we believe, with a careful design and judicious choice of metal and ligand systems, can be employed as versatile building blocks for the construction of luminescent molecular and oligomeric materials.

Early work on metal acetylides dated back to as early as 1960 when copper and mercury acetylides in polymeric form were reported and were proposed to have a linear geometry.[2] However, these materials were found to be intractable which precluded their purification and characterization. In the late 1970s, Hagihara and coworkers reported the first soluble polyynes containing platinum and palladium metal atoms in the main chain.[3a,b] Subsequent work by the same group had resulted in general synthetic routes to group 10 metal-containing one-dimensional polyynes.[3] Recent works by the groups of Lewis[4] and Marder[5] and others[6] have developed new routes to incorporate group 8, 9 and 10 metals into the polyyne backbone. Despite all these important contributions, studies on these polymeric systems present several difficulties, such as the exact arrangement of the structure, the molecular weight distribution, linear chains *vs.* side chains, heterogeneity of the samples, reproducibility and many others, which would render a direct understanding of the structure–property relationship and the fundamental understanding on the spectroscopic origin of these chromophores less straightforward and less amenable to study.

In order to provide a more thorough and fundamental understanding on the structure–property relationship and the spectroscopic origin of these carbon-rich metal-containing materials, it is therefore crucial to design and synthesize discrete C_n-containing and C_n-bridged metal-based molecular materials and to study their chemical and physical properties.[7]

In this article, the focus will be directed towards the rhenium(I) acetylide system and our recent efforts to design luminescent carbon-rich rhenium(I) complexes with extended carbon chains. Application of these rhenium(I) acetylides as metalloligands to generate mixed-metal luminescent molecular materials will also be described.

Mononuclear rhenium(I) acetylides

The first report on the synthesis, molecular structures and chemistry of rhenium(I) acetylide complexes dates back to 1968 when Bruce *et al.* reported the synthesis of $[Re(CO)_5(C{\equiv}CR)]$ (R = Ph or C_6F_5)[8] from the reaction of $[Re(CO)_5Cl]$ and the corresponding lithiated acetylide. Later on, Beck and coworkers reported the synthesis, molecular and electronic structures of a series of mononuclear and dinuclear pentacarbonylrhenium(I) acetylide complexes $[Re(CO)_5(C{\equiv}CR)]$ (R = CH_3, $SiMe_3$, H)

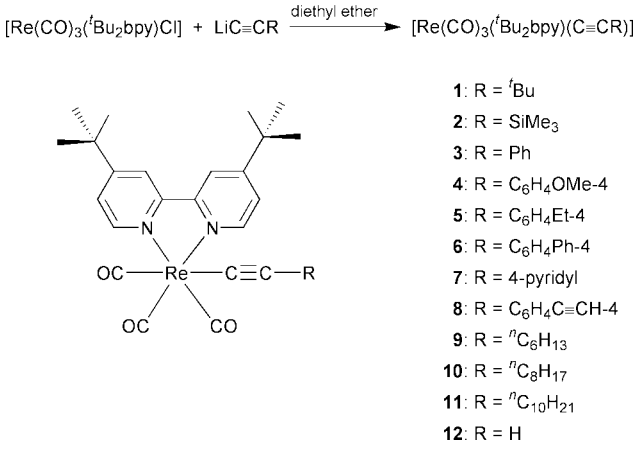
Vivian W. W. Yam was born in Hong Kong in 1963. She graduated with her first class honours BSc degree in 1985 from The University of Hong Kong. After this she obtained her PhD degree under the supervision of Professor Chi-Ming Che on high-valent metal–oxo chemistry from the same university in 1988. After spending two years as a lecturer in the Department of Applied Science at the City Polytechnic of Hong Kong (now City University of Hong Kong), she moved back to The University of Hong Kong as a lecturer in 1990. She was appointed to a Senior Lectureship in 1995, Readership in 1997, and the Chair of Chemistry in 1999. She is now also the Head of the Chemistry Department. Her research interests include inorganic/organometallic photophysics and photochemistry, polynuclear metal complexes and clusters with special emphasis on metal acetylides, chalcogenides and chalcogenolates, supramolecular chemistry, inorganic/organometallic molecular functional materials for spectrochemical and luminescence sensing and molecular recognition, optoelectronics, photoswitching and molecular devices.

DOI: 10.1039/b006694j

and $[(CO)_5Re–C\equiv C–Re(CO)_5]$.[9] Reactions of these complexes with other transition metal centres with different coordination geometry have also been studied.[10] Recently, the syntheses of rhenium(I) polyyne complexes such as $[Re(Cp)(NO)(PPh_3)\{(C\equiv C)_nR\}]$ (R = Me, $SiMe_3$, H, Ph, 1-naphthyl, n = 1–5) and $[Cp(NO)(PPh_3)Re(C\equiv C)_nReCp(NO)(PPh_3)]$ (n = 2, 4, 6, 8, 10), have been reported by Gladysz and coworkers.[11] The chemical properties and the electrochemical behaviour of these complexes and the mixed-metal systems prepared from such complexes with terminal acetylides have also been studied.[11*f,g,i*,12] The synthesis and molecular structures of metal clusters containing rhenium(I) acetylide units have also been described.[13]

In view of the well documented metal-to-ligand charge transfer (MLCT) excited state chemistry of rhenium(I) α,α′-diimine complexes,[14] in which the first report on their luminescence behaviour appeared in 1974 when the photophysical properties of $[Re(CO)_3(phen)Cl]$ were described and a metal-to-ligand charge-transfer (MLCT) excited state assignment was proposed by Wrighton and Morse,[14*a*] together with the interesting structural characteristics of rhenium(I) acetylides, the photophysical and photochemical studies of mononuclear and polynuclear luminescent organometallic rhenium(I) α,α′-diimines, especially those containing an acetylide moiety, should represent a challenging area of research. In addition, incorporation of strong σ-donating acetylide ligands would raise the energy of the d–d states of the rhenium(I) centre and thereby improve the population of the MLCT state.

In 1995 we reported the synthesis of the first luminescent rhenium(I) acetylide complexes.[15*a*] A series of mononuclear rhenium(I) acetylides, $[Re(CO)_3(^tBu_2bpy)(C\equiv CR)]$ (R = ^{t}Bu **1**, $SiMe_3$ **2**, Ph **3**, C_6H_4OMe-4 **4**, C_6H_4-Et-4 **5**, C_6H_4Ph-4 **6**, 4-pyridyl **7**, $C_6H_4C\equiv CH$-4 **8**, $^nC_6H_{13}$ **9**, $^nC_8H_{17}$ **10**, $^nC_{10}H_{21}$ **11**, H **12**), have been synthesized (Scheme 1) by the reaction of $[Re(CO)_3(^tBu_2bpy)Cl]$ with LiC≡CR in diethyl ether (prepared *in situ* by the reaction of ^{n}BuLi with the corresponding RC≡CH), which were subsequently characterized and their photophysical properties studied.[15,16] Fig. 1 shows the perspective drawing of **1**. In general, the electronic absorption spectra of these complexes in acetone show an intense low energy absorption band at *ca*. 391–440 nm, attributable to a MLCT $[d_\pi(Re) \rightarrow \pi^*(^tBu_2bpy)]$ transition.



Scheme 1

A red shift of this MLCT absorption band relative to that of the chloro counterpart $[Re(CO)_3(^tBu_2bpy)Cl]$ has been observed. This finding has been ascribed to the presence of a more electron-rich rhenium(I) centre in the acetylide complexes as a result of the stronger σ-donating ability of the acetylides than the chloro ligand. The MLCT absorption energies have also been found to follow the order: **11** ≈ **10** ≈ **9** < **1** ≈ **4** ≈ **5** ≈ **3** < **2** < **12**, in line with the σ-donating ability of the acetylides:

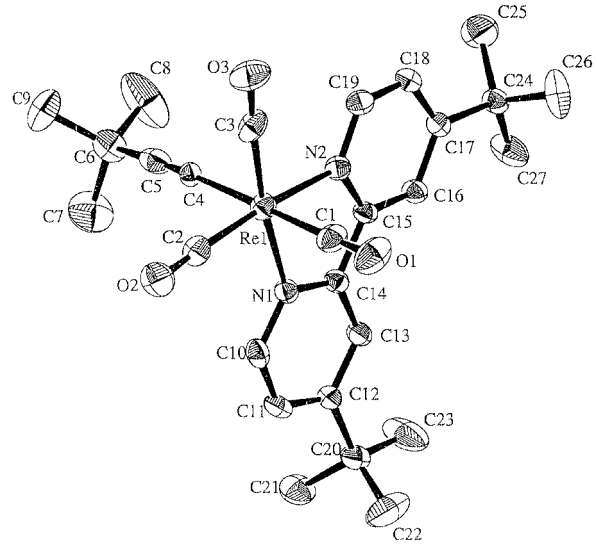


Fig. 1 The perspective drawing of **1**. Hydrogen atoms have been omitted for clarity. Reproduced with permission from ref. 15(*a*).

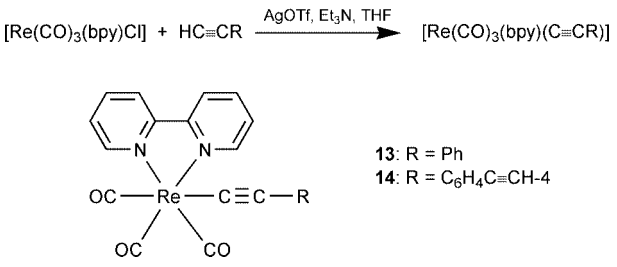
–C≡C^{n}C$_{10}$H$_{21}$ ≈ –C≡C^{n}C$_8$H$_{17}$ ≈ –C≡C^{n}C$_6$H$_{13}$ > –C≡C^{t}Bu ≥ –C≡CC$_6$H$_4$OMe-4 ≈ –C≡CC$_6$H$_4$Et-4 > –C≡CPh > –C≡CSiMe$_3$ > –C≡CH. This is also in agreement with the fact that a more electron-donating acetylide would render the rhenium(I) centre more electron rich and thereby decrease the MLCT transition energy. Similar observations have also been reported in the photoelectron spectroscopic studies of the $[FeCp(CO)_2(C\equiv CR)]$ (R = H, Ph, ^{t}Bu)[17] and in the $[W(\equiv CH)(dmpe)_2X]$ (X = C≡CPh, C≡CSiMe$_3$, C≡CH) systems.[18] This low energy absorption of the rhenium(I) acetylides is also found to be sensitive to the polarity of the solvent. For example, the absorption maximum of **1** in MeOH at 391 nm is red-shifted to 464 nm in *n*-hexane. This further supports the MLCT assignment of the low energy absorption as similar solvatochromic shifts are commonly observed for rhenium(I) α,α′-diimine complexes.[14*i,l*,19]

Attempts to synthesize rhenium(I) acetylide complexes with α,α′-diimine ligands other than that of 4,4′-di-*tert*-butyl-2,2′-bipyridine using the method described above were unsuccessful, yielding intractable solids in all cases. The use of LiC≡CR has limited the choice of the solvents employed, and in most cases the starting precursor complexes $[Re(CO)_3(N\text{-}N)Cl]$, unlike the 4,4′-di-*tert*-butyl-2,2′-bipyridine analogue $[Re(CO)_3(^tBu_2bpy)Cl]$, are insoluble or very sparingly soluble in the solvents used. Thus an improved route was developed which precluded the necessity of employing lithiated reagents. By refluxing a mixture of $[Re(CO)_3(bpy)Cl]$, RC≡CH, AgOTf and Et_3N in THF (Scheme 2), a series of $[Re(CO)_3(bpy)(C\equiv CR)]$



Scheme 2

were obtained in reasonable yield (R = Ph **13**, $C_6H_4C\equiv CH$-4 **14**).[20] It has been found that both the absorption and emission of the 2,2′-bipyridine counterparts occur at a lower energy than the $^tBu_2bpy$ analogues with the same acetylide ligand. This

observation further supports the involvement of the π* orbital of the α,α′-diimine ligands in the MLCT excited state of the complexes while the possibility of a MLCT [d_π(Re) → π*(C≡C)] excited state has been ruled out as an opposite trend in the absorption energies would be observed.

Upon excitation at λ > 350 nm, these mononuclear rhenium(I) acetylide complexes all show intense and long-lived orange–red luminescence in the solid state and in solutions, with lifetimes in the microsecond to sub-microsecond range. Unlike other rhenium(I)–alkyl or –aryl complexes which only emit at low temperature and undergo photodissociation reactions readily upon excitation into their σ(M–C) → π*(N–N) transition bands,[19,21] these rhenium(I) acetylide complexes are emissive in solutions at room temperature and are fairly photostable. With reference to other luminescent rhenium(I) α,α′-diimine systems,[14] the origin of the emission has been ascribed to a ^{3}MLCT [d_π(Re) → π*(N–N)] excited state; the lifetimes of which are also in the range typically found for this class of excited states.[14] The emission of the rhenium(I) acetylide complexes has also been found to occur at a lower energy relative to that of [Re(CO)$_3$(N–N)Cl]. Besides, the MLCT emission energies of the rhenium(I) α,α′-diimine complexes with different acetylide ligands also show a similar trend as observed in the electronic absorption spectra. In general, more electron-donating acetylides give a lower energy MLCT emission band and this is consistent with the σ- and π-donating ability of the acetylide moieties. The emission spectra of the starting material, [Re(CO)$_3$(^{t}Bu$_2$bpy)Cl], **1** and **12** are shown in Fig. 2. However, unlike other rhenium(I) α,α′-diimine

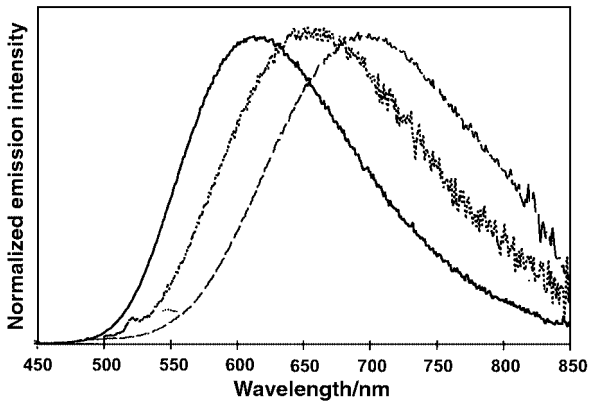


Fig. 2 The emission spectra of [Re(CO)$_3$(^{t}Bu$_2$bpy)Cl] (—), **1** (----) and **12** (·····) in degassed THF at 298 K.

complexes whose luminescence properties are strongly dependent on the solvent,[14*i*,*l*,19] the emission energies of these rhenium(I) acetylides are not very sensitive to the solvent polarity. On the other hand, these luminescent rhenium(I) acetylides have also been found to exhibit interesting rigidochromism. For example, the orange–red emissions of **9** (λ_{em} = 690 nm) and **12** (λ_{em} = 660 nm) in a EtOH–MeOH (4:1, v/v) solution at 298 K are blue-shifted to λ_{em} = 560 and 545 nm for **9** and **12**, respectively, in a 77 K glass of the same solvent mixture. Such luminescence rigidochromism has also been reported in other Re(I) α,α′-diimine systems.[14*a*,*i*,19]

Recently, we have extended our work to the use of the diynyl and triynyl units as ligands for the extension of the carbon chain. A series of mononuclear luminescent rhenium(I) α,α′-diimine complexes containing a diynyl moiety, [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CH)] **15** and [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CPh)] **16**, and triynyl moiety, [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡C–C≡CPh)] **17**, [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡C–C≡CSiMe$_3$)] **18** and [Re(CO)$_3$(Me$_2$bpy)(C≡C–C≡C–C≡CSiMe$_3$)] **19**, have been synthesized (Scheme 3) and characterized in our laboratory.[22] Reaction of [Re(CO)$_3$(^{t}Bu$_2$bpy)Cl],[14*a*] KF, AgOTf and Me$_3$SiC≡C–C≡CSiMe$_3$ in MeOH under reflux conditions afforded [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CH)] **15**, while reaction of [Re(CO)$_3$(^{t}Bu$_2$bpy)Cl], AgOTf, NEt$_3$ and PhC≡C–C≡CH in refluxing THF gave [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CPh)] **16**. The perspective drawing of **15** is shown in Fig. 3.

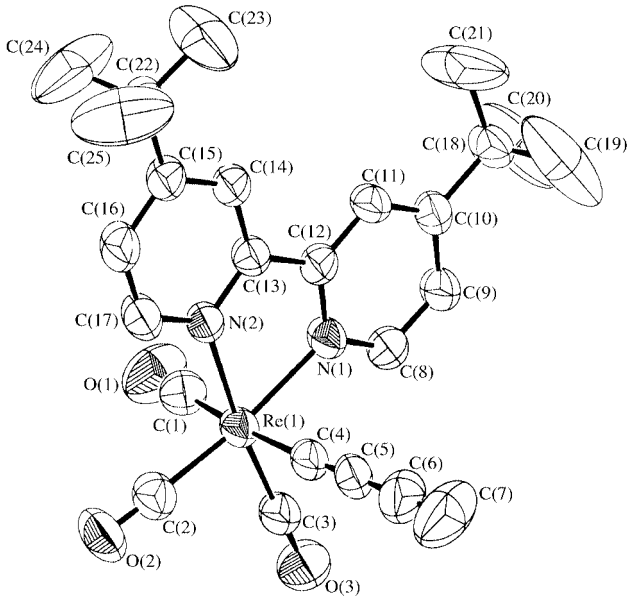

Fig. 3 The perspective drawing of **15**. Hydrogen atoms have been omitted for clarity. Reproduced with permission from ref. 22(*a*).

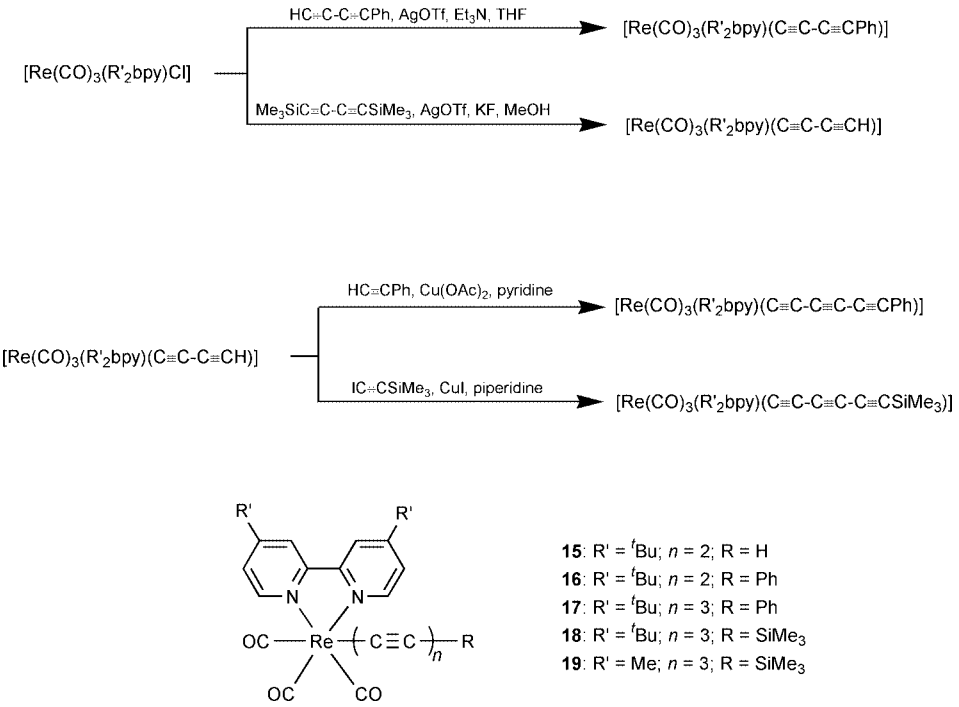
The triynyl complexes were synthesized by the heterocoupling reactions of [Re(CO)$_3$(N–N)(C≡C–C≡CH)] with the corresponding RC≡CH in the presence of a copper(I) catalyst and a base.[22*b*] Reaction of [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CH)] **15**,[22*a*] PhC≡CH and Cu(OAc)$_2$ in pyridine under reflux conditions afforded [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡C–C≡CPh)] **17**, while reaction of [Re(CO)$_3$(N–N)(C≡C–C≡CH)], IC≡C-SiMe$_3$, piperidine and CuI in THF at room temperature gave [Re(CO)$_3$(N-N)(C≡C–C≡C–C≡CSiMe$_3$)] (N–N = ^{t}Bu$_2$bpy **18**; N–N = Me$_2$bpy **19**).

In THF, complexes **15** and **16** show intense absorption bands at *ca.* 404 and 416 nm, respectively, similarly assigned as the spin-allowed MLCT [d_π(Re) → π*(^{t}Bu$_2$bpy)] transition. The lower MLCT absorption energy for **16** than **15** is consistent with the better σ- and π- donating abilities of PhC≡C–C≡C than HC≡C–C≡C,[17,18,23] which render the Re(I) centre more electron-rich, and raise the Re d_π orbital energy, similar to that observed in the related mono-alkynyl system [Re(CO)$_3$(^{t}Bu$_2$bpy)X],[15] in which the MLCT absorption band occurs at higher energy for X = HC≡C than for X = PhC≡C.

Similarly, in the triynyl series, the intense absorption bands of **17** (426 nm), **18** (412 nm) and **19** (420 nm), in THF have been tentatively assigned as the d_π(Re) → π*(^{t}Bu$_2$bpy or Me$_2$bpy) MLCT transition. Similar to the monoynyl and diynyl systems, the lower MLCT absorption energy for **17** than **18** is again consistent with the better π-donating abilities of PhC≡C–C≡C–C≡C than Me$_3$SiC≡C–C≡C–C≡C, which render the Re(I) centre more electron-rich, and raise the Re d_π orbital energy.

Excitation of **15** and **16** both in the solid state and in solutions at room temperature at λ > 400 nm resulted in strong orange luminescence, attributed to the ^{3}MLCT phosphorescence. The excitation spectra of **15** and **16** in THF show an excitation band at *ca.* 400 and 410 nm, respectively, which closely resembles that of the MLCT absorption maxima. The slightly lower MLCT emission energy of **16** than **15** in THF is in line with the stronger σ- and π-donating abilities of the phenyldiynyl unit than the butadiynyl ligand, *i.e.* PhC≡C–C≡C **16** (625 nm) < HC≡C–C≡C **15** (620 nm). Similar trends have been observed in



15: R' = ^{t}Bu; *n* = 2; R = H
16: R' = ^{t}Bu; *n* = 2; R = Ph

Scheme 3

the monoacetylide analogues [PhC≡C **3** (688 nm) < HC≡C **12** (670 nm)].[15]

Similarly, excitation of the triynyl complexes **17**–**19** both in the solid state and in solutions at room temperature at λ > 400 nm resulted in strong orange luminescence, attributed to the ^{3}MLCT phosphorescence. All the lifetimes of the diynyl and triynyl complexes were in the microsecond to sub-microsecond range; as are typically found for ^{3}MLCT states of rhenium(I) systems.[14] The lower MLCT emission energy of **17** than **18** in THF is again in line with the stronger π-donating abilities of the phenyltriynyl unit than the trimethylsilyltriynyl ligand, *i.e.* PhC≡C–C≡C–C≡C **17** (620 nm) < Me_3SiC≡C–C≡C–C≡C **18** (596 nm). Both **17** and **18** emit at higher energies than their respective monoynyl and diynyl counterparts, *i.e.* in the [Re(CO)$_3$(^{t}Bu$_2$bpy)X] system, the emission energies in THF follow the order: PhC≡C–C≡C–C≡C **17** (620 nm) > PhC≡C–C≡C **16** (625 nm) > PhC≡C **3** (688 nm); Me_3SiC≡C–C≡C–C≡C **18** (596 nm) > Me_3SiC≡C **2** (670 nm). Fig. 4 shows the

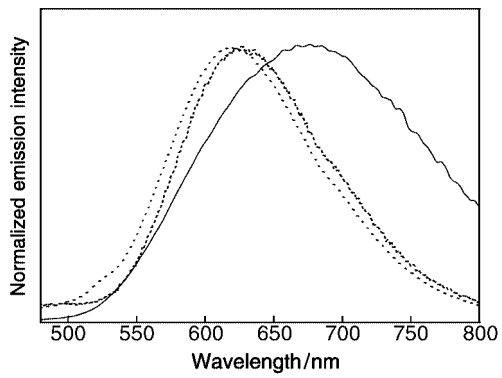

Fig. 4 The emission spectra of **3** (—), **16** (----) and **17** (·····) in THF solution at 298 K.

emission spectral trend of the complexes as a function of the acetylenic carbon chain length. The observation of a blue shift in emission energies upon increasing the number of the C≡C units disfavours an assignment of a ^{3}MLCT {d_π(Re) → π*[(C≡C)$_n$R]} or a metal-perturbed ^{3}IL {π[(C≡C)$_n$R] → π*[(C≡C)$_n$R]} origin (*n* = 1, 2, 3) and is suggestive of an assignment of a ^{3}MLCT [d_π(Re) → π*(^{t}Bu$_2$bpy)] origin. Preliminary molecular orbital studies using Extended Hückel molecular orbital (EHMO) theory on **17** and its diynyl analogue [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CPh)] **16** show that in both the diynyl and triynyl systems, the LUMO mainly consists of π*(^{t}Bu$_2$bpy) character while the HOMO is mainly dominated by the antibonding character of the Re–(C≡C)$_n$Ph (*n* = 2, 3) moiety resulted from the overlap of the d_π(Re) and π[(C≡C)$_n$Ph] orbitals, which is supportive of a d_π(Re) → π*(^{t}Bu$_2$bpy) MLCT character for the electronic transition. An increase in the HOMO–LUMO energy gap has also been observed on extending the C≡C unit from the diynyl to the triynyl species, in which the LUMO energies remain more or less the same while the HOMO energies decrease with an increasing number of C≡C units. The observed trend of a higher MLCT emission energy in the triynyl system than the diynyl and hence the monoynyl systems, in line with EHMO studies, may originate from a decreased overlap integral between the d_π(Re) and the triynyl π(RC≡CC≡CC≡C) orbitals than that of d_π(Re) and the π(RC≡CC≡C) and π(RC≡C) orbitals resulting from the delocalization of electron density across the C$_n$ unit, despite the better energy match between π(RC≡CC≡CC≡C) and the d_π(Re) orbital, *i.e.* the overlap of the more closely energy-matched d_π(Re) and π(RC≡CC≡CC≡C) orbitals does not necessarily raise the d_π(Re) orbital to an energy higher than that for the diynyl and monoynyl cases, and may give rise to the anomalous energy trend in which the MLCT emission energy is in the order: PhC≡C–C≡C–C≡C > PhC≡C–C≡C > PhC≡C. An alternative rationale for the increased MLCT energies upon increasing the number of the C≡C units is that given the similar σ-donating properties of the monoynyl, diynyl and triynyl unit,[17,23] the much better π-accepting ability of RC≡C–C≡C–C≡C than RC≡C–C≡C which in turn is better than RC≡C may become the dominating factor, stabilizing the Re d_π orbitals to a greater extent, and hence gives rise to a higher energy ^{3}MLCT [d_π(Re) → π*(^{t}Bu$_2$bpy or Me$_2$bpy)] emission. However, in view of the much less importance of the d_π(Re)–π*[(C≡C)$_n$R] interaction, as reflected from EHMO studies, such possibilities are not favoured.

23

Dinuclear rhenium(I) acetylides

Besides mononuclear complexes, dinuclear rhenium(I) α,α′-diimine complexes with a bridging acetylide ligand, [(^{t}Bu$_2$bpy)-(CO)$_3$Re–C≡C–C≡C–Re(CO)$_3$(^{t}Bu$_2$bpy)] **20**,[15b] [(^{t}Bu$_2$bpy)-(CO)$_3$Re–C≡C–C≡C–C≡C–C≡C–Re(CO)$_3$(^{t}Bu$_2$bpy)] **21**, [(^{t}Bu$_2$bpy)(CO)$_3$Re–C≡C–C≡C–C≡C–C≡C–C≡C–C≡C–Re-(CO)$_3$(^{t}Bu$_2$bpy)] **22** and [(^{t}Bu$_2$bpy)(CO)$_3$Re–C≡C-C$_6$H$_4$–(C≡C-4)–C≡C–C$_6$H$_4$–(C≡C-4)–Re(CO)$_3$(^{t}Bu$_2$bpy)] **23**, have also been synthesized by homo-coupling reactions involving the respective [(^{t}Bu$_2$bpy)(CO)$_3$Re–(C≡C)$_n$H] complexes in the presence of Cu(OAc)$_2$ and pyridine. The perspective view of **20** is depicted in Fig. 5. Upon photoexcitation, complex **20** exhibits long-lived luminescence at *ca.* 660–690 nm which has been proposed to originate from a ^{3}MLCT [d_π(Re) → π*(^{t}Bu$_2$bpy)] excited state. Upon excitation at λ > 430 nm, complex **23** emits at *ca.* 640 nm which is at a slightly higher energy than that of the mononuclear counterpart **8** (λ_{em} = 670 nm). The solid-state emission spectra of **23** at 298 and 77 K show vibronically structured emission band with vibrational progressional spacings of *ca.* 1500 and 2000 cm^{-1}, typical of ground-state aromatic ν(C⋍C) and acetylide ν(C≡C) stretching frequencies, respectively.

Mixed-metal acetylides

In order to further explore the possibility of utilizing the rhenium(I) acetylides as versatile building blocks in molecular architecture, we have successfully synthesized mixed-metal acetylide complexes using the 'metal complex as ligand' or the so-called metalloligand approach. The first approach we employed was to utilize the [Re(CO)$_3$(bpy)(C≡CPh)] **13** complex as an η^2-ligand towards Cu(I) and Ag(I) ions.[24] Reaction of [Re(CO)$_3$(bpy)(C≡CPh)] **13** with [Cu(MeCN)$_4$]PF$_6$ in THF at room temperature afforded [{η^2-Re(CO)$_3$-(bpy)(C≡CPh)}$_2$Cu]PF$_6$ **24**. Similarly, reaction of [Re(CO)$_3$-(bpy)(C≡CPh)] with [Ag(MeCN)$_4$]PF$_6$ under similar conditions gave the analogue, [{η^2-Re(CO)$_3$(bpy)(C≡CPh)}$_2$Ag]PF$_6$ **25**. The perspective drawings of the complete cations of **24** and **25** are shown in Figs. 6 and 7, respectively. The slightly longer C≡C bond distances in **24** [1.20(1)–1.23(1) Å] and **25** [1.199(8)–1.203(8) Å] relative to the [Re(CO)$_3$(bpy)(C≡CPh)] **13** precursor [1.199(9) Å], together with the bond weakening observed in IR spectroscopy where lower ν(C≡C) values have been observed for **24** (2029 cm^{-1}) and **25** (2033 cm^{-1}) than [Re(CO)$_3$(bpy)(C≡CPh)] **13** (2083 cm^{-1}), are consistent with the π-coordination mode of the alkynyl group to the d^{10} metal centres.

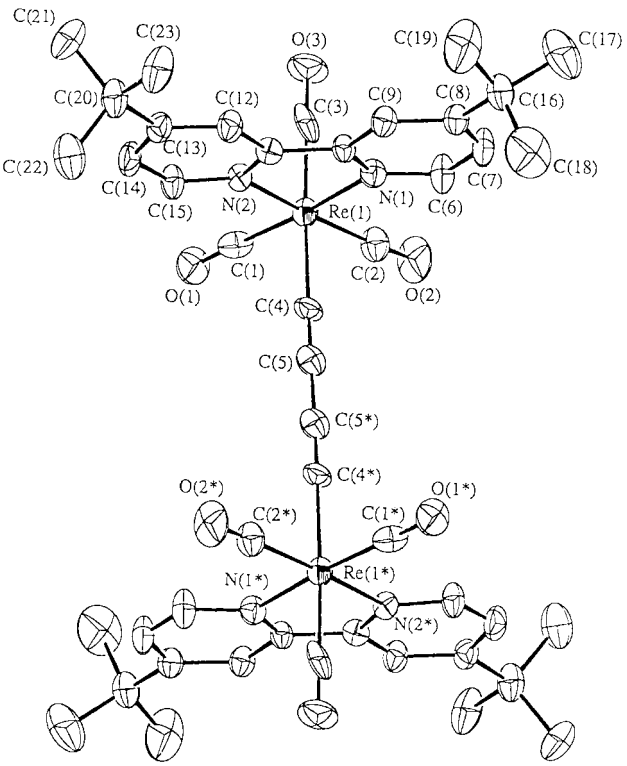

Fig. 5 The perspective drawing of **20**. Hydrogen atoms have been omitted for clarity. Reproduced with permission from ref. 15(*b*).

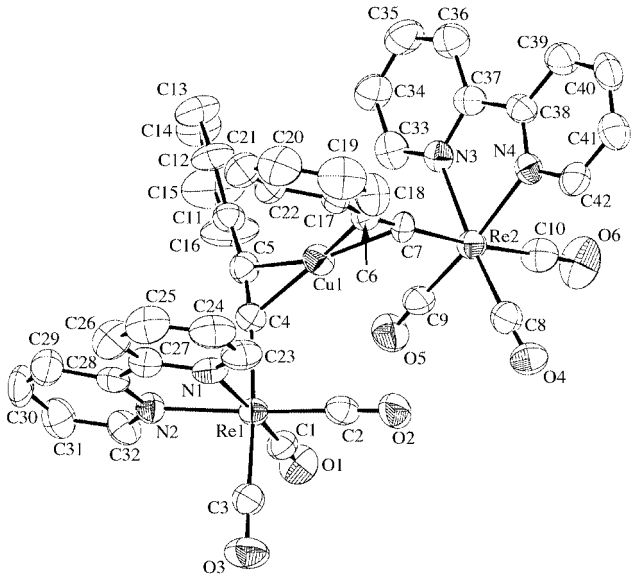

Fig. 6 The perspective drawing of the complex cation of **24**. Hydrogen atoms have been omitted for clarity. Reproduced with permission from ref. 24.

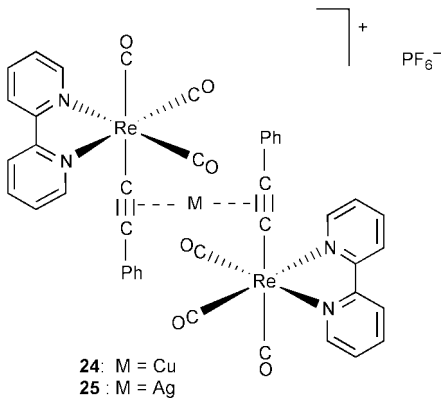

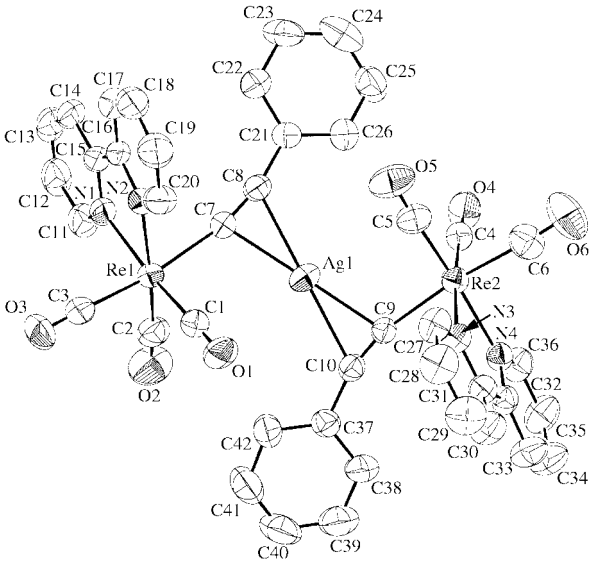

Fig. 7 The perspective drawing of the complex cation of **25**. Hydrogen atoms have been omitted for clarity. Reproduced with permission from ref. 24.

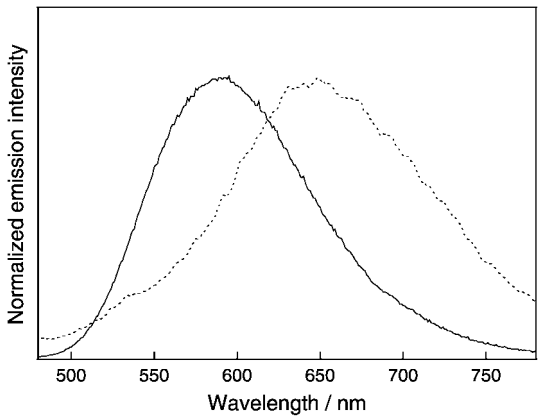

Fig. 8 The emission spectra of **13** (·····) and **24** (—) in degassed CH_2Cl_2 at 298 K.

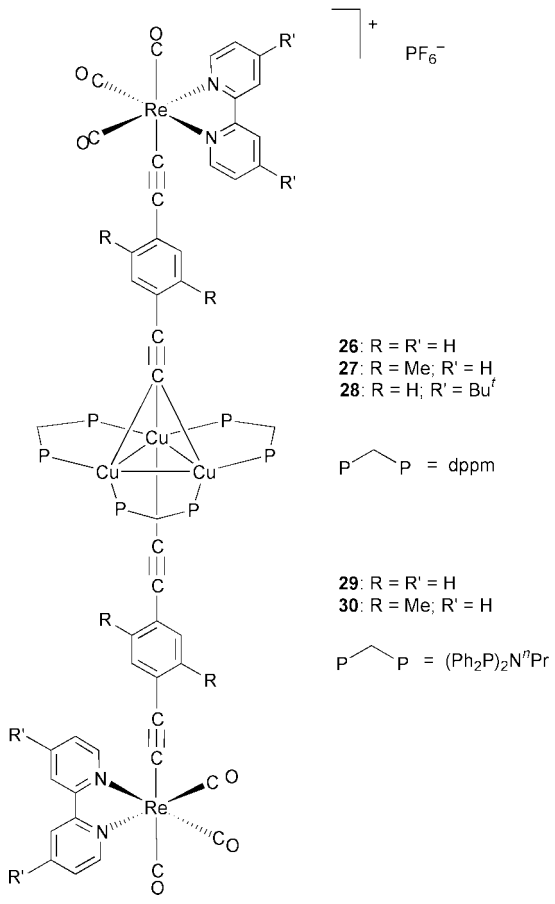
The electronic absorption spectra of **24** and **25** show an intense MLCT absorption band at *ca.* 396 nm in dichloromethane solution. The shift of the MLCT absorption to the blue relative to that of $[Re(CO)_3(bpy)(C{\equiv}CPh)]$ **13** (420 nm) is in line with the lower-lying d_π(Re) orbital in **24** (396 nm) and **25** (396 nm), resulted from the reduced π-donating ability of the acetylide ligand upon π-coordination to the d^{10} metal ions.

Excitation of **24** and **25** also resulted in orange ^{3}MLCT phosphorescence. Similar to the absorption studies, the emissions of **24** (590 nm) and **25** (600 nm) in CH_2Cl_2 are shifted to higher energies compared to that of $[Re(CO)_3(bpy)(C{\equiv}CPh)]$ **13** (654 nm). Fig. 8 shows the emission spectra of **13** and **24** in degassed CH_2Cl_2 at 298 K. Such a trend is consistent with an assignment of a ^{3}MLCT [d_π(Re) → π*(bpy)] emission origin and disfavours the assignment of a ^{3}MLCT [d_π(Re) → π*(C≡CPh)] origin, since the acetylide becomes a poorer π-donor upon coordination to Cu(I) and Ag(I), lowering the energy



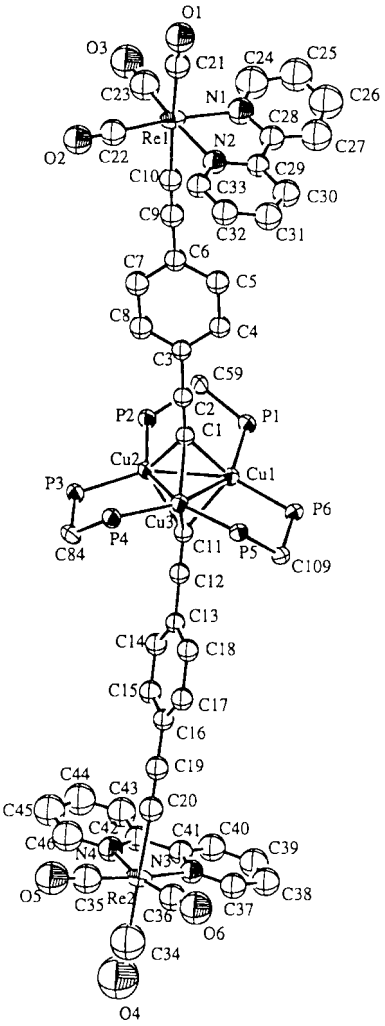


Fig. 9 The perspective drawing of the complex cation of **26**. Hydrogen atoms have been omitted for clarity. Reproduced with permission from ref. 26.

of the Re d_π orbitals, and hence leading to a higher energy ^{3}MLCT [d_π(Re) → π*(bpy)] emission.

A second approach was to utilize the rhenium(I) acetylides with terminal –C≡CH groups as the metalloligand. Recent works by us have shown that luminescent copper(I) acetylides are also promising building blocks for the construction of rigid-rod oligomeric and polymeric materials.[25] As a further step towards this goal, a series of pentanuclear mixed-metal copper(I)–rhenium(I) acetylide complexes $[Cu_3(\mu\text{-P–P})_3\{\mu_3\text{-}\eta^1\text{-C}\equiv\text{C–C}_6H_2R_2\text{-2,5-C}\equiv\text{C-4–Re(N–N)(CO)}_3\}_2]^+$ [P–P = dppm, N–N = bpy, R = H **26**, Me **27**; P–P = dppm, N–N = ^{t}Bu$_2$bpy, R = H **28**; P–P = $(Ph_2P)_2N^n$Pr, N–N = bpy, R = H **29**, Me **30**] have been synthesized and their luminescence properties studied.[26] The perspective view of the complex cation of **26** is displayed in Fig. 9. The electronic absorption spectra of these complexes reveal, in addition to the high energy intraligand (IL) absorption bands at *ca*. 250–300 nm and the vibronically structured bands at *ca*. 348–378 nm, a lower-energy absorption at *ca*. 440 nm, which is assigned to a MLCT [d_π(Re) → π*(N–N)] transition. All the complexes display strong orange luminescence upon photoexcitation. The low energy emission bands at *ca*. 600–660 nm have been suggested to arise from a ^{3}MLCT [(d_π(Re) → π*(N–N)] excited state. The energy trend of this low energy emission is in line with the π* orbital energies of the diimine ligands. The complexes with more electron-rich $(Ph_2P)_2N^n$Pr phosphine ligands are found to emit at slightly lower energy than that of the dppm counterparts. This can be rationalized by the fact that the more electron-donating $(Ph_2P)_2N^n$Pr phosphines would render the copper(I) centres more electron rich, and in turn destablilize the Re(I) d_π orbitals and therefore the ^{3}MLCT [d_π(Re) → π*(N–N)] emission occurs at lower energy.

Conclusion

It is interesting to realize that the rhenium(I) acetylide system offers, indeed, a very versatile and powerful building block for the construction of various luminescent rigid-rod and mixed-metal carbon-rich complexes. By careful planning and the judicious choice of the diimine ligands, the acetylide ligands, the extension of the C≡C units, the nature of the heterometals in the mixed-metal complexes, and the spectator ligands on the heterometal centres, one could readily tune the spectroscopic and emission properties of the systems. An interesting observation is the blue shift in the emission energy upon extending the carbon chain in these complexes, which differs from the common concept of tuning the emission energy to the red by extending the number of acetylenic units in organic polyynes. Besides, the tuning of emission energies by π-coordination of the rhenium–acetylide moiety to d^{10} metal ions or σ-coordination of the acetylide to the trinuclear copper(I) diphosphine units using the metalloligand approach would represent a new concept in the design of luminescent molecular materials. All these examples demonstrate the importance and versatility of systematic structural variation in elucidating the spectroscopic origins of these systems and the flexibility of emission energies tuning simply by changing the nature of the excited state through perturbations on the metal and ligand orbital energies.

The first isolable dialkyl iodophosphates

Christopher M. Timperley* and Matthew J. Waters

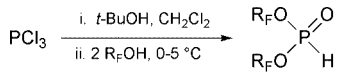
Defence Science and Technology Laboratory, Chemical and Biological Defence Sector, Porton Down, Salisbury, Wiltshire, UK SP4 0JQ. E-mail: cmtimperley@dera.gov.uk

Received (in Cambridge, UK) 30th January 2001, Accepted 16th March 2001
First published as an Advance Article on the web 5th April 2001

The synthesis and characterization of the first dialkyl iodophosphates to be isolated in a pure state is described; $(CF_3CH_2O)_2P(O)I$ and $[(CF_3)_2CHO]_2P(O)I$ have electronegative fluoro-ester groups and can be distilled under vacuum.

The study of derivatives of phosphoric acid is one of the oldest branches of organic chemistry. In 1868, Wichelhaus isolated the first member of the dialkyl halophosphate series, diethyl chlorophosphate $(CH_3CH_2O)_2P(O)Cl$.[1] Later work led to the fluorophosphate $(CH_3CH_2O)_2P(O)F$[2] and the bromophosphate $(CH_3CH_2O)_2P(O)Br$; the latter is unstable and decomposes after 3 days at room temperature.[3] The corresponding iodophosphate $(CH_3CH_2O)_2P(O)I$, like all known iodophosphates, decomposes extremely easily and has not been obtained out of solution.[4–6] In continuation of our studies on fluoroalkyl phosphoryl compounds,[7,8] we now describe the synthesis and characterization of the first isolable dialkyl iodophosphates (and the first such molecules containing fluoro-ester groups). Our results indicate that the presence of electronegative fluorine atoms[9] significantly enhances thermal stability.

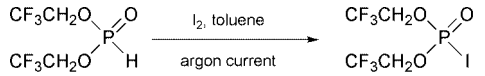
We prepared bis(fluoroalkyl) phosphites **1a** and **1b** in good yield by treating the intermediate from tertiary butanolysis of phosphorus trichloride, namely $Cl_2P(O)H$, with two molar equivalents of trifluoroethanol or hexafluoroisopropanol (Scheme 1).† The synthesis of compound **1a** this way was reported by Gibbs and Larsen; modification of their procedure[10] gave the new phosphite **1b**. Both bis(fluoroalkyl) phosphites can be stored in glass vials in a refrigerator for many months without change.



$R_F = CF_3CH_2$ δ_P 7.0 **1a** 89%
$(CF_3)_2CH$ δ_P 7.9 **1b** 71%

Scheme 1

Treatment of bis(trifluoroethyl) phosphite **1a** with a solution of iodine in toluene,[11] with argon blowing through the mixture to help remove hydrogen iodide, gave iodophosphate **2a** (Scheme 2). It was purified by vacuum distillation (bp 40 °C/0.02 mmHg).‡ This is the first time iodination of a dialkyl phosphite has permitted the isolation of a pure iodophosphate: the reaction with diethyl phosphite is complicated by dealkylation of diethyl iodophosphate by hydrogen iodide, and pure product cannot be obtained.[4] The greater ease of dealkylation of the $CH_3CH_2O–$ group compared to the $CF_3CH_2O–$ group is because the ethoxy oxygen is more basic than the trifluoroethoxy oxygen, and thus more easily converted into a

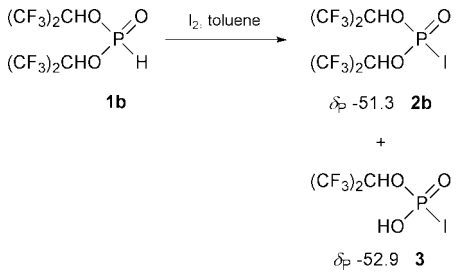


1a δ_P -47.7 **2a** 46%

Scheme 2

leaving group by protonation, and also because the α-carbon of the $CH_3CH_2O–$ group is a softer acid than that of the $CF_3CH_2O–$ group, making it more vulnerable to attack by iodide ion, itself a soft base.

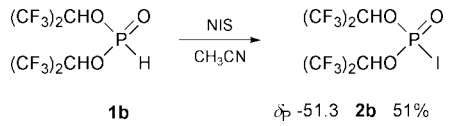
Iodination of bis(hexafluoroisopropyl) phosphite **1b**, without argon blowing through the reaction mixture, gave a 1 : 2 ratio of iodophosphate **2b** and iodo acid **3** (Scheme 3), as shown by multinuclear NMR experiments. The iodo acid arises from dealkylation of the iodophosphate by resident hydrogen iodide; the by-product $(CF_3)_2CHI$ was not detected, but most likely escaped due to its volatile nature.



1b δ_P -51.3 **2b** + δ_P -52.9 **3**

Scheme 3

Although bis(fluoroalkyl) iodophosphates resist dealkylation more than their unfluorinated counterparts, hydrogen iodide formation is best avoided during their synthesis. Treatment of bis(hexafluoroisopropyl) phosphite **1b** with *N*-iodosuccinimide (NIS), a convenient source of 'positive' iodine, led to good conversion to the iodophosphate, as shown by GC-MS analysis of the reaction mixture (Scheme 4). Iodophosphate **2b** was purified by vacuum distillation (bp 46 °C/2 mmHg).§



1b δ_P -51.3 **2b** 51%

Scheme 4

Iodophosphates **2a–b** are pale yellow liquids that deposit traces of black solid on storage in a refrigerator. In line with other dialkyl halophosphates,[1] the iodophosphates might be expected to be colourless. The yellow colour is probably attributable to contamination by iodine vapour during distillation; the deposit during storage is assumed to be precipitated iodine. The phosphorus chemical shifts in deuteriochloroform for bis(trifluoroethyl) iodophosphate **2a** and bis(hexafluoroisopropyl) iodophosphate **2b** are −47.7 and −51.3 ppm. Values for $(CH_3CH_2O)_2P(O)I$ and $(CCl_3CH_2O)_2P(O)I$ in chloroethane are −41 and −50 ppm respectively.[6]

In summary, we have developed routes to two dialkyl iodophosphates that comprise the first such species to have been isolated and characterized properly. This discovery, which lags behind the first isolation of a pure dialkyl phosphorochloridate by over 130 years, opens up new frontiers in organic phosphorus and iodine chemistry. Further studies relating to the synthesis of

a range of bis(fluoroalkyl) phosphites and their reactions with halogens will be reported in due course.

We thank the Ministry of Defence UK for funding the work.

Notes and references

† *Materials and methods:* trifluoroethanol and hexafluoroisopropanol were purchased from Apollo Scientific Ltd UK. Analytical information was obtained using documented instrumentation and techniques: see C. M. Timperley, M. Bird, I. Holden and R. M. Black, *J. Chem. Soc., Perkin Trans. 1*, 2001, 26. NMR data were recorded in $CDCl_3$ solution.

‡ *Bis(trifluoroethyl) iodophosphate* **2a**: a solution of iodine (5.08 g, 0.02 mol) in toluene (100 cm^3) was added dropwise to bis(trifluoroethyl) phosphite (4.92 g, 0.02 mol) in toluene (75 cm^3) at 0–5 °C with stirring and passage of argon through the solution. After addition, the purple solution was left for 2 h. Residual iodine was removed by filtration through a small plug of silica gel. Removal of toluene and double distillation of the residue gave **2a** as a pale yellow liquid (3.42 g, 46%). Bp 40 °C/0.02 mmHg. δ_H (500 MHz) 4.45 (4H, m, OCH_2); δ_C (125 MHz) 121.4 (dq, J = 13 and 278 Hz, CF_3), 69.4 (dq, J = 5 and 37 Hz, OCH_2); δ_F (470 MHz) −74.1 (6F, t, J = 7 Hz, CF_3); ν_{max}/cm^{-1} (film) 1454, 1421, 1296 (P=O), 1174, 1070, 962, 883, 849; *m/z* (CI) 373 (M + 1), 353 (M − F), 245 (M − I); HRMS (+ve ion EI): Calc. for $C_4H_4F_6IO_3P$ 371.939 ([M − HF]$^+$ = 351.933), found 351.933 (error 0.7).

§ *Bis(hexafluoroisopropyl) iodophosphate* **2b**: a solution of *N*-iodosuccinimide (2.62 g, 11.65 mmol) in acetonitrile (20 cm^3) was added dropwise by cannula to a stirred solution of bis(hexafluoroisopropyl) phosphite (4.45 g, 11.65 mmol) in acetonitrile (30 cm^3). After 2 h, GC-MS analysis showed good conversion to product. Removal of solvent and double distillation of the oily residue gave **2b** as a pale yellow liquid (3 g, 51%). Bp 46 °C/2 mmHg. δ_H (500 MHz) 5.28 (2H, dsep, J = 5 Hz, OCH); δ_C (125 MHz) 119.9 (dq, J = 6 and 282 Hz, CF_3), 71.9 (dsep, J = 7 and 37 Hz, OCH); δ_F (470 MHz) −72.3 (6F, m, CF_3), −73.2 (6F, m, CF_3); ν_{max}/cm^{-1} (film) 1379, 1300 (P=O), 1280–1205 (strong bands), 1117, 1068, 904, 879, 854; *m/z* (CI) 509 (M + 1), 489 (M − F), 381 (M − I); HRMS (+ve ion EI): Calc. for $C_6H_2F_{12}IO_3P$ 507.933 ([M − HF]$^+$ = 487.927), found 487.926 (error 1.6).

Received (in Cambridge, UK) 1st February 2001, Accepted 16th March 2001
First published as an Advance Article on the web 17th April 2001

Photolysis of substituted *N*-alkoxythiazolethiones 1 in aqueous solvents furnishes alkoxyl radicals 2 which, upon stereoselective 5-*exo-trig* cyclization, are trapped by water soluble thiols (L-cysteine, L-cysteine ethyl ester, or the reduced form of glutathione, GSH) to afford disubstituted tetrahydrofurans 3 in synthetically useful yields and with satisfactory to excellent diastereoselectivities.

Oxygen radicals are transients in a number of biosyntheses of structurally diverse secondary metabolites.[1–3] In view of the significance of such transformations it is surprising to note that only a limited number of laboratory studies have been performed under biomimetic conditions in order to explore the properties of proposed O-radical key intermediates in water.[4,5] Major drawbacks for adapting standard radical procedures from organic to aqueous solvents originate from an insolubility of the selected reagents such as the radical precursor itself and the trapping reagent, for instance Bu_3SnH.[6] Therefore, we have investigated the feasibility of stereoselective alkoxyl radical reactions in homogeneous and heterogeneous aqueous solvents under neutral (*i.e.* non-oxidative) conditions and disclose our latest results in this communication.

N-Alkoxy-4-(*p*-chlorophenyl)thiazole-2(3*H*)-thiones **1a–d** were selected as O-radical precursors. Thione **1b** had been prepared previously.[6] Heterocycles **1a**, **1c–d** are new compounds which were obtained from the corresponding alkyl chloride (**1a**) or tosylates (**1c**, **1d**) and *N*-hydroxy-*p*-chlorophenylthiazole-2(3*H*)-thione tetraethylammonium salt according to standard procedures.[6]† Thiones **1a–d** themselves are poorly soluble in water. Therefore, all photoreactions of **1** with polar thiols were performed in two phase systems ($C_6H_5CF_3$–H_2O) or in homogeneous mixtures of 1,4-dioxane (hereafter dioxane) and water. Thiols of different polarity and molecular size were selected as hydrogen atom donor: L-cysteine, L-cysteine ethyl ester (as its hydrochloride, L-CysOEt·HCl) and the reduced form of glutathione (GSH, γ-L-glutamyl-L-cysteinylglycine).[7] The selection of $C_6H_5CF_3$ as organic solvent, which is less toxic than benzene, was based on the necessity of direct comparison of the newly obtained data with those from photoreactions of thiones **1** using Bu_3SnH as state of the art reagent.‡ Thus, a solution of 1-phenyl-5-methylhexenoxythiazolethione **1a** and L-CysOEt·HCl in a mixture of $C_6H_5CF_3$–H_2O was treated with a 2 M solution of NaOH and was photolyzed at room temperature in a Rayonet photoreactor (λ_{max} = 350 nm). After complete consumption of **1a**, the pH of the aqueous phase is adjusted to 2 in order to extract residual hydrogen donor into the aqueous phase. The organic layer affords upon workup 68% of 2,5-*trans*-disubstituted tetrahydrofuran **3a** (entry 1, conditions 1, *cis*:*trans* = 30:70) (Scheme 1).‡§

Alternatively we found that tetrahydrofuran **3a** could be prepared in similar yields from thione **1a** in a homogeneous mixture of dioxane and water by application of L-CysOEt·HCl as hydrogen atom donor and neat Na_2CO_3 as base (entry 1, conditions 2, 64%, *cis*:*trans* = 30:70). Other organic cosolvents such as CH_3CN, acetone, or MeOH, were found to be inferior to dioxane. In a third experiment, 53% of tetrahydrofuran **3a** was obtained from the photoreaction of thiazolethione **1a** and GSH in dioxane–H_2O (entry 1, conditions 3, 53%, *cis*:*trans* = 30:70). These findings indicate, that efficient stereoselective alkoxyl radical cyclizations in homogeneous aqueous solvents are feasible. However, it is essential to use 10 equiv. of L-cysteine derivatives as hydrogen atom donors at the given concentration level, since lower thiol strengths lead to the formation of alkoxyl radical-derived alcohols besides the corresponding carbonyl compounds in 1:1 molar ratios. Compared to the corresponding Bu_3SnH-mediated reactions the yields decrease only slightly whereas stereoselectivities are not affected by the change in solvent.‡

The best conditions 1–3 (Scheme 1) were subsequently applied for experiments using 2-phenylpentenyloxythiazolethione **1b** (entry 2) and derivatives **1c–d** (entries 3–4). Photoreactions using 2-substituted 4-pentenyloxythiazolethiones **1b** and **1c** afforded *cis*-2,4-disubstituted tetrahydrofurans **3b** and **3c** as major products which is in line with the general guidelines of stereoselective 5-*exo-trig* alkoxyl cyclizations[8–10] and with the Beckwith–Houk model[11] for carbon radical ring closure reactions (entries 2 and 3). The observed high stereoselectivity for the formation of 4-*tert*-butyl-2-methylte-

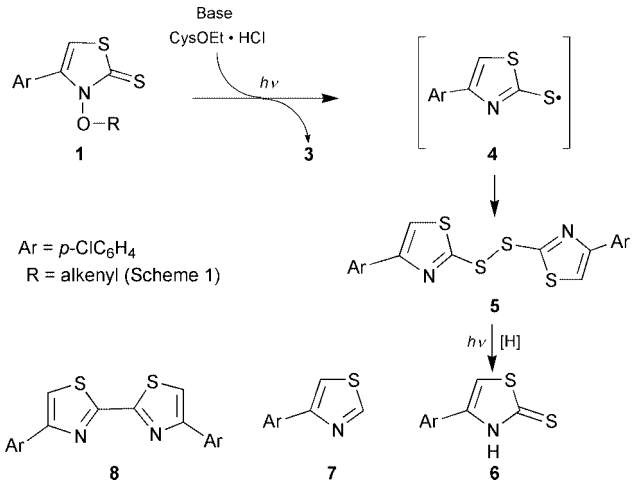
DOI: 10.1039/b101097m



Scheme 2 Formation of thiazoles **5**–**8** from *N*-alkoxythiazolethiones **1**.

trahydrofuran **3c** from the corresponding alkenoxyl radical **2c** (entry 3, *cis*:*trans* = 90:10) is considered to originate from beneficial steric effects of the *tert*-butyl substituent. This interpretation is supported by a noteworthy 2,3-*trans*-selectivity for the formation of 3-*tert*-butyl-2-methyltetrahydrofuran **3d** from the corresponding thiazolethione **1d** (entry 4).[7,10,11]

According to the data which are reported in Scheme 1 it is obvious that heterogeneous and homogeneous conditions 1 and 2 (Scheme 1), which demand L-CysOEt·HCl as hydrogen atom donor and a suitable base, are superior to the GSH for preparing tetrahydrofurans **3** from thiones **1**. It is worth mentioning, that GSH requires the presence of water in order to deliver its hydrogen atom to cyclized *O*-radicals, although GSH is partially soluble in pure dioxane. Similar observations were made for free amino acid L-cysteine as hydrogen atom donor which affords almost identical yields and selectivities of **3** as GSH does (not shown in Scheme 1). Further, syntheses of tetrahydrofurans **3** fail if photolyses of thiones **1** and GSH are performed in heterogeneous mixtures. For example, the photoreaction of radical precursor **1b** and GSH in $C_6H_5CF_3$–H_2O affords 2-phenylpent-4-en-1-ol (34%) and the corresponding aldehyde 2-phenylpent-4-enal (21%) as sole products.

In almost every photochemical run, formation of a colorless to yellowish precipitate was observed. This material was soluble in acetone, but less soluble in diethyl ether. It was shown to be a mixture of strongly UV-absorbing compounds which were characterized as different primary and secondary photoproducts presumably of the starting thiones **1** (Scheme 2). Expected addition products of either glutathionyl or cysteinyl radicals to the thiocarbonyl group in parent thiones **1a–d** were surprisingly absent in the reaction mixtures.[6] According to control experiments it is likely that the disulfide **5** is formed as primary product which then undergoes further absorption of UV light to afford both 4-(*p*-chlorophenyl)thiazole-2(3*H*)-thione (**6**) and thiazole **7** besides the bisthiazole **8**. Evidence for this assumption is derived from products obtained after photodecomposition of disulfide **5** at λ = 350 nm in dioxane–water (4:1, v/v) which affords 43% of thiazole **7** and 16% of thiazolethione **6**. It is interesting to note that the thiazole-derived photoproducts **5**–**8** (Scheme 2) are identical to those isolated from photochemical studies using the parent acid of **1**, *i.e.* *N*-hydroxy-4-(*p*-chlorophenyl)thiazolethione, as hydroxyl radical source for DNA-strand break in photobiological studies.[12]

In conclusion, we have demonstrated that L-cysteine-derivatives, *e.g.* L-CysOEt, or the tripeptide GSH can be applied as useful radical traps for the stereoselective formation of disubstituted tetrahydrofurans **3** *via* an alkoxyl radical pathway in aqueous solvents. These investigations point to the feasibility of *O*-radical reactions using *N*-alkoxythiazole-2(3*H*)-thiones, *e.g.* derivatives of **1**, under biomimetic conditions. Further work is in progress in order to pursue *O*-radical chemistry in water as the sole solvent.

This work was generously supported by the Deutsche Forschungsgemeinschaft (Project Ha1705/3–2). Also, we express our gratitude to Dipl.-Chem. Philipp Schmidt for providing samples of thiazolethione **1a** and Dr Hideki Okamoto for helpful discussions.

Notes and references

† Satisfactory analytical data were obtained for all new compounds in this study: thiazolethiones **1a**, **1c**, and **1d**, and tetrahydrofurans **3c** and **3d**.

‡ For comparison, yields of tetrahydrofurans **3** from photoreactions of **1** and Bu_3SnH in $C_6H_5CF_3$ were determined. Figures in brackets denote the *cis*–*trans* ratios: **3a**: 93% (30:70), **3b**: 60% (88:12), **3c**:97% (90:10), **3d**:88% (<2:>98).

§ In a typical run thiazolethione **1** (1 mmol) was dissolved in the organic solvent ($C_6H_5CF_3$ or 1,4-dioxane, 20 ml). L-CysOEt·HCl (10 mmol) and a base (9 mmol, see Scheme 1), or GSH, or L-cysteine (10 mmol) were dissolved in water (5 mL). Both solutions were combined while stirring to afford the reaction mixture which was photolyzed at ambient temperature in a Rayonet® photoreactor (λ = 350 nm). Upon complete consumption of **1** (*ca.* 30 min), the colorless to yellowish precipitate was filtered-off and the remaining solution was worked up as follows. For reactions with CysOEt in $C_6H_5CF_3$–H_2O, 2 M HCl was added with agitation to adjust to pH 2 in the aqueous phase. Subsequently, phases were separated and the aqueous layer was extracted with diethyl ether (2 × 10 mL). The combined organic phases were dried with $MgSO_4$ and concentrated *in vacuo*. The product **3** was purified by column chromatography (SiO_2, petroleum ether–Et_2O = 2:1, v/v). If dioxane is used as solvent, the organic solvent is first evaporated from the reaction mixture. Subsequently, diethyl ether was added (20 mL) to the aqueous phase and tetrahydrofurans **3** were isolated as described above.

Influence of water on the chirality of camphorsulfonic acid-doped polyaniline

Veronica Egan, Robert Bernstein, Laura Hohmann, Thu Tran and Richard B. Kaner*

Department of Chemistry & Biochemistry and Exotic Materials Institute, University of California, Los Angeles, Los Angeles, CA 90095-1569, USA. E-mail: kaner@chem.ucla.edu

Received (in Irvine, CA, USA) 2nd November 2000, Accepted 20th March 2001
First published as an Advance Article on the web 5th April 2001

Polyaniline doped with *R*-(−)- or *S*-(+)-camphorsulfonic acid produces an inexpensive chiral substrate; the presence or absence of water can be used to invert the dopant-induced circular dichroism (CD) absorbance at 450 nm, shedding light on conflicting literature reports.

Chiral polyaniline has potential applications in molecular recognition and enantiomeric separations.[1–3] In searching the literature of chiral camphorsulfonic acid-doped polyaniline, we discovered that alternating directions have been reported for the main dopant-induced circular dichroism (CD) absorbance peak centered at 450 nm. For example, when doped with *S*-(+)-camphorsulfonic acid, the CD absorbance at 450 nm is sometimes reported to be in the positive direction,[3–6] whereas at other times it is reported to be in the negative direction.[1,5–9] If chiral polyaniline is to be useful as an active material in sensors and separations[1,2] this phenomenon needs to be understood. Here, we demonstrate that the chirality of polyaniline is critically dependent upon the water content of the polymer before exposure to the chiral acid dopant.

Polyaniline is a simple conjugated polymer, which can be polymerized *via* either chemical[10] or electrochemical oxidation of aniline.[11] Aniline is an inexpensive achiral molecule heavily used in the dye industry.[12] The half-oxidized emeraldine base form of polyaniline can be readily doped to the conducting emeraldine salt form when mixed with a strong acid (Scheme 1).

Emeraldine base doped with either enantiomer of camphorsulfonic acid produces a chiral form of polyaniline.[1,4,6] Since camphorsulfonic acid is only optically active below 300 nm, the doping-induced peak at 450 nm can be attributed exclusively to chiral polyaniline, and therefore, this absorbance can be used to monitor chirality in the polymer. Here, the emeraldine base form of polyaniline was chemically synthesized according to a literature procedure[10,13] and camphorsulfonic acid doping in *N*-methylpyrrolidinone was carried out using a 2:1 mass (5:1 molar) ratio of emeraldine base to camphorsulfonic acid.†

To study the effects of water upon chiral polyaniline, one sample of emeraldine base was placed in a 60 °C oven for four days and allowed to dry thoroughly, while a second sample from the same batch was soaked in deionized water for four days followed by brief vacuum filtration. The dry (3–5% water content determined by thermogravimetric analysis) and wet (>50% water content determined by thermogravimetric analysis) emeraldine base samples were then doped with either *S*-(+)- or *R*-(−)-camphorsulfonic acid in *N*-methylpyrrolidinone and CD spectra obtained. Surprisingly, a CD peak at 450 nm could be induced to give either a positive or a negative signal simply by thoroughly wetting or drying the emeraldine base polyaniline prior to doping with *S*-(+)-camphorsulfonic acid in *N*-methylpyrrolidinone (see Fig. 1): the dry sample doped with *S*-(+)-camphorsulfonic acid results in the positive CD peak; the wet sample doped with *S*-(+)-camphorsulfonic acid gives the negative CD peak. Tests performed on different batches of wet and dry emeraldine base all exhibited the same trends in CD direction at 450 nm. Therefore, the water content of the emeraldine base prior to doping with camphorsulfonic acid has a dramatic affect upon the chirality of the doped polyaniline.

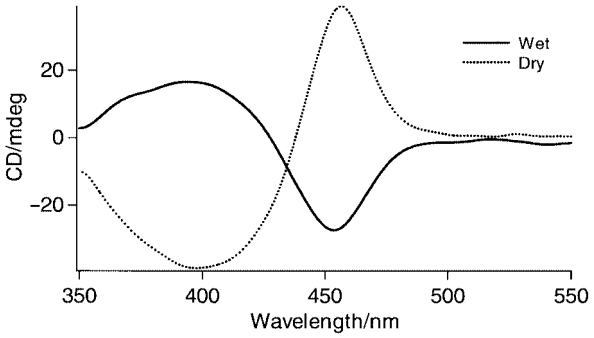

Fig. 1 Resulting CD spectra of polyaniline dried prior to doping with *S*-(+)-camphorsulfonic acid in *N*-methylpyrrolidinone (Dry) and wetted prior to doping with *S*-(+)-camphorsulfonic acid in *N*-methylpyrrolidinone (Wet).

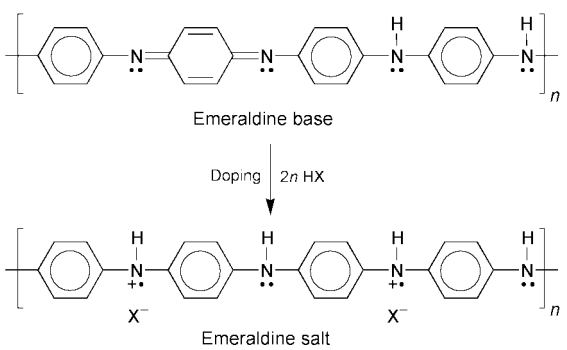
Wet and dry emeraldine base samples doped with *R*-(−)-camphorsulfonic acid in *N*-methylpyrrolidinone gave exactly analogous, but inverted, CD results (see Fig. 2). Note that the direction of the CD peak at 450 nm induced with *R*-



Scheme 1 Fully doped polyaniline; molar ratio of emeraldine base to dopant acid (HX) is 2:1.

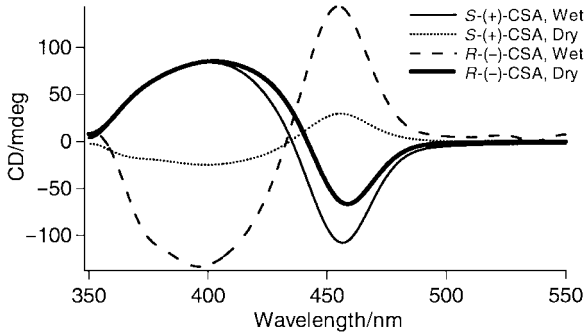


Fig. 2 Resulting CD spectra of polyaniline doped with *R*-(−)- or *S*-(+)-camphorsulfonic acid after exposure to either drying or wetting conditions prior to doping in *N*-methylpyrrolidinone.

Table 1 Effects of water on the chirality of camphorsulfonic acid-doped polyaniline in *N*-methylpyrrolidinone

Condition of emeraldine base prior to doping with camphorsulfonic acid	CD direction at 450 nm	
	S-(+)-Camphorsulfonic acid	*R*-(−)-Camphorsulfonic acid
Wet	−	+
Dry (60 °C)	+	−
Dry (60 °C) → Wet	−	+
Wet → Dry (60 °C)	+	−
Wet → vacuum dried, room temperature	+	−

(−)-camphorsulfonic acid for wet polyaniline is now in the positive direction, whereas the dry sample is now in the negative direction. Therefore, polyaniline can be readily manipulated to produce the same form of optically active polyaniline when doped with opposite enantiomers. The direction of the CD signal is dependent upon both the condition of the emeraldine base prior to doping, and upon which enantiomer is used for doping. Additionally, all of the solutions were cast as thin, doped emeraldine films onto quartz plates and CD spectra obtained. All the samples gave the same CD peak direction at 450 nm as when in solution. Therefore, this phenomenom exists regardless of whether the sample is in solution or in the solid state.

In order to rule out that the drying temperature caused a chemical change to the emeraldine base structure, a sample of polyaniline dried at 60 °C for a four-day period was subsequently soaked in deionized water to produce the wet form of emeraldine base. The sample was then doped with *S*-(+)-camphorsulfonic acid in *N*-methylpyrrolidinone overnight and analyzed by CD. The resulting CD peak at 450 nm was negative which is the same CD direction observed for unheated, wet polyaniline doped with *S*-(+)-camphorsulfonic acid (see Table 1). To further rule out heating at 60 °C as the cause for the reversal in chirality, water elimination *via* vacuum drying at room temperature was substituted for oven drying. A sample of wet emeraldine base was dried for seven days under vacuum at room temperature and then doped with *S*-(+)-camphorsulfonic acid in *N*-methylpyrrolidinone. The resulting CD direction–positive at 450 nm–was the same as for emeraldine base dried at 60 °C. When the inverse experiment was performed, *i.e.* using wet emeraldine base dried in a 60 °C oven for several days, a positive CD signal at 450 nm was obtained after doping with *S*-(+)-camphorsulfonic acid. This is the same direction as observed for emeraldine base dried at 60 °C as summarized in Table 1. Thus, polyaniline behaves according to the last environment that it is exposed to. This indicates that water is the causal factor rather than a chemical reaction (*e.g.* cross-linking) of the polyaniline itself or involving some impurity. This also demonstrates that the process is fully reversible prior to doping.

The above temperature experiments were also performed with *R*-(−)-camphorsulfonic acid instead of the *S*-(+)-form. A sample of emeraldine base polyaniline dried at 60 °C for a four-day period was subsequently soaked in deionized water and doped with *R*-(−)-camphorsulfonic acid in *N*-methylpyrrolidinone overnight. A second emeraldine base sample was first soaked in water and then dried in a 60 °C oven before doping with *R*-(−)-camphorsulfonic acid. Additionally, wet emeraldine base polyaniline that was dried at room temperature under vacuum was also doped with *R*-(−)-camphorsulfonic acid. All samples were analyzed with CD and the results are summarized in Table 1. The *R*-(−)-camphorsulfonic acid-doped polyaniline behaves analogously to *S*-(+)-camphorsulfonic acid doped polyaniline except that all CD directions at 450 nm are now inverted.

The discovery that water can cause a reversal in chirality, and its ability to make polyaniline doped with opposite enantiomers appear to have the same chiral configuration based on CD is significant because it could explain the observed inversion of expected chiralities reported in the literature.[3,7,14] For example, Wallace and coworkers have shown that chiral polyaniline doped with the same enantiomer of camphorsulfonic acid prepared electrochemically produces an inverted CD peak at 450 nm to that produced chemically.[3,5,7] Their electrochemically prepared chiral polyaniline when doped with *S*-(+)-camphorsulfonic acid produces a negative 450 nm peak, whereas their chemically generated polyaniline doped with *S*-(+)-camphorsulfonic acid in *N*-methylpyrrolidinone produces a positive CD peak at this wavelength. The authors conclude that there must be different configurations for the electrochemically and chemically prepared chiral polyanilines.[5] However, since the electrochemically prepared chiral polyaniline was electropolymerized in an aqueous solution and its CD is similar in direction to the wet polyaniline described here, it is likely that the water used in the electrochemical process contributes to the chiral configuration of the polyaniline.

Thus, the CD spectra of *S*-(+)- and *R*-(−)-camphorsulfonic acid doped polyanilines in *N*-methylpyrrolidinone can appear identical depending upon the water content of the emeraldine base prior to doping. This process is fully reversible before doping and is simply a function of the water content and is not related to the drying temperature.

This work was supported by the University of California Campus Laboratory Collaboration program (CLC).

Notes and references

† All samples were made with 60 mg of polyaniline and 30 mg (1.3×10^{-4} mole) of camphorsulfonic acid in 4 mL of *N*-methylpyrrolidinone. The mixtures were shaken and allowed to dope for at least four hours and then filtered through cotton. Each sample for CD analysis consisted of 40 μL of a stock solution that was diluted with 150 μL of *N*-methylpyrrolidinone. Films were prepared by placing a few drops of solution onto quartz plates that were dried at 60 °C for two hours. All CD analyses were carried out using a Jasco J715 CD Spectropolarimeter and a Fast Fourier Transform to filter out high frequency noise. Owing to the difficulty of completely dissolving polyaniline in *N*-methylpyrrolidinone, the concentrations, and therefore the CD intensities, vary from sample to sample. The CD spectra presented in Fig. 2 for *S*-(+)- and *R*-(−)-camphorsulfonic acid-doped polyaniline used polymer powder from the same synthesis, whereas the analogous spectra for *S*-(+)-camphorsulfonic acid- doped polyaniline in Fig. 1 used polymer powder from a different synthetic batch.

The organometallic cations $[(\eta^5\text{-}C_5H_5)_2Co]^+$ and $[(\eta^5\text{-}C_5H_5)_2Fe]^+$ are fully miscible in the solid state and form the mixed crystalline material $[(\eta^5\text{-}C_5H_5)_2Co_xFe_{1-x}][PF_6]$, which undergoes two fully reversible phase transitions that can be tuned by varying the molar ratio of the two cations; the water-soluble organometallic salt thus possesses the behaviour of a molecular alloy.

Crystal polymorphism is the property of a substance to exist in different crystalline phases resulting from different arrangements of the molecules in the solid state.[1,2] Polymorphic modifications of the same substance may differ markedly in chemical and physical properties such as diffraction pattern and solid state spectroscopy. We are investigating polymorphism and solid state dynamic behaviour in a systematic manner, with a focus on organometallic systems.[3] In particular, we are interested in obtaining new crystal forms by non-solution methods (*e.g.* grinding,[4] seeding,[5] desolvation[6]) and in controlling the interconversion between polymorphs and between pseudo-polymorphs. The study of polymorphism falls into the mainstream of (molecular) crystal engineering.[7]

In this context, we have recently investigated by single crystal and powder X-ray diffraction as well as by calorimetric methods the phase transition behaviour of the crystalline salts $[(\eta^5\text{-}C_5H_5)_2M][PF_6]$ (M = Co, Fe).[8] The two crystalline materials are isomorphous at room temperature and undergo two fully reversible solid-to-solid phase transitions on changing the temperature. A RT $\rightleftharpoons$ LT transition occurs on cooling the room temperature phases below 252 (M = Co) and 213 K (M = Fe), whereas a RT $\rightleftharpoons$ HT transition is observed on heating the crystalline materials above 314 (M = Co) and 347 K (M = Fe). Hence, the main difference between the two materials arises from the interval of thermal stability of the intermediate RT phase (*ca.* 62 K for M = Co and 134 K for M = Fe). The relationship between the three solid phases is shown in Fig. 1.

The close structural similarity between the two complexes of $[(\eta^5\text{-}C_5H_5)_2M]^+$ (M = Co, Fe) prompted us to explore the possibility of growing crystals from solutions containing mixtures of the two cations. We were seeking answers to the following questions: (i) would the two cations form co-crystals or separate out in crystals of the two salts? (ii) In the former case, could we expect to be able to control the phase transition behaviour by varying the $[(\eta^5\text{-}C_5H_5)_2Co]^+$:$[(\eta^5\text{-}C_5H_5)_2Fe]^+$ molar ratio? In this design we were also helped by the large difference in colour: $[(\eta^5\text{-}C_5H_5)_2Co][PF_6]$ is bright yellow, and $[(\eta^5\text{-}C_5H_5)_2Fe][PF_6]$ is deep blue.

We have discovered that, in the solid state, the two cations are fully miscible in the whole range of composition and that the composition is the same as that of the *water solutions* from which the mixed-crystals are precipitated, *e.g.* the mixed salts can be formulated as $[(\eta^5\text{-}C_5H_5)_2Co_xFe_{1-x}][PF_6]$ (with $0 < x < 1$). Moreover, the phase transition behaviour depends linearly on the composition. The temperatures at which the two solid-to-solid phase transitions occur vary regularly, as a direct function of the molar ratio, between the two extremes defined by the homo-cationic crystals.

Mixed crystals were precipitated from water solutions containing $[(\eta^5\text{-}C_5H_5)_2Co]^+$:$[(\eta^5\text{-}C_5H_5)_2Fe]^+$ in the molar ratios: 90:10, 75:25, 50:50 and 25:75. The pure Co and Fe compounds have closely similar unit cell dimensions [data at room temperature for Co/Fe: a = 13.355(3)/13.408(6), b = 9.441(8)/9.530(2), c = 9.427(6)/9.482(2) Å, β = 92.87(4)/93.17(3)°, V_{cell} = 1187(1)/1209(1) Å^3];[8] hence one could expect the mixed crystals to obey Vegard's rule of linear change in lattice dimensions with composition.[9a] Since deviations from this behaviour are known[9b] the diffraction patterns for all the bulk precipitates were measured to ensure that only the same phase as that of the starting materials had formed. The colours of the precipitates were also very indicative of the formation of mixed-crystals since $[(\eta^5\text{-}C_5H_5)_2Co_x\text{-}Fe_{1-x}][PF_6]$ are green and the colour changes from green to

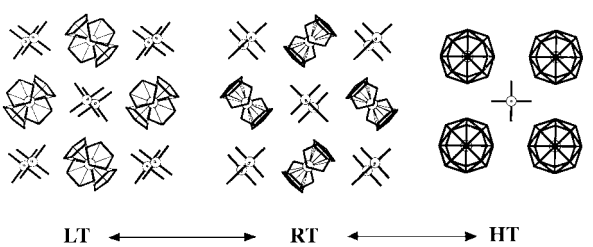

Fig. 1 The relationship between the ion arrangements in $[(\eta^5\text{-}C_5H_5)_2M][PF_6]$ (M = Co, Fe) in their (a) low, (b) room and (c) high temperature phases; in the case of M = Fe also the anions are orientationally disordered in the high temperature phase.

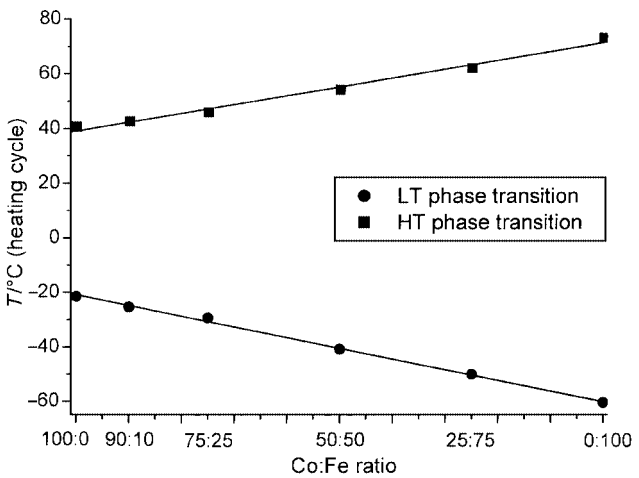

Fig. 2 The temperature variation of the RT $\rightleftharpoons$ LT and RT $\rightleftharpoons$ HT transitions with $[(\eta^5\text{-}C_5H_5)_2Co]^+$ and $[(\eta^5\text{-}C_5H_5)_2Fe]^+$ in the molar ratios 100:0, 90:10, 75:25, 50:50, 25:75, 0:100.

DOI: 10.1039/b101749g

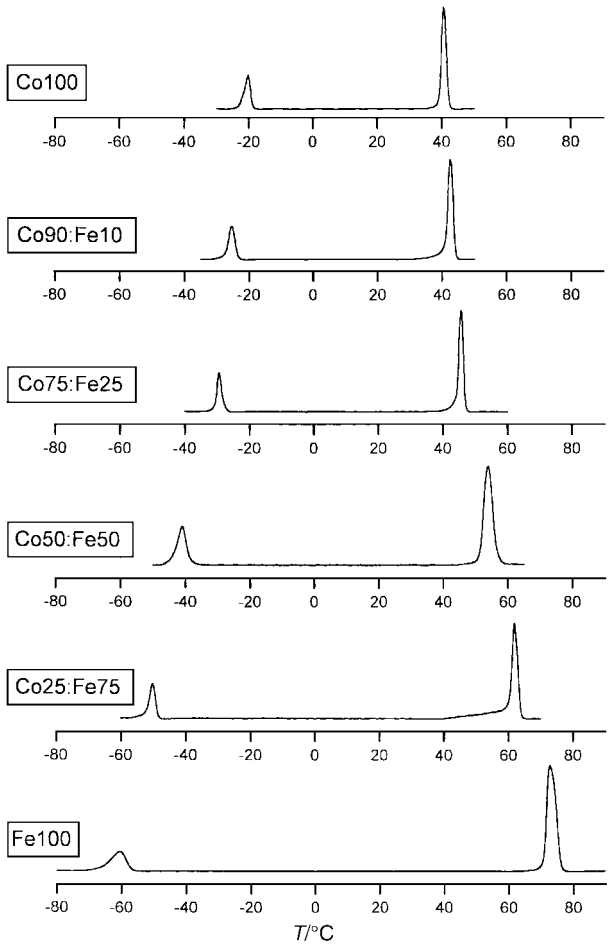

Fig. 3 DSC thermograms (heating cycle) showing how the RT ⇌ LT and RT ⇌ HT transitions 'diverge' from the values observed in the case of $[(\eta^5\text{-}C_5H_5)_2Co]^+$ as the percentage of $[(\eta^5\text{-}C_5H_5)_2Fe]^+$ in the mixture is increased. (For the sake of clarity and comparison, all baselines have been subtracted from the DSC thermograms.)

blue–green with the increasing molar fraction of the Fe component. Each mixed salt powder was subjected to a full cycle of differential calorimetry measurements (DSC), both in the cooling and in the heating regimes, to measure the temperatures of the two solid-to-solid phase transitions. The temperature variation of the RT ⇌ LT and RT ⇌ HT transitions with composition is shown in Fig. 2 (for the heating cycle). A comparison of the DSC thermograms is shown in Fig. 3: note how the peaks corresponding to the RT ⇌ LT and RT ⇌ HT transitions diverge as the percentage of $[(\eta^5\text{-}C_5H_5)_2Fe]^+$ is increased. As in the cases of the pure materials the two processes are fully reversible.[10]

In conclusion, we have been able to *tune* the phase transition behaviour of the crystalline material $[(\eta^5\text{-}C_5H_5)_2Co_x\text{-}Fe_{1-x}][PF_6]$ by varying the $[(\eta^5\text{-}C_5H_5)_2Co]^+$:$[(\eta^5\text{-}C_5H_5)_2Fe]^+$ molar ratio, because the $[(\eta^5\text{-}C_5H_5)_2Co]^+$ and $[(\eta^5\text{-}C_5H_5)_2Fe]^+$ cations form fully miscible solid solutions. The linear response of physical properties with composition is typical of inorganic alloys[11] and of crystals constructed by almost isostructural species (*e.g.* naphthalene and 1,2,4,5-tetrachlorobenzene, or 2-chloronaphthalene and 2-bromonaphthalene)[11] but, to the best of our knowledge, it has never been reported for organometallic molecular salts. Thus, the mixed-crystal $[(\eta^5\text{-}C_5H_5)_2Co_xFe_{1-x}][PF_6]$, though being composed of molecular ions and soluble in water, possesses the features of a random A_xB_{1-x} alloy.

We plan to explore the behaviour of the salts $[(\eta^5\text{-}C_5H_5)_2M][PF_6]$ (M = Co, Fe) on changing the counterions, *i.e.* by doping the crystals with isostructural anions such as $[AsF_6]^-$ and $[SbF_6]^-$, and/or by using other isoelectronic, quasi-isomorphous, organometallic salts, *e.g.* $[(\eta^5\text{-}C_5H_5)(\eta^6\text{-}C_6H_6)Ru][PF_6]$ (one phase transition RT ⇌ HT at 332.5 K)[12] or $[(\eta^6\text{-}C_6H_6)_2Cr][PF_6]$ (no phase transition between 200 and 373 K).[8]

We thank M.U.R.S.T. (projects *Supramolecular Devices* and *Solid Supermolecules*), the Universities of Bologna (project *Innovative Materials*) and Sassari for financial support, and C. Righetti for helping us with some of the DSC measurements. We thank C. Aakeröy for asking one of us (D. B.) a stimulating question on the occasion of a talk at the University of Strasbourg, and J. Dunitz and J. Bernstein for useful suggestions.

10 For the general preparation procedure for the salts $[(\eta^5\text{-}C_5H_5)_2M][PF_6]$ (M = Co, Fe) see ref. 8. Powder diffractograms were collected on a Philips PW-1100 automated diffractometer (Cu-Kα, graphite monochromator). DSC thermograms were measured on a Perkin-Elmer DSC-7 apparatus in sealed aluminium pans, at the scanning rate of 5.0 °C min^{-1} (for Co:Fe 90:10, 75:25 and the pure Co salt) and 10.0 °C min^{-1} (for Co:Fe 50:50, 25:75 and the pure Fe salt). Correspondence between solution and solid chemical compositions was demonstrated by the absence of any trace of starting material in the DSC plots after crystallization. Mechanical mixing of the two species by *grinding* together powders of the two crystalline materials in different molar ratios yielded mixtures that showed the features of both crystals, *i.e.* the presence of four peaks in the DSC resulting from the superimposition of the DSC plots of the pure samples.

A novel radical cyclization of 2-bromoindoles. Synthesis of hexahydropyrrolo[3,4-*b*]indoles

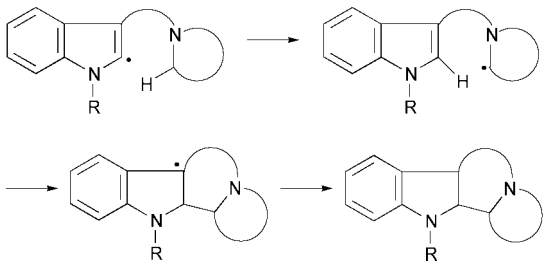
Gordon W. Gribble,* Heidi L. Fraser and Jeanese C. Badenock

Department of Chemistry, Dartmouth College, Hanover, NH 03755-3564, USA.
E-mail: grib@dartmouth.edu

Received (in Corvallis, OR, USA) 16th February 2001, Accepted 14th March 2001
First published as an Advance Article on the web 17th April 2001

Hexahydropyrrolo[3,4-*b*]indoles 6, 10, and 13 are obtained from 2-bromo-3-carboxamides 5, 9, and 12, respectively, by a 1,5-radical translocation process followed by 5-*endo-trig* cyclization to the indole C-2 position.

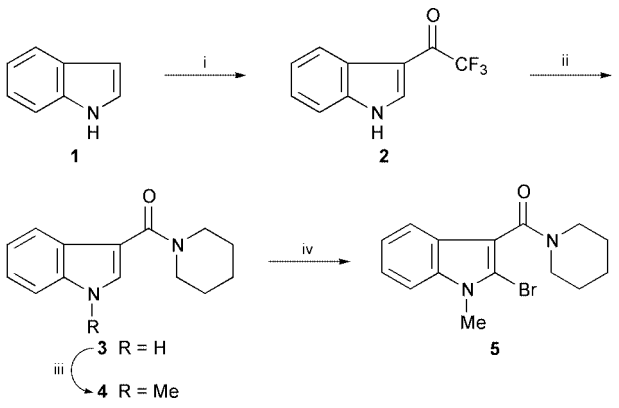
We wish to describe a new synthesis of hexahydropyrrolo[3,4-*b*]indoles from 2-bromoindole-3-carboxamides involving sequential indole C-2 radical generation, 1,5-hydrogen atom abstraction, and 5-*endo-trig* cyclization to the indole C-2 position. In connection with our interest in pyrrolo[3,4-*b*]indoles[1] and indolo[2,3-*a*]quinolizidines,[2] we envisioned the free radical sequence shown in Scheme 1 as an attractive route to these ring systems.



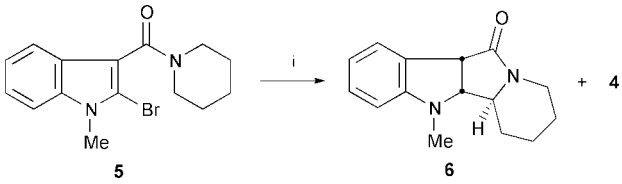
Scheme 1

We herein report the viability of this sequence for the synthesis of hexahydropyrrolo[3,4-*b*]indoles. The radical precursor 2-bromoindole **5** was prepared as shown in Scheme 2. Indole (**1**) was converted to amide **3** in two steps as previously described.[3] Subsequent *N*-methylation and C-2 bromination using the conditions described by Bergman[4] for *N*-carboxyindole afforded **5**† in excellent overall yield. An X-ray crystal structure determination confirmed the structure of **5**.[5]

The radical cyclization was performed by the slow addition over 36 h of a degassed solution of tri-*n*-butyltin hydride and catalytic AIBN in toluene to a refluxing solution of bromoindole **5** in toluene. This resulted in the formation of the desired



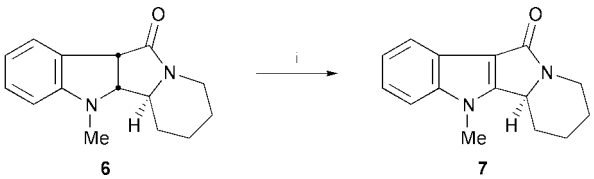
Scheme 2 *Reagents and conditions*: i, $(CF_3CO)_2O$, Et_2O, 0 °C (87%); ii, BuLi, piperidine, THF, 0 °C (97%); iii, NaOH, EtOH, MeI, acetone, rt (99%); iv, Bu^{t}Li, THF, $BrCl_2CCCl_2Br$, −78 °C to rt (88%).



Scheme 3 *Reagents and conditions*: i, Bu_3SnH, AIBN, toluene, reflux, 36 h (**6**, 54%; **4**, 42%).

dihydroindole **6**† (54%), along with the reduction product **4** (42%) (Scheme 3). The structure of **6** is fully supported by spectral and analytical data, including an X-ray crystal structure determination.[5]

We believe that this reaction involves the sequence (1) generation of the expected C-2 radical, (2) 1,5-H atom abstraction to give the α-amidoyl radical, (3) 5-*endo-trig* cyclization to the indole double bond, and (4) hydrogen abstraction to give indoline **6**. The first two steps in this process have been termed 'radical translocation' by Snieckus and Curran.[6] Attempts to improve the yield of **6** relative to reduction product **4** using other radical generation methods have not been successful. Treatment of indoline **6** with DDQ (CH_2Cl_2, rt) gave indole **7** in 50% yield (Scheme 4).



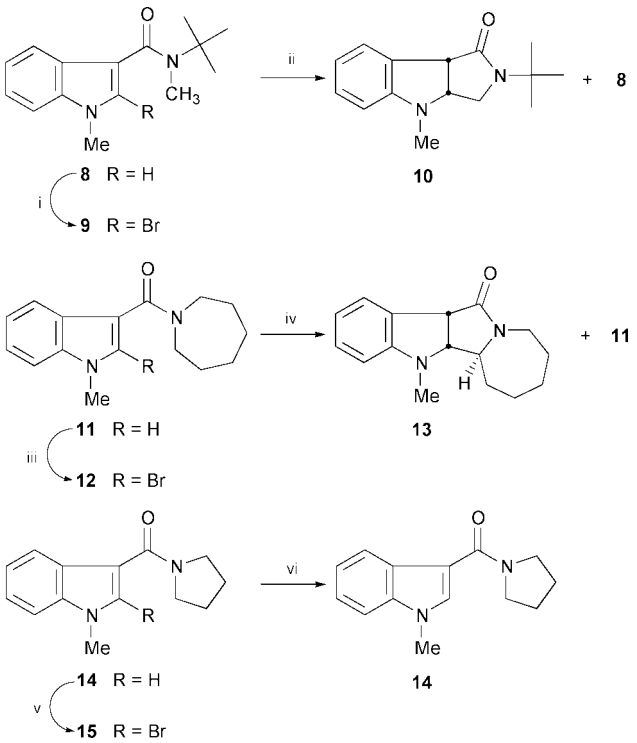
Scheme 4 *Reagents and conditions*: DDQ, CH_2Cl_2, rt, 18 h (50%).

As summarized in Scheme 5 we have applied this radical cyclization to several other substrates (**9**, **12**, **15**) and two of these afforded the expected cyclized pyrrolo[3,4-*b*]indoles **10** and **13**. However, only reduction product **14** was obtained from **15**.

Amides **8**,† **11**,† and **14**,† were synthesized by *N*-methylation of the corresponding indole-3-carboxamides[3] in 97, 77, and 80% yields, respectively, as illustrated in Scheme 2 for **4**. The usual bromination procedure afforded the 2-bromoindoles **9**,† **12**,† and **15**† in excellent yields. The structures of **9**, **12**, and **15** were confirmed by X-ray crystallography.[5]

Although radical cyclizations to the indole C-2 position are precedented[7] and the generation of indole C-2 radicals has been described by Jones,[8,9] our work is the first example of a 1,5-hydrogen atom transfer reaction of a 2-bromoindole-3-carboxamide and subsequent 5-*endo-trig* cyclization to the indole double bond. Following the completion of our initial work, Jones reported[9] a similar 1,5-H atom abstraction from the radical derived from 2-bromo-3-formyl-*N*-(4-phenylbutyl)indole and subsequent radical translocation and 5-*exo-trig* cyclization to the indole C-2 position. Jones has also recently described[10] a radical translocation sequence leading to indole C-3 5-*exo-trig* cyclization. Some other hydrogen atom abstrac-

DOI: 10.1039/b101859k



Scheme 5 *Reagents and conditions*: i, Bu^{t}Li, THF, $BrCl_2CCCl_2Br$, −78 °C to rt (86%); ii, Bu_3SnH, AIBN, toluene, reflux, 48 h (**10**, 51%; **8**, 22%); iii, Bu^{t}Li, THF, $BrCl_2CCCl_2Br$, −78 °C to rt (90%); iv, Bu_3SnH, AIBN, toluene, reflux, 72 h (**13**, 51%; **11**, 30%); v, Bu^{t}Li, THF, $BrCl_2CCCl_2Br$, −78 °C to rt (94%); vi, Bu_3SnH, AIBN, toluene, reflux, 72 h.

tion–translocation of α-amidoyl radical schemes not involving indoles have been reported.[6,11] While we favor the direct 5-*endo-trig* radical cyclization pathway shown in Scheme 1, of which there are precedents,[12,13] a 4-*exo-trig* cyclization to a spiro β-lactam intermediate followed by a 1,2-alkyl migration (ring expansion), as suggested by a referee, cannot be ruled out. However, such 1,2-alkyl shifts for radicals are rare[14] and the migration terminus is a nucleophilic carbon-centered radical. Moreover, based on the work of Ikeda,[13] we would have expected to isolate spiro β-lactams if a 4-*exo-trig* radical cyclization pathway was operating.

We thank the National Institutes of Health (GM58601) for support and Drs Mukund Sibi, Jack Li, and Larry Yet for helpful discussion.

Induced assembly of a catenated chain of edge-sharing silver(I) dodecahedra with embedded acetylide by silver(II)-tmc (tmc = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane)

Received (in Cambridge, UK) 6th December 2000, Accepted 12th March 2001
First published as an Advance Article on the web 9th April 2001

In the mixed-valent complex $[Ag^{II}(tmc)(BF_4)][Ag^{I}_6(C_2)(CF_3CO_2)_5(H_2O)]\cdot H_2O$, a $[Ag^{II}(tmc)(BF_4)]^{+1}_{\infty}$ cationic column induces the assembly of a novel, anionic zigzag chain constructed from edge-sharing of silver(I) triangulated dodecahedra each enclosing a C_2^{2-} species.

Recent studies have furnished convincing spectroscopic and structural evidence for the existence of argentophilicity,[1–4] namely the d^{10}–d^{10} closed-shell attraction[5] that promotes the aggregation of silver(I) centers. Our efforts in this direction have yielded a series of novel double,[2] triple[3] and quadruple[4] salts containing Ag_2C_2 as a component, in which the C_2^{2-} species (commonly known as the acetylide dianion, IUPAC name acetylenediide) is fully encapsulated in a variety of silver polyhedra. In these silver acetylide-containing systems, bridging anionic ligands such as fluoride, nitrate, trifluoroacetate and triflate have been used to connect the $C_2@Ag_n$ (n = 6–9) units into layers and three-dimensional networks. A natural sequel is to investigate the effect of co-existing metal ions on the assembly of polyhedral silver(I) cages, and for this purpose we choose the macrocyclic *N*-donor ligand 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (tmc) for *in situ* generation of $[Ag^{II}(tmc)]$. A decided advantage of this strategy is to avoid the introduction of a different metal, which may cause complications such as competition with silver(I) for ligand binding or precipitation of undesirable products. Proceeding in this way, we have successfully isolated a novel, mixed-valent silver complex $[Ag^{II}(tmc)(BF_4)][Ag^{I}_6(C_2)(CF_3CO_2)_5(H_2O)]\cdot H_2O$ **1**, which represents the first example of an acetylide-containing, one-dimensional coordination polymer composed of edge-sharing $C_2@Ag_8$ cages.

Compound **1** was obtained by dissolving freshly prepared Ag_2C_2 in an aqueous solution of CF_3CO_2Ag and $AgBF_4$, to which tmc was then added.† The propensity of divalent silver to act as an oxidizing agent is well documented,[6] and this unusual oxidation state can be stabilized by macrocyclic ligands, especially aza-crowns and nitrogen heterocycles.[7] In the present instance, the addition of tmc led to disproportionation of silver(I) to give elemental silver and complexed silver(II). X-Ray structural analysis‡ indicated that the square planar $[Ag^{II}(tmc)]^{2+}$ cation (mean atomic deviation from least squares plane 0.06 Å) exhibits disorder, being a superposition of two distinct *RSSR* and *RSRS* configurations[8] in a 2:1 ratio. For *RSSR*, the four methyl groups of tmc are arranged in two pairs, one on each side of the AgN_4 plane [Fig. 1(a)]; this conformation is also designated as Type III for the possible stereoisomeric forms of tmc.[8] For *RSRS*, all four methyl groups lie on the same side of the AgN_4 plane, corresponding to the Type I conformation [Fig. 1(b)]. The Ag–N bond lengths in the range 2.180(8)–2.206(8) Å are in agreement with 2.195 Å found in $[Ag^{II}(tmc)](ClO_4)_2$.[9] Weak axial interactions of the d^9 silver(II) center, which is subjected to Jahn–Teller distortion, with adjacent BF_4^- ligands at Ag7–F1, 2.972 Å and Ag7–F2′ (1 + x, y, z), 2.934 Å serve to link the complexed Ag(II) cations into a $[Ag^{II}(tmc)(BF_4)]^{+1}_{\infty}$ column running parallel to the *a* axis [Fig. 2(a)]. The Ag–F distances fall within the range 2.60–3.02 Å for CF–Ag contacts in some silver(I) complexes containing fluorinated organic ligands.[10]

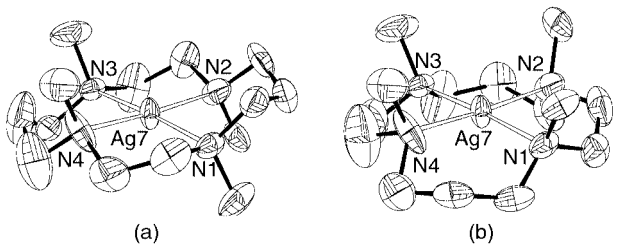

Fig. 1 Disordered $[Ag^{II}(tmc)]^{2+}$ cation involving superposition of two conformations of the tmc ligand: (a) Type III (*RSSR*) and (b) Type I (*RSRS*) in a ratio of 2:1. Both types share the same set of N atoms and two methyl groups. Thermal ellipsoids are drawn at the 30% probability level. Selected bond lengths (Å): Ag7–N1 2.196(7), Ag7–N2 2.206(8), Ag7–N3 2.184(7), Ag(7)–N4 2.180(8).

Induced by the presence of such a cationic column, a parallel polymeric anionic chain [Fig. 2(b)] is assembled from the Ag(I), C_2^{2-} and $CF_3CO_2^-$ species. The building block of its backbone is an unprecedented triangulated dodecahedron as shown in Fig. 3. Atom sets Ag1–Ag2–Ag3–Ag4 and Ag5–Ag5a–Ag6–Ag6b are each coplanar within 0.088 and 0.109 Å, respectively, making a dihedral angle of 80.2°. This dodecahedron can be regarded as the fusion of two sets of tetrahedra, elongated Ag2–Ag3–Ag5a–Ag6 and flattened Ag1–Ag4–Ag5–Ag6b. The C_2^{2-} species retains its triple bond character with C–C bond length 1.17(1) Å. In contrast, much longer C–C bond distances are found for interstitial C_2 units in organometallic compounds, such as 1.39(2) Å in $[Co_9(C_2)(CO)_{19}]^{2-}$ and 1.48(2) Å in

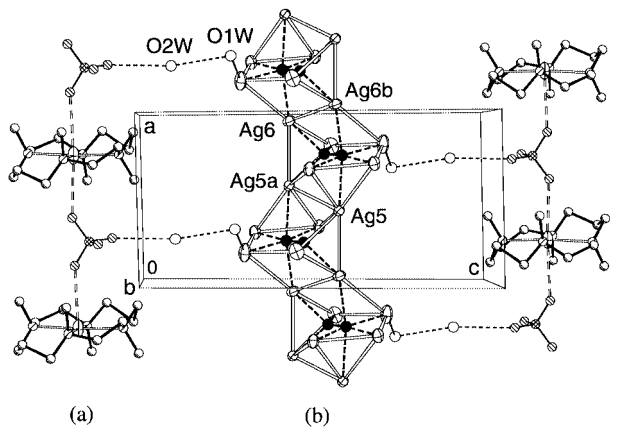

Fig. 2 Crystal structure of **1**. Hydrogen bonds are shown as dashed lines, and trifluoroacetate ligands have been omitted for clarity. (a) A column-like $[Ag^{II}(tmc)(BF_4)]^{+1}_{\infty}$ cationic column. The disordered $[Ag^{II}(tmc)]^{2+}$ cation is represented by its major configuration, and the weak axial $Ag^{II}\cdots F$ interactions are shown by dashed open lines. (b) Polymeric $[Ag^{I}_6(C_2)(CF_3CO_2)_5(H_2O)]^{-1}_{\infty}$ zigzag chain formed from edge-sharing of silver dodecahedra. The mid-points of the Ag5–Ag5a and Ag6–Ag6b bonds are located at inversion centers.

DOI: 10.1039/b009765i

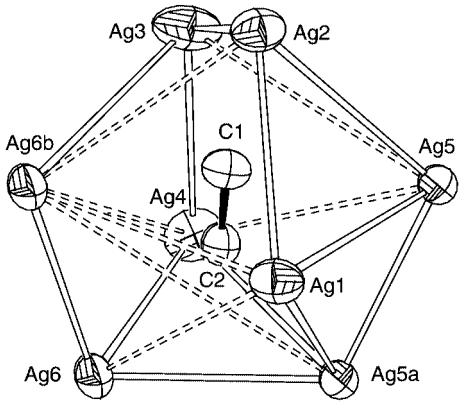

Fig. 3 Silver(I) triangulated dodecahedron with an encapsulated C_2^{2-} anion. Ag···Ag distances longer than 3.4 Å (twice the van der Waals radius of silver) are represented by broken open lines. Thermal ellipsoids are drawn at the 30% probability level. Symmetry codes: (a) $-x+1, -y+1, -z+1$; (b) $-x+2, -y+1, -z+1$.

$[Rh_{12}(C_2)(CO)_{25}]$.[11,12] The present C_2^{2-} ion has σ-type interactions with all seven silver(I) atoms at Ag–C = 2.172(8)–2.497(9) Å. The Ag···Ag distances lie in the range 2.818–3.366(1) Å, which is suggestive of significant argentophilic interactions.[1–4] The dodecahedra share edges of the type Ag5–Ag5a and Ag6–Ag6b to generate a chain-like structure [Fig. 2(b)]. An alternative description is that the silver atoms of type Ag5 and Ag6 construct a nearly planar zigzag chain with type Ag1, Ag2, Ag3 and Ag4 silver atoms hitched to it through the binding of C_2^{2-} anions. The aqua ligand O1W is coordinated to Ag3 at 2.426(7) Å, while one μ_3 and four μ_2 trifluoroacetate ligands chelate Ag···Ag edges or act as bridges between silver polyhedra. The Ag–O bond distances are in the range 2.208(7)–2.546(6) Å. The crystal structure of **1** is composed of a parallel packing of $[Ag^{I}_6(C_2)(CF_3CO_2)_5(H_2O)]^{-1}_{\infty}$ anionic zigzag chains and $[Ag^{II}(tmc)(BF_4)]^{+1}_{\infty}$ cationic columns, with lattice water molecule O2W forming hydrogen bonds with O1W and a F atom of the tetrafluoroborate group (Fig. 2).

The silver polyhedra with embedded C_2^{2-} that have been found so far are all single cages except for the face-sharing double cage in the quadruple salt $2Ag_2C_2{\cdot}3AgCN{\cdot}15CF_3CO_2Ag{\cdot}2AgBF_4{\cdot}9H_2O$.[4] The single cages are either connected by bridging ligands or directly linked through vertex sharing into two- or three-dimensional networks. Compound **1** represents the first example of a chain-like structure constructed from edge-sharing $C_2@Ag_8$ polyhedra.

Metal–macrocyclic complexes have been employed as templating agents in the synthesis of inorganic polymers and oligomers, two recent examples being the utilization of crown-ether complexes for generating one- and two-dimensional cadmium–thiocyanate coordination solids[13] and thio-crown-ether complexes for extended polyiodide networks.[14] Very recently, crown ethers have been used to isolate discrete clusters containing a $C_2@Ag_7$ unit in our laboratory.[15] In the present work, the unique capability of the tetraaza macrocyclic ligand to generate and stabilize a higher oxidation state of silver was exploited, and the resulting Ag(II)–tmc complex then utilized as a template to induce the formation of the $C_2@Ag_8$ dodecahedra and their inter-linkage into a silver(I) polymeric zigzag chain. Further investigation of the structural diversity of silver acetylide-containing systems and the role played by various metal–macrocycle templates is in progress.

Notes and references

† Ag_2C_2 was prepared as described previously.[2] **CAUTION**: thoroughly dried Ag_2C_2 detonates easily upon mechanical shock or heating, and only a small quantity should be used in any chemical reaction.

Synthesis of **1**: Ag_2C_2 was added to 1 mL of a concentrated aqueous solution of $AgCF_3CO_2$ and $AgBF_4$ (molar ratio *ca.* 1 : 1) in a plastic beaker with stirring until saturated. Excess Ag_2C_2 was filtered off, and 45 mg of tmc were added to the filtrate. The colorless solution turned rapidly to dark red along with the precipitation of black metallic silver, which was removed by filtration. The red filtrate was allowed to stand without disturbance, and dark-red block-like crystals of **1** were obtained in *ca.* 40% yield after several days. Compound **1** is relatively stable in the dark but readily decomposes in common solvents such as water and ethanol.

First published as an Advance Article on the web 9th April 2001

The synthesis and properties of new hexagonal ordered mesostructured phases of framework containing adamantane $[Ge_4Q_{10}]^{4-}$ (Q = S, Se) clusters linked by Sb^{3+} and Sn^{4+} ions and templated with cetylpyridinium surfactant are reported.

Mesoporous non-oxidic semiconductor materials have the potential to combine electronic and optical properties with shape selectivity.[1–3] However this potentially large class of materials remains an underdeveloped area. Chalcogenide analogs to mesostructured silicates[4,5] are still scarce because their synthesis remains a challenge although progress in this area has been reported recently.[6–8] We are exploring the use of cetylpyridinium bromide (CPBr) surfactant in the synthesis of mesostructured chalcogenido frameworks. We recently reported that hexagonally ordered metal germanium sulfides form with $[Ge_4S_{10}]^{4-}$ anions and tetrahedral cations and show intense photoluminescence.[9] In order to probe whether the stability of the phases depends on the coordination properties of the linking metal ion, we explored ions that generally do not adopt tetrahedral coordination such as Sb^{3+}, Bi^{3+}, Sn^{2+}, Pb^{2+}, or are capable of several coordination environments *e.g.* Sn^{4+}. We find that many of these in fact fail to produce hexagonal mesostructures under our synthetic conditions. Namely, Bi^{3+}, Sn^{2+} and Pb^{2+} form highly disordered phases.[10] Only Sb^{3+} and Sn^{4+} form readily hexagonal sulfido and selenido frameworks of the type $CP_2M_xGe_4Q_{10+y}$ and are described here. The Sb/Ge_4Se_{10} analog features the smallest semiconductor energy gap reported so far in this class of materials.

The $CP_2M_xGe_4Q_{10+y}$ phases (denoted as CPMGeQ where M = Sb^{3+}, Sn^{4+} and Q = S, Se) were synthesized by the addition of a formamide (FM) solution of Sb^{3+} or Sn^{4+} in to a solution of supramolecularly organized $[Ge_4Q_{10}]^{4-}$ and CP surfactants in warm FM. In a typical experiment, $K_4Ge_4Q_{10}$ (1 mmol) and 4 g cetylpyridinium bromide monohydrate ($CPBr{\cdot}H_2O$) were dissolved in 20 mL of FM. On adding 1 mmol of SbI_3 or SnI_4 in 10 mL of FM to this solution precipitation occurs immediately. The mixtures were aged for 24 h at 80 °C, filtered, washed with hot FM and methanol and dried under vacuum. The sulfide phases were yellow and the selenides were brown in color. The elemental C, H, N and EDS analyses of these phases are given in Table 1. These analyses did not show potassium or halide ions in the products. Thermal gravimetric analyses (TGA) are in agreement with the C, H, N analyses results (see Table 1). The results suggest chemical formulae $CP_2Sb_{1.3}Ge_4S_{11}$, $CP_2Sn_{1.6}Ge_4S_{11.8}$, $CP_2Sb_{1.5}Ge_4Se_{11.5}$ and $CP_2Sn_{1.7}Ge_4Se_{12.3}$ for the mesophases. The compositions observed are similar to those reported for $CTA_2M_2Ge_4S_{10}$ (M = Ni^{2+}, Zn^{2+}, Co^{2+}, Cu^{2+})[11] and $CPM^{III}GeS$ (M^{III} = Ga and In) phases.[9] The charge balance of the CP^+ and Sb^{3+}/Sn^{4+} cations in the compounds is presumably achieved by both $Ge_4Q_{10}^{4-}$ clusters and Q^{2-}

anions.[12] Such framework materials incorporating mixed $[Ge_4S_{10}]^{4-}/[S^{2-}]$ species have already been observed in the crystal structure of TMACuGS-2 (TMA = tetramethylammonium).[13]

Powder X-ray diffraction (XRD) patterns of the CPSbGeQ phases (Fig. 1) show a strong peak followed by two weak reflections at $2 < 2\theta < 6°$, similar to those of hexagonal mesoporous silica.[4] The three peaks could be indexed in a hexagonal unit cell as (100), (110) and (200) reflections with a_H lattice parameter of 40.0(6) and 42.2(6) Å for the sulfide and selenide phases, respectively. The presence of well defined higher order (110) and (200) reflections in the XRD patterns of CPSbGeQ indicate that the pores of the inorganic framework posses long range hexagonal order. In the CPSnGeQ phases, the first strong peak could be indexed as the (100) reflection of hexagonal lattice with a_H parameter of 39.7(6) and 41.3(6) Å for CPSnGeS and CPSnGeSe respectively. However, the higher order (110) and (200) reflections are not well resolved giving a broad peak at $3 < 2\theta < 6°$. This is attributed to the smaller coherence lengths of the hexagonal regions arising from disordered pore regions occurring in between. This is observed in the TEM images discussed below.

The pore organization of CPSbGeQ phases was readily observed by transmission electron microscopy (TEM). Fig. 2(a) shows typical TEM image of CPSbGeS with the uniform hexagonal arrangement of pores occupied by the assembly of CP molecules. The pore to pore separations are in good agreement with those obtained from the powder XRD data. Fig. 2(b) shows a characteristic TEM image of CPSnGeS down the pore channel axis. In this case (and in CPSnGeSe), the TEM image shows that the hexagonal domains are smaller (< 30 nm) and separated by disordered domains with worm-holes. This is consistent with the powder XRD patterns discussed above.

IR spectroscopy of the CPMGeQ phases shows the fingerprint pattern of the adamantane Ge_4Q_{10} clusters. For example, CPSbGeS showed broad bands at 470, 426, 383 and 302 cm^{-1}. The band at 426 cm^{-1} corresponds to the terminal sulfur stretching modes of the adamantane Ge_4S_{10} cluster bonded to metal cations and that at 383 cm^{-1} is due to vibrations of the inner cage Ge_4S_6.[14] These bands occur at 307 and 285 cm^{-1} in the corresponding Se phase.

The oxidation state of Sn in CPSnGeQ was probed with ^{119}Sn Mössbauer spectroscopy, a powerful tool for the characterization of tin compounds. The observed spectra show one type of Sn present in the structure with isomer shift (IS) and quadrupole splitting of 1.11, 0.45 mm s^{-1} for CPSnGeS and 1.49, 0.40 mm s^{-1} for CPSnGeSe, respectively, Fig. 3(a). These values are fully consistent with a Sn^{4+} oxidation state and confirm that no reduction of the metal has taken place.[15]

Optical absorption spectroscopy of the mesostructured chalcogenides show well defined sharp band gaps in the range 1.7–2.8 eV [Fig. 3(b), Table 1]. These energies lie in the same range as several useful semiconductors such as CdS, CdSe, GaP *etc*. Therefore, these materials may be potentially interesting, for a number of opto-electronic investigations. CPSnGeQ phases have higher band gaps than the corresponding Sb^{3+} phases. The band gaps for the selenium compounds generally occur at lower energies than those of the corresponding sulfur analogs. Accordingly, CPSbGeSe showed the lowest band gap (1.74 eV) in the CPMGeQ systems reported here.

The CPSbGeS phase shows intense photoluminescence (PL) when excited with light above the band gap. [Fig. 3(c)]. With an excitation line of 3.48 eV (356 nm) green emission was observed at 77 K, with a maximum at 2.35 eV (528 nm).[16] The PL originates most likely from the pyridinium chromophore[17] but it is believed to involve the inorganic framework as well. This is because each component alone (surfactant or framework) is not capable of producing the observed response. Typically the pyridinium chromophore alone emits at much higher energy 2.87 eV (432 nm). Further, removal of the pyridinium group at 250 °C under vacuum, resulted in the loss of PL property. Because both the organic and the inorganic components are required for green emission, the reported materials are true nanocomposites.

The support of this research by NSF-CRG grant CHE 99-03706 is gratefully acknowledged. This work made use of the SEM and TEM facilities of the Center for Advanced Microscopy, MSU.

12 The source of Q^{2-} (Q = S, Se) ions could be adventitious K_2Q present in the starting material $K_4Ge_4Q_{10}$ or fragmentation of $[Ge_4Q_{10}]^{4-}$ clusters. The lack of a characteristic signature for Q^{2-} makes it difficult to detect and characterize these species by standard techniques.

16 In contrast CPSnGeSe and CPSbGeSe do not show PL at 77 K suggesting that the lower band gap frameworks quench the PL.
17 The PL may originate from the pyridinium chromophore of the surfactant, yet excitation spectra show that PL is observed even with excitation energies below the π–π transition of pyridinium.

Synthesis of aza-*C*-galacto disaccharides from C1-substituted galactals

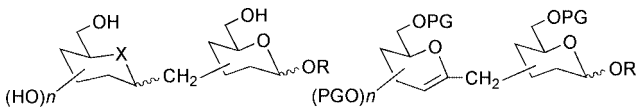
Xuhong Cheng, Govindaraj Kumaran and David R. Mootoo*

Department of Chemistry, Hunter College/CUNY, 695 Park Avenue, New York, New York 10021, USA. E-mail: dmootoo@shiva.hunter.cuny.edu

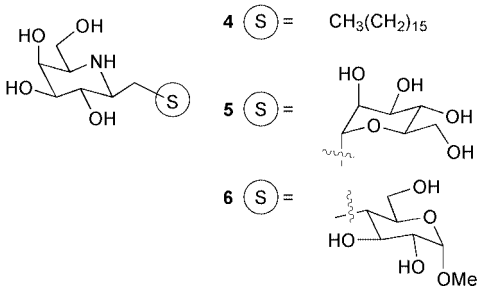
Received (in Corvallis, OR, USA) 15th February 2001, Accepted 13th March 2001
First published as an Advance Article on the web 17th April 2001

C1-substituted galactals are transformed *via* the double reductive amination on their 1,5-diketone derivatives, to aza-β-*C*-galacto-disaccharides.

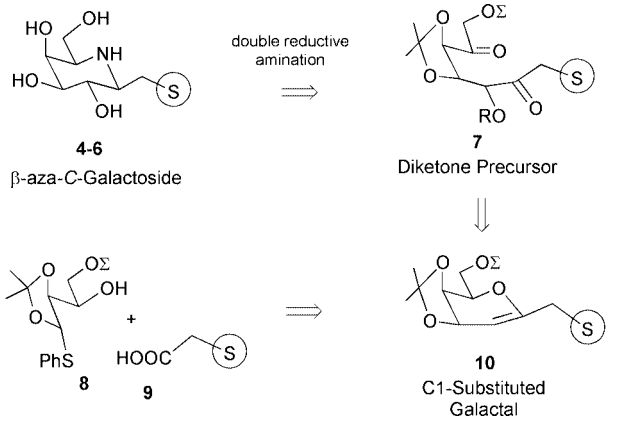
Interest in polyhydroxylated azaheterocycles as biochemical tools and therapeutic agents has been extensively documented.[1] Attention has focused on their potent activity as glycosidase inhibitors.[1,2] Guidelines for the design of glycone specific glycosidase inhibitors are well known, but models for aglycone specific inhibitors,[2] or for mimetics associated with other carbohydrate mechanisms are not as well developed.[3] Structures with a high degree of structural complexity, for example as found in disaccharide analogues, are of interest as probes of recognition specificity.[2a,b] Of these, *C*-disaccharides (*e.g.* **1**, **2**) have the added benefit of stability towards chemical and enzymic hydrolysis. We and others have shown that C1-substituted glycals **3** are attractive precursors to *C*-disaccharides **1**.[4–6] Herein, we illustrate the versatility of such C1 substituted glycals, by the synthesis of the novel, biologically interesting aza-β-*C*-galactosides **4**–**6**. N-linked lipid iminocyclitols related to **4** have recently shown potential as inhibitors of gp-120/galactosylceramide binding.[3c] Azasugar **5** is an analog of the ubiquitous lactose subunit and **6** is a potential mimetic of a recently discovered selectin antagonist.[7]



1 X = O *C*-Disaccharide
2 X = NH Aza-*C*-Disaccharide
3



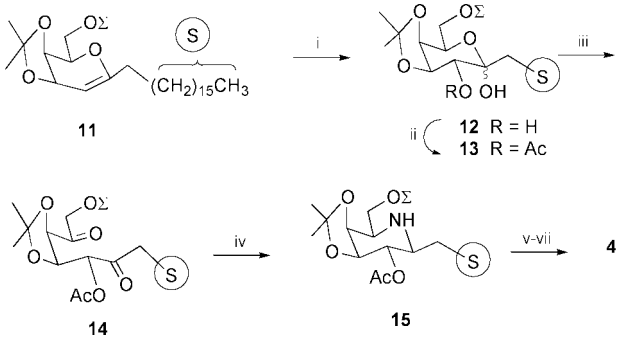
We envisaged a route to aza-*C*-disaccharides which is based on the stereoselective double reductive amination on a complex diketone **7** (Scheme 1).[8] Our optimism was guided by several examples of highly stereoselective double reductive aminations in polyhydroxylated dicarbonyl substrates.[9] An attractive aspect of this approach is the introduction of the amine in a single operation at a relatively late stage in the synthesis, thereby reducing protecting group inefficiencies. In addition the synthetic precursors are C1-substituted glycals which may be assembled *via* convergent syntheses, and therefore appropriate for complex disaccharide structures. Prompted by a recent report of a similar double reductive amination strategy to aza-β-(1 → 6)-*C*-disaccharides,[10] we describe a preliminary account of our results. In the former case, the diketone substrates were prepared from 'disaccharide' ketal precursors, obtained *via* the



Scheme 1

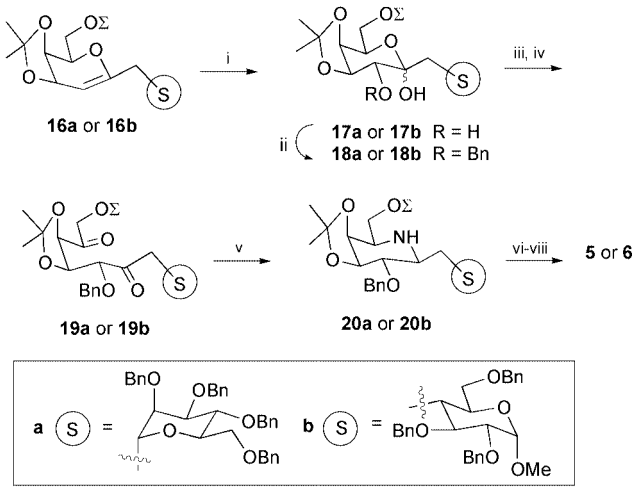
addition of monosaccharide lithio acetylides to pyranolactones. While applicable to 1 → 6 type disaccharide systems, this type of organometallic coupling strategy is not generally applicable to methylene linked structures (*e.g.* 1 → 2, 1 → 3 and 1 → 4 linked disaccharide analogues). By comparison, the diketones in our approach are obtained through dihydroxylation of C1-substituted glycals (*e.g.* **10**). Such glycals may be obtained through our oxocarbenium ion cyclization methodology, starting from the ester derived from the 1-thio-1,2-isopropylidene acetal (TIA)-alcohol **8** and the acid partner **9**,[4] or *via* other protocols.[6] The esterification reaction used for the 'glycone'–'aglycone' coupling is experimentally straightforward and allows access to C1-pyrano substituted glycals (and hence *C*-disaccharide derivatives) with intersaccharide linkers of any length.

The methodology was first applied to the galactal **11** (Scheme 2). Dihydroxylation of **11** with osmium tetroxide–NMNO proceeded with complete α-selectivity to provide lactol **12** in 80% yield. Selective acetylation of **12** and PCC oxidation of the monoacetate **13** led to the diketone **14** in 78% overall yield from **12**. Treatment of **14** with 1.5 equiv. of $NaCNBH_3$, 1.2 equiv. of ammonium formate in anhydrous methanol in the presence of freshly activated 4 Å molecular sieves afforded the



Scheme 2 (i) OsO_4, NMNO, acetone, 80%; (ii) Ac_2O, DMAP, EtOAc, 95%; (iii) PCC, CH_2Cl_2, NaOAc; Celite, 4 Å MS, 82%; (iv) $NaCNBH_3$, NH_4HCO_2, 4 Å MS, anhyd. MeOH, 72%; (v) NaOMe, MeOH; (vi) Bu_4NF, THF; (vii) HCl, MeOH, 58% over three steps.

DOI: 10.1039/b101598m

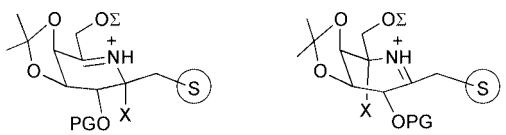


Scheme 3 (i) OsO_4, NMNO, acetone, **17a** (81%), or K_3FeCN_6, DBU, acetone, **17b** (83%); (ii) BnBr, AgOTf, CH_2Cl_2, **18a** (87%), **18b** (62%); (iii) $NaBH_4$, EtOH; (iv) Swern's Ox. **19a** (60%), **19b** (64%), over two steps; (v) $NaCNBH_3$, NH_4HCO_2, 4 Å MS, anhyd. MeOH, **20a** (72%), **20b** (68%); (vi) Bu_4NF, THF; (vii) HCl, MeOH; (viii) H_2, Pd/C, EtOH, HCOOH, **5** (67%), **6** (60%) over three steps.

aza-β-*C*-galactoside **15** as a single stereoisomer in 72% yield.[11] The stereochemistry of **15** was assigned on the basis of *J* values ($J_{1,2}$ = 9.9, $J_{2,3}$ = 7.7, $J_{3,4}$ = 5.1, $J_{4,5}$ = 2.2 Hz) and observation of 1% NOE effects between H1, and H3 and H5 respectively.[12] Removal of protecting groups in **15** under standard conditions provided the desired aza-β-*C*-galactoside **4** in 58% overall yield from **15**.[13]

Dihydroxylation of galactal **16a** (Scheme 3) under the aforementioned conditions produced a single ketal **17a** in 80% yield. These conditions led to lower yields for the reaction of the gluco linked galactal **16b**. However use of potassium ferricyanide instead of NMNO as co-oxidant in the presence of DBU led to high yield of the desired hydroxy ketal **17b**.[14] Although the secondary alcohols in **17a,b** could be selectively converted to their acetate derivatives, this protecting group proved to be incompatible with subsequent steps. Compounds **17a,b** were therefore converted to the respective benzyl ethers **18a,b**. Unlike the case for ketal **12**, direct oxidation of **18a,b** to the requisite diketones was not successful. Diketones **19a,b** were eventually obtained *via* a two step reduction–oxidation procedure on **18a,b**. Treatment of **19a,b** under reductive amination conditions provided the *C*-aza derivatives **20a,b** in 72 and 64% yields respectively. The stereochemistry in **20a,b** was assigned from NOESY experiments in a similar fashion as described for **15**. Standard deprotection procedures on **20a** and **20b** provided the desired β-aza-*C*-disaccharides **5** and **6** respectively.[15]

The high stereoselectivity of these double reductive aminations is consistent with the model developed by Stevens for the hydride reduction of six membered cyclic iminium ions.[16] Thus preferred α-face reduction on imium ions like **21** and **22** would



lead to the observed β-aza-*C*-galacto motif. The observation of the same sense of stereochemical bias in gluco and manno type diketones, supports this stereochemical model.[8c,10] Therefore, given the availability of C1-substituted glucals and galactals, and the amenability of such compounds to conversion to different C2 substituted ketals, the methodology described herein is expected to provide access to a wide variety of aza-β-*C*-glycosides. These directions are currently being explored.

We thank the National Institutes of Health (NIH), General Medical Sciences (GM 57865) for their support of this research. 'Research Centers in Minority Institutions' award RR-03037 from the National Center for Research Resources of the NIH, which supports the infrastructure (and instrumentation) of the Chemistry Department at Hunter, is also acknowledged.

First published as an Advance Article on the web 6th April 2001

The reaction of (CF$_3$)$_2$C=C(F)CF$_2$CF$_3$ or CF$_3$CF=CF$_2$ with Ru(dmpe)$_2$H$_2$ affords the bifluoride fluoride complex *cis*-Ru(dmpe)$_2$F(F···HF), whereas reaction with Ru(dcpe)$_2$H$_2$ yields the cation [Ru(dcpe)$_2$H]$^+$ with [(CF$_3$)$_2$C=C(O)CF$_2$CF$_3$]$^-$ as the anion.

Considerable advances have been made in the past few years on the activation of carbon–fluorine bonds and there is now a wide range of both early and late transition metal complexes available that can be employed in this regard.[1] Among these studies, several metal hydride complexes stand out due to their ability to cleave both saturated and unsaturated perfluorocarbons under very mild conditions.[2] Indeed, Rh(PMe$_3$)$_4$H has proved sufficiently active to bring about the catalytic hydrogenation of C$_6$F$_6$ to C$_6$F$_5$H with only very mild heating.[3] In most of these cases, C–F activation is accompanied by elimination of HF, which provides a strong thermodynamic driving force for the reaction, to give metal hydride products.

We have previously reported that *cis*-Ru(dmpe)$_2$H$_2$ (**1**, dmpe = Me$_2$PCH$_2$CH$_2$PMe$_2$) activates the C–F bond in C$_6$F$_6$ at −78 °C to give *trans*-Ru(dmpe)$_2$(C$_6$F$_5$)H, thus releasing HF, which subsequently reacts with **1** to form the bifluoride hydride complex *trans*-Ru(dmpe)$_2$H(FHF), **2**.[4] This facile C–F activation by Ru(dmpe)$_2$H$_2$ prompted us to investigate its reactivity with other unsaturated fluorocarbons. Thus, we now report that **1** reacts with (CF$_3$)$_2$C=C(F)CF$_2$CF$_3$ or CF$_3$CF=CF$_2$ to give the bifluoride fluoride complex, *cis*-Ru(dmpe)$_2$F(F···HF), **3**, in preference to a hydride product. In contrast, Ru(dcpe)$_2$H$_2$ [dcpe = (C$_6$H$_{11}$)$_2$PCH$_2$CH$_2$P(C$_6$H$_{11}$)$_2$] reacts with the same perfluoroalkenes to give the 16-electron hydride species [Ru(dcpe)$_2$H]$^+$ and a perfluoroenolate anion.

Treatment of a benzene or THF solution of **1** with (CF$_3$)$_2$C=C(F)CF$_2$CF$_3$ (ratio 1 : 1) at room temperature results in the rapid formation of **2** and *cis*-Ru(dmpe)$_2$F(F···HF) **3** (ratio *ca.* 1 : 4) as shown by multinuclear NMR spectroscopy.† The ^{1}H NMR spectrum of **3** in C$_6$D$_6$ exhibited a doublet at δ 14.2 with a $^1J_{HF}$ coupling constant of 328 Hz. The corresponding ^{19}F NMR spectrum displayed a doublet at δ −174 with the same coupling constant and two broad multiplets at δ −343 and −362 corresponding to the two types of Ru–F bond. The ^{31}P{^{1}H} NMR spectrum of **3** showed a complex multiplet at δ 57 and an 'apparent' quintet signal at δ 42. The latter was assigned to the mutually *trans* P atoms which show similar couplings to both *cis*-P and *cis*-F atoms. GC–MS analysis of the fluoro-organic products showed that a mixture of four compounds with *m*/*z* 246 [*i.e.* replacement of 3F by 3H in (CF$_3$)$_2$C=C(F)CF$_2$CF$_3$] was formed, although it has not proved possible to characterise this mixture any further using multinuclear NMR.

When the same reaction was conducted in the presence of ten equivalents of Et$_3$N, the formation of **2** was completely suppressed, allowing the isolation of **3**. The X-ray crystal structure determination of **3**‡ (Fig. 1) shows the *cis* disposition of the two fluoride ligands and a strong hydrogen bonding interaction between one of them and the HF moiety. The Ru–FHF bond length is significantly lengthened [2.168(3) Å] compared to the unperturbed Ru–F bond [2.101(3) Å]. Both Ru–F distances are noticeably longer than those found in the difluoride complex *cis*-Ru(dppp)$_2$F$_2$ (dppp = Ph$_2$PCH$_2$CH$_2$CH$_2$PPh$_2$) (average 2.06 Å), which is the only other well characterised ruthenium fluoride complex that is not stabilised by carbonyl ligands.[5] A comparison of the F···F distance in **3** and related complexes reveals that the value of 2.292(8) Å is slightly longer than that in the bifluoride complex **2** [2.276(8) Å][4] but considerably shorter than the corresponding distances in M(PMe$_3$)$_4$H$_2$F(FHF)[6] [M = Mo, 2.351(8) Å; M = W, 2.390(13) Å] or Pd(PPh$_3$)$_2$(Ph)FHF (2.36 Å).[7] The M–F···F unit is bent in all of these cases with an angle at the metal-bound fluorine in the range 129–157°. The Ru–F···F angle in **3** is 142°. These data suggest that Ru(dmpe)$_2$F(F···HF) is most accurately described as a bifluoride fluoride complex in the solid state, although in solution the magnitude of J_{HF} points to a weakening of the Ru–F···H--F interaction.

A change of the chelating phosphine from dmpe to dcpe results in a dramatic change in the reactivity at the metal centre which allows the fate of the fluorocarbon to be more accurately determined. Although Ru(dcpe)$_2$H$_2$ shows no reaction towards C$_6$F$_6$, even upon heating to 80 °C, addition of an equimolar amount of (CF$_3$)$_2$C=C(F)CF$_2$CF$_3$ in benzene gives orange crystals in 31% yield at room temperature overnight. A single crystal X-ray diffraction study confirmed these crystals to be [Ru(dcpe)$_2$H]$^+$[(CF$_3$)$_2$C=C(O)CF$_2$CF$_3$]$^-$, **4**, (Fig. 2).‡ While the gross structure is similar to that reported by Winter and Hornung for the [BPh$_4$] salt,[8] there are some differences between the structural parameters in our structure which we attribute to crystal packing effects. In the perfluoroenolate anion, lengthening of the C=C bond [1.426(9) Å] and shortening of the C–O bond [1.228(7) Å] suggest delocalisation of charge across the C=C–O unit.[9] Formation of [(CF$_3$)$_2$C=C(O)CF$_2$CF$_3$]$^-$ arises from hydrolysis by adventitious water, since addition of excess water (10 equivalents) to a

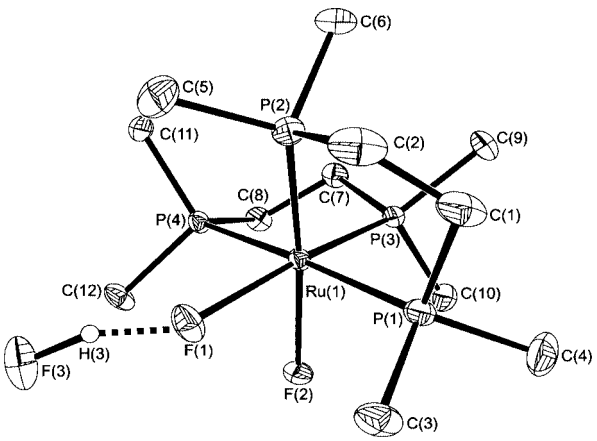

Fig. 1 ORTEX view of the molecular structure of **3**. Ellipsoids are shown at the 30% level. Principal bond lengths (Å) and angles (°): Ru–F(1) 2.168(3), Ru–F(2) 2.101(3), F(1)–F(3) 2.292(8); F(3)–F(1)–Ru 141.8(2), F(1)–Ru–F(2) 85.4(1).

DOI: 10.1039/b009862k

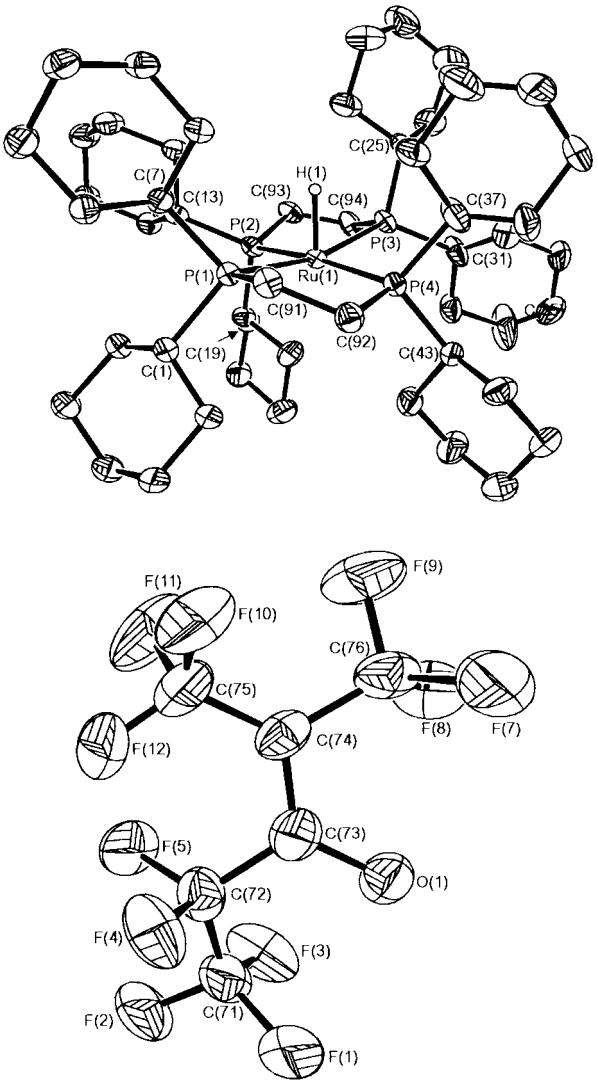

Fig. 2 ORTEX view of the molecular structure of **4**. Ellipsoids are shown at the 30% level. Selected bond distances (Å) and angles (°): C(72)–C(73) 1.514(10), C(73)–C(74) 1.426(9), C(73)–O(1) 1.228(7); P(2)–Ru–P(3) 81.62(4), P(1)–Ru–P(4) 83.56(4).

1 : 1 mixture of $Ru(dcpe)_2H_2$ and $(CF_3)_2C{=}C(F)CF_2CF_3$ affords **4** in quantitative yield in 12 hours. The $^{31}P\{^1H\}$ NMR spectrum† of **4** in d_8-THF displayed a singlet at δ 73.4 whereas the proton NMR showed a high field quintet at $\delta -31.9$ (J 19.22 Hz), in agreement with the reported values for $[Ru(dcpe)_2H]^+$.[8] The ^{19}F NMR spectrum of **4** showed the expected four resonances for the anion.[10]

Addition of hexafluoropropene to the dihydride complexes resulted in very similar reactivity to that seen with $(CF_3)_2C{=}C(F)CF_2CF_3$. Addition of 1 atmosphere of $CF_3CF{=}CF_2$ to a THF solution of **1** resulted in the formation of **3** as the only inorganic product. Analysis of the fluoro-organic products by ^{19}F NMR revealed the presence of both *Z*- and *E*-$CF_3CF{=}CFH$ and $CF_3CF{=}CH_2$ in a ratio 4 : 1 : 3. Addition of $CF_3CF{=}CF_2$ to a THF solution of $Ru(dcpe)_2H_2$ gave $[Ru(dcpe)_2H]^+$ with $[(CF_3)_2C{=}C(O)CF_2CF_3]^-$ unexpectedly present as the anion.

In summary, we have shown that the pathways for C–F bond activation of perfluoroalkenes by $Ru(P{-}P)_2H_2$ is highly dependent upon the phosphine substituents. The mechanism(s) surrounding the formation of **3** and **4** are presently under investigation.

We thank EPSRC and the University of Bath for financial support, Johnson Matthey plc for the loan of $RuCl_3$ and Dr Michael Rüf of Bruker AXS GmbH Analytical X-Ray Systems for collecting data on compound **3**. We thank Dr Trevor Dransfield (University of York) for GC–MS measurements and wish to acknowledge Professors R. N. Perutz (University of York) and W. D. Jones (University of Rochester) for helpful discussions.

A low band gap conjugated metallopolymer with nickel bis(dithiolene) crosslinks

Christopher L. Kean and Peter G. Pickup*

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X7. E-mail: ppickup@mun.ca

Received (in Cambridge, UK) 16th January 2001, Accepted 16th March 2001
First published as an Advance Article on the web 6th April 2001

A low band gap conjugated metallopolymer has been prepared by the electrochemical polymerization of bis[1,2-di(2-thienyl)-1,2-ethenedithiolene]nickel.

The incorporation of transition metal complexes into conjugated organic polymers offers a new dimension for the development of advanced electronic, catalytic, and sensing materials.[1,2] Dithiolene complexes[3] are attractive building blocks for such systems because of their aromaticity, and the ease of reduction (n-doping) of the aromatic system. The observation of superconductivity[4] and non-linear optical properties[5,6] in metal dithiolene salts provides great incentive for their hybridization with conjugated polymers.[2]

We report here on a dithiolene based conjugated metallopolymer prepared by the electrochemical polymerization of bis[1,2-di(2-thienyl)-1,2-ethenedithiolene]nickel **1**.[7] The extensive conjugation of this complex, and the electron donating effect of the peripheral thiophenes make it an attractive unit for constructing intrinsic (neutral) molecular conductors.[8]

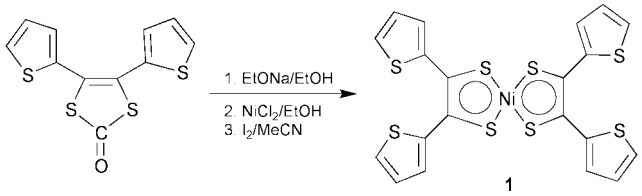

Fig. 1(a) shows a cyclic voltammogram of **1**† in solution. Reversible waves appear at formal potentials (*vs.* SSCE) of $E^{\circ\prime}(-1 \leftrightarrow -2) = -0.66$ V, $E^{\circ\prime}(0 \leftrightarrow -1) = +0.13$ V, $E^{\circ\prime}(+1 \leftrightarrow 0) = 1.08$ V, and an irreversible oxidation (not shown) begins at *ca.* +1.26 V. The first two waves have been assigned as reductions of the aromatic metal dithiolene unit to the anion and dianion by analogy with the electrochemistry of other ditholene complexes.[9] The third wave ($E^{\circ\prime} = +1.08$ V) must then be due to oxidation of the complex to the cation. The reversibility of this wave suggests that the positive charge is localized on the metal dithiolene unit. However, since cycling into this wave leads to deposition of a polymer on the electrode surface, there is presumably some delocalization onto the peripheral thiophene rings. Cycling into the forth (irreversible) wave at higher potentials leads to more rapid polymer deposition and therefore this wave must correspond to oxidation of one or more of the thiophene rings.

Fig. 1(b) show cyclic voltammograms of a poly-**1** coated electrode‡ in the absence of **1** in solution. The new broad wave starting at +0.5 V is characteristic in both shape and position of a conjugated oligothiophene backbone, and provides clear evidence that anodic polymerization of **1** has occurred at the vacant α-positions of the thiophenes. The oxidation current increases sharply at potentials higher than the limit of +1 V used for Fig. 1(b), and this leads to loss of the polymer's electrochemistry, which is again consistent with an oligothiophene-based material. The two Ni–dithiolene based waves seen for the monomer (at −0.66 and +0.13 V) are both retained by the polymer, indicating that the Ni–dithiolene center remains intact. The anodic shifts of these waves (to −0.49 and +0.19 V) are due primarily to the change in junction potential (*ca.* 80 mV) on changing the electrolyte to MeCN + Et_4NClO_4. Their broadening and splitting into multiple overlapping waves can be attributed to the variety of slightly different Ni sites that would arise from factors such as coupling of different combinations of the four peripheral thiophenes, different conjugation lengths, and defects causes by the reaction of peripheral thiophenes with trace water in the solvent. The unusual voltammetric wave shapes observed for the polymer and the apparent lack of reversibility are presumably due to ion transport effects which commonly produce complex voltammetric behaviours for polymer films.

Fig. 2 shows electronic absorption spectra of **1** in solution, and a poly-**1** film on an indium/tin oxide electrode at various

potentials. Comparing the monomer spectrum with that of the polymer at +0.45 V (same oxidation state), it is seen that the monomer π–π^* absorbance at 973 nm is shifted significantly to higher wavelength (1193 nm) in the polymer, which is consistent with the increase in energy of the HOMO that would result from its extended delocalization in the polymer and is evidenced by the decrease in potential of the thiophene based electrochemistry in Fig. 1. The new absorbance seen as a shoulder at *ca*. 450 nm for the polymer is consistent with an expected π–π^* transition for a conjugated oligothiophene-like backbone.

Partial oxidation of the polymer (at +0.8 V) causes a partial bleaching of the complexes π–π^* absorbance and an increase in absorbance at *ca*. 800 nm. These changes are consistent with partial depletion of the π band, and the formation of polaron or bipolaron states within the polymer's band-gap. Reduction of the polymer at -0.7 V causes bleaching of the Ni complex's π–π^* absorbance, consistent with the filling of its LUMO (π^*) band.

Preliminary conductivity measurements by impedance spectroscopy and using an interdigitated array electrode indicate that the electronic conductivity associated with the 0/-1 mixed valent state is *ca*. 10^{-6} S cm^{-1}, and that oxidation (p-doping) of the backbone at +1 V increases the conductivity to *ca*. 10^{-4} S cm^{-1}. Although these conductivities are disappointing, they should be regarded as lower limits that can be improved by optimization of the film forming procedure. The band gap of poly-**1**, estimated from the onset of the 1193 nm absorbance, is < 0.8 eV (*ca*. 0.35 eV based on the difference between $E^{0\prime}(0 \leftrightarrow -1)$ and the onset of the backbone oxidation at *ca*. +0.54 V), which offers significant promise for the development of intrinsic conductors.

The presence of four peripheral thiophene rings on **1** presumably results in a highly crosslinked polymer without extended linear chains. Better electronic conductivities may therefore be achieved by using **1** as a crosslinking agent in a linear polymer (*e.g*. by copolymerization with bithiophene), or by use of similar complexes with fewer thiophene substituents. Both of these approaches are currently being explored.

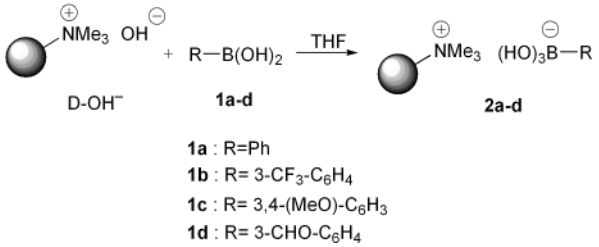
Aryl boronic acids can be trapped by an ammonium hydroxide-form Dowex® Ion Exchangers resin (D-OH$^-$) leading to polymer-ionically bound borates and cyclized, when properly designed, into macroheterocycles under Suzuki–Miyaura coupling conditions.

Biarylcyclopeptides are important targets[1] since such compounds are potentially promising therapeutic agents.[2] The solid phase synthesis of macrocyclic systems involving a transition metal catalysed C–C bond formation is a current challenge investigated with polymer-covalently bound precursors.[3] However, such synthetic strategies involving an aryl–aryl coupling at a final stage are scarse. To the best of our knowledge, only one example describing the synthesis of a β-turn mimic *via* a Suzuki–Miyaura ring-closing reaction has been reported.[4] These approaches generally required sophisticated multistep synthesis on the solid support prior the crucial C–C bond formation.

In this context, we thought that the application of the 'resin-capture–release' hybrid technique[5] to the generation of polymer supported borate species bearing a remote aryl halide moiety followed by a releasing cyclisation under Suzuki–Miyaura's conditions could bring an efficient and easy solution to the synthesis of biarylic macrocyles. In order to check this idea, we developed a simple resin-capture method to immobilize arylboronic acids species by reaction with macroporous ammonium hydroxide-form Dowex® Ion Exchangers resin (D-OH$^-$) as B^{IV}-arylborates. The simple addition of a dilute THF solution of boronic acids **1** onto D-OH$^-$ resin resulted in the quaternization of the boron atom, leading to the formation of the corresponding immobilized hydroxyborate adduct **2** (Scheme 1).

Loading of the resin was easily achieved and controlled with **1a–d** featuring various functionalities. In all cases, about 75% of the given theoretical capacity (*ca.* 1.6 mmol g^{-1} of dry resin) can be reached.[6] The strength of this ionic linkage was evaluated by submitting the phenylhydroxyborate resin **2a** (as a representative example) to continuous extraction with Soxhlet apparatus. With water as solvent, only 10% leaching of **1a** from **2a** was observed after 72 h while no leaching could be detected after 18 h using THF. Another interesting feature is that despite their total insolubility, resins **2** can be readily analysed by standard ^{11}B NMR spectroscopic methods as a heterogeneous suspension in classical solvents. The NMR spectra of such



Scheme 1 Resin-capture of arylboronic acids.

First published as an Advance Article on the web 6th April 2001

The decrease of the magnetic response under irradiation at very low temperature was interpreted as a new evidence of synergy between magnetic interaction and spin transition in an iron(II) binuclear SC compound.

The design and the synthesis of polynuclear complexes with versatile chemical and physical properties are of current interest in the areas of molecule-based electronic, photochemistry and magnetism. The goal is to develop novel materials whose properties can be controlled by the input of external information. In this context, particular interest has been focused on iron(II) spin-crossover (SC) compounds because they can be considered among the best examples of switchable coordination molecules. A reversible transition between the paramagnetic high-spin state (HS, $S = 2$) and the diamagnetic low-spin state (LS, $S = 0$) can be induced by a change in temperature, pressure or by light irradiation.[1] This latter effect opens some interesting perspectives to design optical switches. In 1984, Decurtins *et al.* discovered that by irradiation with green light the SC compound $[Fe(ptz)_6](BF_4)_2$ (ptz = 1-propyltetrazole) at 20 K could be converted from the stable LS state to the metastable HS state.[2] Later, Hauser reported the reverse-LIESST effect, wherein red light is used to convert back the compound into the LS state.[3]

Up to now, most of the SC compounds exhibiting LIESST properties are assemblies of monomeric units with through-space rather than through-bond interactions. Allowing SC centers to communicate by chemical bridges, *i.e.* oligomeric or polymeric species, is an important strategy to explore and enhance cooperativity of a given system.[4,5] Along this line, binuclear compounds of formula $[\{Fe(L)(NCX)_2\}_2(bpym)]$ (L = bpym (2,2′-bipyrimidine), bt (2,2′-bithiazoline) and X = S, Se) represent one of the most unusual family in the SC field. These compounds are the simplest example of polynuclear SC complexes exhibiting a rich variety of magnetic regimes. Further, they are the only iron(II) example where the interplay between both spin crossover and intramolecular magnetic exchange phenomena are present in the same molecule. In $[\{Fe(bpym)(NCS)_2\}_2(bpym)]$ the two iron(II) ions are in the HS state and couple antiferromagnetically through the bridge bpym ($J = -4.1$ cm^{-1} in the zero-field Hamiltonian $H = -JS_AS_B$) giving an $S = 0$ ground pair state HS–HS at low temperature.[6] In contrast, $[\{Fe(bpym)(NCSe)_2\}_2(bpym)]$ shows a one-step transition involving 50% of iron atoms at $T_c = 125$ K,[7] whereas an almost complete two-step spin transition in the range 160–210 K takes place for $[\{Fe(bt)(NCS)_2\}_2(bpym)]$.[8] This behavior was interpreted in terms of the occurrence of LS–LS ↔ LS–HS ↔ HS–HS pair spin states in each binuclear unit.[8] The stabilisation of the LS–HS mixed spin pair was assigned to the synergy effect between anticooperative intramolecular and cooperative intermolecular interactions.

Recently, we have reported the unusual photomagnetic behavior stemming from the interplay between spin-crossover and magnetic coupling phenomena.[9] At low temperature, light switches $[\{Fe(bt)(NCS)_2\}_2(bpym)]$ from the $S = 0$ spin state of the LS–LS pair to the $S = 0$ spin state of the HS–HS pair. Warming the sample first reveals the latent magnetic coupling between the HS iron(II) ions as the $S = 1$, 2, 3 and 4 excited states are populated, then switches off this virtual pair spin state at temperatures as high as 60 K where molecules have enough energy to overcome the barrier associated with the change of molecular geometry upon spin conversion. As a continuation of this study we have investigated the LIESST effect on $[\{Fe(bpym)(NCSe)_2\}_2(bpym)]$. As mentioned above, this compound exhibits an incomplete thermal spin transition interpreted in terms of HS–HS ↔ LS–HS conversion at 125 K (Fig. 1). The slight decrease of the magnetic response as T approaches absolute zero is due to zero-field splitting of the $S = 2$ spin state of the mixed-spin pair.

At 10 K, we observed that green light irradiation (530.9 nm, power 10 mW cm^{-2})[10] induces a decrease of $\chi_M T$ from 2.6 to 1.6 cm^3 K mol^{-1}. Similar behavior was recorded at 647–679, 759–799 and 830 nm. Usually, the observation of a decrease in the magnetic response under light irradiation is a signature of reverse-LIESST as the HS state is converted into the LS state. However, for $[\{Fe(bpym)(NCSe)_2\}_2(bpym)]$ this situation is no longer valid because of the occurrence of the unusual HS–LS state and the virtual excited HS–HS state which involves a latent antiferromagnetic interaction similar in magnitude as observed for $[\{Fe(bt)(NCS)_2\}_2(bpym)]$.[9] Hence, a decrease of the magnetic response should be expected upon irradiation.

Fig. 1 compares $\chi_M T$ *vs.* T (χ_M is the molar magnetic susceptibility and T the temperature) of the photoinduced

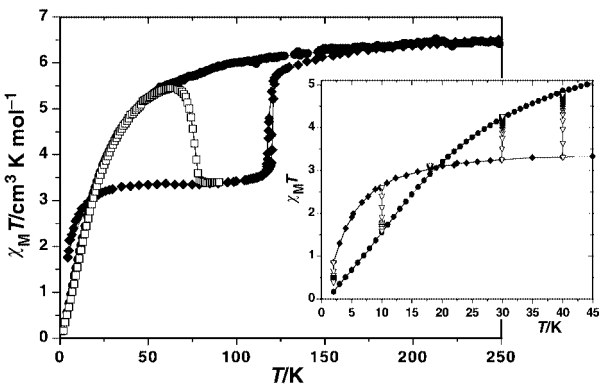

Fig. 1 $\chi_M T$ *vs.* T for (◆) $[\{Fe(bpym)(NCSe)_2\}_2(bpym)]$ and (●) $[\{Fe(bpym)(NCS)_2\}_2(bpym)]$. (□) refers to the warming mode of $[\{Fe(bpym)(NCSe)_2\}_2(bpym)]$ after the irradiation was applied for 1 h at 10 K, then turned off. Inset: data obtained with irradiation (▽) for 1 h at 2, 10, 17, 30 and 40 K.

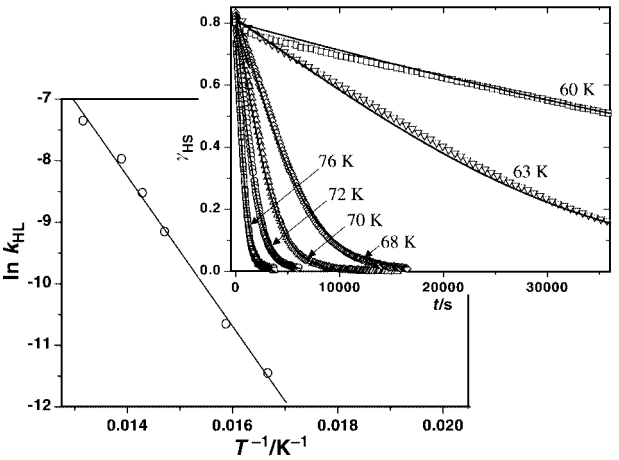

Fig. 2 Ln k_{HL} *vs.* 1/*T* curve of [{Fe(bpym)(NCSe)$_2$}$_2$(bpym)]. Inset: time dependence at various temperatures of the HS molar fraction generated by light irradiation at 10 K.

[{Fe(bpym)(NCSe)$_2$}$_2$(bpym)] with the binuclear [{Fe(bpym)(NCS)$_2$}$_2$(bpym)] compound containing two iron(II) ions in the HS–HS state in the whole temperature range.[6–8] Both magnetic responses are similar below 40 K. It is well known that the interaction parameter, *J*, in a coupled binuclear compound depends essentially on the nature of the chemical bridge. As for both compounds the bridging network is similar, in case of a quasi-quantitative LS–HS → HS–HS conversion (LIESST effect), the magnetic properties of [{Fe(bpym)(NCSe)$_2$}$_2$(bpym)] after irradiation and [{Fe(bpym)(NCS)$_2$}$_2$(bpym)] should be very similar. In contrast, a LS–LS population (reverse-LIESST) should lead to a diamagnetic ground state for [{Fe(bpym)(NCSe)$_2$}$_2$(bpym)] very different from the magnetic properties of [{Fe(bpym)(NCS)$_2$}$_2$(bpym)]. The data displayed on Fig. 1 are in favor of the first alternative.

Fig. 1 also shows the $\chi_M T$ value of [{Fe(bpym)(NCSe)$_2$}$_2$(bpym)] under light irradiation at 2, 10, 17, 30 and 40 K. In all cases, the photostationary point reached the $\chi_M T$ limit of [{Fe(bpym)(NCS)$_2$}$_2$(bpym)], confirming the HS–HS population.[11] What is remarkable is that at 17 K, both before and after irradiation, the compound has a similar magnetic response. This does not mean that the LIESST effect does not occur. In fact, we are faced with two totally different spin states. Before irradiation, the system acts as a HS–LS mixed-spin pair, resulting in a $S = 2$ spin state with a $\chi_M T$ value of 3 cm^3 K mol^{-1}. After irradiation, the two iron(II) are HS and coupled antiferromagnetically with a thermal population of the low-lying spin states, $S = 1$–4, located at energies $E(S) = -JS(S + 1)/2$ above the ground state $S = 0$. At 17 K, the population of the HS–HS pair, assuming a *J* factor of −4.1 cm^{-1} and a *g* value of 2.13, is 16% $S = 0$, 35% $S = 1$, 29% $S = 2$, 15% $S = 3$ and 5% $S = 4$. The resulting $\chi_M T$ value is then 3 cm^3 K mol^{-1} and similar to that of the HS–LS mixed-spin pair.

The kinetics of the relaxation were investigated from 2 K up to 75 K (Fig. 2). Below 55 K, the relaxation is very slow, for instance, at 10 K the magnetic response varies by *ca.* 0.01% in 13 h, which requires relaxation rates smaller than 10^{-6} s^{-1}. From 55 to 75 K, the dynamic of the relaxation is faster and falls within the time window of our set-up. This behavior matches the theory of HS → LS relaxation proposed by Buhks *et al.*[12] which predicts a temperature-independent relaxation rate, *i.e.* a tunneling process, at low temperature and an activation relaxation process at higher temperatures. The decays of the HS molar fraction, γ_{HS}, *vs.* time, at various temperatures, are also represented in Fig. 2; γ_{HS} is deduced from $[(\chi_M T)_{h\nu} - (\chi_M T)_{HS-LS}]/[(\chi_M T)_{AF} - (\chi_M T)_{HS-LS}]$.[13] An analysis of these data indicates that the relaxation curves can be satisfactorily fitted by a sigmoidal law.[14] This reflects a self-acceleration process as γ_{HS} decreases. The plot of ln k_{HL} *vs.* 1/*T* (Fig. 2) gives a straight line, with an activation energy $E_a = 850$ cm^{-1}, a pre-exponential factor $k_\infty = 6.6 \times 10^3$ s^{-1} and an additional activation energy associated to the cooperativity $E_a^* = 53$ cm^{-1}. Such parameters allow understanding of the shape of the T_c(LIESST) experiment[14] reported in Fig. 1. In the tunneling region where the kinetic of the relaxation back to the HS–LS state is very slow, the $S = 1$–4 spin states of the local HS–HS pair are progressively populated and $\chi_M T$ increases. Above 55 K, the relaxation process of the local HS–HS pair becomes thermally activated and a deviation appears with the magnetic properties of [{Fe(bpym)(NCS)$_2$}$_2$(bpym)]. The critical T_c(LIESST) temperature is found at 75 K.

In summary, this communication reports a new example of synergy between magnetic interaction and spin transition under light irradiation in an iron(II) binuclear SC compound. For the first time at very low temperature, the photoconversion of a LS–HS into a HS–HS pair, according to the LIESST effect, results in a decrease in the magnetic response. This behavior in the complex [{Fe(bpym)(NCSe)$_2$}$_2$(bpym)] arises from the conversion of the $S = 2$ initial state into an $S = 0$ low-lying spin state by light irradiation.

We are grateful for financial assistance from the European Commission for granting the TMR-Network 'Thermal and Optical Switching of Spin States (TOSS)', Contract No. ERB-FMRX-CT98-0199. Also we would like to thank the financial assistance of the Spanish DGICYT through Project PB97-1397 and of the PICASSO program.

An unprecedented interpenetrating structure with two covalently bonded open-frameworks of different dimensionality

Jack Y. Lu* and Amy M. Babb

Department of Chemistry, University of Houston-Clear Lake, 2700 Bay Area Blvd., Houston, TX 77058, USA. E-mail: lu@ch.uh.edu

Received (in Cambridge, UK) 17th January 2001, Accepted 22nd March 2001
First published as an Advance Article on the web 6th April 2001

A chemical rearrangement under hydrothermal conditions resulted in an unprecedented interpenetrating structure with two covalently bonded open frameworks of different dimensionality: {[$Cu_2(IN)_4{\cdot}3H_2O$]·[$Cu_2(IN)_4{\cdot}2H_2O$]}·$3H_2O$ (IN = isonicotinate).

Interpenetrating network structures have been one of the fascinating subjects in crystal engineering of coordination polymers owing to their attractive new topologies and intriguing structural features.[1–8] Many of these structures have been reviewed recently.[9] Although interpenetrating networks consisting of chemically and topologically different components are rare, Robson and coworkers[10] reported interpenetrating nets of different topology where a single, rhombohedral α-polonium-related net interpenetrates with two types of hydrogen-bonded sheets, one consisting entirely of water and the other of F^- ions and water molecules, while Zaworotko and coworkers[11] synthesized the first example of interpenetrating covalent and non-covalent 2D networks. While some of the interpenetrating structures may be predictable, structural control of metal–organic reactions remains a great challenge, and often, unexpected structures may result. Here we report an unprecedented interpenetrating structure with two covalently bonded open frameworks of different dimensionality formed from a chemical rearrangement under hydrothermal conditions: {[$Cu_2(IN)_4{\cdot}3H_2O$]·[$Cu_2(IN)_4{\cdot}2H_2O$]}·$3H_2O$ (IN: isonicotinate) **1**.

The reaction of $Cu(NO_3)_2{\cdot}2.5H_2O$ with nicotinic acid and *trans*-1,2-bis(4-pyridyl)ethylene in a mole ratio of 1 : 1 : 1 under hydrothermal conditions at 140 °C for three days produced dark blue crystals of **1** in 59% yield suitable for single crystal X-ray diffraction analysis.† The structure consists of a covalently bonded three-dimensional (3D) open-channel network and a covalently bonded two-dimensional (2D) open-framework which are mutually interpenetrating. The 3D network contains three crystallographically distinct copper atoms (Fig. 1). Atom Cu(1) is square pyramidal coordinated by two pyridyl groups from two IN units and two carboxylate groups from the other two IN units in a monodentate fashion. A water molecule occupies the remaining site. Atoms Cu(2) and Cu(3) are in octahedral sites surrounded by two water molecules occupying the axial positions, with two pyridyls and two carboxylates from four IN units occupying the equatorial positions. Both Cu(2) and Cu(3) clearly show John–Teller distortion. The square pyramidal and octahedral Cu centers are linked by four two-connected tridentate IN units into a single-net 3D open-channel-network. The large rectangle in the open-channel-network consists of six Cu and six IN units (Fig. 1). The four Cu atoms at each corner of the rectangle display separations of 17.776 × 8.928 Å. The large rectangular channels in the 3D network extend into two directions, perpendicular to each other (Fig. 1). The topology of this 3D network is similar to a single net of tetragonal $CdSO_4$ type suggested by O'Keeffe *et al.*[12] The 2D open-framework consists of two independent copper atoms. Atoms Cu(4) and Cu(5) are in square pyramidal positions (Fig. 2). Each copper atom is coordinated by two carboxylate groups from two IN units in a monodentate fashion, and two pyridyl groups from the other two IN units. A water molecule occupies the remaining apical site. The square pyramidal copper atoms are linked by four two-connected tridentate IN units into a two-dimensional square grid network (Fig. 2). The Cu–Cu lengths in the square grid are 8.871 × 8.862 Å. The 3D and 2D open-frameworks interpenetrate to form an unprecedented mixed-

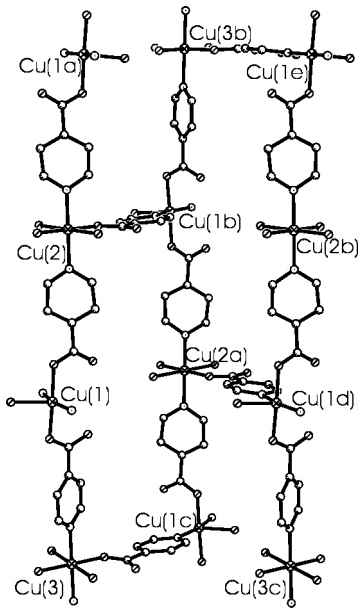

Fig. 1 View of the rectangular open framework in the 3D structure with copper atoms labeled and complete coordination shown.

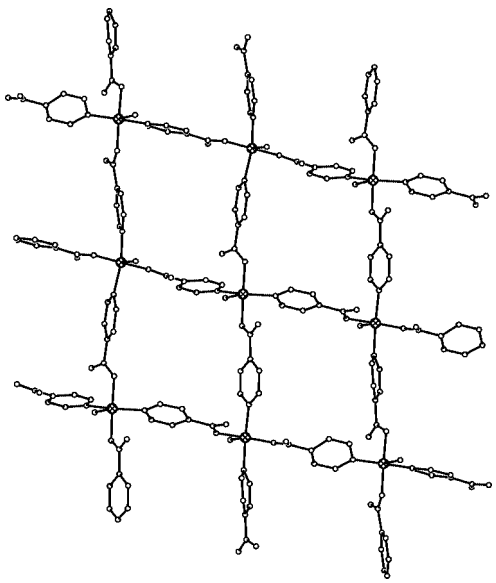

Fig. 2 View of a representative section of the 2D lattice. Note that all Cu atoms have square pyramidal coordination.

DOI: 10.1039/b100634g

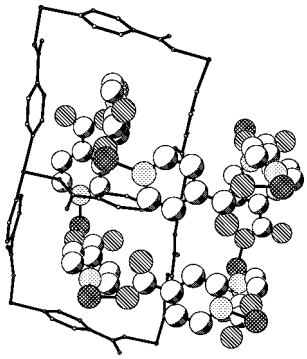

Fig. 3 Interlocked units in the interpenetrating structure. Only two of the four 2D square grids are shown for clarity.

2D–3D structure. The interpenetration is in such a way that each 3D closed-circuit displaying a 'table-frame' shape interlocks with four square grids of a 2D sheet (Fig. 3), so that each rectangular open-channel in the 3D network interpenetrates with two 2D sheets. Although several coordination polymers of isonicotinate and its derivatives have been reported, the structural feature in complex **1** has not been observed.[13] In spite of the interpenetrating networks in **1**, a dozen water molecules are included in a unit cell. Numerous hydrogen-bonding interactions found in the interpenetrating structure link the coordinating water molecules and the carboxylate groups of IN units between the 3D and 2D networks [O(9)···O(13) 2.864 Å, O(9)···O(15), 2.924 Å, O(11)···O(15) 2.865 Å, O(21)···O(4) 2.794 and 2.855 Å]. Thermal analysis indicated that the interpenetrating framework lost water molecules below 150 °C, and started to decompose at *ca*. 275 °C.

The reaction to prepare **1** was conducted *via* a self-assembly process under fairly mild hydrothermal conditions. The interpenetrating structure is stabilized owing to an unexpected chemical rearrangement of the ligand. While the reaction is fully reproducible, many attempts made to produce compound **1** from using isonicotinate instead of nicotinate as starting materials all failed.[14] The chemical rearrangement from nicotinate to isonicotinate under hydrothermal conditions is not well understood, while in other cases, rearrangements under hydrothermal conditions have been observed such as with 2,2-dipyridylamine.[15] The *trans*-1,2-bis(4-pyridyl)ethylene present in the reaction mixture is a necessary component for the preparation of compound **1**. Although the present research results might indicate that structural control of metal–organic reactions and prediction of interpenetrating networks under hydrothermal conditions could be a long-term challenging task in some cases, we are actively seeking clear directions from related investigations as well as searching for other unexpected structures under hydrothermal conditions.

We are grateful for financial support from the Welch Foundation. This work made use of MRSEC/TCSUH Shared Experimental Facilities supported by the National Science Foundation and the Texas Center for Superconductivity at the University of Houston.

Acceleration in nitroxide mediated 'living' free radical polymerizations

Eva Harth, Brooke Van Horn and Craig J. Hawker*

Center for Polymeric Interfaces and Macromolecular Assemblies, IBM Almaden Research Center, 650 Harry Road, San Jose, CA, 95120-6099, USA. E-mail: hawker@almaden.ibm.com

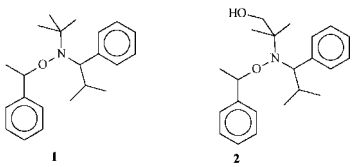
Received (in Columbia, MO, USA) 6th February 2001, Accepted 21st March 2001
First published as an Advance Article on the web 9th April 2001

Intramolecular H-bonding has been shown to be a powerful tool in increasing the performance of alkoxyamine initiators for nitroxide mediated living free radical polymerizations.

The continued evolution of nanoscale science as a major research area has attracted significant attention in recent years.[1–3] In concert with this evolution, the field of polymer synthesis has witnessed an increase in sophistication with a wide range of new synthetic techniques being developed for the preparation of well defined, functionalized macromolecules. Prime examples are the preparation of dendritic macromolecules,[4,5] single site catalysts,[6–8] and the elucidation of a variety of different living free radical polymerization strategies.[9,10] These include nitroxide mediated,[11,12] atom transfer radical polymerization (ATRP),[13,14] and radical addition fragmentation/transfer procedures (RAFT).[15,16] While there are advantages and disadvantages to each procedure, our recent work has concentrated on nitroxide mediated processes since it has the potential to be the simplest of the three procedures.

A major recent advance in nitroxide mediated polymerizations has been the development of α-hydrido nitroxides, in which the presence of a hydrogen atom on the α-carbon leads to a significant increase in the range of vinyl monomers that undergo controlled polymerization.[17,18] While these new nitroxides, or their corresponding alkoxyamines such as **1**, can now be used to prepare poly(acrylates) with polydispersities in the range 1.05–1.10, the typical reaction times and temperatures (48 h at 125 °C) are still unacceptable for reactive monomers that may undergo unwanted side reactions. Also from an industrial point of view, reaction times of less than 6 h and temperatures of *ca.* 100 °C are more economically desirable.

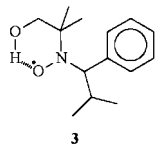
In developing new nitroxides for living free radical polymerizations we were drawn to an observation from our initial work[19] in which the hydroxy-substituted alkoxyamine **2** was observed



1 **2**

to yield slightly faster rates of polymerization when compared to the parent alkoxyamine **1**. While the effect was not dramatic it did correlate with the tendency of nitroxides to act as H-bond acceptors, thereby modifying their reactivity.[20] These observations, coupled with a seminal report by Studer[21] of enhanced dissociation rates for hydroxy-substituted alkoxyamines prompted an investigation into the influence of H-bonding on nitroxide mediated living free radical polymerizations. Since dissociation of **2** leads to the nitroxide **3** which is able to form a favored six-membered intramolecular H-bond (Fig. 1), it was decided to maximize the potential of this intramolecular H-bonding effect by examining the initiating ability of the tris-hydroxy derivative, **4**.

The synthesis of **4** starts from the cheap and readily available 2,2,2-tris(hydroxymethyl)nitromethane **5** which was protected

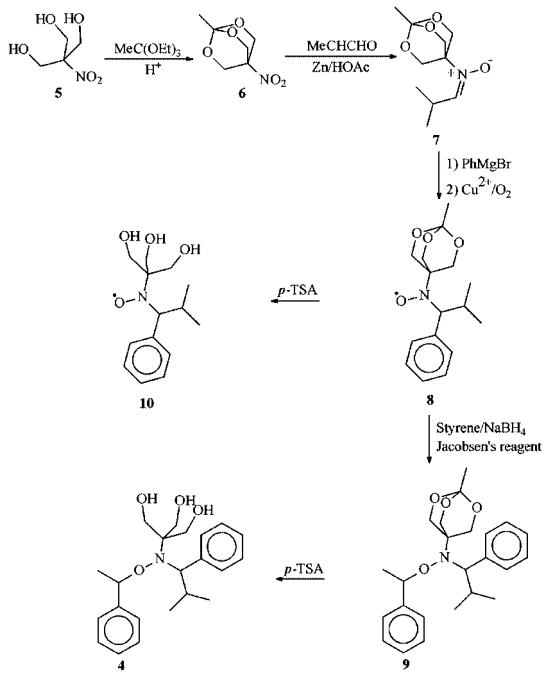


3

Fig. 1 Structure of proposed intramolecular H-bonding in nitroxide **3**.

as its ortho ester **6** before reductive coupling with isobutyryl aldehyde in the presence of zinc/HOAc to give the nitrone **7**. Reaction with phenyl magnesium bromide at reduced temperatures affords the protected nitroxide **8** which can then be coupled with styrene under catalytic Jacobsen's conditions[22] yielding the protected alkoxyamine **9**. Deprotection of either **8** or **9** could be accomplished under mild conditions with *p*-toluenesulfonic acid to give the corresponding tris(hydroxymethyl) derivatives, **10** and **4**, in essentially quantitative yields (Scheme 1).

The ability of **4** to mediate living free radical polymerization was initially examined using styrene as the monomer. Under identical conditions, the alkoxyamine initiator, **1** or **4**, was dissolved in 200 equivalents of styrene and heated at 125 °C under argon with samples being removed at various intervals. Comparison of the results showed an increase in the rate of polymerization for **4** of *ca.* 50% with high conversion being obtained in 3–4 h (*cf.* 5–6 h for **1**). More importantly, the increased rate of polymerization was accompanied by a decrease in polydispersity with values of between 1.07 and 1.09 typically being obtained (*cf.* 1.10–1.12 for **1**). This increased reactivity for **4** also allowed the polymerization temperature to



5 **6** **7** **8** **9** **10** **4**

Scheme 1

DOI: 10.1039/b102145c

be reduced while still maintaining acceptable polymerization times. For example, the polymerization of styrene at 85 °C for 48 h resulted in moderate conversions (50–55%) and low polydispersities (1.15–1.20). Extension of this work to 1,3-dienes such as isoprene also showed a similar trend, increased rate of polymerization and a reduction in polydispersity.[23]

A more significant result was observed when the polymerization of polar monomers was examined. For acrylates, the polymerization rate was increased by at least an order of magnitude by the use of the tris(hydroxymethyl) derivative, **4**. As can be seen in Fig. 2, the polymerization of *n*-butyl acrylate initiated by **4** in the presence of 5 mol% of the corresponding nitroxide **10** reaches 80% conversion after only 2 h at 120 °C, in direct contrast to **1** and 5 mol% of **12**, for which a conversion of only 6% is obtained. It should also be noted a loss of control did not accompany this increased rate of polymerization, narrow polydispersities in the region of 1.1 and controlled molecular weights were obtained with **4**. This improvement now permits acrylate monomers to be polymerized to high conversion under controlled living free radical conditions in only 2–3 h compared to 36–48 h for **1**. Attempts to perform the polymerization of acrylate monomers at lower temperatures were also successful with moderate conversions (*ca*. 40–50%) being obtained after heating at 100 °C for 24 h. At these lower temperatures, the unfunctionalized initiator **1** did not result in any detectable polymerization.

This anomalous behavior of acrylate monomers, when compared to styrene and 1,3-dienes, suggested that the increased efficiency of **4** was monomer dependent and to address this question the polymerization of acrylamides was examined. Interestingly, an increase in the rate of polymerization was again observed with **4** and high conversions were obtained after 7–8 h.[23] While not as dramatic an increase as for acrylates, it is significantly greater than the rate increase observed for styrene or isoprene.

The unique ability of the tris(hydroxymethyl) substitution pattern to facilitate nitroxide mediated polymerizations suggested that H-bonding might be a key feature. To elucidate the effect of H-bonding, similar experiments to those described above were performed with the protected alkoxyamine **9** which is not capable of forming H-bonds. Surprisingly, **9** proved to be a poor initiator for all the monomer families studied with high polydispersities and low polymerization rates being obtained in each case. For example, polymerization of 200 equivalents of styrene in the presence of **9** for 2 h at 125 °C resulted in only 19% conversion with high conversions requiring 16 h (*cf*. 3–4 h for **4** and 5–6 h for **1**). The polymers obtained were also poorly defined with polydispersities typically in the range of 1.4–1.5. Similar decreased rates of polymerization and levels of control were observed for other monomer families suggesting that the protected initiator **9** is a poor initiator for nitroxide mediated living free radical polymerizations. Since the substitution pattern in **4** is similar to **9**, the substantially improved performance of **4** is most likely a result of intramolecular H-bonding and not steric or electronic effects. Additional support for the importance of H-bonding comes from the kinetic observations of Marque[24] coupled with preliminary work from Matyjaszewski[25] using phosphonic acid derivatives of 2,2,6,6-tetramethylpiperidinyloxy, TEMPO.

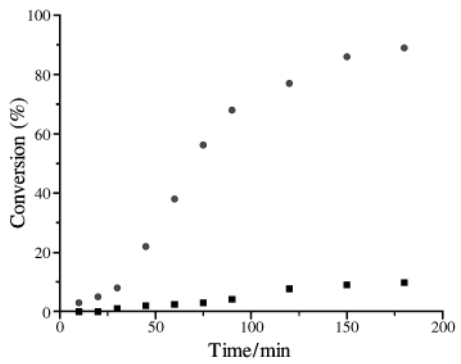


Fig. 2 Plot of percent monomer conversion *vs*. time for the polymerization of *n*-butyl acrylate (200 equivalents) in the presence of **4** (1.0 equivalent) and **10** (0.05 equivalents) (●) and **1** (1.0 equivalents) and **12** (0.05 equivalents) (■) at 125 °C.

In conclusion, intramolecular H-bonding has been shown to be a powerful tool in increasing the performance of alkoxyamine initiators for nitroxide mediated living free radical polymerizations. Increases in the rate of polymerization were observed for polar monomers such as acrylamides and especially acrylates, while only moderate improvements were obtained for non-polar monomers, such as styrene and isoprene. In each case, the degree of control during the polymerization was improved which led to lower polydispersities and a better correlation between experimental and theoretical molecular weights.

Financial support from the MRSEC Program of the NSF under Award Number DMR-9808677 for the Center for Polymeric Interfaces and Macromolecular Assemblies and the IBM Corporation is gratefully acknowledged.

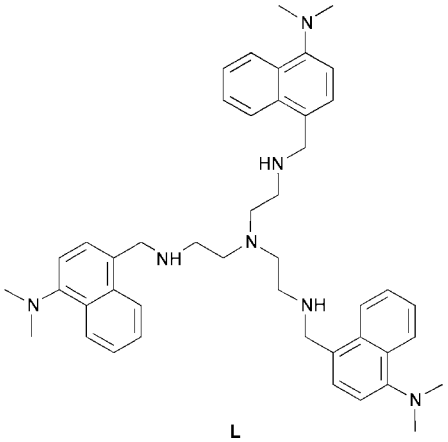
In a MeOH solution the complex $[Zn^{II}(L)]^{2+}$ gives an adduct with the coumarin-343 anion and an electronic energy transfer process takes place from the fluorophore placed on the ligand L to the fluorescent anion, according to a mechanism which can be reversively switched OFF–ON following an acid–base input.

Photonic energy can be transferred from an excited fragment Fl_1 (adsorbing light at wavelength λ_1) to a proximate fragment Fl_2, which emits light at a distinctly higher wavelenth λ_2. A typical mechanism involves the occurrence of a double electron transfer process between Fl_1 and Fl_2, according to a circular pathway, and requires that the two fragments experience occasional van der Waals contacts so that their orbitals can overlap.[1] When Fl_1 and Fl_2 are (or belong to) distinct molecules, a large excess of one of the fluorophores is required in order to ensure the occurrence of the occasional contact: the electronic energy transfer (EET) has an intermolecular nature and the photophysical response (*e.g.* the increase of the fluorescence intensity, I_F, at λ_2) must follow Stern–Volmer behaviour. However, the process can also take place intramolecularly, if Fl_1 and Fl_2 are covalently linked by a relatively short spacer, which makes their encounter much more probable.[2] Intramolecular EET can also be achieved in supramolecular systems in which Fl_1 and Fl_2 belong to distinct moieties held together by non-covalent interactions (*e.g.* hydrogen bonding).[3] EET processes in supramolecular systems are of interest in the fast-growing area of molecular level devices, molecular computing and elementary nanotechnology.[4] We describe here an example of an intramolecular EET process in a system held together by metal–ligand interactions. Metal-mediated inter-component energy transfer has been observed in a few cases.[5] The involved metal is the Zn^{II} cation, which is photophysically inactive and plays an architectural role,[6] bringing Fl_1 and Fl_2 to a suitable distance for the occurrence of an efficient EET process. From this perspective, in the molecule **L** a tripodal tetramine platform



L

has been equipped with three equivalent luminescent fragments that absorb UV light (*N*,*N*-dimethylamine-1-naphthalene: Fl_1; absorption band centred at λ_{max} = 330 nm, emission band centred at λ_{max} = 424 nm).† On the other hand, the dye coumarin-343 was chosen as Fl_2, showing a strong emission at λ_{max} = 475 nm and containing a carboxylic function. Substantial overlap of the absorption band of Fl_1 and of the emission band of Fl_2 fulfils the prerequisite for the occurrence of an EET process.[7]

The tetramine **L** must be preliminarily organised through Zn^{II} coordination, according to a process which can be spectrofluorimetrically monitored. In particular, titration of an ethanolic solution of **L** with Zn^{II} induces an increase in the Fl_1 emission intensity, at 330 nm; a limiting value (2.5-fold enhancement) is achieved with the addition of one or more Zn^{II} equivalents. This behaviour is consistent (i) with the formation of a $[Zn^{II}(\mathbf{L})]^{2+}$ complex, and (ii) with the fact that Zn^{II} coordination prevents the occurrence of an electron transfer (eT) process from the proximate amine nitrogen atom to the photoexcited Fl_1 fluorophore—this eT process was responsible for partial quenching of the fluorescence. On formation of the $[Zn^{II}(\mathbf{L})]^{2+}$ complex, full emission of Fl_1 is restored.

Subsequently, an ethanolic solution of $[Zn^{II}(\mathbf{L})]^{2+}$ (1×10^{-5} mol dm^{-3}), irradiated at 330 nm, was titrated with a standard solution of Fl_2. Progressive addition of the titrating solution induced a progressive decrease in the emission band of Fl_1 and the development of an emission band at 475 nm, indicating Fl_2 sensitisation and the occurrence of an EET process involving Fl_1 and Fl_2 (see Fig. 1).

The fluorescence intensity, I_F, of the band at 424 nm *vs.* equiv. of Fl_2 profile (decreasing), as well as the I_F at 475 nm *vs.* equiv. of Fl_2 profile (increasing, see inset in Fig. 1) correspond to the formation of a 1:1 adduct between $[Zn^{II}(\mathbf{L})]^{2+}$ and coumarin-343. The log K values for the adduct formation equilibrium, calculated through non-linear, least squares treatment of the titration profiles, are 5.98 ± 0.04 (λ = 335 nm) and 6.01 ± 0.03 (λ = 475 nm). This behaviour can be explained considering that: (i) the tripodal tetramine **L** imposes a trigonal bipyramidal stereochemistry on the Zn^{II} ion, leaving one vacant axial position; in the absence of coordinating anions, this

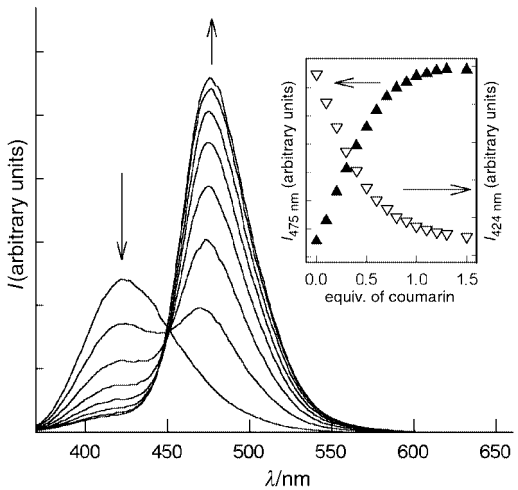


Fig. 1 Selected emission spectra recorded during the spectrofluorimetric titration of a MeOH solution of $[Zn^{II}(\mathbf{L})]^{2+}$ (1×10^{-5} M) with a standard MeOH solution of coumarin-343. The corresponding titration profiles (fluorescence intensity *vs.* equiv. of coumarin) are shown in the inset.

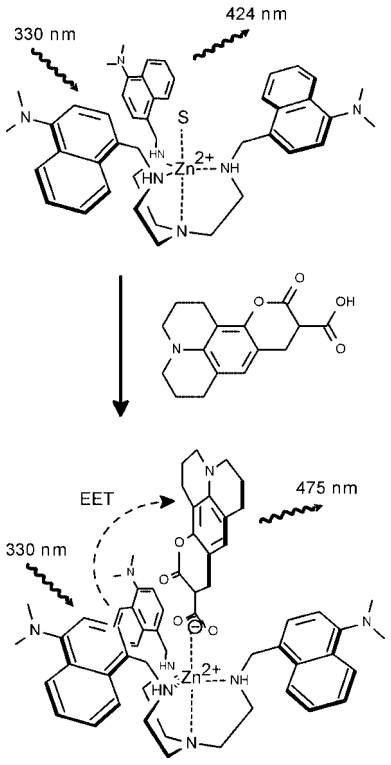
DOI: 10.1039/b101113h



Scheme 1

position can be occupied by a solvent molecule; (ii) the CO_2H group of coumarin-343 deprotonates and the carboxylate fragment replaces the solvent molecule loosely bound in the axial position; (iii) coordination to the metal brings the photoexcited Fl_1 substituent close enough to Fl_2 to ensure the occurrence of an efficient EET process, thus leading to a substantial sensitisation of Fl_2 emission. Any intermolecular contribution to the process was found to be negligible at this low concentration scale of the reagents (10^{-5} mol dm^{-3}). The mechanism of the process is illustrated in Scheme 1.

Thus, the Zn^{II} ion acts as a glue, sticking together the two fluorogenic fragments. It should be noted that an energy transfer rate constant larger than 3.5×10^9 s^{-1} can be calculated from the equation $k_{EET} = (\Phi_0/\Phi - 1)/\tau^\circ$, where τ° is the lifetime of Fl_1 in the $[Zn^{II}(\mathbf{L})]^{2+}$ complex (2.6 ns), and Φ_0 and Φ are the values of the quantum yield of Fl_1, in the $[Zn^{II}(\mathbf{L})]^{2+}$ complex and in the $[Zn^{II}(\mathbf{L})(Fl_2)]^{+}$ adduct, respectively.[8]

When the titration experiment is repeated in the absence of the metal cation, no evidence of adduct formation is observed. In this case, a small development of the coumarin emission band at 475 nm occurs, while a small quenching of Fl_1 emission is observed. This behaviour is ascribed to intermolecular dynamic quenching *via* energy transfer, and was found to obey strictly the Stern–Volmer relationship along the investigated concentration range (up to 5×10^{-5} mol dm^{-3}).

In order to check the role of the metal cation in the EET process further, a solution containing equimolar amounts of ligand **L** and of coumarin-343 was titrated with a Zn^{2+} standard solution, whilst recording the emission spectra (λ_{exc} = 330 nm). Addition of the metal ion switches ON the electronic energy flow: the emission at 475 nm increases as Zn^{2+} is added, reaching a *plateau* with the addition of one equivalent of the metal ion. The $[Zn^{II}(\mathbf{L})(Fl_2)]^{+}$ ternary complex displays an interesting switching behaviour with respect to the addition of standard acid and base. In fact, when a methanolic solution of $[Zn^{II}(\mathbf{L})(Fl_2)]^{+}$ is titrated with triflic acid, the sensitised coumarin-343 emission decreases and completely disappears upon the addition of 4 equiv. acid (see Fig. 2). In other words, H^+ ions switches OFF the electronic energy flow between Fl_1 and Fl_2. This effect is due to the successful competition of the protons for the amine groups, which leads to demetallation and to the moving away of Fl_1 and Fl_2. The electronic energy flow can be switched ON again on titration with standard base. In

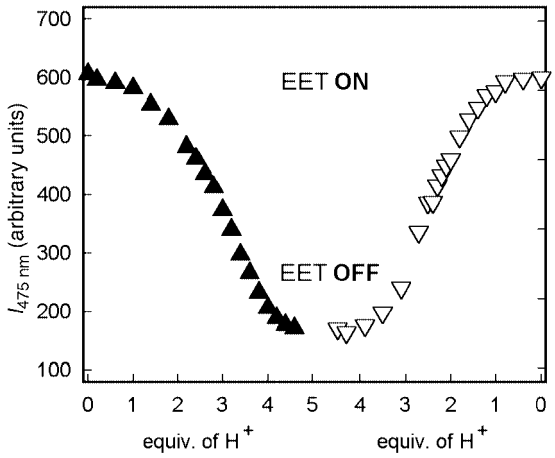


Fig. 2 The effect of an acid–base input on the emission of the $[Zn^{II}(\mathbf{L})(Fl_2)]^{+}$ system when excited at λ_{exc} = 330 nm.

particular, upon addition of an ethanolic solution of NaOH, the emission at 475 nm is progressively restored, to reach its original intensity after 4 equiv., thus ensuring the complete formation of the $[Zn^{II}(\mathbf{L})(Fl_2)]^{+}$ ternary complex. In this sense, the system under investigation shows some similarity to the *plug-and-socket* devices, recently introduced by Balzani and coworkers.[8] Analogy is not complete due to the fact that in the $[Zn^{II}(\mathbf{L})(Fl_2)]^{+}$ system we do not observe a penetration of the socket by the plug. In any case, previously reported examples were based on weak and reversible hydrogen bonding interactions. In the present study, we took profit from the distinctly stronger metal–ligand interaction, which ensures the formation of an especially stable adduct, thus guaranteeing a firm contact between the two photoactive components. Moreover, the lability of the Zn^{II} cation provides quick reversibility and a prompt ON–OFF response, following the acid–base stimulus.

† *Preparation* of **L**: a solution of 4-dimethylamino-1-naphthaldehyde (9.1 mmol in 50 mL of MeOH) was added dropwise over 2 h under magnetic stirring to a solution of tris(2-aminoethyl)amine (3 mmol in 100 mL of MeOH). The reaction mixture was kept at 40 °C for 36 h, and then $NaBH_4$ was carefully added in small portions and the reaction was heated at 50 °C overnight. The solvent was then removed under reduced pressure and the resulting sticky solid was suspended in 100 mL of water. The aqueous phase was extracted with CH_2Cl_2 (3 × 50 mL). The organic phase was dried with $MgSO_4$ and the solvent distilled off, giving **L** as a light yellow oil, which was washed with several portions of diethyl ether. Yield: 67%. Supramolecular tapes formed by a catanionic cyclodextrin in water

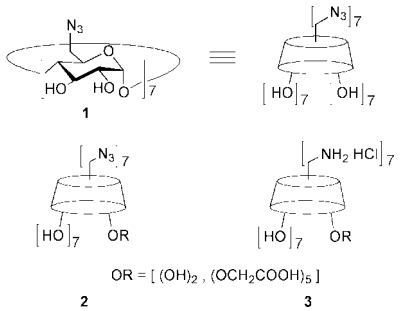
A β-cyclodextrin substituted with amino and carboxymethyl groups on the primary and secondary side respectively, has a positively charged primary face and a negatively charged secondary face at neutral pH, and self-assembles in water into supramolecular tapes that are 50–300 nanometres wide and up to 20 micrometres long.

'Janus' cyclodextrins are cyclodextrins with distinctly different primary and secondary faces.[1] The preparation of such cyclodextrins is not trivial since it requires synthetic differentiation of the primary and secondary sides of the cyclodextrin molecule.[2] However, several types of Janus cyclodextrins have been prepared to date, all of which show interesting self-assembling properties. The largest class of Janus cyclodextrins comprises amphiphilic molecules in which one face of the cyclodextrin has been substituted with large hydrophobic groups while the other face is substituted with polar or ionic groups, or is left unsubstituted. Many of these cyclodextrins are very hydrophobic and insoluble in water. However, recent reports describe micelles as well as bilayer vesicles composed entirely of amphiphilic cyclodextrins.[3,4] A second group of Janus cyclodextrins contains thiol or sulfide substituents exclusively on one face of the molecule, which induce assembly into monolayers on gold surfaces.[5] Yet another class contains small hydrophobic substituents on one face and polar or ionic substituents, or none, on the other face. These molecules form dimers in several solvents.[6] Finally, cyclodextrins with polar or ionic substituents on one face of the molecule (and no substituents on the other face) can form dimers in polar solvents,[7] and even specific heterodimers between ionic cyclodextrins of opposite charge in water.[8] We now report a new Janus β-cyclodextrin **3** bearing amino groups on the primary face and carboxymethyl groups on the secondary face, to give a cyclic oligo-aminoacid structure designed to assemble in water by multiple ion-pairing.

Heptakis(6-azido-6-deoxy)-β-cyclodextrin **1**[9] was reacted with sodium iodoacetate in the presence of potassium *tert*-butoxide at 80 °C in DMF to yield 6-azido-6-deoxy-2-*O*-carboxymethyl-β-cyclodextrin **2**. This product was isolated by precipitation from water at pH 2. ^{1}H NMR (300 MHz, d_6-DMSO) showed a signal for the methylene protons of the carboxymethyl group at 4.35 ppm and separate signals for H_1' at 5.15 and H_1 at 4.92 ppm. According to the relative integration of these ^{1}H NMR signals, a reproducible average of five carboxymethyl groups was introduced in **2**. The resolution of the NMR spectra of **2** is poor due to a combination of aggregation and loss of molecular symmetry. Cyclodextrin **2** was then reduced to 6-amino-6-deoxy-2-*O*-carboxymethyl-β-cyclodextrin **3** by conventional phosphine reduction.[10] Product **3** was isolated by precipitation in water at pH 2 and purified by size exclusion chromatography. Despite our best efforts, the final product retained traces of phosphines. The structure of **3** (with five carboxymethyl groups on O-2) was confirmed by NMR. ^{1}H NMR (300 MHz, D_2O) shows a signal for the methylene protons of the carboxymethyl group at 4.28 ppm and signals for H_1' at 5.07 as well as H_1 at 5.30 ppm. ^{13}C NMR (500 MHz, D_2O) shows the carbonyl and the methylene carbon of the carboxymethyl group at 174.4 and 69.1 ppm, respectively, as well as C_2' at 80.0 and C_2 at 68.0 ppm. No shift was observed for C_3' relative to C_3, confirming substitution at O-2 instead of O-3, as anticipated for this type of reaction at the secondary side of cyclodextrins.[2] As for **2**, the resolution of the NMR spectra of **3** is poor due to a combination of aggregation and loss of molecular symmetry.



Cyclodextrin **3** readily dissolves in 10 mM HEPES buffer (pH 7.4) upon gentle agitation at rt. The solution (0.1–1.0 mg mL^{-1}) is not completely transparent. Using transmission electron microscopy (with either uranyl acetate or phosphotungstic acid as negative stain)[11] we observed that cyclodextrin **3** self-assembles into elongated tape-like structures (Figs. 1 and 2). The tapes are between 50 and 300 nanometres wide and up to 20 μm long, yet only several nanometres thick. They seem quite flexible, since multiple twists, bends and folds are observed. However, the tapes are also rather fragile, and readily break into smaller fragments during the preparation of samples for electron microscopy. A significant fraction of the cyclodextrin is present as amorphous aggregates. As expected, no tapes but only amorphous aggregates are observed when the pH is either reduced from 7.4 to 4, or increased from 7.4 to 10, or when 0.5 M NaCl is added to the cyclodextrin solution. At high and low pH, and also in the presence of more than 0.1 M NaCl,

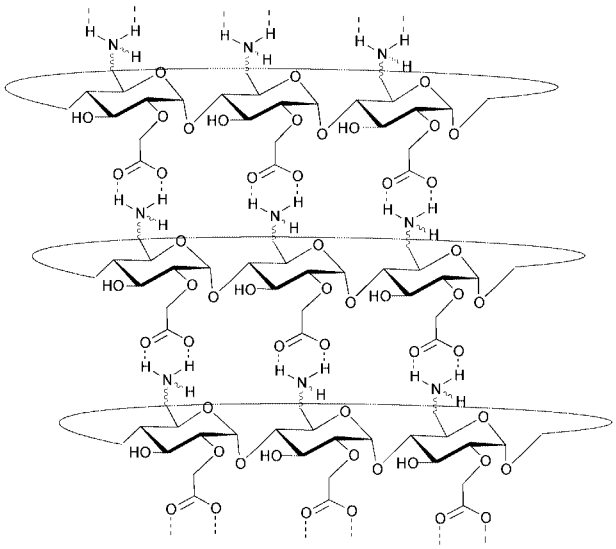

Fig. 3 Schematic illustration of the self-assembly of cyclodextrin **3**.

the solution of cyclodextrin **3** becomes completely transparent. Clearly, the elongated tapes at neutral pH and low ionic strength scatter visible light much more than the smaller, amorphous aggregates present at high and low pH, and at high ionic strength. The intensity of the scattered light at 400 nm as a function of NaCl concentration is constant up to 40 mM of added NaCl, and rapidly decreases at higher ionic strength. This demonstrates that the elongated tapes only form in aqueous solution of low ionic strength.

We propose that the elongated tapes result from ion-pairing of the catanionic cyclodextrin **3**. At neutral pH and low ionic strength, molecules of **3** assemble face to face, similar to the heterodimers described in the literature,[8] except that here each molecule has oppositely charged faces, so that the molecular pairing can continue indefinitely in two directions. The cyclodextrins can form an efficient intermolecular hydrogen bond network, with each molecule providing multiple NH hydrogen bond donor sites and CO hydrogen bond acceptor sites (Fig. 3). In this way they imitate the self-assembly of certain cyclic peptides to form nanotubes in water,[12] although here the protonated amino and carboxylate groups operate each on one side of the molecule, rather than alternately on the same side as do the hydrogen bonding NH and CO groups in the case of the peptides. The supramolecular structure adopted by cyclodextrin **3** is fundamentally different from previous examples of cyclodextrin self-assembly in polar solvents (including water), which have been induced by elongated guest molecules, namely the poly(rotaxanes)[13] and diphenylhexatriene inclusion compounds.[14]

The molecular faces of **3** may not perfectly superimpose. In crystal structures, cyclodextrins not only form channel structures, but also each molecular face can overlap with more than one other face to form cage structures.[15] Here, the molecules apparently assemble in three directions, two of which seem to be favoured over the third, as when bricks are used to form a wall. This would result in the formation of elongated tapes of variable width, but constant thickness. Further structural and computational investigations, as well as synthetic modifications, will contribute to a better understanding of the self-assembly of this novel catanionic Janus cyclodextrin.

Received (in Cambridge, UK) 24th January 2001, Accepted 13th March 2001
First published as an Advance Article on the web 17th April 2001

A method involving laser irradiation is shown to lead to selective modification of core–shell gold–silver nanoparticles.

In recent years, a large range of preparations have been proposed for the design of novel metallic nanoparticles. For both uncoated and passivated metallic nanoparticles like thioalkane or thionicotinamide-coated gold nanoparticles,[1,2] numerous chemical or physical procedures for their preparation have been published and compared,[3–6] in particular with respect to the size and shape distributions.[7] For spherical nanoparticles, a strong emphasis has always been given to the diameter of the particles and the width of the distribution around the mean diameter. These properties are usually assessed by UV–VIS absorption spectroscopy and Transmission Electron Microscopy (TEM). Routinely, particles with diameters between 5 and 25 nm with a standard deviation between 1 and 2 nm are reported. One general aim is to reduce even further the standard deviation of the size distribution since many physical properties of the particles are size dependent. This is true for the wavelength corresponding to the maximum of the absorption spectrum of the particles in solution and also for the hyperpolarisability of the particles.[8,9]

The control of the size distribution is not very efficient during nanoparticle formation when the metal salt reduction technique is used. However, this is probably the most widely used technique although it does not yield a very narrow distribution. Subsequent size separation processes are therefore required.[10] The search for a convenient way to narrow the size distribution for monodisperse aqueous solutions of nanoparticles is thus required and recently laser irradiation has been proposed with the report of both size reduction and shape changes of metal particles in solution.[2,11–13] Nevertheless, the physical mechanisms at work have not been fully elucidated although melting, photoejection of electrons and fragmentation have been observed depending on the laser irradiation conditions. In this work, we report the laser irradiation of core-shell gold–silver nanoparticles with a diameter *ca.* 23.4 nm and their subsequent changes for different laser fluences when pulses with a 5 ns duration at a 532 nm wavelength are used.

Silver coated gold nanoparticles were prepared by reduction of a gold tetrachloroaurate salt containing 10 mg of gold in 190 mL of water made up to 200 mL with 10 mL of a 38.8 mM sodium citrate solution.[14] The ruby red coloured solution was then cooled down to room temperature before being boiled again. Near the boiling point, silver nitrate was added to 60 mL of the gold solution in aliquots of 200 μL with the amount of silver adjusted to the desired mole fraction with respect to gold. The stoichiometric equivalents of citrate were added after each silver addition to ensure the complete reduction of the silver ions. Here we present the results for a solution with a mole fraction of gold of 0.60 although other ratios can be obtained by this preparation method. The size distribution of the solution was characterized by TEM on a Philips CM20 transmission electron microscope and UV–VIS absorbance spectra were recorded with a Varian 1E UV–VIS spectrophotometer. For the TEM measurements, a drop of the solution was deposited on a copper grid on a carbon film and dried under a N_2 atmosphere in a glove box. The size distribution was then deduced from the measurements of the diameter of 200 particles from 6 different batches. The average diameter measured was 23.4 nm with a standard deviation of 1.4 nm. The laser irradiation was performed with a nanosecond Continuum Minilite II Nd^{3+}–YAG laser, delivering pulses at a repetition rate of 10 Hz at 532 nm. The cross section of the irradiation beam was controlled with a 10 cm focal lens and measured to be 0.125 cm^2 at the entrance of the cell. At energies varying between 12 and 2 mJ per pulse, this corresponds to fluences between 96 and 16 mJ cm^{-2}, respectively. In all experiments, the nanoparticle solutions were used directly as prepared without further additions of others species such as oxidising agents. The volume of the aqueous solution of nanoparticles was maintained at 1.5 mL in a quartz cell. Irradiation times were varied but the results presented here all correspond to irradiation times of 60 minutes. The UV–VIS absorbance of the initial orange coloured solution of the nanoparticles consisting of a gold core with a silver outer-shell is presented in Fig. 1. The absorbance of the core–shell nanoparticle exhibits two surface plasmon resonances at 410 and 502 nm characteristic of this bimetallic phase system. It is important to realise though that one cannot attribute a particular band to the surface plasmon excitation of one single metal phase only. Indeed, from a Mie theory calculation for such a core–shell system, one calculates the absorption cross-section of the core–shell particle altogether. It can however be noticed that the absorption cross-section is always dominated by the gold core absorption at all wavelengths.[15] From the TEM measurements, no rod shaped particles were observed and therefore the particles are assumed spherical hereafter.

Upon 60 minutes of irradiation of the sample with 532 nm light at a high fluence of 96 mJ cm^{-2}, the UV–VIS absorbance spectrum is substantially modified, now presenting only one surface plasmon excitation located at 510 nm, see Fig. 2, which

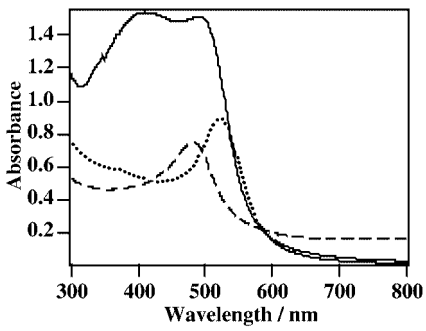

Fig. 1 UV–VIS spectra for Au 0.6 Ag 0.4 core–shell nanoparticles of different morphologies: mixed core–shell (solid line), homogeneous (dashed line) particles. The spectrum of pure gold is also given (dotted line).

DOI: 10.1039/b100856k

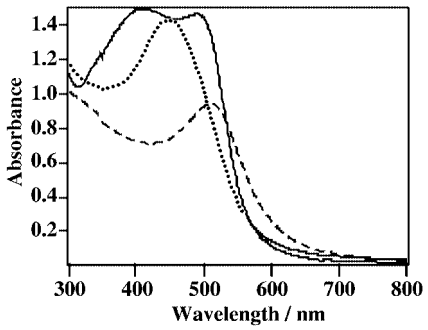

Fig. 2 Absorption spectra of Ag coated Au nanoparticles after irradiation with different fluences for 60 min: no irradiation (solid line), irradiation at low fluence (dotted line) and at high fluence (dashed line).

is a value very close to the position of the surface plasmon band for pure gold particles. From the TEM measurements of the irradiated samples, it appears that particles with diameters larger than 15 nm are not observed anymore whereas the number of particles with a diameter between 3 and 15 nm increased. When the solution is irradiated during an equal amount of time with a lower fluence of 16 mJ cm^{-2}, the absorbance spectrum is different with a single surface plasmon band observed located at a wavelength of 455 nm, see Fig. 2. This is the exact location of the surface plasmon band excitation for a mixed gold–silver nanoparticle with the same mole fraction of 0.6 for gold. Such a homogeneous particle can be produced by the simultaneous reduction by citrate of a mixed salt of sodium tetrachloroaurate and silver nitrate with an initial mole fraction of gold of 0.6. From the TEM measurements, the diameter of the particles ranged between 3 and 17 nm and no particles with a diameter larger than 17 nm were observed. These results at low fluence have recently been observed by Hodak *et al*.[16] The origin of the difference in the resulting UV–VIS absorbance spectra after irradiation is the result of the competition between two dominant processes: surface oxidation and melting. At low fluences with an irradiation wavelength of 532 nm, the absorption is preferentially localised into the gold core because of the smaller absorptivity of silver compared to the gold at this wavelength.[17] The plasmon excitation is the dominant process leading to a rapid phonon excitation through electron–phonon coupling in less than 1 ps and thermal relaxation within the nanosecond pulse duration by phonon–phonon coupling. This process induces the melting of the particle since internal temperatures reached are above the melting temperature for gold, the bulk value of which is 1339 K. However, this phenomenon occurs on a very short timescale since phonon–phonon equilibration with the surrounding medium is complete within 100 ps.[18] The internal diffusion process involving the mixing of the gold internal core and the outer silver shell must then be rapid, with a timescale of the same order of magnitude of 100 ps. It is likely that complete homogeneity is only obtained after a number of pulses.[16] In contrast, at high fluences, the process is different leading to the removal of the silver layer. Absorption of more than one photon is a process known to occur.[12] At high fluences with a wavelength of 532 nm, the process of the absorption of at least two photons, or an energy of more than 4.64 eV, a value above that of the work function of silver equal to 4.3 eV, induces the photooxidation of silver. The redox reaction is similar to an electrochemical anodic dissolution of silver ($E^0_{Ag^+/Ag}$) concomitant with the reduction of the electrolyte. The gold inner shell is not affected by photooxidation as the work function of gold is higher (5.2 eV). The process of evaporation of atoms of both silver or gold is highly unlikely from a physical statistics point of view and thus the successive absorption of photons with time intervals greater than 100 ps cannot be regarded as a dominant channel of relaxation. No pure silver particles were observed in solution after irradiation as seen from the absence of any plasmon band excitation around 400 nm. The silver cations formed therefore by photooxidation are not reduced again in solution to form silver nanoparticles.

The irradiation fluence was observed to change the shape as well as the diameter of the nanoparticles. This work demonstrates the possibility of the use of laser irradiation as a tool to selectively change the morphology of core–shell gold–silver nanoparticles.

This work is supported by the Swiss National Fund for Research under the grant n° 21-55762.98. We thank Valerie Devaud for her help , Juliette Rinuy, Dr Alastair Wark and Cyril Cayron for the TEM measurements and Paolo Galletto and Jean Lerme for fruitfull discussions.

First published as an Advance Article on the web 10th April 2001

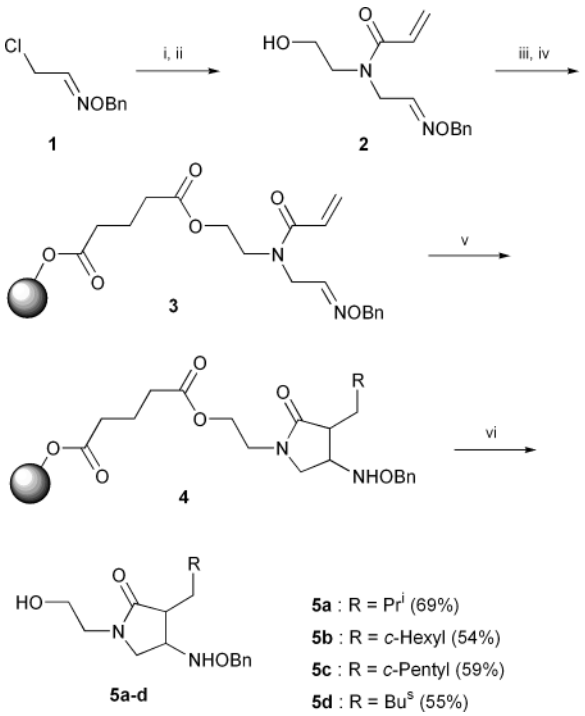
The solid-phase tandem C–C bond-forming reactions of oxime ethers connected with α,β-unsaturated carbonyl groups proceeded effectively under iodine atom-transfer reaction conditions to give the azacycles or chiral oxacycles after cleavage of the resin.

Solid-phase radical reactions have been developed for an important carbon–carbon bond-forming method on solid support under mild reaction conditions.[1] We have recently demonstrated that triethylborane as a radical initiator has the potential to induce intermolecular and intramolecular radical reactions on solid support.[2] Moreover, the employment of triethylborane and its related radical initiator such as diethylzinc at low reaction temperature would facilitate the control of stereochemistry in solid-phase reactions.[3] Within our program directed towards solid-phase radical reactions, the development of solid-phase multi carbon–carbon bond-forming reactions and their stereocontrol is the new focus of our efforts. We now report the tandem radical addition–cyclisation reaction of oxime ethers anchored to a polymer support.

In our studies on the radical reaction of various oxime ethers in solution,[4] we have recently succeeded in the solution-phase tandem radical addition–cyclisation reaction of substrates having two different radical acceptors such as acrylate and aldoxime ether moieties.[5] On the basis of the results in the solution-phase reactions, we first examined the simple solid-phase tandem radical addition–cyclisation reaction of aldoxime ether **3** connected with the α,β-unsaturated carbonyl group.

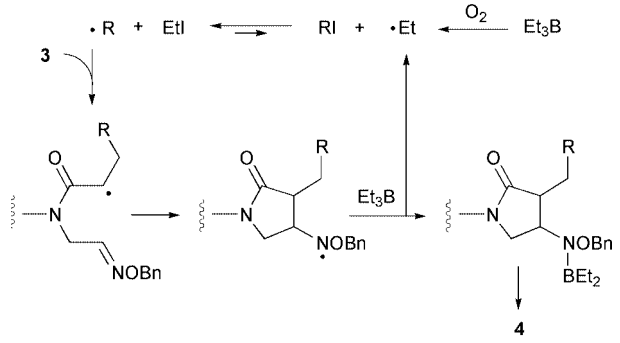
Preparation of **3** anchored to a polymer support is shown in Scheme 1. Treatment of α-chloroacetaldoxime ether **1** with 2-aminoethanol followed by acylation with acryloyl chloride gave oxime ether **2**. To enhance the reactivity of resin-bound substrate, we introduced a temporary spacer by the reaction of **2** with glutaric anhydride. The oxime ether having the spacer moiety was attached to Wang resin by treatment with DCC in the presence of DMAP to give **3**. The loading level of Wang resin-bound oxime ether **3** was determined to be 0.81 mmol g^{-1} through quantification of nitrogen by elemental analysis.

To a flask containing aldoxime ether **3** and Pr^iI (30 equiv.) in toluene a commercially available 1.0 M solution of triethylborane in hexane was added three times (3 equiv. × 3) as a radical initiator at 100 °C (Scheme 1). The reaction mixture was stirred at 100 °C for 2 h, then the resin was filtered and successively washed with CH_2Cl_2, AcOEt, and MeOH. The cleavage of the resin by treatment with NaOMe gave the desired azacyclic product **5a** in 69% isolated yield. However, the radical cyclisation of oxime ether **3** at 25 °C did not proceed.[2b] Good chemical yields were also observed in the radical reaction using different radical precursors such as cyclohexyl, cyclopentyl, and *sec*-butyl iodides under the iodine atom-transfer reaction conditions. Moreover, it is noteworthy that this iodine atom-transfer radical reaction has a practical advantage over the reaction using toxic tin reagent. A remarkable feature of these reactions is the construction of two carbon–carbon bonds on solid support under mild reaction conditions without strictly anhydrous solvents and reagents. In this reaction, triethylborane would act as a reagent for trapping the intermediate aminyl radicals to regenerate an ethyl radical; therefore, more than a stoichiometric amount of triethylborane would be required (Scheme 2).



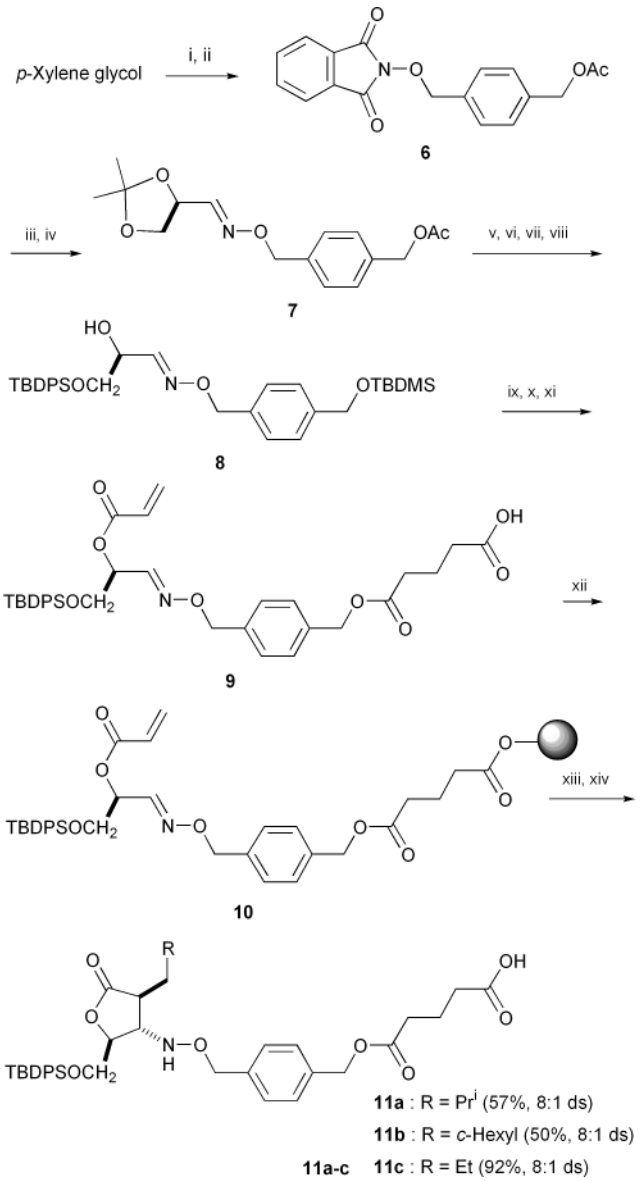
Scheme 1 *Reagents and conditions*: i, 2-Aminoethanol, 20 °C, 88%; ii, CH_2=CHCOCl, Na_2CO_3, acetone, H_2O, 0 °C, 87%; iii, Glutaric anhydride, Py, 80 °C, 93%; iv, Wang resin, DCC, DMAP, CH_2Cl_2, 20 °C; v, RI, Et_3B in hexane, toluene, 100 °C; vi, NaOMe, MeOH, THF, H_2O, 20 °C.

Stereocontrol in solid-phase radical reactions has been of great importance in SPOS (solid-phase organic synthesis). Based on the above results, we next examined the control of stereochemistry in the solid-phase tandem radical addition–cyclisation reaction. Preparation of **10** anchored to a polymer support is shown in Scheme 3. Monoacetylation of *p*-xylene glycol, mesylation of monool with mesyl chloride in the



Scheme 2

DOI: 10.1039/b101074n



Scheme 3 *Reagents and conditions*: i, Bu^{n}Li, AcCl, THF, 0 °C, 65%; ii, MsCl, Et_3N, CH_2Cl_2, 0 °C and then *N*-hydroxyphthalimide, Et_3N, CH_2Cl_2, reflux, 71%; iii, $N_2H_4{\cdot}H_2O$, MeOH, 20 °C, 99%; iv, 2,3-isopropylidene-D-glyceraldehyde, Py, 25 °C, 73%; v, PPTS, MeOH, 65 °C, 74%; vi, TBDPSCl, imidazole, DMF, 20 °C, 75%; vii, K_2CO_3, aq. MeOH, 20 °C, 99%; viii, TBDMSCl, imidazole, DMF, 20 °C, 75%; ix, CH_2=CHCOCl, Et_3N, CH_2Cl_2, 0 °C, 65%; x, PPTS, MeOH, 65 °C, 80%; xi, glutaric anhydride, Py, 80 °C, 99%; xii, Wang resin, DCC, DMAP, CH_2Cl_2, 20 °C; xiii, Et_3B in hexane, RI:toluene = 4:1, 100 °C; xiv, TFA, CH_2Cl_2, 20 °C.

presence of triethylamine, and then treatment of the resulting mesylate with *N*-hydroxyphthalimide in one-pot afforded the imide **6** in 71% yield (Scheme 3). Treatment of **6** with hydrazine monohydrate and subsequent condensation of the resulting alkoxyamine with 2,3-isopropylidene-D-glyceraldehyde gave the chiral oxime ether **7**, which was easily converted to the secondary alcohol **8**. The reaction of **8** with acryloyl chloride followed by treatment with pyridinium toluene-*p*-sulfonate in MeOH gave deprotected benzyl alcohol, which was then treated with glutaric anhydride to give carboxylic acid **9** (Scheme 3). The carboxylic acid **9** was attached to Wang resin by treatment with DCC in the presence of DMAP in CH_2Cl_2 at 20 °C for 12 h to give the resin-bound oxime ether **10**.

The reaction of **10** with an ethyl radical proceeded effectively by treatment with triethylborane to give the chiral oxacycles **11c** in 92% yield after cleavage of the resin, which was carried out under acidic reaction conditions due to the base-sensitivity of **11c** (Scheme 3). However, the reactivity of chiral oxime ether **10** towards other alkyl radicals was quite different from that of oxime ether **3**. The treatment of **10** with Pr^{i}I (24 equiv. × 3) and triethylborane (6 equiv. × 3) in toluene at 100 °C gave a large amount of the ethylated product **11c** and a small amount of the isopropylated product **11a** after cleavage of the resin. This result suggests that, in this reaction, the addition of ethyl radical, generated from triethylborane, competes with the iodine atom-transfer process because triethylborane, having Lewis acidic character, probably coordinates the substrate on the polymer-support and is concentrated on the surface of the resin. A similar trend has been observed in our previous studies.[3] Selective formation of the desired isopropylated product **11a** was observed in the reaction of **10** (50 mg) using triethylborane (5.9 equiv. × 3) in Pr^{i}I–toluene (4:1, v/v, 5 mL) at 100 °C. Based on ^{1}H-NMR analysis, a 8:1 diastereomeric mixture of the isopropylated oxacyclic product **11a** was obtained in 54% isolated yield. Additionally, in the solid-phase reactions, the often tedious workup to remove excess reagents from the reaction mixture was eliminated simply by washing the resin with solvents. The addition of a bulky cyclohexyl radical proceeded in slightly low chemical efficiency under the same reaction conditions to give the alkylated product **11b** but with a similar diastereoselectivity.

In conclusion, we have demonstrated that tandem radical reactions are an excellent method for the stereoselective construction of multi carbon–carbon bonds on solid support.

New discovery in the traditional Baylis-Hillman reaction of arylaldehydes with methyl vinyl ketone

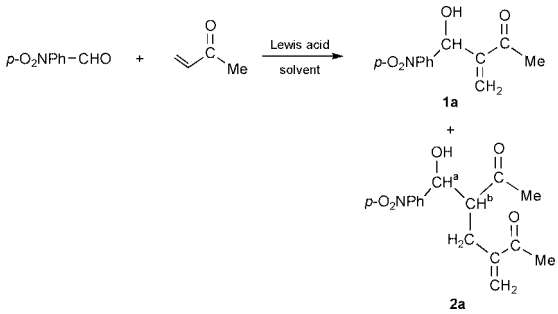
Min Shi,* Chao-Qun Li and Jian-Kang Jiang

Laboratory of Organometallic Chemistry, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, 354 Fenglin Lu, Shanghai 200032 China. E-mail: mshi@pub.sioc.ac.cn

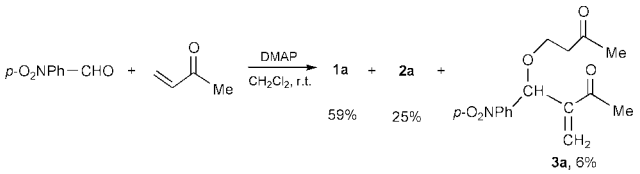
Received (in Cambridge, UK) 31st January 2001, Accepted 13th March 2001
First published as an Advance Article on the web 10th April 2001

In the Baylis-Hillman reaction of arylaldehydes with methyl vinyl ketone, we found that, besides the normal Baylis-Hillman reaction product 1, the diadduct 2 can also be formed at the same time and the yield of 2 can reach 55% by increasing the amount of methyl vinyl ketone; but for acrylonitrile and methyl acrylate, only the normal Baylis-Hillman adduct was obtained; the substituent's effects were also examined and a plausible reaction mechanism was proposed for the formation of 2.

The Baylis-Hillman reaction has progressed,[1] and now includes a catalytic asymmetric version,[2] since Baylis and Hillman first reported the reaction of acetaldehyde with ethyl acrylate and acrylonitrile in the presence of catalytic amounts of 1,4-diazabicyclo[2,2,2]octane (DABCO) in 1972.[3] However, during our own investigation on this simple and useful reaction,[4] we found that, in the reaction of arylaldehydes with methyl vinyl ketone (MVK) catalyzed by DABCO, the reaction products are not as simple as those reported before. For example, using *p*-nitrobenzaldehyde (1.0 eq.) and MVK (2.0 eq.) as substrates in the presence of catalytic amounts of DABCO (0.1 eq.) in DMSO or DMF, we found that, besides the normal Baylis-Hillman reaction product **1a** compound **2a** was also formed at the same time as a *syn* and *anti* mixture (2 : 3)[5] (Scheme 1, Table 1, entries 1–3). If using *p*-dimethylaminopyridine (DMAP) as a Lewis base in DMSO or DMF, **1a** was exclusively obtained in high yields under the same reaction conditions (Scheme 1, Table 1, entries 4–5). However, in CH_2Cl_2 using DMAP as a Lewis base, **1a** and **2a** were formed along with **3a**, a Michael addition product of **1a** with MVK (Scheme 2).[6] At present, we do not understand why **3a** should be formed in CH_2Cl_2. Increasing the amount of MVK in the reaction system raised the yield of **2a**. Using 4.0 or 8.0 eq. of MVK, the yield of **2a** reached 53 and 55%, respectively (Table 1, entries 6 and 7). The reaction temperature slightly affected the yield of **2a** (Table 1, entries 8 and 9). At higher temperature, the dimer of MVK was formed as well.[7] The formation of **2a** indicates that another important reaction process can operate in the traditional Bayliss-Hillman reaction.



Scheme 1



Scheme 2

For *m*-nitrobenzaldehyde, *p*-bromo or *p*-chlorobenzaldehyde and *trans*-cinnamaldehyde similar results were obtained (Scheme 3, Table 2, entries 3, 9, 11, 16). Using DMAP as a Lewis base, **1** was exclusively formed (Scheme 3, Table 2, entries 4, 10, 12, 17). For benzaldehyde or aliphatic aldehyde, only the corresponding normal Baylis-Hillman adducts **1** were formed under the same reaction conditions (Scheme 3, Table 2,

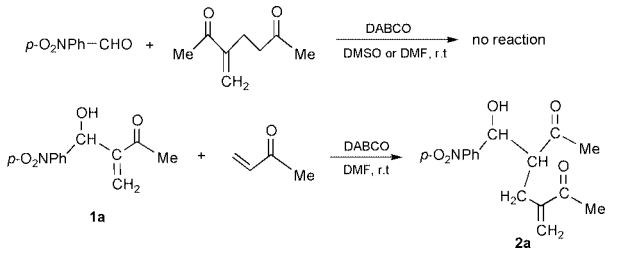
entries 13, 18) and for *p*-ethylbenzaldehyde, no reaction occurred at all (Scheme 3, Table 2, entry 15). But surprisingly we found that, for *o*-nitrobenzaldehyde, the Baylis-Hillman adduct **1** was produced as the single product (Table 2, entries 4–6). This result suggested that the *o*-nitro group on the phenyl ring could block out the further reaction of **1** with MVK.

In the traditional Baylis-Hillman reaction for simple methyl vinyl ketone (MVK), this phenomenon has never been reported before. Only in the reaction of dicarbonyl compounds with acrylonitrile in the presence of DABCO, the diadduct, which was thought to be derived either from reaction of acrylonitrile dimer with starting material or from the conjugated addition of the anion derived from a second molecule of acrylonitrile to the Baylis-Hillman adduct, was obtained as a minor product.[8] In order to clarify the mechanism for the formation of **2a**, we carried out the reactions of **1a** (1.0 eq.) with MVK (2.0–8.0 eq.) and *p*-nitrobenzaldehyde (1.0 eq.) with MVK dimer (1.0 eq.) in the presence of catalytic amounts of DABCO (0.1 eq.), respectively (Scheme 4). We found that **2a** was indeed formed



Scheme 4

from the reaction of **1a** with methyl vinyl ketone (MVK) in the presence of catalytic amounts of DABCO (0.1 eq.) as a *syn* and *anti* mixture (2 : 3), but that no reactions occurred between *p*-nitrobenzaldehyde and MVK dimer under the same reaction conditions (Scheme 4). The yield of **2a** can reach 41 or 48% if using 4.0 or 8.0 eq. of MVK, respectively. Thus, we can conclude that two reactions occur for the traditional Baylis-Hillman reaction of aryaldehydes with MVK. One is the normal Baylis-Hillman reaction which is the 1,2-addition of the anion derived from MVK to *p*-nitrobenzaldehyde. The other is the conjugated addition (Michael addition) of the anion derived from a second molecule of MVK to **1**.

In conclusion, we found that in the Baylis-Hillman reaction of arylaldehydes with methyl vinyl ketone, besides the normal Baylis-Hillman adduct **1**, diadduct **2** was also formed and was confirmed to be derived from the further reaction of **1** with MVK *via* a conjugated addition reaction. Efforts are underway to elucidate the mechanistic details of this reaction and to disclose the scope and limitations of this reaction. Work along this line is currently in progress.

We thank the State Key Project of Basic Research (Project 973) (No. G2000048007) and the National Natural Science Foundation of China for financial support. We also thank the Inoue Photochirogenesis Project (ERATO, JST) for chemical reagents.

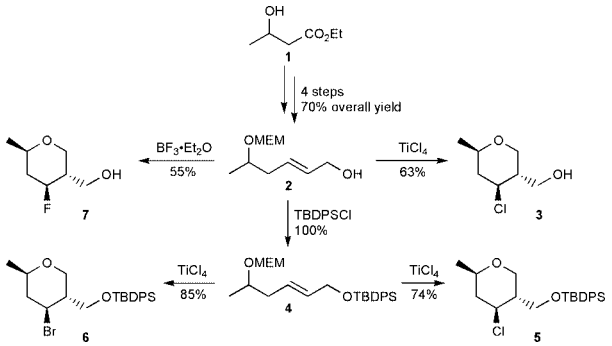
Cyclisation of homoallylic acetals under acidic conditions leads to the formation of 2,4,5-trisubstituted tetrahydropyrans with the creation of two new asymmetric centres with excellent stereocontrol. By varying the acid and the nucleophile, the reaction may be adapted for the preparation of 2,4,5-trisubstituted tetrahydropyrans with either a halide, alcohol, acetate or amide at C-4.

Substituted tetrahydropyrans are common features of many natural products and biologically active compounds and many strategies for their synthesis have been reported. One valuable approach to the preparation of tetrahydropyrans is a Prins type cyclisation in which treatment of a homoallylic acetal (or a mixture of a homoallylic alcohol and carbonyl compound) with acid leads to formation of an oxocarbenium cation intermediate which undergoes an intramolecular reaction with the alkene.[1] Upon cyclisation, the fate of the resulting carbocation intermediate is dependent upon the reaction conditions and substrates employed. Thus, Thompson and coworkers have shown that acetals derived from (*E*)- or (*Z*)-hex-3-en-1-ol cyclised in the presence of titanium tetrabromide or tetrachloride to give the *trans*- or *cis*-3-ethyl-4-halotetrahydropyrans respectively with good stereocontrol.[2] Prins type cyclisations have been widely used for the synthesis of 2,4,6-trisubstituted tetrahydropyrans[3] but examples of their use in the preparation of tetrahydropyrans with other substitution patterns has been rather more limited.[4] In this paper we describe a direct method for the preparation of 2,4,5-trisubstituted tetrahydropyrans from homoallylic acetals[5] which enables the creation of two asymmetric centres with excellent stereocontrol and in which a variety of functional groups may be introduced at C-4.

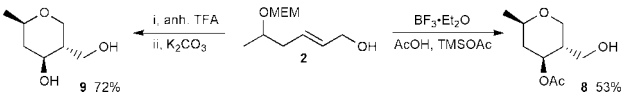
The substrate used for our initial cyclisation studies was the homoallylic acetal **2** which was readily prepared in 4 steps from ethyl 3-hydroxybutanoate **1** (readily available in both enantiomeric forms) by MEM (methoxyethoxymethyl) protection of the alcohol, DIBAL-H reduction to the aldehyde followed by Horner Wadsworth Emmons chain extension with triethyl phosphonoacetate and finally a further DIBAL-H reduction of the resultant (*E*)-α,β-unsaturated ester. In the first cyclisation study, homoallylic acetal **2** was treated with titanium tetrachloride in CH_2Cl_2 giving the 2,5-disubstituted 4-chlorotetrahydropyran **3** in 63% yield (Scheme 1). From the ^1H and ^{13}C-NMR spectra and NOE studies it was apparent that a single product had been isolated in which all three substituents were in an equatorial position.[6] When the primary alcohol of **2** was protected as the TBDPS ether **4**, the $TiCl_4$ mediated reaction gave an improved 74% yield of the cyclic product **5** again as a single diastereomer. By using other Lewis acids, further halides could be introduced at C-4 of the tetrahydropyran. Thus, treatment of **4** with titanium tetrabromide gave the 4-bromo derivative **6** in 85% yield and reaction of **2** with $BF_3{\cdot}Et_2O$ in CH_2Cl_2 gave a 55% yield of the 2,5-disubstituted 4-fluorotetrahydropyran **7**.

The synthetic utility of these cyclisations would be greatly extended if functional groups other than a halide could be introduced at C-4. Several methods have been reported for the introduction of oxygenated substituents at C-4 in Prins type



Scheme 1

cyclisations with varying success. These include the use of mercuric triflate,[7] scandium triflate,[8] $BF_3{\cdot}Et_2O$–AcOH,[3e,9] and TFAA–AcOH.[3f] We investigated a range of methods to cyclise homoallylic acetal **2** with the introduction of an oxygen nucleophile into C-4 of a tetrahydropyran. One of the more efficient procedures proved to be treatment of **2** with $BF_3{\cdot}Et_2O$ in the presence of AcOH as the nucleophile and TMSOAc to act as a fluoride trap to prevent competing formation of the 4-fluoro derivative **7**. Under these conditions, acetate **8** was obtained in 53% yield. Alternatively, treatment of **2** with anhydrous trifluoroacetic acid gave diol **9** in 72% yield after hydrolysis of the resultant 4-trifluoroacetate with potassium carbonate in MeOH, (Scheme 2). Again these reactions proceeded with good stereocontrol and only the all equatorial diastereomer was isolated.

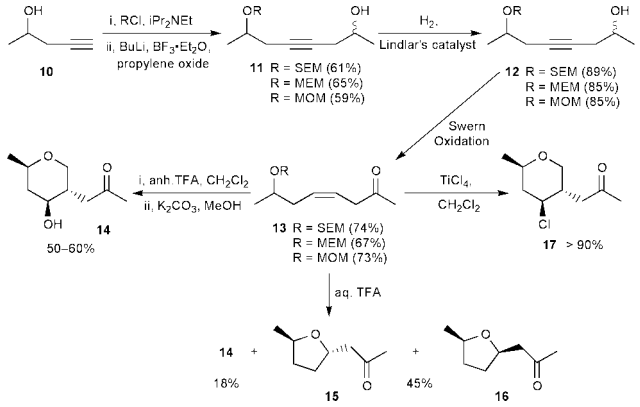


Scheme 2

To further examine the use of TFA for the cyclisation of homoallylic acetals to give 2,4,5-trisubstituted tetrahydropyrans, a series of substrates with a *cis* double bond and a SEM, MEM or MOM group were prepared from pent-4-yn-2-ol **10** (Scheme 3). The hydroxy group of **10** was converted to the acetal prior to reaction of the alkyne with butyllithium, $BF_3{\cdot}Et_2O$ and propylene oxide giving a mixture of diastereomeric alcohols **11**. Catalytic hydrogenation of **11** in the presence of Lindlar's catalyst gave the (*Z*)-alkenols **12** and then oxidation under Swern conditions gave the three required homoallylic acetals **13**. Treatment of the SEM acetal **13** with aqueous TFAA gave three products in which the tetrahydropyran **14** was formed in only 18% yield. The major products were the diastereomeric tetrahydrofurans **15** and **16** formed *via* rearrangement of the double bond into conjugation, hydrolysis of the acetal and an intramolecular conjugate addition to the resultant enone.

However, treatment of each of the acetals **13** with anhydrous TFA in dichloromethane gave, after hydrolysis of the initially formed trifluoroacetate, the 2,5-disubstituted-4-hydroxytetra-

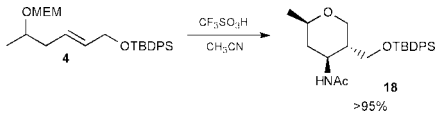
DOI: 10.1039/b101414p



Scheme 3

hydropyran **14** in 50–60% yield with all three substituents again in an equatorial position. Interestingly the stereochemical outcome of this reaction differs from that reported for the cyclisation of MEM protected (*Z*)-hex-3-en-1-ol with $TiCl_4$ in which a *cis* relationship of the vicinal halide and alkyl group predominated.[2] In addition, Rychnovsky and co-workers have shown that although the $TiCl_4$ mediated cyclisation of an (*E*)-unsaturated homoallylic acetal gives an all equatorial 2,5,6-trisubstituted 4-chlorotetrahydropyran, the reaction on the analogous (*Z*)-isomer leads to a mixture of diastereomers in which the 4-chloro-5-alkyl substituents are *cis* in the major isomer.[9] Thus the MEM acetal **13** was cyclised using $TiCl_4$ and the product **17** was obtained in 92% yield again with all the substituents equatorial.

To the best of our knowledge Prins type cyclisations of homoallylic acetals to tetrahydropyrans have never been conducted in the presence of nitrogen nucleophiles although products from such reactions would be of great general value in synthesis. It would be expected that the acidic reaction conditions required for formation of the oxocarbenium cation would not be compatible with the use of amines as nucleophiles. Indeed we found this to be the case. However, on treatment of homoallylic acetal **4** with triflic acid in acetonitrile the 4-amido derivative **18** was obtained in excellent yield (Scheme 4).



Scheme 4

In conclusion, Prins type cyclisation of homoallylic acetals provides a versatile approach to the synthesis of 2,4,5-trisubstituted tetrahydropyrans. Our initial investigations indicate that excellent stereocontrol may be achieved with both *cis* and *trans* alkenes giving the all equatorial product and this merits further investigation. By varying the acid and nucleophile a halide (bromide, chloride or fluoride), oxygenated group (hydroxy, ether or ester) or a nitrogen containing substituent may be introduced at C-4 of the tetrahydropyran.

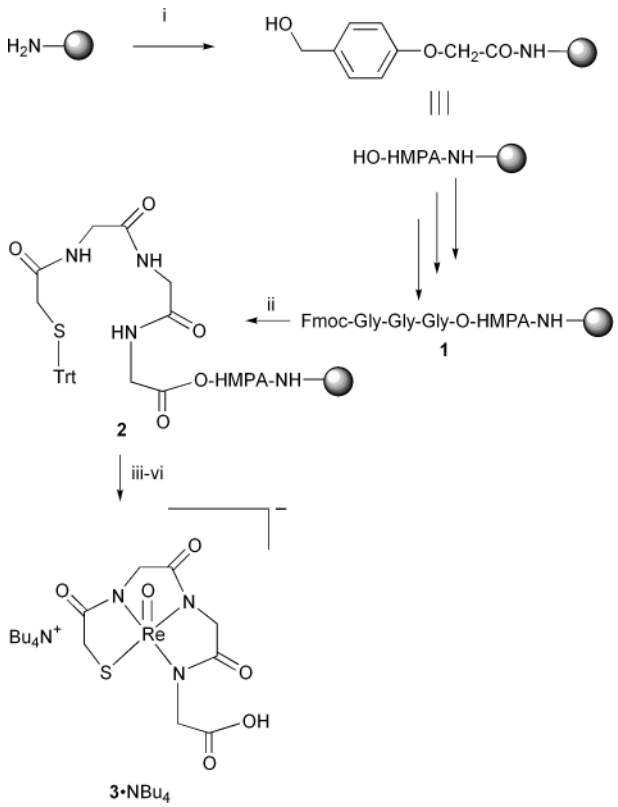
Received (in Cambridge, UK) 2nd January 2001, Accepted 7th March 2001
First published as an Advance Article on the web 11th April 2001

The solid phase synthesis of tetrabutylammonium oxo-(mercaptoacetylglycylglycylglycine) rhenate(v) has been achieved by utilising $ReOCl_3(PPh_3)_2$ as a stable source of Re(v) and provides a synthesis of bi-functional chelates for use in nuclear medicine.

Over the last 10 years, there has been tremendous progress in transferring solution-phase expertise into solid-phase organic synthesis (SPOS). Here, we wish to report the solid-phase synthesis of oxo(mercaptoacetylglycylglycylglycine)rhenate(v) ($ReOMAG_3$)[1] an analogue of ($^{99m}TcOMAG_3$) the widely used renal imaging agent. The advantages of a solid phase approach in this area being the relative ease of synthesis, the ability to directly load the resin with the metal agent of choice, and the prospect of making bead based libraries that can be readily screened using radioactivity to pinpoint the desired ligand. The physical properties of ^{186}Re (1.07 MeV beta max, 3.7 d half life, 137 keV gamma photons (9%) and ^{188}Re (2.12 MeV beta max, 0.9 d half life, 155 KeV gamma photons (15%)) have prompted nuclear medicine chemists to use $^{186/188}Re$-labelled bio-molecules[2] as therapeutic tools in the treatment of cancers. Another important driving force is that Re chemistry can provide a non-radioactive alternative to ^{99m}Tc, the most widely used radionuclide in diagnostic nuclear medicine, when studying the coordination chemistry of Tc.[3] This is due to the lanthanide contraction such that Re and Tc have very similar physical characteristics, although rhenium complexes are harder to reduce and kinetically more inert than those of technetium. In the indirect labelling method, a bifunctional chelate is first metallated and then conjugated to a monoclonal antibody capable of targeting a specific tumour-associated antigen. $ReOMAG_3$ has been the choice of preformed chelate by a number of groups.



Scheme 1 Solid-phase synthesis of $ReOMAG_3$ (**3**). (i) 4-Hydroxymethylphenoxyacetic acid, DIC, HOBt, CH_2Cl_2–DMF (4 : 1), overnight; (ii) (a) 20% piperidine, DMF, (b) Trt-S-CH_2CO_2H, DIC, HOBt, CH_2Cl_2:DMF (4 : 1), 4 h; (iii) 2% TFA, 2% TIPS; (iv) $ReOCl_3(PPh_3)_2$, DBU, DMF, 18 h; (v) 60% TFA, 5% H_2O in CH_2Cl_2, 4 h; (vi) Bu_4NCl, H_2O–CH_2Cl_2.

4-Hydroxymethylphenoxyacetic acid (HMPA) (Scheme 1) was anchored onto TentaGel-S-NH_2 (130 μm, 0.29 mmol g^{-1}, Rapp Polymere) using equimolar amounts of HOBt and DIC.[4] The first Fmoc-Gly residue was attached using a similar procedure but with a catalytic amount of DMAP. Following standard Fmoc chemistry, Fmoc-triglycine (**1**) was synthesised on the solid support. After thoroughly drying the resin was deprotected and subjected to a quantitative ninhydrin test to give a loading of 0.17 mmol g^{-1} (theoretical loading 0.25 mmol g^{-1}). After Fmoc deprotection of **1**, tritylmercaptoacetic acid[5] was coupled to the resin using HOBt and DIC as coupling reagents. The free thiol group was obtained by treating the resin eight times with 2% TFA, 2% TIPS in DCM for 15 min each time. Shorter reaction times were not successful. The resin was then treated with $ReOCl_3(PPh_3)_2$[6] as the most efficient source of Re(v). Optimal conditions were a 1 : 2 molar ratio of Re-$OCl_3(PPh_3)_2$[6] with DBU in DMF for 18 h. The use of higher molar ratios or higher temperatures gave worse results. After

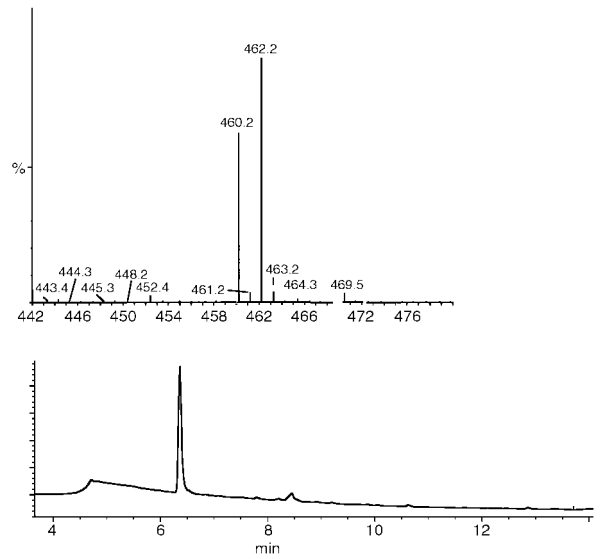


Fig. 1 MS and HPLC analysis of the solid-phase synthesis of $ReOMAG_3$.

DOI: 10.1039/b100004g

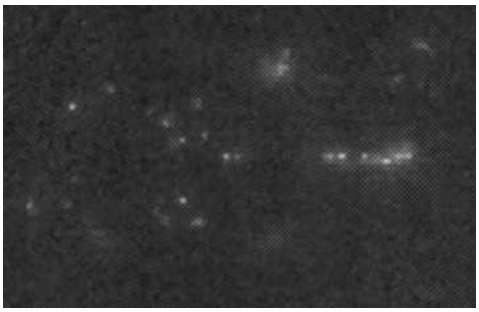

Fig. 2 Phosphoimager scan of resin-bound $^{99m}TcOMAG_3$.

TFA cleavage and counter ion exchange chromatography, $[Bu_4N][ReO(MAG_3)]$ (**3**·NBu_4) was obtained[7] in 91% purity (following RP-HPLC),[8] (Fig. 1). This compound showed identical RP-HPLC retention time, ESMS and IR to a sample prepared in solution following the procedure of Fritzberg *et al*.[9] The same series of reactions was also carried out successfully on aminomethylpolystyrene resin (1% DVB, 1.24 mmol g^{-1}).

To demonstrate the use of resin linked chelates for the screening of resin based libraries of MAG_3 derivatives, a solid phase labelling experiment using MAG_3 as a ligand for ^{99m}Tc was carried-out. In this fashion, Trt-$SMAG_3$ immobilized onto TentaGel-S-NH_2 *via* the HMPA linker was first submitted to trityl deprotection conditions as above and then to $^{99m}TcO_4^{2-}$, sodium gluconate and $SnCl_2$ in saline. After thorough washing of the resin, 45% of the radioactivity was retained. This resin was then swollen in water and carefully plated in a 1% agarose solution poured over a glass surface. Using automatic autoradiography or a Storm Phosphoimager it was possible to localize areas in the gel containing radioactive beads (Fig. 2).

A similar experiment where the thiol deprotection step was intentionally omitted resulted in no ^{99m}Tc complexation, as indicated by the absence of activity in the washed resin. Other controls such as acetylated TentaGel-S-NH_2 submitted to direct labelling conditions ($^{99m}TcO_4$ in saline) or to ligand exchange labelling conditions ($^{99m}TcO_4$, sodium gluconate and $SnCl_2$ in saline) showed no technetium complexation by the polymeric support.

In conclusion the synthesis of tetrabutylammonium oxo-(mercaptoacetylglycylglycylglycine)rhenate(v) has been achieved in high purity by using a preformed Re(v) complex as the source of Re(v). This opens the possibility of screening libraries of ligands for Re affinity and therefore new ligands for binding Tc for medicinal imaging applications.

7 Typical procedure: *ca*. 30 mg of resin loaded with Trt-$SMAG_3$ was pre-swollen in CH_2Cl_2 (1mL) for 10 minutes in a peptide vessel. Solvent was removed by applying N_2 pressure. The resin was treated with a solution of 2% TFA, 2% TIPS in CH_2Cl_2 (*ca*. 10 mL × 15 min × 8 times). The resin was washed with CH_2Cl_2 and pre-swollen in DMF for 10 min. After removing excess solvent, a solution of $ReOCl_3(PPh_3)_2$ (23 mg, 28 μmol) and DBU (8.5 μL, 56 μmol) in DMF (3 mL) was added to the resin. After shaking on a mechanical shaker for 12 h at rt, the resin was filtrated and washed thoroughly with DMF, CH_2Cl_2, MeOH and Et_2O. The compound was cleaved from the resin with 60% TFA, 5% H_2O in CH_2Cl_2 for 4 h. TFA was removed *in vacuo* and the residue suspended in H_2O. Bu_4NCl (8 mg, 29 μmol) was added and the compound was extracted into CH_2Cl_2. Negative ESMS: m/z = 462 $[M]^-$. IR: 975 cm^{-1} (Re=O).

8 Analytical HPLC: chromatograms were obtained on a Hewlett Packard HP-1100 system equipped with a Phenomenex Prodigy C18 reverse phase column (3.0 mm × 150 mm). Solvents used were: A: 0.1% TFA in H_2O and B: 0.042% TFA in CH_3CN, gradient 0% B to 100% B over 20 min. The column effluent was monitored using a detector wavelength of 220 nm. The retention time of $ReOMAG_3$ was 6.4 min.

Novel acylation of a vinyl group by the reaction of an aldehyde and a vinylselenonium ylide

Shin-ichi Watanabe, Tomokazu Kusumoto, Chikayo Yoshida and Tadashi Kataoka*

Received (in Cambridge, UK) 17th January 2001, Accepted 23rd March 2001
First published as an Advance Article on the web 11th April 2001

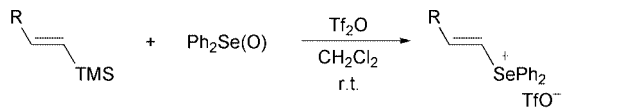
Vinylselenonium ylide, which was generated from (*Z*)-vinylselenonium salt with a base such as sodium or potassium hydride, reacted with aromatic aldehydes to produce the α,β-unsaturated ketones, which were obtained in better yields from the aldehydes with an electron-withdrawing group than from those with an electron-donating group.

Generally, vinylonium salts, for example vinylphosphonium,[1] sulfonium,[2] and selenonium[3] salts, are utilized as Michael acceptors against nucleophiles to produce saturated alkyl ylides, which are among the most important synthons of the C–C bond forming reaction. If the α-hydrogen of a vinylonium salt is abstracted by a base, a vinyl onium ylide is formed. There have been few reports about the reactivity of vinylphosphonium ylide, which reacts with carbonyl compounds to afford allene derivatives through the Wittig olefination.[4] However, reports on the reaction of other vinylonium ylides with carbonyl compounds have been lacking.

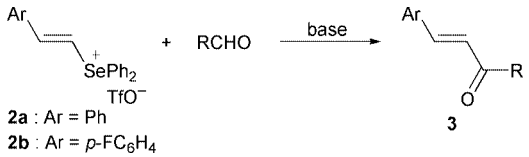
In the course of our studies on alkenylselenonium salts,[5] we have focused on the reactivity of vinylselenonium ylides with great interest. To our astonishment, the reactions of vinylselenonium ylides with aromatic aldehydes did not bring about the Wittig type reaction but caused an acylation reaction of a vinyl group. Although there have been a few reports on the efficient acylation of the vinyl group using aldehyde *via* alkoxyvanadium[6] or alkoxyzirconocene intermediates,[7] our reaction is quite different from these reactions which use an organometallic reagent. This transformation is a novel and original reaction, and would attract the interest of many chemists in the unprecedented behavior of vinyl ylides. We report herein the first example of acylation reactions of vinylselenonium ylides with aldehydes affording *trans*-chalcone derivatives efficiently *via* umpolung of a carbonyl group like the Lapworth condensation.[8]

Firstly, vinylselenonium salts bearing an α-hydrogen were prepared from the reactions of vinylsilanes with diphenyl selenoxide and Lewis acid in CH_2Cl_2 at rt by reference to the procedure for alkynylselenonium salts (Scheme 1).[9]† (*E*)-Trimethylstyrylsilanes **1a** and **1b** reacted cleanly in the presence of trifluoromethanesulfonic anhydride for 4 and 2 h to afford the vinylselenonium triflates **2a** and **2b** in 87% and 59% yield, respectively, with retention of configuration. The (*Z*) stereochemistry of **2b** was established by observation of the NOE enhancement (10%) between the α-vinylic proton and *ortho*-protons of the *Z*-aryl group.

Next, we investigated the reactions of vinylselenonium ylides with aldehydes (Scheme 2). The ylides were generated by the

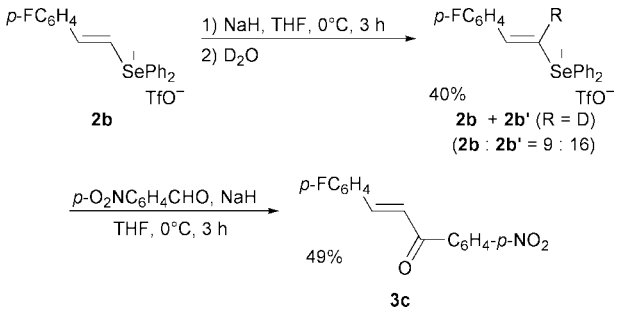


Scheme 1



Scheme 2

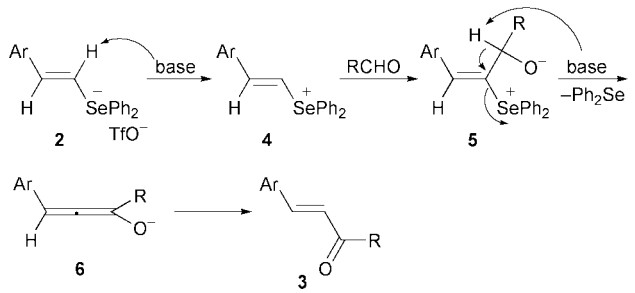
reaction of vinylselenonium salts **2** with sodium hydride. The reaction of vinylselenonium salt **2a** (1 equiv.) with *p*-nitrobenzaldehyde (1 equiv.) in the presence of 1.3 equiv. of sodium hydride at 0 °C for 3 h in THF gave *p*-nitrophenyl styryl ketone **3a** in 65% yield but did not proceed at −78 °C. Since *p*-chlorobenzaldehyde gave *p*-chlorophenyl styryl ketone **3b** (11%) with recovery of the aldehyde (30%), 2 equiv. of sodium hydride were used and the yield of **3b** was improved up to 58%. However, the reactions with benzaldehyde or *p*-tolualdehyde gave complex mixtures including unreacted aldehyde, and α,β-unsaturated ketones were not isolated. To confirm the formation of the vinylselenonium ylide, vinylselenonium salt **2b** was stirred with 1 equiv. of sodium hydride in THF at 0 °C for 3 h without the aldehyde, followed by treatment with D_2O to afford a mixture of **2b** and **2b′** (**2b**:**2b′** = 9:16) in 40% yield. The mixture of **2b** and **2b′** was treated with sodium hydride in the presence of *p*-nitrobenzaldehyde under the same conditions as for the reaction of **2a** with *p*-nitrobenzaldehyde to give the compound **3c**, which contained no deuterium, in 49% yield (Scheme 3). This finding indicated that the above reactions proceeded *via* a vinylselenonium ylide. On the other hand, the reaction of vinylselenonium salt **2b** and benz(aldehyde-*d*) with sodium hydride in DMF at 0 °C for 4 h was conducted to trace the hydrogen atom of an aldehyde. 3-(4-Fluorophenyl)-1-phenylpropenone **3d** obtained in 14% yield did not contain any deuterium.



Scheme 3

On the basis of these results, we propose a plausible mechanism for the reactions of vinylselenonium salts with aldehydes (Scheme 4). Vinylselenonium ylide **4** is formed from the reaction of vinylselenonium salt **2** with sodium hydride followed by reaction with an aldehyde to produce betaine **5**. Deprotonation from the betaine **5** by a base gives rise to the β-elimination to generate allenoate ion **6**, which isomerizes to the α,β-unsaturated carbonyl compound **3**.

DOI: 10.1039/b100660f



Scheme 4

Next, potassium hydride, as a stronger base than sodium hydride, was adopted in this reaction to improve the yield of compound **3** (Table 1).‡ The reaction of *p*-nitrobenzaldehyde with 2 equiv. of vinylselenonium salt **2a** in the presence of 3 equiv. of potassium hydride in THF at 0 °C for 0.5 h afforded the chalcone derivative **3a** in excellent yield (entry 1). The reactions of *p*-halobenzaldehydes also gave the corresponding α,β-unsaturated carbonyl compounds **3b** and **3e** in high yields compared with the reactions using sodium hydride (entries 2 and 3). Although no chalcone derivative had been obtained from the reaction of benzaldehyde or *p*-tolualdehyde using sodium hydride, *trans*-chalcone **3f** was given using potassium hydride in THF–DMSO (13 : 1) at −30 °C in up to 60% yield (entry 5); moreover, the reaction with *p*-tolualdehyde bearing the electron-donating group afforded chalcone derivative **3g** in moderate yield (entry 6).

Table 1 Reactions of vinylselenonium salt **2a** with aldehydes in the presence of KH[a]

Entry	RCHO	Conditions	Product (% yield)
1	*p*-$O_2NC_6H_4CHO$	KH, THF, O °C, 0.5 h	**3a** (94)
2	*p*-ClC_6H_4CHO	KH, THF, O °C, 0.5 h	**3b** (77)
3	*p*-BrC_6H_4CHO	KH, THF, O °C, 0.5 h	**3e** (76)
4	PhCHO	KH, THF, −10 °C, overnight	**3f** (43)
5		KH, THF–DMSO,[b] −30 °C, 2 h	**3f** (60)
6	*p*-MeC_6H_4CHO	KH, THF–DMSO,[b] −30 °C, 3.5 h	**3g** (49)

[a] **2a**: RCHO : KH = 2 : 1 : 3. [b] THF : DMSO = 13 : 1.

In conclusion, we have shown the first example of the reactions of vinylselenonium ylides with aldehydes, which proceed *via* the β-elimination of the adducts of the vinylselenonium ylides and the aldehydes because the selenonio group is a good leaving group to produce *trans*-chalcone derivatives. The results described in this paper implies that the vinylselenonium ylides would react with other carbonyl compounds differently from vinylphosphonium ylides, and we continue our study on the vinylselenonium ylides to exploit their new reactions.

Received (in Cambridge, UK) 4th January 2001, Accepted 22nd March 2001
First published as an Advance Article on the web 12th April 2001

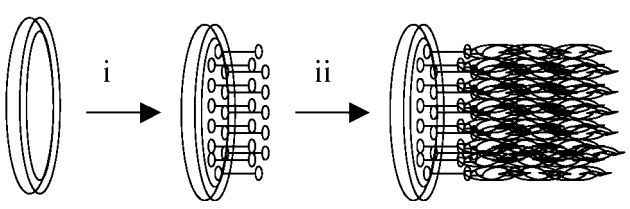
A new development in quartz crystal resonant sensor (QCRS) technology allows real-time analysis of binding by small molecules to DNA and has been tested using superoxide dismutase mimics.

Low molecular weight compounds interact with DNA in a variety of ways, from intercalation by π-stacking and hydrogen bonding to covalent bond formation.[1] The strength of the interaction is a good indication of each compound's binding mode with DNA and may be a direct indication of mutagenicity. We have developed a test based on the quartz crystal resonant sensor (QCRS) to measure DNA–analyte binding directly in real time. The QCRS is a robust sensor for which applications as diverse as volatile organic compound detection,[2] monitoring of antibody–antigen agglutination[3] and gene sensing have been found.[4] The technique uses surface modified piezoelectric quartz crystals to register the presence of chemical and biological species in the liquid phase *via* the change in resonant frequency as a function of analyte adhesion with time. Our method allows the determination of the type of interaction between DNA and small molecules, together with direct observation of any destructive effects such as DNA scission.† Briefly, thin film gold electrodes on the quartz crystals are coated with a bifunctional binder (NeutrAvidin™) followed by suitably functionalised DNA (Scheme 1). Solutions of small molecule analytes are then passed over the sensor in a flow-through cell and the frequency changes resulting from binding, due to the concomittant mass increase of the sensor, are monitored. The duration of the experiment makes the technique ideally suited to rapid screening of small molecule–DNA interactions. To confirm that the binding observed was indeed to DNA and not to one of the substrates on the QCRS, test runs were performed on partially modified sensors. Solutions of compounds were passed over crystals which had NeutrAvidin™, but no DNA, attached. Any observed frequency changes were short lived and final deviations from the base frequency were approximately 5% of the deviation shown when DNA was present. To ensure consistency all tests were carried out at the same flow rate (5 μl min^{-1}).

Analytes expected to bind to DNA in a variety of different ways were chosen to test the technique. Cisplatin **1** was chosen to probe strong, irreversible binding.[5] 5-Aminoacridine **2** and 9-amylaminoacridine **3**[6] were chosen to represent varying degrees of intercalation. Bleomycin **4** was included as an example of a well known DNA cleaving agent.[7]

To complement the behaviour of these analytes we also tested manganese(III) salen chloride **5**[8] and its 3,3′-methoxy analogue **6**.[9] These compounds act as successful superoxide dismutase mimics *in vivo* and have recently been shown to extend average lifespan in nematode worms, *Caenorhabditis elegans*.[10] Observation of the binding, if any, to DNA may reveal how they work and will represent a true trial of the system.

Fig. 1 shows that **1** took less than two minutes from injection to saturate the sensor and exhibited a drop in resonant frequency of 68 Hz. As expected, **2** bound slowly, taking about 8 min to saturate binding sites, and gave an overall frequency change of 8 Hz. The binding profile for **3** has a similar pattern to that of **2** but a greater frequency change (32 Hz) was observed due to the increased hydrogen bonding available to this compound. Compound **4** showed initial binding followed by a plateau which we speculate is due to a rearrangement process. The frequency then dropped again before finally rising after a further 8 minutes. This behaviour is consistent with cleavage of DNA and its subsequent removal from the surface of the sensor. Initial association rates calculated for each compound show a greater than 10-fold difference between cisplatin and 9-amylaminoacridine, and an additional 75-fold difference when compared with 5-aminoacridine (Table 1). Early literature studies involving acridines suggest that more than one site is involved in the intercalation process.[11] A mechanism published for proflavin suggested that its mechanism was distinct from either intercalation or electrostatic attraction.[12] It is thought unlikely that our observed responses are due solely to the binding of low molecular weight compounds to DNA. In particular, a degree of reorganisation is likely within the structure of the DNA that may cause frequency shifts due to viscoelastic interfacial changes additive to the initial mass change. Similar phenomena have been observed with ligands binding to RNA.[13,14]



Scheme 1 Sensor preparation: i, surface modification of gold covered quartz crystal with NutrAvidin™; ii, addition of biotinylated DNA.

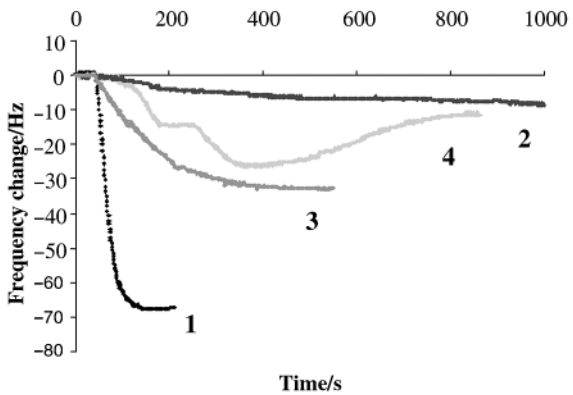


Fig. 1 Binding curves for compounds **1**, **2**, **3** and **4**.

DOI: 10.1039/b100175m

Table 1 Mass changes and initial binding rates for analytes

Compound	Mass change upon addition to sensor/μg[a]	Initial association rate/s^{-1}
Cisplatin **1**	0.60	1.54
5-Aminoacridine **2**	0.50	0.02
9-Amylaminoacridine **3**	0.60	0.14
Bleomycin **4**	0.56	0.20
[Mn(III)(salen)]$^+$ **5**	0.70	0.25
[Mn(III)(3,3′-methoxysalen)]$^+$ **6**	0.71	0.03

[a] Calculations assume saturation of compounds on DNA.

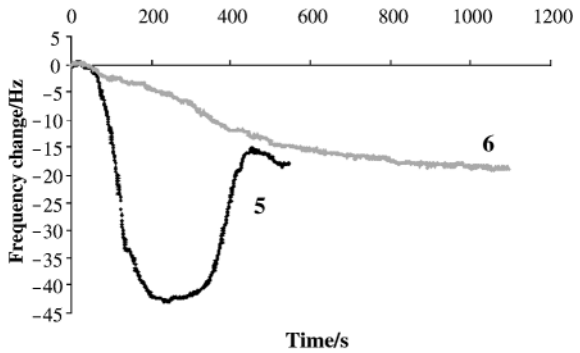

Fig. 2 Binding curves for compounds **5** and **6**.

It can be seen from Fig. 2 that **5** has a similar profile to that of **4** indicating initial strong binding to DNA followed by cleavage. To confirm this interpretation we stained the QCRS-tethered DNA with acridine orange. Fluorescence microscopy of the QCRS prior to addition of **5** showed a spatially homogeneous distribution of stained DNA across the sensor surface. Further microscopy of the eluent, following addition of **5**, showed that it contained acridine orange-stained DNA, confirming that **5** had pro-oxidant activity towards free DNA. Conversely the 3,3′-methoxy analogue, **6**, appeared to intercalate weakly, with a similar profile to the acridine derivatives, giving a maximum frequency drop of 20 Hz. Staining DNA with acridine orange prior to addition of **6** and examination of the eluent post addition indicated no significant cleavage. After 8 min the binding profile of **5** follows that of **6** indicating that they both act as weak intercalators in the long term.

Melov *et al*. have shown that both **5** and **6** extend lifespan of *C*. *elegans*; however, only **6** gives rise to re-emergent fertility in longer lived worms.[10] We conclude that the lack of pro-oxidant activity of **6**, as indicated by the QCRS, is responsible in part for its greater benefits.

It appears that both the magnitude of the frequency change and, more importantly, the binding profile due to each analyte are directly related to the type of analyte–DNA interaction. The QCRS is therefore an ideal technique to study the interactions of a wide variety of small molecules with DNA and other biological macromolecules.

This research has been supported by the A-T Children's Project and GlaxoSmithKline Pharmaceuticals.

Notes and references

† *Experimental conditions*: 8.6 mm diameter, 10 MHz AT-cut quartz crystals (Hi-Q International, Cambridge, UK) were furnished with 100 nm thick gold electrodes (19.5 mm^2 area), placed into an in-house fabricated flow-through liquid cell (20 μl volume) and connected to a novel gain control oscillator[15] designed specifically to work in liquid environments of high viscosity and density. Output from the crystals was monitored using a Fluka-6689 frequency counter capable of sub-single hertz resolution, data being collected once per second *via* Fluka Timeview software. Crystals were washed with HPLC grade ethanol prior to deposition of Neutr-Avidin™ (Pierce, IL, USA). The electrodes were coated with Neutr-Avidin™ by a single 20 μl injection of the binding agent (2 mg ml^{-1} in Sorensen's phosphate buffer) *via* an all PEEK™ Rheodyne MMB six-way valve into the running buffer until a stable baseline with noise below 0.2 Hz was observed. Once a stable signal had been obtained for the modified crystal, it was washed with biotinylated DNA (b-DNA, Vector Laboratories Ltd, Peterborough, UK) at 50 μg ml^{-1} in Sorensen's phosphate buffer (20 μl injection loop, 1 μg per injection). Washes were repeated until no further frequency change was observed in order to ensure that the sensor surface was saturated (*ca*. 2.5 μg of DNA on the surface). The b-DNA contained a range of lengths from 125 to 23 100 base pairs to ensure variation in potential binding sites for the analytes. Modified electrodes were exposed to solutions of the DNA binding agents (500 μM in phosphate buffer solution, Table 1, flow rate 5 μl min^{-1}, 22 ± 0.5 °C) and resultant frequency changes monitored for up to 20 min. Run-to-run reproducibility was better than 5% (N = 3) in all cases.

First published as an Advance Article on the web 12th April 2001

A new approach to superior optical limiting materials, utilizing planar 'open' skeleton heterothiometallic clusters, is reported by incorporating heavy atoms and altering cluster skeletons and is found to decrease the limiting thresholds to as low as 0.07 J cm^{-2}, among the best for OL materials.

Rapid recent developments of both high-power frequency-tunable lasers and optical signal detection techniques have led to increasing demands for broadband nonlinear optical materials.[1] These materials have been designed either to protect sensitive optical sensors such as the human eye from intense optical radiation[2] or to be used in optical computers and broadband communications for data acquisition, storage, transmission, and processing.[1,3] Over the past decades, research in the optical limiting (OL) materials has been largely focused on inorganic semiconductors, conjugated polymers, organic molecules, and organometallic compounds.[1–6] The general relationships between molecular structures and OL performance in various existing OL materials are, however, yet to be well established, and this has presented a difficult task in the effort to improve the OL properties through molecular structure design.[5d]

We have recently developed Mo(W)/S/Cu(Ag) heterothiometallic clusters as a new class of OL materials.[7] These clusters combine the advantages of inorganic heavy atoms, organic ligands, and versatile cluster structures. Studies have been conducted on the relationship between the structures and OL properties of these clusters with various skeleton shapes such as butterfly, nest, half-open cubane, trinuclear linear, cubane, hexagonal-prismatic, twin-nest, twenty-nuclear supercage and cluster polymer.[7,8] Unlike some traditional OL materials, the skeletons and constituent elements in these clusters were found to have considerable influence on their OL performance. Changes in cluster compositions (skeletal or terminal elements), such as incorporation of heavy atoms, generally enhance the OL performance of these clusters. Moreover, cubane-shaped and hexagonal-prismatic clusters show large OL effects.[7a,c] The OL effect of these two kinds of clusters are comparable to those of fullerene C_{60} and phthalocyanine derivatives, respectively, which are generally regarded to be among the best OL materials.[1,5,6] The enhancement in the OL properties of the hexagonal-prismatic clusters over the cubane-shaped clusters suggested that modification of cluster structures may further enhance their OL properties.

With these in mind, we have thus studied the OL properties of a series of planar clusters $[MS_4Cu_4X_2(py)_6]$ (X = I, M = W, **1**, Mo, **2**; X = Br, M = W, **3**, Mo, **4**; X = Cl, M = W, **5**, Mo, **6**) and $(Et_4N)_2[MS_4Cu_4(NCS)_4(2\text{-pic})_4]$ (M = W, **7**; Mo, **8**). The clusters **1**–**8** were all synthesized in our laboratories;[7b,8a] **1**–**6** were prepared from the reactions of $(NH_4)_2MS_4$, CuX and py† while **7** and **8** were obtained from the reactions of $(Et_4N)_2MS_4$ and CuSCN with 2-pic.[8a] The structures of **1**, **3** and **4** were determined by IR, elemental analyses and X-ray diffraction.‡

These clusters all have a pentanuclear planar 'open' structure with a $[MS_4Cu_4]$ aggregate of approximate D_{2d} symmetry (Scheme 2). Their electronic spectra show a relatively weak linear absorption in the VIS–NIR region.† The OL effects of clusters **1**–**8** in DMF solutions were measured with linear, polarized 8 ns duration laser pulses at 532 nm generated from a Q-switched frequency-doubled Nd:YAG laser.

The NLO process in these clusters can be approximately represented by eqn. (1)[6c]

$$\frac{dI}{dz} = -\left[\alpha_0 + \left\{\left(1 + K_\alpha \frac{I}{I_s}\right)\sigma_g N \Big/ \left(1 + \frac{I}{I_s}\right)\right\}\right] I \qquad (1)$$

where α_0 is the linear absorption coefficient of the solvent, σ_g is the absorption cross-section of the ground-state molecular solution, N is the concentration of the cluster sample solution, $I_s = h\gamma/\sigma_g\tau_{eg}$ is the saturable intensity, with τ_{eg} being the lifetime of the excited-state, and $K_\alpha = \sigma_e/\sigma_g$ is the ratio between the excited-state absorption cross-section and the ground-state absorption cross-section. The limiting thresholds of these clusters, which is defined here as the incident fluence at which the transmittance falls to 50% of the linear transmittance, were found to be 0.07, 0.08, 0.08, 0.10, 0.10 and 0.15 J cm^{-2}, respectively. Representative energy-dependent transmittance data for cluster **1**, shown in Fig. 1, shows a reduction in transmittance at high fluence. The limiting thresholds of **1**–**5** are comparable to those (*ca.* 0.1 J cm^{-2}) of phthalocyanine derivatives[6a,b] and hexagonal-prismatic $Mo_2Ag_4S_8(PPh_3)_4$,[7c] and, to our knowledge, among the lowest reported so far.[9] The limiting thresholds of **7** and **8** were found to be 0.3 and 0.5 J cm^{-2}, respectively, and higher than those of the neutral clusters $MS_4Cu_4X_2(py)_6$ (**1**–**6**) with halide and pyridine ligands.

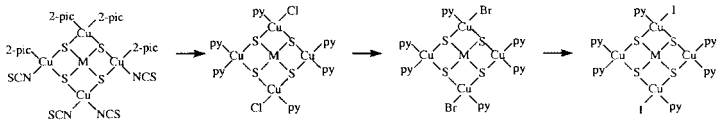
DOI: 10.1039/b100395j



Scheme 2

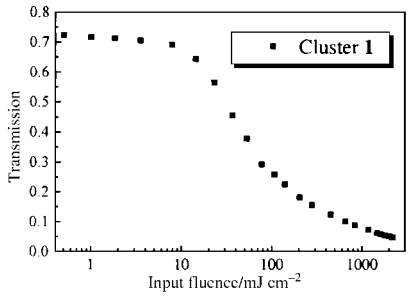


Fig. 1 The energy-dependent transmittance of **1**.

The alteration of the cluster skeleton (cubane-shaped → hexagonal-prismatic → pentanuclear planar) led to significant enhancements in OL properties of these clusters (Scheme 1). In addition, in the pentanuclear planar clusters, the substitution of light elements by heavy elements [Mo by W, and Cl or N (in SCN) by Br or I, respectively] further reduced the limiting thresholds (Scheme 2). The ESI gives a list of the limiting thresholds of these pentanuclear planar W(Mo)/S/Cu heterothiometallic clusters (**1**–**8**) and other OL materials reported earlier.†

Pump–probe measurements were conducted on clusters **1**–**8** to further investigate the physical origin of their optical nonlinearities.† A frequency-doubled Nd : YAG pulse laser with a 532 nm wavelength and 8 ns pulse width was used as a pump beam (pulse energy: 300 μJ). A CW He–Ne laser with 632.8 nm wavelength was used as a probe beam (optical power: 20 mW). The change of the probe beam intensity *vs*. the delay time was recorded after the pump beam by using BOXCAR. The optical nonlinearities of the clusters and fullerene C_{60} were studied using the same experimental setup. The pump–probe experimental results indicate that the optical nonlinearity responses of the clusters are similar to that of fullerene C_{60} which exhibits a typically excited-state nonlinearity.[5b] We can therefore reasonably conclude that the OL ability in clusters mainly arises from excited-state absorption processes. In the meantime, the results of *Z*-scan experiments[10] show that clusters **1**–**8** have remarkable and very strong nonlinear optical absorption effects.† The NLO absorptive experiment under an open-aperture configuration of **1** is depicted in Fig. 2. These NLO absorptive properties meet the essential requirements of ideal OL materials. We speculate that OL properties of **1**–**4** were enhanced in part by the planar skeleton and the heavy atoms in the clusters. The heavy atom effects of the planar 'open' structures in **1**–**4** may allow better spin–orbital couplings, and thus intersystem crossing at the excited states.[5d,7a] Large spin–orbital couplings might be beneficial if the nonlinear absorption of desired excited states are associated with the T_1–T_n electronic transitions as found for fullerene C_{60} and phthalocyanine systems.[5,6] In addition, the use of heavy atoms such as W and I may introduce more sublevels into the energy hierarchy, and provide more allowed electronic transitions for the initial excited state in **1**–**4**. The increased numbers of the allowed electronic transitions probably enhance the nonlinear absorption of the initial excited state to higher excited states. On the other hand, the planar clusters have higher symmetry than the cubane-shaped and hexagonal-prismatic clusters. The higher symmetry, as in the phthalocyanine systems,[5d] may decrease the probability of ground-state electronic transitions and give a smaller absorption cross-section σ_g and a larger σ_e/σ_g (K_α) ratio, which are obtained from the *Z*-scan measurements.

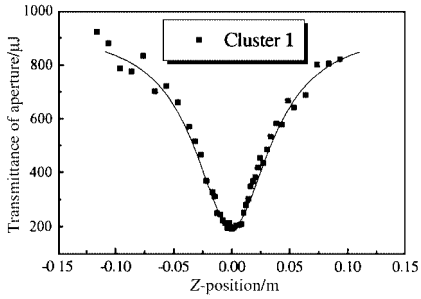

Fig. 2 The *Z*-scan experiment under an open-aperture configuration of **1**.

The current work showed that molecular engineering approaches such as incorporating heavy atoms and altering cluster skeletons are perhaps a promising research direction in search of better OL materials. Studies are under way to further probe the ultrafast OL mechanism of these planar 'open' heterothiometallic clusters **1**–**8** and to design and prepare better OL materials.

Received (in Cambridge, UK) 8th February 2001, Accepted 7th March 2001
First published as an Advance Article on the web 17th April 2001

Cluster formation can be induced *in situ* in SWNTs filled with $ZrCl_4$ by electron beam irradiation of SWNT/$ZrCl_4$ composites within a field emission gun transmission electron microscope (FEGTEM); the process represents a possible route to the synthesis of 1D-quantum dot arrays formed by related materials.

Single-walled carbon nanotubes (SWNTs)[1] can be filled by solution-deposition[2] or capillarity methods[3] similar to those used to fill multi-walled carbon nanotubes (MWNTs).[4,5] There is now considerable theoretical[6,7] and experimental[8–11] evidence indicating that doped SWNTs show enhanced conductive or opto-electronic properties compared to untreated tubules. In addition, as most SWNTs fall within a narrow 1.2–1.6 nm diameter range when formed by vaporisation of catalytically doped carbon,[12,13] their capillaries can template the formation of atomically thin crystals of tubule-specified diameters. Recently these have included 2×2 and 3×3 atomic layer thick KI crystals,[14,15] helical iodine chains,[9] 1D polyhedral chains of lanthanide halide crystals[16] and chains of fullerene or endofullerene molecules.[17–20] In this study, we show how discrete $ZrCl_x$ (with $0 \leqslant x < 4$) clusters of constrained diameters can be formed within SWNTs by electron-beam irradiation of tubules filled with $ZrCl_4$.

The SWNTs used in this work were prepared by a catalytic arc synthesis method.[13] $ZrCl_4$ was resublimed at 693 K under N_2 from the as-supplied product (Aldrich, 99.9%). As-prepared SWNT material was mixed with $ZrCl_4$ in a 1 : 1 ratio by mass under dry box conditions and ground thoroughly. Each sample was sealed under vacuum in a silica glass ampoule and heated at 2 K min^{-1} to 623 K in a tube furnace, held at that temperature for 1 h and then furnace cooled to room temperature. The specimen was characterised in a JEOL 3000F FEGTEM operated at 300 kV and equipped with a Gatan 794 (1 k $\times$ 1 k pixel) CCD camera. The beam density in imaging mode was *ca.* 5×10^5 e^- nm^{-2} s^{-1} which is equivalent to a current of *ca.*2.7 $\times$ 10^{-14} A. The chemical identity of the specimen was confirmed by energy-dispersive X-ray microanalysis (EDX) using a 0.5 nm diameter focussed electron probe, a LINK 'Pentafet' detector and an Oxford Instruments 'ISIS' 300 system.

When examined under the FEGTEM, both nanotube bundles and discrete SWNTs were observed to be filled continuously with 1D chains of $ZrCl_4$. EDX microanalysis performed on discrete filled SWNTs confirmed the chemical identity of the filling material. As a spread electron beam of specified electron density (see above) was held upon regions of filled SWNTs, the filling material underwent progressive changes in morphology as it segregated to form discrete clusters. The sequence of events was followed over periods of up to 20 min, after which the encapsulating SWNTs denatured.

Fig. 1 shows a sequence of ten FEGTEM images obtained over *ca.* 4 min. In the initial image **I**, two continuously filled SWNTs can be seen with the upper tubule being terminated by a cap visible on the right of the image. By image **II**, the filling in the bottom tubule has already segregated into three *ca.* 3–4 nm long clusters. By image **V**, the arrowed clusters have different lengths of 3, 2 and 4 nm, respectively. By image **VI**, the material in the topmost tubule had also segregated into two clusters (arrowed). By the final image **X**, discrete *ca.* 1 nm long clusters can be seen in the two nanotubes with the number of clusters in the bottom tubule increased from three (see image **V**) to four. It is important to note that during these initial transformations (*i.e.* before the denaturing of the SWNTs) the walls of the tubules remained relatively unchanged, indicating that no chemical interaction between the carbon walls and the filling material had occurred. A minimum length of *ca.* 1 nm for the clusters was eventually obtained after irradiation for *ca.* 8 min.

The microstructure of the filling material in image **I** is indistinct whereas several of the longer clusters in images **II**, **III** and **V** consist of 1D arrays of dark spots similar to those reported recently for lanthanide halides of the form $LnCl_3$ (Ln = La, Nd, Sm, Eu, Gd, Tb, Yb) formed within SWNTs.[16] In those structures, the dark spot arrays were attributed to 1D chains of edge-sharing $LnCl_6$ polyhedra, with the heavy Ln^{3+} cations dominating the image contrast over the less strongly scattering

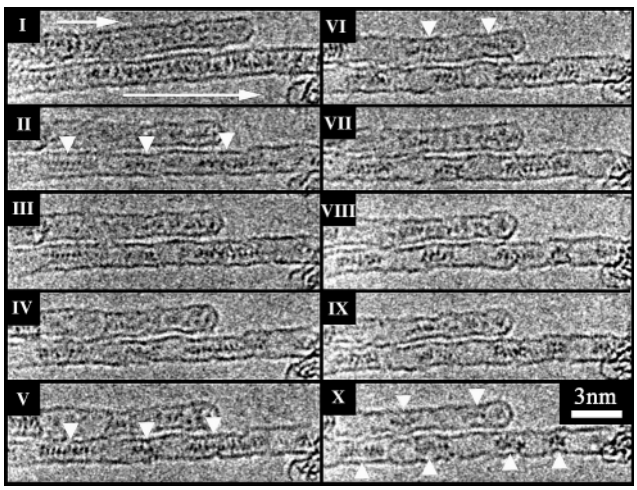

Fig. 1 Sequence of images **I** to **X** obtained at *ca.* 20 s intervals showing gradual clusterisation of $ZrCl_4$ within SWNTs induced by electron-beam irradiation within a FEGTEM. Image **I** shows two SWNTs continuously filled with $ZrCl_4$ (large arrows). After *ca.* 80 s (image **V**), filling in the bottom tubule has reformed into three distinct separated clusters (small arrows). After *ca.* 100 s (image **VI**) filling in the top tubule has segregated into two clusters. After 4 min (image **X**), the filling has segregated into a total of six distinct clusters (small arrows). In images **II**, **III** and **V**, distinct 1D arrays of dark spots are visible. Note 'bulging' either side of the central cluster in the lower SWNT in images **VI** and **VII**.

DOI: 10.1039/b101261o

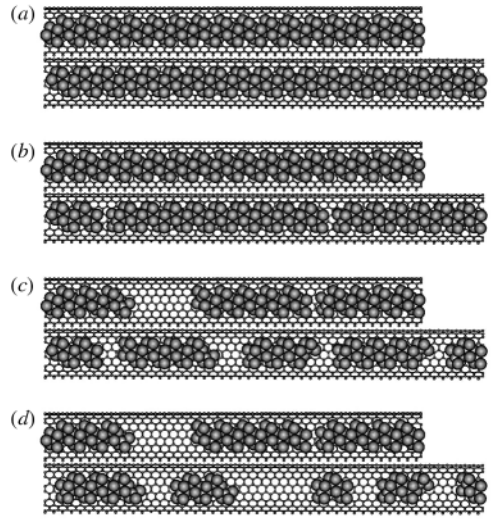

Fig. 2 Idealised structural representation of cluster formation within a pair of SWNTs. SWNTs continuously filled with $ZrCl_4$ (*a*) undergo beam irradiation until a break occurs in the filling after *ca.* 4–10 s (*b*). Either side of the break, the chains will terminate in reduced polyhedra. After 40–50 s, several long clusters are formed (*c*) and beam reduction continues until complete clusterisation occurs (*d*). This process may continue until all the chlorine is eliminated from the clusters.

Cl^- anions. It is therefore reasonable to assume that $ZrCl_4$, which forms an edge-sharing '*trans*' octahedral chain structure in the bulk,[21] forms similar 1D chains within SWNT capillaries and that the dark spots visible in images **I–X** in Fig. 1 correspond to more strongly scattering Zr^{4+} ions rather than to the weaker scattering Cl^- ions.

An additional interesting point is that the SWNTs distort during the clusterisation process. For example, in images **VI** and **VII** (Fig. 1) the lower tubule, which has a constant diameter of *ca.* 1.4 nm in the initial image (*i.e.* image **I**, Fig. 1), shows symmetric 0.1 nm 'bulges' either side of the central $ZrCl_x$ cluster. We believe that these 'bulges' are caused by complimentary ovaloid distortions in the SWNTs resulting from asymmetric distortions induced in the $ZrCl_x$ clusters by the beam rearrangement process. Such distortions will cause an apparent local variation in the SWNT diameter when viewed in projection in a FEGTEM.

Electron beam bombardment of MX_n halides at intermediate accelerating voltages (typically 100–400 kV) produces isolated stoichiometric Frenkel-type defects in bulk crystals.[22,23] However, in smaller volume halide crystallites (*ca.* 1 μm^3 particle size) elimination of halogen and the formation of surface metal occurs instead.[24] We propose therefore that the 1D $ZrCl_4$ chains undergo sequential elimination of chlorine to form clusters of $ZrCl_x$, of progressively lower stoichiometry (*i.e.* x decreases from 4 to 0), according to the schematic depiction in Fig. 2(*a*)–(*d*). Complete elimination of chlorine would result in the formation of metallic Zr clusters although we have not yet been able to verify this. Similarly, it has not been possible to determine the nature of the eliminated chlorine species (*i.e.* such as radicals, ions, charged molecular fragments, *etc.*). We assume that chlorine diffuses out of side-wall defects or open ends of SWNTs in the same way that gaseous endofullerene molecules have been demonstrated to diffuse into them.[19,20] As no significant damage to the SWNT walls was observed during clusterisation, carburisation of the clusters is not thought to occur, although surface reaction of the carbon with the eliminated chlorine species (see above) remains a possibility.

In conclusion, $ZrCl_4$ contained within SWNTs can be beam-reduced *in situ* to form $ZrCl_x$ clusters (with $0 \leqslant x < 4$) of controlled diameter. While beam-induced coalescence of fullerene molecules has been reported within SWNTs,[17,18] this is the first time that cluster segregation has been reported. If this phenomenon can be extended in a controlled way to bulk SWNT samples containing semiconducting or metallic species (or their precursors) then this may represent a route to the synthesis of one dimensional arrays of quantum dots within SWNTs. In addition, more detailed analytical studies of the clusterisation phenomena (*e.g.* high resolution EELS studies[20]) should lead to a better understanding of the mechanism of halide decomposition for these virtually 'all surface' crystals.

{2Fe3S} clusters related to the di-iron sub-site of the H-centre of all-iron hydrogenases

Mathieu Razavet, Sian C. Davies, David L. Hughes and Christopher J. Pickett*

Department of Biological Chemistry, John Innes Centre, Norwich, UK NR4 7UH.
E-mail: chris.pickett@bbsrc.ac.uk

Received (in Cambridge, UK) 8th March 2001, Accepted 16th March 2001
First published as an Advance Article on the web 17th April 2001

The first synthetic {2Fe3S} clusters structurally related to the sub-site of the H-centre of the all-iron hydrogenases are described: tripodal dithiolate thioether ligands allow the synthesis of di-iron pentacarbonyls with differential (2:3) S ligation of the Fe atoms.

X-Ray crystallographic data for Fe-only hydrogenases isolated from *Desulfovibrio desulfuricans*[1] and *Clostridium pasteurianum*[2] together with IR evidence show that the active centre of the enzyme possesses an unprecedented {2Fe3S} sub-site at which CO and CN ligands are bound.[3] The two Fe atoms of the sub-site share two bridging sulfur ligands of a propanedithiolate or related unit[4] with one of the Fe atoms additionally sulfur ligated by a cysteinyl ligand bridged to a {4Fe4S} cluster, Fig. 1(a). Molecules with a {2Fe2S} propanedithiolate core and CO/CN ligation have been synthesised[5] which possess structural elements of the CO inhibited sub-site.[6] We now show that formal backbone modification of the propanedithiolate ligand allows access to carbonyls with a {2Fe3S} core with differential S-ligation of the iron atoms, Fig. 1(b).

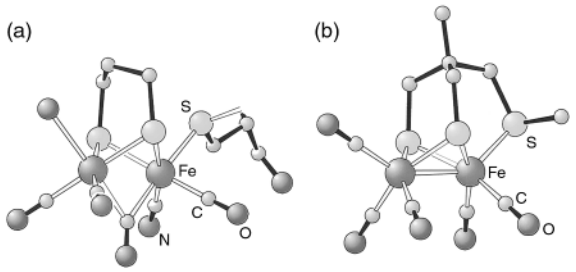

Fig. 1 (a) Proposed structure of the H-centre of Fe-only hydrogenases; this is a composite model combining features reported by Peters (PDB code 1FEH) and Nicolet (code 1HFE). (b) View of a molecule of the product **D**.

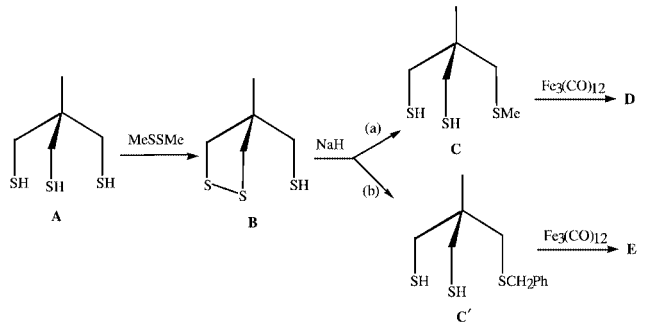
Two thiolate sulfur ligands of the tripodal thiolate **A**[7] are readily coupled with dimethyl disulfide with formation of a stable five-membered ring **B**, Scheme 1. This allows chemistry to be carried out on the unprotected thiol group. Reaction with MeI gives the thioether derivative, and subsequent reductive cleavage of the disulfide bond gives the backbone functionalised propanedithiol ligand **C**, Scheme 1.† The ligand reacts with $[Fe_3(CO)_{12}]$ to yield the {2Fe3S}-carbonyl **D** which has been fully characterised by X-ray crystallography, Fig. 1(b), and spectroscopy.‡



Scheme 1 Routes to ligands and complexes. *Reagents*: (a) i, MeI; ii, $LiAlH_4$; iii, H_2SO_4; (b) i, $PhCH_2Br$; ii, $LiAlH_4$; iii, H_2SO_4.

There are two independent molecules (plus their mirror image molecules) in crystals of **D**. The two molecules are essentially identical, and in each, the Fe–Fe distance is short, mean value 2.512(4) Å, indicative of an iron–iron bond. Each iron atom has five other contacts, in a square pyramidal coordination pattern, with the iron atom displaced (mean) 0.382(10) Å from the mean base plane towards the apical carbonyl ligand and 0.322(5) Å towards the thioether S atom. In each molecule, the normals to the square base planes are inclined at (mean) 74.7(6)° and the planes are hinged through the two bridging thiolate sulfur atoms of the S_3 ligands; the Fe–$S_{bridging}$ distances have a mean value of 2.254(1) Å. The third S atom, the thioether S, is coordinated to one of the iron atoms at a similar, mean distance of 2.254(3) Å and occupies the apical coordination site. Two carbonyl ligands occupy the base planes on each iron and one occupies the apical site of the second iron atom. The S_3 ligand thus lies atop the $Fe_2(CO)_5$ unit and is symmetrically arranged (with a pseudo-mirror plane through the iron atoms and the apical groups) except for the thioether methyl group which veers to one side or the other of the mirror plane. Both enantiomers are present in these centrosymmetric crystals.

The structural similarities between the enzyme sub-site and the model compound are evident from Fig. 1. The Fe···Fe bond distance in **D** and the average bridging Fe–S bond lengths are similar to those distances estimated from the protein crystallographic data, which are 2.6 and 2.3 Å, respectively[1,2] but the thioether Fe–S distance in **D** is shorter than the corresponding sub-site Fe–$S_{cysteine}$ distance in the enzyme which is *ca* 2.5 Å.

The benzyl analogue **E** is obtained by straightforward modification of the synthesis, Scheme 1. Its crystal structure, Fig. 2, confirms a conformation very similar to that of **D** with only very minor differences in bond angles and dimensions.‡

We have monitored the reaction of complex **D** with 2 equivalents of cyanide [K^+(18-crown-6) salt; MeCN]. This reveals its conversion within 30 min to a new species **F** which shows two distinct CN stretches, three terminal CO bands and a bridging CO band at 1780 cm^{-1}, Scheme 2. **F** is indefinitely stable in MeCN at 0 °C but on standing for 18 h at RT it slowly transforms to a new species **G** . The IR pattern and frequencies of **G** very closely resemble those of $[Fe_2(CO)_4(CN)_2$-

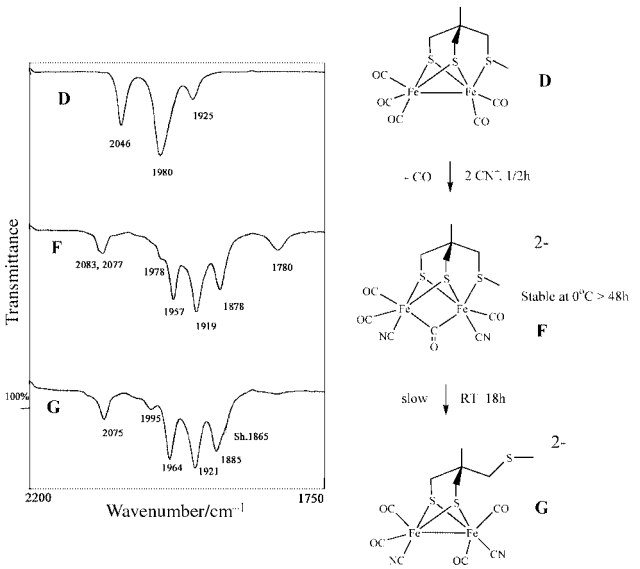
DOI: 10.1039/b102244j



Scheme 2 Solution IR time course for reaction of **D** with cyanide in MeCN and proposed pathway to the species **F** and **G**.

$(SCH_2CH_2S)]^{2-}$,[5] showing a single ν(CN) at 2075 cm^{-1}, Scheme 2. FAB-MS of **G** shows a strong parent ion at 759 for {(K+18-crown-6)$[Fe_2(CO)_4(CN)_2\{MeSCH_2C(Me)(CH_2S)_2\}]$}. These preliminary results are consistent with the initial formation of a CO bridged di-cyanide species **F** which slowly isomerises to the metal–metal bonded terminal carbonyl species **G** with dissociation of the methyl thioether group, Scheme 2. This provides the first tentative evidence for the genesis of a model complex with all the principal structural features of the CO inhibited form of the natural sub-site: two cyanide groups, terminal and bridging CO ligands, and a {2Fe3S} core.§

Finally, we see in the preparation of **E** that a thiolate-*protected* rather than -*blocked* group can been introduced at one of the iron atoms: this or other S-protection/deprotection approaches should open up further chemistry of the synthetic sub-site.

We thank the BBSRC and the John Innes Foundation for supporting this work. Drs D. J. Evans and J. R. Sanders are thanked for helpful discussion.

§ Well-resolved IR data for the *oxidised* CO inhibited H-centre have been reported recently by De Lacey *et al.*[10] giving: ν(CN) at 2096 and 2089 cm^{-1}; $\nu(CO_{terminal})$ at 2016, 1972 and 1963 cm^{-1}; and $\nu(CO_{bridging})$ at 1811 cm^{-1}. In this paramagnetic state the di-iron sub-site is magnetically described as a localised mixed-valence state, though critically whether Fe^{II}–Fe^{III} or Fe^{I}–Fe^{II} was undecided.[11] The data we have at hand for the Fe^{I}–Fe^{I} species **F** show: ν(CN) at 2083 and 2077 cm^{-1}; $\nu(CO_{terminal})$ at 1957, 1919 and 1878 cm^{-1}; and $\nu(CO_{bridging})$ at 1780 cm^{-1}. Thus $\Delta\nu(CO_{terminal})$ corresponds to 59, 53 and 85 cm^{-1} respectively with $\Delta\nu(CO_{bridge})$ = 31 cm^{-1}. These magnitudes are consistent with the oxidised CO-form of the sub-site having the Fe^{I}–Fe^{II} configuration (*i.e.* it is one-electron oxidised with respect to **F**) and lends support to the deduction of De Lacey *et al.* that proximal iron atom is in the Fe ^{II} state {$\Delta\nu$(CO) = 85 cm^{-1}} with the less perturbed distal iron atom {$\Delta\nu$(CO) = 59, 53 cm^{-1}} in the Fe^{I} state.

First published as an Advance Article on the web 17th April 2001

Reactions of the diplatinum complex $[Pt_2(\mu\text{-}H)(\mu\text{-}PPh_2)I_2(PPh_3)_2]$ with the carbonylmetalates $[MCp(CO)_3]^-$ (M = Mo, W) or $[Co(CO)_4]^-$ afforded the new 44e clusters $[Pt_2M(\mu\text{-}CO)_3(\mu\text{-}PPh_2)Cp(PPh_3)_2]$ (M = Mo, 2; M = W, 3) and $[Pt_3(\mu\text{-}CO)_2(\mu\text{-}PPh_2)I(PPh_3)_3]$ 5, respectively, whose structures can be analysed as formed by a 26e $[Pt_2(\mu\text{-}PPh_2)(PPh_3)_2]^+$ cation and a bridging, 4e donor anion, $[MCp(CO)_3]^-$ in 2 and 3, or the new 18e fragment $[PtI(CO)_2(PPh_3)]^-$ in 5.

In the search for versatile synthetic methods, numerous metal–metal bonded complexes and clusters have been obtained by reaction of carbonylmetalates with mononuclear halide complexes,[1,2] whereas fewer studies have been concerned with dinuclear halide precursors.[3] The reactions of the diplatinum complex $[Pt_2(\mu\text{-}H)(\mu\text{-}PPh_2)I_2(PPh_3)_2]$ **1**, prepared by reaction of $[Pt_2(\mu\text{-}PPh_2)(\mu\text{-}o\text{-}C_6H_4PPh_2)(PPh_3)_2]$[4a] with 2 equiv. of HI in THF,[4b] with three different carbonylmetalates has now afforded clusters whose structures reveal an unexpected bonding similarity between the 18e metalloligands $[MCp(CO)_3]^-$ (M = Mo, W) and $[PtI(CO)_2(PPh_3)]^-$ which are best viewed as 4e donors towards a d^9–d^9 Pt(I)–Pt(I) unit.

Reaction of 1 equiv. of **1** with 3 equiv. of $[MCp(CO)_3]^-$ in thf afforded the mixed-metal clusters $[Pt_2M(\mu\text{-}CO)_3(\mu\text{-}PPh_2)Cp(PPh_3)_2]$ (M = Mo, **2**; M = W, **3**) (Scheme 1).§ Their $^{31}P\{^1H\}$ NMR spectra contain a triplet at low field for the μ-PPh_2 ligand and a doublet for terminal phosphines, both with satellites due to couplings with two Pt atoms. In addition, the pattern of the resonance of the phosphine ligands is typical for a P→Pt–Pt←P chain. An X-ray diffraction study of **2**¶ established that the metal atoms form an isosceles triangle with a Pt–Pt edge bridged by a PPh_2 group (Fig. 1). Two CO ligands occupy a semi-bridging position on the Pt–Mo edges and the third one is semi-triply bridging over the metallic face. This arrangement is reminiscent of that in the tetranuclear cluster $[Pt_2Mo_2(\mu\text{-}CO)_6Cp_2(PEt_3)_2]$ **4**,[5a] its palladium analogue,[5b] or in the trinuclear cluster $[Pd_2Mo(\mu\text{-}Cp)(\mu\text{-}CO)_3Cp(PPr^i_3)_2]$.[6] Each Pt atom is ligated by a PPh_3 ligand and the Mo atom by a η^5-cyclopentadienyl ligand. The metal–metal distances in **2** are comparable with those in **4**.[5a] The Pt–(μ-P)–Pt angle (69.55(4)°) is one of the narrowest for a PPh_2 group bridging a metal–metal bond. It is close to that in $[Pt_2(\mu\text{-}PPh_2)_2(PPh_3)_2]$ (*ca.* 69.0°)[7] but smaller than in $[Pt_2\{\mu\text{-}Co(CO)_3(PPh_3)\}(\mu\text{-}PPh_2)(PPh_3)_2]$ (72.41(8)°),[8] which is consistent with a longer Pt–Pt bond of 2.664(1) Å in the latter. The three P atoms are almost in the metal plane, at +0.140(2), +0.044(2) and +0.050(2) Å, respectively. The PPh_3 ligands are almost aligned with the Pt atoms.

The highest yields of clusters **2** and **3** were obtained with a ratio of three $[MCp(CO)_3]^-$ anions for one dinuclear complex **1**. Since one anion enters in the composition of the clusters, the other two are probably eliminated with other ligands of **1**, *i.e.* H and I.

Reaction of 3 equiv. of $[Co(CO)_4]^-$ with 1 equiv. of complex **1** unexpectedly afforded the new homonuclear triplatinum cluster $[Pt_3(\mu\text{-}PPh_2)(\mu\text{-}CO)_2I(PPh_3)_3]$ **5**§ instead of Pt–Co cluster(s). The $^{31}P\{^1H\}$ NMR spectrum contains three signals flanked by ^{195}Pt satellites. The singlet at δ 279.6 is assigned to a PPh_2 group bridging two equivalent Pt atoms and the doublet

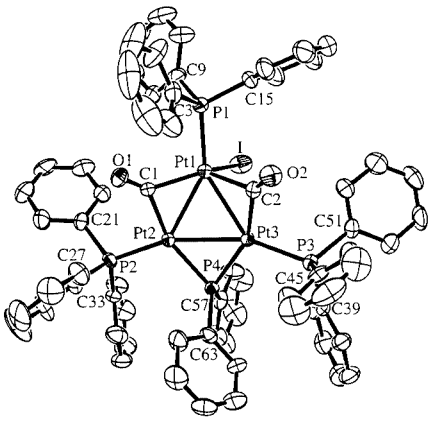

Fig. 2 Molecular structure of $[Pt_3(\mu\text{-}PPh_2)(\mu\text{-}CO)_2I(PPh_3)_3]$ **5**. Selected interatomic distances (Å) and angles (°): Pt(1)–Pt(2) 2.6832(13), Pt(1)–Pt(3) 2.694(2), Pt(2)–Pt(3) 2.736(2), Pt(1)–I 2.8165(17), Pt(1)–P(1) 2.268(3), Pt(2)–P(2) 2.238(3), Pt(3)–P(3) 2.256(3), Pt(2)–P(4) 2.279(3), Pt(3)–P(4) 2.273(3), Pt(2)–Pt(1)–Pt(3) 61.17(4), P(1)–Pt(1)–I 99.72(8), Pt(1)–Pt(2)–Pt(3) 59.62(5), P(2)–Pt(2)–Pt(3) 160.76(7), P(3)–Pt(3)–Pt(2) 159.33(7), Pt(3)–P(4)–Pt(2) 73.90(8).

at δ 33.8 to the phosphine ligands in the $Ph_3P\rightarrow Pt\text{–}Pt\leftarrow PPh_3$ moiety. These phosphines are coupled with a third phosphorus, which resonates as a triplet at δ 75.2. From the intensities of its ^{195}Pt satellites, it is deduced that this phosphine is coordinated to a Pt atom, which is itself linked to two equivalent Pt atoms. Cluster **5** should contain a triangle of Pt atoms, each bearing a phosphine ligand, with two Pt atoms being bridged by a PPh_2 group. An X-ray diffraction study¶ established the structure of **5** in which the shortest edge of the metal triangle, Pt(2)–Pt(3), is bridged by a PPh_2 group and the other two are each symmetrically bridged by a CO group (Fig. 2). A PPh_3 ligand is coordinated to each Pt atom and an iodine atom is bonded to Pt(1). The P(1)Pt(1)C(1)C(2)I atoms form the apices of a trigonal pyramid with P(1) in an apical position. The P(1)–Pt(1) bond makes angles of *ca*. 100° with the three basal bonds Pt(1)–I, Pt(1)–C(1) and Pt(1)–C(2).

Formation of **5** implies a complex reaction mechanism, where carbonyl groups have exchanged between cobalt and platinum, probably *via* a mixed Pt–Co complex. Fragmentation of the Pt_2 entity of complex **1** is required to form the Pt_3 framework and iodine could either remain on one of the Pt atoms or I^- attack an intermediate species. Complex reactions between Pt(II) halide complexes and $[Co(CO)_4]^-$ have been described from which heterometallic Pt–Co clusters with diverse Pt/Co compositions were isolated[9] and when the isoelectronic metalates $[Mn(CO)_5]^-$ or $[Fe(CO)_3(NO)]^-$ were used instead, no Pt–Mn or Pt–Fe clusters were observed, respectively, but rather $[Pt_5(CO)_6(PR_3)_4]$ which resulted from selective reductive carbonylation of the Pt(II) precursor complex.[10]

The 44e clusters **2** and **3** can formally be viewed as formed of two fragments, the cationic, 26-valence electrons (VE) entity $[Pt_2(\mu\text{-}PPh_2)(PPh_3)_2]^+$, which possesses two vacant fragment orbitals (2a′ and 2a″ in C_s symmetry)[11] and a bridging, 18-VE carbonylmetalate $[MCp(CO)_3]^-$. The HOMOs of the latter ($1a_1$ + 1e) can formally donate 4e to the dinuclear cation,[12] so that each Pt atom achieves its usual 16 VE count. The 44e count in cluster **5** is not unusual for Pt_3 clusters (with two 16e and one 18e metal centres), although the 42e alternative is more frequently encountered.[13] By analogy with the bonding behaviour of $[MCp(CO)_3]^-$, one can view the fragment $[PtI(CO)_2(PPh_3)]^-$ as a bridging group formally donating 4e to the $[Pt_2(\mu\text{-}PPh_2)(PPh_3)_2]^+$ cation, through two Pt–Pt bonds and two bridging CO groups, *i.e*. 2e to each Pt atom. In terms of electron counting, this makes these metalates behave remarkably similar to bridging halides or $\mu\text{-}PR_2^-$. To our knowledge, the anionic 18e complex $[PtI(CO)_2(PPh_3)]^-$ has not been isolated previously.

We are grateful to Professor J. Fischer and Dr A. DeCian for the crystal structure determination of **2** and thank the CNRS, the Ministère de la Recherche and the Ministère des Affaires Etrangères (Paris) and the Ministère des Affaires Etrangères (Alger) for support of the Strasbourg-Constantine Cooperation Project 96 MDU 371.

First published as an Advance Article on the web 18th April 2001

Ni/La_2O_3 catalyst exhibits high activity and good long term stability for steam reforming of ethanol to hydrogen production and is a good candidate for ethanol reforming processors for fuel cell applications.

Fuel cells may be a promising alternative means of electricity generation for stationary decentralized applications. They offer significant advantages which include absence of pollutant emission, since they use hydrogen as the fuel, and high conversion efficiency, which may be even higher when they operate on the co-generation mode. In recent years, fuel cells have been seriously considered for electric vehicle operation, making possible so-called Zero Emission Vehicles.

An important source of hydrogen for stationary fuel cell applications is natural gas, while for transportation, methanol and gasoline are being considered. These fossil fuels do not address the issue of carbon dioxide emissions, however, which may only be addressed by the use of a renewable fuel as the hydrogen source. Ethanol can be produced renewably from several biomass sources, including energy plants, waste materials from agroindustries or forestry residue materials, or even organic fractions of municipal solid waste. Thus, in contrast to the fossil-fuel-based systems, the bioethanol-to-hydrogen-system has the significant advantage of being nearly CO_2 neutral, since the carbon dioxide produced is consumed for biomass growth, thus offering a nearly closed carbon loop. In addition, the use of ethanol offers important storage and handling safety advantages.

In the present communication, the catalytic steam reforming of ethanol for hydrogen production is discussed, with respect to catalyst performance characteristics. The steam reforming of ethanol for hydrogen production has been shown to be entirely feasible from a thermodynamic point of view.[1–3] An issue of major importance is then to develop highly active, selective and durable catalysts for the reaction. Although much work has been carried out on methanol reforming, only a limited number of reports have appeared in the literature dealing with the reforming of ethanol.[4–6] Here, we report results obtained over a Ni/La_2O_3 catalyst, which has been previously found to exhibit good performance characteristics under conditions of carbon dioxide reforming of methane to synthesis gas.[7] It is shown that under certain operating conditions, the Ni/La_2O_3 catalyst is very active and stable for the steam reforming of ethanol and is characterized by high selectivity toward hydrogen production.

The 17% Ni/La_2O_3 catalyst employed in the present study was prepared by the wet impregnation method using $Ni(NO_3)_2$ and La_2O_3 (Alfa Products) as starting materials, following a procedure that has been described in detail elsewhere.[7] Catalytic performance tests have been conducted in the temperature range 300–800 °C, over catalyst samples previously reduced *in situ* with hydrogen (500 °C, 2 h). In a typical experiment, a water–ethanol mixture (molar ratio 3:1) is pumped into a heated chamber and vaporized. The water–ethanol gas stream (160 cm^3 min^{-1}) is then fed to a quartz micro-reactor containing 100 mg of catalyst. The composition of the reactor effluent is analyzed by means of two gas chromatographs, connected in series: the first is equipped with two packed columns (Porapak, Carbosieve) and two detectors (TCD, FID) and uses He as carrier gas. Porapak is used for the separation of C_2H_5OH, H_2O, CH_3CHO, CH_4, C_2H_4 and C_2H_6. Carbosieve is used for the separation of CO, CO_2 and CH_4. The second gas chromatograph, which uses N_2 as carrier gas, is equipped with a Carbosieve column and a TCD detector and is solely used for the analysis of the produced hydrogen.

Typical experimental results obtained are presented in Fig. 1, in which the conversion of ethanol and the selectivities to various reaction products are shown as a functions of reaction temperature. At temperatures below 300 °C, steam reforming of ethanol does not occur appreciably. Instead, dehydrogenation of ethanol occurs to an appreciable extent producing acetaldehyde and hydrogen. Increasing reaction temperature results in a progressive decrease of selectivity toward acetaldehyde, which drops to zero at temperatures above 550 °C. In this temperature range the reforming reactions of both acetaldehyde and ethanol prevail. It is interesting to observe that no ethylene is detected in the reaction products, indicating that no dehydration of ethanol is taking place, as might be expected. This is due to the fact that this particular catalyst, which utilizes La_2O_3 as the carrier material, does not possess any acidic sites, which are required for the dehydration route. Steam reforming of ethanol takes place to a significant extent at temperatures above 400 °C, as evidenced by the sharp increase of ethanol conversion and by the increase of selectivities toward CO and H_2 (Fig. 1). By-products of the reaction are CO_2 and CH_4, which are formed by reaction of CO with water (shift reaction) and with hydrogen (methanation), respectively. Selectivities toward CO_2 and CH_4

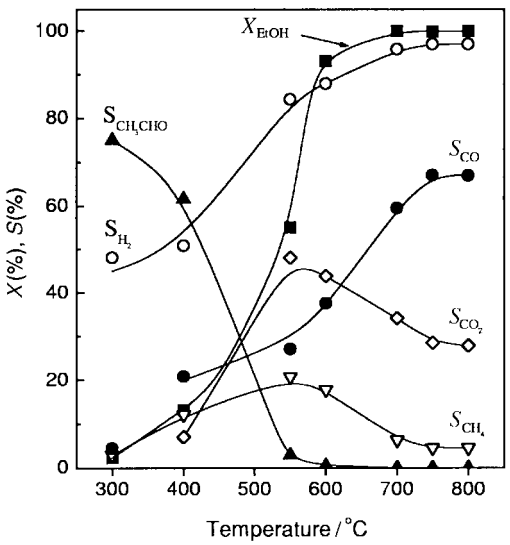

Fig. 1 Effect of reaction temperature on the conversion of ethanol (X_{EtOH}) and on selectivities toward acetaldehyde (S_{CH_3CHO}), carbon monoxide (S_{CO}), carbon dioxide (S_{CO_2}), methane (S_{CH_4}) and hydrogen (S_{H_2}), obtained over the 17% Ni/La_2O_3 catalyst. *Experimental conditions*: mass of catalyst: 100 mg; particle size: 0.25–0.50 mm; H_2O:EtOH molar ratio: 3:1; flow rate: 160 cm^3 min^{-1} (W/F = 0.0375 g s cm^{-3}); P = 1 atm.

DOI: 10.1039/b101455m

increase with increasing temperature and go through maxima at *ca.* 550 °C. Above this temperature, the reformation of methane with CO_2 and with H_2O becomes thermodynamically feasible, resulting in a decrease of the selectivities of both CH_4 and CO_2, since the Ni/La_2O_3 catalyst is known to be very active for these reforming reactions.[7] The observed decrease in the production of CO_2 may be due in part to the inverse shift reaction. At temperatures above 600 °C, the conversion of ethanol reaches 100% and the selectivity toward hydrogen exceeds 90% (Fig. 1). Under these conditions, the only undesirable product is methane, which competes with H_2 for hydrogen atoms. However, from a practical point of view, a small concentration of methane in the reformate may be tolerated since methane present at the exhaust of the fuel cell can be burned, along with unreacted hydrogen, to provide the heat necessary for the highly endothermic reforming reaction. In any event, conversion of methane *via* reforming with CO_2 and H_2O proceeds at higher reaction temperatures, resulting in increased yield of H_2 production.

The contact time dependence of the conversion of ethanol and of the selectivity toward reaction products, as well as the stability of the catalyst with time-on-stream were examined over a catalyst in which the active component (Ni/La_2O_3) was deposited on γ-Al_2O_3 pellets (Engelhard) of a surface area of 180 $m^2\ g^{-1}$. This type of catalyst formulation may be necessary for a practical application since La_2O_3 is hydroscopic and pellets made out of this material do not possess the necessary strength in the presence of steam, especially at low temperatures. This problem is avoided if lanthana is dispersed over the surface of materials which have the necessary strength, such as alumina pellets. For the experiment described here, the γ-Al_2O_3 pellets were impregnated with $La(NO_3)_3$ and then calcined in air at 900 °C for 30 h. The resulting material was then impregnated with $Ni(NO_3)_2$, dried at 110 °C for 24 h, reduced in H_2 at 500 °C for 5 h and crushed to particles of 0.25–0.50 mm in diameter.

The effect of contact time on the catalytic performance of the $(Ni/La_2O_3)/Al_2O_3$ catalyst at the reaction temperature of 750 °C is shown in Fig. 2, in which the conversion of ethanol and the selectivities towards various reaction products are plotted as functions of W/F. It is observed that for contact times >0.1 g s cm^3 the conversion of ethanol is 100% and the reaction is highly selective toward hydrogen ($>95\%$), the only unwanted by-product being methane ($<5\%$). As the contact time decreases, the conversion of ethanol progressively drops, accompanied by a decrease of the selectivity toward the reformation products (CO and H_2) and by an increase of the selectivity toward CO_2 and by-products, such as CH_3CHO, C_2H_4 and C_2H_6. It is interesting to observe that at low contact times (low ethanol conversion) appreciable amounts of ethylene are formed, obviously by dehydration of ethanol over acidic Al_2O_3 sites. This reaction did not occur measurably over the Ni/La_2O_3 catalyst which does not possess acidic sites.

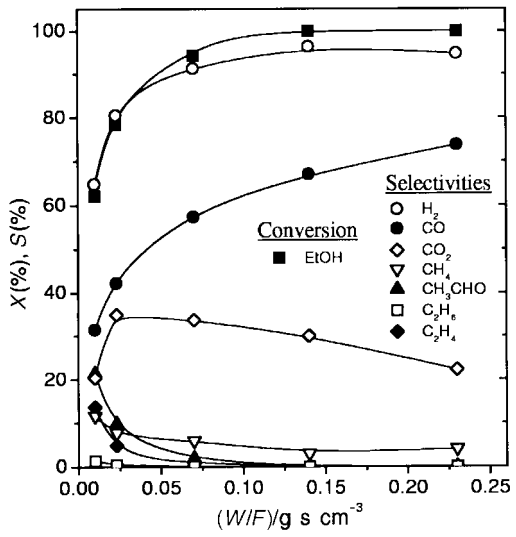

Fig. 2 Effect of space time (W/F) on the conversion of ethanol and on the selectivities toward reaction products, over the $(Ni/La_2O_3)/Al_2O_3$ catalyst. *Experimental conditions*: mass of catalyst: 100 mg; particle size: 0.25–0.50 mm; H_2O:EtOH molar ratio: 3:1; T = 750 °C; P = 1 atm.

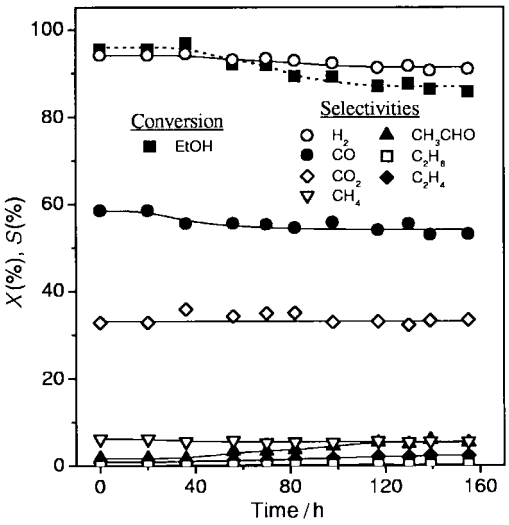

Fig. 3 Conversion of ethanol and selectivities toward reaction products as functions of time-on-stream, obtained over the $(Ni/La_2O_3)/Al_2O_3$ catalyst. *Experimental conditions*: mass of catalyst: 100 mg; particle size: 0.25–0.50 mm; H_2O:EtOH molar ratio: 3:1; flow rate: 87 $cm^3\ min^{-1}$ (W/F = 0.0690 g s cm^{-3}); T = 750 °C; P = 1 atm.

The stability of the $(Ni/La_2O_3)/Al_2O_3$ catalyst has been examined at 750 °C and the results are shown in Fig. 3, in which the alterations of activity and selectivity are plotted as functions of time-on-stream. Under the experimental conditions employed (see legend of Fig. 3), a small deactivation of the catalyst is observed during the first 80–100 h on stream, where conversion of ethanol drops from 95 to 88%, while further exposure of the catalyst to the reaction mixture does not result in further deactivation. It is interesting to observe that selectivity toward hydrogen does not change significantly and slightly decreases from the initial value of 94 to 91% after 155 h on stream. Selectivities toward the formation of other products, such as CO, CO_2, CH_4, CH_3CHO, C_2H_4 and C_2H_6 also stabilize after 100–120 h.

Summarizing, the present results reveal that the Ni/La_2O_3 catalyst, or the $(Ni/La_2O_3)/Al_2O_3$ pelleted form, exhibits high activity and, most importantly, good long term stability for steam reforming of ethanol to hydrogen production and is a good candidate to be used in ethanol reforming processors for fuel cell applications.

This work was funded in part by the Commission of the European Community, under contract ERK6-CT-1999-00012, and by the Hellenic General Secretariat of Research and Technology (EPET II).

Converting a layer perovskite into a non-defective higher-order homologue: topochemical synthesis of $Eu_2CaTi_2O_7$

Raymond E. Schaak, Erin N. Guidry and Thomas E. Mallouk*

Department of Chemistry, The Pennsylvania State University, University Park, PA 16802, USA

Received (in Columbia, MO, USA) 15th November 2000, Accepted 15th March 2001
First published as an Advance Article on the web 17th April 2001

Topochemical reduction of $CaEu_2Ti_2O_8$, a new $n = 1$ mixed Ruddlesden–Popper/Dion–Jacobson phase prepared by divalent ion-exchange of $NaEuTiO_4$, yields the non-defective $n = 2$ Ruddlesden–Popper phase $Eu_2CaTi_2O_7$.

Transition-metal oxides that possess the perovskite structure are important materials that exhibit a wide range of useful properties, including ferroelectricity, superconductivity, colossal magnetoresistance, and catalytic activity. Layered perovskites that belong to the Ruddlesden–Popper,[1] $A_2[A'_{n-1}B_nO_{3n+1}]$, and Dion–Jacobson,[2] $A[A'_{n-1}B_nO_{3n+1}]$, families are known to possess similar properties, which often depend sensitively on the thickness of the perovskite block. As an example, the Curie temperature and magnetoresistive effects vary with increasing n (the number of octahedra that stack in the perovskite block) in the Ruddlesden–Popper manganate series $(La,Sr)_{n+1}Mn_nO_{3n+1}$.[3]

Many layered perovskites also undergo interlayer ion-exchange reactions, so they are ideal precursors to new metastable materials. For example, Dion–Jacobson phases that contain divalent interlayer cations,[4] as well as perovskite/copper-halide[5] and vanadate[6] intergrowths, can be synthesized at relatively low (< 500 °C) temperatures from layered perovskite precursors. Similarly, A-site defective three-dimensional perovskites can be synthesized by dehydrating proton-exchanged Ruddlesden–Popper phases,[7] and non-defective perovskites can be synthesized by topochemically reducing the appropriate Dion–Jacobson precursors.[8] In general, it is not possible to make these same ordered phases by direct, high temperature synthesis.

Since the electronic and magnetic properties of layered perovskites vary with the perovskite block thickness, the ability to convert among similar homologues in a series is a potentially useful tool for fine-tuning their properties. Recently, Gopalakrishnan and coworkers converted $HLnTiO_4$ (Ln = La, Nd, Sm, Gd), a family of $n = 1$ Ruddlesden–Popper phases, into $Ln_2\square Ti_2O_7$, an A-site defective $n = 2$ Ruddlesden–Popper series, by carefully dehydrating the $n = 1$ precursor.[9] The unique ordering of the lanthanide cations and the protons in $HLnTiO_4$ (or alkali cations in the parent phase $NaLnTiO_4$) in alternate rows imparts interlayer reactivity only to every other layer, which is necessary for the conversion from an $n = 1$ to an $n = 2$ phase.

Topochemical reduction is a powerful alternative to dehydration, because it can create *non-defective* condensed structures. One can envision a similar conversion reaction that transforms $NaLnTiO_4$ into a non-defective $n = 2$ phase (Fig. 1). $NaEuTiO_4$, the $n = 1$ Ruddlesden–Popper parent phase, contains the easily reducible Eu^{3+} cation, which converts to Eu^{2+} when heated in hydrogen. The concomitant loss of oxygen from the lattice is necessary for the topochemical collapse to occur. $NaEuTiO_4$ contains twice the number of interlayer Na^+ cations than are needed to fill the A-sites of a perovskite block, so divalent ion exchange must first be done to give the correct stoichiometry of interlayer cations, forming $A^{II}_{0.5}EuTiO_4$. Subsequent reduction can collapse the perovskite layers over the divalent A-site cations, resulting in the $n = 2$ Ruddlesden–Popper phase $A^{II}_{0.5}EuTiO_{3.5}$ (or $Eu_2A^{II}Ti_2O_7$).

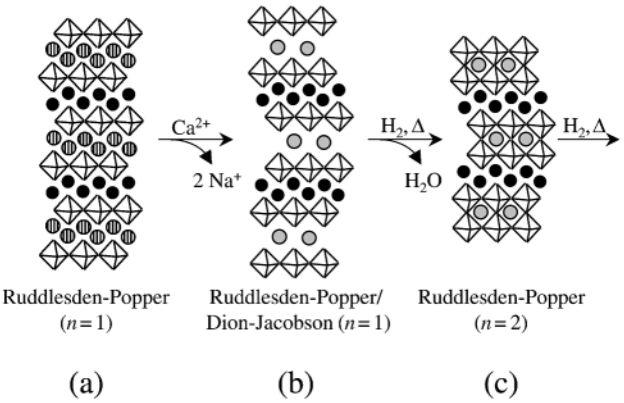

Fig. 1 Topochemical transformation of an $n = 1$ Ruddlesden–Popper phase into a non-defective $n = 2$ phase, which includes (a) $NaEuTiO_4$, (b) $CaEu_2Ti_2O_8$, and (c) $Eu_2CaTi_2O_7$.

$NaEuTiO_4$ was synthesized as reported in the literature[10] and reacted with 1 M $Ca(NO_3)_2$ for 1 week at 45 °C to form $Ca_{0.5}EuTiO_4$ (or $CaEu_2Ti_2O_8$). Energy-dispersive X-ray analysis (EDAX)[11] confirms that 85% of the sodium is replaced by calcium, which is consistent with the efficiencies of other aqueous and non-aqueous divalent ion-exchanges.[4,8] (Attempts at ion exchange using Sr^{2+} and Ba^{2+} resulted in significantly less exchange, presumably due to the size mismatch between Na^+ and the large divalent cations.) Fig. 2(b) shows the X-ray

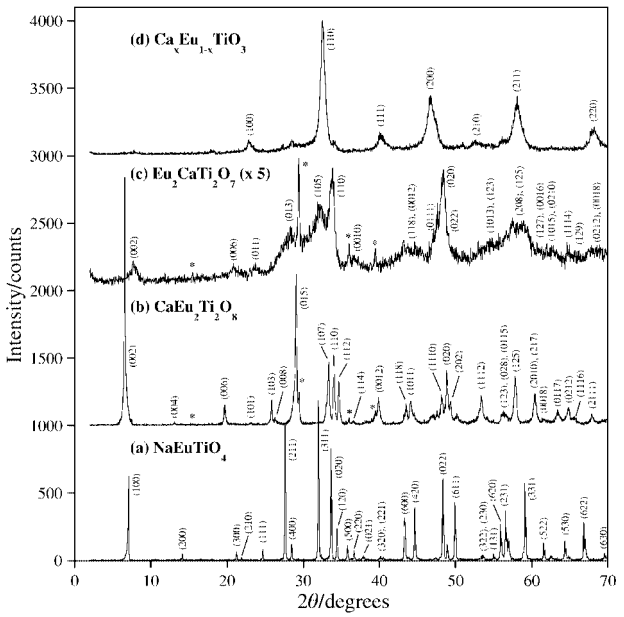

Fig. 2 XRD patterns for (a) $NaEuTiO_4$, (b) $CaEu_2Ti_2O_8$ formed by divalent ion exchange of $NaEuTiO_4$, (c) $Eu_2CaTi_2O_7$ synthesized under H_2 at 650 °C, and (d) $Ca_xEu_{1-x}TiO_3$, the thermodynamically stable product formed at 800 °C. A pyrochlore impurity is labeled with an asterisk in (b) and (c). Note that the vertical scale in (c) is expanded by a factor of 5.

Table 1 Lattice parameters and selected data for layered perovskites

Compound	Description	Colour	Space group	Lattice parameters/Å
$NaEuTiO_4$	n = 1 RP	White	*Pbcm*[a]	a = 12.5471(2) b = 5.3307(2) c = 5.3328(1)
$CaEu_2Ti_2O_8$	n = 1 RP/DJ	White	*I*4/*mmm*	a = 3.7302(2) c = 27.125(3)
$Eu_2CaTi_2O_7$	n = 2 RP	Black	*I*4/*mmm*	a = 3.78(2) c = 24.2(3)

[a] The space group is taken from ref. 10.

diffraction (XRD)[12] pattern for $CaEu_2Ti_2O_8$. The proposed structural model of $CaEu_2Ti_2O_8$ contains alternating staggered and eclipsed layers, as shown in Fig. 1b. Thus, $CaEu_2Ti_2O_8$ can be considered as a mixed $n = 1$ Ruddlesden–Popper/Dion–Jacobson phase. After drying for 1 h at 400 °C to remove interlayer water, $CaEu_2Ti_2O_8$ was indexed on a tetragonal unit cell (Table 1) with a doubled c-axis due to the staggered alternate layers. A pyrochlore impurity is identified in Fig. 2(b), and $CaEu_2Ti_2O_8$ decomposes completely to CaO and pyrochlore-type $Eu_2Ti_2O_7$ upon further heating in air.

Interestingly, a related compound, $Ca_{0.43}Na_{0.14}LaTiO_4$ (prepared by Wiley and coworkers by divalent ion-exchange in anhydrous calcium nitrate),[4b] is also a mixed $n = 1$ Ruddlesden–Popper/Dion–Jacobson phase, but unlike $CaEu_2Ti_2O_8$, each layer remains staggered as in the parent $NaLaTiO_4$ phase. In this case, as well as for $ZnEu_2Ti_3O_{10}$ reported earlier,[8] aqueous ion exchanges give the perovskite sheets lateral mobility to adopt an eclipsed conformation, while ion-exchanges using anhydrous nitrates or molten chlorides retain the staggered symmetry of the parent crystal.

When $CaEu_2Ti_2O_8$ is heated in hydrogen to reduce Eu^{3+} to Eu^{2+} and remove oxygen from the lattice, the perovskite layers above and below the Ca^{2+} cations collapse, encasing Ca^{2+} in the A-sites of the two bridged perovskite slabs to form the $n = 2$ Ruddlesden–Popper phase $CaEu_2Ti_2O_7$, or $Eu_2CaTi_2O_7$ (written in the traditional form to emphasize the location of Eu^{2+} in the interlayer). Unfortunately, $Eu_2CaTi_2O_7$ [Fig. 2(c)] is a low temperature phase, since it decomposes to perovskite-type $Ca_xEu_{1-x}TiO_3$ [Fig. 2(d)] when heated above 650 °C in hydrogen. (While Eu^{3+} fits well in the rocksalt-type interlayer sites, Eu^{2+} is too large to adopt the same coordination, so the reduced structure is unstable.) As with the metastable $Ln_2{\square}Ti_2O_7$ series, a short reaction time is needed in order to isolate the topochemical product. Thus, $Eu_2CaTi_2O_7$ has a limited stability window and is formed only by heating $CaEu_2Ti_2O_8$ for 30 min in hydrogen at 625 °C. Below 600 °C, the reduction does not occur.

The XRD pattern of $Eu_2CaTi_2O_7$ is shown in Fig. 2(c). A highly crystalline pyrochlore impurity, which was a minor impurity phase in Fig. 2(b), remains unchanged upon heating in hydrogen. Thus, Fig. 2(c) can be indexed as a mixture of phases—a crystalline $Ca_xEu_{2-x}Ti_2O_7$ pyrochlore phase, and the $n = 2$ Ruddlesden–Popper phase $Eu_2CaTi_2O_7$, which is characterized by much broader peaks. The broad peaks and low intensity indicate that the product is not very crystalline and that the topochemical collapse introduces disorder over large regions. Although broad, all of the peaks can be indexed to a tetragonal unit cell consistent with that of an $n = 2$ Ruddlesden–Popper phase (Table 1). $Eu_2CaTi_2O_7$ appears to be isostructural with $K_2SrTa_2O_7$.[13] The a axis lattice parameter of $Eu_2CaTi_2O_7$ is contracted relative to $K_2SrTa_2O_7$ (a = 3.9768, c = 21.7062 Å, from ref. 13) and related $n = 2$ phases, while the c axis lattice parameter is significantly larger (Table 1), which is consistent with the size variations between Ti^{4+}/Ta^{5+} and Eu^{3+}/Eu^{2+}. The absence of a major peak around $2\theta = 41°$ in Fig. 2(c), which corresponds to the (111) cubic perovskite peak, indicates minimal decomposition to $Ca_xEu_{1-x}TiO_3$ (the thermodynamically stable phase upon further heating in hydrogen). Likewise, the presence of an intense low angle reflection, as well as higher-index peaks consistent with a tetragonal unit cell, indicates that a layered structure is retained.

The progression of low-angle XRD peaks for $NaEuTiO_4$, $CaEu_2Ti_2O_8$ and $Eu_2CaTi_2O_7$ (Fig. 2) shows the layer spacings expected for an $n = 1$ Ruddlesden–Popper phase, an $n = 1$ Ruddlesden–Popper/Dion–Jacobson intergrowth, and an $n = 2$ Ruddlesden–Popper phase, respectively. $CaEu_2Ti_2O_8$ has a larger layer spacing (13.56 Å) than $NaEuTiO_4$ (12.55 Å), which is consistent with the expected increase from the eclipsed perovskite slabs. Likewise, the decrease in the layer spacing for $Eu_2CaTi_2O_7$ (*ca.* 12.1 Å) relative to $CaEu_2Ti_2O_8$ can only be explained by the bridging of octahedra from the perovskite slabs. Reduction without topochemical collapse (*i.e.* an oxygen-deficient $n = 1$ phase) would result in a larger layer spacing than $CaEu_2Ti_2O_8$ (due to the larger Eu^{2+} cation), so the (002) peak would have shifted to lower angles instead of higher angles.

While the topochemical conversion of an $n = 1$ to a defective $n = 2$ Ruddlesden–Popper phase has already been demonstrated,[9] this work represents the first route to a non-defective higher order layered perovskite. This kind of topochemical reaction could have interesting implications for fine-tuning the properties of carefully designed magnetic and ferroic phases. Additionally, it is an important extension of the topochemical reduction reaction that converts layered perovskites into three-dimensional perovskites, since it involves lower-order Ruddlesden–Popper homologues and results in a two-dimensionally bonded product. Indeed, this work demonstrates that topochemical reduction can be viewed as a generalized approach for the rational synthesis of metastable non-defective perovskites.

Ring opening metathesis poymerisation (ROMP) followed by catalytic dihydroxylation affords macromolecules with 1,2-diol structures. These new macromolecular compositions represent *C*-glycoside analogues of ribofuranose polymers that are thermally and hydrolytically stable.

Carbohydrate–protein interactions play an important role in many biological processes. Polysulfates derived from carbohydrates were recognized as potent and selective inhibitors of the *in vitro* replication of HIV and other enveloped viruses. In the case of sulfated dextrans the activity strongly depended on the molar mass of the oligosaccharides.[1,2] The design of new carbohydrate-analogue polymers is of special interest in polymer chemistry and life sciences—applications range from drug systems to novel biocompatible materials and surface coatings. Ring-opening metathesis polymerisation (ROMP) offers attractive potential for the synthesis of well defined carbohydrate analogue polymers. The modern catalyst generations, developed by Schrock and Grubbs, tolerate polar groups and afford living polymerisation which is the key to molar mass control. Novel families of ROMP glycopolymers were prepared by Kiessling, Schrock, Grubbs and co-workers[3–7] using sugar-substituted derivatives of norbornene and 7-oxanorbornenes as monomers. Since conventional polysaccarides are prone to metabolic degradation by glycosidases due to their glycosidic linkages,[2] hydrolytically stable carbohydrate-analogue compounds without glycoside linkages in the backbone represent interesting candidates for biomedical applications (Fig. 1).

Here we present a versatile synthetic method for the preparation of novel polyribofuranose analogue polymers which do not contain glycoside linkages between the monomeric units in the polymer backbone that are prone to metabolic degradation by glycosidases. This should provide an oligosaccharide analogue structure with improved biocompatibility and longer half-life times. Initial research on related oligosaccharide-analogue polymers was reported by Clark and Lee[8] who used ROMP of 7-oxanorbornene diol derivatives. Since the double bonds of the polymer backbone were hydrogenated, the resulting saccharide-analogue polymers contained only two hydroxy groups per repeating unit. The objective of our research was the synthesis of polymers containing fully hydroxylated repeating units. These are pseudo-polyribofuranoses, with structures very similar to those of natural carbohydrates. The synthetic strategy displayed in Scheme 1 employs ROMP of dihydroxy-substituted bicyclic olefin monomers and subsequent dihydroxylation of the double bonds in the polymer backbone.

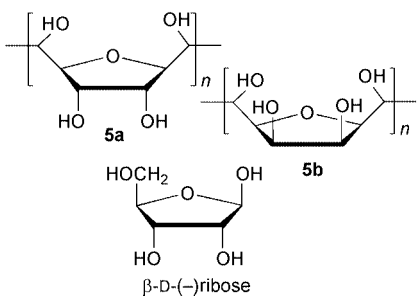

Fig. 1 Comparison between β-D-(−)ribose and the novel carbohydrate analogue polymers **5a**,**b**.

Both pure 2-*exo*, 3-*exo*-7-oxanorbornene diol **1a** and the corresponding *endo* isomer **1b** were synthesized according to a literature procedure.[9] Unfortunately, all attempts to perform ring-opening metathesis polymerisation in water, employing the water soluble Grubbs catalyst $RuCl_2(=CHPh)$-$[Cy_2PCH_2CH_2N(CH_3)_3{}^+Cl^-]_2$ **7** failed. Therefore, compounds **1a** and **1b** were transformed into their corresponding ketals **2a** and **2b** as reported by Schrock and co-workers.[10] ROMP in THF gave high yields (80–90%) using the well known Grubbs catalyst **6**. The monomer to catalyst ratio was varied in order to obtain polymers with different molecular masses. Properties of the obtained polymers are listed in Table 1. The resulting polymers **3a**,**b** were soluble in THF, acetone, $CHCl_3$ and CH_2Cl_2 but not in water or methanol. A polydispersity index M_w/M_n of 1.5, determined by size exclusion chromatography (SEC), reflects a relatively narrow molecular mass distibution (*cf.* Table 1). A significant difference was observed with respect to the *cis*/*trans* double bond ratio in **3a** and **3b**, respectively. The *cis* double bond content of **3a** was 30% compared to 80% for **3b**.

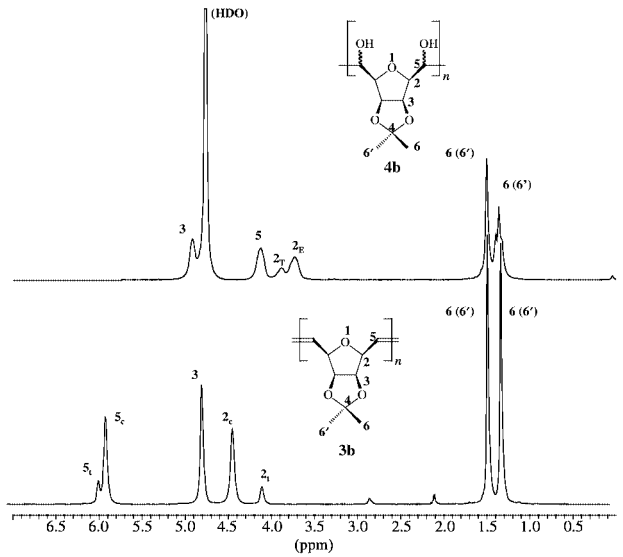

Fig. 2 ^{1}H NMR spectrum of **3b** (acetone-d6, 300 MHz) in comparison to **4b** (D_2O, 300 MHz).

The NMR-peaks were assigned based on COSY and DEPT-NMR techniques and by comparison with chemical shifts of related structures.[11] It is noteworthy that the *exo* and *endo* polymers also differ strongly in their glass transition temperatures (T_g) (**3a** T_g = 85 °C, **3b** T_g = 155 °C).

So far, typical polymer analogue reactions for the derivatisation of the double bonds produced by ROMP have employed sulfonation, hydrogenation, the formation of carbonamide[12] and epoxidation.[12,13] In order to produce the desired pseudo-polyribofuranose structures we decided to dihydroxylate the double bonds in the backbone of the ROMP polymers **3a**,**b**. To the best of our knowledge this is the first time that successful catalytic dihydroxylation of ROMP polymer has been achieved. While catalytic dihydroxylations are well known for many low molecular weight oligoalkenes[14a] it has rarely been successfully applied in polymer functionalisation.[14b]

It is even more surprising that for the ROMP polymer **3a/b** a quantitative conversion of all double bonds into 1,2-diol structures could be achieved. SEC measurements confirmed that polymer degradtion did not occur during dihydroxylation. In the ^{1}H NMR spectra displayed in Fig. 2 the signals at δ = 5.86 ppm and 5.94 ppm, which are assigned to the *cis* and *trans* double bonds of **3b**, completely disappeared after the dihydroxylation step. The signal for the protons in the 5 position was shifted to δ = 4.1 ppm. The signal for the proton in the allylic position to the *cis* and *trans* double bonds 2c, 2t were shifted from δ = 4.38 ppm and 4.04 ppm to 3.8 ppm and 3.6 ppm respectively. In accordance with the dihydroxylation of double bonds of low molecular weight compounds, the *cis* double bonds are converted selectively to *erythro* diols and the *trans* double bonds to the corresponding *threo* diols.[15] In the case of **3b** the dihydroxylation method described for oligoalkenes[14a] and polyalkenes[14b] was well suited to obtain the fully hydroxylated pseudo-polyribofuranose **4b** which was completely water and methanol soluble. However, it was not soluble in THF, acetone and other organic solvents. In the case of **3a** the fully dihydroxylated polymer **4a** was only partially soluble in water but fully soluble in methanol. Therefore methanol was added instead of water as medium for the dihydroxylation in order to achieve a quantitative conversion. After deprotection of the ketal groups of **4b** by means of CF_3COOH–H_2O (9 : 1 vol. ratio) a water insoluble polymer **5b** was obtained which formed fine needles after precipitation from solution. These needles were only soluble in DMF or DMSO. ^{1}H-NMR data showed that the polymer was fully deprotected, which was indicated by the lack of peaks in the region of δ = 1.0–1.7 ppm. The hydrolytic stability of this carbohydrate analogue polymer towards acidic media (see above) is much better with respect to that of natural carbohydrates containing acetal linkages in the backbone. The solubility behaviour of these new pseudo-furanose derivatives is very similar to that of *e.g.* cellulose (cellulose is water insoluble, methyl cellulose with up to 45% ether bonds is water soluble), thus indicating that the pseudo-polyribofuranoses are likely to exhibit superstructures *via* intermolecular hydrogen bonding. The structure–property relationships of these new polyribofuranose analogue compounds will be investigated in more detail.

The authors gratefully acknowledge financial support by the European Union (TMR-Project GLASSCYCLICS Contract No. FMRX-CT97-0116). We thank Sven Kasper and Christina Schmutz for technical assistance and Professor Walter Burchard for many helpful discussions relating to the characterization of polyhydroxy compounds.

A new series of dendrimers with 4,4′-bipyridinium cores capable of fast electron transfer reactions

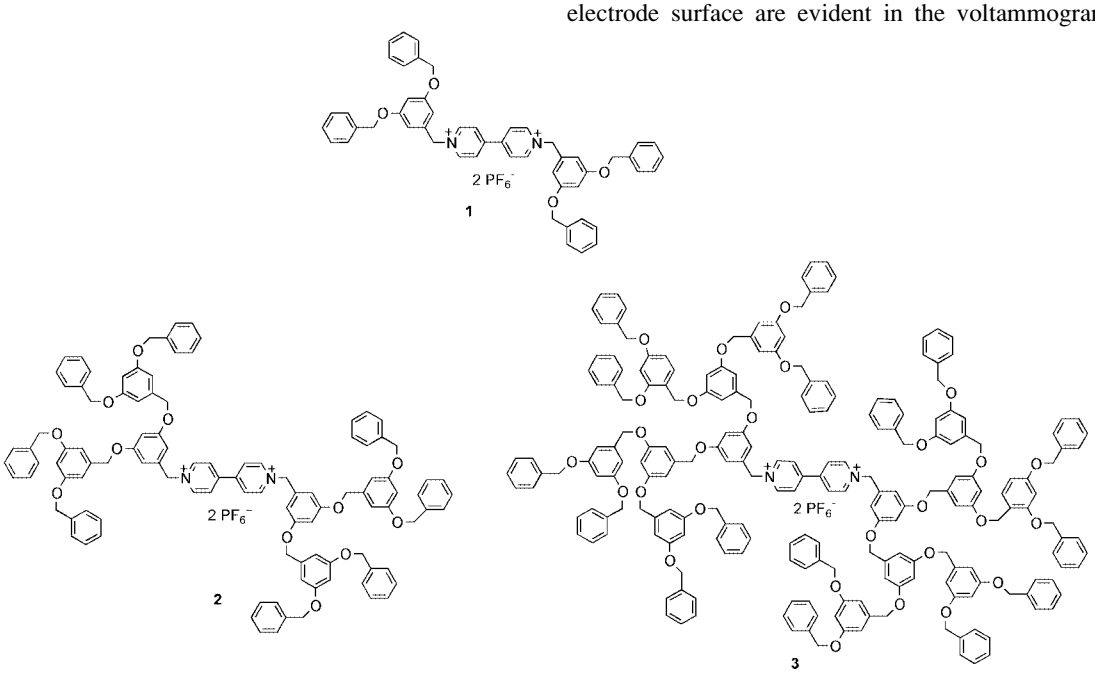
Received (in Columbia, MO, USA) 17th January 2001, Accepted 22nd March 2001
First published as an Advance Article on the web 17th April 2001

A new series of dendrimers containing a single 4,4′-bipyridinium (viologen) core has been synthesised and characterized that exhibit fast heterogeneous electron transfer reactions from the first to the third generation of dendritic growth.

Dendrimers with redox active cores have been proposed as promising materials for miniaturized information storage circuits.[1] Ideally, injecting/extracting electrons into or from the core of the dendrimer would be a simple way to store and/or read a bit of information in a single molecule. However, the redox active core must be surrounded by a considerable amount of inert material to prevent electronic 'cross-talk', that is, self-exchange electron transfer reactions between neighboring dendrimers that would lead to data losses in a two-dimensional storage array. To the best of the authors' knowledge, the isolation of the redox core by growing dendritic branches has always led to significantly decreased rates of heterogeneous electron transfer.[2] This trend has been clearly demonstrated with dendrimers synthesized around porphyrin,[3] ferrocene[4] and a variety of redox active, metal complex centers.[5] Here, we report the preparation and characterization of a new series of three dendrimers (compounds **1**–**3**, see structures below) containing a single 4,4′-bipyridinium (viologen) core residue covalently attached to two identical Fréchet-type dendrons[6] (first to third generation). The voltammetric behavior of these compounds reveals that the first one-electron reduction of the viologen core is reversible (fast) and rather insensitive to the size of the dendrons throughout the series, an unexpected finding from the available reports on related dendritic systems.[3–5]

The synthetic strategy for the preparation of the dendritic viologens utilized a convergent method. The benzyl bromide dendrons were prepared according to the procedure reported by Fréchet and Hawker.[7] Menschutkin reaction between 4,4′-bipyridine and two equivalents of the corresponding dendron bromides (DMF at 55 °C) afforded, after counterion exchange, the symmetrical dendrimers with a viologen unit at the core.† Their structure was confirmed by ^{1}H and ^{13}C NMR spectroscopies.‡ All compounds yielded satisfactory elemental analyses and exhibited very good correlation with the calculated molecular masses as evidenced by their FAB or MALDI-TOF mass spectra.‡

The influence of the dendritic structure on the electrochemical behavior of the core viologen units was investigated by cyclic voltammetry in acetonitrile solution. Typically, viologen derivatives exhibit two reversible reduction waves that correspond to the formation of a cation radical ($V^{2+} \rightarrow V^{+}$) and a neutral ($V^{+} \rightarrow V$) species.[8] The first reduction is generally very fast, and the second is often coupled to precipitation processes due to the uncharged nature of the fully reduced species, which is insoluble in solvents of intermediate to high polarity.[9] In agreement with the results reported for a different series of bipyridinium-based dendrimers,[10] we found (see Table 1) that the half-wave potentials ($E_{1/2}$) for the first reduction process shift to less negative values as the dendrimer generation increases. Analysis of the peak-to-peak potential splittings (ΔE_p) indicates that this electrochemical process is reversible at moderate scan rates for all dendrimers, even for the third generation compound **3**. However, some distortions associated with precipitation of the one-electron reduced species on the electrode surface are evident in the voltammograms for the



DOI: 10.1039/b102134f

[a] All electrochemical parameters were measured with a glassy carbon working electrode immersed in 0.25 mM **1–3** + 0.1 M $TBAPF_6$ solutions in acetonitrile. The reported half-wave potential values were measured at 0.1 V s^{-1}.

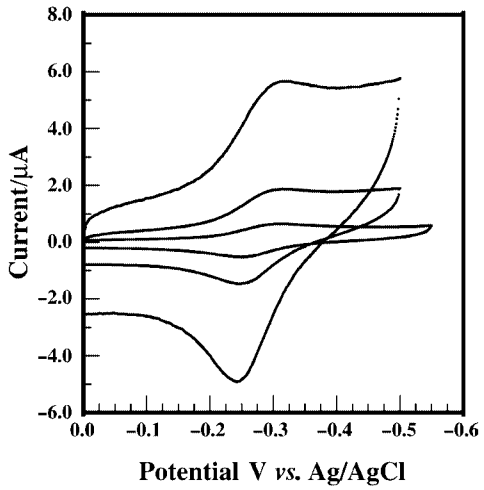

Fig 1 Cyclic voltammetric waves (at scan rates 0.1, 0.5 and 3.0 V s^{-1}) corresponding to the first one-electron reduction of dendrimer **3** (0.25 mM) in 0.1 M $TBAPF_6$–MeCN. Data were recorded with a glassy carbon working, platinum auxiliary and Ag/AgCl reference electrodes.

largest dendrimer (see Fig. 1). At faster scan rates (up to 3 V s^{-1}), our voltammetric data still reveal that the first reduction is quite fast (the largest ΔE_p value measured in these experiments was 78 mV). The distortions mentioned above precluded us from obtaining reliable values for the apparent heterogeneous rates of electron transfer.

The half-wave potentials corresponding to the second electron uptake exhibit the same trend, shifting to less negative values with increasing dendrimer generation. The kinetics of the electron transfer reaction appear to be fast, although very marked precipitation effects were observed. As was the case for the first reduction process, these effects were most visible for the third generation dendrimer **3**. Overall, the trend observed in the $E_{1/2}$ values reveals that the reduction process is thermodynamically more favored as the dendritic structure grows. We attribute this observation to the increasing hydrophobic character of the dendrimer core, which makes it progressively harder to solvate effectively the two positive charges of the viologen core. Therefore, reduction (partial or total elimination of the core charges) becomes more favorable with increasing dendrimer generation.

To our knowledge this is the first example of dendrimers containing a single electroactive core unit that shows relatively fast heterogeneous electron transfer reactions even in the third generation, as measured at scan rates as fast as 3 V s^{-1}. Taken together, these results open some interesting possibilities and suggest that dendrimers with viologen cores are promising in the search for electrochemically active dendrimers with practical applications. We are currently working on methods to immobilize these or similar dendrimers at interfaces in order to obtain electrochemical behavior that will not be affected by precipitation effects.

Notes and references

† A solution of the dendron bromide (0.06 mmol) and 4,4′-bipyridine (4.7 mg, 0.03 mmol) in DMF (1 ml) was stirred under inert atmosphere at 55 °C for 24 h. After cooling to room temperature, the solvent was removed under reduced pressure and the residue dissolved in acetone (1 ml). An aqueous solution of NH_4PF_6 was added. The solvents were removed *in vacuo* and the solid triturated in water. The precipitate was filtered off, washed with water and diethyl ether. The resulting solid was purified by size-exclusion chromatography (Sephadex LH-20), eluting with MeCN to yield the pure dendrimer.

‡ Dendrimer **1**: Yield 90%; ^{1}H NMR (200 MHz, CD_3CN): δ 5.11 (s, 8H), 5.72 (s, 4H), 6.72–6.76 (m, 6H), 7.32–7.49 (m, 20H), 8.36 (d, 4H, ^3J (H, H) 6.8 Hz), 8.95 (d, 4H, ^3J (H, H) 6.8 Hz); ^{13}C NMR (50 MHz, CD_3CN): 65.5, 70.9, 103.9, 109.3, 128.3, 128.6, 128.9, 129.4, 135.5, 137.6, 146.4, 151.1, 161.5; FB MS: *m*/*z* 907 $(M - PF_6^-)^+$, 762 $(M - 2PF_6^-)^+$.

Dendrimer **2**: Yield 86%; ^{1}H NMR (200 MHz, CD_3CN): δ 5.03 (s, 24H), 5.68 (s, 4H), 6.56–6.67 (m, 18H), 7.30–7.38 (m, 40H), 8.18 (d, 4H, ^3J (H, H) 6.8 Hz), 8.82 (d, 4H, ^3J (H, H) 6.7 Hz); ^{13}C NMR (50 MHz, CD_3CN): 65.5, 70.6, 102.3, 104.1, 107.4, 109.4, 128.1, 128.5, 128.8, 129.4, 135.4, 137.9, 140.2, 146.3, 150.7, 160.9, 161.3; FAB MS: *m*/*z* 1756 $(M - PF_6^-)^+$, 1611 $(M - 2PF_6^-)^+$.

Dendrimer **3**: Yield 78%; ^{1}H NMR (200 MHz, CD_3CN): δ 4.84 and 4.95 (each s, 56H), 5.52 (s, 4H), 6.46–6.60 (m, 56H), 7.19–7.33 (m, 80H), 8.04 (d, 4H, ^3J (H, H) 6.7 Hz), 8.72 (d, 4H, ^3J (H, H) 6.8 Hz); ^{13}C NMR (50 MHz, CD_3CN): 65.5, 70.4, 70.7, 102.2, 102.4, 104.1, 107.5, 109.4, 127.9, 128.6, 128.9, 129.4, 135.4, 138.0, 140.2, 140.6, 146.3, 150.5, 160.8, 160.9, 161.4; MALDI-TOF MS: *m*/*z* 3308.4 $(M - 2PF_6^-)^+$.

Received (in Irvine, CA, USA) 14th November 2000, Accepted 9th March 2001
First published as an Advance Article on the web 18th April 2001

The large-pore nickel(II) phosphate, VSB-1, shows excellent selectivity (> 80%) for the dehydrocyclodimerization of butadiene to ethylbenzene at 400 °C; conversion to 4-vinylcyclohexene and oligomeric byproducts is < 5% in each case.

The widespread utility of aluminosilicate zeolites in the field of shape-selective catalysis[1] has led to a quest for other families of nanoporous materials that might exhibit catalytic activity. In spite of the enormous amount of work that has been done in this area,[2] only two other families of materials, the aluminum phosphates[3] and the titanosilicates,[4] have yielded molecular sieves with exciting catalytic properties. For example, SAPO-34, an $AlPO_4$ with the chabazite structure, is being exploited for the conversion of methanol to olefins,[3] and the titanosilicate, TS-1, is a very effective for selective oxidations using hydrogen peroxide.[4] Attempts to make nanoporous transition metal phosphates have led to the discovery of many new phases, *e.g.* V–P–O,[5] Fe–P–O[6] and Co–P–O,[7] but, as is the case with most non-silicate open-frameworks, the poor thermal stability of these systems leads to the collapse of the pore structures on activation, thus rendering them unsuitable for applications that require porosity. Recently, however, we described the first example of an open-framework nickel phosphate, VSB-1 (Versailles/Santa Barbara-1),[8] whose porosity can be readily accessed by low temperature calcination. The structure is stable to *ca.* 550 °C. In the present work, we show that this phase is catalytically active in the dehydrocyclodimerization of butadiene to ethylbenzene.

VSB-1 was prepared as a green powder from a hydrothermal reaction at 180 °C for 6 d between nickel(II) chloride hexahydrate and phosphoric acid (85% by weight) in the presence of ammonium fluoride. Further details are given in ref. 8. This new material has a large unidimensional channel composed of 24 NiO_6 and PO_4 polyhedra, and the free diameter of the channel is estimated to be 8.8 Å (Fig. 1). Its surface area and chemical composition are 82 $m^2\ g^{-1}$ and $Ni_{18}(HPO_4)_{14}(OH)_3F_9(H_3O/NH_4)_4 \cdot 12H_2O$, respectively.[8] Zeolite NaX (Si : Al = 1.40, S_{BET} = 875 $m^2\ g^{-1}$), used for comparison of the catalytic activity, was obtained from Fluka Chemie AG.

The cyclodimerization of 1,3-butadiene to 4-vinylcyclohexene (VCH) and its dehydrogenation to ethylbenzene or styrene (Scheme 1) could provide an attractive route for styrene production and is regarded as an interesting alternative to the classical ethylbenzene dehydrogenation process.[9] VSB-1 and NaX were investigated for this reaction. The catalytic runs were carried out in a fixed-bed, vertical flow quartz reactor mounted inside a tubular furnace at 400 °C and atmospheric pressure. After the catalyst had been placed in the reactor it was heated up to 450 °C in an oxygen flow for 4 h for activation and to remove any adsorbed species. The reactor was then purged with helium for 1 h at the same temperature and cooled down to the desired reaction temperature. 1,3-Butadiene (99%, Matheson) was delivered with a constant flow (typically 3 ml gas min^{-1}) and preheated to 200 °C and mixed with helium (10 ml min^{-1}) in a baffled gas-phase mixer within an oven at 200 °C. Product gases were analyzed downstream by on-line gas chromatograph (HP 5890II) with a flame ionization detector (FID). The capillary column (J&W, DB-WAX) of the gas chromatograph allowed the separation of the products.

Fig. 2 shows the conversion of butadiene *via* Diels–Alder cyclodimerization at 400 °C over VSB-1 and NaX. The thermal (non-catalytic) conversion of butadiene to 4-vinylcyclohexene or ethylbenzene in a Pyrex-filled glass reactor under the same conditions as our catalyst testing was less than 1%. We find that NaX gives very high butadiene conversion, at least initially [Fig. 2(*b*)], but very poor selectivity for cyclodimerization (< 30%). The main products over NaX are oligomeric ones such as polyalkenes, presumably due to residual acidity in the zeolite at high temperatures.

According to our unpublished results, VSB-1 has much weaker acidity than zeolite NaX, so there is a reasonable expectation that oligomerization will be less than in the aluminosilicate. This behavior is confirmed in our experiments [Fig. 2(*a*)]. Steady state conversions are obtained after approximately 1 h and are sustained for at least 5 h. Although the activity of VSB-1 is relatively low, it exhibits high selectivity (> 90%) towards the cyclodimerization products, ethylbenzene and VCH. In particular, it is noted that VSB-1 shows remarkably high selectivity for ethylbenzene (82%). The

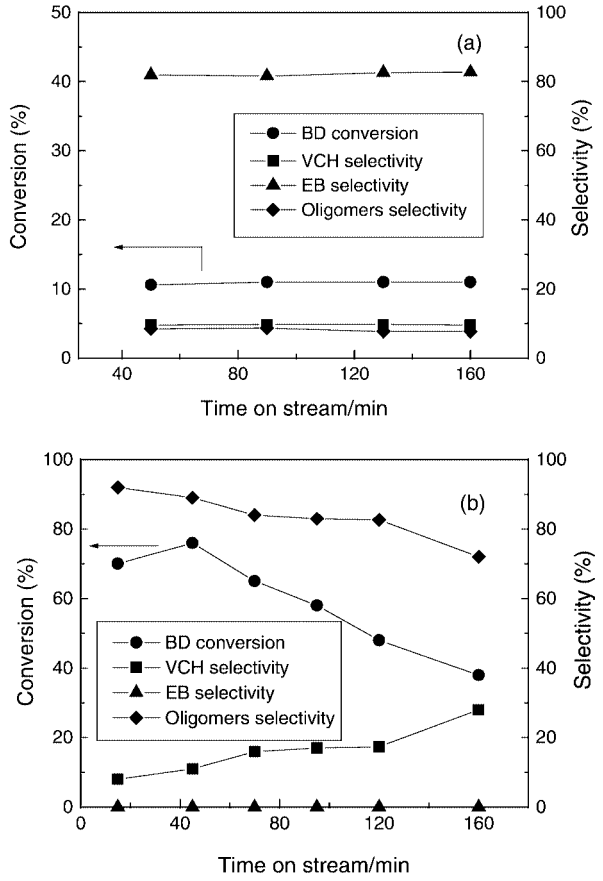

Fig. 2 The Diels–Alder cyclodimerization of 1,3-butadiene over (a) VSB-1 and (b) NaX. Reaction conditions: T = 400 °C, GHSV = 7800 h^{-1}, feed gas = 1,3-butadiene–helium (3/10). Notation: BD; 1,3-butadiene, VCH; 4-vinylcyclohexene, EB; ethylbenzene.

reaction certainly involves the cyclodimerization of butadiene to VCH followed by dehydrogenation to form ethylbenzene; that is, the whole process is better described as a dehydrocyclodimerization. In contrast, NaX did not produce any ethylbenzene or styrene. Interestingly, VSB-1 displays 2% selectivity to styrene at 425 °C (data not shown), but catalyst deactivation is observed at this temperature due to the deposition of oligomeric products.

The Diels–Alder cylcodimerization of 1,3-butadiene to VCH is a well-known thermally-initiated electrocyclic reaction, that is kinetically second-order in butadiene.[10] Neither acidic nor basic catalysts have been used successfully for this reaction.[11] In addition to homogeneous catalyst systems,[12] the cyclodimerization of butadiene has been found over large-pore molecular sieves such as CuY,[13] NaZSM-20,[11] NaBeta[11] and NaX.[13] The catalytic role of non-acidic zeolites in the Diels–Alder reaction has therefore been understood in terms of the ability of zeolites to concentrate hydrocarbons within their cavities.[11] Thus, by increasing the butadiene concentration inside the zeolitic pores relative to that in the external gas phase, the zeolite can enhance the rates of bimolecular reactions such as the Diels–Alder reaction. In the present work, the high selectivity of VSB-1 for the cyclodimerization may again be ascribed to the concentration effect within its large pore channel (8.8 Å). Moreover, the high selectivity towards ethylbenzene over VSB-1 points to the role of the Ni species within its open framework in the partial dehydrogenation step. This type of selectivity has been seen with other nanoporous materials containing transition metals, but not with acidic or basic catalysts. For example, a Ni-impregnated aluminum phosphate catalyst was reported to be active in the dehydrogenation of cyclohexane at 400 °C.[14]

Although the active sites for this reaction are unclear as yet, the high selectivity of VSB-1 for ethylbenzene highlights the bifunctional role of VSB-1. Another important feature of VSB-1 is its excellent stability. The catalytic performance is very stable over several hours, and, significantly, no appreciable deactivation is observed. The stability of VSB-1 is consistent with a previous report that it is thermally stable in air to 550 °C,[8] in contrast to most other open-framework transition metal phosphates. In the case of NaX, severe catalyst deactivation was noted as the reaction proceeded due to the formation and deposition of oligomeric cokes.

In summary, our work shows that the nanoporous nickel(II) phosphate, VSB-1, has some interesting catalytic properties, exhibiting good stability and high selectivity for ethylbenzene in the dehydrocyclodimerization of 1,3-butadiene. The catalytic performance is ascribed to the bifunctional role of VSB-1, *i.e.* the dehydrogenation ability of Ni species and the concentration effect of the nanoporous structure. Further studies are in progress to elucidate the active sites of VSB-1 for the cyclodimerization and dehydrogenation. In the light of earlier work that demonstrated the dehydrogenation of EB to styrene at temperatures as low as 250 °C,[15] we are also exploring the possibility that a single stage conversion of butadiene to styrene might be possible.

Coexisting covalent and noncovalent nets: parallel interpenetration of a puckered rectangular coordination polymer and aromatic noncovalent nets

Susan A. Bourne,[b] Jianjiang Lu,[a] Brian Moulton[a] and Michael J. Zaworotko*[a]

[a] *Department of Chemistry, University of South Florida, 4202 E. Fowler Ave (SCA 400), Tampa, F 33620, USA. E-mail: xtal@usf.edu*

Received (in Columbia, MO, UK) 20th February 2001, Accepted 21st March 2001
First published as an Advance Article on the web 18th April 2001

[Zn(*m*-isophthalate)(1,2-bis(4-pyridyl)ethane)]$_n$·*x*A (A = benzene, nitrobenzene, toluene, benzaldehyde, dioxane) represent the first examples of parallel interpenetration between noncovalent and metal–organic frameworks.

Crystal engineering[1] has provided chemists with a useful paradigm for the development of rational approaches to the design of solid-state structures that are based upon self-assembly of metal nodes and multifunctional ligands.[2] However, it has become clear that interpenetration[3] and supramolecular isomerism[4] are common phenomena in coordination polymers and that subtle factors such as choice of solvent and the presence of templates bring an added level of diversity and uncertainty to the outcome of a particular experiment. Batten and Robson[3] have delineated the modes in which coordination polymers can exhibit self-interpenetration and describe such systems in terms of 'nets' (*i.e.* a collection of nodes with some clearly defined connectivity or topology). We[5] recently suggested how topological considerations can be used to explain interpenetration of two very different types of net: 2-D square grids formed from octahedral metal ions coordinated to two linear bifunctional ligands such as 4,4′-bipyridine[6] and planar noncovalent nets comprising organic guest molecules.[7] That the square coordination polymer grids are flat ensures inclined interpenetration between the two types of network. Such 'hybrid' structures might bring with them the intriguing possibility of combining the structural and functional features of two very different types of molecular component.[8]

We report herein several structures† that exhibit the coexistence of coordination polymer and noncovalent nets *via* a parallel interpenetration mode that is possible because the coordination polymer exists as a novel, puckered 2-D grid. We also demonstrate that the absence of a suitable component for the noncovalent nets precludes formation of the 2-D coordination polymer, and rather affords a novel 3-D supramolecular isomer of the coordination polymer. Self-assembly of Zn(II) ions with 1,3-benzenedicarboxylate (bdc) and 1,2-bis(4-pyridyl)ethane (bpeta) in the presence of an appropriately sized guest affords a novel, puckered, rectangular grid structure, [Zn(bdc)(bpeta)]$_n$ **1**. **1** crystallizes from EtOH if benzene (**1a**), nitrobenzene (**1b**), toluene (**1c**), benzaldehyde (**1d**) or 1,4-dioxane (**1e**) are also present. However, if the solvent is changed to pure MeOH, MeOH/naphthalene or CH_2Cl_2, a different supramolecular isomer of **1** is formed—a 3-D structure, **2**—which can also be formulated as [Zn(bdc)(bpeta)]$_n$. The covalent network in **1a** is sustained by a tetrahedral Zn(II) ion coordinated to two bdc and two bpeta ligands. Four of these units give rise to a rectangular cavity incorporated in a (4,4)-network in which zinc ion serves as node. The tetrahedral geometry around the zinc ion causes adjacent rectangular cavities to fold with an angle of 99.94° between Zn ions, producing a 'puckered' layer of cavities, as shown in Fig. 1. Adjacent cavities have slightly different environments in that the orientation of the aromatic rings of the bdc units differs: in one (cavity A) the rings are coplanar with the plane of the

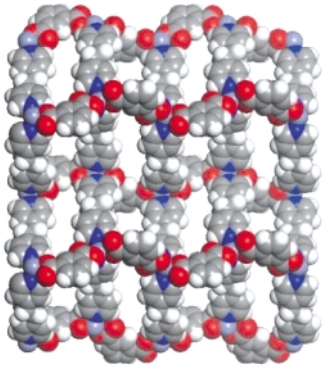

Fig. 1 Space-filling views of the puckered, rectangular, grid coordination polymer network in **1a**. The puckering of the (4,4)-network can be clearly seen and affords cavities and channels within the plane of the network.

cavity, while for the next cavity (B) opposite bdc moieties orient up and down with respect to the plane of the cavity. Effective dimensions for the cavities are 4.8 × 13.3 Å (for A) and 6.0 × 13.6 Å (for B). The bpeta ligands contain pyridyl rings that are only slightly twisted (torsion angle 167.7°) and these ligands are bowed when viewed down the Zn···Zn direction. The coordination polymer layers pack close to one another, with metal centres and cavities stacked above one another, when viewed down [1 0 0]. The interlayer separation is 9.672 Å and there are C–H···π and π···π interactions between layers (the C···$\pi_{centroid}$ distance is 3.532 Å and the $\pi_{centroid}$···$\pi_{centroid}$ distances are 3.611 and 3.705 Å, consistent with distances to be expected for such interactions).

The organic guest molecules in **1a**–**e** form what could be regarded as (6,3)-'puckered brick wall' networks that are sustained by noncovalent interactions (Fig. 2). Fig. 3 illustrates how two of the noncovalent networks engage in parallel interpenetration with the coordination polymers, thereby forming a structure that is similar to the laminated, self-interpenetrated structure exhibited by 1,3,5-benzenetricarboxylic acid and 4,4′-bipyridine.[9]

The critical influence of the solvent and organic components on the self-assembly process is clearly illustrated by the formation of **2**, which exhibits a dramatically different structure that can be described as a pseudo-tetrahedral framework

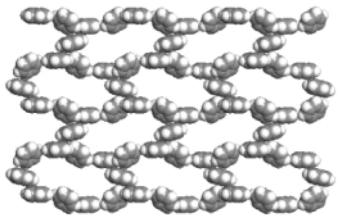

Fig. 2 A view of the noncovalent nets that are formed by benzene molecules in **1a**.

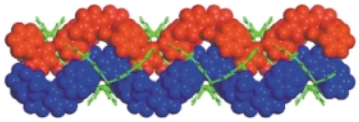

Fig. 3 An illustration of how two noncovalent networks (illustrated in space-filling mode) generate parallel interpenetration with one puckered rectangular grid (illustrated in stick mode) in **1a**.

because the tetrahedral Zn ions are linked by angular and linear spacer ligands. Zn···Zn separations in **2a** are 9.90 and 13.34 Å; this inequality in spacer length leads to a distortion of the diamondoid network that would otherwise be formed (Fig. 4). The large void generated within the pseudo-diamondoid cage is filled by the mutual interpenetration of three independent networks (Fig. 5). Guest molecules in **2a** occupy cavities between the metal-coordination networks, and are isolated from one another. Each cavity has a volume of 91 Å^3, and represents 4.4% of the unit cell volume. Thus the total volume occupied by guest molecules in this structure is only 17.6%.[10]

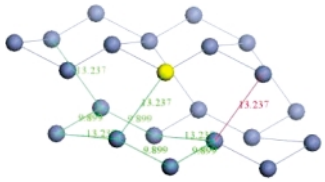

Fig. 4 The pseudo-diamondoid network in **2a**. The bridging ligands are omitted for clarity.

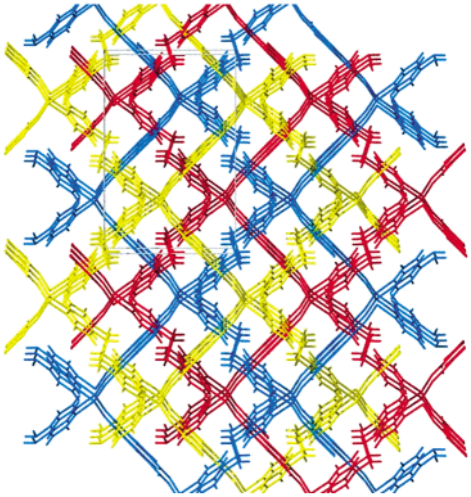

Fig. 5 An illustration of the three pseudo-diamondoid networks that interpenetrate in **2a**.

The existence of the novel supramolecular isomers **1** and **2** is not in itself surprising. However, that their existence appears to be closely linked to whether or not topologically complementary noncovalent nets can be formed provides insight into how chemists can control such supramolecular isomerism and in the process generate hybrid structures that are based upon very different molecular components.

Notes and references

† *Synthesis and data:* 2D-[Zn(bdc)(bpeta)]$_n$·x(A), **1**(**a**–**e**) and 3D-[Zn(bdc)(bpeta)]$_n$·(solvent), **2**(**a**,**b**), were prepared by dissolving $Zn(NO)_3·6H_2O$ (typical example: 0.149 g, 0.5 mmol) and 1,3-benzenedicarboxylic acid (0.166 g, 1 mmol) in ethanol and layering this with a solution of 1,2-bis(4-pyridyl)ethane (0.184 g, 1 mmol) in A. Colorless, rod-shaped crystals were formed at the solvent interface. Intensity data for **1a**–**e** and **2a**,**b** were collected at −100 °C on a Bruker SMART-APEX diffractometer using Mo-Kα radiation (λ = 0.7107 Å). The data were corrected for Lorentz and polarization effects and also for absorption using the SADABS program. Structures were solved using direct methods and refined by full-matrix least squares on $|F|^2$.[11] All non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed in geometrically calculated positions and refined with temperature factors 1.2 × those of their parent atoms.

1b, **1c**, **1d** and **1e** are isostructural with **1a**: they crystallize in $P2_1/n$ with similar cell parameters, they have similar, but not identical, host:guest ratios [for **1a** and **1e** this is 1:2.5, for **1b**–**1d** (which encapsulate slightly larger guests) it is 1:2]; their interlayer separations are in the range 10.244–10.546 Å and they possess cavities with effective dimensions of *ca.* 5 × 13 Å (cavity type A) and *ca.* 5.5 × 14.5 Å (cavity type B). **1b**–**d** have Zn–Zn–Zn angles of 87–89°, while **1e** has an angle of 100.64°, which is closer to that observed in **1a**.

Crystal data for **1a**: monoclinic, $P2_1/n$, a = 9.672(1), b = 20.217(2), c = 14.977(2) Å, β = 93.545(2)°, V = 2923.2(5) Å^3, Z = 4, D_c = 1.384 g cm^{-3}, μ = 0.883 mm^{-1}, F(000) = 1268, $2\theta_{max}$ = 25°. Final residuals (for 377 parameters) were R_1 = 0.0406 and wR_2 = 0.0764 for 3242 reflections with $I > 2\sigma(I)$, and R_1 = 0.0680, wR_2 = 0.0817 for all 5077 data. Residual electron density was 0.75 and −0.48 e Å^{-3}. [Cell parameters for **1b**: a = 10.546(2), b = 18.400(3), c = 15.209(2) Å, β = 90.971(3)°, V = 2950.8(7) Å^3. Cell parameters for **1c**: a = 10.243(3), b = 18.317(5), c = 15.391(4) Å, β = 91.116(5)°, V = 2887(1) Å^3. Cell parameters for **1d**: a = 10.437(2), b = 18.516(4), c = 15.190(3) Å, β = 90.119(4)°, V = 2935(1) Å^3. Cell parameters for **1e**: a = 10.545(1), b = 20.202(2), c = 14.239(2) Å, β = 96.781(2)°, V = 3012.3(6) Å^3].

Crystal data for **2a**: orthorhombic, *Pnna*, a = 10.020(1), b = 15.195(5), c = 13.689(1) Å, V = 2084.1(4) Å^3, Z = 8, D_c = 1.589 g cm^{-3}, μ = 1.466 mm^{-1}, F(000) = 1016, $2\theta_{max}$ = 26°. Final residuals (for 138 parameters) were R_1 = 0.0444 and wR_2 = 0.1146 for 1934 reflections with $I > 2\sigma(I)$, and R_1 = 0.0483, wR_2 = 0.1167 for all 2151 data. Residual electron density was 0.72 and −0.58 e Å^{-3}. [Cell parameters for **2b**: a = 9.676(3), b = 15.470(5), c = 13.547(5) Å, V = 2028(1) Å^3].

High resolution thermogravimetric analysis (TA Instruments TGA 2950) shows a multi-step weight loss between ambient temperature and 200 °C, which can be attributed to the release of guest (for example, **1a**: observed mass loss 33.6%, calc. for 2.5 benzene 32.1%) followed by further thermal decomposition at 300–400 °C, apparently caused by destruction of the coordination polymer.

Nanoballs: nanoscale faceted polyhedra with large windows and cavities

Brian Moulton, Jianjiang Lu, Arunendu Mondal and Michael J. Zaworotko*

Department of Chemistry, University of South Florida, 4202 E Fowler Ave (SCA 400), Tampa, FL 33620, USA. E-mail: xtal@usf.edu

Received (in Columbia, MO, USA) 11th March 2001, Accepted 21st March 2001
First published as an Advance Article on the web 18th April 2001

Self-assembly of molecular polygons by linking their vertices provides nanosized faceted polyhedra that are porous, contain chemically accessible sites on their facets, are chemically robust, neutral and soluble in common laboratory solvents.

In recent years chemists have developed synthetic design strategies that are based upon the concepts of self-assembly. This supramolecular approach to synthesis, a 'bottom-up'[1] approach to nanoscience, has afforded a new generation of discrete, high molecular weight compounds. These compounds are exemplified by nanoscale spheroid architectures that are based upon Platonic (regular) and Archimedean (semi-regular) solids.[2–9]

Nanoscale versions of Platonic and Archimedean solids have been prepared by one of two approaches: edge-sharing of molecular polygons,[7] or connection of appropriately designed molecular vertices by linear bifunctional rod-like ligands.[10] Edge-sharing of molecular polygons affords closed convex polyhedra whereas connection of vertices generates open structures that are the edge-skeletons of polyhedra. However, there exist other examples of uniform polyhedra[11,12] that to our knowledge remain unexplored in the context of synthetic chemistry. Uniform polyhedra include prisms and antiprisms, polyhedra having star faces and vertices, and polyhedra with both concave and convex faces.[13] In particular, there are nine uniform polyhedra that are closely related to Platonic and Archimedean solids but differ in that their convex faces can be constructed by linking the vertices of regular polygons. Such structures are termed faceted polyhedra[14] since they must contain both open (concave) and closed (convex) faces (*i.e.* faceting).

As revealed by Fig. 1 there are three faceted uniform polyhedra that can be generated by linking the vertices of squares and which one occurs will be strongly influenced by the angle subtended by the 'spacer' moiety that links the vertices: *cubohemioctahedron* (90°) < *small rhombihexahedron* (120°) < *small rhombidodecahedron* (144°). Therefore, judicious control of the angle subtended by the vertices of the squares should afford control over which polyhedron will result. The molecular squares that we have targeted for study are the previously reported metal-organic secondary building units[15] (SBUs) $M_2(RCO_2)_4$ **A**. **A** is illustrated in Fig. 2 and represents a ubiquitous SBU that is present in nearly 900 crystal structures in the Cambridge Structural Database (CSD).[16] It should be noted that it has already been demonstrated that use of polycarboxylate ligands in $M_2(RCO_2)_4$ (*e.g.* benzene-1,4-dicarboxylate[17] or benzene-1,3,5-tricarboxylate[18]) affords self-assembled infinite structures with predictable topology and relatively high thermal stability. It occurred to us that the angular bifunctional ligand benzene-1,3-dicarboxylate, bdc, which subtends an angle of 120°, offers the possibility of generating discrete nanoscale *small rhombihexahedra* or supramolecular isomers[19] in the form of novel infinite coordination polymers.

Nanoscale *small rhombihexahedra* **1**, are formed by layering methanolic $Cu(NO_3)_2$ and H_2bdc onto a solution of pyridine that contains templates such as nitrobenzene or 1,2-dichlorobenzene. Single crystals of $[(L)(S)Cu_2(bdc)_2]_{12}$, L = pyridine, S = methanol, **1a**, form within hours. Alternatively, microcrystals of **1a** can be obtained quantitatively by direct mixing of the above reagents. The crystal structure of **1a**† is illustrated in Fig. 3 and reveals that it can be described as being composed of vertex linked molecular squares (green) that self-assemble into *small rhombihexahedra*. **1a** contains pyridine ligands that are axially bonded to the metal ions that lie at the exterior surface and MeOH ligands at the interior surface metal binding sites. The internal cavity has a volume of *ca.* 1 nm^3 that is easily large enough to encapsulate C_{60}. To our knowledge, **1a** represents the largest spheroid structure that has yet been crystallographically characterized. It has a molecular volume of >10 nm^3 and a molecular weight of 6.80 kDa. **1** can also be formed for L = S = methanol, **1b**. Thus far we have isolated two crystalline phases that contain **1b**, a monoclinic and a cubic phase.†

An isomer of the *small rhombihexahedron* $[(MeOH)_2Cu_2(bdc)_2]_{12}$ **2** crystallizes under similar conditions with 2,6-dimethylpyridine, a non-coordinating base, present instead of pyridine. **2** is illustrated in Fig. 4 and the connectivity of the SBUs is different. **2** has a molecular weight of 6.23 kDa, a molecular volume of *ca.* 10 nm^3 and exhibits textbook hexagonal close packing. Molecular modelling indicates insignificant difference in terms of torsional strain between **1** and **2** (calculated using MSIs Cerius² Minimizer module).

1 and **2** are distinguished by the following features: they are neutral and soluble in organic solvents; they are chemically robust because of the stability of the square SBU (confirmed by high resolution mass spectrometry); they are likely to be chemically diverse because **A** exists for so many metals,

Fig. 1 The three types of faceted uniform polyhedra that can be generated by linking the vertices of squares only: *cubohemioctahedron*, *small rhombihexahedron* and *small rhombidodecahedron*.

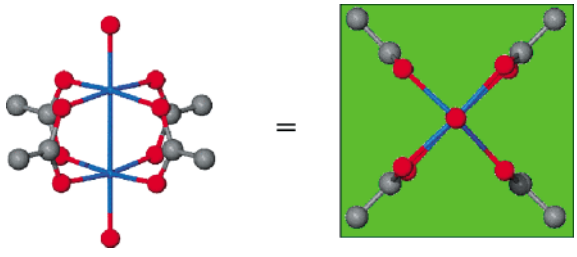

Fig. 2 The square SBU, $M_2(RCO_2)_4$ **A**, employed in this study. In the compounds described herein, **A** is schematically represented as a square (green).

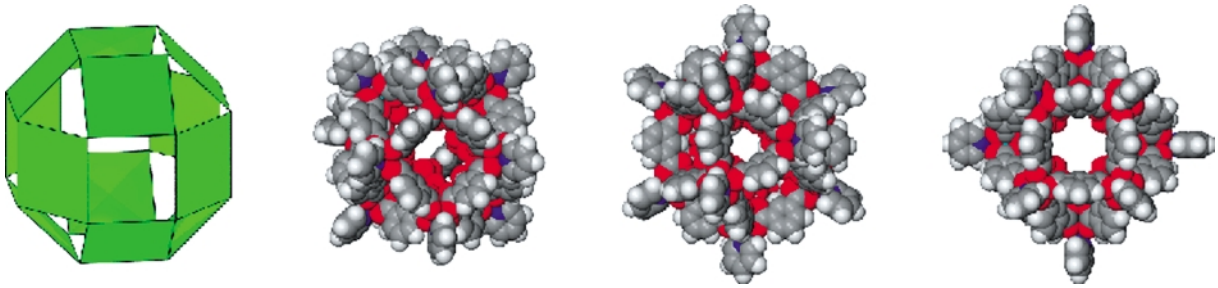

Fig. 3 Crystal structure of $[(L)(S)Cu_2(bdc)_2]_{12}$, L = pyridine, S = methanol, **1**. The schematic illustrates how linking of molecular squares generates the edge-skeleton of **1**. Note how the large bowl-shaped square and triangular windows provide access to the interior of **1**. Disordered solvent is found in these windows and in the 1 nm^3 internal cavity. There is high thermal motion and/or disorder in the ligands and the guest molecules but the structure of the core is well determined and unambiguous.

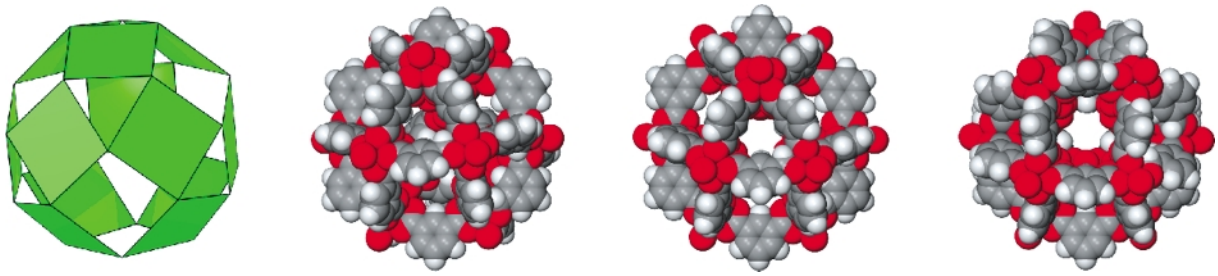

Fig. 4 Crystal structure of $[(S)_2Cu_2(bdc)_2]_{12}$, S = methanol, **2**. The schematic illustrates the subtle differences between the connectivity in **1** and **2**.

including magnetically active and catalytically active metals; they have both internal and external sites that are suitable for further chemical modification. Indeed, it is possible to envisage **1** and **2** as the building blocks for much larger structures by acting as the node of infinite networks[20] or as the core of mesoscale dendritic structures; their interior cavities can be accessed *via* triangular or square windows, which are bowl shaped and contain organic guests. Loss of coordinated molecules occurs at higher temperatures. Furthermore, judicious selection of angular spacers in the presence of molecular polygons should ultimately generate all nine faceted polyhedra and their structural isomers.

Notes and references

† *Crystallographic data:* intensity data for **1** and **2** were collected at 173 K on a Bruker SMART-APEX diffractometer using Mo-Kα radiation (λ = 0.7107 Å). The data were corrected for Lorentz and polarization effects and for absorption using the SADABS program. Structures were solved using direct methods and refined by full-matrix least squares on $|F|^2$.[11] All non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed in geometrically calculated positions and refined with temperature factors 1.2 times those of their bonded atoms.

Crystal data: for **1a**: triclinic, $P\bar{1}$, a = 26.202(9), b = 27.756(10), c = 28.408(10) Å, α = 92.583(5), β = 96.393(5), γ = 92.643(5)°, V = 20 483(12) Å^3, Z = 2, D_c = 1.279 g cm^{-3}, μ = 1.29 mm^{-1}, F(000) = 7752, $2\theta_{max}$ = 37.88° ($-23 \leqslant h \leqslant 23$, $-25 \leqslant k \leqslant 25$, $-25 \leqslant l \leqslant 20$). Final residuals (for 2529 parameters) were $R1$ = 0.1386 for 10 314 reflections with $I > 2\sigma(I)$, and $R1$ = 0.2849, $wR2$ = 0.4220, GOF = 1.082 for all 31 316 data. Residual electron density: 0.93 and −0.51 e Å^{-3}.

For **1b** (monoclinic phase): monoclinic, $C2/c$, a = 33.933(7), b = 36.925(7), c = 29.577(6) Å, β = 93.4595(28)°, V = 36 991.0 Å^3, Z = 4, D_c = 1.353 g cm^{-3}, μ = 0.76 mm^{-1}, F(000) = 15 582, $2\theta_{max}$ = 34.61° ($-28 \leqslant h \leqslant 28$, $-30 \leqslant k \leqslant 30$, $-24 \leqslant l \leqslant 13$). Final residuals (for 823 parameters) were $R1$ = 0.1353 for 3512 reflections with $I > 2\sigma(I)$, and $R1$ = 0.3056, $wR2$ = 0.4226, GOF = 1.031 for all 11 089 data. Residual electron density: 0.66 and −0.44 e Å^{-3}.

For **1b** (cubic phase): cubic, $Im\bar{3}m$, a = 27.6895(17) Å, V = 21 229.8 Å^3, Z = 2, D_c = 1.016 g cm^{-3}, μ = 1.24 mm^{-1}, F(000) = 6454, $2\theta_{max}$ = 46.50° ($-30 \leqslant h \leqslant 27$, $-26 \leqslant k \leqslant 30$, $-29 \leqslant l \leqslant 30$). Final residuals (for 100 parameters) were $R1$ = 0.0784 for 996 reflections with $I > 2\sigma(I)$, and $R1$ = 0.1069, $wR2$ = 0.2953, GOF = 1.138 for all 1501 data. Residual electron density: 0.83 and −0.44 e Å^{-3}.

For **2**: hexagonal, $P6_3/m$, a = b = 28.6458(19), c = 28.1649(26), V = 20 015.2 Å^3, Z = 2, D_c = 1.222 g cm^{-3}, μ = 1.32 mm^{-1}, F(000) = 7326, $2\theta_{max}$ = 45.11° ($-21 \leqslant h \leqslant 30$, $-27 \leqslant k \leqslant 27$, $-22 \leqslant l \leqslant 30$). Final residuals (for 728 parameters) were $R1$ = 0.1116 for 4003 reflections with $I > 2\sigma(I)$, and $R1$ = 0.1837, $wR2$ = 0.3416, GOF = 1.317 for all 8931 data. Residual electron density: 1.16 and −1.53 e Å^{-3}.

Confinement of the ions [M⊂[2.2.2]cryptand]$^+$ and [cobalt(III)-bis(dicarbollide)]$^-$ in the divergent curved surfaces of a Ni(II) macrocycle

Michaele J. Hardie,† Nino Malic, Colin L. Raston*† and Brett A. Roberts

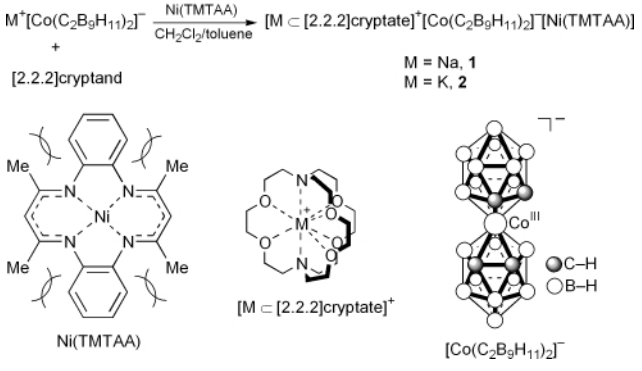
School of Chemistry, Monash University, Clayton, Melbourne, Victoria 3800, Australia

Received (in Columbia, MO, USA) 24th January 2001, Accepted 26th February 2001
First published as an Advance Article on the web 18th April 2001

Treatment of M[Co($C_2B_9H_{11}$)$_2$], M = Na or K, with [2.2.2]cryptand and 5,7,12,14-tetramethyldibenzo[*b*,*i*]-1,4,8,11-tetraazacyclotetradecinenickel(II) results in a 1:1:1 complex, assembled with the cobalticarborane anion snugly residing in the phenyl lined face of the Ni(II) macrocycle through C–H···N and C–H···π interactions, with the ensuing [M⊂[2.2.2]cryptand]$^+$ supercation residing in the smaller methyl faced cavity of the macrocycle.

The nickel(II) macrocycle 5,7,12,14-tetramethyldibenzo[*b*,*i*]-1,4,8,11-tetraazacyclotetradecinenickel(II) [Ni(TMTAA)] is a versatile receptor for neutral molecules, forming supramolecular host–guest complexes, as perched structures, with a range of globular cage molecules including C_{60}, *o*-carborane (icosahedral 1,2-$C_2B_{10}H_{12}$) and the phosphorus chalcogenides P_4(S or Se)$_3$,[1,2] and also for disc-shaped [$(H_2O)_2$∩18-crown-6][3] and torus shaped *cyclo*-octasulfur.[2] Ni(TMTAA) is a rigid, saddle-shaped macrocycle possessing two divergent concave surfaces which arise from the steric interactions of the methyl groups and the adjacent H-atoms on the aromatic rings. It can act as a heterotopic divergent receptor with C_{60}, or it can self-associate into dimers through the phenyl-lined face with the supermolecule acting as a homotopic divergent receptor for a range of molecules. A related macrocyle with two methyl groups on each of the aromatic rings (*trans* to the N-centres) forms 1:1 complexes with C_{60}[4] and C_{70}.[5]

We now report the formation of a multicomponent supramolecular array where the Ni(TMTAA) receptor acts as a divergent heterotopic receptor for globular-type ionic species, both the super-cationic and anionic species [M⊂[2.2.2]cryptate]$^+$, M = Na or K, and [Co($C_2B_9H_{11}$)$_2$]$^-$, Scheme 1. For the anion this takes on a novel C–H hydrogen bonding array with Ni(TMTAA), with a pre-programmed complementarity of curvature of the two interacting components, which is also the case for the cation to macrocycle interplay. The cobalticarborane or cobalt(III) bis(dicarbollide) is a weakly coordinating anion,[6] able to act as a soft anion in building up supramolecular architecture.[7]



Scheme 1

Slow evaporation of CH_2Cl_2/toluene solutions containing a 1:1:1 mixture of sodium cobalticarborane, [2.2.2]cryptand and Ni(TMTAA) affords the complex [Na⊂[2.2.2]cryptate]$^+$-[Co($C_2B_9H_{11}$)$_2$]$^-$[Ni(TMTAA)], **1**, in high yield, Scheme 1.‡ The potassium analogue **2** was similarly prepared by first converting the sodium salt of the cobalticarborane to the potassium salt by treating a 1:1 mixture of sodium cobalticarborane and [2.2.2]cryptand with excess KPF_6. Both compounds were characterised by NMR and microanalysis and their structures in the solid state established from X-ray diffraction studies.§

Compounds **1** and **2** are isomorphous and isostructural, crystallising in the space group $P2_1/c$ with the asymmetric unit comprised of [M⊂[2.2.2]cryptate]$^+$, [Co($C_2B_9H_{11}$)$_2$]$^-$ and one Ni(TMTAA) molecule. Salient features of the structure are borne out in Fig. 1. There is a striking snug fit of the cobalticarborane in the phenyl-lined face of the macrocycle. Moreover, the pairs of C–H groups (one from each carborane ligand) are adjacent to each other in a staggered conformation, as established elsewhere for this anion,[7] such that the C–H groups from each carborane ligand furthest from each other form non-classical C–H···π hydrogen bonds to their closest aromatic ring, and the other C–H groups form weak hydrogen bonds to a N-centre. Associated distances for C–H···$\pi_{centroid}$ (C···$\pi_{centroid}$) are 2.60 (3.66) and 3.10 (4.14) Å for **1** and 2.72 (3.79) and 2.88 (3.94) Å for **2**. Distances for C–H···N (C···N) are 2.69 (3.63) and 2.46 (3.51) Å for **1** and 2.52 (3.56) and 2.73 (3.73) Å for **2**. The C–H···$\pi_{centroid}$ distances are comparable with those reported for complexes of cyclotriveratrylene and *o*-carborane.[8–11] *Ab initio* calculations for a C–H···π interaction

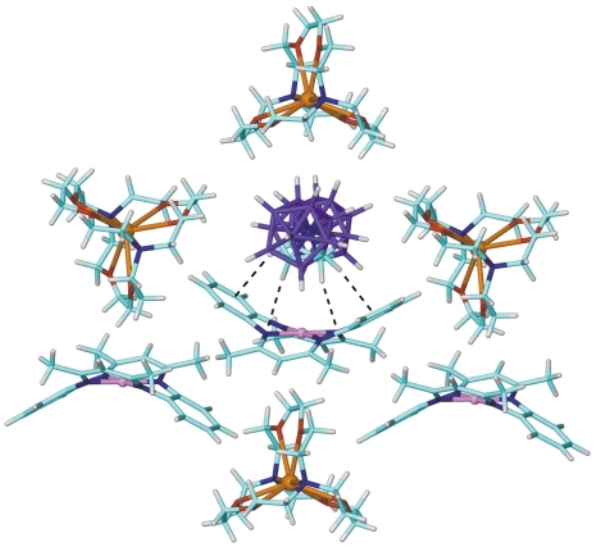


Fig. 1 Projection showing the interplay between the ions of [K⊂[2.2.2]cryptand]$^+$, [Co($C_2B_9H_{11}$)$_2$]$^-$ and Ni(TMTAA). Broken lines correspond to C–H···π and C–H···N hydrogen bonding interactions.

† Present address: School of Chemistry, University of Leeds, Leeds, UK LS2 9JT. E-mail: c.l.raston@chem.leeds.ac.uk

between the same carborane and benzene gave a C–H···π distance of 2.694 Å, and a weak energy of interaction of 2.72 kcal mol^{-1}.[8] The acidic C–H groups of carboranes also form hydrogen bonds to O-centres of 18-crown-6,[12] and to other hydrogen bond acceptors.[13] Recent studies have established that the cobalticarborane can form close inter-anion contacts associated with C–H···H–B interactions at 2.40 Å.[7]

The supercation [M⊂[2.2.2]cryptate]$^+$ also interacts with Ni(TMTAA), with one arm of the [M⊂[2.2.2]cryptate]$^+$ sitting in the methyl face of the macrocycle at the van der Waals limit, thereby maximising steric complementarity between the two curved surfaces. Thus, with the anion residing in the other face, Ni(TMTAA) acts as a divergent receptor for the ions as part of a linear array, Fig. 1. The other two arms of the supercation form a cavity in which the cobalticarborane anion sits, the closest B–H···O contacts being 3.40 Å. Related to this work is the binding of various metal ion complexes of [2.2.2]cryptand in bowl-shaped cavities of calix[4]resorcinarenes.[14]

The extended structure also has the aromatic protons of Ni(TMTAA) lying astride two arms of the cryptate, Fig. 1. This packing is more efficient for complex **2** compared with **1** which relates to the smaller size of the sodium cation (0.98 Å radius) with respect to the [2.2.2]cryptand cavity (approx. 1.4 Å radius).[15] Here the coordination environment is distorted, as evidenced by the N–Na–N angle at 168.57(7)° and acute O–Na–O angles at 57.78(6)–64.56(6)°. In contrast, the cavity is a better fit for the potassium cation (1.33 Å radius)[15] and the supercation approximates to D_{3h} symmetry (ignoring the ethylene linkages); the N–K–N angle is now 176.47(9)° and acute O–K–O angles more uniform at 57.36(10)–61.22(10)°. Metal to N- and O-centre distances in the supercations are unexceptional, Na–O 2.371(2)–2.919(2) Å, Na–N 2.668(2) and 3.014(2) Å, *cf.* K–O 2.730(3)–2.866(3) Å, K–N 2.993(4) and 3.014(4) Å.

UV–Vis experiments were conducted for Ni(TMTAA) *versus* [Na⊂[2.2.2]cryptand]$^+$[Co($C_2B_9H_{11}$)$_2$]$^-$ in dichloromethane, nitromethane and chlorobenzene, albeit without any evidence of complex formation in solution. Electrospray mass spectra were collected of the complex **2** in dichloromethane/methanol solution. However, no peaks corresponding to any multicomponent species in the gaseous phase were observed.

In conclusion, we have established a new class of compounds based on a divergent receptor for supercations and anions which show steric and electronic complementarity, with the success of the work in part attributed to the rigidity of the Ni(II) macrocycle receptor.

We are grateful to the Australian Research Council for support of this work.

Notes and references

‡ *Synthesis* of [M⊂[2.2.2]cryptand][Co($C_2B_9H_{11}$)$_2$][Ni(TMTAA)] M = Na, **1**: Na[Co($C_2B_9H_{11}$)$_2$] (20 mg, 57.7 μmol) and [2.2.2]cryptand (22 mg, 57.7 μmol) were dissolved in CH_2Cl_2 (3 ml), then Ni(TMTAA) (23 mg, 57.7 μmol) was added followed by toluene (3 ml), after it had dissolved. Slow evaporation of the solvent over several days yielded a purple–brown crystalline solid. Yield 48 mg (74%), mp. 275 °C, $C_{44}H_{80}B_{18}CoN_6NaNiO_6$ requires: C 47.0, H 7.17, N 7.47%. Found: C 47.14, H 7.16, N 7.55%. ^{1}H NMR ($CDCl_3$, 300 MHz) δ 2.07 (s, 12H, CH_3), 2.64 (t, ^3J 5.1 Hz, 12H, NCH_2), 3.58 (t, ^3J 5.1 Hz, 12H, NCH_2CH_2), 3.62 (s, 12H, OCH_2), 3.98 (br s, 4H, BCH), 4.84 (s, 2H, CH), 6.53–6.57 (m, 4H, ArH), 6.65–6.70 (m, 4H, ArH).

For M = K, **2**: Na[Co($C_2B_9H_{11}$)$_2$] (15 mg, 43.3 μmol), [2.2.2]cryptand (16 mg, 42.5 μmol) and KPF_6 (300 mg) were dissolved in acetone. The acetone was quickly evaporated and the residue extracted with CH_2Cl_2 and filtered, whereupon the CH_2Cl_2 filtrate was evaporated. The dissolution–evaporation–extraction procedure was then repeated with a further 300 mg KPF_6. To the final, orange-coloured CH_2Cl_2 extract (*ca.* 4 ml) was added Ni(TMTAA) (32 mg, 79.8 μmol) followed by an equal volume of toluene, and the solution allowed to evaporate slowly overnight. The resulting crystalline precipitate was filtered off, washed with toluene and air dried. Mp 287 °C, $C_{44}H_{80}B_{18}CoKN_6NiO_6$ requires: C 46.34, H 7.07, N 7.37%. Found: C 46.35, H 7.06, N 7.27%. ^{1}H NMR ($CDCl_3$, 300 MHz) δ 2.07 (s, 12H, CH_3), 2.53 (t, 4.8 Hz, 12H, NCH_2), 3.53 (t, 4.8 Hz, 12H, NCH_2CH_2), 3.60 (s, 12H, OCH_2), 4.00 (br s, 4H, BCH), 4.84 (s, 2H, CH), 6.53–6.57 (m, 4H, ArH), 6.65–6.70 (m, 4H, ArH).

Taxol, a molecule for all seasons

David G. I. Kingston

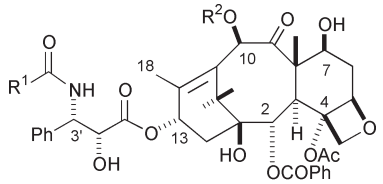
Department of Chemistry, M/C 0212, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061, USA. E-mail: dkingston@vt.edu

Received (in Cambridge, UK) 3rd January 2001, Accepted 19th February 2001
First published as an Advance Article on the web 26th March 2001

The diterpenoid natural product taxol, first discovered in the 1960's has proved to be the most important new anticancer drug introduced in the last ten years. A brief history of taxol's development from laboratory curiosity to blockbuster drug is followed by a summary of its chemistry, including an overview of the six completed syntheses of taxol. The review concludes with a discussion of its bioactivity as a promoter of tubulin polymerization and as a drug.

Introduction

With the possible exception of Viagra, probably no new drug in the last 20 years has generated as much public interest and excitement as has taxol (paclitaxel or Taxol™, **1**).[1] This interest



1 R^1 = Ph, R^2 = Ac
2 R^1 = Me_3CO, R^2 = H

was fueled primarily by taxol's excellent clinical activity against ovarian and breast cancers, but it was intensified by the severe supply problems that were in effect during the period leading up to its general clinical use. These problems were successfully solved, as will be described below, and taxol is now widely available and is the largest-selling anticancer drug of all time, with sales of over $1.5 billion in 1999.[2] This review will give a brief history of the development of taxol from a laboratory curiosity to a blockbuster drug, and will then describe some recent advances in the chemistry and biology of this fascinating compound.

History of taxol's development as an anticancer drug

Discovery of the bioactivity now known to be due to taxol was made in 1962, when Arthur Barclay, a botanist working for the US Department of Agriculture under contract to the US National Cancer Institute (NCI), made a collection of the stem and bark of *Taxus brevifolia* Nutt. in Washington State. These plant samples, along with many others, were duly extracted and tested for bioactivity, and in 1964 the extract from *T. brevifolia* was found to be cytotoxic to KB cells. The extract was assigned to Dr Monroe Wall at Research Triangle Institute, and taxol was isolated in 1967.[3] The structure was elucidated by a combination of X-ray studies of two degradation products and ^{1}H-NMR analysis of the intact molecule, and was published in 1971.[4]

Initial reaction to taxol as a potential anticancer drug was less than enthusiastic. Although it was clearly an active compound, with activity both in cell culture and also *in vivo* against various leukemias and the Walker 256 carcinosarcoma, its activity was only modest in these assays. To add to its problems, it was highly insoluble in water, and would thus clearly present formidable formulation problems, and it was isolated in only very modest yield from the bark of a relatively uncommon and slow-growing tree. Not a good outlook for a potential drug candidate!

Fortunately testing was carried out in some new *in vivo* bioassays that were introduced by NCI in the early 1970's, and it proved to be strongly active in a B16 mouse melanoma model. On the basis of this activity, and with enthusiastic support from Dr Matthew Suffness at NCI and Dr Monroe Wall, taxol was selected as a development candidate in 1977. Development of taxol as a drug was a challenging task because of the problems with solubility and supply noted earlier, and also because of its relatively low potency. The solubility problem was successfully overcome with a formulation in ethanol and Cremophor EL, and this turned out to be important in both negative and positive ways. On the negative side, the high levels of Cremophor required led to hypersensitivity reactions and almost led to the withdrawal of taxol from clinical trials. On the positive side, there is some evidence that Cremophor has a pharmaceutical effect over and above its surfactant properties, and may act to reverse multidrug resistance.[3]

Interest in taxol as a drug candidate was increased significantly when Susan Horwitz reported in 1979 that it had what was then a completely new mechanism of action, in that it promoted the assembly of the proteins α- and β-tubulin into microtubules.[5] A schematic representation of taxol's effect on the tubulin polymerization process is shown in Fig. 1.

Microtubules are required for chromosome segregation and for other operations such as intracellular transport and positioning of internal cellular organelles, and all of these activities require that the microtubules be in dynamic equilibrium with monomeric tubulins. Several compounds, including the clinically used drugs vinblastine (Velban™) and vincristine (Oncovin™), were known to operate as spindle poisons by *preventing* the assembly of tubulin into microtubules, but taxol was the first compound in which the activity was linked to *promotion* of microtubule assembly. This discovery proved to be important in maintaining interest in the development of taxol at a time when its initial clinical results were discouraging. Taxol's mechanism

David G. I. Kingston was born in London, and received his BA and PhD degrees (Lord Todd and D. W. Cameron) from Cambridge University in 1960 and 1964, respectively. After postdoctoral appointments at MIT and Cambridge, he moved to the USA, where he is currently a University Distinguished Professor at Virginia Polytechnic Institute and State University. In addition to his work on taxol, he is carrying out biodiversity conservation and drug discovery work in Suriname and Madagascar, and he also serves as one of several lay pastors in his local church, the Blacksburg Christian Fellowship.

DOI: 10.1039/b100070p

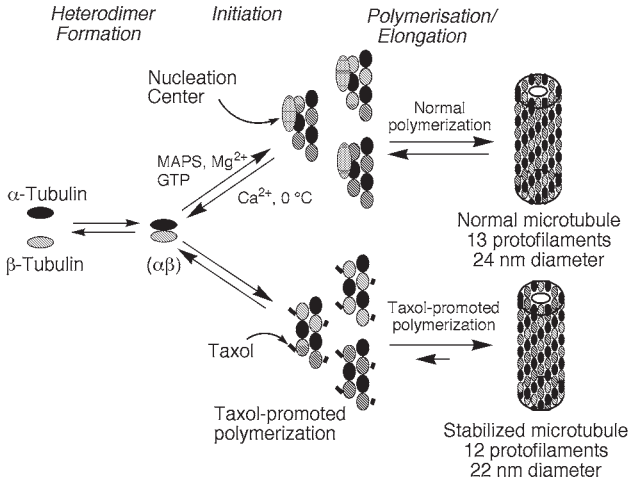


Fig. 1 Schematic representation of normal microtubule assembly (upper) and taxol-promoted microtubule assembly (lower).

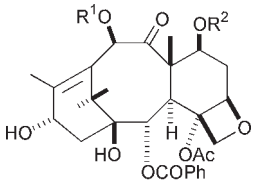
of action, and specifically its binding to microtubules, will be discussed in more detail in a later section of this review.

Taxol went into Phase I clinical trials in 1984, and into Phase II trials in 1985. These trials were limited by the supply of the drug, but gave the first clear evidence of activity with clinically relevant responses in ovarian cancer and in breast cancer reported in 1989[6] and 1991[7] respectively. Taxol and its semisynthetic analog docetaxel (Taxotere™, **2**) are now used (either as single agents or in combination with other drugs such as cisplatin) for the treatment of ovarian cancer, breast cancer, and non-small-cell lung cancer.[8]

The taxol supply crisis and its solution

The recognition of taxol's clinical activity created a crisis in the supply of the drug, since at the time it was only available in low yield from the bark of *T. brevifolia*. Since this tree is relatively uncommon, occurring most abundantly in the old-growth forests of the Pacific Northwest of the USA, the prospects of the large-scale logging needed to supply taxol to the clinical market raised serious environmental concerns.[9]

The responsibility for solving this problem fell to the Bristol-Myers Squibb Company, which had obtained the rights to develop taxol from the NCI under a Cooperative Research and Development Agreement. The various options for increasing the supply included increased harvesting of *T. brevifolia* bark, the isolation of taxol from a renewable resource such as yew needles, the semisynthesis of taxol from other taxoids in yew, and bioproduction through plant tissue culture. Initial supplies of taxol for clinical use were obtained by increased harvesting of *T. brevifolia* bark. The real breakthrough came from a combination of Potier's discovery that needles of the English yew, *T. baccata*, contained substantial amounts of 10-deacetylbaccatin III (**3**), in addition to smaller amounts of baccatin III (**4**),[10] with Holton's discovery of an efficient semisynthesis of taxol from the protected baccatin III (**5**) through a β-lactam



3 $R^1 = R^2 = H$
4 $R^1 = Ac$, $R^2 = H$
5 $R^1 = Ac$, $R^2 = SiEt_3$

intermediate; the details of this synthesis will be described later.[11] This invention was licensed to Bristol-Myers Squibb, and enabled the company to produce enough taxol to meet an escalating demand, with sales rising from about $400 million in 1994 to an estimated $1600 million in 2000.[2]

In addition to this and other semisynthetic routes, several workers have investigated the production of taxol by plant tissue culture methods, and at least two companies (Phyton Inc. and ESCA Genetics) have developed production methods.[12] Reported yields range from 0.012–0.05%, with specific production rates of 0.3 mg g^{-1} dry cell weight per day for up to 40 days.[13] These yields are close to those needed for commercially viable production, and it is thus quite probable that full-scale bioproduction of taxol will begin within the next few years, especially since Bristol-Myers Squibb signed agreements in 1998 with Phyton Inc. to commercialize Phyton's plant cell fermentation technology. The production of taxol by the fungus *Taxomyces andreanae* was reported by Stierle *et al*. in 1993, but the yield was extremely low (25–50 ng L^{-1}) and a large increase in this yield through strain improvement will be needed before a fungal culture method would be commercially viable. More recently Strobel and his coworkers have found that the fungus *Periconia* sp. isolated from *Torreya grandiflora* produces taxol at the 800 ng L^{-1} level when stimulated with benzoic acid.[14] Other sources of taxol have also been discovered, with one of the more interesting ones being hazelnut cultivars and their associated fungal endophytes.[15] Since taxol appears to be produced by the hazelnut cultivars as well as by their fungal endophytes, this is the first example of taxol being found in a plant outside the Taxaceae family.

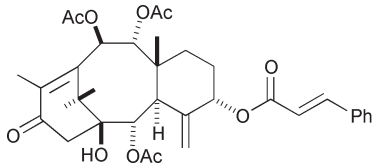
The quest to understand taxol's structure–activity relationships

The chemistry of taxol has been thoroughly investigated by a large number of academic and industrial researchers, and this review will thus not attempt to provide a complete coverage. Readers interested in a more comprehensive review can consult any of the several available books[16–19] and reviews,[20–23] including a comprehensive forthcoming review.[24] This section will thus describe some of the early work from the author's laboratory, and will then summarize the major findings for each section of taxol's structure.

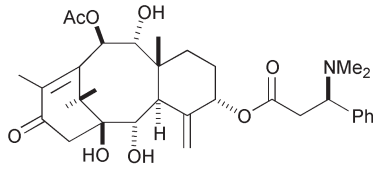
Early studies

Our work on taxol began in 1979 with a conversation between the author and Bob Holton, who at that time was a member of the Virginia Tech faculty. He had developed the outline of a synthetic approach to taxol, and we agreed that we would collaborate on this synthesis. He would start at the beginning in a 'bottom up' approach, while I would start with taxol and study its chemistry in a 'top down' approach. Since we did not have a supply of taxol, I decided to begin by looking at the possible conversion of *O*-cinnamoyltaxicin I triacetate (**6**), available by Lythgoe's procedure from taxine B (**7**)[25] into taxol or taxol-like compounds. I isolated about 100 mg of crude taxine B from yew bushes growing on the Virginia Tech campus, converted it into **6**, and did some preliminary work on forming the oxetane ring. At this point I also contacted Dr Matthew Suffness at the US National Cancer Institute, and was able to obtain a small amount of pure taxol, together with larger amounts of various side cuts from the large-scale purification of taxol for the pending clinical trials. With these extracts in hand the need for the conversion of **6** into taxol-like compounds was removed, and this aspect of the project was dropped. It was thus very gratifying to find that Scheeren,[26] Potier,[27] and Saicic[28] have all published conversions of taxine to taxol-like compounds within the last few years.

Bob Holton and I submitted a proposal to the National Institutes of Health in 1980 for funding of our joint approach to taxol, but there was little interest in the compound at that time



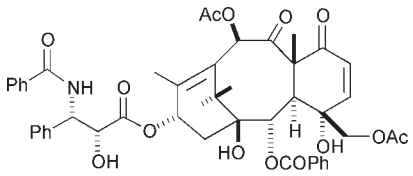
6



7

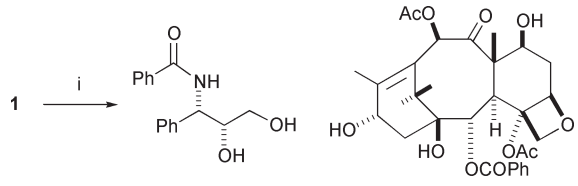
and the proposal was not funded. At this point we decided to try our luck at separate proposals, and so while Bob went back to NIH (where he eventually did get funded for his work) I chose to apply to the American Cancer Society. To their credit the reviewers at the ACS saw the value of studying the chemistry of taxol, and we received a modest grant in 1982.

Our basic approach in these early days, when little was known about the chemistry of taxol, was to try to modify its functional groups one at a time, to see whether they were individually necessary for the activity of the drug. We began by showing that the side-chain hydroxy group at the 2′-position was much more reactive to acetylation than that at the 7-position, and Susan Horwitz, with whom we had begun to collaborate, showed that the resulting taxol acetates still retained much of taxol's activity.[29] The reverse proved true on oxidation, however, and the 7-hydroxy group could be oxidized selectively to the corresponding 7-oxo derivative. This product proved to be unstable, and readily underwent β-elimination to give the ring-opened product **8**. Compound **8** turned out to be essentially non-cytotoxic, thus providing the first hint of the importance of the oxetane ring to taxol's activity.[30]



8

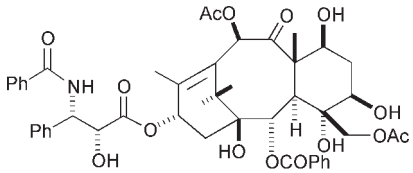
With a molecule as complex as taxol, not every experiment gave the expected result. Sometimes the unexpected results were useful, although more often they were not. One of the useful results came from our desire to reduce the C-9 keto group to an alcohol. Treatment of taxol with sodium borohydride left the keto group essentially untouched, but removed the side chain in good yield; the yield was later improved by the use of tetrabutylammonium borohydride in dichloromethane (Scheme 1).[31]



Scheme 1 *Reagents and conditions*: i, Bu_4NBH_4 (excess), CH_2Cl_2, rt, 24 h 98%.

This unexpected reduction of an ester in the presence of a keto group was due to the extremely hindered location of the 9-keto group and to the presence of an α-hydroxy group on the side chain. The reduction products were the diol **9** and baccatin III (**4**), and this formation of baccatin III from taxol or (equally well) from crude taxol–cephalomannine mixtures available from the National Cancer Institute gave us and other workers ready access to baccatin III.

Another surprising reaction was that of taxol with Meerwein's reagent, $Et_3O^+BF_4^-$. The reaction was originally carried out in an attempt to cleave the side-chain amide group, since it was known that amides react selectively with Meerwein's reagent in the presence of esters to yield imino ethers.[32] In the event, the amide group was unreactive but the oxetane ring underwent an assisted ring-opening to give compound **10**.[33] Compound **10**, like compound **8**, was essentially inactive in tubulin-assembly and cytotoxicity assays, thus emphasizing the importance of the oxetane ring to taxol's activity.

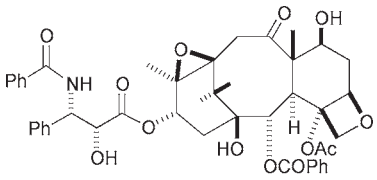


10

In the following sections the chemistry and structure–activity relationships of taxol will be summarized, with an emphasis on work carried out at Virginia Tech but including key results from other laboratories. The discussion will follow a clockwise route, starting with the 'northern hemisphere' and proceeding around the oxetane ring to the 'southern hemisphere' and thence to the side chain.

The northern hemisphere

The C-11–C-12 double bond in the A-ring of taxol is relatively unreactive, as indicated by the fact that hydrogenation of baccatin III gives a hexahydro product in which the C-2 benzoyl group is reduced to a cyclohexylcarbonyl group while the C-11–C-12 double bond is untouched.[34] Epoxidation of taxol with *m*-chloroperbenzoic acid also fails, but the epoxide **11** could be prepared by oxidation of 10-deacetoxytaxol; compound **11** turned out to be more active than taxol in a tubulin-assembly assay but less cytotoxic to B16 melanoma cells.[35]

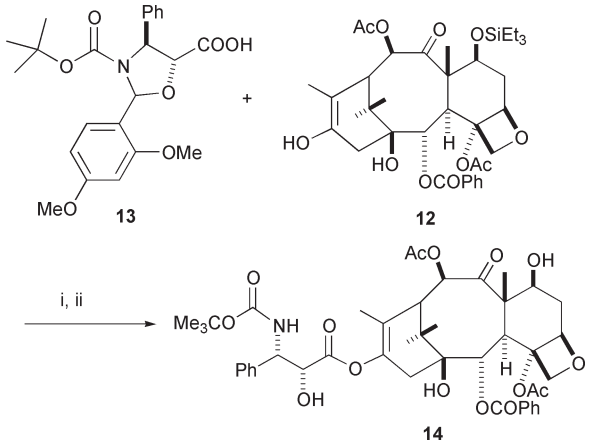


11

Interestingly the enol **12**, obtained by reduction of 7-(triethylsilyl)-13-oxobaccatin III with Zn–AcOH, is stable and can be acylated. Acylation with the oxazolidine **13** (Scheme 2) gave the isotaxol derivative **14**; compound **14** is slightly more cytotoxic than taxol.[36]

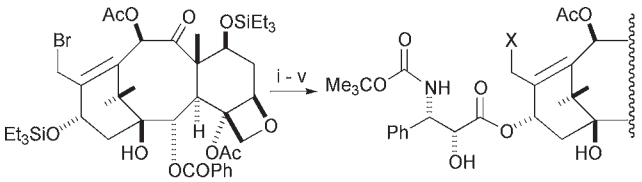
Allylic bromination of 7,13-di(triethylsilyl)baccatin III gave the bromide **15**, which gave the corresponding C-18 analogs on treatment with nucleophiles such as Me_2CuLi, NaN_3, Bu_4NOAc and KCN. Attachment of the taxol side chain and deprotection gave the C-18 analogs **16** (X = Me, N_3, OAc or CN), all of which were less cytotoxic than taxol, with the methyl derivative being the most active (Scheme 3).[37]

Taxol can be selectively deacetylated at C-10 to give 10-deacetyltaxol by treatment with hydrazine[38] or with sodium bicarbonate and hydrogen peroxide.[39] Deoxygenation of the 10-hydroxy group was originally achieved using Barton's xanthate chemistry,[40] but a simpler method was developed by treating taxol with samarium diiodide.[41,42] The resulting 10-deacetoxytaxol **17** had a similar cytotoxicity to taxol,[40] and



13 **12** **14**

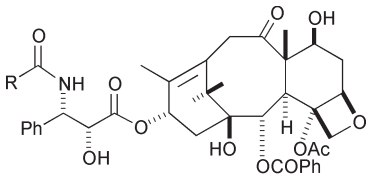
Scheme 2 *Reagents and conditions*: i, DCC, DMAP; ii, AcOH–H_2O, rt, 4 days, 40% overall.



15 **16**

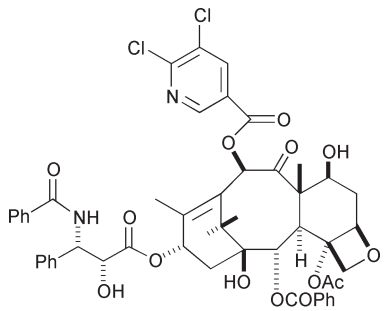
Scheme 3 *Reagents and conditions*: i, Me_2CuLi, THF, −78 °C; ii, HF–pyridine, rt; iii, TES-Cl, imidazole, DMF, 0 °C, 40%; iv, NaHMDS, THF, −78 °C, then β-lactam synthon; v, HF–pyridine, rt, 53%.

the same was true for the corresponding docetaxel analog **18**.[42]



17 R = Ph
18 R = Bu^tO

Acylation of 10-deacetyltaxol at the C-10 position has yielded a number of useful analogs, including the dichloronicotinyl derivative **19** which is more cytotoxic than taxol

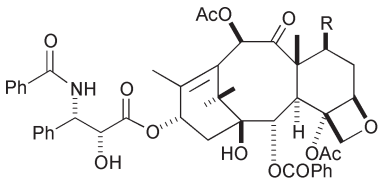


19

against both normal and drug-resistant MCF-7 cells.[43] Taxol analogs with isobutyl or isobutenyl substituents replacing the 3′-phenyl group and various C-10 acyl groups have been prepared by Ojima, and several of these have shown improved cytotoxicity against the resistant cell line MCF7-R.[44]

The C-7 hydroxy group can be removed selectively by the Barton xanthate deoxygenation route to give 7-deoxytaxol **20**, and the same intermediate can be used to convert 7-*epi*taxol to taxol.[45] 7-Deoxytaxol has the same cytotoxicity as taxol in the HCT116 cell line, suggesting that the 7-hydroxy group is not essential for taxol's activity.[45,46]

Although the 7-hydroxy group may not be necessary for taxol's activity, modifications at C-7 have yielded analogs with improved properties, and the thiomethyl derivative **21** has been selected by Bristol-Myers Squibb for development as a 'second-generation' taxol analog: it is currently in clinical trials, with preliminary reports that it is performing well.[47]



20 R = H
21 R = OCH_2SCH_3

Dehydration at C-7 can be accomplished by treatment of the 7-triflate derivative with a non-nucleophilic base such as DBU to give 6,7-dehydrotaxol (**22**),[38,48] which was slightly less cytotoxic than taxol to CA46 cells.[48] Osmylation of **22** gave the 6α,7α-diol **24**. Protection of **22** as its TBDMS ether gave **23**, which could be converted to the 2′-protected diol **25**; this was converted to the C-nortaxol analog **26** by reaction with lead tetraacetate and deprotection.[49] Compound **26** was significantly less cytotoxic than taxol, which is surprising given the very similar shapes of the two compounds. Diol **25** could also be converted to 6α-hydroxytaxol (**27**), which is the major human metabolite of taxol.[50] Although the yield was low, the starting material was recovered unchanged and could be recycled to effect a good overall conversion (Scheme 4).

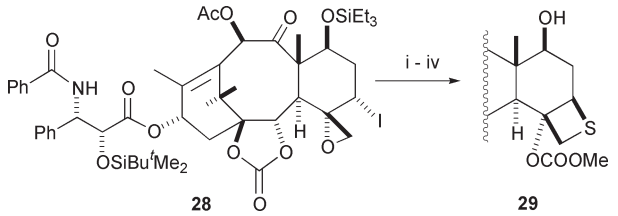
The oxetane ring

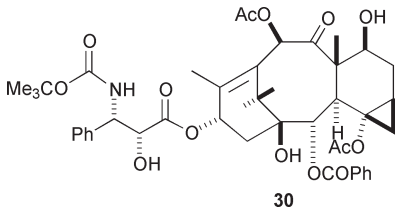
As noted earlier, opening of the oxetane ring to give compounds **8** or **10** essentially eliminated taxol's cytotoxicity and tubulin-assembly activity. The question thus arose as to the reason for this effect; putting the question another way, why is the oxetane ring necessary for taxol's activity? It is clearly not involved in any covalent binding to tubulin, since taxol can be exchanged with labeled taxol on tubulin, and we thus elected to test whether changing the size and electronegativity of the hetero-

atom had any effect. The sulfetane analog **29** was selected for study, and was prepared by reaction of the key intermediate **28** with Li_2S, followed by acylation at C-4, reaction with phenyllithium to open the cyclic carbonate, and deprotection (Scheme 5). Sulfetane **29** was significantly less active than taxol in both tubulin-assembly and cytotoxicity assays.[51]



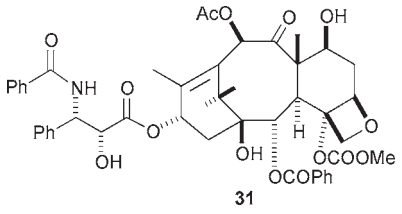
Scheme 5 *Reagents and conditions*: i, Li_2S, THF, rt, 28 h, then Im_2CO, imidazole, rt, 12 h, 56%; ii, LHMDS, THF, −78 °C (7 min), rt (1 min), −78 °C (2 min) then $ClCO_2Me$, 39%; iii, PhLi, THF, −78 °C, 3 min, 61%; iv, HF–pridine, rt, 9 h, 76%.

The reason for the lack of activity of **29** as compared with taxol, and the reason for the lack of activity of oxetane ring-opened analogs, has been discussed by Snyder on the basis of a minireceptor model of the binding site for taxol on tubulin.[52] These authors note that oxetane ring-opened analogs such as **8** and **11** also lack the C-4 acetate function, which has been shown to be necessary for activity, and conclude that hydrogen bond acceptor properties and the rigidification of the taxol ring system by the oxetane ring also play a role in stabilizing the taxol–tubulin complex. The lack of activity of the thietane analog **29** is explicable because the larger sulfur atom does not fit well in the binding site. The predictions of the Snyder model were supported by the observation that the cyclopropyl derivative **30** is almost as active as taxol in a tubulin assembly assay.[53]

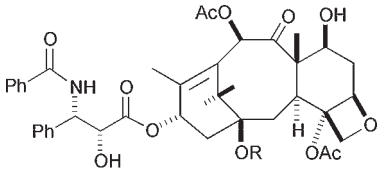


The southern hemisphere

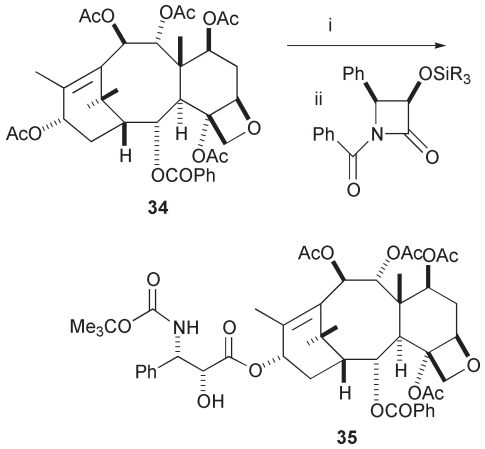
The C-4 acetate function, or at least a C-4 acyl function, is necessary for activity, as mentioned above. Thus C-4 deacetyltaxol is significantly less active than taxol,[54] and 4-deacetoxytaxol is also much less active than taxol.[55] Some C-4 derivatives are more active than taxol, however, and the carbonate **31** is in clinical trials.[56,47]



Modifications of the C-2 benzoate have yielded a number of interesting derivatives. The benzoyloxy group or a similar group is necessary for activity, since 2-debenzoyloxytaxol (**32**)[57] and 1-benzoyl-2-debenzoyloxytaxol (**33**)[58] are both inactive. Replacement of the C-2 benzoyl group with other acyl groups results in taxol analogs which can be significantly less active or more active than taxol.[59,60] Interestingly the difference in activity is modulated by the position of substituents on the benzene ring of substituted benzoyl groups; 2-*p*-azidobenzoyltaxol is essentially inactive, while 2-*m*-azidobenzoyltaxol is almost an order of magnitude more active than taxol.[59]

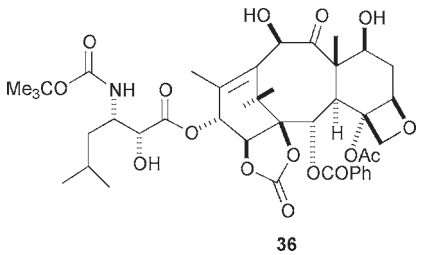


It has not proved possible to remove the C-1 hydroxy group by Barton deoxygenation or other deoxygenation methods; an attempt to do so led to formation of the C-2 deoxy product **33**.[58] Some C-1 deoxytaxol derivatives were, however, prepared from the natural product baccatin VI (**34**) by selective deacetylation and side-chain attachment (Scheme 6). The 1-deoxy-9-dihydrodocetaxel analog **35** was about one third as active as taxol in tubulin assembly and cytotoxicity assays.[61]



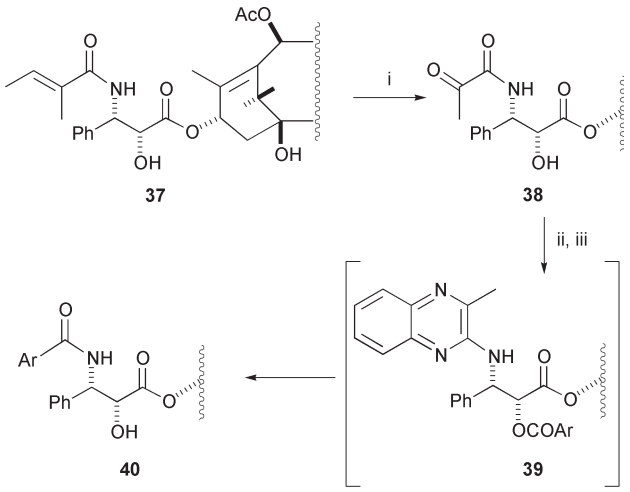
Scheme 6 *Reagents and conditions*: i, Red Al, THF, 77%; ii, NaH, THF, β-lactam, 0 °C–rt, 86%; HF–pyridine, −20 °C, 87%.

Analogs at the C-14 position have also been prepared by Ojima and Appendino from the naturally-occurring 14β-hydroxy-10-deacetylbaccatin III. The most interesting analogs have come from a series of compounds with a carbonate group linking the C-14 and C-1 hydroxy groups;[62] the derivative **36** is under development by Bayer as an orally active anticancer drug.[63]



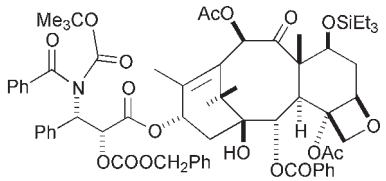
The side chain

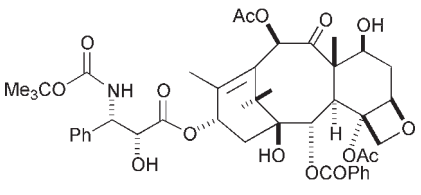
Our work on the side chain has been concerned largely with finding direct methods for the conversion of taxol or its congener cephalomannine (**37**) into other N-acyl analogues. The initial success came with the finding that cephalomannine could be ozonized selectively in high yield to give the ketoamide **38** (Scheme 7). Acylation of **38** with a desired substituted benzoic acid gave the corresponding 2′-acyl derivative selectively, and this could be reacted with *o*-phenylenediamine under anhydrous acidic conditions to give an *N*-acyl analog of taxol. Reaction proceeds *via* the 2-aminoquinoxaline derivative **39**, which is cleaved under the acidic conditions to the free 3′-amine. This amine then undergoes a spontaneous *O* → *N* intramolecular acyl transfer reaction to give the final product **40**.[64]



Scheme 7 *Reagents and conditions*: i, O_3, CH_2Cl_2, −78 °C, 30 min, 97%; ii, $ArCO_2OH$, DCC, 4-pyrrolidonopyridine, EtOAc, 2 h, 90%; iii, 4 Å sieves, PhH, *o*-phenylenediamine, *p*-TsOH (cat.), reflux, 12 h, 80%.

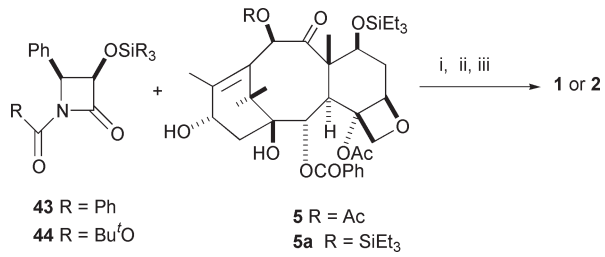
A second pathway was developed to convert taxol into docetaxel.[65] Protection of taxol as its 2′-(benzyloxycarbonyl)-7-(triethylsilyl) derivative was followed by reaction with di-*tert*-butyl dicarbonate and DMAP to give the imide **41**. Compound **41** was then converted into 10-acetyldocetaxel **42** by reaction with magnesium methoxide followed by HF–pyridine to deprotect the 7-position.





Many routes have been developed to prepare the taxol side chain and to attach it to a protected baccatin III derivative to prepare taxol or an analog thereof, and this chemistry has been reviewed.[11,66] Because of the congested position of the 13-hydroxy group of baccatin III, esterification with a simple protected taxol side chain is difficult and proceeds in only modest yield.[67] The most important synthetic methods are thus those which use a cyclically protected form of the taxol side chain, and these are the methods used commercially in the synthesis of taxol and docetaxel.

As mentioned earlier, taxol is prepared commercially by acylation of a 7-protected baccatin III derivative (**5**) with a β-lactam such as **43** (Scheme 8); the use of other β-lactams such as **44** yields docetaxel analogs.[11] The β-lactams needed for the synthesis of Scheme 8 are prepared by condensation of an enolate with an imine, but there have been many different approaches to the details of this synthesis. In Holton's original approach the β-lactam was prepared by a Staudinger reaction of acetyl glycolyl chloride with the imine from benzaldehyde and *p*-anisidine; this gave the desired *syn* lactam stereoselectively, but of course in racemic form.[11] Several enantioselective syntheses of suitably protected β-lactams have been developed, with Georg's route from Oppolzer's chiral auxiliary[68]



Scheme 8 *Reagents and conditions*: i, **5** (0.1 M in THF), *n*-BuLi, −45 °C; ii, **43** or **44** (0.2 M in THF), warm to 0 °C, 2 h, 95%; iii, HF–pyridine, MeCN, 98%.

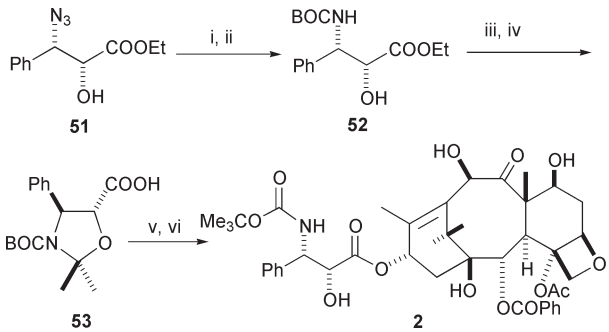
Other chiral syntheses of the β-lactam have been developed by Farina,[70] Commerçon,[71] and Fujisawa[72] from chiral imine precursors, by Holton[73] and by Palomo[74] from oxazolidinone auxiliaries, and by Lee by means of a Sharpless oxidation,[75] to name just a few. A convenient enzyme-catalyzed resolution of racemic β-lactam has also been published by Sih.[76]

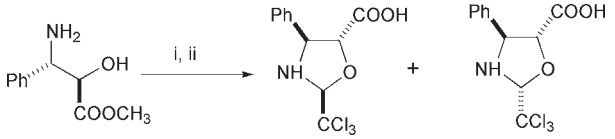
The second major synthetic route is through an oxazolidine carboxylic acid intermediate. This pathway was originally developed by Commerçon and his co-workers, and is illustrated in Scheme 11 below.[77] The azido ester **51** can be prepared by



Scheme 11 *Reagents and conditions*: i, H_2, Pd/C; ii, $(BOC)_2O$, 65%; iii, $CH_2=C(OCH_3)CH_3$, PPTS; iv, LiOH, EtOH–H_2O, 99%; v, 7,10-diTroc-10-deactylbaccatin, III, DCC, DMAP, 99%; vi, HCO_2H, then $(BOC)_2O$, then Zn, AcOH, H_2O, 62%.

ring-opening of an epoxide derived from a Sharpless epoxidation,[78] by the Staudinger reaction previously mentioned,[71] or in

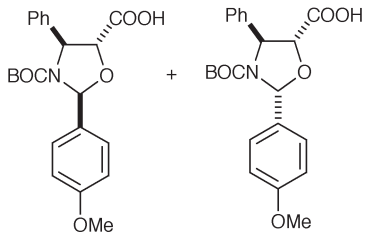
several other ways. Reduction and protection of **51** gave the carbamate **52**, which was converted to the oxazolidine **53** and thence to docetaxel (**2**). The weakness of the original approach lay in the deprotection and reprotection steps necessary to open the oxazolidine ring, but this weakness has been resolved in several ways. In one approach (Scheme 12) the trichloromethyl



54 55 56

Scheme 12 *Reagents and conditions*: i, CCl_3CHO, PPTS; ii, LiOH, MeOH, then HCl.

oxazolidines **55** and **56** could be coupled directly with 7,10-ditrocbaccatin III without the necessity of protecting the nitrogen; the resulting coupled product was converted to docetaxel by treatment with zinc and acetic acid followed by N-acylation.[79] In a second approach from the same group it was found that the *p*-methoxybenzylidene oxazolidines **57** and **58**



57 58

could be coupled with protected baccatin III derivatives in almost quantitative yield, and that the coupled products could then be treated with toluenesulfonic acid to remove the *p*-methoxybenzylidene group selectively;[80] this approach thus provides a very efficient route to docetaxel.

A third general approach is through an oxazoline intermediate. Coupling of the oxazoline **59** with 7-(triethylsilyl)baccatin III proceeded in excellent yield to give the coupled product **60**, which could be hydrolyzed to taxol in one step (Scheme 13).[81] The simplicity of this route has attracted several

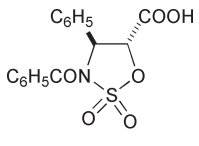
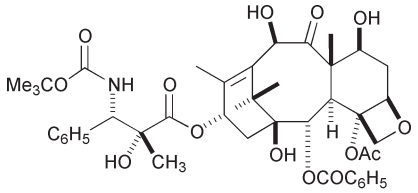
syntheses of suitable oxazolines, including syntheses of racemic material from cinnamyl alcohol through addition of phenylselenyl triflate and azide ion[82,83] and a synthesis of chiral oxazolines from (L)-phenylglycine.[84] One unexpected synthesis of the oxazoline derivative **60** was derived from the dioxooxathiazolidine **61**, which gave **60** on coupling with 7-(triethylsilyl)baccatin III.[85]



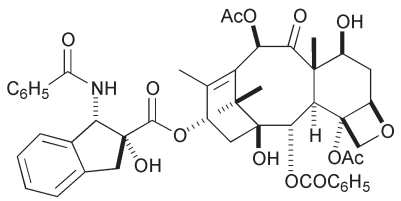
61

Many taxol analogs with modified side chains have been prepared in studies to find improved analogs of taxol. The best-known such compound is docetaxel (**2**), which was prepared early on by Potier and his colleagues and has entered clinical use.[86] The other noteworthy compound with a modified side chain is the 14β-hydroxytaxol derivative **36**, which as noted earlier is in clinical trials. The side chain of this compound differs from that of taxol by having an isobutyl group replacing the 3′-phenyl group and a *tert*-butoxycarbonyl group replacing the 3′-*N*-benzoyl group. Other analogs with modified side chains have been reviewed.[21,66]

Some taxol analogs with highly modified side chains are of interest because of the light they throw on the conformation of the side chain. Thus the methylated analog **62** is more cytotoxic than taxol to HCT116 colon carcinoma cells and has an increased binding affinity to tubulin.[87–89] Its enhanced potency may be due to a reduction in the degree of freedom of rotation of the C-2′–C-3′ bond, or possibly to an additional hydrophobic binding interaction of the methyl group with the microtubule binding site. The conformationally restricted analog **63** has



62



63

comparable cytotoxicity to taxol in several cell lines,[90] suggesting that the side chain may exist in an 'open' conformation rather than the hydrophobically collapsed conformation that has been proposed.[91]

The synthesis of taxol

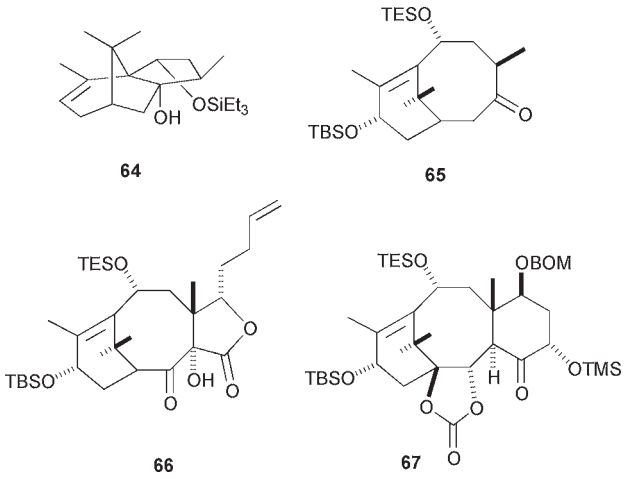
The synthesis of taxol presented one of the more difficult challenges to synthetic chemists, both because of its complex ring system and because of its many chiral centers. It is a tribute to the current development of synthetic methodology that six independent syntheses have been achieved to date, using a variety of approaches.

Since baccatin III has been converted into taxol by many different routes, as noted earlier, a synthesis of baccatin III constitutes a synthesis of taxol. The six routes will not be discussed in detail because of space limitations, but a brief summary of each will be provided.

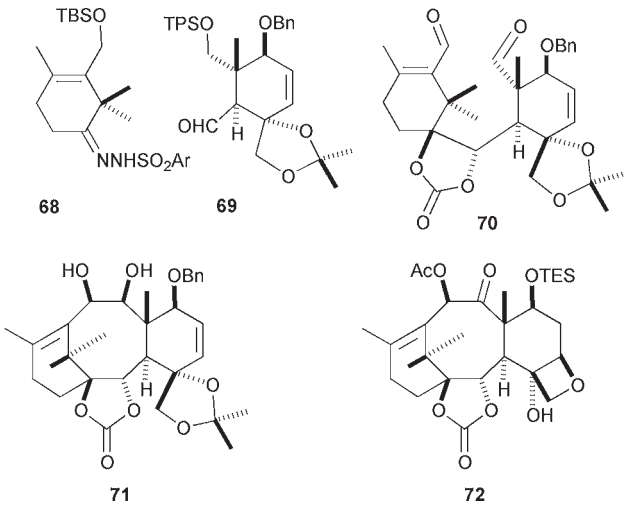
The first two syntheses were published essentially simultaneously in 1994 by Holton and Nicolaou. In the Holton synthesis (Scheme 14), the natural product β-patchoulene served as the starting material to generate the protected diol **64**. A clever ring-opening of the epoxide of **64** then gave the AB ring system **65**, and this was elaborated to the ABC system **67** through intermediate **66**. Final elaboration of ring D and functional group manipulations then gave baccatin III.[92]

In the Nicolaou synthesis (Scheme 15), the A and C ring precursors **68** and **69** were both made by Diels–Alder chemistry, and were then coupled by a Shapiro reaction and elaborated to the AC system **70**. A McMurry coupling of **70** generated the ABC system **71**, which was then converted to the ABCD system **72** and thence to baccatin III.[93]

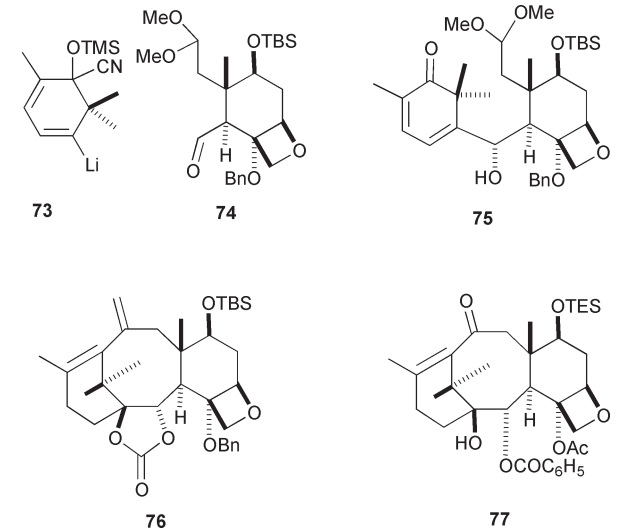
The Danishefsky synthesis (Scheme 16) is the only one to date to start with a preformed D-ring. The key to the success of



Scheme 14 The Holton synthesis.



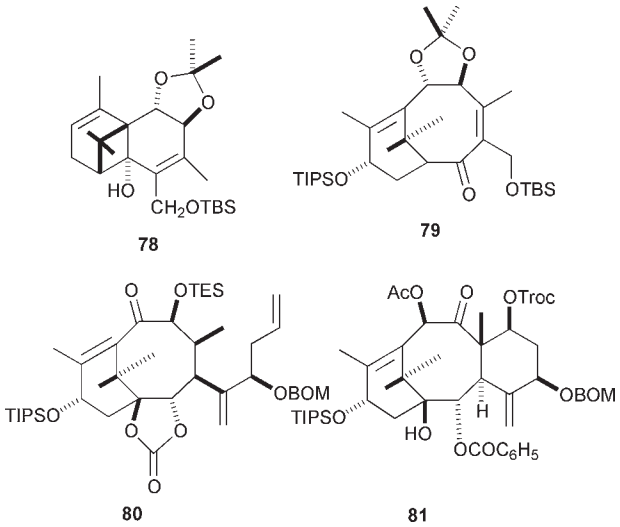
Scheme 15 The Nicolaou synthesis.



Scheme 16 The Danishevsky synthesis.

this approach was the protection of the C-4 hydroxy group as a benzyl ether rather than as an acetate, thus avoiding complications from neighbouring group participation by this group. The CD ring system **74** was prepared from the Wieland–Miescher ketone, and this was then coupled with the A-ring synthon **73** to give the A–CD unit **75**. Cyclization to the ABCD system **76** was achieved by the Heck reaction, and oxidation and functional group manipulations gave **77**, which was converted to baccatin III by appropriate oxidation chemistry.[94]

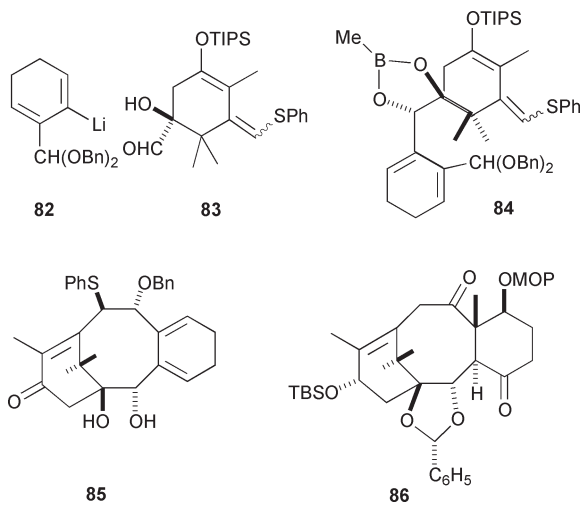
The Wender synthesis (Scheme 17), like the Holton synthesis, is of the form A → AB → ABC → ABCD, but it started



Scheme 17 The Wender synthesis.

from verbenone, which provided 10 of the 20 carbons of the baccatin III ring system. Some ingenious chemistry converted verbenone to intermediate **78**, which then underwent oxidative cleavage in a manner reminiscent of the conversion of **64** to **65** in the Holton synthesis. Intermediate **79** was then converted into **80** through elaboration of the C-3 position and aldol condensation, and the synthesis was completed by formation of the oxetane ring. The overall synthesis, at 37 steps from verbenone, is claimed to be the shortest recorded synthesis of taxol.[95]

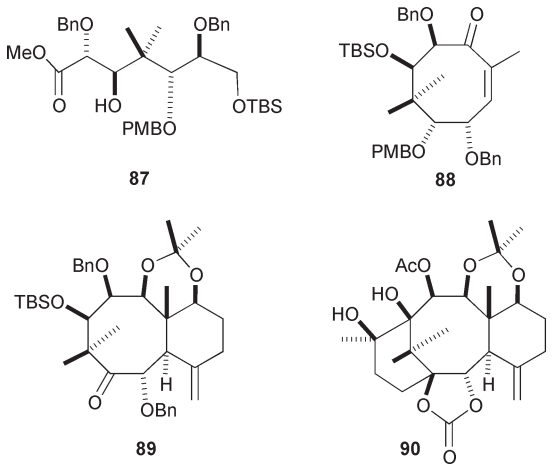
The Kuwajima synthesis, first reported in 1998 with the full report appearing in 2000, uses the A + C → A–C → ABC → ABCD approach (Scheme 18).[96] The A-ring synthon **83** was



Scheme 18 The Kuwajima synthesis.

prepared in 16 steps from propargyl alcohol, and this was coupled with the C-ring synthon **82** to give the A–C adduct **84**. Adduct **84** was cyclized by a novel reaction to give **85**, and this was elaborated to **86**; the C-18 methyl group was introduced *via* a cyclopropane intermediate. Final incorporation of the oxetane ring gave baccatin III.

The final synthesis by Mukaiyama, reported in 1999 (Scheme 19), is unique in starting with the acyclic precursor **87** and cyclizing it to the stereochemically defined B-ring synthon **88**. Rings C and A (in that order) were then built onto ring B to



Scheme 19 The Mukaiyama synthesis.

give intermediate **89** and then **90**, and addition of ring D completed the synthesis.[97]

The bioactivity of taxol

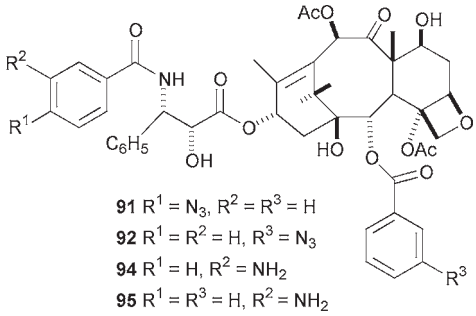
As noted in the introduction to this review, taxol was discovered on the basis of the antileukemic and cytotoxic activities of *T. brevifolia* extracts, but its mechanism of action was found to be its ability to promote the assembly of tubulin into microtubules. In brief, taxol binds to the assembled microtubule with a stoichiometry of approximately 1 mole of taxol to 1 mole of tubulin dimer and stabilizes it to dissociation (Fig. 1). This binding occurs in the absence of any cofactors, and the resulting disruption of the equilibrium between tubulin and microtubules also disrupts cell division and ultimately leads to cell death by apoptosis.[98,99]

The binding of taxol to tubulin polymers and the associated interruption of the cell cycle was thought for a long time to be its only significant mechanism of action, but in recent years it has been increasingly clear that taxol can bring about apoptotic cell death by a second mechanism which is independent of mitotic arrest.[100,101] The protein Bcl-2 has been identified as a second taxol-binding protein[102] which undergoes dose-dependent hyperphosphorylation in the presence of taxol.[103] The situation is complex, however, since it has also been shown that Bcl-2 phosphorylation in the presence of taxol is linked to the latter's tubulin-assembly activity, and it has thus been proposed that taxol-promoted assembly of microtubules leads to Raf-1 activation and Bcl-2 phosphorylation, and thence to apoptosis.[104] The binding of taxol to tubulin is thus clearly biologically significant, and has been studied extensively by several methods. A detailed understanding of this binding has become much more achievable in recent years thanks to the work of Downing and his collaborators, who have reported the structure of tubulin at a resolution of 3.7 Å using electron crystallography on crystalline sheets formed in the presence of zinc.[105,106]

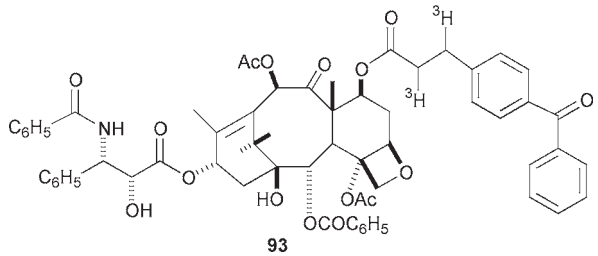
The interaction of taxol with tubulin

Several different methods have been used to study the interaction of taxol with tubulin. In studies by the photoaffinity labeling technique, various labeled taxol analogs have been used to study the location of the binding site of taxol on tubulin. Thus 3′-(*p*-azidobenzamido)taxol (**91**) photolabeled the N-terminal 31 amino acid unit of β-tubulin preferentially,[107] while 2-(*m*-azidobenzoyl)taxol (**92**) labeled a peptide containing amino acids 217–231 of β-tubulin,[108] and the photoaffinity probe **93** was shown to bind to Arg^{282} in β-tubulin.[109]

A second useful technique has been that of fluorescence spectroscopy. This technique has the significant advantage that



91 $R^1 = N_3$, $R^2 = R^3 = H$
92 $R^1 = R^2 = H$, $R^3 = N_3$
94 $R^1 = H$, $R^2 = NH_2$
95 $R^1 = R^3 = H$, $R^2 = NH_2$

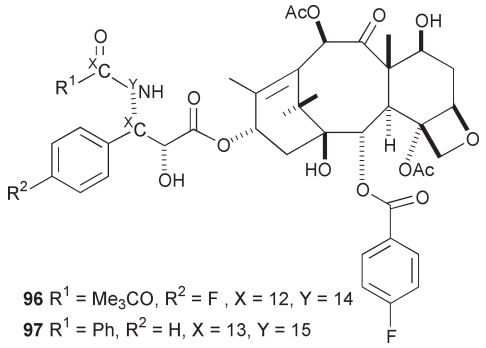


93

it is performed on systems in solution, thus avoiding potential problems with changes in shape on preparing solid samples for analysis. As one example, 2-(*m*-aminobenzoyl)taxol (**94**) gave solvent-dependent absorption and emission spectra. Using this information it was possible to show that the fluorophore binding site on the microtubule is in an environment of intermediate polarity, and also that tubulin has two binding sites for taxol, one high affinity site and one low affinity site.[110] Studies using fluorescence resonance energy transfer measurements showed that the distance between the taxol and colchicine binding sites is approximately 17 Å.[111] A recent paper describes results with the 3′-*N*-(*m*-aminobenzoyl)taxol **95**.[112] It was found that **95** bound to two types of site on the microtubules, with binding affinities of 61 nM and 3.3 μM. It bound to a single site on microtubules assembled from GDP-tubulin with a dissociation constant of 2.5 μM, and it bound to a single site on microtubules assembled from the GTP analog GMPCPP with a dissociation constant of 15 nM. It was thus proposed that although all the subunits of the microtubule at the steady state are the same 'GTP–tubulin–taxol', they are formed through two different pathways: either from taxol binding to a tubulin subunit before GTP hydrolysis (a high affinity binding) or taxol binding to a tubulin subunit after GTP hydrolysis (a low affinity binding). Studies with fluorescent taxol derivatives have also been carried out by others.[113,114]

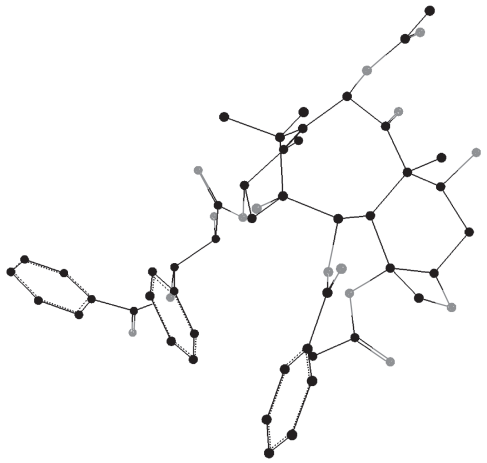
A number of investigators have studied the NMR spectra of taxol in various solvents in an attempt to determine the solution conformation. In non-polar solvents such as chloroform taxol seems to exist primarily in a set of 'open' conformations in which the side chain is oriented away from the 2-benzoyl group,[115,116] but in polar aqueous solvents it adopts a set of 'hydrophobically collapsed' conformations in which the 3′-phenyl group is oriented towards the 2-benzoyl group.[91] Over-interpretation of these results in terms of a 'binding conformation' of taxol to tubulin is, however, dangerous, since taxol exists in chloroform (and presumably also in polar solvents) as a population of different conformations.[117] It is possible that taxol's relatively weak association with tubulin may be due in part to the presence of a large number of nonproductive conformers.

NMR studies of taxol bound to microtubules can be made using the technique of solid state magic angle spinning, and two such studies have been reported. In one study fluorine-containing taxol analogs were used to obtain an F–F distance of 6.5 Å in the difluoro analog **96**.[118,119] In the second study, internuclear distances between ^{13}C and F were obtained by the REDOR technique on the quadruply labeled analog **97**, and these results were coupled with fluorescence data to lead to the



96 $R^1 = Me_3CO$, $R^2 = F$, X = 12, Y = 14
97 $R^1 = Ph$, $R^2 = H$, X = 13, Y = 15

proposal of structure **98** as the most probable conformation of taxol on tubulin.[120]



98

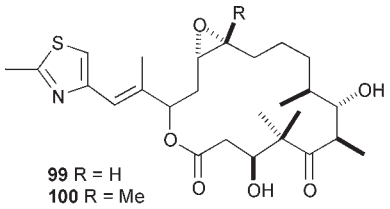
Taxol mimics

For many years taxol was the only compound known to promote the assembly of tubulin into microtubules, but over the past few years several other natural products have been discovered with the same or similar activity. The most important compounds of this class are the epothilones A (**99**) and B (**100**),[121,122] discodermolide (**101**),[123] and eleutherobin (**102**),[124,] but other compounds with this activity have also been discovered. These include rhazinilam,[125] which inhibits the disassembly of microtubules but has a different mechanism of action than taxol, laulimalide and isolaulimalide,[126] WS9885B,[127] and poly-isoprenylated benzophenones such as guttiferone E.[128] The naturally occurring 3(2*H*)-furanone derivative geiparvin has been found to counteract the microtubule-assembly effects of taxol, suggesting that it is a competitive inhibitor at the taxol-binding site of tubulin.[129]

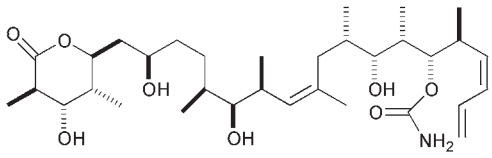
The taxol pharmacophore

Much of the chemical work reported in the previous sections was carried out with a view to determining structure–activity relationships for taxol and its analogs and thus to defining the pharmacophore in chemical terms. Some of this work can be summarized as in Fig. 2 opposite, where the key structure–activity relationships of taxol are shown.

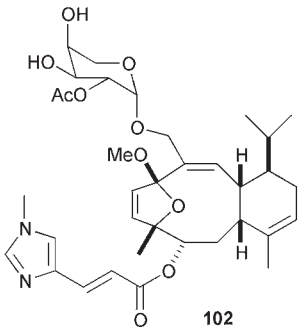
The discovery of the tubulin-assembly properties of the natural products referred to in the previous section opened up a second way of delineating the taxol pharmacophore, since comparisons could be made between the structures of taxol and of these taxol mimics. Various approaches to this important question have been made, with most studies concentrating on a



99 R = H
100 R = Me



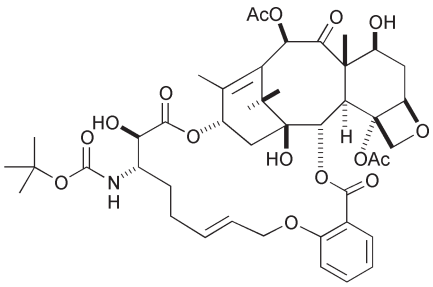
101



102

comparison of the structures and activities of taxol and its analogs and the epothilones.

In one approach various bridged analogs of taxol such as **103** were prepared by olefin methathesis.[130] Three related analogs



103

were found to be cytotoxic to the human breast cancer cell line MDA-435/LCC6-WT with IC_{50} values of less than 1 μM. These activities are significantly less than that of taxol in the same cell line (0.0031 μM), but the compounds also showed tubulin-assembly activity that was only only slightly less than that of taxol, so they are presumably binding to the same binding site as taxol. These data were used to support a model of the pharmacophore in which the aryl sector of epothilone overlaps the C-13 acyl side chain of taxol and in which the baccatin portion of the taxol molecule is relatively non-essential.

A second approach, developed by Giannakakou and his collaborators, was based on a comparison of the effects of taxol and various epothilone analogs on the polymerization of native tubulin and of modified tubulins carrying β-tubulin mutations near the taxol-binding site.[131] Two possible common overlaps of the epothilones and taxol were found. In the first the C-2 benzoyl group of taxol overlapped with much of the 1-methyl-2-thiazolyl side chain of the epothilones, while in the second the thiazole portion of the epothilones overlapped with the side chain of taxol.

A third approach deduced a different binding based on the finding that the side chain of taxol is not as essential for activity as was previously thought, since 2-(*m*-azidobenzoyl)baccatin III is significantly active as a promoter of tubulin polymeriza-

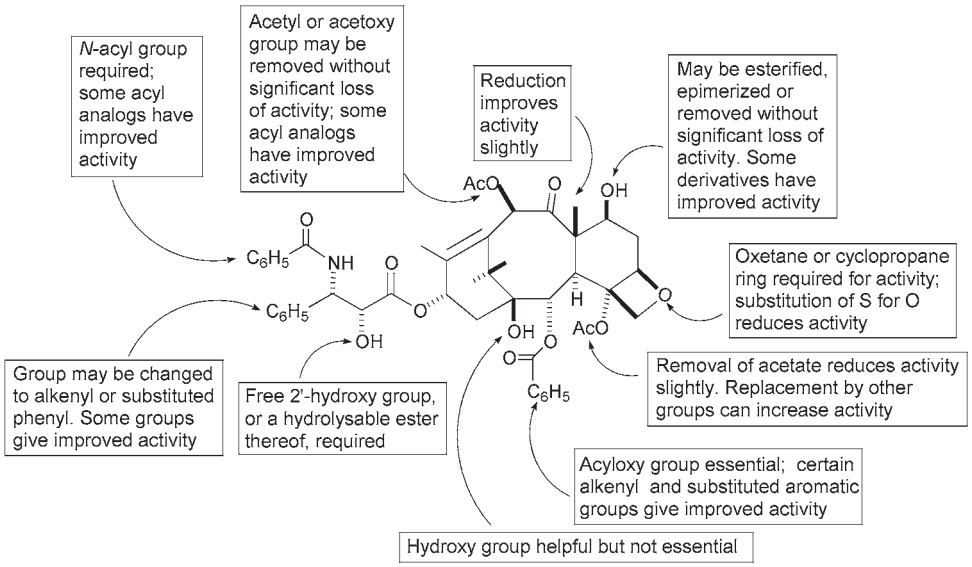


Fig. 2 Structure–activity relationships of taxol.

tion and is a competitive inhibitor of the binding of taxol to microtubules.[132] These studies led to the proposal of a pharmacophore model similar to the first binding mode of Giannakakou *et al*. A perceptive evaluation of the various models has been published.[133]

A different approach was taken by Snyder, who developed a minireceptor model for the binding of taxol and epothilone to the microtubule based on an analysis of tubulin-assembly data.[134] This model places the thiazole ring of the epothilones in the same region of the receptor as the side chain of taxol, consistent with the second binding mode of Giannakakou *et al*.[131] It also predicts much of the SAR data for taxol and the epothilones and appears to be an interesting first step towards the development of a full binding site model.

In summary, the taxol pharmacophore is still under development, with at least two rather different competing hypotheses, and further work will be needed to clarify the situation. It is reasonable however to expect that a final model of the taxol pharmacophore will eventually be developed and will be used in a predictive way to create new and improved taxol analogs.

Conclusion

The preceding review has just scratched the surface of the enormous amount of work that has been done on taxol. In addition to the chemical work summarized above, an enormous amount of work has been done on optimizing the clinical use of taxol in cancer treatment, and several recent reviews of this work have appeared.[8,135–137] The big question, of course, is what sort of difference have the taxoid drugs (taxol and docetaxel) made to cancer treatment? Have they improved cancer survival significantly? The literature on this subject is surprisingly sparse, in part because optimum combination therapies of the taxoids with other drugs are still being worked out; it is expected that such combinations will significantly enhance their use.[137] At present the taxoids are routinely used for the treatment of breast, lung, and ovarian carcinomas, and for AIDS-related Kaposi's sarcoma, and they have been called 'the most powerful compounds' (among the chemotherapeutic drugs introduced in the last decade).[135] In spite of the wide use of the taxoid drugs over the last decade, it appears that improvement in patient survival is modest at best. The greatest number of studies has been done with breast cancer, and for this disease Miller and Sledge state 'Combination therapy (of taxol or docetaxel with other drugs) has increased response rates but as yet has not improved the overall survival of patients with metastatic disease. Improved survival with the addition of paclitaxel to standard adjuvant therapy reported in a recent trial suggests the true impact of the taxanes has not yet been realized.'[137] A slightly more cautious view is expressed by Nabholtz and his colleagues 'However, the impact of taxanes on the natural history of breast cancer is yet to be defined, despite the trend of results suggesting that these agents have the potential for significant improvements in advanced and, most importantly, adjuvant therapy of breast cancer.'[136] A third evaluation was made by a panel of experts convened by the US National Institutes of Health in November 2000. The NIH Consensus Statement approved by this panel reads in part 'Currently available data are inconclusive and do not permit definitive recommendations regarding the impact of taxanes on either relapse-free or overall survival.'[138]

Although the impact of the taxoid drugs on patient survival is thus still a matter of research and debate, the outlook remains bright. The new analogs referred to earlier in this review will almost certainly improve patient survival, while increased understanding of the way taxol binds to tubulin and advances in such areas as drug targeting[139] will most probably lead to even better agents in the future. These factors thus suggest that taxol and its analogs will continue to be important cancer chemotherapeutic drugs well into the new millennium.

Acknowledgements

The work described above from the author's laboratory could not have been accomplished without a large group of talented and hard-working colleagues and collaborators, whose names are given in the references cited from my laboratory; I owe them all a great debt for their excellent work. The tubulin and REDOR studies described in the last section were done in collaboration with Dr Susan Bane (SUNY Binghamton) and Dr Jacob Schaefer (Washington University, St. Louis), and I am enormously grateful to them and their colleagues for these exciting results. I would like to pay especial tribute to Dr Matthew Suffness, who was a leading proponent of research on taxol within the National Cancer Institute, and who provided much help and encouragement to the author. His tragic early death in 1995 deprived the natural products community of a staunch supporter and a good friend. Financial support was provided by the American Cancer Society and by the National

Cancer Institute from grants CA48974, CA55731, and CA69571, and I am most grateful for this crucial component of our work.

References

1 The chemical compound **1** was named taxol by its discoverers in 1971. Unknown to them a French company had trademarked the name Taxol in the 1930's for a laxative product. Rights to this trademark were acquired by Bristol-Myers Squibb, who then applied it to their formulation of the chemical substance **1**. Because of the greater familiarity of most readers with the name taxol than the alternate USAN paclitaxel, the former will be used in this review. No infringement of the Bristol-Myers Squibb trademark is implied by this usage.

***myo*-Inositol derivative as a host assembles around crystallographic 2-fold axis selectively accommodating dihalomethanes as guests having a C_2 symmetry; formation of highly stable host–guest complexes is attributed to halogen···oxygen and C–H···O interactions.**

An intermolecular recognition process is a result of a number of non-covalent interactions that exist between the molecules.[1] Recently much effort has been concentrated upon recognizing and analyzing the nature of such interactions due to the demands of designing the functional molecular assemblies[2] which span wide areas—from molecular selectivity in separation techniques to drug–receptor interactions in drug design and to material science. In this paper we report a serendipitous discovery of highly selective encapsulation of dihalomethanes by the *myo*-inositol derivative **2**‡ (Scheme 1) due to halogen···oxygen interactions.

The compound **2**, which resisted crystallization in most of the common solvents like chloroform, ethyl acetate, carbon tetrachloride *etc*. readily formed good quality crystals when crystallized from dichloromethane. We further noted that this 'spontaneous' crystallization of **2** occurred only from dihalomethanes, (CH_2X_2, X = Cl, Br and I). So much was the dependence on CH_2X_2 in crystal formation that even their presence at 2.5% (v/v) along with other solvents induced crystallization of **2**. The presence of dihalomethanes in these crystals was revealed by elemental analysis§ and ^{1}H NMR spectroscopy. The DSC¶ of **3** and **4** indicated that dihalomethanes were retained in crystals close to their melting points (183–192 °C for **3** and 186–188 °C for **4**), suggesting a strong association of the guest molecules with the host.‖ The X-ray structures** of two inclusion complexes of **2** with dihalomethanes revealed that halogen···oxygen interactions, or what is termed as 'halogen bonding',[3] played a vital role in forming a stable host–guest assembly, a bonding recognized as a strong driving force in formation of co-crystals and controlling the construction of supramolecular architectures. It is thought that the remarkable specificity for dihalomethanes in the formation of crystals with **2** will have applications in the separation of halocarbon compounds, through the design of suitable organic hosts such as compound **2**.

View of the molecular packing of **3** down the *c*-axis (Fig. 1) clearly reveal the thorough open channels of dimensions ~6.5 × 4.5 Å formed by the host assembly containing the guest molecules. Amongst all possible host–guest interactions, notable ones are halogen···oxygen short contacts (Fig. 2) in **3** (Cl···O = 2.968 (9) Å) as well as in **4** (Br···O = 3.336 (7) Å) which are shorter than the sum of their van der Waal's radii (3.20 and 3.35 Å respectively). The short halogen···oxygen distances were analyzed earlier[4] to understand the exact nature and favored geometry of their interactions.[5] Although C–X···O linear geometry is suggested for stronger interactions, the present structure shows some deviation from linearity (139.5° (4) and 142.1° (2) for **3** and **4** respectively).[6] Even then it is striking that this 'halogen bonding' has induced the assembly of the host. However, solvent retention is a multi-point recognition phenomenon[7] as evidenced by other weak interactions between the CH_2X_2 guest molecules and the host, which certainly aid in the host–guest stabilization. For instance, there are C–H···O contacts[8] between the CH_2 hydrogens of the guest with the carbonyl oxygens O2 and O4 of the host in both **3** and **4**. The halogen atoms are also involved in weak C–H···X interactions with the phenyl C–H groups of the neighbouring assembly.

It is noteworthy that solvents CH_2Cl_2, CH_2Br_2 and CH_2I_2 readily form crystals with **2,** whereas halogenated solvents

which lack C_2 symmetry (chloroform, methyl iodide) do not yield crystals. Clathrating hosts with open channel formation around the two fold symmetry axis have been reported,[9] but the inclusion of the guest was found to be non-specific, accommodating a wide range of guest molecules; whereas the host **2** is highly specific to dihalomethanes which occupy a crystallographic two-fold axis. But there seems to be a restriction on the steric size of the guest—only the guests having a C_2 symmetry of molecular diameter of ~6.0 Å such as CH_2X_2 are accommodated (to produce crystals), while the higher homologues like 1,2-dichloroethane or 1,2-dibromoethane are not. We believe that the guest induces the assembling process by bringing the second molecule of the host (related by a crystallographic two-fold axis) around it (Fig. 2) making strong halogen···oxygen contacts. The other half of the cavity is completed by the two host molecules related by a center of symmetry (Fig. 2). These two halves are cemented to each other by significant C–H···O interactions to complete the elliptical open framework. All the hydrophobic phenyl groups point outward while the hydrophilic carbonyl oxygens point toward the center of the cavity.

In summary, a novel host–guest assembly held together, notably by halogen···oxygen non-bonded contacts, has been prepared and characterized. Study of such systems, which lack polar groups (OH, COOH, NH_2 *etc*.) is essential to further extend our knowledge of weak interactions among molecules, which play a vital role in crystal growth, enzyme–substrate recognition and ligand–receptor binding.[10] The present adducts re-emphasize the role of 'halogen bonding' in self-assembly and molecular recognition. The work presented shows there is potential for the exploitation of these interactions in the separation of traces of dihalomethanes from other organic compounds or solvents.

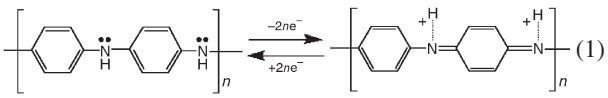
Received (in Cambridge, UK) 7th February 2001, Accepted 22nd March 2001
First published as an Advance Article on the web 20th April 2001

Surface plasmon resonance (SPR) spectroscopy is used to follow the swelling and shrinking processes of a polyaniline redox-active polymer; SPR provides a reading signal for the electrochemical stimuli that activate the polymer.

Phase transitions of polymers and signal-triggered swelling processes of polymers are subjects of extensive research efforts.[1,2] Volume changes of polymers are triggered by temperature,[3] pH,[4] solvent composition[5] and light.[6] Electrochemical activation of redox-polymers provides a means to stimulate swelling.[7] Recently the stress induced on an AFM cantilever as a result of the redox-activation of polyaniline was used to develop an electrofueled microdevice[8] that may act as a micro-robot or micro-pump. Surface plasmon resonance (SPR) has been recently applied to study interfacial phenomena associated with electrochemical transformations of thin films at electrode surfaces.[9] Here we describe the SPR transduction of the redox-activation of polyaniline films, and the accompanying swelling and shrinking processes using *in situ* electrochemical/SPR measurements.

Polyaniline was generated on a Au-covered glass-slide (*ca.* 0.64 cm^2) used for SPR-measurements (Bio-Suplar 2, Analytical μ-Systems, Germany) by the electropolymerization of aniline, 0.1 M, in an electrolyte solution composed of H_2SO_4, 0.1 M, and Na_2SO_4, 0.5 M, (applied potential 0.8 V *vs.* Ag-wire quasi-reference electrode for 5 s).[10] The resulting film obtained upon passing charge of 9.7 mC, that corresponds to the formation of *ca.* 10 μg of the polymer, was washed with background solution composed of H_2SO_4, 0.1 M, and Na_2SO_4, 0.5 M, to exclude from the cell the residual monomer. The polyanilin film can be reversibly oxidized and reduced, eqn. (1), and the polymer exists in the oxidized positively charged state, $(An^{2+})_n$, and reduced neutral state, $(An)_n$, at the potential 0.4 and 0.0 V, respectively.[12]



(1)

Fig. 1, inset (I), curve (x), shows the SPR spectrum of the bare Au-surface. The polyaniline film, $(An)_n$ was equilibrated at the potential 0.0 V in the electrolyte solution prior the SPR-measurements. Fig. 1, inset (I), curve (y), shows the spectrum of the polyaniline film assembled on the Au-surface immediately after the application of the potential corresponding to 0.4 V on the electrode resulting in the oxidation of the polymer layer. While the dots correspond to the experimental points, the solid line corresponds to the theoretical fitting[11,12] of the data according to the Fresnel equation. The derived film thickness corresponds to *ca.* 150 nm. Fig. 1(A), curves (a–e), shows the SPR spectra at the potential of 0.4 V, conditions that retain the polymer in its oxidized state, $(An^{2+})_n$. These spectra are time-dependent and a decrease of the reflectance minimum is observed, because of the polymer swelling.[13] The spectrum recorded 10 min after the application of the oxidizing potential of 0.4 V, Fig. 1(A), curve (e), corresponds to a polymer thickness of *ca.* 180 nm. Thus, the swelling process occurring at 0.4 V results in the increase of the polymer thickness by *ca.* 30 nm. It should be noted that the similar thickness change was observed by AFM upon the electrochemically-induced shrinking–swelling process of a polyaniline layer.[14] Fig. 1(A), curve (f), was recorded under conditions where the applied potential

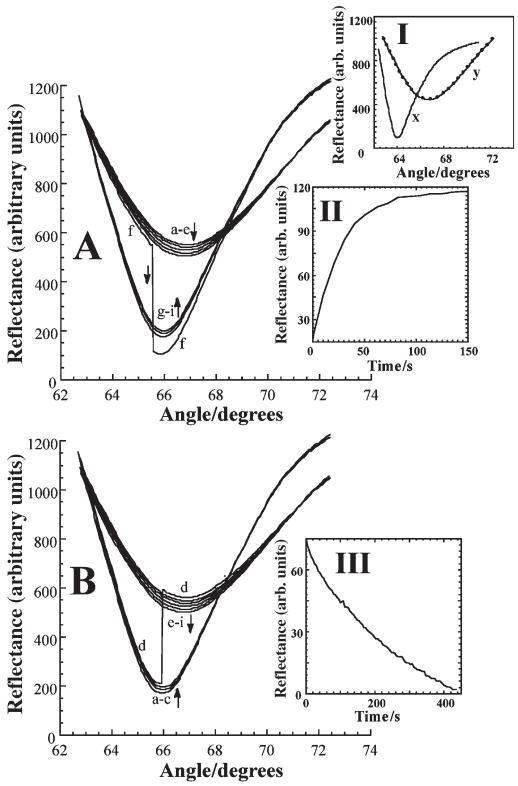


Fig. 1 SPR spectra measured for the polyaniline-modified Au-surface upon electrochemically-induced shrinking and swelling processes. (A) The polymer was equilibrated at 0.0 V for 5 min prior to the measurements. (a–e) The spectra measured after the potential was changed to 0.4 V. (f) The spectrum measured during the potential change to 0.0 V. (g–i) The spectra measured after the potential was changed to 0.0 V. (B) The polymer was equilibrated at 0.4 V prior to the measurements. (a–c) The spectra measured after the potential was altered to 0.0 V. (d) The spectra measured during the potential change to 0.4 V. (e–i) The spectra measured after the potential was changed to 0.4 V. Inset I: (x) The SPR spectrum for the bare Au-surface and (y) the SPR spectrum for the oxidized polymer film measured at 0.4 V (the dots show selected experimental points and the solid line is the best theoretical fit). Inset II: Time-dependent reflectance changes measured at a fixed angle of incidence (θ = 65°) immediately after the applied potential was changed from 0.4 to 0.0 V. Inset III: Time-dependent reflectance changes measured with the fixed angle of incidence (θ = 65°) immediately after the applied potential was changed from 0.0 to 0.4 V. All SPR measurements were performed in the background solution: H_2SO_4, 0.1 M, and Na_2SO_4, 0.5 M.

† Visiting scientist from the Institute of Physics of Semiconductors, National Academy of Sciences of Ukraine, Prospect Nauki, 45, Kiev, Ukraine.

DOI: 10.1039/b101243f

on the polymer-modified electrode was suddenly altered from 0.4 to 0.0 V. This spectrum shows the transition from the oxidized state of the polymer, $(An^{2+})_n$ to the reduced state, $(An)_n$. The instantaneous change in the spectrum mainly originates from the change of the refractive-index of the polymer as a result of its reduction. The subsequent SPR spectrum recorded at the potential of 0.0 V, Fig. 1(A), curve (g), shows a noticeable increase of the reflectance minimum after which only minor changes of the spectra were observed, Fig. 1(A), curves (h) and (i). These spectra changes can be attributed to the shrinking process of the reduced polymer and they reach a constant value after *ca*. 4 min. The main decrease in the polymer thickness as a result of the shrinking process occurs in the first minute after the potential change to 0.0 V, faster than the time-interval required to record the complete SPR spectrum. Thus, measurements with a fixed angle of incidence (θ = 65°) were applied to evaluate the kinetics of the shrinking process upon the potential change from 0.4 to 0.0 V, Fig. 1, inset II. The experimental results reveal a biexponential kinetics with rate constants corresponding to 9×10^{-3} and 5×10^{-4} s^{-1}. The fast and slow components exhibit the same population. The fast shrinking component may be attributed to the collapse of the hydrophobic polymer chains, formed upon reduction to a metastable configuration. The slow component is then attributed to the formation of an organized, densely-packed structure that expels the residual water. Similar biexponential dynamic changes were observed upon the compression of proteins.[15]

The second experiment was started by equilibration of the polymer-modified electrode at 0.4 V when the polymer is oxidized. The first SPR spectrum was recorded after the potential was shifted to 0.0 V, Fig. 1(B), curve (a). It should be noted that the time-scale of the measurements did not allow us to register the SPR spectrum characteristic of the metastable shrunken polymer film. The secondary slow kinetics of the shrinking process at the potential of 0.0 V is clearly visible in the SPR spectra, Fig. 1(B), curves (a–c). These changes reach a constant value after *ca*. 3 min. During the registration of the next spectrum, Fig. 1(B), curve (d), the applied potential was changed from 0.0 to 0.4 V. The immediate change of the SPR spectrum originates mainly from the change of the refractive-index of the polymer as a result of its oxidation. Continuous SPR measurements at the potential 0.4 V show the decrease of the polymer layer reflectance corresponding to the slow swelling process, Fig. 1(B), curves (d–i). The kinetics of the swelling process was recorded at a fixed angle of incidence (θ = 65°), Fig. 1, inset III. The kinetics of the swelling process corresponds to a first-order monoexponential process with a rate constant of 3×10^{-4} s^{-1}. It should be noted that upon redox-induced swelling and shrinking of the polymer film the uptake and release of counter-anions may change the conductivity of the film and thus may alter the reflectance. For redox-active films that lack swelling, *e.g*. Prussian blue, the reflectance changes due to ion transport are, however, minute.

The sequence of potential steps applied in the two experiments results in similar changes in the thickness values of the reduced or oxidized polymer films independently on the sequence of the reduction or oxidation steps that lead to a shrunken or swollen polymer film, respectively. Thus, the reversible transformation of the polymer layer between shrunken and swollen states with different thicknesses is possible. However, the complete shrinking–swelling cycle proceeds on the time scale of minutes. Realizing that the refractive index of the polymer undergoes very fast changes upon the reduction–oxidation process, one may use the polyaniline film as an interface for the reversible SPR transduction of electronic signals that actuate the polymer. Fig. 2(A) shows the chronoamperometric transients upon oxidation (0.4 V) and reduction (0.0 V) of the polyaniline layer. In this experiment, a potential-step that oxidizes $(An)_n$ to $(An^{2+})_n$ is applied. The polymer is not allowed to swell, and the opposite reductive potential-step is applied to generate the metastable $(An)_n$ that is oxidized again before it undergoes shrinking. By the cyclic application of the oxidative and reductive potential steps, the reversible SPR transduction of the polymer state is accomplished, Fig. 2(B).

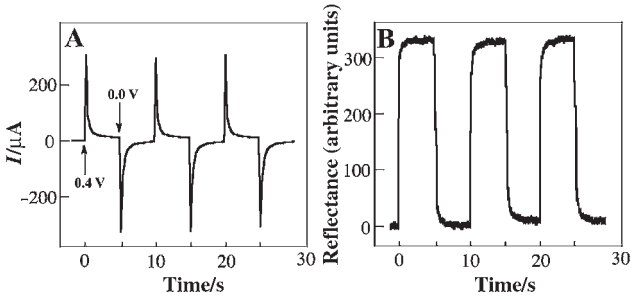

Fig. 2 (A) Multi-potential step chronoamperometric measurements corresponding to the oxidative and reductive transformations of the polyaniline layer. (B) Time-dependent reflectance changes measured at a fixed angle of incidence (θ = 65°) upon the multi-potential step experiment. The arrows show the time of the application of the oxidative (0.4 V) and reductive (0.0 V) potentials. The chronoamperometric and *in situ* SPR measurements were performed in a background electrolyte solution composed of H_2SO_4, 0.1 M, and Na_2SO_4, 0.5 M.

In conclusion, we have applied surface plasmon resonance spectroscopy for following the swelling and shrinking processes of a polyaniline redox-active film. SPR provides a reading signal for the electrochemical stimuli that activate the polymer.

Parts of this study were supported by the National Science Foundation Administered by the Israel Academy of Sciences and Humanities. The support of the Max-Planck Research Award for International Cooperation (I. W.) is gratefully acknowledged.

12 The experimental SPR spectra of the polymer layer in the reduced and oxidized state were fitted to the theoretical curves based on five-phase Fresnel calculations using the Neelder–Mid algorithm of minimization. The computer fitting of the SPR spectra was performed primarily for the reduced state of the polyaniline layer using the known refractive index, n = 1.4, λ = 670 nm, (D. Mo, Y. Y. Lin, J. H. Tan, Z. X. Yu, G. Z. Zhou, K. C. Gong, G. P. Zhang and X.-F. He, *Thin Solid Films*, 1993, **234**, 468). The complex refractive-index of the oxidized state, $(An^{2+})_n$, was then calculated (n_{re} = 1.39, n_{im} = 0.46) by assuming the same polymer thickness immediately after the polyaniline film oxidation. The polymer film thickness in the oxidized state after the complete swelling was derived using the calculated values of the complex refractive index.

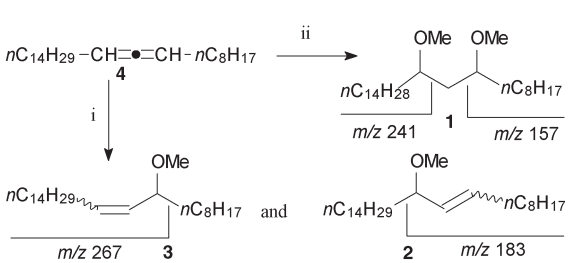
Received (in Cambridge, UK) 26th February 2001, Accepted 28th March 2001
First published as an Advance Article on the web 20th April 2001

Allenic hydrocarbons, previously unknown as a molecular class from insects, are represented by $CH_3(CH_2)_n$-CH=•=CH-$(CH_2)_7CH_3$ (n = 11–15, 17, 19) in several Australian melolonthine scarab beetles and with demonstrated (*R*)-chirality when n = 11 and 13.

Melolonthine scarabs are pests of field crops and pastures,[1] and we have undertaken studies of the chemistry of certain sugarcane scarabs from north-eastern Australia. Cuticular hydrocarbons[2] from female adults were of surprisingly limited constitutional variation. In *Antitrogus consanguineus*, one component represents (GC analysis) *ca*. 50% of the cuticular hydrocarbons and this appeared to be a C-25 hydrocarbon with a molecular ion *m*/*z* 348 ($C_{25}H_{48}$), confirmed by GCMS-CI analysis. A minor component was the bis-homologue $C_{27}H_{52}$ (M^+, 376). On this basis, both incorporated two degrees of unsaturation.

A methoxymercuration–reductive demercuration ($NaBH_4$) protocol was conducted to locate the sites of unsaturation, with the resulting methyl ether groups guiding the mass spectral fragmentations.[3] This reaction provided a mixture of several mono- and bis-methyl ethers with the two most abundant bis-methyl ethers exhibiting identical mass spectra. These were deduced to be stereoisomers of 9,11-dimethoxypentacosane **1** on the basis of their fragmentations (Scheme 1). Two further components were similarly deduced to be mixtures of stereoisomers of 11-methoxypentacos-9-ene **2** and 9-methoxypentacos-10-ene **3**, resulting from initial mono-methoxymercuration and then reduction. This indicated that the C-25 hydrocarbon was $\Delta^{9,10}$-pentacosadiene **4** (Scheme 1). GC-MS analyses of the methyl ethers resulting from $NaBD_4$ reduction support these conclusions. In the case of bis-ethers **1**, two deuterium atoms were incorporated (*e*.*g*. M-15 at *m*/*z* 399 from *m*/*z* 397) but the ions at *m*/*z* 241 and 157 were unchanged. This confirms that both Hg atoms became attached to the central carbon of the allene (*i*.*e*. C-10), so that on reduction 10-$^2H_2$-**1** was formed.



Scheme 1 *Reagents and conditions*: i, $Hg(OAc)_2$–MeOH then $NaBH_4$; ii, as for i (double addition/reduction).

† Electronic supplementary information (ESI) available: analytical data for **4**, **5**, **6** and **9**, and proposed McLafferty rearrangements for **4**. See http://www.rsc.org/suppdata/cc/b1/b101801i/

Similarly the minor C-27 component was concluded to be $\Delta^{9,10}$-heptacosadiene **5**, based on the formation of two isomers of 9,11-dimethoxyheptacosane, and also 9-methoxyheptacos-10-ene and 11-methoxyheptacos-9-ene. A more varied mixture of regioisomeric mono- and bis-methyl ethers would be anticipated from both conjugated and non-conjugated dienic hydrocarbons.

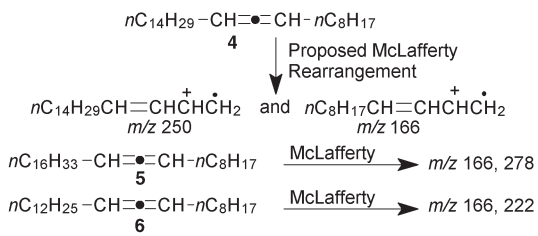
These conclusions were supported by diagnostic ions at *m*/*z* 166 and *m*/*z* 250 (for the C-25 compound) and *m*/*z* 166 and *m*/*z* 278 (for the C-27 compound), attributable to McLafferty rearrangement ions, known to appear in the mass spectra of acyclic allenes[4] (Scheme 2).

The major component was partially purified (HPLC:silica–hexane, *ca*. 0.3 mg). The ^1H NMR signal at δ 5.04 (br, m) correlated (HSQC) with the ^{13}C NMR signal at 90.8 ppm, (representing both sp^2-carbons), both signals being consistent with the allene structure. The signal for the central carbon of the allene group (expected ~200 ppm) was not discernible from this dilute sample.[5]

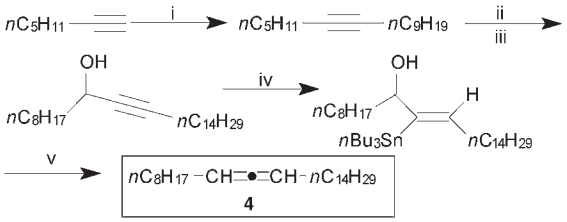
GCMS comparisons established that the C-25 allene **4** was also a minor cuticular component in two other sugarcane beetles, *Lepidiota negatoria* and *Dermolepida albohirtum*. Extracts from *D*. *albohirtum* and *L*. *picticollis* contained as a major component an allene with M^+ 320 ($C_{23}H_{44}$) and diagnostic ions at *m*/*z* 166 and *m*/*z* 222, again indicating 9,10-di-unsaturation. The $\Delta^{9,10}$-tricosadiene structure **6** was proposed for this constituent. When co-injected with a set of standard alkanes, the allenes **4**, **5** and **6** eluted just prior to the corresponding alkane and have equivalent chain lengths of 24.9, 26.9 and 22.9, respectively.

To confirm the identity of these three components, syntheses of **4**, **5** and **6** were then undertaken and a route was developed for delivery of both racemic and enantiomerically enriched systems. Key steps utilised were the 'acetylene zipper' reaction,[6] regioselective addition of $^nBu_3SnH$ to a propargylic alcohol, and *anti* elimination of $^nBu_3SnOMs$ (or $^nBu_3SnOAc$)[7] to install the propa-1,2-diene unit. This approach is shown in Scheme 3 for $\Delta^{9,10}$-pentacosadiene **4**.

Similar approaches furnished the racemic $\Delta^{9,10}$-tricosadiene **6** and $\Delta^{9,10}$-heptacosadiene **5**. GC-MS comparisons, including co-elution studies, established that the natural components were



Scheme 2

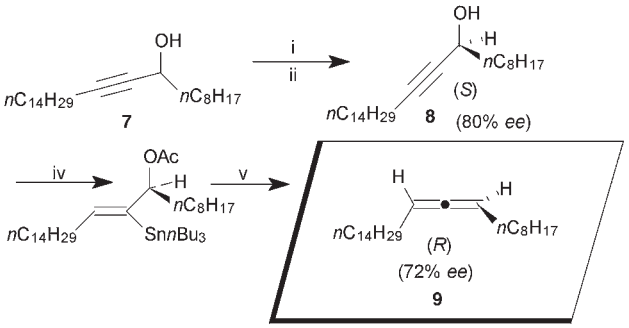


Scheme 3 *Reagents and conditions*: i, *n*BuLi, THF −78 °C/−40 °C then $nC_9H_{19}Br$, HMPA (97%); ii, KH, DAP (79%); iii, *n*BuLi, THF −78 °C/−40 °C then $nC_8H_{17}CHO$ (51%); iv, nBu_3SnH, AIBN 90 °C; v, MsCl, Et_3N (60% from alkynol).

6, **4** and **5**. In the case of the synthesised $\Delta^{9,10}$-pentacosadiene **4**, its ^1H and ^{13}C NMR spectra matched precisely the spectra of the natural component.

The chirality of the natural allenes was then addressed. The enantiomers of (±)-$\Delta^{9,10}$-tricosadiene **6** and (±)-$\Delta^{9,10}$-pentacosadiene **4** were base-line separated on a heptakis(6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-methyl) β-cyclodextrin column, after *ca*. 160 min at 155 °C and *ca*. 200 min at 165 °C respectively. The natural $\Delta^{9,10}$-pentacosadiene (from *A*. *consanguineus*) was of high ee, and co-eluted with the first eluting enantiomer of the racemate. This applied also to $\Delta^{9,10}$-tricosadiene from *D*. *albohirtum*. The present allenes provide remarkable examples of the separation efficacy of these modified cyclodextrin phases.[8]

Nonracemic allenes of known predominating chirality were required next. The C-25 propargylic alcohol **7** (Scheme 4) was first oxidised to the ketone, and reduction with Me-CBS[9] afforded the (*S*)-alcohol **8** (80% ee, Mosher's ester analyses).[10] The predominant configuration was confirmed by converting the alcohol into decane-1,2-diol, whose rotation ($[\alpha]_D$ −7°; *c*, 0.12, MeOH) may be compared with that for the authentic (*S*)-isomer, ($[\alpha]_D$ −11.9°; *c*, 0.43, MeOH).[11] The (*S*)-propargylic alcohol **8** was then hydrostannylated, acetylated and treated with TBAF in DMSO to effect *anti*-elimination of $^nBu_3SnOAc$[12] and give the (*R*)-enantiomer, **9** ($[\alpha]_D$ −17° (*c*, 0.54, $CHCl_3$)[13] in 72% ee (enantioselective gas chromatography). Co-injection studies established that natural $\Delta^{9,10}$-pentacosadiene in *A*. *consanguineus* was predominantly the (*R*)-enantiomer (89% ee).



Scheme 4 *Reagents and conditions*: i, TPAP, NMO (82%); ii, (*S*)-MeCBS (2.5 equiv.) $BH_3{\cdot}SMe_2$ (5 equiv.) −30 °C 1 h (70%); iii, nBu_3SnH AIBN 90 °C neat; iv, Ac_2O, pyridine (14% from alkynol); v, TBAF, DMSO reflux (77%).

An analogous approach with (*S*)-tricosa-10-yn-9-ol (80% ee) provided predominantly (*R*)-$\Delta^{9,10}$-tricosadiene (77% ee, 36% from the alcohol). Natural $\Delta^{9,10}$-tricosadiene was then shown to be (*R*)-configured with 86% ee. Given the consistency of the location of the $\Delta^{9,10}$-propadiene unit, a predominating (*R*)-chirality is likely for $\Delta^{9,10}$-heptacosadiene, as well.

Examination of males of a further cane beetle species, *L*. *crinita* has revealed the presence of the higher allene, $\Delta^{9,10}$-hentriacontane, $C_{31}H_{60}$ (M^+ = 432 and McLafferty ions at *m*/*z* 334 and 166). A lower level component is $\Delta^{9,10}$-nonacosadiene, the C-29 allene (M^+ = 404, *m*/*z* 306 and 166). Co-occurring with the dominant C-25 allene in *A*. *consanguineus*, are much lower levels of the *even carbon numbered* $\Delta^{9,10}$-tetracosadiene (M^+ 334, *m*/*z* 246, 166) and $\Delta^{9,10}$-hexacosadiene (M^+ 362, *m*/*z* 264, 166), in the former case confirmed by synthesis.

All allenes identified have $\Delta^{9,10}$-unsaturation, and those odd numbered in carbon are considerably favoured. Administration of labelled potential precursors is being conducted to reveal possible routes to these hydrocarbons. As far as we are aware, allenic hydrocarbons were previously unknown from insects, although the male-produced pheromone of the dried bean beetle (*Acanthoscelides obtectus*) incorporates an allene moiety.[14] The biological role of these compounds is being investigated.

The authors are grateful to the Australian Research Council (SPIRT award) for support, to Professor R. W. Rickards for valuable suggestions, and to David Logan (BSES, Ayr, Australia) for provision of *D*. *albohirtum* specimens.

Ionic liquids as catalytic green solvents for nucleophilic displacement reactions

Christy Wheeler,[a] Kevin N. West,[a] Charles L. Liotta[b] and Charles A. Eckert*[a]

[a] *School of Chemical Engineering, Georgia Institute of Technology, Atlanta, GA, 30332-0100, USA. E-mail: cae@che.gatech.edu*
[b] *School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400, USA*

Received (in Corvallis, OR, USA) 31st January 2001, Accepted 16th March 2001
First published as an Advance Article on the web 20th April 2001

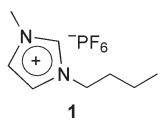
We demonstrate the use of room-temperature ionic liquids as a catalytic, environmentally benign solvent for the cyanide displacement on benzyl chloride, replacing phase-transfer catalyzed biphasic systems and thus eliminating the need for a volatile organic solvent and hazardous catalyst disposal.

Ionic liquids have recently gained recognition as possible environmentally benign alternative chemical process solvents. Because of their vanishingly low vapor pressures, ionic species do not contribute to VOC emissions as do most organic solvents. Examples of their application in both reactions[1,2] and separations[3,4] have been demonstrated. Although many types of reactions have been investigated in ionic liquids, examples of nucleophilic substitution reactions are absent from the literature.

Nucleophilic displacement reactions are often carried out using phase-transfer catalysis (PTC) to facilitate the reaction between the organic reactants and the inorganic ionic salts that provide the nucleophiles.[5] The phase-transfer catalyst, often a tetraalkylammonium salt, acts as a shuttle for the reactant anion between a polar phase that contains the salt reactant and a non-polar phase that contains the organic reactant. This technique not only overcomes the problem of contacting the reactants, but also provides activation of the nucleophilic anion, since it is much less tightly bound to a tetraalkylammonium cation than it would be to a metal cation. In conventional PTC typical organic solvents are environmentally undesirable species such as methylene chloride or *o*-dichlorobenzene, and catalyst separation and recovery are significant challenges. With ionic liquids as both the solvent and the catalyst, there are zero VOCs, and it has been shown that product recovery is facile by CO_2 stripping.[3]

Because ionic liquids are comprised of bulky organic cations, they seem well suited for the types of reactions for which PTC is effective. There even exists the possibility that the solvent itself can act as a catalyst to activate the anion for reaction. The ionic liquid cation might not be as effective a catalyst as most PTCs; however, as a solvent, its high concentration should overcome this limitation, yielding a high reaction rate.

We chose the cyanide displacement on benzyl chloride to yield phenylacetonitrile, depicted in Scheme 1, as a model reaction. For the solvent, we selected the ionic liquid 1-*n*-butyl-3-methylimidazolium hexafluorophosphate (**1**), often called



1

[bmim][PF_6]. The reaction was chosen because it has been well characterized in a variety of other systems. The choice of solvent was motivated by its being one of the most widely used, and therefore the most widely available, ionic liquids.

Scheme 1 Cyanide displacement on benzyl chloride.

These reactions were carried out in a 25 ml volumetric flask set in a recirculating heated bath and stirred with a magnetic stir bar. The concentration of benzyl chloride in the ionic liquid was 1 M, and the amount of potassium cyanide was three times the stoichiometric amount of benzyl chloride. While all of the benzyl chloride was visually observed to be soluble, solid potassium cyanide was present in the systems at all times. Before introduction of benzyl chloride, the salt was stirred overnight in the liquid so that the uniform particle sizes would form and the salt would reach an equilibrium concentration.[6] After the introduction of benzyl chloride, samples were drawn and dissolved in cold acetonitrile before being analyzed by HPLC equipped with a UV-Vis detector.

Reactions were carried out at 40, 60, and 80 °C, and conversion is plotted in Fig. 1. Reaction rates were high, with the reaction at 80 °C reaching complete conversion in less than half an hour. Although the reactions at 60 and 80 °C show the expected pseudo-first-order kinetic behavior (since the amount of cyanide available for reaction should be constant), the reaction at 40 °C appears to be zero order. This behavior indicates that mass transfer of potassium cyanide into the solvent is probably the rate-limiting step at the lower temperature, which is consistent with the fact that the viscosity of the ionic liquid is observed to decrease steeply with an increase in temperature. Although solid salt is always present in the reacting systems, the transfer into the liquid at higher temperatures is apparently faster than the reaction step itself, such that an equilibrium concentration of cyanide is achieved and pseudo-first-order behavior is exhibited.

The rate constants for each temperature are listed in Table 1. An effective activation energy of 19 kcal mol^{-1} is calculated using the data at 60 and 80 °C. Because the nature of the solvent changes with temperature, this activation energy includes several factors other than the temperature dependence of the intrinsic reaction rate, most especially the solubility of potassium cyanide.

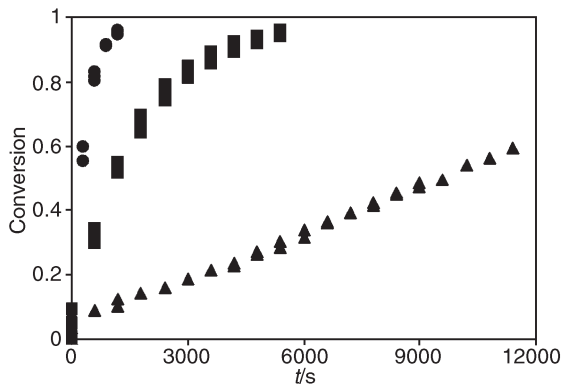


Fig. 1 Conversion of benzyl chloride to benzyl cyanide (● 80 °C, ■ 60 °C, ▲ 40 °C).

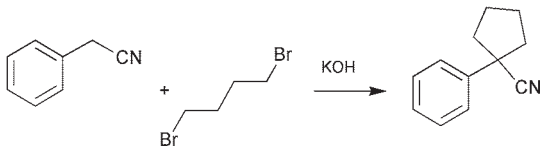
Table 1 Rate constants for reaction of benzyl chloride with potassium cyanide. Uncertainty is represented by 95% confidence intervals

Temperature/°C	Rate constant
40	[a](4.76 ± 0.12) × 10^{-5} mol L^{-1} s^{-1}
60	[b](5.45 ± 0.38) × 10^{-4} s^{-1}
80	[b](2.54 ± 0.10) × 10^{-3} s^{-1}

[a] Zero order. [b] Pseudo-first order.

Another reaction that has been demonstrated in a similar system is the base-promoted cyclo-alkylation of phenylacetonitrile with 1,4-dibromobutane, shown in Scheme 2. Kinetic data were not taken, but the reaction was complete in less than three hours. As in the previous example, the organic reactants were dissolved in the ionic liquid, and excess solid potassium hydroxide was present at all times.



Scheme 2 Cyclo-alkylation of phenylacetonitrile with 1,4-dibromobutane.

Once the reaction is complete, we must turn our attention to product recovery and solvent recycle. As demonstrated by Blanchard *et al*., supercritical CO_2 can be incorporated to extract non-volatile organic compounds from ionic liquids.[3,7] Heating is sufficient to remove more volatile compounds from the solvent. Fig. 2 illustrates a proposed environmentally benign reaction and separation solvent system for reactions of organic compounds with inorganic salts. The low solubility of ionic liquids in water and in CO_2 allows for facile separation steps that should result in minimal solvent loss, although loss of ionic liquid in a water extraction must be considered when selecting the ionic liquid.

In conclusion, we have demonstrated the viability of ionic liquids as a solvent for reactions between organic compounds and inorganic salts. This opens many opportunities for environmentally friendly processing, especially when combined with the benign separations techniques that have already been demonstrated.

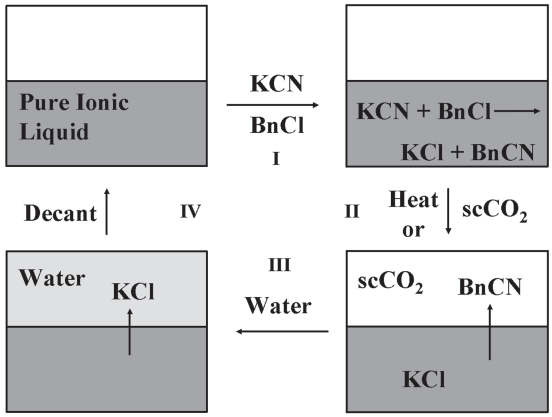


Fig. 2 A recyclable ionic liquid solvent system for nucleophilic substitution reactions. In step I, the reactants are added to the ionic liquid and the reaction is allowed to proceed. Step II involves the removal of the organic reactant *via* vaporization or supercritical fluid extraction. Washing with water, as in step III, will remove the salt product and after decantation, step IV, the purified ionic liquid is obtained and available for another reaction cycle.

We gratefully acknowledge the assistance of Ashley Wallin and Jessica Ryan in performing experiments. We also thank John Kantzes and Roger Moulton of SACHEM, Inc., in Austin, Texas, for provision of the ionic liquid.

6 The [bmim][PF_6] was obtained from SACHEM, Inc., and used as received. Two separate bottles were used in these experiments, one labeled 97% pure, with the balance water, and the other without indication of water content. However, the results obtained with each were the same. The overnight heating of the solvent prior to reaction should allow the water content to come to an equilibrium level.

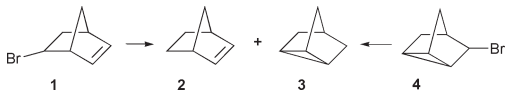
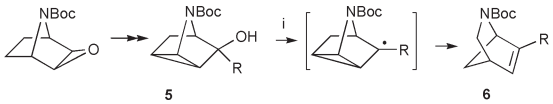
Received (in Cambridge, UK) 2nd March 2001, Accepted 2nd April 2001
First published as an Advance Article on the web 20th April 2001

Addition of thiols to 7-azabicyclo[2.2.1]heptadienes such as 16 leads exclusively to 7-thio-substituted 2-azabicyclo[2.2.1]-hept-5-enes 17 in good yields *via* tandem intermolecular radical addition—homoallylic radical rearrangement.

Radical cyclisations and rearrangements are amongst the most powerful and versatile methods for the construction of mono and polycyclic systems.[1] Radical reduction of norbornenyl sbromide **1** or nortricyclyl bromide **4** is known to produce the same (~1:1) mixture of norbornene **2** and nortricyclene **3** (Scheme 1).[2] However, during the development of novel analgesics related to epibatidine by a strategy involving indirect skeletal interconversion of 7-aza to 2-azabicyclo[2.2.1]heptyl ring systems, we reported that radical deoxygenation of azanortricyclanol **5** delivers a single product **6**, even when R is potentially radical stabilising (*e.g.* Ar, Scheme 2).[3]

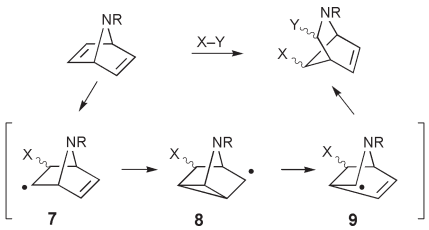


Scheme 1



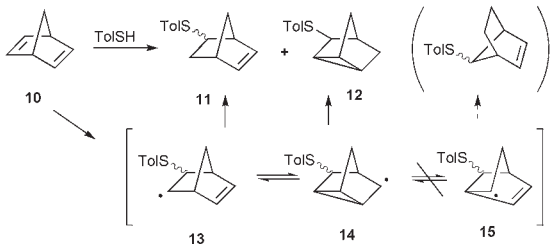
Scheme 2 *Reagents and conditions*: i, $ClCOCO_2Me$, DMAP, then Bu_3SnH, AIBN.

Following this demonstration of 'nitrogen-directed' radical rearrangement, we considered that a synthetically attractive direct skeletal interconversion might be possible by intermolecular radical addition–homoallylic radical rearrangement (Scheme 3). This would provide convergent access to synthetically important 2-azabicyclo[2.2.1]heptyl ring systems containing substitution not easily available by other methods.[4] Here we communicate our preliminary results concerning the realisation of this concept.



Scheme 3

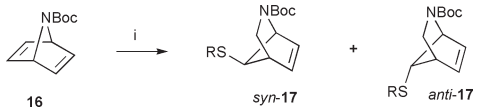
Radical additions to norbornadiene **10** (and substituted norbornadienes), using thiols for example, have been well-studied and usually result in substituted nortricyclanes as the major products.[5] Consistent with these earlier studies, we found that addition of *p*-thiocresol to norbornadiene **10** (both 2 mol dm^{-3} in toluene) at 25 °C led preferentially to nortricyclyl sulfide **12**, with bicyclic sulfide **11** (*exo*- : *endo*-, 5:1)[6] being the only other product detected (**11**:**12**, ~1:3, Scheme 4).



Scheme 4

Further experiments at increasing dilution indicated that the product ratio reached a constant level (**11**:**12**, ~ 1:6), once the concentration of each reactant was < 0.1 mol dm^{-3}. These latter results indicate attainment of equilibrium between the substituted norbornenyl and nortricyclyl radicals **13** and **14**. The presence of the sulfur substituent therefore leads to preferential cyclopropane opening in **14** back to **13** (rather than from **14** to **15**), with H-atom transfer to **14** to give nortricyclyl sulfide **12** being faster than H-atom transfer to **13** to give bicyclic sulfide **11**; hence the product profile observed does not reflect the **13**/**14** equilibrium position. This is in contrast to Scheme 1, where the rates of H-atom transfer to the norbornenyl and nortricyclyl radical intermediates leading to **2** and **3** are likely to be similar and therefore the product profile should reflect the ratio of radicals at equilibrium.

By comparison to the reactions of norbornadiene with thiols, the corresponding 7-aza systems such as **16** (available in two steps from the alkoxycarbonyl-protected pyrrole and tosyl ethyne)[7] behave in dramatically different fashion (Scheme 5, Table 1), but in accord with the earlier analysis (Scheme 3).



Scheme 5 *Reagents and conditions*: i, RSH (0.9 equiv.), benzene or toluene, 25 °C (R = aryl) or 80 °C (R = alkyl), 6–24 h.

Pleasingly, both aromatic and aliphatic thiols were found to react cleanly with only a slight excess (1.1 equiv.) of azadiene **16** in benzene or toluene (0.1 mol dm^{-3}) to give rearranged sulfides **17** in 6–72 h, depending on the reactivity of the thiol. In the case of the less reactive aliphatic thiols, heat was required for completion of the reaction in a satisfactory time. Aliphatic thiols are considerably poorer H-atom transfer agents than their aromatic counterparts.[8] This may explain the lower yields in these cases, as polymerisation could compete with atom

DOI: 10.1039/b101984h

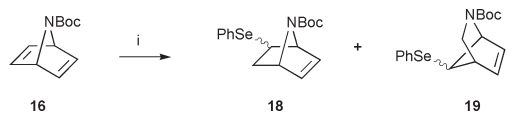
Table 1 Thiol additions to 7-azabicyclo[2.2.1]heptadiene **16**

Thiol	T/°C	*t*/h	Yield (%)	*syn*-**17**:*anti*-**17**
TolSH[a]	20	24	92	3:1
PhSH	20	24	92	4:1
2,6-diMeC_6H_3SH	20	24	90	4:1
4-$NO_2C_6H_4SH$	20	72	50	7:1
Bu^nSH	80	6	59	2:1
Bu^tSH	80	24	48	5:1
$HO(CH_2)_3SH$	80	14	56	4:1

[a] TolSH with **16** (Boc = CO_2Me) at 20 °C for 4 h gave **17** (R = Tol, Boc = CO_2Me) in 66% yield (*syn*- : *anti*-, 4:1).

transfer. The major diastereoisomer in the reaction with *p*-thiocresol was shown by NOE analysis to be the *syn*-isomer arising from initial *exo*-attack of thiyl radical on azadiene **16**, and the predominant isomer obtained with the other thiols is assigned as *syn* by analogy. Evidence that the product sulfides **17** possess the rearranged 2-azabicyclo[2.2.1]hept-5-ene framework is, for example, that oxidation of **17** (R = Tol) using buffered peracetic acid (6 equiv., 25 °C, 18 h) gave in 91% yield the epimeric sulfones **17** (RS = Ts) with spectral data distinctly different from the 2-Ts-7-Boc-7-azabicyclo[2.2.1]hept-5-enes[9] that would be obtained from oxidation of the product of simple addition across one double bond in azadiene **16**. Subsequent desulfonylation of sulfones **17** (RS = Ts) with 6% sodium–amalgam (MeOH, 25 °C, 12 h) gave the known 2-azabicyclic alkene **6** (R = H)[3,10] in 33% yield as the only identifiable product.

Benzeneselenol shows similar behaviour with unsaturated systems to aromatic thiols, but is an order of magnitude superior as an H-atom transfer agent.[8] Under otherwise identical conditions to the earlier reactions of aromatic thiols (Table 1), it was found that benzeneselenol with azadiene **16** gives a small proportion (12%) of the selenide **18** arising from simple addition across one double bond, as well as the expected rearranged selenide **19** (81%, Scheme 6).



16 18 19

Scheme 6 *Reagents and conditions*: i, PhSeH (0.9 equiv.), benzene, 25 °C, 24 h.

This result allows an estimation of the rate constant for the rearrangement **7** → **9** (Scheme 3). Given that no products other than the 2-azabicyclic epimers **17** are observed in the addition of aromatic thiols, it seems probable that the rate constant for the rearrangement is between 1 and 2 orders of magnitude greater than the initial rate of H-atom transfer from the thiol. A thiol concentration of 0.1 mol dm^{-3} (typical in our studies) and an approximate second order rate constant for H-atom transfer of 10^8 mol^{-1} dm^3 s^{-1} (ref. 8), suggests a rate constant of $\approx 10^8$—10^9 s^{-1} for the rearrangement at 25 °C.

The absence of tricyclic products in any of the reactions with azadiene **16** suggests that the lifetime of the azatricyclic intermediate **8** is much shorter than that for either of the bicyclic intermediates **7** and **9** (Scheme 3). In kinetic studies of the nortricyclyl–norbornenyl radical rearrangement [**13** (Tos = H) and **14** (Tos = H), Scheme 4], the rates of ring opening and ring closure have been shown to be similar: $\approx 10^7$ s^{-1} at 25 °C.[11] In the azabicyclic system, however, it seems probable that the ring opening step (**8** → **9**) is significantly faster, with the transition state being lowered in energy by the stabilisation of the developing radical α- to nitrogen.[12] Rate constants for the ring opening of cyclopropyl methyl radicals to but-3-enyl radicals are known to be strongly influenced by substitution.[13]

In summary, we describe the first examples of free radical additions to 7-azanorbornadienes. The process demonstrates a new approach to the 2-azabicyclo[2.2.1]heptyl ring system by homoallylic radical rearrangement, which uses a nitrogen atom to promote and guide cyclopropane ring opening.[3,14] Extensions of the principle to other addition reactions, different ring systems and manipulation of the adducts towards targets of biological interest, are under investigation.

We thank AstraZeneca Pharmaceuticals and the EPSRC for an Industrial CASE award (to M. W. P. B.) and the EPSRC National Mass Spectrometry Service Centre for mass spectra. We also thank Professors S. J. Cristol and B. Giese for useful discussions and Dr B. Odell for expert assistance with structure elucidation using NMR.

Received (in Corvallis, OR, USA) 4th January 2001, Accepted 29th March 2001
First published as an Advance Article on the web 24th April 2001

We report the first experimental solid-state ^{17}O NMR and theoretical (B3LYP/6-311++G) study of the ^{17}O electric-field-gradient and chemical shielding tensors in a free nucleic acid base, thymine.**

NMR spectroscopy is an important technique for studying structures of biological macromolecules. Most successful NMR applications have been based primarily on observation of spin-1/2 nuclei such as ^{1}H, ^{13}C and ^{15}N. Although oxygen is also an important element in biological molecules, ^{17}O (S = 5/2 and natural abundance = 0.037%) NMR studies are far less common.[1] To explore the potential of solid-state ^{17}O NMR spectroscopy in studying organic and biological compounds, we recently investigated a number of important oxygen-containing functional groups such as amides,[2] urea,[3] carboxylic acids,[4] phenols[4] and the oxonium ion.[5] Oxygen is also common in nucleic acids. Base pairing between nucleic acid molecules often directly involves oxygen atoms, *e.g.* G:C and A:U base pairing. To our knowledge, solid-state ^{17}O NMR has not been applied to compounds related to nucleic acids.

As a first step, we report solid-state ^{17}O NMR results for a free nucleic acid base, thymine; see Fig. 1. We synthesized [2-^{17}O]thymine and [4-^{17}O]thymine by acid-catalyzed exchange with $H_2{}^{17}O$ (40.9 atom% ^{17}O, ISOTEC, Miamisburg, Ohio) from 5-methyl-2-thiouracil and thymine, respectively. Solid-state ^{17}O NMR spectra were recorded on a Bruker Avance-500 spectrometer operating at 67.78 MHz for ^{17}O nuclei. Fig. 2 shows the experimental and simulated ^{17}O magic-angle spinning (MAS) NMR spectra of [2-^{17}O]thymine and [4-^{17}O]thymine. Analysis of these spectra yielded the following ^{17}O NMR parameters: O2, δ_{iso} = 200 ± 5 ppm, C_Q = 6.65 ± 0.02 MHz, η_Q = 1.00 ± 0.02; O4, δ_{iso} = 325 ± 5 ppm, C_Q = 8.40 ± 0.02 MHz, η_Q = 0.10 ± 0.02. Following the standard procedure,[2,6] we were also able to analyze the stationary ^{17}O NMR spectra shown in Fig. 2 and obtain the magnitude and relative orientation of the ^{17}O chemical shift (CS) tensors. The results are summarized in Table 1.

It can be seen from Table 1 that O2 and O4 exhibit drastically different ^{17}O NMR tensors. In particular, the amide-type oxygen, O4, shows a much larger C_Q, 8.40 MHz, than the urea-type oxygen, O2, 6.65 MHz. The difference between the ^{17}O CS tensors for O2 and O4 is also striking. The isotropic ^{17}O chemical shifts for O2 and O4 differ by 125 ppm. In addition, the span ($\Omega = \delta_{11} - \delta_{33}$) of the ^{17}O CS tensor for O4 is more than twice of that for O2. It is also apparent from Table 1 that, whereas the isotropic ^{17}O chemical shifts measured for O4 in the solid and solution states are essentially identical, the corresponding values for O2 differ by approximately 50 ppm! This is clearly a consequence of the strong intermolecular hydrogen-bonding interaction at O2 in crystalline thymine; see Fig. 1.

In order to evaluate quantitatively the influence of intermolecular hydrogen bonding interactions on the ^{17}O EFG and CS tensors in crystalline thymine, we chose to perform quantum chemical calculations using four different models. Model-I is simply an isolated thymine molecule. Model-II consists of two hydrogen-bonded thymine molecules, **1** and **2** as defined in Fig. 1. Model-III also consists of two thymine molecules, **1** and **3**. Model-IV is a trimeric cluster containing **1**, **2** and **3**. The experimental X-ray diffraction structure of thymine[7] was used in all the calculations. The positions of the hydrogen atoms were computed using the standard bond lengths and angles. The density functional theory (DFT) calculations were performed on a PC (400 MHz Pentium II processor, 128 MB RAM, 12 GB of

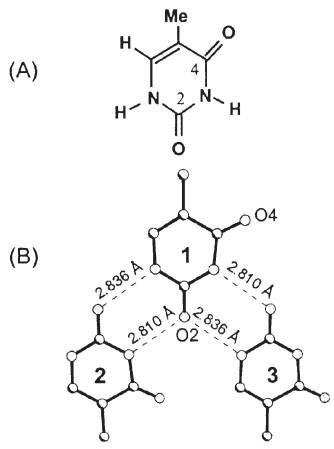

Fig. 1 (A) Chemical structure of thymine. (B) H-bond environment in crystalline thymine.[7] Thymine molecules are related by twofold screw axes. Hydrogen atoms are not shown for clarity.

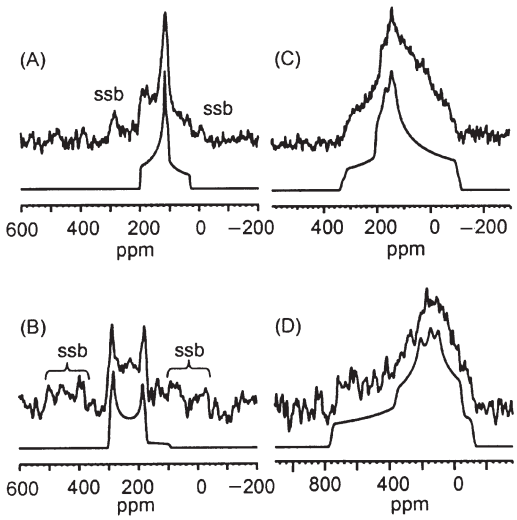

Fig. 2 Experimental (upper) and simulated (lower) ^{17}O MAS NMR spectra of (A) [2-^{17}O]thymine (3753 scans) and (B) [4-^{17}O]thymine (5236 scans). Experimental (upper) and simulated (lower) ^{17}O stationary NMR spectra of (C) [2-^{17}O]thymine (7400 scans) and (D) [4-^{17}O]thymine (5376 scans). The sample spinning frequency was 14.5 kHz. The B_1 field strength at the ^{17}O frequency was about 70 kHz. Spinning sidebands are marked as 'ssb'. A Hahn-echo pulse sequence was used in acquiring the stationary spectra. The recycle time was 10 s in all experiments.

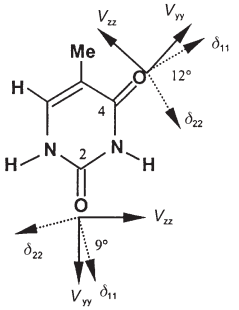

Fig. 3 Illustration of the orientations of the ^{17}O NMR tensors in thymine.

disk space) using Gaussian 98 program[8] with the standard 6-311++G** basis set and the B3LYP exchange functional.[9] The theoretical results are also presented in Table 1.

Close examination of the theoretical results reveals a remarkable difference between the ^{17}O NMR tensors for O2 and O4. In particular, both the ^{17}O quadrupole coupling tensor and the CS tensor at O2 exhibit a strong dependence on the cluster model used in the calculation, whereas the ^{17}O NMR tensors at O4 are essentially independent of the model. This clearly reflects the difference in the H-bond environment between O2 and O4. In the discussion that follows, we focus only on the ^{17}O NMR tensors for O2. As seen from Table 1, Model-I predicted Ω = 393 ppm and C_Q = 8.42 MHz for O2, which are considerably larger than the observed values, Ω = 270 ppm and C_Q = 6.65 MHz. When two H-bonds were considered in either Model-II or Model-III, smaller values were obtained for Ω and C_Q. When a complete H-bond network is included in the calculation (Model-IV), the theoretical results become much closer to the experimental values, Ω= 282 ppm and C_Q = 7.12 MHz. The observed decrease in the isotropic ^{17}O chemical shift (increase in *shielding*) from Models I to IV results mainly from the changes in δ_{11} and δ_{22}. The large difference between the isotropic ^{17}O chemical shifts measured in the solid state and in solution, 200 *vs*. 247.8 ppm, was well reproduced by the calculations of Model-I and Model-IV. The quadrupole coupling constant exhibits a reduction of approximately 1.3 MHz upon hydrogen bonding, the ^{17}O EFG tensor increases monotonically from Models I, II, III to IV. Finally, the agreement between the calculated results from Model-IV and the experimental data is reasonable; but it is also clear that all calculated ^{17}O NMR parameters are larger than the observed values by approximately 10%. These discrepancies are likely due to the limitation of the current theory.

Another piece of useful information from the quantum chemical calculations is the absolute orientations of ^{17}O NMR tensors in the molecular frame. As seen from Fig. 3, the *orientations* of the ^{17}O NMR tensors for O2 and O4 are similar, despite the large difference in the magnitude of the individual tensor components. It should be noted that the relative orientation between the ^{17}O EFG and CS tensors shown in Fig. 3 is in agreement with the experimental determination from the analysis of static ^{17}O NMR spectra.

In summary, we have presented the first solid-state ^{17}O NMR study of a free nucleic acid base. The present study demonstrates that it is feasible to obtain solid-state ^{17}O NMR spectra for ^{17}O-labeled nucleobases and that ^{17}O NMR *tensors* are excellent indicators of H-bond formation. These features are potentially useful for probing base pairing in nucleic acids. With the availability of very high magnetic fields (18.8 T or higher) and the advances in solid-state NMR methodology, it is anticipated that solid-state ^{17}O NMR will become a new addition to the arsenal for studying biological macromolecules.

G. W. thanks NSERC of Canada for research and equipment grants, Queen's University for a Chancellor's Research Award and the Government of Ontario for a Premier's Research Excellence Award. This research was partially supported by a grant from the Advisory Research Committee of Queen's University.

Evidence for weak base site participation in the vapour phase methylation of catechol over solid base catalysts

Received (in Cambridge, UK) 15th February 2001, Accepted 2nd April 2001
First published as an Advance Article on the web 24th April 2001

The vapour phase alkylation of catechol over supported caesium catalysts gives good selectivity to guaiacol formation, and TPD studies indicate that this result can be correlated with the presence of weak basic sites on the catalyst.

Vapour phase alkylation of catechol is commercially important for the production of oxy-alkylated products, namely guaiacol and veratrole. These are synthetic intermediates used in the production of flavourings, fragrances and pharmaceuticals.[1] Studies on phenol alkylation have shown that product selectivity depends on the acid–base property of the catalyst surface.[2] The addition of metal ions to alumina is known to generate new active sites which are basic in nature.[3] Available literature on the vapour phase alkylation of catechol over solid base catalysts, though limited, suggests that the basic sites are primarily responsible for the formation of C-/O-alkylated products.[4,5] This is further supported by the report that CO_2 adsorption over the basic sites leads to catalyst deactivation.[6,7] However, there is no evidence to suggest that the weak sites over the base catalysts are primarily important for the formation of mono oxy-methylated products, in particular guaiacol. Here, for the first time, such a correlation is proposed, *i.e.* that a correlation exists between the weak base sites on a catalyst surface and selectivity to guaiacol.

The supported caesium catalysts were prepared by impregnating Al_2O_3, SiO_2 and TiO_2, all of commercial origin, with an appropriate amount of an aqueous solution of caesium hydroxide (10% Cs by mass). The resulting solids were dried and calcined in air at 673 K for 4 h. Temperature programmed desorption (TPD) was performed using CO_2 gas at a heating rate of 10 K min^{-1} in the temperature range 373–973 K.

The vapour phase alkylation of catechol with methanol was carried out in a vertical flow-type reactor at 623 K at atmospheric pressure (*ca.* 650 mm Hg). Before the start of the experiment, the catalyst (*ca.* 2 g) was activated in the reactor at 673 K for 1 h in nitrogen and then the solid was cooled to the reaction temperature. A pre-mixed catechol–methanol (1 : 3 w/w ratio) mixture was fed from the top of the reactor at a fixed rate of 5.1 ml min^{-1} (methanol-free catechol flow rate 0.95 mol h^{-1}) by means of a Sage syringe pump. After 1 h the liquid products were analysed by GC (FID) using a DB-1 capillary column. The reaction products were further confirmed by GC–MS (VG-11-250 data system) and ^{13}C NMR (Brucker AC-400) spectroscopy.

The reaction data for the vapour phase alkylation of catechol over unsupported and supported catalysts are shown in Table 1. The acidic oxides (Al_2O_3, SiO_2 and TiO_2) do not show much guaiacol formation. However, the basic oxide MgO shows a selectivity of 65% for guaiacol. This suggests that the basic sites on the catalyst *surface* are involved in the formation of guaiacol. It is interesting to note that caesium oxide alone shows a low activity and selectivity towards guaiacol formation. However, impregnation of caesium on to the acidic oxides (Al_2O_3, SiO_2 and TiO_2), increased the selectivity for guaiacol significantly. Both alumina and caesium-modified alumina show the highest reaction activity as compared to the other unsupported and supported oxides. This suggests that the stronger and larger number of acidic sites on the catalyst surface promotes more ring alkylation than side (O-) alkylation. In the case of both alumina and caesium-modified alumina a significant amount of polyalkylated products is also formed. The formation of phenol, and to a lesser extent diphenyl ether, indicates that both dehydration and ring alkylation are the two competitive

Table 1 Reaction data on unsupported and supported cesium catalysts

reactions operating over the acidic sites. This is supported by the fact that both TiO_2 and $Cs–TiO_2$ show a significant amount of dehydrated products as compared with Al_2O_3 and $Cs–Al_2O_3$ catalysts.

The distribution of basic sites over unpromoted and promoted catalysts are shown in Fig. 1 and 2. The TPD profiles of CO_2 over Al_2O_3 and MgO (Fig. 1) show that although Al_2O_3 is more

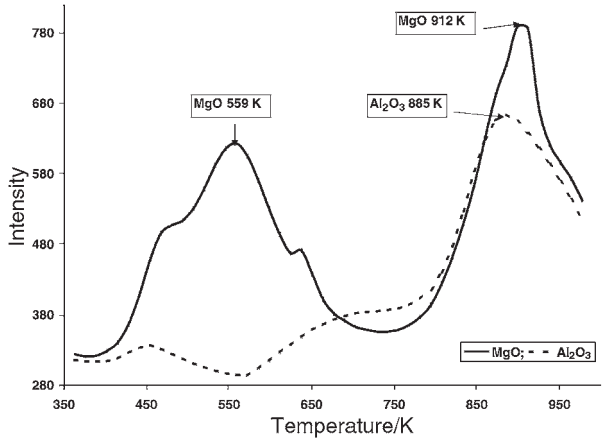

Fig. 1 CO_2 TPD profiles of MgO and Al_2O_3.

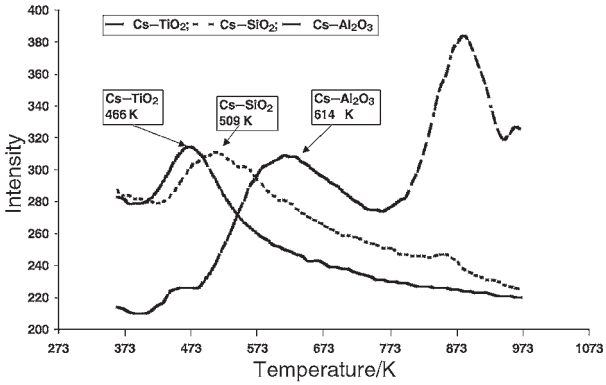

Fig. 2 CO_2 TPD profiles of Cs on TiO_2, SiO_2 and Al_2O_3.

acidic than MgO it also has a larger number of strong basic sites (885 K) with respect to MgO (912 K). The stronger basic sites on MgO at 912 K indicate that, apart from O^{2-} basic sites of MgO, the adjacent Mg^{2+} sites may also participate in CO_2 adsorption.[8] On the other hand, MgO has a greater number of weaker basic sites (559 K) than Al_2O_3. The fact that more guaiacol is formed on MgO than Al_2O_3 indicates that weaker basic sites may be primarily involved for the higher selectivity of guaiacol. Fig. 2 clearly demonstrates this finding. Here it is seen that addition of caesium to acidic supports transforms stronger base sites into weak sites, thus enhancing the selectivity for guaiacol. The higher selectivity for guaiacol at weaker basic sites over $Cs–SiO_2$ (75%) as compared with $Cs–Al_2O_3$ (58%) further supports the assumption that the formation of guaiacol is related to the strength and the number of the weak basic sites. However, in the case of $Cs–TiO_2$, the lower selectivity for guaiacol (37%) may suggest the possibility of an interaction between the promoter and titania, leading to compound formation.

In conclusion, it is evident from the foregoing results that the transformation of stronger basic sites to weaker ones upon addition of Cs_2O results in higher selectivity for guaiacol. Further work is in progress to explain the characteristic aspects of the title reaction in detail.

We wish to thank the University, THRIP and the NRF for financial support. The leave of absence granted by IICT, India, to V. V., to spend time at the University of the Witwatersrand, is acknowledged.

Metallaboranes of the earlier transition metals. An *arachno* nine-vertex, nine-skeletal electron pair rhenaborane of novel shape: importance of total vertex connectivities in such systems

Received (in Irvine, CA, USA) 28th February 2001, Accepted 3rd April 2001
First published as an Advance Article on the web 24th April 2001

The synthesis and characterization of $Cp^*_2Re_2B_7H_{11}$ provides the first example of an open hypoelectronic metallaborane which is shown to possess an *arachno* geometry based on a total vertex connectivity identical with that of a canonical *arachno* nine-vertex, twelve-skeletal electron pair cluster.

Extensive catenation is a characteristic shared by the adjacent elements boron and carbon albeit expressed differently in structure, *e.g.* cages *vs.* rings and chains. The origin of the differences is well understood and the established relationship between geometry and the number of skeletal electron pairs (sep) for borane cages serves to provide interconnections between borane, heteroborane, carbocation, transition metal cluster and Zintl phase cluster chemistries.[1–6] The metal sites in a heteroborane, *e.g.* a metallaborane, perturb the borane bonding network and the structural response can be measured.[7,8] In an expression of the isolobal analogy, metallaboranes containing late transition metals frequently mimic simple main group fragments generating geometries that conform to the canonical structures associated with equivalent sep (the term cannonical refers to the set of shapes and associated sep's exhibited by the known boranes).[9,10]

The observations of Kennedy and coworkers of 'disobedient' metallaboranes[11] with *closo* geometries deviating from most spherical deltahedra (most homogeneous vertex connectivities)[12] have been interpreted in terms of a metal providing more orbitals to meet the $p + 1$ sep rule ('*isocloso*'–missing electrons localized on the metal)[13] or fewer electrons (p sep) demanding a skeletal shape with no borane analog ('*hypercloso*'–missing electrons delocalized over the skeleton).[14] Despite these contrasting analyses, what is clear is that the observed geometric structures are related by diamond–square–diamond (dsd) rearrangements.[15] Recently, we have described a homologous series of *closo*-metallaboranes, $Cp^*_2Re_2B_nH_n$ (n = 7–10, Cp^* = η^5-C_5Me_5), with $p - 2$ sep.[16] In addition, we completed a 10-atom, closed metallaborane series for sep running from $p + 1$ to $p - 2$.[17,18] These results demonstrate that the formal sep can vary widely from the canonical number and, as it decreases, the cluster shape deviates from that of a most spherical deltahedron. Taking the canonical shapes and sep's as the standard, we follow Corbett and designate these compounds as hypoelectronic.[19] Note that because hypoelectronic and canonical structures are related by dsd rearrangements, the total connectivity of the deltahedral framework is the same for a given value of p.

Kennedy and coworkers have also described examples of '*isonido*' metallaboranes ($p + 1$ sep) related to canonical *nido* geometries ($p + 2$ sep) in the same manner as '*isocloso*' are to *closo*.[11] For this reason we have sought examples of open clusters of the earlier metals in which the formal sep is even lower. Herein we describe an open rhenaborane with p sep and show how it can be classified as an *arachno* shape which normally requires $p + 3$ sep.

As previously reported, the reaction of BH_3·thf with $Cp^*_2Re_2H_4B_4H_4$ leads to the formation of $Cp^*_2Re_2B_7H_7$ and subsequent conversion to the higher analogs.[16,20,21] A minor product with an R_f higher than $Cp^*_2Re_2B_7H_7$ was greatly enhanced by using a lower borane to metallaborane ratio and reduced temperature and reaction time.† This new compound, **1**, has been isolated in modest yield and characterized spectroscopically and by a single crystal X-ray diffraction study.‡ The molecular mass corresponds to $Cp^*_2Re_2B_7H_{11}$ **1**, and the ^{1}H (temperature independent to −90 °C) and ^{11}B NMR spectra suggest two planes of symmetry. Besides the $BH_{terminal}$ protons (1 : 2 : 4) two equivalent BHB and two equivalent BHRh protons are also observed. A ^{1}H/^{11}B HETCOR experiment shows the latter four protons to be coupled exclusively to the four boron atoms equivalent in the NMR spectrum.

The framework structure of **1** only became clear when the solid state structure was determined (Fig. 1). Yet again an unanticipated shape is observed for a rhenaborane. **1** displays an open structure such that the edges defining the opening describe a boat shaped cyclohexane-like ring. Although the B–B and Re–B distances are comparable to those found in $Cp^*_2Re_2B_7H_7$[22,23] and higher homologues,[16] the ReRe distance is *ca.* 0.15 Å longer. On the other hand it is nearly the same as the W–W distance in $Cp^*_2W_2H_2B_7H_7$[20,21] and, thus, we suggest the presence of cross-cage metal–metal bonding in **1**. Based on the NMR results, the extra hydrogens can be placed on this skeleton in two ways as shown in Fig. 2(a) and (b). In (a) the ReH hydrogens lie in the plane of symmetry containing the two Re atoms and the unique B atom. In (b) they bridge two of the four

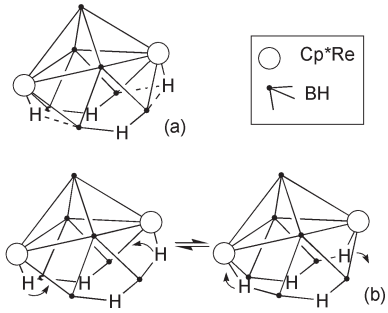

Fig. 2 Two possible placements of the four endo hydrogen atoms on **1**.

Re–B edges on the hexagonal opening thereby demanding a low barrier process for the exchange shown. We favor (b) as it is difficult to explain the observed coupling to boron with model (a).

As the Cp*Re fragment is a zero-electron fragment, the formal number of sep in **1** is 9; however, we find no way of connecting the geometry of **1** to either the canonical deltahedra or the observed deltahedra of $Cp^*_2Re_2B_nH_n$, (n = 7–10) by simple vertex removal. Therefore, we suggest an alternative approach which promises some generality. As already mentioned, the geometries adopted by $Cp^*_2Re_2B_nH_n$ (n = 7–10), have total vertex connectivities (tvc) equal to those of the canonical deltahedra, *e.g.* $Cp^*_2Re_2B_7H_7$ possesses two six-coordinate, two five-coordinate, five four-coordinate vertices (tvc = 42) whereas the canonical tricapped trigonal prism has six five-coordinate, three four-coordinate vertices (tvc = 42). An examination of the canonical *closo* series for p = 6–12 shows that the tvc increases monotonically in units of 6, *i.e.* tvc runs from 24 to 60.[16] This holds true for $Cp^*_2Re_2B_nH_n$ (n = 7–10) as well.[15] Likewise, if one uses Williams' preferred *nido* and *arachno* geometries,[24] one finds, that for *nido* cages, p = 6–11, tvc runs from 20 to 50 in units of 6 and for *arachno* cages, p = 6–10, tvc runs from 18 to 42 in units of 6. The assumption that tvc is conserved for *nido* and *arachno* structures, as already demonstrated for *closo* structures, yields a shape independent method for classifying non-canonical geometries.

Consider the new rhenaborane. **1** has an open structure with a tvc = 36. The canonical nine fragment *closo, nido* and *arachno* shapes have tvc's of 42, 38 and 36, respectively (Fig. 3). Thus, **1** is classified as a 9 sep *arachno* analog of a 12 sep canonical *arachno* borane. This parallels the relationship of 7 sep *closo* $Cp^*_2Re_2B_7H_7$ to a 10 sep *closo* canonical cage. The beauty of the approach is that it avoids the question of how many electrons a metal fragment actually contributes to cluster bonding ('*isocloso' vs. 'hypercloso'*) and suggests that, provided tvc is conserved, the shape adopted can be tailored to the electronic demands of the metal. The drawback is that, although this approach limits the number of shapes possible, it is not predictive. However, with the characterization of an increasing number of metallaboranes containing earlier metals, the role of the metal may eventually become sufficiently well defined to permit predictions as well as rationalizations.

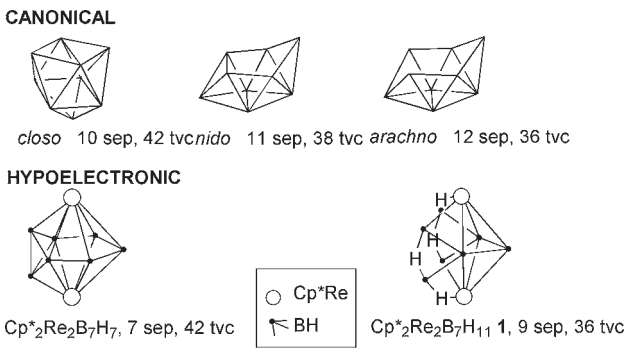

Fig. 3 Comparison of the canonical nine-atom *closo*, *nido* and *arachno* geometries with observed examples of *closo* and *arachno* hypoelectronic rhenaboranes with formal sep's three lower than the canonical values.

† *Synthetic procedure* for **1**: to a 100 mL Schlenk tube, containing 0.15 g (0.21 mmol) of $(Cp^*ReH_2)_2B_4H_4$ in 15 mL of toluene was slowly added a three-fold excess of BH_3·thf. The reaction mixture was thermolysed for 15 h at 75 °C after which volatiles were removed *in vacuo*, the residue was extracted in hexane, and the extract filtered through Celite. After removal of solvent from the filtrate, the residue was chromatographed on silica gel TLC plates. Elution with hexane yielded four very closely spaced bands. The first yellow band to elute was $Cp^*_2Re_2B_7H_{11}$ **1** (0.026 g, 17%) and the subsequent bands were $(Cp^*Re)_2B_nH_n$ (n = 7–10).

Selected data for **1**: ν(hexane)/cm^{-1} 2498w, 2444w (B–H_{term}); δ_H(C_6D_6, 22 °C) 10.61 (pcq, 1BH_t), 7.51 (pcq, 4BH_t), 0.72 (pcq, 2BH_t), 0.04 (br, 2B–H–B), 1.76 (s, 30H, 2Cp*), −10.77 (s, 2Re–H–B); δ_B(C_6D_6, 22 °C, J/Hz) 98.1 (d, J_{BH} 162, 2B), 28.3 (d, J_{BH} 130, 4B), −7.2 (d, J_{BH} 141, 2B); HR-EIMS, m/z: $^{12}C_{20}{}^{1}H_{41}{}^{11}B_7{}^{187}Re_2$, calc. 732.2982, obs. 732.2948; isotope distribution corresponding to 7B, 2Re.

‡ *Crystal data* for $(Cp^*Re)_2B_7H_{11}$: M = 759.5, triclinic, $P\bar{1}$, yellow, a = 8.7967(2), b = 17.7865(3), c = 18.0509(4) Å, α = 111.5640(10), β = 102.924(2), γ = 99.4110(10)°, V = 2464.21 Å^3, Z = 4, Z' = 2, D_c = 2.046 g cm^{-3}, μ(Mo-Kα) = 98.2 cm^{-1}, $R(F)$ = 0.0485, $R(wF2)$ = 0.1372. Of 20 160 reflections collected, 8614 were independent. All non-hydrogen atoms were refined anisotropically. All Cp* hydrogen atoms were placed in idealized locations; the seven terminal B–H hydrogen atoms were located and refined. The four bridging hydrogen atoms were not located. CCDC 155582. Extremely high *trans* selectivity of Ti-MWW in epoxidation of alkenes with hydrogen peroxide

Peng Wu and Takashi Tatsumi*

Division of Materials Science & Chemical Engineering, Faculty of Engineering, Yokohama National University, 79-5 Tokiwadai, Hodogaya-ku, Yokohama 240-8501, Japan. E-mail: ttatsumi@ynu.ac.jp

Received (in Cambridge, UK) 13th February 2001, Accepted 16th March 2001
First published as an Advance Article on the web 24th April 2001

A novel titanosilicate with MWW topology, Ti-MWW, exhibits a behavior not observed on other titanosilicates such as TS-1, TS-2 and Ti-beta, in that it selectively epoxidizes *trans* isomers from a mixture of *cis*/*trans* alkenes with retention of stereochemistry.

The microporous titanosilicate TS-1 of MFI structure has attracted considerable attention of researchers since it is found to be an effective liquid-phase catalyst in the oxidation of various organic compounds using dilute hydrogen peroxide as an oxidant.[1] Ti-beta,[2,3] Ti-MOR[4] and Ti-ITQ-7[5] have also been prepared successfully with a purpose to make full use of various zeolite structures. Recently, we turned our attention to MWW zeolite (typically known as MCM-22[6]) because it has the structural diversity of supercages, 10-membered ring (MR) channels and side pockets, succeeding for the first time in preparing its titanosilicate derivative, Ti-MWW.[7]

In the epoxidation of lower olefins, Clerici *et al*. reported that TS-1 was more active for *cis*-but-2-ene than for *trans*-but-2-ene, which made TS-1 applicable to the production of epoxy derivatives with *cis*-configuration by starting from a mixture of alkenes containing *cis*/*trans* isomers.[8] We also observed that TS-1 was more selective for the *cis* isomers in the epoxidation of a *cis*/*trans* mixture of hex-2-enes.[9] The *cis*-selectivity of TS-1 is attributed to the higher reactivity of the *cis* isomer in epoxidation of various C_4 olefins.[1,8] However, we have discovered a totally opposite catalytic feature of Ti-MWW in the epoxidation of olefinic stereoisomers, which may bring about reconsideration of the stereoselectivity of titanosilicates in olefin epoxidation and give rise to investigation of the relationship between shape selectivity and microstructure of Ti active sites.

Ti-MWW was prepared by treating a Ti-containing lamellar precursor with MWW topology with acid solution, and subsequent calcination. The Ti-containing precursor was hydrothermally synthesized from fumed silica (Cab-o-sil M7D) and tetrabutyl orthotitanate in the presence of boric acid and using piperidine as a structure-directing agent (SDA) as reported in detail elsewhere.[7] Acid treatment with 2 M HNO_3 on the lamellar precursor removed extraframework Ti species together with some framework boron. The samples were then calcined in air at 803 K to burn off the organic SDA to obtain the Ti-MWW catalysts. The samples were proved to have the MWW topology by X-ray diffraction, and contain only isolated Ti species in the framework as evidenced by the predominant band at 220 nm in the UV–VIS spectrum (Fig. 1).

Other titanosilicates for control experiments, TS-1, TS-2, Ti-beta and Ti-MOR were prepared by a hydrothermal synthesis method or post-synthesis method using $TiCl_4$ vapor.[4] The liquid-phase oxidation of *cis*/*trans* mixtures of alkenes with hydrogen peroxide was carried out at 333 K in a round-bottom flask (20 ml) fitted with a condenser and a magnetic stirrer. For a typical run, a mixture of 0.05 g of catalyst, 10 mmol of alkenes, 10 mmol of hydrogen peroxide (31 wt% aqueous solution) and 10 mL of solvent was heated at a set temperature under vigorous agitation. The reaction mixture was analyzed using a gas chromatograph (Shimadzu 14 B) equipped with a 50 m OV-1 capillary column. The amount of hydrogen peroxide remaining in the reaction mixture was determined by titration with 0.1 M $Ce(SO_4)_2$ solution.

Table 1 shows the results of epoxidation of hex-2-ene isomers with a *cis*/*trans* ratio of 41 : 59 over various titanosilicates. The major products were 2,3-epoxyhexane with both *cis*- and *trans*-configurations. A small amount of diol product due to epoxide hydrolysis over acid sites was also obtained, especially for Ti-beta, owing to the rather strong acidity relating to the framework Al. The conversion of hex-2-enes depended greatly on the reaction conditions; Ti-MWW showed the highest specific catalytic activity in MeCN and higher efficiency in H_2O_2 utilization. What is more interesting is that Ti-MWW exhibited an extremely high selectivity for the epoxide with *trans*-configuration, while TS-1, TS-2, Ti-beta and Ti-MOR produced the *cis*-epoxide with a selectivity higher than the percentage of *cis*-isomer in the initial substrate. The selectivity of Ti-MWW for *trans*-epoxide was independent of its Ti content (entries 1–3) and the reaction time (entries 2 and 4) although the conversion increased with increase in Ti content. This unique property was not affected when using the protic solvent MeOH though the conversion was greatly decreased (entry 5). Furthermore, in the epoxidation of other olefins such as hept-2-enes, hept-3-enes and oct-2-enes all with a *cis*/*trans* ratio of 50 : 50, Ti-MWW showed a selectivity of 80, 72 and 81% for the corresponding *trans*-epoxides, respectively. All these findings allow us to draw the conclusion that Ti-MWW is a catalyst with a unique selectivity in the epoxidation of a mixture of *cis*/*trans* isomers.

Since the epoxidation of a mixture of *cis*/*trans* isomers is a competition reaction, the reaction of individual isomers would make the matter clearer. Fig. 2 compares Ti-MWW with TS-1 for the epoxidation of *cis*- and *trans*-oct-2-enes. Retention of seterochemical configuration was found for both Ti-MWW and TS-1, *i.e*. *cis*-oct-2-ene gave exclusively the *cis*-epoxide, and *trans*-oct-2-ene resulted in the *trans*-epoxide. This indicates no isomerization occurred during the reaction for both the substrate and epoxide. Ti-MWW exhibited the reactivity order of *trans*-oct-2-ene > *cis*-oct-2-ene, while TS-1 showed the reverse order. The higher reactivity of the *trans* isomer on Ti-MWW is

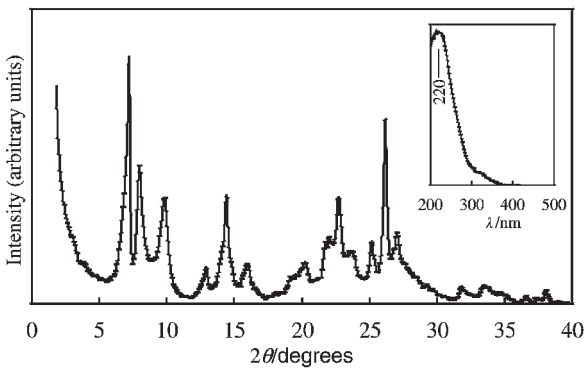

Fig. 1 X-Ray diffraction pattern and UV–VIS spectrum of Ti-MWW (Si : Ti = 64).

Table 1 Epoxidation of hex-2-ene isomers with hydrogen peroxide over various titanosilicates

				Prod. sel. (mol%)		Epoxide distribution (mol%)[a]		H_2O_2 (mol%)

[a] Cat., 0.05 g; hex-2-enes (*cis*/*trans* = 41 : 59), 10 mmol; H_2O_2, 10 mmol; MeCN, 10 ml; temp., 333 K; time, 2 h. [b] The reaction time was 5 min. [c] MeOH used as solvent.

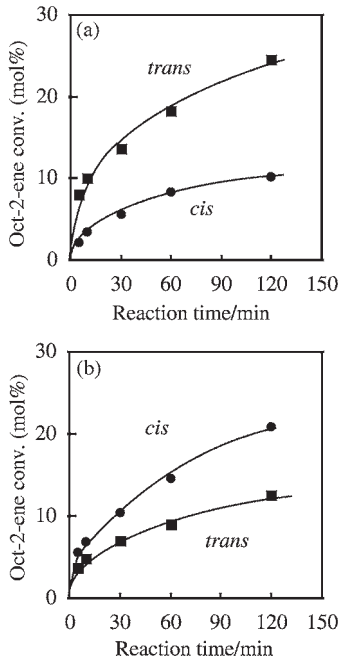

Fig. 2 Epoxidation of *cis* and *trans*-oct-2-ene over Ti-MWW (a) and TS-1 (b). Cat., 0.05 g; oct-2-ene, 10 mmol; H_2O_2, 10 mmol; MeCN, 10 mL; temp., 333 K.

thus consistent with its unique selectivity observed above in the reaction of mixtures.

Liquid-phase adsorption of a hex-2-ene mixture using the bulky solvent 1,3,5-triisopropylbenzene was carried out to investigate the different catalytic behavior between Ti-MWW and other titanosilicates. TS-1 adsorbed more selectively the *trans* isomer with smaller molecular size because of its medium pores of 10-MR. However, Ti-MWW, containing both 10-MR and 12-MR pores, exhibited similar adsorption phenomena to large-pore Ti-beta, that is, both adsorbents showed no obvious difference in the adsorption rate for the two isomers. Therefore, the high *trans* selectivity of Ti-MWW is not due to easier accommodation for the *trans* isomers.

Selective poisoning of the Ti sites in open space side pockets with 2,4-dimethylquinoline resulted in an unchanged conversion of hex-2-enes and the same *trans* selectivity for the epoxide, which indicates little contribution of the side pockets to the present epoxidation reactions. Therefore, the unique selectivity of Ti-MWW is presumed to originate mainly in its 10-MR channels and supercages, both restricted by 10-MR entrances. In particular, the 10-MR system of the MWW structure is defined by two-dimensional sinusoidal channels.[10] The unique tortuosity of the sinusoidal configuration would make the alkene molecules of *trans* configuration approach more easily to the Ti species than those of *cis* configuration, so resulting in higher *trans* selectivity. On the other hand, the channels of TS-1 and Ti-beta are suggested to favor the *cis* molecules approaching the Ti sites, owing to the characteristic tunnel-like channel structures. Further investigation in more detail is still required to clearly determine how the microstructure of Ti active sites affects the selectivity for substrates of different configurations. Nevertheless, the uniqueness of Ti-MWW strongly suggests the importance of considering 'steric compatability' between the substrate molecules and the Ti species when investigating shape selectivity.

As a result, this study clearly shows that Ti-MWW is an unusual catalyst in the oxidation of alkene stereoisomers, revealing a new concept of shape selectivity in constrained spaces in zeolite crystals.

First structural characterization of a mixed valent thallium(I/III) amide bearing an *n*-butylthallium(III) unit stabilized by a tripodal amido ligand

Christian H. Galka and Lutz H. Gade*

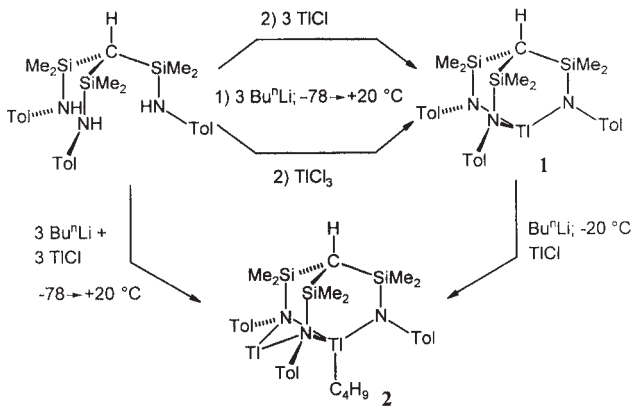
Laboratoire de Chimie Organométallique et de Catalyse, UMR 7513, Institut Le Bel, Université Louis Pasteur, 4, rue Blaise Pascal, 67000 Strasbourg, France. E-mail: gade@chimie.u-strasbg.fr

Received (in Cambridge, UK) 22nd January 2001, Accepted 10th April 2001
First published as an Advance Article on the web 24th April 2001

Lithiation of the tripodal amine HC{SiMe$_2$NH(*p*-Tol)}$_3$ with Bu^{n}Li in the presence of TlCl yielded the Tl(I/III) mixed valent complex [HC{SiMe$_2$N(*p*-Tol)}$_3$(TlBu^n)(Tl)] 2; an X-ray diffraction study established the central *n*-butyl–thallium(III) unit coordinated by the amido tripod in which two of the amido functions are additionally bridged by the Tl(I) atom.

The chemistry of formally closed shell low valent heavy p-block metals is characterized by unusual patterns of aggregation in the solid state through attractive metal–metal interactions.[1,2] We have recently begun to systematically investigate the structural chemistry of amidothallium(I) compounds in which the metal atoms occupy exposed positions thus making the molecules potential building blocks for larger aggregates.[3,4] The tripodal amido ligands developed by us were found to provide the platform for a whole series of polynuclear thallium(I) amides.[5,6] These are generally obtained by metal exchange reaction of the *in situ* generated or isolated lithium amides with TlCl in an ether or hydrocarbon solvent. In all cases the complete lithiation of the amine precursor was achieved before the metal exchange step. A simultaneous reaction of the alkyllithium reagent and thallium(I) chloride was expected to yield products which differ significantly from the compounds studied to date, and provide an entry into new types of mixed amido/alkylthallium complexes. Here, we report the remarkable first results of these variable metallation strategies.

Complete lithiation of the tripodal amine HC{SiMe$_2$NH(*p*-Tol)}$_3$ with Bu^{n}Li and subsequent reaction with either 3 molar equivalents of TlCl or 1 equivalent of $TlCl_3$ gave the Tl^{III} amide [HC{SiMe$_2$NH(*p*-Tol)}$_3$Tl] **1** which was characterized by elemental analysis as well as ^{1}H and ^{13}C NMR spectroscopy (Scheme 1).† However, upon carrying out the lithiation and transmetallation in one step by addition of 3 molar equivalents of *n*-butyllithium and thallium(I) chloride to the amine at



Scheme 1 Preparative routes leading to compounds **1** and **2**. In the conversion of **1** → **2** Bu^{n}Li probably first adds across one Tl^{III}–N bond alkylating the Tl^{III} centre. Subsequent Li–Tl^I exchange then gives **2**.

−78 °C in *n*-pentane and subsequent slow warming to ambient temperature over a period of 15 h a different type of compound was obtained as a yellow–orange crystalline solid **2**. The yield of the compound isolated in several preparations varied between 15 and 35% based on the amine starting material. The same material was isolated in higher yield (*ca.* 50%) upon reaction of **1** with 1 equivalent of *n*-butyllithium and transmetallation with TlCl. Its elemental analysis was consistent with two thallium atoms per ligand unit, and ^{1}H and ^{13}C NMR spectroscopy indicated that the product contained one residual *n*-butyl group.† A single crystal X-ray structure analysis confirmed the molecular structure of the Tl(III)/Tl(I) mixed metal complex **2** in which an *n*-butylthallium(III) unit is coordinated by the tripodal amido ligand while two of the donor atoms are bridged by a thallium(I) atom (Fig. 1).‡ The observation that the reaction of the lithium amide with TlCl exclusively leads to the Tl^{III} amide **1** which may be rationally converted to **2** by addition of Bu^{n}Li across a Tl^{III}–N bond and subsequent metal exchange (Scheme 1) suggests a formation of the *n*-butylthallium species along a similar route in the reaction of a mixture of Bu^{n}Li and TlCl with the amine.

Compound **2** is the first example of a structurally characterized long chain alkylthallium complex in contrast to the considerable number of methylthallium derivatives reported in the literature.[7] Such nonfunctionalized long chain alkylthallium species are thought to be thermally labile,[8] and it seems to be this particular coordination environment which renders **2** sufficiently stable to allow its isolation and characterization. The central thallium atom is not symmetrically coordinated by the ligand tripod due to the external bonding of the Tl(1) atom which not only draws the donor functions N(2) and N(3) together [N(2)–Tl(1)–N(3) 83.5(3)° in comparison to N(1)–Tl(1)–N(2) 99.3(3) and N(1)–Tl(1)–N(3) 104.7(3)°] but also induces an lengthening of the two Tl(1)–N bonds involved [Tl(1)–N(2) 2.321(7) Tl(1)–N(3) 2.326(7) Å in comparison to Tl(1)–N(1) 2.155(7) Å]. In contrast, the Tl–N bonds to monovalent Tl(2) are, as expected, significantly longer [Tl(2)–N(2) 2.694(7) and Tl(2)–N(3) 2.721(8)], in fact longer than those found in all thallium(I) amides hitherto investigated.[3–6,9] This may be a consequence of the extreme steric congestion in this part of the molecule in which the two heavy metal atoms are forced into close proximity by the bridging donor atoms; this leads to a remarkably short Tl(1)···Tl(2) contact of 3.3620(9) Å. The Tl(1)–C(40) bond length of 2.188(9) lies in the usual range of alkyl–Tl bonds in $TlMe_2$-complexes.[7]

The ^{1}H and ^{13}C NMR spectra of **2** recorded at 295 K in d_8-toluene are consistent with an effective threefold symmetry. The signals are broadened and coalesce upon cooling to 200 K, however, the rapid precipitation of the complex prohibited the detection of the low temperature limit. These observations suggest that the compound is fluxional with the 'external' Tl(I) atom exchanging between the different bridging positions. Such a 'rotation' of a monovalent metal atom coordinated to an amido tripod is reminiscent of the dynamic behaviour of the tripodal lithium triamidostannates investigated previously by us[10] and a similar dynamic behaviour has also been observed by Veith

et al. for a range of mixed Li–group 13 metal amido complexes.[11]

A closer inspection of the crystal structure of **2** revealed that the complex is aggregated in the form of weakly associated dimers [Fig. 1(b)]. This type of association occurs through weak π-arene–Tl(I) contacts[12] with, respectively one tolyl group of the neighbouring molecule: Tl(2)–C(Ar′) 3.26–3.51 Å; Tl(2)–centroid: 3.093 Å. This arrangement is supplemented by a relatively short intermetallic distance of Tl(2)–Tl(2′) 3.7615(13). While being significantly shorter than the sum of the van der Waals radii (4.0 Å) this Tl–Tl contact is nevertheless at the long end of the range found for such metal–metal contacts and therefore thought to play a secondary role.

We thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the CNRS (France) for funding.

Control of calcium carbonate morphology by transformation of an amorphous precursor in a constrained volume

Eva Loste and Fiona C. Meldrum*

Department of Chemistry, Queen Mary, University of London, Mile End Road, London, UK E1 4NS. E-mail: F.C.Meldrum@qmw.ac.uk

First published as an Advance Article on the web 24th April 2001

Calcium carbonate crystals of defined morphology have been produced on transformation of an amorphous calcium carbonate precursor within a constrained volume.

The range of morphologies exhibited by inorganic crystals in biological systems is truly remarkable and provides a unique inspiration for synthetic crystal growth experiments.[1,2] Indeed, many biominerals display complex forms and curved surfaces that are as yet quite impossible to replicate in the laboratory. As an important step forward in understanding control of calcium carbonate growth *in vivo*, it has recently been demonstrated that certain biological calcite crystals actually comprise two mineral phases, calcite and amorphous calcium carbonate (ACC).[3–5] Examination of the mechanism of calcification in sea urchin embryos has further shown that in this organism, not only do ACC and calcite co-exist, but that ACC transforms into calcite over time.[3,4] The ACC therefore acts as a transient precursor to the more stable calcite phase,[3] and transformation of ACC to calcite within the constrained volume imposed by the spiculogenic cavity results in single crystals of calcite with a tri-radiate form and curved surfaces.

The role of ACC in the biological calcification process has not been entirely resolved, although it has been suggested that it may provide a temporary storage site in some organisms, or that in combination with a crystalline phase may provide a skeletal element with superior mechanical properties.[5,6] The experiments described here investigate whether ACC may also play an important role in morphological control. Indeed, it has been demonstrated that thin films of calcite can be formed in association with Langmuir monolayers *via* transformation of an ACC precursor film.[7] In common with the calcification mechanism active in sea urchins, in the current experiments ACC was contained within a restricted volume, and the morphological changes of the calcium carbonate particles on transformation to calcite were studied.

As a simple model system, 10 μm thick polycarbonate track-etch membranes were used as the crystallisation environment.[8] These membranes possess extremely regular cylindrical channels of diameter 3 μm, which are similar to the dimensions to sea urchin embryo spicules. ACC was precipitated in the membrane pores by placing a membrane between two half U-tube arms, and filling one tube with $CaCl_2$ solution and the other with Na_2CO_3 solution.† The experiments were carried out at 4–6 °C in order to stabilise ACC, by reducing the rate of transformation to calcite. Counter-diffusion of ions through the membrane pores resulted in precipitation of $CaCO_3$. The experimental conditions used generate ACC in bulk solution. Microscopic examination of the membrane after crystallisation revealed two populations of crystals. 15 μm crystals with intergrown, rhombohedral morphologies precipitated on the surface of the membrane. Particles were also observed within the membrane pores, and exhibited a circular cross section of the same dimensions as the membrane channel [Fig. 1(a)]. The morphologies of the intra-membrane crystals were further examined subsequent to dissolution of the membrane. Again, the two populations of crystals were observed but were readily distinguished on the basis of size and morphology. The intra-membrane crystals were of dimensions 3 × 10 μm and displayed cylindrical morphologies and curved surfaces, as shown in Fig. 1(b). Thus, both the size and shape of these crystals had been clearly dictated by the geometry of the membrane channels in which they had formed.

The crystals deposited on the membrane surface were adhered strongly to it, which compromised opportunities for *in situ* analysis of the intra-membrane crystals. To confirm that the intra-membrane crystals formed from an initial ACC phase, they were isolated by dissolution of the membrane at early stages of the experiment. Microscopic examination of the separated crystals clearly showed that the cylinders formed *via* an ACC precursor [Fig. 2(a)]. Spherical particles of diameter 0.5 μm, which are characteristic of ACC,[9,10] were observed to initially coat the walls of the pores, before filling in the entire volume and generating the final cylindrical form. Identical particles were produced in a control experiment by mixing the $CaCl_2$ and Na_2CO_3 solutions at low temperatures in the absence

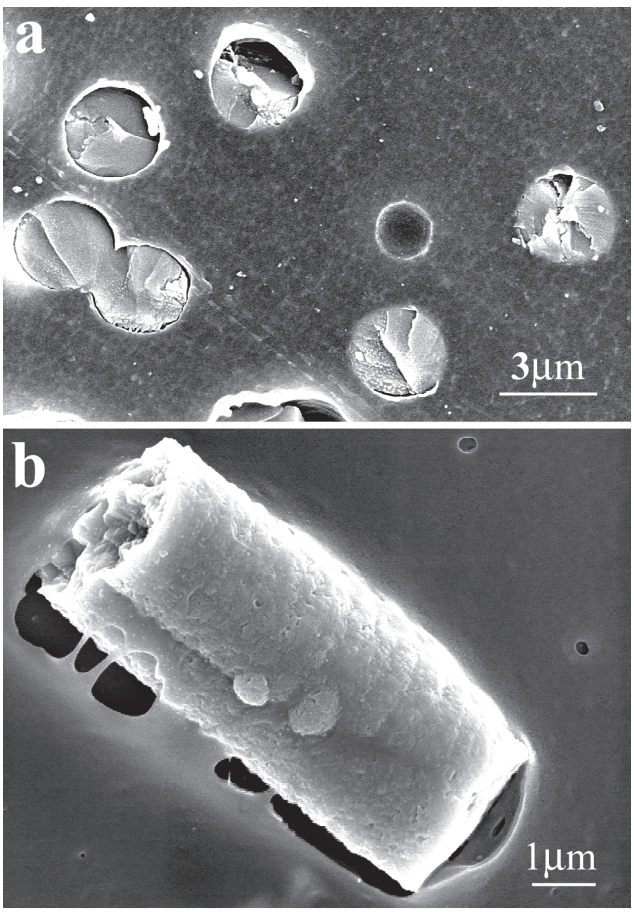

Fig. 1 (a) Calcium carbonate crystals grown within membrane pores. (b) Intra-membrane crystal isolated from the membrane, showing cylindrical morphology and dimensions identical to the membrane pores. Both images are of samples after 24 h.

DOI: 10.1039/b101563j

of the membrane, and were confirmed to be ACC using FTIR and XRD.

Comparison of the images of the intra-membrane particles at early stages [Fig. 2(a)], and after longer times [Fig. 1(b)] shows that the structure of the cylindrical particles alters with time. While the distinct spherical morphologies of the amorphous precursor particles are initially clearly observed within the cylindrical particle, continued incubation in solution results in transformation to a cylindrical particle with indentical overall morphology but with uniform structure. Examination of the ends of the mature cylindrical crystals frequently shows blocky crystal faces typical of rhombohedral calcite [Fig. 2(b)]. It has not as yet been impossible to conclusively identify the crystals as calcite, or to probe whether they are single crystal or polycrystalline as they are too small to investigate using standard laboratory XRD. However, selected area electron diffraction, carried out in a transmission electron microscope (TEM) was performed on the mature crystals in an attempt to obtain a diffraction pattern from a thinner edge area. Some diffraction patterns were obtained, all of which could be fitted to calcite. In addition, examination of the cylindrical particles between crossed polars in an optical microscope demonstrated that they were anisotropic, which again suggests crystallinity.

In order to investigate whether the precursor ACC phase was necessary for the precipitation environment to impose its structure on the final morphology of the crystal, the experiments were repeated at room, rather than low temperature. In the absence of the membrane, calcite precipitated immediately from solution. Precipitation within the membrane pores resulted in crystals of irregular, as opposed to cylindrical morphologies.

These experiments demonstrate that transformation of ACC within a constrained volume can produce a crystalline particle of morphology imposed by the environment. Both the ACC precursor phase and the constrained volume appear to be essential to this mechanism of morphology control. Biology obviously does not apply low temperature as a route to producing ACC. However, there is increasing evidence that organisms synthesise organic macromolecules specifically for stabilising ACC with respect to the thermodynamically stable phase calcite.[5,7,11] We therefore suggest that deposition of ACC within a vesicle may provide organisms with a route to producing crystals with elaborate forms and curved surfaces, such as the remarkable fenestrated calcitic skeletal plates of sea urchins.

We would like to thank the Department of Materials, Queen Mary, for access to electron microscope facilities.

Notes and references

† A polycarbonate track-etch membrane (pore diameter 3 μm) was placed between two, identical, half-U tube arms, which were clamped at the membrane position to form a U-tube. A small volume of cold water was introduced into the U-tube to wet the membrane. Equal volumes of 0.1 M solutions of Na_2CO_3 and $CaCl_2$ in Millipore water, which had been previously filtered and cooled to 4–8 °C were then simultaneously poured into each of the U-tube side-arms. The apparatus was placed in a refigerator at 4–6 °C for a period ranging from 15 min to 24 h. On completion of the experiment, the membrane was washed with water and was dried using compressed air. The $CaCO_3$ crystals produced in association with the membrane were examined using scanning electron microscopy (SEM) either *in situ* in the membrane, or after dissolution of the membrane in chloroform. All samples were Au-coated prior to examination in a JEOL 6300F scanning electron microscope (SEM), fitted with a field emission source and operating at 10 kV. Selected-area electron diffraction was also carried out on the $CaCO_3$ crystals after isolation from the membrane. A drop of an ethanolic solution of the isolated crystals were placed on a C-coated, Formvar-covered Cu TEM grid, and was examined in a JEOL 2010 transmission electron microscope (TEM) operating at 200 kV.

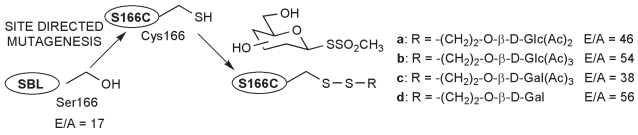
Site-selective glycosylation at position 166 at the base of the primary specificity S_1 pocket in the serine protease subtilisin *Bacillus lentus* (SBL) created glycoproteins that are capable of catalyzing the coupling reactions of not only L- amino acid esters but also D-amino acid esters to give the corresponding dipeptides in good yields as a result of greatly broadened substrate specificities that can be rationalized by the interaction of the glycans acting as chiral auxiliaries in stereochemically mismatched pairs.

Enzymatic peptide coupling requires minimal protection of the substrate, proceeds under mild condition and without racemization.[1] In spite of these advantages, two major problems have limited the use of serine proteases in peptide synthesis. One is their efficient proteolytic (amidase) activity which causes hydrolysis of the coupled peptide product, and the other is their stringent structural and stereo-specificity which typically confines their use in synthesis to a limited range of L-amino acid substrates. Controlled site-selective glycosylation can be used to create glycosylated proteases with greatly improved esterase activities and enhanced esterase–amidase activity ratios (E/As) that are up to 8.4- and 17.2-fold enhanced over their unglycosylated wildtype (WT) counterparts, respectively.[2] By virtue of their higher esterase and lower amidase activities, these glycosylated enzymes are excellent candidates for efficient amide bond formation as they possess enhanced acylating properties and yet substantially reduced hydrolytic activity towards the peptide products of coupling. Moreover, these catalysts can be constructed on scales of hundreds of milligrams, thereby allowing their use in multigram scale syntheses. We reasoned that such glycosylated enzymes would not only be efficient catalysts for peptide ligation but that the presence of an internally bound carbohydrate might influence the stereospecificity of such ligations. Carbohydrates are effective chiral auxiliaries[3] and we wished to probe the effect of introducing the homochiral groups **a**–**d** (Scheme 1) into the primary binding region of an enzyme as a tactic for broadening substrate stereospecificity, perhaps by increasing the potential for stereochemically mismatched pairs.[4]



Scheme 1

Representative carbohydrates were attached to the interior of the primary S_1[5] binding pocket, which modulates P_1 specificity, of the serine protease subtilisin *Bacillus lentus* (SBL, EC 3.4.21.14) by site-selective glycosylation[2,6] at position 166. Gratifyingly, this also resulted in enhanced E/A values relative to unglycosylated SBL-WT (Scheme 1).[2]

Firstly, we probed the structural breadth of the P_1 specificity of S166C-S-**a**–**d** by examining the ligation of L-amino acids, (**1**)–(**3**) as acyl donors, with glycinamide (**7**) as an acyl acceptor (Scheme 2, Table 1)† using 1 mg ml^{-1} of active enzyme[7] in simple 1 : 1 water–DMF solutions. In accord with our goals of not reducing the existing substrate breadth of SBL, these results indicated that the introduction of carbohydrate groups **a**–**d** did not affect the essential, inherent ability of SBL to accept L-amino acids as acyl donors in peptide coupling reactions. Good

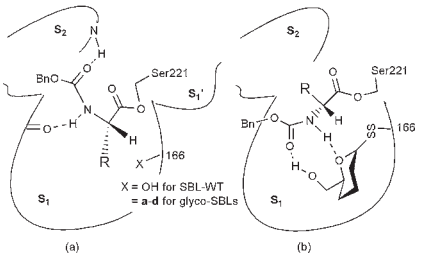

Fig. 1 Summarized representation of molecular mechanics analysis which showed different binding modes of (a) L-amino acids in SBL-WT or glyco-SBLs and (b) D-amino acids only in glyco-SBLs

to excellent yields of **9**, (91–95%), **10**, (77–92%), and fair yields of **11**, (54–67%) compared well, or were superior to, those for SBL-WT.

Our next goal was to investigate any secondary effects of S_1 pocket glycosylation upon P_1' specificity using the α-branched L-alaninamide (**8**) as a challenging acyl acceptor probe. The restricted S_1' specificity of the unglycosylated SBL-WT enzyme is demonstrated by its ability to catalyze only the coupling of **8** with the preferred L-phenylalaninate acyl donor **1**. Remarkably, in spite of the small S_1' pocket[8] all of the glyco-SBLs S166C-S-**a**–**d** were catalysts for the coupling of L-amino acids **1**–**3** with **8**. In the synthesis of **13**, low absolute yields were observed yet these represent a significant breakthrough in comparison with the absence of coupling activity prior to glycosylation. Excitingly, the yields of the coupling of **3** with **8** were similar to those obtained using unhindered **7** (48–55%). These results represent a dramatic improvement of the S_1' specificity of SBL. Interestingly, chemically-modified mutant enzymes bearing non-polar modifications at position 166 do not catalyze this ligation.[9] Possibly by exploiting polar interactions, we have obtained our goal of broadening substrate specificity, here of P_1' towards L-Ala to allow the synthesis of **12**–**14**, without diminishing the natural breadth of SBL. Indeed, previous molecular mechanics analysis of similarly internally glycosylated enzymes have indicated that such internally-bound carbohydrates may act as hydrogen-bonding motifs that give rise to enhanced kinetic parameters.[2]

Finally, we examined these powerful glyco-SBLs in the coupling of D-amino acids (**4**)–(**6**) as acyl donors with acyl acceptor **1**. The number of examples of enzyme catalyzed coupling of D-amino acids at the *C*-terminus of peptides by using D-amino acid acyl donors is vanishingly small and even then proceed with typically low efficiencies.[10] For example, to the best of our knowledge, yields above 10% for the incorporation of D-Glu have never been achieved.[9] Consistent with this, SBL-WT did not accept D-amino acids as acyl donors and starting materials **4**–**6** were recovered. In dramatic contrast, *all* of the glyco-SBLs S166C-S-**a**–**d** were able to catalyze the coupling of all three of these D-amino acid esters with acyl acceptor **1**. The reactions of **4** in all cases were slow and gave **15** in low yields, the best being 8% using S166C-S-**b**,**d**, and starting material **4** was recovered after 48 h in all cases. Peptide couplings of **5**, **6** with **7** proceeded more rapidly, and the yields were dramatically improved. In fact, the good yields of the D-dipeptide **17** (62–64%) were, surprisingly, superior to those found for coupling of L-Glu. Indeed, S166C-S-**c** showed a 1.2 : 1 stereochemical preference for D-glutamate **6** over L-glutamate **3**. Very high yields (up to 80%) of D-Ala dipeptide (**16**) were also observed.

Such is the remarkable nature of these broadened P_1 stereospecificities that we speculated that these glyco-SBLs may bind D-amino acids in a different mode from L-amino acids. Molecular mechanics analyses of SBL-WT and S166C-**a**–**d** with substrates **1**–**6** resulted in the models summarized in Fig. 1. In SBL-WT the normal binding mode for the acyl-enzyme intermediate, which is shown in Fig. 1(a), operates. The amino acid side chain (R) binds in the S_1 pocket with the reacting acyl group covalently linked to O_γ of the side chain of Ser221. This binding mode is not available to D-amino acids. In contrast, in the glyco-SBLs, Fig. 1(b), the presence of a homochiral auxiliary at position 166 with correct stereochemical disposition of its C-6 hydroxymethyl group and ring oxygen creates a hydrogen bond acceptor and donor motif which allows binding of the NHZ group in the S_1 pocket. Thus, glyco-SBLs may operate either by binding mode (a) *or* (b). However, in these glyco-SBLs, neither L-amino acids with the (a) mode nor D-amino acids with the (b) mode represent optimally matched diastereomeric pairs. This is consistent with their broadened specificity. By introducing a carbohydrate moiety at position 166 we have therefore tailored an enzyme with previously exclusive L-stereospecificity and excellent efficiency (matched pair) into an enzyme that has broadened L- and D-stereospecificity and reduced, but still good, efficiency due to mismatched pairing. This modified enzyme clearly has greater synthetic utility. This molecular mechanics analysis therefore raises the interesting possibility that the stereochemistry of the sidechain at 166 may influence stereospecificity through a double diastereoselective process. Further studies, including the synthesis of diastereomeric protein glycosylating reagents, to explore whether this is correct or whether location of just polar achiral groups at this position will have the same effect are now in progress. In addition, we are probing the precise effects of these modifications upon kinetic parameters k_{cat} and K_M using L- and D-amino acid substrates as both acceptors and donors in order to correlate the observed yield enhancements with true kinetic specificity.

In conclusion, glyco-SBLs S166C-S-**a**–**d** accept a wide range of substrates including D-amino acids as acyl donors and an α-branched acyl acceptor to give a variety of dipeptides, many in very high yields, that cannot be synthesized with SBL-WT. Furthermore, these dramatic improvements have been achieved without the loss of the natural ability of SBL to handle L-amino acids. It therefore represents a true broadening of synthetic utility and demonstrates that this site-selective glycosylation technology is a powerful tool for enhancing the application of enzymes in organic synthesis.

We acknowledge NSERC (Canada) and Genencor International, Inc for generous funding. We are also grateful to Genencor International, Inc., for providing WT- and S166C-SBL enzymes, and to Drs Rick Bott and Kanjai Khumtaveeporn for helpful discussions. We also thank the EPSRC (UK) for access to the Mass Spectrometry Service at Swansea and the Chemical Database Service at Daresbury.

Solid state supramolecular assemblies of charged supermolecules (Na[2.2.2]cryptate)$^+$ and anionic carboranes with host cyclotriveratrylene†

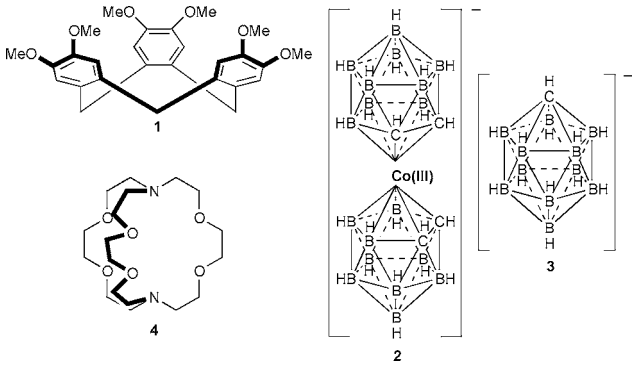
Michaele J. Hardie‡ and Colin L. Raston*‡

School of Chemistry, Monash University, Clayton, Melbourne, Victoria 3800, Australia

Received (in Cambridge, UK) 29th November 2000, Accepted 7th March 2001
First published as an Advance Article on the web 1st May 2001

The complex {(Na[2.2.2]cryptate)[CTV][Co($C_2B_9H_{11}$)$_2$]}$_2$(MeCN) (CTV = cyclotriveratrylene) features (Na[2.2.2]cryptate)$^+$∩CTV interplay as well as a closely packed chain of [Co($C_2B_9H_{11}$)$_2$]$^-$ counter-anions exhibiting dihydrogen bonding, and a similar cation–CTV assembly is found in (Na[2.2.2]cryptate)[CTV]($CHCl_3$)$_3$[$CB_{11}H_{12}$].

Cyclotriveratrylene (= CTV) **1** is a curved host molecule which forms ball-and-socket supermolecules with a number of large guest molecules such as fullerenes,[1,2] carborane,[2,3] and organometallic sandwich complexes;[4] and lattice inclusion structures with smaller organic guest molecules.[5] CTV can also be a π type donor ligand[6] or a chelating ligand for group 1 metals.[7] Chelating M(CTV) complexes feature polymeric or extended hydrogen bonded structures with solvent as intracavity CTV guest molecules and carborane $C_2B_{10}H_{12}$ or the anionic



carboranes [Co($C_2B_9H_{11}$)$_2$]$^-$ **2** or [$CB_{11}H_{12}$]$^-$ **3** as lattice type guests.[7] The carboranes appear to play an important steric role in the stabilisation of the crystalline species. Entirely different host–guest and overall supramolecular behaviour between CTV and M$^+$(carborane)$^-$ is expected if M$^+$ is completely encapsulated by another host molecule such as [2.2.2]cryptand **4**, thus preventing the formation of M(CTV) chelate rings. This also introduces a large supercation (M[2.2.2]cryptate)$^+$ as a potential guest molecule for CTV, noting that the confinement of such species in container molecules is limited,[8] along with the large carborane anion. The crystalline complexes formed by (Na[2.2.2]cryptate)[Co($C_2B_9H_{11}$)$_2$] and (Na[2.2.2]cryptate)[$CB_{11}H_{12}$] with CTV are reported herein.

A yellow powder of (Na[2.2.2]cryptate)[Co($C_2B_9H_{11}$)$_2$] is obtained in high yields by mixing Na.**2** with **4** in aqueous solution. Combining this powder with 1 equivalent of CTV yields yellow–orange crystals of {(Na[2.2.2]cryptate)[CTV][Co($C_2B_9H_{11}$)$_2$]}$_2$(MeCN) **5** from MeCN–H_2O solution.† The structure was determined by single crystal X-ray diffraction techniques,§ and is shown in Fig. 1. Two cations, two **3** anions, two CTV hosts and one molecule of CH_3CN comprise the asymmetric unit. Each CTV molecule acts as a host for one molecule of (Na[2.2.2]cryptate)$^+$. There are two such (Na[2.2.2]cryptate)$^+$∩CTV supermolecules, each with a different orientation of the (Na[2.2.2]cryptate)$^+$ within the molecular cavity of the CTV, although both with hydrophobic ethylene groups within the CTV bowl. In one (Na[2.2.2]cryptate)$^+$∩CTV assembly the N–Na–N axis of the [2.2.2]cryptate is close to parallel with the plane formed by the three methylene carbons of the CTV. The distance between the Na and the centre of this plane is 7.66 Å and N–Na···plane centroid angles of 95.9 and 87.7° are observed. The other (Na[2.2.2]cryptate)$^+$∩CTV assembly is more skewed Na–N···centroid angles 64.9 and 114.9°. CTV molecules within the extended crystal lattice do not feature any π···π interactions, instead showing close contacts between the methylene groups of one CTV and methoxy oxygens of an adjacent molecule (C–H···O distances 2.3–2.4 Å).

The cobalticarborane anions stack in columns along the *b* axis, and are remarkably close given their electrostatic repulsion, with C–H···H–B separations under 2 Å, and closest C···B distance 3.65 Å. These distances are consistent with the formation of nonclassical H···H hydrogen bonds or dihydrogen bonds. Dihydrogen bonds have been previously reported for X–H···H–B (X = N, O) systems with similar H···H separations.[9] The C–H groups of carboranes are acidic and are known to form both classical hydrogen bonds,[10] and nonclassical C–H···π hydrogen bonds.[3,11] The anions are in one of two alternating orientations (Fig. 1) approximately perpendicular relative to one another. The torsion angle between the cobalticarborane vectors (vector defined as that between the two apical B positions *para* to the Co) is −65.9°. The anions are situated close to the methyl groups of the CTV, at closest B···C_{methyl} separation 3.71 Å. The siting of a carborane or anionic carborane near methyl groups or within methyl-lined cavities within a crystal lattice has also been observed in a number of other materials containing both carboranes and CTV[7] and is emerging as a structural trend.

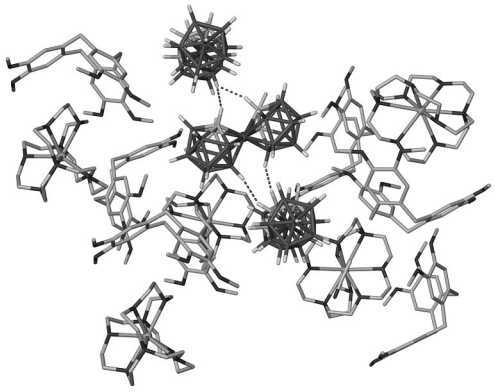


Fig. 1 Partial packing diagram from the crystal structure of {(Na[2.2.2]cryptate)[CTV][Co($C_2B_9H_{11}$)$_2$]}$_2$(MeCN) **5**. All C–H···B-H contacts < 2.3 Å between [Co($C_2B_9H_{11}$)$_2$]$^-$ anions consistent with dihydrogen bonds are shown as dashed lines.

† Electronic supplementary information (ESI) available: Synthesis of complexes **5** and **6** and discussion of structure solution and refinement for **5**. See http://www.rsc.org/suppdata/cc/b0/b009581h/

‡ Present address: School of Chemistry, University of Leeds, UK LS2 9JT. E-mail: c.l.raston@chem.leeds.ac.uk

Colourless crystals of (Na[2.2.2]cryptate)[CTV]-$(CHCl_3)_3[CB_{11}H_{12}]$ **6** grew from diffusion of hexane into a mixture of (Cs[2.2.2]cryptate)$[CB_{11}H_{12}]$, CTV and NaOH in $CHCl_3$–MeOH.† The structure was determined by single crystal X-ray diffraction techniques,§ and, as for complex **5**, features (Na[2.2.2]cryptate)$^+$∩CTV supermolecules as the primary host–guest species, [Fig. 2(a)]. The (Na[2.2.2]cryptate)$^+$ guest molecule is positioned in a more end-on fashion than was seen in **5**, with a longer Na-to-host centroid distance at 7.85 Å, and N–Na···centroid angles 55.0 and 134.8°. The CTV molecules also show secondary inclusion behaviour, with a molecule of $CHCl_3$ at distances consistent with the formation of bifurcated hydrogen bonds to each CTV dimethoxy group [Fig. 2(a)] at Cl_3C–H···OMe distances ranging from 2.23 to 2.52 Å (corresponding C···O separations 3.09 to 3.24 Å). Similar hydrogen bonding of $CHCl_3$ to two dimethoxy groups is observed in crystalline CTV$(CHCl_3)_2$.[5] Two of the $CHCl_3$ molecules have their donating C–H group in-plane with their respective acceptor dimethoxy groups, while the third binds in a different mode, with the C–H out-of-plane with the dimethoxy groups and the $CHCl_3$ molecule tilted in towards the molecular cavity of the CTV. One of the chlorines of this $CHCl_3$ is directed into the cleft of the (Na[2.2.2]cryptate)$^+$ guest molecule, shown in space filling representation in Fig. 2(b), hence both the CTV and the (Na[2.2.2]cryptate)$^+$ can be regarded as acting as host molecules for this $CHCl_3$.

As with complex **5**, the carborane anion is involved in hydrogen bonds *via* the acidic C–H. In **6** the $[CB_{11}H_{12}]^-$ anion forms a bifurcated hydrogen bond to two chlorine atoms of the out-of-plane $CHCl_3$ (Fig. 2). Notably, an identical reaction mixture with CH_2Cl_2, which is less likely to form hydrogen bonding interactions than $CHCl_3$, failed to produce crystalline products, indicating that these interactions are important in stabilising the crystalline product. The CTV molecules within the extended crystal lattice associate in pairs *via* a single, long π···π interaction, with coplanar aromatic rings at a centroid···centroid separation of 3.79 Å.

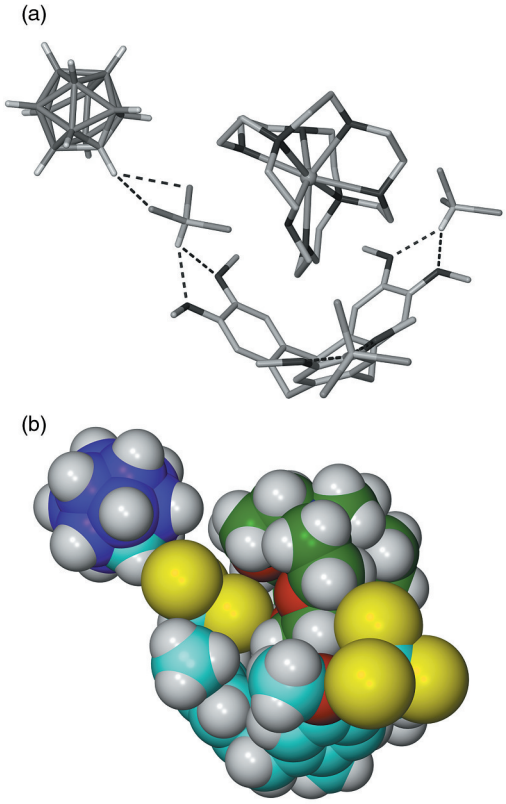

Fig. 2 Crystal structure of (Na[2.2.2]cryptate)[CTV]$(CHCl_3)_3[CB_{11}H_{12}]$ **6**. (a) Hydrogen bonding interactions between the molecular components (see text), only hydrogen positions on the $CHCl_3$ molecules and **3** anions are shown for clarity; (b) space filling representation, highlighting how a Cl from one $CHCl_3$ molecule is directed into the cleft of the (Na[2.2.2]cryptate)$^+$. Carbon atoms of [2.2.2]cryptate shown in green, others in blue.

The cation (Na[2.2.2]cryptate)$^+$, itself a host–guest complex, behaves as an intracavity guest for the host molecule CTV, while the bulky counter-anions $[Co(C_2B_9H_{11})_2]^-$ and $[CB_{11}H_{12}]^-$ are lattice counter-ions within the crystal packing. These and other carborane anions may be used to build up complicated supramolecular assemblies and generate new types of materials.

Support of this research from the Australian Research Council and helpful discussions with Dr Janet Scott are gratefully acknowledged.

Notes and references

§ *Crystal data*: X-ray data were collected at 123(1) K on an Enraf-Nonius KappaCCD single crystal diffractometer with Mo-Kα radiation (λ = 0.71073 Å). The structures were solved by direct methods with SHELXS-97 and refined by full-matrix least squares on F^2 using SHELXL-97. Carbon positions within carborane cages were assigned by an analysis of displacement parameters and bond lengths. All non-hydrogen atoms were refined anisotropically and hydrogens included at geometrically estimated positions, unless otherwise indicated. {(Na[2.2.2]cryptate)[CTV]-$[Co(C_2B_9H_{11})_2]\}_2(CH_3CN)$ **5**: $C_{100}H_{179}B_{36}Co_2N_5Na_2O_{24}$, M_r = 2388.48, monoclinic, space group $P2_1$, a = 16.5391(7), b = 12.7151(3), c = 29.6858(12) Å, β = 92.349(1), U = 6237.6(4) Å^3, Z = 2, D_c = 1.272 g cm^{-1}, μ = 0.341 mm^{-1} (no correction), yellow–orange needle, 0.33 × 0.12 × 0.05 mm, $2\theta_{max}$ = 50°, 36186 reflections measured, 19710 unique reflections (R_{int} = 0.107), 711 parameters, R_1 = 0.1270 (on 14445 observed data [$I > \sigma(I)$]), wR_2 = 0.2787 (all data), S = 1.061. The crystal was weakly diffracting, and the structure showed pseudosymmetry (see ESI†), with only the Na and Co refined anisotropically. Received (in Cambridge, UK) 26th February 2001, Accepted 9th April 2001
First published as an Advance Article on the web

A method for determining the three-dimensional structure of inorganic specimens using images formed from Rutherford scattered electrons, at a spatial resolution of 1 nm in all directions, is described and illustrated with results from a study of Pd–Ru bimetallic nanocatalysts supported on mesoporous silica: a 3D animation demonstrating the results may be viewed at *http://www-hrem.msm.cam.ac.uk/~mw259/Work/Tomo.html*

Though not universally acknowledged, the electron microscope is one of the most versatile and powerful instruments for the complete chemical analysis of any solid material. Not only can it cope with sample masses (10^{-18} g and less) that are far beyond the reach of X-ray analysis, it yields structural, mechanistic, compositional and electronic (valence states of ions and bonding between atoms) information on minute crystallographic phases that may contain hardly more than a dozen or so atoms. All this is possible because of the multiplicity of modes in which the microscope may be deployed. Thus it may give[1] bright field (BF) or dark field (DF) images (from forward scattered or Bragg scattered electrons, respectively) electron stimulated X-ray emission (XRE) spectra and elemental maps as well as electron energy loss spectra (EELS),[2] that can reflect such features as plasmon modes, the atomic coordination of light elements,[3] inter-atomic distances, d-electron population of transition metal ions and the momentum densities of electrons in amorphous solids.

Scanning transmission electron microscopy (STEM) is particularly useful in studies of nanoparticle catalysts supported within mesoporous silica because, by using a high angle annular dark field (HAADF) detector (see Fig. 1), which collects electrons that undergo Rutherford scattering, images can be acquired where the intensity is approximately proportional to Z^2 (Z is the atomic number of the scattering atom).[4] Fortunately many catalytically significant elements (Pd, Pt, Ru, Re, *etc*) have high Z, so that when they are supported on low Z material such as SiO_2 they are readily visible using HAADF detectors,[5] see Fig. 2. In addition the small probe sizes involved, *ca*. 0.8 nm in diameter, mean the resultant images have very high resolution. By also recording the electron-stimulated XRE from the nanoparticles their identity can be determined unambiguously (see, for example, ref. 4).

Valuable as the information yielded by STEM HAADF and XRE mapping undoubtedly is, especially in investigating nanocatalysts (and other nanoscientific problems), it is limited to providing 2D projections of 3D arrangements. The need exists to analyse, non-destructively, specimens fully in three dimensions especially if we seek to understand the factors responsible for the loss of activity, selectivity and stability of nanoparticle catalysts.

A suitable approach is electron tomography,[6] where the 3D structure is reconstructed from a tilt series of 2D projections. In practice this is achieved by tilting a specimen on one axis using the microscope goniometer and taking a micrograph at a range of tilts, typically every 1–2°, correcting for specimen move-

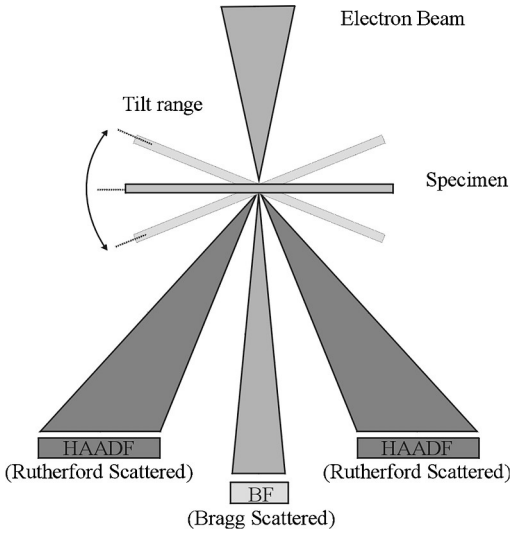

Fig. 1 Schematic of the detector layout in a scanning transmission electron microscope (STEM). The diameter of the tip of the electron beam is 0.8 nm.

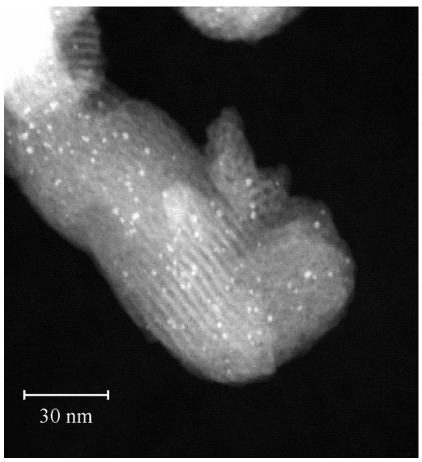

Fig. 2 HAADF image from a Pd–Ru nanocatalyst supported on mesoporous silica and mounted on a holey carbon grid. The mesopores (3 nm in diameter) and the nanocatalyst particles (1 nm in diameter) are clearly visible.

† Electronic supplementary information (ESI) available: 3D animations of a Pd–Ru bimetallic catalyst generated from a tomographic reconstruction of HAADF STEM images. See http://www.rsc.org/suppdata/cc/b1/b101819c/

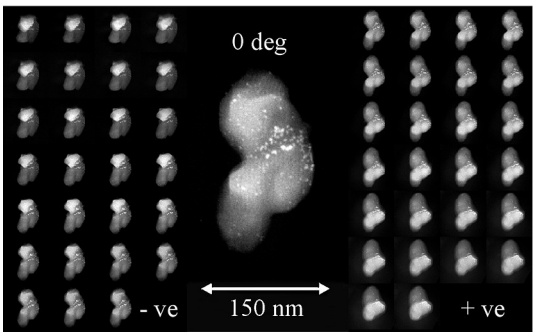

Fig. 3 Montage of the acquired tilt series showing all images and an enlargement of the zero tilt image.

ment, focus change and astigmatism throughout. In our case, the series is then processed offline using routines based on the Radon Fourier-slice theorem,[7] to reconstruct the full 3D structure.

In conventional electron tomography such a series is acquired using BF images dominated by Bragg-scattered electrons.[6] However, the large beam currents of conventional TEM means that such an approach cannot be used on specimens that are beam sensitive. The framework structure of mesoporous silica, for example, degenerates rather rapidly under TEM illumination and so is unsuitable for the prolonged acquisition times required for a tilt series. By using STEM, however, far smaller total beam exposure is involved. (Although the current density within the STEM probe is high, its energy can be dissipated to the surrounding (non-illuminated) areas unlike conventional static beam TEM). Another advantage arises from the scattering geometry in that HAADF imaging excludes almost all the electrons scattered coherently through low angles. This means that the resulting images are free from the misleading complications of electron phase contrast and, as such, they are 'true-projections' of the structure. As HAADF STEM images are formed primarily from incoherently scattered electrons, the combination of STEM HAADF imaging coupled with high operating voltages, to minimise inelastic interactions and thus ionisation damage, is an ideal basis for the tomography of catalysts.

We illustrate the power of HAADF STEM tomography by examining Pd–Ru bimetallic catalysts[8] supported on mesoporous silica. A HAADF tilt series was acquired on a CM300 field emission gun transmission electron microscope (FEGTEM), operating at 300 kV, in STEM mode using an on-axis Fischione HAADF detector. The series was acquired from +60° to −48° with an image every 2° giving a total of 55 images. These were spatially aligned using a cross-correlation algorithm applied sequentially to images stretched using an inverse cosine function that takes into account the variation in image width with tilt. After determining the tilt-axis for the data set, a 3D reconstruction was achieved using a weighted back-projection of consecutive 2D slices.[6a] The additional weighting function corrects for the relative oversampling of low frequencies when combining the image series from successive tilts.[6a]

The resultant reconstructions[9] have been displayed using multi-level voxel[10] projections, see Fig. 3. The multi-level voxel projection is achieved by contrast-selecting intensities from the reconstruction and assigning them definite colour and opacity values. This allows clear differentiation between the silica support (coloured grey) which has low intensity in the reconstruction from the low Z SiO_2, and the active nanoparticles (coloured red) which have high intensity in the reconstruction due to the high Z of the Pd/Ru. The reconstruction has sufficient resolution (1 nm^3) to allow a direct visualisation of the relative positions of mesopores and nanoparticles in all directions. Here we can show only 2D projections, but for the full 3D picture the reader may view an animation in the supplementary information (ESI†) on the RSC web site or at our web site.[11]

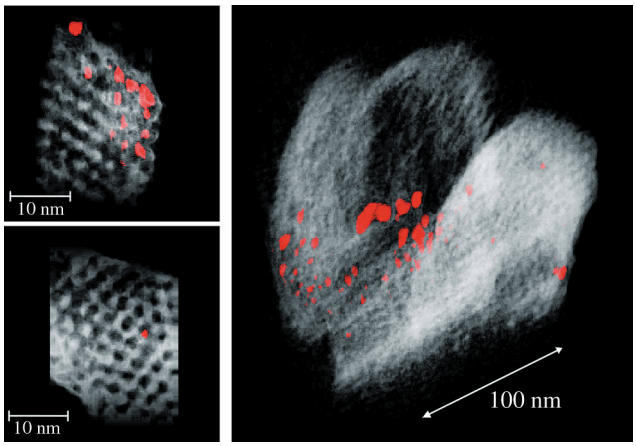

Fig. 4 Results from the tomographic reconstruction from the tilt series in Fig. 3. All images are multi-level voxel[10] red, green, blue, opacity (RGBO) projections. (a) and (b) are regions selected from the full reconstruction and (c) illustrates the reconstruction of nanoparticles and channels in multiple directions. The Pd–Ru particles are coloured red in all figures.

The reconstruction, as seen here or with the animations, reveals a number of important factors. On a practical level, it is clear that the silica framework has been reconstructed faithfully with essentially no beam damage even though long acquisition times are needed for the full series. The nanoparticles have a clear size distribution with larger particles sitting on the outside of the silica and smaller ones within the silica channels. The larger particles are those in which the original Pd_6Ru_6 metal clusters have coalesced. Those that have diameters >3 nm cannot be incorporated into the silica framework without severe disruption. Fig. 4(b) and the accompanying animation show a single nanoparticle anchored to the side of the wall of the silica channel exactly as suspected from other studies.[8] It is this type of nanoscale structural information, retrieved by non-destructive methods in contrast to atom-probe tomography,[12] coupled with bulk chemical analysis, which will be invaluable in developing and evaluating catalysts in the future.

Although we have demonstrated this technique primarily for the purposes of characterising supported catalysts, it has patently wide applications across the entire corpus of nanoscience and nanotechnology.

We acknowledge with thanks continued support from EPSRC (rolling grant to J. M. T.) and BNFL Research and Technology (studentship for M. W.).

Noncovalent binding of the halogens to aromatic donors. Discrete structures of labile Br_2 complexes with benzene and toluene†

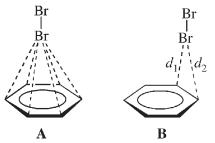
Aleksandr V. Vasilyev, Sergey V. Lindeman and Jay K. Kochi*

Department of Chemistry, University of Houston, Houston, Texas, 77204-5641, USA. E-mail: jkochi@pop.uh.edu

Received (in Columbia, MO, USA) 14th February 2001, Accepted 4th April 2001
First published as an Advance Article on the web 1st May 2001

Precise molecular structures resulting from the noncovalent interaction of Br_2 with benzene (and toluene) reveal the unusual localized bonding to *specific* (one or two) carbon centers in prereactive complexes leading directly to the transition states for electrophilic aromatic brominations.

Noncovalent interactions of benzene donors with a variety of small molecules including Brønsted acids (*e.g.* HF, HCl, $HOCH_3$), halogens (X_2 = F_2, Cl_2, Br_2, I_2) and Lewis acids (SO_2, NO, $AlCl_3$), *etc.* are under active investigation.[1,2] Molecular structures of these weak (intermolecular) complexes have been experimentally deduced with the aid of various spectroscopic techniques,[2,3] but their *fine structures* established by X-ray crystallographic methods are largely restricted to the halogen adducts.[4] Since the latter are prereactive intermediates critical to electrophilic aromatic halogenation,[5] it is important to establish the precise location of the noncovalently-bonded halogen relative to the aromatic ring. Unfortunately, the classic X-ray crystallography of the benzene complex of bromine by Hassel and Strømme at −40(−50) °C merely reveals the completely delocalized 'axial' orientation **A**, in which the Br–



Br bond (2.28 Å) lies on the six-fold symmetry axis (at a bromine separation of 3.36 Å from the mean plane) of benzene.[6] (In other words, the six π electrons comprising the C–C bonds are all equally involved in the 'bonding' to bromine.) Moreover, the corresponding chlorine complex determined by the same workers at −90 °C shows these noncovalently bound crystals to be isomorphous with **A**[7] (which they also considered as further proof for their interesting axial model).

Although the axial model is generally accepted and widely cited, it is at variance with several (recent) theoretical studies which identify a significantly less symmetrical model **B**,[8,9] in which the more localized bonding locates the halogen directly above one C–C bond (*i.e.* η^2) or above a carbon atom (η^1).[10] Since a number of detailed IR studies[11,12] have been unable to resolve the ambiguity between the delocalized and localized models of halogen binding to benzene,[13] we sought the more definitive X-ray crystallographic analysis of the bromine complex with benzene as well as with toluene.

Owing to very weak intermolecular interactions, the requisite (1 : 1) bromine complexes with benzene and toluene for our studies were necessarily prepared *in situ* by (low-temperature) crystallization in a glass capillary.[6,7] Very careful temperature modulation was the critical factor in the successful growth of single crystals of the benzene and toluene complexes suitable for X-ray crystallography at −150 °C.†‡

In both the benzene and toluene complexes, dibromine is uniformly oriented perpendicular to the aromatic planes (with slight deviations α of typically $< 8°$); and the bromine approach occurs at a distance D = 3.01–3.17 Å which is significantly shorter than the sum of the van der Waals radii of 3.55 Å (see Table 1†).[14] Most importantly, the bromine does not coordinate to the benzene ring symmetrically—in striking contrast to the coaxial (delocalized) model **A** reported by Hassel and Strømme.[6] Instead, bromine is positioned over the rim (not above the center) of the benzene ring, being shifted by *ca.* 1.4 Å from the main symmetry axis (see Fig. 1 and δ in Table 1†). In all cases, there is an asymmetric coordination of bromine as given by the shortest Br···C distances d_1 and d_2 (see the localized structure **B**). However from the relative values of $(d_1^2 - D^2)^{1/2}$ and $(d_2^2 - D^2)^{1/2}$, we estimate the hapticity of coordination as: $\eta = 1 + 2(d_1^2 - D^2)^{1/2}/[(d_1^2 - D^2)^{1/2} + (d_2^2 - D^2)^{1/2}]$. Indeed, this evaluation leads to $\eta = 1$ if $d_1 = D$ ('over-atom' coordination) and $\eta = 2$ if $d_1 = d_2$ ('over-bond' coordination).

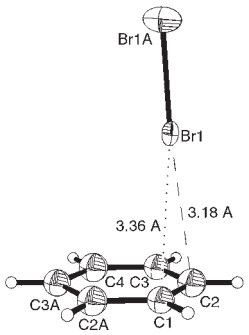


Fig. 1 ORTEP diagram showing the localized (over-atom/bond) coordination of Br_2 to benzene. Thermal ellipsoids of nonhydrogen atoms are shown at 50% probability level.

In the benzene/Br_2 complex, the calculated value of η = 1.52 (Table 1†) corresponds to coordination midway between the 'over-atom' and 'over-bond' configurations. In the toluene complex, the hapticities vary from 1.70 to 1.86 (in four non-equivalent moieties) and thus lie closer to the 'over-bond' coordination model. Moreover, the 'over-bond' coordinated bromine is remarkably shifted toward the *ortho-* or *para-*carbons (see Fig. 2) which correspond to the positions of highest electron density.

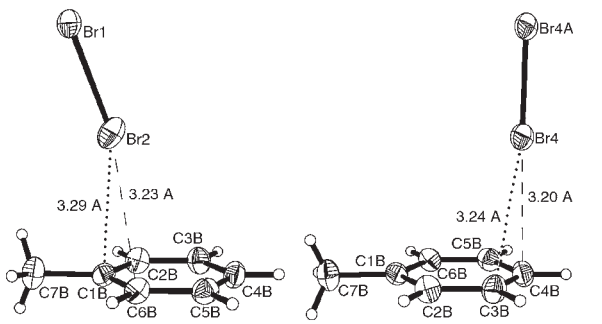

Fig. 2 Localized bonding of bromine to *ortho-* (left) and *para-* (right) centers of toluene in the charge-transfer complex.

† Electronic supplementary information (ESI) available: crystallization of $C_6H_6{\cdot}Br_2$ and $C_6H_5Me{\cdot}Br_2$, crystal data, and their principal geometric parameters. See http://www.rsc.org/suppdata/cc/b1/b102148f/

Such an experimental location of bromine is in a good agreement with the results of high level theoretical calculations which consistently discriminate against the symmetrical coaxial η^6-coordination, and favor both 'over-atom' and 'over-bond' (*i.e.* η^1 and η^2) coordinations without a significant energy barrier between them.[8,9,15] It is also noteworthy that the 'over-rim' coordination modes of Br_2 are highly reminiscent of those found in silver(I) complexes, as representing another general class of electron acceptors showing charge-transfer (non-covalent) binding to arene donors.[16,17]

The charge-transfer complex $[C_6H_6,Br_2]$ is presently the weakest EDA complex of dibromine studied in the solid state. Although the C···Br separation of 3.18 Å is 0.37 Å closer than the equilibrium van der Waals distance,[14] the contraction is perceptibly less than those previously reported in a series of complexes with slightly polarizable and weakly nucleophilic donors.[18] [For example, the X···Br distance contraction (relative to the corresponding equilibrium van der Waals separations) is 0.55 Å in the acetone/Br_2 complex (O···Br 2.82 Å),[20] 0.56 Å in the acetonitrile/Br_2 complex (N···Br 2.84 Å),[21] 0.57 Å in the $[Te_2Cl_{10}]^{2-}/Br_2$ complex (Cl···Br 3.03 Å),[22] and 0.60 Å in the $[Se_2Br_{10}]^{2-}/Br_2$ complex (Br···Br 3.10 Å).[22,23]] Moreover, the average C···Br separation of 3.156 Å in the toluene/Br_2 complex is somewhat shorter than that in the benzene complex, as expected from the better donor strength of toluene.[24]

The weak C(arene)···Br charge-transfer interaction is reflected in an almost unperturbed geometry of the coordinated dibromine. [The Br–Br bond length is actually very sensitive to coordination/polarization effects and readily elongates from 2.284 Å in the non-coordinated molecule (bond order $n = 1$) to 2.53 Å in $[Br_3]^-$ anion[25] (bond order $n = ½$).] As such, the Br–Br bond lengths of 2.301(2) Å in the benzene complex and an average of 2.302(1) Å in the toluene complex do not exhibit much elongation during complex formation. For comparison, the Br–Br bond lengths vary within a narrow range (2.28–2.33 Å) in the weakly coordinated acetone, acetonitrile, dioxane and methanol complexes.[20,21,26,27]

In the absence of significant polarization, dibromine can be coordinated equally well from either end (owing to the σ*-orbital which is localized at both bromine centers); and this explains why dibromine has often been found to be symmetrically coordinated to a pair of donor molecules (in a bridging manner), especially in complexes with weak donors.[4] In the benzene and toluene complexes, dibromine is also positioned symmetrically between the coordinated benzene rings forming infinite (weak) chains ···Ar···Br–Br···Ar···Br–Br···Ar··· through the crystal, and there are no specific interactions other than van der Waals contacts between the chains. Although the chains are highly symmetrical in the benzene/dibromine crystals—with two-fold axes (through the diagonals of the benzene rings and through the centers of the dibromine molecules) across the chains, the chains in the toluene/dibromine crystals are less so. Thus, two of the three dibromines (Br3–Br3A and Br4–Br4A) occupy inversion centers and are thus symmetrically coordinated, but the third dibromine (Br1–Br2) does not show crystallographic symmetry. Indeed, the latter exhibits some signs of larger polarization as a result of a less symmetric coordination (Table 1), and it has the shortest contact C···Br 3.053(4) Å as well as the longest Br–Br bond length 2.307(1) Å in the series. Interestingly, a similar asymmetric coordination of dibromine is found in the complex with methanol,[26] in which the O···Br distance is shorter (2.705 *vs.* 2.723 Å) and the Br–Br bond length is longer (2.324 *vs.* 2.303 Å) than those in the closely related (but symmetric) dioxane complex.[27] This structural effect predicts that polarization in isolated donor/acceptor dyads (as extant in dilute solutions) will be somewhat stronger than that observed in (crystalline) polymeric chains.

We thank the National Scientific Foundation and R. A. Welch Foundation for financial support.

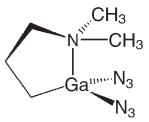
First published as an Advance Article on the web 1st May 2001

The investigation of the pyrolysis of the single-source precursor $Me_2N(CH_2)_3Ga(N_3)_2$ 1 by matrix-isolation FTIR spectroscopy revealed monomeric $Ga(N_3)$ as a reactive intermediate.

The group 13 nitrides of Al, Ga and In and their ternary alloys $Al_xGa_yIn_zN$ ($x + y + z = 1$) are wide direct band gap materials with promising applications as new microelectronic and optoelectronic devices.[1] For example, blue-light emitting diodes and lasers based on gallium nitride can be constructed.[2] Usually, thin films of the nitrides can be epitaxially grown by chemical vapor deposition (CVD) from the trialkyl compounds MR_3 with a large excess of ammonia.[1,2] These organometallics are toxic, pyrophoric, and very sensitive to air and moisture and several efforts have been made to synthesize alternative precursors. If the element is equipped with a ligand that is capable of intramolecular coordination, then non-pyrophoric organometallics are accessible. In particular, the 3-dimethylaminopropyl ligand, $Me_2N(CH_2)_3$, has been successfully applied to various precursors: for example, the diazide $Me_2N(CH_2)_3Ga(N_3)_2$ **1** is a single-source precursor for the MOCVD of GaN.[3]



1

For a deeper understanding of a CVD process and a rational design of improved precursors, detailed knowledge of fragmentation mechanisms is needed. Recently, we started to investigate the fragmentation of intramolecularly coordinated alanes and gallanes of the type $Me_2N(CH_2)_3MX_2$ (X = Cl, Br, Me) using matrix isolation techniques.[4–7] In this procedure a carrier gas/precursor mixture is transported through a small pyrolysis tube and reactive intermediates produced by the fragmentation of the organometallic precursor are trapped on a CsI window at 15 K.

A series of high vacuum thermolysis experiments with the diazide **1** and argon as carrier gas was performed between ambient temperature and 800 °C.† Up to 450 °C compound **1** passes the thermolysis oven unchanged, but above this temperature new IR bands in the matrix IR spectra indicate the beginning of the fragmentation of **1**. Fig. 1 shows a typical IR spectrum of matrix-isolated products recorded after a thermolysis experiment at 520 °C (spectrum A). Under these conditions precursor **1** was completely fragmented; its typical IR absorptions could no longer be detected in argon matrices. In the common region of asymmetric stretching modes of azido groups two intense IR bands at 2135.4 and 2106.0 cm^{-1} were observed (Fig. 1A). The IR band at 2135.4 cm^{-1} unequivocally belongs to hydrazoic acid, HN_3, which has a well-known set of bands at 3316.7, 2286.2, 2135.4, 1264.1 and 1146.0.[8] That the second intense IR band, that at 2106.0 cm^{-1}, belongs to a second azide was revealed by photolysis experiments (Fig. 1B). Irradiation of the matrix-isolated thermolysis products with an Xe arc lamp for *ca*. 30 s selectively bleached the band at 2106.0 cm^{-1} plus an IR band at 1340.3 cm^{-1};‡ the frequencies, intensity pattern, and low half-band widths ($h_{\frac{1}{2}} < 2$ cm^{-1}) of these bands are indicative of a small molecular azide and we assign these two bands to the symmetric and asymmetric N_3 stretching mode of $Ga(N_3)$. The calculated harmonic frequencies and intensities [B3LYP/6-311+G(d)][9] of the two modes $\nu_{as}(N_3)$ [2230.7 cm^{-1}; 1080 km mol^{-1}] and $\nu_s(N_3)$ [1408.2 cm^{-1}; 249 km mol^{-1}] are in good agreement with our measured values. Recently, gallium(I) azide was observed for the first time by co-deposition matrix experiments of laser-ablated Ga atoms with nitrogen.[9] Among other Ga–N species, Zhou and Andrews identified $Ga(N_3)$ in excess of solid N_2 by IR bands at 2103.6 / 2096.8 cm^{-1} [$\nu_{as}(N_3)$] and 1331.3 / 1328.3 cm^{-1} [$\nu_s(N_3)$]; both bands were split by matrix site effects.[9] This assignment was strongly supported by nitrogen isotopic substitutions and DFT calculations. According to B3LYP/6-311+G(d) calculations, $Ga(N_3)$ is a C_s symmetrical molecule with a linear N_3 group and a Ga–N–N angle of 149.5°.[9] From the six normal modes only the two azide stretching vibrations and the Ga–N stretching mode are expected to have a sufficiently high transition moment to be detectable. The harmonic frequency of the Ga–N stretch was predicted at 384.3 cm^{-1} with an intensity of 133 km mol^{-1}, but it could not be detected in the laser-ablation experiments.[9]

DOI: 10.1039/b101987m

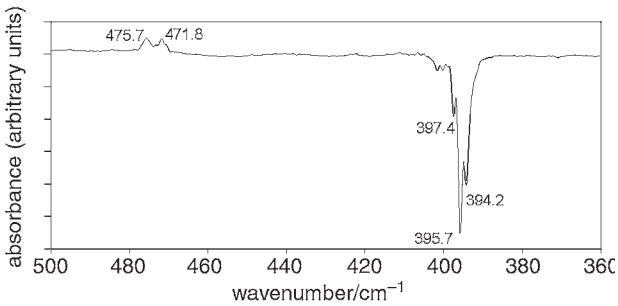

Fig. 2 Low-frequency region of the photolysis of the thermolysis products of **1** (see text for details).

We investigated the photolysis reaction of the thermolysis products of **1** in the frequency region 200–700 cm^{-1}. As depicted in Fig. 2 a set of three IR bands at 397.4, 395.7 and 394.2 cm^{-1}, disappears on irradiation. We assign this set to the missing ν(GaN) of $Ga(N_3)$. The experimental frequencies fit quite well to the predicted frequency of 384.3 cm^{-1}; the B3LYP method is known to underestimate low frequency modes.[10] Because of the natural abundance of the two isotopes, ^{69}Ga (60%) and ^{71}Ga (40%), two IR bands are expected for this vibrational mode. If we assign the most intense IR band at 395.7 cm^{-1} to $\nu(^{69}GaN)$ then the same mode for the ^{71}Ga isotope should occur at 393.9 cm^{-1} [B3LYP/6-311+G(d)], which is in good agreement with the measured band at 394.2 cm^{-1}. The appearance of three IR bands could be caused by an overlap of resonances of $Ga(N_3)$ in at least two different matrix sites: one site with 397.4 (^{69}Ga) and 395.7 cm^{-1} (^{71}Ga), and the other site with 395.7 (^{69}Ga) and 394.2 cm^{-1} (^{71}Ga). This interpretation is in accordance with the expected isotopic shifts, but the expected intensity pattern would be a little different from the observed one; the IR band at 395.7 cm^{-1} is expected to have a higher intensity. Furthermore, the IR band at 394.2 cm^{-1} shows a shoulder to its low frequency side indicating another overlap of IR bands.

GaN is the expected product of the photolysis of $Ga(N_3)$ in matrices. As a result of the photolysis reaction only two unresolved IR bands of low intensity at 475.7 and 471.8 cm^{-1} evolved (Fig. 2). Zhou and Andrews assigned an unresolved IR band at 484.9 cm^{-1} to GaN in N_2 matrices.[9] Because of a large mismatch between the calculated frequency (580.9 cm^{-1}) and the measured value, the authors interpreted the IR band at 484.9 cm^{-1} as being due to a GaN$\cdots$N$_2$ complex. We tentatively assign the two IR bands at 475.7 and 471.8 cm^{-1} to GaN, which might be perturbed by the N_2 molecule produced photochemically in the same matrix cage.

In addition to HN_3 and $Ga(N_3)$ the matrix containing the thermolysis products of **1** at 520 °C (Fig. 1) contained the well-known molecules NH_3, $H_2C{=}NCH_3$, $H_2C{=}CH_2$, CH_4 and HCN, which were identified by comparison with published data. With the exception of ammonia, all fragments have been found previously in similar thermolysis experiments with alanes and gallanes of the type $Me_2N(CH_2)_3MX_2$ (X = Cl, Br).[4,5]

Prior to our work, compound **1** was investigated by mass spectrometry[11] which is commonly used for *in situ* analysis of gas-phase species in CVD processes. Within this work $HGaN_6$, GaN_6, $HGaN_2$ and GaN_2 were identified close to the substrate surface. On the basis of the experimental data, however, the authors could not explain the formation of these species. Furthermore, it was not possible to distinguish between β-hydrogen elimination and homolysis of the Ga–C bond of **1**. The main aim of our investigation was to understand the fragmentation of the single-source precursor **1**. A β-hydrogen elimination of **1** would result in $HGa(N_3)_2$ and allyldimethylamine; this amine was not detected in any of our experiments. We checked independently that allyldimethylamine is stable under our applied thermolysis conditions.[4] This means that a β-hydrogen elimination can be excluded unequivocally for **1**.

We identified the monomeric hydrides HMX_2 in thermolysis reactions with alanes and gallanes of the type $Me_2N(CH_2)_3MX_2$ (X = Cl, Br).[4,5] Even though allyldimethylamine was not obtained in any of these experiments, the results were explained by β-hydrogen eliminations. We proposed that the temperatures needed for fragmentation reactions (> 800 °C) were so high that allyldimethylamine, formed as an intermediate, fragmented further to the obtained carbon-containing species. In order to prove this interpretation, we synthesized selectively deuterated starting compounds $Me_2NCH_2CD_2CH_2MBr_2$ (M = Al, Ga) and investigated them by matrix isolation techniques.[12] In none of the thermolysis experiments did we find the expected deuterates $DMBr_2$; only hydrides $HMBr_2$ were formed. That β-hydrogen elimination can occur for intramolecularly coordinated gallanes with high efficiency had been shown for the dimethyl derivative $Me_2NCH_2CD_2CH_2GaMe_2$.[7]

In summary, the following picture for the fragmentation of $Me_2N(CH_2)_3MX_2$ (X = Cl, Br, N_3) is in accordance with all experimental results. Homolysis of the M–C bond results in radicals of the type MX_2. These radicals presumably trap H atoms on their way to the matrix window. In the case of X = Cl or Br, the respective hydrides HMX_2 are stable enough to be detectable in an excess of solid argon. In the case of the azide **1** the proposed intermediate $HGa(N_3)_2$ eliminates HN_3 to give $Ga(N_3)$, an interpretation in accordance with the detected mixtures of HN_3 and $Ga(N_3)$.§ In terms of the CVD process with **1** as a single-source precursor, it is feasible that gallium(I) azide is a key intermediate in the GaN deposition.

This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft. We thank A. Devi (RUB) for the synthesis of **1** and R. A. Fischer (RUB) for his support.

Notes and references

† The matrix isolation apparatus is described in ref. 7. For the photolysis experiments a 150 W Xe arc lamp (XBO 150 W/4 in an Oriel arc lamp housing 66055-M) equipped with a cut-off filter for λ = 225 nm (Schott WG 225) was used.

‡ Because of matrix site effects, the intense band at 2106.0 cm^{-1} is accompanied by a low intensity band at 2102.7 cm^{-1}.

§ According to DFT type calculations at the BP/DZVP level of theory (R. Schmid, TU Munich, Germany) the free energy of activation (including zero point vibrational energy) at 600 K, for the elimination of $HGa(N_3)_2$ to HN_3 and $Ga(N_3)$ is 42.1 kcal mol^{-1}. This fragmentation is energetically preferred over an N_2 loss reaction.

Received (in Columbia, MO, USA) 17th January 2001, Accepted 21st March 2001
First published as an Advance Article on the web 1st May 2001

Stable, electroactive SAMs of oligothiophene–fulleropyrrolidine dyads have been prepared by spontaneous adsorption; electro-oxidation of the oligomeric system results in desorption.

Self-assembled monolayers (SAMs) provide unique opportunities to develop chemically tailored surfaces with specific chemical and physical properties.[1,2] Besides the considerable amount of work devoted to the development of selective electrochemical sensors,[1,2] SAMs have attracted increasing interest due to potential use in molecular electronics.[3]

In this context, there have been several reports concerning the preparation and characterization of SAMs derived from various kinds of linear π-conjugated oligomers on gold surfaces.[3–5] However, until now, all of these monolayers were prepared from oligomeric systems possessing one or two terminal alkanethiol groups eventually connected to the conjugated system *via* a flexible alkyl spacer. Recently, this approach has been successfully applied to the preparation of SAMs of C_{60}-derivatized oligothiophenes.[5] On the other hand, despite some theoretical controversy, the adsorption of thiophene onto Au(111) was recently demonstrated.[6]

Here, we show for the first time that stable SAMs can be produced on Au(111) surfaces by spontaneous adsorption of C_{60}-derivatized, π-conjugated oligomers of the thiophene and thienylenevinylene[7] series. Although the fulleropyrrolidine group represents a very convenient electroactive probe, its role in the process of SAM formation is not clearly elucidated at the present time.

Compounds **1**–**6** (Chart 1) were newly synthesized by reacting the appropriate carbaldehyde with C_{60} in the presence of *N*-methylglycine according to the methodology of Prato and coworkers[8] with a slight modification as reported for the synthesis of C_{60}–thiophene dyads by ourselves.[9] All new compounds were fully characterized by the usual spectroscopic and analytical techniques giving satisfactory results.†

SAMs were prepared by dipping ultra-clean, spherical, gold (99.9999%) bead electrodes‡ for 24–72 h in 1 mM *o*-dichlorobenzene (ODCB) solutions of compounds **1**–**6**. The electrodes were then thoroughly rinsed with ODCB and CH_2Cl_2, dried under an argon flow and immersed in 0.05 M Bu_4NPF_6–ODCB for electrochemical characterization. Sonication in ODCB did not remove the SAMs, indicating that the compounds are chemically adsorbed and not simply physisorbed.

The cyclic voltammogram (CV) of a SAM of **3** (Fig. 1) shows two well-resolved reversible cathodic waves with $E^0_1 = -0.65$ V and $E^0_2 = -1.04$ V corresponding to the first two one-electron reductions of the C_{60} fragment.[10] Scanning the potential to −1.8 V (*vs.* Ag/AgCl) allowed the observation of the reversible third reduction at −1.57 V (not shown in Fig. 1 due to an impurity present in OBCD at around −1.2 V). Within

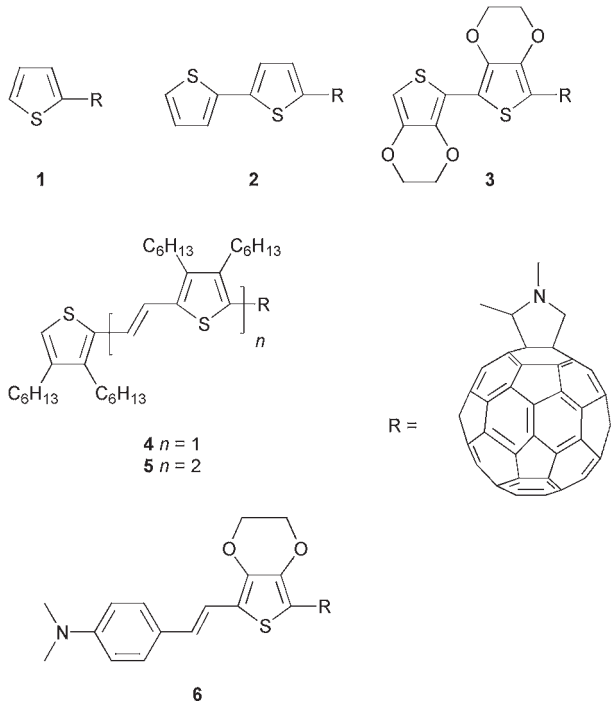

Chart 1

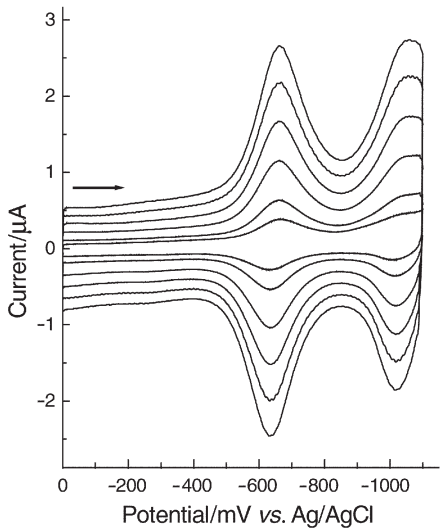

Fig. 1 CVs of a SAM of **3** in 0.05 M Bu_4NPF_6–ODCB system, scan rates between 100 (smallest current) and 1000 (largest current) mV s^{-1}.

DOI: 10.1039/b102132j

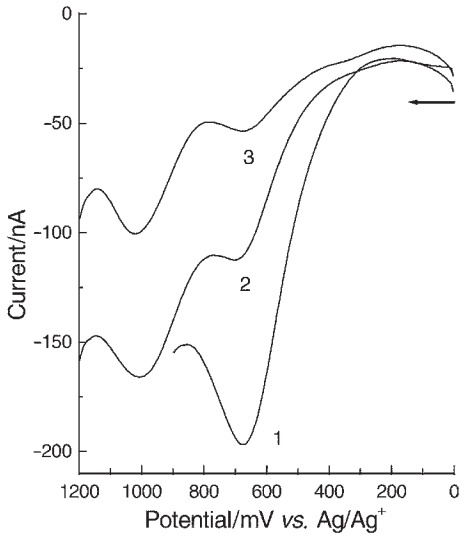

Fig. 2 Repetitive oxidation of a SAM of **3** by Osteryoung square-wave voltammetry in 0.05 M Bu_4NPF_6–ODCB system using a sweep width of 25 mV, frequency of 15 Hz, step potential of 4 mV, and a quiet time of 2 s.

the range of scan rates investigated (100–1000 mV s^{-1}), peak currents increased linearly with the scan rate while the peak potentials and peak-to-peak separations (ΔE_p) (19 and 27 mV for the first and the second reductions, respectively) were independent of scan rate. These characteristics together with the Gaussian shape of the CV waves are typical for surface-confined electroactive species.

Further confirmation of the formation of a surface-attached monolayer on the gold surface was obtained by analyzing the CV response of the $Ru(NH_3)_6^{3+/2+}$ couple at a bare gold electrode and at an electrode modified by a SAM of **3**. The CV recorded in the first case exhibits a reversible redox couple with $E^0 = -0.16$ V and $\Delta E_p = 63$ mV at 100 mV s^{-1}. In contrast, the CV recorded at the modified electrode reveals a drastic decrease of the intensity of the cathodic peak currents together with a *ca*. 50 mV negative shift of the E_{pc} and almost disappearance of the corresponding anodic wave. These results indicate that electron transfer at the interface between the modified gold surface and the solution redox species is severely hindered by the presence of the insulating monolayer.

SAM formation was investigated for the other compounds. Similar results were obtained for compounds **2**, **4** and **5**, but the surface coverage (Γ) decreased from 2.1×10^{-10} mol cm^{-2} for **3** to about 1.1×10^{-10}, 0.4×10^{-10} and 0.3×10^{-10} mol cm^{-2} for **2**, **4** and **5**, respectively.§ It is noteworthy that these Γ values are significantly larger than those reported for SAMs of C_{60}-derivatized oligothiophenes prepared *via* thiol attachment.[5] On the other hand, and despite many attempts using many different conditions (solvent, concentration, time of immersion), no SAM formation could be detected for compounds **1** and **6**.

SAMs derived from compounds **2**–**5** were stable under repetitive cycling in the negative potential region (up to −1.8 V *vs*. Ag/AgCl) and no modification of the CV response was observed after several weeks of storing the modified electrodes under ambient conditions. However, application of a positive potential corresponding to the first oxidation of the oligomeric π-conjugated system produces the rapid desorption of the SAMs (Fig. 2). Desorption was confirmed by the simultaneous disappearance of the fullerene-based reduction peaks. This behavior, which contrasts strikingly with the oxidative stability of SAMs derived from oligothiophenes attached *via* an alkanethiol,[4] suggests that the electron density of the sulfur atom, which depends on the redox state of the π-conjugated oligomer, could play an important role in the adsorption–desorption process.

To summarize, we have demonstrated that stable, electroactive SAMs of dyads involving fulleropyrrolidine and thiophene-based, π-conjugated oligomers can be readily formed on a gold surface and that these SAMs can be easily desorbed by electro-oxidation of the π-conjugated system. Although these preliminary results pose intriguing questions regarding the relationships between the process of SAM formation and the structural variables of the molecules (C_{60} group, substitution of the thiophene ring, presence of a free α-position at the terminal thiophene ring, chain length of the oligomeric system, *etc*.), the unique combination of properties exhibited by this new class of SAMs can open interesting perspectives in the field of thiophene-based molecular electrochemical and electronic devices.

Asymmetric synthesis of novel polyhydroxylated derivatives of indolizidine and quinolizidine by intramolecular 1,3-dipolar cycloaddition of *N*-(3-alkenyl)nitrones†

Piotr Gębarowski and Wojciech Sas*

Warsaw University of Technology, Faculty of Chemistry, ul. Noakowskiego 3, 00 664 Warszawa, Poland. E-mail: sas@ch.pw.edu.pl

Received (in Cambridge, UK) 31st January 2001, Accepted 10th April 2001
First published as an Advance Article on the web 1st May 2001

Reaction of 3-*O*-benzyl-1,2-*O*-isopropylidene-1,5-pentadialdo-α-D-xylofuranose with *N*-(1,1-dimethylbut-3-enyl)-hydroxylamine followed by intramolecular 1,3-dipolar cycloaddition yields 7-oxa-1-azabicyclo[2.2.1]heptane derivative 4, which is easily converted into novel polyhydroxylated quinolizidine 6 and indolizidine 8.

Polyhydroxylated derivatives of indolizidine and quinolizidine (frequently named as azasugars) are powerful glycosidase inhibitors and potential therapeutics.[1] Consequently, these compounds are targets of intensive synthetic studies.

Many syntheses of azasugars use derivatives of natural sugars as starting materials.[1] Based on our experience in intramolecular 1,3-dipolar cycloaddition of *N*-(3-alkenyl)nitrones[2,3] we envisaged that this reaction, proceeding with high regio- and diastereoselectivity,[4] might be a useful tool for conversion of sugar dialdehydes, with one carbonyl group masked, into bicyclic azasugars **E** (Fig. 1).

We reasoned that the nitrone **C**, attained from the protected cyclic or acyclic sugar dialdehydes **A** and *N*-homoallylhydroxylamine **B**, (a sugar ring in Fig. 1 is symbolised by the dashed bow) might undergo intramolecular 1,3-dipolar cycloaddition to give the **7**-oxa-1-azabicyclo[2.2.1]heptane derivative **D** with high stereoselectivity induced by the sugar moiety.‡ Subsequent unmasking of the carbonyl function, which could be combined with a modification of the sugar residue (*e.g.* shortening of the carbon skeleton by a diol cleavage), followed by hydrogenolysis of the N–O bond accompanied by intramolecular reductive amination would complete the synthesis of the target derivative **E**.

We describe herein the transformation of the cyclic sugar dialdehyde 1,2-*O*-isopropylidene-1,5-pentadialdo-α-D-xylofuranose **1**,[5] readily available from α-D-glucose, into the novel polyhydroxylated quinolizidine **6** and indolizidine **8**, possessing a tertiary carbon at an α position to nitrogen, to illustrate the usefulness of the proposed method for the bicyclic azasugar preparation (Scheme 1).

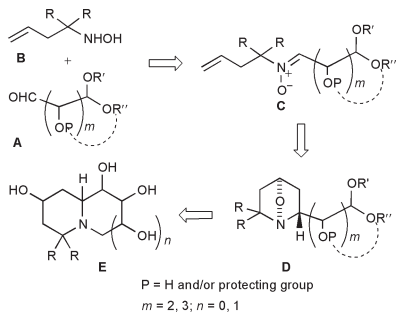

Fig. 1 General approach for asymmetric synthesis of bicyclic azasugars **E** by intramolecular 1,3-dipolar cycloaddition of *N*-(3-alkenyl)nitrones.

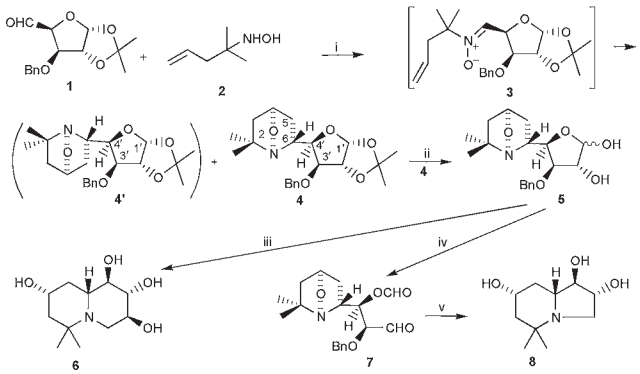

Scheme 1 *Reagents and conditions*: i, toluene, argon, 85–90 °C, 43 h, 52%; ii, 5% HCl aq., rt, 2 d, 96%; iii, H_2 (10 bar), Raney-Ni, MeOH, 75–80 °C, 21 h, 70% based on **4**; iv, $NaIO_4$, MeOH–H_2O, 0 °C; v, H_2 (10 bar), Raney-Ni, MeOH, rt, 24 h then 45 °C, 24 h, 55% based on **4**.

The *N*-homoallylhydroxylamine **2**, necessary for the preparation of **4**, was obtained from the aluminium amalgam reduction of 4-methyl-4-nitropent-1-ene (readily accessible from palladium(0)-catalysed *C*-allylation of 2-nitropropane[6]).[3] The aldehyde **1** heated with **2** in toluene, under argon, gave *N*-(3-alkenyl)nitrone **3** (Scheme 1), which *in situ* underwent intramolecular 1,3-dipolar cycloaddition. Although the possibility exists for formation of two adducts **4** and **4′**, we separated only one diastereoisomer **4** in 52% yield.§ Its structure was determined from ^{1}H NMR spectra and molecular modelling (AM1). The coupling constant between H_6 and $H_{4'}$ was very helpful for configurational assignment; the value of this constant, $^3J_{6,4'}$ = 9.9 Hz, is characteristic for protons in an antiperiplanar arrangement. Molecular modelling revealed that only for the adduct **4** did the lowest energy minimum correspond to the conformation in which H_6 and $H_{4'}$ are antiperiplanar.

The conversion of **4** into quinolizidine **6** was straightforward. Removal of isopropylidene protection by acidic hydrolysis gave cleanly the derivative **5**, which was hydrogenated in the presence of Raney-nickel to afford directly the quinolizidine **6** in 70% yield based on **4**. The structure of **6** from its ^{1}H NMR spectrum is consistent with the structure of **4**. Thus the heterobicyclic system adopts a structure close to *trans*-decaline and all hydroxy groups occupy equatorial positions.

The preparation of the indolizidine **8** was also easy. In this case the carbon skeleton of **5** was cut down by sodium periodate 1,2-diol cleavage to give the aldehyde **7**, which also without purification was hydrogenated in the presence of the nickel catalyst to yield **8** in 55% yield, based on **4**.

In conclusion, it has been shown that the intramolecular 1,3-dipolar cycloaddition of *N*-(3-alkenyl)nitrones, obtained from *N*-homoallylhydroxylamines and sugar dialdehydes, is very useful for the synthesis of polyhydroxylated derivatives of both quinolizidine and indolizidine. Further studies on improve-

† Electronic supplementary information (ESI) available: configurational assignment of the adduct **4** and experimental details of preparation and characterisation of **6** and **8**. See http://www.rsc.org/suppdata/cc/b1/b101057n/

ment and extension of this approach for the synthesis of bicyclic azasugars are in progress.

Notes and references

‡ To our best knowledge the intramolecular 1,3-dipolar cycloaddition reaction of *N*-(3-alkenyl)nitrones, obtained from non-racemic chiral aldhydes, has never been investigated.

§ All new compounds were fully characterised by ^{1}H and ^{13}C NMR, IR spectroscopy, high resolution mass spectrometry and optical rotation. Compound **4**: The aldehyde **1**[5] (0.58 g, 2.09 mmol) and the hydroxylamine **2**[3] (obtained from 0.50 g, 4.0 mmol of 4-methyl-4-nitropent-1-ene) were heated in toluene (4 cm^3), under argon, at 85–90 °C for 43 h. 5-*Exo-dig,* 5-*exo-trig* cascade radical cyclisation on sugar-furanose templates: entry to angularly fused oxa- and dioxa-triquinane skeletons

Mukund K. Gurjar,* S. V. Ravindranadh and Punit Kumar

National Chemical Laboratory, Pune 411 008, India. E-mail: gurjar@dalton.ncl.res.in

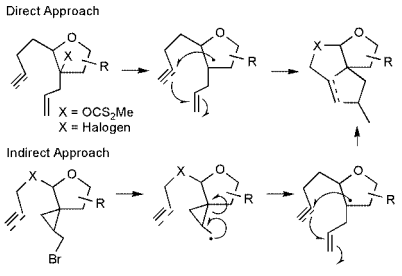
Received (in Cambridge, UK) 20th February 2001, Accepted 10th April 2001
First published as an Advance Article on the web 1st May 2001

Serial radical cyclisation on sugar-furanose templates to create angularly fused oxa- and dioxa-triquinane skeletons has been described, the salient feature of this approach being to incipiently generate a tertiary radical from cyclopropylmethyl bromide with simultaneous release of allyl group and to subsequently incorporate it in the triquinane system.

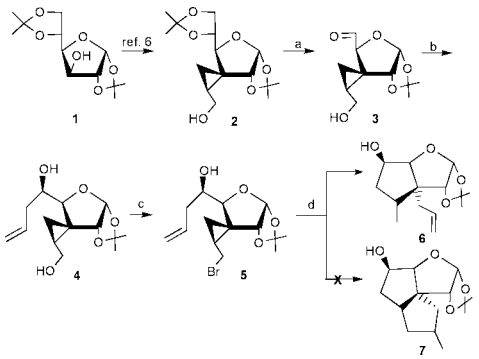
Ever since their isolation, the angularly fused triquinanes have attracted intense attention of synthetic organic chemists as challenging targets.[1] Structural complexity associated with significant biological activity has necessitated development of very many approaches for their synthesis.[2] Among them, the radical cascade reactions are by far the most elegant and efficient approaches as significantly demonstrated by the work of Curran and others.[3] Bis-annulated sugars are also useful synthons for triquinane synthesis. For example, Fraser-Reid and coworkers[4] have performed some novel transformations mediated by serial radical cyclization of pyranose based sugar synthons[5] to create pyranosin diquinanes, elaborated to naturally occurring triquinanes.

We feel that radical cascade reactions on furanose ring systems of sugar derivatives would be interesting to explore primarily to understand the stereo-chemical behavior but more importantly to obtain synthons potentially useful for angularly fused, unknown and structurally novel oxa-triquinanes. The direct approach for oxa-triquinane would be to trigger a cascade of radical reactions by generating tertiary radicals on synthons with prefabricated radical acceptors (Scheme 1). Realistically, formation of a tertiary radical is a difficult proposition because its precursor, namely tertiary halide or tertiary thiocarbamate, is not easily accessible by conventional methods. However, the indirect formation of a tertiary radical with concomitant installation of an allylic side chain as radical acceptor, by our recently developed approach[6] of radical ring opening of spirocyclopropyl methyl bromide, could constitute an elegant and ideal proposition for this endeavor. This study forms the basic premise of this communication.

1,2:5,6-Di-*O*-isopropylidene-α-D-glucofuranose (**1**) was converted into the 3,3-spiro cyclopropylmethanol derivative (**2**) in five steps (Scheme 2).[7] It was then exposed to 0.8% sulfuric acid in methanol at rt to give the triol derivative whose oxidative cleavage with $NaIO_4$ absorbed on silica gel[8] in CH_2Cl_2 yielded the aldehyde (**3**). Compound **3** was immediately treated with



Scheme 1

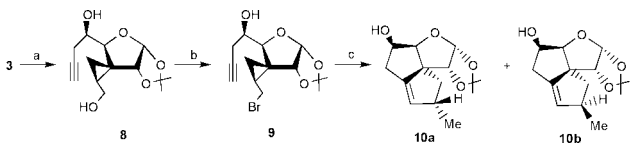


Scheme 2 *Reagents and conditions*: (a) (i) 0.8% H_2SO_4, MeOH, rt, 10 h; (ii) silica gel adsorbed $NaIO_4$, CH_2Cl_2, 15 min, 78% (two steps); (b) allyl bromide, Zn, aq. NH_4Cl, THF, 0 °C, 6 h, 72%; (c) PPh_3, CBr_4, pyridine, CH_2Cl_2, rt, 1 h, 83%; (d) TBTH, AIBN (cat), $C_6H_5CH_3$, 100 °C, 1 h, 70%.

Zn, allyl bromide under aqueous Barbier conditions[9] to give a predominantly (90%) and chromatographically separable allyl addition product (**4**) whose stereochemical assignment was based on literature precedents.[10] Compound **4** upon treatment with CBr_4–PPh_3 in CH_2Cl_2 in the presence of pyridine at rt gave the corresponding bromo derivative (**5**). Treatment of **5** with tri-*n*-butyl tin hydride (TBTH), AIBN in toluene (0.05 M) at 100 °C gave a single product whose fused bicyclic structure (**6**) was assigned on the basis of NMR and MS studies. Presence of compound **7** was not noticed. The formation of **6** indicated premature termination of serial radical cyclisation after the first *exo-trig* addition. This abrupt termination could be attributed to the poor reactivity of the methyl radical.[11] In order to circumvent this problem, we sought to explore the vinyl radical primarily for its pronounced reactivity coupled with the ease with which it could be generated.[12]

Accordingly, **3** was subjected to Barbier reaction in aqueous conditions with Zn and propargyl bromide to afford **8** as an exclusive product. The transformation of **8** into **9** was carried out as described earlier (Scheme 3).

The radical reaction of **9** with TBTH and AIBN (cat.) in dry toluene (0.05 M) at 100 °C gave the angularly fused oxa-triquinane derivatives **10a** and **10b,** whose formation was attributed to 5-*exo-dig*, 5-*exo-trig* serial cyclisations. The structure of the product was thoroughly investigated by high resolution ^1H NMR, ^{13}C NMR, MS and elemental analysis. The ^1H and ^{13}C NMR spectra indicated that it was a 8.5 : 1.5 mixture of diastereomers **10a** and **10b**. However, COSY and NOSY



Scheme 3 *Reagents and conditions*: (a) HC≡C–CH_2Br, Zn, aq. NH_4Cl, THF, 0 °C, 6 h, 74%; (b) PPh_3, CBr_4, pyridine, CH_2Cl_2, rt, 1 h, 80%; (c) TBTH, AIBN (cat), $C_6H_5CH_3$, 100 °C, 1 h, 74%.

DOI: 10.1039/b101641p

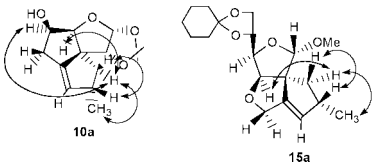


Fig. 1 NOSY studies.

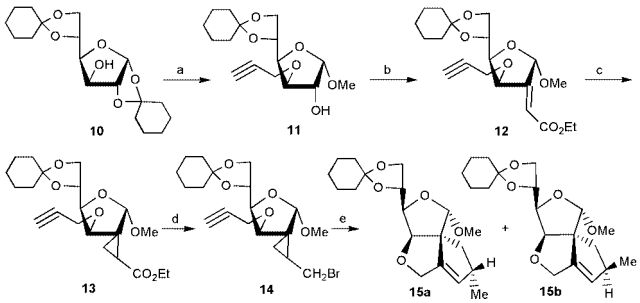
studies (Fig. 1) on the major diastereomer **10a** revealed the absolute stereochemistry of the methyl group as indicated.[12]

We also synthesized starting from 1,2:5,6-di-*O*-cyclohexylidene-α-D-glucofuranose (**10**) the 2,2-spirocyclopropyl methyl bromide derivative **14** *via* intermediates **11**–**13** as shown in Scheme 4. Subsequent radical cascade reaction of **14** with TBTH and AIBN (cat.) in toluene at 100 °C gave the fused ring derivatives **15a** and **15b**. The ^{1}H and ^{13}C NMR spectra of the product showed to be a 8:2 mixture of diastereomers. The COSY and NOSY studies (Fig. 1) predicted the stereochemistry of the methyl group of the major product **15a** as indicated.[13]



Scheme 4 *Reagents and conditions*: (a) (i) NaH, HC≡C–CH_2Br, DMF, 0 °C, 90%; (ii) H_2SO_4, MeOH, Δ, chromatography, 65%; (b) (I) IBX, DMSO, rt, 10 h; (ii) PPh_3=$CHCO_2Et$, C_6H_6, 80 °C, 2 h, 74% (two steps); (c) Me_2SOCH_3I, NaH, DMSO, rt, 3 h, 55%; (d) (i) DIBAL-H, CH_2Cl_2, 78 °C, 0.5 h, 87%; (ii) PPh_3, CBr_4, pyridine, rt, 82%; (e) TBTH, AIBN (cat), $C_6H_5CH_3$, 100 °C, 1 h, 80%.

In conclusion, we have developed a one pot, stereoselective 5-*exo-dig*, 5-*exo-trig* cascade radical cyclization utilizing the incipiently formed *C*-allyl radical leading to useful and structurally novel oxa-triquinane system.

S. V. R. thanks CSIR, New Delhi for a research fellowship.

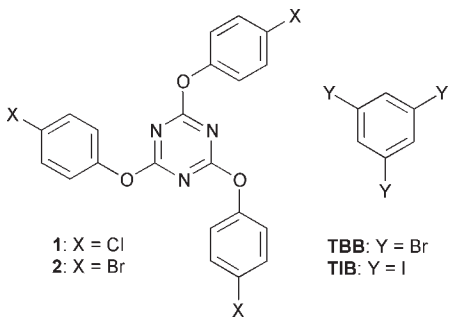
Crystallization of four isomorphous host–guest complexes in the polar space group $P6_3$ is ascribed to the recurring halogen(guest)···π(host) interaction.

Self-assembly of chiral crystals from achiral components[1] is a current endeavor in crystal engineering with applications in asymmetric synthesis and materials science. Crystallization of achiral or racemic molecules in acentric space groups is relevant not only for the design of functional solids, such as host–guest,[2] nonlinear optics,[3] but also has implications in our fundamental understanding of spontaneous resolution during crystallization.[4] In this context, it was recently noted by some of us[5] that co-crystallization of 2,4,6-tris(4-chlorophenoxy)-1,3,5-triazine **1** and 1,3,5-tribromobenzene (TBB) from an equimolar mixture



of benzene and ethyl acetate afforded a 1:1 complex, **1**·TBB, that belongs to the non-centrosymmetric space group $P6_3$. In **1**·TBB, the triazine molecules form a hexagonal network *via* the robust Cl···Cl trimer synthon. Tribromobenzene guest molecules located in the channels are bonded *via* C–Br···π and C–H···π interactions[6] to the C=C bond mid-point of the host phenyl ring rather than to the ring centroid, as ascertained by neutron diffraction.[5] In this paper we demonstrate the structural significance of halogen···π interactions[7] in inducing polar aggregation of molecules in the solid state. The description of space groups using terms such as (non)centrosymmetric, acentric, chiral and polar has been clarified in the crystallographic literature.[8]

Crystallization of chlorotriazine **1** and 1,3,5-triiodobenzene (TIB) from PhH–EtOAc afforded crystals of **1**·TIB (1:1) in space group $P6_3$.† The TIB guest species are accommodated in an open hexagonal network formed by a triangulo halogen synthon (Cl···Cl 3.56 Å, 107.0°, 167.0°) of triazine host molecules (Fig. 1). The hexahost framework of **1** and **2** with trihalobenzene guests is virtually identical to the intermolecular interaction network observed in their channel inclusion complexes with other guest species: benzene, hexamethylbenzene (HMB), hexachlorobenzene (HCB), trinitromesitylene (TNM), 1,3,5-trinitrobenzene (TNB), mesitylene (MES), 2,4,6-collidine (CLN) and hexamethylphosphoramide (HMPA).[9] However, the latter host–guest structures are centrosymmetric (space group

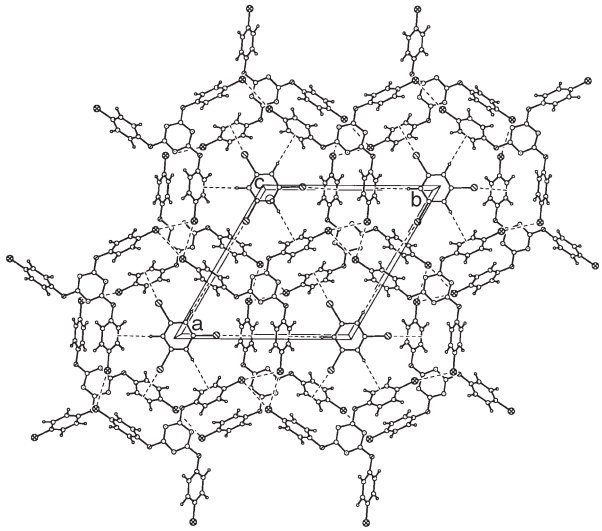


Fig. 1 Hexa-host network in **1**·TIB assembled through Cl···Cl triangulo synthon. TIB guest molecules are bonded *via* C–I···π and C–H···π interactions. Notice the herringbone motif between host phenoxy rings of adjacent channels.

$P6_3/m$) with the triazine core lying on a crystallographic mirror plane. Thus inclusion of trihalobenzene guests in the hexagonal nanotubes induces significant structural changes in the mutual orientation of host phenyl rings. Yet there is minimal change in the lattice parameters of **1**·TBB and **1**·TIB compared to the centrosymmetric structures (Table 1). Adjacent phenoxy rings are parallel in the $P6_3/m$ structures while they are twisted by an angle (τ) of 51.3° and 54.3° to each other in **1**·TBB and **1**·TIB. As a result of phenyl group tilting, away from the halogen and closer to the hydrogen, the guest molecules form short C–I···π

(3.43 Å, 158.3°; Σ vdW radii = 2.0 + 1.7 = 3.7 Å) and long C–H···π (3.00 Å, 177.4°) interactions with different C=C bonds of the host phenyl ring.‡ Three such sinusoidal motifs stabilize the polar host–guest architecture (Fig. 2). The C–I···π interaction is polarization-induced, such that the C–I$^{\delta(+)}$ vector points towards the mid-point of a $\pi^{\delta(-)}$ bond, and is reminiscent of the type II halogen···halogen interaction[9] between host molecules. In effect, a slice of the host–guest layer in **1**·TIB is stabilized by Cl···Cl, C–I···π and C–H···π interactions (Table 2). The halogen···π radial motif in **1**·TIB channel resembles the Cl···π interaction observed recently in the pseudo-threefold cavity of calix[6]pyrrole with 2,2,2-trichloroethanol guest.[10] The interplay of numerous weak interactions, aryl–aryl, C–H···N, aryl–halogen and inter-halogen, resulting in microcavities that are tailored to the guest structure has been noted in a halogenated tweezer host molecule.[11]

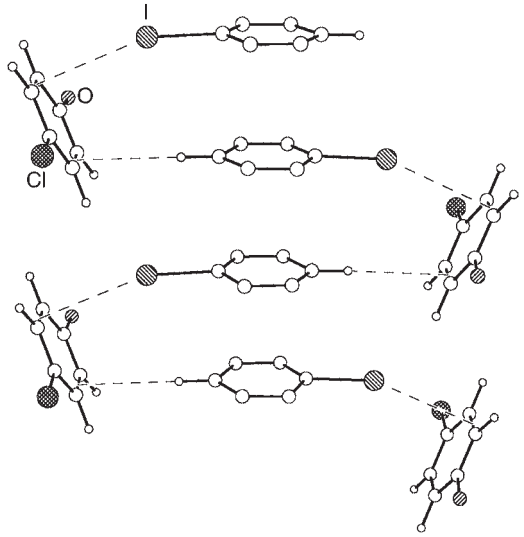

Fig. 2 Sinusoidal chain of C–I···π and C–H···π interactions in **1**·TIB that result in polar crystallization. Three such motifs rotated by 120° stabilize the host–guest channel architecture. Molecular fragments are truncated for clarity.

The 1:1 inclusion complexes of tribromobenzene and triiodobenzene with 2,4,6-tris(4-bromophenoxy)-1,3,5-triazine **2**, **2**·TBB and **2**·TIB respectively,† are isostructural with the corresponding inclusion complexes of **1** (Table 1). The mutual orientation of host phenyl rings and metrics of C–Br/I···π and C–H···π interactions are given in Table 2. Although the exact reasons as to why achiral or racemic molecules adopt non-centrosymmetric crystal packing are difficult to dissect,[1,4] the present case of four isomorphous structures offers a clue. Three polar chains of C–Br/I···π and C–H···π guest–host interactions rotated by 120° to each other stabilize the hexagonal nanotubes. The crystal structure would be centrosymmetric if such motifs in adjacent chains run anti-parallel and non-centrosymmetric if they are aligned in the same direction. The polarity of one nanotube is transmitted to adjacent channels *via* the edge-to-face[12] herringbone packing between host phenoxy rings related by a two-fold screw axis. Since inclusion complexes of **1** and **2** with many other guests are all centrosymmetric,[9] polar aggregation with TBB and TIB species in space group $P6_3$ appears to be guest-induced. Thus, the halogen- and hydrogen-bonded synthon in Fig. 2 is the minimum ensemble necessary to amplify polarity in the three-dimensional crystal, in other words it is a supramolecular chiron.[13] The mechanism for polar crystallization with flexible hosts **1** and **2** (guest–host X···π interaction) is conceptually different from the phenomenon for parallel alignment of D–π–A chromophores in the constrained channel of perhydrotriphenylene (guest–guest D···A interaction).[3]

Received (in Cambridge, UK) 30th January 2001, Accepted 22nd March 2001
First published as an Advance Article on the web 3rd May 2001

The molecular structure of the oxo-peroxovanadium complex $[VO(O_2)(bpaH)]ClO_4{\cdot}2H_2O$, containing the new ligand *N,N*-bis(2-pyridylmethyl)-β-alanine (bpaH) reveals tight binding of the carboxylic acid function to the vanadium centre through its doubly bonded oxygen; the carboxylic acid proton mediates hydrogen bonding interactions comprising the peroxo group and the two waters of crystallisation, thus providing the basis for the potential formation of a hydroperoxo species.

Authentic peroxovanadium complexes as well as peroxovanadium complexes generated *in situ* have been employed as catalysts and in stoichiometrically conducted reactions as oxo transfer reagents for alcohols, arenes, alkenes and thioethers.[1,2] Likewise, the bromination of functionalised arenes is carried out by peroxovanadium complexes, or by vanadium compounds in the presence of H_2O_2.[3,4] Peroxovanadium intermediates have also been proposed for the enzymatic conversion of halide to hypohalous acid (or another Hal^+ species) by vanadate-dependent algal and fungal haloperoxidases in the presence of peroxide,[4–7] an assumption which has been fortified by the structural characterisation of the peroxo form of chloroperoxidase from the fungus *Curvularia inaequalis*.[8] Both the *in vitro* and *in vivo* oxidation of halide such as bromide is facilitated by an increase of the electrophilicity at the reaction site, *i.e.* by the intermediate formation of a hydroperoxo complex (Fig. 1, left) in the case of the peroxo ligand representing the reaction site,[4,5,9] a suggestion which finds support in the fact that (i) protons are consumed in these reactions,[9] (ii) alkylperoxo complexes are often more effective than the parent peroxides,[1] (iii) the cationic hydroperoxo–oxovanadium moiety is on a lower energy level (more stable) than the corresponding peroxo–oxovanadium species,[10] and (iv) a hydroperoxo form of the active site vanadium in bromoperoxidase from the marine alga *Ascophyllum nodosum* is quite within the bounds of probability as based on ^{17}O NMR evidence.[10] The asymmetric side-on coordination of RO_2^- has previously been reported for $[VO(O_2)(HO_2)(bipy)]$ (bipy = 2,2′-bipyridyl[12a]), $[VO(H_2O)(tBuO_2)(dipic)]$ (dipic = dipicolinate(2−))[12b] and $[\{VO(O_2)_2\}(\mu\text{-}\eta^1,\eta^2\text{-}O_2)\{VO(O_2)H_2O\}]^{2-}$.[13] Based on kinetic investigations, hydroperoxo intermediates have also been made plausible in oxo transfer reactions to metal-centred thiolates using $[VO(O_2)_2(pic)]^{2-}$,[14] and peroxidative halogenations with $[VO(O_2)(bpg)]$ (bpgH = *N,N*-bis(2-pyridylmethyl)glycine).[5,9] An additional point of considerable interest in the context of peroxovanadium complexes is their ability to inhibit phosphotyrosine phosphatases and thus act as insulin mimetics.[15]

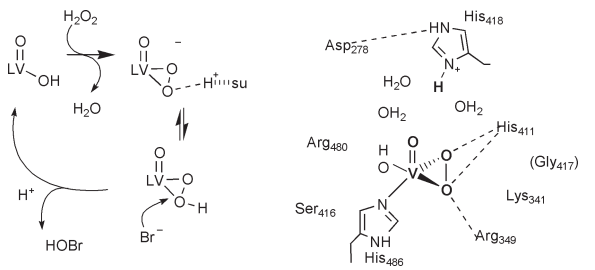

Fig. 1 Left: proposed mechanism for bromide oxidation (su = supporting group). Right: active site of the peroxo form of vanadate-dependent bromoperoxidase from *A. nodosum*, based on the structure of the native *A. nodosum* enzyme[18] and the peroxo form of the *C. inaequalis* peroxidase.[8] Potential mediators for proton transfer are His418, His411 and Asp278.

In the present work we report on a peroxovanadium complex giving rise to a tight hydrogen bonding network in which three different functionalities participate, *viz.* a coordinated and protonated carboxylate, two inter-lattice water molecules and the peroxo ligand. Hence a complex which may represent a preformed hydroperoxo species, or a compound which is able to rapidly and reversibly provide a proton for a hydroperoxo intermediate in catalytic turnover. Our complex thus models a situation which, in the haloperoxidases, is represented by aspartate or the distal histidine plus water molecules at the active site of the enzyme (Fig. 1, right). Aspartate as a mediator for proton-transfer has also been reported for vanadate-incorporated phytase,[16] a semi-synthetic vanadium peroxidase.[17]

The new ligand *N,N*-bis(2-pyridylmethyl)-β-alanine (bpaH) was synthesised† (Scheme 1) by modifying the procedure described for *N,N*-bis(2-pyridylmethyl)-glycine (bpgH).[19] The complex $[VO(O_2)(bpaH)]ClO_4{\cdot}2H_2O$ was obtained† by adding the ligand to an aqueous solution of $K[VO_3]$, followed by treatment with H_2O_2 and finally with dilute $HClO_4$ to adjust the solution to pH 1.7. Orange-coloured crystals were obtained from the ethanolic solution in the cold.

The molecular structure‡ of the compound is shown in Fig. 2; hydrogen bonding interactions have been indicated by dashed lines. The basic structure of the cation $[VO(O_2)(bpaH)]^+$ is a pentagonal bipyramid, with the peroxo ligand (O1 and O2) and the three nitrogens (N1, N2 and N3) of bpaH in the plane, and the oxo group O3 and carboxylic acid oxygen O4 in the apical positions. The ligand bpaH coordinates to the vanadium forming one six-membered and two five-membered chelate rings. The two pyridines are in the equatorial plane. The five atoms in the equatorial plane are nearly coplanar; the vanadium

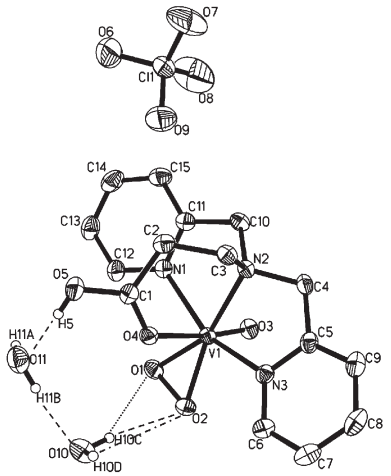

Fig. 2 Molecular structure of $[VO(O_2)bpaH]ClO_4{\cdot}2H_2O$ at the 50% probability level, including the hydrogen bonds (dashed lines). Selected bond lengths (Å) and angles (°): V–O1 1.8734(16), V–O2 1.8827(16), V–O3 1.5877(15), V–O4 2.2095(16), V–N1 2.132(2), V–N2 2.192(2), V–N3 2.133(2), O1–O2 1.422(2), C1–O4 1.222(3), C1–O5 1.302(3), O5–H5 0.8201(10); O1–V–N1 81.68(8), O1–V–O2 44.48(7), O2–V–N3 81.83(8), N1–V–N2 75.53(7), N2–V–N 374.13(7), O3–V–O4 172.25(7). Hydrogen bonds (Å): O1···H10C–O10 3.250, O2···H10C–O10 2.995, O2···H10D–O10 2.806, O5–H5···O11 2.550, O11–H11B···O10 2.711, O11–H11A···O6 (perchlorate) 2.993.

centre is displaced from this plane by 0.2163(8) Å towards the oxo group. The unusual coordination mode of the carboxylic acid function – through the doubly bonded oxygen O4 – has been described previously for a number of dipicolinato complexes of copper,[20] iron[21] and zinc[22] with bond lengths ranging from 2.3 to 2.5 Å (as compared to *ca*. 2.1 Å for the corresponding bond lengths of *de*protonated carboxylic acid functions). The angle O3–V–O4, 172.25°, only slightly deviates from linearity. The bond V–O4 [d = 2.2095(16) Å] is thus surprisingly strong, even more as it is subject to the *trans* effect exerted by the oxo group. It compares to the V–O (carboxylate) distances of 2.144 and 2.045 Å for the carboxylato group *trans* and *cis* to V=O, respectively, in $[VO(L)H_2O(O_2)]^-$ (H_2L = carboxymethylhistidine),[23] d[V–O (carboxylate)] = 2.138 Å for the *trans*-standing carboxylate in $[VO(O_2)(bpg)]$,[9] and d[V-O(carboxylate)] between 2.01 and 2.04 Å in other peroxovanadium complexes containing supporting ligands with *cis*-standing carboxylato functions.[24,25] The complex is the first example of a cationic monoperoxo–oxovanadium complex with an N_3O donor set. Other cationic vanadium complexes which have been described so far contain two NO donor sets ($[VO(O_2)(picolinamide)_2]^+$),[26] or one or two N_2 sets ($[VO(O_2)$-$(phen)(H_2O)_2]^+$;[27] $[VO(O_2)L_2]^+$, L = phen, bipy[28]).

The uncoordinated OH of the carboxylic acid group of $[VO(O_2)(bpaH)]^+$ links a water of crystallisation (O11) *via* a strong hydrogen bond of 2.550 Å, which in turn hydrogen binds to the perchlorate anion and a second water of crystallisation, O10. Two hydrogen bonds of weak to medium strength keep this water in the proximity of the coordinated peroxo group.§ Although only O2 of the peroxide is involved in this H-bonding network to a sizable extent, there are no significant differences in the V–O (peroxide) bond lengths. Bonding parameters [d(V–O1) 1.8734(16), d(V–O2) 1.8827(16) Å; angle O1–V–O2 = 44.48(7)°] are comparable to those in other peroxovanadium complexes;[9,13,23–25,29] the O–O bond length, 1.421(3), is in-between the margins noted for $[V_2O_2(O_2)_4H_2O]^{2-}$ [13] and $[VO(O_2)(tp)(pz)]$ (tp = tris(pyrazolyl)borate, pz = pyrazole).[30]

This special arrangement of carboxylic acid, water and peroxide provides a basis for a mechanism for rapid – and reversible – transfer of a proton to the activated (by coordination to vanadium) peroxo function, and hence a mechanism by which the electrophilicity of this site can be adapted to an appropriate substrate to be oxidised, such as bromide; *cf*. Fig. 1.

Propeller-shaped molecules based on a triphenylbenzene crux bearing three oligomeric phenylenevinylene branches have been designed; very large first-order hyperpolarisabilities (up to $\|\beta\|$ = 800 10^{-30} esu) were obtained while maintaining wide transparency in the visible region by taking advantage and boosting of intramolecular charge transfer between the centre and the periphery.

Molecular nonlinear optics (NLO) has attracted increasing interest over the past twenty years,[1] owing to numerous applications in various fields such as telecommunications, optical data storage and information processing.[2] A substantial effort has been devoted to the design of molecules with enhanced NLO responses. Molecular engineering of conjugated one-dimensional (1D) compounds has been particularly successful, leading to push–pull compounds displaying giant off-resonance first-order (β)[3] and/or second-order (γ)[4] hyperpolarisabilities. Yet it became increasingly clear over recent years that multidimensional and multipolar structures offer challenging possibilities.[5] Lehn, Zyss and coworkers have opened a pioneering route towards octupolar molecules.[6] Such 2D or 3D structures take benefit from the tensorial nature of β, and potentially lead to very large β[7] and γ[8] values but most often at the expense of significantly reduced transparency in the visible region.[9] In order to achieve an improved nonlinearity–transparency trade-off, we have prepared nanoscale propeller-shaped molecules whose design is based on the grafting of three extended blades bearing an electron-withdrawing or an electron-releasing tip on a triphenylbenzene crux (Scheme 1). Oligomeric phenylenevinylene rods were selected to ensure effective electronic conjugation and preserve transparency. The triphenylbenzene core maintains a large distance between the conjugated branches, thus preventing sterical hindrances.

Based on this strategy, we have prepared homologous molecules with radius varying between 1.4 and 2.5 nm. The first generation (n = 1) was prepared from 1,3,5-tris(4-formylphenyl)benzene (**C_0**[10]) *via* either a triple Wittig or Wittig–Horner–Emmons reaction whereas the second generation (n = 2) was obtained from **C_1** *via* a triple Wittig–Horner–Emmons condensation with extended conjugated aldehydes X–Ph–CH=CH–Ph–CHO. The key reagent **C_1** was synthesized from **C_0** in a three-step procedure (Scheme 1). The conjugated aldehydes were primarily prepared in nearly quantitative yield by reacting terephthalaldehyde mono(diethyl acetal) with one equivalent of phosphonium salt X–Ph–CH_2–$P(Ph)_3I$ (X = $N(nC_6H_{13})_2$,[4b] or X = OnC_8H_{17}) or of diethyl 4-(methylsulfonyl)benzyl phosphonate (X = SO_2CH_3) followed by acid-catalysed hydrolysis. Molecules **1**–**6** were characterised by NMR spectroscopy, elemental analysis and/or high-resolution mass spectra, in agreement with the assigned structures.

All molecules show good transparency in a wide range of the visible region and an intense absorption in the near UV–blue visible region whose position is dependent on both the nature of the peripheral groups and the length of the transmitter system (Table 1). As expected, a red shift of the absorption band is observed with increasing electron-withdrawing or electron-releasing strength of the end groups. Interestingly, a bathochromic shift of the absorption band is obtained with increasing solvent polarity (Fig. 1a) and a noticeably more pronounced positive solvatochromism is observed in emission (Fig. 1b), indicative of a polar excited state. Such characteristic behaviour hints to significant charge redistribution taking place upon excitation, consistent with a multidimensional intramolecular charge transfer (MDICT) occurring between the core and the peripheral groups. The large Stokes shift values (4050

[a] In chloroform. [b] Absorption solvatochromic shift = $1/\lambda_{max}$(toluene) $-1/\lambda_{max}$(DMSO). [c] The modulus $\|\beta\| = \sqrt{\sum_{ijk}\beta_{ijk}^2}$ is derived from β_{HLS} according to $\|\beta\| = \sqrt{\frac{21}{2}}\,\beta_{HLS}$ for molecules with C_{3h} symmetry, and to $\|\beta\| = \beta_{zzz} = \sqrt{\frac{35}{6}}\,\beta_{HLS}$ for 1D dipolar chromophores such as *p*-nitroaniline (*p*NA). [d] Static values are calculated using a two-level dispersion factor.[6b] [e] In DMSO.

cm^{-1} for molecule **2** in chloroform, and 8500 cm^{-1} for molecule **4** in DMSO) corroborate that important nuclear reorganisation is taking place after excitation, prior to emission as a result of significant electronic redistribution.

The first hyperpolarisabilities β have been determined by performing harmonic light scattering (HLS) experiments which yield the HLS molecular averaged hyperpolarisability $\sqrt{\langle\beta^2\rangle} = \beta_{HLS}$.[11] HLS experiments were performed at 1.064 or 1.34 μm in order to locate the second harmonic signal in the transparency region of the chromophores and to avoid contamination by two-photon fluorescence.[12] Comparison of homologous molecules bearing electron-releasing (**1**,**2**) or electron-withdrawing (**3**,**4**) end groups clearly shows that increasing the donating or accepting strength of the three terminal substituents results in a significant enhancement of β (Table 1), providing evidence that MDICT strongly influences the nonlinear responses. Following this observation, increasing the distance between the core and the periphery appeared as a rational way to boost the nonlinear responses. This strategy proved particularly successful: molecule **5** was found to exhibit a $\|\beta(0)\|$ value about six times larger than molecule **2**, whereas molecule **6** exhibits a first-order hyperpolarisability *one order of magnitude larger* than its shorter analogue **3**, while increasing by no more than 36% in weight and maintaining suitable transparency in the visible region. This is particularly advantageous in terms of efficiency-transparency trade-off: molecule **6** exhibits a $\|\beta(0)\|$ value about forty times larger than the prototypical push–pull compound *p*-nitroaniline (*p*NA), with a molecular weight no more than eight times larger.

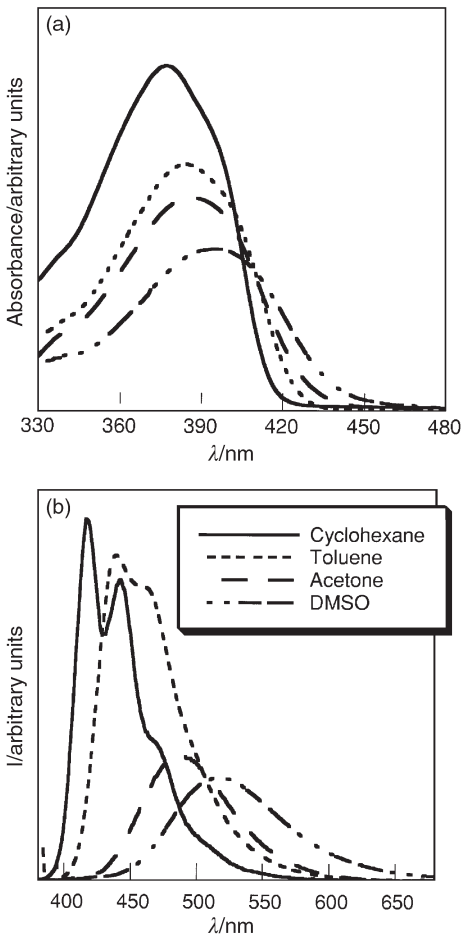

Fig. 1 Solvatochromic absorption (a) and emission (b) behaviour of molecule **2**.

Finally, by grafting either electron-donating or electron-withdrawing groups on the edges of conjugated blades branched on a triphenylbenzene crux, propeller-shaped molecules exhibiting high NLO properties and wide transparency in the visible range have been designed. Optimization leads to compounds presenting an improved transparency–nonlinearity trade-off ($\|\beta(0)\|$ = 500 10^{-30} esu, λ_{max} = 377 nm) as compared to tris-donor tris-acceptor octupolar 2D molecules. In addition, the superlinear dependence of β on size and their particular concave shape makes elongated analogues attractive candidates for incorporation in polymeric materials.

Direct resolution of C_{76} enantiomers by HPLC using an amylose-based chiral stationary phase

Chiyo Yamamoto,[a] Tomoko Hayashi,[a] Yoshio Okamoto,*[a] Shingo Ohkubo[b] and Tatsuhisa Kato[bc]

[a] *Department of Applied Chemistry, Graduate School of Engineering, Nagoya University, Chikusa-ku, Nagoya 464-8603, Japan. E-mail: okamoto@apchem.nagoya-u.ac.jp*

Received (in Cambridge, UK) 1st March 2001, Accepted 17th April 2001
First published as an Advance Article on the web 2nd May 2001

A chiral fullerene C_{76} was directly resolved by high-performance liquid chromatography (HPLC) using a chiral stationary phase, amylose tris(3,5-dimethylphenylcarbamate), bonded onto silica gel and the mirror-imaged CD spectra of the enantiomers were in good pattern agreement with those of the previous report.

In 1993, Hawkins and Meyer reported the kinetic resolution of C_{76} enantiomers by asymmetric osmylation,[1] and this method was successfully applied to the resolution of other chiral fullerenes, C_{78} and C_{84}.[2] However, direct resolution of chiral fullerenes by HPLC with a chiral column appears very difficult judging from the tiny structural differences in the C_{76} enantiomers as pointed out by Hawkins and has so far been unsuccessful,[1] although chiral fullerene C_{60} derivatives with achiral substituents have been successfully resolved into enantiomers using chiral stationary phases (CSPs) based on a cellulose derivative[3] and a tetranitrofluorenylidene derivative.[4]

Phenylcarbamate derivatives of polysaccharides, particularly cellulose and amylose, show high chiral recognition abilities when used as CSPs for HPLC.[5–7] Among the many derivatives, 3,5-dimethylphenylcarbamates of cellulose[8] and amylose[9] are very useful CSPs with an excellent ability of resolving a wide range of racemates. These CSPs have been prepared by coating or adsorbing the polysaccharide derivatives on silica gel, and therefore cannot be used with solvents such as $CHCl_3$ and THF that dissolve or swell the derivatives. On the other hand, amylose tris(3,5-dimethylphenylcarbamate) (Chiralpak AD) bonded to silica gel only at its terminal residue has been prepared *via* enzymatic polymerization, and can be used with $CHCl_3$ and THF.[10]

In the present study, we succeeded in the first direct HPLC resolution of the smallest chiral fullerene C_{76} on the chemically bonded Chiralpak AD using a hexane–$CHCl_3$ (80 : 20) mixture as the eluent.

The racemic C_{76} sample was isolated as a chlorobenzene solution by HPLC and identified by mass spectroscopy. The concentration of the solution was estimated to be *ca.* 0.36 mM l^{-1} based on the UV spectrum measurement.[11] The chemically bonded Chiralpak AD column was prepared by our group in Nagoya.[10] Chromatographic resolution was performed on a modified JASCO PU-980 chromatograph equipped with a UV and CD dual detector (JASCO CD-1595) and a recycle valve unit (HV-1592-01). The racemic C_{76} solution (100 μl) was injected into the chromatographic system with a Rheodyne Model 7125 injector. A hexane–$CHCl_3$ (80 : 20) mixture was used as the eluent at a flow rate 1.0 ml min^{-1}. UV spectra were measured in hexane–$CHCl_3$ and toluene solutions using a JASCO Ubest V-570 spectrophotometer. The CD spectra of the C_{76} enantiomers in hexane–$CHCl_3$ and toluene were taken on a JASCO J-720 L apparatus with a 0.2 cm quartz cell at ambient temperature.

When the resolution of the racemic C_{76} sample was examined on the commercial Chiralcel OD and Chiralpak AD columns using a hexane–propan-2-ol mixture as the eluent, the elution of the sample was not clearly observed probably because of very low solubility of C_{76} in this eluent which resulted in a very long retention time. This forced us to use chiral columns that can be used with a $CHCl_3$ eluent system. We then examined the resolution on the chemically bonded Chiralpak AD and Chiralcel OD phases using the hexane–$CHCl_3$ eluent, and found that Chiralpak AD had better resolution. The results of the resolution are shown in Fig. 1. Both the UV and CD signals were monitored by the dual detector. The UV signal always showed a single peak sometimes with a shoulder, while the CD signal monitored at 400 nm showed the first (+) peak followed by the second (–) peak. This indicates that a low degree of resolution was attained and in the first cycle two (+) peaks were clearly observed. The reason for the appearance of the two peaks is not immediately clear, but may be due to sample overloading. Very low loading capacity of the column seems to indicate that chiral recognition of the C_{76} enantiomers may be performed at specific chiral sites containing multi amylose chains. In all the recycle separations, only the front main part of the (+) fraction was recycled, and the late main portion of the (–) fraction was collected during each recycle. Therefore, as the number of recycles increased the UV intensity decreased, and after 8 recycles, almost no (–) peak was observed. After 5 recycles, the intensity ratio of the UV and CD detection at the peak top became almost constant. These results suggest that the (+) isomer after 8 recycles may have a higher enantiomeric excess (ee).

The HPLC analysis of the (+) and (–) fractions resolved by the recycling are shown in Fig. 2. The (+) fraction shows a very good agreement between the UV and CD curves indicating that this fraction has a high enantiomeric purity. On the other hand, the (–) fraction shows a small (+) peak besides a main (–) peak, indicating lower enantiomeric purity of this fraction.

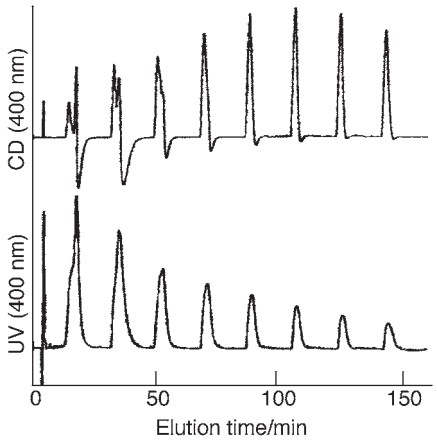

Fig. 1 Chromatographic recycled resolution of C_{76} on chemically bonded Chiralpak AD column. Column, 25 × 0.46 cm (id); eluent, hexane–$CHCl_3$ (80 : 20); flow rate, 1.0 ml min^{-1}.

DOI: 10.1039/b101972b

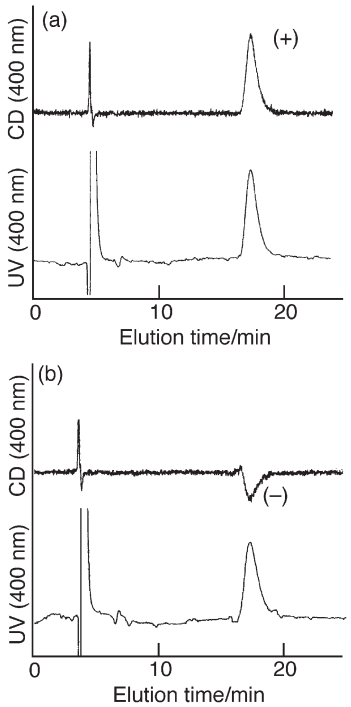

Fig. 2 HPLC chromatograms of the first (a) and the second (b) eluted enantiomers isolated after recycled resolution of C_{76}. (Column, chemically bonded Chiralpak AD; eluent, hexane–$CHCl_3$ (80:20); flow rate, 1.0 ml min^{-1}.)

Fig. 3 shows the CD spectra of the obtained C_{76} enantiomers in hexane–$CHCl_3$. When the solvent was replaced with toluene, almost identical spectra were observed. The spectral pattern is very similar to that for the C_{76} isolated by kinetic resolution,[1] but the intensity for the (+) fraction in this study is about 1.6 times greater than that for the above C_{76} which has been expected to have nearly 100% enantiomeric purity.[1] This means that our C_{76} would impossibly have over 100% ee based on the reported data. Since we used the same UV data[11] to estimate the C_{76} concentration,[12] the sample isolated in ref. 1 might have a lower enantiomeric purity, or the UV and CD measurements in ref. 1 might contain some error. Therefore, the reason for this disagreement in the CD data is not clear at this stage.

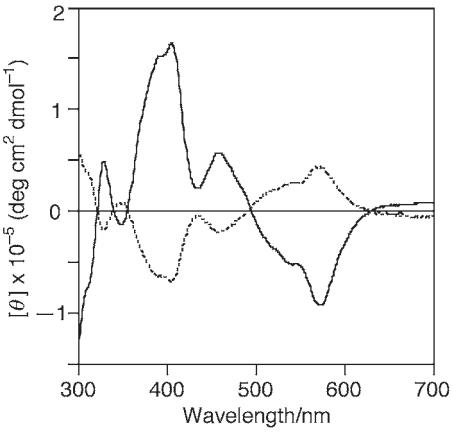

Fig. 3 CD spectra of C_{76} (first eluted enantiomer, solid line; second eluted enantiomer, dotted line) in toluene.

The promoting effect of CeO_2 in a Cu/CeO_2 catalyst for CO oxidation and NO reduction compared to CuO and Cu/ZrO_2 is deduced to be based on lowering of redox potentials of copper species in the Cu/CeO_2 matrix in relation to CuO and Cu/ZrO_2.

CeO_2 is an active support for precious metal as well as base metal catalysts and is widely used as a promoter for three way catalysts (TWCs). The promoting effect of CeO_2 is largely attributed to enhancement of metal dispersions, surface segregation of active metal, oxide ion defects for oxygen mobility and oxygen storage capacity (OSC).[1–5] Enhancement of catalytic activity by CeO_2 is observed in terms of reduction in the reaction temperature and decrease in activation energy. Complete CO oxidation over pure CeO_2 occurs above 500 °C while the temperature is brought down to 150 °C over Cu/CeO_2.[6–8] In contrast, 100% CO conversion occurs at 225 °C over bulk CuO. There seems to be an electronic interaction between Cu and CeO_2 which plays a vital role for the lowering of the reaction temperature and enhancement of the catalytic activity. Similar effects are also seen over Pt/CeO_2 and Pd/CeO_2 catalysts.[9] Several studies exist on the metal–support interaction and its effects on catalytic activity.[10–12] However, the exact nature of the interaction between metal ions and CeO_2 is not yet fully understood. We consider it worthwhile to investigate the Cu–CeO_2 interaction by electrochemical methods which can provide the redox properties of Cu species in a CeO_2 matrix. Here, we report for the first time, cyclic voltammetry and temperature programmed reaction (TPR) studies of a Cu/CeO_2 catalyst in comparison with CuO and Cu/ZrO_2. We show that the redox potentials of the Cu^{2+}/Cu^{+} and Cu^{+}/Cu^{0} couples in a CeO_2 matrix are lower than those in CuO and ZrO_2 matrices. The catalytic properties are consistent with the electrochemical behavior.

5% Cu/CeO_2 catalyst was prepared by the solution combustion method.[8] For the preparation of 5% Cu/ZrO_2 by this method, carbohydrazide (CH) was used as the fuel along with zirconyl nitrate and copper carbonate at 400 °C. X-Ray diffraction studies have shown that Cu^{2+} ions are substituted for Ce^{4+} to lead to a $Ce_{1-x}Cu_xO_{2-\delta}$ solid solution. Cu is in a +2 oxidation state as seen from X-ray photoelectron spectroscopy of the Cu 2p core level region as well as by electron paramagnetic resonance (EPR) spectra of Cu/CeO_2.[8]

Electrochemical studies were carried out with a CH-660A Electrochemical Analyzer (CH Instruments, USA) using a three-electrode cell configuration. The working electrodes were made by mixing 65 wt% graphite and 35 wt% Cu based materials. The mixture was ground thoroughly and 10 mm pellets of 1.5 mm thickness were prepared and subsequently mounted on a glass tube using conductive silver paint (Eltecks Corporation, India). Cu wire was used as the current collector. The electrode was polished to give a shining mirror finish using fine grade emery (SiC) paper. The counter electrode used was a Pt foil and saturated calomel electrode (SCE) was used as the reference electrode. The electrolyte solution was 0.05 M sodium sulfate (Na_2SO_4). The electrolyte was degassed by bubbling with N_2 prior to the measurement. In most cases the electrodes were cycled from +1.6 to −0.8 V at different scan rates. All experiments were performed at ambient temperature (*ca.* 25 °C).

The gas–solid reactions were carried out in a home-made TPR system equipped with a quadrupole mass spectrometer QXK300 (VG Scientific Ltd., England) using a packed bed tubular reactor.[8,9] Typically 0.1–0.2 g of the catalyst was loaded in a quartz tube reactor of 20 cm length and 6 mm diameter and the reactor was heated from 30 to 750 °C at a rate of 15 °C min^{-1}. The reactant gases were passed over the catalyst at a flow rate of 25 μmol s^{-1}.

The cyclic voltammogram of the Cu/CeO_2 electrode in 0.05 M Na_2SO_4 solution is shown in Fig. 1. The voltammogram obtained for the CuO electrode is also shown for comparison. The voltammograms consist of two cathodic and two anodic peaks for both bulk CuO and 5% Cu/CeO_2 samples in the scan range of 1.6 to −0.8 V *vs.* SCE. The Ce^{4+}/Ce^{3+} redox couple is not observed in the potential range studied. Similar voltammograms were observed for 5% Cu/ZrO_2 (not shown). The first peak labeled A is attributed to the reduction of Cu(II) to Cu(I) and the second peak B is due to reduction of Cu(I) to Cu(0) in all three cases.[13] The reduction potential values of $Cu^{2+} \rightarrow Cu^{+}$

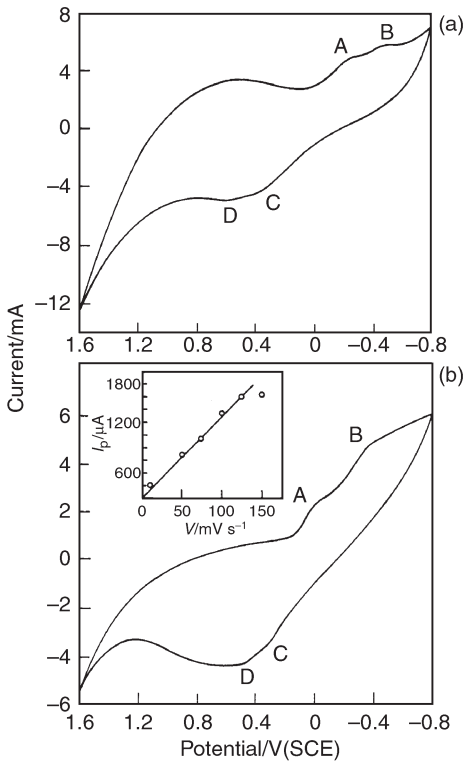

Fig. 1 Cyclic voltammograms of Cu species in (a) CuO and (b) 5% Cu/CeO_2 in 0.05 M Na_2SO_4 electrolyte at a scan rate of 50 mV s^{-1} (inset: peak current *vs.* scan rate relationship for peak B).

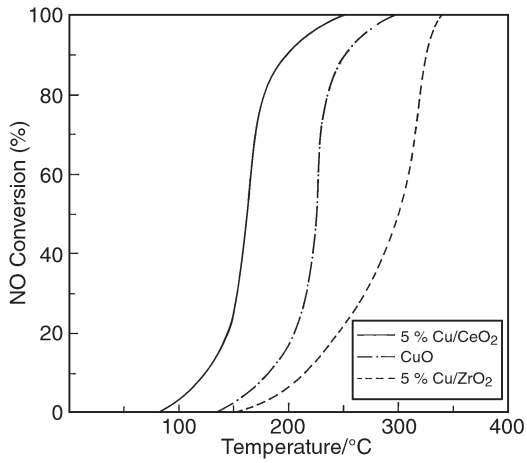

Fig. 2 NO conversion (%) over different Cu based catalysts for NO + NH_3 reaction.

and $Cu^{+} \rightarrow Cu^{0}$ in the CeO_2 matrix are −0.12 and −0.40 V, respectively, whereas the values for the CuO and Cu/ZrO_2 electrodes are −0.28, −0.50 and −0.38, −0.55 V, respectively. Oxidation potential values for $Cu^{0} \rightarrow Cu^{+}$ (peak C) and $Cu^{+} \rightarrow Cu^{2+}$ (peak D) in CeO_2 substrate are +0.25 and +0.50 V which are lower than those observed with CuO (+0.36 and +0.60 V) and Cu/ZrO_2 (+0.40 and +0.73 V) electrodes. The potential values indicate that Cu species in a Cu/CeO_2 matrix require less energy to be reduced and oxidized than in the case of pure CuO and Cu/ZrO_2 matrices. The plot of the second peak [B in Fig. 1(b)] as current (I_p) *vs*. scan rate (V) is shown as an inset in Fig. 1(b) for the Cu/CeO_2 system in 0.05 M Na_2SO_4 solution. The linear relationship indicates that the redox active species is surface confined.

NO conversions (%) for the NO + NH_3 reaction over 5% Cu/CeO_2, CuO and 5% Cu/ZrO_2 as a function of temperature are shown in Fig. 2. It is clear that complete NO conversion occurs at 250 °C over 5% Cu/CeO_2 whereas this requires 350 °C over 5% Cu/ZrO_2 with the reaction temperature over CuO lying in between. The reaction temperatures over these catalysts also follows the same trend for NO + CO and CO + O_2 reactions.

NO reduction by NH_3 involves electron transfer from NH_3 to NO. NH_3 is adsorbed on a Cu^{2+} site partially reducing the Cu^{2+} ion. This charge can be transferred to Ce^{4+} which can be picked up by NO to give [N] + [O]. Based on the electronic interaction between Ce 4f, O 2p and Cu 3d orbitals, electron transfer can be facilitated in Cu/CeO_2 as follows:

$$-Ce^{4+}-O^{2-}-Cu^{2+}- + e \rightleftharpoons -Ce^{4+}-O^{2-}-Cu^{+}- \rightleftharpoons -Ce^{3+}-O^{2-}-Cu^{2+}- \rightleftharpoons -Ce^{4+}-O^{2-}-Cu^{2+}- + e$$

Such a scheme involves the redox couples Cu^{2+}/Cu^{+} and Ce^{4+}/Ce^{3+}. These couples are available only for Cu/CeO_2 and not for CuO and Cu/ZrO_2 systems. A decrease in redox potentials of Cu species in Cu/CeO_2 as revealed in the voltammograms provides direct evidence of the promoting action of CeO_2. This will result in a decrease in the energy required for the electron transfer from NH_3 to NO and consequently a decrease in reaction temperature.

In conclusion, we have shown the correlation of catalytic properties of Cu/CeO_2 with the electrochemical behavior of the Cu species. The promoting action of CeO_2 is thus deduced to be *via* the lowering of redox potentials of Cu^{2+} ions in the CeO_2 matrix.

We thank Professor S. Vasudevan, Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore for useful discussions. One of the authors (P. B.), thanks the Council of Scientific and Industrial Research (CSIR), Government of India, for the award of a research fellowship. The structure of a one-dimensional crystal of Sb_2O_3 encapsulated within a single-walled carbon nanotube and conformation of the latter have been solved simultaneously by high resolution transmission electron microscopy.

In this paper we report the characterisation of a one-dimensional crystal of Sb_2O_3, incorporated within a helical (21, −8) single-walled carbon nanotube (SWNT) achieved by object wave restoration from a focal series of high resolution transmission electron microscopy (HRTEM) images.† Within the nanocrystal, the atomic thickness in projection of individual antimony columns was determined and a substantial lattice contraction of the crystal along the tube axis observed. A simultaneous analysis of asymmetric fringe contrast in the tube walls provides convincing evidence for the chiral conformation of the nanotube.

SWNTs were produced using a metal catalysed arc synthesis technique similar to a method previously reported[1] and filled by capillary wetting.[2] Energy dispersive X-ray microanalysis (LINK 'ISIS' system) performed with a 0.5 nm electron probe confirmed the chemical identity of the filling material. HRTEM simulations, giving the complex wave function of the objects in question, were performed using a standard multislice algorithm[3,4] utilising a code provided by Kirkland.[5]

Fig. 1(a) shows the experimental restored HRTEM phase image of a 1.45 nm diameter SWNT containing an encapsulated single crystal of Sb_2O_3. The right tube wall displays a periodic lattice spacing of 0.224 nm, whereas the contrast variations on the left wall are effectively random. The observed periodic spacing on the right wall corresponds to the centre-to-centre spacing ($1.5d_{C–C}$ = 0.216 nm) between neighbouring 'zigzag' rows of carbon atoms in the SWNT wall lattice viewed in projection. The visibility of these spacings is determined by the SWNT conformation, the tilt angle of the cylinder relative to the electron beam and the HRTEM resolution (*ca.* 0.16 nm).

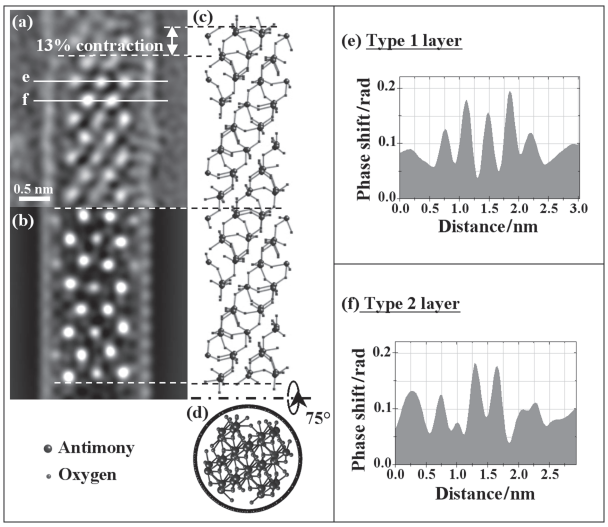

Fig. 1 Composite diagram showing the experimental restored phase image (a), the simulated phase image (b) and the structural model in the observed projection (c) and in end-on view (d), single pixel line profiles through type 1 (e) and type 2 (f) layers, respectively.

Fig. 2 illustrates the relationship between the observed wall periodicity, nanotube conformation and tilt angle together with corresponding simulations. Atomic coordinates for (*n, m*) nanotubes were generated by mapping the strip $\{\boldsymbol{r} \mid 0 \leq \boldsymbol{r} \cdot \boldsymbol{C}_h < |\boldsymbol{C}_h|^2\}$ of an unrolled hexagonal graphene lattice (with a carbon–carbon distance $d_{C–C}$ = 1.44 nm and lattice vectors $\boldsymbol{a}_1$, $\boldsymbol{a}_2$) onto a cylinder surface (Fig. 2). The structure of the SWNT is uniquely defined by the integers (*n,m*) with $n > 0$ and $-n/2 < m \leqslant n$‡ *via* the chiral vector $\boldsymbol{C}_h = n\boldsymbol{a}_1 + m\boldsymbol{a}_2$.[6] (*n*,0) and (*n*,*n*) represent the non-chiral zigzag and armchair configurations, respectively. All other (*n,m*) nanotubes are chiral with (*n* + *m*, −*m*) being the mirror image of (*n,m*).

The three differing conformation SWNTs shown in Fig. 2 (*i.e.* the (10,10) tubule in (a), the (18,0) tubule in (b) and the

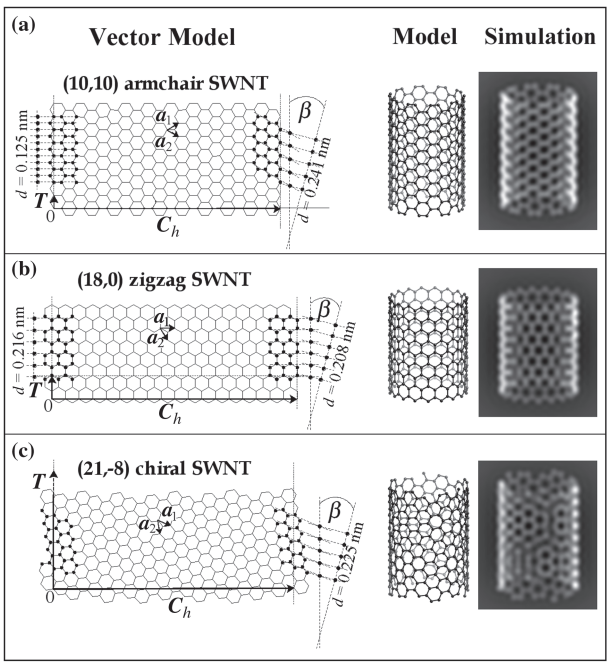

Fig. 2 (a)–(c) Schematic illustrations of the observable resolution of lattice fringes along SWNT walls of armchair, zigzag and chiral conformations, depending on the conformation, and the tilt angle β. The left column shows the unrolled graphene sheet, illustrating how the orientation of the chiral vector $\boldsymbol{C}_h$ w.r.t. the unit vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ defines the rolling of a strip of the width $|\boldsymbol{C}_h|$ into a nanotube of a specific conformation and diameter. The middle column displays a modeled fraction of the SWNT, tilted by β = 15° out of the image-plane. The right column shows simulated phase images of the displayed models.

DOI: 10.1039/b102348a

(21,−8) tubule in (c)) all have diameters close to the *ca*. 1.4 nm diameter SWNT shown in Fig. 1(a).

As illustrated on the right sides of the vector models, contrast on the right tube wall is only observable when the 'zigzag' rows of carbon atoms are well aligned to the projection direction, *i.e.* when the difference $\delta_r = |\alpha - (-\beta)|$ between the chiral angle $\alpha = \angle(C_h,\boldsymbol{a}_1) = \arctan(\sqrt{3}m/(2n + m))$ and the tilt angle β of the tube axis out of the image plane is small. Similarly, contrast on the left wall is observed when $\delta_l = |\alpha - \beta|$ is small. As the numbers of atoms in projection on the tube wall is small, strong contrast will be visible for values of δ of up to 10° and the observed spacing will be given by $1.5d_{C-C}\cos\beta/\cos\alpha$ (Fig. 2(c)). For achiral tubes $\delta_l = \delta_r$ for any tilt angle and the contrast will therefore be equal on both walls. For $\beta = 0$ strong contrast will be visible on both walls of a zigzag-nanotube, whereas for the armchair tube, the difference $\delta = 30°$ is too large for an observation of any contrast due to the projection of the spacing between zigzag rows. Instead, the relevant projected spacing is that of $\sqrt{3}a/2 = 0.125$ nm between hexagon edges and centres (Fig. 1(b), left), which is too small to be resolved. For the chiral (21, −8) tube shown in Fig. 1(c), strong contrast is observed on the right wall when the top end of the tube is tilted towards the viewer. By measurement of the change in defocus along the tube, it was established that the top end of the tube was higher in the electron beam path and hence this tube must also have negative chirality.

The orientation of the incorporated crystal fraction can best be matched to an approximately $\langle 1\ 0\ -1 \rangle$ projection through a fragment of Sb_2O_3 derived from the orthorhombic valentinite structure, believed to be the high pressure form of Sb_2O_3.[7] The bulk valentinite structure consists of infinite double chains of SbO_3 units, running parallel to $\langle 0\ 0\ 1 \rangle$. In these double chains each Sb atom within the infinite Sb_2O_3 chains is coordinated by three oxygen atoms, one of which bridges between two Sb atoms.[7] The other cubic senarmonite form of antimony oxide consists of molecular Sb_4O_6 units.[8] Fig. 1(c) shows the proposed structure model (Fig. 1(d), end-on view) of the Sb_2O_3/SWNT composite.

The white spots in the reconstructed phase image represent atomic columns of antimony only in projection. The oxygen-sublattice could not be resolved, due to the weak scattering properties of oxygen and the staggering of the oxygen atoms in projection. Multislice simulations of the restored phase of Sb_2O_3 lattice fractions of appropriate thickness confirmed that the phase contrast due to the oxygen sublattice is negligible compared to that due to the antimony sublattice.

In the observed Sb_2O_3/SWNT composite the $\langle 4\ -1\ 2 \rangle$ Sb_2O_3 crystal direction, which subtends an angle of 78.3° with the optimum $\langle 1\ 0\ -1 \rangle$ viewing direction, is aligned along the tube axis. Therefore, the tube inclination of $\beta = 15°$, applied to the model and simulation in order to account for the observed contrast within the tube wall, is plausible as a small deviation from this viewing direction will not alter significantly the observed contrast of the crystal. Other preferred orientations of Sb_2O_3 were also observed but these always conformed to fragments of the valentinite strucure rather than senarmonite.

The repeating structural motif of the imaged encapsulated Sb_2O_3 crystal can be described as an alternating sequence of a layer containing three columns of Sb atoms (type 1 layer) followed by a layer containing two columns of Sb atoms (type 2 layer) arranged perpendicular to the long axis of the tube (Fig. 1(a)). Within each layer, the intensities due to the individual antimony columns vary in a complex fashion. The line profile through a type 1 layer (Fig 1(e)) shows a stacking pattern of 3–2–3 Sb atoms in projection. By contrast the line profile though a type 2 layer (Fig. 1(f)) gives two peaks of equal intensity approximately equivalent to the higher peak within the three-member layer indicating Sb columns three atoms in thickness. The multislice simulation in Fig. 1(b) also shows weak contrast close to the tube walls, resulting from single atom columns at the edge of the encapsulated crystal fragment. These were added to the periphery of the crystal model in order to account for corresponding weak peaks at these sites in the obtained phase image. However, the intensity of these peaks are not significantly higher than the background noise and it is impossible to assign these peaks to single-atom columns without a more accurate analysis of the phase contrast. The proposed model therefore consists of a Sb_2O_3 crystal fragment with sequences of 3–2–3 and (1–)3–3(–1) layers repeating every fourth equivalent layer along the $\langle 4\ -1\ 2 \rangle$ direction (Fig. 1(c)).

Since the oxygen sublattice was not resolvable, the oxygen coordination is predicted from the bulk valentinite structure. However, in order to fit the modeled Sb_2O_3 crystal into a 1.4 nm diameter SWNT, some oxygen atoms on the crystal surface were omitted. This can be justified in terms of an anticipated reduction in coordination at the Sb_2O_3/SWNT interface (*cf.* 2 × 2 and 3 × 3 KI crystals formed in SWNTs[9,10]).

Significant lattice distortions were observed in the Sb_2O_3 crystal. A comparison with the bulk structure of valentinite, shows that the encapsulated crystal displays a longitudinal contraction of 13% along the $\langle 4\ -1\ 2 \rangle$ axis (Fig. 1(a)–(c)). A similar contraction was also observed in a 3 × 3 KI crystal encapsulated within a SWNT.[9] In the Sb_2O_3/SWNT composite, lattice measurements from line traces show an average spacing of *ca*. 0.552 nm between type 1 or type 2 rows respectively, whereas in bulk Sb_2O_3 equivalent rows are spaced at *ca*. 0.638 nm. The observed lattice contraction may be caused by local interactions between the Sb_2O_3 crystal and the SWNT walls although the wall periodicity of a chiral nanotube cannot be commensurate with a periodic crystal over the long range, as was noted previously.[11] Additional distortions may be caused by the reduction in coordination at the Sb_2O_3/SWNT interface.

A more detailed account of this work is in press.[12]

Perfectly polar assembly of molecular dipoles in crystals of Zn(II)(DMAP)(acac)$_2$: a case of self-poling†

S. Philip Anthony and T. P. Radhakrishnan*

Molecular dipoles assemble with a perfectly polar alignment in the crystals of the title complex and the hierarchy of intermolecular interactions in the lattice adheres to the requirements of a previously reported stochastic model for the production of polarity in supramolecular assemblies.

Molecular materials with a polar organization of the constituent dipoles are of great current interest because a variety of technologically important solid state properties such as pyroelectricity, piezoelectricity and nonlinear optical (NLO) effects may be realized in them.[1] Such materials would be the basis for the development of novel electro-optic (EO) and photorefractive devices[2] and nanoscale components such as molecular rectifiers.[3] Parallel alignment of molecular dipoles embedded in polymer films is achieved through electric field poling.[4] Non-centrosymmetric lattices are not common in molecular crystals;[5] special design strategies are often employed to induce noncentrosymmetricity.[6] Still rarer are highly polar molecular crystals with molecular dipoles aligned parallel to a single axis. Marder *et al.* have developed the 'salt methodology' wherein the anion sheets provide the driving force favoring a net polar alignment of cation sheets;[7] the well-known NLO crystal DAST has molecular dipoles in the crystal *ab* plane oriented at *ca.* 20° on either side of the *a* axis.[7b] Optimal chromophoric orientation for EO applications has been achieved through co-crystallization approaches by Bosshard and coworkers.[8] Another successful strategy is the inclusion of polar guest molecules in channels of host molecules developed by Hulliger *et al.*[9] The latter have also carried out stochastic modeling of the growth of polar bulk structures.[10] One of the significant conclusions from their study is that polarity in supramolecular assemblies is a tunable property controlled by the energetics of intermolecular interactions in different directions. While bonding interactions are required to assemble chains or sheets of polar molecules aligned along the direction of polarity evolution, the lateral interactions are required to be non-bonding recognitions to achieve 3-D polar alignment. The low density of the active molecules in two-component salts, co-crystals and the host–guest inclusion materials leads to less effective utilization of the bulk material to achieve the desired solid state effects. If molecular design involves a dipolar backbone with an optimal decoration that dictates weak or non-bonding lateral recognition, the assembly should lead to a polar crystal lattice with a higher density of the active species, a situation ideally suited for EO applications.[11] A potential candidate would be a 'screw'-shaped molecule with a dipolar axis and a 'head' which curtails lateral interactions without obstructing 1-D head-to-tail Coulombic interactions. We have realized this paradigm in the perfectly polar lattice of (4-dimethylaminopyridyl)bis(acetylacetonato)zinc(II) (ZNDA); DMAP–Zn forms the polar entity and the acac ligands the 'head'. This material also possesses good thermal stability and transparency.

ZNDA was synthesized by the direct replacement of the water molecule in Zn(acac)$_2$·H$_2$O by DMAP. Colorless crystals could be grown from methanol. X-Ray analysis revealed the orthorhombic space group F*dd*2 with half a molecule in the asymmetric unit;[12] C_2 rotation generates the other half. Zinc and the coordinated pyridine nitrogen, the *para* carbon and dimethylamino nitrogen atoms on DMAP lie on special positions on the *c*-axis. Zn(II) has distorted square-pyramidal coordination with normal bond parameters;[13] Fig. 1 shows clearly the 'screw'-shaped structure. The molecules pack into a perfectly polar lattice with the dipoles aligned along the *c* axis (Fig. 2) by virtue of the special position of Zn and DMAP. The origin of this organizational motif may be sought in the interplay of intermolecular interactions in the ZNDA lattice.

ZNDA is expected to have a sizeable dipole moment due to the push–pull nature of the DMAP–Zn(II) combination; AM1 calculation[14] on the molecular geometry from the crystal structure gives a value of 8.919 D. The electrostatic interaction between the dipoles directs the head-to-tail chain formation along the *c* axis. This is augmented by weak intermolecular H-bonds[15] between the carbon atoms of the dimethylamino groups of the DMAP ligand and oxygen atoms of the acac ligand of neighboring molecules ($r_{C7\cdots O12}$ = 3.679 Å; $\theta_{C7-H7B\cdots O12}$ = 158.7°). A further network of weak intermolecular H-bonds ($r_{C4\cdots O8}$ = 3.612 Å, $\theta_{C4-H4\cdots O8}$ = 139.6°; $r_{C7\cdots O8}$ = 3.526 Å,

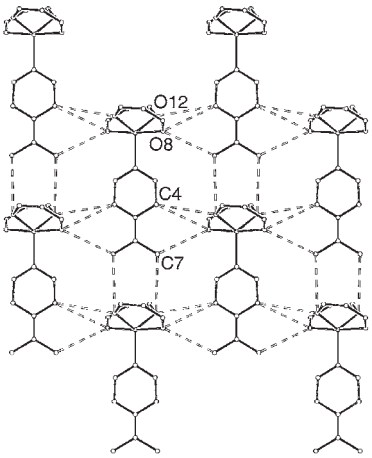

Fig. 3 Non-covalent interactions (dashed bonds) in the sheets of ZNDA molecules in the *bc* plane; all H atoms and methyl carbon atoms of the acac ligand are omitted for clarity.

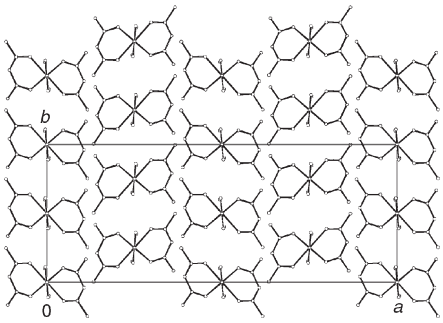

Fig. 4 Projection of the crystal lattice of ZNDA onto the *ab* plane; H atoms are omitted for clarity.

$\theta_{C7\text{-}H7A\cdots O8}$ = 155.6°; $r_{C4\cdots O12}$ = 3.585 Å, $\theta_{C4\text{-}H4\cdots O12}$ = 151.0°) between DMAP and acac binds the ZNDA molecules into a sheet parallel to the *bc* plane (Fig. 3). The sheets are well separated in the *a*-direction with a distance of *ca.* 7 Å between adjacent DMAP planes (Fig. 4). Neither strong nor even the weak bonding interactions present within the sheets are observed between the sheets. Thus the 3-D lattice structure of ZNDA is built from electrostatic interactions along the *c* axis and weak non-covalent interactions within the *bc* plane leading to sheet structures with no bonding recognition between the sheets in the *a* direction. This bulk organization[16] is in perfect accord with the Hulliger model for the generation of polarity in supramolecular systems.

The polar arrangement in molecular lattices is of interest in NLO applications. We have measured the second harmonic generation (SHG) from microcrystalline powders of ZNDA using the Kurtz–Perry technique.[17] SHG comparable to that of urea is observed. The low SHG is due to the small hyperpolarizability (AM1/TDHF[18] calculation on the molecular geometry from crystal structure gives a static hyperpolarizability of 4.4 × 10^{-30} esu) and the non-optimal molecular orientation in the crystals, for phase-matched SHG.[19] Large single crystals or oriented crystalline films have to be fabricated to carry out EO studies. Our current efforts are directed towards these goals. The good thermal stability (mp = 240 °C) and damage-free sublimation coupled with the large transparency range (λ_{max} = 282 nm, $\lambda_{cut\text{-}off}$ = 330 nm for methanol solutions) of ZNDA make it a promising candidate for further explorations.

In conclusion, the perfectly polar lattice of ZNDA, a case of self-poled assembly of molecular dipoles, reveals a hierarchy of intermolecular interactions in different directions in line with the requirements put forth in the stochastic model for the generation of polar supramolecular assemblies.

Financial support from the DST (Swarnajayanti Fellowship) and the use of the National Single Crystal Diffractometer Facility funded by the DST at the School of Chemistry, University of Hyderabad are gratefully acknowledged.

First published as an Advance Article on the web 2nd May 2001

Pure silica mesoporous materials that exhibit remarkable hydrothermal stability may be prepared by restructuring calcined MCM-41 *via* secondary synthesis involving extended recrystallisation.

Mesoporous silicas, such as MCM-41, are potentially useful as sorbents, heterogeneous catalysts and as hosts for the preparation of composite materials for advanced applications.[1] The preparation of mesoporous silicas which exhibit good hydrothermal stability (in hot water and under steaming conditions) is one of the most important requirements with respect to their use. To date, most of the work reported on the hydrothermal stability of mesoporous silicas has dealt with stability in boiling water.[2–6] This is mainly because stability in hot aqueous solutions is considered essential to ensure succesful post-synthesis modifications such as grafting and ion-exchange. Recent advances indicate that the hydrothermal stability of pure silica MCM-41 in boiling water can be improved by a variety of methods which include repeated pH adjustment and/or stabilisation *via* salt effects during synthesis,[2,5,7] restructuring of the as-synthesised material,[3,6] or the preparation of materials with thicker and more polymerised pore walls.[4] Stabilisation *via* a pore wall thickening approach appears to be the most straightforward, but no appropriate synthesis strategies for the control of wall thickness have so far been reported. Here we report on the remarkable steam and boiling water stability of restructured pure silica MCM-41 materials that are prepared *via* a seeded crystallisation route. The restructured materials are prepared *via* a route which involves the use of calcined MCM-41 as 'silica source' for secondary synthesis which is performed over extended periods of time. By extending the time allowed for high temperature recrystallisation during the secondary synthesis step it is possible to systematically increase the pore wall thickness. We believe that the remarkable stability observed here is due to a combination of thicker pore walls and a less strained silica framework. Restructuring during the extended 'recrystallisation' may act to heal any defects and relieve strains in the parent MCM-41 framework.

The parent MCM-41 was prepared using a normal procedure as follows: tetramethylammonium hydroxide (TMAOH) and cetyltrimethylammonium bromide (CTAB) were dissolved in distilled water by stirring at 35 °C to give a clear solution. The silica source, fumed silica (Sigma), was then added to the template solution under stirring for 1 hour. After further stirring for 1 h to allow the silica to be fully dispersed, the resulting synthesis gel of composition SiO_2:0.25CTAB:0.2 TMAOH:40 H_2O was left to age for 20 h at room temperature following which the gel was transferred to a Teflon-lined autoclave and heated at 150 °C for 48 h. The solid product was obtained by filtration, washed with distilled water, dried in air at room temperature and calcined in air at 550 °C for 8 h to yield the parent MCM-41. For restructuring, a synthesis gel of molar ratio as above was assembled except that the parent MCM-41 was used as the 'silica source'.[8–10] The experimental procedures were exactly as described above except that during the secondary synthesis the heating at 150 °C was performed for 96, 140 or 168 h. The restructured samples were designated MCM-41(RX) where X is the crystallisation time in hours, *i.e.* MCM-41(R96), MCM-41(R140) and MCM-41(R168) for 96, 140, 168 h, respectively. Hydrothermal stability was tested by heat treatment at 900 °C in a flow of nitrogen saturated with water vapour at room temperature.

The textural parameters of the parent and restructured MCM-41 materials before and after hydrothermal treatment are given in Table 1. First we note that the basal spacing of the restructured materials remains much the same despite the differences in the time allowed for recrystallisation. This is in contrast with previous results, which show that increasing the crystallisation time during high temperature (≥150 °C) synthesis of MCM-41 favours larger basal spacing.[13,14] The most likely explanation for the non-changing basal spacing observed here is that the structural backbone of the parent MCM-41 is maintained during the recrystallisation.[8–10] The main event during the recrystallisation may therefore involve further growth or linking of the existing parent MCM-41 particles as previously described.[4,9] We note that this is a strong indication of the previously proposed seeding mechanism.[8–10] The surface area and pore volume of the restructured materials gradually decrease with increasing recrystallisation time. The decrease in surface area and pore volume is presumably due to the formation of thicker pore walls; it is envisaged that the wall thickening occurs within the existing pores of the parent MCM-41.[4,9] This then causes the pore size to decrease as shown in Table 1. The pore wall thickness calculated for the materials increases by more than 50% from 10.0 Å for the parent MCM-41 to 11.4, 13.9 and 15.2 Å for MCM-41(R96), MCM-41(R140) and MCM-41(R168), respectively. This clearly represents a systematic increase in pore wall thickness of pure silica MCM-41 by simply changing the recrystallisation time. It is worth pointing out that the emphasis here is on the increase (*i.e.* >50%) rather than the actual pore wall thickness values, which can vary depending on the calculation method.[4] Powder XRD patterns of the parent and restructured MCM-41 materials are shown in Fig. 1A. In all cases well ordered materials were obtained as indicated by the XRD patterns which show an intense (100) diffraction peak and at least two higher order peaks. In contrast to extended direct synthesis, no significant

Table 1 Textural properties of the study materials

Sample	d_{100}/Å	Surface area/m^2 g^{-1}	Pore volume/cm^3 g^{-1}	Pore size[a]/Å

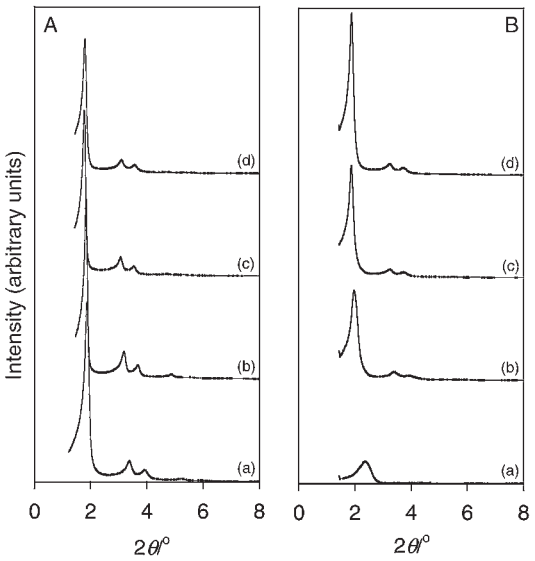

Fig. 1 Powder XRD patterns of (a) parent pure silica MCM-41, and restructured (b) MCM-41(R96), (c) MCM-41(R140) and (d) MCM-41(R168) materials before (A) and after (B) hydrothermal treatment at 900 °C under a flow of N_2 saturated with water vapour at room temperature. The intensity scales are the same for A and B.

diminution of structural ordering is observed even after recrystallisation for 168 h.[14]

Fig. 1B shows the powder XRD patterns of the parent MCM-41 and restructured materials after hydrothermal treatment at 900 °C. The parent sample is severely degraded after the hydrothermal treatment at 900 °C; the XRD pattern of the steamed parent sample exhibits only a weak (basal) 100 peak and no higher order peaks. The N_2 sorption isotherm of the steamed parent MCM-41 (not shown) exhibited virtually no mesoporous character and its surface area and pore volume reduced by more than 80% as shown in Table 1. We note that these observations are consistent with previous results on the steam stability of pure silica MCM-41 materials. For example, Chen *et al*. observed degradation of conventionally synthesised Si-MCM-41 after treatment at 850 °C in water vapour (8 Torr)[15] while materials prepared *via* repeated pH adjustment were severely degraded after 2 h at 800 °C in a flow of O_2 saturated with water vapour at room temperature.[7] In the present study steam stability was remarkably improved after restructuring. Fig. 1B indicates a much higher steam stability for the restructured samples compared with the parent MCM-41. It is also apparent from Fig. 1 that the stability of the restructured samples is higher for materials that have been recrystallised for longer periods of time. Indeed, for sample MCM-41(R168) there is virtually no change in the XRD pattern after the hydrothermal treatment at 900 °C. The N_2 sorption isotherms of the restructured samples (not shown) exhibit a sharp mesopore filling step characteristic of well ordered MCM-41 materials. The restructured samples are able to retain much of their original surface area and pore volume after steaming as indicated in Table 1. Sample MCM-41(R96) retains 78 and 66% of its original surface area and pore volume, respectively. Samples recrystallised for 140 and 168 h retain *ca*. 90% of their surface area and pore volume. These small reductions in surface area and pore volume observed for the steamed, restructured samples contrast sharply with the > 80% decrease for the parent MCM-41 material. Furthermore, the stability of the restructured framework is illustrated by the small lattice contractions observed for MCM-41(R140) and MCM-41(R168), *i.e*. only *ca*. 5% reduction in basal spacing compared with 20% contraction for the parent MCM-41.

We also investigated the stability of the restructured MCM-41 samples in boiling water. This was performed by refluxing the samples for 24 h in distilled water at a solid : liquid ratio of 1 g per litre. The trends observed in 'boiling water' stability were similar to those discussed above for steamed samples; the restructured samples retained their structural integrity while the parent MCM-41 sample was severely degraded. The surface area of the refluxed parent sample decreased by 75% compared with a reduction of typically < 17% for the restructured samples (see Table 1). Interestingly, the pore volume of the restructured samples was virtually unchanged after refluxing. (It is worth noting that MCM-41 materials prepared *via* repeated pH adjustment undergo severe degradation after 12 h in boiling water.[2] Restructuring of as-synthesised MCM-41 in the mother-liquor or water can yield slightly more stable materials which are nevertheless considerably degraded after 22 h in boiling water).[3] We also note that the restructured materials exhibit good thermal stability in static air; after calcination at 1000 °C for 6 h the parent MCM-41 was completely destroyed (its surface area reduced to 24 $m^2\ g^{-1}$) while MCM-41(R96) and MCM-41(R168) retained some structural ordering and surface area of 244 and 401 $m^2\ g^{-1}$ respectively. It appears therefore that the restructured materials reported here are exceptionally stable and in any case more hydrothermally stable than any previously reported MCM-41 with the possible exception of those stabilised with the addition of salts during synthesis.[5] Stabilisation in the present case is achieved *via* thicker and more polymerised pore walls which provide a silica framework which has fewer defects compared with that of the parent MCM-41. A higher extent of silica condensation in the restructured materials was confirmed by the proportion of fully condensed silica species in the as-synthesised samples; $Q^4 : Q^3$ ratios obtained from ^{29}Si MAS NMR analysis were in the range 3.5–4.5 for the restructured samples, compared with 1.5 for the parent MCM-41 material. It is likely that the restructuring, in addition to increasing pore wall thickness and silica condensation, also serves to heal any defects present in the parent material. The restructured materials therefore undergo little forced silica condensation during calcination thereby resulting in stabilised and less strained silica frameworks. This is consistent with the observation that on calcination, the restructured samples undergo virtually no lattice contraction, compared with a 9% decrease in the lattice size of the parent MCM-41 sample. It is also possible that the large particle size of the restructured materials contributes to their hydrothermal stability.[9]

The author is grateful to the EPSRC for an Advanced Fellowship.

Incorporation of [U-^{13}C]glycerol defines plausible early steps for the biosynthesis of methylenomycin A in *Streptomyces coelicolor* A3(2)†

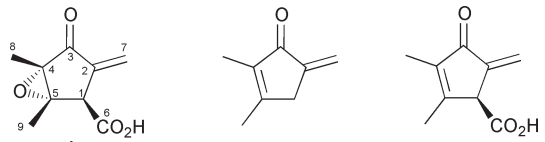
Gregory L. Challis*‡ and Keith F. Chater

Department of Genetics, John Innes Centre, Colney Lane, Norwich, UK NR4 7UH. E-mail: greg.challis@bbsrc.ac.uk; Fax: +44 (0)1603 450045; Tel: +44 (0)1603 450000

Received (in Cambridge, UK) 19th February 2001, Accepted 4th April 2001
First published as an Advance Article on the web 2nd May 2001

Incorporation of [U-^{13}C]glycerol into the linear plasmid-encoded secondary metabolite methylenomycin A, both intact and indirectly *via* metabolism to acetyl CoA, was observed in *Streptomyces coelicolor* suggesting plausible early biosynthetic steps for this unusual antibiotic.

Methylenomycins A and B, **1** and **2** respectively,[1] are the most well studied members of a small group of cyclopentanone antibiotics produced by various *Streptomyces* spp. Other members of this group include xanthocidin,[2] vertimycin,[3]



pentenomycin,[4] and sarkomycin,[5] which is an antitumour agent that has been used clinically in Japan. The *mmy* cluster of genes encoding methylenomycin biosynthesis and its regulation, as well as self-resistance, is localised on a large linear plasmid that is not essential for growth in *Streptomyces coelicolor* A3(2) and a large circular plasmid in *Streptomyces violaceoruber*.[5] Recently, the entire *mmy* cluster of *S. coelicolor* has been sequenced.[6] As a first step towards understanding how the enzymes encoded by this cluster assemble **1** and **2** we have reinvestigated the primary metabolic origins of these antibiotics.

Previous investigations showed that radiolabelled desepoxy-4,5-didehydro methylenomycin A **3**, which is also a metabolite of *S. coelicolor*, is incorporated into **1**.[7] Thus epoxidation of **3** appears to be the final step in the biosynthesis of **1**, whereas **2** probably derives from spontaneous decarboxylation of **3**. Additional experiments using radiolabelled precursors showed significant incorporation of acetate, pyruvate, succinate, aspartate and glycine into the carbon atoms of **1**.[8] Intact incorporation of acetate into C-4, C-8 and C-1, C-6 of **1** was deduced by ^{13}C NMR analysis of a sample isolated from a culture of *S. coelicolor* fed with [1,2-$^{13}C_2$]acetate (Scheme 1).[8]

Scheme 1

To further investigate the primary metabolic origins of the carbon atoms in **1**, the incorporation of [U-^{13}C]glycerol was examined.§ Surprisingly, the results of this experiment were inconsistent with the previously reported incorporation of [1,2-^{13}C]acetate into C-4, C-8 of **1**. The original interpretation of the acetate incorporation experiment depended on the assignment of the signal at 13.8 ppm in the ^{13}C NMR spectrum of **1** to the C-5 methyl substituent. This assignment was made on the basis of an apparent ^4J coupling between the C-5 methyl group and the hydrogen atom attached to C-1 in the ^{1}H NMR spectrum, in conjunction with heteronuclear decoupling experiments.[8] To resolve the conflict we measured the HMBC spectrum of **1**, which unambiguously showed that the signals at 13.8 and 8.2 ppm in the ^{13}C NMR spectrum are due to the C-4 and C-5 methyl groups, respectively (Fig. 1).

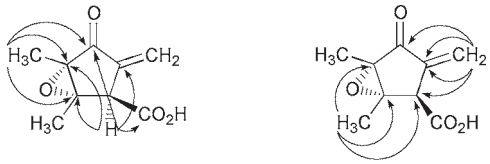


Fig. 1 Summary of HMBC correlations observed for **1**.

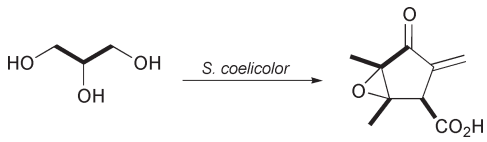
These assignments forced us to conclude that [1,2-^{13}C]acetate is incorporated intact into C-5, C-9 and C-1, C-6, rather than C-4, C-8 and C-1, C-6 as previously reported.[8] Consistent with this reinterpretation, the ^{13}C NMR spectrum of **1** isolated from the glycerol feeding experiment showed indirect incorporation of [U-^{13}C]glycerol into C-5, C-9 and C-1, C-6 presumably by catabolism *via* pyruvate to [1,2-^{13}C]acetyl CoA. In addition, double doublets centred on the signals for C-3 and C-8 were also observed in the spectrum, demonstrating that these carbons are coupled ($^2J_{C-C}$ = 3.4 Hz; Fig. 2), which is consistent with intact incorporation of [U-^{13}C]glycerol into C-3, C-4 and C-8. Such intact incorporation of glycerol is relatively unusual and has only been reported for four other microbial secondary metabolites.[9] The results of the glycerol incorporation experiment are summarised in Scheme 2.



Scheme 2

On the basis of these results, we propose a pathway for the biosynthesis of **1** in *S. coelicolor* involving nucleophilic addition of C-2 of lactate (X = H, Y = OH) or of a glycolytic intermediate such as glyceraldehyde-3-phosphate (X = OPO_3^{2-}, Y = H) to C-3 of acetoacetyl ACP. This pathway, which is mechanistically distinct from those proposed for the incorporation of glycerol into other metabolites,[9] is consistent with the presence of the *mmyA* and *mmyC* genes in the methylenomycin cluster, which encode homologues of an ACP and ketoacyl synthase III (KAS III), respectively.[6] However, reduction of acetoacetyl ACP to 3-hydroxybutyryl ACP followed by nucleophilic displacement of the hydroxy group with C-2 of lactate or glyceraldehyde-3-phosphate cannot be

† Electronic supplementary information (ESI) available: HMBC, ^{1}H and ^{13}C NMR spectra of methylenomycin A. See http://www.rsc.org/suppdata/cc/b1/b101615f/

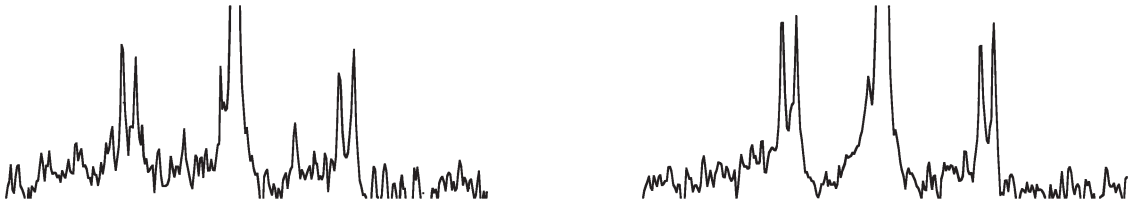

Fig. 2 Sections of the ^{13}C NMR spectrum of **1** isolated from cultures of *S. coelicolor* fed with [U-^{13}C]glycerol showing double doublets flanking the C-3 (left; 196.4 ppm) and C-8 (right; 8.2 ppm) resonances. While the larger splitting in each is due to ^{1}J coupling between C-3 or C-8 and C-4, the smaller splitting of 3.4 Hz in both is due to ^{2}J coupling between C-3 and C-8, consistent with intact incorporation of [U-^{13}C]glycerol into C-3, C-4 and C-8 of **1**.

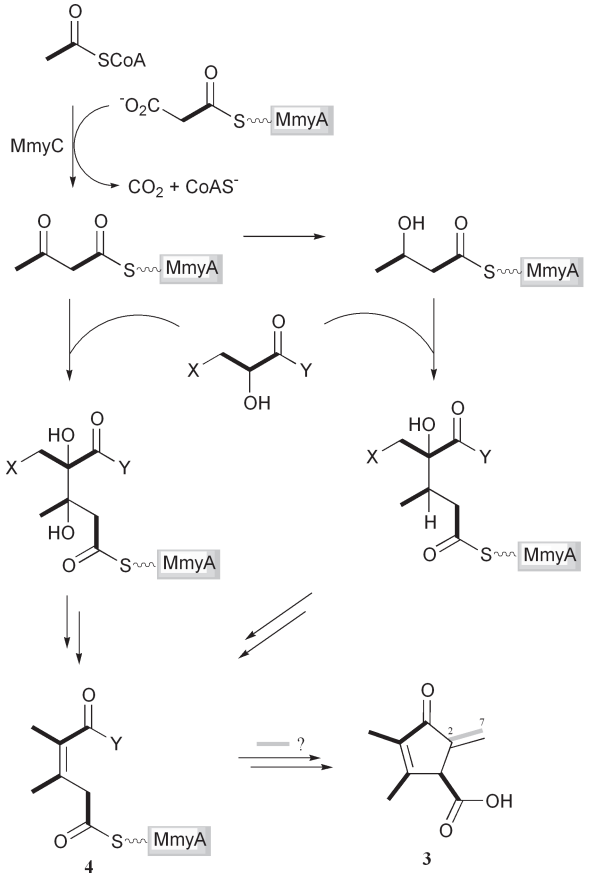

Scheme 3

ruled out.[10] In either case, several alternating dehydrations and enoyl reductions of the product would yield the common intermediate **4** (Scheme 3).

Conversion of **4** to the known biosynthetic intermediate **3** would require condensation with unknown precursors of C-2 and C-7 and hydrolysis of the thioester linkage to the ACP MmyA. Previous experiments eliminated the possibility that C-2 and C-7 are derived either from actetate as an intact two-carbon unit or from two *S*-adenosylmethionine methyl groups.[8] However, radioactivity from [2-^{14}C]glycine, has been shown to incorporate into **1** and this amino acid could therefore act as either an intact two-carbon precursor of C-2, C-7 or as a one-carbon donor for C-2 and C-7 *via* metabolism to methylene tetrahydrofolate.[8] To test this hypothesis we examined the incorporation of [1,2-$^{13}C_2$]glycine into **1**. To our surprise, there was no incorporation of ^{13}C into C-2 or C-7, instead approximately equal labelling of individual molecules at either C-5 and C-9, or C-1 and C-6 was observed. This result can be explained by transfer of ^{13}C-2 from one molecule of [1,2-$^{13}C_2$]glycine to another by serine hydroxymethyltransferase to give [U-^{13}C]serine, which is then metabolised to [1,2-$^{13}C_2$]acetyl CoA *via* pyruvate and incorporated into **1**. Thus, we have ruled out the derivation of C-2 and C-7 from intact glycine or from two one-carbon units donated by methylene tetrahydrofolate. Further experiments will be required to identify the cryptic two-carbon precursor of C-2 and C-7.

In conclusion, intact and indirect incorporation of [U-^{13}C]glycerol has elucidated the metabolic origins of the majority of carbon atoms in **1** and has defined plausible early steps for the biosynthesis of this metabolite in *S. coelicolor* A3(2).

Financial support by the Wellcome Trust (grant no. 053086) is gratefully acknowledged. We thank A. C. Foster and Professor S. V. Ley (University of Cambridge) for recording NMR spectra.

Notes and references

§ A solution of 50 mg of labelled glycerol in water was added to a 3-day-old 500 ml culture of *S. coelicolor* U9 grown in complete medium at 28 °C from spores as in ref. 8. After 24 h further incubation, the culture was filtered, and the filtrate was adjusted to pH 2 with 6 M HCl and extracted with an equal volume of ethyl acetate. **1** was purified from the organic extract by flash column chromatography (silica, AcOH–PhMe 1:9) and analysed by ^{13}C NMR spectroscopy at 100 MHz.

First published as an Advance Article on the web 2nd May 2001

Monodispersed nanocrystalline CeO_2 powders of size *ca.* 2.0 nm displaying quantum size effects have been prepared by microwave irradiation in an aqueous solution containing $(NH_4)_2Ce(NO_3)_6$, PEG and NaAc.

Ceria (CeO_2) is a rare earth oxide with a high refractive index and a very sharp fundamental absorption edge and is a semiconductor with a band gap of 3.2 eV. It is also a highly efficient UV absorber and is used as an additive to glass (2–4% CeO_2) to protect light-sensitive materials, as a coating for corrosion protection of metals, as an oxidation catalyst, and as a counter electrode for electrochromic devices[1] as proposed recently. It is currently also being used as an oxygen ion conductor in solid oxide fuel cells (SOFCs), electrolyzers, oxygen pumps and amperometric oxygen monitors owing to its high oxygen ion conductivity.[2] Many studies have been conducted to prepare fine CeO_2 powders by using urea-based homogeneous precipitation,[3] hexamethylenetetramine-based homogeneous precipitation,[4] hydrothermal synthesis,[2] or cathodic electrogeneration of base.[5] Transparent colloidal solutions of ultrafine ceria particles were also directly obtained by Masashi *et al*,[6] by the reaction of cerium metal in 2-methoxyethanol at 200–300 °C. However, the preparation of nanocrystalline CeO_2 is very difficult using conventional conditions, and it is thus a challenge to find a novel approach to prepare the nanocrystalline oxide.

Since 1986, microwave irradiation has found a number of applications as a heating method in chemistry. As a quick, simple and energy efficient method, microwave synthesis has been developed, and is widely used for the synthesis of zeolites and ceramic materials.[7–11] Compared with conventional methods, microwave synthesis has the advantages of very short reaction times, production of small particles with a narrow particle size distribution, and high purity. Jansen *et al.* suggested that these advantages could be attributed to fast homogeneous nucleation and ready dissolution of the gel.[7] Unfortunately the exact nature of the interaction of the microwaves with the reactants during the synthesis of materials is somewhat uncertain and speculative. However, it is well known that the interaction between dielectric materials, liquids or solids, and the microwaves leads to what is generally known as dielectric heating in which electric dipoles in such materials respond to the applied electric field. In liquids, this constant reorientation leads to a friction between the molecules, which subsequently generates heat.[12] Many microwave phenomena are poorly understood such as non-thermal effects and the superheating effect.[2,13] In this study, a novel method for the preparation of ultrafine nanocrystalline cerium oxide is reported. Monodispersed nanocrystalline CeO_2 powders were successfully prepared by microwave irradiation by means of hydrolysis of $(NH_4)_2Ce(NO_3)_6$ in an aqueous solution containing poly(ethylene glycol)-2000 (PEG) and NaAc. Analysis of the results showed that the resulting CeO_2 powders were well crystallized, of *ca.* 2 nm size and showing a large quantum size effect.

An aqueous solution of 1 wt% PEG, 0.01 mol L^{-1} $(NH_4)_2Ce(NO_3)_6$ and 1 wt% NaAc was exposed to microwave radiation at a power level of 30% (the microwave operating in a 30 second cycles, on for 9 s, and off for 21 s at a total power of 650 W for 10 min), and then cooled to room temperature.‡ The resulting precipitate was centrifuged, washed with distilled water and dried in air. The final yellow product was collected for characterization.

The obtained powders were characterized by X-ray powder diffraction (XRD) (Fig. 1). The XRD pattern of the as-prepared product showed the presence of broad peaks, which corresponded to the (111), (220), (311) planes for a cubic fluorite structure.[14] The broadness of the peaks indicated that the crystallite size was very small. The microstructure of the sample was examined by high-resolution transmission electron microscopy (HRTEM). Typical TEM and HRTEM images of the sample are shown in Fig. 2(a) and (b). It is clear that as-prepared CeO_2 powders are crystalline with *ca.* 2 nm particle size (HRTEM image). In addition monodispersed nanocrystals were observed.

The UV–VIS absorption spectrum of the product dispersed in toluene is shown in Fig. 3 and shows a very large shift compared with the pure bulk crystal. The band gap E_g was 4.25 eV as calculated by the direct conversion method (in Fig. 4).[15] This is 1.0 eV larger than that of the pure bulk crystal (E_g = 3.19 eV).[1] The increase in the magnitude of the band gap is a consequence of the quantum size effect.

The proposed mechanism of microwave heating hydrolysis synthesis of CeO_2 nanoparticles may be as follows: first, hydrated Ce^{4+} ions can form complexes with H_2O molecules or OH^- ions. Polymers of this hydroxide, $Ce(H_2O)_x(OH^-)_y^{(4-y)+}$, can then serve as the precursors of the oxide. The starting precipitate from the Ce(IV) salt may be formed by nucleation of hydrated $Ce(H_2O)_x(OH^-)_y^{(4-y)+}$ so leading to very fine precursors for the final oxide. In aqueous solution, H_2O as a polar molecule tends to take protons away from coordinated hydroxide and the reaction equation can be expressed by eqn. (1).[2]

$$Ce(H_2O)_x(OH^-)_y^{(4-y)+} + H_2O \rightarrow CeO_2{\cdot}nH_2O + H_3O^+ \quad (1)$$

Compared with conventional heating methods, microwave heating presents a more rapid and simultaneous nucleation due

to the fast and homogeneous heating effects of microwaves. Moreover, uniform small particles can be synthesized due to the simultaneous nucleation and homogeneous heating. In addition, PEG, as a dispersion stabilizer, can inhibit segregation so as to obtain homogeneous precipitation. Use of PEG is a general method to synthesize nanocrystalline oxides with some nanocrystalline oxides such as TiO_2 and SnO_2 being successfully prepared *via* this route.

In conclusion, a microwave heating hydrolysis method has been successfully used for the preparation of ultrafine nanocrystalline CeO_2 powders. The advantage of this process is that it is fast, simple and energy efficient. It is predicted that upscaling of the process may lead to large quantities of nanosized CeO_2 crystallites. It also represents a general method to obtain other oxide nanocrystals.

Solving the riddle of the intradiol and extradiol catechol dioxygenases: how do enzymes control hydroperoxide rearrangements?

Timothy D. H. Bugg* and Gang Lin

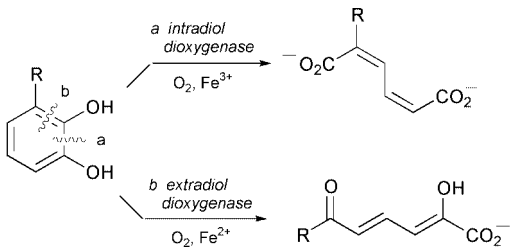
Department of Chemistry, University of Warwick, Coventry CV4 7AL

Received (in Cambridge, UK) 12th January 2001, Accepted 7th March 2001
First published as an Advance Article on the web 20th April 2001

Metallo-enzymes catalyse a rich variety of biochemical reactions, some of which have little or no precedent in laboratory chemistry.[1] Studies of such enzyme-catalysed reactions have benefited greatly in recent years from the pace of new protein X-ray crystallographic structures, but a detailed understanding of enzyme-catalysed reactions at the molecular level has required an interplay between structural studies, mechanistic studies, and small molecule model studies. This article will describe recent studies on an intriguing and long-standing puzzle in mechanistic enzymology, that of the non-haem iron-dependent catechol dioxygenases.[2]

Discovery of the catechol dioxygenases

A number of soil bacteria, especially *Pseudomonas*, have the metabolic capability to degrade aromatic compounds and utilise these compounds as the sole carbon source for growth.[3] A key step in these catabolic pathways is the oxidative cleavage of catechol, or substituted catechols, to give acyclic products. Two families of dioxygenase enzyme were discovered by O. Hayaishi which can catalyse the oxidative cleavage of catechol, both families utilising dioxygen as a substrate (see Scheme 1).[4–6] The intradiol dioxygenases, typified by catechol 1,2-dioxygenase (or pyrocatechase), cleave the carbon–carbon bond between the phenolic hydroxy groups to yield muconic acid as product, and require Fe^{3+} as a cofactor.[4] The extradiol dioxygenases, typefied by catechol 2,3-dioxygenase (or meta-pyrocatechase), cleave the carbon–carbon bond adjacent to the phenolic hydroxy groups to yield 2-hydroxymuconaldehyde as product, and require Fe^{2+} as a cofactor.[5]



Scheme 1 Reactions catalysed by intradiol and extradiol dioxygenases.

Unlike the cytochrome P450-dependent oxygenases, which were discovered at this time, the metal co-factors were utilised as non-haem iron by these enzymes. Hayaishi was able to demonstrate, using $^{18}O_2$ labelling experiments, that catechol 1,2-dioxygenase incorporated both atoms of oxygen from dioxygen into the reaction products,[4] hence the designation as a dioxygenase. The mechanism invoked by Hayaishi to explain these results was that a four-membered dioxetane ring was formed during the reaction (see Scheme 2), which fragmented to form the reaction products.[6]

The reason for the different metal ion requirement of the two families of enzyme, however, remained a mystery. The intradiol dioxygenases were entirely selective for Fe^{3+}, and were inactivated by treatment with reducing agents; while the extradiol dioxygenases were entirely selective for Fe^{2+}, and were inactivated by treatment with oxidising agents. Each family of enzyme was quite specific for the production of their respective reaction product with a range of substrates. Furthermore, although catechol is well known to be sensitive to aerial oxidation, oxidative cleavage of catechol was a reaction unprecedented in organic chemistry.

X-Ray crystallography of catechol dioxygenases

Although the catechol dioxygenases were demonstrated by Hayaishi to be crystalline enzymes,[4] it was not until 1988 that the first X-ray structure of a catechol dioxygenase, the intradiol-cleaving protocatechuate 3,4-dioxygenase from *Pseudomonas putida*, was solved by Ohlendorf *et al.*[7] The enzyme consists of two subunits, in an oligomeric $(\alpha\beta Fe)_{12}$ structure (see Fig. 1**B**). The non-haem iron(III) cofactor was found to be ligated by four amino acid sidechains: the imidazole sidechains of His-460 and His-462, and the phenolic sidechains of Tyr-408 and Tyr-447 (see Fig. 1**D**). A fifth water ligand completes a trigonal bipyramidal structure. The two tyrosinate ligands are thought to stabilise the iron(III) cofactor and give the enzyme its characteristic deep red colour due to ligand-to-metal charge transfer interactions.[7] X-ray structures of protocatechuate 3,4-dioxygenase from *Pseudomonas aeruginosa* and *Acinetobacter* sp. ADP1 have also been solved.[8,9]

Recently another member of the intradiol dioxygenase family, catechol 1,2-dioxygenase from *Acinetobacter* sp. ADP1, has also been solved.[10] This enzyme consists of an α_2 homodimer with one iron(III) cofactor per subunit. The tertiary structure of the 1,2-CTD enzyme is similar to that found in 3,4-PCD, although 1,2-CTD contains a novel helical zipper motif at the interface of the two subunits, and contains two molecules of bound phospholipid (see Fig. 1**A**). The active site of 1,2-CTD contains a very similar arrangement of iron(III) ligands: Tyr-200 and His-226 are the axial ligands, and Tyr-164, His-224 and a water molecule are the equatorial ligands (see Fig. 1**C**).[10]

Structural elucidation of the iron(II)-dependent extradiol dioxygenases has proved more challenging, due largely to the facile oxidation of the cofactor. By carrying out the enzyme purification and crystallisation under an anaerobic atmosphere, Han *et al.* were in 1996 able to solve the structure of 2,3-dihydroxybiphenyl 1,2-dioxygenase (BphC) from *Pseudomonas* LB400,[11] a strain capable of degrading chlorinated biphenyls. The tertiary structure of the enzyme consists of two similar $\beta\alpha\beta\beta\beta$ domains, only one of which contains an iron(II) cofactor (see Fig. 2**A**). A funnel-shaped cavity leads to the active site, where the iron(II) centre is ligated by three amino acid sidechains: His-146, His-210 and Glu-260 (see Fig. 2**D**).[11] This His_2Glu/Asp motif is found in a number of other non-haem iron(II)-dependent oxygenases, including the α-ketoglutarate

Active site of 2,3-CTD,[14] showing iron(II) cofactor, ligands (in blue), bound acetone molecule, and nearby active site residues. **F.** Active site of LigAB,[15] showing iron(II) cofactor, ligands (in blue), bound substrate protocatechuic acid (in red), and nearby active site residues.

dependent dioxygenases and isopenicillin N synthase.[12] The crystal structure of BphC from *Pseudomonas* KKS102 has also been solved with bound substrate, yielding a similar co-ordination geometry; however the crystallised form of the enzyme contains iron(III) rather than iron(II).[13]

The crystal structures of three other extradiol dioxygenases have now been solved. In 1998 Kita *et al.* reported the structure of catechol 2,3-dioxygenase from *Pseudomonas putida mt-2*, an α_4 tetramer.[14] The subunit structure is very similar to that of BphC, and the iron(II) cofactor is bound by His-153, His-214 and Glu-265 (see Fig. 2**B**,2**E**).[14] In 1999 Sugimoto *et al.* reported the structure of protocatechuate 4,5-dioxygenase from *Sphingomonas paucimobilis* SYK-6, which is composed of an $\alpha_2\beta_2$ tetramer.[15] This enzyme has no sequence similarity to BphC, yet the disposition of iron(II) ligands is very similar: the metal centre is co-ordinated by His-12, His-61 and Glu-242 (see Fig. 2**C**,2**F**).[15] In 2000 Titus *et al.* reported the structure of human homogentisate dioxygenase, a non-haem iron(II)-dependent dioxygenase involved in the mammalian degradation of L-phenylalanine and L-tyrosine.[16] This enzyme bears no sequence similarity to the bacterial extradiol catechol dioxygenases, yet its active site features are very similar: the iron(II) cofactor is bound by His-335, Glu-341 and His-371.[16]

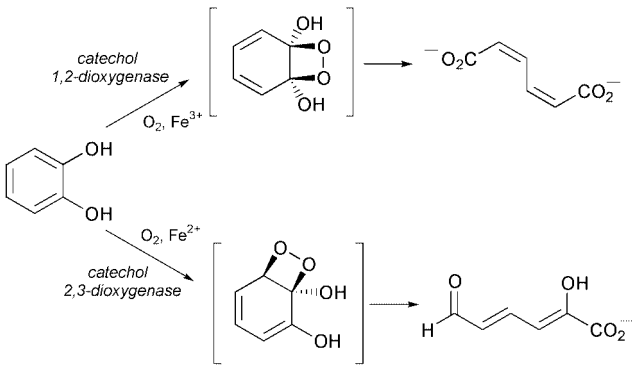
Thus, the solution of several X-ray structures has shown that each family of catechol dioxygenases has a specific set of amino acid ligands for the non-haem iron cofactor. The iron(III) cofactor of the intradiol dioxygenases is ligated by two tyrosine residues and two histidine residues, whereas the iron(II) cofactor of the extradiol dioxygenases is ligated by two histidine residues and one glutamic acid residue. Yet how does this small difference in co-ordination chemistry relate to the choice of reaction pathway? The active site structures do not reveal obvious differences which would explain why one yields the intradiol cleavage product and the other the extradiol cleavage product.

Furthermore, recent structures of co-crystals of protocatechuate 3,4-dioxygenase have demonstrated that the axial tyrosine ligand, Tyr-447, swings away from the iron(III) centre upon binding of substrate analogues, leaving only three amino acid ligands for the iron(III) centre (see Fig. 1**E**).[17] The riddle of the intradiol *vs.* extradiol dioxygenases therefore becomes more intriguing: why Fe^{3+} and a His_2Tyr_2 motif (one of which appears to dissociate during the reaction) for intradiol cleavage, and why Fe^{2+} and a His_2Glu motif for extradiol cleavage?

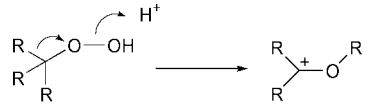
Evidence for 1,2 (Criegee) rearrangements in the catechol dioxygenases

The catalytic mechanism proposed by Hayaishi involved the formation of a cyclohexadienone hydroperoxide in both the intradiol and extradiol dioxygenases, followed by the formation of a four-membered dioxetane ring.[4] Once formed, the strained dioxetane would readily undergo retro[2+2] cleavage to give the acyclic products, with complete incorporation of both atoms of oxygen from dioxygen (see Scheme 2). There was, however, some disquiet about this mechanism: the formation of dioxetanes was thought to be a highly endothermic process, and their breakdown should be accompanied by luminescence, which is not observed for the catechol dioxygenases.[18] Indeed, the only well-characterised example of a dioxetane intermediate in an enzyme-catalysed reaction was the firefly luciferase reaction, in which decomposition of a dioxetane intermediate yields the luminescence characteristic of the firefly.[19]

An alternative mechanism involves a 1,2-rearrangement of the intermediate hydroperoxide. It is well precedented that alkyl hydroperoxides can undergo migration of a carbon substituent onto the neighbouring electron-deficient oxygen, with loss of the second oxygen atom *via* heterolytic O–O cleavage (see Scheme 3). In the case of an alkyl hydroperoxide this is known as a Criegee rearrangement.[20] This type of 1,2-rearrangement is



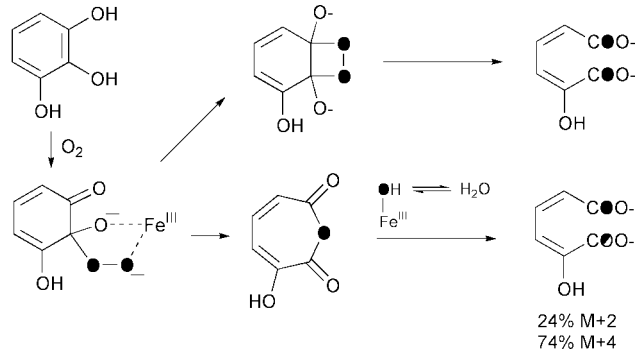
Scheme 2 Dioxetane intermediates proposed by Hayaishi for the catechol dioxygenases.



Scheme 3 1,2-Rearrangement of a hydroperoxide.

also commonly observed during the Baeyer–Villiger oxidation of ketones,[21] where an intermediate hydroperoxide is formed upon attack of hydrogen peroxide or a peracid on a ketone.

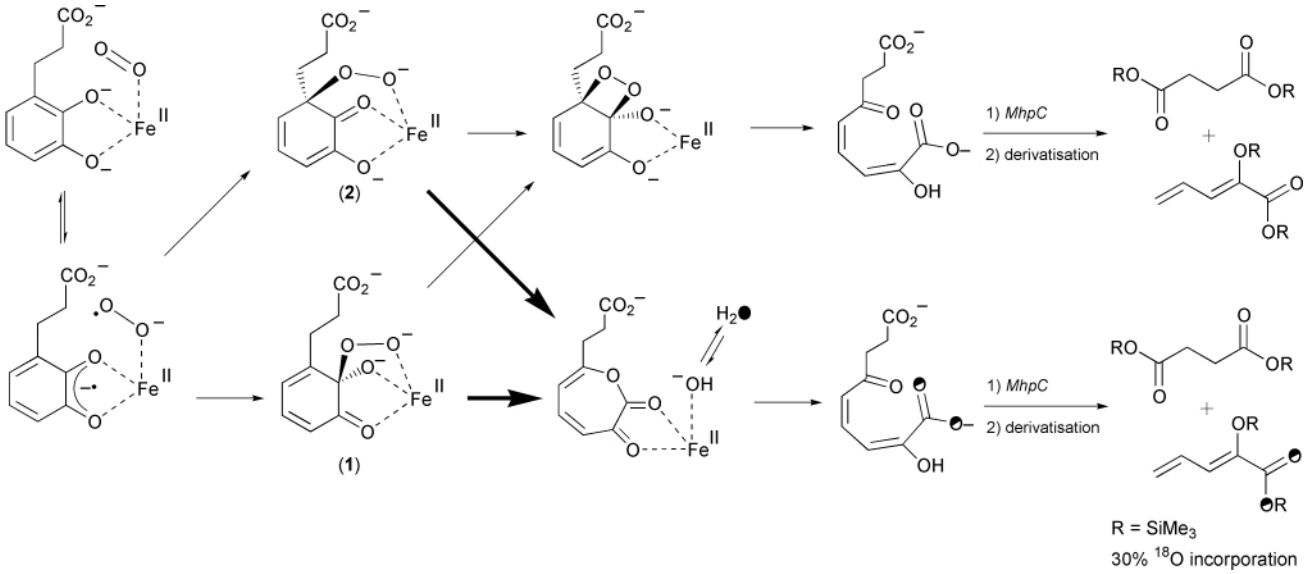
For intradiol cleavage, upon formation of a cyclohexadienyl hydroperoxide, migration of the adjacent acyl group (acyl migration) would yield muconic anhydride as an intermediate, which would undergo hydrolysis to give the product muconic acid. $^{18}O_2$ labelling studies on catechol 1,2-dioxygenase from *Pseudomonas arvilla* have revealed that the intradiol cleavage products contain 99% incorporation of a single atom of ^{18}O, and 74% incorporation of a second atom of ^{18}O, with 24% incorporation of only one atom of ^{18}O (see Scheme 4).[22] These



Scheme 4 $^{18}O_2$ labelling studies on the reaction of pyrogallol with catechol 1,2-dioxygenase from *Pseudomonas arvilla*.

data are not consistent with a dioxetane intermediate, but could be explained by a Creigee rearrangement to give an anhydride intermediate, followed by the partial exchange of the iron(III) ^{18}O-hydroxide with solvent water.[22] Interestingly, no single atom isotope incorporation is observed with the natural substrate catechol, implying a lack of exchange or a more efficient hydrolysis of the anhydride intermediate.[22] Model reactions for intradiol cleavage (see below) have in some cases yielded muconic anhydrides as reaction products, again consistent with a 1,2-rearrangement.

In the case of extradiol cleavage, there are two possible cyclohexadienyl hydroperoxides which could undergo 1,2-rearrangements. The first possibility is that proximal hydroperoxide (**1**) is formed, as for intradiol cleavage, which undergoes migration of the adjacent alkene (alkenyl migration) to give an α-keto-lactone intermediate, which then undergoes hydrolysis by iron(II) hydroxide to give 2-hydroxymuconate semi-aldehyde. The second possibility is that a distal hydro-



Scheme 5 Mechanistic schemes for MhpB-catalysed reaction showing ^{18}O labelling pattern.

peroxide (**2**) is formed, which undergoes 1,2-rearrangement *via* acyl migration to give the same α-keto-lactone intermediate (see Scheme 5). $^{18}O_2$ labelling studies carried out on *E. coli* 2,3-dihydroxyphenylpropionate 1,2-dioxygenase (MhpB) revealed that although both the acid and ketone carbonyls could be labelled with ^{18}O from $^{18}O_2$, upon reaction in $H_2{}^{18}O$ the carboxylate position was labelled to the extent of 30%, consistent with the formation of an α-keto lactone intermediate, and exchange of iron(II) hydroxide with solvent ^{18}O-labelled water (see Scheme 5).[23] The enzyme was also found to catalyse the hydrolysis of a saturated seven-membered lactone analogue (**3**; see Scheme 6).[23] These studies implicate a lactone intermediate arising from Criegee rearrangement in the extradiol cleavage reaction mechanism.

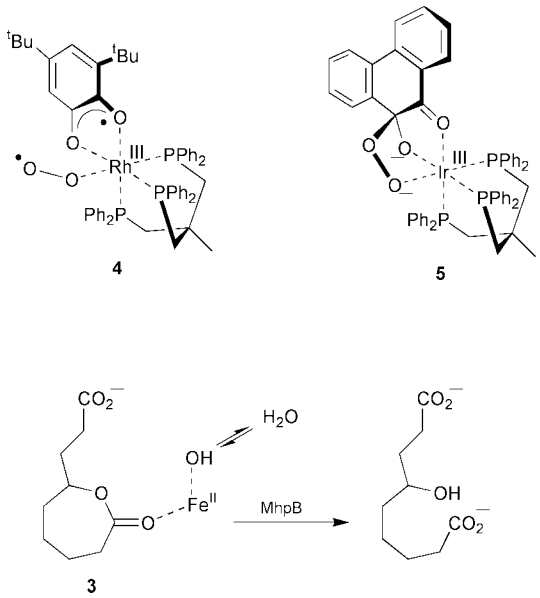
Thus, evidence from ^{18}O labelling experiments and model studies has revealed that both intradiol and extradiol cleavage reactions involve 1,2-rearrangements taking place on cyclohexadienyl hydroperoxide reaction intermediates, in close proximity to the non-haem iron cofactors.

Formation of cyclohexadienyl hydroperoxides *via* single electron transfers

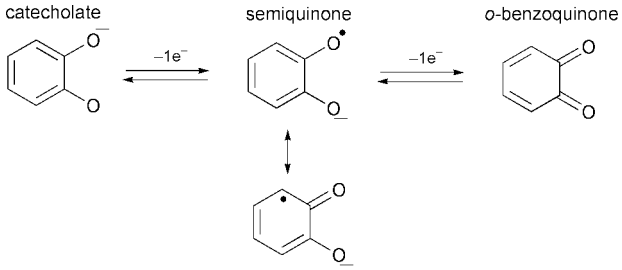
The formation of cyclohexadienyl hydroperoxides is implicated in both intradiol and extradiol cleavage reactions from the studies discussed above. How are they formed? What are the differences between the Fe^{3+}-based intradiol reaction and the Fe^{2+}-based extradiol reaction?

There are several clues from known chemistry that single electron transfers may be involved in each case. First of all, it is well established that the triplet ground state of dioxygen is forbidden to react with paired-electron reagents, however it can react with radical species, and it can accept one electron from certain transition metal ions to form the much more reactive superoxide species.[24] Indeed, there are many examples of divalent transition metals (*e.g.* Fe^{II}, Co^{II}, Ir^{II}) which can form stable metal(III)-superoxide complexes upon reaction with dioxygen.[24] The next clue is that catechol readily undergoes single electron oxidation, *via* a stable semiquinone intermediate, to an *ortho*-quinone species (see Scheme 7). Thus, a redox-active metal such as iron could mediate one-electron transfers between catechol and dioxygen.

There are specific examples from transition metal chemistry which suggest that this may be the case. The X-ray crystal structure of a rhodium(III)–triphos–catecholate complex (**4**) with dioxygen synthesised by Bianchini *et al.* shows that dioxygen is bound as superoxide, and that catechol is bound as



Scheme 6 Lactone hydrolysis catalysed by MhpB.



Scheme 7 Single electron oxidation of catechol.

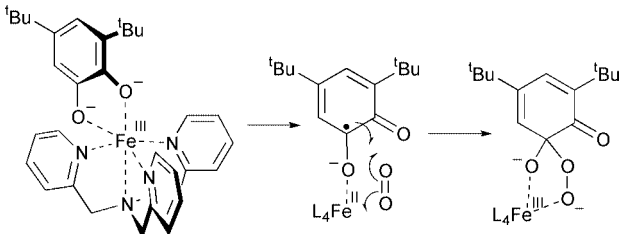
its semiquinone.[25] This metal–semiquinone–superoxide complex could be formed by one-electron transfer from Rh^{III} to dioxygen, followed by one-electron transfer from catechol to Rh^{II}. The X-ray structure of the corresponding iridium(III) complex (**5**) shows a C–O bond formed between the catechol ring and dioxygen,[26] indicating that C–O bond formation between metal-bound semiquinone and metal-bound superoxide is feasible, to give a cyclohexadienyl hydroperoxide. A similar cyclohexadienyl hydroperoxide has been reported for a

Rh^{III} complex, formed by reaction of $Rh^{I}(PPh_3)_3Cl$ with 9,10-phenanthrenequinone.[27] One final clue for the involvement of superoxide is the existence of a model reaction for catechol cleavage involving treatment of catechol in DMSO with solid potassium superoxide, which gives a 5–10% yield of 2-hydroxymuconic semialdehyde, the extradiol cleavage product.[28]

EPR spectroscopic studies have shown that the iron(III) cofactor of the intradiol dioxygenase family ligates to the catechol hydroxy groups, by displacement of a bound water molecule; however no transient iron(II) intermediates are detectable during turnover.[29,30] EPR spectroscopic studies of the NO complex of the extradiol dioxygenase protocatechuate 4,5-dioxygenase have shown that the iron(II) cofactor binds both catecholic hydroxy groups, and binds NO; however no iron(III) intermediates could be detected during turnover.[31] Thus, EPR spectroscopy has provided no experimental evidence for the involvement of one-electron transfers in the catechol dioxygenase reactions. However, if the one-electron transfers were very fast, then no build-up of intermediates would be observable.

The existence of carbon-centred radicals in enzyme-catalysed reactions has been probed in several cases using 'radical trap' substrates containing a cyclopropyl group adjacent to the radical-bearing carbon atom.[32] Formation of the radical intermediate would then lead to an extremely rapid opening of the cyclopropane ring, yielding a new reaction product or leading to enzyme inactivation. A cyclopropyl-containing substrate analogue (**6**) was synthesised as a substrate for 2,3-dihydroxyphenylpropionate 1,2-dioxygenase (MhpB) from *E. coli*.[33] Both *cis*- and *trans*-substituted cyclopropyl analogues were found to be efficiently processed by the enzyme. However, when the products were analysed by further enzymatic degradation, it was found that isomerisation of the cyclopropyl ring substituents had occurred: processing of the *trans*-substituted substrate gave 94% *trans*-product and 6% *cis*-product; while processing of the *cis*-substituted substrate gave only 10% of the *cis*-product, and 90% of the *trans*-product (see Scheme 8). Having established that epimerisation *via* solvent exchange was not occurring, the only reasonable explanation of these results is that a radical-mediated reversible opening of the cyclopropyl ring is taking place.[33] Since the equilibrium position of ring-closed *vs.* ring-opened product is governed by the stability of ring-closed *vs.* ring-opened products, the reversible ring opening can be explained by the high stability of the initial semiquinone radical. These data provide some experimental evidence for a transient iron(II)–semiquinone–superoxide intermediate in the extradiol catechol dioxygenase reaction mechanism.

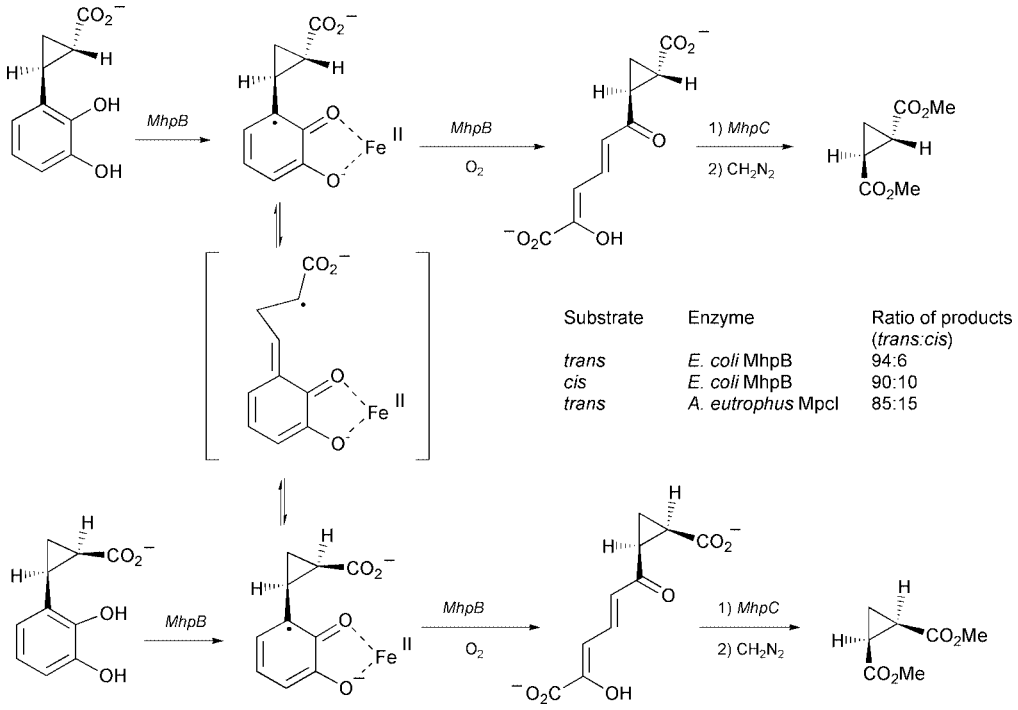
Evidence from model studies of intradiol cleavage also suggests the involvement of one-electron transfers. Analysis of a Fe^{III}tris(2-pyridylmethyl)amine complex (**7**), which showed high activity for intradiol catechol cleavage, by X-ray crystallography and ^{1}H NMR spectroscopy revealed a very strong iron–catecholate interaction, and increased semiquinone character in the bound substrate.[34,35] It was therefore proposed that formation of a transient Fe^{II}–semiquinone intermediate preceded reaction with dioxygen (see Scheme 9).[35] Since no



Scheme 9 Semiquinone activation proposed for intradiol cleavage.

binding of O_2 or NO to the iron(III) centre of the intradiol dioxygenases has been observed by EPR spectroscopy,[29,30] it is proposed that the iron(II)-bound semiquinone reacts directly with dioxygen, without prior binding of dioxygen to the iron centre.[35]

Thus, both intradiol and extradiol dioxygenases utilise single electron transfers to form a cyclohexadienyl hydroperoxide intermediate, although the order of steps is different in the two enzymes. In the extradiol dioxygenase active site single electron transfer from iron(II) to dioxygen is followed by single electron transfer from catechol to iron(III), to give a transient iron(II)–semiquinone–superoxide intermediate, which then undergoes C–O bond formation. In the intradiol dioxygenase active site single electron transfer from catechol to iron(III) gives an iron(II)-semiquinone intermediate which reacts directly with dioxygen to form the C–O bond. Both families make use of the



Scheme 8 *Cis–trans* isomerisation of a cyclopropyl radical trap (**6**) catalysed by extradiol dioxygenase MhpB.

single electron redox chemistry of iron and catechol, but *via* a different sequence.

Evidence for a proximal hydroperoxide in the extradiol catechol dioxygenases

Returning to the cyclohexadienyl hydroperoxide intermediate formed after the single electron redox chemistry described above, there is one important issue to be resolved. The extradiol cleavage mechanism could proceed *via* either of two possible cyclohexadienyl hydroperoxides (Scheme 5). As discussed in Section 3, either a proximal hydroperoxide could undergo alkenyl migration to give an α-keto-lactone, or a distal hydroperoxide could undergo acyl migration to give the same α-keto-lactone. Which is it?

Several pieces of circumstantial evidence favour the intermediacy of a proximal hydroperoxide, rather than a distal hydroperoxide. Inspection of models reveals that the geometry required to form the distal hydroperoxide is rather strained, and inspection of the X-ray structures of BphC also indicates that reaction at the proximal position of the substrate is more readily achievable than reaction at the distal position.[11,13] The iridium(III) model complex (**5**) containing a cyclohexadienyl hydroperoxide also exhibits a proximal hydroperoxide.[26]

More definitive evidence has been obtained for the extradiol dioxygenase 2,3-dihydroxyphenylpropionate 1,2-dioxygenase (MhpB) from *E. coli*. It was known from structure–activity relationships that MhpB would process substrates containing a diverse range of functional groups at the 3-position (*e.g.* alkyl, –CH=CHCO$_2$H, –OCH$_2$CO$_2$H) with comparable efficiency, which is hard to reconcile with the formation of a distal hydroperoxide at the 3-position.[33] A series of analogues of the proximal and distal hydroperoxides were synthesised, in which the –OOH functional group was replaced by –CH$_2$OH, and the cyclohexadienyl ring simplified to a cyclohexanone ring.[36] These 'carba' analogues are shown in Fig. 3. It was found that the carba analogue **7** of the distal hydroperoxide showed no inhibition of MhpB at 10 mM concentration. However, analogues **9** and **10** of the proximal hydroperoxide did show modest competitive inhibition of MhpB, with K_i values of 4.9 mM and 0.7 mM respectively. In contrast, the methyl-substituted analogue **8** showed no enzyme inhibition. Analysis by ^{1}H NMR spectroscopy revealed that in **9** and **10** the hydroxymethyl substituent is positioned in an axial oritentation with respect to the cyclohexanone ring, whereas in **8** the hydroxymethyl group was equatorial (see Fig. 3).[36] These data provided some experimental evidence in support of a proximal hydroperoxide, and furthermore indicated that the conformation adopted by the hydroperoxide was of importance, an axial hydroperoxide being required at the extradiol dioxygenase active site.

This result has an important consequence for the reaction mechanisms of both families of enzyme, namely that both reactions converge on the same proximal cyclohexadienyl hydroperoxide intermediate (see Fig. 4). In the case of the intradiol dioxygenases, this intermediate undergoes acyl migration to give a muconic anhydride, whereas in the extradiol dioxygenases the proximal hydroperoxide undergoes alkenyl migration to give an α-keto-lactone. Therefore, in spite of the differences in the early steps of the reaction mechanism, the inescapable conclusion is that the choice of intradiol *vs.* extradiol reaction pathways is controlled by the choice of acyl *vs.* alkenyl migration of a reactive proximal hydroperoxide intermediate. How might this choice of 1,2-rearrangements be controlled?

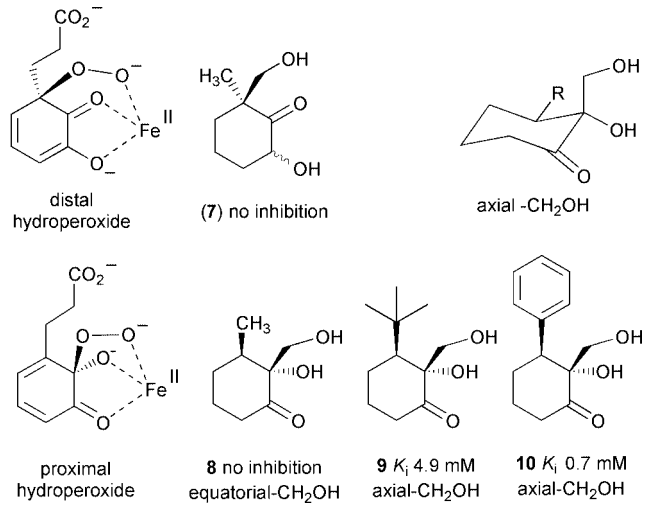


Fig. 3 Carba analogues of proximal and distal hydroperoxide reaction intermediates, tested as inhibitors for 2,3-dihydroxyphenylpropionate 1,2-dioxygenase (MhpB) from *Escherichia coli*.[36]

Acyl *vs.* alkenyl migration in hydroperoxide rearrangements

In order to address the question of acyl *vs.* alkenyl migration, we must first look at examples of hydroperoxide rearrangements in organic chemistry. This section will describe instructive examples from Criegee rearrangments and Baeyer–Villiger oxidations.

The first example which provides a good model for the desired proximal hydroperoxide occurs in the Baeyer–Villiger oxidation of 1,2-diketones, in which anhydride products are formed in a range of examples.[21] Thus, upon attack of peroxide or a peracid upon one ketone centre, an intermediate α-ketohydroperoxide is formed, which undergoes acyl migration (see Scheme 10). This example provides clear precedent for the acyl migration step of intradiol cleavage, to give an anhydride

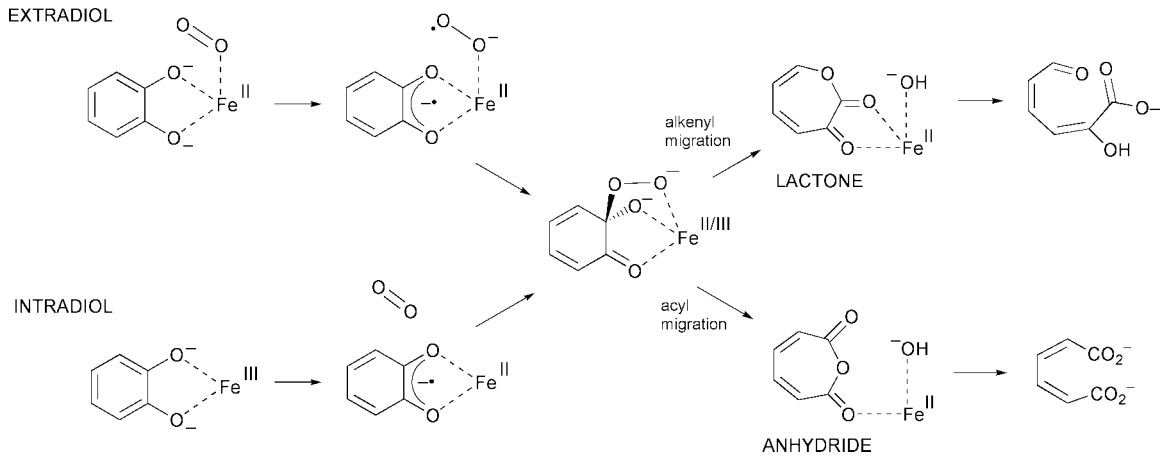

Fig. 4 Proposed mechanistic convergence of the catalytic mechanisms of the extradiol and intradiol catechol dioxygenases onto a common proximal hydroperoxide intermediate, and their divergence *via* alkenyl or acyl migration to give extradiol or intradiol reaction products.

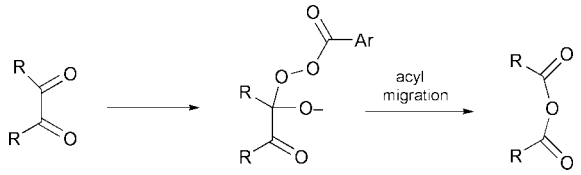
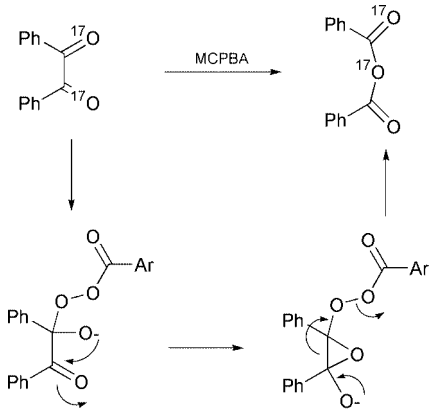


Scheme 10 Baeyer–Villiger oxidation of 1,2-diketones.

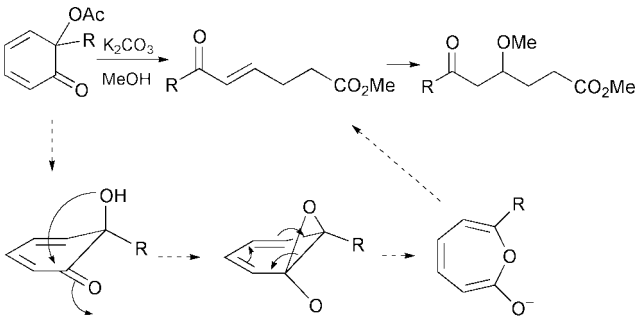
product. However, the mechanism of acyl migration may not be as straightforward as it seems. Baeyer–Villiger oxidation of ^{17}O-labelled benzil gave anhydride product containing ^{17}O in the bridging position, not consistent with a direct migration of an acyl group (see Scheme 11).[37] A mechanism was proposed



Scheme 11 Epoxide mechanism proposed for Bayer–Villiger oxidation of benzil.

involving attack of the alkoxide ion upon the adjacent ketone, to form a 1,2-epoxide, followed by C–C fragmentation to give the anhydride product (see Scheme 11).[37] It is known that the presence of electron-withdrawing groups reduces migratory aptitude in Baeyer–Villiger oxidations,[38] therefore the facile migration of an electron-deficient acyl group in this case could be rationalised by this alternative mechanism.

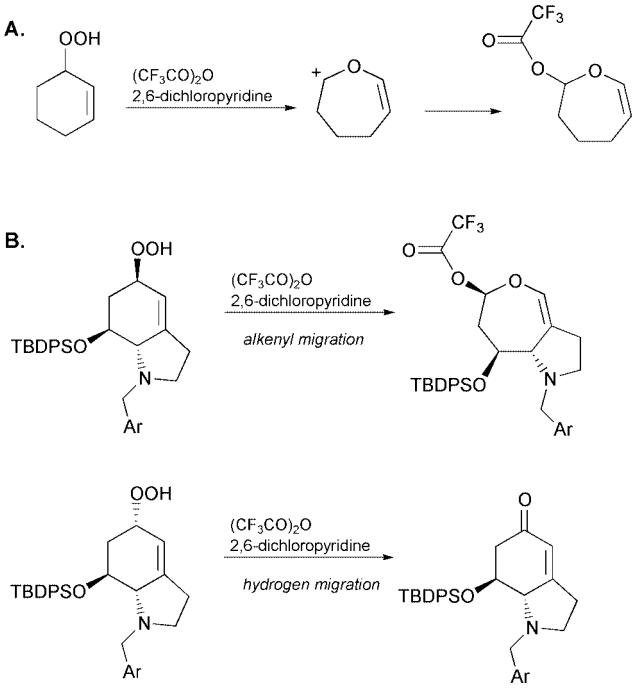
One recent observation suggests that such a mechanism might operate in the acyl migration of cyclohexadienyl hydroperoxides. Treatment of 6-alkyl-6-acetoxycyclohexa-2,4-dienones with carbonate buffer in water–methanol leads to a rapid C–C cleavage reaction, resulting in the production of acyclic esters (see Scheme 12). Studies of the mechanism of this



Scheme 12 Solvolytic C–C cleavage of 6-alkyl-6-acetoxycyclohexadienones (R = CH_3, Ph).

C–C cleavage reaction indicate that hydrolysis of the acetyl group is essential for ring cleavage, hence that a mechanism involving attack of the tertiary alcohol on the adjacent ketone, followed by a benzene oxide–oxepin interconversion, may mediate ring cleavage in this system (see Scheme 12). This mechanism provides an alternative pathway for acyl migration in the intradiol dioxygenase reaction.[39]

Recent work by Goodman and Kishi provides clear examples of alkenyl migration: treatment of a cyclohexenyl hydroperoxide with trifluoroacetic anhydride yields products arising from alkenyl migration in preference to alkyl migration (see Scheme 13A).[40] In cases where the hydroperoxide group is positioned on a bicyclic carbon skeleton, as shown in Scheme 13B, the choice of migrating group is determined by stereoelec-



Scheme 13 Alkenyl migration of a cyclohexyl hydroperoxides.

tronic factors: the group which preferentially migrates is the one which is positioned anti-periplanar to the O–O bond which is being broken,[40] as one might expect from stereoelectronic arguments.[41]

This idea provides an attractive rationalisation of the results obtained using the carba-analogues of proximal hydroperoxide intermediates in the MhpB-catalysed reaction.[36] If the hydroperoxide functional group is positioned axially with respect to the cyclohexadienone ring, and is ligated to the iron(II) centre, then the O–O bond will be aligned in an antiperiplanar geometry with the C–C bond to the neighbouring alkenyl group which migrates in the extradiol reaction (see Fig. 5A). Thus, one factor

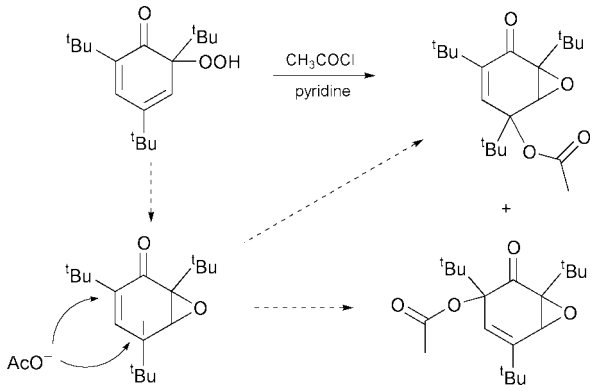
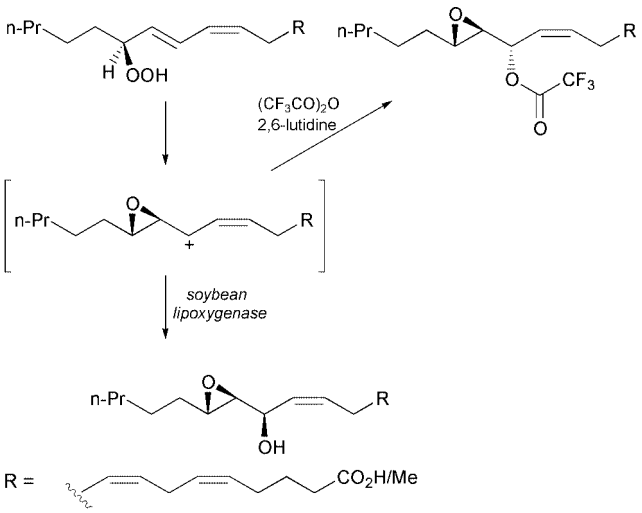
which could control the acyl *vs.* alkenyl migration of a common hydroperoxide intermediate is the conformation of the bound intermediate and hence precise positioning of the O–O bond.

Further reactions of alkenyl hydroperoxides provide an alternative mechanism for alkenyl migration. Nishinaga *et al.* have reported that treatment of a tributyl-substituted cyclohexadienone hydroperoxide with acetyl chloride–pyridine leads to the formation of two epoxides (see Scheme 14).[42] These



Scheme 14 Epoxide formation in cyclohexadienyl hydroperoxide rearrangement.

epoxides could be formed by nucleophilic participation of the neighbouring alkene to form an epoxide intermediate containing an allylic carbocation, which could be quenched by acetate. Note that in this case the *tert*-butyl substituent will ensure that the hydroperoxide is held axially with respect to the ring, which would bring the hydroperoxide in close proximity to the π system of the neighbouring diene. Further examples of the reaction of polyunsaturated fatty acid hydroperoxides to form epoxides have also been reported by Corey *et al.* (see Scheme 15).[43,44] Again an adjacent diene is present, so that the intermediate carbocation arising from nucleophilic participation would be a stabilised allylic carbocation.



Scheme 15 Epoxide formation in polyunsaturated fatty acid hydroperoxide rearrangement.

This π participation mechanism could be applied to the alkenyl migration step of the extradiol reaction pathway.[36] If the hydroperoxide functional group is held axially with respect to the cyclohexadienone ring, then the π system of the diene would overlap with the σ* orbital of the O–O bond, leading to the formation of a transient epoxide species bearing an adjacent allylic carbocation, which would rapidly undergo C–C fragmentation to give the α-keto-lactone (see Fig. 5B). Thus, there are two subtly different mechanisms for alkenyl migration of an axial proximal hydroperoxide: either σ bond migration of an antiperiplanar alkenyl group, or π participation of the adjacent diene.

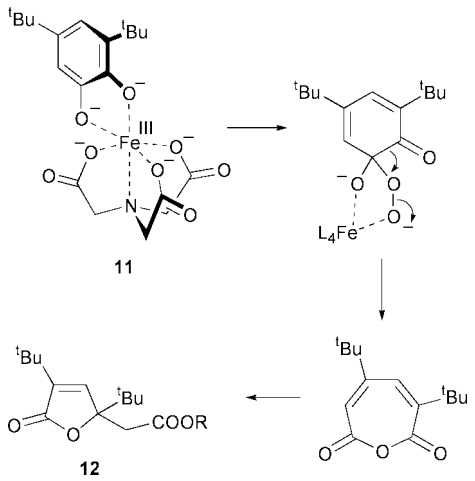
In conclusion, there are literature examples of both acyl migration and alkenyl migration in hydroperoxide 1,2-rearrangements in organic chemistry. The control of migratory group *via* stereoelectronic factors would provide an attractive means by which an enzyme active site might dictate intradiol *vs.* extradiol cleavage. However, the examples in this Section lack one crucial feature of the enzyme-catalysed reactions: the proximity of the non-haem iron centre, whose effects upon intradiol *vs.* extradiol cleavage will be discussed next.

Transition metal-based model reactions for oxidative catechol cleavage

Since the discovery of the catechol dioxygenases, many attempts have been made to mimic these reactions non-enzymatically. The intriguing iron cofactor specificity of the catechol dioxygenase suggested that the iron cofactor played a major role in the active site chemistry, hence most attempts have involved metal ion complexes of catechol substrates. Does the character of the iron centre control the choice of cleavage pathways?

Model systems for intradiol cleavage

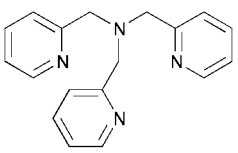
The first model system for intradiol cleavage was an Fe^{III}–nitrilotriacetate complex **11**, which was reported to convert 3,5-di-*tert*-butylcatechol catalytically over a period of 4 days in the presence of oxygen to give the furanone derivative **12** in 80% yield.[45,46] An X-ray crystal structure of this complex showed the catechol substrate bound in bidentate fashion, with the geometry around the central Fe^{III} close to octahedral.[46] Labelling studies with $^{18}O_2$ on this system revealed the incorporation of one atom of $^{18}O_2$ into furanone **12**, consistent with the existence of an anhydride intermediate as shown in Scheme 16.[46]



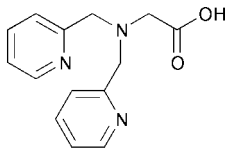
Scheme 16 Intradiol cleavage catalysed by Fe^{III}(NTA) complex **11**.

Subsequent studies using a range of iron(III) complexes showed a correlation between the reactivity of the Fe^{III}–ligand system and the Lewis acidity of the metal centre, which could be quantitatively assessed by measuring the redox potential for the catechol-to-semiquinone oxidation.[47] Of the complexes studied, the Fe^{III}–nitrilotriacetate complex **11** showed the highest reactivity, and the highest redox potential of +59 mV (and hence the highest affinity of the catechol ligand for the Fe^{III} centre).[47]

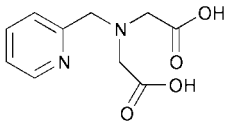
Further studies by Que and co-workers led to the discovery of more reactive Fe^{III} complexes,[34,35] the most active of which was Fe^{III}–tris(2-pyridylmethyl)amine **13**. This complex was found to react with dioxygen within minutes to form furanone **12** in 98% yield, at a rate of 15 M^{-1} s^{-1}, approximately 1000-fold faster than complex **11**. Analysis of complex **13** by X-ray crystallography and ^{1}H-NMR spectroscopy revealed a very strong iron–catecholate interaction, and increased semiquinone character in the bound substrate. It was therefore proposed that formation of a transient Fe^{II}–semiquinone intermediate preceded reaction with dioxygen, as shown previously in Scheme 9. Each of these tetradentate ligands **13**–**16**, when complexed to Fe^{III}, showed activity for intradiol cleavage, revealing that two easily accessible *cis* coordination sites are needed for coordination of the catecholate ligand and its subsequent reaction with dioxygen. The order of reactivity of the coordinated 3,5-di-*tert*-butylcatecholate ligand $(dbc)^{2-}$ was in the order $[Fe(\mathbf{13})(dbc)]^+$ > $[Fe(\mathbf{14})(dbc)]^+$ > $[Fe(\mathbf{15})(dbc)]^+$ > $[Fe(\mathbf{16})(dbc)]^+$, and is correlated to the Lewis acidity of the iron(III) centre.[34,35,45]



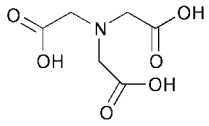
(**13**;TPA)



(**14**;BPG)

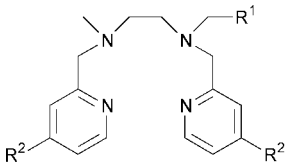


(**15**;PDA)

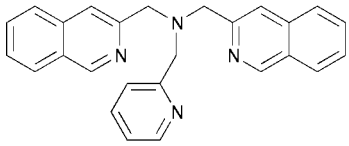


(**16**;NTA)

Girerd and co-workers have investigated the structures and reactivity of Fe^{III} complexes of **17**–**20** with 3,5-di-*tert*-butylcatechol, which all formed [Fe(L)(dbsq)] complexes with



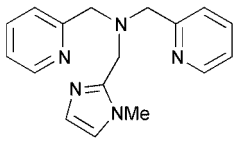
17 R^1 = H, R^2 = H
18 R^1 = H, R^2 = Cl
19 R^1 = 2-pyridyl, R^2 = H



20

significant semiquinone character.[48] Reactivity for intradiol cleavage was found to correlate inversely with the λ_{max} value, the order of reactivity being **13** (874 nm) > **17** (935 nm) > **18** (941 nm) > **19** (957 nm).[48]

In most studies, 3,5-di-*tert*-butylcatechol has been used as a model substrate in functional investigations, however Krebs and co-workers have reported studies of iron(III) complexes of bis[(2-pyridyl)methyl][(1-methylimidazole-2-yl)methyl]amine **21** with a series of catechols.[49] The position of the ligand-metal

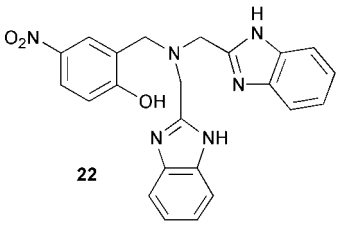


21

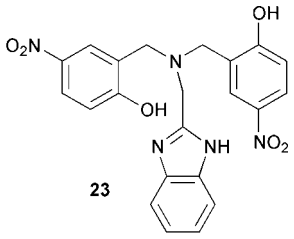
charge-transfer (LMCT) bands were observed to shift to lower energies by varying the substituents on the catecholate from electron-withdrawing to electron-donating. The reaction with dioxygen exhibits pseudo-first-order kinetics, and the order of activity correlates with the energy of the lower energy LMCT band of the complexes: electron-donating substituents on the catechol result in a higher dioxygenase activity.[49]

Palaniandavar *et al*. have studied a series of iron(III) complexes of tetradentate tripodal ligands **22**–**24**, and found that not only the phenolate-to-iron(III) charge transfer band but also the L^{2-}/dbc^{2-} to Fe^{III} charge transfer band is remarkably sensitive to the primary ligand environment.[50] The simultaneous appearance of the dbc^{2-} to Fe^{III} charge transfer band, the dbsq/dbc redox wave, and the lowering of the Fe^{III}/Fe^{II} redox potential on adding $dbcH_2$, even in the absence of added base, demonstrate the spontaneous deprotonation of the catechol substrate on binding to iron(III). Thus it is suggested that one function of the iron(III) center is to promote the loss of both protons of the substrate.[50]

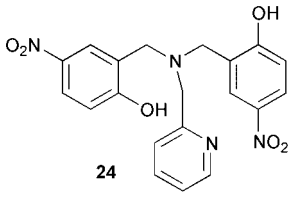
Attempts to mimic the ligating abilities of histidine in the active site of the enzyme have been reported, by introducing benzimidazole moieties into a tripodal ligand.[51] Ligands **25**,**26** showed intradiol cleaving activity when complexed to Fe^{III}, the



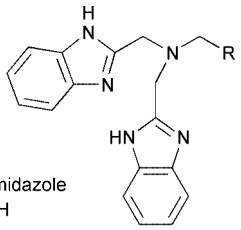
22



23

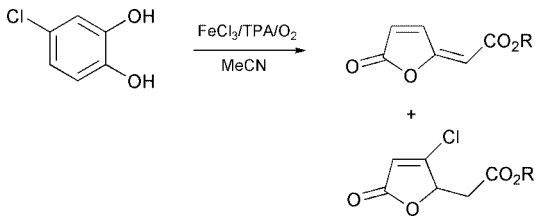


24



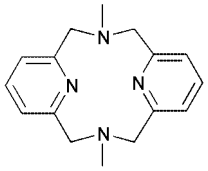
25 R = benzimidazole
26 R = CH_2OH

reaction rate depending on the steric and electronic properties of the coordinating ligand moieties.[51] Funabiki *et al*. have reported the first example of the oxidative cleavage of 3- and 4-chlorocatechols with dioxygen by an Fe^{III}(tpa) complex.[52] 4-Chlorocatechol was oxygenated at 25 °C in acetonitrile under an oxygen atmosphere by the iron complex prepared *in situ* by mixing $FeCl_3$ and tris(2-pyridylmethyl)amine (tpa), giving rise to intradiol cleavage products as shown in Scheme 17.[52]



Scheme 17

Finally, Kruger *et al*. have reported a highly reactive and catalytically active model system by using *N*,*N*′-dimethyl-2,11-diaza[3,3](2,6)pyridinophane (**27**, L-N_4Me_2) as a macro-



27

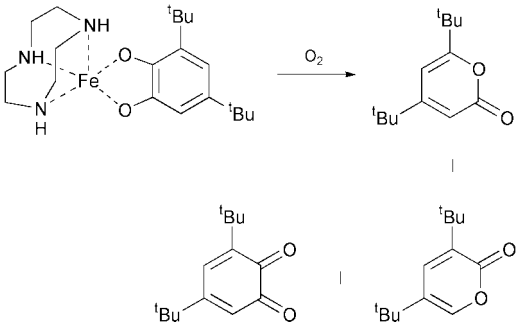
cyclic ligand.[53] For catalytic reaction, two equivalents of a base are needed per iron(III). With 1% of the iron(III) catalyst, a yield of 54% of muconic anhydride was obtained after a reaction time of 30 h.[53]

In summary, intradiol cleavage activity is observed with a number of tetradentate nitrogen ligands, complexed to Fe^{III}. High activity is correlated with Lewis acidity of the Fe^{III} centre, and semiquinone character of the bound catechol substrate. The tetradentate co-ordination geometry of these systems parallels the tetradentate Fe^{III} co-ordination state in the intradiol dioxygenase active sites (see Fig. 1).

Model systems for extradiol cleavage

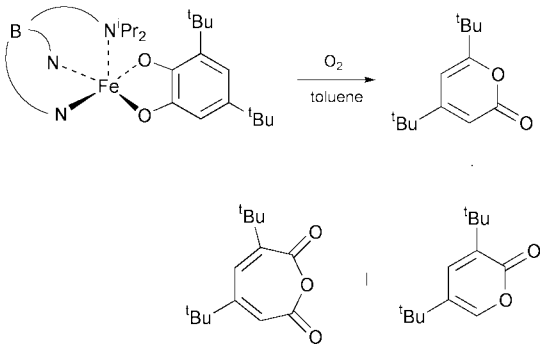
Although most of model reactions for catechol oxidative cleavage perform intradiol cleavage, there are a few examples of oxidative cleavage by synthetic iron complexes to give 2-pyrone products which are believed to be of extradiol origin, although they are lacking one carbon atom. Funabiki *et al.* found that $FeCl_2/FeCl_3$ complexes with bipyridine/pyridine prepared *in situ* cleave 3,5-di-*tert*-butylcatechol to give a mixture of 2-pyrones, which incorporate ^{18}O label from $^{18}O_2$.[54] The 2-pyrones are proposed to derive from decarbonylation of the α-keto-lactone extradiol cleavage intermediate.[54]

Dei *et al*. found that the complex [Fe^{II}(TACN)(dbc)]Cl (**28**) yielded 2-pyrones upon exposure to O_2 in 35% yield (see Scheme 18).[55] Que *et al*. used the same complex to give an



Scheme 18

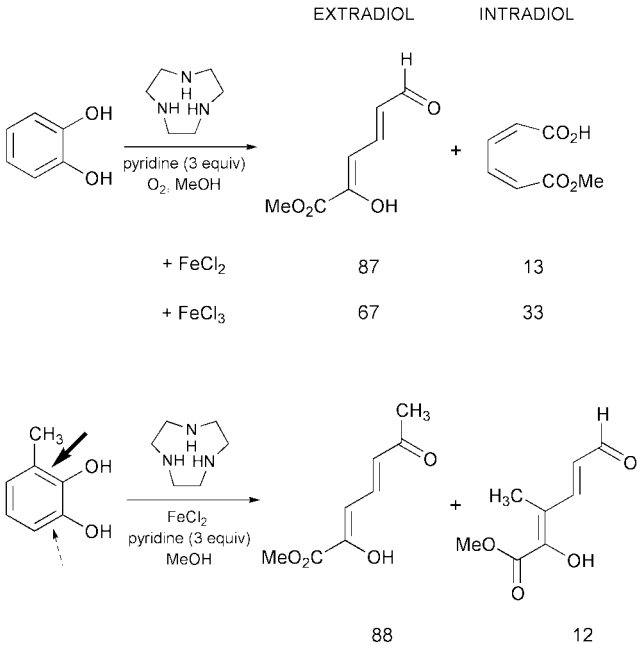
almost quantitative yield of 2-pyrones using a modified procedure with additional base/ligand in favor of extradiol cleavage.[56] Moro-oka *et al*. found that oxygenation of the square pyramidal complex [Fe^{III}(hydrotris(3,5-diisopropyl-1-pyrazoyl)borate)(dbc)]Cl (**29**) results in the formation of 2-pyrones and an intradiol-derived anhydride (see Scheme 19).[57] They report that a related complex which adopts a



Scheme 19

trigonal bipyramidal geometry gives no 2-pyrone products, therefore a vacant co-ordination site appears to be required for oxygen activation.[57]

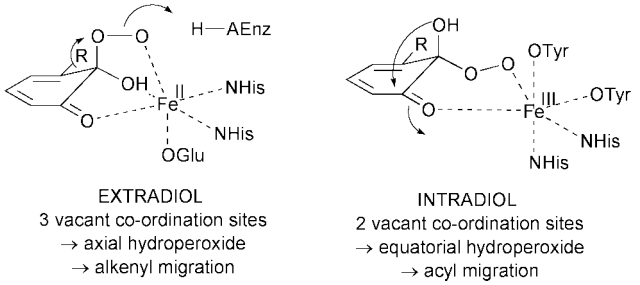
We have reported that the oxygenation of catechol by O_2 in the presence of $FeCl_2$ or $FeCl_3$, 1,4,9-triazacyclononane (TACN), and pyridine in methanol gives the authentic extradiol product 2-hydroxymuconic semi-aldehyde methyl ester in 50% yield.[58] In this model system $FeCl_2$–TACN shows higher selectivity for extradiol:intradiol cleavage (7 : 1) compared with $FeCl_3$–TACN (2 : 1), as shown in Scheme 20. Extradiol cleavage is only observed with the facial N_3-tridentate ligand TACN, and not with N,O-macrocycles, nor with N-substituted TACN macrocycles. We have found that this model reaction is highly regioselective for proximal 2,3-extradiol cleavage over distal 1,6-extradiol cleavage when using 3-methylcatechol (35 : 1), or 4-methylcatechol (> 99), or 3-(2,3-dihydroxyphenyl)propionic acid (> 99 : 1) as substrates.[59] The reaction proceeds in the absence of pyridine using monosodium



Scheme 20 $FeCl_2$–TACN model reaction for extradiol cleavage.

catecholate, but not disodium catecholate, implying that catechol binds to the iron centre as the monoanion,[59] the same conclusion reached from EXAFS studies on the 2,3-CTD–catechol complex.[60]

Studies of the mechanism of the $FeCl_2$–TACN model reaction have shown that the role of pyridine is two-fold: one equivalent of pyridine is required as a base to generate catechol monoanion, but one equivalent of pyridinium chloride is subsequently required as a proton donor to assist the Criegee rearrangement for extradiol cleavage.[59] Cleavage in the presence of methanol, ethanol or isopropanol yields the respective various alkyl esters of 2-hydroxymuconic semialdehyde, implying the intermediacy of a 7-membered α-keto-lactone, as for the enzymatic reaction.[59] The close similarities of regioselectivity and substrate selectivity between this model reaction and the *E. coli* MhpB-catalysed enzymatic reaction suggest that they follow a similar mechanism.



Scheme 21 Axial/equatorial hypothesis for extradiol/intradiol dioxygenase selectivity.

In summary, model systems for extradiol cleavage have proved more elusive, but extradiol cleavage is observed for a tridentate macrocyclic ligand, complexed with Fe^{II}, which shows high selectivity and appears to follow the same mechanism as the enzyme-catalysed reaction. It is interesting to note that both Fe^{II} and Fe^{III} are capable of extradiol cleavage in this system, but that Fe^{II} shows higher rate and selectivity, providing some insight into why Fe^{II} is found as the cofactor in the extradiol dioxygenases. The two-fold role of pyridine in this model reaction also suggests a role for an active site base, and a proton donor, in the extradiol dioxygenase active sites. All of the extradiol dioxygenases which have been structurally elucidated have, as well as the iron(II) ligands, an additional histidine residue near to the substrate binding site, and a

tyrosine–histidine pair which could function as a proton donor (see Fig. 2).

A hypothesis for extradiol *vs*. intradiol selectivity

At this point the reader will see that the choice of intradiol *vs*. extradiol reaction pathway will be influenced strongly by the co-ordination chemistry of the metal centre, but that the choice of acyl *vs*. alkenyl migration which ultimately dictates the reaction products will also be influenced by stereoelectronic factors, notably the positioning of the hydroperoxide O–O bond. In this section we will present a hypothesis which may rationalise the selectivity shown by the extradiol and intradiol dioxygenases using a stereochemical model.

In Section 5 we reached the important conclusion that, although there is a different order of initial events in the intradiol *vs*. extradiol reaction mechanisms, the two reaction mechanisms converge on a common proximal hydroperoxide intermediate. The choice of intradiol *vs*. extradiol reaction pathways is then determined by acyl *vs*. alkenyl migration rearrangements of this hydroperoxide intermediate. In Section 6 we saw that there is chemical precedent for both acyl migration and alkenyl migration, but that the choice of migratory group may be governed by stereoelectronic factors. In Section 7 we saw that the co-ordination chemistry of the metal centre is also important for choice of reaction pathway: tetradentate iron(III) complexes are effective catalysts for intradiol cleavage, but that the more elusive extradiol cleavage reaction can be catalysed by a facial tridentate iron(II) complex. These co-ordination states mimic the situation observed in the respective dioxygenase active sites.

Our hypothesis to rationalise these observations is that there are two stable conformations for the proximal hydroperoxide intermediate: one in which the hydroperoxide group is situated in a pseudo-axial orientation, and one in which the hydroperoxide is situated in a pseudo-equatorial orientation. In the extradiol dioxygenase active site the His_2Glu motif provides three protein ligands for iron(II) (as found in the TACN model reaction). Assuming that the iron(II) centre can access an octahedral co-ordination geometry during the catalytic cycle, then it is able to bind substrates and reaction intermediates *via* three co-ordination sites. It is therefore able to bind the proximal hydroperoxide intermediate in a tridentate fashion, and hence access the conformation in which hydroperoxide is pseudo-axial. In this conformation the hydroperoxide group is optimally aligned for alkenyl migration (*via* either σ bond migration or π participation) and hence undergoes extradiol cleavage.

In the intradiol dioxygenase active site the His_2Tyr_2 motif provides four protein ligands for iron(III) (as found in the tetradentate iron(III) models). Assuming that the iron(III) centre can access an octahedral co-ordination geometry during the catalytic cycle, then it is able to bind substrates and reaction intermediates *via* only two co-ordination sites. Bidentate co-ordination of the proximal hydroperoxide is not able to access the pseudo-axial hydroperoxide conformation, but instead binds as the pseudo-equatorial conformation, which then undergoes acyl migration. Why should an equatorial hydroperoxide promote acyl migration? One argument is that acyl migration is the 'default' option, as shown by the Baeyer–Villiger oxidation of 1,2-diketones. Alternatively, the axial hydroxy group is well positioned to attack the neighbouring ketone, which could initiate acyl migration *via* electrocyclic ring opening.[39]

The weakness in this argument in the latter case is that the axial tyrosine ligand (Tyr-447) of 3,4-PCD has been shown to swing away from the iron(III) centre upon substrate binding, leaving only three protein ligands.[17] However, presumably Tyr-447 is re-ligated to the iron(III) centre at the end of the catalytic cycle, so it is not clear whether it remains dissociated from the iron(III) centre throughout the reaction cycle, or becomes re-attached at some point. The observation that the majority of intradiol catalysts are tetradentate iron(III) complexes suggests that the availability of only two co-ordination sites may be a feature of the intradiol reaction.

Would this model explain the other amino acid sidechains found in the extradiol and intradiol active sites? Studies of the TACN extradiol model reaction imply a requirement for one base for substrate ligation, and one proton donor to assist alkenyl migration. In each of the extradiol active sites (see Fig. 2) there is a nearby histidine residue which could function as a base (His195 in BphC is situated 4.0 Å from the iron(II) centre),

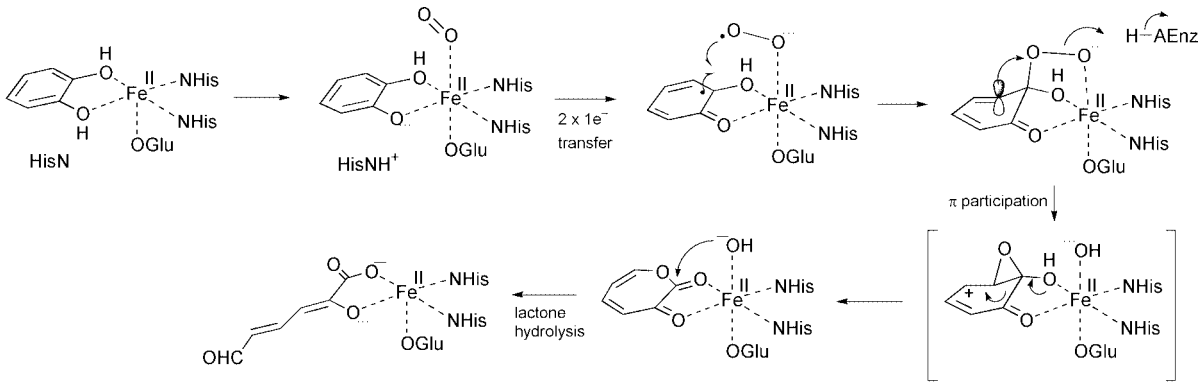


Fig. 6 Proposed catalytic mechanism for extradiol catechol cleavage, *via* an axial proximal hydroperoxide intermediate.

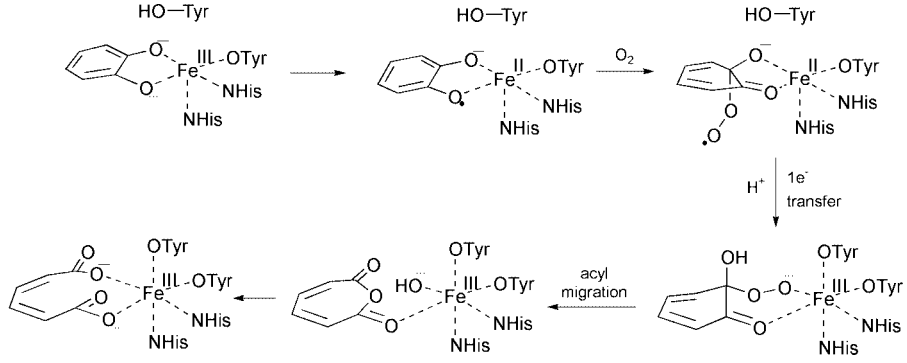

Fig. 7 Proposed catalytic mechanism for intradiol catechol cleavage, *via* an equatorial proximal hydroperoxide intermediate.

and also a nearby tyrosine–histidine pair which could function as a proton donor (Tyr250 in BphC is situated 3.8 Å from the iron(II) centre, with nearby His-241). The active sites of 3,4-PCD and 1,2-CTD (see Fig. 1) are, apart from the iron(III) ligands, notable for the absence of acid/base or polar amino acid sidechains, suggesting that the intradiol reaction requires relatively little catalytic assistance by the enzyme, consistent with the observation that a wide variety of tetradentate model systems are able to catalyse intradiol cleavage.

The overall catalytic mechanisms proposed for extradiol and intradiol cleavage are shown in Fig. 6 and 7. For extradiol cleavage, an active site base is required to generate the catechol mono-anion, and a proton donor is required to assist alkenyl migration. The iron(II) centre is able to activate both catechol and dioxygen, mediate one-electron transfers, assist alkenyl migration *via* Lewis acid catalysis, and activate Fe^{II}-hydroxide for lactone hydrolysis. For intradiol cleavage, substrate deprotonation appears to be driven by the stronger Lewis acidity of iron(III), which then activates the substrate for reaction with dioxygen, then mediates acyl migration, and assists hydrolysis of muconic anhydride. Both families of enzyme demonstrate the range of chemical functions carried out by non-haem iron in enzyme catalysis. A combination of mechanistic enzymology and small molecule model studies, in combination with protein crystallography, are now beginning to provide a rationalisation of how Nature has evolved two catalytic strategies for this difficult transformation, and the subtle chemical factors which control the choice of reaction pathway.

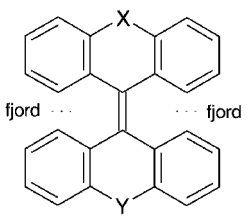
Received (in Cambridge, UK) 26th February 2001, Accepted 4th April 2001
First published as an Advance Article on the web 9th May 2001

A criterion for thermochromism has been derived from *ab initio* DFT B3LYP/6-31G* calculations of the *anti*-folded, *syn*-folded and twisted conformations of thermochromic and non-thermochromic overcrowded bistricyclic aromatic enes (BAEs) 1–8: the thermochromic species is the twisted conformation, a necessary condition being a small energy difference, < 30 kJ mol^{-1}, between the global minimum *anti*-folded and the thermochromic conformations.

Four score and a dozen years ago the phenomenon of thermochromism—reversible change of color with change of temperature—was revealed in bianthrone (**1**),[1] a leading overcrowded bistricyclic aromatic ene (BAE).[2] The BAEs are attractive substrates for the study of the conformational behavior of overcrowded ethylenes and for the interplay of strain and delocalization effects.[2] Thermochromic and photochromic BAEs and related overcrowded enes serve as candidates for chiroptical molecular switches and molecular motors.[3] Derivatives of **1** are topologically related to hypericin, wide spread in St. Johns Wort, an important remedy for depression.[4]



BAE

	X	Y
1	CO	CO
2	O	O
3	S	S
4	—	—
5	CH=CH	CH=CH
6	—	O
7	—	CO
8	O	CO

The thermochromism of **1** and related BAEs in solution has been attributed to a thermal equilibrium between two distinct and interconvertible conformers ($\mathbf{A} \overset{kT}{\longleftrightarrow} \mathbf{B}$),[5] where **A** is the room temperature, *anti*-folded (**a**), yellow conformer and **B** is the thermochromic, green–blue conformer. It is generally agreed that the thermochromic, piezochromic, and photochromic[6] **B** forms are identical. The prerequisites for thermochromism in BAEs have been a controversial issue.[7] Zwitterionic valence isomers, diradicals, thermally populated triplets, Woodward and Wasserman's electrocyclized isomer, planar, twisted, and double chair conformations have been suggested as the **B** form.[7] Previous studies applying various force fields[6a] and the semiempirical MINDO/3,[8] AM1,[9] and PM3[2c,d] methods failed to rationalize thermochromism in the BAEs series. Although PM3 calculations of the dynamic stereochemistry of BAEs agreed with experiment, they failed to rationalize the thermochromic behavior.[2c,d] We report here a theoretical approach, applying *ab initio* Hartree-Fock (HF) and Density Functional Theory (DFT), with the objective of determining whether a given BAE should be thermochromic.

The homomerous BAEs bianthrone (**1**), dixanthylene (**2**), dithioxanthylene (**3**), bifluorenylidene (**4**), bisdibenzocycloheptenylidene (**5**), and the heteromerous BAEs fluorenylidene-xanthene (**6**), fluorenylidene-anthrone (**7**), and xanthylidene-anthrone (**8**) were subjected to *ab initio* HF/6-31G* and DFT B3LYP/6-31G*[10] calculations using Gaussian 94.[11] All geometries were fully optimized subject to symmetry constraints as indicated. Minima and transition states were verified by computing vibrational frequencies at HF/STO-3G, and B3LYP/STO-3G optimized geometries. The following conformations were calculated: homomerous BAEs **1**–**5**, D_2 twisted (**t**), C_{2h} *anti*-folded (**a**) and C_{2v} *syn*-folded (**s**); **8**, C_2 twisted (**t**), C_s *anti*-folded with uneven degrees of folding (**au**), and C_s *syn*-folded with uneven degrees of folding (**su**); **6** and **7**, C_2 twisted (**t**), C_s *anti*-folded with uneven degrees of folding (**au**). Table 1 gives the calculated B3LYP/6-31G* and HF/6-31G* relative energies (ΔE_{rel}) of the optimized conformations. The experimental enthalpy values of the thermochromic **B** form, $\Delta H_{A\rightarrow B}$, and some geometrical parameters are also included.

According to the B3LYP/6-31G* results, three types of conformational behavior appear:

Table 1 Calculated and experimental relative energies of BAEs[a]

 DOI: 10.1039/b101797g

Type 1: BAEs **1**, **2**, and **8** have *anti*-folded global minima **a**. For **1** and **2**, *anti*-folded conformations were found in the X-ray crystal structures, which correspond to the respective **A** forms.[2b,c] The twisted conformations **t** are only ΔE_{rel}(**1**) = 12.0 kJ mol^{-1}, ΔE_{rel}(**2**) = 24.4 kJ mol^{-1}, and ΔE_{rel}(**8**) = 10.8 kJ mol^{-1} higher in energy and thus may be populated thermally. The DFT calculated energies are in very good agreement with the experimentally determined enthalpies of the blue–green thermochromic **B** forms:[12] $\Delta H_{A\rightarrow B}$(**1**) = 12.6 kJ mol^{-1},[5f,13] $\Delta H_{A\rightarrow B}$(**2**) = 20.5,[5b] or 23.4[5c] kJ mol^{-1}, and $\Delta H_{A\rightarrow B}$(**8**) = 14.6 kJ mol^{-1}.[5c] The *syn*-folded conformations of **1**, **2**, and **8** are considerably higher in energy (ΔE_{rel}(**s**) = 38 to 43 kJ mol^{-1}). While the *anti*- and *syn*-folded conformations are colorless or pale yellow, the high twist in the central double bond reduces the π-overlap causing a substantial red shift and smaller HOMO–LUMO gaps in twisted conformations. This rationalizes the color change observed in thermochromic BAEs. Even a small population of the twisted conformation at elevated temperatures leads to a striking change of the visible color from yellow to green or blue-green (Fig. 1).

Type 2: BAEs **3** and **5** also adopt *anti*-folded conformations as global minima. However, in these cases the *syn*-folded conformations **s** are more stable than the twisted conformations **t**. The B3LYP/6-31G* conformational energies are ΔE_{rel}(**s**) = 35.0 and 19.9 kJ mol^{-1}, while ΔE_{rel}(**t**) = 86.6 and 166.9 kJ mol^{-1} for **3** and **5** (in **5**, **t** is a transition state). The twisted conformations cannot be populated in thermal equilibrium, explaining the absence of thermochromism in these compounds.

Type 3: BAEs **4**, **6**, and **7** have twisted global minima. This is in accord with the deep color of the three BAEs (thermochromic **B** form) at room temperature. The *anti*-folded conformation of **4** is considerably higher in energy, ΔE_{rel}(**a**) = 39.0 kJ mol^{-1}, while the folded conformations of **6** and **7** are only ΔE_{rel}(**au**) = 4.5 and 5.5 kJ mol^{-1} higher than the twisted conformations. Thus, the folded conformations of **6** and **7** may easily be populated. Packing effects may favor the folded conformations.[14] Indeed, yellow crystals with folded conformations have been observed in **6** and **7**.[2b,14]

The relative B3LYP/6-31G* conformational energies ΔE_{rel}(**t**) agree within ±4 kJ mol^{-1} with the experimental $\Delta H_{A\rightarrow B}$ of the thermochromic species. On the other hand, the Hartree-Fock results show substantial, systematic deviations from the experimental data. For HF/6-31G*, the average absolute error is 50 kJ mol^{-1}. The conformational energies of the twisted thermochromic **B** conformers are systematically overestimated by the HF calculations. According to the HF/6-31G* results, **s** is more stable than **t** in **1**, **2**, and **8**, leading to a Type 2 conformational behavior (non-thermochromic). Furthermore, at HF/6-31G*, **6** and **7** would have folded global minima and should be yellow at room temperature.

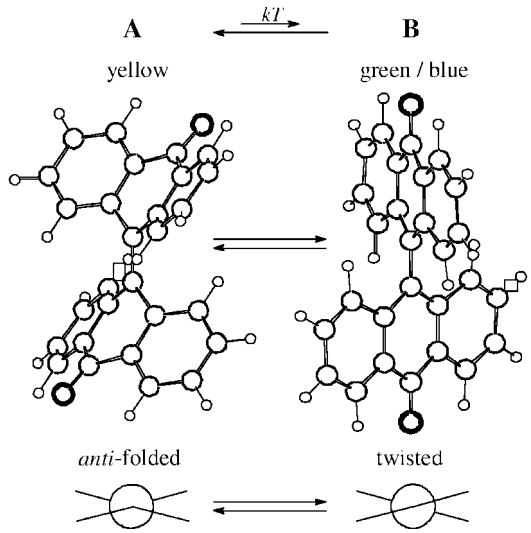

Fig. 1 The mechanism of thermochromism of BAEs using 3D structures of bianthrone (**1**) calculated at B3LYP/6-31G*.

The unique molecular architecture of BAEs gives rise to three conformations, *anti*-folded, *syn*-folded and twisted. Each conformation represents a different compromise between π-delocalization and steric strain. The bridges **X** and **Y** play an important role in the relative stability of the three conformations, leading to thermochromism in favorable cases.

In conclusion, the following necessary conditions for the thermochromic behavior of BAEs are deduced: (i) the global minimum of a thermochromic BAE is *anti*-folded (**a**) or unevenly *anti*-folded (**au**), whereas the thermochromic conformation is twisted (**t**); (ii) the energy difference between these conformations is small: (E(**t**) − E(**a**)) < 30 kJ mol^{-1}. While previous theoretical studies and *ab initio* Hartree-Fock calculations are flawed, giving conformational energies of twisted conformations that are systematically too high, inclusion of electron correlation *via* the DFT method solves this difficulty. The B3LYP/6-31G* ΔE_{rel}(**t**) and the experimental $\Delta H_{A\rightarrow B}$ of the thermochromic species agree within ±4 kJ mol^{-1}.

First published as an Advance Article on the web 9th May 2001

Treatment of ketones with thallium(III) triflate in amide solvents at 60 °C for 30 min followed by addition of small amounts of H_2O cleanly provided the corresponding α-acyloxy ketones.

The α-hydroxy ketone subunit is found in a variety of biologically interesting natural products.[1] The formate and acetate groups can serve as useful protective groups for the hydroxy functions in α-hydroxy ketones.[2,3] The α-acetoxy ketones can be prepared *via* various ways which include the reaction of α-bromo ketones with carboxylate ions,[4] the oxidation of morpholine enamine with thallium(III) triacetate,[5] anodic oxidation of enol acetates in acetic acid,[6] and $Cu(acac)_2$ catalyzed insertion reactions of α-diazo ketones with carboxylic acids.[7] In addition, it has been reported that the solvolytic reaction of α-keto triflate in acetic acid or formic acid can provide corresponding α-acyloxy ketones,[8] but potential difficulties in preparing α-triflyloxy ketone precursors (*e.g.* α-triflyloxy propiophenone) limits their further synthetic applications. There exist only a few methods that deal with the direct preparation of α-acetoxy ketones from ketones. These involve the oxidation of ketones with lead tetraacetate,[9] the oxidation of ketones with manganese(III) acetate in acetic acid,[10] and the oxidation of aromatic ketones with hypervalent iodine reagent followed by solvolysis in acetic acid in the presence of silver carbonate.[11] Although many procedures have been reported for the preparation of α-acetoxy ketones, relatively little is known for the preparation of α-formyloxy ketones. The only reported method involves anodic oxidation of enol carbonate in DMF–$LiClO_4$.[12] To the best of our knowledge, no general method for the one-pot conversion of ketones to their corresponding α-formyloxy ketones has been reported.†

We now report a new and highly efficient preparation method for the α-formyloxy ketones and α-acetoxy ketones. This methodology is based on the hydrolysis of iminium salt intermediates **3** formed by the reaction of α-triflyloxy ketone with amide solvent. Initial treatment of ketones with thallium(III) triflate, formed *in situ* by the reaction of thallium(III) acetate with trifluoromethanesulfonic acid, in DMF at 60 °C followed by addition of small amounts of H_2O cleanly provided the α-formyloxy ketones in excellent yields. The probable mechanism is shown in Scheme 1. The thallium(III) organosulfonate mediated α-sulfonyloxylation of ketones is well established.[13] Therefore, the reaction of ketones with thallium(III) triflate at room temperature for 10 min should provide α-triflyloxy ketone intermediates **2** which undergoes rapid solvolytic reaction with DMF at 60 °C for 20 min to give iminium salts **3**. These intermediates are instantaneously hydrolysed to give desired α-formyloxy ketones in the presence of H_2O. Although the utility of DMF as a formate anion equivalent for the preparation of alkyl formates has been reported,[14] application of this method for the α-formyloxylation of ketones is unprecedented. Among the ketones examined, aliphatic ketones such as acetone and pentan-3-one gave complex product mixtures under the present reaction conditions. In the case of cyclopentanone, α-formyloxy cyclopentanone was detected in 98% yield as judged by GC analysis but a number of attempts to isolate pure α-formyloxy cyclopentanone by column chromatographic separation failed owing to the decomposition of the compounds. When the present reaction conditions were applied to cyclohexanone, a mixture of α-hydroxy cyclohexanone and α-formyloxy cyclohexanone was obtained in a ratio of 84 : 16 as indicated by GC, probably due to the highly unstable preformed α-formyloxy cyclohexanone undergoing further hydrolysis.

When the same reaction protocol used in α-formyloxylation of ketones was conducted in *N*,*N*-dimethylacetamide instead of DMF, α-acetoxylation of ketones took place remarkably well to give uniformly high yields of α-acetoxy ketones with all of the ketones examined. The representative results are summarized in Table 1. It is important to note that the solvolytic reaction of iminium salts in DMF was carried out at 60 °C to obtain the best results. Elevated temperature gave a number of side products. The intermediates iminium salts **3** were not stable enough to be isolated.

We have also studied the cleavage reactions of α-formyloxy and α-acetoxy ketones to their corresponding α-hydroxy ketones. We found the lithium hydroxide in aqueous solution to be suitable for the cleavage of the formyl and acetyl groups. Treatment of isolated α-formyloxy ketones or α-acetoxy ketones in THF–H_2O (3 : 1, v/v) solution of lithium hydroxide at room temperature for 2 min afforded the corresponding α-hydroxy ketones **5** in excellent yields ranging from 95 to 98%.

In conclusion, the facile conversion of ketones to the α-formyloxy ketones and α-acetoxy ketones has been accomplished in excellent yield. The present approach provides efficient entry for installation of α-acyloxy moieties into ketones and their clean deprotection should find wide applica-

Notes and references

† **Caution**: *Thallium compounds are highly toxic; they should therefore be handled with extreme caution and all operations must be carried out in an efficient fume hood.* The experimental procedure for the preparation of α-formyloxy acetophenone is representative. To thallium(III) acetate (0.572 g, 1.5 mmol) in DMF (5 mL) was added trifluoromethanesulfonic acid (0.675 g, 4.5 mmol) at rt under nitrogen with stirring for 10 min. To the reaction mixture acetophenone (0.120 g, 1.0 mmol) was added and stirred at 60 °C for 20 min. After reaction, the temperature was brought down to rt, H_2O (1 mL) was added and stirred for an additional 10 min. The reaction mixture was diluted with CH_2Cl_2 (30 mL), washed with saturated $NaHCO_3$ aqueous solution, water, and dried over $MgSO_4$. Evaporation of solvent, followed by short column chromatography on silica gel (ethyl acetate–hexane 1:2) yielded the α-formyloxy acetophenone.

2-Phenyl-*N*-tosylazetidine as a formal 1,4 dipole precursor†‡

Ioana Ungureanu, Philippe Klotz, Angèle Schoenfelder and André Mann*

Laboratoire de Pharmacochimie de la Communication Cellulaire, UMR 7081, Faculté de Pharmacie, 74 route du Rhin, BP 24, F-67401 Illkirch, France. E-mail: Andre.mann@pharma.u-strasbg.fr; Fax: +3(0)3 90 24 43 10; Tel: +33 (0)3 90 24 42 27

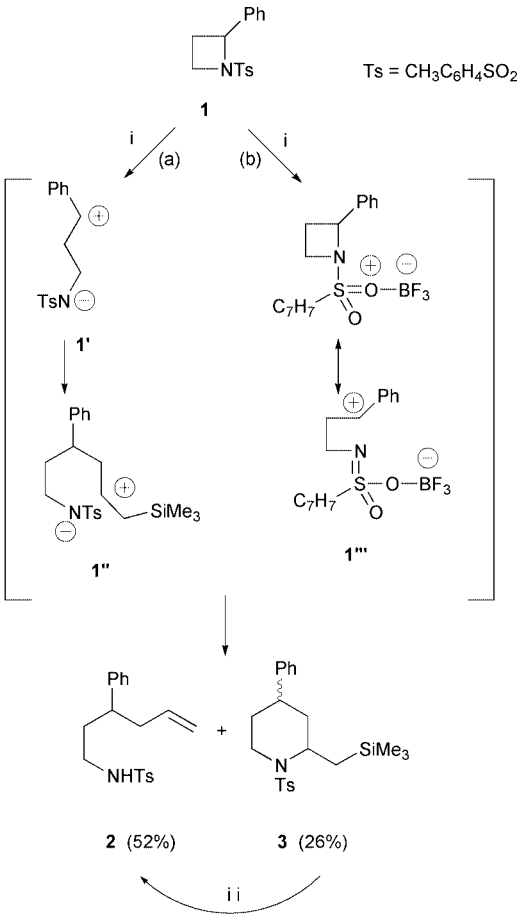
First published as an Advance Article on the web 9th May 2001

_N_-Tosyl-2-phenylazetidine 1 in the presence of $BF_3{\cdot}Et_2O$ reacts as a formal 1,4 dipole with various activated or non activated alkenes.

Recently we reported that phenyl-*N*-tosylaziridines, in the presence of Lewis acids generate a double *exo* stabilized 1,3 dipole, suitable for [3 + 2] dipolar cycloadditions.[1] If the concept of dipole with *exo* stabilisation could be extended to phenyl-*N*-tosylazetidine **1**,[2,3] a zwitterionic or 1,4 dipole **1′** would be produced. Herein we present evidences for the existence of **1′** and several examples of its utilisation in [4 + 2] cycloaddition reactions (Scheme 1).

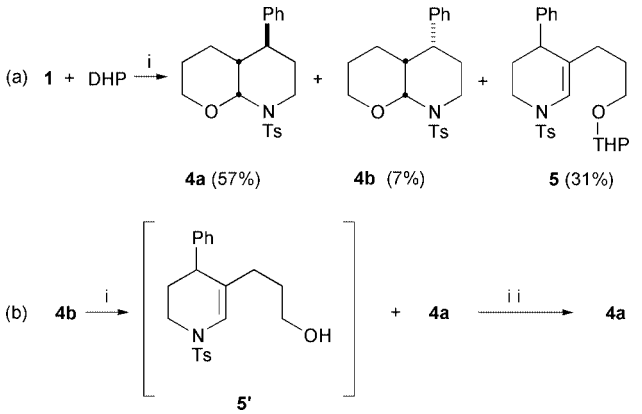
If azetidin-2-ones have received considerable attention, activity on the related azetidines has been less fevered.[4–6] As the benzylic C–N bond in **1** can be regioselectively broken,[7] we speculated that conditions might be found to open the azetidine ring and to realize complete charge separation, producing a transient dipole **1′**. This putative 1,4 dipole **1′** can be described as follows:[8] **1′** is a dipole of zwitterionic type according to the Huisgen's classification[3] with the two charges stabilized in an *exo* manner by the benzyl and tosyl groups. Indeed 1,4 dipole **1′**, if opposed to olefins, could represent a device to realise a formal *carboamination* for the rapid construction of azaheterocycles (Scheme 1).



Scheme 1 *Reagents and conditions*: (i) allyltrimethylsilane $BF_3{\cdot}Et_2O$, −78 °C, CH_2Cl_2; (ii) TBAF, THF (95%).

For the generation of the dipole **1′** we expected that a Lewis acid might cause the desired charge separation.[1] To trap both the benzylic carbocation and the amide function in the elusive dipole **1**, we chose allyltrimethylsilane as a 'probe'.[9] Indeed, azetidine **1** reacts with allyltrimethylsilane in the presence of $BF_3{\cdot}Et_2O$. The obtained allylated product **2** and silylated piperidine **3** may have a common intermediate, a 1,6 zwitterion **1″**. If desired, the conversion of piperidine **3** to allylamine **2** can be performed in refluxing THF with TBAF [pathway (a) in Scheme 1]. However, a slightly different mechanism can also be proposed: BF_3 activates the oxygen (or nitrogen atom) of the sulfonamide function, the formed intermediate **1‴** is then ready for a nucleophilic attack at the benzylic cation operated by allylsilane and subsequent intramolecular capture or desilylation of the newly formed cation can then produce either **2** or **3** [pathway (b) in Scheme 1]. If from a theoretical point of view there is a great difference between a naked dipole such as **1′** and a more conventional zwitterion such as **1‴**, in practice the observed reactivity of **1** is best explained using the simplified intermediate **1′**.

According to our previous experience, dihydropyran (DHP) seems to be a better reagent than allylsilane for a dipole 'capture'.[1,10] Indeed in the presence of $BF_3{\cdot}Et_2O$ and a threefold excess of DHP, **1** is quantitatively transformed into three adducts **4a**, **4b** and **5**, but the chemical events are more complex than expected. A [4 + 2] cycloaddition takes place. The formation of the adducts **4a** (*exo*), **4b** (*endo*) and **5**, a di-substituted tetrahydropyridine with a pyranyl appendage, are accounted for by Scheme 2a. The structure of **4a** was obtained by a single crystal X-ray analysis.[11]



Scheme 2 *Reagents and conditions*: DHP, $BF_3{\cdot}Et_2O$, −78 °C, CH_2Cl_2; (ii) pTSA, toluene, reflux.

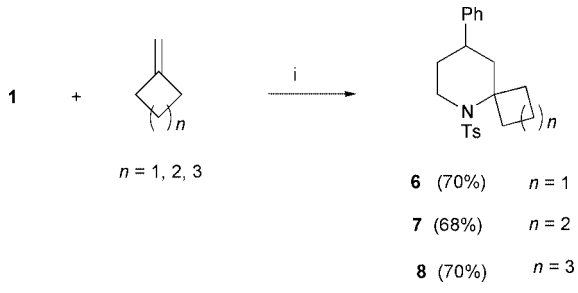
† This paper is dedicated to Professor Camille-Georges Wermuth.

‡ Electronic supplementary information (ESI) available: experimental details and characterization for key intermediates, including the ORTEP figures of the X-ray structures for compounds **4a** and **10**. See http://www.rsc.org/suppdata/cc/b1/b101168p/

 DOI: 10.1039/b101168p

The formation of **5** is best explained in the following way: under the reaction conditions the pyranyl ring in **4a** and/or **4b** is opened through an immonium/enamine acid catalysed process and the transiently formed alcohol **5′** is trapped by the excess of DHP present in the reaction mixture. In fact we suspect that the major pathway which produces **5** is the transformation of **4b**. Indeed in complementary experiments, we verified the stability of the two cycloadducts **4a** and **4b** in presence of $BF_3{\cdot}Et_2O$ at −78 °C. After 30 min **4a** was recovered unchanged, while **4b** was completely transformed into **4a** and **5′**, as shown by the analysis of the crude reaction mixture by NMR. Now if heated in toluene in the presence of pTSA, the mixture of **4a** and **5′** is totally converted to **4a** (Scheme 2b). Therefore it can be concluded that the reaction between **1** and DHP is a sequence of equilibria, the thermodynamic bicycle **4a** surviving under the reaction conditions, whereas **4b** evolves to **5** *via* **5′**. It should be noted that only the *cis* aza, oxo [4.4.0] bicycle was observed because the geometrical condition required for a maximal anomeric effect is accomplished only in a *cis* aza, oxo [4.4.0] bicycle.[12] Finally, it has to be emphasized that the chemical potentialities of **4a** as N,O acetal are considerable.[13]

Another question which was addressed: does **1′** react with simple non-activated double bonds? We selected commercially available exomethylene cycloalkanes (cyclobutane, pentane, and cyclohexane) as partners for **1**. In this case the formation of spiropiperidines was precisely anticipated. Indeed the adducts isolated and characterised were respectively the spiro compounds **6**, **7** and **8** (Scheme 3). These results confirm nicely the reactivity of **1** as a formal 1,4 dipole in [4 + 2] cycloaddition to olefins and are in line with the results obtained with the corresponding aziridine.[1] This sequence constitutes a new and rapid entry to spiropiperidine rings.

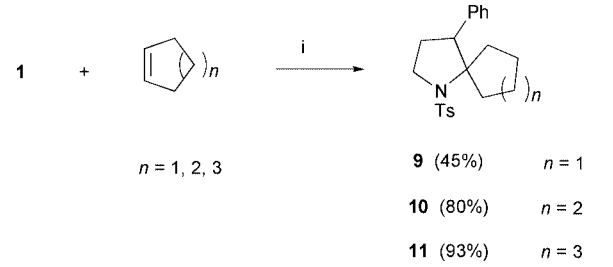


Scheme 3 *Reagents and conditions*: $BF_3{\cdot}Et_2O$, −78 °C, CH_2Cl_2.

The results from using cycloalkenes (cyclopentene, cyclohexene, cycloheptene) as 'dipolarophiles' were a surprise: cycloalkenes reacted with azetidine **1** in the presence of $BF_3{\cdot}Et_2O$, but no trace of the expected [4 + 2] cycloaddition products was observed. A complete NMR analysis of the obtained products showed the exclusive formation of spiro-pyrrolidines **9**–**11**. The single crystal X-ray analysis of **10**[14] confirmed the structural assignment made by NMR (Scheme 4). These unexpected results are best explained if the two following arguments are considered: hydride shift is assumed to provide the intermediate with the more stable tertiary (carbocation in respect to the secondary) and the formation of **9**–**11** is accounted for by the preferential formation of five over six-membered rings. These results are in sharp contrast with those for the corresponding aziridine where [3 + 2] cycloaddition was always the major pathway.[1]

Finally the formation of spiro-pyrrolidines results from a formal [4 + 1] cycloaddition of dipole **1′**. The hydride shift can be seen as additional proof for a stepwise, not concerted, mechanism of cycloaddition reactions of **1** on non-activated 1,2 disubstituted double bonds. *To the best of our knowledge no examples of such a reaction have been reported.* This sequence is a new entry to spiro-pyrrolidines, which constitute the core of some natural products.[15]

In summary, in this work we demonstrate that the 1,4 dipole **1′** with double *exo* stabilisation is accessible from azetidine **1**; **1′** reacts under mild conditions with several olefins to produce spiro-pyrrolidines or -piperidines by [4 + 2] or formal [4 + 1] cycloadditions; **1′** reacts with DHP to produce aza oxo [4.4.0] bicycles which are valuable intermediates. Finally, azetidine **1** allows, in one chemical step, a new and unique entry to azaheterocycles.



Scheme 4 *Reagents and conditions*: $BF_3{\cdot}Et_2O$, −78 °C, CH_2Cl_2.

The synthesis of 1,9-dihydro-3-phenyl-4*H*-pyrazolo[3,4-*b*]quinolin-4-one and its pH-dependent fluorescent properties for extreme pH measurement are presented.

The accurate measurement of pH is very important because it usually plays a key role in a variety of systems. The most popular and direct device for pH measurement is the glass pH electrode. However, the known limitations of the glass pH electrodes (*e.g.* its electrical interference or mechanical damage to small cells, and the presence of acid error and especially alkaline error[1]) make them unsuitable for certain applications: intracellular pH and microscopy studies as well as the measurements of extreme pH values below 1 or above 9. In contrast to the electrochemical methods, optical measurements, based on fluorescent probes that are either protonated or deprotonated, have no such drawbacks.[2] Moreover, fluorescent measurements are convenient to microscopy studies, and can reflect the H^+ distribution and change within cells.[3] It is not surprising, therefore, that the researches on pH-dependent fluorescent probes have received a great attention,[4] particularly on the probes which are pH-sensitive to the near neutral pH value of normal body fluids for the point of biological application. To the best of our knowledge, however, relatively less attention was paid on the fluorescent probes which are pH-sensitive in the lower pH region (pH < 5) or the higher pH region (pH > 9), though in some cases pH changes (*e.g.* within the stomach) can enter the extreme pH ranges.[1,5] It is also a challenge to design a fluorescent probe with linear response over a broad range, because pH measurement can be accurately made only over a range of about two pH units, *i.e.* p*K*a ± 1. Although some attempts have been made to broaden the response range of pH measurement by using a mixture of multiple pH indicators,[6] this makes the system rather complex. Another feasible approach to the problem is to develop a probe with multiple steps of H^+ binding.[7] Unfortunately, the typically used pH-dependent groups such as –COOH, –OH, *etc*., have a high affinity for common metal ions, thus resulting in complexation and nonspecific response of the probe to H^+.

The objective of this research was to design a novel fluorescent probe which is both pH-selective and pH-sensitive for extreme pH ranges, by assembling several electronegative atoms in the different positions of a highly conjugated molecule. Scheme 1 shows the synthetic route to such a fluorescent probe, 1,9-dihydro-3-phenyl-4*H*-pyrazolo[3,4-*b*]quinolin-4-one **5**.[8] The reaction of 2-benzoylketene dithioacetal **1**[9] with **2** gave methylthio-substituted quinolone **3**. Upon treatment with hydrazine, **3** was converted quantitatively to hydrazone **4** which was then transformed into the designed product **5** by further heating in pyridine.

In order to increase the selectivity for H^+, the use of carboxyl which is easy to complex with metal ions was avoided. pH-dependent amino groups, though they are also strong ligands for metal ions, were mainly chosen as H^+ receptors because of their convenient arrangement in synthesis and the wealth of proton binding data available.[10] The arrangement of multiple H^+ receptors is conducive to obtaining a broad pH response range, and three nitrogen atoms and one oxygen atom were set in the probe **5**. To achieve the fluorescent response to extreme pH values, the environmental difference among the electronegative atoms in the conjugated molecule should be as large as possible. The potential binding sites for H^+ in **5** were therefore placed in quite different environments. Particularly following the known data,[11] one nitrogen atom [*e.g.* N(9)] was arranged in an electron-deficient position and another one N(1) in an electron-rich position, expecting the generation of considerably different p*K*a values. In addition, for improved selectivity, the arrangement of all the electronegative atoms in the structure should not provide a suitable cavity or a convenient formation of five- and six-membered ring complexes for metal ions. As shown in Scheme 1, the prepared probe **5** does not possess any favorable complexation sites for metal ions. The benzene ring in the position 3 of the probe would render a steric hindrance for any possible complexation of either the adjacent oxygen or nitrogen atom with metal ions.

The experimental results showed that the probe has a notable fluorescence quantum yield of φ_{base} = 0.14 in basic media (pH = 13.0) or φ_{acid} = 0.12 in acidic media (pH = 1.0) with an appreciable fluorescence lifetime of 11.12 ± 0.04 ns,[12] and its fluorescence spectra are highly dependent on pH (Fig. 1). Titration of fluorescence intensity with pH gave two p*K*a values of 2.61 and 12.44 (Fig. 1, insets),[13] which correspond to the protonations of the two nitrogen atoms N(9) and N(1) in the probe, respectively. It is understandable that only two of the electronegative atoms exhibit pH-sensitivity, because the basicity of the other two (one nitrogen and one oxygen) is largely weakened by their lone electron pairs participating in the system conjugation. As a result, the probe is capable of measuring the extreme pH values over the two pH ranges of 1.8–3.4 and 11.6–13.3, respectively. Further, the probe was stable and no obvious changes in fluorescence were observed within 5 months at rt. It should be pointed out that the probe is unsuitable for neutral pH measurements, since a nonlinear response of fluorescence intensity to pH was observed in that region.

To test the selectivity of the probe, the effects of various diverse ions upon the emission spectra were examined. The results showed that the selectivity of this probe for H^+ over other

 DOI: 10.1039/b101685g

Table 1 The tolerable concentration of foreign ions for the measurement of pH[a]

M^{n+}	Ca^{2+}	Cu^{2+}	Fe^{2+}	Fe^{3+}	K^+	Mg^{2+}	Mn^{2+}	Zn^{2+}	NO_3^-	PO_4^{3-}	CO_3^{2-}	SO_4^{2-}
$c/10^{-4}$ M[b]	10	10	0.70	0.40	20	0.80	40	2.6	0.50	2.0	0.20	4.0
$c/10^{-5}$ M[c]	20	4.5	3.6	3.4	20	0.32	0.20	2.2	1.0	1.0	8.3	20

[a] The tolerable concentration was estimated by the criterion at which a species gave a relative error of no more than 5% in the analytical signal (fluorescence intensity) of the probe (2.0×10^{-3} g dm^{-3}) in the presence of 0.1 M NaCl. [b] Measured in acid medium (pH = 2.0). [c] Measured in basic medium (pH = 12.0).

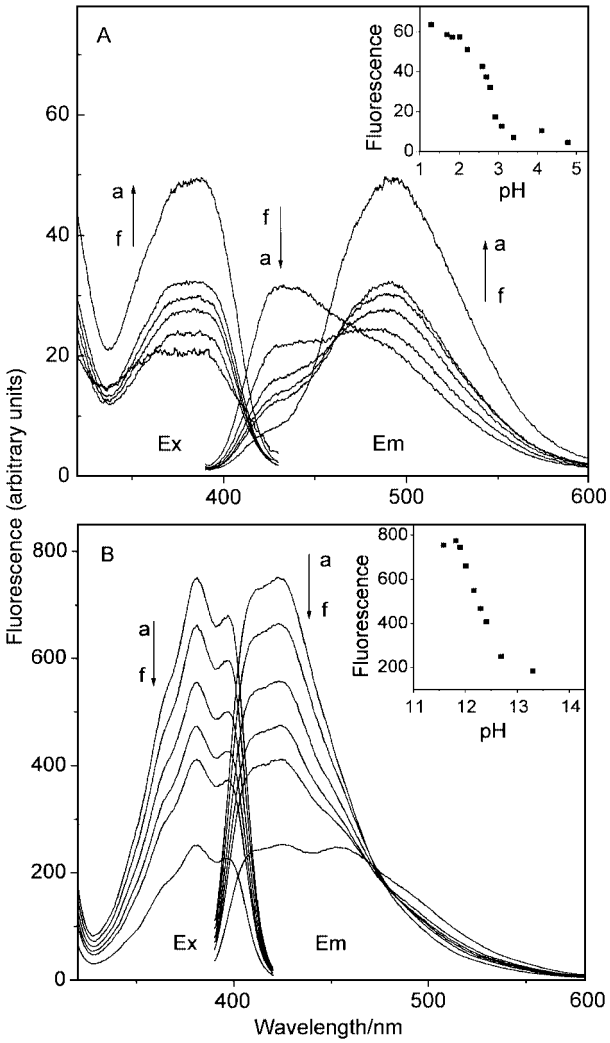

Fig. 1 pH-dependence of the fluorescence spectra of **5** (5×10^{-3} g dm^{-3}) in 0.1 M NaCl at various pH values (A): 1.29 (a), 2.59 (b), 2.72 (c), 2.81 (d), 3.09 (e), 3.41 (f); and (B): 11.82 (a), 12.01 (b), 12.17 (c), 12.29 (d), 12.41 (e), 12.69 (f). Different pH values were obtained by adding small amounts of 0.1 M HCl or NaOH to the solution. The excitation was at 385 nm for both of the emission spectra (Em) of (A) and (B); the emission was at 493 and 433 nm for the excitation spectra (Ex) of (A) and (B), respectively. Inset shows the variation of fluorescence emission intensity with pH at 493 (A) and 433 nm (B), respectively.

ions (Table 1) is of specificity, making it very useful for accurate measurement of extreme pH values.

The mechanism of the probe's fluorescence response to pH is complex due to the influence of protonation/deprotonation and the possible presence of enol–amide tautomerism, but it may be interpreted largely according to photoinduced electron transfer (PET) principle, which has been widely used to design a variety of fluorescent ion sensing molecules.[14] Nitrogen atoms often serve as both H^+ receptors and electron donors in the PET process. In acid media, the probe **5** has a longer fluorescence emission of 493 nm at the optimal excitation of 385 nm (Fig. 1A), and the H^+ binding equilibrium of the N(9) atom yields an isosbestic point at 462 nm. Further protonation of the probe may inhibit the related PET, resulting in fluorescence enhancement (Fig. 1, curve a). On the other hand, the deprotonation of the N(1) atom in basic media presumably revives the corresponding PET, causing fluorescence quenching at 433 nm (Fig. 1B).

In summary, a novel fluorescent pH probe **5** has been prepared by arranging several electronegative atoms in the different environments of a conjugated molecule. Although this probe is far from being an ideally broad pH sensor, it greatly complements glass pH electrodes. Further work in this area would be beneficial to designing more excellent fluorescent pH probes.

Financial supports from the NNSF of China and the CMS fund of CAS are acknowledged.

Rhodium-catalyzed formation of boron–nitrogen bonds: a mild route to cyclic aminoboranes and borazines

First published as an Advance Article on the web 10th May 2001

Secondary amine–borane adducts $R_2NH{\cdot}BH_3$, which are stable to H_2 elimination below 100 °C, undergo efficient catalytic dehydrocoupling at 25–45 °C in the presence of Rh^I or Rh^{III} complexes to quantitatively form cyclic aminoboranes $[NR_2–BH_2]_2$ (1: R = Me or 2: *cyclo*-C_4H_8); under similarly mild conditions, the analogous adducts $NH_3{\cdot}BH_3$ and $MeNH_2{\cdot}BH_3$ yield borazines $[RN–BH]_3$ (3: R = H or 4: R = Me) in yields limited by intermolecular coupling reactions.

The application of transition metal catalysis to organic synthesis is of enormous current importance. In contrast, the development of analogous methods for the formation of homonuclear or heteronuclear bonds between main group elements is relatively unexplored. Nevertheless, the discovery of new synthetic methods, which can complement the classical reactions used in main group chemistry such as salt eliminations, is likely to be of key future importance for the general development of molecular and macromolecular p-block chemistry. Recent work has focused on catalytic dehydrocoupling routes[1] and the well-established catalytic dehydropolymerization of silanes, germanes and stannanes represents a key advance.[2–6] More recently, homodehydrocoupling chemistry has been extended to include P–P bond formation[7] and catalytic heterodehydrocoupling reactions to form B–Si,[8] Si–P,[9] Si–N,[10] and Si–O bonds[11,12] have also been reported. Recently, we reported the first examples of the transition metal-catalyzed formation of P–B bonds.[13] Thus, dehydrocoupling of phosphine–borane adducts at 60–130 °C in the presence of a range of precatalysts (*e.g.* Rh^I complexes) was found to provide a new route to phosphinoborane rings, chains and macromolecules.[13,14] In this preliminary communication we report well-characterized examples of the use of catalytic dehydrocoupling to form new boron–nitrogen bonds under mild conditions.[15]

Amine–borane adducts undergo thermally-induced dehydrocoupling at elevated temperatures to afford mixtures of small rings such as cyclic aminoboranes and borazines. For example, dimethylamine–borane, $Me_2NH{\cdot}BH_3$, eliminates hydrogen at 130 °C to quantitatively yield the cyclic dimer $[Me_2N–BH_2]_2$ **1**.[16] However, when a solution of $Me_2NH{\cdot}BH_3$ in toluene was treated with *ca.* 0.5 mol% of $[Rh(1,5\text{-cod})(\mu\text{-Cl})]_2$ (1,5-cod = 1,5-cyclooctadiene) or $RhCl_3{\cdot}3H_2O$ at 25 °C for 48–60 h, the quantitative formation of the cyclic aminoborane **1** was detected by ^{11}B NMR spectroscopy. The reaction time was reduced to 24 h when the temperature was raised to *ca.* 45 °C or the amount of catalyst increased to 5 mol%. The iridium complex $[Ir(1,5\text{-cod})(\mu\text{-Cl})]_2$ also catalyzed the dehydrocoupling reaction but this precatalyst (*ca.* 0.5 mol%) proved less active with the reaction time for quantitative conversion to **1** increasing to 72 h at 45 °C. Significantly, prolonged heating of neat $Me_2NH{\cdot}BH_3$ in the absence of catalyst over a period of 7 days at 45 °C resulted in the quantitative recovery of unreacted adduct, which clearly demonstrated the catalytic effect of the Rh and Ir complexes.

Cyclic aminoborane **1** was isolated as a colorless, extremely volatile yet air-stable crystalline solid.† The ^1H-coupled ^{11}B NMR spectrum showed a triplet at δ 4.75 ($^1J_{BH}$ 110 Hz), which was consistent with the coupling of two hydrogens to the boron centre. While ^1H and ^{13}C NMR spectra were also consistent with the proposed product, single-crystal X-ray diffraction‡ provided definitive confirmation (Fig. 1).[17] Notably, the B–N bond lengths of **1** (1.595(4) Å) closely match those of the analogous cyclic trimer $[Me_2N–BH_2]_3$ (1.61(4) Å)[18] and moreover, are in the range observed for amine–boranes (*ca.* 1.58 Å). The four-membered ring appears to be strained with bond angles deviating significantly from the tetrahedral ideal with values of 93.7(2) and 86.3(2)° for the N(1)–B(1)–N(1A) and B(1)–N(1)–B(1A) angles, respectively.

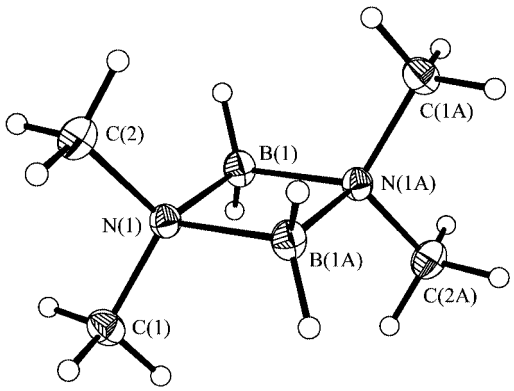

Fig. 1 Molecular structure of **1**. Selected bond lengths (Å) and angles (°): N(1)–B(1) 1.596(4), N(1A)–B(1) 1.595(4), N(1)–C(1) 1.478(4); N(1)–B(1)–N(1A) 93.7(2), B(1)–N(1)–B(1A) 86.3(2).

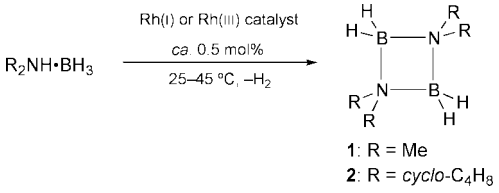
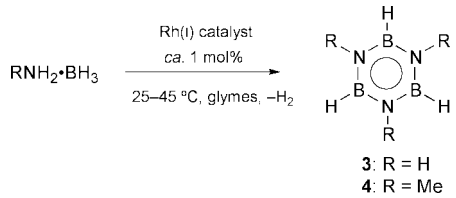
The formation of the cyclic dimer **1** *via* metal-catalyzed dehydrocoupling of a secondary amine–borane adduct represents a new, mild route to boron–nitrogen rings. We found that the strategy can be extended to other adducts such as pyrrolidine–borane, $(CH_2)_4NH{\cdot}BH_3$. Thus, the addition of catalytic (*ca.* 0.5 mol%) amounts of $[Rh(1,5\text{-cod})(\mu\text{-Cl})]_2$ or $RhCl_3{\cdot}3H_2O$ to a solution of the adduct (toluene, 25 °C, 24 h) similarly led to the quantitative formation of the cyclic aminoborane **2** (Scheme 1). Cyclic **2** was also characterized by multinuclear NMR spectroscopy† and by single-crystal X-ray diffraction.[19]

The catalytic dehydrocoupling methodology is not restricted to secondary amine–borane adducts. Thus, in the presence of $[Rh(1,5\text{-cod})(\mu\text{-Cl})]_2$ (1.5 mol%), the parent ammonia–borane adduct $NH_3{\cdot}BH_3$ was found to eliminate *two* equivalents of hydrogen to form borazine **3** (diglyme or tetraglyme, 45 °C, 72 h) by ^{11}B NMR (Scheme 2).[20] However, isolation from the reaction mixture by vacuum fractionation proved difficult; pure



Scheme 1

 DOI: 10.1039/b102361f



Scheme 2

3 was isolated in only *ca.* 10 % yield† with the major products being non-volatile, oligomeric species.[21,22]

Current preparations of borazine (*e.g.* from $NaBH_4$ and $(NH_4)_2SO_4$) require rather forcing conditions (elevated temperatures of 140–160 °C),[23] and, in our hands, are aggravated by similar difficulties in isolation. If optimized, the metal-catalyzed route may be advantageous, which is potentially significant as borazine and borazine oligomers have been shown to be useful precursors to cyclolinear polymers, boron nitride ceramics and nanotubes.[24–27]

In an attempt to minimize the intermolecular dehydrocoupling reactions, we also investigated the catalytic elimination of H_2 from *N*-methylamine–borane adduct. Indeed, we found that $MeNH_2{\cdot}BH_3$ undergoes dehydrocoupling in the presence of $[Rh(1,5\text{-cod})(\mu\text{-Cl})]_2$ (5 mol%), under similarly mild conditions (monoglyme or diglyme, 45 °C, 60 h) to afford *N*-trimethylborazine **4** by ^{11}B NMR. Pure **4** was isolated† in moderate yield (*ca.* 35–40%) by vacuum fractionation.[21,22] Previously developed routes to **4** typically involve high temperature dehydrogenation reactions such as the thermolysis of $MeNH_2{\cdot}BH_3$ at 100 °C to give the cyclic trimer $(MeNH{-}BH_2)_3$, followed by further pyrolysis at 200 °C.[28] Interestingly, through monitoring of the Rh catalyzed reaction by ^{11}B NMR, dehydrocoupling to form the cyclic aminoborane $(MeNH{-}BH_2)_3$ was found to occur first ($\delta -5.1$, $^1J_{BH}$ 108 Hz; lit. $\delta -5.4$, $^1J_{BH}$ 107 Hz),[29] followed by further loss of hydrogen to yield **4**. The isolation of a *ca.* 50% yield of non-volatile residue, indicates that intermolecular coupling also occurs in this case.[22] This process may involve catalytic dehydrocoupling of the intermediate $(MeNH{-}BH_2)_3$.

In summary, amine–borane adducts undergo B–N bond formation reactions under mild conditions in the presence of rhodium dehydrocoupling precatalysts (Schemes 1 and 2). Future work will involve an expansion of the scope of this new chemistry, which offers the prospect of improved routes to B–N compounds, and mechanistic investigations.

This research was supported by the Natural Science and Engineering Research Council of Canada (NSERC) and the Petroleum Research Fund (PRF) administered by the ACS. C. A. J. would like to thank the University of Toronto for a U of T Open Fellowship and K. T. thanks NSERC for a Postgraduate Scholarship (1997–2001). We would also like to acknowledge Professor William E. Buhro and Carolyn R. Jones from the Department of Chemistry, Washington University for many helpful discussions.

15 To our knowledge, no examples of transition metal catalyzed dehydrocoupling routes to B–N bonds have appeared in the open literature. A patent (see Y. Blum and R. M. Laine, *US Pat.*, 4,801,439 1989) claims the catalytic formation of partially characterized mixtures of B–N compounds (including borazines) and insoluble polymeric products by the dehydrocoupling of mixtures of primary amines and $Me_3N{-}BH_3$ over extended periods of time at elevated temperatures. The conditions for the examples cited, typically 30–80 h, *ca.* 60 °C, in the presence of $Ru_3(CO)_{12}$, are also more forcing than with the Rh catalysts used in this communication.

Synthesis of spiro- and fused heterocycles by palladium catalysed carbo- and heteroannulation cascades of allenes

Ronald Grigg,* Ines Köppen, Marcello Rasparini and Visuvanathar Sridharan

Molecular Innovation, Diversity and Automated Synthesis (MIDAS) Centre, School of Chemistry, Leeds University, Leeds, UK LS2 9JT. E-mail: R.Grigg@chem.leeds.ac.uk

Received (in Cambridge, UK) 5th March 2001, Accepted 23rd April 2001
First published as an Advance Article on the web 10th May 2001

Two novel palladium catalysed cascade processes involving the generation of a (π-allyl)palladium intermediate from allenes in an intra- or intermolecular fashion, followed by regioselective intramolecular nucleophilic addition of amines, alcohols or malonates provide spiro- or linear fused heterocycles in good yield.

The importance and versatility of palladium catalysed processes involving allenes for the construction of carbon–carbon and carbon–heteroatom bonds is amply documented in a recent review.[1]

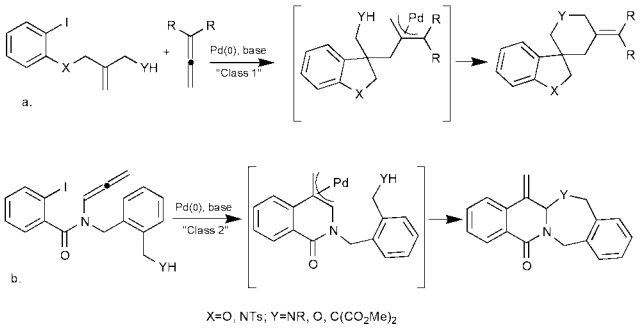
We have demonstrated that allenes are powerful relay switches in palladium catalysed polycomponent (poly)-cyclisation anion capture cascades.[2] Reaction of aryl/vinyl palladium(II) intermediates with allene leads to the formation of (π-allyl)palladium species able to undergo a wide range of transformations including attack by nucleophiles,[3] electrophiles[4] or transmetallation.[5]

The tactical combination of these transformations in an inter- and/or intramolecular fashion[6] enables expeditious increments of the molecular complexity of the products that are limited only by the ingenuity of the chemist.

We now report two novel palladium catalysed cascades ('Class 1' and 'Class 2') characterised by intramolecular anion capture[2] as the termination step. Both cascades are initiated by oxidative addition of Pd(0) into an Ar–I bond. In the 'Class 1' process this step is followed by an *exo-trig* cyclisation, intermolecular allene insertion and intramolecular capture of the resultant (π-allyl)palladium complex with a tethered nucleophile (amine or malonate anion) (Scheme 1a). This cascade results in the formation of three bonds and a spiro-fused ring system.

In the 'Class 2' process the (π-allyl)palladium complex is generated by an *exo-dig* cyclisation of the Ar–Pd species onto a proximal 1,2-dienamide. Subsequent interception of the resulting (π-allyl)palladium(II) species by a nucleophile leads to bicyclic lactams with formation of two rings and two new bonds (Scheme 1b).

The substrates for 'Class 1' process (Y = NR, $C(CO_2Me)_2$) were prepared in two steps by displacement of the allylic chlorides **1** or **3** with amines or dimethyl malonate (Scheme 2).

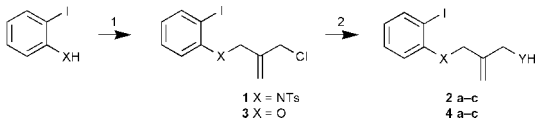


Scheme 1

Substrates **2a–c** and **4a–b** were then reacted with allene (1.0 bar) or 3-methylbuta-1,2-diene (dimethylallene) in the presence of a base and Pd(0) to afford the spirocyclic products in good yield[7] (Table 1). When dimethylallene was employed, exclusive formation of the regioisomer arising from attack at the less hindered end of the (π-allyl)palladium moiety was observed in all the cases.

We then focused our attention on a fully intramolecular process: a scaffold precursor **7** was synthesised in 57% overall yield from 2-bromobenzaldehyde (Scheme 3).

The formyl group was then exploited for the introduction of the desired nucleophiles (Scheme 4). The *N*-propargyl amides were then isomerised to the relatively labile *N*-allenyl amides



Scheme 2 *Reagents and conditions*: (1) 2-iodo-*N*-tosylaniline, NaH, 3-chloro-2-chloromethylpropene, DMF, rt, 48 h, 95% or 2-iodophenol, 3-chloro-2-chloromethylpropene, K_2CO_3, MeCN, reflux, 2 h, 91%; (2) primary amine (see Table 1), K_2CO_3, MeCN, reflux, 18 h (**2a**, 64%; **2b** 54%; **4a**, 61%, **4b**, 60%) or dimethyl malonate, K_2CO_3, CH_3CN, reflux, 18 h (**2c**, 80%, **4c**, 84%).

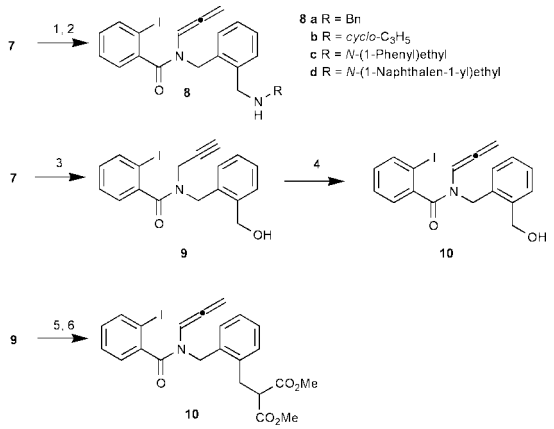
4 (**8d**)	*N*-(1-Naphthalen-1-yl)ethyl	Ag_2CO_3	24	**12d**[c]	54
5 (**10**)	O	Cs_2CO_3	48	**12e**	50
6 (**11**)	$C(CO_2Me)_2$	Cs_2CO_3	48	**12f**	45

[a] For experimental, see ref. 8. [b] 1.2 : 1 mixture of diasteroisomers (HPLC). [c] 1.5 : 1 mixture of diastereoisomers (^{1}H NMR). [d] Isolated analytically pure products.



Scheme 4 *Reagents and conditions*: (1) Primary amine, $MgSO_4$, DCM, then MeOH, $NaBH_4$ 0 °C, 10 min, (**8a**, 85%, **8b**, 76%, **8c**, 71%, **8d**, 84%); (2) THF, *t*-BuOK (1.0 eq.), 0 °C, 1 min; (3) MeOH, $NaBH_4$ 0 °C, 10 min, 87%; (4) THF, *t*-BuOK (2.0 eq.), 0 °C, 1 min; (5) MsCl, TEA, DCM, 0 °C then DMF, sodium dimethyl malonate, 0 °C to rt, 60%; (6) THF, *t*-BuOK (2.0 eq.), 0 °C, 1 min.

immediately prior to the last Pd(0) catalysed step. The best conditions employed *t*-BuOK (1.1 eq. or 2.1 eq. when alcohols or malonates were used) in THF at 0 °C for 1 min. The transformation is nearly instantaneous and longer reaction times result in further isomerisation to *N*-prop-1-ynyl amides and to the formation of alcoholysis products.

All the substrates **8a**–**d** and **10**–**11** cyclised in 24–48 h in toluene at 50 °C in the presence of Pd(0) and an inorganic base[8] (Table 2).

We employed two chiral amines (**8c** and **8d**) in order to establish if the stereocenter α- to the nitrogen is able to induce a diastereofacial preference during the nucleophilic attack on the (π-allyl)palladium complex. When K_2CO_3 was employed, in both the cases a 1 : 1 mixture of diasteroisomers was obtained. Little improvement was achieved using Ag_2CO_3 (entry 3) or by increasing the steric hindrance around the nitrogen (entry 4). However, the two diasteroisomers were easily separated by crystallisation from EtOH.

A stronger base (entry 11) and longer reaction times were required (entry 10) for the less nucleophilic alcohol and malonate moieties.

In conclusion we have shown that this methodology permits access to unusual spiro- and fused heterocyclic frameworks.

We thank Leeds University and the EU for support.

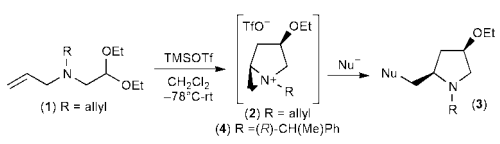
Received (in Cambridge, UK) 6th March 2001, Accepted 12th April 2001
First published as an Advance Article on the web 11th May 2001

A novel tandem cationic cyclisation–aziridinium ion formation–nucleophilic ring opening procedure has been developed which provides powerful new methodology for the stereocontrolled synthesis of a wide variety of substituted pyrrolidines from acyclic precursors. The intermediate bicyclic aziridinium ions can be isolated and their structure has been confirmed by X-ray crystallography.

Saturated nitrogen heterocycles, including pyrrolidines and piperidines, occur in a wide variety of natural products and biologically active compounds.[1] Their synthesis has attracted much attention over the years, and methods which allow the construction of polysubstituted compounds with stereochemical control are particularly valuable.[2] Our research group has been involved in developing new chemistry of aziridinium ion intermediates, and alongside other workers in the field,[3] have shown them to be versatile, yet underused intermediates in synthetic organic chemistry.[4] Bicyclic aziridinium ions such as (**2**) have been known for some time, and are usually generated from the corresponding pyrrolidine-2-methanols or 3-hydroxypiperidines or halide derivatives thereof.[5] The reaction of these bicyclic aziridinium ions with nucleophiles is very useful synthetically, and is also of mechanistic interest as both pyrrolidine or piperidine products can be formed depending on the regioselectivity of the aziridinium ion cleavage reaction. However this methodology is limited due to the availability of suitable precursors, which are usually derived from proline or piperidine derivatives.

We have recently reported mechanistic and synthetic studies on the Lewis acid mediated nucleophilic cleavage of α-amino acetals.[6] In the course of this work we chose to investigate a range of substitution patterns, including *N*,*N*-diallylamines which were of interest as deprotection could be readily achieved under mild conditions to give the free primary amine.[7] At low temperatures, acetal substitution occurs,[6] however if the intermediate is allowed to warm to rt prior to addition of a nucleophile, then the final product is the substituted pyrrolidine (**3**) *as a single diastereoisomer* (Scheme 1). This can be rationalised by a cationic cyclisation of an *N*-allyl group onto the α-oxocarbenium ion, generated by cleavage of acetal (**1**). The nitrogen atom then intercepts the developing cationic centre directly forming the bicyclic aziridinium ion (**2**), followed by regioselective ring opening by the nucleophile.



Scheme 1

† Author to whom communications regarding X-ray crystallography should be addressed.

The rearrangement to form the aziridinium ion proceeds in high yield, and such intermediates can be observed by ^{1}H NMR prior to addition of the nucleophile. Alternatively, they can be isolated as crystalline tetraphenylborate salts by addition of $NaBPh_4$ to an acetone solution of the triflate salts (**2**) followed by addition of ether to induce precipitation. The aziridinium ions isolated in this way, can be stored indefinitely, and are particularly attractive synthetic intermediates. This also allowed the use of X-ray crystallography to unambiguously determine the relative stereochemistry of the aziridinium ion (**4**) (Fig. 1) derived from *R*-(+)-α-methylbenzylamine, obtained by fractional crystallisation of the crude product mixture.[8]

Previous studies on the reactivity of bicyclic aziridinium ions such as (**2**) suggested that the regioselectivity of the ring opening reaction may be a problem, particularly if pyrrolidines were desired. However, we found that this was generally not the case (Table 1), and that a range of synthetically useful nucleophiles could be employed, leading to the synthesis of a diverse range of 1,2,4-trisubstituted pyrrolidines. Only in the case of oxygen nucleophiles were significant quantities of piperidine products formed, and in such cases, this could be improved by using more reactive synthetic equivalents.

Although these results were encouraging, the methodology did not offer the opportunity for control of absolute stereochemistry unless a resolution was used. We therefore also investigated more complex examples derived from substituted α-amino acetals which overcame this limitation. Examples are shown in Scheme 2.[6,9] In general, good selectivity is observed, which is essentially independent of nucleophile, consistent with the aziridinium ion intermediates (**7**) and (**10**). Importantly, even a substituent as small as a methyl group still allows for a good degree of stereocontrol for formation of aziridinium ion (**10**).

The observed stereocontrol can be rationalised by assuming all substitutents adopt a pseudo-equatorial position in a chair-like transition state in the cyclisation reaction (Fig. 2).

The remaining limitation on this chemistry lies in the nature of the acetal chosen. Although methyl and ethyl acetals are readily accessible, they do not allow for ready deprotection in the presence of sensitive functionality to give the more useful alcohol substituent. To address this problem we synthesised the

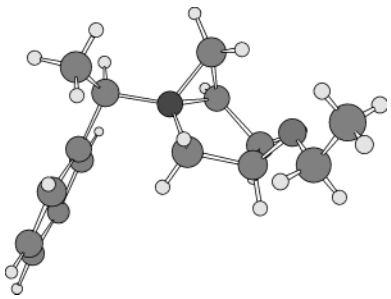


Fig. 1 X-Ray crystal structure of (**4**) (BPh_4 omitted for clarity).

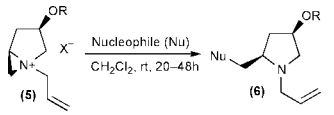
 DOI: 10.1039/b102124i

benzyl acetal (**12**). This underwent smooth cyclisation with comparable efficiency and selectivity to other acetals (Scheme 3), and the product benzyl ether (**13**) should now be capable of hydrogenolysis, which would also allow concomitant N-deprotection to the parent substituted 3-hydroxypyrrolidine.

In summary, we have developed a novel tandem cationic cyclisation–aziridinium ion formation–nucleophilic ring opening procedure which provides powerful new methodology for the stereocontrolled synthesis of a wide variety of substituted pyrrolidines.[9] We are currently investigating this reaction further to determine its generality, and to exploit its potential in natural product synthesis. The results of these studies will be reported in due course.

Table 1 Nucleophilic opening of bicyclic aziridinium ions



Entry	R	X[a]	Nucleophile	Product	Yield[b]
1	Me	BPh_4^-			81%
2	Et	TfO^-			65%[c]
3	Et	BPh_4^-	$^nBu_2CuLi$		56%[c]

A one-step synthesis of a free base secochlorin from a 2,3-dimethoxy porphyrin†

Jonathan L. Sessler,* Sergiy V. Shevchuk, Wyeth Callaway and Vincent Lynch

Department of Chemistry and Biochemistry, Institute for Cellular and Molecular Biology, The University of Texas at Austin, Austin, TX 78712-1167, USA. E-mail: sessler@mail.utexas.edu; Fax: 1-512-471-7550

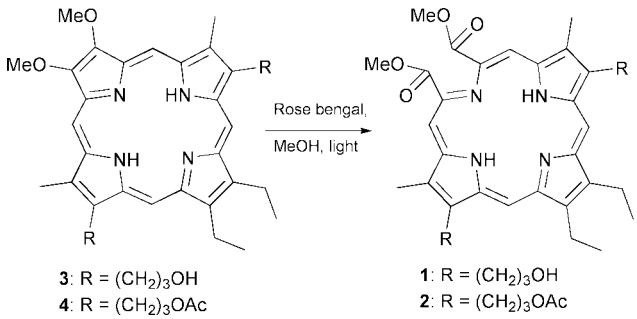
Received (in Corvallis, OR, USA) 7th March 2001, Accepted 5th April 2001
First published as an Advance Article on the web 10th May 2001

The synthesis and X-ray structure of a C_2 symmetric secochlorin 2, obtained by a photosensitized oxidative ring opening of a 2,3-dimethoxy porphyrin, is described.

Photodynamic therapy (PDT), a promising treatment for a number of medical disorders, relies on selectively retained photosensitizers that are able to produce an efficient cytotoxic response upon activation with light. Currently, several porphyrin- or expanded porphyrin-type macrocycles are in advanced clinical testing or recently approved as PDT photosensitizers.[1] A range of other pyrrolic macrocycles are also being considered as photosensitizers, among them secochlorins.[1a] The first secochlorin to be characterized structurally was obtained as the result of an unexpected oxidative ring-opening of a corrinato nickel(II) salt.[2] Secochlorin diketones and dialdehydes have also been obtained from an analogous oxidative cleavage involving the corresponding nickel(II) chlorin diols.[3–5] As yet, however, these compounds have not been prepared in their non-metalated forms. On the other hand, several synthetic, structural, and spectroscopic studies of free base secoporphyrazines have been reported in recent years. For instance, a secoporphyrazine was formed as a minor side product during the synthesis of magnesium(II) porphyrazine as the result of the Linstead macrocyclization of 2,3-bis(dimethylamino)-2(*Z*)-butenedinitrile.[6] The same compound was also obtained in high yield by subjecting simple free base porphyrazine to manganese dioxide-mediated oxidation.[7] This latter method was further extended to core-metalated (*e.g.* Zn^{II}) and unsymmetrical free base porphyrazines. We now report the synthesis of the C_2 symmetric free base secochlorins **1** and **2** obtained in the form of their bis(methyl esters) as a result of an oxidative ring opening of dimethoxy-substituted porphyrins. To the best of our knowledge, compounds **1** and **2** represent the first example of a non-porphyrazine derived secochlorin to be characterized structurally in its free base form.

The porphyrin **3** containing a 3,4-dimethoxypyrrole unit was chosen as the starting material for the present secochlorin synthesis. This choice reflects the fact that attempts to prepare **3** from the readily available tripyrrane precursor 2,5-bis[(5-formyl-3-(3-hydroxypropyl)-4-methylpyrrol-2-yl)methyl]-3,4-diethylpyrrole[8] and 3,4-dimethoxypyrrole[9] using the standard '3 + 1' approach[10] gave rise not only to the expected porphyrin but also to secochlorin **1** as a minor side product. The chemical composition of **1** was inferred from CI mass-spectrometric analysis. Unfortunately, it proved impossible to separate the secochlorin from the major reaction product, porphyrin **3**, by column chromatography unless the side chain 3-hydroxypropyl groups were acetylated. This done, however, the desired separation was easily effected to give **2** in low (~5%) yield.

The interesting nature of **1** and its acetylated derivative **2**, led us to seek a more efficient synthesis. Here, we were inspired by the realization that **1** could have arisen from an air-based oxidation of the dominant 2,3-dimethoxyporphyrin product **3**. Based on such thinking, we considered that treating porphyrins, such as **3**, with singlet oxygen would effect conversion into the corresponding secochlorin. On a more practical level, we also thought it might prove useful to start with the bis-acetoxy porphyrin **4**, rather than **3**, so as to simplify purification of the corresponding secochlorin **2**, assuming it were to be produced. Accordingly, as shown in Scheme 1, porphyrin **4** (*ca.* 0.1 mol dm^{-3}) was dissolved in O_2-saturated methanol containing Rose Bengal (*ca.* 150 mg l^{-1}) and subject to irradiation using a 250 W projection lamp as a light source for *ca.* 10 h. Under these conditions, wherein singlet oxygen is the dominant oxidant,[11] the C_2 symmetric secochlorin was obtained in *ca.* 70% yield.



Scheme 1

UV-vis spectral analysis revealed that the Soret band of secochlorin **2** is red-shifted by approximately 11 nm as compared to porphyrin **4** (Fig. 1). More significant spectral changes were observed in the so-called Q-band region of the visible-spectrum. In particular, compound **2** was found to display a broad Q-type absorption band at 678 nm that is *ca.* 50 nm red-shifted compared to what is observed for the corresponding porphyrin **4**. This red-shifting of the lowest energy transition makes secochlorin **2** potentially interesting as a PDT photosensitizer.

Proton NMR spectroscopic studies of **2** and **4** revealed,‡ in accord with expectations, that the OCH_3 signal is shifted upfield

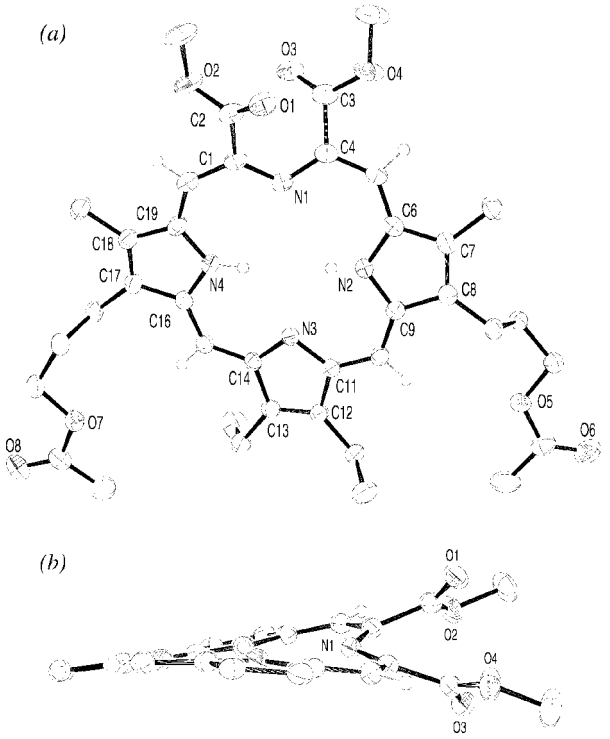

Fig. 2 Crystal structure of **2** showing a partial atom labelling scheme: *(a)* top and *(b)* side view. In the latter view, the pyrrole alkyl substituents are not shown on *(b)*. Thermal ellipsoids are scaled to the 50% probability level.

by *ca*. 0.6 ppm in secochlorin **2** (δ = 4.20 ppm) as compared to where it is seen in the case of porphyrin **4** (signal observed at 4.78 ppm). Presumably, it is the result of significant structural differences between **4** and **2**. Whereas the methoxy groups of **4** are bound directly to one of the porphyrin pyrroles, and hence in electronic contact with the main aromatic periphery, the methoxy groups of **2** are further removed from the principal secochlorin conjugation pathway. Further, they are tied up as ester groups. Separate from this, the four *meso*-carbon protons of porphyrin **4** were found to resonate as one singlet at 10.06 ppm, whereas in the case of **2** the corresponding protons resonate at slightly higher field and appear as two singlets (*i.e.* at 9.65 and 9.70 ppm, respectively).

A single-crystal X-ray diffraction analysis of **2** was also performed.§ This analysis confirmed the proposed secochlorin structure. In particular, it revealed that, on going from **4** to **2**, the dimethoxypyrrolic unit of porphyrin **4** gets transformed into a bis(methyl ester) moiety, without the connectivity of the macrocycle being otherwise modified (Fig. 2). The carbon–carbon bond lengths of the bis(methyl ester) unit [C1–C2 1.513(2), C3–C4 1.513(3) Å] are somewhat longer than the bond lengths in the pyrrole subunits [C6–C7 1.429(2), C8–C9 1.435(2), C11–C12 1.461(2), C13–C14 1.459(2), C16–C17 1.431(2), C18-C19 1.437(2) Å]. The C–N–C bond angle of the bis(methyl ester) [∠C1–N1–C4 120.24(14)°] was found to be significantly different from the bond angles seen for the pyrrolic units [∠C6–N2–C9 110.3(2)°, ∠C11–N3–C14 104.62(13)°, ∠C19–N4–C16 110.0°] and somewhat bigger than found for *meso*-tetraphenylsecochlorinato nickel(II)[6] [∠C1–N1–C4 114.3(3)°].

In summary, the synthesis of a novel secochlorin system by oxidative ring opening of a porphyrin is described. This convenient method, based on the singlet oxygen mediated ring opening of a 2,3-dimethoxyporphyrin, offers the prospect of allowing a range of new secochlorins to be prepared and isolated in their free base forms. Current work is focused on exploring the metallation chemistry of these new systems.

Support for this work came from the National Institute of Health (grant CA 68682 to J. L. S.) and Pharmacyclics, Inc.

Al distribution in ZSM-5 zeolites: an experimental study

J. Dědeček, D. Kaucký and B. Wichterlová

J. Heyrovský Institute of Physical Chemistry, Academy of Sciences of the Czech Republic, Dolejškova 3, CZ-182 23 Prague 8, Czech Republic. E-mail: wichterl@jh-inst.cas.cz

Received (in Cambridge, UK) 29th November 2000, Accepted 19th April 2001
First published as an Advance Article on the web 10th May 2001

Al atoms are not randomly distributed in ZSM-5 zeolites but their distribution is affected by the Si/Al composition and the synthesis procedure.

Zeolites with low concentration of aluminium in the framework (Si/Al > 8), such as *e.g.* those with the ZSM-5 structure, constitute a basis for catalysts of high significance in both acid–base and redox catalysis. Because of the low aluminium content, local Si–Al sequences described as 'Al pairs' [Al–O–$(Si–O)_{1,2}$–Al] and 'single' Al atoms [Al–O–$(Si–O)_{\geqslant 3}$–Al] that are far apart, are present in their frameworks.[1] Therefore, with divalent cations complete ion exchange is not possible.[2] Spatial distribution of the Si–Al sequences also leads to variations in the aluminium distribution in the zeolite channel system. As the occurrence and distribution of Al in the zeolite framework controls the presence, distribution and properties of catalytically active sites, *i.e.* of protonic and metal ion sites, the distribution of aluminium in the framework is very important for the catalytic properties of these materials. The presence of Al pairs is necessary for the exchange of divalent cations,[3] and the geometry of zeolite rings accommodating Al pairs affects coordination of the cations in zeolites.[3] However, no method is available for determination of the distribution of Al in silicon-rich zeolites. ^{29}Si MAS NMR can distinguish only Al–O–Si–O–Al pairs (representing only a minority of the Al pairs, < 5% Al, in ZSM-5[4]), while Al–O–$(Si–O)_2$–Al sequences cannot be distinguished from single Al atoms. Also ^{27}Al MAS NMR spectroscopy cannot provide such information. The theoretical approach using Monte Carlo simulation, based on the premise that Al distribution in zeolites is random, or quantum chemical studies modeling small clusters thus face severe limitations. Moreover, they cannot reflect the potential dynamic effect occurring during zeolite synthesis.

We suggest an indirect method for the estimation of the number of Al pairs and single Al atoms present in zeolites and of the distribution of Al pairs in framework local structures (cationic sites) in the zeolite channels. The method is based on monitoring of the distribution of bare divalent Co(II) ions, coordinated exclusively to framework oxygen atoms, at the cationic sites of dehydrated Co-zeolites exchanged to the maximum degree. To balance the positive charge of these bare divalent cations, two negative AlO_2^- charges are required at the cationic site. The d–d transitions of bare Co(II) ions in the Vis region reflect their coordination at the local geometry of the framework cationic sites. Three different cationic sites denoted as α, β and γ were suggested for bare Co(II) ions in mordenite, ferrierite and ZSM-5 structures.[5–7] In the case of the ZSM-5 matrix, Co(II) ions in the α site, characterized by a single band at 15 100 cm^{-1}, represent the Co(II) ions located above four framework oxygens forming a plane in the deformed six-membered ring composed of two five-membered rings. The Co(II) ions in the β site are located in another type of deformed six-membered ring, and their spectrum is composed of four bands at 16 000, 17 150, 18 600 and 21 200 cm^{-1}. The Co(II) ions in the 'boat shaped' γ site lead to a doublet of bands at 20 100 and 22 000 cm^{-1}. A schematic representation of these cationic sites is given in Fig. 1, (for details see ref. 7). Quantitative analysis of the corresponding Co(II) spectra provided the concentration and distribution of the Co(II) ions in the individual cationic sites of pentasil ring zeolites. Because bare Co(II) ions must be balanced by two framework AlO_2^- tetrahedra, the distribution of the bare Co(II) ions among the cationic sites in Co-ZSM-5 with maximum loading of the exchanged bare Co ions reflects the distribution of Al pairs [Al–O–$(Si–O)_{1,2}$–Al] at different cationic sites. Therefore, the bare Co(II) ions with characteristic spectral features can serve as probes for the distribution of Al pairs in zeolites.

To guarantee that the monitored Co(II) ions are counter ions to Al pairs, they should be present in the form of bare cations bound only to framework oxygens without coordinating extraframework ligands. This was confirmed by the NIR–Vis–UV spectra of dehydrated Co-ZSM-5 and supported by FTIR and EXAFS results. The absence of Co(II) ions coordinated to weak extraframework ligands, such as water or OH groups, was evidenced by the absence of the combination vibration bands around 5200 cm^{-1} (water) and 7200 cm^{-1} (water and OH). Also the band at 3650–3660 cm^{-1}, which reflects OH groups bound to Co or extraframework Al, was not found in the IR spectra of Co-ZSM-5 as well as in those of parent Na-ZSM-5. The latter information together with the ^{27}Al MAS NMR of Na-ZSM-5, indicating only T_d coordinated aluminium, evidenced that all aluminium was present in the zeolite frameworks. Coordination of the Co(II) ion to strong ligands such as an extraframework oxygen atom (Co–O–Co species) lead to intense charge transfer bands, which, however, are not found in the UV spectral region. Moreover, EXAFS results on Co-ZSM-5/A (Si/Al 14.1) showed Co(II) ions coordinated only to framework oxygens, and Co–O–Co type bonding was not detected.[8] Thus, the NIR–Vis–UV spectra can be used to provide evidence for the dominant presence of bare Co(II) ions in dehydrated Co-zeolites and for the estimation of the concentration and distribution of the Co(II) ions at the cationic sites.

The concentration of Al pairs in ZSM-5/A and B series† was obtained from the above described quantitative analysis of the Co(II) VIS spectra of Co-ZSM-5 zeolites with maximum loading of bare Co(II) ions (see ref. 7 and above). The effect of the procedure of zeolite synthesis and of the framework aluminium content in the ZSM-5 matrix (expressed as Si/Al ratio) on the relative concentration of Al pairs in α, β and γ sites (derived from absolute concentrations) is depicted in Fig. 2. The sum of the concentrations of Al pairs in α, β and γ sites

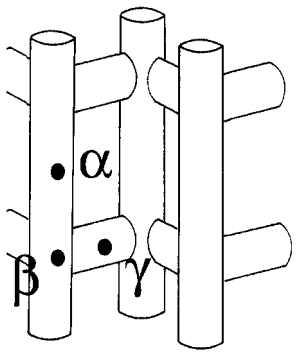

Fig. 1 Position of α, β and γ sites of the Co(II) ions in ZSM-5.

 DOI: 10.1039/b009589n

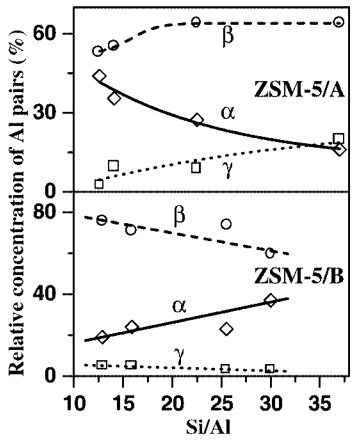

Fig. 2 Effect of Si/Al on relative concentration of Al pairs in α (——), β (– – –) and γ (···) sites for ZSM-5/A and /B.

represents the total concentration of Al pairs in the zeolite framework. The concentration of single Al atoms can be obtained as a difference between the total framework Al concentration (from bulk analysis, note that the extraframework Al species were not detected) and the concentration of Al pairs. The effect of the procedure of zeolite synthesis and of the framework aluminium content on the relative concentration of Al pairs and single Al atoms is described in Fig. 3. It is evident that the total concentration of Al pairs and single Al atoms as well as the relative concentration of Al pairs at the α, β and γ

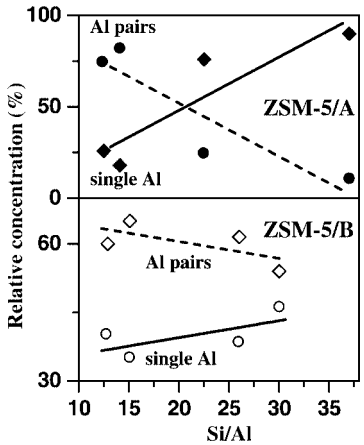

Fig. 3 Effect of Si/Al on relative concentration of single Al atoms (——) and Al pairs (– – –) for ZSM-5/A and /B.

cationic sites depend dramatically on the Si/Al composition and on the synthesis procedure.

The assumption of random or statistically controlled distribution of aluminium[1] cannot explain the dramatic differences in the Al distribution in zeolites synthesized under different conditions, and the dependence of the relative concentration of Al pairs in the α, β and γ sites on the Si/Al ratio. The results imply that the aluminium distribution in ZSM-5 is not random and not controlled exclusively by statistical rules. Preferences for the formation of single Al atoms and Al pairs in specific framework local structures play a significant role during zeolite synthesis and depend on the synthesis conditions.

It can be concluded that the Al distribution in silicon-rich molecular sieves is not random, but depends on the chemical composition of the zeolite and on the conditions of synthesis. The bare Co(II) ions detected by Vis spectroscopy represent a powerful tool for investigation of the Al distribution in silicon-rich zeolites. This provides a potential (i) for investigation of the relation between the activity of catalysts based on silicon-rich zeolites and the aluminium distribution in their framework, and (ii) for controlling the Al distribution in the framework of these zeolites by variation of synthesis procedures.

Notes and references

† ZSM-5 zeolites were prepared by two types of synthesis procedure. ZSM-5/A (Si/Al 12.5, 14.1, 22.5, 37) was provided by Slovnaft, Slovakia and ZSM-5/B (Si/Al 12.9, 15.9, 25.5, 30) was provided by the Research Institute of Inorganic Chemistry, Inc., Czech Republic. The parent Na-zeolites were ion-exchanged three times with 0.1 M $Co(NO_3)_2$ at ambient temperature. Dehydration of the samples was conducted at 770 K for 3 h under a dynamic vacuum up to 10^{-5} Torr.

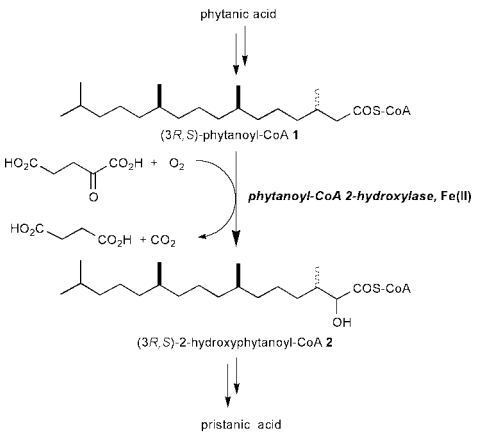
Received (in Cambridge, UK) 30th January 2001, Accepted 19th April 2001
First published as an Advance Article on the web 10th May 2001

The *in vitro* catalytic activity of two clinically observed mutants of phytanoyl-CoA 2-hydroxylase, an iron(II)/2-oxoglutarate-dependent oxygenase causing Refsum's Disease, was partially rescued by the use of alternatives to the natural cosubstrate, 2-oxoglutarate; this is the first demonstration of 'chemical co-substrate rescue' of mutations to an enzyme causing human disease.

Phytanic acid in the human diet is derived from the phytol sidechain of chlorophyll, but the presence of a 3-methyl group prevents its degradation *via* the fatty acid β-oxidation pathway. Instead, a preliminary pathway effects α-oxidation of phytanic acid, excising a methylene group to give pristanic acid.[1,2] Within this pathway, hydroxylation of phytanoyl-CoA to 2-hydroxyphytanoyl-CoA is catalysed by phytanoyl-CoA 2-hydroxylase (PAHX),[3,4] an iron(II) and 2-oxoglutarate-dependent oxygenase (Scheme 1).[5] Mutations to PAHX cause *ca.* 45% of adult Refsum's Disease (ARD) with other cases being associated with a second locus.[6]

Two common point mutations in human PAHX, R275W and R275Q, are present at an allele frequency of 3/40 (7.5%) and 5/40 (12.5%), respectively, in Dutch/Scandanavian patients with ARD.[3,7] Sequence analyses revealed that Arg-275 is conserved in all reported PAHX enzymes and closely related sequences. Analysis of the sequences in the light of crystal structures[8,9] for two other 2-oxoglutarate oxygenases suggested that Arg-275 binds the 5-carboxylate of the co-substrate *via* an electrostatic interaction.[8] We postulated that the PAHX R275Q and R275W mutants were inactive due to defective 2-oxoglutarate binding or utilisation, and that it may be possible to rescue their activity using alternative co-substrates.

The two clinically observed mutants of Arg-275 in human PAHX (R275Q and R275W)[3,7] and a further mutant R275A, made for comparison, were constructed by site-directed mutagenesis. The desired proteins were expressed *via* standard techniques in recombinant *E. coli* and purified as mature (*i.e.* without their peroxisomal targeting sequences) enzymes to > 95% homogeneity (by SDS-PAGE analysis). Mutations were confirmed by DNA sequencing and ESI MS analyses. Analysis of the secondary structure by circular dichroism suggested that all mutants had a similar overall structure to the wild-type enzyme.



Scheme 1 The role of phytanoyl-CoA 2-hydroxylase in the peroxisomal degradation of phytanic acid.

Activity of the wild-type enzyme and mutants was assayed by conversion of phytanoyl-CoA to 2-hydroxyphytanoyl-CoA.[10] Assays were performed (at least in triplicate) according to a modified version of a published procedure[11] and included ATP to obtain maximum activity.[12] The activity was further enhanced *ca.* two-fold by the use of tris(carboxyethyl)phosphine (TCEP) in place of the previously used dithiothreitol (DTT).[11] Two concentrations of 2-oxoacid (2 and 60 mM) were used in order to facilitate detection of low levels of activity. Assay mixtures for the analogues contained: 50 mM Tris-HCl, pH 7.5, 1 mM $FeSO_4$, 50 μM synthetic (3*RS*,7*R*,11*R*)-phytanoyl-CoA, 0.44 mM β-cyclodextrin, 100 μM TCEP, 10 mM ascorbate, 4 mM ATP and *ca.* 20 μg enzyme (2 mM 2-oxoacid) or 10 μg enzyme (60 mM 2-oxoacid). Reactions were quenched with 250 mM EDTA after incubation for 60 min (2 mM 2-oxoacid) or 5 min (60 mM 2-oxoacid). Samples were centrifuged and analysed by HPLC using a Hypersil C_{18} column (250 × 4.6 mm) monitoring at 254 nm.[11]

Using the natural co-substrate, 2-oxoglutarate, the activity of the two clinically observed mutants was < 0.5% of that of the wild-type enzyme (Table 1). A range of 2-oxoacids was tested in an attempt to restore the activity of the mutants. Homogentisate, 4-hydroxyphenylpyruvate, indole-3-pyruvate, 2-mercaptosuccinate all gave specific activities of < 0.2 nmol min^{-1} mg^{-1} with wild-type enzyme and all mutants. The activity of the R275Q and R275W mutants was significantly 'rescued' compared to the wild-type activity with 2-oxoglutarate as a co-substrate using certain 2-oxoacids at a concentration of 60 mM (Table 1). Optimum rescue of mutants with hydrophobic/aliphatic residues in place of Arg-275 is achieved using 2-oxoacids with side-chains of 2–4 carbon atoms or equivalent length side-chains. Effective examples are in the use of 2-oxobutyrate with R275Q mutant (Table 1, entry 4) and 2-oxo-5-thiahexanoate with the R275W mutant (Table 1, entry 9). The latter case is striking because 2-oxo-5-thiahexanoate cannot be substituted for 2-oxoglutarate (< 0.5%) in assays with the wild-type enzyme. The dramatic change in co-substrate selectivity resulting from PAHX Arg-275 mutations may be useful for the clinical identification of these particular mutants using a modified assay with alternative 2-oxoacids.

Even higher levels of rescue were obtained in the case of the R275A mutant where most of the hydrophobic analogues tested (Table 1, entries 3–9), led to 22–28% rescue at 60 mM. An exception was 2-oxooctanoic acid (Table 1, entry 10), which was inactive with the wild-type enzyme, and all mutants assayed, presumably due to its carbon chain being too large to

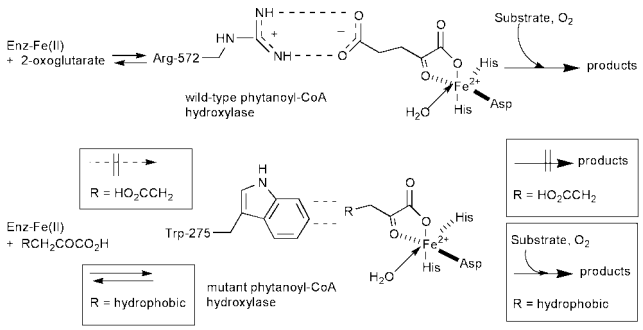
be accommodated in the proper orientation in the active site. The R275A mutant was also less selective than the wild-type or other tested mutants, presumably due to a relaxation of steric and electrostatic constraints reflecting the presence of a small, hydrophobic and neutral side-chain.

2-Oxoacids are metabolically related to proteinogenic amino acids *via* transamination reactions. Several of the 2-oxoacids which rescue the activity of the clinically observed R275W and R275Q mutants are thus accessible *via in vivo* amino acids, *e.g.* 2-oxovalerate from valine and 2-oxo-5-thiahexanoate from methionine. Thus, certain forms of ARD might be treated *via* dietary supplements containing the appropriate amino acids. Maple syrup urine disease is caused by a deleterious accumulation of excess 2-oxacids, and is treated, in the reverse of this proposed therapy, by a diet low in branched-chain amino acids.[13] Restoration of complete wild-type activity may not be required, as 5% of wild-type activity is apparently sufficient to effectively correct inherited homocystinuria[14] with vitamin B6.

To our knowledge the only other example of the rescue of enzyme activity with a modified co-substrate has involved the elegant use of ATP analogues to study *in vivo* activity of



Scheme 2 'Chemical co-substrate rescue' of a PAHX mutant as exemplified for R275W. R = hydrophobic/aliphatic group. Wild-type enzyme showing interaction of guanidino group of Arg-275 and 5-carboxylate of 2-oxoglutarate (above). Unfavourable interaction between aromatic sidechain of Trp-275 and 5-carboxylate of 2-oxoglutarate; rescue of activity *via* hydrophobic interactions in 2-oxoacid binding site (below). The relative arrangement of the iron ligands is that of deacetoxycephalosporin C synthase (DAOCS).[8]

kinases.[15] The *in vitro* work that is reported here is the first demonstration of the 'chemical co-substrate rescue' of mutations in an enzyme (Scheme 2) implicated in a human disease. *In vivo* studies directed towards demonstrating the technique in cell lines are in progress.

Conversion of the carboxy group of sialic acid donors to a protected hydroxymethyl group yields an efficient reagent for the synthesis of the unnatural beta-linkage

Xin-Shan Ye, Xuefei Huang and Chi-Huey Wong*

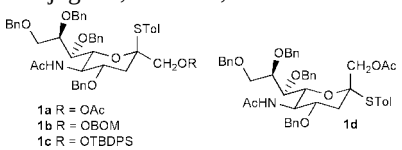
First published as an Advance Article on the web 10th May 2001

New sialyl donors with a protected hydroxymethyl group at the anomeric center are over 1000 times more reactive than the normal ester containing sialylation reagent and give excellent yield (> 90%) with unusually high β-stereoselectivity in sialylation.

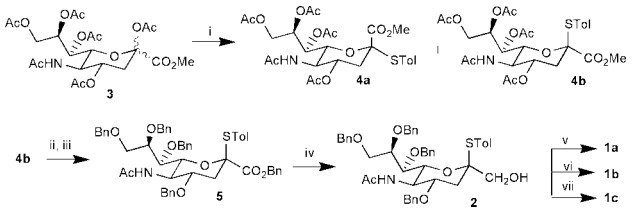
N-Acetylneuraminic acid (sialic acid) residues are often located at the non-reducing end of glycoconjugates, and play important roles in many biological recognition events such as cancer metastasis and bacterial or viral infection.[1,2] The synthesis of sialyl glycoconjugates, however, remains a challenge.[3]



In a typical sialylation reaction, the electron withdrawing carboxy group at the anomeric center of sialic acids significantly destabilizes the oxonium ion forming transition state thus lowering the reactivity of sialyl donors towards nucleophiles. Furthermore, the steric hinderance at the anomeric center leads to elimination and low yields of sialylation. Various methods have been developed to overcome these problems, including, for example, introduction of an additional *N*-acetyl moiety,[4,5] installation of an anchimeric assisting group at the C3 position[5–8] or a carboxy equivalent at the anomeric center.[9,10] The latter approach includes utilizing a less electron withdrawing furyl substituent as the carboxy surrogate.[9] This method, however, failed to yield any disaccharides with secondary sugar alcohols. Increased reactivities towards *N*-iodosuccinimide (NIS) have also been observed with the reduced 2,3-didehydro sialic acid derivatives, but these reactions gave very low yields (~ 20%).[10]

To tackle the aforementioned problems, we converted the carboxy group of sialic acid to the hydroxymethyl group and prepared derivatives **1a**–**1d** for investigation (Scheme 1). The peracetylated sialic acid **3**[11] was treated with *p*-thiocresol to give thio-sialic acid **4b** in 75% yield together with 20% of the α isomer **4a**. The protective groups of **4b** were exchanged for benzyl groups to give compound **5** in two steps in 55% yield. Reduction of the ester moiety was accomplished with $LiBH_4$ in 90% yield to give the hydroxymethyl sialic acid derivative **2**, the hydroxy group of which was protected with the acetyl, benzyloxymethyl (BOM) or *tert*-butyldiphenylsilyl (TBDPS) group to give sialyl donors **1a**–**1c**. The α sialyl donor **1d** was prepared from **4a** in a similar manner as the β sialyl donor **1a**.

The relative reactivity values (RRV) of known and new sialic acid donors **1a**–**1d**, **2**, **4b** and **5** were measured as previously described[12] and shown in Table 1. Compared to the benzyl protected sialic acid **5**, over *three orders of magnitude* increase in RRV was observed with all the reduced sialic acid derivatives **1a**†–**1d** and **2** (RRV for **1a**, **1b**, **1c**, **1d** and **2** are 4.0×10^4, 2.3×10^5, 7.8×10^4, 8.0×10^4 and 3.3×10^5 respectively). The reactivities of all these reduced sialic acids (**1a**–**1d** and **2**) are



Scheme 1 *Reagents and conditions*: (i) *p*-Thiocresol, $BF_3{\cdot}Et_2O$, CH_2Cl_2, 20% for **4a**, 75% for **4b**; (ii) NaOMe, MeOH, 100%; (iii) NaH, BnBr, DMF, 55%; (iv) $LiBH_4$, THF, MeOH, 90%; (v) Ac_2O, pyridine, 96%; (vi) BOMCl, Pr^i_2NEt, CH_2Cl_2, 86%; (vii) TBDPSCl, imidazole, DMF, 96%.

comparable to or even higher than perbenzylated L-fucose **6** which was the most reactive thioglycoside measured previously.[12]

With the RRV values in hand, sialylation of donors **1a**–**1d** was performed. The TBDPS protected sialyl donor **1c** failed to undergo glycosylation with galactose acceptor **7**, presumably due to the large TBDPS group. With the smaller acetyl protective group, donor **1a** underwent smooth sialylation with galactose acceptor **7** to give disaccharides **8** and **9** in 95% yield (**8**:**9** = 15:1) in acetonitrile using dimethyl(methylthio)sulfonium triflate (DMTST) as the promoter[13,14] (Scheme 2a). No elimination product was isolated. The hydroxymethyl moiety of the products can be subsequently unmasked after sialylation and selectively oxidized to the carboxy group in three high yielding steps as demonstrated by transformation of compound **8** to **10** (Scheme 2b) and **9** to **12** (Scheme 2c). However, quite unexpectedly the predominant product **8** formed in the sialylation contains a β linkage between the two monosaccharides. The near zero $^3J_{C1,H3a}$ value in the EXCIDE[5,15] spectra of **8** and **11**‡

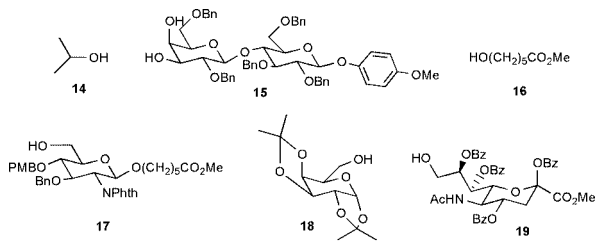
indicated the β-configuration, while the $^3J_{C1,H3a}$ value of **13**§ was determined to be 6.1 Hz indicating its α-configuration. Comparison of the chemical shifts of H_{3eq} of compound **11** (2.64 ppm) and **13** (2.72 ppm)[16] further confirmed the assignment following the empirical rules of chemical shift.[4] The stereoselectivity does not vary much with different acceptors. Sialylation of various acceptors such as isopropyl alcohol **14**, lactose derivative **15** as well as primary alcohol **16**, glucosamine **17** and galactose **18**, with donor **1a** using DMTST as the promoter, gave predominantly the β-linked disaccharide[17] (β : α > 10 : 1) in high yields (> 90%). The exception was the sialic



acid derivative **19** which gave a ratio of 3 : 1 favoring β-disaccharide in 90% total yield. Sialylations in solvents such as ether, toluene and dichloromethane gave even more β anomer than those performed in acetonitrile. The acetonitrile effect[18] could not significantly alter the anomeric selectivity. Sialylation of galactose **7** with the BOM protected donor **1b** or α sialyl donor **1d** gave the product with similar yield and stereoselectivity to those with donor **1a**.

Sialylations with promoters other than DMTST were also tested. MeOTf[19] failed to activate sialyl donor **1a** while with PhSOTf[20] only the β isomer was isolated when galactose **18** was sialylated with **1a**. The use of NIS and triflic acid (TfOH) improved the α-selectivity (α : β = 1 : 2.5) when galactose acceptor **7** was sialylated with **1a** in 90% total yield.

In conclusion, it has been demonstrated that the reactivity of sialic donors can be dramatically increased by reducing the carboxy group at the anomeric center to the hydroxymethyl moiety. Subsequent sialylation with these novel sialyl donors proceeded in excellent yield (> 90%) but with unusually high β stereoselectivity, probably due to a significant anomeric effect. The hydroxymethyl moiety can be easily oxidized to the carboxy group in high yield. The high reactivity of sialyl donors could find uses in the preparation of enzymatically stable unnatural oligosaccharides containing β-sialic acid. Oligosaccharides with unnatural glycosidic linkage could have important biological implications, as illustrated in the study of CD-1 mediated T-cell activation.[21] The new glycosylation reagents can also be utilized in programmable one-pot synthesis, where the sialylation reaction often has to be the first and most reactive as sialic acid is often located at the non-reducing end of bio-active oligosaccharides.[12] Introduction of a C-3 auxiliary may give the α-linkage.

First published as an Advance Article on the web 10th May 2001

An octadentate Na^+ complex of chiral cholesterol-armed cyclen has a quadruple helicated structure and forms a stable self-aggregate in aqueous solution which offers chirality induction of achiral 5-dimethylaminonaphthalen-1-ylsulfonylglycine anion.

Several kinds of transition and lanthanide metal complexes are recognized as useful building blocks for supramolecular architecture,[1] because of their well-defined coordination topology, high thermodynamic stability and inert kinetics. In contrast, alkali metal complexes usually have versatile coordination structures, low stability and rapid kinetics, and hence their use for this purpose is limited. We demonstrate here that an octadentate Na^+ complex of chiral cholesterol-armed cyclen **1** forms a stable self-aggregate in aqueous solution which provides a unique microenvironment for chirality induction of achiral 5-dimethylaminonaphthalen-1-ylsulfonylglycine anion (DNS-Gly^-).[2] The employed cyclen **1**–Na^+ complex is a new type of chiral amphiphile furnished with three functional components (Fig. 1):[3] ester-armed cyclen as a twisted octadentate ligand;[4] four cholesterol groups as chiral and hydrophobic walls;[5] and the Na^+ ion as a charged group of amphiphile.[6] Since this Na^+ complex exhibits unexpectedly high stability and inert kinetics (log$K$ = 11.2 in C_2D_5OD), its self-aggregate is expected to offer three different levels of chirality in the aqueous solution: (1) chirality of cholesterol moieties; (2) helicity on asymmetrically twisted octadentate Na^+ complex; and (3) integrated chirality of highly structured Na^+ complexes on a supramolecular scale.

A series of metal complexes with tetra-armed cyclens are known to have C_4 symmetry in which four sidearms are arranged as a quadruple helicate *via* twisted square-antiprismatic coordination.[7] Actually, cyclen **2**–NaCl complex gave ^{13}C NMR signals for two carbons of the cyclen ring separately resonating at 51.50 and 49.51 ppm in $CDCl_3$ at 295 K, while a single signal was observed at 55.12 ppm for N-CH_2-CO-carbons of four sidearms. Although the enantiomerization can proceed either by a rotation of the four sidearms or an inversion of the cyclen cycle,[8] these observations indicated that cyclen **2**–Na^+ complex maintained unique quadruplicated helical structures in the solution (Fig. 1). Chiral cyclen **1**–NaCl complex similarly exhibited two separate ^{13}C NMR signals for cyclen ring carbons at 53.01 and 48.46 ppm, though each cholesterol moiety on the cyclen arm has several asymmetric carbons. As reported in some Na^+ complexes with chiral tetra-armed cyclens,[9] cyclen **1**–Na^+ complex is thought to have only a single C_4 orientation in which four chiral cholesterol moieties are arranged in an asymmetrically helicated fashion.

Cholesterol-armed cyclen **1**–NaCl complex spontaneously aggregated in an aqueous ethanol solution (H_2O–EtOH = 80/20, v/v; pH = 7.2, bis-tris-HCl)[10] and gave no precipitate from its aqueous solution after 10 days. The critical aggregation concentration was estimated as 4.0×10^{-6} mol dm^{-3} by fluorescence titrations, which was much smaller than those of common micelle-forming surfactants. Dynamic light scattering experiments showed that the aggregate had a mean hydrodynamic radius of 600 Å, and a TEM picture taken after treatment of uranyl acetate also indicated that it was of similar size (Fig. 2). Interestingly, this self-aggregate accommodated DNS-amino acid anions in the hydrophobic domains. When an excess of self-aggregate was added to an aqueous ethanol

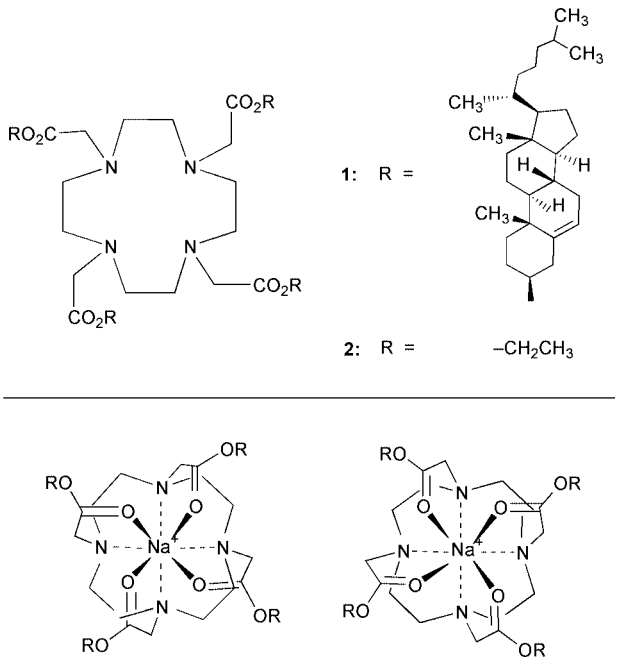

Fig. 1 Armed cyclens and quadruplicated helical structures of their Na^+ complexes.

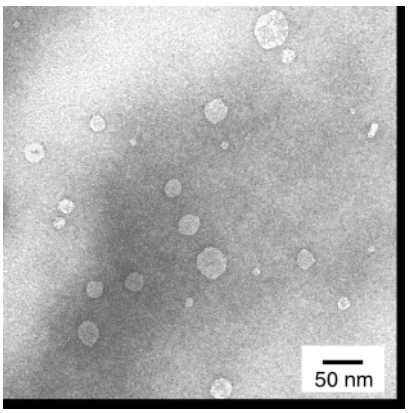

Fig. 2 TEM Picture of dispersed self-aggregates of cyclen **1**–NaCl complexes.

 DOI: 10.1039/b101438m

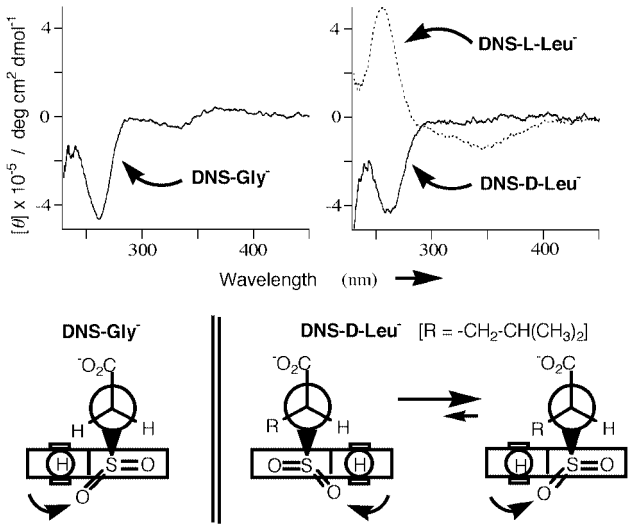

Fig. 3 CD Spectra and preferred conformations of dansyl-glycine (DNS-Gly) and dansyl-leucine (DNS-Leu) anions incorporated in self-aggregate of cyclen **1**–NaCl complexes. [**1**–NaCl] = 3.0×10^{-5} mol L^{-1}; [DNS-Gly$^-$] = 5.0×10^{-5} mol L^{-1}; [DNS-Leu$^-$] = 6.5×10^{-5} mol L^{-1}. The indicated CD spectra of DNS-D- and L-Leu anions were corrected by subtraction of those in the bulk aqueous phases.

solution of DNS-L-leucine anion (DNS-L-Leu$^-$), the fluorescence maximum of the guest anion shifted from 538 nm to 507 nm and the intensity was enhanced 6.5-fold. Cholesteryloxycarbonyl-4-methylmorpholine was examined for comparison. This also formed a water-soluble aggregate in the presence of Na^+ ion, but the resulting aggregate rarely accommodated DNS-amino acid anions. Therefore, the assembling of four cholesterol moieties on the octadentate Na^+ complex platform provided an effective microenvironment for inclusion of DNS-amino acid anions in the aqueous solution.

The self-aggregate of cyclen **1**–NaCl complexes further offered chirality induction of achiral anion substrates upon inclusion. Typically, DNS-Gly$^-$ was incorporated in the self-aggregate and exhibited a negative CD signal around 280 nm (Fig. 3). Both sign and intensity of the observed CD spectrum were similar to those of DNS-D-Leu$^-$ recorded in the self-aggregate, indicating that the conformation of DNS-Gly$^-$ was asymmetrically fixed as true in DNS-D-Leu$^-$ system. Such chirality induction phenomena were reported when the degree of freedom of achiral molecules was severely restricted in the solids, membranes, micelles and inclusion compounds.[11] Polonski *et al.* reported that the CD signal observed with chiral DNS-amino acid originated from unsymmetrical twisting of the sulfonamide group in relation to the naphthalene plane under the influence of hydrogen atom in the *peri*-position (Fig. 3).[12] Since the preferred conformation of DNS-D-Leu$^-$ was determined by the steric problem around the S=O bond rather than the *peri*-positioned hydrogen atom, the negative CD signal was indicative of 'anti-clockwise' conformation. The obtained CD results suggested that the 'anti-clockwise' conformation of DNS-Gly$^-$ was more stable than the 'clockwise' one, when this achiral anion was incorporated in the self-aggregate.

We demonstrated above that the self-aggregate of cyclen **1**–NaCl complexes having an asymmetrically helicated structure allowed chirality induction of the achiral guest anion upon inclusion. Since there are many structural variations in the armed cyclen–alkali metal complexes, their characteristic coordination chemistry provides further possibilities in the development of supramolecular architecture with fascinating functions.

The authors are grateful to Professors Takeshi Nagasaki of Osaka City University and Atsushi Yoshizawa of Hirosaki University for valuable comments on characterizations of the self-aggregate. This research was supported in a part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Culture and Sports, Japan.

A structural model of the ferrichrome type siderophore: chiral preference induced by intramolecular hydrogen bonding networks in ferric trihydroxamate†

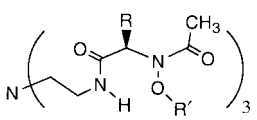
Kenji Matsumoto, Tomohiro Ozawa, Koichiro Jitsukawa, Hisahiko Einaga and Hideki Masuda*

Department of Applied Chemistry, Faculty of Engineering, Nagoya Institute of Technology, Showa-ku, Nagoya 46-8555, Japan. E-mail: masuda@ach.nitech.ac.jp; Fax: +81-52-735-5228; Tel: +81-52-735-5228

Received (in Cambridge, UK) 8th January 2001, Accepted 19th April 2001
First published as an Advance Article on the web 10th May 2001

Tris{2-[(*N*-acetyl-*N*-hydroxy)-D-alanylamino]ethyl}amine (*R*-TAAE) has been synthesized as a chiral trihydroxamate artificial siderophore with hydrogen bonding networks, whose crystal structure of the iron(III) complex revealed Λ configuration induced by interstrand hydrogen bonding networks and steric repulsion by optically active amino acid residues.

Siderophores are low molecular weight iron(III)-sequestering agents produced by bacteria and fungi that form very stable iron(III) complexes.[1,2] A large number of siderophores form chiral complexes, because the ferric siderophore complexes are absorbed by microorganisms through specific receptors that recognize the absolute configuration of complexes on the cell membrane.[1,2] The absolute configurations of iron(III)–siderophore complexes have been determined *via* X-ray crystallography and circular dichroism (CD). For example, ferrichrome, a trishydroxamate siderophore, and enterobactin, a triscatecholate iron carrier, form complexes with a left-handed (Λ) and right-handed (Δ) helicity, respectively.[3–5] The chirality of siderophore–iron complexes differs, although they are induced by the same optically active L-amino acid. In order to examine the factors responsible for determining the chirality of siderophores, many analogues have been synthesized. Shanzer and coworkers have reported that intramolecular hydrogen bonds in chiral siderophore analogues are important for the chiral preference and stability of complexes.[6] However, crystal structures of chiral siderophore analogue complexes with such hydrogen bonds have not been reported yet. Recently, we reported a crystal structure of a racemic mixture of iron(III)–tris{2-[(*N*-acetyl-*N*-hydroxy)glycylamino]ethyl}-amine (TAGE, Scheme 1) and observed a triple-stranded helix with both *intra- and interstrand* hydrogen bonding networks.[7] Such a triple helix structure is expected to induce a pronounced difference between diastereomers by introduction of a sterically hindered chiral group. Next, tris{2-[(*N*-acetyl-*N*-hydroxy)-D-alanylamino]ethyl}amine (*R*-TAAE, Scheme 1) was synthesized as a chiral trihydroxamate artificial siderophore, where chiral centers are introduced in the TAGE ligand by replacing the Gly residues with D-Ala residues. Here, on the basis of the crystal structure and CD data of the iron(III) complex with *R*-TAAE, we describe the influence of the intramolecular hydrogen bonding networks on the chiral preference of the iron(III) complex of artificial siderophores.



R = H, R′ = H : TAGE
R = Me, R′ = H : *R*-TAAE
R = H, R′ = Bn : TABGE
R = Me, R′ = Bn : *R*-TABAE

Scheme 1 TREN based trihydroxamate ligands with hydrogen bonding networks.

The ligand *R*-TAAE was synthesized according to a modification of a previously published method.[8] The iron(III) complex of *R*-TAAE (**1**) was prepared by reaction of Fe(acetylacetonato)$_3$ with *R*-TAAE in a biphasic ethyl acetate–water solution.[9] The crude complex was dissolved in an ethyl acetate solution containing a small amount of methanol, and then after slowly concentrating the solution for a few weeks, a deep-red colored single crystal of **1** suitable for X-ray diffraction analysis was obtained.‡

Initially the space group of the single crystal of **1** could not be distinguished from either $P4_12_12$ or $P4_32_12$ due to the enantiomorphous relationship between the two space groups. From the configuration of the ligand (*R*), the anomalous dispersion effect with Cu Kα radiation, and the difference in R_w values for Λ(*R*,*R*,*R*) and Δ (*S*,*S*,*S*) forms, 3.2 and 8.5, respectively, the space group and the absolute configuration of **1** were eventually determined to be $P4_12_12$ and Λ(*R*,*R*,*R*), respectively. The absolute configuration of **1** is identical to that of ferrichrome, although the chirality of the ligand differs from ferrichrome with Λ(*S*,*S*,*S*). As shown in Fig. 1, the iron ion has a distorted octahedral geometry with three hydroxamates and the overall structure is twisted with a pseudo-3-fold axis.

The average bond lengths between the iron(III) atom and the coordinating *N*-hydroxy O(N) and carbonyl O(C) atoms are Fe–O(N) = 1.970(7) and Fe–O(C) = 2.035(8) Å. The average

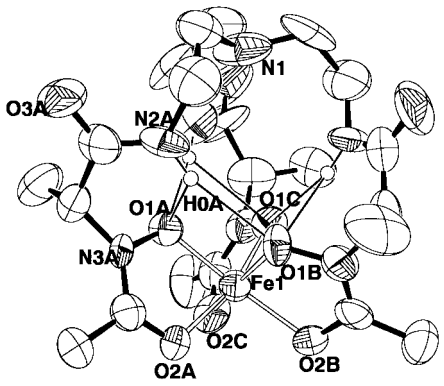


Fig. 1 Crystal structure of **1** showing the atom numbering schemes. Selected bond lengths (Å) and angles (°): Fe–O(1A) = 1.973(7), Fe–O(1B) = 1.964(7), Fe–O(1C) = 1.973(8), Fe–O(2A) = 2.029(8), Fe–O(2B) = 2.038(8), Fe–O(2C) = 2.037(8), O(1A)–Fe–O(2A) = 78.8(3), O(1B)–Fe–O(2B) = 78.8(3), O(1C)–Fe–O(2C) = 79.0(3). Intra- and interstrand hydrogen bond distances (Å): N(2A)···O(1A) = 2.78(1), N(2B)···O(1B) = 2.82(1), N(2C)···O(1C) = 2.92(1), N(2A)···O(1B) = 3.25(1), N(2B)···O(1C) = 3.17(1), N(2C)···O(1A) = 3.12(1).

† Electronic supplementary information (ESI) available: UV-vis and CD spectra of **1** and details of the determination of the absolute configuration and the space group of **1** are deposited as supporting information. See http://www.rsc.org/suppdata/cc/b1/b100306m/

 DOI: 10.1039/b100306m

O(N)–Fe–O(C) bond angle is 78.9(3)°. These values are quite comparable to those for natural trihydroxamate siderophores[2,3] and Fe^{III}TAGE.[7] The twist angle[10] determined for **1** is 44.0°. This is slightly larger than those of natural siderophores (ferrichrome = 42.5, ferricrocin = 40.4°)[2d] and is comparable to the calculated value (45.7°). As the difference between the observed and calculated twist angles is caused by deviation from the idealized C_3 symmetry,[2d] these findings reflect the difference in the symmetries of ligands. The average distances between amide nitrogen and coordinating *N*-hydroxy oxygens are 2.84 and 3.18 Å between intrastrands and interstrands, respectively. These values are slightly shorter than those observed for Fe^{III}TAGE (2.88 and 3.20 Å),[7] indicating that the intramolecular hydrogen bonding networks are enhanced by the introduction of optically active D-Ala to the ligand TAGE. The formation of such a strong intramolecular hydrogen bond is also supported by the ^{1}H NMR data of the benzyl-protected precursor of *R*-TAAE (*R*-TABAE, Scheme 1). The NMR data revealed a pronounced anisotropy in the benzyl protons ArCH_2 and tris(2-aminoethyl)amine (TREN) backbone protons NCH_2CH_2NH in $CDCl_3$ but not in DMSO-d_6. This anisotropy is evidently due to the restriction of rotation induced by intramolecular hydrogen bonding networks.[6b] On the other hand, such anisotropy was not observed for TABGE (a similar precursor of TAGE, Scheme 1) in both $CDCl_3$ and DMSO-d_6.

In aqueous solution at pH 7.4, the UV-vis spectrum of **1** showed a characteristic absorption band at 420 nm corresponding to the tris(hydroxamato)iron(III) complex. This indicates that the structure of **1** determined by X-ray crystallography is maintained in an aqueous solution. The CD spectrum of **1** exhibited positive and negative Cotton effects at 444 ($\Delta\varepsilon$ = +1.0) and 358 nm ($\Delta\varepsilon$ = −0.8). These values are qualitatively similar to those determined from the solution and crystalline CD spectra of ferrichrome,[3] indicating that, like ferrichrome, the absolute configuration of **1** is Λ in both the solution and solid states.

Consequently, the observed chiral preference of **1**, crystalline and in solution, is reasonably explained as a result of the orientation of the triple helix induced by intramolecular hydrogen bonding networks becoming tightly fixed by steric repulsion between optically active amino acid residues and terminal methyl groups. This result strongly supports the proposal by Shanzer *et al.*[6] In addition, it is revealed that intramolecular hydrogen bonding networks in the benzyl-protected precursor of *R*-TAAE and its iron(III) complex are easily formed due to the existence of an asymmetric site within the hydrogen bonded six-membered ring. These observations suggest that both intramolecular hydrogen bonding networks and optically active amino acid residues operate in concert, which play an important role for the chiral preference of artificial siderophore complex **1**. The bioavailability of **1** was also investigated using *Microbacterium flavescens* which has ferrichrome receptors but lacks the ability to produce siderophores. Interestingly, complex **1** promoted the growth of this mutant. Therefore, the Fe^{III}*R*-TAAE complex, which has structural features that are similar to those of ferrichrome, might be a good functional model compound for the ferrichrome-type siderophore. Detailed investigations are now under way.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture of Japan (H. M.), for which we express our thanks.

Chiral oxovanadium complex catalyzed enantioselective oxidative coupling of 2-naphthols†

Chang-Ying Chu, Der-Ren Hwang, Sheng-Kai Wang and Biing-Jiun Uang*

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 300, Republic of China. E-mail: bjuang@mx.nthu.edu.tw; Fax: +88 6 3 5711082; Tel: +88 6 3 5721224

Received (in Cambridge, UK) 20th February 2001, Accepted 20th April 2001
First published as an Advance Article on the web 15th May 2001

The enantioselective oxidative coupling of 2-naphthols using 2 mol% chiral oxovanadium complex under mild conditions afforded chiral BINOLs in moderate enantioselectivity.

Vanadium plays a vital role in biological systems with its participation in redox processes catalyzed by enzymes such as bromoperoxidase[1] and nitrogenase.[2] The utility of vanadium complexes in oxidation, reduction and Lewis acid promoted reactions is well documented.[3] Except for oxidation of sulfides[4] and epoxidation of allylic alcohols,[5] there are very few vanadium complex catalyzed enantioselective reactions. Recently we reported the aerobic oxidative coupling of 2-naphthols and phenols catalyzed by $VO(acac)_2$.[6] Replacement of acac in this complex by chiral bidentate ligands, such as 3-formylcamphor and 3-heptafluorobutyrylcamphor, did not lead to any enantioselectivity in coupling products. Earlier, Fujita had utilized some chiral tridentate Schiff base ligands containing vanadium complexes in asymmetric oxidation of sulfides with moderate enantioselectivity.[4a]

In the light of these observations, we have studied the oxidative coupling of 2-naphthols using chiral tridentate oxovanadium complexes as a method for the enantioselective synthesis of chiral BINOLs; although enantioselective coupling of naphthols has been earlier reported, Katsuki used a ruthenium complex and Nakajima employed a copper complex as the catalyst in their reactions.[7] Herein, we report chiral oxovanadium complex catalyzed C–C bond formation in aryl compounds with 51% ee and 50–91% isolated yield (Scheme 1).‡

Following the literature procedure,[8] we have synthesized chiral oxovanadium complexes from aldehyde, (*S*)-valine or (*S*)-phenylalanine and vanadyl sulfate, and applied them in our reactions. At first, we examined oxidative coupling of 2-naphthol by using 10 mol% complex **1** as catalyst, molecular oxygen as oxidant and dichloromethane as solvent, but the product could only be isolated in trace amounts (Table 1, entry 1). Earlier Carrano and Tsuchida reported that vanadium(IV) undergoes disproportion to vanadium(III) and vanadium(V) in strong acidic condition.[9] When we added a catalytic amount of trifluoromethanesulfonic acid to the reaction mixture, it led to improved chemical yield but with only 27% ee (Table 1, entry 2). Catalysts **2** to **4** gave similar enantioselectivity in these reactions (Table 1, entries 3–5). Complexes containing bulkier amino acids, such as (*S*)-*tert*-leucine and (*S*)-phenylglycine as ligands, did not produce appreciable enantioselectivity. We

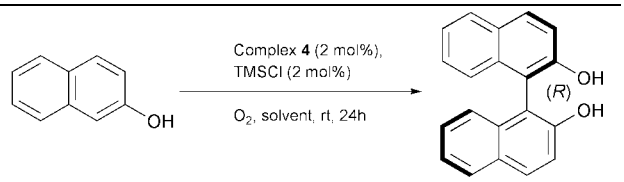
 DOI: 10.1039/b101670i

Table 3 Solvent effect for enantioselective oxidative coupling of 2-naphthol



Entry	Solvent	Yield (%)	Ee (%)[a]
1	CH_2Cl_2	73	48
2	$CHCl_3$	82	51
3	$(CH_2Cl)_2$	38	46
4	CCl_4	12	13
5	CH_3CN	46	8
6	THF	24	0

[a] Determined by HPLC with Kromasil 100-5CHI-DMB column (iPrOH–hexane = 5:95, 1 mL min^{-1}).

presumed that the electronic effect of substituents in the aromatic ring could influence catalyzing oxidative coupling, and investigated complexes containing 3,5-di-*tert*-butyl, 3-*tert*-butyl, 5-methoxy and 5-nitro substituents, but no significant enantioselectivity was observed with these complexes. However, we observed a marginal increase in enantioselectivity when the concentration of the substrate was increased from 0.1 to 0.5 M (Table 1, entry 7). An interesting feature was that enantioselectivity increased with decrease in concentration of complexes from 10 to 2 mol%, more so, in the case of complex **4** (Table 1, entry 8), and (*R*)-binaphthol was obtained in 42% ee.

To study the promoter effect, we used various additives. The enantioselectivity was better in TMSCl than in TMSOTf, and the chemical yield was a little lower (Table 2, entry 4). There was no change in enantioselectivity with variation of silyl groups in the additives, but it affected the reaction rate (Table 2, entries 4–6). Polar chlorosolvents such as dichloromethane, chloroform and 1,2-dichloroethane merely improved the enantioselectivity (Table 3).

Table 4 Enantioselective oxidative coupling of 2-naphthol derivatives

Entry	Naphthol	Time/h	Yield (%)	Ee (%)[a]
1		24	82	51
2		24	91	51
3		24	50	51
4		69	trace	—

[a] Determined by HPLC with Kromasil 100-5CHI-DMB column (*i*PrOH–hexane = 5:95, 1 mL min^{-1}).

The results obtained from the enantioselective oxidation of other substituted 2-naphthols catalyzed by complex **4** are summarized in Table 4. No variation in enantioselectivities was observed, but reaction rate was increased with electron donating capacity of the substituent.

In conclusion, oxovanadium complex has been used for the first time[10] in the enantioselective coupling of 2-naphthols. A low concentration requirement of catalyst, mild reaction conditions and high chemical yields render our method attractive.

We are grateful to the National Science Council, Republic of China, for support of this work.

Notes and references

‡ *Representative procedure for enantioselective oxidative coupling of 2-naphthols*: to a stirred solution of complex (0.1 mmol) and TMSCl (13 μL, 0.1 mmol) in chloroform (10 mL) exposed to molecular oxygen at room temperature was added 2-naphthol (5 mmol). After 24 h, the reaction mixture was treated with 6 M HCl (10 mL) and extracted with dichloromethane (3 × 20 mL). The combined organic extracts were dried (Na_2SO_4), and concentrated. The residue was purified by silica gel column chromatography eluting with ethyl acetate–hexane (1:5) to furnish the coupling product.

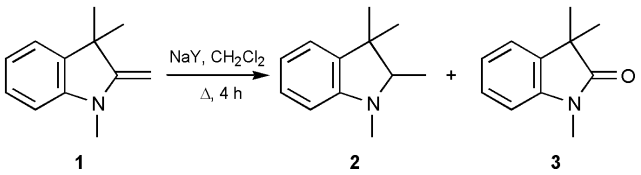
Received (in Cambridge, UK) 6th March 2001, Accepted 9th April 2001
First published as an Advance Article on the web 11th May 2001

The first observation of an acid-catalysed reaction subordinated to the occurrence of an electron transfer upon the incorporation of an electron-rich alkene in NaY zeolite is reported; the key point is the generation in the electron transfer process of suitable hydride donor species that react with the carbocation generated in the acid catalysed mechanism.

It is well documented that acid zeolites can behave either as solid acids or as electron aceptors.[1–8] In the former case the resulting reaction mechanism generally involves carbocations while in the latter case the key reaction intermediates are radical cations. Studies showing the concurrent ocurrence of both type of processes are rare. Herein by using an electron-rich alkene, 1,3,3-trimethyl-2-methyleneindoline **1** (Scheme 1), we provide



1 **2** **3**

Scheme 1

evidence that: (i) the products of both mechanisms (proton or electron transfer) are different and characteristic of each type of reaction intermediate and (ii) formation of the acid-catalysed product does not occur unless the electron-transfer product is formed previously (subordination).

A highly reactive, electron-rich alkene **1** was selected for the present study.† Upon stirring a dichloromethane solution of this indoline in the presence of thermally dehydrated NaY zeolite at reflux temperature under aerated conditions the progressive disappearance of the starting material, accompanied by the formation of 1,2,3,3-tetramethylindoline **2** (40%) and 1,3,3-trimethyl-2-indolinone **3** (60%) was observed (Scheme 1). This product distribution is not unprecedented and it parallels those found in the reaction of 1,1-diphenylethene over CaY zeolite wherein 1,1-diphenylethane and benzophenone were formed.[9–11]

Addition of a small amount of pyridine (10 mg g^{-1}) totally quenches the reaction and neither of the two products was formed. This can be taken as evidence that the reaction involves the weak acid sites present in commercial batches of NaY. Precedents for acid-catalyzed reactions promoted by NaY have been reported previously for vinylanisole and anethole dimerisation[12] and spectroscopic titration of NaY acid sites has also been reported.[13] We have found that this product distribution is not specific to NaY but that liquid acids such as trifluoroacetic or methanesulfonic acids behave analogously.

It is obvious that the formation of indolinone **3** should involve as reagent either molecular oxygen or water, or both. In an attempt to clarify this point, the reaction of indoline was carried out under argon atmosphere. However, when indoline **1** was refluxed in the presence of thermally activated NaY under Ar atmosphere, not only the formation of indolinone **3** but also the formation of 1,2,3,3-tetramethylindoline **2**, which does not incorporate any oxygen atoms in its molecular formula, is quenched. Clearly, the formation of both products is inhibited by adding a base or in the absence of molecular oxygen.

Raman spectra of indoline **1** adsorbed into NaY zeolite under Ar atmosphere indicates that under conditions in which no products are observed in the liquid phase, indoline **1** is stable upon incorporation within NaY.

Fig. 1 shows the diffuse reflectance UV–VIS spectra of the corresponding NaY sample obtained after incorporation of indoline **1** under argon atmosphere (a) and under aerated conditions (b). In the latter case, the extra band at 440 nm matches the absorption band of indolinone **3** in dichloromethane solution, thus providing spectroscopic evidence that this product is formed rapidly upon incorporation of **1** within NaY in the presence of air.

To disclose the reaction mechanism of formation for both products, indoline **1** was submitted to photochemical oxidation under typical electron transfer conditions. It is known that 1,4-dimethoxybenzene (DMB, E = 1.34 V, *vs.* SCE) in the presence of oxygen is a selective electron transfer photosensitizer that does not generate singlet oxygen.[14] Photosensitized irradiation of indoline **1** (E = 0.76 V, *vs.* SCE) in acetonitrile (0.5 wt% water content) containing DMB gives rise to the formation of indolinone **3** with almost complete selectivity at 98% of indoline conversion (Scheme 2). Thus, based on the known ability of zeolites to promote single electron transfer reactions[15] and on the results of the photoinduced electron transfer that shows that the radical cation of compound **1** leads exclusively to indolinone, we propose that the most reasonable reaction mechanism to explain the formation of indolinone involves the indoline radical cation (Scheme 3).

Concerning the formation of tetramethylindoline **2**, it has been reported that treatment of 1,1-diphenylethylene and benzonorbornadiene with CaY leads to the corresponding saturated 1,1-diphenylethane and benzonorbornane through the

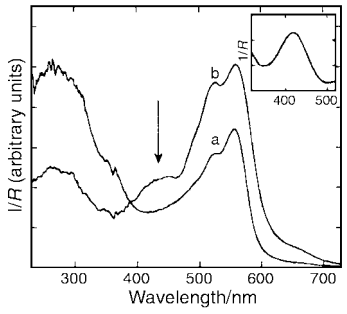


Fig. 1 Diffuse reflectance UV–VIS spectra of indoline **1** adsorbed onto NaY in the presence of air (a) and under Ar atmosphere (b). The insert shows the UV–VIS spectra of a dichloromethane solution of indolinone **2**.

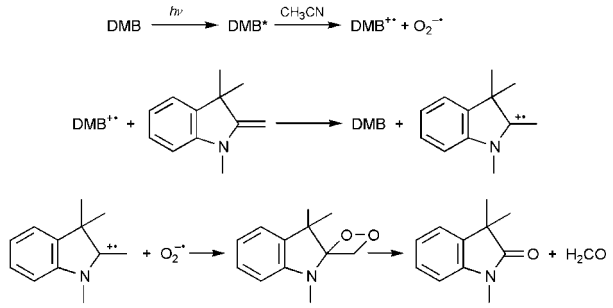
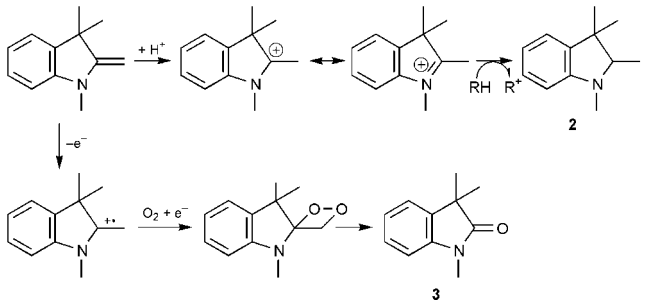
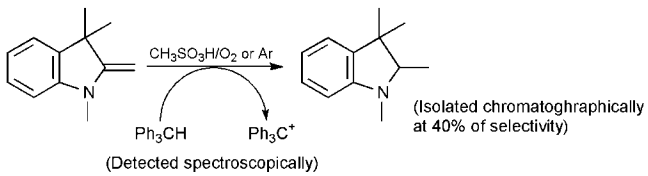


Scheme 2



Scheme 3

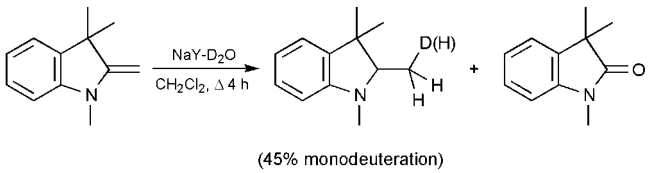
corresponding radical cation.[16] Other reports have invoked a radical cation intermediate to affect the C=C double bond hydrogenation.[17] However, the fact that the photoinduced DMB electron transfer reaction does not give detectable amounts of compound **2**, seems to rule out this possibility. An alternative explanation for the formation of **2** would be acid-catalyzed protonation to generate a carbocation followed by hydride abstraction. To support this reaction mechanism, a reactive hydride donor such as triphenylmethane (TPM) was added to a solution of indoline **1** in methanosulfonic acid (Scheme 4).



Scheme 4

Under these conditions, both in the presence or absence of oxygen, 1,2,3,3-tetramethylindoline was formed in 40% selectivity at 90% indoline conversion.‡ Concurrently the triphenylmethyl cation characterized by 405 and 425 nm bands in the UV–VIS spectrum of the acid solution was observed.

To further support the mechanism shown in Scheme 4, the NaY zeolite was submitted to deuteration by two consecutive cycles consisting in soaking the NaY solid with D_2O and subsequent drying at 110 °C. The resulting deuterated zeolite was used for the reaction with **1**. The corresponding GC–MS of the reaction mixture showed the presence of 2-deuteromethyl-1,3,3-trimethylindoline at a level of 45% of the total amount of **2** (Scheme 5). This result supports that formation of **2** occurs

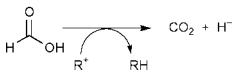


Scheme 5

through proton transfer from the zeolite framework to the 2-methylene substituent in a Markovnikov manner. The incomplete deuteration can be explained by the incomplete deuteration of the zeolite OH or by back H/D exchange.

The absence of oxygen should exclusively inhibit formation of compound **3** the only product containing oxygen. To explain why the absence of oxygen also inhibits formation of **2**, we speculated on the possibility that the hydride donor required in the formation of **2** arises from the formation of **3**. In this context, it should be noted that formation of **2** according to the conditions of Scheme 3 should occur equally well both in the presence or absence of oxygen.

Thus, we suggest that formaldehyde, formic acid or any product derived thereof could act as hydride donors in the formation of **2**. Since these species are formed concommitantly with **3** this would explain why **2** is not formed under conditions in which **3** is inhibited. In this regard, it is well documented that formic acid can be an effective reducing agent and also can act as a hydride donor according to eqn. (1).[18]



(1)

In summary, incorporation of an electron rich alkene 1,3,3-trimethyl-2-methyleneindoline within the voids of NaY zeolite gives rise to a product distribution characteristic of the concurrent operation of two different reaction mechanisms involving electron transfer and acid catalysis. In the latter case, formation of the corresponding product requires a hydride donor species that arises in the electron transfer pathway. Our report constitutes the first example establishing a connection between the products of these two different mechanisms.

Notes and references

† Adsorption of indoline (Aldrich) within NaY (P.Q. Industries), was accomplished by heating at reflux temperature under magnetic stirring a suspension of NaY zeolite (1 g) previously dehydrated (500 °C, 5 h) in a solution of indoline **1** (100 mg) in CH_2Cl_2 (25 ml) for 4 h. At the end of the reaction the solid was filtered off, and Soxhlet extracted with CH_2Cl_2. The combined CH_2Cl_2 supernatant and extraction liquor was analysed by GC and GC–MS.

‡ Residual amounts of water interact with the formed cation decreasing the process selectivity.

X-Ray analysis of two biomimetic $(N_3ZnL)^{2+}$ complexes with L = ethanol and formamide revealed that hydrogen bonding and CH/π interactions between the guest ligand L and the calix[6]arene host structure play a key role in their stabilization.

Recognition of the importance of zinc enzymes in biological processes is ever increasing. The active site of mononuclear enzymes often displays a pseudo-tetrahedral Zn^{2+} ion coordinated by three amino-acid residues and a labile water molecule. Among them, the recurrent tris(histidine) coordination set (as in Adamalysin II, Atrolysin C, Carbonic Anhydrase)[1] has motivated the design of synthetic analogues based on N_3 ligands. However, tetrahedral dicationic zinc complexes have proved difficult to stabilize. We have recently described a supramolecular system based on a *tert*-butylcalix[6]arene functionalized in alternating positions by three imidazole groups.[2–4] The neutral ligand $X_6Me_3ImMe_3$, which presents three *N*-methyl imidazole donors (ImMe) associated to a cavity that mimics the enzyme pocket, was shown to stabilize four-coordinated zinc species N_3ZnL^{2+} with various neutral molecules L, including amines, alcohols, amides, nitriles and even aldehydes. An amino and a nitrilo complex were characterized crystallographically.[2] We describe here two novel adducts $[Zn(X_6Me_3ImMe_3)L]^{2+}$, one with ethanol (L = EtOH) and the other with formamide (L = NH_2CHO). Their X-ray structures revealed that hydrogen bonding and CH/π interactions between the calix[6]arene host and the guests L play an important role in stabilizing of the complexes. To our knowledge, they provide the first examples of stable four-coordinated Zn dicationic complexes presenting a terminal aliphatic alcohol[5] or amide[6] ligand. Both compounds are strongly relevant to the enzyme/substrate complexes in mononuclear zinc biological systems.

As previously demonstrated by ^{1}H NMR spectroscopy, the water ligand in complex $[Zn(X_6Me_3ImMe_3)(H_2O)](ClO_4)_2$ is easily displaced by alcohols and amides (Scheme 1). We succeeded in growing X-ray quality crystals† of the ethanol adduct $[Zn(X_6Me_3ImMe_3)(EtOH)]^{2+}$ out of an acetone solution of the aqua complex to which 10 molar equivalents of EtOH were added. The molecular structure, displayed in Fig. 1, shows a tetrahedral complex where Zn^{2+} is wrapped by the three imidazole arms of the calixarene-based ligand. The average Zn–

 DOI: 10.1039/b102322p

N_{Im} bond length (1.981 Å) is comparable to those of the related propionitrile adduct (1.996 Å) but shorter than in the heptylamine complex (2.007 Å).[2] A bound EtOH molecule is buried deeply inside the calixarene conic cavity. The Zn–O distance [1.984(5) Å] is similar to that of the only other reported four-coordinate Zn–alcohol complex [1.993(3) Å].[5] It is however significantly shorter than those reported for the Zn–alcohol adducts in Liver Alcohol Dehydrogenase (2.0–2.1 Å). This may be attributed to a different overall charge in the coordinated metal center, which is negative in the enzyme.[7] The ethanol OH group points selectively toward one of the OCH_2ImMe units. The corresponding shorter O···O distance (2.86 *vs.* 3.56 and 3.40 Å for the others) indicates the presence of a strong hydrogen bond. Also noteworthy is the position of the ethanol carbon skeleton in the π-basic cavity. The methyl group stands just in front of an aromatic anisole ring with a perpendicular C···Ar distance of 3.67 Å. The methylene group points toward another anisole moiety at a perpendicular C···Ar distance of 3.82 Å. These values are typical of CH/π interactions.[8]

The X-ray structure† of an amide adduct was obtained with a slightly modified ligand, $X_6Et_3ImEt_3$.‡ Single crystals of $[Zn(X_6Et_3ImEt_3)(NH_2CHO)]^{2+}$ were grown by Et_2O diffusion into a benzonitrile solution of the aqua precursor to which 20 molar equivalents of formamide were added. As in the other related structures, the tetrahedral Zn^{2+} ion is coordinated to all three imidazoles with a comparable averaged $Zn–N_{Im}$ bond length (1.984 Å). The amide ligand sits inside the calixarene cavity (Fig. 1) with a short Zn–O distance [1.897(9) Å],[6] which again reflects a highly acidic zinc center. Two additional anchorage points fix the guest molecule in the center of the cavity. On one side, a hydrogen bond hangs the NH_2 group next to one oxygen from the calixarene skeleton [d(N···O) = 3.08 Å and correspondingly, d(NH···O) = 2.29 Å]. In the opposite direction, a CH/π interaction draws the guest CH group in front of one of the aromatic rings of the host with a perpendicular C···Ar distance of 3.60 Å.

The ability of calixarene to undergo a host–guest relationship with organic molecules has already been described in terms of CH/π interaction.[8,9] It has also been recognized that these interactions can help in stabilizing an enzyme–substrate complex.[8,10] In the specific case of Liver Alcohol Dehydrogenase,[7] Phe-93 interacts with sulfoxide-based inhibitors that coordinate the zinc dication.[11,12] The reported distances (3.7–3.8 Å) are very similar to that (3.67 Å) described above for the methyl group of the ethanol ligand. More important however, are the interactions of the calixarene aromatic structure with the CH groups that are directly connected to the O-atom coordinating the metal center (OCH_2– and O=C*H*– for L = EtOH and NH_2CHO, respectively). Indeed, these hydrogen atoms have an exacerbated acidic character that should increase the stabilizing effect of the interactions with π systems. Again, an interesting comparison can be made with the X-ray structure of LADH reporting a tetrahedral Zn center that binds EtOH in close contact with Phe-93.[7] The distance from the ethanol $–CH_2–$ hydrogen atom closest to the center of the aromatic ring is 3.15 Å in the enzyme. For the calixarene-based Zn model complexes, we found 2.92 Å for $–CH_2OH$ (L = EtOH) and 2.70 Å for –C*H*=O (L = NH_2CHO). The distance from the Zn ion to the center of the same phenyl rings is, in each case, 5.45, 5.41, 5.42 Å, respectively. Hence, this can be viewed as a metal ligand aromatic cation/π interaction, as recently suggested in a study concerned precisely with metalloproteins.[10] Finally, hydrogen bond networks have often been observed in enzyme active sites and in particular for the zinc-bound alcohol and Ser-48 in LADH.[13]

In conclusion, we have structurally characterized two novel dicationic tetrahedral Zn complexes that display unusual and remarkable stability. Both the ethanol and the formamide adducts are interesting structural models for the species involved in the catalytic cycle of Zn peptidases or LADH as these enzymes present similar stabilizing interactions. It is worth noting that these new data suggest that a sulfur-rich coordination core as in LADH is not a specific requirement for the stabilization of tetrahedral zinc–alcohol complexes, but might rather be necessary for substrate activation toward hydride transfer. We are currently studying the reactivity of these so-called *Zn funnel complexes*.

Notes and references

† The crystals were measured on a Nonius KappaCCD diffractometer. The structures were solved by direct methods and refined using the program SHELXL97. As usual with this series of compounds, the crystals were very sensitive to desolvation. The hydrogen atoms were added at idealized positions. In the calculations, they were treated as riding atoms and the U_{iso} were free to refine, except for the two hydrogens bonded to the nitrogen of the amide ligand. For these latter, the U_{iso} were fixed at 1.5 × U_{eq} of the nitrogen atom before the last cycles of refinement. *Crystal data* for $[Zn(X_6Me_3ImMe_3)(EtOH)](ClO_4)_2{\cdot}Me_2CO$: $C_{89}H_{120}N_6O_{16}Cl_2Zn$, M_w = 1666.24, triclinic, space group $P1$, a = 13.639(1), b = 16.006(1) c = 22.799(1) Å, α = 88.68(1), β = 78.12(1), γ = 68.24(1)°, V = 4515.8(5) Å^3, Z = 2, D_c = 1.225 g cm^{-3}, μ(Mo-Kα) = 0.396 cm^{-1}, 13013 reflections measured at 173 K, 1039 parameters refined on F^2 using 12869 unique reflections to final indices $R[F^2 > 4\sigma F^2]$ = 0.112, wR = 0.307 [w = $1/[\sigma^2(F_o^2) + (0.2P)^2 + P]$ where P = $(F_o^2 + 2F_c^2)/3$]. One Bu^t and one counter ion oxygen were split on two distinct sites with multiplicities of 0.7 and 0.3 because of static disorders. The final residual Fourier positive and negative peaks were equal to 0.70 and −0.78, respectively.

Visible light induced ring-opening metathesis polymerisation of cyclooctene

Lionel Delaude, Albert Demonceau and Alfred F. Noels*

Center for Education and Research on Macromolecules (CERM), Institut de Chimie (B6a), Université de Liège, Sart-Tilman par 4000 Liège, Belgium. E-mail: af.noels@ulg.ac.be

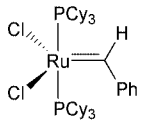
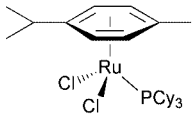
Under visible light irradiation, ruthenium–arene complexes bearing *N*-heterocyclic carbene ligands with aryl substituents – either preformed or generated *in situ* – are active catalyst precursors for the ROMP of cyclooctene already at room temperature.

Thanks to the development of well-defined ruthenium-based catalyst precursors, ring-opening metathesis polymerisation (ROMP) has become a valuable tool for the preparation of synthetic macromolecules.[1] A major breakthrough was achieved in the mid-nineties by Grubbs and coworkers with the discovery of complex **1**, a very efficient and highly tolerant catalyst precursor for olefin metathesis reactions.[2] At approximately the same time, we reported that the 18-electron complex **2** was also a versatile and efficient promoter for the ROMP of both strained and low-strain olefins when activated by a suitable carbene precursor such as trimethylsilyldiazomethane (TMSD).[3]



1



2

Replacement of one of the two phosphine ligands in **1** with more electron-donating *N*-heterocyclic carbene ligands (NHCs) significantly improved its metathesis activity and paved the way for a new generation of ruthenium–alkylidene catalyst precursors.[4] Herein, we present preliminary results obtained for the ROMP of cyclooctene (a typical low-strain cyclic olefin) when a variety of NHCs were substituted for the tricyclohexylphosphine ligand in **2**. Thus, we have prepared complexes **3a–i** and **4** from $[RuCl_2(p\text{-cymene})]_2$ and the corresponding NHCs.[5,6] The free carbene ligands were obtained from the parent imidazole-2(3*H*)-thiones[7] (**3a**,**c**,**e**,**h**) or from imidazol(in)ium chlorides[8] (**3b**,**d**,**f**,**g**, **4**) by reduction with potassium or deprotonation with potassium *tert*-butoxide or hydride, respectively. The dichlorocarbene in **3i** was the adduct of 1,3-dimesitylimidazol-2-ylidene and CCl_4.[9]

Polymerisation of cyclooctene in PhCl for 4 h at 60 °C served as a test reaction for our initial screening. These experimental conditions, complemented by TMSD initiation, were found optimal in our previous studies with **2**.[3] Transposed to the case of ruthenium–NHC catalyst precursors, they led to dichotomous results. Complexes **3a–e** bearing alkyl-substituted imidazol-2-ylidene ligands were devoid of any significant activity for the ROMP of cyclooctene, even in the presence of the TMSD carbene precursor. Monomer conversion stagnated below 16% and no polymer was isolated. Aryl-substituted ligands, on the other hand, afforded much more active catalysts. With **3f** and **3g**, gelation of the reaction mixture occurred within a few minutes and a near quantitative yield of polyoctenamer was obtained after 4 h at 60 °C. When the reaction temperature was lowered to *ca*. 20 °C, this remarkably high activity was maintained. Most interestingly, we found that the polymerisation of cyclooctene with catalysts **3f** and **3g** performed equally well in the absence of TMSD, whereas the addition of a diazo compound was a requisite with complex **2**.[3] The presence of light played a key-role in the nucleophilic carbene-based system and the intervention of a photochemical activation step was evidenced from the results gathered in Table 1.† With exclusion of light, a mere 20% yield of polymer was obtained after 2 h at room temperature. Normal lighting in the laboratory, a combination of daylight and of fluorescent light, was sufficient to raise the conversion to 93% within the same period. More intense visible light sources brought the reaction to completion while ensuring reproducible conditions. Thus, recourse to an ordinary 40 W 'cold white' fluorescent tube or to a 250 W incandescent light bulb standing 10 cm away from the standard Pyrex reaction flasks afforded quantitative yields of polyoctenamer. The differences in the emission spectra of the two light sources did not have any incidence on the polymer microstructure. In both cases, the polyoctenamer obtained was mainly *trans* and had a relatively narrow molecular weight distribution.

To the best of our knowledge, the only precedents of photoinduced ROMP described in the literature involved UV light irradiation. Systems based either on Schrock-type tungsten catalysts or on ruthenium– and osmium–arene complexes similar to **2** were able to polymerise strained cyclic olefins upon exposure to a 200 W Hg lamp, although high molecular weights and broad molecular weight distributions were obtained.[10] It was of note that neon light or strong daylight significantly enhanced the catalytic activity of complex **2** itself or of a

stoichiometric mixture of $[RuCl_2(p\text{-cymene})]_2$ and PCy_3 toward the ring closing metathesis (RCM) of numerous dienes in refluxing CH_2Cl_2.[11] Complexes **3f** and **3g**, on the other hand, displayed the same efficiency in the RCM of diallyl malonate, whether the reaction was carried out in the presence or in the absence of visible light.[6] This is in sharp contrast with our observations for the ROMP of cyclooctene, as we confirmed that complex **2** was completely inactive toward the olefin if the TMSD initiation was replaced by visible light illumination.

The UV–VIS spectra of **2** and **3g** freshly dissolved in PhCl were recorded under the exclusion of air and moisture. The phosphine derivative **2** had an absorption maximum at 369 nm while the carbene compound **3g** displayed two less intense bands centred at *ca.* 350 and 450 nm. The band at 350 nm corresponds to the absorption of the free carbene ligand while the band at 450 nm was more visible when $[RuCl_2(p\text{-cymene})]_2$ and 1,3-dimesitylimidazol-2-ylidene (2 equiv.) were mixed in the UV cell immediately prior to the analysis. Upon exposure to intense visible light for 30 min the band at 450 nm completely disappeared. Hence, we tentatively assign this visible absorption to the *p*-cymene moiety in **3g**. ^{1}H NMR spectroscopy confirmed that free *p*-cymene was released from **3g** when a PhCl-d_5 solution of the complex was irradiated in the presence or in the absence of cyclooctene. A similar arene decoordination had already been reported when **2** was treated with TMSD.[3] In that case concomitant formation of $[Ru]{=}CHSiMe_3$ active species was evidenced, whereas in the present system no propagating carbene was detected by NMR. However, the light-induced decomplexation of the η^6-arene ligand is believed to generate a highly reactive coordinatively unsaturated ruthenium species that triggers the catalytic process, though the exact nature of the active species in solution, as yet, remains elusive.

Next, we synthesised the new complexes **3h**, **3i** and **4** to compare their activities with those of **3f** and **3g**. Thus, the ROMP of cyclooctene initiated by various catalyst precursors was carried out under visible light irradiation and monitored by GC. Fig. 1 depicts the time-course of the polymerisations in PhCl at 20 °C. Compound **3g** remained the best catalyst precursor under the experimental conditions adopted. It slightly outperformed complex **3f** and the Grubbs' catalyst **1** and was a much better ROMP promoter than its saturated imidazolidine analogue **4**. Surprisingly, disubstitution of the 4,5 positions on the heterocyclic imidazole ring by methyl groups (in **3h**) gave a very poor catalyst, while the dichloro derivative **3i** displayed a steady albeit moderate activity, close to that observed with the TMSD-activated complex **2**.

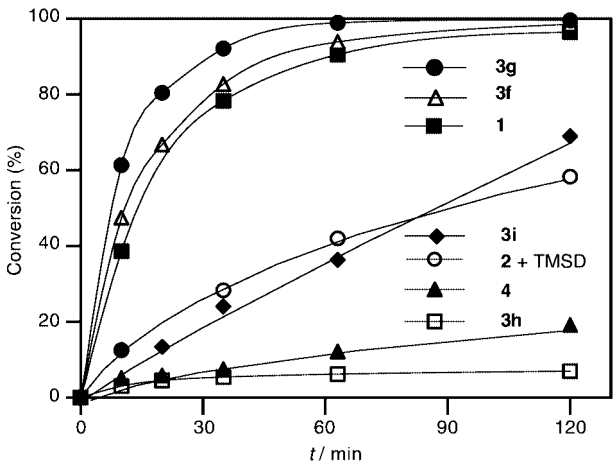

Fig. 1 ROMP of cyclooctene using catalysts **1**, **2**, **3f–i** and **4**. *Conditions*: 0.06 mmol of catalyst in PhCl (5 mL) at 20 °C, neon light irradiation, monomer/catalyst ratio 150. Conversion determined by GC.

Table 2 ROMP of cyclooctene at 60 °C catalysed by complex **3g** preformed or generated *in situ*

Catalyst precursor	Monomer conversion[a] (%)	Isolated yield (%)	σ_c[a]	$10^{-3}\ M_n$[a]	M_w/M_n[a]
5 + **6** + Cs_2CO_3	56	47	0.44	623	3.62
5 + **6** + KOBu^t	99	92	0.20	659	2.02
3g	> 99	84	0.17	269	1.97

[a] See Table 1 for details.

Finally, we examined the replacement of complex **3g** in our reactions by more easily available, commercial precursors. For this purpose, we tested mixtures of $[RuCl_2(p\text{-cymene})]_2$ **5** and 1,3-dimesitylimidazolium chloride **6** (2 equiv.) in the presence of various bases (4 equiv.) *viz*. 2,6-di-*tert*-butyl-4-methylpyridine, Cs_2CO_3, and KOBu^t. With all three bases, cyclooctene conversion did not exceed 10% after 2 h at room temperature, maybe because the ionic components were poorly soluble in PhCl at that temperature. When the polymerisations were carried out at 60 °C, the sterically hindered, non-nucleophilic pyridine did not afford any polymer, but Cs_2CO_3 led to a decent yield of polyoctenamer (Table 2)†. Most gratifyingly, we also noted that complex **3g** generated *in situ* with KOBu^t as a base was almost as effective as the preformed complex, opening the way to new, simple, straightforward polymerisation procedures.

We thank the EUTMR programme (HPRU-2000-10) for financial support.

Notes and references

† *Typical polymerisation procedure*: complex **3g** (3×10^{-5} mol) was dissolved in 5 mL of dry PhCl under Ar. The solution was irradiated by a 40 W 'cold white' fluorescent tube placed 10 cm away from the Pyrex reaction flask. Cyclooctene (7.5×10^{-3} mol) was added *via* a syringe and the reaction mixture was stirred for 2 h at r.t. or at 60 °C. The resulting gel was diluted with $CHCl_3$ (2×10 mL) and slowly poured into 500 mL of MeOH under vigorous stirring. The precipitated polyoctenamer was dried under high vacuum and characterised by NMR and GPC.

First published as an Advance Article on the web 11th May 2001

This is the first report of using ultrasound radiation for depositing a nanosized catalyst (iron oxide) into the pores of a mesoporous material (titania); the resulting catalyst is used for the oxidation of cyclohexane under mild conditions.

The synthesis of mesoporous materials offers a new possibility for the creation of catalysts that are effective in many technological processes. Their high surface area, large adsorption capacity, and ordered pore structure make them very useful for oil refining, petrochemistry, and organic synthesis.[1] At the same time, mesoporous materials have found many applications as supports for metal oxides, organometallic compounds, and other precursors, achieving high dispersion and functionalization of the active phase.[2] It has been shown that the incorporation of transition metals into the framework of MCM-41 allows the preparation of catalysts which are active in the oxidation of organic compounds.[3] The catalytic activity in the liquid-phase oxidation of cyclohexane with aqueous H_2O_2, exhibited by an iron catalyst incorporated into mesoporous molecular sieves (MCM-41), has been attributed to the formation of heterogenized iron complexes.[4] The yield of target products (cyclohexanol and cyclohexanone) with this catalyst did not exceed 3.5%.

As reported by Suslick *et al.*, the sonochemical method can be used as a tool to prepare nanosized amorphous metals.[5] If ultrasound irradiation is applied in the presence of an oxide support (such as silica, titania, alumina), the initially formed nanoscale clusters can be trapped in the support. Recently, sonication has been further developed to drive the deposition of iron, nickel, and cobalt on the surface of silica and alumina particles.[6] Sonochemistry has also been used for the preparation of mesoporous silica (MCM-41),[7a] mesoporous titania,[7b] and mesoporous yttria–zirconia. The main advantage in using sonochemistry for the synthesis of mesoporous materials is the drastic shortening of the time involved in the fabrication of the products from days to hours. It has been demonstrated that the wall thickness is perhaps also greater when the sonochemical technique is used. This communication is the first report where sonochemistry is employed to deposit amorphous nanoparticles into the pores of a mesoporous material.

The question as to whether or not sonochemistry can also be used for the deposition of a catalyst into the inner pores of mesoporous materials is examined here. Iron oxide was chosen as a testing probe for this purpose, which can be used as a catalyst in the oxidation of alkanes. We have reported recently on the oxidation of cyclohexane using sonochemically prepared nanostructured amorphous iron and cobalt catalysts or an amorphous iron–nickel alloy.[8] In that work, the reaction was carried out under high oxygen pressure (40 atm) at room temperature without a solvent, using isobutyraldehyde as an activator and a catalytic amount of acetic acid. Under these conditions, a high conversion of cyclohexane (*ca.* 40%) was obtained with an almost 80% selectivity to the target products cyclohexanone and cyclohexanol. Later it was found that the active catalyst was the nanostructured, sonochemically prepared transition metal (TM) oxide and not the amorphous TM.[9] In fact, due to the high reactivity of the amorphous materials, it is almost impossible to avoid oxidation of the nanophased TM. We report herein the results of cyclohexane oxidation with an iron oxide catalyst supported over mesoporous titania (MSPT). The preparation of the MSPT and the deposition of the iron oxide into its pores were carried out by a sonochemical method. In our synthesis we have followed the sonochemical preparation of nanophased amorphous Fe_2O_3 described previously.[10] The synthesis was carried out in the presence of mesoporous TiO_2. The activity of this catalyst was tested in the oxidation of cyclohexane under mild conditions.

The mesoporous titanium oxide was synthesized from titanium isopropoxide by ultrasound irradiation, as described elsewhere.[7b] Its surface area, measured by the BET nitrogen adsorption method (Micromeritics Gemini) after removal of the surfactant, reached 850 $m^2\ g^{-1}$ with a pore size of 1.5 nm and a pore volume of 0.53 ml g^{-1}.

The as prepared titania was irradiated by ultrasound with a solution of iron pentacarbonyl in decalin under an atmospheric pressure of air at 0 °C for 3 h.[11] The surface area of the sample was reduced to 570 $m^2\ g^{-1}$, with a pore size of 1.3 nm and a pore volume of 0.23 ml g^{-1}. The reduction in surface area and pore volume is due to the insertion of iron oxide into the mesopores.

The particle size of the titanium oxide, obtained from TEM measurements (microscope JEOL-JEM 100) is of the order of 100–200 nm. The outer surface area is *ca.* 1–2 $m^2\ g^{-1}$ as calculated from the particle size. Coating the outer surface with 5 nm catalyst particles (as estimated from particles found outside the pores) would not lead to the measured reduction in surface area for the titania/iron oxide composite. We, therefore, conclude that the major part of the iron oxide is inserted into the mesopores.

XRD analysis was performed with a Rigaku diffractometer (Model 2028, Cu-Kα radiation). In the as prepared sample, iron oxide was in an amorphous state. After heating under argon at 300 °C for 24 h, it crystallized in the form of magnetite.

Elemental analyses, performed using energy dispersive X-ray (EDX) analysis (Link ISIS Oxford) and atomic adsorption spectroscopy (AAS) (Perkin Elmer 2380 spectrometer) showed a difference in iron content (Table 1), the iron concentration obtained by EDX being higher than in the AAS results. This indicates that part of the iron is located on the surface of the catalyst, since EDX measures the surface concentration of the element, while AAS gives the total quantity. Nevertheless, the difference in concentration between these two analytical methods for the catalysts (prepared by the same method of sonochemical irradiation on mesoporous titania support) is lower than on commercial titania (Degussa P-25) (Table 1). This can occur because of the larger pore volume of mesoporous titania in comparison to that of conventional TiO_2 and thus a deeper impregnation of the active phase in the pores.

The binding energy measured by XPS for the $Fe2P_{3/2}$ and Ti $2P_{3/2}$ did not differ very much for the catalysts supported on

titania and sonochemically prepared iron oxide and were close to the values corresponding to conventional Fe_2O_3 and TiO_2 (Table 1).

We have studied the reaction of cyclohexane oxidation with iron oxide supported on mesoporous titania under mild conditions.[12] Table 1 presents the conversion of cyclohexane into oxidation products, using three forms of the catalyst: (a) unsupported nanophased amorphous Fe_2O_3; (b) amorphous Fe_2O_3 deposited on TiO_2 (Degussa P-25), which we have reported on previously[9] and (c) amorphous Fe_2O_3 deposited on TiO_2 (MSPT). Of these the Fe_2O_3/TiO_2 (MSPT) showed the highest activity in cyclohexane oxidation. The main products (selectivity almost 90%) were cyclohexanol and cyclohexanone, in the ratio 1.5:1. GC analysis revealed that in the presence of acetic acid, the activator (isobutyraldehyde) first reacted with oxygen, and the final oxidation product was isobutyric acid. The perisobutyric acid formed *in situ* during this process may react with metal species supported on the carrier to form oxometal complexes. Hydrogen abstraction from cyclohexane by oxometal complexes, followed by the formation of cyclohexanone and cyclohexanol, probably takes place as a result of the same free radical mechanism described earlier.[13]

After the first reaction the liquid phase was separated by centrifugation and the solid catalyst reused under the same conditions.[12] The conversion of a fresh portion of cyclohexane was scarcely changed in comparison with the first cycle. On the basis of these results it is reasonable to conclude that the sonochemically prepared nanosized iron oxide deposited on MSPT is a stable and effective catalyst. It can be used for the oxidation of cyclohexane, other hydrocarbons, and a number of other organic functional groups, which are currently under investigation.

In summary, this work demonstrates that sonochemistry can be used for anchoring nanomaterials in the pores of mesoporous compounds to produce effective catalysts.

11 *Synthesis of mesoporous iron–titania catalyst*: 0.5 g of mesoporous titania prepared by a previously reported method[7b] was added to 80 ml of decalin, and 0.8 ml of iron pentacarbonyl added to the solution (molar ratio of initial substances was 1:1). The mixture was irradiated by ultrasound under an atmospheric pressure of air at 0 °C for 3 h. The product was washed thoroughly with pentane and dried in vacuum.

12 The oxidation of cyclohexane was performed in a thermostated glass reactor using 2 ml (18.5 mmol) of cyclohexane, 2.5 ml (27.75 mmol) of isobutyraldehyde (molar ratio 1.5:1), a catalytic amount of acetic acid (0.06 ml, 1 mmol), and an amount of the catalyst equivalent to 0.015 mmol of iron oxide. The reaction mixture was magnetically stirred at 70 °C and 1 atm of oxygen for 15–17 h. The reaction products were analyzed by GC using the starting alkane as an internal standard. Conversion is defined as the percentage of the starting alkane converted into the products.

We have demonstrated the first application of multi-step synthesis within a micro reactor and have shown that peptides may be prepared in quantitative yield in a period of 20 min, compared with batch reactions where only moderate yields (40–50%) were obtained in a 24 h period.

During the past ten years, there has been a rapid growth in the development of micro-Total Analytical Systems (μ-TAS)[1–3] which exploit electroosmotic flow (EOF).[4] The development of micro reactor devices for chemical synthesis based on complementary technology is less common. However, recent research has shown that Suzuki[5] and Wittig[6] reactions may be performed using micro reactor systems.[7]

Peptides have been commonly prepared *via* solid supported techniques since its introduction by Merrifield in 1963.[8] Solid phase peptide synthesis is based on the addition of a protected amino acid residue to an insoluble polymeric support. The acid-labile Boc group[9] and base-labile Fmoc group[10] have been commonly used for *N*-protection. After removal of the protecting group the next protected amino acid may be added using either a coupling reagent or a pre-activated amino acid derivative. If this dipeptide is the desired product, it may be cleaved from the polymer support using various reagents, one of the more common methods being treatment with 25–80% HF.[11] If a longer peptide is required additional amino acids can be added by repeating further coupling reactions.

Solid phase peptide synthesis has the disadvantage that a fairly expensive polymer support is required. In addition, extra steps are added to the synthesis as a result of initially linking the amino acid to the support and finally having to remove the peptide from the polymer. In this paper a micro reactor has been used to prepare peptides using solution phase chemistry in an attempt to overcome some of the current problems associated with such syntheses.

The micro reactor devices used in this work were prepared using standard procedures developed at Hull.[12] A schematic of a typical micro reactor produced using such fabrication techniques is shown in the graphical abstract.† Microporous silica frits[13] were placed in the channels to prevent hydrodynamic flow occurring.

In the first instance a one-step reaction was considered in which an *N*-protected β-amino acid was reacted with an *O*-protected β-amino acid, to prepare the protected β-dipeptide. To enable the methodology to be applicable to the synthesis of more complex peptides, the use of orthogonal protecting groups was clearly required. After careful consideration, the base-labile Fmoc protecting group[10] was selected for *N*-protection while the Dmab ester[14] was chosen for protection of the carboxylic acid. Importantly, both protecting groups may be removed under mild conditions, since electroosmotic flow is retarded if the pH of the reaction is outside the range 3–10.

Commercially available Boc-β-alanine **1** was protected as the Dmab ester using an EDCI [1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride] and DMAP coupling reaction, to give the ester **2** in 92% yield in a bulk reaction (Scheme 1). Treatment of **2** with trifluoroacetic acid furnished the desired amine **3** in 61% yield, which was subsequently reacted with Fmoc-β-alanine **4** *via* a carbodiimide coupling reaction, to give a synthetic sample of dipeptide **5**.

Having prepared dipeptide **5**, it represented a synthetic target for preparation using the micro reactor. Prior to synthesis, the micro reactor channels were primed with anhydrous DMF to remove any air and moisture from the channels and the microporous silica frits. A standard solution of Fmoc-β-alanine **4** (50 μl, 0.1 M) in anhydrous DMF was added to reservoir A, a solution of EDCI (50 μl, 0.1 M) was placed in reservoir B and a solution of amine **3** (50 μl, 0.1 M) was placed in reservoir C. Anhydrous DMF (40 μl) was placed in reservoir D, which was used to collect the products of the reaction. Platinum electrodes were placed in each of the reservoirs (A, B and C positive, D ground) and an external voltage was applied to the channels inducing electroosmotic flow of the reagents. The reactions were conducted at rt for a period of 20 min, in order to acquire sufficient volume of product to determine the yield of the reaction. Analysis was achieved by high performance liquid chromatography (Jupiter C_{18} 10 μm, 4.6 × 250 mm, obtained from Phenomenex), mobile phase composition: 0.1% TFA in water and 0.1% TFA in acetonitrile, using a gradient system of 30% aqueous to 70% aqueous over 20 min, with a flow rate of 2.5 ml min^{-1} at rt).

When stoichiometric quantities of the reagents were used only *ca*. 10% conversion to peptide **5** was achieved when a voltage of 700 V was applied to the reagents (A, B and C). However, by using two equivalents of EDCI (0.2 M solution) the yield of the reaction was increased to *ca*. 20%. By applying a stopped flow technique (2.5 sec injection length with flow stopped for 10 sec) the yield of the reaction was further increased to 50%. Since the yield of the reaction appeared to greatly depend on the number of equivalents of EDCI used, we wished to further investigate the effect of carbodiimide concentration on the reaction, however we found that EDCI was insoluble in DMF above 0.2 M concentrations. In further experiments DCC was used as the coupling reagent as it was considerably more soluble in DMF. Using 5 eq. of DCC (0.5 M solution in reservoir B) a 93% yield of dipeptide **5** was obtained using the optimised conditions described above.

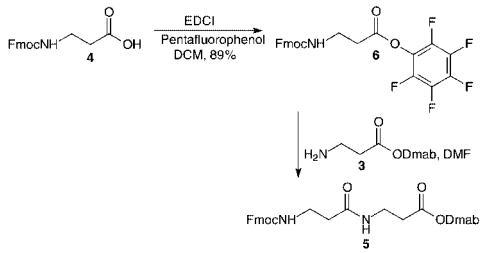
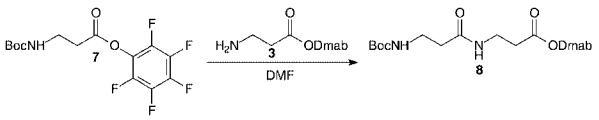
Another common method utilised in peptide bond formation involves the reaction of a pre-activated amino acid derivative, such as a pentafluorophenyl ester, with an amine.[15,16] Fmoc-β-alanine **4** was activated as the pentafluorophenyl ester **6** *via* an EDCI coupling reaction (Scheme 2). The pentafluorophenyl ester **6** was stable and could be stored indefinitely in the freezer. The ester **6** was subsequently reacted in bulk with amine **3** to produce dipeptide **5**.



Scheme 2 Preparation and reaction of pentafluorophenyl esters of Fmoc protected amino acids.

Having prepared dipeptide **5** *via* the alternative pre-activated strategy, we wished to investigate if the reaction could be performed in a micro reactor. A standard solution of the pentafluorophenyl ester of Fmoc-β-alanine **6** (50 μl, 0.1 M) in anhydrous DMF was added to reservoir A, a solution of amine **3** (50 μl, 0.1 M) was placed in reservoir B and anhydrous DMF (40 μl) was placed in reservoir D, which was used to collect the products of the reaction. It was found that using continuous flow of both reagents, where the ester **6** was maintained at 700 V and the amine **3** was maintained at 600 V, dipeptide **5** was produced in quantitative yield in just 20 min. This represented a significant increase in yield compared with the traditional batch synthesis where only 40–50% conversions were obtained.

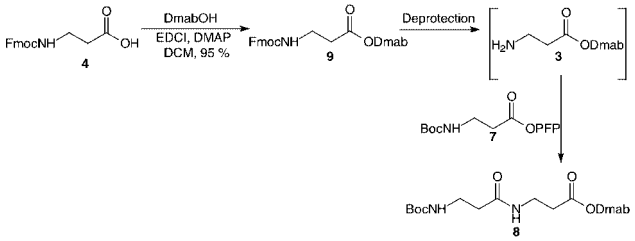
Similarly, the reaction between the pentafluorophenyl ester **7** of Boc-β-alanine and amine **3** was also investigated in the micro reactor (Scheme 3). In this case, when the reagents were mixed under a continuous flow regime, with both reagents maintained at 700 V, a quantitative yield of peptide **8** was observed. Importantly, this result demonstrates that both Boc and Fmoc protecting groups are suitable for use in the preparation of peptides using micro reactors.



Scheme 3 Reaction of pentafluorophenyl esters of Boc-β-alanine.

Having successfully demonstrated that peptide bonds could be formed in micro reactors using two common methods, we wished to show that we could extend the methodology to the preparation of longer chain peptides. Consequently, we needed to be able to conduct deprotection reactions in the micro reactor and subsequently perform further peptide bond forming reactions. Fmoc-β-alanine **4** was converted into the Dmab ester **9**, in a bulk reaction, using standard conditions (Scheme 4). It was proposed to convert ester **9** into amine **3** by deprotection of the Fmoc group in the micro reactor and subsequently react the amine '*in situ*' with pentafluorophenyl ester **7**, to give the dipeptide **8**. Treatment of **9**, with 10 eq. of piperidine in DMF using the micro reactor, resulted in 60–70% deprotection over a 20 min period, to give amine **3**.[17]

Subsequently, a standard solution of the Dmab ester of Fmoc-β-alanine **9** (50 μl, 0.1 M) in anhydrous DMF was added to reservoir A, a solution of piperidine (50 μl, 1.0 M, 10 eq.) was placed in reservoir B and a solution of pentafluorophenyl ester **7** (50 μl, 0.1 M) was placed in reservoir C, in an attempt to prepare dipeptide **8** using this multi-step approach. Anhydrous DMF (40 μl) was placed in reservoir D, which was used to collect the products of the reaction. The HPLC of the reaction mixture showed that Fmoc deprotection had occurred, however



Scheme 4 Multi-step peptide synthesis.

no peptide was evident. It was however found that the excess piperidine used in the reaction was reacting with the pentafluorophenyl ester **7** to give amide **10**.

As a result, an alternative method of Fmoc deprotection was required that would not cause the aforementioned problem. Using the micro reactor, the Dmab ester of Fmoc-β-alanine **9** was reacted with one equivalent of DBU to give the free amine **3** which was then reacted with the pentafluorophenyl ester of Boc-β-alanine **7**, in an attempt to form the dipeptide **8**.

In this case, when the reagents were mixed using continuous flow, with the reagents maintained at 700 V, product **8** was observed in typically 25% yield. By comparing the flows of each reagent at this stage we were able to optimise the reaction. The Dmab ester of Fmoc-β-alanine **9** was maintained at 750 V while reacted with DBU at 800 V. The deprotected amine was then reacted, using continuous flow, with the pentafluorophenyl ester of Boc-β-alanine **7** to give a conversion of 96%, based on the amount of Dmab ester **9** present at the end of the reaction.

Having shown that more complex peptides could be produced by removal of the *N*-protecting group we wished to determine if we could remove the Dmab protecting group using hydrazine. Hence, a solution of the Dmab ester of Fmoc-β-alanine **9** (50 μl, 0.1 M) in anhydrous DMF was added to reservoir A and a solution of hydrazine (50 μl, 0.1 M) was placed in reservoir B. Anhydrous DMF (40 μl) was placed in reservoir D, which was used to collect the products of the reaction. Using continuous flow of both reagents, maintained at 700 V, quantitative deprotection was observed to give carboxylic acid **4**.

We wish to thank Novartis Pharmaceuticals (P. W. and C. W.) for financial support. We are grateful to Dr Tom McCreedy (University of Hull) for help in fabricating the micro reactor devices.
