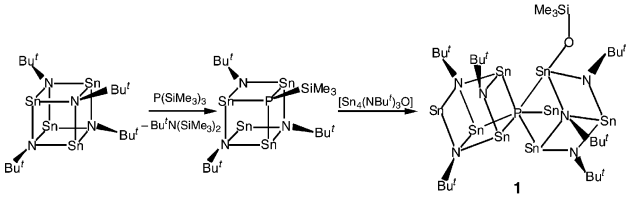
The reaction of $[SnNBu^t]_4$ (1 equiv.) with an excess of $P(SiMe_3)_3$ in THF–$PhCH_3$ was undertaken initially in order to obtain the substituted cubane $[Sn_4(NBu^t)_3(PSiMe_3)]$ [*via* elimination of $Bu^tN(SiMe_3)_2$]. However, unexpectedly the title complex [{$Sn_4(NBu^t)_3P$}{$Sn_4(NBu^t)_3(OSiMe_3)$}] **1** was obtained as the only isolable crystalline product (in low yield). The incorporation of the O centre within the $OSiMe_3$ group of **1** was confirmed by the subsequent structural characterisation of the complex, and is supported by the observation of a Si–O stretching band in the IR spectrum at 1175 cm^{-1}.[7] The low solubility of the complex once isolated precluded more extensive investigations of its solution structure. However, the observation of only two Bu^t resonances in the ^1H NMR spectrum of **1** (δ 1.15 and 1.11) suggests that the behaviour of the complex in solution is far from simple. The likely pathway to **1** involves the addition reaction of $[Sn_4(NBu^t)_3(PSiMe_3)]$ and the oxo cubane $[Sn_4(NBu^t)_3O]$ (as depicted in Scheme 1). It was assumed that the latter species arose from trace hydrolysis of the imido Sn^{II} cubane $[SnNBu^t]_4$ during storage of the reaction mixture; a previously established route to the oxo cubane.[6] This view is supported by the isolation of **1** from the reaction of $[SnNBu^t]_4$ (1 equiv.) and an excess of $P(SiMe_3)_3$, followed by addition of $[Sn_4(NBu^t)_3O]$ (1 equiv.).† Significantly, attempts



Scheme 1

to prepare the complex by reaction of $[Sn_4(NBu^t)_3O]$ (2 equiv.) with $P(SiMe_3)_3$ (1 equiv.) failed to produce **1**, indicating that the imido cubane $[SnNBu^t]_4$ is involved in the initial step.

The X-Ray crystallographic study of **1** shows that molecules of the complex consist of a pseudo 'double-cubane' $Sn_8(NBu^t)_6P$ core (Fig. 1),‡ in which the two $Sn_4(NBu^t)_3$ cubane subunits are linked together by a P^{3-} ion. Although other Group 13 and 14 metal complexes containing the P^{3-} ion have been structurally characterised,[2] **1** is the first example in

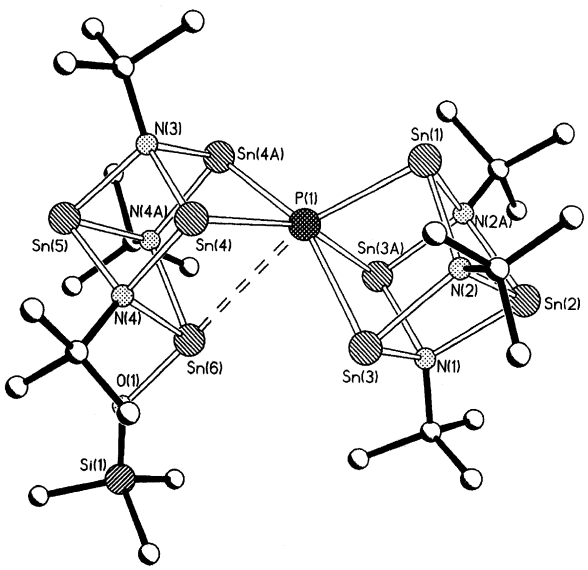


Fig. 1 The cage structure of **1**. H-atoms have been omitted for clarity. Key bond lengths (Å) and angles (°): Sn(1)–P(1) 2.580(4), Sn(1)–N(2) 2.219(7), Sn(1)–N(2) 2.219(8), Sn(2)–N(1) 2.20(1), Sn(2)–N(2,2A) 2.219(8), Sn(3)–P(1) 2.725(3), Sn(3)–N(1) 2.207(6), Sn(3)–N(2) 2.235(7), Sn(4)–P(1) 2.630(3), Sn(4)–N(3) 2.198(7), Sn(4)–N(4) 2.177(7), Sn(5)–N(3) 2.22(1), Sn(5)–N(4,4A) 2.187(7), Sn(6)···P(1) 3.298(4), Sn(6)–N(4) 2.265(8), Sn(6)–N(4A) 2.265(7), Sn(6)–O(1) 1.981(9), Si(1)–O(1) 1.64(1); Sn–N–Sn range 96.9(3)–107.0(3), N–Sn–N range 78.1(3)–81.4(3), N–Sn–P range 82.2(2)–98.3(2), Sn(1)–P(1)–Sn(3) 84.8(1), Sn(1)–P(1)–Sn(4) 118.0(1), Sn(2)–P(1)–Sn(3) 98.8(3), Sn(3)–P(1)–Sn(3A) 101.3(4), Sn(3)–P(1)–Sn(4) 94.70(5), Sn(3)–P(1)–Sn(4A) 155.4(2), Sn(4)–P(1)–Sn(4A) 82.7(1), N(4)–Sn(6)–O(1) 99.8(3), Sn(6)–O(1)–Si(1) 140.5(7).

DOI: 10.1039/b008108f

which the p-block metal is in a low-oxidation state (*i.e.* in which the metal lone-pair of electrons is retained).

Although they occur over fairly broad ranges, the Sn–N bond lengths [2.177(7)–2.265(8) Å] and Sn–N–Sn [96.9(3)–107.0(3)°] and N–Sn–N [78.1(3)–81.4(3)°] angles in **1** are similar to those found in structurally characterised imido Sn(II) cubanes of the type $[SnNR]_4$ [*cf.* Sn–N range 2.15(1)–2.34(2) Å, Sn–N–Sn mean 98.4°, N–Sn–N mean 81.9°].[5,8] An unusual feature of **1** is the distorted six-coordinate geometry of the P^{3-} centre. The five Sn–P bonds involved with Sn(1) [2.580(4) Å], Sn(3,3A) [2.725(3) Å] and Sn(4,4A) [2.630(3) Å] fall within the range previously reported for bonds between anionic (R_2P^- and RP^{2-}) P centres and Sn^{II} (2.60–2.80 Å).[9,10] However, the remaining contact with the chemically distinct tin centre Sn(6) [3.298(3) Å] {which is bonded to the O centre of an Me_3SiO group [Sn–O 1.981(9) Å][11]} is clearly much weaker, and is around the value which could be estimated for that between a neutral phosphine (R_3P) and Sn^{II}.[10] The weakness of this contact is consistent with the absence of a vacant p orbital on Sn(6) and the apparent orientation of the metal lone pair towards the core of **1**. The coordination number of the Sn(II) centre and range of Sn–P distances in **1** are similar to that found in the NaCl-type lattice structure of tetragonal SnP [with Sn–P bond lengths of 2.55(6), 2.74(1) and 3.41(1) Å].[12] However, the bonding pattern in **1** is markedly different to that found in all previously reported molecular p-block metal compounds containing P^{3-} anions, which have three-coordinate P atoms and electron-precise metal–P bonding.[2] Two bonding schemes may be used to rationalise the Sn_6P unit in **1**. Although the description of the structure of **1** as a donor complex of the $[Sn_4(NBu^t)_3P]^-$ anion and a $[Sn_4(NBu^t)_3(OSiMe_3)]^+$ fragment is an attractive one [*i.e.* containing a 2e–3c bond between P(1) and Sn(4) and (4A)], a model involving a 2e–3c bond with Sn(3) and Sn(3A) appears to be most consistent with the variation of the Sn–P bond lengths in the complex.

In conclusion, the first low-oxidation state p-block metal complex containing a P^{3-} anion has been prepared. The synthetic route used in its preparation ('silyl/imido elimination') exemplifies a new, potentially broad-ranging approach to a variety of molecular main group as well as transition metal species containing 'bare' P centres.

† *Synthesis of* **1**: $[SnNBu^t]_4$ (0.42 mmol) was prepared *in situ* by reaction of Bu^tNH_2 (0.18 mL, 1.70 mmol) with $Sn(NMe_2)_2$ (0.35 g, 1.70 mmol) in $PhCH_3$ (15 mL). The reaction mixture was brought to reflux briefly and stirred (2 h), to give a bright yellow solution. To this solution was added $P(SiMe_3)_3$ (0.42 mL, 1.45 mmol, excess) at room temperature. Immediately, a solution of $[Sn_4(NBu^t)_3O]$ (0.44 mmol) in THF (10 mL) was added. Stirring at room temperature (20 min) produced a deep red solution. Filtration followed by reduction of the solvent under vacuum (to *ca.* 3 mL) and storage (18 °C, 3 d) gave deep red cubic crystals of **1**. These were washed with Et_2O (2 × 5 mL) prior to analysis. Yield 0.090g (14%). Decomp. 153 °C to black solid. IR (Nujol mull), ν_{max}/cm^{-1} 1355m, 1250m, 1237w, 1175s (Si–O str.), 1092s, 1021s, 937m, 916m, 899w, 871w, 822s(sh), 801vs (air exposure led to a gradual loss of the bands at 1175, 937, 916, 899 and 822 cm^{-1} and to a change in color from red to yellow). ^{1}H NMR (+25 °C, 400.132 MHz, [D$_8$]-THF): δ = 1.15 (s, 18H, Bu^tN), 1.11 (s, 36H, Bu^tN), 0.11 (s, 9H, Me_3Si). ^{31}P NMR (+25 °C, 161.976 MHz, [D$_8$]-THF): δ = ×245.0 (s, poorly resolved shoulders). Anal. Found: C, 21.7; H, 4.2; N 5.4. Calc.: C 21.7; H, 4.2; N, 5.6%.

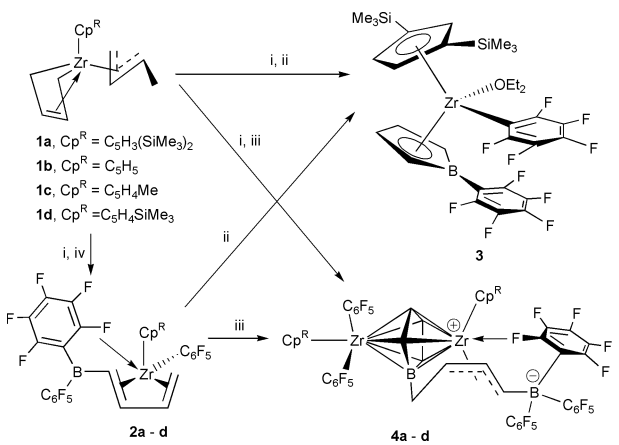
Warming mixtures of $(Cp^R)Zr(\eta^3\text{-}C_4H_7)(\eta^4\text{-}C_4H_6)$ and $B(C_6F_5)_3$ leads to complete transfer of all three C_6F_5 substituents of a $B(C_6F_5)_3$ molecule to give borole-bridged triple-decker complexes with a Zr_2C_4B core, a zwitterionic structure and an unusually strong Zr–F donor interaction.

Early transition complexes of the borole dianion $[C_4H_4BR]^{2-}$ have attracted attention as potential alkene polymerisation catalysts.[1] Two general synthetic strategies have been employed: the dehydrogenation of 2,5-dihydo-1*H*-boroles with various transition metal compounds,[2] or the reaction of metal halides with a pre-formed borole dianion.[3] We found recently that zirconium 1,3-diene complexes $(Cp^R)Zr(\eta^3\text{-allyl})(\eta^4\text{-diene})$ **1** react with $B(C_6F_5)_3$ *via* C–H activation and C_6F_5 transfer steps to give boryldiene compounds **2**;[4,5] for Cp^R = 1,3-$C_5H_3(SiMe_3)_2$ **2a**, this decomposes further under carefully controlled conditions (prolonged storage at 5 °C) *via* another C–H activation step to give the pentafluorophenylborole complex **3** (Scheme 1).[6] We now report a similar reaction sequence leading to the unexpected formation of zirconium triple-decker complexes **4** containing a novel *ansa*borole-allyl ligand.

Warming an equimolar mixture of $B(C_6F_5)_3$ and $Zr(\eta^3\text{-}C_4H_7)(\eta^4\text{-}1,3\text{-butadiene})Cp''$ [Cp″ = 1,3-$C_5H_3(SiMe_3)_2$] to 50 °C for 2 h gave a red solution which did not contain the expected **3** but a new product **4a** in high yield. Removal of the volatiles and recrystallisation from diethyl ether provided a red crystalline solid, identified as the triple-decker zirconium complex $Zr_2Cp''_2(C_6F_5)_2\{\mu\text{-}\eta^5:\eta^5\text{-}C_4H_4BCH_2\text{-}\eta^3,\kappa F\text{-}CHCHCHB(C_6F_5)_3\}\cdot 2Et_2O$ (**4a**·2Et$_2$O).† Formation of this product involves complete transfer of all three C_6F_5 substituents of one $B(C_6F_5)_3$ molecule, with C–H activation and loss of one C_6F_5 group as pentafluorobenzene. The role of the boryldiene complex **2a** as a reaction intermediate is supported by the formation of the same product from isolated **2a**.



Scheme 1 *Reagents and conditions*: i, $B(C_6F_5)_3$; ii, $-C_6F_5H$, toluene, 5 °C, 4 weeks, followed by addition of Et_2O; iii, $-C_6F_5H$, toluene, 50 °C, 2 h; iv, toluene, room temperature, reduced pressure, 2 h, $-C_4H_8$.

The ambient temperature ^{19}F NMR spectrum features a signal at δ −217.2 indicative of coordination of one of the *o*-F atoms of the formally anionic butenyl–$B(C_6F_5)_3$ moiety to the metal centre. Signal broadening due to *o*-F exchange is observed on heating to 70 °C. Similar evidence of *o*-F coordination is seen in the zwitterionic complex $Cp_2Zr(\eta^3\text{-}CH_2CHCHCH_2B(C_6F_5)_3]$[7] ($\delta$ −213.2), although in this case cooling to −86 °C was required to reach the slow exchange limit. Evidently the Zr···F interaction in **4a** is significantly stronger. The ^{11}B NMR spectrum shows two signals, one extremely broad peak at δ *ca*. 3 (borole-B) and a sharp peak at δ −12.8 for the butenyl–$B(C_6F_5)_3$ moiety. The borole is low-field shifted by *ca*. 20–30 ppm compared with other alkyl–borole systems,[8] probably due to the bridging nature of the ligand.

The structure of **4a** was confirmed by single crystal X-ray diffraction (Fig. 1).‡ The most striking feature of the structure is the bridging borole ligand, the boron atom of which is derived from $B(C_6F_5)_3$ that has lost all three C_6F_5 substituents. The boron is instead bonded to the butenylborate unit which in turn is η^3-bonded to Zr(1). This Zr atom is further coordinated to an *o*-F atom of the butenylborate ligand. The coordination sphere of the second metal centre Zr(2) is completed by a Cp″ and two C_6F_5 ligands.

There is little difference in the bonding distances of the two zirconium atoms with regard to the borole ring, with an average Zr–C length of 2.522(5) Å for Zr(1) and 2.521(5) Å for Zr(2). The Zr–B distances do differ however, with Zr(1)–B(1) of 2.534(6) Å and Zr(2)–B(1) of 2.609(6) Å; this is most probably due to the distortion imposed by the coordination of the allylic fragment to Zr(1). For the related borole complex $Cp''Zr(C_6F_5)\text{-}(\eta^5\text{-}C_4H_4BC_6F_5)\cdot OEt_2$[6] the Zr–C distances are shorter (average Zr–C of 2.455 Å). The Zr–F distance of 2.355(3) Å is significantly shorter than Zr···F interactions in comparable complexes, for example $[NEt_4]_2[\{C_5H_4B(C_6F_5)_3\}Zr(\mu\text{-}Cl)Cl_2]_2$ [2.430(2) Å],[9] $Cp''Zr(C_6F_5)\{\eta^4\text{-}C_4H_5B(C_6F_5)_2\}$ [2.441(7) Å],[4d] and $Cp_2Zr\{\eta^3\text{-}C_4H_6B(C_6F_5)_3\}$ [2.423(3) Å].[7] This is a reflection of the strength of this interaction, in agreement with the ^{19}F NMR evidence.

The reaction leading to **4a** is remarkable in several respects. Although triple-decker complexes involving a central borole ligand have been reported,[10–13] **4a** is the first example containing a group 4 metal. $B(C_6F_5)_3$, widely used as an activator for metallocene polymerisation catalysts because of its chemical stability,[14] acts here as a boron source after loss of all three of its C_6F_5 groups. The decomposition pathways of the boryldiene system **2a** are evidently strongly temperature dependent and are diverted from the formation of **3** at 5 °C to the binuclear complex **4a** by the simple expedient of raising the temperature. However, while **3** is formed only in the case of Cp″, the selective formation of complexes of type **4** is quite general and has led to isolation in high yields of **4b** (Cp^R = C_5H_5, 73%), **4c** (C_5H_4Me, 72.7%) and **4d**, ($C_5H_4SiMe_3$, 66%).

This work was supported by the Engineering and Physical Sciences Research Council.

Notes and references

† *Synthesis* of **4a**: a solution of Zr(C$_4$H$_7$)(C$_4$H$_6$)Cp″ (1.63 g, 3.98 mmol) in toluene (30 cm^3) at −78 °C was treated with a solution of B(C$_6$F$_5$)$_3$ (1.98 g, 3.87 mmol). The reaction was maintained at this temperature for 30 min and then allowed to reach room temperature. The volatiles were removed *in vacuo*, toluene (40 cm^3) was introduced and the reaction was stirred at 50 °C for 2 h. Removal of the solvent *in vacuo* provided a brown foam which was extracted with diethyl ether (50 cm^3). Concentration of this red solution to *ca*. 10 cm^3 and cooling to −20 °C gave **4a** as red crystals, yield 2.56 g, (82.3%). Anal. Found: C, 45.4; H, 3.3. $B_2C_{60}H_{51}F_{25}Si_4Zr_2$ requires C, 46.1; H, 3.3%. ^{1}H NMR (300 MHz, C$_6$D$_6$, 20 °C): δ −0.38, −0.01, 0.08, 0.20 (s, 9H each, SiMe$_3$), 1.51 (d, 2H, *J* 8.04 Hz, C*H*$_2$CHCHCHB(C$_6$F$_5$)$_3$), 3.36 (q, 1H, *J* 8.27 Hz, CH$_2$C*H*CHCHB(C$_6$F$_5$)$_3$), 4.81 (d, 1H, *J* 19.44 Hz, CH$_2$CHCHC*H*B(C$_6$F$_5$)$_3$), 5.81 (d, 1H, *J* 6.46 Hz, CH$_2$CHC*H*CHB(C$_6$F$_5$)$_3$), 3.91, 7.87 (m, 2H, *m*-C$_4$H$_4$B), 4.98, 6.81 (m, 2H, *o*-C$_4$H$_4$B), 5.51, 6.03, 6.66, 7.08 (m, 4H, 4,5-C$_5$H$_3$), 5.89, 6.74 (m, 2H, 2-C$_5$H$_3$) ^{11}B{^{1}H} NMR (96.2 MHz, C$_6$D$_6$, 20 °C): δ 3.0 (vbr, C$_4$H$_4$B), −12.8 [B(C$_6$F$_5$)$_3$]. ^{13}C NMR (75.6 MHz, C$_6$D$_6$, 20 °C): δ −1.20, −0.84, −0.69, −0.21 (SiMe$_3$), 14.95 [*C*H$_2$CHCHCHB(C$_6$F$_5$)$_3$], 81.40 [CH$_2$*C*HCHCHB(C$_6$F$_5$)$_3$], 98.71, 126.64 (*m*-C$_4$H$_4$B), 105.72, 111.34 (*o*-C$_4$H$_4$B), 119.73, 124.01, 124.78, 129.95 (4,5-C$_5$H$_3$), 121.54 [*C*HB(C$_6$F$_5$)$_3$], 123.87 [*C*HCHB(C$_6$F$_5$)$_3$], 127.69, 129.50 (2-*C*$_5$H$_3$). ^{19}F NMR (75.6 MHz, C$_6$D$_6$, 20 °C): δ −108.2 (s, br, 1F), −112.8 (s, vbr, 1F), −119.9 (s, vbr, 1F), −120.2 (s, br, 1F), −126.2 (s, 1F), −130.0 (s, vbr, 2F), −132.9 (s, br, 2F), −217.2 (m, 1F) (all *o*-C$_6$F$_5$), −152.1 (t, $^3J_{FF}$ 19.8 Hz, 1F), −152.5 (t, $^3J_{FF}$ 19.8 Hz, 1F), −157.1 (t, $^3J_{FF}$ 19.8 Hz, 1F), −157.6 (t, $^3J_{FF}$ 19.8 Hz, 1F), −159.0 (t, $^3J_{FF}$ 19.8 Hz, 1F) (all *p*-C$_6$F$_5$), −160.2 (t, $^3J_{FF}$ 19.8 Hz, 1F), −160.5 (m, 3F), −161.5 (s, br, 1F), −162.6 (m, 1F), −164.2 (m, 2F), −164.4 (m, 2F) (all *m*-C$_6$F$_5$).

β-Benzyl-γ-butyrolactones were synthesized in four transition metal catalysed reactions from butynediol, and alkylated to afford new, biologically active lignan analogues.

Lignans, dimers of phenylpropenes, are ubiquitous secondary plant metabolites.[1] They exhibit notable biological activities, in particular antiviral,[2] cytotoxic[3] and canceroprotective[4] properties. Many lignan syntheses have been reported in the past.[1,5] Two different strategies were most frequently followed for the synthesis of butyrolactone lignans **1**: 1. oxidative dimerization of *p*-hydroxycinnamic acids[6] and 2. alkylation of β-benzyl-γ-butyrolactones **2**.[7] Following these routes, between 6 and 13 steps were necessary to obtain this class of lignans. We reported recently the Stille coupling[8] of unsymmetrically protected 2-tributylstannylbuten-1,4-diols **3** with a variety of benzyl bromides.[9] This coupling reaction was the key step for the preparation of lactones **2** from butynediol **4** (Scheme 1, Route A) but several protecting group manipulations were necessary and the overall yields were low (6–15%). Thus, a regioselective oxidation of 2-tributylstannylbut-2-en-1,4-diol (**5**) to lactone **6** was desirable for a short synthesis of lactone **2** (Scheme 1, Route B). Herein we report the synthesis of lactone **2** using only four transition metal catalysed reactions. Key step was the hitherto unknown, regioselective oxidation of diol **5** to lactone **6**.[10]

The palladium catalysed *cis*-selective addition of tributylstannane to butynediol **4** is well documented.[11] The quality of diol **4** was crucial in this step. Purification of this compound prior to its use was necessary to obtain diol **5** in 92% yield (Scheme 2).

The hydroxy group at C(4) of diol **5** can be regioselectively protected using bulky silyl groups like the TBDMS group.[12] We assumed that selective oxidation of this hydroxy group may occur if a sterically demanding oxidation reagent like TPAP[13] in conjunction with NMO was employed. The selective oxidation of a primary hydroxy group in the presence of a secondary using this oxidation system was reported by Bloch and Brillet[14] but a regioselective oxidation of one of two primary hydroxy groups has not been published yet.

Treatment of diol **4** with 2.5 equivalents of NMO and 5 mol% TPAP at rt for 17 h afforded the lactones **6** and **7** in 15% yield and in a 4:1 ratio (Table 1, entry 1). The major compound isolated was furane **10** (30%) formed by elimination of water after initial oxidation to lactol **11** (Scheme 3).

Improved yields and selectivities were achieved when the initial temperature was below 0 °C and the reaction mixture gradually warmed to rt over a period of 17 h (entries 2 and 3). Increasing the amount of TPAP and longer reaction times produced the lactones **6** and **7** in *ca.* 50% yield but the

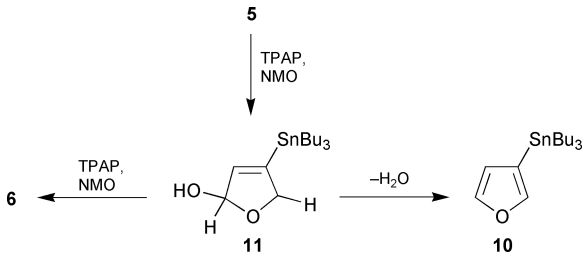

Scheme 3

selectivity decreased with higher contents of the oxidation reagent (entries 4–6).

Lactones **6** and **7** were inseparable by flash chromatography and were therefore used as a mixture for the Stille coupling. This reaction was performed with benzyl bromides **8a**–**h** as described previously.[9] The α,β-unsaturated lactones **9a**–**h** were isolated as isomerically pure compounds (Scheme 2). Sweeney *et al.* described recently, that the reaction rates for the Stille coupling of lactones **6** and **7** with aryl halides are different.[15] In analogy, only lactone **6** reacted with benzyl bromides **8a**–**h** to the coupling products **9a**–**h** (Table 2).

Table 2 Benzyl bromides **8a**–**h** employed for the Stille coupling and yields of the reaction products **9a**–**h**

Entry	Residue (R)	Bromide	Lactone	Yield (%)
1	4-Mesyl-3-methoxy	**8a**	**9a**	80
2	3,4,5-Trimethoxy	**8b**	**9b**	56
3	4-Methyl	**8c**	**9c**	76
4	H	**8d**	**9d**	70
5	4-Nitro	**8e**	**9e**	24
6	2,4,6-Trimethyl	**8f**	**9f**	77
7	3-Methoxy	**8g**	**9g**	59
8	3,4-Methylendioxy	**8h**	**9h**	45

Hydrogenation of lactones **9a**–**h** to lactones **2a**–**h** were achieved by means of 10% Pd on charcoal or Ra-Ni T4 (Table 3). The former catalyst, however, gave irreproducible results or no conversion. Additionally, high pressure (100 bar) and long reaction times (> 24 h) were required. With Ra-Ni T4 as catalyst, complete conversion was found in all cases within 2 h at 0.1 bar positive pressure.

Table 3 Hydrogenation of the unsaturated lactones **9a**–**h** using different catalysts

Entry	Unsat. lactone	Product	Catalyst	*p*/bar	*t*/h	Yield (%)
1	**9a**	**2a**	Pd/C	0.1	14	93
2	**9a**	**2a**	Ra-Ni T4	0.1	2	98
3	**9b**	**2b**	Pd/C	0.1	14	0
4	**9b**	**2b**	Ra-Ni T4	0.1	2	70

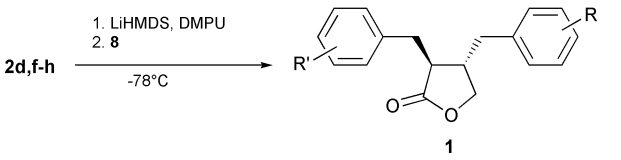
8	**9f**	**2f**	Pd/C	0.1	14	0
9	**9f**	**2f**	Pd/C	100	72	88
10	**9f**	**2f**	Ra-Ni T4	0.1	2	98
11	**9g**	**2g**	Pd/C	100	14	92
12	**9h**	**2h**	$Pd(OH)_2$	100	16	0
13	**9h**	**2h**	Ra-Ni T4	0.1	2	70

Alkylation of lactones **2** with benzyl halides using LDA as base and HMPA as cosolvent provides lactone lignans **1**.[1,7,16] We found that alkylation using LHMDS as base and DMPU[17] as non-carcinogenic substitute for HMPA afforded lactones **1** in moderate yields (Scheme 4 and Table 4).

Bioassay of the synthetic lignan analogues using colon-tumor lines HT29 revealed that compound **1f** possesses high cytotoxic activity (IC_{50} = 40 mM).[18]

We have shown that β-benzyl-γ-butyrolactones **2** were effectively synthesised from butynediol **4** in four transition



Scheme 4

Received (in Cambridge, UK) 1st September 2000, Accepted 11th January 2001
First published as an Advance Article on the web 1st February 2001

The formation of an elaborate H-bonding network between heptanuclear cations, consisting of a hexacyanochromate capped by six $[Mn(dmptacn)]^{2+}$ moieties, and hexacyanochromate counterions results in the assembly of novel 1-D chains with short-range ferrimagnetic behaviour occurring between the $S = 27/2$ clusters and $S = 3/2$ ions.

A major challenge in the field of molecular magnetism is to design discrete polynuclear entities with high-spin ground states and tunable magnetic properties.[1–3] Such materials allow the study of the transition from molecular to bulk-like magnetic behaviour exhibited by, for example, bulk ferromagnets. An important area is that of 'single-molecule' magnets based on high-spin clusters, *e.g.* $Mn_{12}O_{12}(O_2CR)_{16}(OH_2)_4$, for which magnetic anisotropy and negative zero-field splitting are prerequisites.[1,2] One approach to isolating discrete molecules with high-spin states, albeit of a symmetrical type, has focussed on the use of hexacyanometallates as building blocks in the construction of heterometallic assemblies.[4–7] We have reported the structure of $[Fe\{(CN)Cu(tpa)\}_6](ClO_4)_8{\cdot}3H_2O$, [tpa = tris(2-pyridylmethyl)amine]. While this was the first heptanuclear complex of this type to be structurally characterized, new techniques, such as X-ray MCD, have since been applied to probe the magnetisation in $Mn_6^{II}Cr^{III}$ and $Ni_6^{II}Cr^{III}$ complexes, for which X-ray structures were not obtained.[6] Two other structurally characterised cyano-bridged clusters with large high-spin ground states were reported recently.[8,9] Based on octacyanometallates, they consist of $Mn^{II}_9M^{V}_6$ fully-capped cubane structures but, surprisingly, that with M = W[8] has an $S = 39/2$ ground state (*i.e.* $S = 9S_{Mn} - 6S_W$) while that with M = Mo[9] is reported to have an $S = 51/2$ ground state (*i.e.* $S = 9S_{Mn} + 6S_{Mo}$). Inter-cluster coupling, *via* H-bonded pathways, led to long-range order being observed in the Mo case[9] while some features of single molecule magnetism were noted in the W case.[8] We report here the structure and magnetism of $[\{Mn(dmptacn)(CN)\}_6Cr][Cr(CN)_6](ClO_4)_6{\cdot}6H_2O$ **1** [dmptacn = 1,4-bis(2-methylpyridyl)-1,4,7-triazacyclononane], a complex featuring intimate H-bonding between heptanuclear $[\{Mn^{II}(dmptacn)(CN)\}_6Cr^{III}]^{9+}$ cations and $[Cr(CN)_6]^{3-}$ counter anions.

Complex **1** initially formed in an aqueous solution containing a 1:6 mixture of $[Cr(CN)_6]^{3-}$ and $[Mn(dmptacn)(OH_2)]^{2+}$, a reactant ratio expected to yield a heptanuclear complex. However, microanalysis and crystallography confirmed a Mn:Cr ratio of 3:1, and the IR spectrum exhibited CN stretches attributable to both bridging and terminal CN groups. Reactant ratios corresponding to the product stoichiometry afforded better yields of **1**.† The encapsulation of $[Cr(CN)_6]^{3-}$ by six $[Mn(dmptacn)]^{2+}$ moieties has generated a heptanuclear cation [Fig. 1(a)] whose 9+ charge is balanced by one $[Cr(CN)_6]^{3-}$ and six perchlorates even in the presence of excess ClO_4^-. This gives rise to a novel crystallographic feature described below.‡

The geometry of the Cr centres in **1** is little distorted from octahedral, *viz.*, C–Cr–C(*cis*) and C–Cr–C(*trans*) angles are close to 90 and 180°, respectively, and the Cr–C–N angles in both the 'capped $Cr(CN)_6$' core and $[Cr(CN)_6]^{3-}$ anions are almost linear. These features are common to clusters incorporating $[Cr(CN)_6]^{3}$,[11] except for $(VO)_3[Cr(CN)_6]_2{\cdot}10H_2O$.[10,11] The Mn–N–C(CN) angles in **1** [158.4(5)°] deviate from linearity [Fig. 1(b)]. Such deviations have been found in extended lattices formed by cyanometallates and manganese chelates[12] but not in discrete molecules like **1**. For each Mn^{II} centre, the CN ligand is *cis* to the secondary amine of dmptacn,[13] and the Mn^{II} cations adopt a geometry intermediate between trigonal prismatic and octahedral. A trigonal twist angle of 29.2° is calculated from the orientation of the three tacn N atoms relative to the two pyridyl and cyano N atoms. The slightly bent *trans*-C≡N–Mn–N angles [164.9(2)°] cause the three sets of *trans*-Cr–C≡N–Mn units to adopt *anti*-configurations.

Intimate H-bonding interactions exist between the terminal CN nitrogens in the $[Cr(CN)_6]^{3-}$ counter ion and the hydrogen on the sec. amine of dmptacn [Fig. 1(c)]. The C≡N···H–N distance is 2.53 Å while the C≡N···N distance is 3.075(7) Å.

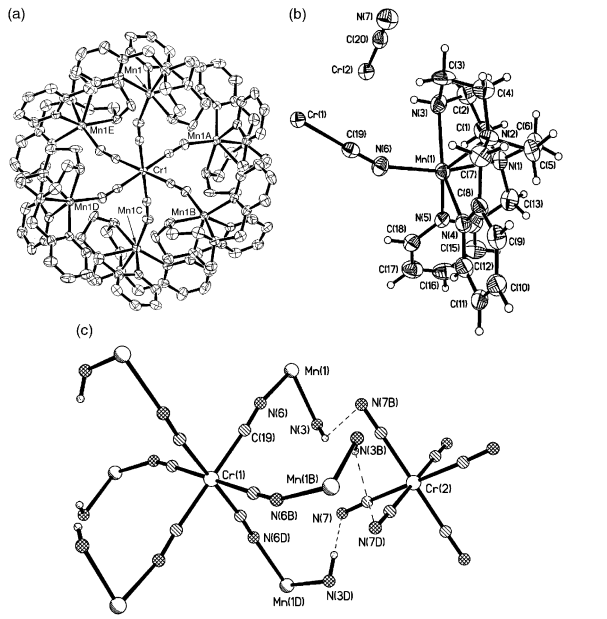

Fig. 1 (a) View of the heptanuclear cation in **1**; (b) atomic labeling scheme (50% probability ellipsoids); (c) 1-D chains formed by H-bonding between the cyano groups on the $[Cr(CN)_6]^{3-}$ counter ion and the secondary amine proton on each dmptacn. Selected bond lengths (Å) and angles (°): Cr1–C19 2.074(6), Cr2–C20 2.050(6), Mn1–N1 2.316(4), Mn1–N2 2.306(4), Mn1–N3 2.236(5), Mn1–N4 2.308(4), Mn1–N5 2.197(4), Mn1–N6 2.196(5), C19–N6 1.150(6), C20–N7 1.173(7), Cr1···Mn1 5.318, Cr2···Mn1 5.849, Cr1···Cr2 6.882, N3···N7b 3.075(7); Cr1–C19–N6 175.0(5), Cr2–C20–N7 177.5(5), Mn1–N6–C19 158.4(5), N1–Mn1–N2 75.4(1), N1–Mn1–N3 76.7(2), N1–Mn1–N5 75.4(2), N1–Mn1–N6 164.9(2), N2–Mn1–N5 140.0(2), N3–Mn1–N4 146.6(2), N3–Mn1–N5 122.3(2), N3–Mn1–N6 88.7(2), N5–Mn1–N6 110.1(2).

DOI: 10.1039/b007113g

This interaction results in a pseudo 1-D chain of alternating $[\{Mn(dmptacn)(CN)\}_6Cr]^{9+}$ cations and $[Cr(CN)_6]^{3-}$ anions running along the *c*-axis. Each complex anion is sandwiched between two heptanuclear cations, forming three H-bonds to one of the two sets of three sec. amine N atoms on each cation. Of importance to the supramolecular assembly of the cations and anions into H-bonded 1-D chains is the geometric arrangement of each set of three sec. amine N atoms, and their hydrogens, at the corners of an equilateral triangle (thus, the cation has a C_{3v} axis of symmetry). The excellent match in the symmetry and size of the extended octahedral faces of $[Cr(CN)_6]^{3-}$ and these triangular arrays of sec. N atoms facilitate the establishment of H-bonded contacts between the exposed N atoms on the anion and the heptanuclear cations.

Fig. 2 shows the temperature dependence of the $\chi_M T$, per Mn_6Cr_2, measured in a field of 1 T. The room-temperature $\chi_M T$ value of 27.1 cm^3 K mol^{-1} is slightly lower than the spin-only value of 30.0 expected for an uncoupled spin system [6(S_{Mn} = 5/2), 2(S_{Cr} = 3/2)] with g = 2.0. As the temperature is lowered, $\chi_M T$ decreases slightly to a broad minimum of 26.3 at 203 K and then slowly increases to 30.1 at 100 K. As the temperature is decreased further, $\chi_M T$ increases rapidly to a maximum of 71.0 at 12 K. This is below the value expected for a fully antiferromagnetically coupled heptanuclear spin system plus $[Cr(CN)_6]^{3-}$ [*viz.*, 99.9 cm^3 K mol^{-1} for {6(S_{Mn} = 5/2) − (S_{Cr} = 3/2)} + (S_{Cr} = 3/2)]. The drop in $\chi_M T$ observed below 12 K can be attributed to a competing intermolecular antiferromagnetic interaction and/or thermal population of low lying Zeeman levels, as noted in other clusters.[14] The χ_M values obey the Curie–Weiss law above *ca*. 140 K with a Weiss constant θ = − 4.2 K. This is consistent with intracluster antiferromagnetic coupling. A ground-state spin value of 27/2 for the cluster corresponds to the spins on the Mn^{II} atoms being antiparallel to those on the central Cr^{III}, *i.e.* $6S_{Mn} - S_{Cr}$. This was also the case for the related $Mn^{II}{}_6Cr^{III}$ cluster[5,6] and the $Mn^{II}{}_9W^{V}{}_6$ cluster.[8] Indeed, a good fit to the $\chi_M T$ *vs.* T data in a field of 1 T was obtained using the spin Hamiltonian of Scuiller *et. al.*,[5] allowing for an additional S_{Cr} = 3/2 Curie contribution in **1**. The best-fit, shown in Fig. 2, corresponds to the parameters of g = 1.96 and J_{Cr-Mn} = −5 cm^{-1} (J_{Mn-Mn} 0) which are similar to those for $[Mn(L)(NC)_6Cr]^{9+}$ {g = 1.97; J_{Cr-Mn} = −8.0 cm^{-1}, L = *N*,*N*,*N*′-[tris(2-pyridylmethyl)-*N*′-methylethane)-1,2-diamine}.[5,6] The ability to simulate the maximum in $\chi_M T$ at 12 K, using the thermodynamic form of the susceptibility,[14] shows that field-dependent Zeeman level depopulation effects are responsible for this maximum.

The broad minimum in $\chi_M T$ noted at 203 K most likely reflects short-range 1D-ferrimagnetic behaviour occurring through weak antiferromagnetic coupling between the S = 27/2 cation and the S = 3/2 $[Cr(CN)_6]^{3-}$ *via* the H-bonding pathways that connect them. Tests for long-range order in **1** proved negative. Thus, the field-cooled and zero-field magnetization data at very low temperatures, in H = 5Oe, showed no bifurcation. At low-fields and 2 K, the magnetization, M, increases rapidly with increasing fields then saturates above H = ≈ 2 T to a M_{sat} value of 24 μ_B, a value consistent with the 1D-ferrimagnet proposal. There is no hysteresis in magnetization at 2 K. Further, the rapid increase in M observed at low fields, such as 100 and 50 Oe, lead to values of $\chi_M T$, as a function of temperature (50–2 K) which do not show the maximum of Fig. 2. Anomalously high values are observed, that continue increasing as T is decreased, reaching $\chi_M T$ of 358 cm^3 K mol^{-1} at 2 K. Such behaviour gives further confirmation of **1** being a 1D-ferrimagnet. However, further work, including ac susceptibility measurements, is needed to fully understand this unusual behaviour at low temperatures and variable fields. Finally, we note that Hashimoto and coworkers,[15] have obtained a 3-D network in their octacyanotungstate(V)–Mn(II) species which is a ferrimagnet displaying long-range order (T_c = 54 K) and with W–CN–Mn chains linking the clusters.

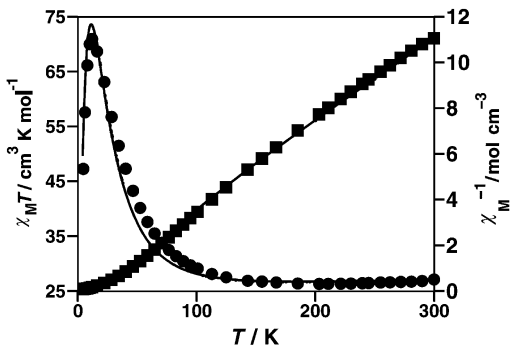

Fig. 2 Plots of $\chi_M T$ (■) and χ_M^{-1} (●) per $Mn_6{}^{II}Cr_2{}^{III}$, for **1** *vs.* T measured in a field of 1 T . The solid line was calculated using the heptanuclear model (see text).

The polymerisation of dibromoalkanes adsorbed in potato starch leads to a novel class of hydrophobic starch–polyalkane composite materials with very high capacity for surface derivitisation.

Starch is the second largest biomass on earth and depleting fossil hydrocarbon resources will require an increasing range of novel applications for starch-based materials.[1] More than 6 MT y^{-1} of starch materials are currently produced in industry with chemically modified starches (through fundamental processes such as hydrolysis, esterification and oxidation) as well as native starches finding diverse uses.[2] Composite materials incorporating starch are less well known although physical mixtures of starch with polyethylene for example, have value as films, coatings and biodegradable plastics.[3] The high degree of functionality of starch along with its low cost, widespread availability and biodegradability makes it a potentially attractive surface-active material but this is hindered by the apparent low site availability and its hydrophobicity and instability in many environments.

The helical structure of native starch leads to hydrophobic channels in which polarisable organic molecules such as haloalkanes can be adsorbed.[2] We have attempted to polymerise intercalated α,ω-dihaloalkanes so as to create a thermally and chemically stable hydrocarbon polymeric core which could open up the starch structure creating a more surface-active material and making it more accessible to derivatisation. Our strategy for accomplishing these goals is illustrated by the following example. Native potato starch was stirred together with 1,10-dibromodecane in cyclohexane. The slurry was then reacted with sodium metal at 80 °C for 24 h. The mixture develops a distinct blue colour over this period and filtration under nitrogen gives an intensely colored blue solid. The FTIR spectrum of the solid shows a number of remarkable features notably a highly resolved hydroxyl stretching region and further sharp bands at 1615, 600 and 450 cm^{-1} (Fig. 1). These bands can at least in part be attributed to a composite matrix stabilised sodium colloid that is also likely to be the origin of the colour.[4] The blue colour of the solid slowly disappears on exposure to the atmosphere and can rapidly be destroyed by washing with water to give a highly particulate white solid. The well resolved FTIR bands noted above are absent in the white solid that has a spectrum essentially consistent with a combination of starch and a polyalkane (Fig. 1). The following discussions refer to the water-washed white solid.

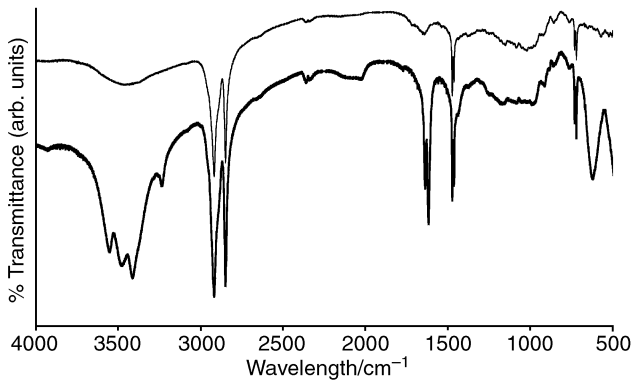

Fig. 1 Diffuse reflectance FTIR spectra of a starch–polyalkane material (STPAM) before (—) and after (—) removal of sodium colloid by water washing.

We have carried out materials preparations as described above at various starch–dibromodecane ratios and thermal analysis can be used to determine the relative amount of the starch and polyalkane (an example of which is shown in Fig. 2). Thermal analysis shows weight losses typical for starch (*ca.* 200 °C) and a polyalkane (*ca.* 400 °C) although it also shows a small but reproducible weight loss between these temperatures which suggests that the two components are not entirely distinct. The bulk of the starch can be removed from the composite materials by treatment with aqueous acid and GPC analysis of the residual polymer shows that it has a rather low molecular weight comparable to that of a polydecane prepared in the absence of starch (Table 1). Bromine analysis reveals the presence of small amounts of organobromine (residual NaBr can be removed by thorough washing) which can be accounted for as polymer terminating CH_2Br groups (based on a 'true' M_w for the polyalkane of 4000).

Other analytical techniques show more obvious evidence of the materials being more than an intimate mixture of starch and polyalkane. Molecular probes can be used to give information about the polarity of surfaces. Reichardt's dye for example, a well known indicator of polarity in the liquid phase can also be used on solids.[5] Remarkably, the spectroscopic shift of the dye adsorbed on the starch–polyalkane composites is considerably greater than that observed for ordinary starch or a polyalkane.

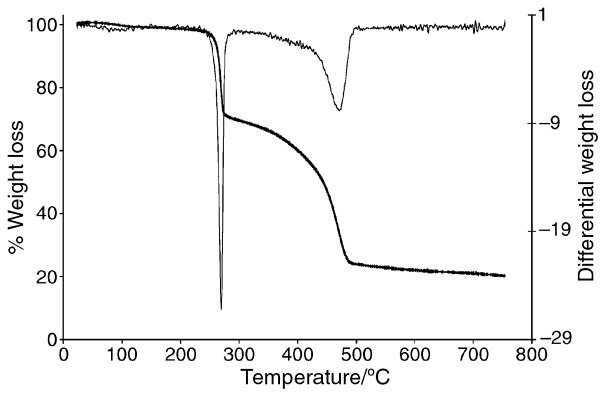

Fig. 2 Thermogravimetric (TG) trace for a typical starch–polyalkane (STPAM) material (10 °C min^{-1}; 20 mg in a ceramic pan; flowing N_2 atmosphere).

Table 1 Representative GPC data for polydecane synthesised with (starch-polydecane material, STPDM) and without (polydecane, PD) the presence of potato starch

Table 2 Comparative surface polarities of starch, a typical polyalkane and a typical starch–polyalkane material

Sample	Polyalkane : starch ratio	$\lambda_{max/nm}$	Sample polarity
Potato starch	N/A	592	0.543
Polyalkane	N/A	630	0.453
Starch–polyalkane material	1.33 : 1	538	0.693

This indicates a surface polarity for the composites that is greater than either of its component parts (Table 2). Scanning electron microscopy may help to explain the origin of this effect (Fig. 3). Potato starch exists as pebble-like granules which vary between 10 and 100 μm in size. The composite materials however, are apparently made up of smaller particles (< 5 μm) bound to larger (polyalkane) particles (up to 200 μm). The higher effective surface area of the starch may also result in a higher available concentration of surface hydroxyl groups leading to greater surface polarity. Despite the relatively high surface polarity as measured by Reichardt's dye, the materials are hydrophobic and float on water unchanged for periods of several weeks before water eventually permeates the structure sufficiently for them to sink.

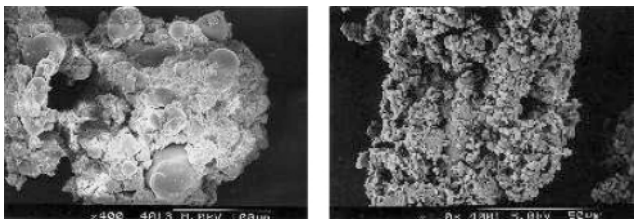

Fig. 3 Scanning electron microscopy (SEM) images of a typical starch–polyalkane material (STPAM) before (left) and after (right) removal of sodium colloid by water washing.

Perhaps the most dramatic effect of the enhanced surface activity of the new materials is their capacity for chemical modification with silanes. Stirring the materials with 3-(trimethoxy)aminopropylsilane in refluxing toluene for 24 h before filtration followed by through washing with toluene and then refluxing aqueous ethanol gives solid materials which were dried at 110 °C for 24 h. The measured loadings of aminoalkyl groups of up to 0.6 mmol g^{-1} (1.4 mmol g^{-1} based on the starch present) are over 10× greater than the maximum loading that can be obtained with potato starch (0.05 mmol g^{-1}). It is interesting to calculate that the level of derivatisation of potato starch corresponds to < 1% of the total number of hydroxyl groups that are present—an indication of the poor availability of these groups. By increasing the availability of the groups in the new materials the degree of functionalisation has increased to *ca.* 10%.

The derivatisation values that can be achieved with the new materials are comparable to those that can be obtained on a high surface area porous silica gel.[6] This comparison is further reinforced by measuring the activity of the aminoalkyl-derivitised starch–polyalkane materials in a typically base-catalysed reaction. The reaction chosen was the Knoevenagel reaction, a useful carbon–carbon bond forming reaction that relies on the base-activation of a carbon acid. The rates of the Knoevenagel reaction between ethyl cyanoacetate and cyclohexanone in cyclohexane catalysed by a typical aminopropyl-starch–polyalkane composite material, an aminopropyl-functionalised mechanical mixture of starch and a polyalkane, and aminopropyl-potato starch are compared in Fig. 4. The

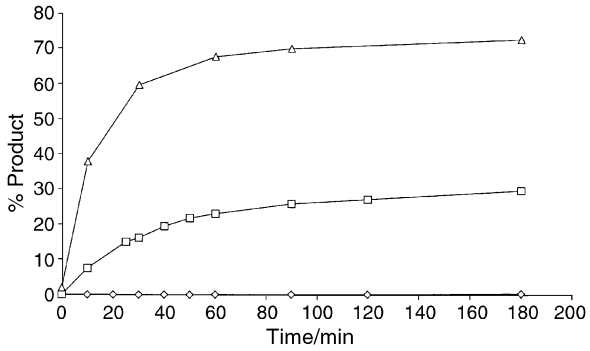

Fig. 4 Reaction profiles for the Knoevenagel condensation reaction of ethyl cyanoacetate and cyclohexanone catalysed by aminopropylsilane on starch (◇), aminopropylsilane on a typical starch–polyalkane material (△) and aminopropylsilane on a mechanical mixture of starch and a typical polyalkane (□).

differences are dramatic. While the ordinary starch based material has almost no activity in the reaction and that based on the starch–polyalkane mechanical mixture is low, the derivitised new material is very active and comparable to their porous silica analogues.[6] Starch that has been treated with sodium metal or sodium hydroxide solution but in the absence of the halocarbon gives a material that has an unchanged FTIR spectrum, thermal analysis and interaction with Reichard's dye compared to ordinary starch. It does however show a higher capacity for reaction with the aminopropylsilane although the resulting material is only as active in the model reaction as the starch–polyalkane mechanical mixture.

We have extended the synthetic methodology to other α,ω-dibromoalkanes. 1,6-Dibromohexane and 1,2-dibromoethane can be used in place of 1,10-dibromodecane with apparently very similar reactions occurring. All of the materials are resistant to water over periods of several weeks, all can be derivatised to high levels with aminoalkylsilanes (0.3–0.6 mmol g^{-1}) and all of the resulting derivatised solids are active solid base catalysts in the test reaction. The ability to increase substantially the availability of the starch hydroxyl groups enabling high degrees of derivatisation while rendering the materials water-resistant would seem to be an attractive combination of properties. The method of polymerising starch-intercalated monomers to achieve this may well open the door to a family of new and useful materials based on an inexpensive renewable resource.

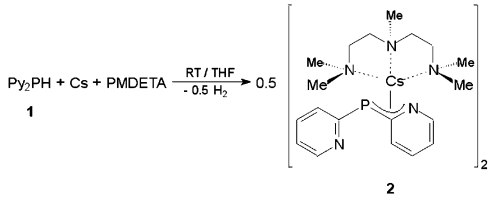
The coordination flexibility of the ambidentate Py_2P^--anion (Py = 2-pyridyl) spans the wide range from σ-all-nitrogen chelation to hard organometallic moieties, σ-phosphorus μ_2-bridging in dinuclear iron complexes to π-N,C,P heteroallyl coordination to the soft caesium.

Primary and secondary alkali metal phosphides MPR_2 and MPHR are key transfer reagents in organophosphorus synthesis and in the introduction of phosphide ligands to catalytically active transition metal fragments.[1] The structural topology of these species has been reviewed recently[2] and is mainly determined by the donor base, *e.g.* in the [(donor)$LiPPh_2$] complexes,[3] by the radius and polariseability of the alkali metal[4] and the size of the substituents.[5] In general, bulky groups (*e.g.* 2,4,6-$(F_3C)_3C_6H_2$[5a] or terphenyl[5b–d]) and heavier alkali metals prompt M–aryl π interactions in addition to M–P σ bonds.[2b] Rather than varying the bulk of the aryl substituent we incorporate donor centres in group 14 and 15 element bonded rings such as di(2-pyridyl)-amides, -phosphides and -arsenides Py_2E^- (Py = 2-pyridyl, E = N, P, As) to modulate the coordinaton behaviour.[6] In the Py_2P^- anion both ring nitrogen atoms chelate the metal to leave the phosphorus divalent.[7] The alkali metal coordination in the substituent periphery opens up the door to unique reactivity in these complexes, *e.g.* the reduction of the iminophosphorane $Py_3P{=}NSiMe_3$ to chiral phosphane amines $RPyPN(H)SiMe_3$ *via* lithium organics involving the cleavage of two P–C Py bonds in a single step.[8] The adaptability of these pyridyl substituted ligands is exemplified by the flexible coordination behaviour towards various metal centres. Thus, the pyridyl nitrogen atoms may be involved in coordination exclusively (Scheme 1, **A**)[6,7] or in conjunction with the bridging heteroatom (Scheme 1, **B**).[9]

Although it is anticipated that in species **A**, the central atom E can further function either as a 2e or 4e donor to form heterometallic derivatives, recent theoretical calculations, supported by experiments, have shown that while in the amides (E = N) the amido nitrogen does function as a typical Lewis base,[9] the situation in the corresponding phosphides (E = P) is different.[10] In the latter, nearly all the charge density couples into the pyridyl rings, leaving the central phosphorus atom only attractive for soft metals in the form of a π-acid type of coordinating centre. In order to test the coordination abilities further, we reacted the pyridyl phosphides with two contrasting type of metals *viz.*, Cs(I) and Fe(II). Towards the soft caesium metal in the complex $[(PMDETA)Cs\{(\mu\text{-}PPy)Py\}]_2$ **2** [PMDETA = $(Me_2NCH_2CH_2)_2NMe$] an unprecedented coordination behaviour of the di(2-pyridyl)phosphide ligand is observed. In this complex the ligand is involved *simultaneously* in a σ (through P and N) as well as a π (through the P–C–N segment) interaction with the caesium ions. This hetero aza allylic coodination represents an entirely new facet of coordination capability of the pyridyl phosphide ligands. In the iron complex $[\{Cp(CO)_2Fe\}_2\{(\mu\text{-}P)Py_2\}][BMe_4]$ **5** the phosphorus atom of the ligand bridges two Fe(II) centres without any further Fe–N contacts. The reaction of di(2-pyridyl)phosphane, Py_2PH[7] **1** with caesium metal in the presence of PMDETA afforded the dimeric complex **2** [eqn. (1)].‡ In an attempt to prepare



(1)

heterobimetallic compounds we have reacted the aluminium derivative $[Me_2Al(Py_2P)]$ **3**[7] with $[CpFe(CO)_3][BF_4]$ **4**[11] where in general a carbonyl group can easily be replaced by a phosphane.[12] We aimed to utilise the vacant phosphorus site for coordination with Fe(II) while retaining the Al–N bonds. However, the Al–N bonds in the complex are cleaved presumably by the formation of the thermodynamically favourable AlF_3 accompanied by the alkylation of the tetrafluoroborate anion. This leads to the formation of $[\{Cp(CO)_2Fe\}_2\{(\mu\text{-}P)Py_2\}][BMe_4]$ **5** [eqn. (2)].‡

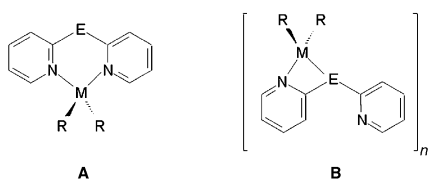

Scheme 1

† Dedicated to Professor Siegfried Hünig on the occasion of his 80th birthday.

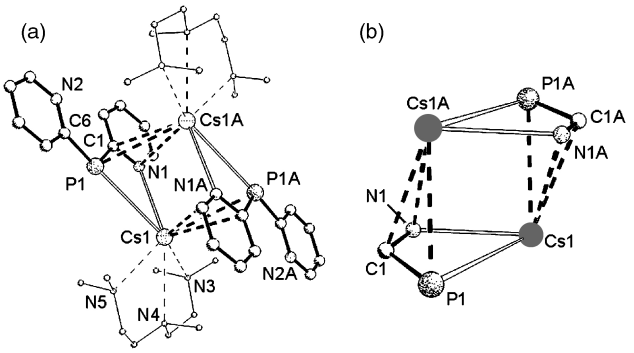

Fig. 1 Solid-state structure of **2**. Selected bond distances (pm) and angles (°): P1–C1 179.4(4), P1–C6 179.8(4), P1–Cs1 365.2(2), P1–Cs1A 369.3(2), N1–Cs1 321.2(4), N1–Cs1a 337.3(4), C1–Cs1a 334.6(4); C1–P1–C6 108.67(18), P1–C1–N1 111.3(3), P1–C6–N2 126.2(3).

Both $[(PMDETA)Cs\{(\mu\text{-}PPy)Py\}]_2$ **2** and $[\{Cp(CO)_2Fe\}_2\{(\mu\text{-}P)Py_2\}][BMe_4]$ **5**, were structurally investigated,§ allowing the ambidentate coordination flexibility of the Py_2P^- anion toward soft metals to be probed. The dimeric structure of **2** comprises of two distinct modes of bonding of the Py_2P^- ligand [Fig. 1(a)].

The atoms P1 and N1 are involved in a σ-type of interaction with Cs1. At the same time the hetero aza allylic P1–C1–N1 moiety is η^3-coordinated through a π-type of interaction with the second caesium ion Cs1A of the dimeric complex [Fig. 1(b)]. One pyridyl nitrogen on each of the Py_2P^- ligands remains non-coordinated. The P–C bond lengths in the anion are not affected by the metal coordination and are identical within esds [179.4(4), π-coordinated and 179.8(4) pm, non-coordinated] and as long as in other metal di(2-pyridyl)phosphides.[7] Even the P–Cs distances are only marginally different [365.2(2), σ-coordinated and 369.3(2) pm, π-coordinated] and are similar to other caesium phosphides.[5] It is only in the N–Cs distances where the different bonding mode is mirrored in different lengths [321.2(4), σ-coordinated and 337.3(4) pm, π-coordinated]. The different coordination of the ring nitrogen atoms gives rise to two different signals in the ^{15}N MAS NMR spectrum (δ −68.2 and −71.7) although these environments equilibrate in solution. The Cs1–C1 bond of 334.6(4) pm is as short as found in Cs–η^6-carbon coordination[1b] and considerably shorter than to terphenyl substituted phosphides.[5] Hence the P,C,N–Cs π bonding has to be considered a hetero aza allyl coordination with the negative charge not only delocalized to the coordinated ring but also to the other. This clearly proves the anticipated ability of the phosphorus centre in the Py_2P^- anion to coordinate soft metals. This is further substantiated in the structure of $[\{Cp(CO)_2Fe\}_2\{(\mu\text{-}P)Py_2\}][BMe_4]$ **5**. Two soft Lewis acidic metal fragments $[CpFe(CO)_2]^+$ are bridged by the phosphorus atom of a single di(2-pyridyl)phosphide ligand to give the $[\{Cp(CO)_2Fe\}_2\{(\mu\text{-}P)Py_2\}]^+$ cation (Fig. 2).

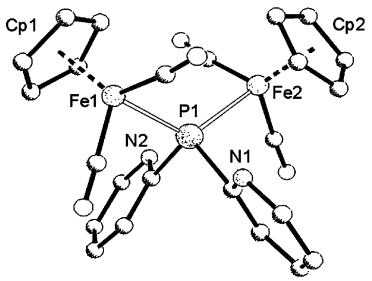

Fig. 2 Solid state structure of the $[\{Cp(CO)_2Fe\}_2\{(\mu\text{-}P)Py_2\}]^+$ cation in **5**. Selected bond distances (pm) and angles (°): P1–C1 184.9(5), P1–C6 184.4(5), P1–Fe1 226.4(2), P1–Fe2 226.5(2), Fe1···Cp1(centre) 172.7, Fe2···Cp2(centre) 171.5, Fe–CO 176.1(7)–176.9(7), C–O 113.7(7)–115.1(7); C1–P1–C6 101.7(3), Fe1–P1–Fe2 120.49(7).

In conclusion the di(2-pyridyl)phosphide ligand shows a metal-dependant coordination response and is involved in a highly unusual σ/π interaction with caesium ion. The latter is clearly reminiscent of the coordination of an allylic type of ligand. On the other hand the phosphorus atom in the Py_2P^- anion is Lewis basic enough to bridge two soft iron metal centres. Yet again the structure determining influence of different metals is obvious.[4]

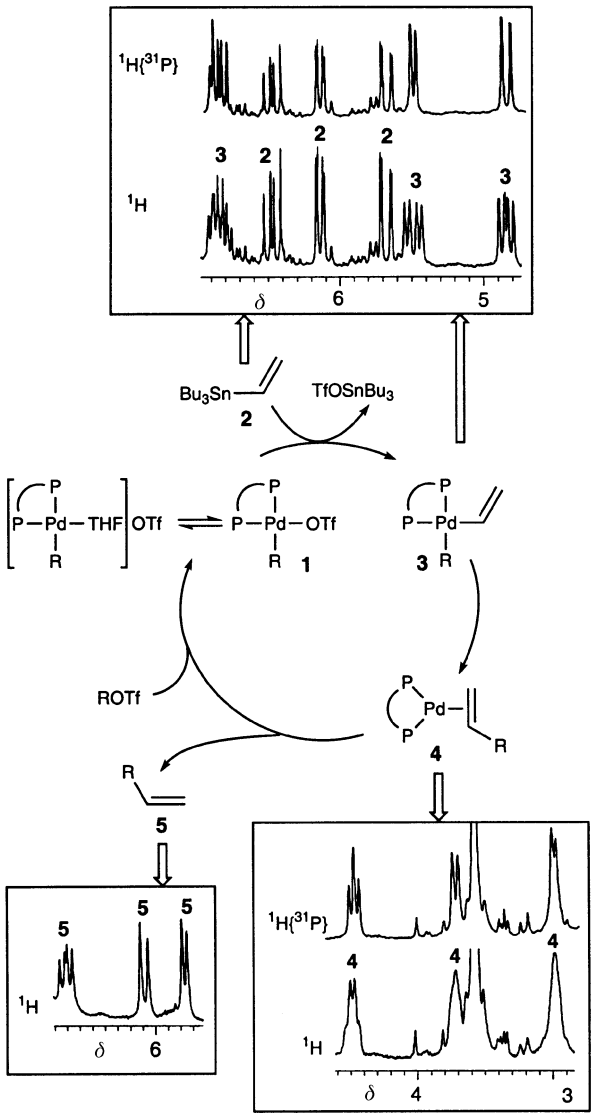
The main sequential intermediates involved in a real catalytic cycle of the Stille reaction (the coupling of ROTf with CH_2=$CHSnBu_3$ catalyzed by [PdR(OTf)(dppe)]; R = aryl) are observed and characterized unequivocally before the coupling product is released.

Only in rare occasions can real intermediates in a catalytic cycle be observed and unambiguously identified. The Stille reaction (palladium-catalyzed coupling of organotin reagents with carbon electrophiles) is nowadays one of the most powerful synthetic methods for the formation of carbon–carbon bonds.[1] Its catalytic cycle involves a number of intermediates, but evidence for these only comes from model reactions outside a real cycle. Echavarren and coworkers have synthesized oxa- and aza-palladacycles using the oxidative addition of haloarylstannanes to Pd(0) complexes, followed by an intramolecular transmetalation, thus the products can be considered intermediates of a frustrated Stille cycle, which do not undergo coupling because of the high energy of the coupling product.[2] We have shown that the coupling of halides R^1I with SnR^2Bu_3 (R^2 = vinyl or phenyl) follows a S_E2 mechanism involving an associative L-for-R^2 substitution on *trans*-[PdR^1IL_2]. This Pd(II) complex, which can be prepared separately, was actually observed as involved in the catalytic cycle.[3] More recently we have observed the formation and fading out of *trans*-[$PdR^1R^2L_2$] in the coupling of triflates R^1OTf with Sn(vinyl)Bu_3.[4] Here we present a catalytic Stille coupling in which all the main intermediates involved are observed, as they are formed and disappear, using ^1H, ^{19}F and ^{31}P NMR spectroscopy.

[$Pd(C_6F_5)$(OTf)(dppe)] **1a** [dppe = 1,2-bis(diphenylphosphino)ethane] is a poor catalyst for the coupling, in THF at 50 °C (Pd : Sn = 1 : 20), of C_6F_5OTf and CH_2=$CHSnBu_3$ **2** to give CH_2=CHC_6F_5. When the reaction was carried out in THF-d^8 at low temperature, starting with [$Pd(C_6F_5)$(OTf)(dppe)] and CH_2=$CHSnBu_3$ in 1 : 1 molar ratio, several intermediate species could be detected and identified until the coupling product was formed. For an easier monitoring of the cycle the studies were repeated on [$Pd(C_6Cl_2F_3)$(OTf)(dppe)] **1b** ($C_6Cl_2F_3$ = 3,5-dichlorotrifluorophenyl), which behaves identically to **1a** and shows the same intermediates, but has more simple ^{19}F NMR spectra, facilitating a more accurate integration of the signals.[5] Scheme 1 shows, step by step, the mechanism of the catalytic cycle and the ^1H NMR spectra of the intermediates identified in the stoichiometric cycle for **1b** while Fig. 1 shows the evolution of the reaction, as monitored by ^{19}F NMR.

The first intermediate in the cycle is **1a** (or **1b**). Under catalytic conditions **1a** is formed very slowly by oxidative addition of C_6F_5OTf to [Pd(0)], but stoichiometrically these compounds are better prepared from [PdRCl(dppe)] (R = C_6F_5, $C_6Cl_2F_3$) and AgOTf. Complexes **1a** and **1b** are stable in the solid state and have been isolated and fully characterized.[6] In solution in dry THF they give the ionic species [PdR(dppe)(THF)](OTf) (specific molar conductivity, Λ_m = 4.66 S cm^{-1} mol^{-1} for **1a**),[7] on which the transmetallation occurs.[4]

The next step is the transmetalation on **1b** leading to a σ-vinyl complex [$Pd(C_6Cl_2F_3)(CH{=}CH_2)$(dppe)] **3**, characterized by NMR. Its ^{19}F NMR spectrum shows the characteristic resonances expected for a $C_6Cl_2F_3$ group linked to Pd(II), with the



Scheme 1 Catalytic cycle showing the ^1H NMR spectra of the products detected in the range of vinylic protons.

F_{ortho} coupled to the *trans* phosphorus atom (coupling to the *cis* phosphorus is not observed). In the $^{31}P\{^1H\}$ NMR spectrum two signals are observed: one for the P *trans* to $C_6Cl_2F_3$, which appears as an overlapped doublet of triplets, and one for the *cis* phosphorus which appears as a doublet. The ^1H NMR spectrum (Scheme 1) shows three resonances for the three vinylic protons, coupled to phosphorus (see changes upon ^{31}P irradiation in the corresponding $^1H\{^{31}P\}$ NMR spectrum).

Complex **3** is unstable and can be observed only at low temperature.[8] In spite of the *cis* configuration of this complex, the reductive elimination step takes place less easily than with PPh_3 because of the small bite angle chelating ligand,[9] and this stabilizes the compound sufficiently for it to be observed.[10] The

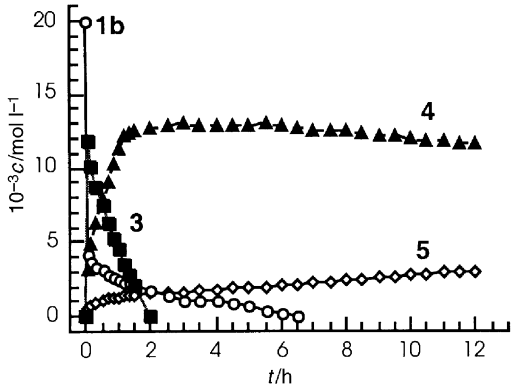


Fig. 1 Profiles of the reaction between [Pd($C_6Cl_2F_3$)(OTf)(dppe)] **1b** and CH_2=CHSnBu_3 **2** in THF at 243 K. Concentrations were obtained by integration in the ^{19}F NMR spectra. Starting concentration: 0.02 mol L^{-1} in **1b**.

coupling product remains coordinated stabilizing a Pd^0 complex [Pd(dppe)(η^2-CH_2=$CHC_6Cl_2F_3$)] **4**. Its ^{1}H NMR spectrum (Scheme 1) shows three broadened signals, at higher field than in the σ-vinyl complex **3** due to the bigger shielding produced by the metallic center. They are coupled to each other (as seen by ^{1}H COSY) and also coupled with the phosphorus nuclei of the dppe ligand. In the ^{1}H{^{31}P} NMR spectrum (Scheme 1) only the coupling between protons is observed. The ^{31}P NMR spectrum of **4** shows an AB system. This chemical inequivalence of the two P atoms is consistent with a trigonal-planar coordination of the palladium, with the double bond of the asymmetric olefin lying in the plane containing the palladium atom and two phosphorus atoms. Similar complexes have been reported in the literature.[11] This compound is again rather stable and can be observed even at room temperature in the stoichiometric reaction. Upon decomposition (or when it undergoes oxidative addition) the olefin CH_2=$CHC_6Cl_2F_3$ **5** is released.

In catalytic conditions the cycle should close upon oxidative addition to **4** or to a low coordinated [Pd(0)] complex formed by decoordination of **5**. This oxidative addition is extremely slow and decomposition pathways compete, causing the low efficiency of the catalyst.[11*a*] However, four to five turnovers are observed showing that the cycle is actually catalytic. Alternatively, the oxidative addition step can be accelerated very efficiently by adding LiCl once **4** has been formed [the accelerating effect of LiCl on some Stille catalytic cycles is well documented in ref. 1(*a*), and is discussed in ref. 11(*a*)]. This leads to the easy formation of [PdRCl(dppe)] on which, however, transmetalation is extremely slow. A thorough discussion of these observations will be made in a forthcoming full paper.

This article is dedicated to Professor Rafael Usón on occasion of his 75th birthday. The work was supported by the Dirección General de Investigación Científica y Técnica (Project No. PB96−0363) and the Junta de Castilla y León (Project No. VA80-99). A. M. G. is grateful for a grant from the Dirección General de Enseñanza Superior (Spain).

Size effects of ultrafine Pt–Ru particles on the electrocatalytic oxidation of methanol

Yoshio Takasu,* Hiroyuki Itaya, Tomoya Iwazaki, Ryo Miyoshi, Takefumi Ohnuma, Wataru Sugimoto and Yasushi Murakami

Department of Fine Materials Engineering, Faculty of Textile Science and Technology, Shinshu University, 3-15-1 Tokida, Ueda 386-8567, Japan. E-mail: ytakasu@giptc.shinshu-u.ac.jp

Received (in Cambridge, UK) 1st November 2000, Accepted 12th January 2001
First published as an Advance Article on the web 31st January 2001

The specific activity, i_{sp}/A m^{-2} (current density per real surface area), of Cl-free well-homogenized Pt–Ru particles at 25 and 60 °C in aqueous acidic solutions has been found to decrease with a decrease in the size of the Pt–Ru alloy particles, and the mass activity, i_{mass}/A g^{-1} (current density per mass of catalyst metal loaded), showed the same dependency when the size of the alloy particles was < *ca.* 3 nm in diameter.

For the development of methanol fuel cells,[1] many investigations have been made on the catalytic activity of Pt–Ru alloy electrocatalysts which perform as active anodes for methanol and carbon monoxide-containing hydrogen.[2] Among the various factors possibly affecting the catalytic activity of the Pt–Ru alloy catalysts for methanol oxidation, the dependence of the Pt–Ru particle size on the catalytic oxidation of methanol, *e.g.* the 'size effect', is an important factor for recognizing the fundamental catalytic properties of ultrafine alloy particles. The size effect of platinum particles of Pt/C catalysts for the oxidation of methanol has been examined by some research groups;[3] however, that for well-homogenized Pt–Ru alloy particles has not yet been reported. Ultrafine catalyst metal particles are often more active compared to larger ones probably due to their higher concentration of low-coordinated surface metal atoms.

The present investigation has been carried out to clarify the 'size effect' for the electrocatalytic oxidation of methanol on well-homogenized ultrafine Pt–Ru particles supported on a carbon. The alloy composition used was Pt_{50}–Ru_{50}, (Pt : Ru = 1 : 1 mol/mol), since this composition was the most active in the binary alloy catalyst system.[4] The Pt_{50}–Ru_{50}/C catalyst powders were prepared by an impregnation method with carbon black powder (Vulcan XC72R; 254 m^2 g^{-1}) and ethanolic solutions of $Pt(NO_2)_2(NH_3)_2$ and $RuNO(NO_3)_x$. The combination of these metal complexes can give well-homogenized alloy particles.[4] The decomposition of the metal complexes supported on the carbon black powder was made in a stream of $H_2 + N_2$ at 450 °C to attain almost complete alloying, while the catalytic activity for the oxidation of methanol decreased with the preparation temperature from 200 to 450 °C.[4]

Fig. 1 shows high-resolution scanning electron micrographs of Pt_{50}–Ru_{50}/C catalysts with different loading amounts of the alloy. The mean size of Pt_{50}–Ru_{50}, *d*, determined from these electron micrographs increases with the amount of catalyst loading. As shown in Fig. 2, the X-ray diffraction patterns of these Pt_{50}–Ru_{50}/C catalysts show that the lattice constant of the fcc Pt_{50}–Ru_{50} alloys is almost the same value as measured by Gasteiger *et al.* using a bulk Pt_{48}–Ru_{52} alloy, 0.38624 nm.[5]

Fig. 3 shows the relationships between the catalytic activities,[6] specific activity (i_{sp}) and the mass activity (i_{mass}), for the oxidation of methanol in 0.5 mol dm^{-3} H_2SO_4 at 60 °C and the loading amount of the alloys. Some of the mean particle sizes of the Pt_{50}–Ru_{50} particles are marked on the figure. It should be noted that i_{sp} decreases with a decrease in the particle size of Pt_{50}–Ru_{50} at all potentials studied, while i_{mass} gives a maximum value at 40 mass% of alloy loading at all polarization potentials,

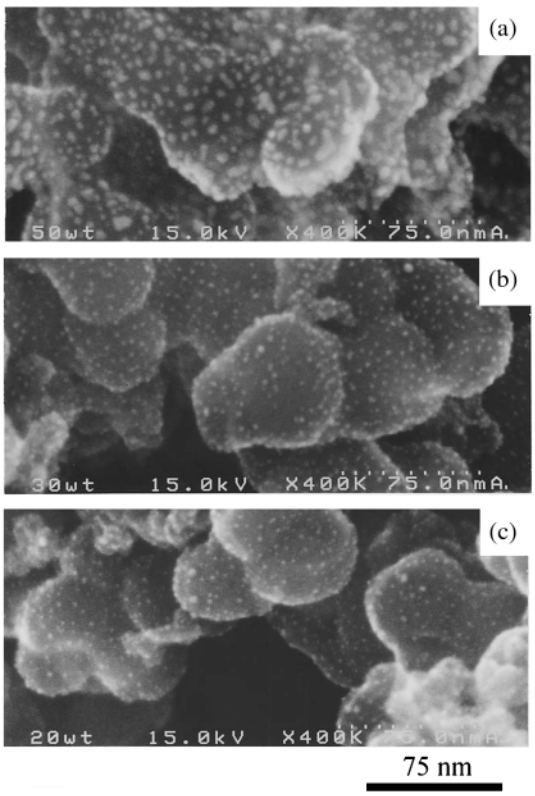

Fig. 1 High-resolution scanning electron micrographs (Hitachi, S-5000) of Pt_{50}–Ru_{50}/C catalysts with different loadings. Loading amount: (a) 20 mass%, (b) 30 mass%, (c) 50 mass%.

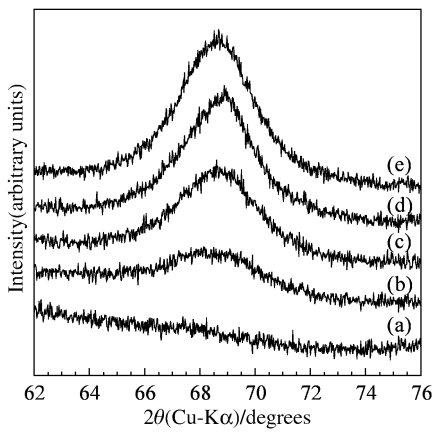

Fig. 2 XRD patterns of Pt_{50}–Ru_{50}/C catalysts with different loadings. Loading amount of Pt–Ru and the mean particle size, *d*, determined from the high-resolution SEM: (a) 10 mass% (*d* = 1.9 Å ± 0.7 nm), (b) 20 mass% (*d* = 2.1 Å ± 0.7 nm), (c) 30 mass% (*d* = 2.7 Å ± 0.6 nm), (d) 40 mass% (*d* = 3.0 Å ± 0.8 nm), (e) 50 mass% (*d* = 3.5 Å ± 1.0 nm).

DOI: 10.1039/b008821h

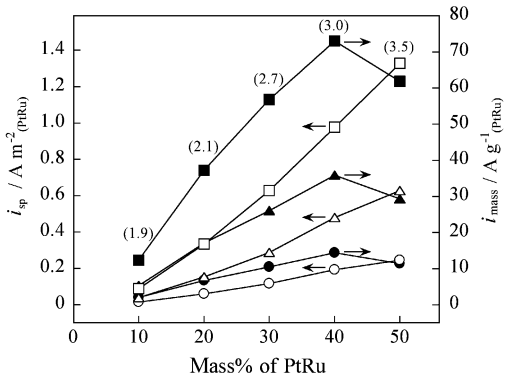

Fig. 3 Dependence of the specific activity (i_{sp}) and mass activity (i_{mass}) for the oxidation of methanol on the size of alloy particles of Pt_{50}–Ru_{50}/C electrodes in 0.5 mol dm^{-3} H_2SO_4 containing 1 mol dm^{-3} MeOH at 60 °C. The values of i_{sp} and i_{mass} correspond to mean quasi-steady state current densities at 30 min after polarization at each electrode potentials per real surface area of alloy particles and per mass of alloy particles, respectively. Open symbols (○, △, □): i_{sp}, Solid symbols (●, ▲, ■): i_{mass}. Polarization potential of the test electrode (*vs.* RHE): ○ and ●, 400 mV; △ and ▲, 450 mV; □ and ■, 500 mV.

where *d* is *ca*. 3 nm. The fact that the specific activities of the larger Pt_{50}–Ru_{50} particles are higher than the smaller ones suggests a larger surface area of alloy particles is more effective for the oxidation. A similar size effect was observed in the experiments at 25 °C. The possible effect of adsorption of the anion, SO_4^{2-}, on the oxidation of methanol can be neglected because similar size effects were also observed in the reaction in 0.020 mol dm^{-3} $HClO_4$. Since no obvious difference in the average distance between Pt_{50}–Ru_{50} particles in Fig.1 (a)–(c) is found, the 'size effect' observed in the catalytic activity is not caused by the diffusion interference between the spherical diffusion areas around the alloy particles.[3] The findings of this investigation suggest, at least, that low-coordinated surface atoms should not be the limiting factor for the electrocatalytic oxidation of methanol.

In order to clarify the origin of the 'size effect' found in this investigation, the electronic structure and surface alloy composition[6] of the Pt–Ru particles as well as the surface species[7] of OH_{ad}, CO_{ad} and CHO_{ad} should be characterized. Such information; however, concerns the overall properties of the alloy catalysts. Furthermore, characterization of the exposed crystal planes[8] and the precise shapes of the alloy particles and elucidation of the optimum ensemble of the surface Pt and Ru atoms[9] for the oxidation of methanol are needed as a function of particle size.

The present work was partly supported by a Grant-in-Aid for Scientific Research on Priority Area of *Electrochemistry of Ordered Interface* from the Ministry of Education, Science and Culture, Japan (grant no. 10131230). We are also grateful to Ishifuku Metal Industry Company Ltd. for supplying us with the platinum complex.

ChemComm

Control of hydrogen bond network dimensionality in tetrachloroplatinate salts†

Alessandro Angeloni and A. Guy Orpen*

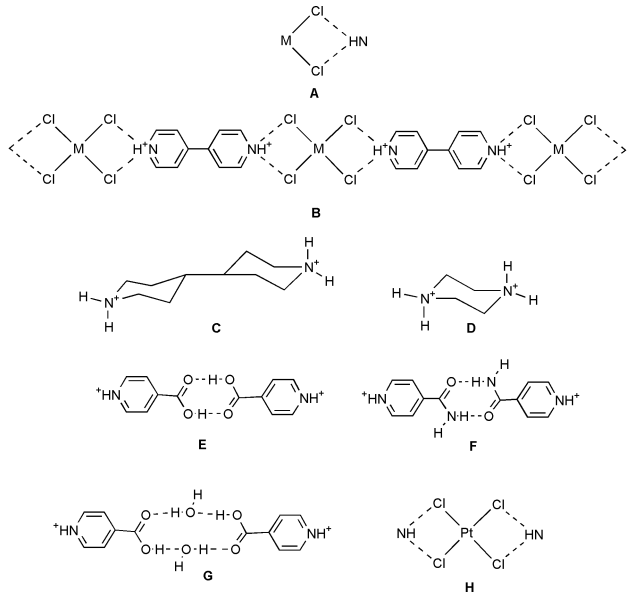
School of Chemistry, University of Bristol, Bristol, UK BS8 1TS. E-mail: guy.orpen@bristol.ac.uk

Received (in Cambridge, UK) 27th November 2000, Accepted 16th January 2001
First published as an Advance Article on the web 5th February 2001

Tetrachloroplatinate salts of 4,4-bipiperidinium, piperazinium and *N*-protonated isonicotinic acid or isonicotinamide show two-dimensional NH···Cl hydrogen bond networks related in a rational way to the one-dimensional ribbon polymer network of [4,4′-H_2bipy][$PtCl_4$].

In the synthesis of crystal structures by design, the assembly of molecular units in predefined arrangements is a key goal.[1] Directional intermolecular interactions are the primary tools in achieving this goal and hydrogen bonding is currently the best among them.[2] We have shown[3] that the chelate hydrogen bond moiety **A** (Scheme 1) is a useful supramolecular synthon[1a,c] for the construction of crystal structure of perhalometallate salts of the 4,4′-bipyridinium dication. In these salts the motif **B** is observed, most clearly in [4,4′-H_2bipy][$PtCl_4$] **1** but also in cases where the MCl_4 species forms a chain polymer [4,4′-H_2bipy][MCl_4] (M = Mn, Cd, Pb).[3c] In **1** the NH···Cl hydrogen bond network is one-dimensional (although there are longer CH···Cl contacts[3c]) and the crystal structure can be viewed as arising from close packing of the **B**-type ribbons.[3] To control the crystal structure more completely it is critical to be able to raise the dimensionality of the hydrogen bond networks in such structures in a rational and planned manner. In so doing we will probe the range of cations able to form **B**-type ribbons.

In the first instance we employed cations with two rather than one NH unit per charge starting with the saturated analogue of [4,4′-H_2bipy]$^{2+}$, 4,4-bipiperidinium ([4,4′-H_2bipip]$^{2+}$, **C**). On treatment of an aqueous solution of $K_2[PtCl_4]$ with 4,4′-bipiperidine hydrochloride a crystalline salt [4,4′-H_2bipip][$PtCl_4$] **2** is formed.‡ The crystal structure of **2** has an



Scheme 1

† Electronic supplementary information (ESI) available: syntheses of **2**–**5**. See http://www.rsc.org/suppdata/cc/b0/b009515j/

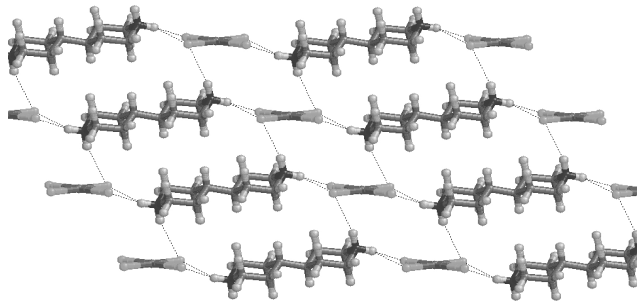


Fig. 1 Structure of the NH···Cl hydrogen bonded layer in crystalline [4,4′-H_2bipip][$PtCl_4$] **2**. The NH···Cl hydrogen bonds are indicated. Hydrogen bond lengths and angles include: in-ribbon NH···Cl 2.79 Å, N–H···Cl 132°, Pt–Cl···HN 89°; NH···Cl 2.45 Å, N–H···Cl 147°, Pt–Cl···HN 98°. Between ribbons: NH···Cl 2.55 Å, N–H···Cl 158°, Pt–Cl···HN 74°.

hydrogen bonded ribbon motif analogous to that of **1** (see Fig. 1). In addition to the chelate hydrogen bond of type **A** in the **B**-like ribbon, which is formed by the equatorial hydrogen at the nitrogens of the [4,4′-H_2bipip]$^{2+}$ cation, a second NH···Cl interaction links parallel ribbons by NH···Cl bonds. The **B**-like ribbons are not flat as they are in **1** because of the chair form of the saturated bipip rings and the inter-ribbon distance is rather larger than in **1** (4.0 Å in **2** compared with 3.5 Å in **1**) as a consequence of the thicker cation in **2**. The chelate hydrogen bond is rather asymmetric in **2**, presumably because one of the chloride ligands involved is also forming a hydrogen bond to the axial NH hydrogen. It is this chloride which forms the longer NH···Cl contact in the **A**-type interaction. The net result is that the NH···Cl hydrogen bond network is two-dimensional. Although, as in **1**, each ribbon is surrounded by six near neighbours the ribbons in **2** are tilted with respect to the hydrogen bonded layers they form so that all ribbons within a layer are parallel but ribbons in adjacent layers are not parallel.

To probe the generality of the NH_2 hydrogen bond donor approach, we also prepared the piperazinium (**D** in Scheme 1) salt, [$C_4H_{12}N_2$][$PtCl_4$] **3** by a similar route.‡ In the crystal structure§ of **3** (Fig. 2) a two-dimensional NH···Cl hydrogen bond network results in which the **B**-like ribbons are more distorted from planarity than in **2**. Thus the type **A** chelate interaction is not planar (see Fig. 3) and is formed by the *axial* NH groups of the piperazinium (*cf.* **2** in which the equatorial NH groups are used). The NH···Cl bonds between **B**-type ribbons are only slightly longer than those within the rows (2.61 *cf.* 2.56 Å) and are also of the chelate type.

Clearly the replacement of the bipyridinium moieties of **1** by bipiperidinium or piperazinium does not prevent the formation of a **B**-type motif. We therefore sought to test other aspects of this motif for robustness by replacing part of the covalent framework of the bipyridinium cation with supramolecular units. Thus protonated isonicotinic acid and isonicotinamide were used in preparation of salts of $[PtCl_4]^{2-}$ from acidic (HCl) aqueous solution in the expectation that supramolecular dications **E** and **F** would replace bipyridinium. In the case of **F**, additional NH hydrogen bond donor capability is available parallel to the plane of the supramolecular dication. In this way

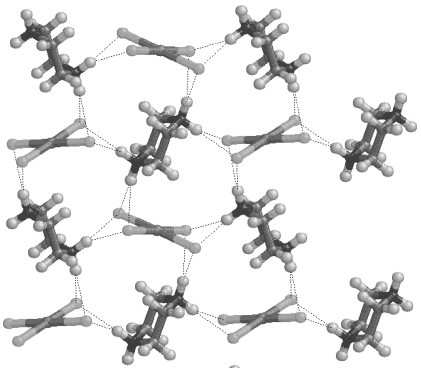

Fig. 2 The NH···Cl hydrogen bonded layer in crystalline [piperazinium][$PtCl_4$] **3**. The NH···Cl hydrogen bonds are indicated. Hydrogen bond lengths and angles include: in-ribbon (across page): NH···Cl 2.56 Å, N–H···Cl 141°, Pt–Cl···HN 87°. Between ribbons: NH···Cl 2.61 Å, N–H···Cl 141°, Pt–Cl···HN 69°.

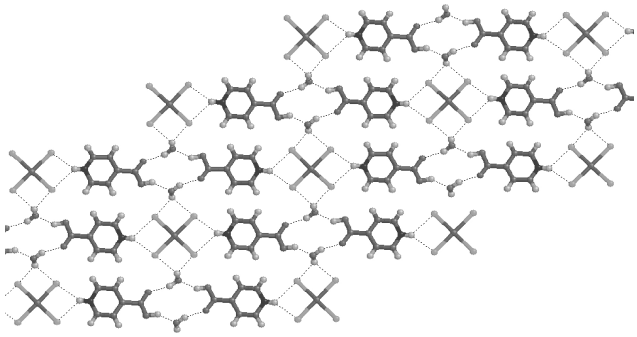

Fig. 3 The hydrogen bonded layer in crystalline [$HNC_5H_4CO_2H$-4]$_2$[$PtCl_4$]·$2H_2O$ **4**. The NH···Cl, OH···Cl and OH···O hydrogen bonds are indicated. Hydrogen bond lengths and angles include: in-ribbon NH···Cl 2.45 Å, N–H···Cl 145°, Pt–Cl···HN 97°; NH···Cl 2.63 Å, N–H···Cl 134°, Pt–Cl···HN 92°; HOH···O(1) 1.90 Å, O-H···O 163°, H···O-C 133°; OH···OH_2 1.74 Å, O-H···OH_2 147°. Between ribbons: OH···Cl 2.63 Å, O–H···Cl 141°, Pt–Cl···HO 85°; OH···Cl 2.77 Å, O–H···Cl 145°, Pt–Cl···HO 82°.

the salts [$HNC_5H_4CO_2H$-4]$_2$[$PtCl_4$]·$2H_2O$ **4** and [$HNC_5H_4CONH_2$-4]$_2$[$PtCl_4$] **5** were prepared‡ and characterised by single crystal X-ray diffraction analyses.§

Both **4** and **5** contain **B**-type ribbons (see Fig. 3 and 4) with supramolecular dications in the chain as anticipated. However the incorporation of water in **4** was unexpected and instead of the R2,2(8) cyclic dimer (**E**), the dihydrate variant (**G**) of this structure, is formed. Thus an R4,4(12) supramolecular motif is incorporated in the **B**-type ribbon of **4** (see Fig. 3). As a result of water incorporation there is a pair of extra hydrogen bond donors present in the supramolecular dication **G** compared with **E**. In contrast **5** has the expected motif containing the classic amide dimer R2,2(8) unit (see Fig. 4). As in **4** there are

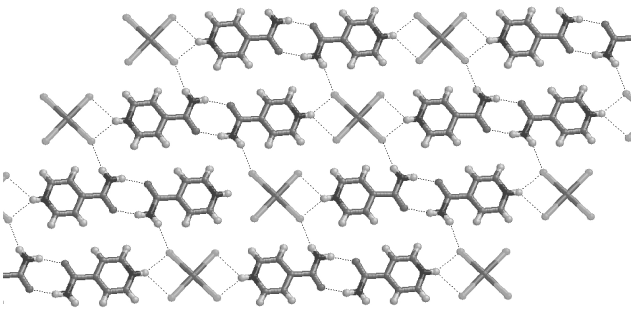

Fig. 4 The hydrogen bonded layer in crystalline [$HNC_5H_4CONH_2$-4]$_2$[$PtCl_4$] **5**. The NH···Cl and NH···O hydrogen bonds are indicated. Hydrogen bond lengths and angles include: in-ribbon NH···Cl 2.47 Å, N–H···Cl 146°, Pt–Cl···HN 97°; NH···Cl 2.60 Å, N–H···Cl 133°, Pt–Cl···HN 80°; NH···O 2.03 Å, N–H···O 161°, NH···O-C 124°. Between ribbons: NH···Cl 2.58 Å, N–H···Cl 156°, Pt–Cl···HN 144°.

additional acidic hydrogens (OH in **4** and NH in **5**) available to cross-link the ribbons. In **4** the spare OH is inclined at 59° to the plane of the ribbon, while in **4** the spare NH bond is near coplanar with the ribbon. As a consequence the resultant cross-linked ribbons are of pleated and planar form in **4** and **5**, respectively.

These results establish:

(1) The robustness of motif **A** in its doubled form **H**; both saturated and aromatic cationic NH donors are compatible with this supramolecular synthon.
(2) The robustness of the periodic structural motif **B** with respect to the nature of the framework to which the NH group(s) are attached, whether saturated or aromatic, molecular or supramolecular. Furthermore the metric of this motif is very flexible, the repeat distance along the **B**-like ribbon in **1** is 15.76 Å while in **2**–**5** it is 15.87, 10.15, 23.38 and 21.32 Å, respectively.
(3) That the presence of additional hydrogen bond donors, beyond those required to form interaction **H** or to form the supramolecular dications of **4** and **5**, may be exploited to add dimensionality to the NH···Cl hydrogen bond network in a rational manner.

Financial support of the EPSRC and the Royal Society and the Leverhulme Trust (a Royal Society Leverhulme Trust Senior Research Fellowship for A. G. O.) is gratefully acknowledged.

Notes and references

‡ *Syntheses* of **2**–**5**. Details are given in ESI†. In general, stoichiometric amount of the nitrogen base (or its hydrochloride) dissolved in aqueous HCl was added to an aqueous solution of K_2PtCl_4 and crystalline samples grown from solution. For **5** this yielded a mixture of products, presumably as a result of hydrolysis of the isonicotinamide. A sample of crystalline **5** was obtained by hand selection of crystals.

Organic Au(I) complexes could be highly effective catalysts for the synthesis of diformamides by carbonylation of aliphatic diamines, with selectivity significantly enhanced in the presence of the appropriate amount of oxygen.

Gold as a catalytic material has recently been receiving growing attention. Many reactions catalysed over Au catalyst such as CO oxidation,[1,2] selective oxidation,[3,4] removal of NO_X,[5] selective hydrogenation,[6] methane combustion,[7,8] carbonylation of olefins,[9] dehydrogenation dimerization of trialkylstannane,[10] asymmetric aldol reactions[11] and C–C bond making reactions,[12–14] have been reported to have excellent performances. These results indicate that the potential of gold as a catalyst may be tremendous and is worthy of further investigation, since gold has been little explored in comparison with precious metals such as Pd, Pt, Rh *etc*.

In this communication, we show that organic Au(I) complexes can be highly effective catalysts for the synthesis of diformamides, which are useful as intermediate compounds to pharmaceutical substances,[15] by carbonylation of aliphatic diamines in the presence of appropriate amounts of oxygen [eqn. (1)].

$$H_2N(CH_2)_mNH_2 + CO \xrightarrow[O_2]{[Au(PPh_3)_a]_bX} OHCHN(CH_2)_mNHCHO \quad (1)$$

m = 6 or 8; a = 1 or 2; b = 1 or 2; X = Cl, NO_3, or S

$Au(PPh_3)Cl$, $Au(PPh_3)_2Cl$, $Au(PPh_3)NO_3$ and $[Au(PPh_3)]_2S$, synthesized according to the literature,[16–18] were used as the catalysts. $HAuCl_4$ and $Pd(PPh_3)_2Cl_2$ were also employed for the purpose of comparison. All reactions were performed in a 90 cm^3 stainless steel autoclave equipped with a magnetic stirrer. Typically, for each reaction we employed catalyst 0.75–1.6 mol% (relative to the substrate), solvent 20 ml, substrate 0.5 ml or 0.5 g (3–6.5 mmol). These were successively charged into the reactor, and then CO 4–5 MPa and O_2 0–1 MPa were successively introduced with an initial pressure 5.0 MPa at room temperature. The reaction was allowed to proceed with stirring at 150–200 °C for 3 h. The resulting liquid mixture was analyzed with a Hewlett-Packard 6890/5793 GC/MS equipped with a HP 5MS column. The concentrations of reactant and product were given directly by the GC/MS chemstation from the area of each chromatograph peak.

The results of carbonylation of aliphatic amines are shown in Table 1. Although the oxygen was not involved directly in the carbonylation reaction according to eqn. (1), it was found that oxygen had a remarkable impact on the selectivity. For example, when 1,6-hexanediamine was used as the substrate in the presence of $Au(PPh_3)Cl$ as catalyst, entry 1, only 47.2% of the selectivity for desired diformamide could be obtained in the absences of oxygen although the conversion was almost 100%. The main by-product was monoformamide (52.5%), and a very small amount of *N*,*N*,*N*′,*N*′-tetramethyl 1,6-hexanediamine was also detected, which probably resulted from the reaction of 1,6-hexanediamine with methanol. The selectivity, however, was significantly enhanced when a small amount of O_2 was introduced, and it can also be seen that high selectivities could not be achieved if the addition of O_2 was deficient or excessive (entries 2–4), *i.e*. there existed an optimum $P(CO):P(O_2)$ ratio for high selectivities of *ca*. 4.5:0.5, under which only monoformamide (8%) was detected. Hexanolactam (1%), an over oxidized by-product, could be found if the ratio of $P(CO):P(O_2)$ reached 4.0:1.0. Since O_2 was not directly incorporated into the products it was conjectured that O_2 plays a role in maintaining the Au species in an appropriately active state during the reaction.

Although 150 °C was high enough for almost complete conversion of the substrate (entry 5), the highest selectivity for

the desired product was achieved at *ca.* 175 °C, and by-products, such as hexanolactam (0.1%) were detected if the temperature was further increased to 200 °C (entry 6). From entries 3, 7 and 8 it can be seen that the best results were obtained when benzene was employed as solvent, with 95% selectivity achieved; 92% and 90% selectivities were obtained if methanol or acetonitrile were used as solvents, respectively.

$Au(PPh_3)_2Cl$, $Au(PPh_3)NO_3$ and $[Au(PPh_3)]_2S$ were also tested for catalytic activity (entries 9–11). The best catalytic performance was achieved with $[Au(PPh_3)]_2S$ although the differences in selectivities for the desired product were not large with these Au complexes, while the selectivity, when using $HAuCl_4$ as catalyst, was significantly inferior to that with the Au(I) complexes, indicating that the chemical state of Au and the organic ligands played an important role in the selectivity.

The carbonylation of other substrates using $Au(PPh_3)Cl$ as catalyst was further examined under the same reaction conditions (entries 13–15). For decanediamine, almost 100% of conversion and 98% of selectivity were achieved. But $Au(PPh_3)Cl$ as catalyst was less effective when n-hexylamine and cyclohexylamine were used as substrates. The selectivities for the desired products were only 51.8% and 70% respectively, and the main by-products were the corresponding dialkylureas. These results suggested that the organic Au(I) complex catalysts used here were especially effective for the carbonylation of aliphatic diamines to form the corresponding alkyldiformamide.

$Pd(PPh_3)_2Cl_2$ as catalyst was also employed for this reaction, and only 79.7% selectivity was obtained at 175 °C (entry 16) although the conversion could be almost 100%. The main by-products were hexanolactam (5.7%) and monoformamide (14.6%). The catalytic performance of $Pd(PPh_3)_2Cl_2$ was even poorer at 150 °C. This indicates that Au(I) complexes as catalysts for such specific carbonylation are better than the corresponding Pd(II) complexes, although it was well known that Pd complexes are the most effective catalysts for many other carbonylation processes.

It is worth noting that the TOFs listed in Table 1 do not distinguish clearly the differences in performance among these catalysts. For example, the TOFs for entries 1–4 are the same. So, in this work, TOFP (turnover frequency for product), *i.e.* mole product per mole catalyst per hour has been used to characterize the performance of a catalyst. The differences in the catalytic performances are clearly shown with TOFP, for example, at 175 °C the best catalyst is $[Au(PPh_3)]_2S$.

In summary, the organic Au(I) complexes mentioned above can effectively catalyse the carbonylation of aliphatic diamines to produce the corresponding diformamides in the presence of an appropriate amount of oxygen. To our knowledge, this is the first reported study of organic Au(I) complexes as homogeneous catalysts for the synthesis of diformamides by carbonylation of aliphatic diamines. Further optimization towards the gold catalyst system for the carbonylation reaction is now ongoing.

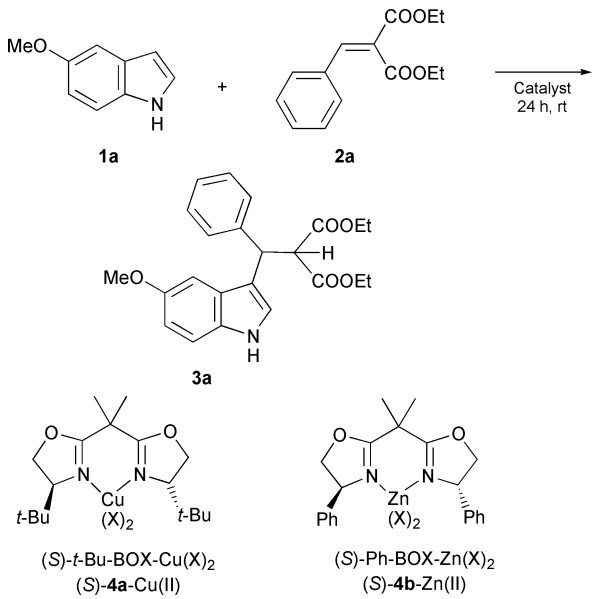
First published as an Advance Article on the web 7th February 2001

A catalytic enantioselective alkylation of heteroaromatic compounds using alkylidene malonates has been developed; the reaction proceeds for different heteroaromatic compounds with alkylidene malonates in high yield and enantiomeric excess.

The addition of aromatic C–H bonds to alkenes, the Friedel–Crafts alkylation, is a highly important reaction in synthetic chemistry for the formation of new C–C bonds.[1] A challenge for the Friedel–Crafts alkylation is to perform the reaction in a catalytic enantioselective fashion as this would be a simple and attractive method for the synthesis of optically active aromatic compounds using easily available starting materials. The first examples of catalytic enantioselective addition reactions of aromatic compounds to conjugated compounds such as carbonyls and imines have recently appeared.[2] In the following we will present the first catalytic enantioselective alkylation of heteroaromatic compounds using alkylidene malonates catalyzed by chiral Lewis acids.

The reaction of indole **1a** with alkylidene malonate **2a**[3] in the presence of the chiral bisoxazoline–metal(II) complexes, (*S*)-**4a**-Cu(II), (*S*)-**4b**-Zn(II), as the catalysts[4] proceeds well giving the Friedel–Crafts alkylation adduct **3a** in good yield and high ee [eqn. (1)]. Table 1 gives some representative results for the screening of catalysts and reaction conditions.



(1)

The reactions were performed with 2 eq. of hexafluoro-*i*-PrOH (HFIP) and 10% catalyst loading.[5] No reaction took place with (*S*)-**4a**-Cu(OTf)$_2$ in MeCN or $MeNO_2$ as solvents, while in Et_2O high conversion to **3a** and good ee was achieved (entries 1–3). The catalyst (*S*)-**4b**-Zn(OTf)$_2$ also gave high conversion, however, the enantioselectivity was low (entry 4). The catalytic activity of (*S*)-**4a**-Cu(OTf)$_2$ in THF was very good and **3a** was obtained in 91% yield and 60% ee (entry 5). The activity increased further by changing counterion from OTf to SbF_6 in CH_2Cl_2 giving high conversion at 0 °C, however, the ee of **3a** dropped from 57 to 35% ee (entry 6 and 7). The effect of addition of HFIP to the reaction was found to be negligible; the reaction rate decreased only slightly and the ee was essentially unchanged in the absence of HFIP (entry 3 *vs.* 8).[5] The effect of other parameters such as lower catalyst loading, concentration and temperature all gave lower conversion to **3a** with very little increase in ee.

Table 1 Screening of chiral Lewis acids and reaction conditions for the reaction of indole **1a** with alkylidene malonate **2a**

Entry	Catalyst	Solvent	X	Conv.[a] (%)	Ee[bc] (%)
1	(*S*)-**4a**-CuX$_2$	MeCN	OTf	—	—
2	(*S*)-**4a**-CuX$_2$	$MeNO_2$	OTf	—	—
3	(*S*)-**4a**-CuX$_2$	Et_2O	OTf	95	60

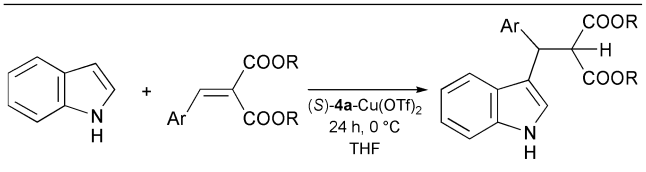
[a] Determined by ^{1}H-NMR spectroscopy. [b] Determined by chiral HPLC. [c] Number in parentheses is ee after recrystallization. [d] Opposite enantiomer. [e] Reaction performed at 0 °C. [f] No HFIP used.

A selection of β-substituted alkylidene malonates **2a**–**e** were examined in this reaction with indole **1b** catalyzed by (*S*)-**4a**-Cu(OTf)$_2$ (Table 2). Indole **1b** reacted with **2a** to give the Friedel–Crafts alkylation product **3b** in 73% yield and 60% ee (entry 1).† The dimethyl benzylidene malonate **2b** was significantly more reactive compared to the diethyl derivative (**2a**) giving the addition product in 95% isolated yield, however, the ee was lower for **3b** (entry 1 *vs.* 2). The reactivity of dimethyl *p*-nitrobenzylidene malonate **2c** was comparable to **2b**, and product **3d** was formed in high yield and with 56% ee

Table 2 Reaction of indole **1b** with various β-substituted alkylidene malonates **2a**–**e** catalyzed by (*S*)-**4a**-Cu(OTf)$_2$



1b **2a-e** **3b-f**

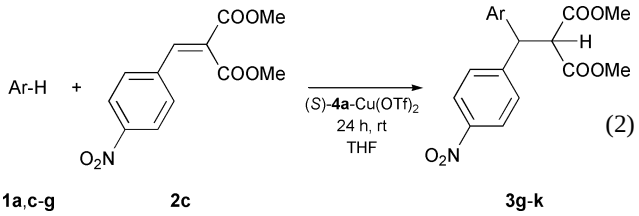
(entry 3). The diethyl 2-chlorobenzylidene malonate derivative **2e** was considerably less reactive compared to the other malonates and required a 30 °C reaction temperature for the reaction to go to completion. The enantioselectivity of **3f** was 69% ee, the highest enantioselectivity obtained in this selection.

Dimethyl *p*-nitrobenzylidene malonate **2c** was then used as a standard substrate to probe the reactivity of different aromatic compounds **1a**, **c**–**f** in this Friedel–Crafts alkylation reaction [eqn. (2)] (Table 3).



(2)

1a,**c**-**g** **2c** **3g**-**k**

Table 3 Friedel–Crafts alkylation reaction of different heteroaromatic compounds **1a**, **c**–**g** with dimethyl *p*-nitrobenzylidene malonate **2c** catalyzed by (*S*)-**4a**-Cu(OTf)$_2$

Entry	Ar	Yield[a] (%)	Ee[bc] (%)
1[d]	5-MeO-indole–**1a**	**3g**–99	58

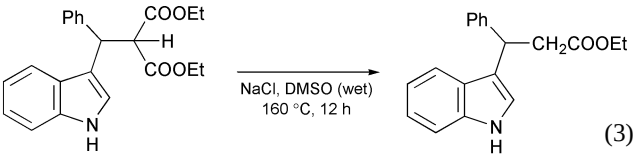
3	*N*-Me-indole–**1d**	**3i**–99	48
4	*N*-Me-pyrrole–**1e**	**3j**–99	36
5	Pyrrole–**1f**	**3k**–99	28
6	2-Me-furan–**1g**	**3l**–99	12

[a] Isolated yield after column chromatography. [b] Determined by chiral HPLC. [c] Determined by chiral HPLC. [d] Reaction performed at 0 °C. [e] Reaction performed at 30 °C.

The reaction with 5-methoxyindole **1a** gave the Friedel–Crafts alkylation product **3g** in excellent yield and with 58% ee (entry 1). 4-Chloroindole **1c** reacted to give the desired product **3h**, although in a lower yield and ee compared to the more electron-rich indole (entry 2). *N*-Methylindole **1d** and *N*-methylpyrrole **1e** both yielded the alkylation products **3i** and **3j**, respectively, with great efficiency and with a small drop in ee (entries 3, 4). Both pyrrole **1f** and 2-methylfuran **1g** reacted in a Friedel–Crafts fashion in excellent yields, but the enantioselectivity of the products was low compared to the other substrates (entries 5, 6).

A further advantage of this Friedel–Crafts alkylation reaction is that the products all are solid and the optical purity can be greatly enhanced to > 90% ee by crystallization as shown for several of the entries in Table 1, 2.

The Friedel–Crafts adducts such as **3b** can undergo decarboxylation[6] to give the mono ester **5** in high yield [eqn. (3)], showing that the present reaction formally can be considered as a Friedel–Crafts alkylation of cinnamates.



(3)

3b **5**
74% isolated yield

In summary, a new catalytic enantioselective alkylation of heteroaromatic compounds using alkylidene malonates catalyzed by chiral bisoxazoline–copper(II) complexes has been presented. The reactions proceed in high yields and with moderate ee for different aromatic compounds and alkylidene malonates. The optical purity of the products can be enhanced by recrystallization and it is demonstrated that the reaction can be considered as a formal Friedel–Crafts alkylation of cinnamates.

Two-dimensional hexagonally ordered CMK-3 carbons were synthesized using SBA-15 templates calcined at a temperature of 1153 K, whereas a disordered carbon was obtained using SBA-15 calcined at 1243 K, demonstrating that the pores connecting ordered mesopores in SBA-15 silica persist up to *ca.* 1153 K, but are eliminated at temperatures close to 1243 K.

During the last several years, SBA-15 silica[1] with a two-dimensional (2-D) hexagonal arrangement of uniform mesopores has attracted much attention and is being evaluated for numerous applications in the fields of catalysis, separations, water purification, and advanced optics devices (see for instance refs. 2 and 3 for references). This remarkable interest stems from the many desirable features of SBA-15, including tailored pore size, high degree of structural ordering, ease of synthesis, availability of economically facile synthesis pathways, high hydrothermal/thermal stability and so forth. Despite all this interest in the synthesis, modification and application of SBA-15, the very structural identification of this material was largely uncertain until recently. Initially,[1] SBA-15 was considered to be an extra-large-pore MCM-41[4] analog with a honeycomb structure of disconnected channel-like pores. Later, much evidence for microporosity in numerous SBA-15 samples was reported,[2,3,5–8] although some SBA-15 samples were claimed to be non-microporous in contrast to others,[7,8] and the very evidence of microporosity was questioned[9] by the authors who first suggested the presence of micropores in SBA-15.[5] As we first pointed out,[2,3] the development of microporosity in SBA-15 and its evolution during the synthesis are consequences of the fact that poly(ethylene oxide) blocks of the poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) template penetrate the silicate walls of as-synthesized SBA-15, which was convincingly shown by others.[10,11] To end the controversy about the SBA-15 structure and to fully reveal its nature, we carried out an extensive study involving platinum[3] and carbon[12] replication, as well as characterization *via* selective pore blocking *via* chemical modification.[3] The latter method in addition to nitrogen and argon adsorption confirmed the presence of micropores and small mesopores (later referred to as complementary pores) of the size below 3.4 nm.[3] In addition, the replication studies revealed for the first time the interconnected nature of SBA-15 porosity, since bundles of ordered platinum nanowires,[3] and high-surface-area carbon (denoted as CMK-3) with uniform pores between 2-D hexagonal arrangement of uniform rods[12] were obtained through SBA-15 templating. It is otherwise known that similar structures cannot be obtained using MCM-41 as a template under analogous conditions.[13–15] It is also noteworthy that replication is widely considered as a convincing and reliable tool of structure characterization,[16] and carbon replication[17] in particular has already been employed[13] to confirm the worm-like interconnected nature of porosity in HMS silica.[18] The SBA-15 samples studied by platinum and carbon replication were synthesized by employing aging at 373 K which is a standard procedure for SBA-15 synthesis[1] (referred to by some authors as hydrothermal treatment).[8] Therefore, our findings about the interconnected nature of SBA-15 porosity are relevant to the overwhelming majority of SBA-15 preparations reported to date, including some of the materials, which were claimed non-microporous in contrast to other SBA-15 samples.[7,8]

In the current study, we employed carbon replication to confirm that not only typical SBA-15 silica has interconnected porous structure, but also the connecting pores are exceptionally persistent and are not eliminated even after calcination at 1153 K, although there is evidence that they are largely eliminated at somewhat higher temperatures. The remarkably high thermal stability of connecting pores and the possibility of their elimination only at temperatures as high as *ca.* 1273 K were suggested in our earlier study based solely on nitrogen adsorption data.[3]

SBA-15 samples were prepared using the triblock copolymer, $EO_{20}PO_{70}EO_{20}$ (Pluronic P123, BASF) and tetraethoxysilane (TEOS, 98%, Acros). The details of the synthesis procedure are described elsewhere.[12] The synthesis procedure was similar to that originally developed by Stucky and coworkers,[1] except for the particle growth under static conditions and the starting composition of 10 g P123 : 0.10 mol TEOS : 0.60 mol HCl : 20 mol H_2O. The SBA-15 products were filtered off, dried without washing, and calcined in dry air flow at various temperatures. The carbon replication was performed with sucrose as described in detail elsewhere.[12] Briefly, the SBA-15 sample was infiltrated twice with sucrose in the presence of sulfuric acid and subsequently, the carbonization was completed by heating at 1173 K under vacuum. These calcined SBA-15 silicas are referred to as SBA-15-*x*, where *x* denotes the calcination temperature, whereas the SBA-15-*x* templated carbons are referred to as CMK-3-*x* or C-*x*, in the case of ordered and disordered carbons, respectively.

As can be seen in Fig. 1(a), SBA-15 retains a highly ordered hexagonal structure even after calcination at 1243 K, despite the large decrease (*ca.* 25%) in the unit-cell size. The structural shrinkage was accompanied by a major loss of the BET specific surface area and total pore volume (from 850 to 390 and 220 m^2 g^{-1}, and from 1.03 to 0.49 and 0.23 cm^3 g^{-1}, after heating at 1153 and 1243 K, respectively) and significant pore size decrease, but the narrow pore size distribution persisted [Fig. 1(b)]. It should be noted that the specific surface areas, total pore volumes, and pore size distributions reported herein were evaluated as described in our previous work.[2,3] When the resulting SBA-15 silica templates were employed in the carbon synthesis, only samples calcined at 823 and 1153 K afforded 2-D hexagonally ordered carbons, whereas SBA-15 template calcined at 1243 K rendered carbon with no long-range ordering [Fig. 1(a)]. All the carbon replicas exhibited high BET specific surface areas and total pore volumes (1160, 1160 and 750 m^2 g^{-1}, as well as 1.24, 1.08 and 0.53 cm^3 g^{-1}, for CMK-3-823, -1153 and C-1243 samples, respectively). However, only CMK-3-823 and -1153 samples exhibited capillary condensation steps on nitrogen adsorption isotherms, and consequently, narrow mesopore size distributions [Fig. 1(c)], whereas C-1243 carbon was primarily microporous with a relatively small amount of

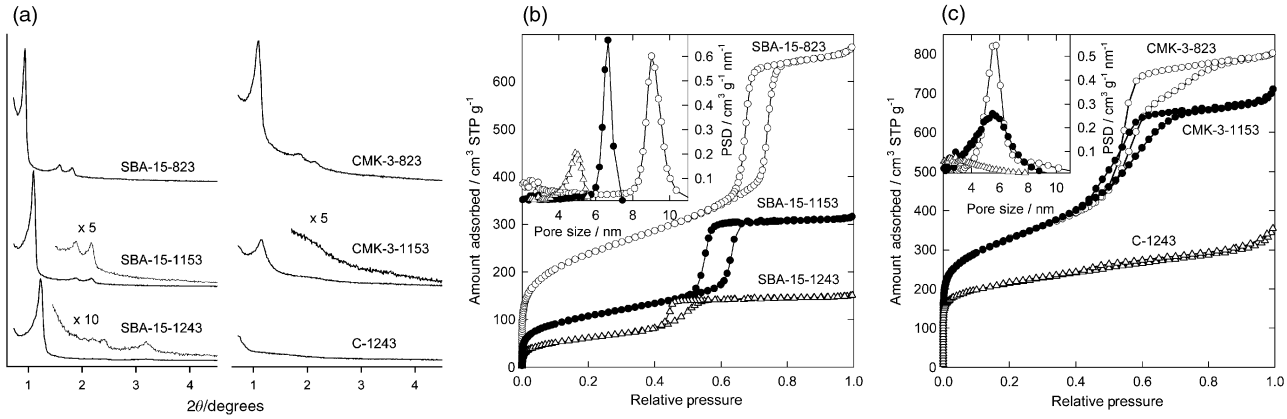

Fig. 1 (a) Powder X-ray diffraction spectra for the SBA-15 and carbon samples. (b) Nitrogen adsorption isotherms and pore size distributions for the SBA-15 silicas. (c) Nitrogen adsorption isotherms and pore size distributions for the carbons synthesized using the SBA-15 silica templates.

disordered mesopores, thus being similar to the high-surface-area carbon synthesized using MCM-41 as a template.[14] It should be noted that the carbon framework of CMK-3 is microporous to some extent,[12] similarly to other ordered mesoporous carbons synthesized using the same carbon precursor.[14,17] Therefore, the overall porosity of CMK-3 is a combination of uniform pores between ordered carbon rods, and micropores within these rods.

The successful synthesis of ordered mesoporous carbons using SBA-15 templates calcined at 823 and 1153 K showed that the structure of SBA-15 prepared under standard conditions is clearly interconnected, otherwise periodic carbon structures would not form. Indeed, as inferred from the structures of C-1243 carbon and carbons templated using MCM-41 silicas,[13,14] disconnected uniform carbon rods do not exhibit a tendency to agglomerate in ordered structures. The carbon templated using SBA-15-1153 exhibited mesoporous structure similar to that of the material prepared from the SBA-15-823 template, thus suggesting that the large structural shrinkage during the high-temperature calcination did not result in the complete elimination of the complementary pores. However, it needs to be kept in mind that the complementary pores are likely to be largely depleted after such a treatment. One can infer this from the examination of the relation between the primary mesopore diameter (w), primary pore volume (V) and primary pore surface area (S) for the SBA-15 templates. Primary pores are defined here as primary (ordered) mesopores and complementary (connecting) pores. The factor wS/V is theoretically expected to be 4 for cylindrical and 4.2 for hexagonal pores. For highly ordered MCM-41 silicas, we found wS/V values of 4.5–5.0 and therefore we can consider this range of values as that characteristic of disconnected cylindrical (or hexagonal) mesopores of size of several nanometers. The difference between the theoretical and experimental values can be largely attributed to the overestimation of surface area using the BET method that was discussed elsewhere.[19] For SBA-15 calcined at 823 K, the wS/V factor was equal to 7.6 (consistent with earlier studies),[3] whereas for the samples calcined at 1153 and 1243 K, it was 5.3 and 4.9, respectively. So, on the basis of data for MCM-41, it is not unexpected that SBA-15 samples with wS/V = 7.6 and 5.3 were suitable as templates for ordered porous carbons, and SBA-15 with wS/V = 4.9 was not. However, it is surprising that as small a difference in wS/V factor as 0.4, and corresponding expected small difference in the pore structure may lead to completely different templating effects. This suggests that either even a small content of connecting pores in SBA-15 is capable of imparting stable CMK-3 frameworks, or connecting pores in SBA-15 are abundant and even their significant depletion leaves an appreciable population, or both of the above. Anyway, further studies of structures of SBA-15 and CMK-3 carbons are highly desirable. In addition, a search for criteria useful for reliable prediction of pore connectivity of templates, and in particular, further work on refinement of the wS/V criterion, appear to be worthwhile. To this end, we should emphasize that w, S and V values need to be evaluated using reliable methodology, for instance the same as or equivalent to that employed herein.[2,3] Where calculation procedures providing different results are used, the threshold value of the wS/V factor for connected pore structures would have to be re-evaluated. Moreover, the value of the wS/V factor should not be treated as fully conclusive as to pore connectivity. The final conclusions about the presence or absence of connecting pores should be based preferably on replication procedures, among which carbon replication appears to be the most convenient.

The controlled glycosylation of a protein with a bivalent glycan: towards a new class of glycoconjugates, glycodendriproteins†‡

Benjamin G. Davis

Department of Chemistry, University of Durham, Science Laboratories, South Road, Durham, UK DH1 3LE. E-mail: ben.davis@durham.ac.uk

Received (in Liverpool, UK) 10th November 2000, Accepted 12th January 2001
First published as an Advance Article on the web 7th February 2001

The use of a novel bivalent carbohydrate modification reagent, based on a flexible, branched divalent core in a combined site-directed mutagenesis and chemical modification strategy has allowed the first controlled synthesis of a pure protein bearing a branched glycan or a first generation glycodendriprotein.

The glycosylation of proteins plays a key role in determining their expression, folding,[1] thermal and proteolytic stability[2] and in the case of enzymes, catalytic activity.[3] Furthermore, the role of glycoproteins as cell surface markers in communication events such as microbial invasion,[4] inflammation,[5] immune responses and tissue development[6] depends crucially on the correct glycosylation pattern.[7] There is evidence that even very slight alterations in the sugars that decorate the exterior of a protein can cause remarkable changes in these properties. For example, we have recently shown that correct and controlled glycosylation of a model enzyme system with a single saccharide unit allows fine tuning of activity to levels that are up to 8.4-fold greater than the native unglycosylated enzyme.[8] Models for glycoprotein interactions, including activity and binding to corresponding receptor proteins, have been suggested[9,10] and the elucidation of the mechanism of this binding and its consequences is a dominant primary goal in glycoscience and continues to drive the synthesis of glycoconjugates.[11] Access to well-defined scaffolds to probe the nature of these models is essential.[12]

Despite their very shallow binding sites, sugar-binding proteins, lectins, show a remarkable specificity in their binding of multivalent complex carbohydrate structures.[13] The monosaccharide–lectin interaction stands out as an unusually weak and relatively undiscriminating one ($K_d \sim 10^{-3}$ M).[14] However, when more than one saccharide of the right type and in the right orientation are clustered together there is a rapid increase in both affinity and specificity by the corresponding lectin.[15] This increase appears in some cases to be greater than would be expected due to the increase in local concentration (statistical effect) alone and has been termed the 'cluster' or 'multivalent effect', although its origin is yet to be rigorously determined.[10]

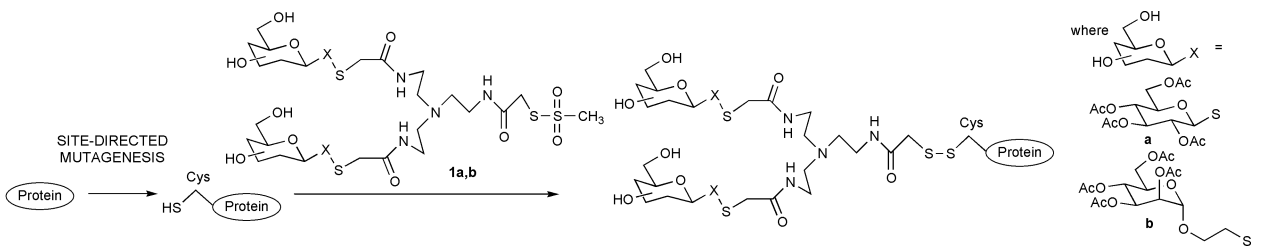
† Some of this work was presented at a joint meeting of the RSC Carbohydrate and Bioorganic groups, Warwick, July 6, 2000 and at the 20th International Carbohydrate Symposium, Hamburg, August 30, 2000.
‡ Electronic supplementary information (ESI) available: selected NMR data. See http://www.rsc.org/suppdata/cc/b0/b009184g/

Exploitation of lectin binding does not necessarily rely on mimicking natural multiantennary structures as long as an energetically efficient method for their presentation to binding sites may be found.[15] We have recently demonstrated that glycoproteins bearing a single monosaccharide ligand bind to lectins with a low affinity that is dependent both on the nature of the carbohydrate and the site of glycosylation.[16] We have set ourselves the goal of constructing glycoproteins bearing branched multivalent glycans at predetermined sites to probe the nature of this binding interaction further. Furthermore, by choosing an enzyme as our protein model we aim to investigate the effect of multivalent site-selective glycosylation, by displaying multiple copies of a glycan that previously allowed dramatic enhancement of enzyme actvities.[8] This communication describes the successful construction of the first generation of this new class of glycoconjugates: glycodendriproteins.

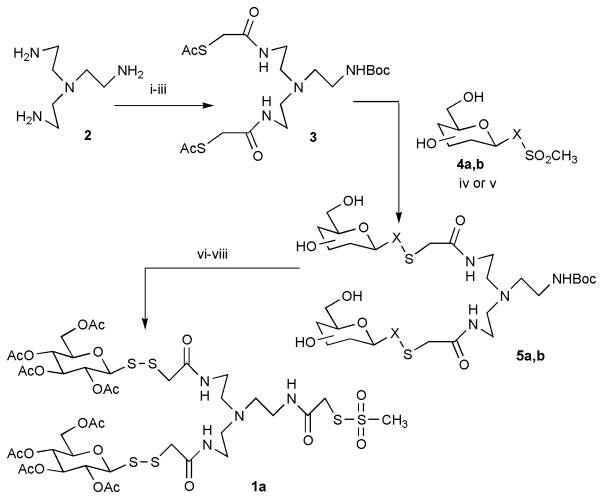
To achieve our goals we employed a combined site-directed mutagenesis (SDM) and chemical modification approach (Scheme 1).[17] This strategy involves the introduction of cysteine as a chemoselective tag at preselected positions within a given protein and then reaction of its thiol residue with (polyglyco)methanethiosulfonate reagents, such as **1**. Methanethiosulfonate (MTS) reagents react specifically and quantitatively with thiols[18] and allow the controlled formation of neutral disulfide linkages. We chose as our model protein the serine protease enzyme, subtilisin *Bacillus lentus* (SBL, EC 3.4.21.14).[19] SBL is an ideal model since wildtype (WT)-SBL contains no natural cysteines and methanethiosulfonate reagents therefore react only with the cysteine residue that has been introduced by SDM. In addition, SBL has been well characterized,[20] has been over-expressed and purified,[21] and its crystal structure is known.[22]

Two representative bivalent branched glycan MTS reagents **1a**,**b** based on a trivalent tris(2-aminoethyl)amine (TREN) core were chosen as targets (Scheme 2). **1a** bears at the end of its two glycan branches the same untethered peracetylglucose unit that had previously allowed dramatic enhancement of enzyme activity.[8] **1b** would bear ethyl-tethered mannose moieties that had been used in the construction of previous glycoproteins that had shown low levels of lectin binding.[16] These two reagents would therefore allow the introduction of multivalent, tethered or untethered, glycans with α or β anomeric stereochemistry from different parent carbohydrates systems.

After differentiation of one of the amine termini of TREN **2** through selective protection as its mono-Boc derivative,[23] the two remaining free amine termini were reacted with chloro-



Scheme 1



Scheme 2 *Reagents and conditions*: i, 1 equiv. Boc_2O, CH_2Cl_2, −78 °C, 68%; ii, $(ClCH_2CO)_2O$, pyridine, CH_2Cl_2, 97%; iii, KSAc, DMF, 50 °C, 88%; iv, NaOH (aq.) then **4a**, 73%; v, NaOH (aq,) then **4b**, 62%; vi, CF_3COOH, CH_2Cl_2, 88%; vii, $(ClCH_2CO)_2O$, pyridine, CH_2Cl_2, 87%; viii, $NaSSO_2CH_3$, DMF, 50 °C, 68%.

acetic anhydride to give the corresponding bis-α-chloroamide. Treatment of this branched dichloride with the potassium salt of thioacetic acid gave the bis-thioester **3** in a good overall yield (58% over 3 steps from **2**). One-pot selective deprotection and glycosylations of **3** were achieved by treatment with dilute aqueous NaOH solution to hydrolyse the labile thioacetates and then modification of the free thiol groups produced with the appropriate untethered β-gluco **4a** or tethered α-manno **4b** methanethiosulfonate reagents to yield the corresponding bivalent branched glycans **5a**,**b** in 73 and 62% yield, respectively. It should be noted that the use of a basic TREN-core as a scaffold allowed the scavenging of **5a**,**b** from reaction mixtures using acidic ion exchange resin and therefore greatly simplified their purification. With the ability to introduce two distinct glycan endgroups **a** or **b** thus suitably demonstrated, **5a** was selected and the remaining Boc-protected amine terminus elaborated to introduce a methanethiosulfonate group and to create **1a** as the first representative reagent that would allow protein modification. Thus, **5a** was deprotected through treatment with CF_3COOH and the free amine produced converted to the corresponding α-chloroamide. Displacement of α-chloro group through treatment with $NaSSO_2CH_3$ in DMF at 50 °C proceeded smoothly and yielded the target bis-glycan MTS **1a** in good yield (52% over 3 steps from **5a**).

We used **1a** as the first example of a bivalent protein glycosylating reagent to treat mutant protein SBL-S156C in aqueous buffer (Scheme 1). S156C was obtained through site-directed mutagenesis of SBL[8] and bears an outwardly directed reactive thiol on its surface close to its substrate-binding region. Gratifyingly, the reaction was rapid and quantitative, as judged by monitoring changes in specific activity and by titration of residual free thiols with Ellman's reagent.[24] The first generation glycodendriprotein S156C-(S-**a**)$_2$ formed was purified by size-exclusion chromatography and dialysis, and its structures confirmed by rigorous ES-MS analysis (Found 27811, Expected 27805 Da, Fig. 1b). The protein also appeared as a single band on non-denaturing gradient PAGE (Fig. 1(a)), thereby establishing its formation as a single glycoform. This is the first example of a homogeneous protein bearing branched multivalent glycans, or first-generation glycodendriprotein, in which both the site of glycosylation and the structure of the glycan introduced has been predetermined.

Work towards the synthesis of higher generations based on this novel-type of disulfide constructed dendrimeric system is now in progress and the details of kinetics and binding analysis of glycodendriprotein S156C-(S-**a**)$_2$ will be published in due course.

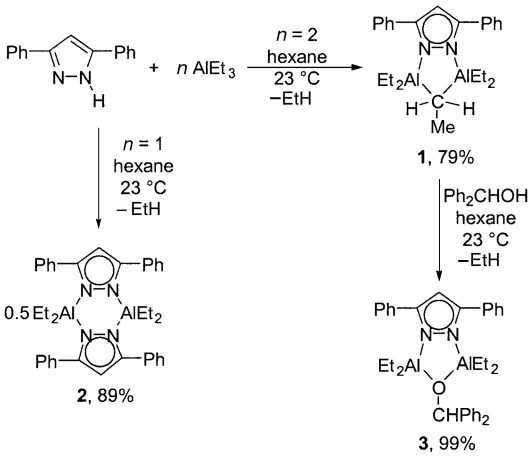
First published as an Advance Article on the web 7th February 2001

Treatment of triethylaluminium (2 equiv.) with diphenylpyrazole (1 equiv) affords a pyrazolate-bridged dialuminium complex that contains a bridging ethyl group between the two aluminium centers; this complex has been structurally characterized and its reactivity and properties are described.

The bridging of saturated hydrocarbon groups between two aluminium ions is widely recognized.[1,2] Despite widespread interest in this phenomenon, there are actually very few such compounds that have been structurally characterized and nearly all contain methyl bridges.[2] Hexakis(cyclopropyl)dialuminium has been structurally characterized and contains two bridging cyclopropyl groups per dimeric unit.[3] In addition to homobimetallic complexes, there is a small family of structurally characterized complexes in which methyl[4] or ethyl[5] groups act as bridges between aluminium and a different metal center [mostly lanthanide(III) ions]. The degree of association of several saturated higher alkyl derivatives of aluminium has been investigated in solution and in the gas phase by several different techniques.[6–9] Triethylaluminium and tri-*n*-propylaluminium were found to be dimeric by freezing point depression measurements in benzene, while triisopropylaluminium and triisobutylaluminium are predominantly monomeric in this medium apparently due to steric hindrance to dimerization.[7] Triethylaluminium was reported to be predominantly dimeric in the gas phase, as determined by vapor density measurements.[8] The low-temperature ^{1}H NMR spectrum of triethylaluminium has been interpreted in terms of a dimeric structure similar to that of trimethylaluminium dimer.[9] However, despite extensive investigation of aluminium alkyls over many years, there have been no reports of structurally characterized complexes in which an *n*-alkyl group other than methyl serves as the bridging group. In this context, we report the synthesis, structure, properties and reactivity of an aluminium pyrazolate complex that contains an ethyl group bridging between two aluminium atoms.

Treatment of diphenylpyrazole with triethylaluminium (2 equiv.) in hexane at ambient temperature led to slow ethane evolution over 18 h. The bridging ethyl complex **1** was isolated as colorless needles after crystallization of the crude residue from hexane (Scheme 1).† The formulation of **1** as the ethyl-bridged structure was suggested initially by the ^{1}H and ^{13}C{^{1}H} NMR spectra. At –40 °C in toluene-d_8, resonances due to terminal ethyl groups were observed in the ^{1}H NMR spectrum at δ 1.27 (t) and −0.30 (q) while another set of ethyl resonances appeared at δ 1.00 (t) and 0.93 (q). The ratio of these two sets of peaks (δ 1.27, −0.30 and 1.00, 0.93) was 4:1, suggesting that the presence of a bridging ethyl ligand. In the ^{13}C{^{1}H} NMR spectrum at −40 °C, the terminal ethyl carbons resonated at δ 9.79 and 1.79, while sharp bridging ethyl ligand resonances were observed at δ 7.35 and 4.08. At or below −40 °C in toluene-d_8, static NMR spectra with sharp resonances were obtained for **1**. Upon warming from −40 to 20 °C in toluene-d_8, the methyl and methylene resonances of the bridging ethyl resonance gradually broadened and shifted downfield slightly. Above 20 °C, only one type of ethyl group was observed, suggesting rapid exchange of terminal and bridging ethyl sites. The bridged ethyl structure of **1** was established in the solid state by X-ray crystallography, as described below.



Scheme 1

Other reactions relating to **1** are outlined in Scheme 1. Treatment of diphenylpyrazole with triethylaluminium (1 equiv.) afforded the dimeric pyrazolato complex **2** (89%) as colorless crystals after crystallization from hexane. Protonolysis of **1** with diphenylmethanol in hexane at 23 °C was complete within 0.25 h to afford the diphenylmethoxo complex **3** (99%) as colorless crystals. The structures of **2** and **3** were established by a combination of spectral and analytical techniques.

The X-ray crystal structure of **1** was determined.‡ Fig. 1 shows a perspective view of **1** along with selected bond lengths and angles. Consistent with the NMR analysis, the molecule consists of a diphenylpyrazolato ligand with a diethylalumino group bonded to each nitrogen atom. An ethyl group acts as a bridge between the two aluminium atoms. The two nitrogen atoms and two aluminium atoms occupy an approximate plane, but the methylene carbon of the bridging ethyl group is situated 0.95 Å above this plane. The aluminium–nitrogen bond lengths are 1.928(2) and 1.936(2) Å. The aluminium–carbon bond lengths lie in the range 1.942(4)–1.967(3) Å for the terminal ethyl groups and are 2.144(4) and 2.150(4) Å for the bridging ethyl group. These aluminium–carbon bond lengths are very similar to the related values in structurally characterized aluminium complexes with bridging methyl groups.[2] The carbon–carbon bond length of the bridging ethyl group [1.535(4) Å] is within the normal range for such bonds and does not differ significantly from the values for the terminal ethyl groups. The geometry about the aluminium centers is distorted tetrahedral.

The crystal structure of **1** provides the first structural documentation of a saturated *n*-alkyl group other than methyl bridging between two aluminium centers. The bridging ethyl ligand in **1** appears to be far more stable than the analogous group in triethylaluminium. In the ^{1}H NMR spectrum of triethylaluminium the bridging methylene resonance is only resolved below −60 °C, suggesting that bridge–terminal ethyl group exchange is fast on the NMR timescale above this temperature.[9] In **1**, the bridging ethyl resonance is resolved at temperatures as high as 20 °C. We have recently reported the synthesis, structure and molecular orbital calculations of pyrazolate-bridged dialuminium complexes that contain bridg-

ing methyl groups.[10] The bridging aluminium–carbon bond strengths in these complexes are 6–7 kcal mol^{-1} stronger than the analogous bonds in trimethylaluminium dimer, and calculations indicate that this increased bond strength is due to extended bonding interactions involving pyrazolate π-orbitals. Similar extended bonding interactions in **1** could account for the slower bridge–terminal exchange of the ethyl groups, compared to triethylaluminium. The preparation of **1** suggests that other main group metal complexes with bridging *n*-alkyl ligands may be accessible synthetically by inclusion of pyrazolate or other unsaturated groups in the cyclic array incorporating the bridging alkyl.

Unprecedented C–H bond oxidative addition of the imidazolium cation to Pt^0: a combined density functional analysis and experimental study

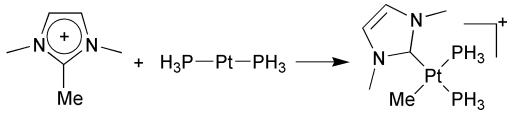
Received (in Cambridge, UK) 4th December 2000, Accepted 17th January 2001
First published as an Advance Article on the web 7th February 2001

Density functional studies predict that oxidative addition of an imidazolium salt to a Pt^0 complex is an exothermic process, and consistent with this proposal, the reaction of the 1,3-dimethylimidazolium cation with $Pt(PPh_3)_4$ yields a hydrido–Pt^{II} carbene complex.

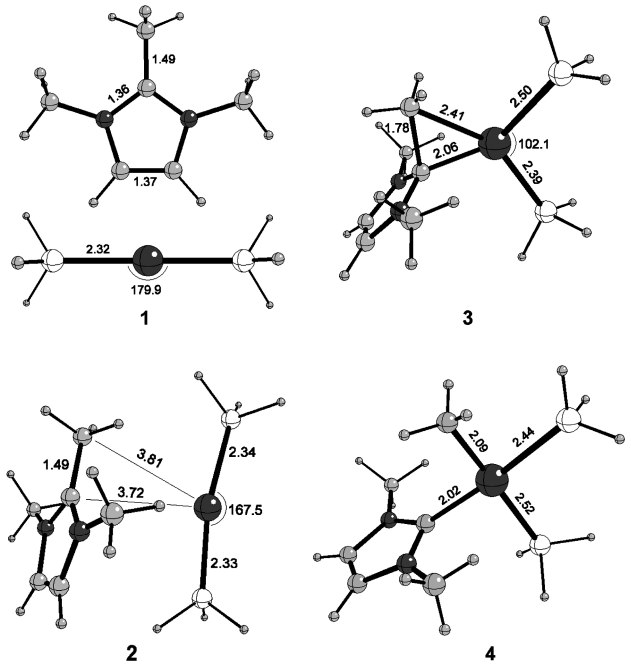
Heterocyclic carbene complexes of transition metals have been reported to act as precatalysts for a variety of reactions,[1] in particular complexes of the group 10 metals have been found to catalyse a number of C–C couplings.[2–5] In recent reports we have shown that heterocyclic carbene complexes of Pd^{II} and Ni^{II} which contain alkyl, aryl or acyl groups may decompose *via* elimination of 2-organyl imidazolium salts,[4,6,7] and that this reaction occurs *via* concerted reductive elimination of the hydrocarbyl and carbene moieties.[8] Inasmuch as hydrocarbyl–metal species are considered to be intermediates in many catalytic reactions, this reaction represents a significant pathway for catalyst deactivation. As a method of catalyst stabilisation, it seems possible that the energetics of this reaction may be shifted such that the oxidative addition of imidazolium to M^0 is favoured over reductive elimination. Related to this, the use of group 10 metals for catalysis in imidazolium based ionic liquids (ILs) is common, and in several cases heterocyclic carbene complexes have been implicated as the active species.[9,10] A recent report on the use of Pd^0 complexes in imidazolium based ionic liquids[11] prompted us to report our results of a density functional theoretical study, which shows oxidative addition of imidazolium to Pt^0 to be energetically feasible, and experimental results which confirm this.

As oxidative addition to Pt^0 is expected to be more favourable than to Pd^0,[12] the oxidative addition of the 1,2,3-trimethylimidazolium cation to $Pt(PH_3)_2$ was modelled† [eqn. (1)]. The



(1)

2-methylimidazolium cation was studied instead of 2*H*-imidazolium to allow comparison with the same reaction with Pd.[8] Furthermore, this reaction is the reverse of the ubiquitous reductive elimination reaction we have observed for hydrocarbyl–Pd carbene complexes.[4,6–8] Optimised geometries of the reactants **1**, precursor complex **2**, transition structure **3** and product **4** are shown in Scheme 1 while a potential energy profile for the reaction is shown in Fig. 1. The first step in the reaction yields the precursor complex **2** with a stabilisation energy of 5.3 kcal mol^{-1}. The initially linear PH_3 groups are slightly distorted such that the angle between them is 167.5°, however the imidazolium cation remains unchanged indicating a weak interaction with Pt. The transition structure **3** lies 33.1 kcal mol^{-1} above **2**, giving an apparent activation enthalpy ($\Delta H^{\ddagger}$) of 27.8 kcal mol^{-1} relative to the separated reactants. The Me–$C_{carbenoid}$ distance increases to 1.78 Å in the transition structure and the Pt–$C_{carbenoid}$ distance is short at 2.06 Å. Importantly, the product of oxidative addition lies 13.5 kcal mol^{-1} *below* the reactants, showing that oxidative addition is



Scheme 1 Optimised geometries (Å and °) of the reactants **1**, precursor complex **2**, transition structure **3** and product **4**.

predicted to be exothermic. In contrast, oxidative addition to the analogous Pd system is found to be slightly endothermic.[8] The Gibbs free energy change of the gas phase reaction (ΔG_{react}) is predicted to be 0.1 kcal mol^{-1}, indicating that oxidative addition should proceed to some extent.

To date we have not been able to observe oxidative addition of the 1,2,3-trimethylimidazolium cation to Pt^0 (or Pd^0). However, oxidative addition of a C–H bond is known to proceed with a lower barrier than oxidative addition of a C–C bond. Furthermore, imidazolium salts used as ILs are usually unsubstituted and have a proton in the 2-position. We therefore studied the reaction of 1,3-dimethylimidazolium tetrafluoroborate with $Pt(PPh_3)_4$. Heating equimolar quantities of the imidazolium salt and $Pt(PPh_3)_4$ in refluxing THF resulted in the formation of *ca.* 15% (by NMR) of the oxidative addition

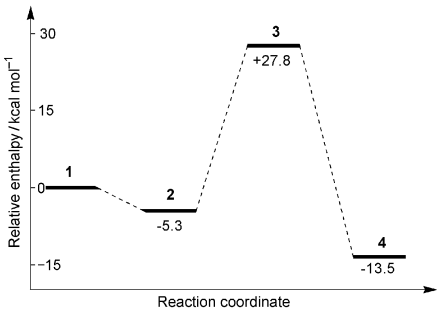


Fig. 1 Potential energy profile for oxidative addition.

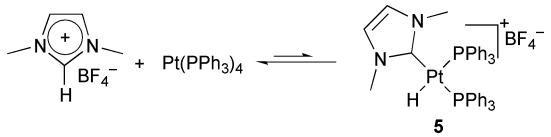
DOI: 10.1039/b009674l

product *cis*-[PtH(1,3-dimethylimidazolin-2-ylidene)$(PPh_3)_2$]-BF_4 **5** relative to unreacted imidazolium and $Pt(PPh_3)_4$ [eqn. (2)]. Complex **5** was identified by ^1H, ^{31}P NMR



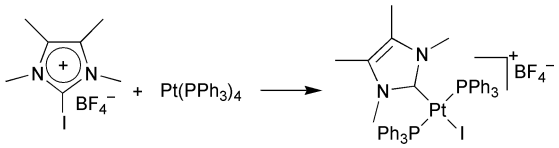
(2)

5

and HRMS. The ^1H NMR spectrum of **5** features a doublet of doublets centred at δ −5.23 (J_{PH} 19, 176 Hz) with Pt satellites (J_{PtH} 511 Hz) corresponding to PtH. The ^{31}P NMR spectrum of **5** gives rise to two doublets (J_{PP} 18 Hz) at δ 24.0 and 20.1 with Pt satellites (J_{PtP} 654, 663 Hz). To the best of our knowledge, this is the first example of oxidative addition of a C–H bond to a Pt^0 complex that does not contain a chelating ligand,[13] which was thought to be requisite for this reaction.[12]

Attempts to drive the reaction to completion by heating the reactants to 150 °C in DMSO resulted in approximately the same amount of oxidative addition product relative to the reactants, however, in this case the *trans* isomer of **5** was formed. This result suggests that the oxidative addition product is in equilibrium with the reactants, and the low amount of **5** results not from a high barrier to oxidative addition but rather the equilibrium concentration of the reactants and product. The ΔG_{react} value is therefore close to zero, which is consistent with the value predicted by the calculations on the theoretical system. The formation of *trans*-**5** can be explained by a *cis–trans* isomerisation of *cis*-**5**, which is probably the kinetically favoured product obtained from oxidative addition. Thermally induced or polar solvent induced isomerisations of Pt carbene complexes are well known,[14] it is therefore not surprising that hot DMSO can promote the isomerisation. The PtH resonance for *trans*-**5** appears as a triplet (J_{PH} 13 Hz) with Pt satellites (J_{PtH} 336 Hz) at δ −6.03 in the ^1H NMR spectrum. The related complex [PtH(1,3-dimethylimidazolidin-2-ylidene)$(PEt_3)_2$]-BF_4 has a very similar hydride resonance.[14]

The oxidative addition of 2-iodo-1,3,4,5-tetramethylimidazolium tetrafluoroborate has also been successfully carried out to give *trans*-[PtI(1,3,4,5-tetramethylimidazolin-2-ylidene)-$(PPh_3)_2$]BF_4 **6** [eqn. (3)]. The complex has been isolated as



(3)

6

colourless crystals and an X-ray structure analysis carried out. Details will be reported in a full paper on this topic.

The above results indicate a potentially important method of limiting decomposition of M–carbene catalysts, by operating in a large excess of the imidazolium ion, any M^0 that forms as a consequence of alkyl–carbene reductive elimination may re-form the M^{II}–carbene complex through oxidative addition of the imidazolium ion. For this reason, catalysts based on heterocyclic carbene complexes should be particularly suited to reactions in imidazolium based ILs. Furthermore, these results show unambiguously for the first time that the imidazolium cation, which is usually considered an unreactive solvent when used as an ionic liquid, can react with low valent metals to give a carbene complex. While interaction of the imidazolium cation with $Pd(OAc)_2$ has been shown to yield carbene complexes,[10] this work shows that a basic metal salt is not necessarily required to deprotonate the imidazolium. Thus, when group 10 metal complexes, particularly M^0 complexes, are used in imidazolium based ILs the possibility of carbene complexes as the active species must be considered. The large excess of imidazolium present under these conditions can be expected to drive the oxidative addition reaction. It is important to note that not only does oxidative addition of an imidazolium ion produce a carbene complex, but it also generates a metal hydride that could effectively initiate numerous catalytic processes.

In summary, density functional studies show that oxidative addition of an imidazolium cation to Pt^0 is possible both in terms of the activation barrier and relative energies of the reactants and product. We have experimentally demonstrated this by the reaction between $Pt(PPh_3)_4$ and the 1,3-dimethylimidazolium cation, which yields the hydrido–Pt carbene complex **5**. Further theoretical and experimental studies are in progress dealing with the effect of different metals, ligands and imidazolium salts on this remarkable oxidative addition reaction. A full account of these results will be reported shortly.

Notes and references

† Full geometry optimisations were carried out with the use of the B3LYP[15,16] density functional level of theory combined with the LANL2DZ basis set which incorporates the Hay and Wadt[17] small-core relativistic effective core potential and double-zeta valence basis set on Pt and P together with the Dunning/Huzinaga[18] double-zeta basis set on other atoms. Sets of five d-functions were used in the basis sets throughout these calculations. For the optimised geometries, harmonic vibrational frequencies were calculated at the B3LYP level and zero-point vibrational energy corrections obtained using unscaled frequencies. The vibrational frequencies were also used to obtain thermodynamic corrections and entropies. All transition structures possessed one and only one imaginary frequency, and they were further characterised by following the corresponding normal mode towards each product and reactant. All structures were treated as singlets and electronic wavefunction stability optimisations reveal no singlet–triplet instability. Finally, single-point energies on B3LYP/LANL2DZ optimised geometries were calculated at the B3LYP level with the LANL2augmented:6-311 + G(2d,p) basis set, which incorporates the LANL2TZ + (3f) basis set on platinum[19] and 6-311 + G(2d,p) on all other atoms.[20–22] The energy values in the text refer to this final level of theory. All calculations were carried out with the Gaussian 98 program.[23]

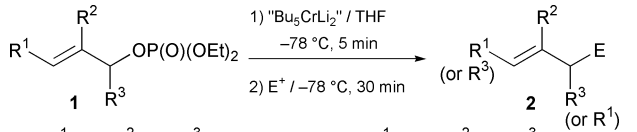
First published as an Advance Article on the web 8th February 2001

A chromium ate-type reagent 'Bu_5CrLi_2' reacts with allylic and propargylic phosphates to generate the corresponding allyl- and propargylchromium (propargyl = prop-2-ynyl) reagents which further react with a variety of electrophiles such as aldehydes, ketones, imines, and isocyanates to afford the corresponding adducts in high yields.

Organochromium(III) reagents are well-known to be nucleophilic, and have been used for the selective transformation of organic molecules. These reagents are usually generated from organic halides or their equivalents by reduction with chromium(II) as a 'one-electron' reductant.[1] We found that a chromium ate-type reagent, 'Bu_5CrLi_2'‡ easily prepared from chromium(III) chloride and butyllithium reacted with an equimolar amount of allylic phosphates to produce a nucleophilic allylation agent[2] where the butylchromium ate reagent served not as an alkylation agent, but formally as a 'two-electron' reductant [eqn. (1)].



1a: R^1 = H, R^2 = H, R^3 = $Ph(CH_2)_2$ **1d**: R^1 = Me, R^2 = H, R^3 = H
1b: R^1 = $Ph(CH_2)_2$, R^2 = H, R^3 = H **1e**: R^1 = H, R^2 = Me, R^3 = H
1c: R^1 = H, R^2 = H, R^3 = H **1 f** : R^1 = H, R^2 = H, R^3 = Me

(1)

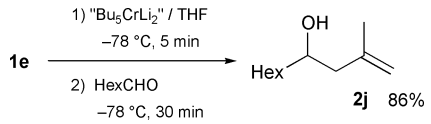
At the outset, we had found that 'Bu_4CrLi' reacted with an allylic phosphate, which can be easily prepared from the corresponding allyl alcohol, to produce reduction products, after aqueous workup. Therefore, we examined the reactivity of some butylchromium(III) reagents to 5-phenylpent-1-en-3-yl diethyl phosphate (**1a**) in a simple reduction to yield a mixture of terminal and internal alkenes. As can be seen in Table 1, 'Bu_5CrLi_2' was the most reactive toward the allyl phosphate **1a**. With 'Bu_4CrLi' it took 3 h to consume the starting material, and in a reaction of 'Bu_3Cr', 31% of **1a** was recovered even after 24 h.§ Next, we tested reactions of allyl bromide,[3] phosphate,[4] and acetate with 'Bu_5CrLi_2'. Allyl phosphate, diethyl 5-phenylpent-2-enyl phosphate (**1b**) was the best choice as precursor of the postulated allylchromium reagent, compared to 5-phenylpent-2-enyl bromide and acetate (Table 2). With an allylic bromide, butylation and dimerization competed with the desired reduction, and the acetate gave the starting allyl alcohol, suggesting a nucleophilic reaction of the 'Bu_5CrLi_2' reagent to the carbonyl of an acetoxy moiety.

By virtue of the reducing ability of the chromium ate-type reagent 'Bu_5CrLi_2', an allylchromium reagent was prepared from allyl phosphate **1c** under mild conditions, and the thus-generated reagent reacted with many types of electrophiles (Table 3).¶ Throughout this conversion, an allylic moiety of phosphate **1c** changes from electrophilic to nucleophilic.[5] Besides aliphatic (entries 1–3) and aromatic aldehydes (entry 4), ketones also reacted with the present allylchromium reagent (entries 5 and 6). To cyclohex-2-enone, 1,2-addition took place to give the corresponding homoallyl alcohol **2g** (entry 7). Imine and isocyanate gave homoallylamine **2h** and but-3-enoyl amide **2i**, respectively, in high yields (entries 8 and 9). The generation and reactions of other substituted allylchromium reagents were also successful. A β-methallyl-type reagent reacted efficiently with an aldehyde [(eqn. (2)]. Unsymmetrical reagents were also

Table 1 Reaction with allyl phosphate **1a**[a]

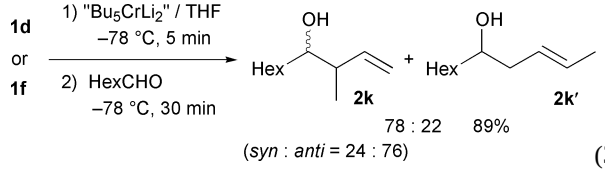
Entry	Chromium reagent	Conditions	Alkene (%)[b]
1	'Bu_5CrLi_2'	−78 °C, 5 min	96 (83 : 17)
2	'Bu_4CrLi'	−78 °C, 1 h	77 (82 : 18)[c]
3	'Bu_4CrLi'	−78 °C, 3 h	91 (83 : 17)
4	'Bu_3Cr'	−78 °C, 24 h	61 (80 : 20)[d]

[a] The reduction was conducted at −78 °C for 5 min using 1.2 equiv. of 'Bu_5CrLi_2'. Reactions were quenched with saturated NH_4Cl solution. [b] Isolated yield and isomeric ratio are shown in parentheses. [c] 20% of starting material **1a** was recovered. [d] 31% of starting material **1a** was recovered.



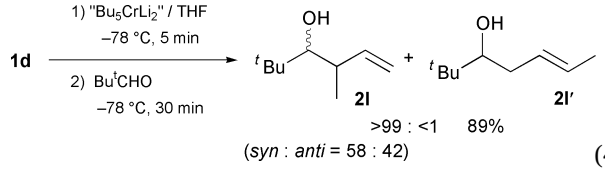
(2)

generated from **1d** and **1f** under the same conditions, −78 °C, 5 min, and these isomeric reagents both reacted with heptanal to give the same mixture of α- and γ-allylation products, suggesting that these reactions proceeded through a common intermediate [eqn. (3)].‖ Interestingly, the same reagent derived



(3)

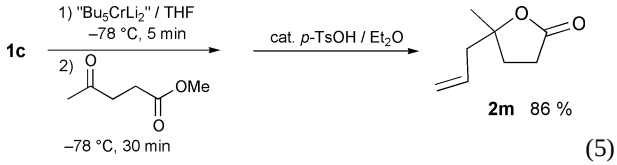
from **1d** afforded only γ-allylation product **2l**, when reacted with pivalaldehyde [eqn. (4)]. These results imply that the



(4)

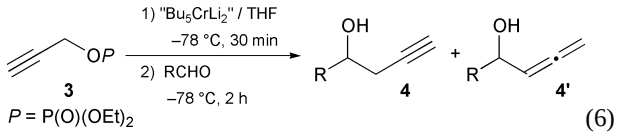
common intermediate would possibly be labile or not responsible for the regiochemical outcome, and the regioselectivity would be affected by the steric requirements of both a bulky allylchromium reagent and an aldehyde in the transition state for the allylation. The reagent was chemoselective for ketones in the presence of esters. The chemoselective allylation with the present allylchromium reagent is exemplified by eqn. (5).

† Electronic supplementary information (ESI) available: experimental details. See http://www.rsc.org/suppdata/cc/b0/b009351n/



(5)

The present protocol can be applied even to the generation of a propargylic reagent[6] from the corresponding phosphate **3** [eqn. (6)]. With aromatic aldehydes, only homopropargyl



(6)

alcohols **4** were obtained, while with an aliphatic aldehyde, allenylmethyl alcohol **4′** was also co-produced as well as homopropargyl alcohol **4** (Table 4).

Table 2 Reactions of allylic bromide, phosphate and acetate with 'Bu_5CrLi_2'[a]

Entry	Substrate	Conditions	Alkene (%)[b]
1	Ph, Br	–78 °C, 5 min	73 (70 : 30)[c]
2	Ph, OP(O)(OEt)$_2$ (**1b**)	–78 °C, 5 min	96 (83 : 17)
3	Ph, OAc	–78 °C, 3 h	18 (69 : 31)[d]

[a]The reduction was conducted at –78 °C for 5 min using 1.2 equiv. of "Bu_5CrLi_2". Reactions were quenched with saturated NH_4Cl solution. [b]Isolated yield and isomeric ratio are shown in parentheses. [c]15% of butylated product and 4% of dimer were detected. [d]35% of allylic alcohol and 40% of the starting material were recovered.

Table 3 Reaction of allyl phosphate **1c** with electrophile[a]

Entry	Electrophile	Product **2**		Yield (%)
1	Hex, H	Hex, OH	**2a**	93
2	Cy, H	Cy, OH	**2b**	85
3	Bu^t, H	Bu^t, OH	**2c**	79
4	Ph, H	Ph, OH	**2d**	91
5	=O	OH	**2e**	96
6	Ph, Me	Ph, OH, Me	**2f**	91

9	PhNCO	Ph, N, H, O	**2i**	75

[a]The reduction was conducted at –78 °C for 5 min using 1.2 equiv. of "Bu_5CrLi_2". To the allylchromium reagent, 4 equiv. of an electrophile were added, and the mixture was stirred at –78 °C for 30 min. Reactions were quenched with saturated NH_4Cl solution. [b]Isolated yield.

Table 4 Reaction of propargylchromium reagent[a]

Entry	R′CHO	Product ratio (%) **4**	**4′**	Yield (%)[b] (**4** + **4**)
1	Ph	99 **4a**	<1	75
2	O	99 **4b**	<1	73
3	Hex	88 **4c**	12 **4c′**	70

[a]The reduction was conducted at –78 °C for 30 min using 1.2 equiv. of "Bu_5CrLi_2". An aldehyde (4 equiv.) was added at –78 °C and the mixture was stirred at the same temperature for 2 h. Reactions were quenched with saturated NH_4Cl solution. [b]Isolated yield.

In conclusion, a chromium ate-type reagent 'Bu_5CrLi_2' reduces allyl and propargyl phosphates to generate allyl- and propargylchromium reagents, respectively, where no alkylation takes place, while these thus-generated reagents act as nucleophilic reagents toward a variety of electrophiles. From a synthetic point of view, many types of allyl- and propargylchromium reagents can be generated by the present protocol, starting from allyl and propargyl alcohols. Further study on the generation and reaction of these reagents is now in progress.

The present work was partly supported by Grants-in-Aid for Scientific Research, Grants-in-Aid for Scientific Research on Priority Areas (No. 706: Dynamic Control of Stereochemistry) from the Ministry of Education, Science, Sports and Culture, Japan.

Notes and references

‡ Formulae 'Bu_nCrLi_{n-3}' are tentatively used, since the precise structures of the species are not clear at present.

§ These 'Bu_nCrLi_{n-3}' species are possibly in equilibrium through disproportionation.

¶ A solution of 'Bu_5CrLi_2' in THF was prepared from BuLi in hexane (1.62 mL, 2.6 mmol) and a suspension of chromium(III) chloride in THF (0.52 mmol in 5 mL) with stirring at −78 °C for 30 min. Allyl phosphate (0.43 mmol) was added at −78 °C, and the mixture was stirred for 5 min. To the flask, an electrophile (1.72 mmol) was added and the resulting mixture was further stirred for 30 min. After quenching with saturated NH_4Cl and conventional workup, the crude mixture was subjected to chromatography to give a pure product.

‖ The stereoselectivity in the reactions of a crotyl-type reagent to aldehydes was not so high compared to that of the reported crotylchromium reagent generated by the reduction with a chromium(II) reagent. At the moment, reaction conditions for the selectivity were not optimized, and more likely, this lower selectivity may possibly be due to the crowded chromium-metal center to which remaining butyls would coordinate.

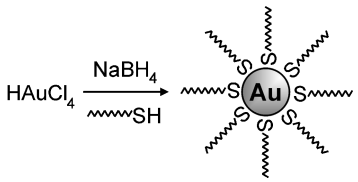
Oxidation of gold nanoparticles protected by thiolated β-cyclodextrin molecules, leads to formation of water-soluble polycyclodextrin nanocapsules held together by S–S bonds.

Recent advances in supramolecular chemistry have given chemists unprecedented control over the composition and shape of nanoscopic objects. An example of such development is the synthesis of nanometer-sized organic hollow spheres, which can find numerous applications in drug delivery/targeting, extraction and as nanoreactors.[1] Here, we describe a new method for preparation of nanometer-sized hollow, monolayer-thick spheres using thiolated β-cyclodextrins templated around gold nanoparticles.

Reduction of Au(III) compounds in the presence of thiols results in the formation of Au nanoparticles coated with organic shells [[eqn. (1)].[2] Re-oxidation of such nanoparticles with



(1)

iodine is known to dissolve gold as a mixture of Au(I) and Au(III) complexes[3] and liberate organic substrates as disulfides [eqns. (2) and (3)].[4,5]

(2)

$$AuI + I_3^- \rightleftarrows AuI_4^- \quad (3)$$

Our strategy relies on these disulfide bridges to form hollow spheres. Indeed, if organic substrate molecules (R–SH) possess several thiol groups, then formation of multiple S–S bonds in reaction (2) would cross-link the whole structure. Such disulfide bridges are often used to stabilize supramolecular assemblies.[6] A minimum of three thiol groups per substrate molecule is required for efficient cross-linking.

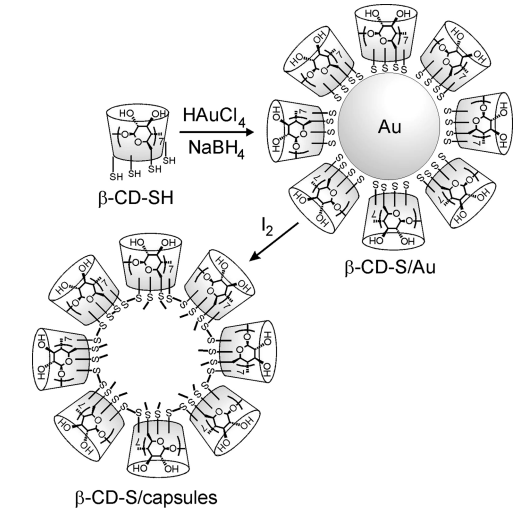
To test this hypothesis, we synthesized 2.3 nm Au nanoparticles coated with a monolayer of thiolated β-cyclodextrin molecules (Scheme 1, β-CD-S/Au), according to a recently published procedure.[7] Every molecule of thiolated β-cyclodextrin (β-CD-SH) contains seven thiol groups, and formation of disulfide bonds will therefore lead to multiple cross-linking of the organic shell (Scheme 1).

Aqueous β-CD-S/Au nanoparticles were added to a dilute solution of excess I_2 in aqueous KI to effect oxidation (Scheme 1). Reaction could be monitored by the disappearance of the brown colour of the Au nanoparticles. Excess iodine is required to prevent decomposition of unstable gold iodide [eqn. (4)].[3]

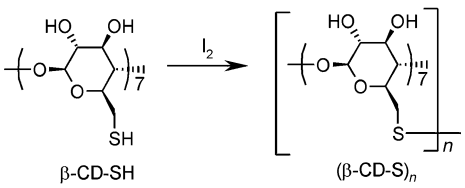
$$AuI_2^- \rightleftarrows Au^0 + I_2 \quad (4)$$

After reaction was complete, gold complexes and excess iodine were extracted into ethyl acetate, and the aqueous phase was exhaustively dialysed to remove KI and filtered to eliminate a small amount of water-insoluble material.

The resulting nanocapsules were characterized by ^{1}H NMR and FTIR spectroscopy. Importantly, NMR spectra of the nanoparticles before (β-CD-S/Au) and after removal of gold (β-CD-S/capsules) were almost identical, an observation consistent with formation of well defined structures containing β-CD-S units (Fig. 1). FTIR spectra of the nanocapsules were found to be identical with the spectrum of a polymer $(\beta\text{-CD-S})_n$ obtained by oxidation of β-CD-SH with I_2 in DMSO [eqn. (5)]. This further confirmed the proposed macrocomposition of the nanocapsules.



Scheme 1 Preparation of polycyclodextrin hollow spheres.



(5)

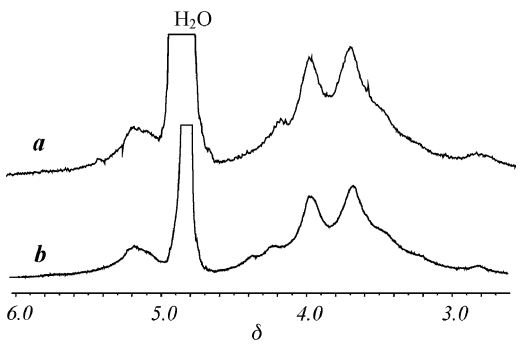


Fig. 1 ^{1}H NMR spectra (D_2O) of thiolated β-cyclodextrin/Au nanocomposites before (β-CD-S/Au, a) and after removal of Au template (β-CD-S/capsules, b).

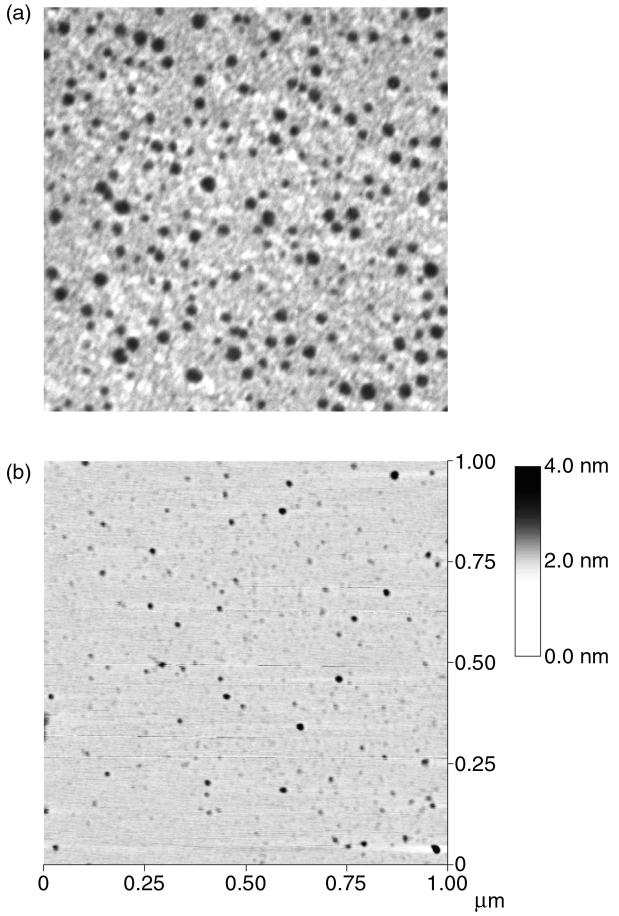

Fig. 2 (a) TEM image (100 nm × 100 nm) of Au nanoparticles protected with thiolated β-cyclodextrin (β-CD-S/Au). (b) AFM image of poly-cyclodextrin hollow spheres (β-CD-S/capsules) deposited on mica.

It proved more difficult to confirm the nanostructure of the materials obtained, *i.e.*, that they are indeed hollow spheres. Strong evidence came from solubility experiments. β-CD-SH is completely insoluble in water due to the hydrophobic nature of the SH group. At the same time, β-CD-S/Au nanoparticles are very soluble in water, as all hydrophobic groups are now hidden inside the nanoparticles, their surface being dominated by the hydrophilic OH groups (Scheme 1). Importantly, β-CD-S/capsules are also very soluble in water, which is consistent with the retention of the shell structure. In contrast, most (> 90%) of the polymer $(\beta\text{-CD-S})_n$ [eqn. (5)] is insoluble in water.

This very different water solubility of polymers $(\beta\text{-CD-S})_n$ and β-CD-S/capsules (materials which have the same molecular composition) confirms the hydrophilic nature of the proposed hollow shell structure.

Prolonged storage (over several weeks) of hollow shells in aqueous solution at room temperature leads to precipitation of insoluble disulfide polymer $(\beta\text{-CD-S})_n$ as a result of a disproportionation reaction (6) which is known to be fast for hydrophilic disulfides in water.[8]

$$2R^1\text{–SS–}R^2 \longrightarrow R^1\text{–SS–}R^1 + R^2\text{–SS–}R^2 \qquad (6)$$

This further supports a non-equilibrium structure for the nanocapsules obtained and is consistent with the hollow sphere model. A better understanding of the kinetics of reaction (6) might lead to a means for controlled release of small molecules within the capsules.

The ultimate proof of the hollow shell structure should come from microscopy. Unfortunately, we have been unable to obtain electron microscopy (TEM) images of hollow spheres due to their small size and low contrast. However, AFM analysis of hollow spheres deposited on mica from a dilute aqueous solution, showed nearly monodisperse round features.[9] The diameter of these features (*ca.* 30 nm) substantially exceeds the diameter of the Au particles [*ca.* 2.3 nm, Fig. 2(a)] due to the tip convolution,[10] which is a familiar scanning probe microscopy phenomenon. The height of the features [*ca.* 1.6 nm, Fig. 2(b)] corresponds approximately to the double height of the β-CD-SH molecule (*ca.* 0.78 nm). This might suggest that the nanocapsules collapse on the mica surface upon drying in air, but one must be cautious in interpreting height data as not much is known about the tip–surface interactions.[11] We believe that our observation of monodisperse round features strongly supports formation of hollow spheres.

The inner surface of the hollow spheres is dominated by the disulfide bonds and is therefore hydrophobic. To probe if the voids inside nanocapsules can accommodate external guests, we studied solubilisation of ferrocene, a hydrophobic molecule, in aqueous β-cyclodextrin (β-CD) and β-CD-S/capsules. Ferrocene is known to form inclusion complexes with β-CD, leading to its partial solubilisation in β-CD solutions.[12] We have found that β-CD-S/capsules can solubilise *ca.* 50 times more ferrocene than β-CD in aqueous solution.[13] This result can be explained either by accumulation of ferrocene in the inner voids of the hollow spheres, or by an increase in the value of the ferrocene-β-CD binding constant. More experiments are needed to distinguish unambiguously between these possibilities.

In conclusion, we have demonstrated a new strategy for synthesizing nanometer-scale organic hollow spheres using Au colloids as templates. The whole structure is held together by S–S bonds. We are currently working on broadening the described strategy to other substrates/templates and probing the encapsulation properties of the hollow spheres.

13 Powdered ferrocene was vigorously stirred overnight with aqueous solutions of β-CD or β-CD-S/capsules. The resultant mixture was then filtered through a 0.45 μm filter and analysed by UV spectroscopy.

Increased selectivity in hydroformylation reactions using dendrimer based catalysts; a positive dendrimer effect

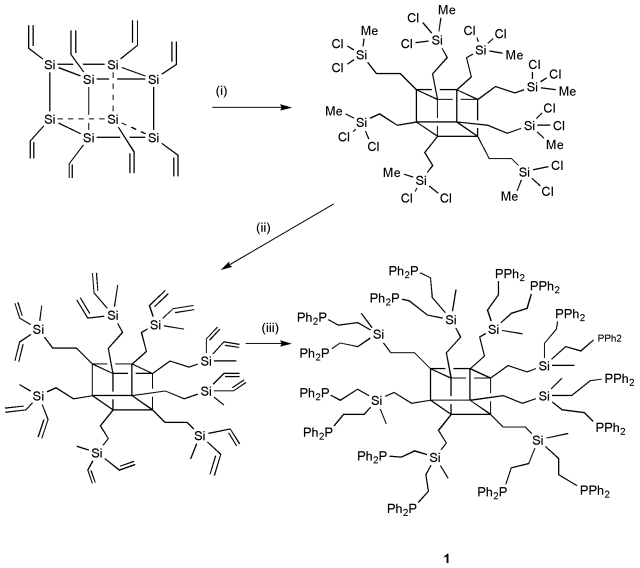
Dendrimers based on polyhedral oligomeric silsesquioxanes (POSS) cores with 16 PPh_2 arms give much higher linear selectivities (14 : 1) than their small molecule analogues (3–4 : 1) in the hydroformylation of oct-1-ene.

Dendrimers are globular molecules in which the groups on the periphery are all the same. They have been used for a variety of applications, but interesting opportunities are offered if the dendrimer is used as a ligand in homogeneous catalysis. Most research in this area is aimed at using the dendrimer to overcome the main problem of homogeneous catalysts, that the reaction products can be hard to separate from the catalyst and the solvent. Because of their persistent shape and size (1–10 nm), there is interest in attempting to remove the catalyst by nanofiltration through a suitable membrane. Filtration of this kind has been demonstrated.[1–3] Another possible advantage of dendrimers is that crowding in the periphery might lead to constrained geometries in the metal binding, which might affect the activity or selectivity of the catalyst. In many cases, reaction rates are slowed in the presence of a dendrimer, but there are also examples of reactions being totally or partially inhibited because the dendrimer is present. In one case it is believed that an unpaired electron is passed from metal to metal on the dendrimer, thus inhibiting its use in the Kharasch reaction.[4]

Examples of enhanced reactivity in C–C coupling reactions have been reported[3,5] and very recently it has been shown that epoxidation reactions can be accelerated if the catalyst is bound to the dendrimer and this is thought to be because the oxidising peroxide binds to one metal, whilst the substrate is activated by another. Having the two metals held in close proximity increases the reaction rate.[6] To our knowledge, examples of positive dendrimer effects on the *selectivity* of catalytic reactions have not been reported, but we now report such an effect in the hydroformylation of oct-1-ene. Hydroformylation using metals bound to dendrimers with phosphines on the periphery have been reported,[7,8] but generally the selectivity to the desired linear product is similar to that using model small molecule ligands, although we noted a slightly enhanced linear selectivity using dendrimer-bound trialkylphosphines.[8]

Dendrimers based on polyhedral oligomeric silsesquioxane (POSS) cores were prepared as shown in Scheme 1 such that they had up to 16 PPh_2 groups on the periphery (**1**). Attempts to prepare the dendrimer with 24 PPh_2 arms leads to incomplete conversion to phosphines, presumably because of excessive steric crowding.[8] Analysis of **1** by NMR and by MALDI-TOF mass spectrometry shows that they have 14, 15 or 16 PPh_2 groups per dendrimer, with the average number being *ca* 15. Within one arm of the dendrimer, the P atoms are separated by five atoms. Simple diphosphines separated by five or six atoms are only expected to favour bidentate binding when constrained, as in the case of Xantphos[9] and bis(diphenylphosphinomethyl)biphenyl (BISBI)[10] ligands. For such constrained ligands, the linear : branched ratios can be very high. Indeed, using the unconstrained small molecules, **2** and **3**, l : b ratios are only of the order of 3-4 (Table 1 and Fig. 1). In contrast, under



1

Scheme 1 Synthesis of 16-arm dendrimer phosphine **1**. *Reagents and conditions*: i, $MeSiHCl_2$, H_2PtCl_6 (catalyst); ii, (vinyl)MgBr; iii, Ph_2PH, azodi(isobutyryl)nitrile. **1** has an average of 15 PPh_2P groups, **5** has an average of 12 PPh_2 groups. In the POSS core, each edge of the cube represents Si–O–Si.

exactly the same conditions, catalysts prepared *in situ* from **1** and [Rh(acac)$(CO)_2$] (acacH = pentane-2,4-dione) give l : b ratios of up to 14. A ratio this high would be very unusual for an unconstrained ligand of this size and certainly shows that a positive dendrimer effect is operating. The reaction rate and l : b ratio increase with increasing temperature or decreasing gas pressure (Table 1) but are only slightly affected by the Rh : P ratio (3.6–10.8) at a given Rh concentration. The generally high l : b ratios suggest that strong bidentate coordination occurs or that the high local concentration of P atoms on the surface of the dendrimer increases the concentration of complexes containing three P donors. Further confirmation that the metal is strongly bound to the dendrimer comes from ^{31}P NMR studies of solutions prepared from [Rh(acac)$(CO)_2$] and **1** (1 : 3) under CO and H_2. Two resonances are observed at room temperature, one (δ 37) for P bound to Rh and the other (δ − 9.5) from the free P atoms (**1** resonates at δ − 9.5). Both resonances are very broad (width at half maximum = 470 and 88 Hz respectively), possibly because of different binding environments for the rhodium since the spectrum is the same in different solvents (CH_2Cl_2, tetrahydrofuran) and the linewidth at half maximum of the signal from the unbound P atoms only changes slightly

[a] [Rh(acac)(CO)$_2$] (2.0×10^{-5} mol); P:Rh = 6:1, toluene (4 cm^3), heated under CO/H$_2$ (6 bar) for 1 h. Oct-1-ene (8.3×10^{-3} mol) injected and pressure increased. Pressure kept constant through mass flow controller and fed from a ballast vessel. Pressure drop in ballast vessel monitored every 5 s. Total reaction time, 2 h. [b] First-order rate constant measured from gas uptake plots at constant pressure. [c] P:Rh = 5.4:1. [d] t = 4 h. [e] t = 19 h. [f] t = 6 h. [g] P:Rh = 10.8. [h] P:Rh = 3.6.

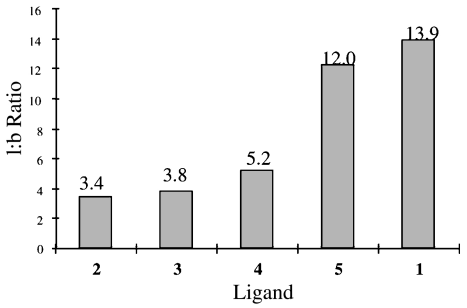

Fig. 1 l:b Ratio of product C$_9$ aldehydes at 120 °C and 10 bar. P:Rh = 6:1, except for **5** (P:Rh = 5.4:1).

between −40 (63 Hz) and +60 °C (150 Hz). This shows that the rhodium is not migrating rapidly around the surface of the dendrimer, nor dissociating on the NMR timescale. The resonance from the Rh-bound phosphines appears as two broad overlapping doublets (δ 37 and 36) at −40 °C, but as a single broad doublet (δ 37 $J_{P-H} \approx$ 130 Hz) at +60 °C, suggesting fluxionality within the bound complex. A broad hydride signal is observed at δ −10.5 (width at half maximum = 80 Hz) in the ^{1}H NMR spectrum at room temperature.

In order to try to understand the higher l:b ratios observed with the dendrimer bound catalysts, we have carried out some molecular modelling of the dendrimer using the Discovery programme contained in the Insight(II) Molecular Modelling Suite of Molecular Simulations Inc.[11] This shows that within an arm, the P atoms are separated by 4–7 Å, whilst between arms there are always some distances in the 5–10 Å region. Rh–P distances are of the order of 2.5 Å, so very little disruption of the ground state structure of the dendrimer is required to facilitate bidentate binding. Presumably the orientation of the PPh_2 groups relative to one another is determined by steric repulsions on the surface of the dendrimer whilst models of the small molecules show that the lowest energy structures have the phosphine groups far away from one another. If this is the case, one might expect that the compound prepared from addition of Ph_2PH across the double bonds of tetravinylsilane **4**, for which the X-ray crystal structure shows that the P atoms are 6.94 and 8.33 Å apart,[12] might show intermediate behaviour between **1** and **3**. Indeed this is the case, with the l:b ratio being 6 (Table 1 and Fig. 1). Reducing the PPh_2 loading on the dendrimer to an average value of 12 PPh_2 groups (**5**)† gives a slightly lower l:b ratio (12.0, Table 1, Fig. 1) than the more completely substituted dendrimer, again suggesting that steric crowding on the dendrimer periphery is important.

It seems that the chain length between the two P atoms is also important since extensive studies on a compound derived from tetravinylsilane containing 16 Ph_2P arms, but with only one CH_2 spacer between Si and P, *i.e.* with a potential ring size of six atoms for bidentate bonding, shows no special enhancement over the small molecule analogue.[7]

We conclude that the dendrimers synthesised here have sufficient steric crowding to make eight-membered ring bidentate coordination favourable and that these rings enhance the linear selectivity in hydroformylation reactions. Whether the binding in five-coordinate intermediates is equatorial–equatorial, which has been shown to give enhanced selectivity,[9,10] whether the P atoms are mutually *trans* throughout the reaction, which may also give enhanced selectivity, or whether the reason for the enhanced selectivity is the locally high Ph_2P concentration is not clear at present, although the low-temperature ^{31}P NMR spectrum of the rhodium complex under CO/H$_2$ suggests that the P atoms bound to rhodium are not all equivalent.

We thank the University of St. Andrews for a studentship (L. R.), the Royal Society for a University Research Fellowship (R. E. M.) and Professor Dieter Vogt and Dr Joost Reek for helpful discussions.

Received (in Cambridge, UK) 21st November 2000, Accepted 17th January 2001
First published as an Advance Article on the web 8th February 2001

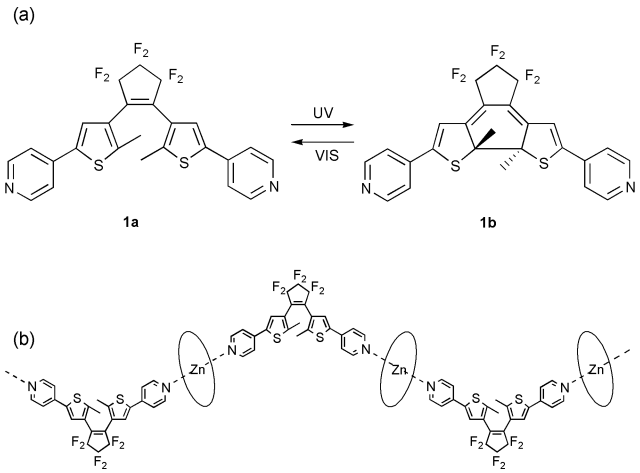
A linear coordination polymer composed of diarylethene and bis(hexafluoroacetylacetonato)zinc(II) has been synthesized and its photochromism in the single-crystalline phase studied by polarized absorption spectroscopy.

Photochromic compounds have attracted much attention because of their potential ability for photonic switching devices.[1] Among them diarylethenes with heterocyclic aryl groups are the most promising compounds for such applications. Diarylethenes undergo fatigue resistant and thermally irreversible photochromic reactions.[2] In addition, it has recently been found that some diarylperfluorocyclopentenes undergo photochromic reactions in the single crystalline phase.[3]

When metal ions are located at both ends of the aryl groups of the diarylethenes, the interaction between metal ions can be switched by photoirradiation, because the π-conjugated bond structures between the two aryl groups are different in the two isomers.[4] Therefore, the use of a diarylethene as a photoswitching bridging ligand is of interest. The synthesis and photochromism of metal complexes of diarylethenes was first reported in 1996 by Munakata *et al.*[5] They prepared a linear polymer, bridged by cyano groups, of *cis*-1,2-dicyano-1,2-bis[2,4,5-trimethyl-3-thienyl)ethene and copper(I) ions. In the present work we report on the synthesis of a linear chain polymer complex of 1,2-bis[2-methyl-5-(4-pyridyl)-3-thienyl]-perfluorocyclopentene **1a**[6] with $Zn(hfac)_2$ (hfac = 1,1,1,5,5,5-hexafluoroacetylacetonate) and its photochromic reaction in the single-crystalline phase (Scheme 1).

Rhombus-shaped single crystals of **1a** were obtained by recrystallization from hexane. An X-ray crystallographic study showed that two independent molecules were present in the asymmetric unit.[7] The distances between the reactive carbons of **1a** were 3.570 and 3.546 Å, short enough to react in the crystalline phase. Single crystals of **1a** turned blue upon irradiation with 366 nm light whilst retaining their shape. The blue color is considered to arise from the closed-ring form isomer **1b**.[3,6] The blue color disappeared upon irradiation with 578 nm light. The color of a crystal was observed under polarized light. Fig. 1(a) and (b) show the polarized absorption spectra and the polar plot. The polarized absorption spectrum at a selected angle showed its maximum at 610 nm. The absorption maximum in the crystal showed a bathochromic shift as much as 20 nm in comparison with the maximum in ethyl acetate solution (λ_{max} = 589 nm). The absorption intensity was strongly dependent on rotation, which indicates that the colored form isomers were regularly oriented in the crystal lattice. The order parameter $[(A_{\parallel} - A_{\perp})/(A_{\parallel} + 2A_{\perp})]$ was as high as 0.72.

$Zn(hfac)_2 \cdot 2H_2O$ was chosen as the metal source for complexation because of its high affinity for pyridyl ligands.[8] A solution of **1a** (200 mg) in dichloromethane (2 mL) was mixed with a solution of $Zn(hfac)_2 \cdot 2H_2O$ (197 mg) in methanol–dichloromethane (1 : 1, 2 mL) to afford a pale green powder. Recrystallization from methanol–dichloromethane (1 : 1) gave



Scheme 1 (a) Photochromism of ligand **1a**. (b) Schematic drawing of the linear chain polymer composed of **1a** and $Zn(hfac)_2$.

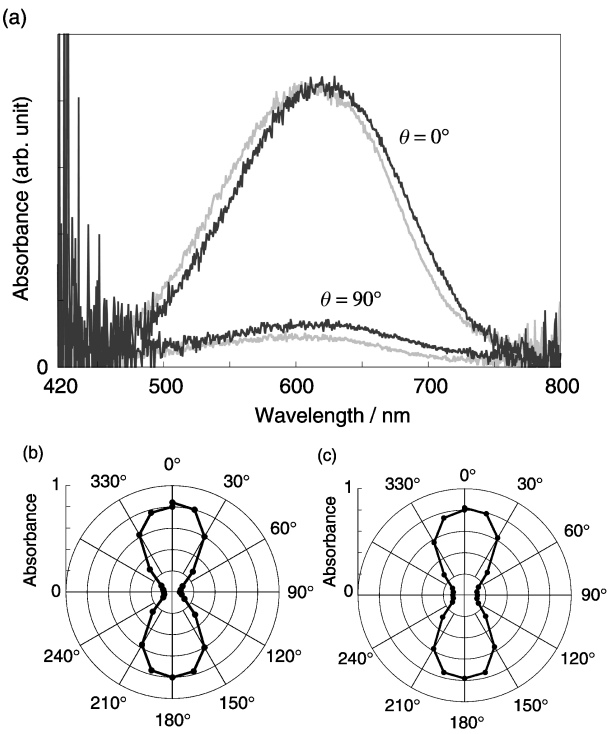


Fig. 1 (a) Polarized absorption spectra of single crystals of **1a** (grey line) and **1a**·$Zn(hfac)_2$ (black line) after irradiation with 366 nm light. (b) Polar plot at the absorption maximum of **1a**. (c) Polar plot at the absorption maximum of **1a**·$Zn(hfac)_2$. The angle of maximum intensity of the absorption is defined as θ = 0° for **1a** and the direction of the linear chain was defined as θ = 0° for **1a**·$Zn(hfac)_2$.

DOI: 10.1039/b009352l

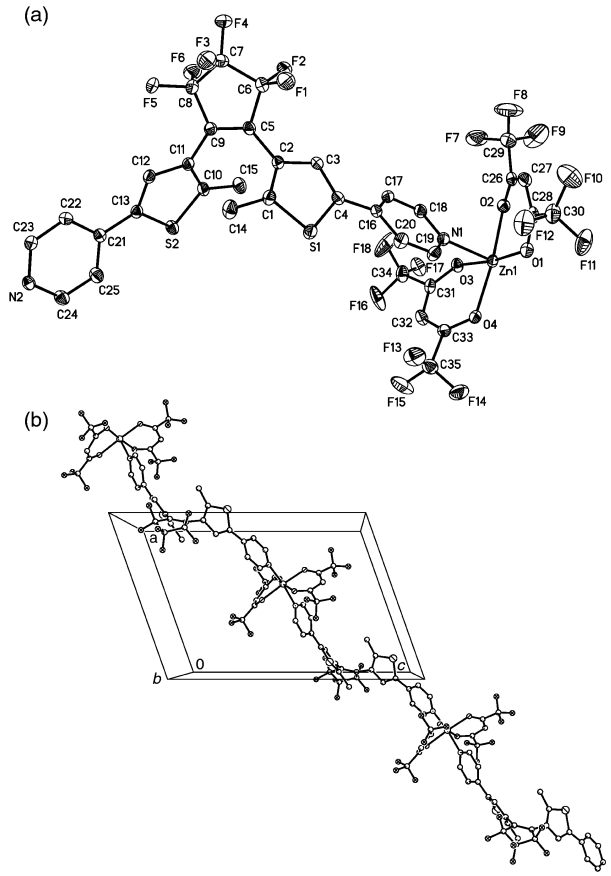

Fig. 2 (a) ORTEP drawing of the molecular structure of **1a**·Zn(hfac)$_2$ for one unit (50% probability) with hydrogen atoms omitted for clarity. (b) Ball-and-stick model of the linear polymer chain of **1a**·Zn(hfac)$_2$ viewed normal to the (010) face.

pale yellow block crystals.[9] The IR spectrum of the crystal was a superposition of **1a** and Zn(hfac)$_2$·2H$_2$O, indicating formation of the complex. X-Ray crystallography revealed the formation of a linear chain polymer complex composed of **1a** and Zn(hfac)$_2$ (Fig. 2).[10] The two pyridyl nitrogens of two different molecules of **1a** are coordinated with Zn(hfac)$_2$ in a *trans* configuration to produce a linear chain structure parallel to the [2 0 −1] direction. The molecular structure of **1a** in the complex is almost identical to that of **1a** itself. The distance between reactive carbons was 3.557 Å, again short enough to react.

An ethyl acetate solution of **1a**·Zn(hfac)$_2$ underwent a photochromic reaction by alternate irradiation with 313 and 578 nm light. The absorption maximum of the colored form isomer **1b**·Zn(hfac)$_2$ was at 590 nm, the same as the maximum of **1b** itself in ethyl acetate solution.

Crystals of **1a**·Zn(hfac)$_2$ also showed photochromic reactivity in the single-crystalline phase. Upon irradiation with 366 nm light single crystals of **1a**·Zn(hfac)$_2$ turned blue with formation of the closed-ring isomer **1b**·Zn(hfac)$_2$ considered to be the origin of the blue color.[3] Upon irradiation with 578 nm light the blue color disappeared. The polarized absorption spectra and the polar plot measured normal to the (010) plane of the face-indexed crystal are shown in Fig. 1(a) and (c). Here, the [2 0 −1] direction, the direction of the linear polymer chain, is defined as θ = 0°. The absorption intensity was strongly dependent on rotation, indicating a regular orientation of the closed-ring form isomer **1b**·Zn(hfac)$_2$. The transition moment was almost identical to the direction of the linear chain. The absorption maximum of **1b**·Zn(hfac)$_2$ in the crystal was 620 nm, 10 nm longer than that observed for crystals of **1b**.

Table 1 summarizes the absorption maxima of the colored closed-ring isomer **1b** and **1b**·Zn(hfac)$_2$, which are generated by irradiation with UV light in solution and in the single crystalline phase. In solution there was no difference between the free ligand and the complex, but in the single-crystalline phase the absorption maximum of the polymer complex showed a bathochromic shift upon complexation. The absorption shift upon complexation in the single crystal can be attributed to an increase in the strain upon complexation.

Table 1 Absorption maxima (nm) of the closed-ring form isomers generated by irradiation with UV light

	1b	**1b**·Zn(hfac)$_2$
In solution	589	590
In single crystal	610	620

In conclusion we have synthesized a linear chain polymer complex composed of 1,2-bis[2-methyl-5-(4-pyridyl)-3-thienyl]perfluorocyclopentene **1a** and Zn(hfac)$_2$. The complex undergoes a photochromic reaction in the single-crystalline state. While there was no shift in solution, the absorption maximum in the single crystal showed a 10 nm bathochromic shift upon complexation.

This work was partly supported by CREST (Japan Science and Technology Corporation) and by a Grant-in-Aid for Scientific Research on Priority Area 'Creation of Delocalized Electronic Systems' (No. 12020244) from the Ministry of Education, Science, Culture, and Sports, Japan.

A unique synthesis of a well-defined block copolymer having alternating maleic anhydride(MAn)/styrene(St) segments and PSt segments was achieved *via* radical addition–fragmentation chain transfer (RAFT) copolymerization and the self-assembly aggregating behavior of its hydrolyzed amphiphilic product in water was demonstrated.

One of the extensively studied CTC (charge transfer complex) forming monomer pairs is the combination of maleic anhydride (MAn) and styrene (St),[1] which can be alternately copolymerized under ordinary free radical initiating techniques to give a functional copolymer by further modification. However, the molecular weight and molecular weight distribution (M_w/M_n) of the copolymer thus obtained are not well-defined.

Recently developed 'living' free radical polymerization has received rapidly increasing interest, since it not only furnishes control over the resulting polymers with narrow M_w/M_n but also can be performed under ordinary radical polymerization procedures avoiding the stringent conditions needed for living ionic polymerization. The preparative technique for well-defined polymers of vinyl monomers *via* precision free radical polymerization has witnessed explosive growth in nitroxide-mediated polymerization,[2] atom transfer radical polymerization (ATRP),[3] and consequently developed radical reversible addition–fragmentation chain transfer (RAFT) polymerization.[4] They are marked with their respective features and limitations. A RAFT polymerization can be achieved by using thiocarbonylthio compounds as a reversible capping agent to produce 'living' polymer chains *via* a free radical mechanism.[4] The 'living' controlled radical copolymerization of electron-deficient and electron-rich monomer pairs is an elusive target, but the works are scarce.[5,6] The challenge associated with ATRP is to obtain an alternating copolymer of MAn, which destroys the ATRP catalytic system. Recently, Hawker *et al.* reported a one-step controlled copolymerization of MAn with St by nitroxide-mediated polymerization, giving a P(St-*co*-MAn)-*b*-PSt block copolymer,[2] and the same polymerization system was also reported for the copolymerization of St with MAn.[7] However, there is no alternating structure observed in the MAn-St copolymer. More recently, there was a report on a copolymerization of MAn and St *via* the RAFT process in which a dithiobenzoate residue was linked to a polyolefine chain end affording a block copolymer.[8] Here we describe a copolymerization of MAn with an excess amount of St in molar feed *via* the RAFT technique affording a well-defined block copolymer, P(MAn-*alt*-St)-*b*-PSt and the self-assembly aggregating behavior of its hydrolyzed amphiphilic product in water.

A typical RAFT initiating system used is the combination of (*S*)-benzyl dithiobenzoate (BTBA) with AIBN. The copolymerization of MAn with St takes place readily at 80 °C and the results are listed in Table 1. During the polymerization, both monomer conversion and number average molecular weight (M_n) increase with polymerization time. The copolymers obtained possess narrow M_w/M_n(~ 1.2), and the composition of P(MAn-*co*-St) is approximately 1:1 in molar ratio. The M_n determined by GPC method increases linearly with the monomer conversion, and matches well with the theoretical value. A thermal copolymerization of MAn with St at 80 °C in the absence of BTBA was demonstrated as a comparison. It can be seen that the copolymer obtained by using AIBN as an initiator possesses a higher M_n up to 6.3×10^4, with a broader M_w/M_n of 2.96. This firmly supports the conclusion that the RAFT copolymerization of MAn and St is of a controlled polymerization nature.

To further reveal the alternating nature of the MAn-St copolymer, a RAFT copolymerization of MAn and St with a molar feed of 1:9 was demonstrated at 60 °C. The conversions of both MAn and St were determined by GC. As can be seen from Fig. 1, the conversion of MAn apparently increases faster than that of St, but the absolute consumption of MAn and St are approximately the same until 80% of MAn was consumed. This indicates that the copolymer obtained possesses a predominantly alternating character at any monomer conversion before MAn has been exhausted. After MAn was completely consumed, the alternating copolymer chain subsequently continued to propagate forming a block copolymer with St sequence. Thus, the copolymerization basically involves: the simultaneous incorporating of MAn and St resulting in an alternating copolymer (Stage I), and the consumption of essentially pure St to continue chain propagation affording a block copolymer with a PSt segment (Stage II). At both stages, Mn increases linearly

Table 1 Molecular weight, molecular weight distribution and composition of MAn-St copolymers obtained *via* RAFT polymerization[a]

Copolymer	Time/h	Conversion (%)[b]	M_n[f] (theory)	M_n[c] (found)	M_w/M_n[c]	St in copolymer (mol%)[e]
MAn-St-1	0.1	17.4	1 580	2 450	1.19	45.9
MAn-St-2	0.3	64.1	5 820	6 180	1.24	48.6

MAn-St-4[d]	0.5	96.5	—	63 000	2.96	50.2

[a] $[MAn]_0:[St]_0:[BTBA]_0:[AIBN]_0 = 90:90:2:1$ in molar ratio, $[MAn]_0 = 2.0$ mol L^{-1}, dioxane, 80 °C. [b] Determined by gas chromatography (GC) method. [c] Determined by GPC, THF as an eluent, 35 °C. [d] Thermal polymerization, the monomer feed was 1:1 in molar ratio, 80 °C; [e] Calculated by ^{1}H-NMR analysis (200 MHz); [f] Mn (theory) = [MW (MAn) + MW (St)] × $[MAn]_0$ × conversion /$[BTBA]_0$.

DOI: 10.1039/b009815i

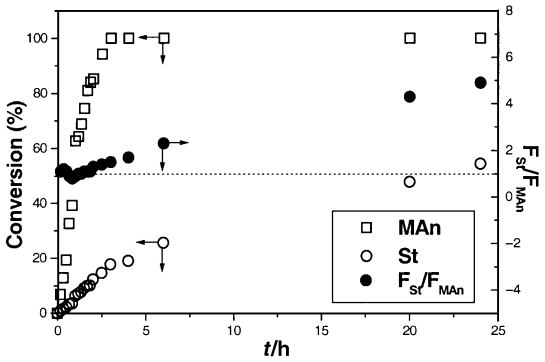

Fig. 1 Evolution of monomer conversions for St and MAn and their consumed molar ratio (F_{St}/F_{MAn}) with the polymerization time *via* RAFT polymerization. $[MAn]_0:[St]_0:[BTBA]:[AIBN] = 100:900:2:1$ in molar ratio, [MAn] = 0.2 mol L^{-1}, 60 °C.

with the conversion and M_w/M_n lies in the range of 1.2–1.4. It is thus concluded that, under RAFT polymerization conditions, the consuming rate of MAn is approximately equal to that of St during Stage I regardless of the large excess of St presented in the monomer feed. A well-defined block copolymer, P(MAn-*alt*-St)-*b*-PSt, composed of P(MAn-*alt*-St) and PSt sequences can thus be obtained by RAFT polymerization. Similar results were also manifested by the RAFT copolymerization of *N*-phenylmaleimide with St conducted at 60 °C.

It should be pointed out that the composition and sequence of the copolymer in the present work were different from the nitroxide-mediated ones reported by Hawker *et al*.[2] and Yoon *et al*.[7] There was no alternating character in the copolymer of MAn-St observed during the early stage of nitroxide-mediated polymerization performed at above 120 °C. In this work, the RAFT polymerization was carried out at 60 °C, where the CTC formation of MAn and St plays an important role in the copolymerization. On the contrary, the nitroxide-mediated copolymerization is always conducted at 120 °C or higher, which would destroy the CTC formed by MAn and St, hence the copolymerization of St or MAn favorably takes place in a 'free' monomer manner. In this regard, Seymour and Garner[1] reported that there is a change of the copolymer sequential distributions from alternating to random structure when the polymerization temperature increased from 80 to 130 °C for the MAn/St comonomer pair. Obviously, the polymerization temperature of 120 °C or higher and the large excess of St would lead to the tendency of homopolymerization of St.

DSC profile can provide valuable information about the block copolymer. The final copolymer possessed two distinct glass transition temperatures (T_g) at 104 and 167 °C, while the copolymer from Stage I showed only one T_g at 164 °C. This also strongly supports the conclusion that the final product is a block copolymer.

The P(MAn-*alt*-St) segment in the block copolymer can easily be hydrolyzed resulting in an amphiphilic block copolymer which can form uniform nanoscale particles by self-assembly. Fig. 2 shows the AFM (atomic force microscopy) image of the amphiphilic block copolymer in water obtained by hydrolyzing P(MAn-*alt*-St)$_{50}$-*b*-PSt$_{80}$ as illustrated in Scheme 1. The particles possess a uniform size with an average diameter of 63 nm and height of 30 nm. In addition, P(MAn-*alt*-St)-*b*-PSt can also form similar micelles in polar solvents such as propan-2-ol. These architectural particles in nanoscale size constructed

by PSt segment as a core, and P(MAn-*alt*-St) or P(MA-*alt*-St) segment as a corona, which provides reactive anhydride or carboxylic groups on the surface of particles, are of interest in further chemical or biological modification. The surface modification of the copolymer micelle and the morphology of their derivatives in selective solvents are underway.

Received (in Cambridge, UK) 13th November 2000, Accepted 17th January 2001
First published as an Advance Article on the web 8th February 2001

Both substituted imidazoles and 1,3-dialkylimidazolium salts can be fully deuteriated on the heterocyclic ring using D_2O over heterogeneous Pd catalysts: deuteriated 1-alkyl-3-methylimidazolium chloride and hexafluorophosphate ionic liquids can also be prepared in good yields utilising readily available and relatively low cost sources of deuterium.

Imidazole and imidazolium salts are key systems in nature (in, for example, histidine and vitamin B_{12}, and as components in DNA base-pair structure, biotin, *etc*).[1] As such they have a tremendous range of applications in pharmaceutical, veterinary and agrochemical products. Other important applications include formulation of high temperature polymers and corrosion inhibitors,[2] for the formation of carbenes (as replacements for phosphine ligands in transition metal catalysis),[3] and as the basis for ionic liquids - clean solvents for catalysis, extraction technology and electrochemical applications.[4]

For our ongoing investigations of the liquid structure of ionic liquids by neutron diffraction, access to deuteriated materials in order to provide neutron-scattering contrast was required. For these studies, it was necessary to prepare significant quantities (3–5 g) of both fully deuteriated and selectively deuteriated (exchange on the ring positions only) samples of 1,3-dimethylimidazolium chloride or hexafluorophosphate and 1-ethyl-3-methylimidazolium chloride or hexafluorophosphate. Only one of these materials, 1-ethyl-3-methylimidazolium-d_{11} chloride, is currently commercially available and is supplied in small quantities and at prohibitively high cost for this experiment. This paper describes a versatile low cost methodology to prepare these deuteriated materials. Although ionic liquids research provided the driving force behind this investigation, these molecules are also of significant interest as mechanistic probes, particularly in biochemical studies, especially where ^{1}H and ^{2}D NMR spectroscopies are utilised.[5]

Ring deuteriation of imidazolium cations has been performed using D_2O by Dieter *et al*.[6] In this study, shaking with D_2O was sufficient to exchange the most acidic ring-hydrogen, H(2); however, exchange of the ring-hydrogens, H(4/5), was found to require more forcing conditions, *i.e.* heating in D_2O–K_2CO_3. Using this method, the ring-deuteriated salt, 1-ethyl-3-methylimidazolium-d_3 chloride could be prepared. In contrast, imidazoles are much less susceptible to H/D exchange (10^6–10^8 times slower) than the corresponding imidazolium salts.[7,8] Full ring deuteriation of imidazole is also possible under forcing acidic conditions. Lui *et al.* incorporated 90% deuterium using D_2O–D_2SO_4 at 200 °C for 4 h after two passes.[5] Here we show that by using D_2O and a heterogeneous catalyst, both imidazolium salts and substituted imidazoles can be ring deuteriated easily under mild, neutral conditions.

The deuteriation of 1-methylimidazole and 1,3-dimethylimidazolium chloride was screened using palladium and platinum catalysts on a variety of supports† (Table 1). The deuteriations were performed following a pre-reduction of the catalyst in flowing dihydrogen at rt. The substrate dissolved in D_2O was added to the catalyst and underwent a number of freeze-pump thaw cycles, after which the temperature was raised to 100 °C and left for 1 h. This technique has been used extensively for the deuteriation of other heterocycles, commonly pyridines and related molecules.[9] Using this method, 1,3-dimethylimidazolium chloride was deuteriated at the ring H(2) (99%) and H(4/5) (90%) positions using a 10% Pd/C catalyst. The general applicability of this system was demonstrated by deuteriation of imidazole, 1-methylimidazole and 1,3-dimethyl-, 1-ethyl-3-methyl- and 1,3-dibutylimidazolium chlorides with 90–96% deuterium incorporation at the ring H(4/5) positions after one cycle. Exhaustive deuteriation of alkylimidazolium salts was tested at elevated temperatures, and showed that, although exchange of the alkyl group hydrogens is possible, it is inefficient. For example, the maximum deuterium incorporation in methyl side chains on 1,3-dimethylimidazolium chloride at 250 °C over any catalyst was 43% after 12 h.

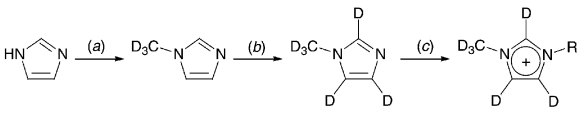
Table 1 Percentage deuterium incorporation at the ring H(4/5) positions in (i) 1,3-dimethylimidazolium chloride and (ii) 1-methylimidazole using various catalysts

	% Of ring H(4/5) deuteriated	
Catalyst[a]	(i)	(ii)
10% Pd/C	90	91
—	99[b]	—
10% Pd/Al_2O_3	95	87
5% Pt/C	33	0
5% Pt/Al_2O_3	45	5

[a] Little difference was found varying the catalyst loading between 5 and 10%. [b] Second deuteriation cycle.

In general, palladium catalysts are much more active for the exchange reaction than platinum catalysts in both imidazole and imidazolium-based systems. The lack of H/D exchange at the H(4/5) positions using platinum is not well understood at present. Explanations include a change in molecular adsorption geometry between the two metals or site blocking by strongly adsorbed molecules (originating *via* a surface reaction of the imidazole).[10,11] Experiments are currently underway to understand this process more fully.

Using the methodology described above to deuteriate the ring positions, a general procedure was devised in which the synthesis and deuteriation of the 1,3-dialkylimidazolium salts is divided into three discrete steps which can be manipulated in a modular fashion (Scheme 1). This involved a sequence in which imidazole is alkylated to 1-alkylimidazole, then ring-deuter-



Scheme 1 (*a*) CD_3OD, $RuCl_3$/(*n*-BuO)$_3$P; (*b*) D_2O, 10% Pd/C; (*c*) RX (CD_3Cl, C_2D_5I).

DOI: 10.1039/b009097m

iated with subsequent quaternisation with a second alkylating agent to yield the desired deuteriated 1,3-dialkylimidazolium salt. The order of the sequence depends on the relative efficiency of each step and the nature of the anions in the final 1,3-dialkylimidazolium salt. It is also important to consider whether deuteriation of the ring should be performed before or after the quaternisation. This is dependant on the relative stability of the H/D exchanged hydrogens with respect to scrambling in the subsequent reactions, *e.g.* quaternisation.

Here, the initial alkylation of the imidazole could not be performed cleanly using conventional procedures,[12] since a number of by-products were also formed. For example, methylation of imidazole with iodomethane under neutral conditions led to the formation of a mixture of 1H-imidazolium iodide, 1-methylimidazole and 1,3-dimethylimidazolium iodide. Under these reaction conditions, the imidazole acts as a base for the alkylation. However, since 1-methylimidazole is more reactive towards methyl iodide than imidazole itself, this leads to a final product mixture, which cannot easily be separated. Due to this problem, this method can only be applied to symmetrically substituted 1,3-dialkylimidazolium salts. In the field of room temperature ionic liquids, cation asymmetry is an important feature in order to provide the variation in properties such as melting point, viscosity and density, which allows their use as tuneable solvents.[13]

Alkylimidazoles may be synthesised *via* a number of other routes. Arduengo *et al.*[14] prepared 1,4,5-trimethyl-d_9-imidazole as a precursor to perdeuteriated carbenes *via* a cyclisation route using perdeuteriated methylamine, prepared by deuteriation of deuteriated nitromethane. Alkylation of imidazole has also been performed catalytically with methanol over a homogeneous ruthenium–tributylphosphite catalyst; Tanaka *et al.*[15] claimed 99.5% conversion and greater than 98% selectivity for the production of methylimidazole. This presents a potentially more effective route than that of Arduengo *et al.*[14] for the formation of 1-methyl-d_3-imidazole using deuteriated methanol as a low-cost methylating agent and also gives the opportunity to utilise longer-chain alcohols (for instance, deuteriated ethanol).

Here, 1,3-dimethylimidazolium-d_9 chloride was prepared from imidazole in three steps, introducing deuteriatated functionality at one nitrogen (*via* an alkyl group), to the ring and finally in a quaternisation step adding a deuteriated methyl group to the second nitrogen.‡ In the first step, imidazole was *N*-methylated with deuteriated methanol to 1-methyl-d_3-imidazole over a homogeneous ruthenium–tributylphosphite catalyst in 1,4-dioxane at 200 °C/40 bar pressure[15] with overall 75% yield (based on recovered imidazole) and was isolated by vacuum distillation. The resulting 1-methyl-d_3-imidazole was then deuteriated on the ring with D_2O over a Pd/C catalyst to give the fully perdeuteriated 1-methylimidazole. This was then alkylated with chloromethane-d_3 to give the 1,3-dimethylimidazolium-d_9 chloride, and with iodoethane-d_5 to 1-ethyl-3-methylimidazolium-d_{11} iodide in good overall yields. This approach allows the greatest flexibility in the chemistry and permits the selective introduction of deuterium to any of the functional areas of the imidazolium cation using relatively inexpensive and readily available deuteriated starting materials. The hexafluorophosphate salts were obtained by metathesis from the halide salt with $Na[PF_6]$ in D_2O. 1-Ethyl-3-methylimidazolium-d_{11} chloride was then isolated from the corresponding hexafluorophosphate salt by metathesis with LiCl in acetone-d_6. All the salts were collected as colourless crystals. ^1H and ^{13}C NMR spectra were obtained to assess the levels of deuteriation in the salts and in all cases the deuterium incorporation was greater than 97%. It should be noted that, for the ring deuteriations, this required two cycles in order to increase the deuterium level from 90 to >97%.

This procedure (Scheme 1) enables the preparation of ionic liquids and other 1,3-dialkylimidazolium salts (*i.e.* as precursors to carbene ligands) in which deuteriation of the cation can be selectively applied to any position; one or two *N*-alkyl substituents and ring. Moreover, combined with the lability of the ring H(2) in aqueous solution, it is also possible to selectively control the H/D substitution of the ring H(2) and H(4/5) by H/D exchange.

Financial support from the Department of Education in Northern Ireland (S. E. J. M.) and the Queen's University Ionic Liquids Laboratory (S. E. J. M., J. D. H) is gratefully acknowledged. Johnson Matthey and Degussa are thanked for the generous donation of the carbon catalysts and aluminium oxide respectively.

Notes and references

† Oxide supported catalysts were synthesised by wet impregnation from $PdCl_2$ and H_2PtCl_6 precursors on Degussa Alumina grade C, the catalysts were then calcined and reduced under hydrogen. ICP analysis of metal content was used to confirm catalyst loading. Pd/C and Pt/C catalysts were supplied by Johnson Matthey.

‡ Methanol-d_4 (99.8%) from Apollo Scientific Ltd. All other reagents were obtained from Aldrich and used as supplied.

1-Methyl-d_3-imidazole. Ruthenium chloride hydrate (0.63 g, 2.41 mmol), tri(*n*-butyl)phosphite (2.30 g, 9.19 mmol) and imidazole (10.78 g, 0.158 mol) were sequentially dissolved in 1,4-dioxane (300 cm^3) in a stirred 1 L autoclave. After addition of methanol-d_4 (20 g, 0.554 mol), the mixture was heated at 200 °C under 40 bar pressure of nitrogen for 18 h. Following reaction, the liquid was decanted from the spent catalyst and solvent/excess methanol were removed. The resulting pale yellow oil was vacuum distilled at 100 °C to give 1-methyl-d_3-imidazole as a colourless oil (6.5 g, 49%) and analysed by GC-MS. *m/z* (EI) 85, accurate mass 85.072 (Calc for $C_4H_3N_2D_3$, 85.072), NMR δ_H/ppm ($CDCl_3$) 7.49 (1H, s), 7.01 (1H, s), 7.86 (1H, s); δ_C/ppm ($CDCl_3$) 135.26 (C2), 126.93 (C4), 118.05 (C5), 30.59 ($-CD_3$); δ_D/ppm ($CDCl_3$) 29.64 ($-CD_3$). Unreacted imidazole (34%) was recovered from the distillation flask. Overall yield, based on imidazole was 75%, unreacted deuteriated methanol was recovered from the solvents by distillation and could be reused.

1-Methylimidazole-d_6. Palladium on activated carbon (2 g, 10% Pd) was reduced under dihydrogen (1 atm), for 1 h at rt. 1-Methylimidazole (10 g, 0.117 mol) was dissolved in pure D_2O (50 g, 0.28 mol), and added to the reduced catalyst. The reaction mixture was degassed by three freeze pump thaw cycles, then heated with stirring at 100 °C for 1 h. The reaction mixture was filtered to remove the catalyst, and the aqueous solvent was removed under reduced pressure, and then *in vacuo* to give the ring-deuteriated 1-methylimidazole (9.4 g, 91%). Extent of deuteriation was analysed by loss in ^1H and changes in ^{13}C NMR.

1,3-Dimethylimidazolium-d_9 chloride. Chloromethane-d_3 (1.0 g, 18.7 mmol) was condensed onto 1-methylimidazole-d_6 (1.0 g, 11.4 mmol) in a carius tube cooled to −180 °C with liquid nitrogen. The tube was then sealed and brought to rt, then heated at 80 °C for 15 h to give the 1,3-dimethylimidazolium-d_9 chloride as a colourless crystalline solid (1.6 g, 99%).

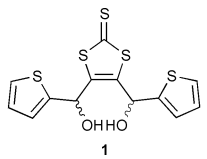
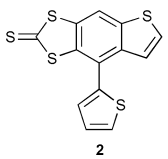
In the presence of perchloric acid, an unusual 1,4-aryl shift is observed for two electron-rich 4,5-bis[hydroxy(aryl)methyl]-1,3-dithiole-2-thiones; the X-ray crystal structure of compound 8 confirms the structural identity of the rearrangement product.

The chemistry of the 1,3-dithiole-2-thione heterocycle and its derivatives has been studied extensively,[1] mainly because these compounds are efficient precursors to tetrathiafulvalenes (TTFs), which are famous components in conducting materials.[2] Innovative steps towards the functionalisation of 1,3-dithiole-2-thiones and TTFs continue to attract attention and the formyl group has been one of the most commonly used functional groups for the preparation of TTFs with simple or complex architecture.[3]

Some of our recent work has involved the synthesis of triaryl systems annelated to the 1,3-dithiole-2-thione heterocycle.[4] During these investigations, we discovered that one of our key intermediates, 4,5-bis[hydroxy(thien-2-yl)methyl]-1,3-dithiole-2-thione **1**, rearranges under acidic conditions to give a variety of products (*e.g* **2**), depending on the choice of solvent



1

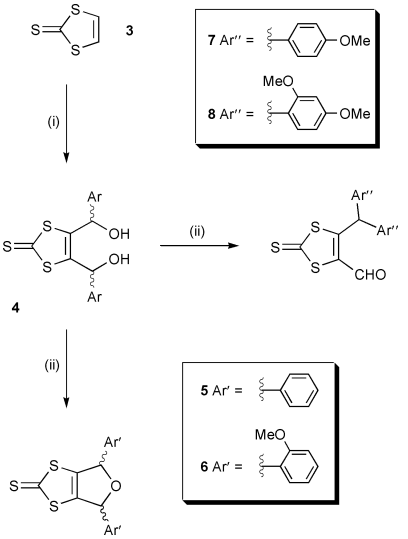


2

and acid.[5] *En route* to a series of dihydrofuran derivatives, we have discovered that electron-rich benzyl analogues undergo a different type of rearrangement to **1**, involving an unexpected 1,4-aryl shift and the concomitant formation of an aldehyde functionality. Herein, we discuss the likely mechanism involved in the reaction sequence and comment on substituent effects.

Using a four-step procedure,[4a] 1,3-dithiole-2-thione **3** can be lithiated by LDA and reacted with aryl carbaldehydes to afford bisalcohol products. Thus, compounds **4** (Ar = phenyl, 2-methoxyphenyl, 4-methoxyphenyl, 2,4-dimethoxyphenyl and 3,5-dimethoxyphenyl) were prepared in 75–90% yield, according to Scheme 1.‡ The diols slowly decomposed under ambient conditions; treatment of 3-6 drops of perchloric acid to solutions of **4** in DCM increased the rate of decomposition of the starting material and in all cases the diol was consumed within 24 h. Dihydrofurans **5** and **6** (87 and 23%, respectively)[6] were isolated from the corresponding diols as mixtures of stereoisomers, whereas the 4-methoxyphenyl and 2,4-dimethoxyphenyl diols gave the rearrangement products **7** and **8** in 44 and 83% yields, respectively. The rearrangement products from **4** were all obtained as the major product (by TLC), however, the diol obtained from the reaction of 3,5-dimethoxybenzaldehyde gave an intractable series of reaction products on addition with $HClO_4$.

† Electronic supplementary information (ESI) available: molecular structure of compound **6**. See http://www.rsc.org/suppdata/cc/b0/b009550h/



Scheme 1 *Reagents and conditions*: (i) LDA (1 eq.), ArCHO (1 eq.), then repeat, −78 °C, THF; (ii) $HClO_4$, CH_2Cl_2, rt.

Crystals of compounds **6**† and **8**§ were grown from DCM–petroleum ether.

The X-ray crystal structure of compound **8**§ (Fig. 1) provides irrevocable proof for the structure of the rearrangement product. There are considerably less weak interactions in **8** when compared to **6**, allowing more flexible conformations of the dimethoxyphenyl substituents and forming a supramolecular assembly of one-dimensional chains (C(13)···2O(5) = 3.394 Å).

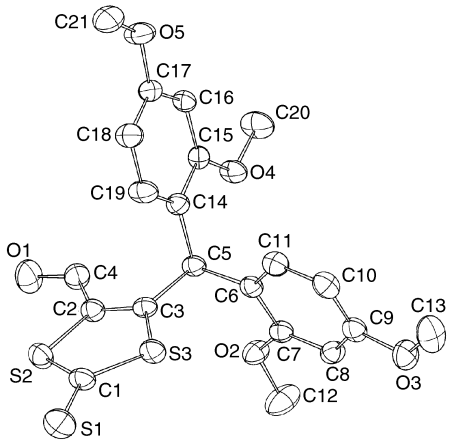


Fig. 1 Molecular structure of compound **8**.

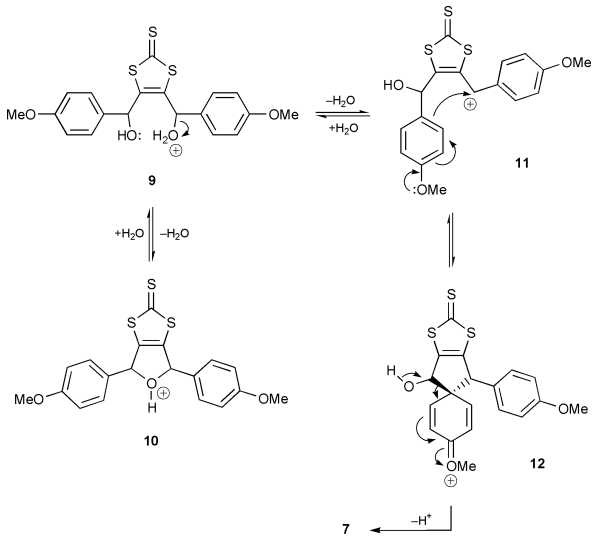
The Pinacol rearrangement of 1,2-diols, affording aldehydes or ketones, is one of the classic transformations in organic chemistry. The reaction involves the acid-mediated 1,2-shift of an alkyl or aryl group as part of a concerted mechanism. Despite the similarity in structure of the reaction products **7** and **8**, one

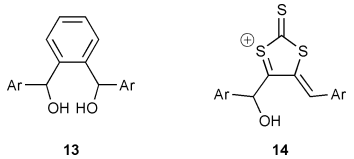


Scheme 2

cannot assume that the mechanism is Pinacol-type. The proposed mechanism for the decomposition of **4** in the presence of perchloric acid is depicted in Scheme 2, using **7** as the example. Protonation of the diol **4** (Ar = 4-methoxyphenyl) gives intermediate **9** which, upon loss of water, generates the dihydrofuran derivative **10** or the free cation **11**. In the case of compounds **5** and **6**, the dihydrofuran species predominates and there is no further transformation. However, for compounds **7** and **8**, the *p*-methoxy group assists in the formation and stabilisation of a phenonium intermediate **12**. The loss of a proton from this species results in **7** *via* an overall step-wise migration of the aryl unit and the formation of a formyl group.

The involvement of a phenonium intermediate in aryl shifts has been seen previously.[7] Theoretical studies have shown that there is significant stabilisation of the phenonium ion through back-bonding from the ethylene unit of spirocyclopropylbenzenium species.[8] However, we propose a spirocyclopentylbenzenium intermediate **12** in Scheme 2, which can only be stabilised by the methoxy unit. The position of the electron releasing groups is important and it is obvious that complications arise in the case of the 3,5-dimethoxy species, since neither the dihydrofuran or 1,4-shift products are observed. In this case, the formation of a spirocyclic intermediate is not possible. It is also unusual that the sole product from the 2-methoxyphenyl species is the dihydrofuran derivative **6**, particularly since the electron donating substituent effect should be identical to that of the 4-methoxy derivative, which gives the rearrangement product **7**. One possible explanation for this can be derived from the X-ray crystal structure of compound **6**.† The intramolecular close contacts between O(2)··S(2) and O(3)··S(3) arise from a π–d orbital interaction, which decreases the electron releasing ability of the methoxy groups towards the benzene ring, thereby conferring a weaker stabilising effect upon the phenonium ion.

Finally, it is worth noting that we have carried out a similar study on analogous benzene derivatives (**13**). In each case, the



addition of perchloric acid resulted in a complex mixture of products, which could not be easily separated. None of the isolated fractions proved to be the dihydrofuran or rearrangement products such as compounds **5**–**8** (by MS and ^{1}H NMR). The function of the 1,3-dithiole heterocycle in stabilising the allylic cation (shown in structure **14**) is, therefore, an important process in the formation of compounds **5**–**8**. To check the generality of this stabilisation effect in diols such as **4**, we also substituted the 1,3-dithiole-2-thione ring with thiophene, *via* the lithiation (*n*-BuLi) of 2,3-dibromothiophene and subsequent reaction with 2,4-dimethoxybenzaldehyde. The resulting diol decomposed to the corresponding dihydrofuran (by MS and ^{1}H NMR) on standing, whilst the addition of perchloric acid did not yield the 1,4-rearrangement product. Clearly, there is further scope to investigate the versatility of structure **14** by replacing the 1,3-dithiole-2-thione unit with alternative electron-rich moieties and this will be the focus of future work.

In conclusion, we have reported the first example of a 1,4-aryl shift in an allylic 1,4-diol system. This reaction is important for understanding the stabilising effects of substituents upon the allylic cation and, independently, the phenonium intermediate, as well as providing an alternative strategy towards the functionalisation of benzylated 1,3-dithiole-2-thione and TTF derivatives.

We thank the EPSRC for research grant GM/M36342 (T. K.).

Received (in Cambridge, UK) 8th December 2000, Accepted 16th January 2001
First published as an Advance Article on the web 8th February 2001

A new methodology has been developed to synthesize gold–silver alloy nanoparticles by laser irradiation of mixtures consisting of gold and silver nanoparticles.

Nanoscale materials have attracted a great deal of interest in scientific research and industrial applications, owing to their unique large surface-to-volume ratio and quantum size effect properties.[1] In principle, the preparations of metal nanometer-sized particles could be classified into two categories: physical and chemical techniques. Evaporation[2] or laser ablation[3] from metal bulk samples is utilized to generate nanoparticles in the physical methods whilst reduction of metal ions to neutral atoms, followed by metal growth is the common strategy in chemical syntheses, including conventional chemical (one- or two-phase systems),[4] photochemical,[5] sonochemical,[6] electrochemical[7] and radiolytic reductions.[8] In this report, a novel methodology is developed to fabricate gold–silver alloy nanoparticles, using laser irradiation of gold and silver colloidal solutions.

Nanocomposites, *i.e.* alloy and core–shell particles, are an attractive subject because of their composition-dependent optical and catalytic properties. To date, Papavassiliou has successfully prepared Au/Ag alloy particles *via*. evaporation of Au/Ag alloys.[2a] Kim and coworkers[4c] and El-Sayed and coworkers[4d] employed simultaneous reduction of gold and silver salts to form Au/Ag alloy nanoparticles of 4 nm and ≈ 18 nm diameter, respectively. Although Lis-Marzán *et al.* used a similar chemical method to synthesize gold–silver bimetallic colloids, the detailed structures of these remained ambiguous.[4b] It should be noted that the formation of alloy particles by co-reduction of different metal salts strongly relies on the reduction rates of the metal ions. A core–shell structure could be readily prepared through a heteronucleation process: the metal with the faster reduction forms the core and the other is the surrounding shell.

Recently, pulsed laser irradiation to nanorods or spherical particles was studied to unravel the photophysical properties of these particulates. The groups of El-Sayed and Koda suggested that the interaction between laser light and metal particles may lead to conformational changes *via* a melting process.[9] We have attempted to take advantage of this melting state, if present, to alloy a mixture containing two different kinds of metal particles under laser light irradiation. A gold–silver system was selected since both metals are miscible in the bulk phase, owing to very similar lattice constants.[10] Moreover, the UV–VIS absorption spectra of the Au/Ag bimetallic particles show a substantial difference between the alloy and a core–shell structure, which has been studied explicitly by experimental and theoretical measurements.[4b–d,11]

In this study, Au and Ag nanoparticles were prepared in aqueous solution following the methods employed by Natan and coworkers[12] and Lee and Meisel,[13] respectively. The mean diameters of the prepared colloids were 13.7 ± 0.8 nm for Au and 16.8 ± 6.6 nm for Ag. Assuming that metal salts ($HAuCl_4$ and $AgNO_3$) are completely reduced into neutral metals completely, gold and silver colloids were mixed in molar ratios (Au : Ag) of 1 : 2, 1 : 1 and 2 : 1 (see ESI†).

Fig. 1 shows the UV–VIS absorption development of the 1 : 1 molar ratio (Au : Ag) colloidal suspensions before and after laser irradiation. Two distinct absorbance maxima at 396 and 519 nm, corresponding to Ag and Au plasmon bands, respectively, indicate segregated Ag and Au particles in the mixed suspension before exposure to laser light [Fig. 1(a)]. For solutions exposed to the laser [Fig. 1(b) and (c)] the absorption spectra changed as the irradiation time was increased. The Au surface plasmon band increases in magnitude and shifts to lower wavelength while the Ag plasmon band moves in the opposite direction with reduced intensity and absorption maximum. This variation in UV–VIS spectra clearly imply changes in the colloidal properties. Further irradiation [Fig. 1(d)], leads to a single absorption peak at 459 nm, located at an intermediate position between the Au and Ag plasmon bands. This surface plasmon band is likely due to the formation of the gold–silver alloy.[4c,d,11] Two plasmon bands (Au and Ag) would be expected if the colloids consisted of individual Au and Ag particles or of bimetallic composites with a core–shell structure.[11] A similar evolution in absorption spectra appeared in mixtures with Au : Ag molar ratios of 1 : 2 and 2 : 1 (see ESI†). A linear relationship was obtained from the plot of the plasmon band position *vs.* the gold mole fraction, as shown in Fig. 2. Previous studies on Au/Ag alloy nanoparticles showed a linear red-shift in the position of the plasmon absorption with an increase in gold composition.[2a,4c,d,11] The final temperatures of the solutions rose by *ca.* 20 °C from room temperature (24 °C) after

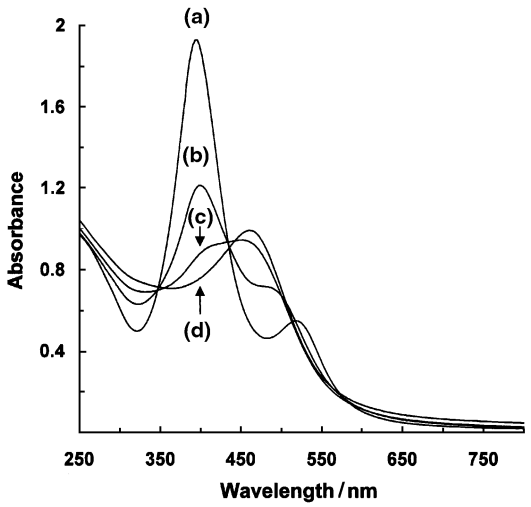

Fig. 1 Development of the UV-VIS absorption spectra of the 1 : 1 molar ratio (Au : Ag) colloidal suspension during irradiation using a pulsed laser, as a function of the exposure time: (a) 0 min, (b) 5 min, (c) 10 min, (d) 25 min. A 532 nm wavelength was utilized as light source and the laser intensity was maintained at 2.45×10^2 mJ pulse^{-1}.

† Electronic supplementary information (ESI) available: experimental details, UV–VIS spectra, TEM images and EDX analysis for molar ratios (Au : Ag) of 1 : 2 and 2 : 1. See http://www.rsc.org/suppdata/cc/b0/b009854j/

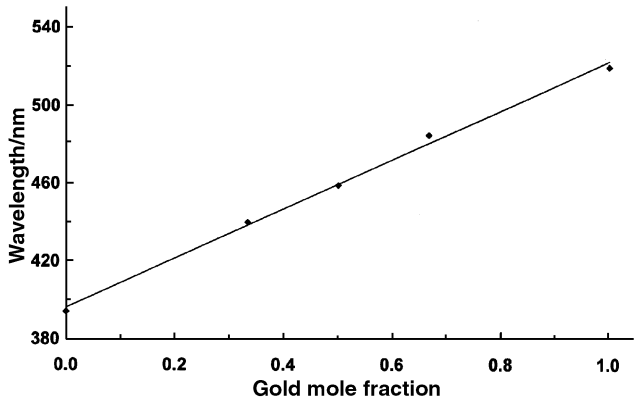

Fig. 2 Absorption position of the surface plasmon maximum as a function of the gold mole fraction.

irradiation. We also found that a lower laser fluence required a longer irradiation time to form gold–silver alloys.

Fig. 3 displays the TEM images of the 1:1 molar ratio (Au:Ag) colloid suspension. The most striking feature is the formation of an interconnected network, as shown in Fig. 3(a). The network appearance can be readily observed at various stages, where two Au and Ag plasmon peaks appeared in the absorption spectra, in the course of colloidal mixture irradiation. On closer inspection of Fig. 3(a), the particles (indicated by arrows) seem to develop as ramification structures in a radial fashion and are interconnected with each other, leading to a network morphology. However, the shape changes back to spherical after the alloying process is complete [Fig. 3(b)]. According to the TEM images, the morphology changes in the alloy nanoparticle formation can be described as follows: spherical (initially prepared Au and Ag particles) → network structure → spherical (alloy particles). Fig. 3(b) indicates highly dispersed tiny gold–silver alloy nanoparticles. The average particle sizes are 4.9 ± 1.8 nm (molar ratio Au:Ag = 1:2), 4.9 ± 1.9 nm (molar ratio Au:Ag = 1:1), and 5.1 ± 2.1 nm (molar ratio Au:Ag = 2:1). The minor variation in size is in contrast to the results of an increase in particle size when increasing the shell element amount in core–shell composites.[4b–d,11] The resulting alloy sizes are significantly less than those of the initially prepared Au and Ag colloids. In addition, the composition of the discrete bimetallic particles was analyzed using EDX. EDX measurements of selected particles, chosen at random, for molar ratio of 1:1 (Au:Ag) suspension, yielded the atomic ratios (Au:Ag): 49.1:50.9, 52.1:47.9, 47.2:52.8, 44.5:55.5 and 44.7:55.3. The compositions of the 1:2 and 2:1 molar ratios (Au:Ag) were also investigated using EDX analysis (see ESI†). Finally, from the viewpoint of their stability, the resulting alloy nanoparticles are preserved for at least one month with no sign of decay under aerobic conditions.

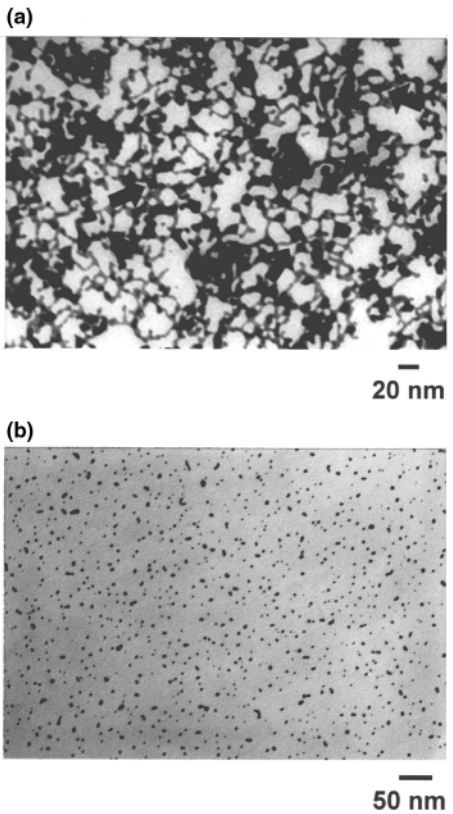

Fig. 3 TEM images of the 1:1 molar ratio (Au:Ag) colloidal suspensions after exposure to laser light for (a) 5 min and (b) 25 min.

In summary, we have demonstrated that Au/Ag bimetallic particles, forming a mixture at the atomic level, can be synthesized *via* the methodology introduced here. It is expected that this strategy could be applied to prepare other binary systems. Although the original idea of this experiment is based on the melting state, leading to alloy particles, the detailed formation mechanism remains to be resolved. However, the intermediate morphology, as seen in Fig. 3(a), reveals that the particles (indicated by arrows) appear to show that the metals are at the melting stage. Studies of the compositions and structures of the irradiated colloidal mixtures as a function of irradiation time are in progress.

We thank the National Science Council of the Republic of China for financial support of this work. We also acknowledge Ms. S. Y. Hsu and Mr. S. Y. Yao for the TEM and EDX measurements at Tainan Regional Instrument Center, National Cheng Kung University, R. O. C.

New paramagnetic ruthenium complexes *via* one-electron reduction of metallacumulenes†

Stéphane Rigaut,* Olivier Maury, Daniel Touchard* and Pierre H. Dixneuf

Institut de Chimie de Rennes, UMR 6509 CNRS-Université de Rennes: Organométalliques et Catalyse, Campus de Beaulieu 35042 Rennes, France. E-mail: daniel.touchard@univ-rennes1.fr

Received (in Cambridge, UK) 6th November 2000, Accepted 11th January 2001
First published as an Advance Article on the web 8th February 2001

One-electron reductions of $[Cl(dppe)_2Ru{=}C{=}C{=}CR_2]PF_6$ (R = Ph, Me) and $[Cl(dppe)_2Ru{=}C{=}C{=}C{=}CPh_2]PF_6$ with $Co(C_5H_5)_2$ provide radical species with the unpaired electron localized on the trisubstituted carbon atom of the cumulene moiety as shown by hydrogen atom capture and EPR spectroscopy.

Transition metal complexes are useful to stabilize the otherwise highly reactive **:**(C=)$_n$CR$_2$ species which behave as strong electron withdrawing ligands. Following the development of vinylidene derivatives[1] [M]=C=CR$_2$, the Selegue methodology[2] has allowed the synthesis and reactivity study of a large variety of metal allenylidene [M]=C=C=CR$_2$.[3,4] This chemistry has been extensively developed towards material science[5] and alkene metathesis catalyst precursors.[6] Stimulated by the fact that radical species have been recently proposed as intermediates in metathesis[7] and by the design of new magnetic materials with carbon-rich chains, monoelectronic reduction of metal allenylidene and higher metallacumulenes now appears as an important field to explore. Apart from a recent specific reduction of a 3-alkylthioallenylidene complex[8] which leads to a heteroatom-bonded carbon-stabilized radical, no information has yet been obtained on the nature of the reduction site, *e.g.* on the metal or on the cumulene ligand. We now wish to report here the preliminary results of a general study on reduction of all carbon metallacumulenes including allenylidene[9] L$_n$Ru=C=C=CR$_2$ and pentatetraenylidene[10] L$_n$Ru=C=C=C=C=CPh$_2$ complexes. We show on the basis of electrochemical, spin trapping and EPR spectroscopic evidences that: (i) monoelectronic reduction leads to a radical stabilized on the most remote carbon of the cumulene chain as a general trend; (ii) a striking difference of reactivity of L$_n$Ru=C=C=C=C=CPh$_2$ with respect to reduction *vs.* nucleophilic addition.

Complexes $[Cl(dppe)_2Ru{=}C{=}C{=}CR_2]PF_6$ [R = Ph (**1**$^+$), Me (**2**$^+$)[9a] and $[Cl(dppe)_2Ru{=}C{=}C{=}C{=}C{=}CPh_2]PF_6$ (**3**$^+$)[10] [dppe = 1,2-bis(diphenylphosphino)ethane], were studied using cyclic voltammetry (Fig. 1). Allenylidene **1**$^+$ undergoes two, well defined, one-electron reduction waves: the first one is reversible ($E°$ = −1.03 V *vs.* ferrocene, ΔE_p = 60 mV, $I_{pa}/I_{pc} \cong 1$), whereas the second one is irreversible (E_{pc} = −2.11 V). By contrast, complex **2**$^+$ undergoes only one irreversible reduction (E_{pc} = −1.31 V) which is consistent with the first reduced species undergoing following chemical reaction. The pentatetraenylidene complex **3**$^+$ shows a similar behavior to **1**$^+$, *i.e.* a reversible reduction ($E°$ = −0.63 V, ΔE_p = 65 mV, $I_{pa}/I_{pc} \cong 1$) followed by an irreversible one (E_{pc} = −1.67 V).

It is worth noting that by replacing the phenyl groups in **1**$^+$ with methyl groups in **2**$^+$ induces a significant cathodic shift of first the reduction wave by more than 250 mV. Lengthening the carbon chain from Ru–(C)$_3$ **1**$^+$ to Ru–(C)$_5$ **3**$^+$ surprisingly lowers the reduction potential by 400 mV and shows that the Ru–(C)$_5$ **3**$^+$ species is dramatically easier to reduce. The strong impact of these modifications of the metallacumulene on the reduction processes is a clear indication of the key role played by the cumulene chain. It is then obvious that increasing the length of the delocalized path on the cumulene ligand has a crucial stabilizing influence on the LUMO.[11]

We attempted to generate *in-situ* the first reduced species allowing further spin trapping experiments or EPR spectroscopy investigations. The most appropriate reducing agent is the cobaltocene, Cp$_2$Co, since (i) the reduction potential[12] ($E°$ = −1.33 V *vs.* ferrocene) will selectively induce the first reduction process in **1**$^+$ and **3**$^+$, and (ii) it is EPR-silent down to temperatures considerably below that of liquid nitrogen.[12b] Indeed, reduction of the deep colored cationic compounds **1**$^+$ (red), **2**$^+$ (green) and **3**$^+$ (blue), carried out with one equivalent of cobaltocene in THF, quickly lead to colorless solutions. Simultaneous addition of Ph$_3$SnH, which is known as a specific radical quencher by H· transfer,[13] leads to the complete disappearance of **1**$^+$, **2**$^+$ or **3**$^+$, on the basis of NMR data, and to the formation of the pale yellow, neutral acetylide compounds [Cl(dppe)$_2$Ru–C≡C–CHPh$_2$] **4**, [Cl(dppe)$_2$Ru–C≡C–CHMe$_2$] **5** and [Cl(dppe)$_2$Ru–C≡C–C≡C–CHPh$_2$] **6** (Scheme 1). These complexes have been characterized by ^{1}H, ^{13}C, ^{31}P NMR and high resolution mass spectrometry.† In addition, characteristic IR vibration stretches are obtained: $\nu_{C\equiv C}$ = 2085 (**4**), 2086 (**5**), 2179 and 2023 (**6**) cm^{-1}. All of these observations show that radical trapping only occurs at the end of the carbon skeleton.

Furthermore, achieving the reduction *in situ* of complexes **1**$^+$, **2**$^+$ and **3**$^+$ by dropping a crystal of cobaltocene in a THF solution into a capped EPR tube allows the direct observation of the radical species **1**, **2** and **3**. Reduced complexes **1** and **3** generated an intense and persistent signal. By contrast, the EPR spectrum generated from **2** disappears within few seconds, indicating fast evolution of the reduced species as observed on the electrochemistry scale.[14a,b] All the reduced forms **1**, **2** and **3** exhibit signals at 293 K in a characteristic region for organic radicals with g = 2.0042, 2.0097 and 2.0089 respectively. The signals

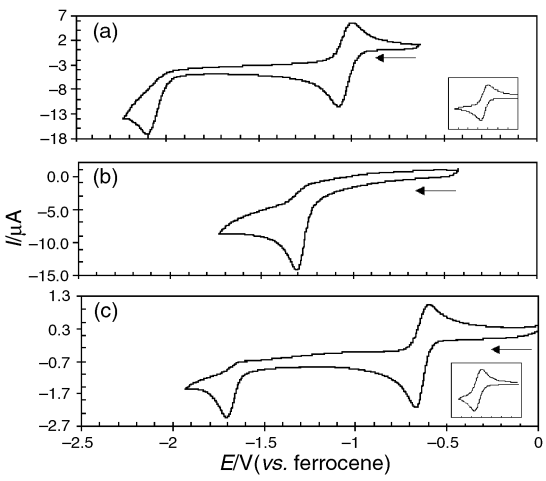

Fig. 1 Cyclic voltammetry responses (CH_2Cl_2, Bu_4NPF_6 0.1 M, scan rate 100 mV s^{-1}) *vs.* internal ferrocene for (a) **1**$^+$, (b) **2**$^+$ and (c) **3**$^+$. Insets show first reduction waves.

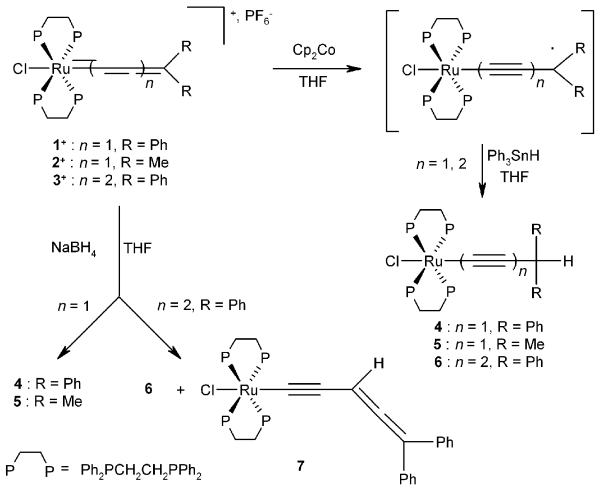
DOI: 10.1039/b008893p



Scheme 1

are resolved only in the case of **1** and **2**. The EPR spectrum of **2** gave a poorly resolved quintet [Fig. 2(b)] showing the hyperfine coupling with the four phosphorus nuclei with a_P = 3.0 G. For compound **1**, the EPR spectrum is complex [Fig. 2(a)]. This could be best rationalized by the coupling of the unpaired electron with the four phosphorus nuclei on one hand and further coupling with the *ortho*, *meta* and *para* hydrogens of the phenyl group of the carbon-rich bridge. These results suggest that the radical is centered on the organic bridges in **1**, **2**, **3** and is stabilized by delocalization along the two neighbouring phenyl rings in **1**. In the case of **2**, identification of such a radical neighbouring methyl groups is quite unexpected. These EPR data added to the trapping experiments indicate the organic nature of radicals **1**, **2** and **3** and show that the radical stabilization on the cumulene chain takes place at the trisubstituted carbon atom and thus is not controlled by the presence of a heteroatom bonded to the unsaturated chain.[8]

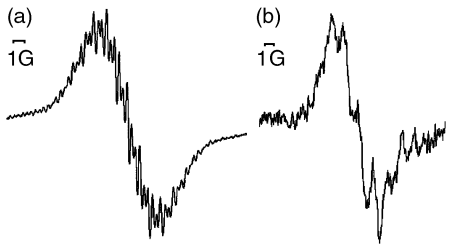


Fig. 2 EPR spectra resulting from reduction of (a) $\mathbf{1}^+$, g = 2.0042; (b) $\mathbf{2}^+$, g = 2.0097.

The synthesis of complexes **4**–**6** were achieved on successive addition to the cumulene chain of one electron and one hydrogen atom. This led us to study the reactivity difference with the simultaneous addition, *i.e.* the nucleophilic addition, of H^-. Nucleophiles are susceptible to attack either the C_α or the C_γ atom of an allenylidene ligand,[3,11*a*] but using the bulky phosphines additions only occur on C_γ.[9*b*] Reductions were performed using $NaBH_4$ in THF (Scheme 1). As expected for $\mathbf{1}^+$ and $\mathbf{2}^+$, additions of H^- take place at the C_γ carbons yielding the acetylide compounds $[Cl(dppe)_2Ru–C{\equiv}C–CHPh_2]$ **4** and $[Cl(dppe)_2Ru–C{\equiv}C–CHMe_2]$ **5**. When complex $\mathbf{3}^+$ was reduced, a mixture of two compounds was obtained. The presence of $[Cl(dppe)_2Ru–C{\equiv}C–CH{=}C{=}CPh_2]$ **7** (42% estimated by ^1H NMR), which displays a ^{13}C NMR signal at δ 216.7 characteristic for the cumulenic carbon (C=*C*=C),† is consistent with the electrophilicity of carbon C_γ in $\mathbf{3}^+$.[10] The main product $[Cl(dppe)_2Ru–C{\equiv}C–C{\equiv}C–CHPh_2]$ **6** (58%) shows the unknown electrophilic character of the C_ε atom. The fact that **7** is not observed in the free radical trapping experiment with H· is very promising, suggesting the location of the radical on the C_ε atom in **3** and the higher selectivity of radical addition *vs.* nucleophilic attack.

This last observation associated with cyclic voltammetry, trapping experiments and EPR spectroscopy re-enforces the conclusion that the reduction of Ru(II) allenylidene or pentatetraenylidene generate radical species located on the termini of the cumulene chain that can be written as shown in Scheme 1. More detailed investigations are in progress, including the study of the striking difference in selectivity between reduction/radical trapping and nucleophilic attack on the pentatetraenylidene complex and the potential of cumulenylidene in radical chemistry.

Received (in Cambridge, UK) 8th November 2000, Accepted 15th January 2001
First published as an Advance Article on the web 8th February 2001

A hydroxo- or carboxylate-bridged dinuclear Ni(II) complexes with *N,N,N′*,N′-tetrakis{(6-methyl-2-pyridyl)methyl}-1,3-diaminopropan-2-ol has been synthesized as models for Ni(II)-substituted phosphotriesterase, which are more active catalysts for hydrolysis of phosphodiester than the corresponding dinuclear Cu(II) and Zn(II) complexes.

It has recently been shown that a number of phosphate esterases are activated by two metal ions.[1] For example, phosphotriesterases which hydrolyze organophosphate triesters, known to be potent insecticides and neurotoxins, require several metal ions [Zn(II), Cd(II), Ni(II), Co(II) and Mn(II)] for their activities.[2] *Pseudomonas diminuta* phosphotriesterase has two Zn(II) atoms per subunit. The binuclear metal site was confirmed by the 2.1 Å resolution X-ray crystal structure of the enzyme.[3] The structure of the active site is very similar to urease, a Ni(II) enzyme catalyzing the hydrolysis of urea, characterized by a bridging carbamylated Lys, two His ligands for each metal ion, and a bridging solvent ligand.[4] Interestingly, Ni(II)-substituted phosphotriesterase has a higher specific activity than the native Zn(II) enzyme, while the Cu(II)-substituted enzyme has a similar activity to the native one.[2] Although there have been numerous reports of esterase model systems using well defined metal complexes [Zn(II), Cu(II), Co(III) and Ln(III)],[5] only a few Ni(II) model complexes have been studied in relation to the structure and reactivity in the hydrolysis of phosphodiesters.[6] In order to understand the mechanistic roles of the metal ions in phosphate ester hydrolysis, we have examined hydrolysis catalyzed by hydroxo- or carboxylate-bridged dinuclear Ni(II) and Cu(II) complexes. We have found that the hydrolysis activities of the dinuclear Ni(II) complexes are significantly greater than those of the Cu(II) and Zn(II) complexes.

$[Ni_2(Me_4\text{-tpdp})(MeCO_2)(H_2O)_2](ClO_4)_2$ **1** was prepared by the reaction of $[Ni_2(Me_4\text{-tpdp})(OH)](ClO_4)_2$ **2** with equimolar $MeCO_2H$ in acetone at room temp. and was recrystallized from MeCN–H_2O as light green crystals.[7] The X-ray crystal structure[8] of **1** reveals that the two hexacoordinate Ni(II) ions bridged by alkoxide and acetate anions are 3.62 Å apart. The geometries of both the Ni(II) sites are octahedral, with oxygen atoms of water molecules at the sixth coordination site. $[Cu_2(Me_4\text{-tpdp})(CH_3CO_2)](ClO_4)_2$ **3** was prepared by the reaction of $[Cu_2(Me_4\text{-tpdp})(OH)(H_2O)](ClO_4)$ **4** with equimolar $MeCO_2H$ in acetone at room temperature and was recrystallized from methanol–diethyl ether as dark green crystals. The X-ray crystal structure[8] of **3** reveals that the two pentacoordinate Cu(II) ions bridged by alkoxide and acetate anions are 3.54 Å apart. The geometries of both the Cu(II) centers are distorted square pyramidal.

As a model reaction of phosphotriesterase, we examined the hydrolysis of bis(4-nitrophenyl)phosphate (BNP) with the dinuclear metal complexes **1**–**4**. The hydrolysis rates (v) catalyzed by the complexes (2.0 mM) were measured by the initial slope method following an increase in the 395 nm absorption band of released 4-nitrophenolate in 20% MeCN aqueous solution at 35.0 ± 0.1 °C. Buffer solutions (20 mM HEPES, pH 6.5–8.0; TAPS, pH 8.5–9.0; CAPS, pH 9.5–10.7)[9] were used, and the ionic strength adjusted to 0.10 with $NaNO_3$. The observed first-order rate constant, k_{obs}/s^{-1} for the hydrolysis reaction was calculated from the dependency of v on the initial concentration (2.0–8.0 mM) of BNP. The second-order rate constants, $k_{BNP}/M^{-1}\ s^{-1}$ for BNP hydrolysis are given by fitting of the kinetic eqn (1).

$$v = k_{obs}[BNP] = k_{BNP}[complex][BNP] \quad (1)$$

The k_{BNP} values for the Ni(II) and Cu(II) complexes (**1**, **2**, **3**, and **4**) were determined to be $(3.4 \pm 0.2) \times 10^{-2}$, $(3.5 \pm 0.1) \times 10^{-2}$, $(1.8 \pm 0.1) \times 10^{-4}$ and $(1.8 \pm 0.1) \times 10^{-4}\ M^{-1}\ s^{-1}$ at pH 10.1 and 35.0 °C, respectively. The results demonstrate that the nucleophilic reactions catalyzed by the Ni(II) complexes are *ca.* 200 times faster than those by the Cu(II) complexes. Koike and Kimura reported that mononuclear Zn(II) complexes [Zn([12]aneN$_3$)(OH) and Zn([12]aneN$_4$)(OH)][10] catalyze the hydrolysis of BNP, with k_{BNP} of 2×10^{-5} and $13 \times 10^{-5}\ M^{-1}\ s^{-1}$, respectively, at 35.0 °C.[5d] The second-order rate constant for BNP hydrolysis with the $Zn_2(Me_4\text{-tpdp})$ complex is $6.7 \times 10^{-4}\ M^{-1}s^{-1}$ under almost the same conditions.[11] It is interesting that the Ni(II) complexes are more effective than the Cu(II) and Zn(II) complexes for phosphate ester hydrolysis. It should be noted that the hydrolysis activity of a mononuclear Ni(II) complex $(Ni(Me_2\text{-bpa})(H_2O)(ClO_4)_2$, **5**)[12] is lower than those of dinuclear **1** and **2**; k_{BNP} for the mononuclear Ni(II) complex ($6.4 \times 10^{-3}\ M^{-1}s^{-1}$ at pH 10.1) is 5–6 times smaller than those for the dinuclear Ni(II) complexes **1** and **2**. The result suggests that the dinuclear Ni(II) complexes are the cooperative hybrid catalysts.[5d]

The DPP-bridged dinickel complexes,[13] $[Ni_2(Me_4\text{-tpdp})(DPP)](ClO_4)_2$ **5**, and the BNP-bridged dicopper complex, $[Cu_2(Me_4\text{-tpdp})(BNP)](ClO_4)_2$ **6**, were obtained by the reaction of **2** with equimolar DPP, and **4** with equimolar BNP in acetone solution, respectively. For X-ray crystal structure analysis, **5** was recrystallized from dry methanol while **6** was recrystallized from dry acetonitrile–diethyl ether. As shown in Fig. 1, the X-ray crystal structures of **5** and **6** reveal that the metal ions are bridged by alkoxide and phosphate diester.[8] The geometries of both the Cu sites in **6** are distorted square pyramidal, while the geometries of both the Ni sites in **5** are octahedral, with oxygen atoms of methanol at the sixth coordination site. The crystal structures of **1**, **3**, **5**, **6** and $[Zn_2(M_4\text{-tpdp})(BNP)]^{2+}$ indicate that the Ni(II) centers are hexacoordinate, whereas the Cu(II) and Zn(II)[11] centers are pentacoordinate; the hexacoordinate Ni(II) sites would be more favorable for the formation of an active intermediate complex bound BNP than the pentacoordinate Cu(II) and Zn(II) sites. The substrate could coordinate to Ni(II) ions under conditions that the nucleophile remains bound, and might react with the nucleophile, whereas the substrate

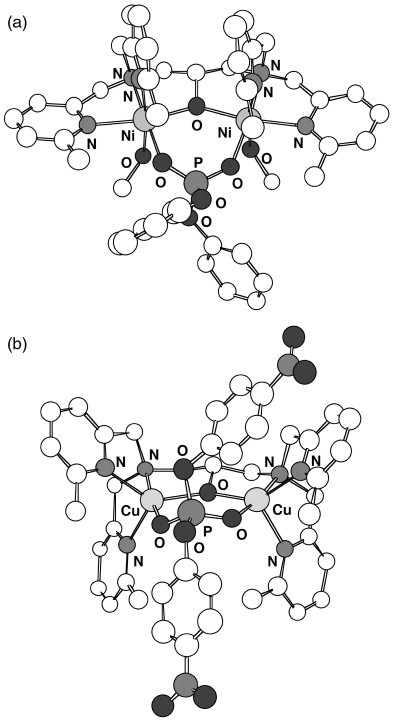

Fig. 1 Perspective views of $[Ni_2(Me_4\text{-tpdp})(DPP)(MeOH)_2]^{2+}$ (a) and $[Cu_2(Me_4\text{-tpdp})(BNP)]^{2+}$ (b). Hydrogen atoms are omitted for clarity.

coordinated to Cu(II) or Zn(II) ions could react only with exogenous nucleophile.

k_{BNP} Values for **1** and **2** are plotted against pH in Fig. 2. The inflection point at pH 8.0 for **2** almost coincides with the pK_a value of 7.9 for the coordinated water of **2**. Therefore, the OH^- ligand in **2** must be a good nucleophile for phosphodiester. On the other hand, the inflection point for **1** is shifted to a higher pH. These findings might be caused by ligand exchange of acetate with the substrate. The pH dependence of the UV–VIS spectrum of **1** was measured at 25.0 ± 0.1 °C. The UV–VIS spectrum of **1** was similar to that of **2** at high pH, with isosbestic points being observed (data not shown). The equilibrium constant for acetate binding was calculated as 25 ± 2 from the absorbance change at 488 nm in the pH range 7.5–11.0 and suggests that the acetate ligand in **1** readily dissociates and exchanges with hydroxide at high pH. This is consistent with the fact that the reactivity of **1** is similar to that of **2** at high pH while acetate ion in **1** would be a competitive inhibitor of the hydrolysis of BNP at low pH. Complex **2** behaves as a catalyst as revealed by the yield of product (>200% relative to complex) when the reaction of 8.0 mM BNP with 2.0 mM complex was carried out for 12 h at pH 10.1 and 35.0 °C. However, BNP hydrolysis with **2** inhibited (by 30%) upon the addition of an equimolar amount of 4-nitrophenyl phosphate (NPP), the hydrolysis product of BNP, at pH 10.1 and 35.0 °C NPP is also a competitive inhibitor with the substrate.

In conclusion, the mechanism of BNP hydrolysis with the dinuclear Ni(II) and Cu(II) complexes can be summarized by

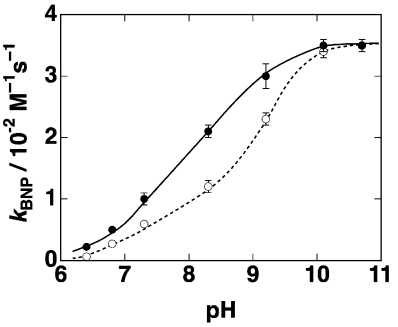

Fig. 2 Dependence of k_{BNP} on pH for the hydrolysis with complex **1** (○) and complex **2** (●) in 20% MeCN aqueous solution at 35.0 °C.

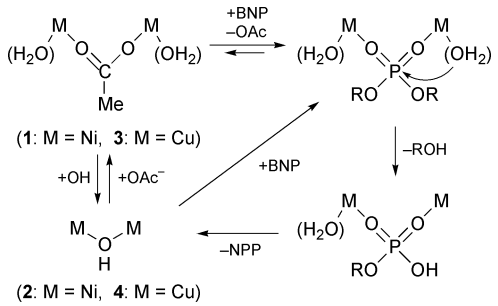

Scheme 1 Suggested mechanism of BNP hydrolysis with hydroxo- or carboxylate-bridged dinuclear complexes (M = Ni or Cu; R = $C_6H_4NO_2$).

Scheme 1. The hexacoordinate dinuclear Ni(II) complexes are more active catalysts for phosphate diester hydrolysis than the corresponding pentacoordinate dinuclear Cu(II) and Zn(II) complexes. The coordination number of the metal ions in an intermediate complex would be important for phosphodiester hydrolysis.

1,1′-Bis(trimethylsilylseleno)ferrocene in cluster synthesis: a redox active surface on a copper–selenide core†‡

Andrew I. Wallbank and John F. Corrigan*

First published as an Advance Article on the web 8th February 2001

1,1′-Bis(trimethylsilylseleno)ferrocene 1 has been prepared from the reaction of [1,1′-Fe(η^5-$C_5H_4SeLi)_2$(TMEDA)] and $ClSiMe_3$ in good yield. The reactive silyl groups on 1 are used as a driving force for the synthesis of [Cu_8{Fe(η^5-$C_5H_4Se)_2$}$_4$($PPh_2Et)_4$] 2, a cluster possessing four peripheral ferrocenyl moieties.

Owing to the inherent redox active metal centre, the functionalisation of the cyclopentadienyl rings in ferrocene and subsequent ligation to metal centres are currently of great research interest in cluster, materials and inorganic synthesis.[1] Many of these ferrocene-containing molecules display interesting charge transport, non-linear optical and magnetic properties related to the metal–metal interactions between the ferrocene units and other metal centres in the structure.[2] It has been demonstrated that nanoparticle (Au) surfaces can be functionalised with ferrocenyl units, although these redox centres are spatially removed from the metallic core due to the micellar type of stabilisation provided by the thiolate ligands.[3] Bidentate 1,1′-bis(diphenylphosphino)ferrocene[4] (dppf) has been shown to be an excellent ligand in carbonyl cluster chemistry due to the flexibility of the ferrocene unit, through a combination of ring twisting and tilting. 1,1′-Ferrocenyldichalcogenolates have many similar characteristics and have been shown to bridge metal centres[5] and bind in a chelating fashion to one metal.[6] These dichalcogenolates are synthesized either *via* insertion of chalcogens into the C–Li bond of dilithioferrocene[7] or *via* deprotonation of the corresponding dichalcogenols.[8]

The use of silylated selenium reagents offers a powerful entry into the formation of metal–selenium bonds in both coordination and polynuclear chemistry.[9] Their utility in the latter exploits the bridging capacity of the selenium centre in alkyl– and aryl–selenolate ligands and has been used to effectively stabilise metal–selenide cores. Herein we describe the unprecedented complexation of 1,1′-diselenolatoferrocene units onto a polymetallic core.

We reasoned that the synthesis of the bis-silylated reagent [Fe(η^5-$C_5H_4SeSiMe_3)_2$] **1** and its use in the synthesis of metal–chalcogen clusters would permit facile introduction of redox active iron centres onto metal–chalcogen cluster surfaces, which may be intimately coupled (*via* the C_5–Se rings) to the cluster core. Owing to the large variety of bonding modes for selenium and the success of the use of silylselenoethers in cluster synthesis,[9] [Fe(η^5-$C_5H_4SeSiMe_3)_2$] **1** was targeted and prepared from the corresponding dilithiodiselenolate.§ When chlorotrimethylsilane is added to a suspension of [Fe(η^5-$C_5H_4SeLi)_2$(TMEDA)][10] in pentane at 0 °C, **1** is isolated as a golden yellow powder in 65% yield. Compound **1** is susceptible to rapid air decomposition both in solution and the solid state. Even under an inert atmosphere, **1** must be stored cold and in the absence of light in order to avoid decomposition. The molecular structure of **1** (Fig. 1) shows that the selenolate groups are held in a *trans* configuration in the solid state with the two Cp rings adopting a staggered conformation. The iron atom sits on a crystallographic inversion centre with the planes of the cyclopentadienyl rings parallel and the selenium atoms lie slightly above (0.02 Å) the C_5 rings.¶

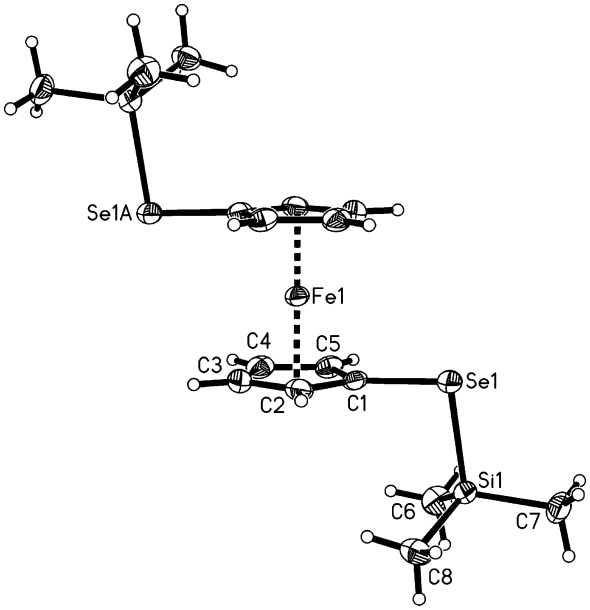

Fig. 1 Molecular structure of Fe(η^5-$C_5H_4SeSiMe_3)_2$ **1**. Selected bond lengths (Å) and angles (°): Fe1–C 2.041(3)–2.048(3), C1–Se1 1.916(3), Sel–Si1 2.2930(8); C1–Se1–Si1 95.32(8).

The reaction of **1** with 2 equivalents of CuOAc : $3PPh_2Et$ in THF affords [Cu_8{Fe(η^5-$C_5H_4Se)_2$}$_4$($PPh_2Et)_4$]·(OC_4H_8) **2**·THF in good yield, the reaction driven by the formation and elimination of Me_3SiOAc.‖ The molecular structure of **2** is shown in Fig. 2. There are two crystallographically independent and chemically equivalent molecules in the unit cell, both of which reside on a two-fold rotation axis.** Bond lengths and angles discussed in the text for **2** refer to molecule 1.

Cluster **2** contains a copper–selenium core shielded by four ferrocenyl and four phosphine ligands. All of the copper centres exhibit a trigonal planar geometry either through a combination of two selenium and one phosphorus bonds (Cu1, Cu3, Cu1A, Cu3A) or three Cu–Se interactions (Cu2, Cu2A, Cu4, Cu4A). The Cu–Se [2.356(1)–2.463(1) Å] and Cu–P distances [2.214(2)-2.226(2) Å] are similar to those found in other copper–selenium clusters.[11] Both of the crystallographically independent ferrocenyl moieties display moderate deviations from co-planarity of the two C_5 rings (2.0 and 5.3° for Fe2 and Fe1, respectively). Whilst the two Cp rings about Fe1 deviate 15.7° from being eclipsed, the two about Fe2 are better described as adopting a staggered (29.5°) conformation. The selenium atoms in **2** are slightly displaced (0.07–0.28 Å) from the planes defined by their respective C_5 rings. Overall, the eight Se centres define a non-bonded [3.352(1)–4.411(1) Å] dodecahedral framework bridging either two (Se1, Se1A, Se3,

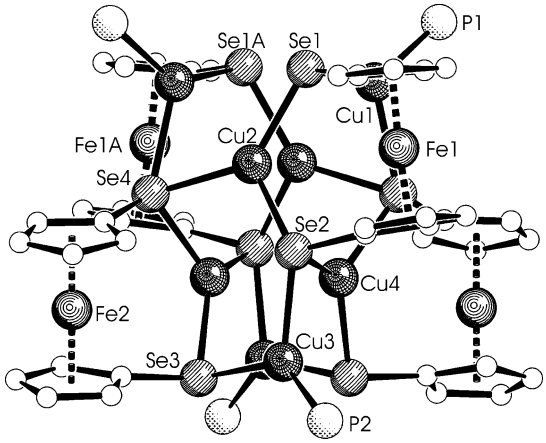

Fig. 2 Molecular structure of $[Cu_8\{Fe(\eta^5\text{-}C_5H_4Se)_2\}_4(PPh_2Et)_4]$ **2** (molecule 1; phosphine carbon atoms omitted). Selected bond lengths (Å): Se(1)–Cu(2) 2.355(1), Se(1)–Cu(1) 2.411(1), Se(2)–Cu(2) 2.362(1), Se(2)–Cu(4) 2.397(1), Se(2)–Cu(3) 2.434(1), Se(3)–Cu(4A) 2.354(1), Se(3)–Cu(3) 2.399(1), Se(4)–Cu(4A) 2.380(1), Se(4)–Cu(2) 2.431(1), Se(4)–Cu(1A)–Cu(1A) 2.463(1).

Se3A) or three (Se2, Se2A, Se4, Se4A) metals. It is interesting to note that the observed Cu_8Se_8 core geometry in **2** has been predicted to be unstable for related $[(FeCl)_{4-x}Cu_{4+x}(SePr^i)_8]$ complexes.[11b]

The cyclic voltammogram of **1** (ESI†) displays one irreversible wave at +1.33 V (*versus* $CoCp_2/CoCp_2^+$), complicated by the deposition of the material onto the electrode surface. In **2**, two irreversible oxidation waves of equal current are observed at +1.11 and +1.35 V,†† although the first wave may be due to oxidation of Cu(I) centres. Unlike surface modified Au particles with ferrocenylalkanethiolate ligands where the Fe centres are spatially 'removed' from the cluster,[3] in **2** the Fe centres are intimately associated with the polymetallic core. Oxidation of **2** to higher potential results in cluster decomposition only. Any electronic communication between the iron and copper centres in the molecular complex **2** suggests similar effects in related *nanoscale* $[Cu_{2m}\{Fe(\eta^5\text{-}C_5H_4Se)_2\}_{m-n}Se_n(PR_3)_x]$ complexes and we are actively pursuing their synthesis.

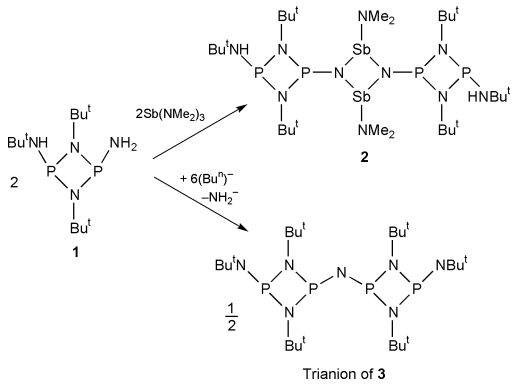
First published as an Advance Article on the web 8th February 2001

The novel precursor $[Bu^tNHP(\mu\text{-}NBu^t)_2PNH_2]$ (1) provides easy access to polycyclic main group systems; reaction with $Sb(NMe_2)_3$ gives the tricyclic species $\{[Bu^tNHP(\mu\text{-}NBu^t)_2\text{-}P]_2\{Me_2NSb(\mu\text{-}N)\}_2]$ (2), whereas reaction with an excess of Bu^nLi results in elimination of $LiNH_2$ and the formation of the co-complex $[\{Bu^tNP(\mu\text{-}NBu^t)_2P\}_2N]Li_3\ (Bu^nLi)_2$, (3), containing the unprecedented $[\{Bu^tNP(\mu\text{-}NBu^t)_2P\}_2N]^{3-}$ trianion.

In recent years the synthesis and coordination chemistry of a range of new anionic ligands based on p-block element frameworks has become a rich area of study. This work has been dominated by a number of related Group 15 and 16 element/nitrogen arrangements, such as the tripodal systems $[E(NR)_3]^{2-}$ (E = S–Te)[1] and $[E(NR)_3]^{3-}$ (E = As, Sb),[2] which provide the means to an extensive range of cage complexes, containing well-defined mixed-element compositions.[2] Such cages have potentially far-ranging applications as single-source materials to a number of technologically important mixed-element phases.[3] The normally easy access to these multifunctional p-block element ligand arrangements contrasts with the generally far more involved synthetic procedures required to prepare related systems based on carbon. However, a key issue is whether systematic routes can be devised to more elaborate polyfunctional p-block element species (beyond the simple systems previously investigated). To this end, we present here a simple design approach to a family of polycyclic Group 15 imido frameworks, providing a new direction in this area.

The principal starting material for these investigations, $[Bu^tNHP(\mu\text{-}NBu^t)_2PNH_2]$ (**1**), is prepared in good yield (59%) by the reaction of $[Bu^tNHP(\mu\text{-}NBu^t)_2PCl]$[4] with NH_3(g) in THF solution.† Previous studies of imido phosphorus anions have dealt almost exclusively with species of the type $[R'NP(\mu\text{-}NR)]_2^{2-}$, prepared by deprotonation of $[R'NHP(\mu\text{-}NR)]_2$.[5] Although **1** has a similar P_2N_2 core arrangement to the latter, it presents the unique opportunity for deprotonation at up to three positions (*i.e.* the Bu^tNH and NH_2 groups). The reaction of **1** with $Sb(NMe_2)_3$ (1:1 equiv.) in toluene gives $[\{Bu^tNHP(\mu\text{-}NBu^t)_2P\}_2\{Me_2NSb(\mu\text{-}N)\}_2]$ (**2**) (Scheme 1). This result is similar to that observed between simple primary amines (RNH_2) and $Sb(NMe_2)_3$,[6] which gives dimers of the type $[Me_2NSb(\mu\text{-}NR)]_2$. However, in the case of **2** a tricyclic arrangement is established in a single step. The low reactivity of the Bu^tNH protons in **2** (which could potentially react further with the Sb-bonded NMe_2 groups) contrasts with the deprotonation of **1** with Bu^nLi (1:3 equiv., respectively). The product is the unusual co-complex $[\{Bu^tNP(\mu\text{-}NBu^t)_2P\}_2N]Li_3{\cdot}(Bu^nLi)_2$ (**3**), the framework of which results from a combination of deprotonation and coupling of the dimer units of **1** (with elimination of $LiNH_2$) (see ESI†).

The low-temperature X-ray structures of **1**, **2** and **3** were obtained.‡ Although simple, **1** is the first non-symmetrically substituted cyclophosphazane containing the NH_2 functionality (Fig. 1). Related species containing the NH_2 functionality are



Scheme 1

rare[7] and the only structurally characterised dimers previously reported are chlorides of the type $[R_2NP(\mu\text{-}NR')(\mu\text{-}NR'')PCl]$[8] and $[Bu^tNHP(\mu\text{-}NBu^t)_2PCl]$[4] (the immediate precursor to **1**). The *cisoid* disposition of the Bu^tNH and NH_2 groups found in molecules of **1** is similar to that observed for the previous chlorides. However, the similarity of the ^1H and ^{31}P NMR behaviour of **1** in toluene solution with that of $[PhNHP(\mu\text{-}NPh)]_2$ suggests that two closely related *cisoid* isomers are present (in *ca.* 2:1 ratio, corresponding to rotation of the Bu^tNH group *exo* or *endo* to the P_2N_2 ring).[9]

Complex **2** (Fig. 2) has a tricyclic arrangement composed of a central Sb_2N_2 ring symmetrically substituted with bridging $[Bu^tNHP(\mu\text{-}NBu^t)_2P]$ groups. The orientation of these ring units approximately *trans* to the Sb_2N_2 ring plane gives molecules an overall S-shape, in which the *cisoid* conformation found in the precursor **1** is retained in the $[Bu^tNHP(\mu\text{-}NBu^t)_2PN]$ ring units of **2**. The bias for the *cisoid* conformation of these substituents is apparently reinforced by H-bonding of the terminal Bu^tNH protons to the *trans* Me_2N groups of the Sb_2N_2 core [N(2)···N(5) 3.178(9) Å (H(2)···N(5) 2.34 Å), N(2)H(2A)···N(5A) 165.3°]. Although (unlike **1**) the

[$Bu^tNHP(\mu\text{-}NBu^t)_2PN$] units of **2** are no longer symmetric, deprotonation of the NH_2 group of the precursor has comparatively little effect on the overall bond lengths and angles found in these units.

The surprising result of attempted deprotonation of **1** with Bu^nLi is the formation of the elaborate cage complex **3**, consisting of a $[\{Bu^tNP(\mu\text{-}NBu^t)_2P\}_2N]^{3-}$ trianion coordinated to three Li^+ cations and further associated with two monomer units of Bu^nLi (Fig. 3). Although uncommon, a number of co-complexes with Bu^nLi of this kind have been structurally characterised in recent years.[10] The composition of **3** resembles that of $[Al_2(NHBu^t)_3(NBu^t)_3Li_3{\cdot}2Bu^nLi]$, which contains an $[Al_2(NHBu^t)_3(NBu^t)_3]^{3-}$ trianion unit and two Bu^nLi monomers.[11c] Nonetheless, the bicyclic $[\{Bu^tNP(\mu\text{-}NBu^t)P\}_2N]_2^{3-}$ trianion is an unprecedented Group 15 imido ligand arrangement. The closest comparison that can be made with the trianion framework of **3** is with the neutral cyclophosphazane

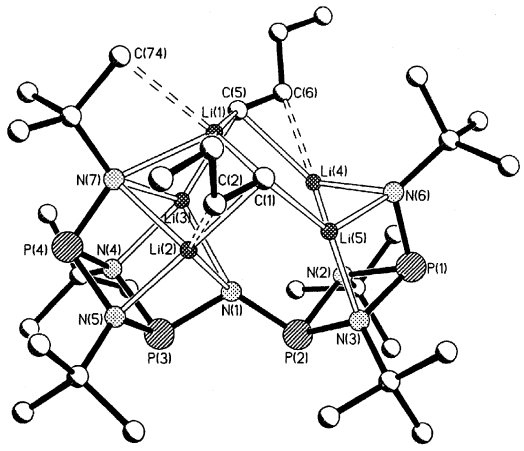

Fig. 3 Cage structure of the co-complex **3**. Key bond lengths (Å) and angles (°): within the $[\{Bu^tNP(\mu\text{-}NBu^t)P\}_2N]_2^{3-}$ trianion: P(1)–N(6) 1.655(3), P(1)–N(2) 1.792(3), P(1)–N(3) 1.784(3), P(2)–N(2) 1.774(3), P(2)–N(3) 1.762(3), P(2)–N(1) 1.676(3), P(3)–N(1) 1.689(3), P(3)–N(4) 1.768(2), P(3)–N(5) 1.768(2), P(4)–N(4) 1.779(2), P(4)–N(5) 1.785(2), P(4)–N(7) 1.668(3); N(2,4)–P(1,4)–N(3,5) mean 82.3, N(2,4)–P(2,3)–N(3,5) mean 83.3, P(2)–N(1)–P(3) 113.1(1); within Li–N/C framework: terminal Bu^tN–Li(2,3,4,5) range 1.987(6)–2.208(6), μ-Bu^tN–Li(2,3,4,5) range 2.014(6)–2.102(6), N(1)–Li(2) 2.313(6), N(1)–Li(3) 2.193(7), N(7)–Li(1) 2.147(7), C(1,5)–Li(2,3,4,5) range 2.124(7)–2.218(6), C(1,5)–Li(1) mean 2.26, C(2)···Li(2) 2.461(6), C(6)···Li(4) 2.341(6), C(74)···Li(4) 2.783(6).

[$\{PhNHP(\mu\text{-}NPh)_2P\}_2NPh$] (a product of condensation of $PhNH_2$ with PCl_3), consisting of a similar arrangement of two P_2N_2 rings linked by an NPh bridge.[11] All five of the Li^+ cations of **3** have distinct coordination geometries. The positioning of Li(2) and Li(3), and Li(4) and Li(5) within the 'hemisphere' of the coordinating $[\{Bu^tNP(\mu\text{-}NBu^t)P\}_2N]_2^{3-}$ trianion of **3** is broadly similar. Each of these cations is coordinated by one of the μ-NBu^t groups and by the terminal Bu^tN group of the [$Bu^tNP(\mu\text{-}NBu^t)P$] halves of the trianion unit. However, presumably owing to the geometric constraints involved, the μ-N centre linking the [$Bu^tNP(\mu\text{-}NBu^t)P$] units [N(1)] only bonds to Li(2) and Li(3) [*cf.* > 2.84 Å for Li(4,5)···N(2)], giving a pseudo-cubane fragment on this side of the molecule which is reminiscent of the structure of $[\{Bu^tNP(\mu\text{-}NBu^t)\}_2Li_2{\cdot}2THF]$.[5b] The two Bu^n groups bridge Li^+ cations associated with each [$Bu^tNP(\mu\text{-}NBu^t)P$] half of the trianion. The involvement of the α-C and β-C centres of each of the Bu^{n-} anions with Li(2) and Li(4) is similar to that found in the hexameric structure of $[Bu^nLi]_6$ in the solid state [*β*-C(–H)···Li *ca.* 2.28 Å;[12] *cf.* C(2)···Li(2) 2.461(6) and C(6)···Li(4) 2.341 (6) Å in **3**]. The remaining Li cation [Li(1)] is located above the pseudo-cubane half of the cage, being bonded to the α-C atoms of both of the $(Bu^n)^-$ anions and to a terminal Bu^tN group. Further agostic interaction with the Me group of this Bu^tN ligand [C(74)···Li(1) 2.783(6) Å[15] results in a pseudo-tetrahedral geometry for Li(1).

We gratefully acknowledge the EPSRC (N. F., S. J. K.) and the Leverhulme Trust (M. A. B.) for financial support. We also thank Dr J. E. Davies for collecting X-ray data for the compounds reported.

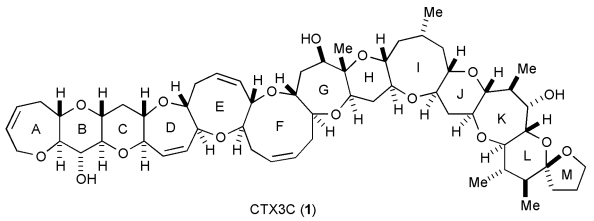
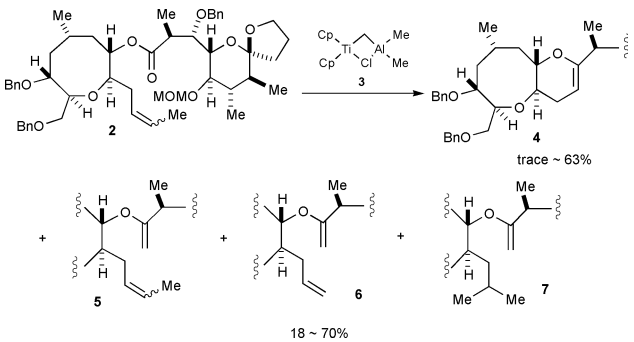
Received (in Cambridge, UK) 27th November 2000, Accepted 18th January 2001
First published as an Advance Article on the web 8th February 2001

The HIJKLM ring segment (27) of the right half portion of ciguatoxin CTX3C (1) has been synthesized using a ring-closing reaction mediated by a low-valent titanium reagent.

During the course of our synthetic studies directed toward ciguatoxins,[1,2] we have recently reported the convergent synthesis of the ABCDE[3] and IJKLM[4] ring fragment of **1**, based



upon an alkylation-ring closing metathesis (RCM) strategy[5,6] and a Tebbe reagent (**3**)[7] mediated ester olefination-ring closing metathesis sequence,[8] respectively. Occasionally, however, the key transformation of **2** into **4** in the latter sequence turned out to be non-reproducible. The yield of **4** fluctuated between trace amount to 63% and concomitant formation of an inseparable mixture of enol ethers, **5**, **6**, and **7** tended to occur (Scheme 1). Unfortunately, irrespective of extensive investigation, secure conditions to yield **4** uniformly could not be found. At low conversions **5** sometimes predominated, while **6** and then **7** gradually increased as the reaction time was extended. Since the intermediacy of the diene **5** in the formation of **4** was conceivable,[8] mixtures which contained **5** as the major product were treated with **3** or the Schrock catalyst, 2,6-(^{i}Pr)$_2$C$_6$H$_3$-N=Mo[OC(CF$_3$)$_2$Me]$_2$=CHCMe$_2$Ph.[9–11] However, in remarkable contrast to literature precedent, **4** was not produced in appreciable amounts; instead **6** and **7** increased.[8] Steric hindrance around the diene system of **5** is likely to account for this unexpected failure of converting **5** into **4**. Mechanistically, there should exist an alternative pathway (**2** ⇌ **8** ⇌ **9** ⇌ **10** ⇌ **4**) to provide **4**, in which the ester carbonyl group reacts with an



Scheme 1

internal carbenoid species such as **9** (Scheme 2). Thus, we reasoned that exclusive formation of **9** would improve the yield of **4** and that **9** could be prepared from the phenylthioacetal **11** using the low-valent titanium complex Cp$_2$Ti[P(OEt)$_3$]$_2$ recently developed by Takeda.[12]

The dithioacetal **11** was synthesized as shown in Scheme 3. Although we had synthesized the I-ring moiety of **1** based on a ring-expansion strategy,[13] we developed an alternative route applicable to large-scale synthesis. Aldol reaction of glycolate **12**[14] with acrolein gave diene **13** as an epimeric mixture of alcohols (47%), which was separated from other diastereomers by flash column chromatography (40% combined yield). RCM reaction of **13** using Grubbs catalyst, (PCy$_3$)$_2$Cl$_2$Ru=CHPh,[15] proceeded smoothly to give the eight-membered cyclic ether **14** (60%). Reduction of the ester **14** followed by selective protection of the resulting primary alcohol as TBDPS ether, and Swern oxidation of the secondary alcohol gave the enone **15** (3 steps, 68%). Stereoselective introduction of the secondary methyl group was successfully achieved by conjugate addition with Me$_2$Cu(CN)Li$_2$ to afford **16** in 74% yield. Removal of the TBDPS group of **16** using TBAF in the presence of AcOH, and reduction of the resulting hydroxy ketone with NaBH(OAc)$_3$ gave the diol **17** as a single isomer (92%).[16] Bis-benzylation, acetal hydrolysis followed by a two step cyanation sequence yielded the nitrile **18** (46% overall yield). Protection, DIBAL-H reduction and thioacetalization gave the dithioacetal **19** (3 steps, 73%), which was condensed with the carboxylic acid **20**[4] to afford **11** (58%). Ring-closing reaction of **11** was then examined. A THF solution of **11** was added to excess Takeda reagent (Cp$_2$Ti[P(OEt)$_3$]$_2$)[12] at rt and then refluxed under an argon atmosphere for 1 h. Using this protocol, the cyclic enol ether was formed reproducibly in 52–67% yield even on a one or two gram scale, while reduction and elimination products of the phenylthio group, **21** and **22**, respectively, were only produced in minor amount, *ca.* 10% combined yield.

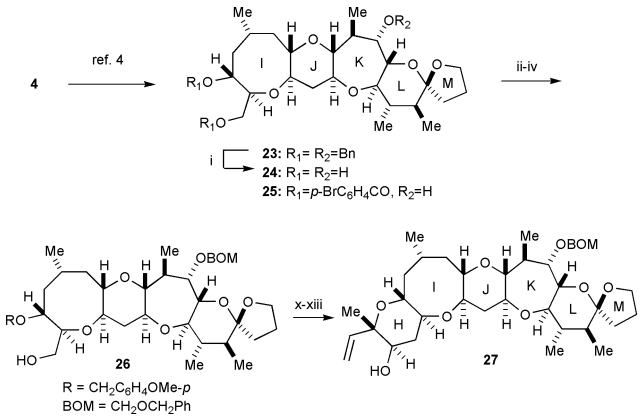

Scheme 4 *Reagents and conditions*: i, H_2, $Pd(OH)_2$/C, EtOAc, MeOH, rt, 1 d; ii, *p*-$MeOC_6H_4CH(OMe)_2$, CSA, CH_2Cl_2, rt, 30 min, 89% (2 steps); iii, BOMCl, $^iPr_2NEt$, $(CH_2Cl)_2$, 40 °C, 12 h, 88%; iv, DIBAL-H, CH_2Cl_2, −80 to −30 °C, 2 h, 85%; v, MsCl, Et_3N, $(CH_2Cl)_2$, 0 °C, 40 min; vi, NaCN, 18-crown-6, DMF, 50 °C, 3 d, 98% (2 steps); vii, DIBAL-H, CH_2Cl_2, −80 to −70 °C, 30 min; viii, Ph_3P=C(Me)CO_2Et, toluene, rt, 3 h, 84% (2 steps); ix, DIBAL-H, CH_2Cl_2, −70 °C, 20 min, 94%; x, D-(−)-DET, $Ti(O^iPr)_4$, Bu^tOOH, MS4A, CH_2Cl_2, −50 to −30 °C, 2 h, 80%; xi, SO_3·Py, Et_3N, CH_2Cl_2, 0 °C to rt, 2 h; xii, $Ph_3P^+CH_3Br^-$, NaHMDS, THF, 0 °C, 20 min, 96% (2 steps); xiii, DDQ, H_2O, CH_2Cl_2, rt, 2 h, 82%.

The enol ether **4** was converted to the IJKLM-ring fragment **23** according to our previously reported procedure (Scheme 4).[4] The stereochemistry of **23** was unambiguously determined by X-ray crystallography of the corresponding bis-*p*-bromobenzoate **25** (Fig. 1).[17] Furthermore, the H-ring moiety was successfully constructed in **23** in a similar manner to our previously established route[18] in 32% overall yield utilizing acid catalyzed vinylepoxide–alcohol cyclization methodology.[19]

In short, a practical synthetic route to the HIJKLM ring fragment **27** has been established. Further studies directed towards the total synthesis of ciguatoxin CTX3C (**1**) are currently in progress in our laboratory.

A route to the organometallic complex 8 is described, along with a study of its antiproliferative effects on breast cancer cell lines; in the examples studied, 8 behaves in a very similar manner to tamoxifen, suggesting new possibilities for applications in organometallic chemistry.

Tamoxifen **1** and its active metabolite, 4-hydroxytamoxifen **2** (Scheme 1) have been the subject of numerous studies owing to their efficacy in breast cancer treatment.[1,2] Currently however, substitutes are being sought in order to obviate the effects of resistance build up, as well as to improve the therapeutic effectiveness of the current treatments.[3,4] Our study is an attempt to potentiate the effects of these medications by introducing an organometallic-type modification to the base skeleton. Some organometallic complexes have in fact proven to be of interest either as antitumour agents, as in the case of the metallocenes of Fe and Ti,[5,6] or as radiopharmaceuticals, for example certain isotopes of Tc and Re.[7,8] If the organometallic moiety could be incorporated into this molecule while still preserving its character as an anti-oestrogen vector, this would provide a route to new products of added interest in a variety of applications. The question of preservation of antagonist activity is not an idle concern; we have shown that merely substituting the phenyl in the β position in **2** with a ferrocenyl group in **3** resulted in a significant drop in anti-oestrogenic effects *in vitro* on breast cancer cell lines, as well as *in vivo*, in nude mice.[9,10] Here we show that by attaching to the diphenylethylene skeleton a moiety of Re(I), in the form of cyclopentadienyl $Re(CO)_3$, small in size and difficult to oxidize, we obtain an anti-oestrogenic organometallic complex comparable to hydroxytamoxifen **2** but with the added advantage, owing to the presence of the metal Re, of allowing access to a new type of radiopharmaceutical compounds of ^{99m}Tc, ^{186}Re or ^{188}Re.

Compound **8** is prepared as shown in Scheme 2 starting from dihydroxybenzophenone **4** and the $(\eta^5\text{-}C_5H_4COEt)Re(CO)_3$ complex **6**, itself prepared by a Friedel–Crafts reaction between cyclopentadienyl rhenium tricarbonyl and propionyl chloride. The aromatic ketone **4** is first reacted with KH, to give the potassium salt, which reacts with dibromobutane. The monobrominated compound **5** is obtained in 35% yield. A McMurry cross-coupling reaction[11,12] between **5** and the organometallic compound **6** in the presence of $TiCl_4$ and Zn in THF under reflux gives **7** in 62% yield, and the latter when heated with dimethylamine in an autoclave produces **8** (***Z*** + ***E*****)** in a yield of 64%.† Separation of the isomers **8*Z*** and **8*E*** was done by reverse phase preparative HPLC. Identification of the isomers was ascertained by NOE NMR on the *E* isomer (effect between the protons $CH_3\text{-}CH_2$ and $C_6H_4\text{-}O(CH_2)_4N(CH_3)_2$, as well as between $\eta^5\text{-}C_5H_4\text{–}Re(CO)_3$ and $C_6H_4\text{-}OH$). In contrast to what is observed in the ferrocene series, no rapid interconversion was noticed between **8*Z*** and **8*E***, then showing a similarity of the rhenium derivatives with tamoxifen.

The relative binding affinity values (RBA) of **8** were measured for the mixture (*Z* + *E*) and for the individual isomers *Z* and *E* on the two oestrogen receptor subtypes ERα and ERβ using a competitive radiometric binding assay, with tritium-labeled oestradiol as tracer and protamine sulfate precipitation

Table 1 Antiproliferative activity of compounds **8**, **2** and E_2 on different cell lines

Compound	Molarity (M)	Cell	
		MVLN[a]	MDA-MB231[b]
8	1×10^{-6}	55.5 [97][c]	n d
	1×10^{-7}	51.5 [101][c]	91
2	1×10^{-7}	51.5	88
E_2	1×10^{-10}	258	91

[a] Cells with a high level of ERα. Results are expressed as percentage of the luciferase induction after 24 h of culture.[14] [b] Cells with no ERα, but presumably with ERβ.[15] Results are expressed as the percentage of DNA/control after 120 h of culture.[16] [c] Value obtained after simultaneous addition in the medium of 10 nM of E_2.

of the bound fraction of the tracer.[13] ERα was prepared from sheep uterus and ERβ, expressed in baculovirus, was obtained commercially from PanVera. The RBA values (mean of 2 or 3 experiments) found at 0 °C for **8** on ERα are 8% for the mixture **8** (***Z*** + ***E***), 7.4% for **8*Z*** and 5.2% for **8*E***, thus showing only a slight difference between the two isomers. In contrast, the RBA value obtained for ERβ is higher with **8*Z*** (17.8%) than for the mixture **8** (***Z*** + ***E***) (6%) or the *E* isomer **8*E*** (5.6%). However it is important to notice that ERβ is a purified receptor devoid of the effectors naturally present in the receptor alpha preparation obtained from sheep. Nevertheless the affinity for both ERα and ERβ are still satisfactory even if these RBA values are lower than the values found for **2** (***Z*** + ***E***) on ERα (38.5%) and ERβ (20%). This decrease probably reflects the greater steric crowding of $(\eta^5\text{-}C_5H_4)Re(CO)_3$ in **8** relative to the phenyl group in **2**.

We studied the agonist–antagonist effect of compound **8 (*Z*** + ***E***) on cell lines derived from breast cancer tumours (MVLN, MDA-MB231) (Table 1). In the MVLN line recently developed by Pons[14] it has been shown that the expression of the luciferase gene is proportional to the oestrogenic effect of the product tested. It contains a high level of ERα while the MDA-MB231 line does not contain any. In these tests, the control value is set by definition at 100%. For any given product, a value above 100% indicates an oestrogenic effect, and a value below 100% an anti-oestrogenic effect. As usual oestradiol is used as the reference for oestrogens and hydroxytamoxifen **2** (***Z*** + ***E***) for anti-oestrogens. The results obtained with MVLN cells show that the Re complex **8** behaves as an anti-oestrogen with almost identical efficacy as **2**. The observed effect with **8** is certainly hormonally based, since it is abolished by addition of oestradiol into the medium (values in square brackets in the Table). On MDA-MB231 cells which do not possess ERα but may possess ERβ,[15] **8** and **2** have no effect. It thus appears that the observed antiproliferative effect is dependent on the oestradiol receptor α, as is also the case with tamoxifen.

It appears that **8** may have a higher potential as an organometallic radiopharmaceutical, despite the fact that up to now the chelate route has been the one explored with tamoxifen;[17] in the latter case the ER binding rate was found to be too small to measure, which was not the case with **8**. It is therefore important to find a rapid route by which to attach useful isotopes of Tc and Re to **8**. To this end, we plan to use a selective photochemical decomplexation reaction that we have recently discovered, followed by rapid recomplexation in water with a new reagent reported by Alberto,[18,19] $(H_2O)_3M^+(CO)_3$ with M = ^{99m}Tc, ^{188}Re.

Notes and references

† Procedure for the preparation of **7** and **8**. Titanium tetrachloride (2 ml, 18 mmol) was added dropwise to a suspension of zinc powder (2.34 g, 36 mmol) in 60 ml of THF at 0 °C. The mixture obtained was heated at reflux for 2 h and then cooled to rt. A second solution was prepared by dissolving 4-(4-bromobutoxy)-4′-hydroxybenzophenone (4.25 g, 6 mmol) and cyclopentadienyltricarbonylrhenium ethyl ketone (2.35 g, 6 mmol) in 30 ml of THF. This latter solution was added dropwise to the first one and then the resulting mixture was heated for 2 h. After cooling to rt, the mixture was stirred with water and CH_2Cl_2. After treatment the pure oily *Z* + *E* mixture of **7** was obtained with a yield of 62%; MS (IE, 70 eV) *m*/*z*: 708 ($M^{+\cdot}$), 624 ($M - 3CO)^+$. Halide **7** (3 mmol) and a solution of dimethylamine in MeOH (2 M, 15 ml, 30 mmol) were heated with stirring in an autoclave at 60 °C for 1 day. After cooling, the solution was concentrated under reduced pressure. After treatment the pure amines **8** (***Z*** + ***E***) were isolated as oil containing a mixture of *Z* and *E* isomers with a yield of 64%; MS (IE, 70 eV) *m*/*z*: 673 ($M^{+\cdot}$). The *Z* and *E* isomers were separated on reverse phase preparative Kromasil C18 column, solvent MeOH phosphate buffer (KH_2PO_4, 25 mM, pH 7) 80/20, flow rate 6 mL min^{-1}. The retention times obtained on an analytical column of the same type (Kromasil C18, 10 μM, 250 mm) are repectively of 19.4 min for **8*Z*** and 26.4 min for **8*E*** in the proportion 48.5/51.5. Selected data for the two isomers: **8*E***: mp 153 °C, ^{1}H NMR δ 7.04 (d, *J* = 8.4 Hz, 2H, H_{arom}), 6.93 (d, *J* = 8.4 Hz, 2H, H_{arom}), 6.78 (d, *J* = 8.4 Hz, 2H, H_{arom}), 6.70 (d, *J* = 8.4 Hz, 2H, H_{arom}), ^{13}C NMR δ (all aromatic carbons) 135.5 (C), 134.6 (C), 130.6 (2 CH), 130.1 (2 CH), 129.9 (C), 115.6 (2 CH), 114.1 (2 CH). **8*Z***: mp 134°C, ^{1}H NMR δ 7.00 (d, *J* = 8.4 Hz, 2H, H_{arom}), 6.99 (d, *J* = 8.4 Hz, 2H, H_{arom}), 6.75 (d, *J* = 8.4 Hz, 2H, H_{arom}), 6.74 (d, *J* = 8.4 Hz, 2H, H_{arom}), ^{13}C NMR (all aromatic carbons) δ 135.9 (C), 134.8 (C), 130.5 (2 CH), 129.9 (2 CH + C), 115.3 (2 CH), 114.3 (2 CH).

Received (in Cambridge, UK) 22nd November 2000, Accepted 18th January 2001
First published as an Advance Article on the web 8th February 2001

A novel μ-oxo diiron(III) complex is capable of fast and selective oxidation of primary and secondary alcohols in the presence of H_2O_2 and a remarkable increase in reaction rate is achieved by addition of 1 eq. of CF_3SO_3H.

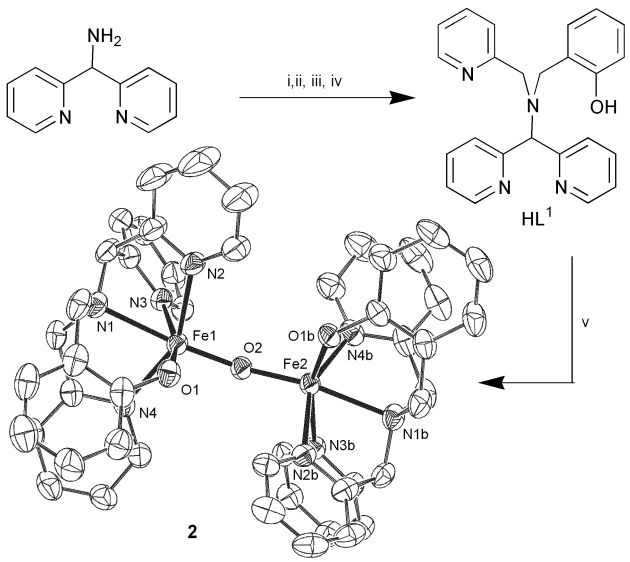
In nature, a variety of non-heme metalloenzymes are present which are capable of oxidation of substrates with high turnover frequencies and excellent selectivity.[1] An example is the mononuclear copper enzyme galactose oxidase (GOase) which catalyses the aerobic oxidation of benzylic and allylic alcohols to their corresponding aldehydes with concomitant formation of H_2O_2. The study of model complexes not only provides invaluable information about metalloenzymes, but also can result in the development of new generations of oxidation catalysts.[2] Beautiful examples are the GOase models developed by the groups of Wieghardt and Stack, which are capable of oxidation of alcohols to the corresponding aldehydes with high yield and selectivity.[3] An iron(II) complex of a pentadentate ligand N4Py† was developed as a model system for Fe-BLM.[4,5]† This system is capable of oxidising alkanes using H_2O_2 *via* a radical type mechanism. To explore the effect of ligand variations on the oxidation behaviour of the complex, we prepared a ligand HL^1† in which one of the pyridyl groups is replaced by a phenolate moiety. The corresponding μ-oxo dinuclear iron complex of HL^1 proved to be a selective and efficient catalyst for the oxidation of alcohols to aldehydes and ketones using H_2O_2 as the oxidant. Yields up to 65% based on H_2O_2 can be reached.

The synthesis of HL^1 is shown in Scheme 1. Complexation of the ligand with $Fe(II)(ClO_4)_2 \cdot x\,H_2O$ in MeOH, in the presence of 1 eq. of Et_3N followed by slow diffusion of ethyl acetate into the methanolic solution yielded purple crystals of complex **1** (λ_{max} = 540 nm, ε_M = 5.6 10^3 M^{-1} cm^{-1}) in 50% yield.‡ The complex was characterised as an antiferromagnetically coupled diiron(III) species based on its EPR silent nature and its ^{1}H-NMR spectrum, which exhibits paramagnetically shifted signals in the 0–40 ppm range. The ESI/MS spectrum shows a peak at *m/z* 445 ($[(L^1)Fe(\mu\text{-}O)Fe(L^1)]^{2+}$), which is consistent with the formulation of **1** as $\{[(L^1)Fe(\mu\text{-}O)Fe(L^1)](ClO_4)_2\}$. Further proof for this assignment was obtained from the crystal structure of the corresponding μ-oxo diiron(III) complex $[(L^1)Fe(\mu\text{-}O)Fe(L^1)](PF_6)_2$ (**2**), depicted in Scheme 1, which was synthesised by adding $Fe(NO_3)_3 \cdot 9H_2O$ to a solution of the ligand in methanol, followed by the addition of 1 eq. of Et_3N and 2 eq. of NH_4PF_6. Dark purple–blue crystals were obtained by slow diffusion of ether into the solution of **2**. Each iron(III) ion adopts a distorted octahedral coordination geometry involving a tertiary amine, three pyridine nitrogens, a phenolate oxygen atom and the bridging oxygen atom, with the Fe–O–Fe angle being 151.22(10)°.§ The crystal structure of **2** gave no indications that a proton is present at the phenolate moiety, which is consistent with the ESI/MS results of **1** (*vide supra*).

Complex **1** was examined as a catalyst (0.1 mol%) in the oxidation of various substrates using H_2O_2 as the oxidant.¶ Primary and secondary alcohols are oxidised rapidly (Table 1).‖

The oxidation of benzyl alcohol was monitored in time by GC. In Fig. 1 the turnovers per iron centre are plotted against time. Surprisingly, already 4 eq. of benzaldehyde have been formed in a reproducible manner, 30 s after the reaction was started by adding H_2O_2. The origin of this initial burst of activity is unclear. After the initial oxidation, a lag phase was observed. A significant increase in catalytic activity occurred after approximately 40 min and after 75 min the catalytic activity ceased because all the H_2O_2 was consumed. A total of 50 turnovers towards benzaldehyde was reached. Although a trace of benzoic acid was obtained, no other side products were produced according to GC. When another aliquot of H_2O_2 is added after 90 min, the catalyst is immediately active and no lag phase is observed. A value of 96 turnovers per iron centre can be obtained after 180 min. This can be repeated at least 3 times without significant loss of activity, showing a good stability of the system during catalytic turnover.

The UV/Vis absorption of **1** at 540 nm was monitored concomitantly with the oxidation of benzyl alcohol to benzaldehyde. During the lag phase the solution remains purple but after 45 min the colour changes to yellow. This colour change coincides with the end of the lag phase, suggesting that the yellow species is responsible for the oxidation activity.



Scheme 1 Synthesis of HL^1 and **2** and crystal structure of the cation of **2** (displacement ellipsoid plot with 50% probability level in which hydrogen atoms are omitted for clarity). *Reagents and conditions*: i, 2-pyridine carbaldehyde, 2 h, 97%; ii, $NaBH_4$, MeOH, 2 h, 90%; iii, 2-(bromomethyl)phenyl acetate, $^iPr_2EtN$, EtOAc, 3 d, 66%; iv, K_2CO_3, MeOH, 1 h, 89%; v, $Fe(NO_3)_3$, Et_3N, NH_4PF_6, 29%; Selected interatomic distances (Å): Fe–O: 1.93, Fe(1)–O(2) 1.79, Fe(1)–N(1) 2.26, Fe(1)–N(2) 2.17Å, Fe(1)–N(3) 2.22, Fe(1)–N(4) 2.13.

DOI: 10.1039/b009368h

Table 1 Turnover numbers (t.o.n.) of the catalytic oxidation experiments with **1** using H_2O_2

Entry	Substrate	Product	Time/min	t.o.n.[a]
1[b]	Benzyl alcohol	Benzaldehyde	75	50
2[c]	Benzyl alcohol	Benzaldehyde	15	50
3[d]	Benzyl alcohol	Benzaldehyde	90	15
4[e]	Benzyl alcohol	Benzaldehyde	180	96
5	Cyclohexanol	Cyclohexanone	60	28
6	Cyclohexanol	Cyclohexanone	60	65
7	Cyclooctanol	Cyclooxtanone	180	11
8	Octan-1-ol	Octanal[f]	180	11
9	*sec*-Phenylethyl Alcohol	Acetophenone	60	50

[a] t.o.n. = mol product/mol catalyst. [b] In the absence of catalyst a negligible amount of 0.004 mmol of benzaldehyde was formed under the standard reaction conditions after 90 min, whereas in the presence of Fe(II)$(ClO_4)_2$ only 8 turnovers were reached. [c] In the presence of 1 eq. CF_3SO_3H. [d] With 100 eq. of substrate instead of 1000 eq. [e] Addition of another aliquot of H_2O_2 after 90 min. [f] Octanoic acid was formed as side product.

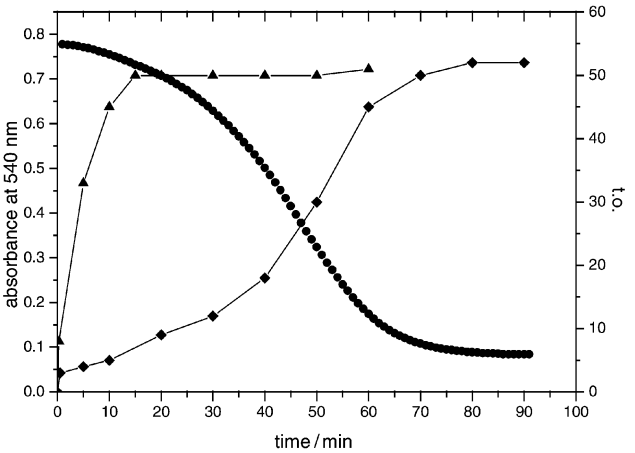


Fig. 1 Catalytic oxidation of benzyl alcohol to benzaldehyde using **1**: (■) time course of the turnovers, (●) time dependent decay of the UV band at λ = 540 nm and (▲) oxidation in the presence of 1 eq. CF_3SO_3H.

Several observations suggest that the active oxidising complex is a mononuclear species. First, complex **1** is EPR silent whereas upon addition of benzyl alcohol and H_2O_2, when the solution becomes yellow, a strong EPR signal can be observed at g = 4.3 which is characteristic for a mononuclear high-spin iron(III) complex.[6] Secondly, it was found that alcohols, which are known to be capable of breaking up the oxo-bridge of some dinuclear iron μ-oxo complexes to form monomeric structures by coordination to the metal centre,[6] are oxidised rapidly. In contrast, the active yellow species is formed very slowly in the absence of substrate or with a non-coordinating substrate like cyclohexene. Finally, we envisaged that protonation of the oxo-bridge in **1** would facilitate the formation of the mononuclear species and hence would speed up the reaction. Upon addition of triflic acid (CF_3SO_3H) to **1** in acetone a blue colour appears. The ^{1}H-NMR spectrum of this solution shows broad signals in the −10 to 120 ppm range consistent with the presence of mononuclear high-spin Fe(III) species. The ESI/MS spectrum shows prominent peaks at m/z 581 and 472, which corresponds to $[L^1Fe^{III}\text{-}OTf]^+$ and $[(HL^1)Fe^{III}(OH)_2]^+$, respectively. Indeed when CF_3SO_3H (1 eq.) was used, the reaction rate increased dramatically (Fig. 1). The yellow species was formed immediately upon addition of H_2O_2 and after 15 min already 50 turnovers are reached in the oxidation of benzyl alcohol.

Although the exact reaction mechanism is not known yet, some tentative conclusions can be drawn. The fact that benzene, which can act as a hydroxyl radical trap,[5] is not oxidised by this system, combined with the large kinetic deuterium isotope effect (KIE, k_H/k_D = 4.0) that was observed in a competition experiment between benzyl alcohol and benzyl alcohol-d_7, it can be concluded that oxidising species more selective than hydroxyl radicals are present. When the KIE was determined 30 s after starting the reaction by addition of H_2O_2, *i.e.* after the initial burst of activity, a value of 1.8 was obtained indicating the presence of a highly reactive oxidising species in the initial stage of the reaction. Finally, since the purple colour of **1** is indicative of a LMCT transition between the phenolic part of the ligand and the iron(III) center,[7,8] it is most likely that the phenolic moiety is no longer coordinated to the iron centre in this yellow species, which is thought to be responsible for oxidation activity.

In conclusion, a new Fe(III) containing catalyst has been developed for selective oxidation of primary and secondary alcohols using H_2O_2. A dramatic enhancement in the reaction rate upon addition of acid has been observed, which is attributed to accelerated formation of the active mononuclear catalyst.

Mrs C. M. Jeronimus-Stratingh is gratefully acknowledged for performing the ESI-MS measurements. This work was supported in part (A. L. S., M. L.) by the Council for Chemical Sciences of the Netherlands Organization for Scientific Research (CW-NWO).

¶ Oxidation reactions were performed in acetone, under an argon atmosphere in a water bath thermostatted at 25 °C. In a typical reaction, 3.5 mmol of substrate (1000 eq.) was added to 4 ml of a stock solution of 1.75 μmol of the catalyst (*i.e.* 3.5 μmol of iron) and a known amount of the internal standard bromobenzene. The reaction was initiated by addition of 35 μl of H_2O_2 (30% solution in water, 100 eq.) and monitored by GC.

‖ Alkenes and alkanes were also investigated, but these reactions are slow (6–18 h), less selective and turnover numbers are lower (typically 10–20).

A new cascade for the one-pot synthesis of linear homoallylic alcohols with an allylic diindium reagent

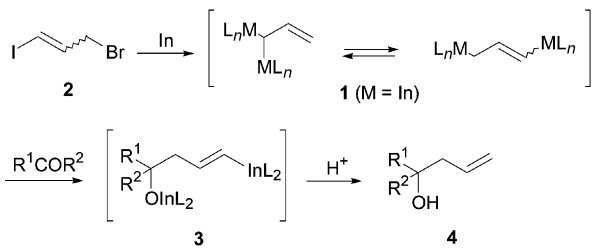
Tsunehisa Hirashita, Hatsuo Yamamura, Masao Kawai and Shuki Araki*

Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466-8555, Japan. E-mail: araki@ach.nitech.ac.jp

Received (in Cambridge, UK) 19th December 2000, Accepted 17th January 2001
First published as an Advance Article on the web 8th February 2001

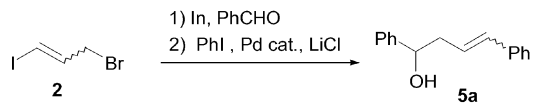
A new cascade based on a novel allylic diindium reagent has been developed; the indium reagent prepared from 3-bromo-1-iodopropene successively coupled with carbonyl compounds and then with aryl, alkenyl or allyl halides in the presence of a Pd(0) catalyst to afford a convenient one-pot synthesis of linear homoallylic alcohols.

Organodimetallic compounds, which possess two metal–carbon bonds in one molecule, are synthetically attractive reagents; because, when they couple successively with two electrophiles, a three-component coupling can be achieved in one pot.[1] Although a number of organodimetallic reagents have hitherto been prepared and utilized, allylic dimetal compounds of type **1** are rare and only a few examples such as M = Li[2], Zn[3] and Sn[4] are known. Recently we described the preparation of the diindium reagent **1** (M = In) by oxidative addition of indium to 3-bromo-1-iodopropene (**2**).[5] This reagent couples readily with carbonyl compounds leading to the corresponding homoallylic alcohols **4** *via* the vinylic indium compound **3** (Scheme 1). However, the reagent **3** could not be utilized for further transformations owing to the poor nucleophilicity of the vinylic indium–carbon bond. Now we have established a new cascade based on **1** (M = In) involving allylation of carbonyls followed by Pd(0)-catalyzed coupling of the resulting vinylindium with aryl, alkenyl or allyl halide, which provides a convenient one-pot synthesis of linear homoallylic alcohols.



Scheme 1

Table 1[a] Tandem couplings of **1** (M = In) with benzaldehyde and iodobenzene



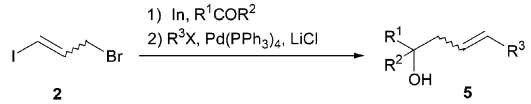
Entry	Solvent	$Pd(PPh_3)_4$/mmol	*T*/°C	Yield of **5a** (%)
1[b]	DMA	0.03	rt	0 [72][c]
2[b]	DMA	0.05	110	18 (*E*:*Z* = 46:54)
3	DMA	0.03	rt	0 [68][c]
4	DMA	0.03	110	56 (*E* only)
5	NMP	0.05	100	57 (*E* only)
6[d]	NMP	0.03	100	34 (*E* only)
7	NMP	0.04[e]	100	47 (*E* only)
8[f]	NMP	0.10	100	67 (*E*:*Z* = 85:15)

[a] Unless otherwise noted, reactions were carried out with **2** (1.0 mmol), PhCHO (0.50 mmol), PhI (1.0 mmol) and LiCl (3.0 mmol) in a solvent (6 mL) for 24 h. [b] Without LiCl. [c] Yield of 1-phenylbut-3-en-1-ol. [d] NaOEt was added in place of LiCl. [e] $Pd_2(dba)_3$ (0.02 mmol) and tris(2-furyl)phosphine (0.13 mmol) were used in place of $Pd(PPh_3)_4$. [f] With PhCHO (0.39 mmol).

Iodobenzene and a catalytic amount of $Pd(PPh_3)_4$ were added to the vinylindium reagent **3** prepared by the indium-mediated coupling of **2** with benzaldehyde at rt for 1 h. Although the addition of the second electrophile did not occur at rt (Table 1, Entry 1), the expected three-component coupling product **5a** was obtained in 18% yield at 110 °C with an *E*:*Z* ratio of 46:54 (Entry 2). The addition of LiCl resulted in the dramatic improvement both in the yield and *E*:*Z* selectivity: (*E*)-**5a** was obtained stereoselectively in 56% yield (Entry 4). The solvent NMP gave almost coincident results (Entry 5). The addition of NaOEt or the use of $Pd_2(dba)_3$–tris(2-furyl)phosphine in place of $Pd(PPh_3)_4$ also resulted in the selective formation of (*E*)-**5a** (Entries 6 and 7). The yield increased with increasing amounts of $Pd(PPh_3)_4$, though the *E*/*Z* selectivity was diminished (Entry 8).

The scope of this cascade was examined by changing the carbonyl compounds and the second electrophiles (Table 2).

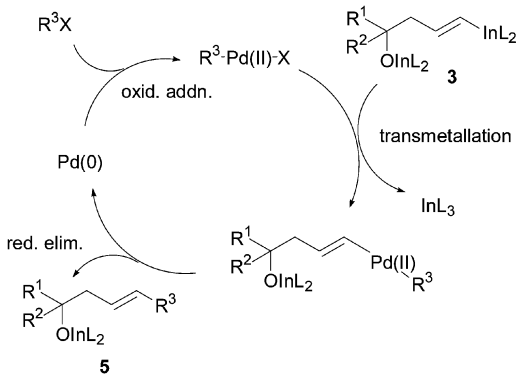
Table 2[a] Scope of the cascade reaction with **1** (M = In)



Entry	R^1COR^2	R^3X	Yield (%) (*E*:*Z*)
1	$CH_3(CH_2)_6CHO$	PhI	 **5b:** 43 (100:0)
2		"	 **5c:** 47 (100:0)
3	$CH_3(CH_2)_5COCH_3$	"	 **5d:** 67 (70:30)
4	$PhCOCH_3$	"	 **5e:** 81 (59:41)
5	"	 (*E*:*Z*=86:14)	 **5f:** 50 (68:32)
6	"		 **5g:** 49 (76:24)[b]

[a] Reactions were carried out in NMP by mixing **2** (1.0 mmol), indium (1.0 mmol) and a carbonyl compound (0.50 mmol) at rt for 1 h, and then the second electrophile (1.0 mmol) was reacted in the presence of $Pd(PPh_3)_4$ (0.10 mmol) and LiCl (3 mmol) at 100–110 °C for 24 h. [b] This *E*/*Z* assignment is tentative.

DOI: 10.1039/b010176l



Scheme 2

Aliphatic and α,β-unsaturated aldehydes gave the corresponding three-component coupling products (Entries 1 and 2). The coupling with the aldehydes underwent with complete *E*-selectivity, though the yields were somewhat lower. Ketones also gave the linear homoallylic alcohols (Entries 3 and 4). As the second electrophiles, β-bromostyrene and allyl chloride were successfully used to give 1,3- and 1,4-dienes, respectively (Entries 5 and 6). The most plausible mechanism is depicted in Scheme 2. The vinylindium **3** undergoes transmetallation to a vinylpalladium(II) intermediate, which gives the three-component coupling products **5** by reductive elimination.

In contrast to the highly reactive nature of allylic indium reagents,[6] the preparation and synthetic applications of vinylic indium compounds are strictly limited.[7] The allylic diindium reagent **1** (M = In) possessing the two indium–carbon bonds of distinct reactivity can be prepared readily and can now be utilized for the tandem couplings with two electrophiles. The success of the present cascade not only provides a new synthetic route for linear homoallylic alcohols, but also expands the scope of organoindium chemistry in organic synthesis by means of a combination with palladium catalysts.[8]

This work was supported by a Grant-in-Aid for Scientific Research (No. 12640515) from the Ministry of Education, Science, Sports and Culture, Japan.

A feature article describing the fundamental characteristics and emerging applications of micro technology in the field of synthetic chemistry.

Introduction

It is interesting to observe that despite the many advances made in synthetic chemistry over recent decades the basic practical methodology used remains unchanged. This situation arises primarily because reactions tend to be carried out on a bulk scale using a batch approach which chemists feel comfortable manipulating. At the molecular level however, it makes little difference fundamentally whether a reaction takes place in a 10 ml or 10 pl container. By applying technology developed for the electronics industry, it is now possible to produce reactors in which one can manipulate and analyse materials on a micron to nanometer scale. It is our belief that so called micro reactor technology can do for synthetic chemistry what the solid-state transistor has done for computing, vastly increasing the versatility and the amount of chemical information that a single person can generate. In short it represents a paradigm shift, changing the way we think about the way we work.

Stephen Haswell is Professor of Analytical Chemistry at the University of Hull. His current research activities are in the areas of micro reactors including analytical developments, microwave enhanced reaction chemistry, trace elemental speciation and process analysis. He is author of over 100 research papers, a number of books and patents and is widely known nationally and internationally for his enthusiastic lectures. For a number of years one of the underlying principles of Professor Haswell's research has been to break down the sectorial walls which exist in science, in particular, the integration of analytical science with main line chemistry, physics, engineering and biology. Many of these ideals are encompassed in his research into micro-chemical reactors the subject of this feature article.

Robert Middleton obtained a B.Sc. (Hons) from the University of Nottingham and carried out postgraduate studies in synthetic organic chemistry with Professor David Knight at Cardiff University focusing on the synthesis of highly substituted tetrahydrofurans via *electrophilic cyclisation. Now working at the University of Hull as part of the 'Lab on a Chip' Consortium, developing enzymatic and other catalytic reactions in micro reactors.*

Brian O'Sullivan obtained a Ph.D. in physical organic chemistry from the University of Exeter, and has spent some time at the University of Reading researching heterogeneous catalysis and organic synthesis in supercritical fluids. He is currently working at the University of Hull as part of the 'Lab on a Chip' Consortium, studying metal-catalysed carbon–carbon bond forming reactions in micro reactors and using electro-osmotic flow to control reagent mobilisation. Brian is also interested in modelling currents within micro reactors, in order to achieve a greater understanding of the fundamental processes underlying this technology.

Victoria Skelton graduated from the University of Hull in 1997 with a B.Sc. Hons. degree in Chemistry with Analytical Chemistry and toxicology. This included a year of industrial pharmaceutical experience in the analytical research and development department within Pfizer Central Research, Kent. Vikki obtained her Ph.D. at Hull University in 2000, investigating the role of micro reactors for organic synthesis and combinatorial applications and has continued a collaboration with GlaxoSmithKline. She is currently developing a number of chemical reactions and detection systems in micro reactors in order to establish the physical and chemical requirements of such devices.

Paul Watts graduated from the University of Bristol in 1995 with a B.Sc. in chemistry. He continued his studies at Bristol, obtaining a Ph.D. in bio-organic chemistry in 1999 under the supervision of Professor Tom Simpson and Professor Chris Willis. His Ph.D. focussed on the synthesis of isotopically labelled compounds for use in the determination of biosynthetic pathways to polyketide-derived natural products of biological interest. Paul is currently researching methods of peptide synthesis using micro reactor technology at the University of Hull. The project is funded by Novartis Pharmaceuticals, Basel, Switzerland.

Peter Styring is Senior Lecturer in the Process Fluidics Group at the University of Sheffield, Department of Chemical and Process Engineering. Previously he was the Thorn-EMI—BNR and DERA Lecturer in Chemistry at the University of Hull between 1990–2000. Peter gained his B.Sc. and Ph.D. from the University of Sheffield, Department of Chemistry. He has a background in Liquid Crystal Chemistry but moved into the field of Chemical Micro Reactors in 1997 where he addresses aspects of high throughput organic chemistry and catalysis within miniaturised devices.

DOI: 10.1039/b008496o

Basic concepts of micro reactors

A micro reactor is generally defined as a series of interconnecting channels (10 to 300 microns in diameter) formed in a planar surface in which small quantities of reagents are manipulated. The reagents can be brought together in a specified sequence, mixed and allowed to react for a specified period of time in a controlled region. The product may then be analytically monitored and if necessary separated for further steps in a reaction, or collected for analysis or testing.

In what is basically a diffusion limited environment, where laminar flow characteristics dominate, the micro reactor confers many advantages over conventional scale chemistry. The decrease in linear dimensions allows heat transfer coefficients to exceed those of conventional heat exchangers by an order of magnitude.[1] Micromixers can reduce mixing times to milli- or nano-seconds.[2] The increased surface to volume ratio in micro reactors (10 000 to 50 000 $m^2\ m^{-3}$, compared to 1000 $m^2\ m^{-3}$ in conventional laboratory vessels) has implications for surface-catalysed reactions.[3] Other properties include localised control of concentration gradients, separation of reaction products and the possibility of eliminating unwanted side reactions. For example, when Ehrfeld *et al.*[4] prepared hydrogen cyanide in a micro reactor *via* the Andrussow route, the rapid cooling of the products by a micro heat exchanger prevented hydrolysis of the HCN to ammonia. Jensen and coworkers[5] demonstrated that the synthesis of organic peroxides from acid chlorides and hydrogen peroxide may even be carried out beyond the 'explosion limit', as the transfer of heat energy from the area of reaction is rapid enough to prevent explosion.

In addition the small scales used reduce exposure to toxic or hazardous materials, and the enclosed nature of the micro reactors means greater ease of containment in the event of a runaway reaction. The greatest contribution to safety is the fact that hazardous materials can be synthesised as required at the point of use, in precisely defined quantities, thus eliminating the problems associated with transportation and storage.

Although the small size of the micro reactors would seem to preclude industrial scale synthesis, it has been shown[6] that only 1000 micro reactors operating continuously could produce 1 kg of material in a day. This so called 'scaling out' concept has clear implications in process development where the costly and time-consuming process of going from lab to pilot plant to full-scale production is by-passed simply by optimising the reaction on a single chip and replicating it 1000 or 1 000 000 times. The main attraction of this approach is not only the elimination of the problems associated with the scaling up procedure but also the ability to maintain the high level of control and selectivity made possible through using micro reactor technology.

The micro total analysis systems (μ-TAS)

In recent years, research in the area of miniaturised analytical systems has become well established with a large rapidly growing number of publications reflecting this trend.[7–14] The first fully miniaturised system fabricated was a gas chromatographic device reported by Terry *et al.*[15] at Stanford University in 1979. This micro device was constructed using a silicon wafer, which included a sample inlet port, a 1.5 m long column, an injector and thermal conductivity detector allowing the separation of a mixture of hydrocarbons within 10 s. However, it took a further 10 years before Manz and colleagues[16] at Ciba-Geigy laboratories in Switzerland fabricated a micro capillary electrophoresis device. The μ-TAS was fabricated from glass and allowed the rapid separation of two fluorescent dyes. During the past decade, the main research thrust in academia and industry has centred on the separation and characterisation of DNA.[17–22] This has now led to commercially available micro analytical devices such as the DNA analyser from Agilent, formerly Hewlett–Packard. More recently, a number of research groups worldwide have shifted the focus of research from μ-TAS to developing micro reactor technology building on the already existing μ-TAS concept. Some of the unique features of such devices will be described in the remainder of this paper but it is worth stressing that integration between μ-TAS and micro reactors is essential if chemical and biochemical reactions, at the micro scale or less, are to be effectively monitored and controlled.

Fabrication techniques

Many of the existing fabrication methods described for the μ-TAS systems have been successfully transferred to the field of chemical micro reactors.[23] A number of materials such as silicon, glass, quartz, metals and some polymers can be used to construct micro reactors. Glass and certain polymers have been particularly useful because of their physical properties and chemical inertness. These substrates also allow the mobilisation of organic reagent and aqueous solutions using a number of pumping mechanisms such as hydrodynamic pumping and electro-osmotic flow (EOF).[24–26] A range of fabrication methods such as photolithography, hot embossing, powder blasting, injection moulding, laser micro forming and LIGA, from the German *Lithographie*, *Galvanioformung* (electroforming) and *Abformung* (moulding), are available and can be both versatile and relatively low cost processes.

Fig. 1 shows the steps that are involved in the popular technique of photolithography and wet etching to produce

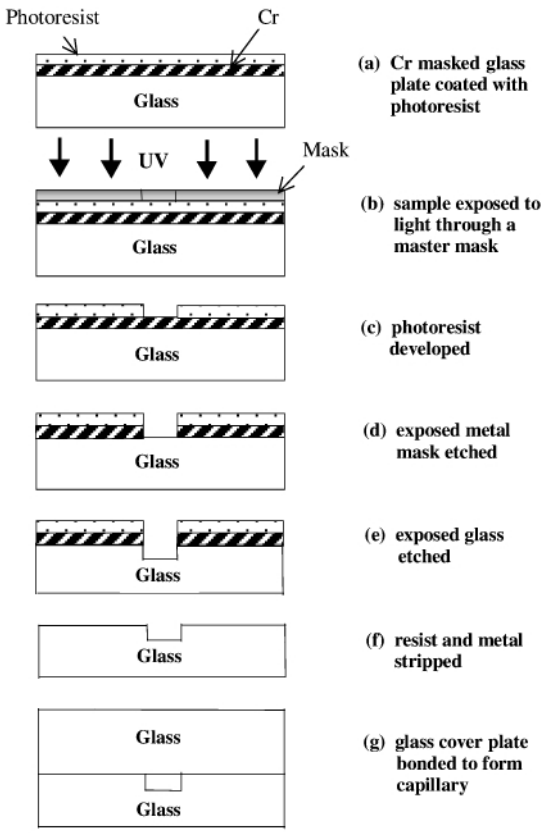

Fig. 1 Sequence of processes in photolithographic fabrication.

channels in a glass micro reactor. A thin layer of metal, such as chromium, is deposited on the surface of a glass plate to control the degree of undercutting during the etching process. A layer of positive photoresist is then spin coated on top of the chromium to a depth of 0.5 to 2.0 μm. The pattern of the required network of interconnecting channels is transferred to the photoresist layer using photolithography. After exposure, the photoresist is developed and removed together with the chromium layer to

reveal the areas of glass to be etched. The plate is then heated to allow volatiles to evaporate, before performing the chemical etch. The channels are then etched using, for example, a mixture of 1% HF and 5% NH_4F in water at 65 °C, resulting in an etch rate of 0.3 to 0.5 μm min^{-1}. A glass top block, with pre-drilled holes to act as reservoirs and if necessary electrode supports, is aligned with the channel geometry and thermally bonded to the glass base plate, producing an all glass device. An example of such a micro reactor, produced by the photolithographic, wet etch and thermal bonding method outlined above is shown in Fig. 2. It should be noted that a range of alternative fabrication

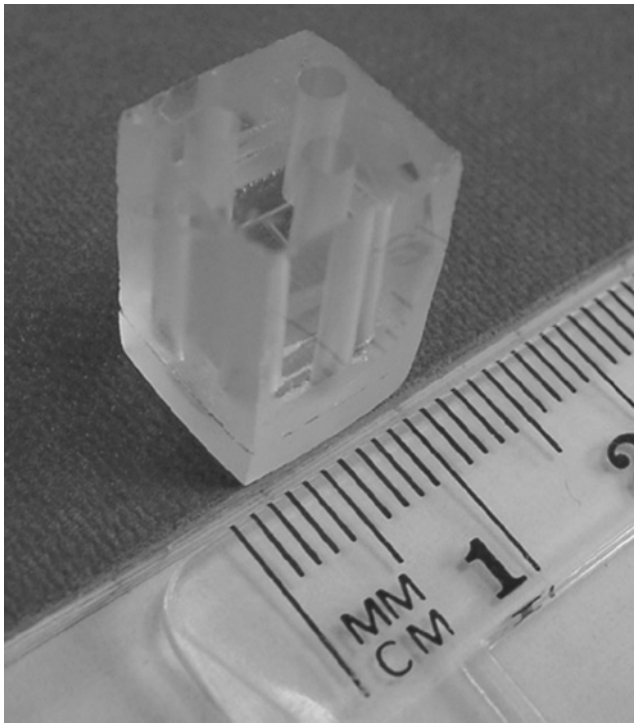

Fig. 2 A simple all-glass micro reactor.

techniques have been reported describing a number of different masking layers, etchant solutions, low temperature bonding, anodic bonding, and polymer based substrates. A recent review of these may be found in ref. 3.

Chemical control in micro reactors

Flow mechanics of liquids in micro channels

One of the main areas that liquid based micro reactor research has focused on to date has been the accuracy with which fluids in capillaries can be manipulated. Owing to the microlitre flow rates that are generally required, some groups have used methods such as syringe pumps, HPLC pumps and peristaltic pumps with high reproducibility being achieved through computer control. Syringe pumps can also be used to infuse and withdraw fluids through channels in both directions. These techniques provide a relatively quick and simple method for pumping reagents through a micro reactor in a controlled manner. However, these systems can build up high back-pressure due to capillary effects, which may lead to pulsing in the flow: this could be a particular problem when using peristaltic pumps.[24] Another problem is the cost associated with HPLC and syringe pumps. These pumps can also be intolerant of mixed-phase liquid systems, or systems that contain particulate matter.

Several companies have developed pumps specifically for micro reactor applications. These pumps are typically based on a piezoelectric driven one way valve to mobilise liquids.[27] For example, the Institut für Mikrotechnik, Mainz has developed a membrane pump that operates with microlitre volumes, but can also pump at up to 0.4 ml min^{-1}. These pumps, which are very small, can deliver the microlitre volumes that are required for managing the movement of liquids in typical devices. However, as they have been constructed from a polymer, practical difficulties may arise when using organic solvents, and depending upon the micro channel geometry, excessive back pressures may be generated.

As one of the attractive features of using micro reactors is their capacity to perform high throughput parallel processing, the use of hydrodynamic pumping may become impractical due to the large number of different solutions that will be required within the reactor. To overcome the need therefore for a large number of pumps and to simplify the construction of micro fluidic systems, electro-osmotic flow (EOF) which has no moving parts, has proved to be a widely preferred method for reagent and solvent pumping.

EOF can be used to move reagents and solvents around a system of channels as a function of applied voltages, with a very high degree of control and allowing the processes to be readily automated. In addition, due to the high electric field (*e.g.* 200 V per centimetre of channel) associated with the EOF, variations in the electrophoretic mobility of individual species enables separation to be achieved. The combination of EOF and electrophoretic mobility can be used to both model and practically control the spatial and temporal position of components in a micro reactor system.[28]

To illustrate the principles of EOF, one can consider a microchannel fabricated from a material (*e.g.* glass), having naturally negatively charged functional groups on its surface. If a liquid, displaying some degree of dissociation, is brought into contact with the material, positive counter ions will form a double layer such that the positively charged ions are attracted to the negatively charged surface. If an electric field is now applied through the liquid phase, the positive mobile ions will migrate to the negative electrode inducing a drag on the bulk liquid. In an aqueous buffered system (pH 3–9) the solution flows towards the cathode with volumetric flow rates in the order of nl min^{-1} to μl min^{-1} depending on the channel dimensions and applied field. The flow velocity achieved with EOF is given by eqn. (1)

$$\upsilon_{EOF} = \frac{V}{L}\mu$$

where V is the applied field, L is the length of the channel and μ is electro-osmotic mobility (dependent on factors such as zeta potential, ionic strength and pH).

Since V and L are controlled by the user, a very high level of control is achievable. Furthermore, this control can be automated and a relatively simple LabVIEW™ program, such as that developed at Hull which allows one to control the output from a power supply to a number of channels in a micro reactor (Fig. 3) has been developed. By varying the potentials across each channel section, it is possible to rapidly optimise the relative flows of different reagents, or to inject plugs of one reagent into a stream of another, or to introduce a number of reagents in a specified sequence for multi-step reactions.

Unlike conventional (hydrodynamic) flow systems, solutions that are moved by EOF have a flat velocity profile across the channel. This, together with an absence of back pressure effects and an inherent low Reynolds number, affords minimal band broadening and efficient electrophoretic separation of reactants and products.

Although EOF has mainly been used in applications with aqueous solutions, it is not restricted to these systems and EOF may be applied to reagents in polar solvents such as methanol, tetrahydrofuran, acetonitrile and dimethylformamide. For example, Harrison and coworkers[29] used EOF to achieve valveless

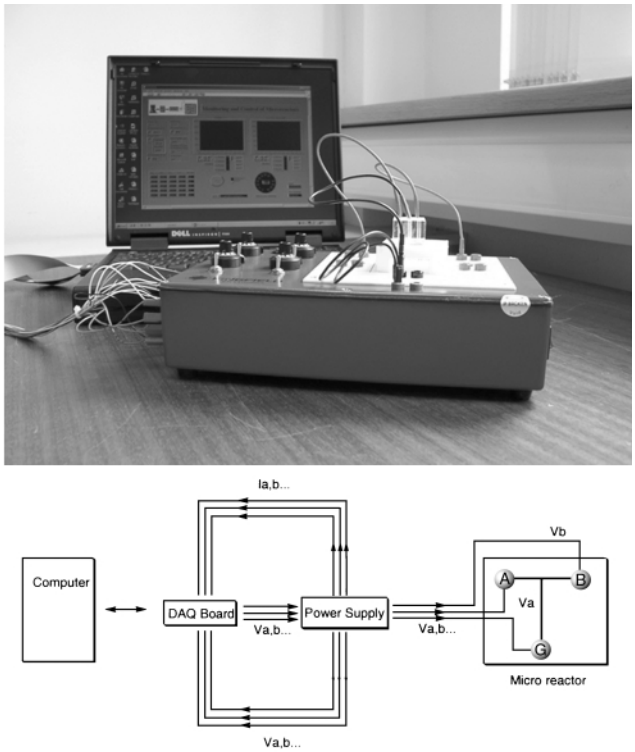

Fig. 3 An automated computer controlled chemical reaction, showing the hardware and a schematic of the system. Using the configuration shown, the duration and magnitude of voltage applied to each reservoir can be selected and the resulting current monitored.

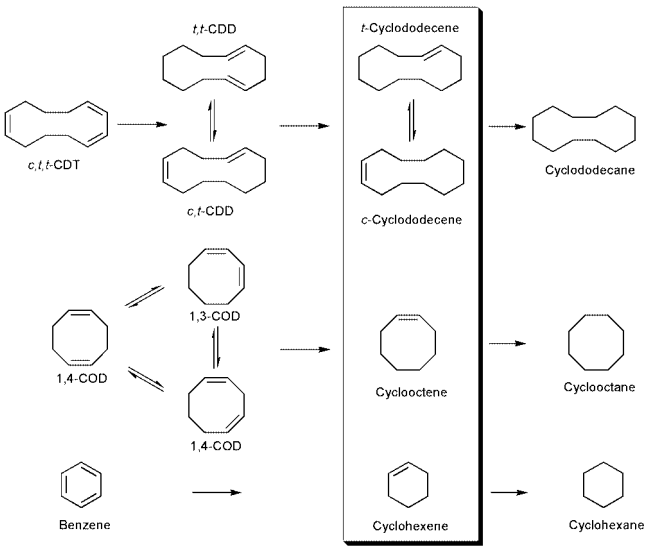
pumping of acetonitrile reagent solutions during the synthesis of an azo dye in a glass micro reactor. This degree of solvent choice greatly extends the types of EOF-controlled chemistry that can be carried out in micro reactors. Obviously the solvent systems used must exhibit some level of polarity, and strictly non-polar solvents cannot be pumped by EOF unless a polar modifier is added.

Applications of micro reactors in synthesis

The inherent benefits of micro reactors, namely rapid generation of small but detectable quantities of reaction products, efficient heat transfer and fluidic control, are now being applied successfully to synthetic chemistry. In theory, these factors might give a research worker using a micro reactor the ability to greatly increase the rate at which new compounds are produced. The work highlighted in this section demonstrates how some of the initial findings obtained by research groups developing micro reactor systems could be applied to high throughput synthesis. There are also some operating characteristics of the micro reactor environment that result in fundamental differences in chemistry. Of more immediate and perhaps significant impact to the research community is the opportunity micro reactors offer in terms of performing a large number (many hundreds) of reactions to explore and optimise a single reaction or a series of chemical reactions. For example, the capability to generate information about reaction conditions, kinetics and product selectivity is now readily accessible using micro reactors, an option not easily available using conventional methodology.

Micro reactor systems have so far been successfully deployed in gas and liquid phase chemistry, including catalyst testing. A recent example of the application of micro reactors to gas phase chemistry was reported at the IMRET 4 conference. Hönicke and coworkers reported the gas phase partial hydrogenation of cyclododeca-1,5,9-triene (CDT), cycloocta-1,5-diene (COD) and benzene over palladium and ruthenium/zinc catalysts (see Scheme 1).[30] The micro reactor system consisted of alumina wafers with mechanically etched channels, which were then



Scheme 1 The mild reaction conditions and the unique mass transfer properties of micro reactors allow hydrogenation of cyclic trienes and dienes to industrially important monoalkenes (ref. 26).

activated by anodic oxidation and impregnation with an organic solution of palladium(II) acetylacetonate. This gave an 18 μm thick activated layer with 0.18 wt% palladium. Twenty four of these wafers were then stacked to give 672 micro channels with internal geometries of 200 μm × 200 μm × 30 mm. A similar process was used for the construction of the Ru/Zn reactor, which contained 0.2 wt% each of ruthenium and zinc. The organic solvent was then removed *via* oxidation in air at 417 °C followed by hydrogen reduction at 150 °C to give the activated catalyst. Although palladium showed no conversion of benzene to cyclohexene, CDT was converted with high yield and selectivity to cyclododecene at 150 °C, with the catalyst bed giving > 80% conversion to cyclododecene for over 20 h. The COD conversion went from 75 to 100% at 150 °C by increasing the residence time in the reactor from 40 to 115 ms. This system proved to be robust, in that throughput could be increased ten-fold from 50 to 500 mg h^{-1} whilst conversion to cyclooctene remained above 80%. Partial hydrogenation of benzene by Ru/Zn was less successful with conversion falling rapidly, and only low yields of cyclohexene were obtained, with the major product being cyclohexane. This work shows that high conversions may be achieved given only a short residence time. By controlling the rate of flow, conversion rate and product yields may be selected or rapidly optimised. This micro reactor system also allows easy re-activation of the catalyst, and it would be readily possible to allow the mixture and velocity of gases to be adjusted automatically in real-time *via* feedback control from analysis of exhaust gases.

Micro reactors using heterogenous catalysts have been applied in liquid-phase organic synthesis. An early, though still comparatively recent development was reported from the Micro Reactor Group in Hull by Greenway *et al.*.[31] The micro reactor utilised EOF to mobilise the reagents and allowed the catalytic synthesis of 4-cyanobiphenyl using a modified Suzuki coupling reaction (Scheme 2). The incorporation of micro porous silica frits[32] within the reactor manifold enhanced EOF and allowed the immobilisation of the heterogeneous catalyst (1.8% palladium on silica). The catalyst immobilisation method produced a leaching rate in the region of ppb (1.2 to 1.6 ppb) removing the need for subsequent purification from metal residues. The micro reactor device was optimised using flow injection analysis principles producing a 67 ± 7% (n = 6) yield of the 4-cyanobiphenyl product at room temperature within 25 min.

The flow injection method adopted allowed the periodic injection of the aryl halide (5 s injection length with a 25 s injection interval) into a continuous flow of phenylboronic acid. Flow was maintained using an external applied voltage of 200 V. The yield obtained using the device was comparable with Suzuki reactions performed on a large (batch) scale using homogeneous catalysts. One of the interesting observations of this reaction was that, unlike conventional Suzuki couplings performed in a flask, base was not required. Although the reason for this is as yet unclear, it is thought that the applied electric field may be sufficient to cause localised ionisation of solvent water to H^+ and OH^- at the metal surface. It may be this so-formed hydroxide that performs the function of a conventional inorganic or amine base. However, the micro reactor demonstrated the potential application of such devices to perform chemical reactions, allowing high throughput screening, rapid method development or reaction optimisation.

The Hull group have also demonstrated that a superacid catalyst (sulfated zirconia) could be immobilised onto the surface of a polydimethylsiloxane (PDMS) micro reactor top plate. This was achieved by dusting the pre-cured PDMS surface with activated catalyst and baking the plate at 100 °C for 1 h. The PDMS top plate (containing the catalyst) was clamped to a glass base plate (with etched micro channels) and syringe pumps were used to mobilise the hexan-1-ol, which underwent dehydration to hex-1-ene. The micro reactor featured an *in situ* resistive heater wire cast into the PDMS top plate, which was operated at 155 to 160 °C.[33]

An attractive feature of micro reactors is their ability to carry out chemical processes that may be hazardous. For example Burns and Ramshaw[34] at the University of Newcastle have described the nitration of toluene and benzene in stainless steel or PTFE micro reactors, demonstrating the approach is suited to a hazardous processes involving organic solvents and concentrated acids. In addition, they are also investigating the challenge of manipulating bi-phasic liquid–liquid systems and the control of product distribution to avoid hazardous trinitrated aromatic products. Their studies have yielded some elegant ways to control immiscible liquid layers in capillary systems that include (i) segmented flow, in which plugs of alternate phases travel down a capillary and (ii) parallel laminar flow, where similar amounts of two phases run together through the capillary producing an interfacial contact zone.

Burns and Ramshaw's studies on benzene nitration also demonstrated that conversion, while showing a near linear relationship with temperature, can be increased substantially by the use of smaller capillaries that enhance diffusion effects by reducing the size of the slugs of material in the channel. Halving the capillary diameter from 250 to 130 μm more than doubled the rate of nitration. Flow rates were also found to be important, with faster flow rates giving rise to higher conversion as they promoted internal circulation of the liquid plugs travelling down the capillary.

In comparison with conventional nitration techniques, the results showed that rate constants for the micro reactor process (1–8 min^{-1}) in 178 μm capillaries were similar to those in the published literature (1–5 min^{-1}). It is expected that further optimisation of the micro reactor device and its operation, particularly by increasing the sophistication of the technology to decrease droplet size, will result in substantial improvement to the efficiency of the devices.

To demonstrate the advantages that micro reactors offer when dealing with potentially hazardous reagents, Chambers and Spink[35] recently reported the development of a micro reactor fabricated from a block of nickel, which was used for the elemental fluorination of organic substrates. Conversions compare well with results from conventional reactors. The small amount of fluorine involved, together with the heat and mass transfer properties of the micro reactor, overcame many of the safety issues associated with this type of reaction.

Optimisation of catalytic processes

To demonstrate the testing and optimisation of catalytic processes, the Hull group has developed a simple procedure for the immobilisation and introduction of supported reagents in micro reactors (Fig. 4). Such configurations enable solutions to

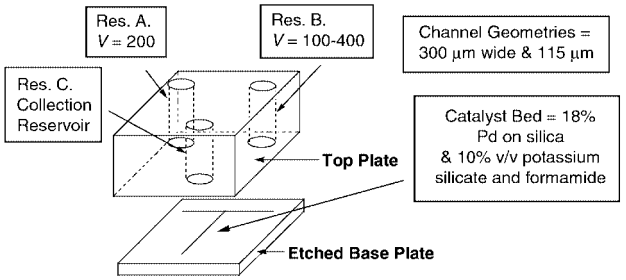


Fig. 4 A Hull micro reactor, configured for the Suzuki reaction. Reservoir A contains 100 μl of 4-bromobenzonitrile (0.1 M) and reservoir B 100 μl of phenylboronic acid (0.1 M), both in 75% $THF_{(aq)}$. Products from the reaction are taken from reservoir C and analysed by GCMS.

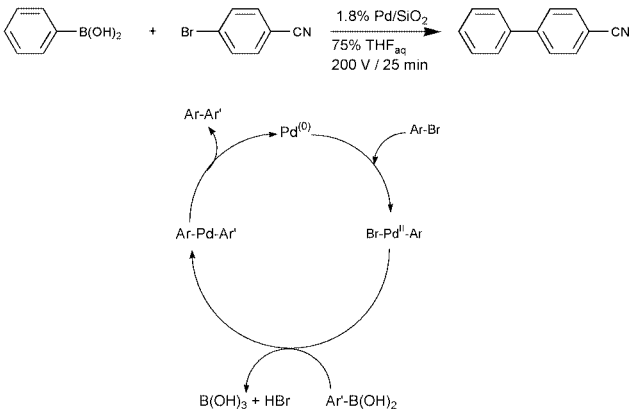
be passed over catalysts in either a continuous or plug mode with a high degree of fluidic control. Catalyst types under investigation include immobilised enzymes (such as lipases and esterase), metals, sulfated zirconia and zeolite-based materials. For example, in the case of an enzyme system based on porcine liver esterase, symmetrical diesters are passed over this catalyst bed to effect desymmetrisation to a chiral mono-ester, creating a high-throughput reactor for biocatalysis.

A second approach is to pulse several different reagents one by one over the catalyst bed. Given the computer-based flow-control possible with micro reactors, it is now relatively easy to achieve accurate and reproducible reaction sequencing. In the Suzuki reaction performed at Hull, the aryl halide and boronic acid were alternately pulsed over a catalyst bed of palladium on silica. This had the effect of increasing yields from < 5% to 68% by simulating the catalytic cycle (Scheme 2).[31] The catalyst was



Scheme 2 The catalytic cycle of the Suzuki reaction.

flushed with the aryl bromide to drive the oxidative addition to the metal, and then flushed with boronic acid to effect conversion to the biphenyls.

Using a system of five continuous flow micro reactors, the Suzuki reaction has been carried out on an industrial scale by Merck in Germany, where researchers found improvements over conventional batch reactors.[30] For example, in the reaction of 3-bromobenzaldehyde with 4-fluorophenylboronic acid, 90% yields were reported for the micro reactors, compared with 50% in stirred flasks.

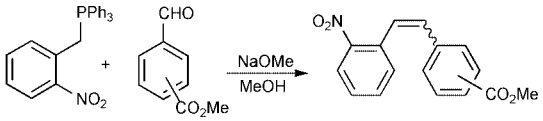
One of the chief limitations of the studies in Hull has been the high temperatures (680 °C) required to anneal the top glass plate

to the etched glass base plate as any organic material would be destroyed in these processes, hence metals on silica have been favoured as catalysts.

These early studies into catalytic processes demonstrate the potential of using micro reactor technology for a continuous production line approach to single compound production. However, the design of such devices could be easily modified to evaluate the performance of a catalyst across a broad range of substrates. Another opportunity would be in using multi-channel systems that would allow the evaluation of a number of different catalysts for a single reaction. These studies allow rapid evaluation of reaction conditions to allow the best catalyst for a given reaction to be studied, or the efficacy of a catalyst over a range of substrates to be evaluated.

Multi-step and analog based reactions

At the recent IMRET 4 conference, the Hull group reported a micro reactor device that allowed the synthesis of a number of nitrostilbene esters using a borosilicate micro reactor.[36] The micro reactor allowed the development of the Wittig reaction investigating a number of reaction features such as stoichiometry, stereochemistry and reaction diversity (Scheme 3).



Scheme 3 The Wittig reaction.

Initial investigations centred on using the device for synthetic method development and optimisation, allowing rapid reaction design in conjunction with EOF as the mobilisation method. With a 2 : 1 reaction stoichiometry (aldehyde in excess) a yield of 70% was achieved using the micro reactor in a continuous flow mode with an optimum voltage of 400 V. The micro reactor demonstrated an increase in reaction efficiency of 10% over the conventional batch method. The reaction stoichiometry was then reduced to 1 : 1 but the yield was poor (39%) so a flow injection technique was adopted. This resulted in the injection of the phosphonium salt into the continuous flow of the aldehyde compound at 400 V. A 59% yield was obtained, but more importantly it allowed a series of aldehydes to be reacted in sequential injections using the optimum conditions established at 1 : 1 stoichiometry. This demonstrated the micro reactors diversity and high through-put capability.

The above research has been extended to investigate the stereoselective control of the chemical reaction by applying electrical fields which generate controlled concentration gradients of the reagent streams.[37] The stereoselective synthesis of the *cis* (*Z*) and *trans* (*E*) isomers was controlled by varying the applied voltages to the reagent reservoirs within the device. The variation in the external applied voltage subsequently altered the relative reagent concentrations within the device producing *Z/E* ratios in the region of 0.57 to 5.21. In comparison, a traditional batch reaction was performed based on the same reaction length, concentration, solvent and stoichiometry resulting in a *Z/E* ratio of 3.0. The unique flow control created in the micro reactor system has allowed the localised concentration gradients, produced by a diffusion limited non-turbulent mixing regime, to generate the observed stereoselectivity. The control of these localised diffusion-limited concentration gradients is an important feature of micro reactors and one that can be effectively exploited for yield and product selectivity.

Multi-step reactions

So far, micro reactors appear to be limited to carrying out a single synthetic step. One of the thrusts of the research in Hull is to develop methodology that will give the chemist the ability to look as multi-step reactions, culminating in target or diversity based synthesis.

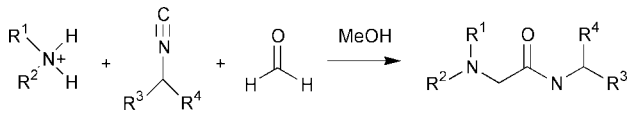
To extend the capability of performing multi step reactions in micro reactors, processes such as peptide synthesis represent a good model system. Peptides have been traditionally prepared combinatorially *via* solid supported techniques[38,39] but this approach has the disadvantage that a fairly expensive polymer support is required and that the product requires post-synthetic cleavage. In addition, extra steps are added to the synthesis as a result of having to initially link the amino acid to the polymer support. The preparation of peptides in micro reactors, using solution phase chemistry, offers the possibility of overcoming such problems.

Using solution phase chemistry there are several methods that may be used to form peptide bonds such as diethyl azodicarboxylate[40] (DEAD) or carbodiimide reagents such as dicyclohexylcarbodiimide (DCC)[41] or 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDCI).[42] In addition acyl halides, anhydrides and azides may be utilised in the formation of peptide bonds.[43] Once the methodology for the formation of peptide bonds has been fully established, selective deprotection of either of the protecting groups will allow longer peptide chains to be assembled. This multi-step synthesis will clearly allow the rapid generation of libraries of peptides, which could then be used in determining their biological properties.

In situ detection methods in micro reactors

As indicated earlier, research focused on μ-TAS has developed a number of suitable detection methods for micron scale systems, with the most common method adopted being fluorescence. Other detection systems developed have included UV–VIS[44–48] and electrochemical[49–52] detection offering sensitivity and simple detection with environmental micro systems. The information provided is however generally insufficient for structural characterisation of unknown chemical species. For the micro reactor system to become truly versatile, the development of hyphenated techniques and specialised equipment such as NMR and Raman spectrometry would allow direct, real time characterisation and spatial determination of concentration and pH information. Currently a range of analytical techniques are being investigated by a number of research groups. These include mass spectrometry (MS)[53] and near infrared (NIR).[54–57]

One area of analysis which has been readily reported in the literature is the hyphenation of micro reactor to mass spectrometers.[58–61] Lazar *et al.*[58] from Oakridge National Laboratories have coupled a micro fluidic device with a nanospray tip for electrospray ionisation, allowing dilute peptide and protein solutions to be characterised using a time of flight mass spectrometer. The hyphenated system allowed the capture of spectra within milliseconds (10 to 20 ms) resulting in 50 to 100 spectra per second. The second study by Mitchell *et al.*, presented at the recent Micro Total Analytical Systems conference,[59] described the detection of a multicomponent reaction using an electrospray ionisation (EIS)-MS. The multicomponent synthesis investigated was the Ugi reaction (Scheme 4) in which a solution of formaldehyde and pure



Scheme 4 The Ugi reaction.

solvent was infused through one of the inlets whilst a multicomponent mixture (isocyanide, amine salt) was also added. The hyphenated micro reactor-MS system allowed the real time detection of the synthetic Ugi coupling reaction.

Other detection systems reported have been NIR and Raman spectrometry. A miniaturised NIR spectroscopic system fabri-

cated in borosilicate glass has been developed by Ache.[56] The micro device contains a circular wave guide covered by a sensing membrane. In addition, the micro NIR system contained an incandescent light source, a NIR micro spectrometer with a self-focusing reflection grating and NIR diode. At the University of Michigan, Reshni and co-workers[62] demonstrated one early example of Raman spectrometry on a micro device. The system was fabricated using a Raman microprobe stage coupled to a capillary electrophoresis chip. Traditionally, Raman spectroscopy has a limit of detection in the millimolar region, however Reshni's micro device achieved a limit of detection in the micromolar region and below. This was due to the addition of a preconcentration stage using isotachophoresis. This system has allowed the successful fingerprinting and quantification of reactions on-chip.

Commercialisation of micro reactor technology

A commercially available chemical synthesiser using micro reaction technology already exists, and is produced by IMM-Mainz. It consists of a pumping module, a micro-reactor that results in very efficient mixing of reagents, followed by a capillary to allow time for the reaction to go to completion. The outflow is then collected for further manipulation by the user. This could be just the first step along a road which will see the integration of automated reagent manipulation, reaction monitoring and product purification into a single instrument containing several interconnected micro reactors, or possibly a single micro reactor device. In common with microelectronic chips, once the facilities to fabricate micro reactors are in place, they become progressively cheaper to produce in quantity. This should make the production of chemicals in massive parallel arrays of reactors an economic possibility. It is likely that some of the peripheral equipment required will still represent a considerable cost, but this should be set against the potential increase in productivity per research worker. In addition, the effective production of molecules in terms of energy, safety and environmental impact will emerge as important factors in the future exploitation of micro reactor technology. One of the underlying features of any future commercially available automated synthesis system must be versatility. Research is now moving towards a 'plug and play' approach in which the reaction and detection configurations can be customised. The next couple of years will undoubtedly see significant development in this area of the technology. We should now prepare ourselves, including university courses for undergraduates, for the impact the micro reactor is going to have on the whole area of chemical research and production.

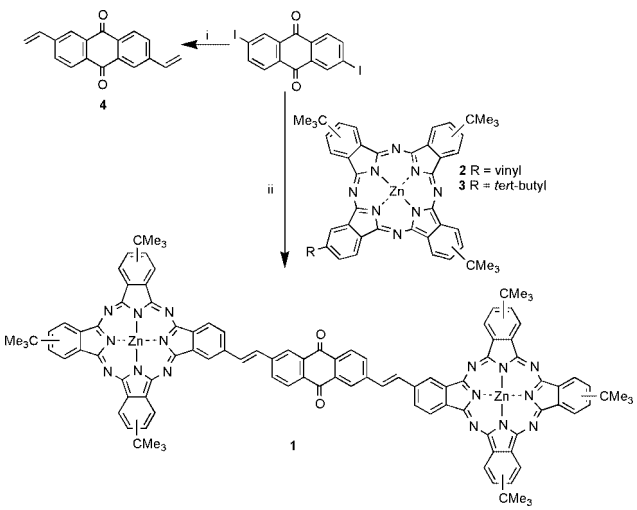
First published as an Advance Article on the web 9th February 2001

Two metallophthalocyanines bridged by ethenyl spacers to an anthraquinone moiety have been synthesized; both spectroscopic and electrochemical experiments have demonstrated strong intramolecular electronic interactions between the phthalocyanine donors and the anthraquinone acceptor unit.

There has been a great deal of recent research on the properties of phthalocyanine (Pc)-based molecular assemblies for the construction of new molecular materials.[1] However, few systems possess sufficient structural constraints to influence the factors that control electron transfer processes between the donor and acceptor moieties. [2–4] We describe here the synthesis and electrochemical behaviour of an anthraquinone (AQ) covalently linked by ethenyl spacers with two tri-*tert*-butylphthalocyaninatozinc(II) moieties **1**† (Scheme 1), for the study of intramolecular electronic interactions between the Pc donor and AQ acceptor.

The synthesis was carried out by palladium-catalysed Heck-type coupling between tri-*tert*-butylvinylphthalocyaninatozinc(II) (**2**)[5a] and 2,6-diiodo-9,10-anthraquinone, which was in turn prepared by a double Sandmeyer reaction from commercially available 2,6-diamino-9,10-anthraquinone. The model compound, 2,6-divinyl-9,10-anthraquinone, **4**, has been prepared for comparison by a Stille coupling reaction.[6]

The UV–Vis spectrum of triad **1** in THF shows a split Q-band at 696 and 675 nm, and a Soret band at 352 nm (Fig. 1). Splitting of the Q-band in this case could be attributed to an effect of 'local asymmetry' in the molecule.[5b] Importantly, comparing the spectra with those of the model compound **2** (675, 351 nm) and tetra-*tert*-butylphthalocyaninatozinc(II) **3** (672, 348 nm)



Scheme 1 Synthesis of bis(tri-*tert*-butylphthalocyanine)–anthraquinone triad **1**, and 2,6-divinylanthraquinone **4**. *Reagents and conditions*: i, tributyl(vinyl)tin, $Pd(PPh_3)_4$, toluene, 100 °C; ii, $(MeCN)_2PdCl_2$, Bu_4NBr, Et_3N, toluene, 100 °C.

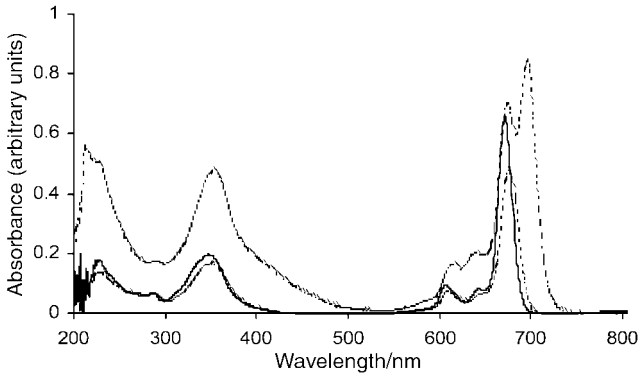


Fig. 1 Electronic spectra of **1** (dashed line), **2** (dotted line) and **3** (solid line) in THF. [C] *ca.* 1×10^{-5} mol L^{-1}.

reveals a very significant red shift of about 21 and 24 nm for the Q-bands with respect to **2** and **3**, respectively. This indicates a substantial extension of the π system in triad **1**. If this is correct, there may also be strong intramolecular electronic interactions between the electron-donating Pc moiety and the acceptor AQ unit. This is perfectly supported by the electrochemical analysis discussed below.

Solution electrochemistry of triad **1** and model compounds **2**, **3**, **4** and AQ in THF was studied by cyclic voltammetry (CV) and Osteryoung square voltammetry (OSWV). The voltammetric results are summarised in Fig. 2 and Table 1. As shown in Fig. 2, the CV of triad **1** shows that it is electrochemically active in both anodic and cathodic sweep directions between +1.2 and −3.0 V. In the anodic scan, all the redox processes are Pc-based because no oxidations can be observed for either AQ or its derivative **4** in this potential region. In the cathodic scan, triad **1** exhibits five reduction waves. Fig. 2 shows that the first wave is a chemically irreversible process when swept to −0.84

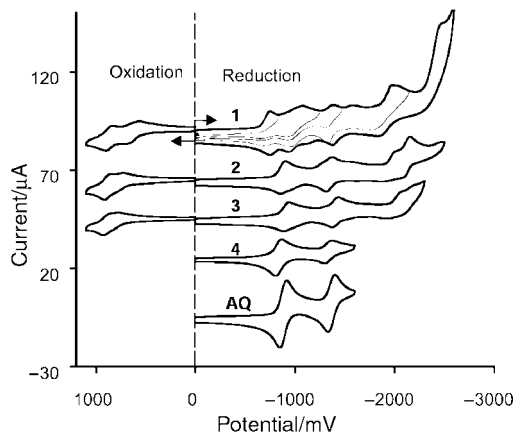

Fig. 2 CVs (0.1 V s^{-1}) for compounds **1**, **2**, **3**, **4** and AQ in THF–$TBAPF_6$ system at room temperature.

[a] OSWVs were obtained using a sweep width of 25 mV, a frequency of 15 Hz, a step potential of 4 mV, and a quiet time of 2 s on a Windows-driven BAS 100w electrochemical analyzer (Bioanalytical Systems, West Lafayette, IN). [b] Pc-based. [c] AQ-based. [d] Pc- and vinyl-based. [e] First AQ and second Pc potentials overlapped. [f] Two-electron process. [g] First Pc and AQ potentials overlapped. [h] Third Pc and Pc-vinyl potentials overlapped.

V at 100 mV s^{-1}, and the process can be assigned to a Pc-based reduction when compared to the results observed for the models **2**, **3**, **4** and AQ. Thus, on the whole, this is a chemically irreversible Pc-based two-electron process (1e per Pc moiety). When the sweep (100 mV s^{-1}) is extended cathodically to −1.5 V, a second reduction process is observed which is chemically reversible but electrochemically irreversible (ΔE_p = 146 mV), and it can be assigned to an overlap of the first AQ-based and the second Pc-based reductions based on direct comparison, for a total of three electrons. Similarly, the next two cathodic processes are assigned to the second AQ-based one-electron process (ΔE_p = 82 mV) and to the third Pc-based electrochemically irreversible reduction, respectively. The fifth reduction process, which is chemically irreversible, can either be assigned to the Pc moiety or to the vinyl groups, but a definitive assignment based solely on comparisons with the model compounds is not possible.

Interestingly and most importantly, all of the measurements discussed above show that the redox behaviour of both the Pc and AQ moieties in triad **1** significantly changed when compared to those of the model compounds, indicating strong electronic interactions (inter- and/or intra-molecular) between the donating Pc and the acceptor AQ at ambient conditions. In the case of intermolecular interactions, a control experiment with an equimolar solution of model compounds **2** and AQ was performed. The results indicate, to some degree, the presence of intermolecular electronic interactions between the electron acceptor AQ and the electron Pc donor **2** since there are some changes in both AQ- and Pc-based redox processes (Table 1). This is not surprising because Pcs are known to self-aggregate as well as with other molecules in solution and in the solid state. Recent results published by us for the [60]fullerene–Pc dyads also showed similar intermolecular electronic interactions.[5a] Although some intermolecular effects are visible, pronounced differences between triad **1** and the mixture **2** + AQ are observed, Table 1, especially for the reduction processes. However, the differences for the reductions between the mixture and models **2** or **3** are much smaller. This means that strong intramolecular electronic interactions are present in triad **1** (compare data in Table 1).

In conclusion, the redox potentials of both Pc and AQ moieties in **1** were significantly changed when compared to the related models, showing some degree of intermolecular electronic interactions, but mainly strong intramolecular electronic interactions between the covalently bonded electron-donating Pc and the accepting AQ moieties at ambient conditions in the ground state. This results in a pronounced negative potential shift for the AQ-based reductions and significant positive potential shift for the Pc-based reductions in triad **1**. Owing to the significant extension of the conjugation as evidenced by the large red shift for the Q-bands, the Pc-based oxidations are negatively shifted.

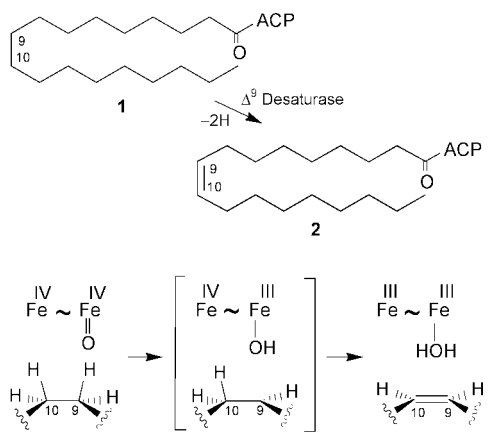
First published as an Advance Article on the web 9th February 2001

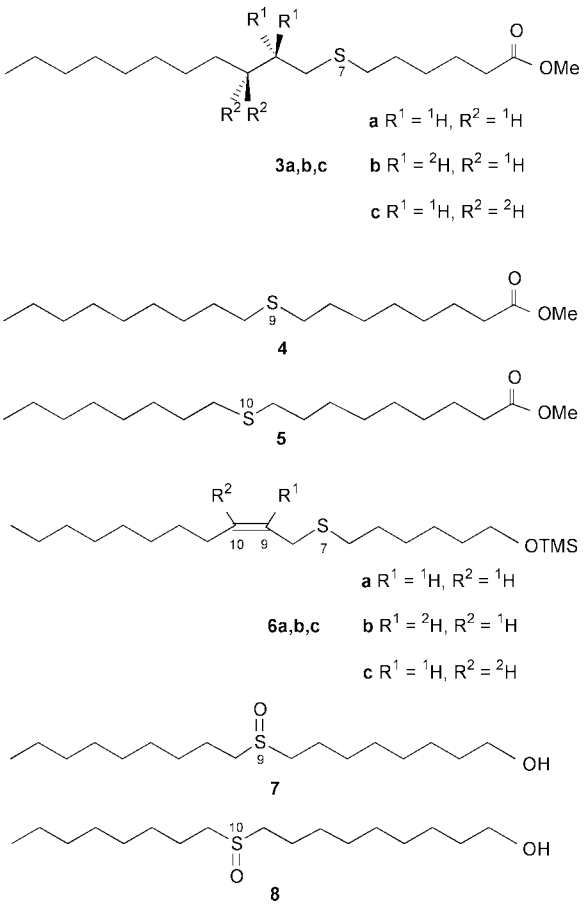
The mechanism of the castor stearoyl-ACP Δ^9 desaturase has been investigated; it has been shown that C–H cleavage at carbons 9 and 10 is not sensitive to deuterium substitution and oxo-trapping experiments using thia analogues revealed that sulfoxidation occurs when the substrate bears sulfur at the 9 and 10 positions.

Fatty acid desaturases[1] constitute an important family of O_2-dependent non-heme diiron-containing enzymes which catalyze the regio- and stereoselective *syn*-dehydrogenation of adjacent unactivated methylene groups. Two structurally unrelated classes[2] of these remarkable catalysts have been identified: a) a large set of membrane-bound proteins which have a probable multi-histidine diiron coordination site[3] and act on CoA- or phospholipid-linked substrates; b) soluble plant desaturases which contain a well-characterized, carboxylate-bridged, diiron cluster[4] similar to that found in methane monooxygenase and which convert the acyl carrier protein (ACP) derivative of substrates to the corresponding product (**1**, **2**, Scheme 1). A generic mechanism for desaturation involves oxidative attack† to give a very short-lived radical intermediate or its iron-bound equivalent which then collapses to give the olefinic product (Scheme 1).‡[5] Recently, a number of substrate-based mechanistic probes[6] have been developed by Buist *et al.*, using a convenient, *in vivo*, yeast Δ^9 desaturase system and some preliminary information has been obtained for the family of membrane-bound desaturases which is consistent with the model presented in Scheme 1.[6] However, very little is known regarding the mechanism of desaturation by the soluble plant desaturases[7] and the issue of whether or not the two classes of desaturases share the same mechanistic features, has yet to be addressed. The availability of homogenous preparations of a soluble plant Δ^9 desaturase from castor seed has prompted us to turn our attention to the bioorganic chemistry of this enzyme system. Here, we describe the application of our kinetic isotope effect (KIE) and 'thia' approaches[6a–c] in the mechanistic study of the soluble castor stearoyl-ACP Δ^9 desaturase.



Scheme 1

Our first experiments involved an attempt to decipher the cryptoregiochemistry (site of initial oxidation) of desaturation by determining the individual primary deuterium isotope effects for each individual C–H cleavage: according to Scheme 1, the first, energetically difficult, hydrogen abstraction should be much more sensitive to isotopic substitution than the second C–H bond cleavage. The required regiospecifically deuterium labelled substrates **3b**,**c** along with the non-labelled parent **3a** were available from previous studies.§[6b] 1 : 1 Mixtures of **3b** : **3a** and **3c** : **3a** as their ACP thioesters (14 nmol) were incubated separately with freshly prepared desaturase (0.02 nmol) and required cofactors[7,8] (total volume of 250 μL) under conditions adjusted to allow *ca*. 15% conversion of substrate.[9] The reactions were quenched *via* addition of THF and after reductive workup ($NaBH_4$), extraction with hexane and derivatization with trimethylchlorosilane (TMCS), the product mixtures **6b** : **6a** and **6c** : **6a** were analyzed by GC-MS (60 m SP-23 capillary column, MS scan rate: 2.14 scans s^{-1}). The competitive primary deuterium KIE was computed by comparing the isotopic content of substrates and products[6b,c] and found to be $k_H/k_D = 1.03 \pm 0.02$ at C-9 and $k_H/k_D = 0.95 \pm 0.02$ at C-10



DOI: 10.1039/b008972i

(average of two incubations). Similar results were obtained when the incubations of **3a**–**c** were run[7,8] in the noncompetitive mode: k_H/k_D = 1.10 ± 0.10 at C-9 and k_H/k_D = 1.13 ± 0.18 at C-10 (average of two incubations). These findings are in marked contrast with those reported for all membrane-bound desaturases studied to date.[6b,c,10] These include bacterial Δ^5, protozoan Δ^6, yeast, algal and bacterial Δ^9, insect Δ^9 and Δ^{11}, plant and algal Δ^{12} and animal and plant ω-3. All of these systems show a similar pattern of isotope effects (one large (k_H/k_D = 4–7), one negligible (k_H/k_D ~ 1)), clearly indicating the stepwise nature of the reaction for this class of desaturase and the kinetic importance of the initial C–H activation step. The absence of a measurable KIE for both C–H cleavages in the case of the soluble stearoyl-ACP Δ^9 desaturase is almost certainly due to the fact that these steps are masked by other enzymatic events such as electron transfer, substrate binding, product release, *etc*.[11] Thus it is clear that the substantial differences in protein structure, enzyme location, and substrate head group for the two classes of desaturases result in very different overall kinetic mechanisms.

We then turned to our 'thia' approach which probes the relative distance between the putative iron oxidant and substrate methylene groups by comparing the efficiency of oxo transfer to 9- and 10-thia analogues. In a preliminary set of experiments, the required pair of thiastearates **4** and **5** along with **3a** as control were incubated separately as their ACP thioesters with soluble stearoyl-ACP Δ^9 desaturase under conditions similar to those used for KIE experiments but adjusted for higher conversion (0.04 nmole enzyme, 10 min incubation). Products of these incubations were isolated and analyzed by GC-MS as the TMS derivatives. Under these conditions, the thia substrate bearing sulfur at the 7-position **3a** was cleanly converted to the corresponding *cis*-olefinic product **6a**; only traces of unreacted starting material were observed for incubations using **4**- and **5**-ACP.

To probe for products of oxo transfer, a second set of incubations was carried out using the ACP-derivative of each thiastearate (**3a**, **4**, **5**, 60 nmol) along with enzyme (4 nmol) and required cofactors[7,8] (in a total volume of 1.5 ml for 30 min). The CH_2Cl_2 extracts of reduced ($NaBH_4$) reaction mixtures were examined by silica gel TLC (90% EtOAc–hexane, H_2O spray detection, detection limit = 1–2 nmole). A search for the anticipated sulfoxide product alcohols was conducted with the use of authentic standards.¶ Significantly, only in the case of 9- and 10-thia substrates (**4**-, **5**-ACP), were the corresponding sulfoxides (**7**, **8**) detected (R_f = 0.20 and 0.16, respectively). Sulfoxidation of **4**- and **5**-ACP was not observed in the absence of enzyme or enzyme lacking a supply of NADPH. No sulfones were detectable. The structural assignments of the sulfoxide products were confirmed by electrospray MS analysis of material isolated from the TLC by CH_2Cl_2 extraction.‖ This constitutes the first report of an *in vitro* desaturase-mediated sulfoxidation and substantiates earlier reports of similar results for an *in vivo* yeast Δ^9 desaturase system.[12] However, it is interesting to note that in the latter case, sulfoxidation of a series of 9-thia-analogues was always more efficient (2–3-fold) than the production of the corresponding 10-sulfoxides,[6a,13] which led to the conclusion that the site of initial oxidation was at C-9 in good agreement with the observance of a large KIE effect at C-9 but not at C-10 (see above).[6b] In contrast, it appears that for the soluble Δ^9 desaturase, the trend is the reverse: we consistently see a greater amount of sulfoxide (7–12-fold)†† from the 10-thia substrate (**5**-ACP) than from the corresponding 9-isomer under conditions of partial and complete substrate consumption. This clearly implies that the 9-thia substrate is being converted to additional products possibly arising from oxidative attack α to the sulfur; experiments designed to address this issue are currently in progress. In addition, the determination of the absolute configuration of the sulfoxide products presents an impressive challenge to the methodology we have developed previously.[6a]

In summary, we have demonstrated fundamental differences in the behaviour of the two major classes of desaturase enzymes and have taken our first steps towards defining the crypto-regiochemistry of a structurally well-defined plant stearoyl-ACP Δ^9 desaturase. It is hoped that these efforts will complement ongoing active-site X-ray crystallographic work[4a] and other mechanistic studies[7] on this fascinating catalytic system.

This work was supported by an NSERC PDF (B. B.), an NSERC operating grant (P. H. B.) and the Office of Basic Energy Research of the U.S. Department of Energy (J. S.). The technical assistance of Dr. Clem Kazakoff (University of Ottawa), and Dr. Simin Maleknia (Albert Einstein College of Medicine) in obtaining the electrospray MS is gratefully appreciated.

Notes and references

† We have chosen to use a generic iron oxo representation of the active oxidant although other structures are possible. For an in depth analysis of the inorganic chemistry involved in diiron-mediated oxidations, see Ref. 4*c*.

‡ The intermediate could collapse rapidly to give alkene *via* a one electron oxidation–deprotonation sequence, simple disproportionation or Lewis acid (Fe^{3+})-catalyzed dehydration of a hydroxy intermediate. Newcomb *et al.*, have recently raised the possibility that these sorts of C–H activations may proceed, in part, *via* cationic intermediates produced by insertion of OH^+ into the unactivated C–H bond as the first step, followed by rapid loss of water from a protonated alcohol intermediate.[5a,b]

§ A trial incubation using **3a**-ACP revealed that this material was an excellent substrate and the structure of the 7-thia alkene **6a** was confirmed by comparison with an authentic standard on the basis of MS and GC retention time. The presence of the thia-substituent does not affect the regiochemistry of desaturation.[6b,c,10] The standard was prepared by LAH reduction of the carbomethoxy group of the methyl 7-thiaoleate available from previous experiments[12] followed by derivatization *via* TMCS.

¶ Authentic standards were prepared from available synthetic methyl thiastearates[12] by LAH reduction of the terminal methyl ester group followed by sulfoxidation using *m*-chloroperbenzoic acid.

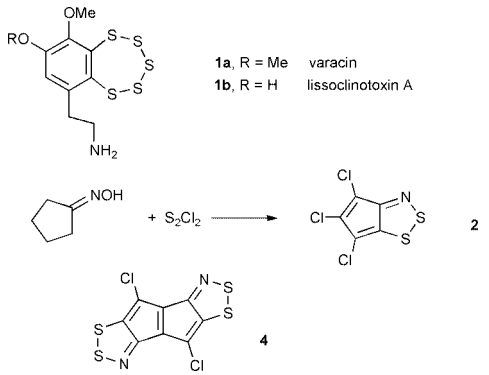
Received (in Liverpool, UK) 9th January 2001, Accepted 16th January 2001
First published as an Advance Article on the web 9th February 2001

An extensive domino sequence, including a vinylogous sulfur-assisted Beckmann fragmentation, is involved in the one-pot conversion of a dioxime 3 by S_2Cl_2 into a cyanoethyl-1,2,3-dithiazole 5 and a novel tricyclic pentathiepin 6; the yield of 6 is increased by added lithium sulfide, and both 5 and 6 are formed in higher yield from 2-(cyanoethyl)cyclopentanone oxime 7; reaction mechanisms are proposed for these cascade reactions.

Benzopentathiepins have attracted much attention recently because of their remarkable stability, the very high barrier (up to *ca*. 30 kcal mol^{-1}) for inversion of the chair-like heterocyclic ring[1] and their potent biological activity. The first naturally occurring examples varacin **1a**[1] and lissoclinotoxin A **1b**,[1,2] and



related dopamine-like structures, have strong antimicrobial and antifungal activity, selectively inhibit protein kinase C,[3] and varacin is highly toxic towards human colon cancer HCT 116.[1] Furthermore 7-methylbenzopentathiepin, lacking the aminoethyl group, is a potent thiol-dependent DNA cleaving agent.[4] The pentasulfur ring appears to be essential for biological activity. However, with the notable exceptions of Chenard's isothiazolo and pyrazolo pentathiepins[5] and Sato's trithiolobenzopentathiepins,[6] very little is known about heterocyclic fused pentathiepins. We now describe an unusual and unexpected one-pot synthesis of a new polyheteroatom pentathiepin **6**.

The reaction of simple saturated ketoximes with disulfur dichloride, S_2Cl_2, in the presence of tertiary amines provides an effective one-pot route to 1,2,3-dithiazoles; the initial cyclocondensation is followed by extensive dehydrogenation and chlorination to yield fully unsaturated heteroaromatic products.[7] A typical example is the conversion of cyclopentanone oxime into the deep violet 10 π pseudoazulene **2**.[8]

In an extension of this work we treated the dioxime **3** of tricyclo[3.3.0]octan-2,6-dione[9] (Scheme 1) with S_2Cl_2 and Et_3N hoping to produce the tetracyclic 18 π bis-dithiazole **4**, but instead we isolated two mono-dithiazoles **5** and **6**.

Better yields of products were obtained from silylated oximes, so we first treated dioxime **3** with TMSCl and Et_3N in boiling THF for 1 h. Then the mixture was cooled (−20 °C) and Et_3N (20 equiv.) and S_2Cl_2 (20 equiv.) were added and the mixture stirred for 3 d at 4 °C. Chromatography gave a purple product **5**, $C_8H_4Cl_2N_2S_2$ (19%) and, in some reactions, a very minor mauve product **6**, $C_8H_4N_2S_7$ (1–3%). The purple product was similar to cyclopentadithiazole **2** but had a nitrile and two methylene groups in addition to the five sp^2 carbons. Based on this, and mechanistic considerations, structure **5** was assigned to this compound. One cyclopenta-1,2,3-dithiazole has been formed but the second carbocyclic ring has been opened, together with dehydrogenation and chlorination, as before.[7]

The mauve product with five extra sulfur atoms in place of the two chlorines in **5** also showed a cyanoethyl group, but now one of the methylenes gave a complex signal in the ^{1}H NMR compounded of two quintets; each quintet was the sum of two overlapping triplets, suggesting the presence of conformational isomers. This information supported the (chiral[10]) structure **6** with a slowly inverting chair-like pentathiepin ring fused to a cyclopentadithiazole, a new ring system.

The pentathiepin ring in **6** is presumably formed by substitution of the chlorines in **5** by some nucleophilic sulfur species. The 7-membered ring could then be completed by S_2Cl_2 in a reaction related to the known formation of benzopentathiepins,[2,5,11] the thermodynamically favoured products. To test this possibility we ran the reaction of dioxime **3** with S_2Cl_2 as before but after 3 days we added Li_2S (20 equiv.), stirred the mixture for 6 h at 4 °C, then added more S_2Cl_2 (20 equiv.) at −20 °C and stirred for 20 min. Chromatography gave a higher yield (17%) of **6** as the only isolable product.

We then synthesized the dithiazoles **5** and **6** in a more rational way from preformed 2-(2-cyanoethyl)cyclopentanone oxime **7**[12] to confirm their structures and improve their yields. Firstly, oxime **7** was treated with S_2Cl_2 (10 equiv.) and Hünig's base (10 equiv.) in THF for 3 d at 4 °C to give **5** (47%) and **6** (3%). Secondly, oxime **7** was treated with S_2Cl_2 (10 equiv.) and Hünig's base (10 equiv.) in THF for 3 d at 4 °C, then with Li_2S (20 equiv.) in THF for 8 h at 4 °C and then with S_2Cl_2 (10 equiv. for 18 h at 4 °C and then another 10 equiv. at RT) all in one pot to give the pentathiepin **6** (30%) as the only product. The same product was obtained in similar yield (28%) when the final aliquot of S_2Cl_2 (20 equiv.) was added in one portion and stirred for 12 min at RT.

Surprisingly, exposure of the reaction mixture to the final portion of S_2Cl_2 (20 equiv.) for longer periods resulted in the

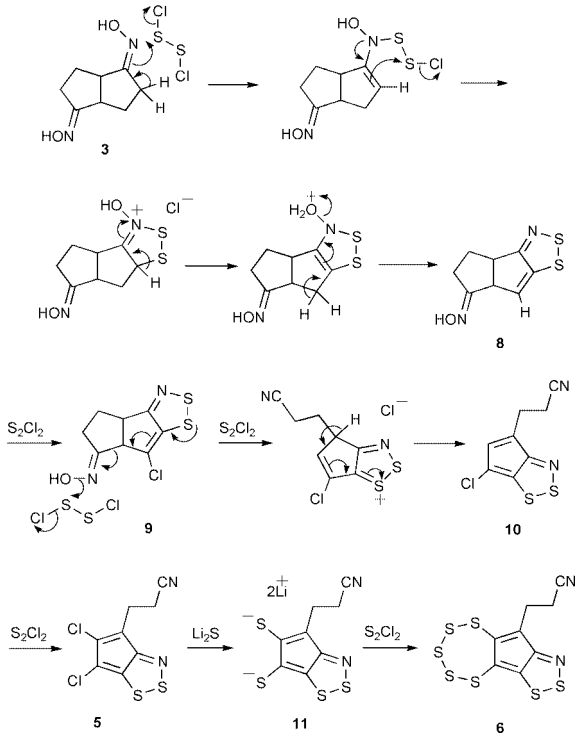

Scheme 2

formation of **5** as well as **6** and, after 1 d at 4 °C, **5** (25%) was the only product isolated. Separate experiments showed that **5** is converted into **6** by excess of sulfide anion followed by S_2Cl_2, and that **6** reverts to **5** when treated with excess of S_2Cl_2 for longer periods. These results, summarised in Scheme 1, support the structures of **5** and **6** and a pathway for the formation of **6** from **3** and from **7**.

A plausible mechanism, starting for simplicity from the free oximes, is shown in Scheme 2. Electrophilic attack by S_2Cl_2 at one oxime (or silylated oxime) group in **3** is followed by cyclisation and dehydration to give the 1,2,3-dithiazole **8**. Both sulfur atoms of **8** would activate it to chorination to give **9** in which the chlorine atom disfavours the *Z* configuration of the oxime necessary for formation of the second dithiazole ring, and the steric repulsion would be greater for the TMS derivative. Thus Beckmann fragmentation (arrows in **9**),[13] catalysed by S_2Cl_2 or by liberated acid, can supervene to give the cyanoethyl intermediate **10**. This ring fission, which is activated by both dithiazole sulfur atoms, is a vinylogous version of the long-known sulfur assisted fragmentation of oximes of β-keto-sulfides.[14] Further chlorination of **10** gives the cyclopenta-1,2,3-dithiazole **5** isolated. Nucleophilic sulfur species produced in, or added to, the reaction mixture could afford the dithiolate **11** and hence, with two equiv. of S_2Cl_2, the pentathiepin **6**, by a mechanism similar to that proposed by Toste and Still.[11]

These one-pot syntheses of the fused pentathiepin **6** from the mono-oxime **7** or the dioxime **3** provide a new and easy route to compounds related to the naturally occurring pentathiepins that are of considerable pharmaceutical and agrochemical potential.

First published as an Advance Article on the web 9th February 2001

The palladium(II)-promoted reaction of a variety of olefins and bromamine T, as the nitrogen atom transfer reagent, provided *N*-tosyl-2-substituted aziridines under mild conditions.

Aziridines have been shown to be valuable starting materials, for the synthesis of useful nitrogen containing compounds, due to the highly regio- and stereoselective ring opening reactions that they undergo.[1,2]

Recently two copper-catalysed aziridination methods for olefins have been reported. Whilst the first,[3] which involved the use of PhI=NTs, is of wide applicability, the second method that utilised chloramine T[4] or bromamine T,[5] as the nitrogen transfer agent, is limited to non-deactivated olefins. The aziridination procedure of Bäckvall[6] [olefins, Pd(II) and primary aliphatic amines] also suffers from a similar disadvantage.

We report herein our preliminary results, collected in Table 1, of a novel $PdCl_2$-assisted aziridination[7]† of olefins **1**, both simple and electron-deficient, by bromamine T.

An examination of the Table shows that all olefins examined participate with varying degrees of efficiency. The electron deficient olefins in general react to give better yields of aziridines than the simple alkenes. Amongst the former class of compounds, *N*,*N*-dimethylacrylamide (**1b**) (entry 2) afforded the highest yield (81%) and phenylvinylsulfoxide (**1g**) (entry 7) the lowest (20%). Whilst methyl acrylate (**1a**) (entry 1) afforded the synthetically useful aziridine **2a**[8] in acceptable yield (60%), as the only isolable product, acrylonitrile (entry 4) however provided a mixture of bromosulfonamide **3d** and the aziridine **2d**[9] in almost equal amounts‡ (*ca.* 20%). A methyl substituent in the β-position **1c** (entry 3) completely inhibited the reaction possibly due to steric reasons. In contrast to styrene (**1i**) (entry 9) and cyclohexene (**1h**) (entry 8), which provided negligible yields of the corresponding heterocycles, allyl alcohol (**1j**) (entry 10), containing an additional metal coordinating centre (OH), afforded the expected product[10] in modest yield (40%). Although the exact nature of the palladium reagent involved in the reaction is not known, a possible mechanism is outlined in Scheme 1 for the substrate *N*,*N*-dimethylacrylamide. Thus, the initially formed π-complex **4** leads, on nucleophilic attack by TsNBrNa,[11] to the σ-alkylpalladium species **5**. Subsequent intramolecular oxidative addition would furnish the 4-member palladocycle Pd(IV) **6**, which collapses to the aziridine **2b**,[12] regenerating the Pd(II) salt. Organopalladium(IV) complexes are known[13] and have been occasionally invoked as intermediates in reactions of Pd(II) species with electrophiles.[14]

Reductive electrolysis of [60]fullerene mono-methanoadducts in THF leads to the formation of bis-adducts in high yields

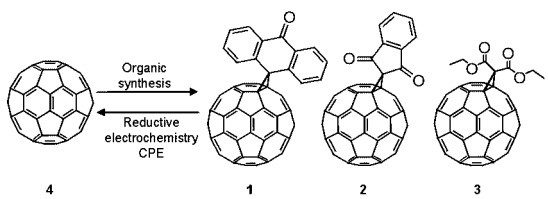
Received (in Columbia, MO, USA) 30th October 2000, Accepted 19th January 2001
First published as an Advance Article on the web 9th February 2001

A new reaction, electrolytically induced adduct transfer between [60]fullerene mono-adducts, leads to bis-adducts with a unique regioisomer distribution.

Cyclopropanation of fullerenes by the addition of malonate derivatives (the Bingel reaction) has been widely used for the preparation of fullerene adducts.[1] The groups of Diederich and Echegoyen reported the reverse of this reaction, the retro-Bingel reaction, an electrolytic reduction reaction performed in dichloromethane, which efficiently removes di[alkoxycarbonyl]methano (Bingel) adducts to yield the parent fullerene (see Scheme 1).[2] The 'Bingel–retro-Bingel' strategy as a protection–deprotection scheme has already found several uses in fullerene chemistry, such as the isolation of enantiomerically pure C_{76}[2a] and of a new C_{2v}-C_{78} bis-adduct,[2b] and in the separation of constitutional isomers of C_{84}.[2c] The groups of Diederich and Echegoyen also described a chemical retro-Bingel reaction (using Mg/Hg, THF, heat) which also efficiently removes the Bingel addends.[3]

Very recently we reported that the range of fullerene adducts that can be removed *via* electrolytic reduction is not limited to di[alkoxycarbonyl]methano adducts (see fullerene **3**), but includes those present in structures **1** and **2** (Scheme 1). Controlled potential electrolysis (CPE) in dichloromethane after the first (**2**) and third (**1**) electrochemical reduction wave induces the efficient removal of the adducts, to form the parent C_{60}.[4]

While electrolytic reduction can lead to the efficient removal of the adducts mentioned, it has been shown that methano-adduct formation can also result from the reaction between electrolytically prepared fullerene anions and dihalo-compounds, even with dichloromethane.[5] Dichloromethane reacts efficiently with the [60]fullerene trianion to form methano-fullerenes of the type $C_{60}>(CH_2)_n$,[5b] and forms similar adducts with C_{84} [$C_{84}>(CH_2)_n$] during the reductive retro-Bingel reaction of di[alkoxycarbonyl]methano-adducts of C_{84}.[2c] In order to avoid these reactions and to further explore the potential and mechanism of the electrolytic methods of fullerene adduct removal, we decided to investigate the electrolysis of compounds **1**–**3** in THF. In the process we found an electrochemically induced intermolecular reaction that leads to the formation of multiple fullerene adducts.[6]



Scheme 1 Protective group system for fullerenes: synthesis of methano-fullerenes **1**–**3** and subsequent adduct removal by reductive electrochemistry.

The cyclic voltammograms of the methanofullerenes **1** and **2** in THF are shown in Fig. 1.[7] These compounds exhibit irreversible electrochemistry in THF, similar to that observed in dichloromethane. Compound **1** exhibits, in addition to several reversible electrochemical processes, an irreversible reduction process between the first and third reduction potentials whilst **2** undergoes an initial two-electron reduction, followed by a one-electron reduction. The irreversible behavior presumably results from the cleavage of one of the cyclopropane bonds connecting the addend to C_{60} after reduction.[8]

Compounds **1** and **2** were subjected to CPE in 0.1 M NBu_4PF_6–THF and the products were separated and analyzed. CPE of **1** was performed at *ca.*100–150 mV more cathodic than the third, reversible, reduction wave (Fig. 1, arrow a); 2.7 electrons per molecule were discharged and clear changes in the CV and OSWV were observed, indicating that a chemical reaction had taken place. Subsequent re-oxidation at 0 V and purification of the product mixture by column chromatography (eluent: toluene) yielded fullerene products in *ca.* 91% yield. Analysis of this mixture by HPLC, UV–VIS spectroscopy, and MALDI-TOF spectrometry clearly showed the formation of C_{60} as the main product (41%). Thus reductive electrochemistry removes the addend in THF (as also observed in CH_2Cl_2), leading to the formation of C_{60}. A second fraction (39%) containing the starting material **1** was also recovered. Interestingly and unexpectedly, a third fraction (11%) with a higher polarity was also isolated. Analysis showed this fraction to be composed of the bis-adducts: fullerenes with two spiro-anthraquinone groups attached (MALDI-TOF: *m*/*z* 1104).

CPE of **2** in THF was performed after the first two-electron reduction wave (Fig. 1, arrow b), and 1.8 electrons per molecule were discharged. Re-oxidation and purification yielded 81% of fullerene products, consisting of 40% C_{60}, 27% recovered **2**, and 14% of bis-adducts. Adduct removal is also the main

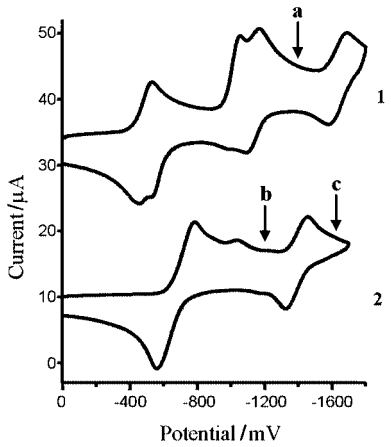


Fig. 1 Cyclic voltammograms of **1** and **2** in THF.

DOI: 10.1039/b008769f

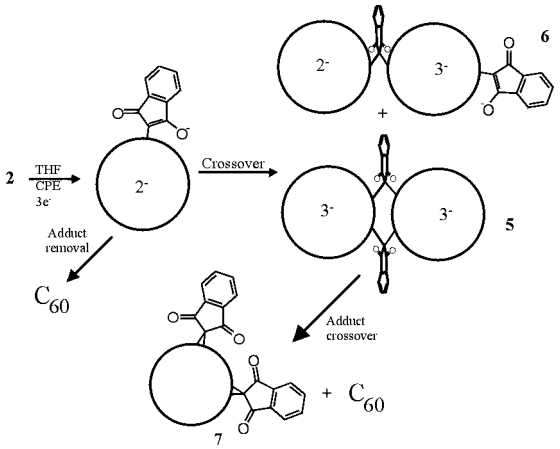
reaction pathway but again a significant amount of regioisomeric bis-adducts was isolated (MALDI-TOF: *m*/*z* 1010). A separate CPE experiment conducted after the second reduction wave (Fig. 1, arrow c) discharged 3.0 electrons and led to similar results (C_{60} : **2** : bis-adducts **7** = 35 : 30 : 19%).

As stated in the introduction, Bingel-adduct removal from fullerenes like **3** by electrochemical (CH_2Cl_2) or chemical reduction (THF) yields C_{60} and starting material (Scheme 1).[2] However, no bis-adduct formation was observed using either of these reductive methods. In view of the results already described for **1** and **2** in THF, we decided to electrolyze **3** in the same solvent. CPE after the second reduction wave of **3** discharged 2.6 electrons, considerably less than the typical value obtained in CH_2Cl_2 (4.0 electrons). Re-oxidation and purification gave fullerene products in a quantitative yield, with 62% C_{60} and 38% **3**. Interestingly, no bis-adducts were detected. Thus profound mechanistic differences exist between the behavior of **1** and **2** and that of **3** under electrolytic conditions.

Our electrochemical experiments show that in THF (but not in CH_2Cl_2) there is a second reaction pathway, besides simple addend removal, that leads to bis-adduct formation. The regioisomer distribution of these bis-adducts is of great interest, as this could provide information on the mechanism of this intermolecular adduct crossover reaction. The unambiguous assignment of regioisomers of several fullerene bis-adducts has been described in detail by Hirsch *et al.*[9] The quantities of bis-adducts that are isolated from the electrolysis experiments in THF are small (typically *ca.* 0.5 mg), thus for characterization purposes we prepared a large amount of the bis-adduct regioisomer mixture (defined as **7**) using the same synthetic procedures used to prepare the original compound, **2**.[10] We separated the regioisomeric bis-adducts **7** on a preparative HPLC column (eluent: toluene). The structures of the different fractions were assigned by ^{1}H NMR spectroscopy and UV–VIS spectroscopy: *trans*-2 14%, *trans*-3 16%, *e* 41%, *cis*-3 5%, *cis*-2 19%. The regioisomers of the bis-adducts obtained by electrolysis were then assigned using HPLC. The two CPE-experiments performed with **2** at different reductive potentials yield similar regioisomer distributions, which are clearly different from that obtained by the regular synthetic route (CPE-b: *trans*-2 3%, *trans*-3 7%, *e* 37%, *cis*-3 49%; CPE-c: *trans*-2 6%, *trans*-3 11%, *e* 43%, *cis*-3 37%).[11] The electrochemical formation of the *cis*-3 bis-adduct as one of the predominant regioisomers is particularly remarkable. Such a relatively large percentage of the *cis*-3 bis-adduct regioisomer had never been seen before during the preparation of bis-Bingel-adducts[9] or bis-methanofullerenes **7**, nor during bis-adduct formation obtained *via* 'shuffle-isomerization' of bis-Bingel adducts[12] or by retro-Bingel of tris-adducts.[13] This offers a possible clue about the mechanism of the reaction in THF.

A possible mechanism to explain these observations is shown in Scheme 2 for **2**. Reductive electrochemistry heterolytically opens the cyclopropane ring, leading to charge formation in the addend as well as in the fullerene core.[8] Two pathways are then possible: (1) the addend can be removed from the fullerene, leading to C_{60} formation, or (2) the anionic addend can add to another fullerene *via* the depicted intermediate **6**, leading to the corresponding bis-adducts.[14] One possible explanation for the favored formation of the *cis*-3 and *e* isomers is the existence of an intermediate like **5**, where both addends interact with the two fullerene cores. Molecular mechanics modeling[15] shows that **5** is highly unfavored for the *trans* isomers while the resulting *cis*-1 and *cis*-2 bis-adducts products have higher energy than the *cis*-3 and *e*.

In conclusion, we have shown an electrolytically induced adduct transfer between fullerenes. The unique bis-adduct regioisomer distribution found deviates significantly from that obtained by the direct synthetic route. These observations are potentially useful for the preparation of specific regioisomer bis-adducts. Mechanistic studies are underway to understand these reaction pathways.



Scheme 2 Possible mechanism for the formation of bis-adducts from electroreduced **2**.

Financial support for this work from the National Science Foundation through grant CHE-9816503, the Netherlands Organization for Scientific Research (NWO, talent stipendium, M. W. J. B.) and the DGICYT of Spain (PB98-0818) is greatly apreciated. We also thank to the Fulbright Foundation (Project 99125) for financial support.

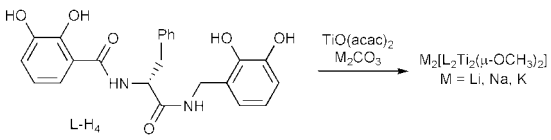
Received (in Cambridge, UK) 1st December 2000, Accepted 25th January 2001
First published as an Advance Article on the web 9th February 2001

The phenylalanine-bridged dicatechol ligand L-H_4 forms under kinetic reaction conditions a double-stranded dinuclear titanium(IV) complex $[(\mathbf{L})_2Ti_2(OCH_3)_2]^{2-}$, as a mixture of seven regio- and stereo-isomers, which in solution transforms into the thermodynamically favored major product and two minor side products.

Peptides are biopolymers which are built up from amino acid monomers. Hereby hydrogen bonding, electrostatic and steric interactions of the amino acid residues lead to the formation of α-helical, β-sheet, turn or random coil structures.[1] Recently we introduced amino acids as spacers into dicatechol ligands to use the unique features of this moiety for the formation of helicates.[2,3]

When we perform a complexation study of the phenylalanine-bridged dicatechol ligand **L**-H_4 with $[TiO(acac)_2]$ and alkali metal carbonate in methanol (15 h, r.t.), we obtain red solids (Scheme 1). Negative ESI MS in methanol (Fig. 1 shows the spectrum of the sodium salt as a representative example) reveals that only traces of a triple-stranded helicate-type complex $M_4[(\mathbf{L})_3Ti_2]$ {*m/z* = 698, charge 2−, $Na_2[(\mathbf{L})_3Ti_2]^{2-}$} are present while the major component $M_2[(\mathbf{L})_2Ti_2(OCH_3)_2]$ is composed of two ligands **L**, two titanium(IV) ions and two coligands CH_3O^- {for M = Na: *m/z* = 1017, charge 1−, $Na[(\mathbf{L})_2Ti_2(OCH_3)_2]^-$; and *m/z* = 497, charge 2−, $Na_2[(\mathbf{L})_3Ti_2]^{2-}$}. The isotopic patterns are in accordance with the proposed formulae.



Scheme 1

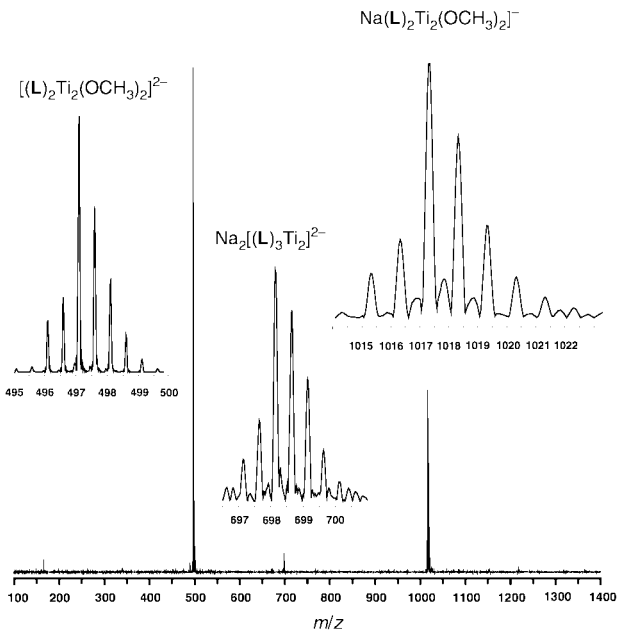


Fig. 1 Negative ESI mass spectrum (methanol) of $Na_2[(\mathbf{L})_2Ti_2(OCH_3)_2]$.

Stack and coworkers already reported a similar dinuclear iron(III) complex. They were able to control the formation of double- *versus* triple-stranded complexes by the stoichiometry of the components.[4] With our system we could not shift the reaction towards the triple-stranded complexes $M_4[(\mathbf{L})_3Ti_2]$.

The NMR spectra of the complexes $M_2[(\mathbf{L})_2Ti_2(OCH_3)_2]$ are very complicated because of the directionality[5] of the ligand **L** and of the stereochemistry at the complex units.[6] Fig. 2 shows a schematic representation of the different stereo- and regioisomers which can be formed. The two directional ligands (N-*versus* C-terminus) can be orientated parallel or antiparallel to each other and the two complex units can be homo- or heterochiral. The isomers **I**, **II** and **IV**–**VII** possess a C_2 axis and lead to only one set of NMR signals for the ligands, whereas **III** possesses C_1 symmetry and thus would result in two sets of signals. If a ^1H NMR spectrum of freshly synthesized (r.t., 15 h, methanol) $[(\mathbf{L})_2Ti_2(OCH_3)_2]^{2-}$ in methanol-d_4 is recorded, up to eight sets of signals—all seven isomers—are observed [Fig. 3 (top), only the signals of one of the diastereotopic benzylic CH_2N protons are shown, the other signals are partly overlapping and cannot be interpreted unambigously].

After two weeks at room temperature the spectrum gets much simpler and one major (a) and two minor species (b, c) are observed [Fig. 3 (bottom)]. From the NMR spectrum it is seen that the complexes which are present in significant amounts belong to the C_2-symmetric isomers **I**, **II** and/or **IV**–**VII**.

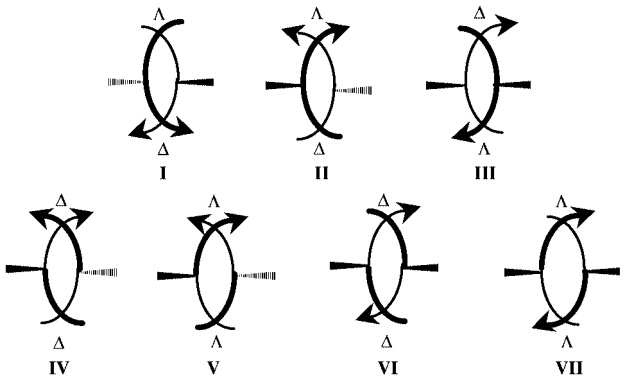

Fig. 2 Schematic representation of the possible isomers of the double-stranded complex $[(\mathbf{L})_2Ti_2(OCH_3)_2]^{2-}$. Only the two directional ligand strands **L** are shown as arrows. Additionally, the configuration at the complex units (Λ or Δ) and at the ligand are indicated. Bold lines are at front, thin lines are at the back.

DOI: 10.1039/b009657l

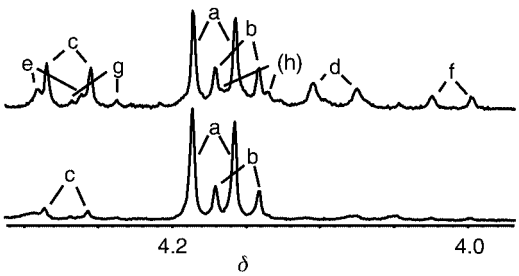

Fig. 3 Part of the ^{1}H NMR spectrum (methanol-d_4) of $Li_2[(\mathbf{L})_2Ti_2(OCH_3)_2]$ (only the signal of one of the diastereotopic protons in benzylic $[NCH_2]$-position is shown). (Top) spectrum of a freshly prepared (r.t., 15 h, methanol) sample of $Li_2[(\mathbf{L})_2Ti_2(OCH_3)_2]$ showing up to eight doublets (a)–(h) (→ seven isomers) ('kinetic control'). (Bottom) spectrum after two weeks at room temperature in methanol-d_4 with the dominating species (a) and the minor components (b) and (c) ('thermodynamic control').

Following the optical rotation of $[(\mathbf{L})_2Ti_2(OCH_3)_2]^{2-}$ (c = 0.1, methanol, 20 °C) we observed a drop of $[\alpha]_D$ from +70° to about 0° within 18 days. Those results indicate that under kinetic control a mixture of complexes is formed which slowly transforms in solution into the thermodynamically most stable coordination compounds as the major product.[7] The decrease of the optical rotation gives some evidence that, initially, the helical isomers **IV**–**VII**, which should lead to high $[\alpha]_D$ values,[8] are formed in significant amounts but are only minor species in the thermodynamically favored mixture. Model considerations indicate, that for the helical structures **IV**–**VII** the stabilizing intramolecular hydrogen bonding is disturbed.

The X-ray structure of $Li_2[(\mathbf{L})_2Ti_2(OCH_3)_2]$ (Fig. 4) shows a central four-membered $[Ti(\mu\text{-}OCH_3)]_2$ unit which is bridged by two ligands **L**.† The two ligands **L** are orientated in opposite directions and are bound in a 'side-by-side' fashion to the metal centers leading to a 'meso'-relation between the two complex units . This unsymmetrical isomer **III**, which should lead to two sets of signals by NMR, cannot be detected in significant amounts in solution. Investigation of a second crystal showed the presence of the same isomer **III**.

A conformational analysis following Ramachandran's method[1] shows that one of the ligands adopts a conformation as found in left-handed α-helical peptides (Φ = 80.53°, Ψ = 30.69°) whereas the other one has a conformation somewhere in-between a right-handed helix and a sheet structure (Φ = −115.11°, Ψ = 5.80°).[1]

Herein we presented the coordination chemistry of the phenylalanine-bridged dicatechol ligand **L** with titanium(IV) ions. ESI MS shows that the ligand **L** preferably forms double-stranded coordination compounds $[(\mathbf{L})_2Ti_2(OR)_2]^{2-}$ and not triple-stranded helicate-type complexes $[(\mathbf{L})_3Ti_2]^{4-}$. Hereby a complex mixture of isomers which is obtained under kinetic control transforms in solution within several days into the more simple 'thermodynamic' product mixture.

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Professor Dr M. Kappes and the Nanotechnology Institute, Forschungszentrum Karlsruhe for facilitating the ESI-MS measurements.

Received (in Cambridge, UK) 6th December 2000, Accepted 22nd January 2001
First published as an Advance Article on the web 9th February 2001

The diyndiyl complex $\{Fe_2(CO)_6(\mu\text{-}PPh_2)\}_2(\mu\text{-}C{\equiv}C{-}C{\equiv}C)$ reacts with $P(OMe)_3$ or $NHEt_2$ to give products derived from addition to C_α and facile P–C, N–C and/or C–C bond formation.

Transition metal diyndiyl (M–C≡C–C≡C–M) complexes are members of a rapidly expanding class of organometallic molecules bearing poly-unsaturated, all-carbon molecules as ligands. While the synthesis of compounds featuring polyynyl and polyyndiyl ligands has advanced rapidly,[1] the reactivity of these carbon-rich materials is relatively unexplored.[2] Herein we describe some remarkable reactions of the diyndiyl complex $\{Fe_2(CO)_6(\mu\text{-}PPh_2)\}_2(\mu\text{-}C_\alpha{\equiv}C_\beta{-}C_\gamma{\equiv}C_\delta)$ (**1**) with the nucleophiles $NHEt_2$ and $P(OMe)_3$.

The tetra-iron diyndiyl complex $\{Fe_2(CO)_6(\mu\text{-}PPh_2)\}_2(\mu\text{-}C_\alpha{\equiv}C_\beta{-}C_\gamma{\equiv}C_\delta$ (**1**), previously obtained in only very low yields from a two-step reaction,[3] may be conveniently obtained (35%) directly from the reaction of $Fe_3(CO)_{12}$ with $Ph_2PC{\equiv}CC{\equiv}CPPh_2$ in THF *via* a facile P–C (alkynyl) bond cleavage reaction. Treatment of **1** with an excess of $P(OMe)_3$ in benzene resulted in the formation of the dark red adduct **2** (Scheme 1, Fig. 1),[4,5]† together with the simple phosphite-substituted complexes $\{Fe_2(\mu\text{-}PPh_2)(CO)_5[P(OMe)_3]\}(\mu\text{-}C{\equiv}CC{\equiv}C)\{Fe_2(\mu\text{-}PPh_2)(CO)_5(L)\}$ [L = CO, $P(OMe)_3$]. Compound **2** is derived from addition of the phosphite reagent to only one ynyl functionality of the original butadiyndiyl ligand at C_α, followed by migration of the associated diphenylphosphido group to C_β and P–C bond formation to give a simple 2e-phosphine. This contrasts with the reactions of the analogous mono-acetylide complex $Fe_2(\mu\text{-}C{\equiv}CPh)(CO)_6(\mu\text{-}PPh_2)$ with $P(OR)_3$ (R = Me, Et, Bu^n) which gave $Fe_2(CO)_6\{C[P(OR)_3]CPh\}(\mu\text{-}PPh_2)$ quantitatively.[6] An examination of the molecular structure of the Et product suggests that C_β is sterically protected by both $P(OEt)_3$ and Ph groups, which probably hinders the migration of the PPh_2 moiety.[6]

While **1** failed to react with the bulky reagents dicyclohexylamine and diphenylamine (benzene, 80 °C), treatment of **1** with an excess of $NHEt_2$ (r.t., 2 d) resulted in the formation of purple **3** (Fig. 2) and red **4** (Fig. 3) in 19 and 33% yield respectively (Scheme 1).[4,5] Complex **3** contains two $Fe_2(CO)_6$ moieties bridged by an unusual 1-diethylamino-3-diphenylphosphinobuteneylidene ligand, obtained from 1,2-addition of the amine N–H bond across one acetylide moiety in **1**, with migration of a PPh_2 phosphino group to C_γ. The major product **4** is also derived from 1,2-addition of the amine to the carbon ligand, although in this case it is a carbonyl ligand rather than the PPh_2 group that has migrated from iron to C_γ yielding the five-membered metallacyclic ligand. The addition of the

nucleophile is accompanied by significant rearrangement of the metal framework. The regiospecific 1,2-addition of $NHEt_2$ to C_α/C_β in the diyndiyl complex **1** is unusual in that the corresponding mono-ynyl iron complexes give β-addition products exclusively,[7] while the related ruthenium diynyl compounds give products derived from 1,4-addition of an N–H bond.[8]

Further studies of these remarkable rearrangements, which proceed with total atom conservation and demonstrate facile N–C, P–C and C–C bond formation involving the diyndiyl ligand, are in progress.

We are grateful to the National Research Council of Canada and the Natural Sciences and Engineering Research Council of Canada for financial support of this work. We thank Dr H. Puschmann for crystallographic assistance. P. J. L. held an NRC/NSERC Canadian Government Laboratories Visiting Fellowship.

First published as an Advance Article on the web 9th February 2001

The solvent strength and polarity of four imidazolium and pyridinium based ionic liquids, as measured using two different fluorescent probes, indicate that these liquids are more polar than acetonitrile but less polar than methanol.

The realization that pollution prevention is frequently more cost effective than remediation has catalyzed tremendous effort in the development of environmentally benign solvents and processes. Room-temperature ionic liquids (ILs) are one such class of solvents. They are organic molten salts that in their pure state are liquids at temperatures around ambient. The typical IL is based on a bulky *N*-alkylpyridinium or *N*,*N*′-dialkylimidazolium cation, with a variety of substituents paired with a variety of anions. These, along with alkylammonium and alkylphosphonium compounds, are most popular.[1] Interestingly, even though ILs are organic solvents, they exhibit vanishingly small vapor pressures.[2,3]

Since the synthesis of air- and water-stable ionic liquids in 1992,[4] they have been widely explored as solvents and/or catalysts in synthetic chemistry. Welton[1] has reviewed many of these reaction studies in a recent paper. For example, catalytic hydrogenation of cyclohexene[5] using rhodium based homogeneous catalysts and hydrogenation of olefins[6] using ruthenium and cobalt based homogeneous catalysts in several ionic liquids showed enhancement in reaction rates and selectivity, compared to normal liquid solvents. In addition, very recent efforts have explored the separation of organic solutes from ILs with water[7] and with carbon dioxide,[8] as well as their use in the extraction of metal compounds such as strontium nitrate.[9]

A significant barrier to the use of ILs is the absence of understanding of how the structure of the IL affects its physical properties and solvent strength. Perhaps more importantly, there is a lack of understanding of how solvent strength and solvent polarity of various ILs affect reaction rates. Since polarity and polarizability are the simplest indicators of solvent strength, organic solvents are frequently classified on their ability to dissolve and stabilize dipolar or charged species. Fluorescent probes are commonly used to determine the solvent strength of organic solvents and recent studies indicate that these probes can be used to determine the solvent strength of ILs. For example, the solvent strength of alkylammonium thiocyanate organic salts was determined to be similar to cyclohexanone using fluorescent probes such as pyrene.[10] Bonhote *et al.* found that the solvent strength of 1-ethyl-3-methylimidazolium bis-(triflyl)amide, using pyrene and pyrenecarbaldehyde, was similar to ethanol and hexane respectively, depending on the choice of the fluorescent probe.[11] In the present paper we report on the polarity of several ILs, (**I**–**IV**, Fig. 1) as measured by two fluorescent probes (**V** and **VI**).‡

While betaine dye (Reichardt's dye) is a common probe used to measure the polarity of homogeneous media,[12] neutral fluorescence probe molecules may be preferred when the large size and charge on the betaine dye is problematic. However, it is still quite common to express microscopic polarities in terms of the absorption energy of the betaine dye, $E_T(30)$. Another advantage with the fluorescent probes is that multiple solvent sensitive parameters, *e.g.* the location of the fluorescence maximum, the fluorescence quantum yield and the fluorescence lifetime, can be monitored. Taking this into consideration, we have chosen AP (**V**) and DAP (**VI**), fairly small, neutral molecules whose fluorescence properties are known to be highly sensitive to the polarity of the media[13–15] to explore the solvent strength of [bmim][PF_6], [C_8mim][PF_6], [bmim]NO_3] and [*N*-bupy][BF_4] (**I**–**IV**). The fluorescence properties of these probe molecules are shown in Table 1 in several protic and aprotic organic solvents. All three properties are very sensitive to the nature of the medium. The effect of the nature of the solvent on the fluorescence properties of these probes has been discussed in detail elsewhere.[12–14]

The frequency maxima, lifetimes and quantum yields of AP and DAP correlate reasonably well with the microscopic solvent polarity parameter, $E_T(30)$. For instance, the λ_{max} of AP can be related to the $E_T(30)$ by $E_T(30)$ (kcal mol^{-1}) = 0.225 λ_{max}(nm) − 62.677 with a correlation coefficient of 0.94. We use these probes as general measures of the solvent strength of the various ILs shown in Fig. 1. As a result, we also report the equivalent $E_T(30)$ values determined from these correlations.[13,14]

The fluorescence properties of DAP were measured in four different ILs **I**–**IV**. The results are shown in Table 2, along with the equivalent $E_T(30)$ values estimated from the correlations that are obtained using the data given in Table 1. It is interesting to note that the solvent strength [as indicated by the equivalent $E_T(30)$ values] of the ILs, does not depend very strongly on which fluorophore is used, as demonstrated by the measurements in **I**. Moreover, the values do not depend strongly on what particular fluorescence parameter (λ_{max}, fluorescence lifetime or quantum yield) is used. These data provide more convincing estimates of the solvent strength than a single $E_T(30)$ measurement. Nonetheless, we did measure the $E_T(30)$ value of **I** using Reichardt's dye. A value of 55 kcal mol^{-1} was obtained and this value compares reasonably well with the estimated values reported in Table 2.

All of the ILs exhibit solvent strengths as great or greater than the most polar aprotic solvent (acetonitrile) shown in Table 1. Clearly, these ILs are more polar than hexane, as has been suggested previously for some other ILs.[11] In fact, the equivalent $E_T(30)$ values for the ILs fall in the range of the various alcohols. The data presented in Table 2 suggest that both **I** and **III** provide more polar environments than those offered by

Table 1 Fluorescence properties of the probe molecules in selected organic solvents at room temperature[13,14]

Solvent	Relative permittivity	$E_T(30)$[12]/ kcal mol^{-1}	AP[13,14]			DAP[13,14]		
			λ_{fluo}^{max}/nm	ϕ_{fluo}	τ_{fluo}/ns	λ_{fluo}^{max}/nm	ϕ_{fluo}	τ_{fluo}/ns
Hexane	1.887	31	416[a]			437[a]		
Diethyl ether	4.2	34.5	425			440		
1,4-Dioxane	2.21	36	435	0.73	15.0	457	0.62	14.9
Tetrahydrofuran	7.58	37.4	445	0.7	12.4	459	0.52	13.8
Acetone	20.56	43.1	457	0.68		483	0.17	
Acetonitrile	35.94	45.3	458	0.63	14.0	490	0.12	3.9
tert-Butyl alcohol	12.42	43.5	501			516		
Propan-2-ol	19.92	48.5	505			523		
Ethanol	25.3	51.9	509[a]			523[a]		
Methanol	32.66	55	518	0.1		534		
Water	78.3	63.1	540	0.01		562		

[a] These values were estimated using the $E_T(30)$ values and the correlations developed.

Table 2 Fluorescence properties of DAP in ILs at room temperature and the estimated $E_T(30)$ values (kcal mol^{-1}) in parentheses for the ILs[a]

Solvent	DAP		
	λ_{fluo}^{max}/nm	ϕ_{fluo}	τ_{fluo}/ns
[bmim][PF_6]	526 (52.39)	0.028 (51.69)	2.9 (46.16)
[C_8mim][PF_6]	503 (46.84)	0.18 (47.16)	8.5 (41.51)
[bmim][NO_3]	525 (52.14)	0.045 (51.18)	
[*N*-bupy][BF_4]	495 (44.91)		2.51 (46.48)
[bmim][PF_6] (dried)	512 (49.01)	0.036 (51.44)	

[a] The steady state emission spectra were obtained in a 1 × 1 cmSuprasil quartz cell using a SLM-AMINCO 8100 spectrofluorometer. The fluorescence lifetime measurements were obtained with a PTI laserstrobe fluorescence spectrometer with excitation at 337 nm.

II and **IV**. In addition, we can conclude that replacing the counter ion, PF_6^-, by NO_3^- does not change the apparent polarity of the medium. This may be caused by the fluorophore preferentially positioning itself near the imidazolium ring, thus not being significantly influenced by the anion. The fact that **I** is determined to be more polar than **II** is understandable, as an octyl group is expected to provide a more hydrophobic (hence non-polar) environment than the butyl substituent.

These ILs are expected to be at least partially miscible with water. In fact, measurements in our laboratory indicate that the equilibrium solubility of water in **I** at room temperature is *ca.* 1.735 M. In addition, the ILs are hygroscopic. In general, we would expect the probes used in the current work to be sensitive to the presence of water. To reduce the amount of water in the samples, they were dried *in vacuo* for at least 48 h at room temperature. Subsequent analysis by Karl–Fisher titration suggests that the water content is reduced to *ca.* 0.43 wt% (0.324 M) with this treatment. To further explore the effect of water on the measured $E_T(30)$ values, **I** was dried under even more stringent conditions, (*in vacuo* at 75 °C for 24 h), and Karl–Fisher analysis indicates that the water content should be down to 0.015 M. The fluorescence properties of DAP in this dried salt were measured and are shown at the bottom of Table 2. As expected, the fluorescence properties of the DAP in the dried sample did change somewhat, but the estimated $E_T(30)$ values indicate that the overall solvent strength of the sample is only reduced slightly from the previous measurements. Thus, we are confident that the solvent strengths of the ILs shown in Table 2 are faithful indications of their relative polarities.

In conclusion, the solvent strengths of **I**–**IV**, as represented by their equivalent $E_T(30)$ values, have been estimated using two fluorescent dyes. The results indicate that **I** is more polar than acetonitrile and less polar than methanol. The replacement of the counter ion, PF_6^-, by NO_3^- did not change the apparent polarity of the medium. Also, both **I** and **III** provide more polar environments than those offered by **II** and **IV**. The presence of small amounts of water was found to have only a small effect on the estimated $E_T(30)$ values.

We appreciate the supply of samples of **II**, **III** and **IV** from the group of Professor Kenneth R. Seddon at the Queen's University of Belfast. In addition, financial support from the Environmental Protection Agency (R826734-01-0) and the National Science Foundation (EEC97-00537-CRCD) is gratefully acknowledged. The Notre Dame Radiation Laboratory is supported by the Division of Chemical Sciences of the U.S. Department of Energy. This is contribution No. NDRL 4254 from the Notre Dame Radiation Laboratory.

Notes and references

‡ **I** was obtained from Sachem. The remaining ILs used in this work were prepared by the group of Professor Kenneth R. Seddon at the University of Belfast. All samples were dried *in vacuo* at room temperature for 24 h unless indicated otherwise in the text. The fluorescent probes were synthesized, as described elsewhere.[13,14]

Low temperature reforming of methane to synthesis gas with direct current pulse discharge method

Shigeru Kado,* Kouhei Urasaki, Yasushi Sekine and Kaoru Fujimoto

Department of Applied Chemistry, School of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. E-mail: tt97208@mail.ecc.u-tokyo.ac.jp

Received (in Cambridge, UK) 7th November 2000, Accepted 24th January 2001
First published as an Advance Article on the web 13th February 2001

Synthesis gas was produced by pulsed irradiation of electrons on a mixture of CH_4 and CO_2 (or H_2O) at low temperature and atmospheric pressure without catalysts; especially in the CO_2 reforming reaction, the H_2:CO ratio could be controlled and depended on the concentration of CO_2 in the feed gas.

Authors have shown that when dc pulse discharge (DCPD) was applied to non-catalytic activation of methane, dehydrogenation of methane proceeded by electron collision and acetylene was produced with 95% selectivity under the conditions of ambient temperature and atmospheric pressure. Coexisting oxygen was found to be very effective in suppressing carbon deposition.[1] In this paper, carbon dioxide or steam was added, a possibility to produce synthesis gas was examined. Because carbon dioxide and steam reforming of methane are highly endothermic reactions, these reactions require temperatures > 800 K in the presence of catalysts. It has been reported that carbon dioxide reforming of methane with plasma techniques, such as di-electric-barrier discharge[2,3] and radio-frequency discharge,[4] give syngas at ambient temperature.

A flow-type tubular discharge reactor (4.0 mm i.d.) used in the present study is the same as that reported previously.[1] In the steam reforming reaction, water was fed as liquid with the micro feeder and vaporized in the preheater upstream of the reactor at 453 K. Before sampling, water was trapped in an ice trap. The temperature of the whole reactor and line to the ice trap was maintained at 453 K to prevent condensation. Carbon dioxide reforming was conducted at ambient temperature. Stainless steel rods of 1.0 mm diameter were used as the electrodes and were located 1.5 mm or 10.0 mm apart. The total flow rate was fixed at 10 cm^3 min^{-1}. All experiments were conducted at atmospheric pressure and all the products were analyzed by gas chromatography. Product selectivity was defined as based on the carbon.

In the presence of CO_2 or steam, the state of discharge was stable and carbon deposition on the electrodes and the wall of the reactor was not observed. Table 1 shows the effect of supplied energy on CO_2 and steam reforming of methane. Since trace amounts of C_3 and C_4 hydrocarbons were produced, the sum of the selectivity did not reach 100%. In the reforming reaction, CO was formed as well as C_2 hydrocarbons in both reaction systems. Also, in the presence of steam, CO_2 was produced by the water gas shift reaction. Although the formation of CO_2 is one of the serious problems in the conventional steam reforming process for making syngas, its selectivity was as low as 4% in the DCPD method in spite of the low reaction temperature of 453 K. The main component of C_2 compounds was acetylene, so the H_2:CO ratio was larger than the stoichiometric ratio. With an increase of supplied energy, the conversion increased and CO selectivity increased slightly while C_2 selectivity decreased slightly. It was clarified that the DCPD method had a possibility to proceed the reforming reaction at low temperature.

Fig. 1 shows the effect of CO_2 content in the feed gas on the conversion, the selectivity and H_2:CO ratio. With increasing CO_2 content, CH_4 conversion rose and reached 76% at CH_4:CO_2 = 1:4 while CO_2 conversion remained almost stable at *ca.* 40%. The selectivity strongly depends on the feed gas composition. With the increase of CO_2 content, C_2 selectivity decreased sharply while CO selectivity increased dramatically. Under the conditions of high CH_4 concentration, the formation

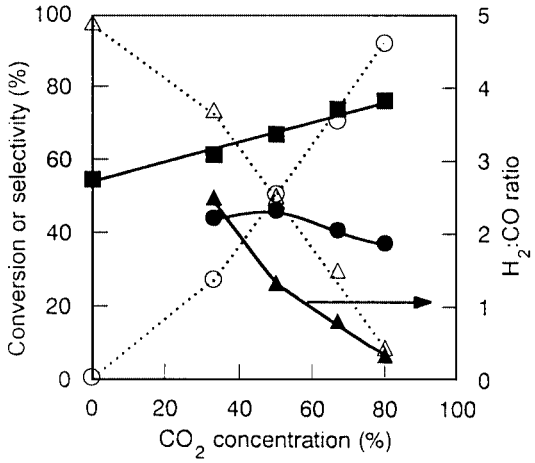

Fig. 1 Effect of carbon dioxide concentration on CO_2 reforming. Reaction conditions: 10 cm^3 min^{-1} total flow rate, ambient temperature, 0.1 MPa, 1.5 mm electrode distance, 52 W supplied energy; (■) CH_4 conv., (●) CO_2 conv., (△) C_2 sel., (○) CO sel., (▲) H_2:CO ratio.

Table 1 Effect of supplied energy on reforming of methane[a]

Added gas	Supplied energy/W	Conversion(%)		Selectivity(%)			
		CH_4	CO_2 or H_2O	C_2	CO	CO_2	H_2:CO ratio
CO_2	3.2	16.3	8.1	64.2	35.6	—	1.74
	10.4	30.4	17.0	62.5	37.3	—	1.56
	21.0	41.2	24.3	54.9	44.7	—	1.48
H_2O	4.4	20.2	9.4	57.0	38.0	3.2	5.44
	11.8	29.9	15.7	52.1	41.3	4.4	5.25
	24.0	39.8	22.2	48.6	45.8	3.7	4.87

[a] Reaction conditions: 10 cm^3 min^{-1} total flow rate, CH_4:CO_2 or H_2O = 1, 1.5 mm distance of electrodes, 0.1 MPa, ambient temperature in CO_2 reforming and 453 K steam reforming.

DOI: 10.1039/b008922m

Table 2 Effect of H_2O concentration and distance of electrodes on steam reforming of methane[a]

CH_4:H_2O	Electrode distance/mm	Conversion(%)		Selectivity(%)			H_2:CO ratio
		CH_4	H_2O	C_2	CO	CO_2	
5:5	1.5	39.8	22.2	48.6	45.8	3.7	4.87
2:8	1.5	49.2	11.7	19.7	64.3	15.3	4.37
2:8	10.0	82.4	19.5	11.0	83.1	5.7	3.46

[a] Reaction conditions: 10 cm^3 min^{-1} total flow rate, 453 K, 0.1 MPa, 3.0 mA.

of C_2H_2 was predominant by the coupling of CH that was produced from CH_4, whereas under conditions of high CO_2 concentration, CO became the main product because of the higher collision probability between CH and activated CO_2 species. The selectivity of C_2 and CO was equal for CH_4:CO_2 = 1:1. The feed gas composition also had a great influence on H_2:CO molar ratio. That ratio was inversely proportional to CO_2 content and could be approximated over the whole range by the formula $R = 1.258 \times r$, where R is the H_2:CO ratio and r is the mixing ratio of CH_4:CO_2. Synthesis gas with a H_2:CO ratio of 2 was obtained at 40% CO_2 content, which is suitable for methanol synthesis *via* a catalytic process.

As shown in Table 2, increasing the steam content caused a decrease in C_2 selectivity together with an increase in CO selectivity during steam reforming. However, CO_2 selectivity increased to *ca.* 15% at CH_4:H_2O = 1:4. Lengthening the distance apart of the electrodes increased CH_4 conversion and CO selectivity dramatically and decreased the C_2 and CO_2 selectivity. The results at a 10 mm distance gave 83% CO selectivity with 82% CH_4 conversion under the conditions of CH_4:H_2O = 1:4.

In CO_2 reforming also, an increased distance apart of electrodes caused the same promotional effect on the conversion and selectivity (Table 3) as was observed in steam reforming. Under the conditions of CH_4:CO_2 = 1:1 and 10.0 mm gap, the discharge region was filled with $Ni_{0.03}Mg_{0.97}O$ prepared by the same method as Tomishige *et al.*[5] NiMgO had a great effect on the selectivity: C_2 selectivity decreased drastically to 1% and CO selectivity increased to 99%. Other hydrocarbons such as C_3 and C_4 compounds were not detected. Also, CO_2 conversion became higher than that of CH_4 probably because of the promotion of the reverse water gas shift reaction. From these results, the catalyst was found to demonstrate some effect on the DCPD reaction at low temperature. The precursor of C_2 hydrocarbons might be adsorbed onto Ni and be subjected to reforming by CO_2. As a consequence, by the combined NiMgO–DCPD system, synthesis gas was produced from methane with 70% CH_4 conversion and little C_2 hydrocarbon formation at ambient temperature.

Table 3 Effect of distance of electrodes and catalyst on CO_2 reforming of methane[a]

Catalyst	Electrode distance/mm	Conversion(%)		Selectivity(%)		H_2:CO ratio
		CH_4	CO_2	C_2	CO	
None	1.5	41.2	24.3	54.9	44.7	1.48
None	10.0	80.9	72.7	33.6	65.4	1.00
NiMgO	10.0	69.5	79.5	1.0	99.0	0.86

[a] Reaction conditions: 10 cm^3 min^{-1} total flow rate, CH_4:CO_2 = 1, ambient temperature, 0.1 MPa, 3.0 mA, $Ni_{0.03}Mg_{0.97}O$ = 0.13 g.

In conclusion, the DCPD method could be applied for CO_2 and steam reforming of methane at low temperature with or without the use of catalysts. The selectivity strongly depended on the composition of the feed gas, and a desired H_2:CO ratio could be obtained. NiMgO had the great effect of increasing CO selectivity to 99%. If the energy efficiency is improved in the future, the catalyst–DCPD combined system has the possibility of being developed as a brand-new reaction process.

First published as an Advance Article on the web 14th February 2001

A novel particulate system carrying CMPO ligands pre-organised on a calixarene scaffold has been synthesised and demonstrated to extract Eu^{3+}, Am^{3+} and Ce^{3+} at high efficiency from simulated nuclear waste streams.

The recovery of lanthanides and actinides from high level nuclear waste is an area of world-wide concern. Current approaches are based on the TRUEX process which utilises the highly efficient, neutral, organophosphorus ligand; octyl(phenyl)(*N*,*N*-diisobutylcarbamoylmethyl)phosphine oxide (CMPO).[1] Previously, we have reported calix[4]arene-based extractants which incorporate CMPO moieties at either the wide[2,3] or narrow rim.[4] Such pre-organisation of the chelating ligands leads to a 100-fold (or greater) increase[2] in extraction efficiency combined with an enhanced selectivity for actinides and lighter lanthanides.[5]

Recently, interest has been focused on magnetic fluidised bed separation technology and the development of magnetically assisted chemical separation (MACS) systems for nuclear waste remediation.[6] These combine the selectivity of a ligand developed for liquid/liquid extraction with improved separation due to the magnetic field, resulting in an effective system suitable for use at low concentrations. Adsorption of CMPO to magnetic polyacrylamide particles enhances extraction of americium and plutonium through a putative synergistic relationship between the extractant and magnetic particle.[7–9]

Here we report the first extraction results, for lanthanides and actinides, obtained with magnetic and non-magnetic silica particles[10] which allow evaluation of the role of pre-organisation of chelating groups through direct comparison of CMPO-substituted calixarenes and derivatives with single CMPO groups. Unlike previously reported systems, in which the extractant is adsorbed onto magnetic particles, our system uses covalent attachment of ligands to the particle surface, allowing controlled ligand loading with defined orientation.

Ligands carrying amines were developed for straightforward attachment to silica particles modified with carboxylic acids. The simple ligand **1** was easily synthesised by monoacylation of 1,5-diaminopentane with 4-nitrophenyl(diphenylphosphoryl)-acetate.[2] In contrast, the calix[4]arene-based system[11] **8** was designed to allow chelation at the wide rim and attachment *via* a two-point interaction at the narrow rim. The multi-step synthesis is outlined in Scheme 1.¶ Selective 1,3 alkylation at the narrow rim with *N*-(3-bromopropyl)phthalimide enabled incorporation of masked amines, whilst subsequent treatment of the remaining 2,4-positions with bromopropane fixed the calix[4]arene in the desired *cone* conformation. *ipso*-Nitration[12]

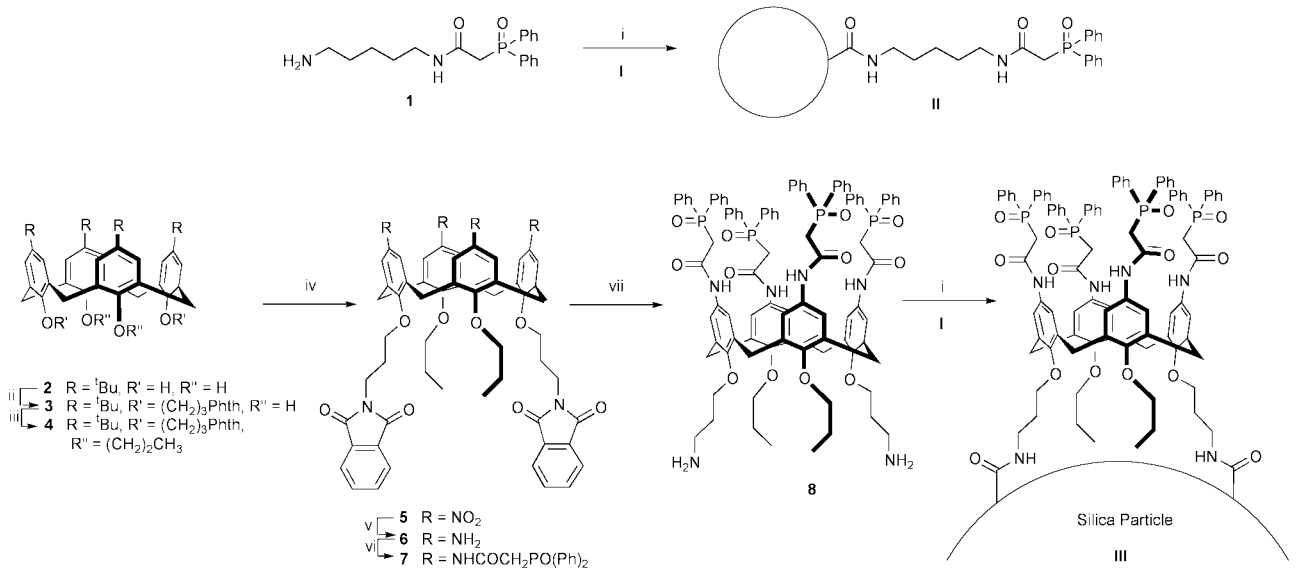

Scheme 1 Synthesis of CMPO particles. *Reagents and conditions*: i, preactivated polymeric beads (I), quant.; ii, $Br(CH_2)_3Phth$, K_2CO_3, MeCN, reflux, 48 h, 68%: iii, $Br(CH_2)_2Me$, NaH, DMF, 2 d, 82%; iv, TFA, HNO_3 (fuming), CH_2Cl_2, 30 min, 65%; v, $Sn(II)Cl_2$, EtOH, reflux, 18 h, 89%; vi, *p*-nitrophenyl(diphenylphosphoryl)acetate, toluene, 50 °C, 68%; vii, hydrazine hydrate, EtOH, reflux, 1 h, 96%.

followed by reduction [Sn(II)Cl_2] yielded the tetraamine derivative **6** which could be effectively acylated to give the pre-organised ligand **7**. Removal of the phthalimide protecting groups gave the required amino ligand **8**.

The amino CMPO derivatives **1** and **8** were covalently bound to the surface of carboxylic acid modified magnetic (**I_m**) and (for comparison) non-magnetic (**I_n**) silica particles *via* carbodiimide activation. The optimal binding capacity of *ca*. 50 μmol CO_2H functions per g particles was determined by preliminary electrokinetic studies. An equivalent loading of CMPO units on the particle surface was achieved through stoichiometric treatment of the particles with either 50 μmol g^{-1} of compound **1** containing a single CMPO unit or with 12.5 μmol g^{-1} of calixarene **8** containing four pre-organised CMPO units.

Solid–liquid extraction experiments were performed under conditions that simulate European nuclear waste streams (4 M $NaNO_3$, 1 M HNO_3). Separation of europium, cerium or americium, as representatives of the early lanthanides and actinides, was evaluated. γ-Ray spectroscopic measurements of the initial nuclide activity in the aqueous phase and the activity after shaking with the particles were used to calculate the percentage extraction (%E = $100(A_0 - A)/A_0$ where A_0 and A symbolise the initial and final activity of the aqueous phase) (Table 1).‖

Table 1 Percentage extraction of lanthanides and actinides by CMPO and CMPO–calix[4]arene silica particles

III_n	62	88	—
Magnetic silica particles			
I_m	4	0	9
II_m	2	1	9
III_m	78	82	92

Attachment of simple CMPO ligands directly onto the particle surface (**II**) enables extraction of the trivalent cations, albeit at a very low level which is only slightly higher than for the untreated silica particles (**I**). However, the calix[4]arene-based particles (**III**), with a comparable concentration of ligating functions, show a significantly higher level of extraction of all cations studied. This demonstrates the importance of pre-organisation of the chelating ligands on a suitable macrocyclic scaffold, prior to their attachment at the particle surface.

Partition coefficients for europium extraction are comparable to those seen for the particulate systems with adsorbed ligands.[13] However, in contrast, larger K_D values per mass of particles are found for americium. Taking into account the lower density of ligands on the particle (50 μmol g^{-1} *vs*. 4.8 mmol g^{-1}), the apparent K_D ($\approx$425 ml g^{-1} *vs.* 3500 ml g^{-1}) represents a *ca*. 12-fold advantage in extraction. This reinforces the importance of initial pre-organisation in imparting selectivity. CMPO extractants, such as octyl(phenyl)(*N*,*N*-diisobutylcarbamoylmethyl)phosphine oxide are unable to discriminate greatly between actinides and lanthanides showing only a slight preference for the heavier lanthanides. In contrast, it has previously been shown, with non-particulate systems,[2,3] that incorporation onto a calix[4]arene allows differentiation between the actinides and lanthanides based on their cationic radii, the actinides and lighter lanthanides with larger radii being extracted more efficiently.

Interestingly, preliminary results on the extraction of ^{139}Ce for the magnetic particles are in marked contrast to those found previously for flexible wide-rim CMPO-calix[4]arenes.[3] The minimal extraction of cerium by CMPO-calix[4]arenes, has been rationalised by the oxidation of Ce^{3+} to the smaller radius Ce^{4+} in the extremely acidic extraction conditions. However, with the solid–liquid extraction conditions reported here, 90% extraction of cerium is achieved within 19 h of shaking, providing an opportunity for effective and selective separation of this cation.

Both non-magnetic and magnetic particles proved effective in the extraction of lanthanides and actinides. However, the ease of separation of magnetic particles from the waste stream using magnetic fluidised bed techniques makes this system more attractive for future industrial development.

These preliminary results are the starting point for a novel MACS process based on particles bearing pre-organised CMPO-calix[4]arenes as ligands. Efficient extraction of americium and europium from simulated nuclear waste conditions has been achieved together with surprisingly high levels of cerium sequestration. Currently, we are developing a range of particulate systems based on suitably functionalised conformationally mobile and narrow-rim CMPO-calix[4]arenes and extending the system to industrial applications.

These studies were supported by the Commission of the European Communities (contract F12W-CT96-0022).

First published as an Advance Article on the web 13th February 2001

ITQ-6, a delaminated material derived from the lamellar precursor of the Ferrierite zeolite, is an excellent support for immobilisation of enzymes; this has been proved by supporting two different enzymes, β-galactosidase from *Aspergillus Oryzae* and penicillin G acylase from *Escherichia Coli*, by electrostatic and covalent interactions, respectively; the adequacy and versatility of the ITQ-6 support and the high stability and catalytic activity of the resultant supported enzymes are shown, with ITQ-6 clearly superior to other already well optimised laboratory and industrial supports for enzymes.

It is well known that enzymes are the most active and selective catalysts for many reactions of commercial interest. However, their low thermal and/or solvent stability and difficult recycling are the major drawbacks for a broader industrial application. In order to improve the stability and performance of enzymes as catalysts, they have been supported in a variety of solids which include organic gels, resins, silicas[1–5] or more recently mesoporous molecular sieves such as MCM-41 or SBA-15.[6–8] Inorganic supports have the advantage of allowing the regeneration of the carrier when the enzyme has been deactivated. Moreover, in the case of ordered mesoporous materials a good selectivity to some enzymes can be obtained by varying the pore diameter and functional groups of the support.[8] Unfortunately, owing to the limited stability in aqueous media of some of these materials and the large steric volume of many enzymes which can result in the blocking of the channels, their possibilities as useful catalysts will be limited. Recently, a series of delaminated zeolites have been obtained as crystalline materials with a well defined external surface area of >600 m^2 g^{-1}, easily accessible to very large molecules, and containing regularly distributed silanol groups.[9,10] By taking advantage of these remarkable properties, it appears that this type of material can offer new opportunities as supports for enzymes.

Generally speaking, with conventional supports, enzyme immobilisation *via* covalent bonding has the advantage of forming strong and stable linkages that result in very robust enzyme supported catalysts. However, the irreversible covalent binding has the drawback that enzyme and support are disposed as waste after deactivation.[1–5,11–13] However, as shown here, when a delaminated zeolite, ITQ-6[10] is used as support, this can be easily recovered and recycled simply by calcination.

There are other cases in where the reversible electrostatic immobilisation of enzymes on pre-existing supports could be of industrial interest. If the enzyme becomes deactivated and can not be further used in the industrial reactor, it can be desorbed and the support can be recovered free of protein, and so available for a new immobilisation of a fresh solution of soluble enzyme.[14] Again, the surface of a delayered zeolite, such as ITQ-6,[10] appears to be highly suitable for activation and use as a reversible enzyme support.

ITQ-6, a delaminated material derived from the lamellar precursor of the Ferrierite zeolite,[10] is an excellent support for immobilisation of enzymes. This has been proved by supporting two different enzymes, β-galactosidase from *Aspergillus Oryzae* and penicillin G acylase from *Escherichia Coli*, by electrostatic and covalent interactions, respectively. The suitability and versatility of the ITQ-6 support and the high stability and catalytic activity of the resultant supported enzymes represent an alternative to other well optimised laboratory and industrial supports for enzymes.

Pure silica ITQ-6, with a specific surface area of 600 m^2 g^{-1} and 0.75 cm^3 g^{-1} pore volume was prepared by a procedure reported previously.[10]

ITQ-6 was functionalised by reacting a solution of 3-aminopropyltriethoxysilane (APS) in toluene with dehydrated ITQ-6 samples resulting in aminopropyl functionalised ITQ-6, denoted N-ITQ-6. When this material (1.0 g) was contacted with a solution of β-galactosidase enzyme (60 mg) from *Aspergillus Oryzae* (MW = 105 kD, pI < 6) to achieve its electrostatic immobilisation on the N-ITQ-6 carrier, it was found that the adsorption of the enzyme was > 99% within 1 h. The amount of adsorbed enzyme was determined from the activity of the resulting solution, after removal of the solid, for the hydrolysis of *o*-nitrophenyl-β-D-galactopiranoside (ONPG) using a 100 mM acetate buffer at pH = 4.5 and 298 K. Hydrolysis of ONPG was monitored by the appearance of a characteristic band of the hydrolysis product at 405 nm. In order to check that the negligible activity of the liquid phase is due to the adsorption of the enzyme onto the solid and not to the deactivation of the enzyme, the solid was recovered and used to catalyse the hydrolysis of ONPG. It is remarkable that the activity of the electrostatically supported enzyme was the same as the activity of the free enzyme before adsorption (the absorbances at 405 nm of the reaction mixtures after 7 min of reaction were 0.43 and 0.41 for the supported and free enzymes, respectively), indicating that all the enzyme has been immobilised, and more importantly, it remains active and accessible to the reactants upon immobilisation. No activity was found when the support, prior of adsorption of the enzyme, was used as catalyst. Also, no leaching of the supported enzyme was detected as can be concluded from the zero activity observed in the reaction media after filtering off the enzyme containing solid.

The immobilised enzyme is highly stable even in contact with solutions of relatively high ionic strength. Specifically, 98% of the immobilised enzyme is still retained on the N-ITQ-6 support in 0.30 M NaCl medium, as determined from the enzyme activity of the resulting solution after removal of the supported enzyme. This level of enzyme retention is much higher than observed for most traditional supports, and it is at least as high as that found for the best performance highly optimised supports (Fig. 1). When desired, the enzymes can be desorbed from N-ITQ-6 by increasing the NaCl concentration of the eluent solution to 1 M. This allows the regeneration of the carrier after the enzyme deactivation in the same reactor or in a fixed bed. At this point the support is ready to be recharged again with enzyme simply by contacting again the regenerated N-ITQ-6 carrier with a fresh solution of the enzyme in the appropriate conditions.

DOI: 10.1039/b009232k

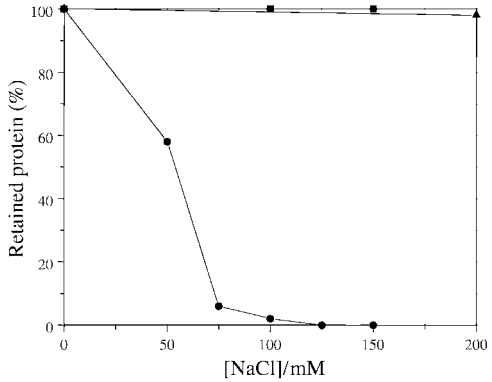

Fig. 1 Desorption of β-galactosidase from *A. Oryzae* adsorbed on diverse supports by increasing ionic strength. (▲) N-ITQ-6; (■) PEI–glyoxil–agarose composite (from ref. 14); (●) DEAE–agarose (from ref. 14).

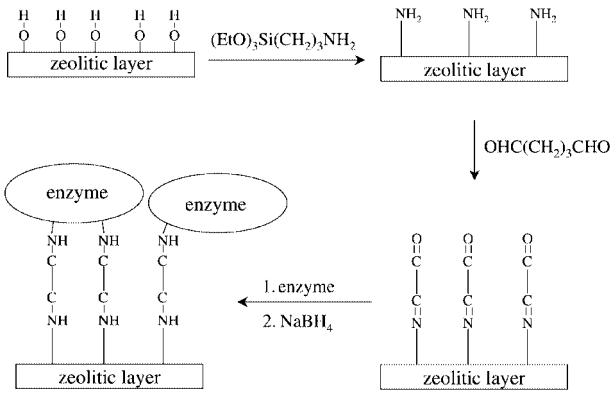
Up to now, enzymes have been supported into mesoporous molecular sieves *via* electrostatic bonding.[6–8] However, for ITQ-6, the enzymes can also be easily supported by covalent bonding resulting in extremely stable catalysts. To do this, a portion of N-ITQ-6 was reacted with a solution of glutaraldehyde at pH = 7 yielding to a material denoted G-ITQ-6. This solid contains imine and aldehyde functional groups and now is ready for covalently immobilising the enzymes by reacting the amino groups of the enzyme with the anchored aldehyde groups at pH = 8, forming imine bonds which are further reduced with sodium borohydride to secondary amines (Scheme 1).



Scheme 1 Covalent immobilisation of enzymes on delaminated mesoporous materials.

Following the above procedure, 2050 IU of a highly voluminous enzyme, penicillin G acylase (PGA, MW = 86000) was immobilised. The catalytic activity and accessibility under reaction conditions of the covalently bonded enzyme were studied by performing the hydrolysis of penicillin G at pH = 8 and 298 K. The progress of the reaction was followed by continuous titration of the released protons with a 25 mM NaOH solution using an automatic burette. In this way, the activity of the supported enzyme was found to be 2440 IU g^{-1} of G-ITQ-6 indicating that the supported enzyme is very active and accessible to the penicillin G reactant.

Moreover, we have proved that the enzyme covalently bonded to the G-ITQ-6 support displays higher stability by comparing its deactivation rate with that of the free enzyme and also with PGA chemically bonded to amorphous silica, which has been widely used as an inorganic carrier of enzymes[15] and particularly for PGA.[16] In order to perform this experiment, aliquots of the covalently supported enzymes on both ITQ-6 and amorphous silica supports (200 IU g^{-1} support) or equivalent amounts of free enzyme were incubated in a 100 mM phosphate buffer at pH = 8 and 319 K for different times. Then, the activity for hydrolysis of penicillin G was measured and compared to that obtained for the non-incubated enzyme. The

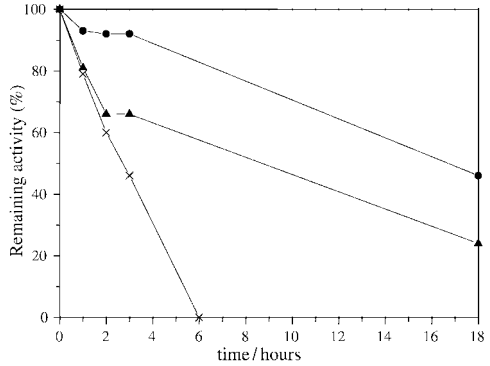


Fig. 2 Deactivation of penicillin G acylase at 319 K and pH = 8 in 100 mM phosphate buffer. (×) Free enzyme remaining activity; (▲) glutaraldehyde-modified silica immobilised enzyme remaining activity; (●) G-ITQ-6 immobilised enzyme remaining activity. Penicillin G hydrolysis reaction was carried out at 298 K and pH = 8, using 25 mM NaOH solution as a titrant.

results shown in Fig. 2 indicate that the stability of the enzyme is substantially improved when it is covalently bonded to the surface of the G-ITQ-6, in such a way that, while the activity of the unsupported enzyme was zero after 6 h of incubation, the remaining activity of the supported enzyme was close to 90%. This value was also clearly higher than that found for the enzyme supported on amorphous silica (60%), The increase in the enzyme stability suggests a multipoint attachment between the enzyme and the supports, perhaps involving the most reactive groups of the protein surface. Moreover, it is reasonable to suppose that a well structured surface, such as that found on ITQ-6, may facilitate the interactions with the enzyme and the dispersion forces might have a positive effect on the enzyme stability.

In conclusion, ITQ-6, owing to its well structured high external surface area and by regularly distributed silanol groups, opens new possibilities for supporting and stabilising many enzymes and using them for reaction with large substrates. It has been proved that the enzymes can be adequately supported by either ionic or covalent bonding whilst retaining full activity.

We thank the Spanish CICYT for financial support (Project MAT97-1016-C02-01 and MAT97-1207-C03-01). J. L. J. thanks the M. E. C. for a doctoral fellowship).

A rapid screening, 'combinatorial-type' survey of the metalloligand chemistry of $Pt_2(PPh_3)_4(\mu\text{-}S)_2$ using electrospray mass spectrometry

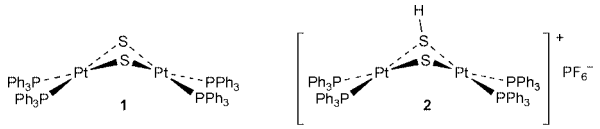
Received (in Cambridge, UK) 30th November 2000, Accepted 25th January 2001
First published as an Advance Article on the web 14th February 2001

Electrospray mass spectrometry is a rapid and powerful technique for a combinatorial-like survey of the chemistry of the metalloligand $Pt_2(PPh_3)_4(\mu\text{-}S)_2$, leading to the successful isolation and crystallographic characterisation of the novel protonated species $Pt_2(PPh_3)_4(\mu\text{-}S)(\mu\text{-}SH)$ together with a range of metallated derivatives.

The sulfido complex $Pt_2(PPh_3)_4(\mu\text{-}S)_2$ **1** has attracted much interest in recent years, particularly for its ability to act as a metalloligand in the assembly of a diverse range of sulfido-bridged higher nuclearity aggregates.[1,2] In this communication, we describe how electrospray mass spectrometry (ESMS) can be used as a rapid, powerful combinatorial-type tool for surveying the metalloligand chemistry of **1** with a range of metal substrates. The utility of ESMS as a general technique for the characterisation of coordination and organometallic complexes is well known,[3] but as far as we are aware there are no previous extensive studies which have used ESMS as the primary screening tool for surveying the reactivity of coordination complexes, the results of which are then used to target subsequent synthetic efforts. Advantages of this approach include the need for only minute amounts of material, rapid screening of potential substrates for further study, and the accepted general agreement between mass spectrometric data and solution speciation.[3] In parallel studies, we are investigating the reactivity of the selenide analogue $Pt_2(PPh_3)_4(\mu\text{-}Se)_2$.[4]

The positive-ion ES spectrum of **1** in methanol gives ions due to protonated **1**, $[\mathbf{1} + 2H]^{2+}$ (*m/z* 752) and $[\mathbf{1} + H]^+$ (*m/z* 1504), together with ions $[(\mathbf{1})_2 + Ag + H]^{2+}$ (*m/z* 1557) and $[(\mathbf{1})_2 + 2Ag]^{2+}$ (*m/z* 1611) formed by adventitious Ag^+ ions in the spectrometer. Addition of a small quantity of formic acid increased the intensity of the *m/z* 752 ion. The novel mono-protonated complex $[Pt_2(PPh_3)_4(\mu\text{-}S)(\mu\text{-}SH)]PF_6$ **2** was subsequently obtained by titration of **1** with HCl, followed by metathesis with NH_4PF_6. This complex, which is related to the monomethyl complex $[Pt_2(PPh_3)_4(\mu\text{-}S)(\mu\text{-}SMe)]^+$,[5] has not been isolated previously. Complex **2** gives two distinct ^{31}P NMR signals [δ 20.2, ^1J(PtP) 2705 and 23.0, ^1J(PtP) 3582, ^2J(PP) 15] together with a resonance for the SH proton at δ 3.48 in the ^1H NMR spectrum. Confirmation of its identity was obtained from an X-ray diffraction study, Fig. 1.† The dihedral angle of the four-membered Pt_2S_2 ring is 135°, which is similar to the methylated analogue $[Pt_2(PPh_3)_4(\mu\text{-}S)(\mu\text{-}SMe)]^+$ (138°).[5] There have only been two previous structural determinations on underivatised Pt(μ-sulfide)$_2$Pt systems, with [(dppe)Pt(μ-S)$_2$Pt(dppe)] being folded (140.2°)[6] and [(dppy)$_2$Pt(μ-S)$_2$Pt(dppy)$_2$] (dppy = 2-diphenylphosphinopyridine)[7] being planar. Structural features of such $\{M_2S_2\}$ systems has attracted recent interest.[1,8] The structure of **2** is the first containing the Pt–SH–Pt moiety, although μ-SH complexes of other metals such as palladium[9] and nickel[10] have been structurally characterised.



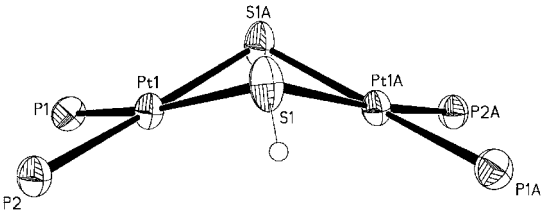


Fig. 1 Molecular structure of $[Pt_2(PPh_3)_4(\mu\text{-}S)(\mu\text{-}SH)]PF_6$ **2**. The phenyl rings of the PPh_3 ligands have been omitted for clarity. Selected bond distances (Å) and angles (°): Pt(1)–S(1) 2.3289(8), Pt(1)–S(1A) 2.3536(8), Pt(1)–P(1) 2.2965(8), Pt(1)–P(2) 2.2712(8), Pt(1)–S(1)–Pt(1A) 91.01(3), Pt(1)–S(1A)–Pt(1A) 91.01(3), S(1)–Pt(1)–S(1A) 78.91(4), S(1)–Pt(1A)–S(1A) 78.91(4), P(1)–Pt(1)–P(2) 98.97(3), P(1)–Pt(1)–P(2) 98.97(3), P(1)–Pt(1)–S(1) 167.60(3), P(2)–Pt(1)–S(1) 92.88(3), P(1)–Pt(1)–S(1A) 89.06(3), P(2)–Pt(1)–S(1A) 171.27(3).

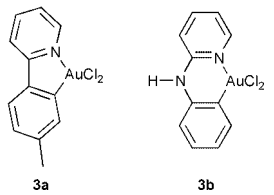

The reactivity of complex **1** towards a range of halide-containing main group (*e.g.* Sn and Hg) and transition metal (*e.g.* Au) complexes can conveniently be monitored by ESMS, and allows the identification of novel, sulfide-bridged aggregates. As an illustrative example, the reaction of **1** with the organogold(III) complexes $AuCl_2$(tolpy) **3a**[11] and $AuCl_2$(pap) **3b**[12] monitored by positive-ion ESMS shows a single major peak in each case, due to the aggregate cations $[Pt_2(PPh_3)_4(\mu_3\text{-}S)_2Au(tolpy)]^{2+}$ and $[Pt_2(PPh_3)_4(\mu_3\text{-}S)_2Au(pap)]^{2+}$, as illustrated for the pap system in Fig. 2, with excellent agreement between observed and calculated isotope patterns. On a synthetic scale, metathesis of the $AuCl_2$(tolpy) reaction solution with NH_4BF_4 gave yellow $[Pt_2(PPh_3)_4(\mu_3\text{-}S)_2Au(tolpy)][BF_4]_2$ **4**, Fig. 3.‡ While there have been several studies on aggregates with $\{M_3S_2\}$ cores containing Pt and Pd,[1,13] this is the first time that the isoelectronic gold(III) centre has been incorporated, though gold(I) and silver(I) derivatives of the $\{Pt_2S_2\}$ core have been known for some time.[1,14] The isolation of silver(I) halide aggregates containing the isoelectronic $\{Au^{III}_2S_2\}$ core has been reported.[15] The successful formation of **4** is facilitated by the increased stability towards reduction (by sulfur-based ligands) of gold(III) complexes bearing *N,C*-cyclometallated ligands.[16] The structure confirms the formulation of **4** as the

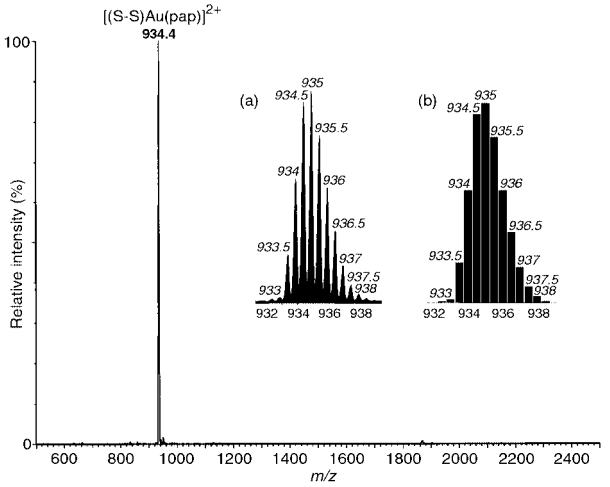

Fig. 2 Positive ion ES spectrum of a 1:1 mixture of **1** and $AuCl_2$(pap) **3b** in MeOH at a cone voltage of 20 V, demonstrating the facile and exclusive formation of $[Pt_2(PPh_3)_4(\mu_3\text{-}S)_2Au(pap)]^{2+}$. The inset shows (a) observed and (b) calculated isotope patterns for the dication.

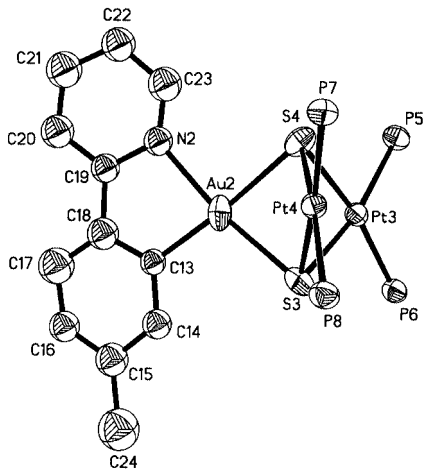

Fig. 3 Molecular structure of one of the cations of $[Pt_2(PPh_3)_4(\mu_3\text{-}S)_2Au(tolpy)][BF_4]_2$ **4** with thermal ellipsoids at the 50% probability level. The phenyl rings of PPh_3 have been omitted for clarity. Selected bond distances (Å) and angles (°): Pt(3)–S(3) 2.371(3), Pt(3)–S(4) 2.362(3), Pt(4)–S(3) 2.377(3), Pt(4)–S(4) 2.360(3), Au(2)–S(3) 2.357(4), Au(2)–S(4) 2.371(4), Pt(3)–P(5) 2.302(3), Pt(3)–P(6) 2.274(3), Pt(4)–P(7) 2.269(3), Pt(4)–P(8) 2.296(3), Au(2)–C(13) 1.94(3), Au(2)–N(2) 2.18(2), Pt(3)–S(3)–Pt(4) 87.66(11), Pt(3)–S(4)–Pt(4) 88.25(11), Pt(3)–S(3)–Au(2) 82.81(11), Pt(3)–S(4)–Au(2) 82.68(11), Pt(4)–S(3)–Au(2) 82.42(11), Pt(4)–S(4)–Au(2) 82.46(11), S(3)–Pt(3)–S(4) 78.20(12), S(3)–Pt(4)–S(4) 78.12(12), P(5)–Pt(3)–P(6) 99.92(12), P(7)–Pt(4)–P(8) 98.92(12), P(5)–Pt(3)–S(3) 167.06(12), S(3)–Au(2)–S(4) 78.31(11), C(13)–Au(2)–N(2) 81.0(9).

first heterometallic aggregate of the $\{Pt_2S_2\}$ core containing gold(III), and the presence of the methyl group allows for unambiguous assignment of N(1) and C(1) on the square-planar gold atom. The $\{Pt_2S_2\}$ ring is, as expected, puckered (126.8°) with average Au–S bond distances 2.358(2) Å.

The successful isolation and characterisation of the novel species, initially identified by mass spectrometry experiments, clearly demonstrates the power of this methodology. It helps researchers to identify possible products before they are synthesized on a macroscopic scale. This pre-synthesis scanning helps to cut down wastage and increases the chance of achieving successful syntheses. Extension to organotin(IV) halides leads to the successful isolation of a range of adducts of complex **1** with $SnMeCl_2^+$, $SnMe_2Cl^+$, and $SnPhCl_2^+$ moieties (derived from $SnMeCl_3$, $SnMe_2Cl_2$ and $SnPhCl_3$, respectively), their formulation being confirmed by single crystal X-ray diffraction studies. Full details will be reported in due course. Although **1** is a good model for this methodology, it is neither unique nor exclusive. One can anticipate similar success in other systems.

We thank the National University of Singapore and the University of Waikato for financial support of this work, including a visiting scholarship (to S.-W. A. F.), and G. K. Tan for assistance with the X-ray crystallography.

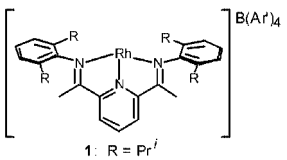
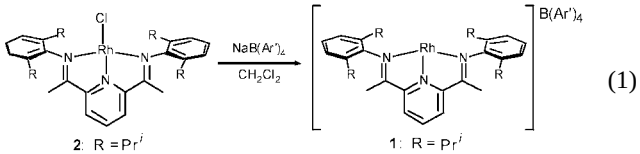
The remarkably stable cationic, three-coordinate, 14-electron rhodium complex 1 has been synthesized, isolated and used as a catalyst for hydrosilation, Mukaiyama aldol and cyclopropanation reactions.

Of the several different catalyst types available for organic reactions, the most diverse are probably the Lewis acids. Ranging from a simple proton to boranes or main group and transition metal complexes, Lewis-acid catalysts now allow for a variety of transformations to be accomplished efficiently and, in many cases, selectively.[1] The requirements for a Lewis-acid catalyst are straightforward: (1) the complex should be electrophilic, and (2) there should be a vacant coordination site. Here, we report the synthesis of the surprisingly stable, cationic, three-coordinate, 14-electron rhodium compound **1**.[2] Complexes of **1** with aldehydes and ketones are also described, in addition to preliminary studies employing **1** in catalytic reactions.



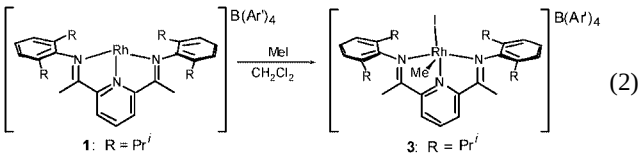
Addition of $NaB(Ar')_4$ [Ar′ = 3,5-bis(trifluoromethyl)phenyl] to a solution of the rhodium(I) chloride compound **2** in dichloromethane results in quantitative formation of the cationic complex **1** after 1–2 h at room temp., as evidenced by the change in solution color from dark green to orange [eqn. (1)].



(1)

After removing the NaCl by cannula filtration, evaporation of the solvent yields **1** as a stable, dark orange solid which usually contains *ca*. 0.25 equiv. of CH_2Cl_2, as determined by ^1H NMR spectroscopy in d_8-THF. Although **1** can be stored under an inert atmosphere for an indefinite period of time, it is extremely susceptible to hydration, such that it is often more convenient to generate **1** *in situ* immediately prior to use in any subsequent experiments.

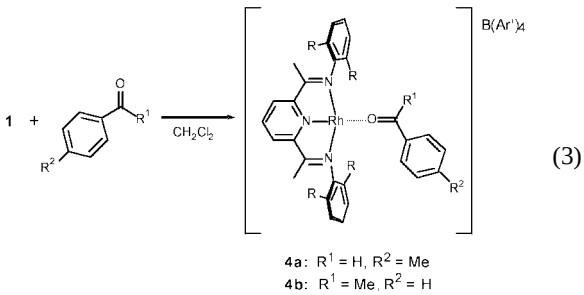
The stability of **1** towards the oxidative addition of dichloromethane, a reaction common to rhodium(I) complexes of this type,[3] is of particular significance.[4] Complex **1** was found to be stable in dichloromethane solution indefinitely at room temperature, and even at 40 °C. In addition, **1** can be heated to 70 °C in chlorobenzene without any decomposition. On the other hand, addition of 1 equiv. of methyl iodide to a dichloromethane solution of **1**, generated *in situ* from **2** and $NaB(Ar')_4$, results in quantitative formation of the rhodium(III) methyl iodide complex **3** after 15–20 min [eqn. (2)]. While we had previously



(2)

synthesized **3** from the ethylene-bound adduct of **1**,[5] this has proven to be a much more simple and convenient route.

The use of chlorinated solvents, whch are very weakly coordinating at best, allows the Lewis-acid characteristics of **1** to be fully exploited. For example, addition of 1 equiv. of either *p*-tolualdehyde or acetophenone to a dichloromethane solution of **1** produces the corresponding adducts **4a** and **4b** [eqn. (3)], which were isolated as stable solids. From the crystal



(3)

structure of the aldehyde complex **4a** (Fig. 1),[6] it can be seen that the aldehyde coordinates in an η^1 fashion. It is also apparent that the imine moieties of the ligand are pulled close to the metal center, such that the attached aryl groups create a 'wedge' in which the aldehyde binds. In fact, when hydrogens are included in the structure, the intramolecular distance of 2.70 Å between the aldehydic hydrogen and the centroid of one of the aryl rings

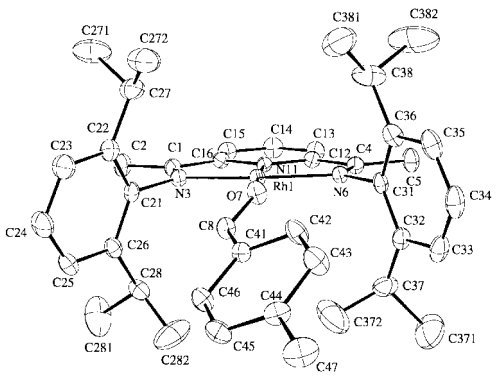


Fig. 1 X-Ray crystal structure of **4a**. Thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths (Å) and angles (°): Rh(1)–O(7) 2.0728(18), Rh(1)–N(3) 2.0124(23), Rh(1)–N(11) 1.8854(20), O(7)–C(8) 1.227(3); Rh(1)–O(7)–C(8) 129.44(19), O(7)–Rh(1)–N(11) 174.81(9), N(6)–C(4)–C(12) 113.80(25), C(1)–N(3)–C(22) −104.8(6), N(3)–Rh(1)–O(7)–C(8) 41.5(3).

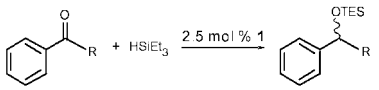
† Electronic supplementary information (ESI) available: experimental information, van't Hoff plot, temperature and equilibrium data, ^1H NMR spectrum of **1** and crystallographic data. See http://www.rsc.org/suppdata/cc/b0/b007815h/

suggests a van der Waals interaction with the aromatic π-cloud. Likewise, the distance of 3.06 Å between the *ortho*-protons on the *p*-tolualdehyde and the other ring indicates a potentially similar interaction. This geometry is verified by the ^{1}H NMR spectrum of **4a**. Resonances for the aldehydic and *ortho* protons appear at 7.45 and 6.68 ppm, respectively, shifted upfield due to the shielding provided by the aryl groups.

When the acetophenone complex **4b** is redissolved in dichloromethane, an equilibrium between the bound and free acetophenone is established. ^{1}H NMR spectroscopy reveals that at room temp., *ca*. 25% of the ketone is not bound to the rhodium center, unlike the aldehyde complex **4a** in which *all* of the aldehyde remains complexed. At lower temperatures, the equilibrium lies further towards complexed acetophenone as expected, and a van't Hoff plot (see ESI†) provides an estimated value of $\Delta H^0 = -16 \pm 2$ kJ mol^{-1} for acetophenone binding.

The availability of complexes **4a** and **4b** led us to screen transformations involving aldehydes and ketones, utilizing **1** as a Lewis acid catalyst. Using 2.5 mol% **1**, the hydrosilation of benzaldehyde and acetophenone with triethylsilane could be effected [eqn. (4)].[1a,7] While the reaction of triethylsilane with

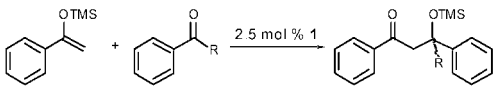


(4)

5a: R = H
5b: R = Me

benzaldehyde proceeds to 95% conversion to **5a** after 2 h at 70 °C in chlorobenzene, the reaction with acetophenone to produce **5b** required *ca*. 17 h to reach 90% conversion under similar conditions. Given the lack of reactivity of triethylsilane with **1** and the steric environment imposed by the ligand, it is believed that this reaction in fact proceeds by a Lewis acid-catalyzed mechanism.

The Mukaiyama aldol condensation of a trimethylsilyl enol ether with benzaldehyde can also be catalyzed by **1** [eqn. (5)].[8]

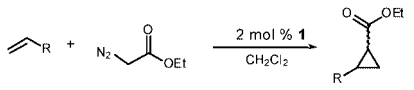


(5)

6a: R = H
6b: R = Me

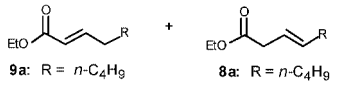
The reaction of benzaldehyde with 1-trimethylsilyloxy-1-phenyl ethylene in chlorobenzene proceeds to 88% conversion to **6a** after heating at 65 °C for 24 h; however, when dichloromethane is used as the solvent, the reaction only proceeds to *ca*. 50% conversion after 24 h at room temperature.

Finally, since carbenes are also two-electron donors, complex **1** seemed to be ideally suited to catalyze cyclopropanation reactions.[9] The reaction of ethyl diazoacetate with α-olefins such as hex-1-ene and oct-1-ene proceeds smoothly; however, carbene insertion into the vinylic C–H bonds was also observed to some extent [eqn. (6)]. Upon monitoring the reaction of



7a: R = *n*-C_4H_9
7b: R = *n*-C_6H_{13}
+

(6)



9a: R = *n*-C_4H_9
9b: R = *n*-C_6H_{13}
8a: R = *n*-C_4H_9
8b: R = *n*-C_6H_{13}

hex-1-ene and ethyl diazoacetate by ^{1}H NMR spectroscopy, it was determined that in addition to forming the cyclopropane **7a**, the C–H insertion product **8a** appears initially as well, and slowly isomerizes to the α,β-unsaturated ester **9a** in what is likely a rhodium-catalyzed process. For oct-1-ene, the combined products **7b**, **8b** and **9b** were isolated in 95% yield, and the product distrubution was determined by ^{1}H NMR to be 85 : 9 : 6 respectively.[10]

Surprisingly, these cyclopropanations do *not* proceed using trimethylsilyldiazomethane as a carbene source. Because of the steric limitations imposed by the ligand, incorporation of the TMS group appears to make the diazoalkyl fragment too bulky to coordinate to the rhodium center through the α-carbon, and thus ultimately produce a reactive carbene. In fact, the N-bound adduct of TMS–diazomethane is actually stable enough to be isolated, and we are currently exploring the unique reactivity that results.[11]

In summary, we have demonstrated that **1** is an easily synthesized, isolable compound which shows remarkable stability for a three-coordinate, 14-electron complex. As expected, **1** is a fairly potent Lewis acid, and the steric environment imposed by the ligand creates a binding pocket that must accommodate potential substrates.[12] It is this steric environment, however, which is responsible for the stability of **1** towards oxidative addition reactions common to Rh(I) complexes—in particular, reaction with chlorinated solvents is suppressed, allowing them to be used as the preferred solvents for synthetic and catalytic applications. In future papers, we will describe the integral role that steric effects play in stabilizing complexes of this type, and report on further studies utilizing **1** as a Lewis acid catalyst.

Enzyme catalysis in ionic liquids: lipase catalysed kinetic resolution of 1-phenylethanol with improved enantioselectivity

Sonja H. Schöfer,[a] Nicole Kaftzik,[a] Peter Wasserscheid[b] and Udo Kragl*[a]

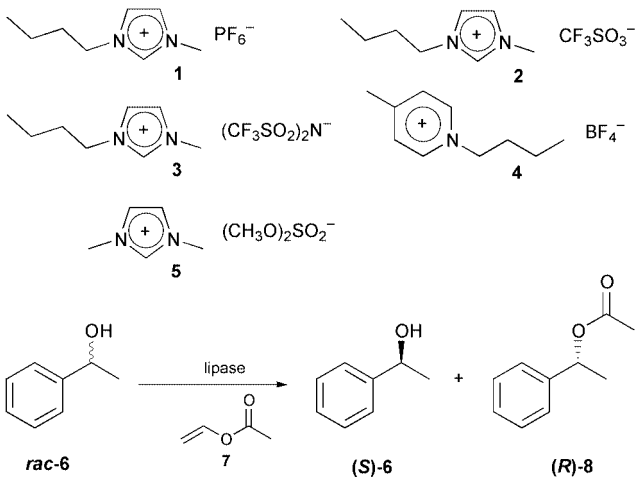
Received (in Liverpool, UK) 16th November 2000, Accepted 26th January 2001
First published as an Advance Article on the web 13th February 2001

Lipases show good activity and, in some cases, improved enantioselectivity when employed in pure ionic liquids for dynamic kinetic resolution of 1-phenylethanol by transesterification.

Today, more than 100 one-step biotransformations making use of whole cells or isolated enzymes are employed on an industrial scale, including a very recent process established by BASF for the kinetic resolution of chiral amines using lipases.[1,2] On a lab scale more than 13000 enzyme-catalysed reactions have been described.[3,4] Nevertheless, there are still problems with substrate solubility, yield or (enantio-)selectivity. Some progress has been made by addition of organic solvents,[5] addition of high salt concentrations[6] or use of microemulsions[7] or supercritical fluids.[8] Recently, ionic liquids (IL) have gained increasing attention for performing all types of reactions with sometimes remarkable results.[9–11] By modification of the cation and anion their properties can be tuned in many ways. For all catalytic processes, there are basically three modes of operation: use of the IL as a co-solvent, as pure solvent or in a biphasic system. After the first trials using ethylammonium nitrate in salt water mixtures more than 15 years ago,[12] recently the first results of the use of pure ILs as a reaction medium for enzymatic reactions have been published.[13,14] A biphasic system containing an IL for *in situ* product extraction for a whole cell process has been described as well.[15]

In this paper we report our results about the application of lipases for an enantioselective reaction in pure ILs based on 1-butyl-3-methylimidazolium (BMIM) ions such as [BMIM]PF_6 **1**, [BMIM]CF_3SO_3 **2** and [BMIM]$(CF_3SO_2)_2N$ **3** or on *N*-butylpyridinium ions such as [4-MBP]BF_4 **4**. As a model system the kinetic resolution of *rac*-1-phenylethanol **6** by transesterification with vinyl acetate **7** was investigated (Scheme 1). Our results on the β-galactosidase catalysed synthesis of *N*-acetyllactosamine are reported elsewhere.[16] In that case, addition of 25% v/v of [MMIM]$MeSO_4$ **5** as a water-miscible co-solvent suppresses the secondary hydrolysis of the formed product resulting in doubling the yield to almost 60%! The reaction investigated here yields two products: the remaining alcohol **(*S*)-6** or the formed acetate **(*R*)-8**. Unless stated otherwise the enantioselectivity is always given for the (*R*)-acetate. When the enzyme shows low enantioselectivity it is not possible to reach high ee-values for the (*R*)-acetate whereas for the (*S*)-alcohol high ee is possible at the expense of the yield.



Scheme 1

A set of nine lipases and two esterases (Roche Diagnostics Chirazyme Screening Set 2) was screened for activity in ten different ionic liquids.[17] The results were compared with the reaction performed in methyl *tert*-butyl ether (MTBE) as solvent. MTBE is widely used as solvent for transesterification in industry and academia. Therefore it was used for this study despite the fact that some other solvents might be favourable as well.

The data are summarised in Table 1. Under the conditions employed the two pig liver esterases showed no activity. Best results were obtained with *Candida antarctica* lipase B (L-2) and *Pseudomonas* sp. lipase (L-6) in several ionic liquids. There is no 'best ionic liquid' in general, but [BMIM]$(CF_3SO_2)_2N$ seems to have some advantages. Surprisingly, with the lipases from *Pseudomonas* sp. and *Alcaligenes* sp. (L-10) the enantioselectivity for the formation of the acetate **(*R*)-8** is improved to a large extent compared to the reaction in MTBE. For the *Candida antarctica* lipase A (L-5) the opposite is observed. The increase of enantioselectivity is reproducible under different conditions. It is likely that the ILs will interact with charged residues found in or near the active centre of the enzyme. For two of the enzymes, L-2 and L-6 concentrations and enantioselectivity were followed as a function of time in MTBE, [BMIM]CF_3SO_3 and [BMIM]$(CF_3SO_2)_2N$. The reaction velocity is equal in both media, MTBE or IL.

One of the major advantages of ILs is that they are not volatile. Therefore it is possible to remove the products by distillation and repeat the catalytic cycle after addition of fresh substrate. This was investigated for L-2 in [BMIM]-$(CF_3SO_2)_2N$. The lipase shows good thermal stability up to 100 °C in MTBE as well as in the IL. Unfortunately, the substrate chosen and the product have boiling points around 200 °C at atmospheric pressure. Therefore, even at a pressure of 0.06 mbar a temperature of 85 °C was necessary to remove the reactants. But the enzyme suspended in the IL could be reused three times with less than 10% loss of activity per cycle. The enantioselectivity was not influenced. Certainly the recycling of the ionic liquid–enzyme system would be easier for other substrates as well as on a larger scale. These aspects as well as the improved enantioselectivity are subject to further studies. Additionally, other factors such as the water content, the viscosity or the question of which of the ions is responsible for the effects will be investigated as well.

The results presented here clearly demonstrate the potential of ionic liquids for enzymatic biotransformations. The variations possible for tailor-made solvents may have a similar impact as the pioneering work of the use of enzymes in pure organic solvents.[18]

[a] BMIM: 1-butyl-3-methylimidazolium. [b] NMIM: 1-methyl-3-nonylimidazolium. [c] HMIM: 1-hexyl-3-methylimidazolium. [d] OMIM: 1-methyl-3-octylimidazolium. [e] 4-MBP: *N*-butyl-4-methylpyridinium. [f] MMIM: 1,3-dimethylimidazolium. [g] EMIM: 1-ethyl-3-methylimidazolium. [h] L-2 *Candida antarctica* lipase B. [i] L-3 *Candida rugosa* lipase. [j] L-5 *Candida antarctica* lipase A. [k] L-6 *Pseudomonas* sp. lipase. [l] L-7 Pig pancreas lipase. [m] L-8 *Thermomyces lanuginosa* lipase. [n] L-9 *Mucor miehei* lipase. [o] L-10 *Alcaligenes sp.* lipase.

In a typical experiment 1 mg of lipase is added to 400 μl substrate solution containing 54 μl ***rac*-6** and 122 μl **7** in 4.4 ml ionic liquid or MTBE. The suspension is incubated for 3 d at 24 °C in a thermomixer. For analysis 100 μl of the reaction mixture are extracted with 1 ml *n*-hexane–propan-2-ol (97.5 : 2.5). The extract is analysed by HPLC using a chiral stationary Phase Chiracel OJ (Daicel). The eluent consists of 96.5% (v/v) *n*-hexane, 3% (v/v) propan-2-ol and 0.5% (v/v) ethanol with a flow rate of 1 ml min^{-1}; temperature 38 °C, UV-detection at 205 nm.

For the distillative workup 600 mg lipase L-2 (10 U mg^{-1}) is mixed with 4 ml [BMIM]$(CF_3SO_2)_2N$, 0.7 ml **6** and 1.2 ml **7**, mixed thoroughly and incubated at 40 °C for 40 min. Non-converted starting material and **(*R*)-8** are removed by vacuum distillation at 85 °C and 0.06 mbar. After cooling down the same amount of substrates is added again and the cycle is repeated.

We thank Roche Diagnostics GmbH, Mannheim, for providing the Chirazyme Screening set and additional amount of CAL, and the *Fonds der Chemischen Industrie* for financial support.

Synthesis and properties of the first series of mixed thioether/telluroether macrocycles

William Levason, Simon D. Orchard and Gillian Reid

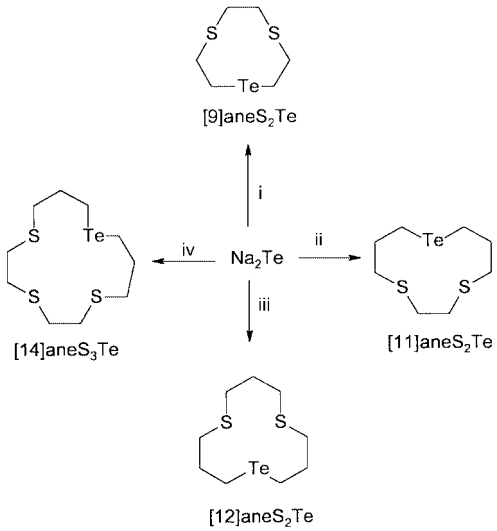
Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ. E-mail: gr@soton.ac.uk

Received (in Cambridge, UK) 17th October 2000, Accepted 22nd January 2001
First published as an Advance Article on the web 13th February 2001

The preparations of the first examples of mixed thioether/telluroether macrocycles, [9]aneS_2Te (1,4-dithia-7-telluracyclononane), [11]aneS_2Te (1,4-dithia-8-telluracycloundecane), [12]aneS_2Te (1,5-dithia-9-telluracyclododecane) and [14]aneS_3Te (1,4,7-trithia-11-telluracyclotetradecane) *via* a 'disguised dilution' method are described, together with the crystal structure of [Ag([11]aneS_2Te)]BF_4 which serves to authenticate the macrocyclic ligand.

In recent years thioether macrocycles have attracted considerable interest in the chemical community. A variety of ring sizes and denticities have been prepared and their metal ion chemistry studied, yielding a diverse range of structures and unexpected electronic and redox responses.[1] The tridentate [9]aneS_3 probably displays the most interesting chemistry, facilitating the stabilisation of a range of unusual oxidation states, including mononuclear Pd(III), Rh(II) and Au(II).[1] We have been conducting comparative studies of the ligating characteristics of acyclic bi- and tri-dentate thio-, seleno- and telluro-ethers to a variety of d- and p-block metal centres and have shown that to low-valent metal centres E→M donation increases in the order S < Se << Te.[2] Incorporation of telluroether functions in a macrocyclic environment is expected to significantly enhance their bonding to metal centres and should lead to rich new chemistry. However, while several macrocyclic selenoethers are now known, telluroether crowns are extremely rare[3] and indeed only a handful of multidentate telluroethers have been synthesised.[4] This really reflects the synthetic difficulties which need to be overcome. Thus, since Te–H and Te–C bonds are considerably weaker than those in their lighter Group 16 analogues, the methods used to prepare thioether and selenoether macrocycles are not usually suited to telluroether derivatives. We have therefore begun to develop new synthetic routes to macrocyclic telluroethers and report here the preparations of four new mixed S/Te-donor macrocycles involving different ring sizes and denticities, including [9]aneS_2Te, the direct analogue of [9]aneS_3. The successful incorporation of dimethylene linkages between the S and Te centres is significant since the ditelluroethers RTe$(CH_2)_2$TeR cannot be isolated, instead undergoing facile elimination of ethene and forming ditellurides.[4] The combination of both S and Te functions within a macrocyclic configuration will permit a direct comparison of their ligating properties to transition metal guests. Silver(I) complexes of the new ligands are also described, together with the crystal structure of [Ag([11]aneS_2Te)]BF_4 which serves to authenticate the macrocyclic ligand.

The synthetic method used for the macrocycles is depicted in Scheme 1.† In a typical preparation a freshly prepared sample of Na_2Te in liquid NH_3 was taken to −78 °C and a THF solution of the appropriate α,ω-dichlorothioalkane species was added dropwise over *ca.* 30 min. Evaporation of the NH_3 followed by subsequent hydrolysis and extraction with CH_2Cl_2 yielded a red oil. The macrocyclic ligands are obtained as light yellow, poorly soluble solids in moderate yields (20–30%) following purification by flash chromatography on silica using ethyl acetate : hexane 1 : 3 or, in the case of [9]aneS_2Te, by recrystallisation from



Scheme 1 *Reagents and conditions*: i, $Cl(CH_2)_2S(CH_2)_2S(CH_2)_2Cl$, THF/$NH_3$(liq); ii, $Cl(CH_2)_3S(CH_2)_2S(CH_2)_3Cl$, THF/$NH_3$(liq); iii, $Cl(CH_2)_3S(CH_2)_3S(CH_2)_3Cl$, THF/$NH_3$(liq); iv, $Cl(CH_2)_3S(CH_2)_2S(CH_2)_2S(CH_2)_3Cl$, THF/$NH_3$(liq); T = −78 °C, reagents added dropwise over 30 min.

CH_2Cl_2–MeOH. NMR spectroscopic studies and microanalyses are entirely consistent with the formulations, while mass spectrometry confirms the products as [1+1] cyclisation species, showing envelopes of peaks with the correct isotopic distributions associated with the parent ion, together with peaks at lower *m*/*z* consistent with fragments arising from Te–C and S–C bond cleavage. There is no evidence from FAB mass spectrometry for higher macrocycles even in the crude reaction products.

The macrocycles (L) react readily with one mol. equiv. of Ag$[CF_3SO_3]$ in CH_2Cl_2 at r.t. for one hour to yield light yellow, very poorly soluble, powdered species of formula [AgL]$[CF_3SO_3]$. Electrospray mass spectrometry (MeCN) shows major peaks associated with $[AgL]^+$ for all four complexes (as well as $[AgL_2]^+$ for L = [9]aneS_2Te, [11]aneS_2Te and [12]aneS_2Te). Crystals of the analogous tetrafluoroborate salt, [Ag([11]aneS_2Te)]BF_4, were obtained from $MeNO_2$–MeOH–Et_2O solution and a crystal structure‡ of this species established unequivocally the macrocyclic configuration. The cation assumes a one-dimensional polymeric structure [Fig. 1(a) and 1(b)] in which Ag centres are bridged by [11]aneS_2Te ligands, with a silver(I) ion coordinated to each macrocyclic donor atom. The Ag(I) ions adopt a distorted trigonal planar coordination environment. The Ag–Te bond distance [2.674(1) Å] is slightly shorter than those observed in [Ag{MeTe$(CH_2)_3$TeMe}$_2$]BF_4 [*d*(Ag–Te) = 2.785(2)–2.837(2) Å],[5] while the Ag–S distances [2.521(3), 2.634(3) Å] are comparable to those observed for [Ag{PhS$(CH_2)_3$SPh}$_2$]-BF_4 [*d*(Ag–S) = 2.573(3)–2.623(3) Å][6] (both of which also adopt infinite structures).

Received (in Cambridge, UK) 13th December 2000, Accepted 22nd January 2001
First published as an Advance Article on the web 13th February 2001

A single chain of schizophyllan, one of the β-1,3-glucan family, can form a stoichiometric complex with poly(dA) and the poly(dA)'s conformation and the complex stability strongly depends on the base length.

Conformational changes in polynucleotides play an important role in biological systems.[1] Powell and Gray[2] have explored the conformational change induced by a single-stranded polynucleotide binding protein (SSB), using poly(dA) as a model single-stranded DNA (ssDNA). Their CD data clearly demonstrated that SSB induces the same conformational change in ssDNA as that of heating poly(dA) or of protonating the polymer at low pH. More recently, Sakurai and Shinkai[3] found that a single chain of schizophyllan (s-SPG) can form a complex with single-stranded RNAs, such as poly(A) and poly(C), and RNA's conformation is altered by complexation.[3] Their finding led us to examine if s-SPG can interact with ssDNA. This report presents our preliminary results for an interaction observed between poly(dA) and s-SPG.

SPG (produced by *Schizophyllum commune* of the Basidiomycota) belongs to the β-1,3-glucan family.[4] SPG exists in a triple helix in water and a single chain in DMSO.[5] When s-SPG in DMSO solution is diluted with water (renature), SPG can gain the triple helical conformation again.[6] We found that when RNA such as poly(C) or poly(A) coexists in the renaturing process, a new triple helix consisting of one polynucleotide chain and two s-SPG chains is formed instead of the original triple helix reforming from three s-SPG chains.[7]

Fig. 1 demonstrates the base lengths (X_b) dependence of the CD spectra ([θ] is the molar ellipticity) for poly(dA) itself (left) and for the mixture of poly(dA) and s-SPG (poly(dA)+s-SPG) (right). The spectra for poly(dA) themselves are overlaid for X_b = 18–60 and that for X_b = 250 shows slight deviation from the others in the 260–280 nm region. Since the overall feature of the spectra seems identical, we can assume that both the helix content and conformation of poly(dA) do not depend on X_b.

On the other hand, the mixtures show that the conformation of poly(dA) strongly depends on X_b. In the case of X_b = 18, there is no difference between poly(dA) itself and the mixture, indicating that no significant interaction exists. From X_b = 30 to 45, the difference between the poly(dA) themselves and the mixtures becomes evident (*i.e.* increase at 260 nm and decrease at 250 nm). Thus complexation occurs at this base length, and becomes more favourable with increasing X_b. In the case of X_b = 60 and 250, the spectra are different from those of $X_b \leqslant 60$ (*i.e.* two new positive bands at 257 and 285 nm and one negative band at 267 nm), indicating that the longer poly(dA) exhibits a different conformation from the shorter poly(dA). As shown in the ESI†[8] this novel interaction is only observed for s-SPG and other polysaccharides (including triple-helix of s-SPG[7]) show no interaction at all.

Fig. 2 presents the temperature dependence of the CD spectra for both poly(dA) and the mixture at X_b = 250. For convenience, the spectra for the shorter wavelength (180–240 nm) and the longer (240–300 nm) are presented on different [θ] scales. For poly(dA) (the solid line), the CD spectrum at shorter wavelength does not change much upon heating. On the other hand, heating induces a dramatic change in that for poly(dA) of the complex. At T = 5 °C, there are two positive bands at 257 and 285 nm and one negative band at 267 nm in the complex. At T = 60 °C, however, there is a strong negative band at 250 nm, a strong positive band at 260 nm, and the 285 nm band disappears. At T = 40 °C, it seems that the spectrum is a hybrid of those at 5 and 60 °C. At T = 90 °C, there is no spectral difference between poly(dA) and the complex. This feature indicates that heating induces a conformational transition of poly(dA) in the complex between 40 and 60 °C, and that the complex is dissociated above 90 °C. Interestingly, the transition

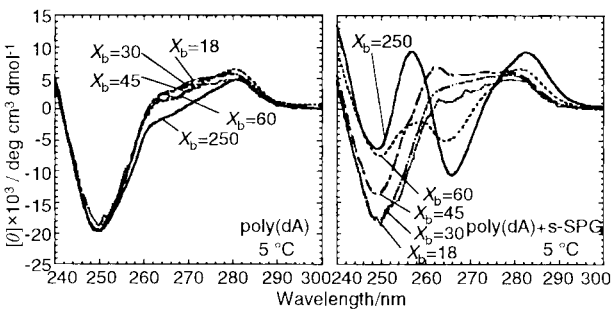

Fig. 1 The base length (X_b) dependence of the CD spectra for poly(dA) (left) and for the mixture made from poly(dA) and s-SPG (right) measured at 5 °C.

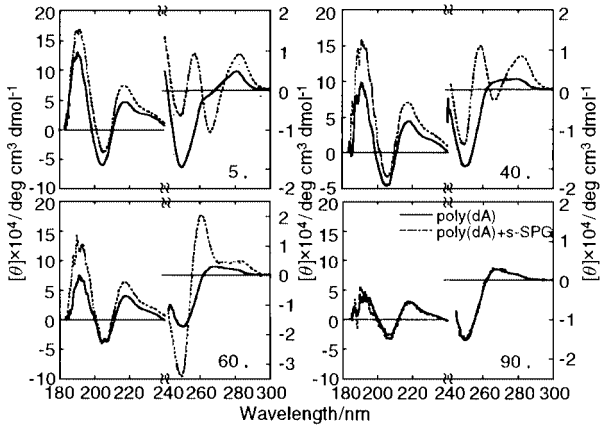

Fig. 2 Spectral change upon heating (from 5 °C, 40 °C, to 90 °C) for both poly(dA) (solid line) and its complex (broken line) for X_b = 250. The spectra at longer wavelengths and at shorter ones are plotted on separate vertical scales to make comparison easy.

† Electronic supplementary information (ESI) available: structure of s-SPG, experimental method, gel electrophoresis of poly(dA) plus dextran (Fig. S1) and s-SPG (Fig. S2). See http://www.rsc.org/suppdata/cc/b0/b009943k/

from 'positive 257 nm + negative 267 nm bands at 5 °C' to 'negative 250 nm + positive 260 nm bands at 60 °C' is correlated with a reverse of the Cotton effect. This feature resembles the feature observed for the B- to Z-form transition in DNA duplexes.[9]

One method to classify polynucleotide conformations is to examine the CD bands related to the phosphoric ester around 170–200 nm. Three typical conformations in DNA duplexes can be characterized as follows: a small negative band at 210 nm and a very large positive band at 190 nm in the A-form, a large positive band (smaller than the A-form) at 190 nm and a fairly small band at 210 nm in the B-form and a relatively large negative band at 185–195 nm and a large positive band at 180 nm in the Z-form. Namely, inversion of the Cotton effect is usually observed between the Z- and B- (or A-) forms. This criterion has been used to study the influence of the ionic strength on the conformational transition from the B- to Z-form[10] and the medium polarity on the conformational transition from the B- to A-form[11]

We apply the above criteria to the present system.[12] By comparing the left hand spectra in each panel in Fig. 2, we can conclude that the poly(dA)'s helicity does not undergo any transition. From the similarity between the spectra of poly(dA) and the complex at 5 °C and the fact that poly(dA) itself takes the B-form (C_2'-*endo* of the ribose and *anti* of the adenosine) in aqueous solution,[1,13] it can be considered that poly(dA) in the complex at 5 °C also takes the B-form. Even for the same type of conformation, the spectra in 240–300 nm are different between poly(dA) and the complex. This difference can be attributed to the difference in the conformation or the electronic state in adenosine, because the complexation can alter both. At 60 °C, the 190 nm band of the complex is larger than that of poly(dA), while the intensities of the 210 nm band are same. This feature can be interpreted in two ways. One possible rationale is that poly(dA) in the complex takes the A-form. This speculation is based on the fact that the CD spectrum in 240–300 nm resembles that of poly(A)[14] which is already known to take the A-form.[1,15] Another rationale is that poly(dA) in complex retains the B-form and the spectral change in 240–300 nm is due to a conformational transition of the adenosine such as *anti* to *syn*. However, the final assignment of the spectral change needs more extensive work using NMR spectroscopy.

Fig. 3 shows the temperature dependence of $[\theta]_{250}$ ($[\theta]$ at 250 nm) in the left panel and of the extinction coefficient at 257 nm (ε_{257}) in the right one, comparing poly(dA) and the mixture. Table 1 summarizes schematically the temperature dependence of the poly(dA) conformation for each X_b. Poly(dA) for all X_b values shows a monotonous increment in both $[\theta]_{250}$ and ε_{257}. We consider that this change is due to decrease in the helix content in the original B-form. On the other hand, for X_b = 250 in the complex, $[\theta]_{250}$ drastically decreases in the range T = 20–60 °C, then increases in the range T = 60–80 °C, and finally merges into the data of poly(dA) itself. The data for the ε_{257} change are clearly correlated with those of CD. This temperature dependence confirms that the poly(dA) in the complex

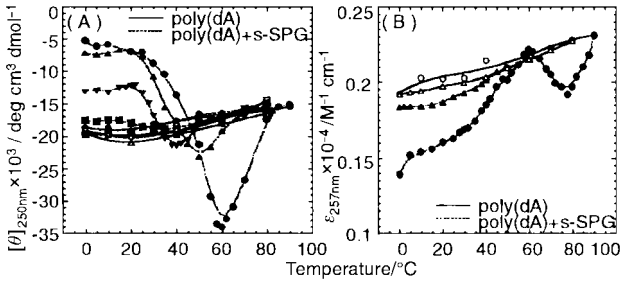

Fig. 3 The temperature dependence of $[\theta]$ at 250 nm (A) and ε at 257 nm (B) for poly(dA) (solid line and unfilled marks) and their mixtures with s-SPG (broken line and filled marks). X_b = 250 (○ and ●), X_b = 60 (△ and ▲), (x_b = 45 (▽ and ▼), x_b = 30 (■ and □) and X_b = 18 (◇ and ◆), respectively.

Table 1 The conformational transition for poly(dA) and poly(dA) in the complex

Poly(dA)	Conformation of poly(dA)			
Poly(dA)	B	→		
Complex				
X_b = 18	B	→		
X_b = 30	LL	→ 22 °C		
X_b = 45	LL	→ 23 °C	H	→ 45 °C
X_b = 60	HL	→ 30 °C	H	→ 65 °C
X_b = 250	HL	→ 30 °C	H	→ 80 °C

B = B-form. LL = conformation of a low molecular weight (Mw) and low temperature (T). HL = conformation of a high Mw and low T. H = conformation of high T.

undergoes a conformational transition (*i.e* a high molecular weight (*Mw*) and low *T* conformation (HL) to a high *T* conformation (H) as denoted in Table 1) before the complex dissociation. With decreasing X_b, H becomes less obvious. At X_b = 45, HL disappears and a low *Mw* and low *T* conformation (LL) is cooperatively dissociated at 35 °C and a small amount of H appears. These features indicate that the presence of this conformation is characteristic of long poly(dA) chains. As discussed above, HL is considered to be the B-form and H can be the A-form or a conformational transition of adenosine. At this moment, however, the origin of LL is not clear yet. In conclusion, we have substantiated that s-SPG forms a novel macromolecular complex with poly(dA). This novel interaction between s-SPG and poly(dA)[16] should provide new insight into the polysaccharide–DNA interactions, frequently important in biological systems.

16 As shown in Fig. S2 (ESI),† we determined the stoichiometric ratio of the complex, using gel electrophoresis. The ratio we found for this system is that two s-SPG repeating units interact with three bases, which is the same result as that for the poly(C) and the poly(A) systems.

Ruthenium complexes bearing π-conjugated pendant moieties for a redox-switching system

Toshikazu Hirao* and Koichiro Iida

Received (in Cambridge, UK) 15th December 2000, Accepted 4th January 2001
First published as an Advance Article on the web 14th February 2001

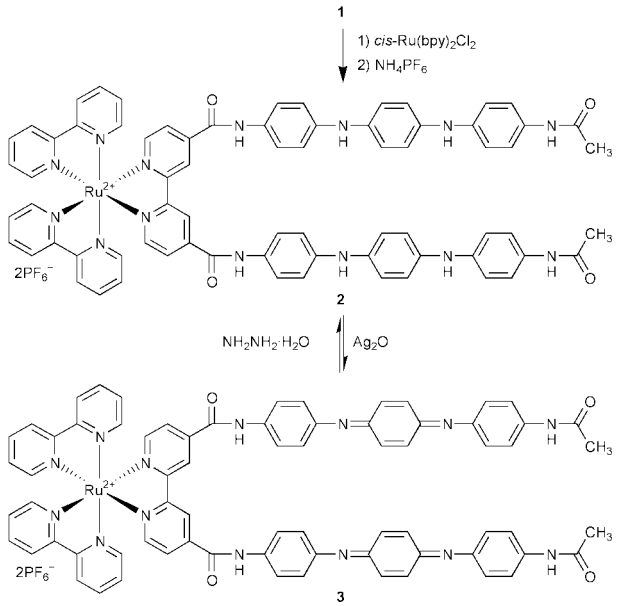
A ruthenium(II) complex bearing *N*,*N*′-bis(4-aminophenyl)-1,4-phenylenediamine moieties, which can be chemically oxidized to the corresponding *N*,*N*′-bis(4-aminophenyl)-1,4-benzoquinonediimine moieties, was synthesized, characterized electrochemically and photochemically, and found to afford a redox-switching system.

The construction of efficient systems for electron transfer is a key factor in the development of versatile catalysts and functionalized materials. Photoinduced electron-transfer systems have been investigated with a variety of ruthenium bipyridyl complexes. A ruthenium complex bearing a redox-active moiety provides an electro-photoswitching device, as exemplified by complexes bearing a benzoquinone[1] or viologen function.[2] Ruthenium(II) complex systems have also been recognized as receptors for anion recognition[3] and photosynthetic models.[4] In a previous paper, quinonediimine derivatives were revealed to afford redox-active catalysts and d,π-conjugated complexes.[5] Furthermore, four π-conjugated pendant groups have been incorporated into a porphyrin scaffold to give atropisomeric three-dimensionally oriented redox-active systems.[6] We herein report redox-switchable ruthenium(II) complexes bearing π-conjugated pendant moieties.

A bipyridyl ligand **1** bearing aniline trimer pendant groups was prepared by amidation of the acid chloride derivative of 2,2′-bipyridine-4,4′-dicarboxylic acid with 2 mol equiv. of *N*-(4-acetylaminophenyl)-*N*′-(4-aminophenyl)-1,4-phenylenediamine.† The ruthenium(II) complex **2** was synthesized by complexation with *cis*-$Ru(bpy)_2Cl_2$ and subsequent treatment with NH_4PF_6. Chemical oxidation of complex **2** was achieved with 2 mol equiv. of Ag_2O to give the corresponding oxidized complex **3** (Scheme 1). Furthermore, **3** could be reduced to **2** on treatment with $N_2H_4{\cdot}H_2O$ at room temperature for 3 h under argon. These complexes were identified by spectral data and cyclic voltammetry.‡ For example, **3** exhibited a CT band at *ca.* 400–600 nm together with an MLCT band, in contrast to the observation of only the MLCT band for **2**.

The redox properties were studied by cyclic voltammetry. The redox waves were assigned by comparison with those of the corresponding complexes **4** and **5** bearing anilino and anilino-anilino groups, respectively (Table 1). The electrochemical behavior of complex **2** in acetonitrile is explained by the redox processes $D^0 \rightarrow D^+ \rightarrow D^{2+} \rightarrow D^{4+}$ of the quinonediimine moieties as shown in Scheme 2. The redox behavior of the ruthenium bipyridyl moiety was similar to that for complexes **4** or **5**. A multiredox system has thus been achieved with complex **2**. It should be noted that the redox processes were found to depend on the solvent. The redox waves in DMF were different from those observed in acetonitrile, suggesting the redox processes $D^0 \rightarrow D^{2+} \rightarrow D^{3+} \rightarrow D^{4+}$ in the former. Two quinonediimine moieties exhibited the same redox potential at each step in both solvents.

The radical cationic species **6** could be generated by treatment of **2** with **3** in the presence of a proton source ($HClO_4$) with the appearance of a broad absorption (600–1100 nm) in the UV–VIS–NIR spectrum.§ EPR spectroscopy also supported the formation of **6** (g = 2.004, A_N = 6.7 G, $A_{H(CH)}$ = 1.6 G, $A_{H(NH)}$ = 3.4 G). These findings are consistent with the reported redox behavior of *N*,*N*′-diphenyl-1,4-benzoquinonediimine and *N*,*N*′-diphenyl-1,4-phenylenediamine.[7] The above-mentioned solvent effect might be due to the difference in equilibrium between the diprotonated quionediimine and corresponding reduced species, and the radical cationic species.



Scheme 1

In the emission spectrum of complex **2** excited at 477 nm, almost complete quenching was observed in acetonitrile (Fig.

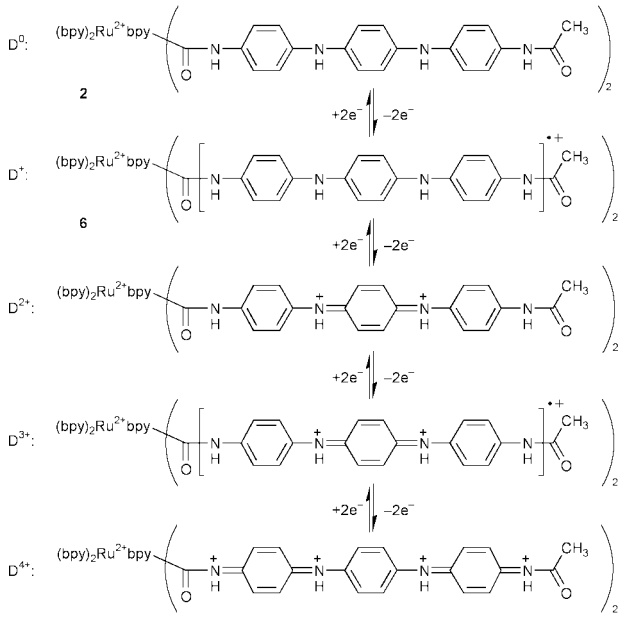

Scheme 2

1). Such quenching was not observed with **4**, indicating that the π-conjugated chain of **2** contributes to the quenching. An efficient photoinduced electron transfer is likely to operate in complex **2**, where the reduced form of the π-conjugated pendant groups serves as an electron donor. Use of the oxidized form **3** also resulted in a quenched spectrum upon excitation at 477 nm. Taking the reported electron-transfer mechanism of complexes bearing viologen or benzoquinone moiety into account,[1,2] this result might be explained by electron transfer in a direction opposite to that of **2**. A much less effective quenching of ruthenium(II) complex **4** with *N*,*N*′-bis(4-acetylaminophenyl)-1,4-phenylenediamine or *N*,*N*′-bis(4-acetylaminophenyl)-1,4-benzoquinonediimine was observed intermolecularly, indicating that the quenching process for both **2** and **3** occurs intramolecularly. Such intramolecular quenching processes are considered to be thermodynamically feasible.

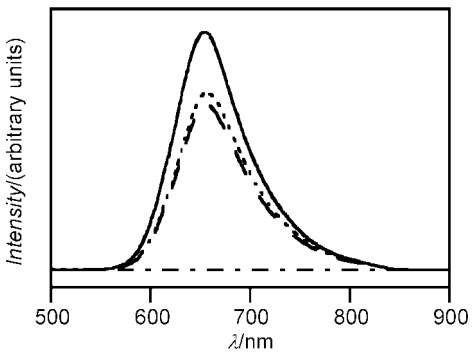

Fig. 1 Emission spectra of **2** or **3** (·-·-), **4** (—), **4** with 2.0 mol equiv. of *N*,*N*′-bis(4-acetylaminophenyl)-1,4-phenylenediamine (····), and **4** with 2.0 mol equiv. of *N*,*N*′-bis(4-acetylaminophenyl)-1,4-benzoquinonediimine (- -). [Complex] = 2.0×10^{-5} M; solv, MeCN, λ_{exc} = 477 nm.

In conclusion, we have described a versatile and efficient redox-switching system with variable oxidation state of the π-conjugated pendant moieties. Further investigation on the electron-transfer mechanism and molecular recognition is now in progress.

Phase-separable catalysis using room temperature ionic liquids and supercritical carbon dioxide

Fuchen Liu, Michael B. Abrams, R. Tom Baker* and William Tumas*

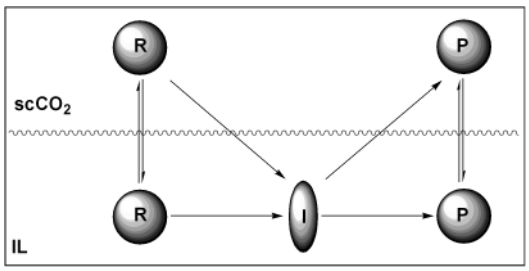
First published as an Advance Article on the web 14th February 2001

A new phase-separable catalysis concept is demonstrated using supercritical carbon dioxide and the room temperature ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate for hydrogenation of alkenes and carbon dioxide.

There is a continuing interest in developing new concepts for biphasic or phase-separable catalysis where a homogeneous catalyst is immobilized in one liquid phase and the reactants and/or products reside largely in another liquid phase.[1] Brennecke and Beckman[2] have recently reported that the room temperature ionic liquid (IL) 1-butyl-3-methylimidazolium hexafluorophosphate, **1**, ([BMIM][PF_6]), exhibits very interesting phase behavior with supercritical carbon dioxide ($scCO_2$), where CO_2 can dissolve significantly (up to 0.6 mole fraction) into the lower IL phase, but no polar IL dissolves in the upper $scCO_2$ phase. They further illustrated that organics such as naphthalene could be extracted from the IL phase using $scCO_2$. Kazarian *et al.*[3] recently provided corroborating spectroscopic evidence that CO_2 dissolves in **1**. This intriguing discovery of phase behavior suggested that a reaction system comprised of $scCO_2$ and an ionic liquid might offer particular advantages as a new biphasic catalysis system. Herein, such a $scCO_2$/IL biphasic system is demonstrated, where a homogeneous transition metal catalyst is immobilized in an IL phase and products can be isolated from a distinct $scCO_2$ phase.[4]

Room temperature ionic liquids[5] and supercritical carbon dioxide[6] have both been extensively studied as alternative solvents for a wide range of homogeneously catalyzed reactions including hydrogenation, hydroformylation, selective oxidation and carbon–carbon bond formation. We chose to examine the $scCO_2$/IL system through investigations of the hydrogenation of dec-1-ene and cyclohexene using Wilkinson's catalyst $RhCl(PPh_3)_3$, **2**, which is insoluble in $scCO_2$ but soluble in water-stable [BMIM][PF_6], **1**.

All reactions were run in custom-designed, high pressure stainless steel view cells with a sapphire window using magnetic stirring at 50 °C, as described previously.[7]† The hydrogenation of dec-1-ene proceeded in 98% conversion to *n*-decane in 1 h at 48 bar H_2 and a total pressure of 207 bar, which implies a time-averaged reaction turnover frequency (TOF) of 410 h^{-1}. The reaction mixture was biphasic throughout the reaction with a colorless carbon dioxide phase above a yellow ionic liquid phase. Hydrogenation of cyclohexene proceeded more slowly under identical conditions with 82% conversion being observed after 2 h reaction at 50 °C (time-averaged TOF = 220 h^{-1}) and 96% conversion measured after 3 h. Product recovery and catalyst recycling were demonstrated for dec-1-ene using a variable volume reaction vessel to transfer the upper $scCO_2$ phase to a separate receiver under high pressure after reaction.[8] The reaction vessel was then recharged with dec-1-ene, hydrogen and carbon dioxide and allowed to react for 1 h. This process was repeated up to four times and the reaction proceeded to *ca.* 98% conversion each time, thereby demonstrating efficient catalyst recycling through immobilization of the rhodium catalyst in the ionic liquid.



Scheme 1 Pictorial illustration of a $scCO_2$/IL biphasic system **R** = reactant, **P** = product, **I** = polar intermediate (*e.g.* carbamate **4**).

Since many organic compounds are not miscible with imidazolium-based ionic liquids, many of the reported catalytic reactions in ILs can be considered to be organic/IL biphasic systems. Product separation has been demonstrated in a number of cases.[9] In order to benchmark the reactivity of the $scCO_2$/IL system with organic/IL systems, we also examined the above hydrogenation reactions using *n*-hexane in place of carbon dioxide, under otherwise identical conditions.‡ The reaction of dec-1-ene to form *n*-decane proceeded to 99% conversion after 1 h at 50 °C in *n*-hexane/[BMIM][PF_6]. Conversions of cyclohexene to cyclohexane were similar to those measured in the $scCO_2$/[BMIM][PF_6] experiments: 88% after 2 h, 98% after 3 h at 50 °C. These results suggest that there is no reactivity advantage for CO_2 over *n*-hexane for simple hydrogenation reactions.

In order to capitalize on advantages arising from the polar nature of the ionic liquid phase, we sought to examine reactions that proceed through polar intermediates which would be soluble in the IL phase and not in $scCO_2$ (Scheme 1). We studied the hydrogenation of carbon dioxide in the presence of dialkylamines to produce *N*,*N*-dialkylformamides. Noyori *et al.*[10] and Baiker *et al.*[11] have reported elegant studies on the catalytic hydrogenation of CO_2 to formamides in $scCO_2$ using $scCO_2$-soluble $RuCl_2(PMe_3)_4$ and $scCO_2$-insoluble $RuCl_2(dppe)_2$ (dppe = $Ph_2PCH_2CH_2PPh_2$), **3**, respectively. These reactions involve ionic carbamate intermediates, since dialkylamines react with CO_2 reversibly to form dialkylammonium dialkylcarbamates, **4** [eqns (3), (4)].[12]

$$CO_2 + H_2 \overset{[cat]}{\rightleftharpoons} HCO_2H \quad (1)$$

$$HCO_2H + R_3N \rightleftharpoons [HNR_3]^+[HCO_2]^- \quad (2)$$

$$HNR_2 + CO_2 \rightleftharpoons R_2NCO_2H \quad (3)$$

$$R_2NCO_2H + NHR_2 \rightleftharpoons \underset{\mathbf{4}}{[NH_2R_2]^+[O_2CNR_2]^-} \quad (4)$$

$$[NH_2R_2]^+[O_2CNR_2]^- + 2HCO_2H \rightarrow 2HCON(R)_2 + 2H_2O + CO_2 \quad (5)$$

Noyori *et al.* reported that salt **4a** (R = CH_3) separated from the $scCO_2$ phase right from the start of the reaction starting with dimethylamine and rates using **4a** were similar to those using dimethylamine. Very high rates for selective *N*,*N*-dimethylformamide (DMF) formation were reported using either liquid **4a**,[10] or dimethylamine.[10,11] Significantly Noyori *et al.* found that activity and selectivity (*i.e.* formic acid *vs.*

Table 1 Production of formamides from amines and CO_2 in different solvent systems

$NH_2(n\text{-}C_3H_7)$[c]	$scCO_2$	$RuCl_2(PMe_3)_4$	100	5	18	30[d]	260	52
$NH(n\text{-}C_3H_7)_2$	$scCO_2$/IL	$RuCl_2(dppe)_2$	80	5	100	> 99	110	> 22

[a] TON = mol product/mol ruthenium. [b] Time-averaged TOF. [c] Ref. 10. [d] Other product is formic acid.

formamide production) decreased rapidly with longer chain amines (R ≠ CH_3) which lead to solid, $scCO_2$-insoluble carbamate intermediates.[10]

In the $scCO_2$/IL system, catalyst **3** and carbamate **4** are both soluble in the IL phase. Carbamate **4a** could be completely converted to DMF after 4 h at 80 °C using 55 bar hydrogen under a total pressure of 276 bar.§ While this unoptimized reactivity is significantly less than that reported by Baiker for the liquid carbamate,[11]‡ we found that the reactivity and more importantly the selectivity is higher for amines other than dimethylamine in the $scCO_2$/IL biphasic system. Under similar reaction conditions, di-*n*-propylamine¶ led to complete amine conversion and exclusive production of the corresponding *N*,*N*-di-*n*-propylformamide after only 5 h at 80 °C. The activity and selectivity are higher than those reported[10] for less bulky diethylamine and *n*-propylamine in neat $scCO_2$ (Table 1). The increased selectivity in the $scCO_2$/IL biphasic system likely arises from the increased solubility of the solid dialkylcarbamate intermediates in the IL phase or through rate enhancement of amidation of formic acid derived from CO_2 hydrogenation [eqn (5)].

The highly polar formamide products appear to be very soluble in the ionic liquid phase, **1**. Preliminary experiments reveal that they do not partition strongly into the $scCO_2$ phase after only one reaction cycle. Quantitative data on the partitioning of organic compounds between ionic liquids and either organic solvents or $scCO_2$ are just starting to appear in the literature.[13,14] We have demonstrated extraction of DMF from IL **1** in a separate experiment. After stirring 30 mL $scCO_2$ (P_{tot} = 276 bar) over a solution of 1.0 mL ionic liquid **1** and 1.0 mL DMF for 1 h at 80 °C, the upper CO_2 phase was transferred under high pressure to another vessel. Subsequent pressure let-down led to 151 mg of isolated DMF (16% recovery). We have been able to demonstrate effective product recovery for *N*,*N*-di-*n*-propylformamide after several reaction/recovery cycles. The recovery yield in the first cycle was poor (less than 5%), however, the yield in the second cycle improved significantly to 61%. *N*,*N*-di-*n*-propylformamide can be almost quantitatively recovered in the third and fourth cycle, suggesting the IL phase becomes saturated with the product in the first two cycles.[15]

In conclusion, we demonstrate one of the first examples[4] of catalysis in a biphasic system incorporating supercritical carbon dioxide and ionic liquids and more importantly the first example involving CO_2 reaction chemistry. High selectivity, catalyst recycling and product recovery were observed for hydrogenation of CO_2 in the presence of dialkylamines, demonstrating the potential advantages arising from dissolving polar reaction intermediates in the IL phase. We are in the process of investigating other reactions, particular those involving polar intermediates, as well as quantifying the partitioning of reactants (including gases), products and catalyst between the two phases.

We gratefully acknowledge support of this research by the U.S. Department of Energy through a Laboratory Directed Research and Development (LDRD) grant at Los Alamos National Laboratory.

† *Typical experimental procedure for olefin hydrogenation*: 20 mg (21 μmol) of **2** were added to 10.5 mmol of olefin (500 equiv. relative to catalyst **2**) and 1 mL of ionic liquid **1** in the reaction cell which was then pressurized with hydrogen (48 bar) and CO_2 to a total pressure of 207 bar. All the experiments were conducted at 50 °C using *n*-nonane as an internal standard.

‡ While magnetic stirring may not be optimal for these reactions, our preliminary experimental conditions allow for a semi-quantitative comparison.

§ *Typical experimental procedure for CO_2 hydrogenation*: 0.5 mL (4.3 mmol) of **4a** was charged into a 33 mL stainless steel reaction cell with a solution of 10 mg (10 μmol) of **3** in 1 mL of **1**. The cell was heated to 80 °C after being filled with 55 bar H_2, then it was pressurized to a total pressure of 276 bar with CO_2. The start of the reaction was defined as the time of CO_2 gas introduction. The yield and identification of formamide were performed by GC, GC-MS and ^{1}H NMR.[10]

¶ 0.15 mL (1.1 mmol) of di-*n*-propylamine and 1 mL of **1** were used. Higher concentration of amine (*e.g.* 7.3 mmol di-*n*-propylamine in 1 mL of **1**) led to precipitation of a white solid (carbamate).

Cr-containing mesoporous silica molecular sieves (Cr-HMS) containing tetrahedrally coordinated isolated chromium oxide (chromate) moieties can operate as an efficient photocatalyst for the decomposition of NO and the partial oxidation of propane with molecular oxygen under visible light irradiation.

Highly dispersed transition metal oxides incorporated within the framework of zeolites and mesoporous molecular sieves show unique reactivities not only for catalytic reactions[1] but also for photocatalytic reactions.[2] In particular, highly dispersed transition metal oxides such as titanium,[3] vanadium[4] and molybdenum[5] exhibit high photocatalytic reactivities for various reactions. However, these metal oxides can operate as efficient photocatalysts only under UV light irradiation and exhibit no photocatalytic reactivity under visible light irradiation. To establish the clean photocatalysis system using the most environmentally ideal energy source—solar light—it is vital to develop a photocatalyst that can operate efficiently under visible light irradiation.

In the present study, chromium-containing mesoporous silica molecular sieves (Cr-HMS) have been prepared and characterized by various spectroscopic methods (XRD, EXAFS, EPR, UV–VIS, photoluminescence) and their photocatalytic reactivities under UV and visible light irradiations have been investigated. It has been found that chromium oxide (Cr-oxide) highly dispersed on the mesoporous silica can adsorb and utilize visible light in photocatalytic reactions such as the decomposition of NO into N_2 and O_2 and the partial oxidation of propane with O_2.

Cr-HMS mesoporous molecular sieves (0.02, 0.2, 1.0, 2.0 wt% as Cr) were synthesized using tetraethyl orthosilicate and $Cr(NO_3)_3{\cdot}9H_2O$ as the starting materials and dodecylamine as a template.[6,7] Calcination of the sample was carried out in a flow of dry air at 773 K for 5 h. Prior to spectroscopic measurements and photocatalytic reactions, the catalysts were degassed at 723 K for 2 h, heated in O_2 at the same temperature for 2 h and then finally evacuated at 473 K for 2 h to 10^{-6} Torr. The photocatalytic reactions were carried out with the catalysts (100 mg) in a flat-bottomed quartz cell (80 ml) connected to a conventional vacuum system (10^{-6} Torr range). Photocatalytic reactions were carried out under UV ($\lambda > 270$ nm) or visible light ($\lambda > 450$ nm) irradiation at 273 K using a high pressure mercury lamp (310–400 nm, 29 W m^{-2}; 360–480 nm, 44 W m^{-2}) through water and colored filters. The photocatalytic decomposition of NO was carried out on a starting amount of 135 μmol and the products in the gas phase were analyzed by GC. For the photocatalytic oxidation of propane with O_2, reactions were carried out on mixtures containing 240 μmol propane and 180 μmol O_2, and products in the gas phase and the products desorbed from the catalysts by heating to 573 K were also analyzed by GC.

The results of the XRD analysis indicated that the Cr-HMS have a mesopore structure[7] and that the Cr-oxide moieties are highly dispersed in the framework of HMS, while no other phases are formed. Cr-HMS exhibited a sharp and intense pre-edge peak in the XANES region which is characteristic of Cr-oxide moieties in a tetrahedral coordination.[8] In the Fourier transforms of EXAFS spectra, only a single peak due to the neighboring oxygen atoms (Cr–O) were observed, showing that Cr ions are highly dispersed in the Cr-HMS. Analysis of EXAFS spectra of Cr-HMS indicated that tetrahedrally coordinated Cr-oxide (chromate) moieties having two terminal C=O bonds existed as in an isolated state [two oxygen atoms (Cr=O) at 1.57 Å and two oxygen atoms (Cr–O) at 1.82 Å]. The EPR technique was also applied to investigate the coordination state of the Cr-oxide species by monitoring the Cr^{5+} ions formed under UV irradiation of the catalyst in the presence of H_2 at 77 K. After photoreduction with H_2 at 77 K, Cr-HMS exhibited a sharp, axially symmetric signal at around $g = 1.9$ ($g_{\|} = 1.880$, $g_{\perp}$ 1.945), attributed to the isolated mononuclear Cr^{5+} ions in tetrahedral coordination.[9]

As shown in Fig. 1, the UV–VIS spectra of the Cr-HMS catalysts exhibit three distinct absorption bands at around 250, 360 and 480 nm which can be assigned to charge transfer from O^{2-} to Cr^{6+} of the tetrahedrally coordinated Cr-oxide moieties.[10] Without Cr ion, HMS exhibit no absorption band above 220 nm. The absorption bands assigned to the absorption of dichromate or Cr_2O_3 cluster cannot be observed above 550 nm, indicating that tetrahedrally coordinated Cr-oxide species exist in an isolated state. Cr-HMS exhibited photoluminescence spectra at *ca*. 550–750 nm upon excitation of the absorption (excitation) bands at *ca*. 250, 360 and 480 nm. These absorption and photoluminescence spectra are similar to those obtained with well defined, highly dispersed Cr-oxides anchored on to Vycor glass or silica[11] and can be attributed to the charge transfer processes on tetrahedrally coordinated Cr-oxide moieties involving an electron transfer from O^{2-} to Cr^{6+} and a reverse radiative decay, respectively.

DOI: 10.1039/b008527h

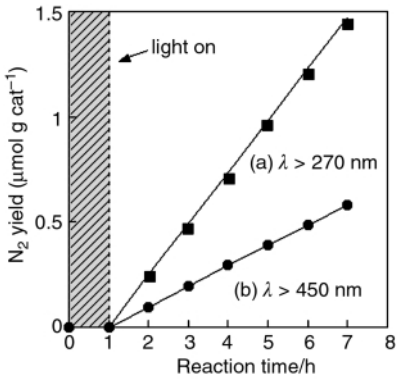

Fig. 2 The reaction time profile of N_2 formation in the photocatalytic decomposition of NO on the Cr-HMS catalyst at 273 K (2.0 wt% as Cr) under UV light irradiation (a) $\lambda > 270$ nm and visible light irradiation (b) at $\lambda > 450$ nm.

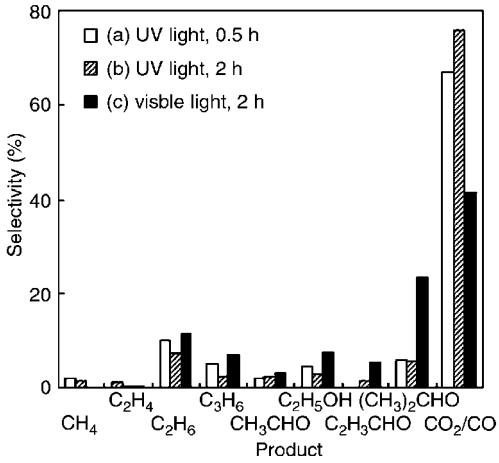

Fig. 3 The distribution of the photo-formed products in the photocatalytic oxidation of propane with O_2 on the Cr-HMS catalyst at 273 K (2.0 wt% as Cr) under UV light irradiation ($\lambda > 270$ nm) for (a) 0.5 h and (b) 2 h, and visible light irradiation ($\lambda > 450$ nm) for (c) 2 h.

UV light irradiation ($\lambda > 270$ nm) of the Cr-HMS in the presence of NO in the gas phase at 275 K led to the photocatalytic decomposition of NO and the evolution of N_2, N_2O and O_2. The Cr-HMS also showed photocatalytic reactivity even under visible light irradiation ($\lambda > 450$ nm). As shown in Fig. 2, the N_2 yields increase linearly with the irradiation time. The reaction stopped immediately when irradiation was ceased. Formation of these reaction products was not detected under dark conditions, or from irradiation of the HMS itself without Cr-oxide. After prolonged irradiation, the amount of decomposed NO to form N_2 per total number of Cr ions included within the catalyst exceeded unity [after 96 h on the Cr-HMS (0.02 wt% as Cr)]. These results clearly indicate that the presence of both Cr-oxide species (included within the HMS) as well as light irradiation are indispensable for the photocatalytic reaction to take place and that the direct decomposition of NO to produce N_2, O_2 and N_2O occurs photocatalytically on the Cr-HMS. Although the reaction rate under visible light irradiation is less than under UV light irradiation, the selectivity for N_2 formation (97%) under visible light irradiation is higher than that of UV light irradiation (45%). These results indicate that Cr-HMS can absorb visible light and act as an efficient photocatalyst under not only UV light but also visible light irradiation, and especially, Cr-HMS can be useful to form N_2 under visible light irradiation.

The addition of NO to the Cr-HMS led to an efficient quenching of the photoluminescence spectrum of the catalyst, its extent depending upon the amount of NO added. These results indicate that the charge transfer excited state of the tetrahedrally coordinated isolated Cr-oxide moieties, $(Cr^{5+}–O^{-})^*$, easily interact with NO, and this photo-excited species plays an important role in the photocatalytic reaction under UV and visible light irradiation.

On the other hand, light irradiation of the Cr-HMS in the presence of propane and O_2 led to the photocatalytic oxidation of propane. As shown in Fig. 3, partial oxidation of propane with a high selectivity for the production of oxygen-containing hydrocarbons such as acetone and acrolein proceeds under visible light irradiation, while further oxidation proceeds mainly under UV light irradiation to produce CO_2 and CO. The selectivity of partial oxidation production under visible light irradiation observed at 12% propane conversion is higher than that observed under UV light irradiation at 26% conversion and even under UV light irradiation for the shorter reaction time with 11% conversion. These results indicate that the tetrahedrally coordinated, isolated Cr-oxide moieties in HMS can exhibit an efficient photocatalytic reactivity for the oxidation of propane under visible light irradiation with a high selectivity for the partial oxidation of propane.

The present results have clearly demonstrated that the Cr-HMS can absorb visible light and act as an efficient and selective photocatalyst under visible light irradiation. This photocatalytic system with tetrahedrally coordinated Cr-oxide moieties dispersed on mesoporous silica seems to be a good candidate for the conversion of abundant visible or solar light energy into useful chemical energy.

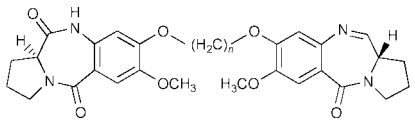
Mixed imine–amide pyrrolobenzodiazepine dimers have been prepared which exhibit potent antitumour activity and have significant DNA binding affinity; one of them, 1c, has been shown to cause a remarkable rise in the melting temperature of calf thymus DNA.

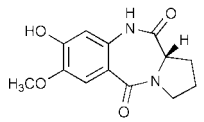
There has been increasing interest in discovering and developing small molecules that are capable of interacting with nucleic acids in a sequence-selective manner.[1–3] Such compounds have potential in the therapy of genetic-based diseases (some cancers),[4] diagnostics, and validation of DNA sequences. The pyrrolo[2,1-*c*][1,4]benzodiazepines (PBD's) are a well known class of antitumour antibiotics with sequence-selective DNA binding ability that are derived from various *Streptomyces* species. Their interaction with DNA has been extensively studied and is considered unique since they bind within the minor groove of DNA, forming a covalent aminal bond between the C11 position of PBD B-ring and the N2-amino group of a guanine base.[5] Further, the requirement of (*S*)-stereochemistry at C11a for these compounds enables a snug fit in the minor groove of DNA.[6] It has also been shown that PBD's inhibit both endonuclease activity and *in vitro* transcription in a sequence-selective manner.[7]

The naturally occurring PBD's (*e.g.* anthramycin and tomaymycin) span approximately 3 base pairs with a preference for purine–guanine–purine sequences. Thurston and co-workers[8] have synthesized C8 diyldioxy ether-linked PBD dimers (DSB-120), that span approximately six base pairs of DNA and in which the sequence selectivity is also increased (*e.g.* purine–GATC–pyrimidine for DSB-120). Moreover, the cytotoxic potency and large change in calf thymus (CT) DNA melting temperature has been attributed to its ability to irreversibly cross-link DNA *via* guanine residues on opposite strands because of the presence of two active sites (*i.e.* two imine functionalities). Recently, another new cross-linking PBD dimer (SJG-136) having C2/C2′-*exo* unsaturation has been prepared by the same group and exhibits extraordinary DNA binding affinity.[9] It has been established that the imine functionality or its equivalent methanolamine form is a primary requirement for the covalent binding, whereas the non-covalent interactions of PBD's with DNA bases help in rationalising the sequence selectivity and drug orientations.[10] Therefore, it has been considered of interest to design and synthesize C8 linked PBD-dimers, wherein one ring of PBD has the imino function while the other has an amide group. It has been envisaged that such a mixed dimer could offer more insight into not only the covalent binding but also the role played by non-covalent interactions with DNA bases.

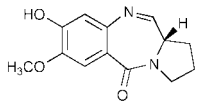
In recent years a number of hybrid molecules containing the PBD ring system have been synthesized to improve upon the DNA binding ability and sequence selectivity.[11] We have been interested in the structural modifications of the PBD ring system and the development of new synthetic strategies.[12–16] In continuation of these efforts, we report a new synthesis of novel mixed dimers of PBD containing the imino function in one of the PBD rings and an amido group in the other, linked at the C8 position by a suitable alkane spacer. Interestingly, the larger sized spacer (n = 5) increases the melting temperature of CT DNA by a significant 17 °C after 18 h incubation at a (PBD) : (DNA) ratio of 1 : 5 for **1c**.



1a n = 3
1b n = 4
1c n = 5



2



3 (DC-81)

Synthesis of the imine–amide mixed dimers of PBD has been carried out employing the commercially available vanillin. Oxidation of vanillin followed by benzylation and nitration by literature methods[17] provides the starting material **4**. L-Proline methyl ester has been coupled to **4** followed by debenzylation with BF_3·OEt_2–EtSH to give the nitro ester **6** (Scheme 1). Another precursor has been prepared from vanillic acid methyl ester **7** by its etherification with dibromoalkanes to afford **8**. The mono alkylation of **7** has been achieved by using 3 molar equivalents of the dibromo alkanes. Nitration of **8** followed by ester hydrolysis and coupling (2*S*)-pyrrolidinecarbaldehyde diethyl thioacetal gives **11**. The key intermediate has been prepared by linking **6** and **11**. Reduction of both nitro groups provides **13** which has a dilactam moiety at one end and the amino functionality on the other. Deprotection of the thioacetal group by using the method of Thurston and coworkers[8] affords the target molecules **1a**–**c** (Scheme 2).

Interestingly, the data presented in Table 1 show that as the size of the linker spacer increases from n = 3 to 5 the DNA stabilization is also enhanced. In this assay for a 1 : 5 molar ratio of (PBD) : (DNA), one of these mixed imine–amide PBD dimers (**1c**) elevates the helix melting temperature of CT DNA by a remarkable to 17.0 °C after incubation for 18 h at 37 °C. Under similar conditions, the dimer having two imino functionalities *i.e.* DSB-120 provides a ΔT_m of 15.4 °C. On the other hand, the naturally occurring DC-81 having only one imino group

[a] For CT-DNA at pH 7.00 ± 0.01, ΔT_m = 66.5 °C ± 0.01 (mean value from 60 separate determinations), all ΔT_m values ± 0.1–0.2 °C. [b] For a 1 : 5 molar ratio of [ligand] : [DNA], where CT-DNA concentration = 100 μM in aqueous buffer [10 mM sodium phosphate + 1 M EDTA, pH 7.00 ± 0.01]. [c] One dose of **1a–c** at 10^{-4} molar concentration.

exhibits a ΔT_m of 0.7 °C. This demonstrates that compound **1c** containing a single imino functionality has a very significant DNA binding affinity. To the best of our knowledge, this is the first synthetic non-cross-linking molecule to exhibit a remarkable DNA binding effect similar to the naturally occurring sibiromycin (ΔT_m = 16.3 °C at 18 h).[11] These data indicates that non-covalent interactions play an important role for the enhancement of DNA binding affinity. The preliminary anticancer assays carried out on three human cell lines; lung (NCI-H460), breast (MCF7) and CNS (SF-268), exhibit significant anticancer activity for these compounds as illustrated in Table 1.

In summary, the synthesis of **1a–c**† reported here describes the importance of non-covalent interactions for increasing the DNA binding affinity and potent antitumour activity of the non-cross-linking mixed imine–amide PBD dimers. These findings may allow researchers to design newer analogues with improved therapeutic potential, particularly for antitumour activity. The sequence selectivity, endonuclease activity and detailed anticancer activity of these non-cross-linking PBD compounds will be reported elsewhere.

We thank the National Cancer Institute, Maryland for the primary anticancer assay in human cell lines. We are also thankful to CSIR, New Delhi for the award of research fellowship to two of us (N. L. and G. R.).

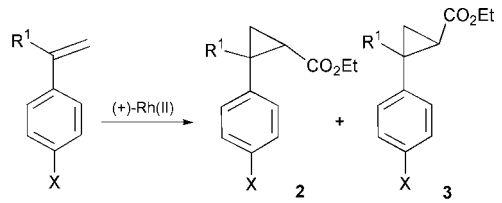
(*P*) and (*M*) dirhodium(II) complexes with *ortho*-metalated aryl phosphines are assessed as chiral catalysts in the enantioselective cyclopropanation of styrenes by ethyl diazoacetate; enantioselectivities up to 91% and up to 87%, respectively, for *cis*- and *trans*-2-arylcyclopropanecarboxylates are observed.

A great deal of effort is presently being devoted to the development of new chiral catalysts to induce enantiocontrol in carbene transfer reactions.[1–3] The catalytic reaction of ethyl diazoacetate with styrene is a model reaction with which stereo- and enantioselectivity for intermolecular cyclopropanation is measured and catalytic effectiveness is determined. Chiral copper catalysts,[4–8] especially those with bis-oxazoline ligands and ruthenium catalysts,[9] have been found to induce the highest levels of enantiocontrol. Thus, enantioselectivities up to 99% for ethyl 2-phenylcyclopropanecarboxylates have been obtained in the cyclopropanation of styrene with ethyl diazoacetate catalyzed by Cu catalysts. In general, chiral dirhodium(II) catalysts do not provide high enantioselectivities; there is a remarkable exception in chiral azetidine-4-carboxylate-ligated dirhodium(II) catalysts.[10] They produce enantioselectivities up to 76 and 52% ee, respectively, for **2a** and **3a** (Scheme 1).†

Dirhodium(II) catalysts of general formula $Rh_2(O_2CR)_2(PC)_2$, containing two *ortho*-metalated aryl phosphines (PC) in a head to tail arrangement,[11] (Fig. 1), have backbone chirality and they can be isolated as pure enantiomers by conventional resolution methods.[12] Until now, all approaches to the design of enantiomerically pure Rh(II) catalysts have depended on the attachment of enantiomerically pure ligands to the dirhodium core.

The racemic $Rh_2(O_2CR)_2(PC)_2$ compounds have been used in intramolecular processes.[13,14] Those with high electron-withdrawing carboxylate groups (CF_3CO_2) have shown the best selectivity values.

We now report, from results obtained with a series of Rh(II) catalysts, $Rh_2(O_2CCF_3)_2(PC)_2$, that they induce low diastereoselectivity in the intramolecular cyclopropanation of styrenes **1a**–**1d** (Scheme 1), but both cyclopropane diastereoisomers are obtained with high optical purity.



1a X = H, R^1 = H
1b X = Cl, R^1 = H
1c X = OMe, R^1 = H
1d X = H, R^1 = Me

Scheme 1 Catalyzed cyclopropanation of styrenes.

Use of catalysts **4**–**8** for cyclopropanation of styrene with ethyl diazoacetate gave the results reported in Table 1 (Fig. 1). Catalysts **4**–**7** showed low diastereoselectivity in the obtention of both diastereoisomers, **2a** and **3a**. However, all of them induced high asymmetry in the cyclopropanation of styrene; those catalysts with a more basic phosphine (catalysts **4**–**6** compared to **7**) led to the best ee values. The influence of the olefin on enantioselectivity was studied using styrenes of varying nucleophilicity (Table 2). Product yields were higher with the more nucleophilic olefins **1c** and **1d**. However, no remarkable differences on diastero- and enantioselectivity were found for catalysts **4**–**7**. These results confirm that degradation to an achiral rhodium catalyst is not a major competing pathway.

Olefin	Yield %	% ee		
		2/3	**2**	**3**
1a	55	48:52	91	87
1b	62	49:51	86	—[a]
1c	88	51:49	—[a]	85
1d	90	51:49	84	—[a]

[a] Not determined.

We suggest that the olefin approaches to the carbenoid through its less substituted carbon and also that the carbene transfer to olefin occurs through an early transition state. The interaction between the carbenoid ester group (CO_2Et) and the olefinic substituents (R, Ar) would be weak in such a case. These two mechanistic details, altogether, could explain the low influence of the olefin on diastereoselectivity observed in our experiments.

A tentative rationale for the observed high ee values for both stereoisomers, and for the sense of asymmetric induction in the cyclopropanation of styrenes with Rh(II) catalysts **4**–**7** is based on the model depicted in Fig. 2 for the *M*-catalyst. The non-metalated aryl substituents of the phosphorus atom protrude into the region where carbene transfer takes place, thereby limiting the possible orientations of the coordinated carbene and favoring those orientations placing the ester group at the less sterically demanding quadrants (orientation $\mathbf{A_1}$ and $\mathbf{B_1}$ in Fig. 2). The cyclopropanation step, $\mathbf{A_1} \rightarrow \mathbf{A_2}$ appears to be more favored than $\mathbf{B_1} \rightarrow \mathbf{B_2}$, since in the latter, a repulsive interaction builds up between the ester group and the metalated aryl group at some level of the proccess.

Additional evidence supporting such a model was obtained from the crystal structure determination of the enantiomerically pure catalyst ***(M)*-8** having bulky carboxylate ligands

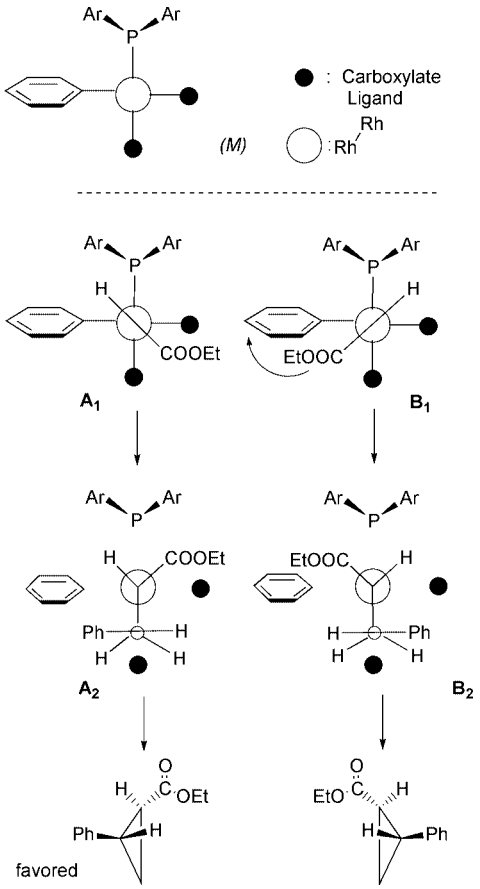

Fig. 2 Model transition state for the reaction of styrene catalyzed by the (*M*)-enantiomer.

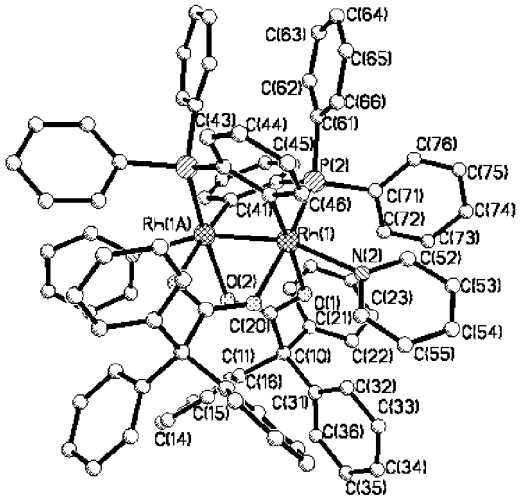

Fig. 3 Molecular view of the complex $Rh_2[(C_6H_5)_3CCO_2]_2[(C_6H_5)_2(C_6H_4)P]_2$ [***(M)*-8**]. Selected distances (Å) are Rh(1)–Rh(1A) = 2.5587(7), Rh(1)–O(2) = 2.151(3), Rh(1)–O(1) = 2.164(3), Rh(1)–P(2) = 2.280(13), Rh(1)–N(2) = 2.302(4). Selected angles (°) are C(41)–Rh(1)–O(2) = 88.08(15), O(2)–Rh(1)–O(1) = 85.65(12), O(2)–Rh(1)–P(2) = 171.46(9), N(2)–Rh(1)–Rh(1A) = 162.02.

$[(C_6H_5)_3CCO_2]$ (Fig. 3). In this case two relevant observations are made: the enantioselectivity was much lower (almost zero for one of the diastereoisomers) and there was a reversal of induction. These two facts may be attributed to increased steric interactions in the area of the carboxylate ligands, due to the higher steric requirements of the $[(C_6H_5)_3CCO_2]$ in **8** compared to (CF_3CO_2) in **4**–**7**, that make a carbenoid intermediate $\mathbf{A_1}$ less favored than $\mathbf{B_1}$ (Fig. 2). Additional studies oriented to confirm the reliability of the model depicted in Fig. 2 are in progress.

In summary, results indicate a high chiral recognition in the intermolecular cyclopropanation of styrenes showed by these dirhodium(II) compounds. The ee values clearly exceed those previously observed with other Rh(II) catalysts for this particular intermolecular reaction.

We thank the Dirección General de Investigación Científica y Técnica (DGICYT) (Project PB98-1437) and the EC (Project TMR Network ERBFMRXCT 60091).

Novel CuX_2-mediated cyclization of acid–base salts of (L)-cinchonidine or (D)-/(L)-α-methylbenzylamine and 2,3-allenoic acids in an aqueous medium. An efficient entry to optically active β-halobutenolides

Received (in Cambridge, UK) 1st November 2000, Accepted 16th January 2001
First published as an Advance Article on the web 15th February 2001

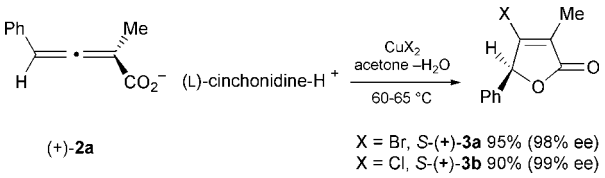
The treatment of 1:1 salts of 2,3-allenoic acid–chiral base with CuX_2 (4 equiv.) in an aqueous medium, *i.e.* acetone–H_2O (2:1), at 60–65 °C afforded β-halobutenolides with high enantiopurities in good to excellent yields.

Polysubstituted butenolides are a class of compounds of current interest due to their potential broad range of biological activities[1] and abundant occurrence in natural products.[2] However, the methods for the highly stereoselective synthesis of optically active butenolides are limited.[3,4] In this paper, we wish to report a highly efficient CuX_2-mediated cyclization of the salts formed between chiral bases and 2,3-allenoic acids. The method provides a novel route to β-halobutenolides with high enantiopurity, important building blocks for polysubstituted butenolides.[5]

Recently, we have developed several methodologies for the synthesis of β-halobutenolides from 2,3-allenoic acids.[5,6] The interesting point of these reactions is that the starting 2,3-allenoic acids are a class of compounds with chirality when properly substituted. Thus, it would be possible to use a cheap optically active base to resolve 2,3-allenoic acids and transfer the axial chirality in allenes into central chirality in butenolides in a highly stereoselective manner. One major issue here is the use of the salt of an optically active base with 2,3-allenoic acids *directly* as the starting point, the release of 2,3-allenoic acids from the salts would not be necessary, which makes this strategy more attractive.

The resolution of racemate 2-methyl-4-phenylbuta-2,3-dienoic acid **1a** with 0.5 equiv. of (L)-cinchonidine, a readily available and relatively cheap base, afforded a salt which could be readily recrystallized in *ethyl acetate* to afford the optically active salt (+)-**2a** in 43% yield with $[\alpha]_D^{20}$ = +85.4°.[7] Release of the acid from the corresponding salt (+)-**2a** by the treatment with dilute H_2SO_4 afforded *S*-(+)-**1a**, indicating the (*S*)-configuration of the allene moiety according to the Lowe–Brewster rule (Scheme 1).[8]

Luckily, when (+)-**2a** was treated with $CuBr_2$ in an aqueous medium (acetone–H_2O (2:1)), at 60–65 °C for 3 h, a methodology recently developed by ourselves for the halolactonization of 2,3-allenoic acids,[6] the reaction afforded (+)-**3a** in 95% yield with 98% ee, [9] the corresponding β-chlorobutenolide (+)-**3b** was also obtained in 90% yield with 99% ee by using $CuCl_2$ instead of $CuBr_2$ (Scheme 2).



With the standard aqueous reaction conditions in hand, a series of β-bromobutenolides with high optical purity were prepared and the results are summarized in Table 1. It is obvious: (1) the yields are from good to excellent; and (2) the efficiency of the chirality transfer process is almost 100% since the %ee of the products from the resolved salts are similar to those from the released free 2,3-allenoic acids (Scheme 3),indicating that the chirality of (L)-cinchonidine has almost no impact on the chirality transfer of the allene moiety. Similar results were obtained for all substrates using $CuCl_2$ in place of $CuBr_2$ to afford β-chlorobutenolides. The absolute configuration of the chiral centers in the products **3c** and **3d** were determined by X-ray diffraction using the bromine atoms as the reference.[10] The absolute configuration of other products are based on these X-ray studies and further confirmed by the study of their CD spectra.[11]

Furthermore, it is interesting to observe when we used (*S*)-(+)-α-methylbenzylamine as the resoluting agent, the salt (−)-**4a** was obtained and its treatment with $CuBr_2$ afforded the opposite enantiomers (*R*)-(−)-**3a** (98% ee) and (*R*)-(−)-**3b** (98% ee) in 90% and 93% yields, respectively (Scheme 4).

By using (*R*)-(−)-α-methylbenzylamine instead of its *S*-enantiomer, the corresponding salt (+)-**4a** afforded the same enantiomer as with (L)-cinchonidine, *i.e.* (*S*)-(+)-**3a** and (*S*)-(+)-**3b** in 92 (98% ee) and 90% yield (97% ee), respectively (Scheme 4).

In conclusion, we have developed an efficient aqueous synthesis of highly optically active β-halobutenolides. The current methodology will show its utility in organic synthesis due to the ready availability of starting materials with different substitution patterns,[7,12] direct cyclization from the salts, and availability of both enantiomers.

At 200 °C and 5 MPa of initial total pressure, the oxidative carbonylation of amines for the synthesis of the corresponding carbamates by Au(I) complexes as catalysts was conducted with excellent conversion and selectivity.

Gold catalysts have been receiving growing attention and many reactions catalyzed over Au catalysts,[1] such as CO oxidation,[2] selective oxidation,[3] water-gas shift reactions,[4] asymmetric aldol reactions,[5] carbonylation of olefins[6] and dehydrogenative dimerization of trialkylstannane,[7] have been reported to be high performance. These reactions indicate that using gold complexes as catalysts for those synthetic reactions traditionally catalyzed with Pd, Rh *etc.* complexes should be not only possible but also practical and even highly efficient.

Produced either by oxidative carbonylation of amines or by reductive carbonylation of nitro compounds in the presence of an alcohol, carbamates as intermediates for the synthesis of isocyanates by non-phosgene routes have been extensively studied over the past two decades.[8] Pd, Ru and Rh complexes and other transition metals were employed as the catalysts,[9] and complexes of Pd coordinated with N-containing compounds were among the most effective of these catalyst systems.[10] Although reductive carbonylation of nitro compounds should be the more attractive route for indirect production of isocyanates, the occurrence of catalyst deactivation due to the reduction of noble metal ions, *e.g.* Pd^{2+} to Pd^0, under the strong reductive conditions may be difficult to be overcome,[11] and the catalyst systems were generally more complicated than those for oxidative carbonylation. Furthermore, no studies concerning the oxidative carbonylation of amines or reductive carbonylation of nitro compounds for carbamate formation by Au complexes have been reported yet.

Herein, the first example of the oxidative carbonylation of amines for the synthesis of the corresponding carbamates by Au complexes, *i.e.* $HAuCl_4$ **1**, $Au(PPh_3)Cl$ **2**, $Au(PPh_3)_2Cl$ **3**, $Au(PPh_3)NO_3$ **4** and $[Au(PPh_3)]_2S$ **5** as the catalysts with excellent performance, is reported:

$$R(NH_2)_n + CO + O_2 + R'OH \xrightarrow[PPh_3]{[Au(PPh_3)_x]_yZ} R(NHCO_2R')_n + H_2O$$

R = Ph, Alkyl; R′ = CH_3, CH_3CH_2; $n = 1$ or 2;

$x, y = 1$ or 2; Z = Cl, NO_3, S.

The oxidative carbonylation of a series of aromatic and aliphatic amines over the above mentioned Au(I) complexes was examined (Table 1). When aniline as substrate was subjected to carbonylation, different catalytic performances were observed over catalysts **1**–**5**. The highest selectivity was 70% over **2**, and the highest conversion 62.2% over **3**. The catalyst **5** was even less effective than catalyst **1**. The main by-product resulting from catalyst **1** was azobenzene, while *N*-methylaniline and quinazoline were detected over the catalysts **2**–**5**. Other by-products such as azoxybenzene over catalyst **1** and quinazoline over catalyst **2** were also identified. When catalyst **1** was employed, decomposition of the catalyst, *i.e.* reduction of Au^{3+} to Au^0, occurred. A very thin film, light-yellow in color, was observed to have been deposited on the wall of the glass tube inside the reactor after the reaction; no such phenomenon was observed with catalysts **2**–**4**.

The conversion and selectivity for the desired products were greatly enhanced if extra PPh_3, (0.1 g) was further added into the reaction, entries 6–9. It is noteworthy that 97.2% conversion and 89% selectivity were achieved over catalyst **2** + PPh_3. The TOF reached 36, which is comparable to the result of $Pd(PPh_3)_2Cl_2$ (**6**) + PPh_3 used as the catalyst, where 98.5% conversion and 86% selectivity was obtained, entry 8. Such enhancement in catalytic activity may partially be attributed to the stabilization of organic Au(I) complexes by the additional PPh_3 which may replace the oxidized ligand, since it is possible that small amounts of PPh_3 could be oxidized under oxidative conditions during the reaction. The same main by-product, quinazoline, was found over catalysts **2** + PPh_3 and **6** + PPh_3, indicating that a similar reaction mechanism occurred over catalysts **2** and **6**.

Using alcohol as one of the reaction substrates and solvent had a strong impact on the reaction. Much higher selectivity could be achieved when methanol was used, entry 6, although slightly higher conversion was obtained with ethanol under the same reaction conditions, entry 7. This may be due to the easier formation of quinoline in the simultaneous presence of aniline and ethanol. Treatment of 2,4-diaminotoluene and 4,4′-diaminodiphenylmethane with carbon monoxide and methanol in the presence of catalyst **2** + PPh_3 afforded excellent conversion and selectivity, entries 11 and 12. The main by-product from 2,4-diaminotoluene was the mono-carbonylated product, while the main by-product from 4,4′-diaminodiphenylmethane was 4,4′-diaminobenzophenone.

An attempt was also made to test the oxidative carbonylation of aliphatic amines using catalyst **2** + PPh_3, the best catalyst system found for the carbonylation of aromatic amines. Although the conversion of the corresponding amines was almost complete for n-hexylamine (entry 13) and cyclohexylamine (entry 14), poor selectivities for the desired product were obtained, but relatively high selectivities for the corresponding alkylureas were achieved. For 1,6-hexanediamine (entry 15) almost no desired product could be observed, but it is noteworthy that 63% selectivity for *N*,*N*′-hexylmethylene diformamide could be achieved. This may imply that the Au(I) complexes could be a promising catalyst for the synthesis of other N-containing compounds from aliphatic amines under suitable reaction conditions.

In summary, the experimental results suggest that organic Au(I) complexes show an excellent performance towards the oxidative carbonylation of aromatic amines to form corresponding carbamates, and also exhibit a promising catalytic performance towards the carbonylation of aliphatic amines to produce either alkylureas or formamides. To the best of our knowledge this is the first reported study of Au(I) complexes for this kind of reaction.

14	cyclohexyl-amine	$Au(PPh_3)Cl$ $+PPh_3$	100	58	30			22	18(2)
15	1,6-hexane-diamine	$Au(PPh_3)Cl$ $+PPh_3$	99	–	30	$(CH_2)_6(NHCO_2CH_3)_2$	$(OHCHN)_2(CH_2)_6$	63	37

[a]Mol substrate converted per mol Au per hour. [b]Unidentified in brackets. [c]Ethanol as solvent. [d]2,4-Diaminotoluene. [e]4,4′-Diaminodiphenylmethane. [f]4,4′-Diaminobenzophenone.

The following experimental procedure was used: the syntheses of the Au(I) complexes were as reported in previous papers.[12] $Pd(PPh_3)_2Cl_2$ (**6**) was also employed for the purpose of comparison. The reactions were performed in glass tubes with magnetic stirring within an autoclave. For each reaction, 0.05mmol Au(I) complex or the mixture of 0.05 mmol Au(I) complex and 0.1 g PPh_3 was added to the solution of amine (0.5 g or 0.5 ml) and alcohol (20 ml, MeOH or EtOH) at rt. Then O_2 (99.99% purity 1 MPa) and CO (99.99% purity, 4 MPa) were respectively introduced into the reactor to 5 MPa total pressure. The reaction was allowed to proceed at 200 °C for 3 h and the resulting liquid mixture was then directly analyzed with a HP 6890/5973 GC-MS.

***In situ*, time resolved, simultaneous multi-edge energy dispersive EXAFS (EDE) reveals Ge precursor induced perturbations of the reduction of supported $Pt(acac)_2$ to form Pt particles, and details the subsequent thermally induced formation of PtGe species.**

Many heterogeneously catalysed processes may be enhanced through the formation of alloyed, rather than elemental, metal particles (*e.g.* hydrocarbon reforming, PtSn,[1] PtRe[1] and PtGe[2,3] rather than Pt) or *via* addition of other oxides (*e.g.* ZnO to Cu/Al_2O_3 in methanol synthesis[4]). It is therefore of considerable interest to delineate the details of how these interactions evolve during synthesis, and are affected by the synthetic approach applied.

Time resolved measurements have the potential for gaining an understanding of the processes resulting in a given catalyst; indeed the combination of Quick EXAFS (QuEXAFS)[5] [or energy dispersive EXAFS (EDE)[6]] and XRD has been reported, but only for the interrogation of a one-elemental edge in EXAFS (Cu K in both cases). EDE has the potential for extremely rapid data acquisition, and therefore considerable potential for quantitative structural and kinetic determinations: we have previously demonstrated this for heterogeneous systems on a timescale of 1–8 s for supported metal systems.[7,8] EDE also potentially allows truly simultaneous multiple edge sampling and analysis. This situation cannot be achieved by QuEXAFS,[5,9] as this still requires movement of a monochromator through a given energy window. Here we show the application of EDE to follow the changes that lead to the formation of Pt/Ge alloy particles from mono-metallic precursors supported upon H_ISiO_2 mesoporous silicas *via in situ* sampling of the Pt L_{III} and Ge K edges simultaneously. PtGe catalysts have been shown to exhibit enhanced properties in hydrocarbon reforming reactions[2,3,10,11] particularly, increased selectivity toward aromatics[10] and tolerance towards sulfur,[11] the latter property being associated with the formation of PtGe alloy particles, which requires reduction at 773 K in H_2 for typical H_2PtCl_2/$GeCl_4$/Al_2O_3 derived catalysts.[11]

The preparation of the mesoporous silica has been described previously.[12] In the current case Pt was incorporated in these supports through impregnation [$Pt(acac)_2$] in dry toluene. The toluene was subsequently removed by rotary evaporation and drying. $GeBu_4$ was incorporated by injection under vacuum to the pre-prepared $Pt(acac)_2/H_ISiO_2$ sample. The final catalyst precursors contained 5 wt% Pt and 1.9 wt% Ge yielding a Pt : Ge ratio of 1 : 1. EDE experiments were performed using a flow microreactor described previously,[7,8] based around thin walled quartz tubes, into which the sieved (*ca.* 100 μm) particles of catalyst precursors were packed into a bed (10 mm long). The experimental conditions used for reduction of these samples under 10% H_2–N_2 (8 ml min^{-1}) were identical to those described previously for the reduction of the analogous elemental [$Pt(acac)_2/H_ISiO_2$] system.[7] The EDE measurements were made on station 9.3 at the SRS using a four-point bending mechanism[13] to manipulate a Si[111] monochromator. Spectra were recorded in 8 s (8 ms × 1000 scans). Data reduction was carried out using PAXAS[14] with multiple scattering spherical wave analysis performed using EXCURVS98.[15] Errors in coordination number are quoted at a fixed ±10%.

Fig. 1 shows EDE spectra derived simultaneously from both Pt L_{III} and Ge K edges whilst the $Pt(acac)_2/GeBu_4/H_ISiO_2$ sample was heated to 673 K under a flow of H_2–N_2. At least two regions of change can be observed as the sample is reduced. The first, occurring in the range 450–473 K, is observed only in the Pt edge spectra with the Ge EXAFS remaining essentially constant. It is only at higher temperature (> 543 K) that changes in the Ge EXAFS, together with further changes in the Pt spectra, are evident. Fig. 2 shows representative k^3 weighted EXAFS from both Pt and Ge edges at 543 K during *in situ* reduction of the sample; Table 1 summarises both the local order and statistical data resulting from spherical wave analysis. The EDEXAFS (8 s of acquisition time) from the Pt edge may be reasonably analysed in the range 2–11 $Å^{-1}$; for the Ge edge this data length is reduced to *ca.* 9 $Å^{-1}$. At temperatures as low as 543 K, Pt–Ge interactions and alloy formation are indicated. At this temperature it also reveals the persistence of Ge–C interactions.

Fig. 3 shows the results of a comprehensive analysis of the spectra shown in Fig. 1 and gives a detailed insight into the formation of the PtGe particles. The temperature dependence of the Pt–Pt, Pt–Ge, Ge–Pt coordination numbers are shown in the temperature range 300–673 K; no Ge–Ge interactions were observed. This clearly shows that the reduction of the precursor

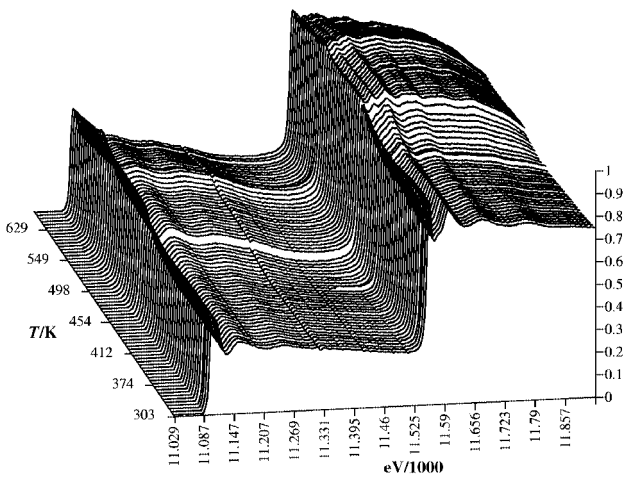

Fig. 1 EDEXAFS spectra for the Pt L_{III} and Ge K edges in the temperature range 298–670 K. Each spectra represents a total acquisition time of 8 s (1000 acquisitions @ 8 ms each).

[a] Δk(Pt L_{III} = 2–12 Å^{-1}).

system to form Pt–Ge alloy particles occurs in at least three stages and allows determination of the effect of Ge on the reductive process.

The initial reduction stage appears to involve only the formation of Pt clusters with no concomitant formation of Pt–Ge bonds. The formation of the Pt particles however is very different to that observed for the analogous Pt only system.[7] The initial reduction is similar in terms of light-off temperature, however, whereas the elemental system develops a Pt–Pt coordination of 10 (±1) over a *ca.* 20 K temperature range, the Pt–Ge sample displays a much slower evolution of Pt–Pt coordination: over a *ca.* 40 K temperature window only a metastable coordination of 4 (±0.4) is reached. At temperatures >440 K the observed Pt–Pt coordination slowly rises to a maximal Pt–Pt coordination of 9 (±1.8) attained at *ca.* 475 K. Low Z (C/O) coordination (from the Pt L_{III} edge) is also retained over a considerably extended temperature range relative to that observed in the elemental system.

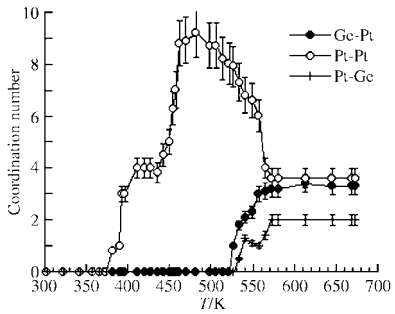

Fig. 3 Temperature dependence of Pt–Pt, Pt–Ge, Ge–Pt coordination during reduction of the $Pt(acac)_2/GeBu_4/H_1SiO_2$ sample from analysis of individual spectra shown in Fig. 1. Error bars are shown at a fixed ±10%.

At temperatures above *ca.* 460 K the Pt–Pt coordination starts to decline indicating either the onset of alloy formation and/or a morphological change in the particulate Pt. Concomitant changes in the Ge environment start to be observable with a gradual loss of low Z (C/O) coordination. Above >500 K a signal fitting Pt–Ge components is apparent. These interactions continue to evolve until a stable phase emerges above 570 K, characterised from the Ge edge by an average coordination of 3.4 Pt coordination, and from the Pt edge by 3.4 Pt and 2 Ge. It is not however until 650 K that the fitting of low Z components at the Ge K edge is not observed to produce a significant reduction in obtained R factor.

Reduction of the mixed organometallic system results in significant alloy formation at temperatures *ca.* 250 K lower than seen in more conventional systems supported upon Al_2O_3,[11] though carbon retention from cracking of the ligands initially present persists to *ca.* 650 K. The EDEXAFS results also indicate the production of alloy particles that are smaller than the elemental particles produced from the Pt-only system;[7] this differential is deemed to be a direct result of the Ge induced modification of the initial stage of the reductive process.

This work shows that considerable structure/phase information may be derived from explicit analysis of the EXAFS from two edges interrogated simultaneously. This methodology could be used for the simultaneous interrogation of a number of systems containing elements showing K or Li_{III} edges in the correct energetic proximity (see ESI†), for example Pt–Au, Cu–Ni and the aforementioned, Cu–Zn system.

This work was carried out under the 'Catalysis and Chemical Processes' initiative of the EPSRC, who are also thanked for access to CLRC Daresbury, postdoctoral funding to M. A. N. and doctoral funding for S. G. F. and T. C. (with CASE support from BNFL Plc). The University of Southampton and BP Chemicals Plc are thanked for provision of a studentship to S. T. We would also like to acknowledge the technical assistance of Mike Caplin, Melanie Hill, Bruce Hancock, and John James.

Synthesis and assembly of $BaWO_4$ nanorods

Serena Kwan, Franklin Kim, Jennifer Akana and Peidong Yang*

First published as an Advance Article on the web

Uniform, large aspect-ratio, monocrystalline $BaWO_4$ nanorods were synthesized using a reversed micelle templating method; novel nanorod superstructures were observed in both as-made materials and Langmuir–Blodgett monolayer assemblies.

There has been a recent heightened interest in one-dimensional nanoscale building blocks, such as nanotubes, nanowires, and nanorods.[1–10] These 1-D systems offer fundamental scientific opportunities for investigating the influence of size and dimensionality with respect to their collective optical, magnetic and electronic properties. Recent efforts have been focused on the development of new synthetic methodologies for making nanorods with uniform sizes and aspect ratios, including, for example, $BaCrO_4$,[4] CdSe,[1,8] Fe,[5] Ag[3] and Au nanorods.[2,7,9] Simple chemical reactions in a micellar or reversed micellar solution have been shown to be powerful in the synthesis of colloidal particles of different sizes and shapes. In these reactions, the size and shape control of the resulting particles was usually achieved by adjusting the water : oil : surfactant ratio. Nanorods of different compositions reported so far generally have small aspect ratios (length : diameter) of 2–10.

With its interesting excitonic luminescence, thermoluminescence and stimulated Raman scattering (SRS) properties, $BaWO_4$ is a potential material for designing all-solid-state lasers that can emit radiation in a specific spectral region and will have applications for medical treatment, up-conversion lasers and spectroscopy.[11,12] Herein, we report a simple reversed micelle templating method for the synthesis of uniform $BaWO_4$ nanorods. These nanorods are highly uniform with diameter of 9.5 nm and length of 1500 ± 200 nm. Owing to the high uniformity of these nanorods, they spontaneously form superstructures resembling crossed haystacks. Furthermore, upon removal of excess surfactant in the system, these uniform nanorods can be used as anisotropic building blocks for Langmuir–Blodgett studies.

A simple reversed micelle templating method was used to synthesize uniform $BaWO_4$ nanorods. Briefly, barium bis(2-ethylhexyl)sulfosuccinate [$Ba(AOT)_2$] reverse micelles[4] were added to NaAOT microemulsion droplets containing sodium tungstate (Na_2WO_4), to give final molar ratios of $[Ba^{2+}]:[WO_4^{2-}]$ = 1 and water content $[H_2O]:[NaAOT]$ = 10. This produced a white precipitate *ca.* 2 h after addition of the reactants under ambient conditions. Transmission electron microscopy (TEM) images of the samples taken from the liquid phase of the microemulsion show nanorod arrays resembling crossed haystacks (Fig. 1a,b). The nanorods are uniform in length (*ca.* 1500 nm) and diameter (*ca.* 9.5 nm), and generally arrange in a side-by-side geometry. Energy dispersive X-ray analysis and X-ray diffraction indicate that the nanorods are single crystalline $BaWO_4$ with a tetragonal Scheelite unit cell (a = 0.561 nm, c = 1.272 nm). Eight slightly broadened diffraction peaks with d spacings of 0.511, 0.336, 0.317, 0.280, 0.245, 0.210, 0.198, 0.187 nm can be readily indexed as (101), (112), (004), (200), (114), (204), (220), (116), respectively, of the Scheelite structures. No impurity peaks were detected in the experimental range.

High resolution TEM studies were carried out to examine the crystallinity of individual nanorods. It was found that each nanorod was separated from the neighboring ones by 1–2 nm (Fig. 1c), consistent with the presence of the surfactant molecules. Although the surface of these nanorods is slightly zigzag shaped, high-resolution TEM images (Fig. 1d) show that these nanorods are monocrystalline. The lattice fringe in Fig. 1d has a spacing of 0.317 nm, indicating that these nanorods grow preferentially along their c axes.

These as-made nanorods were washed with isooctane to remove excess surfactant AOT so that they could be redispersed in isooctane to make a stable nanorod colloidal suspension. This colloidal suspension was spread dropwise (typically 1–2 ml of 3 mg ml^{-1} concentration) on the water surface of a Langmuir–Blodgett (LB) trough (Nima Technology, M611). The nanorod monolayer was then compressed slowly while the surface pressure was monitored. During the compression process, the nanorod assemblies at the water–air interface were transferred carefully onto transmission electron microscope (TEM) grids covered with continuous carbon thin film using the Langmuir–Schäffer horizontal liftoff procedure. Initially, these nanorods were fairly dispersed; the directors of nanorod are isotropically distributed, and no superstructures were observed (Fig. 2a). After compression, these nanorods tend to align in roughly the same direction and form a nematic layer (Fig. 2b). With strong compression, these nanorods form bundles that have almost perfect side-by-side alignment between the nanorods (Fig. 2c).

It should be mentioned that the organization of the $BaWO_4$ nanorods here differs significantly from the assembly of the short $BaCrO_4$ and CdSe nanorods where ribbon-like and vertical rectangular/hexagonal superstructures are favored.[1,4] We believe this is due to the higher aspect ratio (*ca.* 150) of our

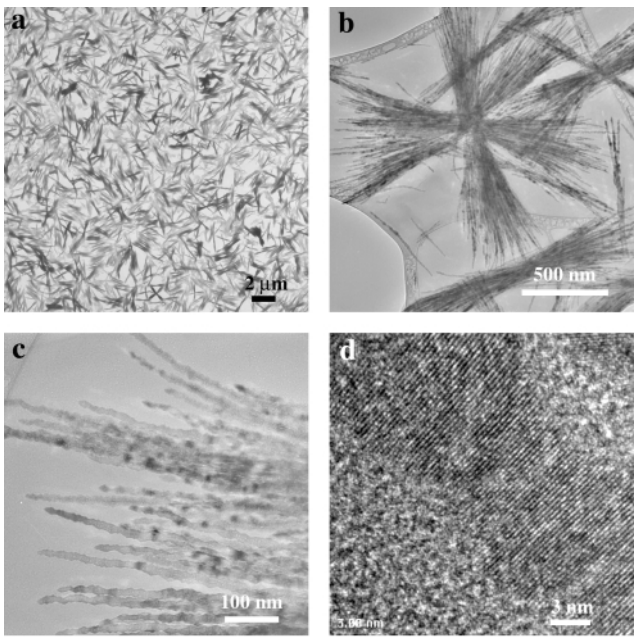

Fig. 1 TEM images of the as-made $BaWO_4$ nanorod assemblies. (a) Large area overview of the sample; (b) individual crossed haystack nanorod superstructure; (c) high magnification image of the assembly; (d) high resolution image of individual monocrystalline nanorods showing the lattice fringe.

nanorods as compared with those (2–10) of $BaCrO_4$–CdSe systems. With a larger aspect ratio, it is less favorable for the nanorods aligning vertically on top of substrates (TEM support) to form a vertical superlattice, instead they prefer to lie parallel to the substrate. The reasons for these rods to align in parallel are two-fold: first, within hard-rod approximation,[13–15] this side-by-side ordering occurs in order to maximize the entropy of the self-assembled structure by minimizing the excluded volume per particle in the array as first proved by Onsager.[15] Secondly, the higher lateral capillary forces along the length of a nanorod, as compared with its width, could be another important driving force for the side-by-side alignment of nanorods rather than end-to-end. We expect that the super-structural formation of these large aspect ratio nanorods should be generally applicable to many other metal or semiconductor systems.

This work was supported in part by a New Faculty Award from the Dreyfus Foundation and start-up funds from the University of California, Berkeley. P. Y. thanks the 3M company for an untenured faculty award. We thank the National Center for Electron Microscopy for the use of their facilities.

Synthesis of an amylose–polymer inclusion complex by enzymatic polymerization of glucose 1-phosphate catalyzed by phosphorylase enzyme in the presence of polyTHF: a new method for synthesis of polymer–polymer inclusion complexes

Jun-ichi Kadokawa,* Yoshiro Kaneko, Hideyuki Tagaya and Koji Chiba

Department of Chemistry & Chemical Engineering, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992-8510, Japan. E-mail: kadokawa@chem.yz.yamagata-u.ac.jp

Received (in Cambridge, UK) 10th October 2000, Accepted 23rd January 2001
First published as an Advance Article on the web 14th February 2001

The enzymatic polymerization of α-D-glucose 1-phosphate (Glc-1-P) with phosphorylase in the presence of polytetrahydrofuran (polyTHF) leads to an amylose–polyTHF (polymer–polymer) inclusion complex; the present reaction system provides a new method for the preparation of polymer–polymer inclusion complexes.

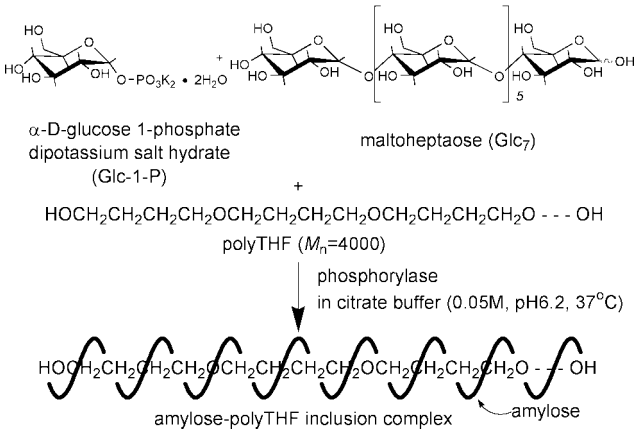
Recent studies on molecular recognition and self-assembly in the field of supramolecular chemistry have received considerable attention because of possible applications in numerous scientific fields, such as materials science and chemical sensing.[1] As it concerns those research fields, host–guest chemistry, which is often compared to the relation between an enzyme and a substrate, has been of importance for chemists, from the viewpoint not only of pure chemistry but also in connection with biological work.[2] Representative host molecules have cyclic structures like crown ethers[3] and cyclodextrins.[4] Amylose, a natural linear polysaccharide linked through (1→4)-α-glycosidic linkages, is also a well-known host molecule forming helical inclusion complexes with monomeric organic compounds by hydrophobic interaction between guest molecules and the cavity of amylose.[5] Although amylose has been reported to form inclusion complexes with a few polymeric guest molecules, *i.e.* polymer–polymer inclusion complexes,[6] the scope and limitation for formation of polymer–polymer inclusion complexes using not only amylose but also the other host molecules has not been well surveyed. The polymeric hosts may not have sufficient ability to include the long chains of the polymeric guests directly into those cavities.

Amylose has been prepared by an *in vitro* approach from α-D-glucose 1-phosphate (Glc-1-P) monomer catalyzed by phosphorylase enzyme.[7] The enzymatic polymerization initiated from a primer of maltoheptaose (Glc_7) proceeds through the following reversible reaction, where a glucose unit is transferred from Glc-1-P to the non-reducing 4-OH terminus of a (1→4)-α-glucan chain, resulting in inorganic phosphate (P).

$$((\alpha, 1 \rightarrow 4)\text{-Glc})_n + \text{Glc-1-P} \rightleftharpoons ((\alpha, 1 \rightarrow 4)\text{-Glc})_{n+1} + \text{P}$$

This polymerization forming amylose has inspired us to develop a new method for preparation of polymer–polymer inclusion complexes, because we have assumed that the polymerization proceeds with the formation of an inclusion complex when the enzymatic polymerization is carried out in the presence of a hydrophobic synthetic guest polymer. Here, we report this new method for preparation of the amylose–polymer inclusion complex by enzymatic polymerization of Glc-1-P monomer catalyzed by phosphorylase enzyme in the presence of polyTHF as a hydrophobic polymer (Scheme 1).†

When the enzymatic polymerization of Glc-1-P from Glc_7 as a primer catalyzed by the phosphorylase (E.C.2.4.1.1)[8] in citrate buffer was carried out in the presence of polyTHF (M_n = 4000), the inclusion complex was obtained (Scheme 1), and its structure was characterized by X-ray powder diffraction and ^{1}H NMR measurements.



Scheme 1

The X-ray powder diffraction scan of the product indicates two strong diffraction maxima at 2θ = 12.4 and 19.8°, corresponding to d = 7.1 and 4.5 Å, respectively. The X-ray pattern of the product is completely different from that of amylose and polyTHF, and is similar to that of the inclusion complexes of amylose with monomeric compounds as shown in previous studies.[9] These data indicate that the product has a conformation similar to that of the helical inclusion complexes obtained from amylose and monomeric guests.

The ^{1}H NMR spectrum in DMSO-d_6 of the product in Fig. 1 shows the signals due not only to the amylose but also the polyTHF, in spite of the washing with MeOH, which is a good solvent of polyTHF. Furthermore, the methylene peak $\mathbf{H_a}$ of polyTHF is broadened and shifts to upfield (δ 1.48) compared to that of the original polyTHF (δ 1.50). This is because each methylene group of polyTHF is basically immobile and interacts with the protons inside the cavity of the amylose. When polyTHF was added to the NMR sample of the product in DMSO-d_6, two different signals due to methylene protons $\mathbf{H_a}$ of polyTHF were observed. This result suggests that the polyTHF of the product exists in a different environment. These NMR data can be taken to support the structure of the helical inclusion complex, which was also confirmed based on the spin-lattice relaxation time (T_1) measurements in the ^{1}H NMR analysis.‡ The T_1 value of the methylene peak $\mathbf{H_a}$ of polyTHF in the product was 0.24 s, whereas that of the original polyTHF was 0.74 s. The shorter T_1 in the product confirms the restriction of the methylene movement due to included conditions.

When the NMR sample was kept at rt, the intensity of the methylene peak $\mathbf{H_a}$ of polyTHF gradually decreased and the solution became turbid. These observations indicate that polyTHF was coming out of the amylose cavity and precipitating owing to the relative lower solubility of the polyTHF in DMSO-d_6. The degree of polymerization (DP) value of the precipitated polyTHF was calculated from ^{1}H NMR analyses to be *ca.* 39 (M_n = 2800), indicating that amylose preferred to

DOI: 10.1039/b008180i

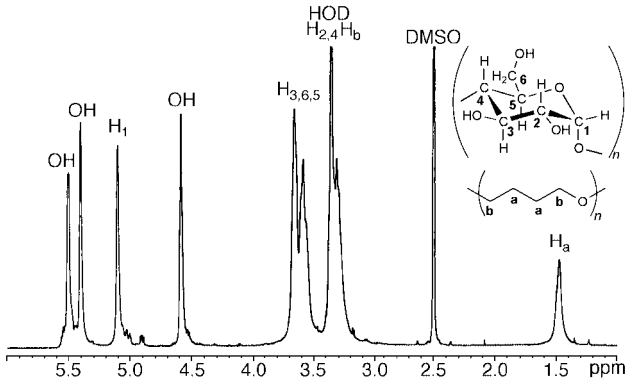


Fig. 1 ^{1}H NMR spectrum of the product in DMSO-d_6. Chemical shifts were referenced to DMSO (δ 2.50 ppm).

include the relative lower molecular weight polyTHF present in the original polyTHF, with an average molecular weight of 4000 (by ^{1}H NMR); the molecular weight was also estimated by gel permeation chromatographic (GPC) measurement as 3200.

Generally, one helical turn of amylose is composed of *ca*. 6 repeating glucose units when linear molecules of small cross reactional area, *e.g*. fatty acids, are included.[10] The repeat distance of the helix of amylose has been reported as 7.95 Å,[10] whereas the length of one unit of polyTHF is presently calculated as *ca*. 6.0 Å,§ as shown in Fig. 2. Therefore, 4.5 repeating glucose units in amylose correspond to the length of one polyTHF unit (Fig. 2). From the above calculations, the integrated ratio of the signal due to **H_1** of amylose to the signal due to **H_a** of polyTHF (H_a/H_1) in the ^{1}H NMR spectrum is assessed to be 0.89. Actually, the integrated ratio of these two signals in the ^{1}H NMR spectrum of the product was *ca*. 1, relatively close to the calculated value. This also supports the structure of the inclusion complex as shown in Scheme 1.

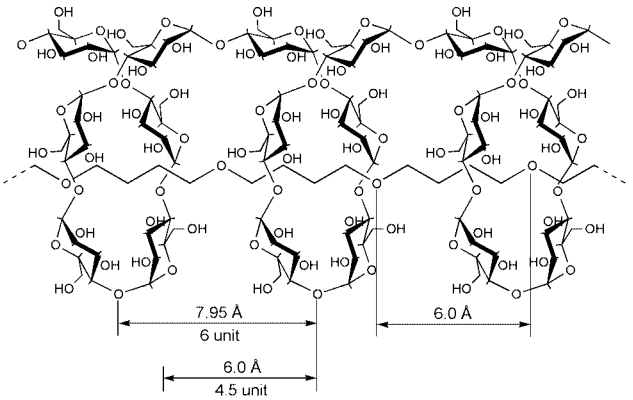

Fig. 2 Illustration of repeat distance of amylose helix and length of one polyTHF unit.

The molecular weight of the amylose in the inclusion complex was evaluated by means of GPC measurement after the acetylation of the inclusion complex and the precipitation of the products into i-PrOH.[11] The GPC value of the precipitated triacetyl amylose was 22800 (M_w/M_n = 1.29), which corresponds to M_n = 12800 of the original amylose. This value is in good agreement with the molecular weight values determined by ^{1}H NMR spectra (M_n = 12200–14600, DP = 75–90).¶ These values correspond to 99–119 Å of molecular lengths in helical form,‖ whereas the chain length of the included polyTHF (M_n = 2800) is calculated as *ca*. 230 Å.§ Therefore, one polyTHF molecule is probably included by two amylose molecules.

The inclusion complex was not formed by mixing amylose (DP = 75–90, M_n = 12200–14600) and polyTHF (M_n = 4000) in the same solvent as described above (sodium citrate buffer, 0.05 mol L^{-1}, pH = 6.20) at 37 °C. This observation suggests that the inclusion complex forms during the enzymatic polymerization. Such a formation behavior for the inclusion complex was further supported by the following experiments. When polyTHF was added to the reaction solution immediately after the general enzymatic polymerization of Glc-1-P had started, an identical inclusion complex to that mentioned above was obtained, judging by the H_a/H_1 value in the NMR spectrum, which was *ca*. 1. However, the H_a/H_1 values decreased as the time delay between adding polyTHF into the solution and the start of the enzymatic polymerization was increased (after 1 h; H_a/H_1 = 0.96, after 3 h; H_a/H_1 = 0.78, after 5 h; H_a/H_1 = 0.33). These observations reveal that the inclusion complex was not formed after the polymerization produced amyloses with relative higher molecular weights. These results indicate that polymerization proceeds with the formation of the inclusion complex.

In conclusion, we have synthesized an amylose–polyTHF (polymer–polymer) inclusion complex by the enzymatic polymerization of Glc-1-P with phosphorylase in the presence of polyTHF. The present reaction system provides a new method for the preparation of polymer–polymer inclusion complexes. Detailed studies on how the complex forms during the polymerization process are now in progress.

We acknowledge the gift of the polyTHF sample from Hodogaya Chemical Co., Ltd., Kanagawa. We are also indebted to Ms M. Karasu and Messrs K. Fujita and S. Nagase of our research group for performing X-ray measurement and technical assistance.

Notes and references

† Synthesis of the amylose–polyTHF inclusion complex: typically, polyTHF (M_n = 4000, 50.0 mg) was suspended in 5 mL of sodium citrate buffer (0.05 mol L^{-1}, pH = 6.20) with ultrasonication and heated to 37 °C. After addition of 2.31 mg (2 μmol) of maltoheptaose (Glc_7) primer, 186 mg (500 μmol) of α-D-glucose 1-phosphate dipotassium salt hydrate (Glc-1-P), and 6.40 mg (~160 units) of phosphorylase, the solution was stirred vigorously for 10 h at 37 °C. The precipitated product was collected by centrifugation, washed with MeOH and water, and then lyophilized, to yield *ca*. 20 mg of the inclusion complex (yields *ca*. 21% based on Glc-1-P and Glc_7, and *ca*. 4% based on polyTHF).

‡ The measurements of T_1 values of inclusion complexes have often been used for the identification of their structures. The T_1 values of the inclusion complexes are shorter than those of the corresponding individual molecules.[3]

§ The calculation of this value was performed with MM2 in the CS Chem 3D program package.

¶ The DP values were calculated by the integrated ratio of the peak of **H_1** of amylose chain (δ 5.1) to the peaks of **H_1** (α and β) of the reducing terminus (δ 4.9 (α) and 4.3 (β)) by the ^{1}H NMR spectra in DMSO-d_6–D_2O. The DPs were changeable depending on reaction conditions, especially the activity of enzyme.

‖ The reported DP 75 and 90 corresponds to 75/6 = 12.5 and 90/6 = 15 helical turns, and hence 12.5 × 7.95 Å = 99 Å and 15 × 7.95 Å = 119 Å represent the length of helical amylose and not that of the extended molecule.

Cationic phosphine ligands with phenylguanidinium modified xanthene moieties—a successful concept for highly regioselective, biphasic hydroformylation of oct-1-ene in hexafluorophosphate ionic liquids

Peter Wasserscheid,*[a] Horst Waffenschmidt,[a] Peter Machnitzki,[a] Konstantin W. Kottsieper[b] and Othmar Stelzer[b]

Received (in Liverpool, UK) 6th December 2000, Accepted 29th January 2001
First published as an Advance Article on the web 14th February 2001

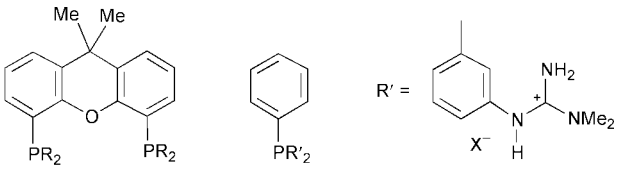
New guanidinium-modified diphosphine ligands with a xanthene backbone show high overall activity and high regioselectivity in the biphasic hydroformylation of oct-1-ene using hexafluorophosphate ionic liquids.

Biphasic catalysis is a well-established method for effective catalyst separation and recycling. In the case of Rh-catalysed hydroformylation reactions this principle is technically realised in the Ruhrchemie–Rhône-Poulenc process where an aqueous catalyst phase is used.[1,2] Unfortunately, this process is limited to C_2–C_5 olefins due to the low water solubility of higher olefins. As an alternative polar medium for biphasic hydroformylation, Chauvin *et al.* suggested novel solvents known as ionic liquids (for general reviews see refs. 3–5). These authors described in detail the biphasic hydroformylation of pent-1-ene with $[Rh(CO)_2acac]$/triarylphosphine in *e.g.* 1-butyl-3-methylimidazolium hexafluorophosphate ($[BMIM]PF_6$).[6,7] However, none of the tested ligands (PPh_3, sulfonated triaryl phosphines) allowed a combination of high activity, complete retention of the catalyst in the ionic liquid and high selectivity for the desired linear hydroformylation product. Recently, some of us described the successful application of cobaltocenium ligands in the Rh-catalysed hydroformylation of oct-1-ene in hexafluorophosphate ionic liquids, demonstrating that the reaction benefits from the use of ligand systems that are specifically designed for this application.[8]

Cationic phosphine ligands containing phenylguanidinium moieties were originally developed to make use of their pronounced solubility in water.[9,10] They have been shown to form active catalyst systems in Pd-mediated C–C coupling reactions between aryl iodides and alkynes[9,11] (Castro–Stephens–Sonogashira reaction) and Rh-catalysed hydroformylation of *n*-hexene in aqueous two-phase systems.[12]

In the present article, we report a new and very general approach to immobilise homogeneous Rh-catalysts in hexafluorophosphate ionic liquids. We found that the modification of neutral phophine ligands with cationic phenylguanidinium groups represents a very powerful tool to immobilise Rh complexes in these ionic liquids. In detail, we describe the synthesis of the new ligand **1a** and its catalytic performance in the biphasic, Rh-catalysed hydroformylation of oct-1-ene using the ionic liquid $[BMIM]PF_6$ as catalyst solvent. This ionic liquid has been prepared from [BMIM]Cl[13] according to a method described by Fuller and Carlin[14] or has been purchased from Solvent Innovation GmbH, Cologne.[15] First experiments aimed to prove the general concept by comparing the ligand PPh_3 with the related guanidinium-substituted ligand **2a** (Table 1, entries 1–5). **2a** was prepared from **2b** by anion exchange with NH_4PF_6 in aqueous solution. **2b** was prepared as previously described by Stelzer *et al.*[10]

In the reaction with PPh_3, good catalytic activity is observed but obviously a significant part of the hydroformylation reaction takes place in the organic layer. After the first catalytic run, 53% of the used Rh is found in the organic layer (according to ICP analysis) (Table 1, entry 1). In contrast, with ligand **2a** the hydroformylation reaction takes place uniquely in the ionic liquid layer (Table 1, entries 3, 4). In the first catalytic run the hydroformylation activity was found to be lower than in the case of PPh_3 (probably due to some mass transfer limitation of oct-1-ene into the ionic liquid). However, due to the excellent immobilisation of the Rh-catalyst with **2a** (leaching is < 0.07% per run according to ICP analysis (detection limit)), the catalytic activity of the ionic catalyst solution is even slightly higher in the third recycling run compared to the first run (probably due to some preformation time of the active catalyst). Since NaTPPTS is the most widely used ligand for immobilisation of Rh-catalysts in aqueous catalyst phases, this ligand was tested as well (Table 1, entries 5, 6). The results reveal good immobilisation of the Rh-complex in the ionic liquid but much lower activity of the resulting catalyst in the hydroformylation of oct-1-ene in comparison with **2a**.



1a: R = R', X = I
1b: R = phenyl
1c: R = H

2a: X = PF_6
2b: X = I

Encouraged by the good results with the guanidinium-substituted ligand, we decided to adopt this new immobilisation

Table 1 Hydroformylation results with different ligands in $[BMIM]PF_6$

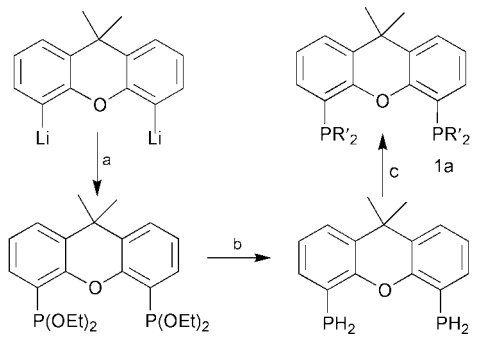
DOI: 10.1039/b009919h

concept to a ligand structure that promises better regioselectivity in the hydroformylation reaction. It is well-known that diphosphine ligands with large natural P–metal–P bite angles form catalysts for highly regioselective hydroformylation reactions.[16] Here, xanthene-type ligands (P–metal–P ~110°) developed from van Leeuwen's group proved to be especially suitable showing, *e.g.* an overall selectivity of 98% towards the desired linear aldeyde in oct-1-ene hydroformylataion.[17–19] Recently, some work has been published where xanthene-based ligands have been immobilised on silica support.[20]

We describe here the first use of xanthene-based ligands in biphasic catalysis using ionic liquids as catalyst solvent. Since xanthene ligands such as, *e.g.* **1b** show highly preferential solubility in the organic phase in a biphasic oct-1-ene/[BMIM]PF_6 mixture, even at rt we developed the guanidinium-modified xanthene ligand **1a** for this purpose. The cationic ligand **1a** was synthesised in four steps according to Scheme 1.†



Scheme 1 Synthesis of ligand **1a**. a) diethylchlorophosphite; b) $LiAlH_4$–chlorotrimethylsilane; c) 4 eq. 3-iodophenylguanidine, 2 mol% Pd_2dba_3 * $CHCl_3$, 80 °C, 24 h in DMF.

The structure of **1a** was established by its mass spectrum and its $^{31}P\{^1H\}$NMR chemical shift ($\delta P = -15.9$) comparable to that of **1b** ($\delta P = -17.9$)[21] and of the *meta* guanidinium phosphines **2a** ($\delta P = -4.7$).[10] The signal at $\delta C = 157.1$ in the $^{13}C\{^1H\}$NMR spectrum of **1a** may be assigned to the carbonium carbon atoms of the guanidinium moieties, the δC value of which compares well with that in **2a**[10] ($\delta C = 155.8$). Some of the $^{13}C\{^1H\}$NMR resonances appear as higher order line pattern (X-parts of AA′X spin systems, A, A′ = ^{31}P, X = ^{13}C) in agreement with the diphosphine structure proposed for **1a**.

After each hydroformylation run, in which **1a** was used as crude product, the organic layer was decanted off (under normal atmosphere) and the remaining ionic catalyst layer remained in the autoclave for the next run. It is noteworthy that the catalytic activity increases during the first runs to obtain a stable level only after the forth recycling run (Table 1, entries 7–10). This behaviour is attributed to a certain catalyst preforming time as well as to impurities of 3-iodophenylguanidine in the used ligand sample (about 5 mass%). The latter are slowly washed out from the catalyst layer over the first catalytic runs. After ten consecutive runs an overall turnover number of 3500 mol oct-1-ene per mol Rh-catalyst could be obtained. In good agreement with the recycling experiments, the Rh-leaching into the organic layer was found to be very low. With AAS and ICP analysis no rhodium could be detected in the organic layer indicating a leaching of less than 0.07%. In all experiments with **1a** very good selectivities for the linear aldehyde were obtained thus proving that the attachment of the guanidinium moiety to the xanthene backbone does not influence its known positive effect on the regioselectivity of the reaction. This is in line with previous IR and NMR studies in our laboratories showing that the steric and electronic properties of arylphosphines is not significantly changed by introduction of polar groups like SO_3^-, PO_3^{2-} and guanidinium in *meta*- or *para*-position to phosphorus.[10]

In conclusion, we could show that the modification of known phosphine ligands with guanidinium groups represents a simple and very efficient method to fully immobilise transition metal complexes in hexafluorophosphate ionic liquids. Hereby, the electronic properties of the phosphine is not changed significantly. Our approach may therefore be of interest not only for hydroformylations but also for many other catalytic reactions in ionic liquids. Further work to develop methods for the immobilisation of neutral catalyst complexes in ionic liquids is in progress.

We wish to thank the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft for financial support. P. W. and H. W. thank Professor W. Keim for his continuous interest in this research and the European Community for founding under the BRITE 96-3745 project.

Oligo-ligandosides: a DNA mimetic approach to helicate formation

Haim Weizman and Yitzhak Tor*

A novel 'ligandoside' dimer, where 2,2′-bipyridine chelators are attached to the anomeric carbons of a D-ribose–phosphate backbone, forms double stranded multinuclear complexes.

The distinct geometry of coordination complexes has been extensively employed for the programmed assembly of exquisite structures.[1] Among these assemblies, double stranded multinuclear complexes known as helicates, have attracted special attention due to their structural resemblance to the DNA double helix and intriguing stereochemistry.[2] While some control over the stereochemical elements involved in helicate formation (*e.g.* the helix chirality and the relative orientation of non-symmetrical strands) has been achieved, controlling this multicomponent assembly remains a challenging problem.[3]

Although assembling helical complexes was inspired by the structure of the DNA double helix, none of the structural elements inherent to DNA has been exploited in helicate design. This is especially intriguing as both the chirality of the DNA helix and its anti-parallel orientation are encoded in the sugar–phosphate backbone.[4] We have sought to explore if incorporation of native DNA structural elements into synthetic binders can be employed to dictate the formation of defined complexes. In these novel structures, ligands are attached to the anomeric carbon of the D-ribose–phosphate backbone replacing the DNA nucleobases (Fig. 1). Unlike helicates where the ligands are integrated into the helical backbone, here the ligands project away from the backbone. Importantly, the backbone phosphodiester groups may be considered as 'built-in' counter ions that can balance the charges associated with metal complex formation. In this contribution we present the design and synthesis of first generation polynuclear complexes based on this approach.

The building block for synthesizing these polytopic ligands is a nucleoside mimic, coined ligandoside, where the heterocyclic base is replaced by a metal-binding ligand.[5,6] Our first model is based on 2,2′-bipyridine (bpy) as a chelator (Scheme 1). A methylene bridge is introduced between the bpy and the sugar to allow for a more relaxed structure and dimensions similar to the DNA double helix. The synthesis of the binding strand utilizes the standard DNA phosphoramidite chemistry.[7] The 5′-protected ligandoside **1** is converted to the phosphoramidite **2** or to the 3′-protected acetate **3**. The two components are then coupled in the presence of 1*H*-tetrazole. Oxidation of the trivalent phosphorus with iodine–water–pyridine mixture gives the phosphate triester derivative **4**. Removal of the protecting groups provides the ditopic ligand **5** (Scheme 1). The structure of **5** was confirmed by NMR and MS.† The development of this phosphoramidite chemistry is particularly attractive for future solid phase synthesis of longer oligomeric strands.

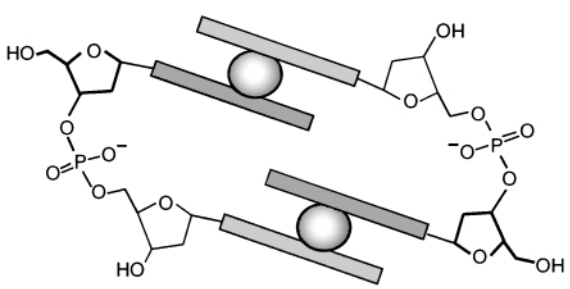

Fig. 1 Schematic representation of a DNA mimetic metal binding dimer.

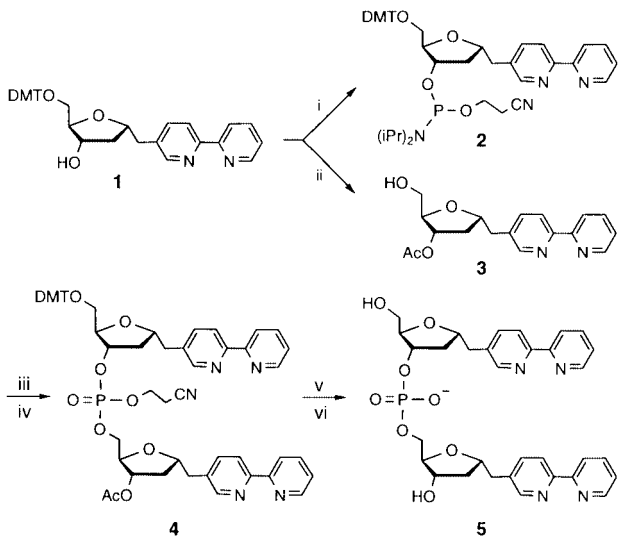
The absorption spectrum of ligand **5** shows the characteristic π–π* absorption bands of the aromatic bpy at 242 and 287 nm. Upon titration with Cu^+ under an inert atmosphere, new bands at 266 and 300 nm appear with three isosbestic points (Fig. 2). An additional metal to ligand charge transfer (MLCT) band at 440 nm, characteristic of copper–bpy complex formation, also emerges. The titration establishes a 1 : 1 ratio between the metal and the ligand. This stoichiometry can be attributed either to the formation of a mononuclear (**5**Cu) or a dinuclear ($\mathbf{5}_2Cu_2$) complex. ESI mass spectrometry reveals the formation of a mononuclear complex only (*m*/*z* 696 calcd. for **5**CuNa). The pattern and isotopic distribution exclude the possibility that this peak represents the doubly charged complex $\mathbf{5}_2Cu_2$.

Titration of ligand **5** with Pd^{2+} results in the appearance of new absorption bands at 248 and 314 nm with two isosbestic points (Fig. 2). The mass spectrum indicates the formation of the mononuclear complex **5**Pd (*m*/*z* 739 calcd. for **5**Pd) together with a dinuclear species (*m*/*z* 1479 calcd. for $\mathbf{5}_2Pd_2$–H, 1500 calcd. for $\mathbf{5}_2Pd_2Na$–H). It is difficult to establish the actual equilibrium ratio between the various species in the mass spectrum due to their different ionization abilities.‡

Upon titration of ligand **5** with Ag^+ in MeOH, complex formation is manifested as a shift in absorption bands to 250 and 296 nm associated with the appearance of three isosbestic points (Fig. 2). This titration verifies the formation of a 1 : 1 complex between the metal ion and the ditopic ligand (Fig. 2). The ESI mass spectrum indicates the formation of the dinuclear complex $\mathbf{5}_2Ag_2$ (*m*/*z* 1483 calcd. for $\mathbf{5}_2Ag_2H$, 1505 calcd. for $\mathbf{5}_2Ag_2Na$).



Scheme 1 *Reagents and conditions*: i, 2-cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropylphophordiamidite, 1*H*-tetrazole, CH_3CN, 1.5 h; ii, a. Ac_2O, Py, 12 h, b. 8 : 2 AcOH–H_2O, 1.5 h; iii, 1*H*-tetrazole, CH_3CN, 3 h; iv, I_2–THF–H_2O–Py; v, 8 : 2 AcOH–H_2O, 1 h; vi, NH_4OH, CH_3CN–MeOH, 12 h.

DOI: 10.1039/b009855h

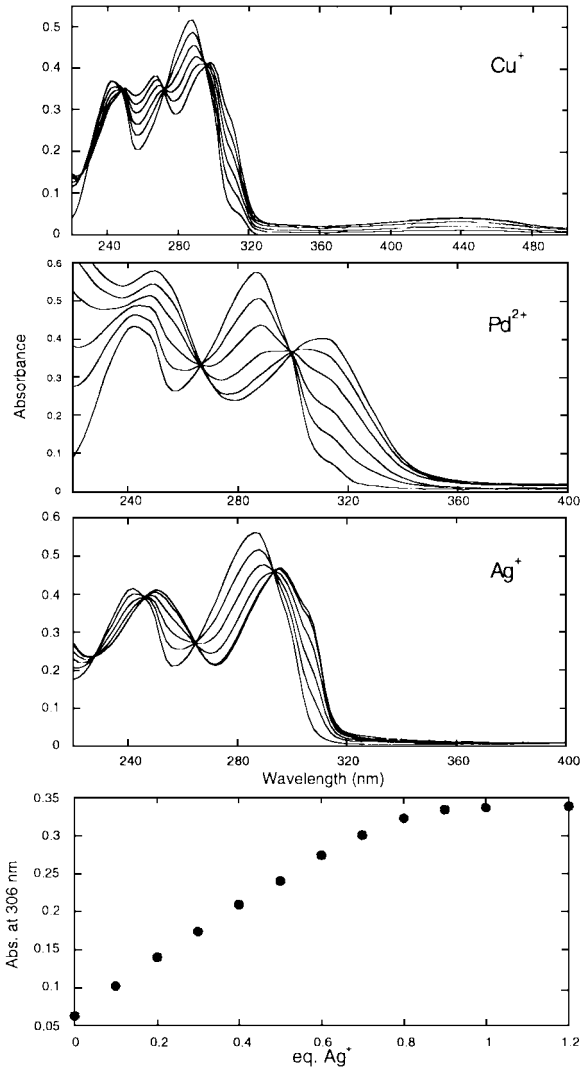


Fig. 2 Uv-vis titrations of di-ligandoside monophosphate **5** in MeOH with a. $Cu(CH_3CN)_4BF_4$ in CH_3CN, b. $Pd(CH_3CN)_4(BF_4)_2$ in CH_3CN, c. $AgCF_3SO_3$ in MeOH. Bottom: a representative curve illustrating the formation of a 1 : 1 complex.

The theoretically predicted pattern and isotopic distribution perfectly matches the experimentally observed one (Fig. 3).

These results demonstrate that threading ligands on a sugar–phosphate backbone can lead to the formation of double stranded structures. In the prototypical ligandoside system described here, the formation of double stranded structures is in competition with the formation of single stranded complexes. This can be attributed to the flexibility of both the sugar–phosphate backbone and the bpy–CH_2 ligand. It is anticipated that further refinement of the ligand structure (*i.e.* changes to the bridging unit between the sugar and the ligand, changes to the connection position of the bpy ring) will further increase the tendency to form double stranded structures.

We thank the National Institutes of Health (Grant Number GM 58447) for generous support.

First published as an Advance Article on the web 14th February 2001

CO interacts with Brønsted acid sites of protonic zeolites to form both ZH···CO and ZH···OC hydrogen bonds (Z = zeolite framework); by means of variable-temperature FTIR spectroscopy, these hydrogen-bonded species were found to be in a temperature-dependent equilibrium which, for the faujasite-type H-Y zeolite, involves an enthalpy change of 4.3 kJ mol^{-1}.

Studies on hydrogen bonding are relevant to a number of biological and chemical fields, including theoretical chemistry,[1] molecular recognition,[2] crystal engineering[3] and catalysis. Regarding the field of heterogeneous catalysis, interaction of CO with acidic hydroxy groups (Brønsted acid sites) of metal oxides and zeolites is well known[4,5] to give rise to OH··CO adducts which can easily be observed by low-temperature IR spectroscopy. In fact, the corresponding shift of the O–H stretching frequency is often used to quantify zeolite Brønsted acidity.[6,7] There is some evidence[8] that CO can also form OH··OC hydrogen bonds when adsorbed on acid (protonic) zeolites, but detailed experimental studies on this interaction mode are not available.

The aim of this work was to analyse variable-temperature FTIR spectra of CO adsorbed on the faujasite-type zeolite H-Y, which show not only that both OH··CO and OH··OC hydrogen-bonded species are formed upon interaction of CO with the zeolite Brønsted acid sites, but also that these hydrogen-bonded adducts are in a temperature-dependent equilibrium; the C-bonded adduct showing the higher interaction energy. These findings extend recent work on cation-exchanged zeolites, where a similar behaviour of adsorbed CO was found.[9] They are also in consonance with the known ability of CO to form hydrogen bonded OC··HF and CO··HF adducts with hydrogen fluoride.[10]

The H-Y zeolite used was prepared following standard methods. For IR studies, a thin self-supported wafer was outgassed (activated) for 2 h at 700 K inside an infrared cell, described elsewhere,[11] which allowed *in situ* high-temperature activation, gas dosage, and variable-temperature spectroscopy to be carried out. After running the blank spectrum of the zeolite, *ca.* 0.3 Torr of helium (to secure good thermal equilibrium)† and 3 Torr of CO (at room temperature) were dosed. The cell was then closed and a series of spectra were taken at *ca.* 10 K intervals from 77 K to room temperature.

As shown in Fig. 1, the blank spectrum of H-Y displays characteristic bands at 3545 and 3648 cm^{-1} arising, respectively, from bridged Si(OH)Al hydroxy groups inside the sodalite cages and in the supercage.[4] A minor silanol band at 3748 cm^{-1} is also observed. After dosing with CO (at 77 K) the band at 3648 cm^{-1} is reduced, and there is a simultaneous growth of a new band at 3353 cm^{-1} which proves hydrogen bonding between CO and the acidic OH groups at the supercage. The band at 3545 cm^{-1} is not affected, which is consistent with the known fact that the sodalite cages are not accessible to CO.

Fig. 2 shows selected variable-temperature spectra in the C–O stretching region. The major band seen at 2173 cm^{-1} (HF band) corresponds to the fundamental C–O stretching mode of OH··CO adducts,[4] while the minor band at 2124 cm^{-1} (LF band), downward shifted with respect to the 2143 cm^{-1} value

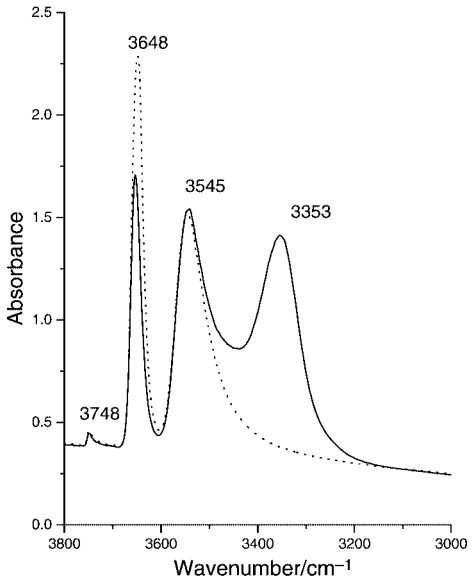

Fig. 1 IR spectra in the O–H stretching region of CO adsorbed, at 77 K, on H-Y. The dotted line is the zeolite blank spectrum while the continuous line is the spectrum obtained after dosing with CO.

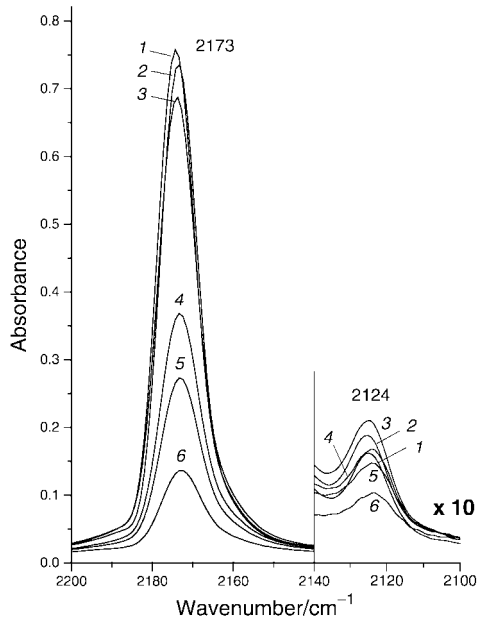

Fig. 2 Selected FTIR spectra of CO (*ca.* 3 Torr) adsorbed on H-Y at variable temperatures: 1, 119; 2, 138; 3, 153; 4, 173; 5, 179; 6, 191 K.

for free CO, is due to OH··OC adducts[9,10,12] in which the CO molecule interacts with a positively charged centre through the oxygen atom. A distinctive feature of the spectra in Fig. 2 is the temperature dependence of the intensity of the HF and LF bands. When temperature is raised from 119 to 153 K, the intensity of the HF band (A_{HF}) decreases, whereas that of the LF band (A_{LF}) increases. At higher temperatures both bands decrease, since the net amount of adsorbed CO decreases, but the ratio of integrated intensities, A_{LF}/A_{HF}, was found to increase over the whole temperature range. It should be noted that the ^{13}CO counterpart of the HF band occurs in the same frequency region as the LF band. For this reason, integrated A_{LF} values were corrected by subtracting 1% of the corresponding A_{HF} values (1% is approximately the natural abundance of the ^{13}CO isotope). A variable contribution from C-bonded ^{13}CO explains the slight variations observed in the peak position of the LF band.

The temperature dependence of the intensity of the HF and LF bands can be explained in terms of a temperature-dependent equilibrium between C- and O-bonded species: [eqn. (1)] (Z = zeolite framework):‡

$$ZH\cdot\cdot CO \rightleftarrows ZH\cdot\cdot OC \quad (1)$$

The equilibrium constant, K, for this process should be equal to the ratio of fractional coverages of O- and C-bonded species. If ε_{LF} and ε_{HF} are the corresponding molar absorption coefficients, the well known van't Hoff relationship [eqn. (2)] leads to eqn. (3):

$$\ln K = -(\Delta H°/RT) + (\Delta S°/R) \quad (2)$$

$$\ln(A_{LF}/A_{HF}) = -(\Delta H°/RT) + (\Delta S°/R) + \ln(\varepsilon_{LF}/\varepsilon_{HF}) \quad (3)$$

Fig. 3 shows that the above equation is obeyed for the whole temperature range studied, therefore proving that hydrogen-bonded OH··CO and OH··OC species are in a temperature-dependent equilibrium. The enthalpy change was found to be $\Delta H° = 4.3$ kJ mol^{-1}, as derived from the linear plot in Fig. 3.§ Knowledge of this enthalpy value is relevant to theoretical studies on weak hydrogen bonding. On the other hand, the amphipathic behaviour shown by carbon monoxide could also be manifested by other heteroatomic molecules adsorbed on zeolites, and this would have important consequences for zeolite mediated catalytic processes. This is a field deserving further studies.

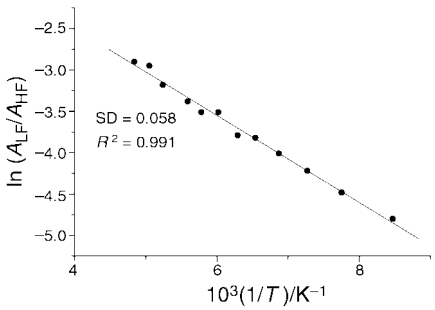

Fig. 3 van't Hoff plot of the natural logarithm of the intensity ratio of the LF and HF bands *vs.* reciprocal temperature.

Finally, it can be stated that preliminary results on the CO/H-ZSM-5 system have shown a similar equilibrium between hydrogen-bonded species as that found for CO/H-Y. It is also relevant to add, that for the CO/Na-Y system,[13] the corresponding enthalpy change for the isomerization equilibrium between C- and O-bonded adducts of CO with Na^+ ions was found to be $\Delta H° = 2.4$ kJ mol^{-1}. It is clear that the value of $\Delta H°$ depends upon the nature of the active centre interacting with adsorbed CO, and on the nature of such an interaction. However, more experimental work is needed before general trends can be established.

Notes and references

† Liquid nitrogen was used for refrigeration, and its gradual removal allowed variable-temperature spectra to be taken. The actual temperature was measured with a platinum resistance thermometer inserted close to the sample wafer.

‡ A similar equilibrium was recently documented[9] for CO adsorbed on Na-ZSM-5, but data for hydrogen-bonded species are reported here for the first time.

§ Correct application of the van't Hoff relationship for equilibrium data obtained over a large temperature range implies constant values of $\Delta H°$ and $\Delta S°$. Theoretical calculations[8,14] have shown that the difference in specific heat, $\Delta C_p°$, between C- and O-bonded adducts of CO with alkali-metal cations is negligible. It seems safe to assume that the same applies to hydrogen-bonded species.

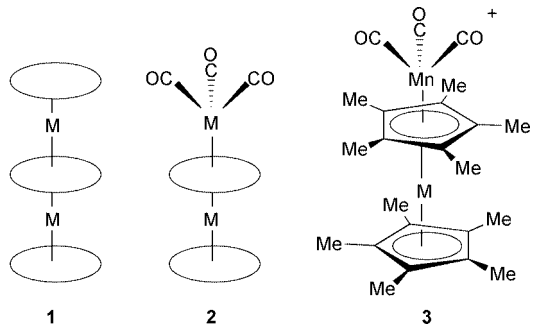
Received (in Irvine, CA, USA) 8th November 2000, Accepted 23rd January 2001
First published as an Advance Article on the web 15th February 2001

Stable bimetallic 'capped' metallocenes are formed by the reaction of Cp^*_2M (M = Fe, Ru, Os) with the manganese tricarbonyl transfer reagent $[(\eta^6\text{-naphthalene})Mn(CO)_3]^+$.

Multimetallic complexes have generated great interest for many years due to their potentially useful electronic, redox and catalytic properties in comparison to monometallic analogues. Bimetallic 'triple-decker' complexes **1** containing cyclopentadienyl, arene, and/or related heterocyclic π-ligands have been widely studied.[1] Bimetallics having the general structure **2**, in which a coordinated π-ring system is 'capped' with a $M(CO)_n$ carbonyl moiety, are much less common. Furthermore, in each complex of type **2** reported, the ring bridging the two metals is heterocyclic, most commonly being a borole based system.[2] Here we report the synthesis and characterization of bimetallic $[Mn(CO)_3]^+$ capped metallocenes **3**-Fe,Ru,Os, in which the bridging ligand is strictly carbocyclic.



1 **2** **3**

It was recently shown by Chung and coworkers,[3] that ferrocene undergoes ring exchange with $[(\eta^6\text{-naphthalene})Mn(CO)_3]^+$ according to eqn. (1). Since it is known[4] that

$$[(\eta^6\text{-}C_{10}H_8)Mn(CO)_3]^+ + [Cp_2Fe] \rightarrow [(\eta^6\text{-}C_{10}H_8)FeCp]^+ + [CpMn(CO)_3] \quad (1)$$

$[(\eta^6\text{-polyarene})Mn(CO)_3]^+$ complexes readily transfer the $[Mn(CO)_3]^+$ moiety to suitable donor sites, it seemed possible that the bimetallic species $[Cp–Fe–Cp–Mn(CO)_3]^+$, in which one of the Cp rings is coordinated to both metals, occurs as an intermediate in this reaction. No such intermediate was actually observed with ferrocene, but we now report that changing the potential 'donor' from Cp_2Fe to the more electron-rich Cp^*_2M (M = Fe, Ru, Os) results in the formation of stable isolable bimetallic capped metallocenes **3**-Fe, **3**-Ru and **3**-Os.

Refluxing equimolar amounts of Cp^*_2M and the manganese tricarbonyl transfer reagent[4] $[(\eta^6\text{-polyarene})Mn(CO)_3]BF_4$ (polyarene = 1-methylnaphthalene or acenaphthene) in CH_2Cl_2, followed by standard work-up procedures, led to moderate yields of the air-stable capped metallocenes $[\mathbf{3}]BF_4$ (M = Fe, Ru, Os).[5] The iron complex is green while the ruthenium and osmium complexes are orange. The capped structure indicated for **3** is supported by IR, elemental analysis, MS, ^{1}H NMR, and ^{13}C NMR data (Table 1). Attempts to grow crystals of $[\mathbf{3}]BF_4$ suitable for X-ray diffraction were not successful. However, acceptable crystals of $[\mathbf{3}\text{-Ru}]PF_6$ were obtained by diethyl ether vapor diffusion into a CH_2Cl_2 solution of $[\mathbf{3}\text{-Ru}]BF_4$ containing a large excess of NH_4PF_6.

Table 1 Characterization data for the capped metallocenes $[Cp^*MCp^*Mn(CO)_3]BF_4$

The X-ray structure of the cation in $[\mathbf{3}\text{-Ru}]PF_6$ is shown in Fig. 1.[6] Both Cp* rings are highly planar (rms deviations 0.030, 0.019 Å) and adopt a staggered conformation. In contrast, the rings in Cp^*_2Ru are eclipsed in the solid state.[7] The singly coordinated Cp* ring in $[\mathbf{3}\text{-Ru}]PF_6$ has an average Ru–C bond length of 2.16 Å and an average ring C–C bond length of 1.42 Å. The corresponding distances in Cp^*_2Ru are 2.18 and 1.42 Å.[7]

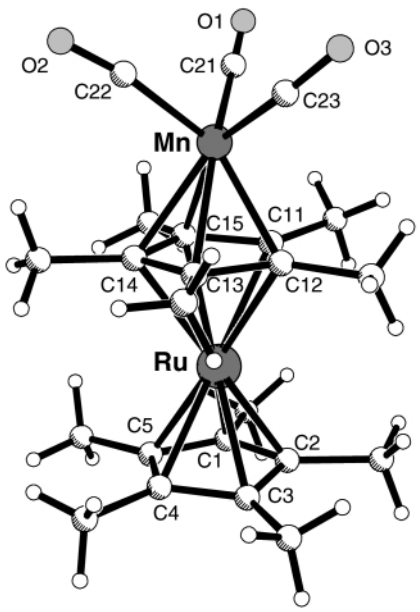

Fig. 1 Crystal structure of the cation in $[\mathbf{3}\text{-Ru}]PF_6$. Selected bond lengths (Å) and angles (°): Mn–C(11) 2.180(7), Mn–C(12) 2.136(9), Mn–C(13) 2.186(5), Mn–C(14) 2.222(10), Mn–C(15) 2.163(13), Ru–C(11) 2.181(7), Ru–C(12) 2.225(7), Ru–C(13) 2.223(5), Ru–C(14) 2.215(11), Ru–C(15) 2.238(12), Ru–C(1) 2.144(5), Ru–C(2) 2.114(13), Ru–C(3) 2.203(12), Ru–C(4) 2.160(9), Ru–C(5) 2.182(9); Mn–C(21)–O(1) 176.1(10), Mn–C(22)–O(2) 169.6(9), Mn–C(23)–O(3) 167.6(10).

The reduced electron density in the doubly coordinated Cp* ring is reflected in longer average Ru–C and C–C bonds, 2.22 and 1.46 Å, respectively. The average Mn–C bond distance to the Cp* ring is 2.18 Å, which is *ca*. 0.04 Å longer than that typically found in neutral [(cyclopentadienyl)$Mn(CO)_3$] complexes.[8]

The ^{1}H NMR data in Table 1 for the Cp* methyls show a resonance at δ *ca*.1.6, which is near that found for free Cp^*_2M. The Cp* ring in **3**-Fe,Ru,Os that is bonded to both metals, however, has methyls shifted *ca*. 1 ppm downfield. This demonstrates the deshielding effect of the cationic $[Mn(CO)_3]^+$ fragment. Table 1 shows that the ν_{CO} bands for **3**-Fe,Ru,Os are at *ca*. 2050 and 1975 cm^{-1}. By comparison, the ν_{CO} bands occur at 2005 and 1914 cm^{-1} for $[Cp^*Mn(CO)_3]$ and at 2062 and 2002 cm^{-1} for $[(\eta^6\text{-}C_6Me_6)Mn(CO)_3]^+$. From this one concludes that electron donation to the $[Mn(CO)_3]^+$ moiety is in the order $C_5Me_5^-$ >> Cp*MCp* > C_6Me_6 and that much of the positive charge (LUMO) in **3** resides on the $[Mn(CO)_3]$ fragment. This assertion is supported by electrochemical data, which show that the 30-electron bimetallic **3** is reduced in a one-electron chemically *reversible* manner at *ca*. −1.4 V relative to ferrocene. This is about the potential at which $[(\eta^6$-mono-arene$)Mn(CO)_3]^+$ complexes undergo reduction, although these species do so in a chemically *irreversible* manner.[9] In any case, the 31-electron neutral radical produced from **3** must have substantial stability for all three metals, and this aspect of the chemistry will be explored in future work.

Complexes **3**-Fe,Ru,Os are remarkably stable in CH_2Cl_2 and did not undergo a detectable reaction with $P(OEt)_3$ over 30 min. Similarly, a CH_2Cl_2 solution of **3**-Ru in the presence of naphthalene was unchanged after refluxing overnight. In MeCN solvent at room temperature, **3**-Ru was found to react with a half-life of *ca*. 1 h to afford predominantly the ring transfer product, $[Cp^*Mn(CO)_3]$, along with $[Cp^*Ru(MeCN)_3]^+$. In contrast, the major products obtained from **3**-Fe in MeCN were $[(MeCN)_3Mn(CO)_3]^+$ and Cp^*_2Fe, with a half-life of *ca*. 5 h. This difference in reaction pathway may be due to easier nucleophilic attack by MeCN at the larger ruthenium center, with concomitant Cp* ring displacement. The isolation and stability of **3**-Fe,Ru,Os strongly suggests a capped bimetallic as an intermediate in eqn. (1). An attempt was made to detect this species in the reaction of $[(naphthalene)Mn(CO)_3]^+$ with the bridged metallocene [3]ferrocenophane, the idea being that the $-(CH_2)_3-$ strap would slow or prevent the Fe–Cp cleavage for entropy reasons. Unfortunately, the reaction was found to proceed analogously to eqn. (1).

In conclusion, we have shown that stable metal carbonyl capped metallocenes can be prepared from Cp^*_2M.

This work was supported by grant CHE-9705121 from the National Science Foundation. We wish to thank Professor Thomas Bitterwolf for providing a sample of [3]ferrocenophane and for valuable discussions.

5 Syntheses: [**3**-Fe]BF_4: [(1-methylnaphthalene)$Mn(CO)_3$]BF_4 (100 mg, 0.275 mmol) and Cp^*_2Fe (99 mg, 0.302 mmol) were added to CH_2Cl_2 (15 mL) under N_2 at room temperature. The solution was refluxed for 40 min, during which the color quickly changed from orange to green. The solution was cooled, the volume reduced to a few mL, and diethyl ether added to precipitate the product as a green powder. The product was redissolved in a minimal amount of CH_2Cl_2 and placed on a silica gel column wetted with CH_2Cl_2. Neutral species were eluted with CH_2Cl_2 and the green product was eluted with 1 : 10 (v/v) acetone–CH_2Cl_2, while unreacted [(1-methylnaphthalene)$Mn(CO)_3$]BF_4 remained on the column. The solvent was stripped and the product taken up in CH_2Cl_2 and reprecipitated with Et_2O. Yield 61% (93 mg); HRMS. calc. for $C_{23}H_{30}FeMnO_3$: *m*/*z* 465.0947; obs.: 465.0925. See Table 1 for other characterization data. [**3**-Ru]BF_4: A procedure essentially identical to that described for [**3**-Fe]BF_4 was followed, with Cp^*_2Ru (112 mg, 0.30 mmol) replacing the Cp^*_2Fe. Yield 32% (53 mg); HRMS: calc. for $C_{23}H_{30}RuMnO_3$: *m*/*z* 511.0626; obs.: 511.0619. See Table 1 for other characterization data. [**3**-Ru]BF_4 was also synthesized in a similar yield by reacting $Mn(CO)_5Br$ with $AgBF_4$ in CH_2Cl_2 solution, followed by the addition of Cp^*_2Ru. [**3**-Os]BF_4: A procedure essentially identical to that described for [**3**-Fe]BF_4 was followed, with Cp^*_2Os (92 mg, 0.20 mmol) replacing the Cp^*_2Fe and [(acenaphthene)$Mn(CO)_3$]BF_4 (83 mg, 0.22 mmol) replacing the [(1-methylnaphthalene)$Mn(CO)_3$]BF_4. Yield 30% (41 mg); HRMS: calc. for $C_{23}H_{30}OsMnO_3$: *m*/*z* 601.1190; obs.: 601.1186. See Table 1 for other characterization data. The yield in this reaction was artificially low because a significant amount of reactant [(acenaphthalene)$Mn(CO)_3$]BF_4 was found to remain when the reaction was stopped.

6 The crystal structure of [**3**]PF_6 was determined by standard procedures. The crystal showed (chiral) $P2_1$ symmetry, but proved to be a racemic twin. The structure was readily solved. Each hydrogen was introduced in an ideal position, riding on the atom to which it is bonded; each was refined with an isotropic temperature factor 20% greater than that of the ridden atom. Both Cp* groups showed some librational disorder, and the atomic parameters were gently restrained to physically possible values. The three carbonyl groups and the PF_6^- anion also showed evidence of disorder. In spite of the somewhat poorly defined parameters of the lighter atoms, the connectivity is clear. *Crystal data* for [**3**]PF_6: $C_{23}H_{30}F_6MnO_3PRu$, M = 655.45, data collected at 25 °C, monoclinic, space group $P2_1$, a = 8.8909(11), b = 8.9536(12), c = 16.406(2) Å, β = 94.905(2)°, V = 1301.2(3) Å^3, Z = 2, μ = 1.193 mm^{-1}, 327 variables refined with 5673 independent reflections (R_{int} = 0.0341) to R = 0.0530, *wR*2 = 0.1113, GOF = 1.319. A novel approach to the construction of medium-ring carbocycles utilising the rearrangement of oxonium ylides generated from metal carbenoids

J. Stephen Clark,*[a] Andrea L. Bate[a] and Trevor Grinter[b]

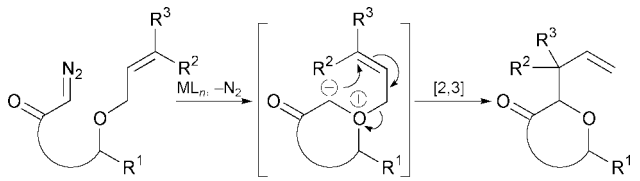
Received (in Cambridge, UK) 8th January 2001, Accepted 25th January 2001
First published as an Advance Article on the web

Medium-ring carbocycles have been prepared by intramolecular reactions of metal carbenoids with tethered α-vinyl methyl ethers and subsequent [2,3] rearrangement of the presumed cyclic oxonium ylide intermediates.

Natural products containing medium-ring carbocycles continue to be important targets because of the synthetic challenges that they present and the potent biological activity they frequently possess.[1] As a consequence, the discovery of new reactions which permit the implementation of novel strategies for medium-ring construction continues to be an important endeavour in organic synthesis.[2]

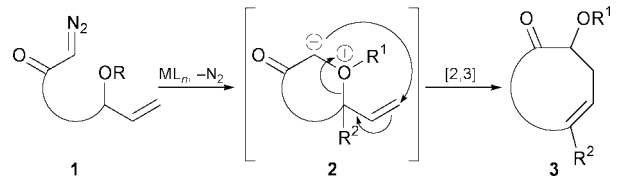
Recently, several research groups, including our own, have shown that cyclic ethers can be prepared by rearrangement of the putative oxonium ylides generated by *intramolecular* reaction of ethers with metal carbenoids derived from diazocarbonyl compounds.[3–11] When allylic ethers are employed as substrates, an apparent [2,3] rearrangement occurs to give the corresponding cyclic ether.[4–6,8,9] In the case of acetals and non-allylic ethers, ylide generation is usually followed by a [1,2] rearrangement,[6,7,8c,10] which is generally efficient when the migrating group is benzylic.[6,7]

The substrates used in our previous studies possess an allylic ether group pendant to the main carbon chain (Scheme 1).[4] In these cases, oxonium ylide formation results in ring closure and subsequent rearrangement delivers the cyclic ether with preservation of ring size.



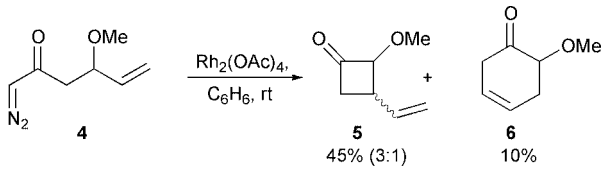
Scheme 1

It occurred to us that it might be possible to broaden the scope of the tandem ylide generation and rearrangement reaction to the preparation of carbocycles, by employing substrates in which the unsaturated group is incorporated into the main chain (Scheme 2). For example, the carbenoid derived from the diazoketone **1** should undergo intramolecular cyclisation to give the cyclic ylide **2** and subsequent [2,3] rearrangement would then deliver the carbocycle **3**. During the rearrangement process, the ring size would be increased by one and the ether substituent would be positioned outside the ring.



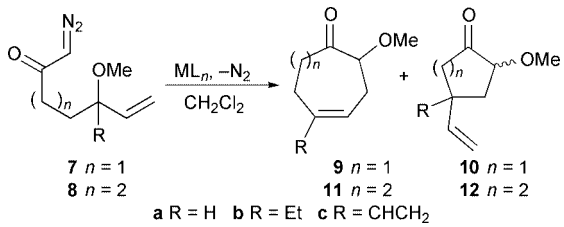
Scheme 2

There are few literature precedents for catalytic oxonium ylide generation and rearrangement using systems of the type shown in Scheme 2. In fact, the only example comes from Johnson's original studies on the generation of oxonium ylides by intramolecular reaction of metal carbenoids with ethers (Scheme 3).[6] In this case however, treatment of the diazoketone **4** with rhodium(II) acetate afforded mainly the cyclobutanone **5**, resulting from [1,2] rearrangement with ring contraction, and only a small amount of the [2,3] rearrangement product **6** was isolated (Scheme 3).[6]



Scheme 3

Although the literature precedent above did not bode well for the development of a general reaction of the type outlined in Scheme 2, we explored the construction of cycloheptenones and cyclooctenones by an analogous ylide formation and rearrangement process (Scheme 4, Table 1). The cyclisation reaction of the diazoketone **7a** was investigated first, and treatment of this precursor with rhodium(II) acetate delivered the required cycloheptenone **9a** in 39% yield. The copper(II) hexafluoroacetylacetonate mediated reaction was also performed with the expectation that it would deliver a higher yield of the required product. However, the yield of cycloheptenone **9a** was



Scheme 4

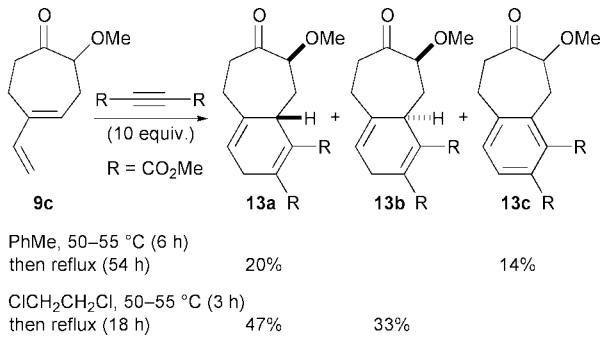
DOI: 10.1039/b100292i

substantially lower than that obtained from the corresponding rhodium carbenoid.† This result was surprising because we have found that copper-catalysed oxonium ylide generation and rearrangement is more efficient than the corresponding rhodium-catalysed process in most cases.[4,7]

It seemed likely that the modest yield of the ketone **9a** was due to the relatively low rate of [2,3] rearrangement as a consequence of vinyl group adopting an equatorial position in the lowest energy conformation of the cyclic oxonium ylide. We reasoned that introduction of another substituent adjacent to the ether should help populate the conformer in which the vinyl group is disposed to participate in the rearrangement reaction. In order to explore this possibility, the substrates **7b** and **7c** were prepared. Higher product yields were obtained from the rhodium- and copper-catalysed cyclisation reactions of the ethyl-substituted diazoketone **7b** (Table 1). The yields were increased further when an additional vinyl substituent was present; treatment of the substrate **7c** with rhodium(II) acetate afforded the expected product **9c** in a yield of 63% and the corresponding copper-catalysed reaction delivered the same product in 46% yield.

The construction of cyclooctenones by oxonium ylide formation and rearrangement was also explored. As expected, treatment of the substrates **8b** and **8c** with rhodium(II) acetate afforded the desired products **11b** and **11c** in much lower yields (8 and 26% respectively) than had been obtained from reactions of the homologues **7b** and **7c** (Table 1). In the case of the diazoketone **8b**, the major product **12b** was that arising from [1,2] rearrangement of the intermediate ylide. The divinyl substrate **8c** underwent cyclisation and [2,3] rearrangement in a higher yield (26%) than the diazoketone **8b**, and a small amount of the corresponding [1,2] rearrangement product **12c** (8%) was also isolated.

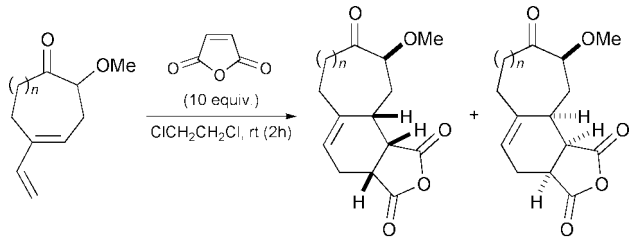
The divinyl susbtrates **7c** and **8c** underwent the most efficient cyclisations in each series and the products from these reactions are synthetically useful because they are amenable to further elaboration as Diels–Alder substrates. The Diels–Alder reactions of the dienes **9c** and **11c** were investigated (Scheme 5). Treatment of the diene **9c** with DMAD in toluene at reflux afforded the 1,4-diene **13a**‡ in 20% yield along with the aromatised product **13c** in 14% yield. When the reaction was performed in 1,2-dichloroethane at reflux, the isomers **13a**‡ and **13b**‡ were obtained in yields of 47 and 33% respectively, without formation of the aromatised product **13c**.



Scheme 5

The Diels–Alder reactions of **9c** and **11c** with the reactive dipolarophile maleic anhydride were also explored (Scheme 6). Cycloaddition of the diene **9c** with maleic anhydride afforded two cycloadducts. The major adduct was the tricyclic compound **14a**‡ produced by *endo* addition of the dipolarophile. The available data suggests that the minor isomer is the product **14b** resulting from *endo* addition of the other face of diene by analogy with the reaction of the same diene with DMAD (Scheme 5). In the case of the diene **11c**, Diels–Alder reaction with maleic anhydride delivered **15a** as a single isolable product in 47% yield.‡

Finally, the oxonium ylide formation and rearrangement reaction and Diels–Alder reaction were performed in a one-pot fashion. Thus, addition of the diazoketone **7c** to a solution of



Scheme 6

rhodium(II) acetate (1 mol%) and DMAD (10 equiv.) in 1,2-dichloroethane at reflux provided the isomers **13a** and **13b** in a combined and unoptimised yield of 34%.

In summary, we have shown that it is possible to construct medium-ring carbocycles by rearrangement of oxonium ylides generated by intramolecular reaction of metal carbenoids with allylic ethers (Scheme 2). We have also shown that the diene products resulting from this reaction undergo Diels–Alder addition, and that the two reactions can be coupled to give a one-pot reaction.

We thank the EPSRC for the award of an Industrial Studentship to A. Bate, and we thank Dr A. J. Blake and Dr C. Wilson for performing X-ray crystallography.

Notes and references

† Carbenoids were also generated using $Rh_2(O_2CCF_3)$, $Rh_2(NHCOCF_3)$, and $Rh_2(O_2CC_3F_7)$, but they generally gave inferior yields of the cycloheptenone **9a**.

First published as an Advance Article on the web 14th February 2001

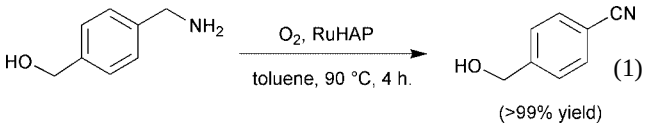
A hydroxyapatite-bound Ru complex could efficiently catalyze the aerobic oxidation of various *primary* amines to nitriles which were further hydrated to amides in the presence of water.

Nitriles are versatile synthetic intermediates which are generally prepared by nucleophilic displacement of halides with cyanide ions, ammoxidation, and the Sandmeyer reaction. These conventional methods often require hazardous reagents and severe reaction conditions. Direct synthesis of nitriles from *primary* amines by the oxidative dehydrogenation is one powerful candidate for a clean synthesis. Many stoichiometric reagents in the above dehydrogenation have, however, been used,[1] which often result in the production of a vast amount of environmental waste.[2] Catalytic methods using molecular oxygen as an oxidant[3] are more desirable from the consideration of 'green and sustainable chemistry'.[2]

We have recently succeeded in creating a monomeric Ru^{3+} species on the surface of hydroxyapatite (RuHAP), which acts as a highly efficient heterogeneous catalyst for the aerobic oxidation of various alcohols.[4] During the course of these studies, we have also found and herein wish to report that the aerobic oxidation of amines to the corresponding nitriles smoothly occurred in the presence of this RuHAP catalyst. Compared with other catalysts for this amine oxidation, *the RuHAP system has many advantages as follows: (i) high catalytic activity for the oxidation of both aromatic and aliphatic amines under mild reaction conditions, (ii) a reusable heterogeneous catalyst, (iii) use of molecular oxygen as an ultimate oxidant, and (iv) applicability to the hydration of nitriles to amides.*

A calcium hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, was synthesized according to the literature procedure.[5] 1.0 g of the calcium hydroxyapatite was stirred at 25 °C for 24 h in 75 mL of a 2.67×10^{-2} M aqueous $RuCl_3$ solution. The obtained slurry was filtered, washed with deionized water and dried overnight at 110 °C, yielding the RuHAP as a dark brown powder (Ru^{3+} content: 1.69 mmol g^{-1}). The surface structure of the present RuHAP was determined by X-ray absorption fine structure.[4] A typical RuHAP-catalyzed amine oxidation is as follows. Into a reaction vessel with a reflux condenser were successively placed the RuHAP (0.2 g, Ru^{3+}: 6.5 mol%), *p*-xylene (15 mL), and *n*-dodecylamine (0.96 g, 5.2 mmol). The reaction mixture was stirred at 125 °C under atmospheric pressure of O_2. After 24 h, the RuHAP was separated by filtration and the organic layer was distilled to afford pure *n*-dodecanenitrile (0.88 g, 94% yield).

Oxidation of various *primary* amines is summarized in Table 1. Many benzylic amines were converted into the benzonitriles in high yields (entries 1–8).† Notably, our RuHAP could oxidize aliphatic amines to the corresponding nitriles in high yields (entries 9–12). It is said that aliphatic amines give low yields of the nitriles in homogeneous Ru-catalyzed systems such as *trans*-$[Ru^{VI}(tmp)(O_2)]$[3a] (H_2tmp = 5,10,15,20-tetramesitylporphyrin) and $RuCl_2(PPh_3)_3$[3c] using molecular oxygen. When an equimolar mixture of *n*-octylamine and octan-1-ol was used as substrate, the oxidation of *n*-octylamine occurred exclusively to afford *n*-octanenitrile in 91% yield for 12 h without any oxidation products derived from octan-1-ol.‡ Also, an intramolecular competitive oxidation of 4-(aminomethyl)-benzyl alcohol afforded chemoselectively 4-cyanobenzyl alcohol in a quantitative yield [eqn. (1)] because the amino function



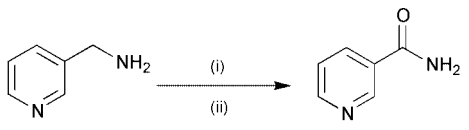
(1)

(>99% yield)

coordinates more strongly to a Ru center than the hydroxy one. 2-(1-Cyclohexenyl)ethylamine and geranylamine gave the allylic and vinylic nitriles in high yields without geometrical isomerization of double bonds, respectively (entries 13 and 14). In a *secondary* amine of dibenzylamine, *N*-benzylidenebenzylamine could be obtained in 91% yield (entry 16). Other *secondary* amines such as *N*-methylbenzylamine and *N*-ethylbenzylamine afforded the corresponding imines accompanied with benzaldehyde through the imine hydrolysis. Oxidation of *tertiary* amines did not proceed under the present conditions. The spent RuHAP catalyst was easily separated from the reaction mixture and the ICP analysis of the filtrate showed that no leaching of the Ru species was observed during the above oxidation. This catalyst could be reused with retention of its high catalytic activity and selectivity for the oxidation (entry 3).

Interestingly, when water was used as a solvent instead of toluene under N_2 atmosphere, the RuHAP could also catalyze the hydration reaction of many nitriles, *i.e. n*-hexanenitrile, *n*-octanenitrile, benzonitrile, 4-methoxybenzonitrile, and 3-cyanopyridine to afford excellent yields of the corresponding amides without any formation of carboxylic acids, respectively, as shown in Table 2. This hydration system using RuHAP has advantages over other reported methods because of its simple and clean operation under neutral conditions and its high reactivity for both aliphatic and aromatic nitriles.[6] Finally, the RuHAP catalyst could be applied to the one-pot synthesis of nicotinamide, a highly versatile intermediate of nicotinamide nucleotides, directly from 3-aminomethylpyridine, giving an excellent yield of a pure amide (Scheme 1).

We here propose a possible mechanism for this amine oxidation. Initially, a ligand exchange between an amine and a surface Cl moiety of the RuHAP[4] gives a Ru–$NHCH_2R$ species, followed by elimination to produce a Ru–H species and an



(91% isolated yield)

Scheme 1 Reaction conditions: (i) RuHAP (0.1 g), amine (10 mmol), 1,2-diethoxyethane (25 mL), O_2 atmosphere, 120 °C, 16 h, (ii) followed by adding water (5 mL), N_2 atmosphere, 150 °C, 48 h.

intermediate imine. Attack of molecular oxygen on the hydride species affords a Ru–OOH species, which reacts with the imine to produce a Ru–N=CHR species. The second dehydrogenation of the imine to nitrile proceeds *via* a similar path to that described above. In the nitrile hydration, the reaction of the surface Cl moiety with water yields a Ru–OH species, which attacks nucleophilically to a nitrile. A formed iminol intermediate, Ru–N=C(OH)R,[6b] subsequently undergoes a ligand exchange with water to give the amide accompanied by the Ru–OH species.

Table 2 Hydration of various nitriles using RuHAP in the presence of H_2O[a]

5		100	97

[a] Nitrile (1 mmol), RuHAP (0.1 g), water (3 mL) , N_2 atmosphere, 150 °C, 24 h. [b] Determined by GC using biphenyl as an internal standard.

In conclusion, the RuHAP efficiently catalyzed the oxidation of many *primary* amines using molecular oxygen, and could be further extended for the nitrile hydration. No leaching of the Ru species in the reaction solution was observed, which allows the hydroxyapatite catalyst to be recycled with retention of its high catalytic activity and selectivity. We have continuously designed hydroxyapatite catalysts containing various other transition metal complexes for developing many functional transformations in organic synthesis.

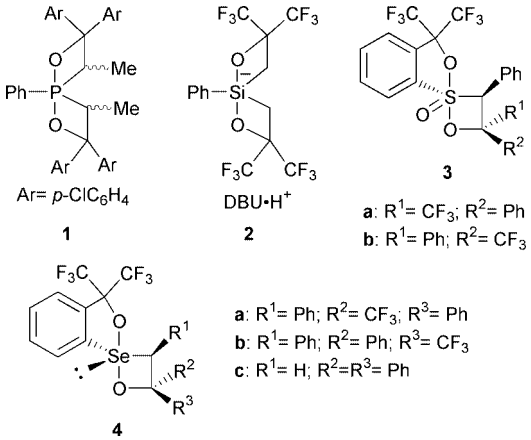
Received (in Cambridge, UK) 6th December 2000, Accepted 29th January 2001
First published as an Advance Article on the web 14th February 2001

The first stable spiroselenuranes bearing two oxaselenetane rings have been synthesized, chracterized by X-ray crystallographic analysis, and shown to be thermally reactive giving two molar equivalents of the corresponding oxirane with elimination of elemental selenium, in sharp contrast to the behavior of the phosphorus and silicon analogues.

In the course of our study on oxetanes containing high-coordinate main group elements at the position adjacent to the oxygen atom,[1] we have reported the syntheses and isolation of intermediates of Wittig- and Peterson-type olefin formation reactions.[2,3] For the purpose of elucidating the influence of ring size of the spiro-ring system on the reactivity of the heteracyclobutanes, we have investigated the synthesis and reactivity



of compounds **1** and **2**, which have two oxaphosphetane and oxasiletane rings, respectively, and found that **1** undergoes double olefin extrusion,[4] while **2** undergoes homo-Brook rearrangement to give the corresponding alcohol.[5] On the other hand, we have recently found that the oxirane formation reactions from pentacoordinate 1,2λ⁶-oxathietanes **3a**,**b** or tetracoordinate 1,2λ⁴-oxaselenetanes **4a**,**b** proceed with retention of configuration,[6] which is the first example for the oxirane formation without backside attack of oxide anion on the carbon attached to the chalcogen atom, in sharp contrast to the Corey–Chaykovsky reaction.[7] These results prompted us to study tetracoordinate 1,5-dioxa-4λ⁴-selenaspiro[3.3]heptanes, a novel type of a spiroselenurane bearing two oxaselenetane rings. We now report, for the first time, their synthesis and unique thermal behavior.

Sequential treatment of $(PhSCH_2)_2Se$ **5** with 1.1 equiv. of lithium diisopropylamide (LDA), with 2.0 equiv. of freshly generated hexafluoroacetone (HFA), and then with aqueous NH_4Cl gave mono(β-hydroxyalkyl) selenide **6** (28%) (Scheme 1). A diastereomer mixture of bis(β-hydroxyalkyl) selenides **7** was obtained from **6** by repetition of the same procedure as the addition of HFA to **5** (2.0 equiv. of LDA and 3.0 equiv. of HFA). Separation by flash column chromatography (SiO_2) gave *dl*-**7** (7%) and *meso*-**7** (61%). Oxidative cyclization of *dl*-**7** and *meso*-**7** with Br_2 in the presence of Et_3N afforded the corresponding tetracoordinate 1,5-dioxa-4λ⁴-selenaspiro[3.3]heptanes *trans-trans*-**8** (30%) and *trans-cis*-**8** (49%), respectively. Recrystallization of *trans-trans*-**8** and *trans-cis*-**8** from hexane–diethyl ether gave colorless plates which melted at 93.5–108.4 and 105.0–106.2 °C with decomposition, respectively.§

In the ^1H, ^{13}C and ^{19}F NMR spectra of *trans-trans*-**8**, the two oxetane rings were observed equivalently, whereas those of *trans-cis*-**8** were non-equivalent. Downfield shifts from *dl*-**7** (δ_H 4.98, δ_C 52.31) to *trans-trans*-**8** (δ_H 6.35, δ_C 88.07) were observed for the proton and carbon of the methine adjacent to the central selenium, which is a common spectral feature for tetracoordinate 1,2-oxachalcogenetanes.[1,6] In the ^{77}Se NMR spectra of *trans-trans*-**8** (δ_{Se} 835.3) and *trans-cis*-**8** (δ_{Se} 882.0) were observed multiplets due to the long-range coupling with ^{19}F nuclei. The large downfield shifts in δ_{Se} from **7** [δ_{Se} 521.1 (*dl*), 521.7 (*meso*)] to **8** and their similar chemical shifts to compounds **4** (**4a**: δ_{Se} 781; **4b**: δ_{Se} 793; **4c**: δ_{Se} 840.8) strongly support the selenurane structure for **8**. We have also synthesized *trans-trans*-**9** with two phenyl groups instead of two phenylthio groups of *trans-trans*-**8**.¶

X-Ray crystallographic analysis indicated that the asymmetric unit of a crystal of *trans-trans*-**9** contains one and a half molecules, A and B, the latter of which is disordered in two different orientations on the crystallographic inversion center.‖ Both molecules have a distorted pseudo-trigonal bipyramidal (TBP) structure with two oxygen atoms at apical positions and two carbon atoms and a lone pair at equatorial positions. The

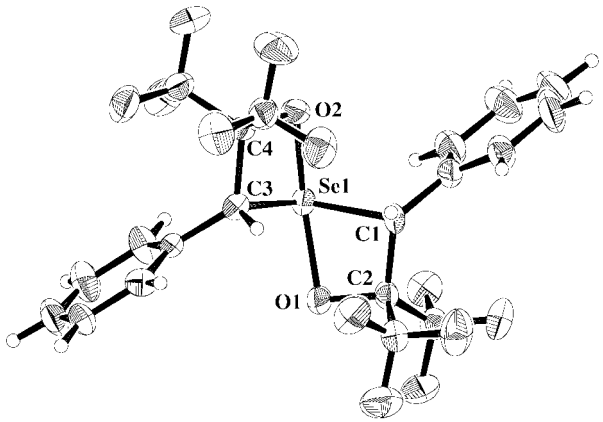

Fig. 1 ORTEP drawing of *trans-trans*-**9** with thermal ellipsoid plot (30% probability for all non-hydrogen atoms). Selected bond lengths (Å), bond angles (°) and torsion angles (°): Se1–O1 1.971(4), Se1–O2 1.955(4), Se1–C1 1.979(6), Se1–C3 1.978(6), C1–C2 1.532(8), C2–O1 1.388(6), C3–C4 1.531(8), O2–C4 1.392(7); O1–Se1–O2 155.26(18), C1–Se1–O1 71.1(2), Se1–C1–C2 90.0(4), C1–C2–O1 103.7(5), Se1–O1–C2 94.7(3), C1–Se1–C3 109.2(3), O2–Se1–C3 71.9(2), O2–C4–C3 104.3(5), Se1–C3–C4 89.1(4); Se1–C1–C2–O1 −5.9(5), Se1–C3–C4–O2 −6.1(5).

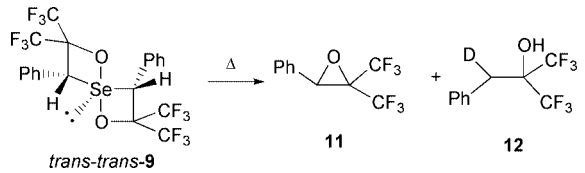
ORTEP drawing of molecule A (Fig. 1) shows that both the phenyl groups at the 3- and 3′-positions are *cis* to the lone pair of selenium and *trans* to the Se–C bond of another four-membered ring. The apical Se–O bonds are bent away from the lone pair leading to the deviation of the O–Se–O angle by 22.74(18)° from linearity, which is a common structural feature of the hypervalent species containing a four-membered ring.[1,4,6*a*] The apical Se–O bond lengths [1.971(4) and 1.955(4) Å)] are between those [1.977(4) and 1.902(4) Å] of selenurane **4c**.[1*b*] The two oxaselenetane rings of *trans-trans*-**9** are almost planar [Se–C–C–O; −6.2195(10)° and −6.5439(10)°] similar to **4c** [Se–C–C–O 4.7(4)°].[1*b*]

Thermolyses of *trans-trans*-**8** (C_6D_6, 120 °C, 11 h) and *trans-cis*-**8** (C_6D_6, 60 °C, 19 h) in a degassed sealed tube gave oxirane **10** in 72 and 83% yields,** respectively, with black precipitates and minor unidentified products, indicating that both compounds underwent double oxirane extrusion reaction. The formation of elemental selenium (black precipitates) was confirmed by observation of the signal due to tris(dimethylamino)phosphine selenide (δ_P 84.9) after treatment of the reaction mixture with tris(dimethylamino)phosphine (δ_P 121.5). On the other hand, the thermolysis of *trans-trans*-**9** ($CD_3C_6D_5$, 200 °C, 12 d) gave a somewhat complicated mixture containing oxirane **11** (31%) and deuterated alcohol **12** (19%). (Scheme 2)** The formation of **12** indicates that radical species were generated by homolytic bond cleavage, probably because drastic conditions were necessary for the thermolysis.



Scheme 2

Although oxetanes containing a pentacoordinate group 14 or 15 element give rise to olefins,[1*a*] spiro oxachalcogenetanes yielded oxiranes, regardless of the ring size (five- or four-membered ring). This indicates that the thermal reactivity mainly depends on the bond energy of the oxygen and the central atom. Investigation of the stereochemistry of the oxirane formation is now in progress.

This work was partially supported by Grants-in-Aid for Scientific Research on Priority Areas No. 09239101 and General Scientific Research (B) No. 10440212 (T. K.) from the Ministry of Education, Science, Sports and Culture, Japan. We are grateful to Professor N. Tokitoh of Kyoto University for the determination of the X-ray structure of *trans-trans*-**9**. We also thank Central Glass, Shin-etsu Chemical, and Toso Akzo Co. Ltd. for the gifts of organofluorine compounds, trialkylsilanes and alkyllithiums, respectively.

First published as an Advance Article on the web 14th February 2001

Cytochrome c (horse heart) has been adsorbed onto a range of mesoporous silicate materials with the extent of adsorption dependent on the silicate pore size; adsorption and activity profiles of the adsorbed protein are reported.

Mesoporous silicate materials (MPS) such as those which are formed by mediated pathways involving surfactants as structure directing reagents[1,2] are very suitable as hosts for large organic molecules[3] and proteins.[4–6] MPS exhibit highly ordered pore structures and very tight pore size distributions, as exemplified by the first type of these materials reported, MCM-41.[1] As a direct consequence of their mesopore structures, MPS possess large surface areas of the order of 1000 $m^2\ g^{-1}$. Owing to their silicate inorganic framework, they are chemically and mechanically stable[2] and are resistant to microbial attack. In addition, it is possible to chemically modify MPS with various functional groups, enabling electrostatic attraction or repulsion between MPS and the protein(s) of interest to be maximised.[7] Materials such as sol–gels display similar stability as MCS and have been used to encapsulate proteins for use as biosensors. However, sol–gels suffer from the disadvantage of possessing a highly variable pore size distribution.[8] More importantly, their preparation can involve the use of harsh conditions or reagents which are detrimental to proteins, resulting in denaturation of the protein.[8] With MPS, protein encapsulation occurs after synthesis of the support, avoiding this difficulty. MPS therefore hold great promise for use as supports to immobilise enzymes,[6,7,9] and may find applications in biosensors,[5] biocatalytic[9] and biomolecule separation[7] systems. For example, Stucky and coworkers[7] have used MPS to sequester and release proteins of similar size but varying charge, while Díaz and Balkus[9] have used MPS to immobilise cytochrome c. To date, there have been no reports on the adsorption isotherms obtained with MPS–protein systems, nor on the catalytic activity of a stable, adsorbed, protein–silicate system. In this report, we describe adsorption isotherms for cytochrome c onto four MPS materials covering a range of pore sizes, and peroxidative activity profiles of the adsorbed protein.

Cytochrome c is a small (12 384 Da) redox protein, with an approximate spherical diameter of 40 Å.[10] The cytochrome c (horse heart) (Sigma-Aldrich) used in this study was *ca.* 95% pure and was further purified using standard methods.[11] The MPS materials used consisted of a commercially available silicate (COS) (Fluka, Reidel-de Haën), a cyano-modified silicate (CNS), an MCM-41 material and an MPS material (MPS-F127) synthesised using a non-ionic triblock surfactant Pluronic-F127 as the structure directing agent. The physicochemical properties of the MPS materials are presented in Table 1 and the pore size distributions in Fig. 1.

Cytochrome c has been previously adsorbed onto MPS materials such as MCM-41,[9] SBA-15[14] (MPS of pore diameter 90–110 Å), Nb-TMS4[4] (MPS modified with Nb^{5+}). However, neither the adsorption isotherms nor the peroxidative activity of the protein were reported. The latter, in particular, is important if MPS are to be of use in biosensors and biocatalytic systems.

Table 1 Physicochemical properties of mesoporous silicates used in adsorption studies

MPS	BET surface area/$m^2\ g^{-1}\ SiO_2$	Average pore size/Å	Mesopore volume /$cm^3\ g^{-1}\ SiO_2$	Cytochrome c maximum load/μmol $g^{-1}\ SiO_2$	Volume cytochrome c adsorbed[a]/ $cm^3\ g^{-1}\ SiO_2$
COS	470	55	0.46	3.8	0.3
CNS	379	130	0.61	10.2	0.7
MCM-41	1000	28	0.31	1.7	0.1
MPS-F127	537	50	0.38	6.8	0.5

[a] The volume of cytochrome c was calculated from the crystal structure to be 121 nm^3.[14]

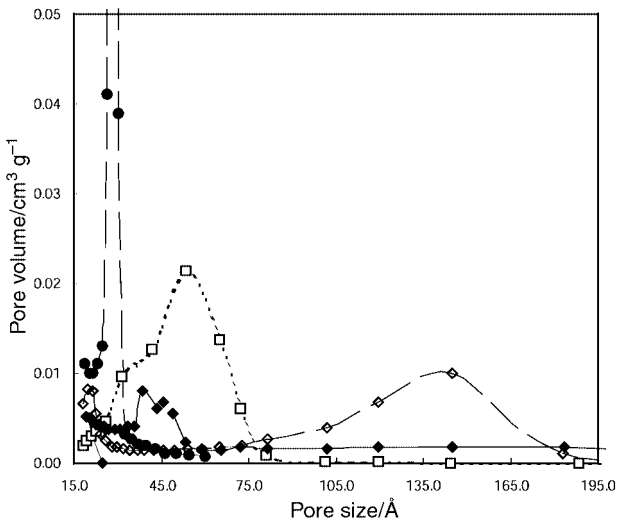

Fig. 1 Pore size distributions of COS (□), MCM-41 (●), CNS (◇) and MPS-F127 (◆).

Fig. 2 shows protein adsorption isotherms for the cytochrome c–MPS systems. It can be clearly seen from Table 1 and Fig. 1 that CNS has the largest average pore size (130 Å) with MCM-41 exhibiting a pore size of 28 Å. The isotherms in Fig. 2 demonstrate that CNS has a much larger affinity for cytochrome c compared with MCM-41. The latter has a very tight pore size distribution at 28 Å (Fig. 1), a pore diameter too small for cytochrome c to penetrate, yielding a maximum adsorption of only 1.7 μmol g^{-1} MCM-41. The CNS material on the other hand, with a much larger pore diameter (130 Å), allows for a maximum adsorption of 10.2 μmol g^{-1} silicate. Clearly, the pore size of the material is a major factor in the adsorption process.[9] The pores in the COS material with an average diameter of 55 Å (Fig. 1) are also large enough to allow penetration of the protein molecule into the pores. With MCM-41, the amount of cytochrome c adsorbed does not change significantly over the range of concentrations studied from the initial 1.7 μmol g^{-1} SiO_2 level), indicating that adsorption is largely confined to the outside surface of the silicate.[9] The MPS-F127 allows for more protein to be adsorbed than in the

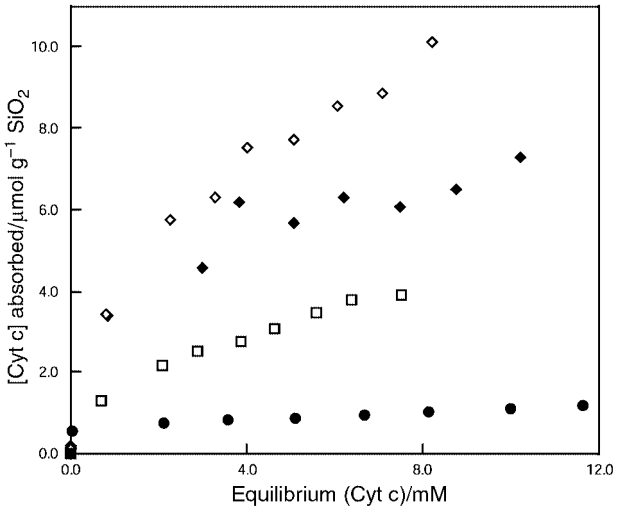

Fig. 2 Adsorption isotherms for pure cytochrome c on to COS (□), MCM-41 (●), CNS (◇) and MPS-F127 (◆).

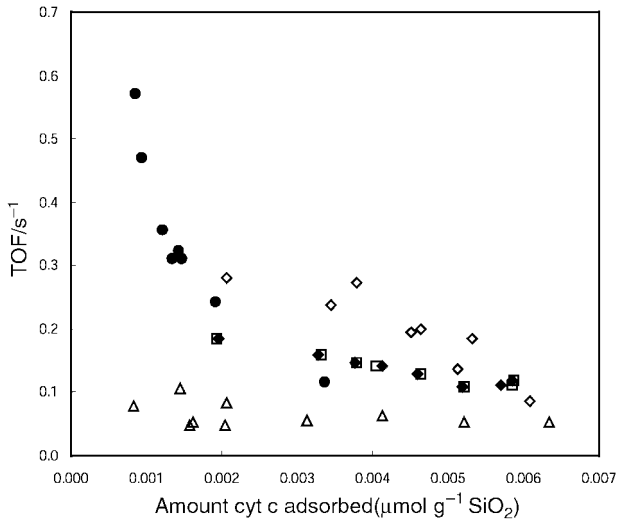

Fig. 3 Peroxidative activity (ABTS assay) profiles for cytochrome c adsorbed on to COS (□), MCM-41 (●), CNS (◇) and MPS-F127 (◆) and of aqueous cytochrome c (Δ). The standard deviations for the assays were 18, 24, 11 18 and 12%, respectively.

case of COS, despite having a similar pore size distribution; this is likely due to the presence of a small subgroup of mesopores with diameters in the range 60–200 Å in the former material (Fig. 1). In contrast to the adsorption of trypsin onto MCM-41,[9] where the enzyme leached out of the silicate, adsorbed cytochrome c was found to be stable to repeated washing in buffer (minimum of four washings). As with the adsorption of conalbumin onto MPS,[7] the ionic strength was found to strongly influence the amount of protein adsorbed, with little absorption occurring at high ionic strengths.[13]

Peroxidative activity profiles‡ over the range of adsorbed cytochrome c are shown in Fig. 3. Aqueous cytochrome c activity was constant over this range (TOF§ ≈ 0.075 s^{-1}). The similarity of the activity profiles of adsorbed protein on COS and MPS-F127 silicates may be a reflection of the similarity in the pore size distributions of these two materials. The general trend of higher TOF at lower amounts of adsorbed protein indicates that access of the ABTS substrate to cytochrome c molecules may be limited at higher protein loadings. This is seen clearly in the MCM-41 profile, where the TOF decreases to that of aqueous solution. From the data in Fig. 1, adsorption of cytochrome c onto MCM-41 appears to occur largely on the outside of the silicate, implying that diffusion of the substrate into the pores cannot be rate limiting. The high TOF values at the lower levels of protein adsorbed may be a result of assaying externally adsorbed protein, where increased substrate access would be expected. The CNS silicate activity profile is similar to the COS and MPS-F127 silicates, but with marginally higher TOF. This is possibly due to the larger pores of the CNS material allowing for faster substrate access. The TOF values obtained for the adsorbed protein are marginally higher for the aqueous protein. This is in marked contrast to the results obtained with trypsin where the activity of the entrapped enzyme was only 13% of that of the protein in solution.[9]

We have shown that a protein–mesoporous silicate system can be readily generated and that cytochrome c is readily adsorbed by such mesoporous materials, provided that the pore sizes of the mesoporous silicate are large enough to accommodate the protein structure and therefore allow access to the large internal surface areas of these materials. The activity of the adsorbed protein at the interface has also been clearly defined and is comparable with the activity of the protein in solution over the same concentration range.

This research was funded by the Higher Education Authority through the Programme for Research in Third Level Institutions (1999–2000).

Notes and references

‡ The activity profiles for each of the silicates were adjusted to reflect only the activity of the adsorbed cytochrome c.
§ TOF is the turnover frequency defined as μmol of reduced ABTS s^{-1}/μmol cytochrome c on silicate.

Received (in Cambridge, UK) 15th December 2000, Accepted 12th January 2001
First published as an Advance Article on the web 19th February 2001

The reaction of $(NBu^n_4)[Mn_8O_6Cl_6(O_2CPh)_7(H_2O)_2]$ with 2-(hydroxymethyl)pyridine (hmpH) or 2-(hydroxyethyl)pyridine (hepH) gives the $Mn^{II}_2Mn^{III}_{10}$ complexes $[Mn_{12}O_8Cl_4(O_2CPh)_8(hxp)_6]$ [hxp$^-$ = hmp$^-$ (1) or hep$^-$ (2)]; these compounds are core isomers with markedly different magnetic properties, compound 1 having an $S = 7$ ground state and displaying strong out-of-phase ac susceptibility signals that establish it as a new class of single-molecule magnet, whereas compound 2 is a low-spin molecule with an $S = 0$ ground state.

In recent years, the search for the ultimate high-density memory devices has afforded so-called single-molecule magnets (SMMs). Each independent molecule in these materials possesses the ability to function as a magnetizable magnet below a critical temperature, owing to intrinsic intramolecular properties rather than intermolecular interactions and long-range ordering. Known SMMs include $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_x]^{n-}$ (n = 0–2),[1–4] complexes with the $[Mn^{IV}Mn^{III}_4O_3X]^{6+}$ core,[5] $[Mn_4(O_2CMe)_2(Hpdm)_6]^{2+}$ salts (pdm = anion of pyridine-2,6-dimethanol),[6] $[Fe_8O_2(OH)_{12}(tacn)_6]^{8+}$ salts (tacn = 1,4,7-triazacyclononane),[7] $[Fe_4(OMe)_6(dpm)_6]$ (dpmH = dipivaloylmethane)[8] and $[V_4O_2(O_2CR)_7(L–L)]^z$ (L–L = 2,2′-bipyridine, pyridine-2-carboxylate anion).[9] A convenient way to detect the slow magnetic relaxation of SMMs is by the appearance of an out-of-phase signal (χ_M'') in ac susceptibility studies, which indicates that the rate of relaxation is insufficient to keep up with the oscillating applied field. We herein report a new class of dodecanuclear Mn-based SMMs with an $S = 7$ ground state and a strong χ'' signal, which occurs at temperatures higher than those observed for all previously reported SMMs, except the $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_x]^{n-}$ family. We also report a structurally related species, whose structural differences result in a low-spin ground state.

Treatment of $(NBu^n_4)[Mn_8O_6Cl_6(O_2CPh)_7(H_2O)_2]$[10] with 4 equivalents of 2-(hydroxymethyl)pyridine (hmpH) or 2-(hydroxyethyl)pyridine (hepH) in MeCN leads to a precipitate after several days. Extraction of the soluble component into CH_2Cl_2 and diffusion of Et_2O into the resulting solution results in crystalline $[Mn_{12}O_8Cl_4(O_2CPh)_8(hxp)_6]$, where hxp$^-$ = hmp$^-$ (**1**) or hep$^-$ (**2**), in yields of ⩽15%.

The centrosymmetric structures of **1** and **2**†‡ (Figs. 1 and 2) each consist of an $[Mn^{III}_{10}Mn^{II}_2(\mu_4\text{-}O)_4(\mu_3\text{-}O)_4(\mu_2\text{-}O)_8(\mu_3\text{-}Cl)_2]$ core, with peripheral ligation provided by six hmp$^-$ (**1**) or hep$^-$ (**2**) ligands, eight O_2CPh^- ligands and two terminal Cl$^-$ ligands. The cores are isomers and can be described as three pairs of face-sharing cuboidal units, (*i.e.* incomplete face-sharing double cubanes). The difference between the cores arises from the manner in which these three units are linked together; the orientation of the 'middle' unit of one compound is related to that of the other by a 120° rotation. Bond valence sums indicate that the two Mn^{II} atoms of each cluster are Mn(6) and Mn(6′). As expected, the ten Mn^{III} atoms in each cluster display a Jahn–Teller elongation. For each cluster, the hxp$^-$ ligands chelate and bridge the Mn atoms of the 'end' units, while the O_2CPh^- groups bridge Mn atoms in the 'middle' unit with those in the 'end' units. However, the arrangement of the peripheral ligands differs between **1** and **2**.

Solid-state dc magnetization measurements were performed on **1** in the range 1.8–300 K in a field of 10.0 kG. The $\chi_M T$ value of 36.6 cm^3 mol^{-1} K at 300 K remains approximately constant as the temperature is decreased until *ca.* 100 K when it begins to increase to a maximum value of 38.3 cm^3 mol^{-1} K at 50 K before rapidly decreasing to 5.3 cm^3 mol^{-1} K at 1.8 K. The spin-only ($g = 2$) value for a unit composed of non-interacting $Mn^{II}_2Mn^{III}_{10}$ ions is 38.8 cm^3 mol^{-1} K. Hence, the molecule appears to have a high spin ground state, with the low temperature decrease assigned to zero field splitting and other effects. In order to determine the ground state spin, magnetization data were collected in the ranges 1.8–4.0 K and 1–70 kG. The data were fit using a full-matrix diagonalization approach; the best fits were with $S = 6$, $g = 2.09$, $D \approx -0.8$ cm^{-1} and $S = 7$, $g = 1.79$, $D \approx -0.6$ cm^{-1}, which were of comparable quality but poorer than those normally obtained. This is a common problem in higher nuclearity Mn_x systems[11,12] and is assignable to relatively low-lying excited states, particularly when Mn^{II} ions are present since these typically give weak exchange interactions. We conclude that the molecule has $S = 6$ or 7, although we favour the latter given that $g < 2$.

Ac magnetization measurements were performed on **1** in the 1.8–10 K range in a 3.5 G ac field oscillating at 50–1500 Hz.

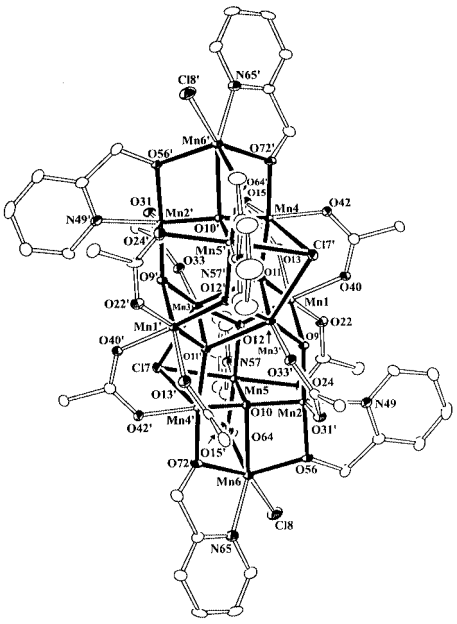

Fig. 1 ORTEP representation of complex **1** at the 50% probability level. For clarity, only the *ipso* carbon atom of each phenyl ring is included.

DOI: 10.1039/b010038m

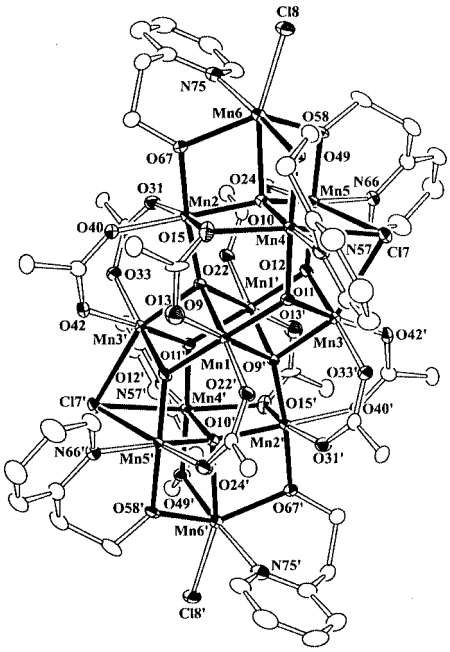

Fig. 2 ORTEP representation of complex **2** at the 50% probability level. For clarity, only the *ipso* carbon atom of each phenyl ring is included.

The in-phase $\chi_M'T$ signal (Fig. 3) shows a frequency dependent decrease at $T < 4$ K, indicative of the onset of slow relaxation on the ms timescale diagnostic of a SMM. This was confirmed by the concomitant appearance of an out-of-phase (χ_M'') signal due to the inability of **1** to relax sufficiently rapidly at these temperatures to keep up with the oscillating field. The χ_M'' signal has a peak at *ca.* 2.75 K at a 997 Hz ac frequency, where the position of the peak corresponds to the temperature at which the relaxation rate is equal to the ac oscillation frequency. Data obtained by varying the frequency of oscillation of the ac field was fit to the Arrhenius equation to obtain the energy barrier (U_{eff}) for the relaxation of the magnetization. The slope of the Arrhenius plot (Fig. 4) gave a U_{eff} of 30.3 K (21.1 cm^{-1}). For an integer spin system, the barrier to thermally activated magnetic relaxation is $S^2|D|$. Thus the experimentally determined kinetic energy barrier of 30.3 K (21.1 cm^{-1}) implies a minimum value of D of −0.62 K (−0.43 cm^{-1}), assuming that $S = 7$. High-field EPR studies will be performed to obtain a more precise value of D.

Solid-state dc magnetization measurements were performed on **2** in the range 1.8–300 K in a 10.0 kG field. The $\chi_M T$ value increases slightly from 37.9 $cm^3\ mol^{-1}$ K at 300 K to 38.5 $cm^3\ mol^{-1}$ K at 200 K before steadily decreasing to 1.5 $cm^3\ mol^{-1}$ K at 1.8 K, indicating a low ground state spin value. Ac susceptibility measurements were performed with a 3.5 G ac field oscillating at 997 Hz. The ac and dc data are essentially superimposable (not shown) except at the lowest temperatures and appear to be heading for $\chi_M T = 0$ $cm^3\ mol^{-1}$ K at 0 K,

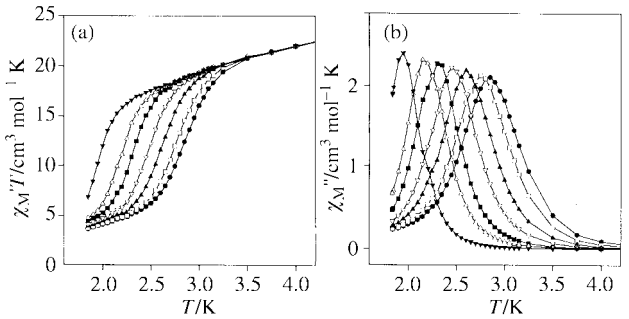

Fig. 3 Plots of (a) the in-phase (χ_M') signal as $\chi_M'T$ and (b) out-of-phase (χ_M'') signal in ac susceptibility studies *vs.* temperature of complex **1** in a 3.5 G field oscillating at 1488 (●), 997 (□), 499 (▲), 250 (▽), 100 (■), 50 (△) and 10 Hz (▼).

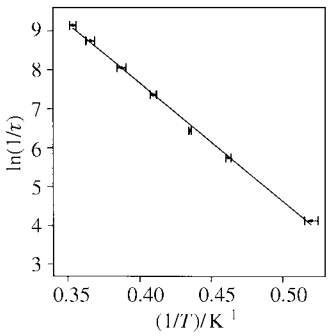

Fig. 4 Arrhenius plot with error bars for complex **1**. The solid line is a fit of the data (see text).

suggesting an $S = 0$ ground state. Its very different S value compared with **1** must clearly be due to the core isomerism, which will affect many of the Mn_2 pairwise exchange interactions in the core. No χ_M'' signal is observed for **2** and thus it is not a SMM. In contrast, the structurally related complex **1** displays strong out-of-phase signals in ac susceptibity studies that firmly establish it as a new class of SMM. These signals for **1** occur at relatively high temperatures reflecting the relatively large value of U_{eff}. Indeed, only $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]^{n-}$ complexes have exhibited greater U_{eff} values (Mn_{12} 70 K, $[Mn_{12}]^-$ 55 K, $[Mn_{12}]^{2-}$ 40 K). Thus, the new Mn_{12} complex **1** represents an important new member of the SMM family, and studies of magnetization hysteresis and quantum tunneling of magnetization in this molecule are in progress.

First published as an Advance Article on the web 19th February 2001

Microtubes, hollow balls, solid balls and square frameworks of amorphous phosphorus nitride imide (HPN_2) were obtained through the reaction of PCl_5 and NaN_3 using benzene as solvent and hydrogen source under mild conditions; as an inorganic polymer, amorphous HPN_2 with these interesting morphologies may be of potential uses in industries.

The discoveries of fullerene and carbon nanotubes as new forms of matter in the nanoscale range have opened a challenging new field in solid state physics, chemistry, and materials science with many possible applications.[1,2] Since then, much attention has been paid to the development of new methods for the preparation of nanotubes and fullerene-like structures of other materials.[3,4] Besides crystalline nanotubes and fullerene-like structures, amorphous microtubes of molybdenum polysulfide have recently been reported, which undoubtedly indicate that amorphous materials can also aggregate into tube- and ball-like morphologies.[5]

As an inorganic polymer, phosphorus nitride imide (HPN_2) is one of the tenary phosphorus nitrides. It has been researched for many years,[6] and has a network structure consisting of PN_4 tetrahedra linked through all four vertices by corner sharing; it has isometric analogues in the silicate family.[7,8] Recently, amorphous phosphorus nitride (P_3N_5) was synthesized in our laboratory by a solvent-free reaction between PCl_5 and NaN_3 in an autoclave.[9] However, when the reaction was carried out in benzene, amorphous HPN_2 was formed instead of P_3N_5. It was also found that microtubes, balls (hollow and solid) and square frameworks of the amorphous HPN_2 could be formed under different reaction conditions. The results are presented here.

The preparation technique was as follows. Manipulations were carried out in a dry glovebox with N_2 gas flowing. Analytically pure PCl_5 (0.005 mol) and NaN_3 (0.025 mol) were put into four stainless steel autoclaves of 25 ml capacity. These were filled with benzene to within 90% of the total volume. Two autoclaves were maintained at 190 °C for 3 d and 10 d, the other two were kept at 250 °C for 12 h and 3 d, respectively. When the heating was over, the autoclaves were allowed to cool to room temperature naturally. The precipitates were collected, washed with carbon disulfide, benzene, absolute ethanol and distilled water several times and dried under vacuum at 80 °C for 4 h.

Elemental† and chemical analyses show that the H : N : P : C ratio in the samples is *ca.* 1 : 2.02 : 0.99 : 0.02. XPS‡ showed that the binding energies of P 2p and N 1s were 133.3 and 398.7 eV, which are close to the values of P_3N_5.[10–12] The quantification of peaks confirmed that the atomic ratio of P : N was nearly 1 : 2.01. No other element except a trace amount of chlorine was detected in the samples. Fig. 1 shows the infrared spectrum§ of the sample, which is in good agreement with the reported spectrum of HPN_2.[7] Taking the above results into consideration, it is believed that the products are phosphorus nitride imide, HPN_2.

TEM¶ images of the samples prepared under different conditions are shown in Fig. 2. Microtubes [Fig. 2(a), (b)] were found to exist in the samples prepared at 250 °C for 12 h and 190 °C for 3 d. The proportion of microtubes in the samples was 20–25%. It is evident that the boundary of the wall of the tubes is quite well defined. The external diameter of the tubes is 350–450 nm and the thickness of the walls is *ca.* 100 nm. However, the samples prepared at 250 °C for 3 d and 190 °C for 10 d consisted of hollow balls (15–20%), solid balls (60–70%) and square frameworks (1–2%) [Fig. 2(c), (d) and (e)], respectively. The balls are perispherical with a diameter of 200–300 nm. The thickness of the shell of the hollow balls is *ca.* 50 nm. The frameworks are a uniform square and the length is about 500 nm. Electron diffraction did not reveal any crystal ordering in the tubes, balls and frameworks, and they may be considered as completely amorphous. The result was consistent with the XRD patterns of the samples.

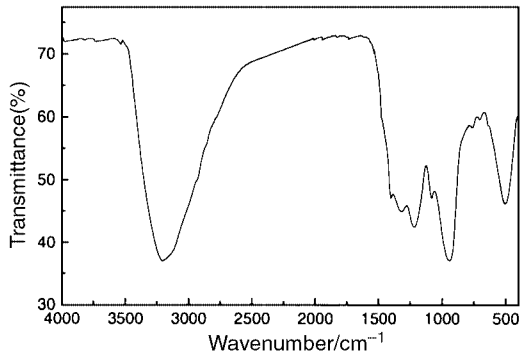

Fig. 1 IR spectrum of the amorphous HPN_2.

It is believed that the hydrogen element in HPN_2 originated from benzene because P_3N_5 instead of HPN_2 was produced when the reaction was carried out in a solvent-free environ-

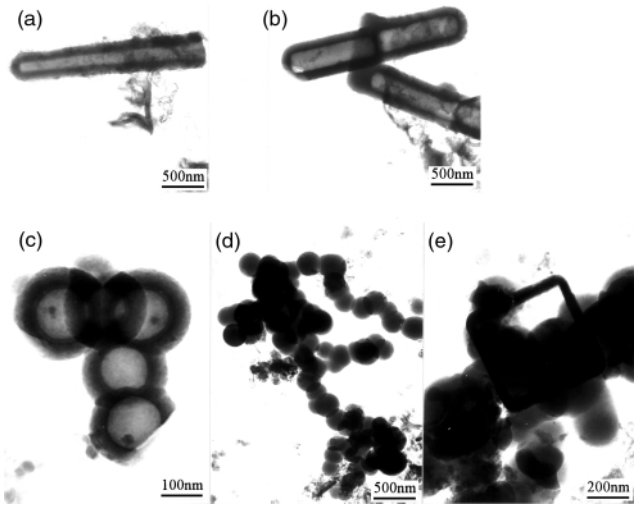

Fig. 2 TEM images of the amorphous HPN_2 prepared (a) at 250 °C for 12 h, (b) at 190 °C for 3 d, and (c–e) at 250 °C for 3 d or 190 °C for 10 d.

DOI: 10.1039/b009994p

ment.[9] Benzene plays an important role in the reaction: it acts not only as a solvent but also as a hydrogen element source, and may be the key to the formation of the interesting morphologies. This process is a complicated reaction and the exact mechanism needs further research. It was found that sodium chloride was the by-product, which was determined by the XRD patterns of the samples not washed with water.

The influence of temperature and time on the synthesis of amorphous HPN_2 was also studied. If the reaction temperature is lower than 190 °C the reaction is very incomplete and only a small amount of HPN_2 can be obtained. But when the reaction temperature is above 300 °C, P–H adsorption at 2080 cm^{-1} is detected through IR spectra, indicating that PN_4 tetrahedra are destroyed.[10] For the sample prepared at 190 °C for 12 h, no special morphology was found. The samples prepared at 190 °C for 3 d and 10 d have the same morphologies as those prepared at 250 °C for 12 h and 3 d, respectively, which indicates that a long reaction time and low temperature have the same effect as a short reaction time and high temperature, in the appropriate temperature range. Considering the facts that balls are formed instead of tubes with lengthened reaction time, and that some tubes are found truncated at the middle part [Fig. 2(b)], it is proposed that the hollow balls are transformed from the tubes. Solid balls might be formed through the aggregation of amorphous fragments, which is consistent with the fact that the ball was the most stable state in liquid.

In the reaction temperature range, nothing dangerous took place in our experiments, which indicated that this process was safe even though PCl_5 and NaN_3 were used. As an inorganic polymer, phosphorus nitride imide, HPN_2, with the above interesting morphologies may have some potential uses in industry.

Invar ($Fe_{65}Ni_{35}$), a 'zero' thermal expansion alloy consisting of Fe and Ni, has been successfully introduced into carbon nanotubes by pyrolysing, at 800 °C, aerosols of $NiCp_2/FeCp_2$ mixtures dissolved in C_6H_6; scanning electron microscopy (SEM) and high-resolution transmission electron microscopy (HRTEM) studies reveal the presence of flake-like structures (*ca.* 1–2 mm²) consisting of filled/aligned carbon nanotubes (⩽200 μm in length and ⩽80 nm in diameter) in a carpet pile-like configuration; analysis of the filling material (⩽500 nm in length and ⩽40 nm in diameter) by X-ray powder diffraction and high-resolution electron energy loss spectroscopy (HREELS) line scans, confirmed that Invar was formed; this appears, to the best of our knowledge, to be the first report of mixed metal alloy nanowires forming inside carbon nanotubes.

Invar ($Fe_{65}Ni_{35}$) alloy, discovered by Guillaume in 1897,[1] exhibits an extremely low thermal expansion coefficient, *ca.* one tenth of that of steel.[2] Furthermore, Fe/Ni alloys are interesting not only for their low thermal expansion, but also for their remarkable magnetic properties. These alloys have various uses in, for instance, the fabrication of electronic devices, aircraft controls, laser systems, bimetallic thermostats, *etc.*[2–4]

To date, various techniques for encapsulating metals, metal oxides and chlorides in multi-walled (MWNT) or single-walled carbon nanotubes (SWNT) have been developed.[5,6] However, the encapsulation of alloys has so far been unsuccessful although the formation of segregated phases of Sn and Pb has been observed in carbon-coated nanowires.[7] High temperature routes involving the arc-discharge of graphite and metal mixtures, such as Fe:Co, Fe:Ni or Ni:Y, results in the formation of SWNTs rather than alloy-filled MWNTs. Here we report, for the first time, the encapsulation of Invar in MWNTs by pyrolysing aerosols consisting of $NiCp_2/FeCp_2/C_6H_6$ mixtures in an Ar atmosphere at 800 °C.

A benzene solution containing $FeCp_2$ (Aldrich, 99%) and $NiCp_2$ (Aldrich, 98%) mixtures (atomic ratios 65:35 Fe:Ni; 5% by weight), was prepared ultrasonically during 3–5 min. The solution was transferred to the reservoir of an aerosol generator (sprayer), then nebulized by a high Ar flow rate (*ca.* 2000 sccm), and dispersed through the sprayer (nozzle diameter *ca.* 0.45 mm). The aerosol was passed through a quartz tube (2 cm i.d. and 50 cm in length) placed in a furnace (30 cm in length) fitted with a temperature-controller. The sprayer was operated for 5 min while the furnace was maintained at 800 °C. Subsequently, spraying was discontinued and the Ar flow rate reduced to 300–500 sccm in order to avoid oxidation of the products upon cooling. The product, a black powder, was scraped from the inner walls of the hot zone of the quartz tube. A detailed description of the aerosol generator is given elsewhere.[8]

SEM studies (JEOL-JSM 6300F operating at 2–5 kV) revealed the presence of flake-like material (*ca.* 1–2 mm²) consisting of arrays of aligned nanotubes (⩽200 μm in length, ⩽80 nm in diameter) similar to those reported previously (Fig. 1).[9] The material resembles a carpet of exceptionally uniform length (or height), and the purity of the material is strikingly high when compared to experiments carried out with $FeCp_2$ only. In this context, only small amounts of particles and other by-products were observed. HRTEM (JEM3000F FEG-TEM operating at 300 kV and JEOL-JEM4000 EX operating at 400 kV) images showed the presence of partly filled nanotubes, the walls of which are relatively disordered in places where there was no metal filling. The nanowires exhibit lengths ⩽500 nm and widths ⩽40 nm and were mainly found within highly crystalline carbon walls (Fig. 2). This result is in agreement with that reported by Itoh and Sinclair, who described the graphitisation of amorphous carbon layers in the presence of Ni.[10] It has also been observed that metal-filled carbon nanotubes, generated by pyrolysis, generally tend to exhibit a higher degree of graphitisation than unfilled nanotubes.[9–12]

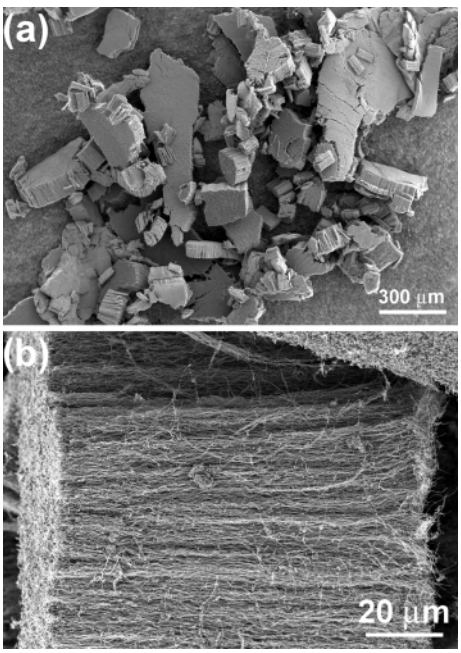

Fig. 1 (a) SEM images of aligned nanotube films (flakes) grown on the walls of the pyrolysis tube; other carbonaceous material is notably absent. (b) Higher magnification of an individual 'flake' showing the degree of alignment and that the nanotubes possess uniform diameters (< 80 nm) and lengths (< 200 μm).

DOI: 10.1039/b100190f

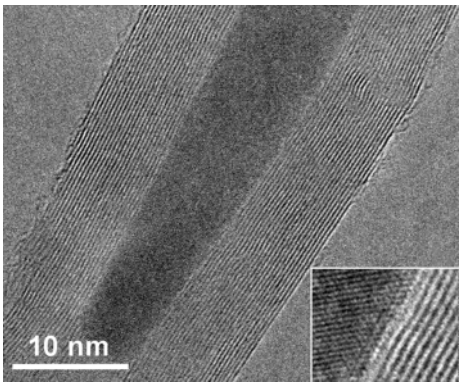

Fig. 2 HRTEM image of an Invar-filled nanotube with an inset showing the crystallinity of the filling (carbon interlayer spacing 0.34 nm).

X-Ray powder diffraction measurements (XRD, Siemens Diffraktometer D5000; Cu-Kα radiation) were carried out on the samples as well as on a commercially available Invar foil (Fe65 : Ni35, Goodfellow) for comparison. The diffraction patterns of the sample exhibit graphite peaks with a small shift of the (00l) reflections due to curvature of the concentric graphene sheets constituting the carbon nanotubes (*d*-spacing 0.34 nm). Distinct peaks for 2θ are observed at *ca.* 43.5, 50.7, 74.7 and 90.7, in agreement with those resulting from the Invar foil. They correspond to the (111), (200), (220) and (311) reflections of γ-FeNi alloys (fcc structure containing 30 atom% Ni and above) respectively. It is noteworthy that individual peaks for Fe or Ni were not observed, confirming the absence of segregated Fe or Ni domains [Fig. 3(a)]. The variation of Ni content in the fcc structure of γ-FeNi alloys induces a linear change in the lattice parameter (Vegard's Law).[13,14] Determinations of this parameter for the fcc structure of the γ-FeNi alloy present in the samples indicate an overall Ni content of *ca.* 45 ± 2 at%.

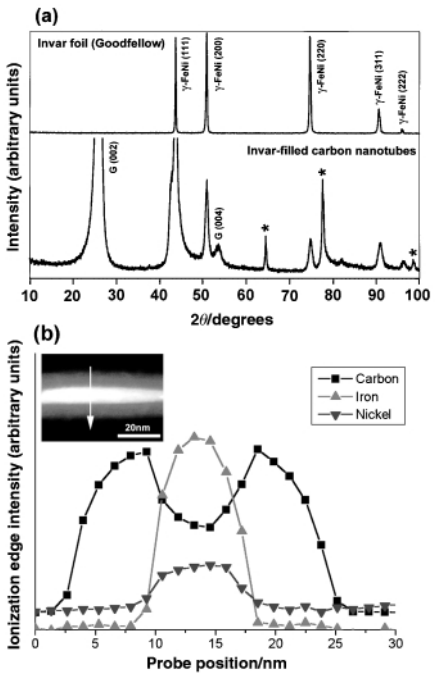

Fig. 3 (a) X-Ray powder diffraction pattern showing distinct peaks for 2θ at *ca.* 43.5, 50.7, 74.7 and 90.7, in agreement with peaks resulting from the Invar foil and corresponding to the (111), (200), (220) and (311) reflections of γ-FeNi alloys (fcc structure containing $\geqslant$30 at% Ni) respectively. (* signals belong to the XRD holder). (b) High-spatial-resolution EELS spectra profile of an Invar-filled nanotube axis (*ca.* 23 nm across) showing the relative concentrations of C, Fe and Ni. Ni and Fe are homogeneously distributed within the inner core of the carbon tube. The inset shows the high angular dark field (HADF) image of the nanowire contained within the carbon nanotube as well as the line-scan recorded during the measurement. The EELS spectra reveal that the wires contain Ni and Fe with a *ca.* 0.55±0.03 Ni/Fe ratio including the Invar composition ($Fe_{65}Ni_{35}$, Ni/Fe = 0.54).

Elemental mapping (Zeiss EM 912 Omega, operated at 120 kV) using EELS revealed that Ni and Fe are uniformly distributed within the wires. HREELS line scans along and across the fillings (carried out using a dedicated STEM VG- HB 501UX equipped with a Gatan Digi-PEELS 766) also confirmed that Ni and Fe concentrations correlate, which is consistent with alloy formation. The C and Ni–Fe concentration profiles anti-correlate, indicating that the metal is located in the nanotube core [Fig. 3(b)]. The presence of sharp features corresponding to the π^* and σ^* excitations on the energy loss near-edge structure (ELNES) of the carbon K edge at 284.5 eV indicates that the material is highly 'graphitic'. The edges at 708 and 854 eV are characteristic of Fe-L and Ni-L respectively. Quantification of representative EEL spectra reveal that the wires consist of Ni and Fe with a *ca.* 0.55 ± 0.03 Ni/Fe ratio, commensurate with the Invar composition ($Fe_{65}Ni_{35}$, Ni/Fe = 0.54).

We have demonstrated that pyrolysis of aerosols obtained from $C_6H_6/NiCp_2/FeCp_2$ mixtures generates aligned Invar-filled carbon nanotubes of high purity. It is important to note that the pyrolysis of $NiCp_2/FeCp_2$ powder mixtures or of hydrocarbons over metal powder mixtures at higher temperatures does not result in the formation of alloy nanowires because the metals tend to segregate. The generation of Invar nanowires opens up new avenues for further exploration at the nanoscale level. The magnetic and mechanical properties of these novel structures may find applications in the fabrication of magnetic storage devices and nanoscale thermostats.

First published as an Advance Article on the web 19th February 2001

This paper describes preliminary findings of a thiolate-capped gold–platinum alloy nanoparticle assembly (metallic core and organic shell) as a novel catalyst for electrooxidation of methanol.

The study of catalytic oxidation of methanol and carbon monoxide has broad technological applications, including fuel-cell technology, purification of air in gas products and in long duration space travel, and conversion in automobile exhaust systems.[1–3] The search for highly effective catalysts and detailed mechanistic understanding[4–7] has spanned to the exploration of nanometer-size catalysts.[1–3] Two critical issues facing the exploration of nanosized catalysts for methanol oxidation are however the propensity of poisoning at traditional platinum group catalysts by adsorbed CO-like species and the tendency of nanoparticle aggregation. To address these issues, we have recently reported a proof-of-concept demonstration of electrocatalytic oxidation of CO at core–shell nanostructured alkyl thiolate-capped gold nanoparticles,[8] a new expansion of recent interest in exploring nanosized bare gold catalysts.[4,5] We report herein preliminary findings of an investigation of thiolate-encapsulated gold–platinum (Au–Pt) alloy nanoparticles as catalysts for methanol electrooxidation (Scheme 1). In addition to aggregation-resistant and poison-resistant properties arising from shell encapsulation and networking, an important attribute is the bimetallic core composition with different catalytic functions: methanol oxidation at Pt-sites and CO oxidation at Au-sites. Whether such encapsulated alloyed nanosites are catalytically active under the encapsulation is a critical question. The basic understanding will also be useful to much of the recent interest in Pt–Ru based bimetallic catalysts[1] and other related systems such as polypyrrole-supported[9,10] and dendrimer-encapsulated[11] Pt nanoparticles.

The catalyst preparation involved Schiffrin's two-phase synthesis of thiolate-capped gold and alloy nanoparticles.[12,13] Fig. 1 shows a transmission electron microscopic (TEM) image of decanethiolate (DT) encapsulated Au–Pt nanoparticles which were synthesized from a 5 : 1 feed ratio (Au : Pt) of $HAuCl_4$ and K_2PtCl_6. The average core size determined was *ca.* 2.5 ± 0.4 nm. The UV–VIS spectrum of the nanoparticles showed a subtle difference of surface plasmon resonance band intensity from Au nanoparticles (*ca.* 2 nm) synthesized under similar conditions, consistent with the presence of Pt in the Au nanoparticles.[13] On the basis of previous XPS data that showed a 1 : 0.3 ratio of Au : Pt in the nanoparticles synthesized from a 1 : 1 feed ratio,[13] the Pt content estimated for our alloy nanoparticles was *ca.* 5%. Using 1,9-nonanedithiol (NDT) as the crosslinking agent, the nanoparticles were assembled on a glassy carbon (GC) electrode surface as a shell-linked particle ensemble *via* an exchange–crosslinking–precipitation route.[14] Briefly, a GC electrode was immersed into a hexane solution of DT-capped nanoparticles (30 mM) and NDT (50 mM) for *ca.* 24 h. The NDT–DT exchange reaction was followed by crosslinking, leading to nucleation and growth of a nanoparticle thin film on GC, *i.e.* NDT–$(Au–Pt)_{2.5\text{-nm}}$. The thickness of the film was controlled by immersion time. A typical film had *ca.* 8 equivalent number of particle layers, estimated from quartz-crystal microbalance measurements.[14] Electrochemical measurements were performed in a conventional three-electrode cell with Ag/AgCl (saturated KCl) as reference electrode. The electrolyte solution was purged with argon before measurements.

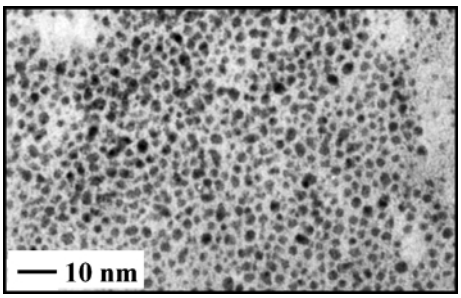

Fig. 1 TEM micrograph of DT-capped Au–Pt (5 : 1) nanoparticles.

As recently demonstrated for the case of CO oxidation,[8] the NDT–$(Au–Pt)_{2\text{-nm}}$/GC electrode was initially activated in the presence of methanol by potential polarization to *ca.* 0.8 V. Fig. 2 shows a typical set of cyclic voltammetric curves [(b)–(e)] at such an activated electrode in an alkaline solution of methanol (99.99%) purged with argon. Curve (a) is the result obtained after transferring the electrode to methanol-free electrolyte. In the absence of methanol (a), the voltammetric curve displays a small and broad oxidation wave at +300 mV extending to the positive potential limit, and a sharp reduction wave at +120 mV. These two waves are attributed to the formation and reduction of surface Au oxide (AuO_x)[8] on the nanocrystals. Contribution from Pt oxide should be minimal because its redox potential is more positive than that of Au oxide and the alloyed Pt is a very small fraction (*ca.* 5%). The shell encapsulation may become partially open as a result of either surface oxide formation or a change in shell packing due to possible thiolate desorption or reorganization. In the presence of methanol of different concentrations [(b)–(e)], two voltammetric features are remarkable. First, a large anodic wave is evident at +300 mV. The anodic peak current (i_{pa}) increases with increasing methanol concentration, exhibiting a linear relationship (Fig. 2, insert). The peak potential closely matches the potential for Au oxide formation, suggesting the participation of Au oxide in the overall catalytic oxidation mechanism. An integration of the

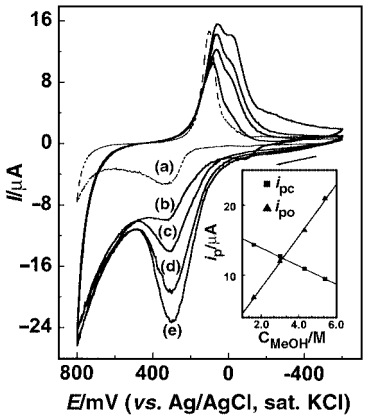

Fig. 2 Cyclic voltammetric curves for an activated NDT–(Au–Pt)$_{2.5\text{-nm}}$/GC electrode in an electrolyte solution of 0.5 M KOH with methanol concentration of 0 (a), 1.6 M (b), 3.0 M (c), 4.3 M (d) and 5.4 M (e). Geometric electrode area: 0.07 cm^2. Scan rate: 50 mV s^{-1}.

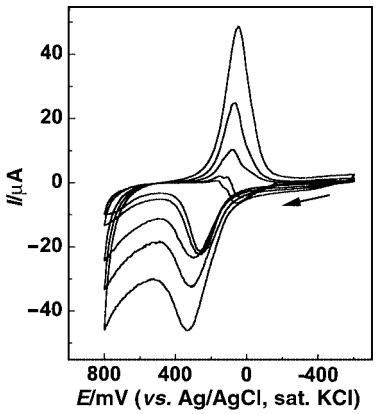

Fig. 3 Scan rate dependence of cyclic voltammetric curves for an activated NDT–(Au–Pt)$_{2.5\text{-nm}}$/GC electrode in a solution of 0.5 M KOH + 5.4 M methanol. Geometric electrode area: 0.07 cm^2. Scan rate: 10, 20, 50, 100 and 200 mV s^{-1}. Both anodic peak and cathodic currents increase with increasing scan rate.

charge from the cathodic wave translates to *ca.* 9×10^{-9} mol cm^{-2} of the amount of reactive Au. Second, in contrast to the trend for the anodic wave, the peak current for the cathodic wave (i_{pc}) decreases with increasing methanol concentration, which also exhibits a linear relationship (Fig. 2 insert). These two features are the first set of evidence demonstrating that methanol is oxidized at the nanostructured catalyst. The opposite trend between the oxidation and reduction peak currents as a function of methanol concentration is suggestive of a catalytic mediation mechanism likely by surface Au oxide species.[6–8]

There is another distinctive feature for the data in comparison with voltammetric characteristics reported for bulk Pt. No oxidation wave is detected in the negative-going sweep of the above data, which is usually observed for Pt-based catalysts due to methanol oxidation at partially reduced surface oxide. Although such an oxidation wave becomes evident at *ca.* −100 mV for a slower scan rate for NDT–(Au–Pt)$_{2.5\text{-nm}}$ (Fig. 3), the relative magnitude of the wave is much smaller. We also note that the overall potential of methanol oxidation is *ca.* 200 mV more positive for the NDT–(Au–Pt)$_{2.5\text{-nm}}$ than Pt. This difference is presumably due to a conductivity effect of the film.[14]

Fig. 3 shows the voltammetric dependence on scan rate (v) as a further piece of evidence for the electrocatalytic mediation of the catalyst. Both i_{pa} and i_{pc} increase with increasing v. A close examination reveals that the i_{pa} *vs.* $v^{1/2}$ relationship is approximately linear for $v > 20$ mV s^{-1}, indicative of an diffusion-controlled process for methanol oxidation. Remarkably, the ratio of i_{pa}:i_{pc} decreases with increasing v, which is characteristic of an surface redox-mediated catalytic oxidation process. At $v < 20$ mV s^{-1}, the reduction wave basically disappears whereas a small anodic wave is evident on the negative-going sweep. This feature resembles those observed for electrooxidation of methanol at a Pt-based surface[3] and of CO at core–shell Au nanoparticle assembies.[8] Overall, the data further support an electrocatalytic mechanism by which the oxidation of methanol is mediated by surface oxide redox species.[6]

Other preliminary data are also supportive of the above assessment. An insignificant change of C–H stretching bands of alkyl thiolates in IR reflection spectroscopic data before and after the catalytic activation supports the presence of shell encapsulation. Voltammetric data with a similar catalytic activity but different characteristics have also been noticed using thiolate-capped Au nanoparticles, which is under further investigation. Moreover, the catalytic activity is remarkably stable against repetitive cycling (at least 2 h at 10–200 mV s^{-1}) in the indicated potential region. We believe that the catalytic oxidation proceeds predominantly at surface Au oxide sites within the core–shell nanoparticle assembly. As reviewed recently by Burke and Nugent[6] for gold-based catalysis, oxygen transfer reactions have been considered using an incipient hydrous oxide/adatom mediator model. In a few recent examples, metal oxides are used as supports for bare Au nanoparticle catalysts.[5]

The result is, to our knowledge, the first example of electrocatalytic oxidation of methanol at core–shell nanostructured Au–Pt nanoparticles upon catalytic activation. A systematic manipulation of the bimetallic core composition is under way, including further investigations using nanoparticle size and shape processing methods,[15] IR reflection spectroscopy and atomic force microscopy to gain insights into effects of nanostructured voids, nanocrystal corners or edges, surface activation and segregation.

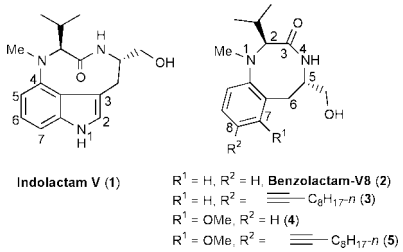
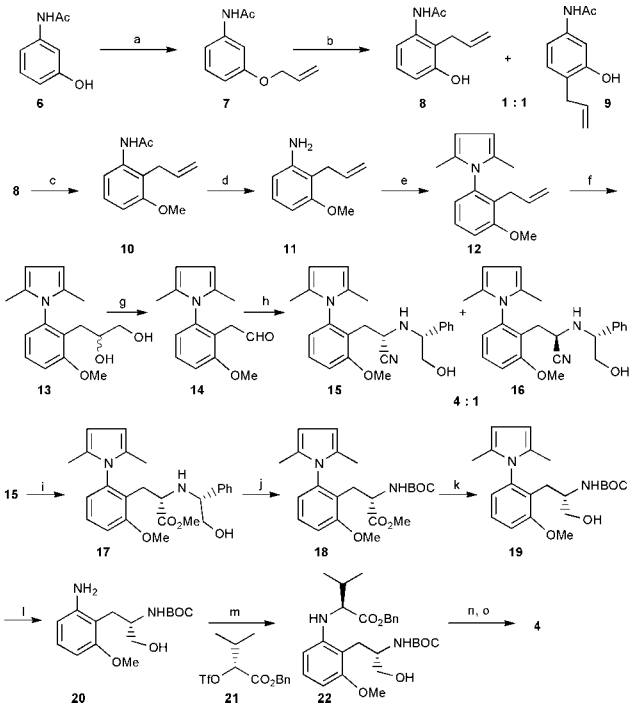
7-Methoxybenzolactam-V8 (4) was synthesized using a diastereoselective Strecker reaction as the key step employing an *ortho*-substituted phenylacetaldehyde and (*R*)-phenylglycinol as the chiral auxiliary.

Protein kinase C (PKC) consists of a growing family of closely related isozymes that mediate a wide range of cellular signal transduction processes.[1] Compounds that are able to selectively modulate the individual PKC isozymes can serve as valuable research tools in the elucidation of their physiological roles. Additionally, such compounds hold promise in the development of novel therapeutics for the treatment of human diseases, such as cancer and Alzheimer's dementia. However, very few isozyme-selective activators have been reported to date. The teleocidins (*e.g.* indolactam V, **1**) are potent PKC activators,



however, they show little selectivity.[2] Endo's group and ours have reported[3] that the benzolactam-V8 derivative **3**, a mimic of the twist-like conformation of indolactam V, is a potent activator of PKC. Recently, our group has shown that introduction of a methoxy substituent at the C7-position of benzolactam-V8 leads to a compound (**5**) that retains potency at PKCα, PKCδ and PKCε.[4] The total synthesis of benzolactam-V8 analogs depends mainly on the effective construction of the 8-membered lactam ring, which in turn depends on an efficient synthesis of a suitably substituted phenylalanine moiety. An improved synthesis of 7-methoxybenzolactam-V8 (**4**) would permit access to further analogs by making use of the heteroatom at the 7-position. We have recently developed the first synthesis of 7-methoxybenzolactam-V8,[4] which makes use of a catalytic asymmetric alkylation. The poor selectivity in this step induced us to explore an alternative approach. In the present communication, we describe a diastereoselective Strecker reaction for the synthesis of the required substituted phenylalanine which after a series of further reactions leads to the title compound **4**.

Our synthetic sequence began with the introduction of an allyl group in the ortho position to the hydroxy group using the Claisen rearrangement. Thus, 3-hydroxyacetanilide (**6**) was transformed into its allyl ether **7** using allyl bromide and potassium carbonate in refluxing acetone in 88% yield (Scheme 1). Compound **7** was subjected to the Claisen rearrangement in refluxing dimethylaniline for 6 h to give a mixture of products **8** and **9** in a 1 : 1 ratio.[5] The required regioisomer **8** was isolated by fractional crystallization and protected as its methyl ether in 82% yield. The *N*-acetyl group in compound **10** was unstable to the conditions of a subsequent nitrile methanolysis step, resulting in the formation of an undesired six-membered lactam.[6] We therefore masked the amine as a 2,5-dimethylpyrrole which can be easily cleaved under mild conditions but is stable to the conditions of acidic nitrile methanolysis. Accordingly, compound **10** was deprotected to give aniline **11**, which on treatment with acetonylacetone in toluene utilizing a Dean–Stark trap for azeotropic water removal gave compound **12** in 72% yield.[7] Compound **12** was converted to the aldehyde in a two step sequence. First, compound **12** on treatment with osmium tetroxide in acetone in the presence of NMO at rt gave diol **13** in 74% yield. Compound **13** was oxidized to the aldehyde **14** using sodium metaperiodate in a 1 : 1 mixture of ^{t}BuOH and H_2O at rt in 69% yield. Compound **14** was now subjected to the Strecker synthesis using (*R*)-phenylglycinol.[8] It is important to note that previously Chakraborty *et al.*[8] reported



Scheme 1 *Reagents and conditions*: (a) K_2CO_3, allyl bromide, acetone, reflux, 88%; (b) $PhNMe_2$, reflux, 6 h, 84%; (c) K_2CO_3, MeI, acetone, reflux, 82%; (d) 7% HCl, reflux, 2 h, 81%; (e) acetonylacetone, toluene, reflux, 24 h, 72%; (f) OsO_4, NMO, rt, acetone, 74%; (g) $NaIO_4$, t-BuOH–H_2O, rt, 69%; (h) i, (*R*)-phenylglycinol, $CHCl_3$, ii, Me_3SiCN, 0 °C–rt, 10 h, iii, TBAF, 66% for three steps; (i) HCl in ether, MeOH, 0 °C–rt, 48 h, 81% (j) i, $Pb(OAc)_4$, CH_2Cl_2–MeOH (2 : 1), 15 min; ii, 20% $Pd(OH)_2$/C, EtOH, 50 psi of H_2, overnight; iii, BOC_2O, Et_3N, THF, rt, 44% for three steps; (k) $LiBH_4$, THF, 0 °C–rt, 8 h, 96%; (l) NH_2OH·HCl, Et_3N, *i*-PrOH–H_2O, reflux, 24 h, 81%; (m) 2,6-lutidine, 1,2-dichloroethane, 87%; (n) H_2, Pd/C, EtOH, quantitative; (o) i, *N*-hydroxysuccinimide–DCC, CH_2Cl_2, ii, trifluoroacetic acid, then $NaHCO_3$, EtOAc, 82%; iii, HCHO, $NaCNBH_3$, AcOH, CH_3CN, reflux, 87%.

DOI: 10.1039/b008970m

that the Strecker reaction of phenylacetaldehyde with (*R*)-phenylglycinol gave a 1 : 1 ratio of isomers. The poor selectivity was attributed to steric factors. Compound **14** on reaction with (*R*)-phenylglycinol in chloroform at rt overnight gave the imine which on reaction with Me_3SiCN at rt for 10 h followed by treatment with tetrabutylammonium fluoride gave the amino nitriles **15** and **16** in a 4 : 1 ratio in 66% yield over the three steps. The amino nitriles **15** and **16** were easily separated by column chromatography. The structure of the isomer **15** was confirmed by X-ray crystallography. This compound was subjected to acidic hydrolysis to afford the ester **17** in 81% yield based on recovered starting material. No cyclization product was formed in the hydrolysis reaction, thus supporting our choice of protecting group. Oxidative removal of the phenylglycinol moiety was carried out with lead tetraacetate in CH_2Cl_2–MeOH to give a Schiff's base, which on catalytic hydrogenation over $Pd(OH)_2$/C gave the free amine. The amine was isolated as the BOC-protected intermediate **18**, and the overall yield for the three steps was 44%.

With the substituted phenylalanine fragment in hand, we now needed to add the valine fragment. Compound **18** was reduced to alcohol **19** using $LiBH_4$ in THF in near quantitative yield. The aromatic amino group was unmasked in good yield by refluxing in a solvent mixture of ^iPrOH–H_2O with hydroxylamine hydrochloride and triethylamine. The aniline **20** was reacted with the D-valine derived triflate **21**[9] to give compound **22** in 87% yield. Compound **22** on hydrogenation gave the carboxylic acid in quantitative yield, which was converted to the eight-membered lactam using the active ester method as reported previously.[3b] *N*-Methylation using HCHO–$NaCNBH_3$–HOAc gave 7-methoxybenzolactam **4** in 87% yield.[10]

In conclusion, we report an improved synthesis of 7-methoxybenzolactam-V8 making use of a diastereoselective Strecker synthesis. This compound may serve as an intermediate in the preparation of a variety of C7-substituted benzolactam analogs, which may exhibit better isozyme selectivity.

Under mild hydrothermal conditions the novel thioantimonate(III) $[Ni(C_4H_{13}N_3)_2]_2Sb_4S_8$ was synthesised using elemental nickel, antimony and sulfur; the structure is composed of cyclic isolated $[Sb_4S_8]^{4-}$ anions and $[Ni(C_4H_{13}N_3)_2]^{2+}$ cations.

Open framework structures based on interconnected chalcogenometallates are of great interest as possible 'zeolite' similar phases, for which highly interesting properties could be expected. Condensation of maingroup-thioanions in the presence of large organic cations[1–3] acting as structure directing agents was achieved under solvothermal conditions. The incorporation of transition metals (tm) into the thiometallate network should lead to new connections and to changed physical properties. Our main goals are the investigation of the synthetic conditions necessary to connect tmS_x fragments with main group thiometallates and to study the influence of the 'template' on the dimensionality of the products. Thioantimonates(III) exhibit a variable coordination behaviour caused by the stereochemically active lone pair.[4–6] However, until now large isolated Sb_xS_y anions were observed in only very few compounds. Recently, we and other groups reported the first examples of transition metal containing thioantimonates(III).[7,8] During our continuing work in this field the new thioantimonate(III), $[Ni(DETA)_2]_2Sb_4S_8$† [DETA = diethylenetriamine], containing the new and unusual isolated ring anion $[Sb_4S_8]^{4-}$ was obtained. The present contribution reports the synthesis and crystal structure of this new compound.

In the crystal structure of $[Ni(DETA)_2]_2Sb_4S_8$‡ two crystallographically independent $[Sb_4S_8]^{4-}$ ring anions [Fig. 1(a) and (b)] and two crystallographically independent $[Ni(DETA)_2]^{2+}$ cations are found. Four pyramidal SbS_3 units sharing common corners build a Sb_4S_4 hetero ring. Each Sb atom is bounded to a terminal S atom thus forming the final $[Sb_4S_8]^{4-}$ anion. The cyclo-octathiotetraantimonate anion belongs to the class of the medium-sized rings that preferably adopt the bent flexible chair conformation. Charge balancing is achieved by the two isolated $[Ni(DETA)_2]^{2+}$ cations.

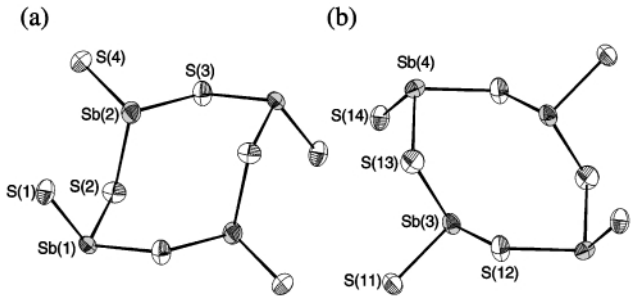

Fig. 1 (a) and (b): The two $[Sb_4S_8]^{4-}$ anions in $[Ni(DETA)_2]_2Sb_4S_8$ with labelling and displacement ellipsoids drawn at the 50% level. Selected bond lengths (Å) and angles (°): Sb(1)–S(1) 2.337(2), Sb(1)–S(2) 2.429(2), Sb(1)–S(3) 2.453(2), Sb(2)–S(4) 2.315(3), Sb(2)–S(3) 2.471(2), Sb(3)–S(11) 2.328(2), Sb(3)–S(13) 2.492(2), Sb(3)–S(12) 2.497(2), Sb(4)–S(14) 2.326(2), Sb(4)–S(13) 2.426(2); S(1)–Sb(1)–S(2) 104.32(7), S(2)–Sb(1)–S(3) 101.62(7), Sb(1)–S(3)–Sb(2) 110.88(7), S(11)–Sb(2)–S(12) 101.48(7), S(14)–Sb(4)–S(13) 100.38(8), Sb(4)–S(13)–Sb(3) 102.60(8).

The Sb–S distances within the Sb_4S_4 rings are between 2.426(2) and 2.497(2) Å and the S–Sb–S angles vary from 87.92(7) to 107.53(8)°, both being in good agreement with data found in the literature.[9] As expected, the terminal Sb-S distances [Sb(1)–S(1), Sb(2)–S(4), Sb(3)–S(11) and Sb(4)–S(14)] are shorter ranging from 2.315(3) to 2.337(2) Å. They are significantly shorter than the Sb–μ_2-S links [Sb(1)–S(2), Sb(2)–S(2), Sb(2)–S(3), Sb(3)–S(12), Sb(3)–S(13), Sb(4)–S(13)], which are often observed in literature.[10] The pertinent angles vary between 93.90(9) and 104.32(7)°. If the lone pair of Sb(III) is considered, the coordination of the SbS_3 pyramids can be viewed as distorted ψ-SbS_3 tetrahedra.[11] The two independent $[Sb_4S_8]^{4-}$ anions have a similar geometry. The Sb_4S_8 rings are stacked onto each other forming rods parallel to the *a*-axis (Fig. 2). We note that the shortest intramolecular Sb–S contacts are above 3.9 Å and no intermolecular Sb–S separations shorter than 4 Å are observed.

The Ni^{2+} cations are in a distorted octahedral environment of six nitrogen atoms of two DETA ligands. The Ni–N distances vary between 2.080(8) and 2.193(6) Å and are in the normal range.[12] The angles range from 78.0(3) to 174.8(3)°. In one cation the DETA ligands take up an u-facial (Ni1) and in the second a *mer* geometry.[20]

The three-dimensional arrangement of cations and anions (Fig. 2) is achieved by N–H···S close contacts. Every anion shows seven such contacts with distances between 2.513 and 2.837 Å and angles N–H···S ranging from 144.15 to 175.53°. The H atoms of $[Ni(1)(DETA)_2]^{2+}$ are involved in eight and those of the second complex in six S···H contacts. It is well known that S···H hydrogen bond interactions are weak and a definite decision as to whether genuine hydrogen bonding occurs cannot be drawn alone on the basis of crystal structure determination. Nevertheless, the distinct differences of intermolecular cation–anion interactions may be responsible for the above mentioned differences in the conformations of the anions and cations. Raman spectra of pure DETA and of the title

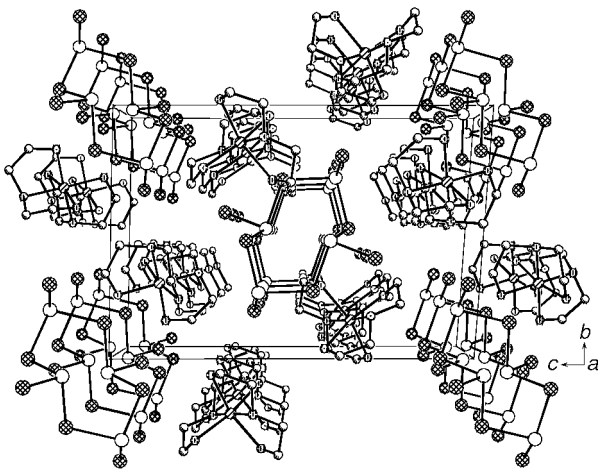

Fig. 2 Crystal structure of $[Ni(DETA)_2]_2Sb_4S_8$ with view along the *a*-axis (hydrogen atoms omitted for clarity).

DOI: 10.1039/b009583o

compound were recorded to monitor the differences in the νNH_2 and δNH_2 regions. For the free ligand the νNH_2 resonances are between about 3100 and 3400 cm^{-1} with a pronounced peak at 3297 cm^{-1}. The δNH_2 line is located at 1601 cm^{-1}. In the title compound the whole region of νNH_2 modes is broader extending from *ca*. 3030 to 3410 cm^{-1} with a peak at 3232 cm^{-1}. The δNH_2 line is slightly shifted to 1594 cm^{-1}. We note that all modes of the $[Ni(DETA)_2]^{2+}$ complexes are in good agreement with data published in the literature.[20–25] The shift to lower wavenumbers as well as the broadening may be caused by both the N–Ni bonding interactions and possible S···H–N hydrogen bonds.

As can be seen in Fig. 3 the material decomposes in two steps with individual weight changes of 31.1 and 2.7% giving a total weight loss of 33.8% which roughly corresponds to the emission of the four DETA ligands (Δm_{theo} = 32.4%).§ Decomposition starts at T_{onset} = 222 °C and is accompanied by two endothermic peaks at T_p = 260 and 319 °C. The first endothermic signal exhibits a complex shape with two shoulders located at T_p = 251 and 273 °C. In further experiments decomposition of the educt was stopped at 300 and 350 °C. The residues were characterised by CHN analysis, X-ray powder diffraction (XPD), energy dispersive X-ray analysis (EDX) and IR spectroscopy. In the XPD pattern of the grey residue [C, 1.8; H, 0.25; N, 1.15; EDX (atom%): S, 48(1); Sb, 32.2(1.4); Ni, 19.7(2.7)] obtained after the 300 °C treatment, NiS, Sb_2S_3, NiSbS and a small amount of an unknown fourth phase were identified. In the IR spectrum no C–H, C–N, C–C or N–H vibrations could be detected. From the elemental analyses it can be assumed that not only DETA is emitted but also S, and a small amount of C, H, and N remain in the residue. In the XPD pattern of the dark grey sample obtained after heating to 350 °C (C, 1.6%; H, 0%; N, 0.72%; EDX(atom%): S, 47.8(8); Sb, 31.7(1.0); Ni, 20.5(1.9)%] the reflections of the unknown phase disappeared and only NiS, Sb_2S_3 and NiSbS could be identified. The small weight loss between 300 and 350 °C of *ca*. 2.7% may be attributed to the decomposition of the unknown phase accompanied by the emission of C, H and N as well as of sulfur.

The endothermic event at T_p = 556 °C agrees well with the melting point of Sb_2S_3 (literature value: T_m = 550 °C). In the grey reaction product the two phases Sb_2S_3 and NiS could be identified.

In conclusion, we note that the stabilisation of the high negatively charged $[Sb_4S_8]^{4-}$ anion may be achieved by an extended hydrogen bond network as well as by the shape and size of the counterion. There is no simple relationship between cation size and shape and the dimensionality of the anionic thioantimonate network. In addition, hydrothermal crystallisations are multicomponent heterogeneous reactions that are not well understood and we are far from being able to predict structures or physical properties of the products. The successful synthesis and characterisation of new thioantimonates(III) may provide the information that is necessary to lead to more rational syntheses of such compounds.

Synthesis of the first polymer-supported tripodal triphosphine ligand and its application in the heterogeneous hydrogenolysis of benzo[*b*]thiophene by rhodium catalysis

Claudio Bianchini,* Marco Frediani and Francesco Vizza

ISSECC-CNR, Via J. Nardi 39, Firenze 50132, Italy. E-mail: bianchin@fi.cnr.it

Received (in Cambridge, UK) 19th December 2000, Accepted 2nd January 2001
First published as an Advance Article on the web 19th February 2001

A *p*-styrenyl substituent attached to the ligand framework allows the tripodal triphosphine moiety –C(CH$_2$PPh$_2$)$_3$ to be introduced as a pendant group in polystyrene matrices *via* free-radical copolymerisation; in conjunction with rhodium(I), the polytriphos material forms an effective heterogeneous catalyst for the hydrogenolysis of benzo[*b*]thiophene to 2-ethylthiophenol and ethylbenzene.

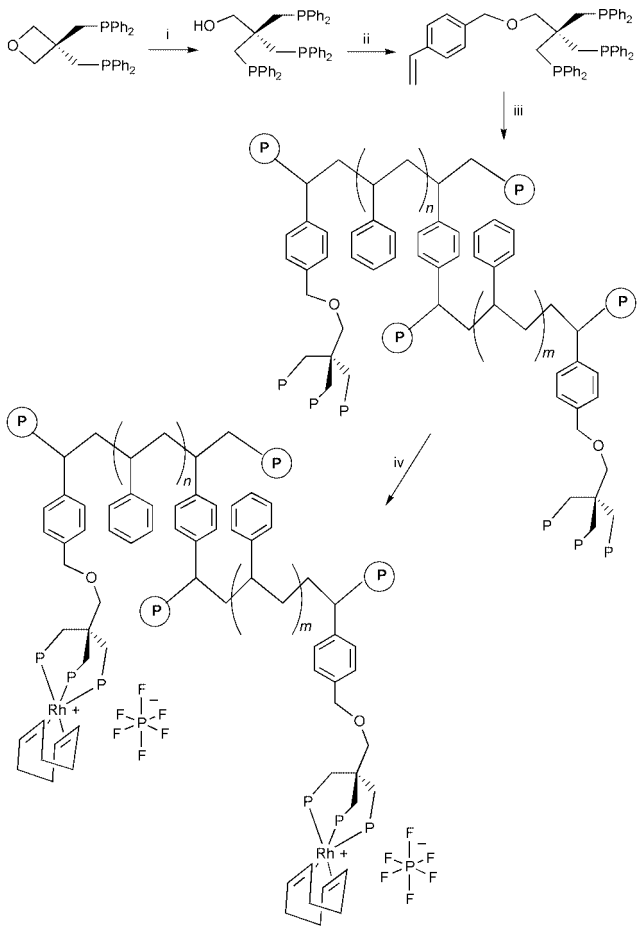
The immobilisation of metal complexes on solid supports to obtain single-site heterogeneous catalysts is a research topic of much current interest. Several heterogenisation techniques are available which span from hydrogen-bonding to covalent grafting, to physical and ionic immobilisation.[1,2] Similarly, many different types of materials (metal oxides, dendrimers, polyolefins, heteropoly acids, gels, *etc*.) may be employed as the support, which may be either inert or chemically interacting with metal, substrate and/or product. Irrespective of the grafting mode and of the type of support, a major drawback of any heterogenised catalyst is represented by metal leaching into the mobile phase. In order to reduce, and ultimately inhibit, undesired loss of metal during the catalysis, the structure of the tethered complex must be thermally and chemically robust. In general, tertiary phosphines meet these requisites and beyond, as they behave as strong ligands towards most transition metals and can also be finely tuned so as to determine the steric and electronic properties of the metal centre. Polydentate phosphines show superior control properties over monophosphines and those having tripodal structure, such as MeC(CH$_2$PPh$_2$)$_3$ (triphos), are almost insuperable with regard to the stability of the metal complexes.[3]

Here, we describe the synthesis of the first tripodal triphosphine anchored to a cross-linked styrene/divinylbenzene polymer and of its complex with the 'Rh(cod)$^+$' moiety (cod = cycloocta-1,5-diene). It is also shown here that the supported rhodium complex is a powerful catalyst for the hydrogenolysis of benzo[*b*]thiophene to 2-ethylthiophenol and ethylbenzene, which represents the first evidence of a successful single-site catalyst in the heterogeneous hydrodesulfurisation (HDS) of a thiophenic substrate.[4,5]

The synthetic route to the triphosphine-containing styrene monomer is illustrated in Scheme 1. The strategy is to prepare a triphos ligand bearing a single reactive hydroxy functionality for attachment of the styrene group. Nucleophilic attack by diphenylphosphide at the heterocycle of 3,3-bis(diphenylphosphinomethyl)oxacyclobutane,[6] followed by reaction with 4-vinylbenzyl chloride is an excellent method to accomplish the high-yield synthesis of the desired *p*-styrenyl-functionalised triphos ligand 2,2,2-tris(diphenylphosphinomethyl)ethyl 4-vinylbenzyl ether (TVBE).† Copolymerisation of TVBE with divinylbenzene alone (DVB) or with styrene–DVB in THF/MeOH using AIBN as the radical initiator generates cross-linked triphosphine polymers (polytriphos) as off-white solids insoluble in organic solvents. Besides elemental analysis (C, H, P), the presence of triphosphine units is shown by CP MAS ^{31}P NMR spectroscopy.‡ The spectrum of a polytriphos sample obtained by copolymerisation of TVBE with DVB (1:1) is given in Fig. 1a. Note that the chemical shift (δ −25.6) is similar to that of monomeric TVBE as well as silica-supported triphos.[2] A soluble polystyrene-bound diphosphine ligand with the 1,3-bis(diphenylphosphino)propane moiety has been described previously.[7]

Advantages of the present technique over heterogenisation procedures involving the reaction of functionalised phosphines with functionalised cross-linked styrene–DVB resins[8] are: (1) the ease of synthesis since only the phosphine needs to be chemically modified; (2) the effective control on the phosphine loading (and hence of the metal loading) by simply varying the phosphine : DVB : styrene ratio; (3) the absence of residual functional groups on the resins.

Supported complexes of the general formula [Rh(cod)(polytriphos)]PF$_6$ have been prepared by stirring CH$_2$Cl$_2$ solutions of [RhCl(cod)]$_2$ and NBu$_4$PF$_6$ in the presence of polytriphos at room temperature for 24 h. The filtered yellow solids are washed with CH$_2$Cl$_2$ at reflux temperature using a Soxhlet



Scheme 1 *Reagents and conditions*: i, HPPh$_2$, BuLi, THF (65%); ii, NaH, 4-vinylbenzyl chloride, DMF (90%); iii, styrene–divinylbenzene, AIBN, THF/MeOH (1:2, v/v), 85 °C; iv, [RhCl(cod)]$_2$, NBu$_4$PF$_6$, CH$_2$Cl$_2$ (98%).

DOI: 10.1039/b010128l

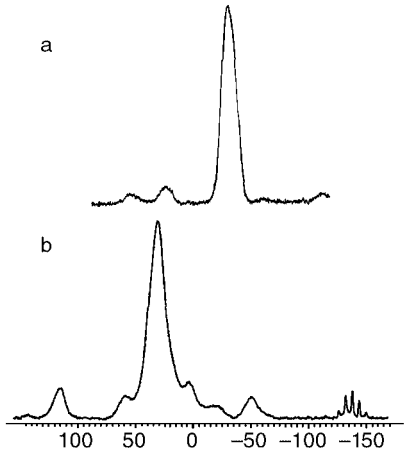


Fig. 1 CP MAS ^{31}P NMR (121.50 MHz) spectra of polytriphos (a) and [Rh(cod)(polytriphos)]PF_6 (b).

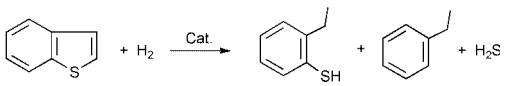
apparatus and then dried. The rhodium content in the heterogeneous catalysts depends on the polytriphos sample; in particular, a loading of 7.24 wt% has been found for a polymer obtained by copolymerising TVBE and DVB in a 1:1 ratio, while a loading of 0.94 wt% has been found for a polymer obtained by copolymerising TVBE, DVB and styrene in a 0.6:1:36 ratio. The coordination of rhodium(I) to the tethered phosphine is demonstrated by the low-field shift to δ 28.4 of the phosphorus resonance as well as the presence of the PF_6^- sextuplet at δ −143.5 (Fig. 1b).

As an example of the great potential of polytriphos metal complexes in heterogeneous catalysis, [Rh(cod)(polytriphos)]PF_6 (0.94 wt%) has been employed to hydrogenate benzo[*b*]thiophene (BT) in tetrahydrofuran (THF) under basic conditions (Scheme 2).[4,5]



Scheme 2 Hydrogenolysis of BT to 2-ethylthiophenol and ethylbenzene.

Under rather harsh experimental conditions (160 °C, 30 bar H_2), the thiophenic substrate is mainly converted to 2-ethylthiophenol (ET) but appreciable formation of the desulfurised product ethylbenzene (EB) also occurs. Interestingly, no trace of 2,3-dihydrobenzo[*b*]thiophene was detected by GC. Table 1 reports catalytic data obtained for runs at 2, 5 and 10 h. In all cases, no rhodium leaching was observed by ICP-AES (< 1 ppm), while an effective catalyst recycling with no loss of catalytic activity was accomplished by removing the liquid phase *via* the liquid sampling valve and recharging the autoclave with a solution containing substrate and base (entries 4 and 5).

Under comparable experimental conditions, both the aqueous-biphase catalyst [Rh(cod)(sulphos)] in MeOH/*n*-heptane [sulphos = $^-O_3S(C_6H_4)CH_2C(CH_2PPh_2)_3$][5] and the homogeneous catalyst [Rh(DMAD)(triphos)]PF_6 in THF (DMAD = dimethyl acetylenedicarboxylate)[9] are slightly less efficient than [Rh(cod)(polytriphos)]PF_6 for the hydrogenolysis of BT to ET (TON *ca*. 90 *vs*. 124) and cannot be recycled after catalysis.

The data reported in Table 1 are of great relevance in the field of model studies of heterogeneous HDS as they show that a single metal site belonging to the class of the HDS promoters[10] can open and hydrogenate a thiophenic substrate without the need of any cooperative effect.[4,5] Besides this important result, we have succeeded for the first time in producing a polymer-supported tripodal triphosphine ligand with which we intend to prepare a large variety of metal catalysts and study their performance in heterogeneous processes.

Table 1 Hydrogenation of BT with [Rh(cod)(polytriphos)]PF_6 (0.94 wt%)[a]

Entry	*t*/h	ET (%)	EB (%)	TON (ET)	Conv. (%)
1	2	48.5	2.5	97	51.0
2	5	62.2	4.0	124	66.2
3	10	74.3	5.5	349	79.8
4[b]	2	47.6	3.1	95	50.7
5[b]	2	48.0	3.5	96	51.5

[a] Experimental conditions: 30 mL THF, Rh 3.5×10^{-2} mmol, BT 7 mmol, Bu^{t}OK 7 mmol, 160 °C, 30 bar H_2, 1500 rpm; product composition determined by GC–MS after acidification of the catalytic mixture with aqueous HCl. [b] Recycling in the same conditions of entry 1.

We are grateful to Claudia Forte (ICQEM-CNR of Italy) for assistance in recording the CP MAS ^{31}P NMR spectra and to MURST (Italy) for financial support (legge 95/95).

Notes and references

† *Selected NMR data* for 2,2,2-tris(diphenylphosphinomethyl)ethyl 4-vinylbenzyl ether (TVBE): ^{1}H NMR ($CDCl_3$) δ_H 2.57 (d, 6H, CH_2P, ^3J 2.91 Hz), 3.16 (s, 2H, OCH_2C$(CH_3)_3$), 3.71 (s, 2H, OCH_2Ph), 5.24 (dd, H_{cis}, CH_2=CH, J_{cis} 10.90 Hz, J_{gem} 0.97 Hz), 5.74 (dd, H_{trans}, CH_2=CH, J_{trans} 17.53 Hz, J_{gem} = 0.97 Hz), 6.71 (dd, 1H C*H*=CH_2), 6.91–7.31 (m, 34H, Ph). ^{13}C{^{1}H} NMR ($CDCl_3$) δ_C 38.87 (m, CH_2P), 43.58 (q, $CH_2C(CH_2PPh_2)$, J(CP) 12.4 Hz), 72.50 (s, O*C*H_2Ph), 77.19 (m, O*C*$H_2C(CH_3)_3$), 114.03 (s, *C*H_2=CH), 123.48-137.42 (m, Ph), 133.92 (s, *C*H=CH_2). ^{31}P{^{1}H} NMR ($CDCl_3$) δ_P −26.1 (s). Satisfactory elemental analyses were obtained for all compounds.

‡ Solid-state ^{31}P NMR spectra were recorded at room temperature on a Bruker AMX 300 WB spectrometer equipped with a 4 mm BB-CP MAS probe at a working frequency of 121.50 MHz. The spectra were acquired using the cross-polarisation pulse sequence under magic angle spinning at a spinning rate of 10 kHz. The 90° pulse was 3.3 μs, and the contact pulse was 1 ms. The spectra of the supported triphosphine were collected after 400 scans with a recycle delay of 1 s and a line broadening of 30 Hz, whereas the spectra of the supported rhodium complex were acquired with 700 scans, a recycle delay of 1 s and a line broadening of 50 Hz. H_3PO_4 (85%) was used as the external standard.

Photocycloaddition reactions of 2-acylcyclohex-2-enones

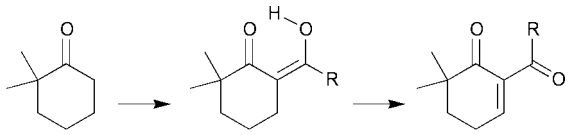
Leticia Oliveira Ferrer and Paul Margaretha*

Institute of Organic Chemistry, University of Hamburg, D-20146 Hamburg, Germany. E-mail: margpaul@chemie.uni-hamburg.de

Received (in Liverpool, UK) 28th November 2000, Accepted 6th February 2001
First published as an Advance Article on the web 19th February 2001

The newly synthesized 2-acylcyclohex-2-enones 1 photocycloadd selectively to the C–C triple bond of 2-methylbut-1-en-3-yne giving diacylcyclobutene derivatives 4 and 5, and they react with 2,3-dimethylbut-2-ene in an overall [4+2]-photocycloaddition to afford benzopyranones 7.

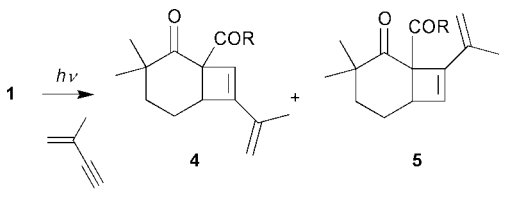
We have recently published results[1,2] on the photocycloaddition of cyclohex-2-enones to 2-methylbut-1-en-3-yne, showing that the substitution pattern on C(2) of the enone has a pronounced influence on the outcome of the reaction. While the (parent) cyclohex-2-enone affords mainly bicyclo[4.2.0]octan-2-ones resulting from [2 + 2]-cycloaddition to the C–C double bond of the enyne, 2-alkylcyclohex-2-enones give naphthalen-1(2*H*)-ones *via* 1,6-cyclization of the triplet biradical intermediate. Finally, 2-cyanocyclohex-2-enone yields a mixture of these two types of compounds and, in addition, one product resulting from cycloaddition to the C–C triple bond of the enyne. Here we report on the synthesis of the hitherto unknown 2-acylcyclohex-2-enones **1a** and **1b** and on their unprecedented behaviour on irradiation in the presence of this same enyne or of 2,3-dimethylbut-2-ene, respectively. *C*-Acylation of 2,2-dimethylcyclohexanone (**2**)[3] with either LDA–acetyl cyanide or NaOMe–ethyl trifluoroacetate affords 2-(1-hydroxyethylidene)-6,6-dimethylcyclohexanones **3a** and **3b** in 60 and 62% yield, respectively.[4] Dehydrogenation to **1a** and **1b** is then achieved by treatment[5] of **3** with PhSeCl and then H_2O_2 in 96 and 90% yield, respectively (Scheme 1).[6–8]



Scheme 1

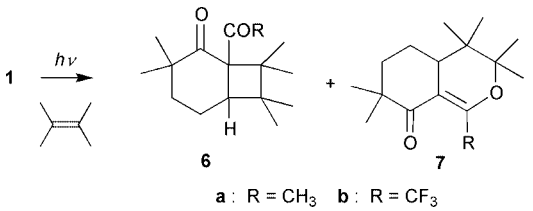
Monitoring the irradiation (λ > 340 nm) of an argon-degassed solution of **1a** (0.1 M) and 2-methylbut-1-en-3-yne (1 M) in benzene by GC indicates the formation of two new products, **4a** and **5a**, in a 1:1 ratio. At degrees of conversion of **1a** higher than 40–45% the photoproducts start to undergo secondary reactions. Under the same conditions **1b** gives a 2:3 mixture of **4b** and **5b**. In preparative runs[9] the photoproducts were separated, isolated and identified as being regioisomeric 1-acylbicylo[4.2.0]oct-7-en-2-ones (Scheme 2).[10]

Similarly, monitoring the irradiation of **1** in the presence of a tenfold molar excess of 2,3-dimethylbut-2-ene in benzene



Scheme 2

indicates the formation of two new products **6** and **7**, in a 3:1 ratio from **1a** and in a 2:1 ratio from **1b**, the major products **6** again undergoing consecutive photoreactions. After isolation as above[9] the major products **6** turned out to be (the expected) 1-acylbicyclo[4.2.0]octan-2-ones—which then undergo α-cleavage to afford aldehydes—while the minor products **7** were identified as being 3,4,4a,5,6,7-hexahydro-8*H*-isochromen-8-ones (Scheme 3).[11]



Scheme 3

The behaviour of **1a** and **1b** contrasts that of 6,6-dimethyl-2-pivaloylcyclohex-2-enone[12] which on the one hand is thermally more stable, *i.e.* it does not enolize, but on the other hand does not photocycloadd to alkenes or enynes, most probably because of the (steric) bulk of the *tert*-butyl substituent. Despite their pronounced lack of (thermal) stability, which can nevertheless be controlled by careful handling,[5,13] 2-acylcyclohex-2-enones **1a** and **1b** turn out to be remarkable substrates for intermolecular photocycloaddition reactions *a*) due to the fact that on reaction with the enyne excited cyclohexenones **1** give (novel) cyclobutene adducts selectively, thus corroborating the assumption[2] that the amount of this type of cycloadduct will increase with decreasing reduction potential of the (excited) enone, and *b)* because photochemical [4 + 2]-cycloadditions of s-*cis* enones to alkenes to give dihydropyrans have not been reported so far in the literature. Further studies aiming at the improvement in the product ratio pyran *vs*. cyclobutane are in progress.

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for support.

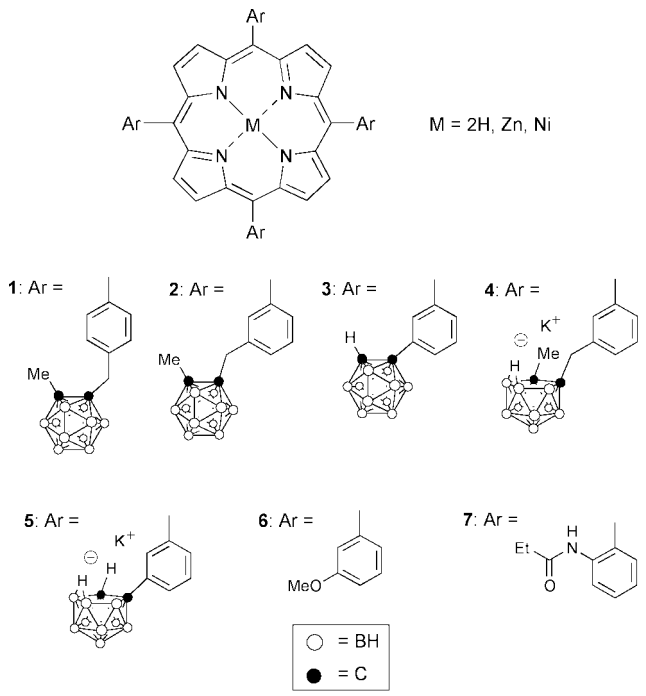
The first definitive crystal structure of a covalently bonded carborane–porphyrin system is reported; unusual inter- and intra-molecular carborane–porphyrin interactions are observed in the molecular structure and in variable temperature ^{1}H NMR experiments.

In the past few decades, porphyrins have assumed broad importance in applications as diverse as medicine,[1,2] catalysis,[3] and molecular electronics.[4,5] Many of these novel applications have employed 5,10,15,20-tetraarylporphyrins as the substrate because this type of porphyrin platform can be readily synthesized.[6] Recently, carboranyl-substituted tetraarylporphyrins have been identified as useful agents in boron neutron capture therapy (BNCT) of cancer because of their ability to localize in tumors, and their high boron content.[7,8] However, to date, carboranyl-substituted tetraarylporphyrins have not been well-characterized and it is not known if the large carborane substituent confers any novel structural or spectroscopic properties on these porphyrins. Herein, we present the first crystal structure of a carboranylporphyrin [**1** (M = Zn)] and detailed proton NMR studies of several carboranyl-substituted tetraphenylporphyrins (**2**–**5**) which demonstrate unusual interactions between the carborane group and the porphyrin macrocycle.



Several *m*- and *p*-carboranylarylporphyrins were synthesized in order to investigate structure–activity relationships in BNCT.[9] Insertion of zinc and nickel using normal procedures ($ZnCl_2$ in THF–CH_2Cl_2 1:10 or Ni(II) acetylacetonate in toluene) produced the corresponding metallo-carboranylporphyrins. Repeated attempts to grow X-ray quality crystals of these compounds were unsuccessful until the *para*-substituted porphyrin **1** (M = Zn) was crystallized and the structure determined.† The molecular structure of **1** (M = Zn), the first definitive crystallographic investigation for a covalently bonded porphyrin–carborane molecule, is shown in Figs. 1 and 2.‡[10]

The porphyrin macrocycle exhibits a non-planar waved conformation[11] (Fig. 2) with a mean deviation of the 24 macrocycle atoms from their least-squares plane of 0.062 Å. The Zn–N bond lengths of 2.062(2) Å are within the range typically seen for zinc porphyrins.[12] An unusual feature of the structure is the close intermolecular contacts between the BH hydrogens of one porphyrin and the zinc atom of another; this produces a *pseudo-hexacoordinate* zinc complex (Fig. 2). Zinc

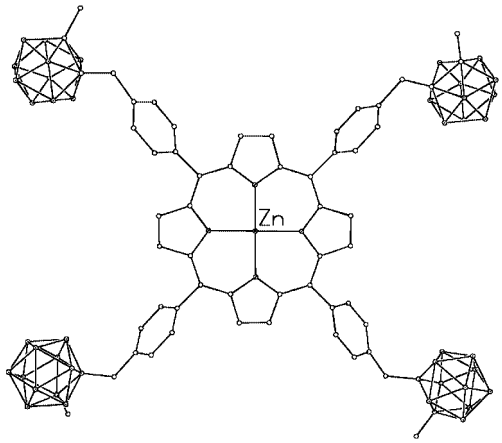


Fig. 1 The molecular structure of **1** (M = Zn). Hydrogen atoms have been omitted for clarity.

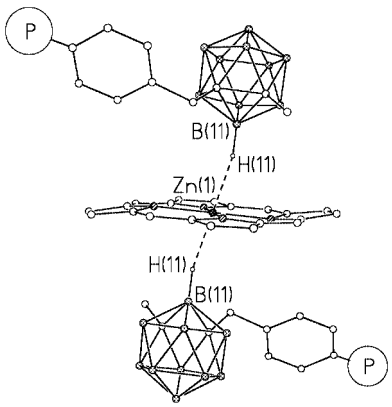

Fig. 2 View of the crystal structure of **1** (M = Zn) showing the waved porphyrin macrocycle and *pseudo-hexacoordinate* zinc(II) ion. Hydrogen atoms, except for the two involved in the B(11)–H(11)···Zn1···H(11)–B(11) bridge, and methylcarboranylphenyl substituents attached to the illustrated porphyrin macrocycle have been omitted (P = porphyrinyl).

Table 1 Activation energies ($\Delta G^{\ddagger}$; kJ mol^{-1}) for aryl–porphyrin rotation in porphyrins **2**–**7**[a]

Porphyrin	M = 2H	M = Zn	M = Ni
2	72 (313 K)[b]	80 (368 K)	
3	72 (323 K)	79 (348 K)	55 (243 K)
4	73 (323 K)	79 (353 K)	
5	71 (323 K)	76 (338 K)	54 (258 K)
6	45[16]		
7	122[15]	131[15]	108[15]
Δ (**7**–**3**)[c]	50	52	53

[a] Proton NMR spectra were measured at 400 MHz using $CDCl_3$ [**2** (M = 2H) and **3** (M = 2H, Ni)], $C_6D_5CD_3$ [**2** and **3** (M = Zn)], CD_3COCD_3 [**4** (M = 2H) and **5** (M = 2H, Ni)] or CD_3SOCD_3 [**4** and **5** (M = Zn)] as solvent. [b] Activation energies for aryl–porphyrin rotation in porphyrins **2**–**5** were calculated at the coalescence temperatures which are given in parentheses. [c] Difference in activation energies for aryl–porphyrin rotation in porphyrins **7** and **3**.

porphyrin structures are generally either four-coordinate or contain one or two axial ligands bound *via* a lone pair from nitrogen or oxygen.[12] The hydrogen atom positions were treated with a riding model which afforded Zn(1)···H(11)–B(11) distances of 2.09 and 1.12 Å [when H(11) was freely refined the bond distances 2.16 and 1.06 Å were obtained]. An examination of the more than 250 zinc porphyrin crystal structures in the Cambridge Structural Database did not reveal any examples of axial ligands coordinating *via* a hydrogen atom, so this appears to be the first example of this type of bonding. There were however, two reported crystal structures that are similar enough to be mentioned; firstly, the structure of [Fe(III)TPP]·[$(CB_{11}H_{12})^-$][13] shows the $(CB_{11}H_{12})^-$ anion coordinated to the Fe(III) ion *via* one of its hydrogen atoms, with Fe···H–B distances of 1.82 and 1.25 Å. Secondly, the structure of $[(C_6H_5)_3P]_3Rh(CB_{10}H_{10}C–C_6H_5)$[14] exhibits a Rh···H–B bridge with a Rh–H distance of 2.06 Å. We believe that the unusual interaction between the carborane and the zinc ion in **1** (M = Zn) is probably a result of the electronic properties of the carborane cages combined with an efficient cell packing of this structural motif.

The ^{1}H NMR spectrum of the *para*-substituted carboranylporphyrin **1** (M = 2H) showed a singlet (8.85 ppm) for the pyrrole protons and two doublets (7.59 and 8.20 ppm, J = 8.0 Hz) for the *ortho* and *meta* phenyl protons, consistent with the fourfold symmetry expected for this molecule. In contrast, the ^{1}H NMR spectra of the *meta*-substituted carboranylporphyrins **2** and **3** (M = 2H) and the open cage species **4** and **5** (M = 2H) showed multiple signals for the pyrrole protons consistent with the presence of atropisomers (due to restricted rotation about the aryl–porphyrin bond).[15] *meta*-Substituted tetraarylporphyrins [*e.g.* **6** (M = 2H)][16] normally show fast exchange between atropisomers at rt. The presence of multiple β-pyrrolic signals for porphyrins **2**–**5** (M = 2H) at rt thus suggests that the barriers for aryl rotation in these compounds are markedly increased by the carborane substituents. This suggestion was confirmed by variable temperature ^{1}H NMR studies, which showed that the activation energies for aryl rotation in porphyrins **2**–**5** (M = 2H) were intermediate between those of porphyrins with *meta*-substituents [*e.g.* **6** (M = 2H)] and porphyrins with *ortho*-substituents [*e.g.* **7** (M = 2H)] (Table 1).

Proof that aryl–porphyrin rotation was the dynamic process being observed was obtained by varying the core substituent M, which is known to modulate the rotational barriers in *ortho*-substituted porphyrins such as **7**.[15] The activation energies determined for the dynamic processes in porphyrins **2**–**5** showed a similar response to the incorporation of zinc or nickel into the porphyrin core (Table 1). Interestingly, no significant difference in the aryl–porphyrin rotational barriers was seen for the *o*-carboranes (**2** and **3**) *vs.* the anionic *nido*-carboranes (**4** and **5**) nor for the porphyrins with methylene bridges between the carborane and aryl groups (**2** and **4**) and those without bridges (**3** and **5**). No attempt was made to physically separate the atropisomers given the short lifetimes calculated from the activation energies in Table 1.

In summary, the present work provides evidence of novel carborane–porphyrin inter- and intra-molecular interactions that can be related to the unusual size and electronic properties of the carborane group.

This research was supported by grants from the Department of Energy (98ER62633) and the National Institutes of Health (HL 22252).

Notes and references

† Crystals were grown by slow diffusion of MeOH into a chlorobenzene solution of **1** (M = Zn) [$C_{60}H_{84.8}B_{40}N_4Zn_{0.6}\cdot(C_6H_5Cl)$, FW = 1447.21]. The crystals were found to consist of **1** (M = Zn) and **1** (M = 2H) due to acid catalyzed demetalation. The selected crystal (0.30 × 0.10 × 0.10 mm) had a monoclinic unit cell, space group $P2(1)/c$, with cell dimensions a = 13.3139(5), b = 18.6428(8), c = 15.7642(6) Å, β = 93.9630(10)°, V = 3903.5(3) Å^3, and Z = 2. Data were collected on a Bruker SMART 1000 diffractometer with a sealed tube source [λ(Mo-Kα) = 0.71073 Å] at 90(2) K. A 2θ cutoff of 55° was applied to the data to afford 33815 total reflections of which 8971 were unique and of those 5897 were observed ($I > 2\sigma$) [R_{int} = 0.071, T_{min} = 0.92, T_{max} = 0.97, ρ_{calc} = 1.226 g cm^{-3}, μ = 0.274 mm^{-1}]. The structure was solved by direct methods and refined (based on F^2 using all data) by full matrix least-squares methods with 515 parameters (Bruker SHELXS-97, SHELXL-97). All hydrogen atom positions were refined with a riding model. The occupancy of the zinc atom was determined to be 60% from free variable refinement with fixed isotropic parameter of 0.020 Å. Final R factors were $R1$ = 0.069 (observed data) and w$R2$ = 0.191 (all data). Atomic coordinates, bond lengths and angles, and thermal parameters for **1** (M = Zn) have been deposited at the Cambridge Crystallographic Data Center (CCDC). Any request to the CCDC for this material should quote the full literature citation and reference number 155418. See http://www.rsc.org/suppdata/cc/b1/b100231g/ for crystallographic files in .cif format.

‡ A search of the Cambridge Structural Database did not reveal any structures of carborane-substituted porphyrins. However, a semiquantitative structure (R = 0.25) has been reported.[10]

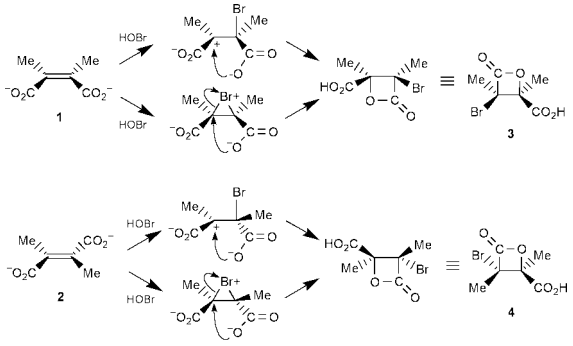
Received (in Cambridge, UK) 8th January 2001, Accepted 5th February 2001
First published as an Advance Article on the web 20th February 2001

Crystallographic analysis of the bromo-β-lactones obtained by addition of bromine to aqueous solutions of disodium 2,3-dimethylmaleate and 2,3-dimethylfumarate reveals stereochemistries opposite to those originally assigned and suggests that the first-formed intermediate in each case is an α-lactone.

It is widely accepted that the addition of halogens to an alkene occurs in two stages and in an *anti* manner.[1] In 1937, Tarbell and Bartlett[2] found that the disodium salts of 2,3-dimethylmaleic acid and 2,3-dimethylfumaric acid (**1** and **2**) reacted stereospecifically with aqueous bromine, each yielding a single crystalline bromo-β-lactone; similar results were obtained with chlorine. The stereospecific nature of the reaction implied that the addition of the two components to the alkene was concerted. The authors proposed that the addition of bromine to give a carbocation was followed 'in the quickest possible succession' by attack of the carboxylate group leading directly to a β-lactone. The structures of the lactones (**3** and **4**, respectively) were assigned on this basis, corresponding to *anti* addition at the double bond. This work shortly predated the important paper by Roberts and Kimball[3] proposing cyclic halonium ion intermediates for halogen addition to alkenes. In Scheme 1 we have illustrated the two possible interpretations given at that time.[2,4]

We suspected that the reaction might be more complex than had been supposed, and have therefore prepared the two bromolactones from **1** and **2** by the published method[2] and established their structures by X-ray crystallography. The structures found (**4** from **1**,† and **3** from **2**,‡ Fig. 1) correspond to overall *syn* addition to the alkene. This unequivocal result is in contrast to the *anti* addition supposed by the Tarbell and Bartlett mechanism or arising from direct attack by carboxylate anion on a cyclic bromonium ion intermediate.[4,5] We believe that the most satisfactory explanation of our results (Scheme 2) involves formation of an α-lactone intermediate[6] (**5** and **6**) as the first step in the decomposition of the bromonium ion. Subsequently the other carboxylate group attacks the α-lactone, with a second inversion of configuration, to give the β-lactone. This scheme accounts simply and satisfactorily for the overall



Scheme 1

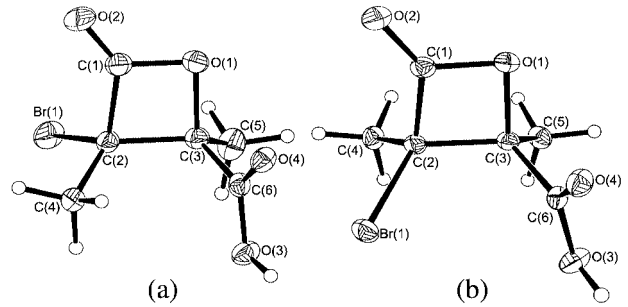


Fig. 1 X-Ray crystallographic structures for bromo-β-lactones: (a) compound **4** from disodium 2,3-dimethylmaleate; (b) compound **3** from disodium 2,3-dimethylfumarate.

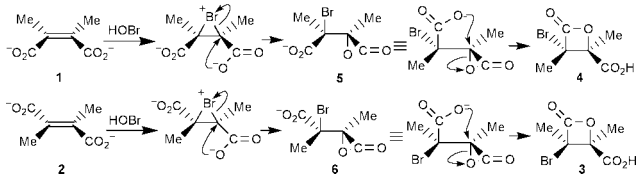
stereochemical outcome. Furthermore, both of the individual steps, the formation of the α-lactone from the bromonium ion followed by formation of the β-lactone, are favoured *exo* processses in the Baldwin sense.[7–10] It is known that β-lactones are formed as kinetically controlled products in halolactonisation of salts of β,γ-unsaturated acids,[11,12] involving ring opening of the halonium intermediate in an *exo* manner.[13] Scission of the bromonium ion derived from a salt of an α,β-unsaturated monocarboxylic acid to give a β-lactone directly has been recognised as a relatively unfavourable pathway,[7,12–14] and can only be achieved under certain conditions.[13–16]

In support of our proposed mechanism, it is known that halogenation of certain allylic alcohols leads to epoxides by rearrangement of the halonium ion.[17–22] More pertinent is the behaviour of maleic acid and fumaric acid towards halogens; bromine in ether converts the free acids into the dibromides expected from *anti* addition.[23] On the other hand, treatment of disodium maleate with aqueous chlorine affords the *erythro* chlorohydrin[24] or, in the presence of an excess of chloride ions, the *erythro* (*meso*) dichloro compound,[25] the products of overall *syn* addition; disodium fumarate reacts *via* both *anti* and *syn* addition (80 : 20).[24,26] During the course of this work we became aware of the suggestion by Badea,[27] without experimental evidence, that an α-lactone intermediate might account for the *syn* addition.

α-Lactones are known to undergo intramolecular nucleophilic attack under aqueous conditions. Reaction of 2-amino-2-deoxy-D-gluconic acid with nitrous acid affords 2,5-anhydro-D-gluconic acid by double inversion *via* an α-lactone intermediate.[28] Similar reactions of L-glutamic acid and L-



Scheme 2

DOI: 10.1039/b100335f

glutamine result in the γ-lactone of L-α-hydroxyglutaric acid.[29,30] It appears that in the system we have studied ring closures are facilitated by alkyl substitution (the 'Thorpe–Ingold' effect);[31] there is no evidence for β-lactone formation during the chlorination of disodium maleate,[24–26] nor in the deamination of L-asparagine.[30]

Despite their high instability,[32] α-lactones may be more prevalent as reaction intermediates than has generally been imagined. Computational studies are in progress to evaluate structural and energetic aspects of the alternative mechanisms in Schemes 1 and 2 in order to elucidate the factors determining the preferred course of reactivity *via* the α-lactone intermediate.

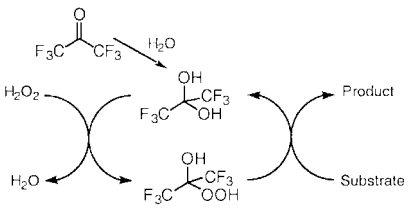
A silane functionalized by octafluoroacetophenone was polymerized by the sol–gel method to form an insoluble silicate with perfluoroketone pendants; the silicate was used as a heterogeneous catalyst for the activation of aqueous hydrogen peroxide and the oxidation of aromatic amines and alkenes.

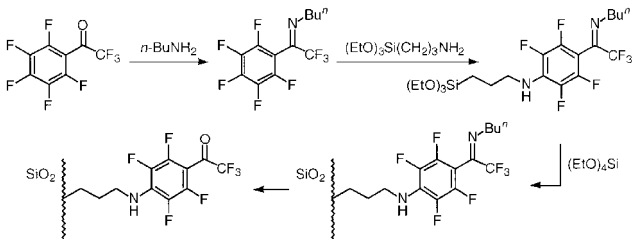
The preparation of heterogeneous catalysts for the activation of hydrogen peroxide and their use for oxidation of organic substrates has been the subject of rather intense research efforts over the last 10–15 years. Almost exclusively this effort has been concentrated on the incorporation of metal-based catalysts onto or into inert matrices. This has been achieved either by substitution of active metals (titanium, vanadium *etc*.) into molecular sieves[1] or amorphous silica,[2] or by encapsulation or attachment of organometallic catalysts onto supports.[3] There are only a few organic compounds capable of activating hydrogen peroxide. Thus, under basic conditions hydrogen peroxide can be used for the epoxidation of electron deficient alkenes[4] and this has led to guanidine functionalized silica for such reactions.[5] A perfluorinated ketone, hexafluoroacetone, also is a known compound capable of reacting with hydrogen peroxide to yield an α-hydroperoxyperfluoro alcohol intermediate capable of reacting with nucleophilic substrates to give oxygenated products,[6] Scheme 1. The high toxicity and volatility of hexafluoroacetone has prevented the wide use of this catalytic system. Recently, a high molecular weight perfluoroketone with less volatility has been suggested as a suitable improvement for hexafluoroacetone in similar oxidation reactions.[7]



Scheme 1

Now we present a silica immobilized perfluoroketone as an effective heterogeneous recyclable catalyst for the oxidation of aromatic amines such as pyridine and its derivatives and aniline and its derivatives in addition to alkenes, using aqueous hydrogen peroxide as oxygen donor. The strategy for the preparation of the perfluoroketone non-metal silicate catalyst is presented in Scheme 2. First, the ketone moiety of octafluoroacetophenone was protected by formation of an imine with *n*-butylamine. The protected perfluoroketone was then attached to an aminosilane by nucleophilic substitution and the insoluble silicate was prepared by co-polymerization with tetraethoxysilane by the sol–gel method. The final heterogeneous catalyst was then obtained by removal of the *n*-butylamine protecting group.†

The perfluoroketone–silicate catalyst was tested for activity with several substrate types.‡ First, the oxidation of pyridine and derivatives to the corresponding *N*-oxides, showed that the catalyst was quite effective for this reaction, Table 1. The yields were generally high for some representative substrates such as pyridine, 2- and 4-methylpyridine, quinoline, and 4-methylquinoline; *N*-oxides were the only products. Interestingly, 8-hydroxyquinoline was less reactive, presumably because of steric considerations, and the electron-poor 2,6-dichloropyridine was unreactive as expected. The oxidation of aniline and its derivatives catalysed by the perfluoroketone–silicate gave somewhat more surprising results, Table 2. Aniline, alkyl-



Scheme 2

Table 1 Oxidation of pyridine derivatives with 60% H_2O_2 catalysed by the perfluoroketone–silicate

Substrate	Product	Yield (mol%)
Pyridine	Pyridine 1-oxide	99
2-Methylpyridine	2-Methylpyridine 1-oxide	84
4-Methylpyridine	4-Methylpyridine 1-oxide	93
Quinoline	Quinoline 1-oxide	87
4-Methylquinoline	4-Methylquinoline 1-oxide	83
8-Hydroxyquinoline	8-Hydroxyquinoline 1-oxide	20
2,6-Dichloropyridine	2,6-Dichloropyridine 1-oxide	0

Reaction conditions: 0.8 mmol substrate, 20 mg (0.05 mmmol ketone) perfluoro–silicate, 1 mL acetonitrile, 3 mmol 60% H_2O_2, 24 h, 80 °C. Yields were computed by GC analysis.

Table 2 Oxidation of aniline derivatives with 60% H_2O_2 catalysed by the perfluoroketone–silicate

Substrate	Product	Yield (mol%)
Aniline	Diphenyldiazene 1-oxide	100
3-Methylaniline	Bis(3-methylphenyl)diazene 1-oxide	100
2-Ethylaniline	Bis(2-ethylphenyl)diazene 1-oxide	100
3-Trifluoromethylaniline	Bis(3-trifluorophenyl)diazene 1-oxide	100
3-Fluoroaniline	Bis(3-Fluorophenyl)diazene 1-oxide	100
3-Nitroaniline	1,3-Dinitrobenzene	100
2-Methyl-4-hydroxyaniline	4-Nitro-5-methylphenol	100
4-Hydroxyaniline	4-Nitrophenol	100
2-Nitroaniline	None	—
4-methoxy-2-nitroaniline	None	—

Reaction conditions: 0.8 mmol substrate, 20 mg (0.05 mmmol ketone) perfluoro–silicate, 1 mL acetonitrile, 3 mmol 60% H_2O_2, 12 h, 80 °C. Yields were computed by GC analysis.

DOI: 10.1039/b100421m

substituted aniline and halogen-substituted aniline derivatives all yielded the dimeric azoxy compounds as *sole* products in quantitative yields. On the other hand aniline with electron donating hydroxy substitution or electron withdrawing nitro substitution yielded the corresponding nitro derivatives, provided the nitro was not *ortho* to the amino substituent. In this latter case there was no reaction, possibly related to intramolecular hydrogen bonding between the amino and nitro substituents. For the other cases, we have as yet no satisfactory explanation for partial oxidation and the *selective* formation of azoxy compounds on the one hand for aniline, alkylated anilines and halogenated anilines and full oxidation to nitro derivatives in the case of 3-nitroaniline and 4-hydroxyaniline.

The catalytic activity of the perfluoroketone–silicate was also tested for oxidation of alkenes, Table 3. For less nucleophilic substrates such as oct-1-ene and oct-2-ene, activity was low although the initial epoxide product formed was stable under the reaction conditions and epoxides were obtained selectively. More nucleophilic substrates such cyclohexene, 1-methylcyclohexene and 2,3-dimethylbut-2-ene were much more reactive and high conversions were obtained. However, selectivity to the epoxide was very low due presumably to acid catalysed formation of diols or pinacol rearrangement. Interestingly, primary allylic alcohols reacted to yield mostly aldehyde as the product using 30% H_2O_2; no epoxidation was observed. Thus, 0.8 mmol (Z)-hex-2-en-1-ol was reacted with 2 mmol 30% H_2O_2 in 1 mL EtOAc at 80 °C for 24 h to yield 94% hex-2-enal.

Finally, the stability and activity of the catalyst was tested in a multi-recycle experiment. Thus, 4 mmol aniline, 100 mg (0.25 mmmol ketone) perfluoro–silicate and 15 mmol 60% H_2O_2 were mixed in 5 mL acetonitrile at 80 °C for 18 h. More than 98% of the aniline reacted to diphenyldiazene 1-oxide. The mixture was filtered and the catalyst washed twice with dichloromethane, dried and reused in an additional reaction. Over a period of five reaction cycles, as described above, no significant loss of activity was observed and yields of diphenyldiazene 1-oxide remained > 95%.

Table 3 Oxidation of alkenes with 60% H_2O_2 catalysed by the perfluoroketone–silicate

Substrate	Products (Yield (mol%))	Conversion (mol%)
Cyclooctene	Cyclooctene oxide (100)	78
Oct-2-ene	Oct-2-ene oxide (100)	16
Oct-1-ene	Oct-1-ene oxide (100)	6
Cyclohexene	Cyclohexane-1,2-diol (80) Cyclohex-2-en-1-ol (15) Other (5)	61
1-Methylcyclohexene	1-Methylcyclohexane-1,2-diol (86) 2-Methylcyclohexanone (10) Other (4)	100
2,3-Dimethylbut-2-ene	2,3-Dimethylbut-2-ene oxide (16) 2,3-Dimethylbutane-2,3-diol (21) 2,3-Dimethylbutan-2-one (63)	100

Reaction conditions: 0.8 mmol substrate, 20 mg (0.05 mmmol ketone) perfluoro–silicate, 1 mL acetonitrile, 3 mmol 60% H_2O_2, 24 h, 80 °C. Yields were computed by GC analysis.

Notes and references

† Octafluoroacetophenone (6 mmol, 1 g) was reacted with *n*-butylamine (6 mmol, 0.57 mL) in 50 mL dry toluene for 5 h at 60 °C in a 250 mL flask. After this time 3-aminopropyl(trimethoxy)silane (6 mmol, 1.43 mL) was added and the solution was heated and stirred under reflux while the reaction was monitored by ^{19}F NMR ($CDCl_3$). The starting compound (Shiff base) has peaks at −75.7 ppm (s, β position, 3F), −161.6 ppm (d, *ortho* position, 2F), −138.2 ppm (m, *meta* position, 2F) and −153.2 ppm (d, *para* position, 1F), whereas the product has peaks at −75.7 ppm (s, β position, 3F), −160.3 ppm (d, *ortho* position, 2F) and −141.5 ppm (m, *meta* position, 2F). After one week the reaction was complete and tetraethoxysilane (9 mmol, 2 mL), water (3 mL), dibutyltin dilaurate (0.09 mL, 0.15 mmol) in 100 mL of ethanol were added; the solution was then heated at 60 °C for 12 h. After this time, the reaction mixture was transferred into a beaker and the solvent(s) was allowed to evaporate at rt until a yellow–brown solid was obtained. After grinding the silicate to a course powder, the solid was treated by Soxlet extraction with diethyl ether followed by dichloromethane. The silicate was then treated with 100 mL 30% H_2O_2 under reflux for 16 h to remove the protecting group (verified by IR spectroscopy—carbonyl peak at 1640 cm^{-1}). The white powder that was obtained was filtered and washed consecutively by water, acetonitrile and finally with dichloromethane. After drying under vacuum at 60 °C overnight, the silicate was used in the catalytic studies.

‡ The reaction ingredients as noted in the tables were placed in 5 mL vials; the vials were closed and placed in an oil bath at 80 ± 2 °C and the contents stirred magnetically for the noted time period. After the reaction was completed the organic phase was extracted with dichloromethane (5 mL) and analyzed by GC and GC-MS using a 30 m 5% phenylmethylsilicone capillary column (0.32 mm id, 0.25 μm coating).

Received (in Cambridge, UK) 11th December 2000, Accepted 6th February 2001
First published as an Advance Article on the web 20th February 2001

Heterogeneous macroporous materials are prepared by the sequential electrostatic deposition of fluorescein isothiocyanate-labeled poly(allylamine hydrochloride) and cadmium telluride nanocrystals onto macroporous titania structures.

Ordered macroporous materials with pore diameters in the nanometer to micrometer range have attracted significant interest because of their unique properties, *e.g.* high specific surface area, high damping capacity, low thermal conductivity and low dielectric permittivity. They have a wide range of applications (both structural and functional), including their use as light-weight structural materials,[1] catalytic supports and surfaces,[2] thermal and acoustic insulators,[3] optical devices[4] and as candidates for high speed computer device packaging.[5]

Recently, considerable effort has been devoted to the use of colloidal assemblies as templates for the fabrication of interconnected three-dimensional (3D) macroporous materials.[6] Monodisperse colloidal spheres, either polystyrene, silica or poly(methyl methacrylate),[6] or emulsion droplets,[7] can self-assemble into ordered 3D arrays. These ordered structures offer a 3D scaffold for a variety of precursor materials, which can be infiltrated in the voids between the colloidal spheres. After subsequent solidification of the precursors and removal of the templated colloids, 3D macroporous materials are obtained. The pore dimensions of the structures depend on the diameters of the colloidal spheres employed. This method provides a simple and effective route to the fabrication of macroporous materials with controlled pore sizes and well-defined periodic structures. In the last few years, a variety of organic, inorganic, and metal precursor materials have been used to prepare a wide range of 3D ordered macroporous structures.[6]

The development of heterogeneous (*i.e.* multicomponent) 3D ordered macroporous structures is expected to yield promising materials for use in the areas of catalysis and optical devices based on photonic crystals. However, to date there have been few studies on the fabrication of such materials. For example, Yin and Wang have recently doped macroporous titania with cobalt by the precipitation of mixed precursors,[8] while Stein and co-workers have prepared 3D ordered macroporous organic/inorganic hybrids[9] and alloys[10] using a similar procedure. Here we report a method for creating 3D heterogeneous structures by using a sequential electrostatic deposition process that involves the post-modification of macroporous titania. This technique is based on the electrostatic attraction between sequentially deposited species, and represents a general approach for the fabrication of multicomponent films on planar supports[11] and colloid particles.[12]

Based on electrostatic attractions, poly(allylamine hydrochloride) (M_w 8000–11 000) labeled with fluorescein isothiocyanate (FITC-PAH) and cadmium telluride (CdTe) nanocrystals (3–4 nm in diameter)[14] were consecutively deposited on macroporous titania (TiO_2), which was produced by templating colloidal crystals of polystyrene (PS) spheres with titanium isopropoxide (TIP). The advantages of our approach are that it allows tailoring of the composition (and consequently function) of the heterogeneous macroporous structures through the electrostatic deposition of charged components that coat the inner surface of the materials.

Colloidal crystals of monodisperse PS spheres of diameter 640 nm were used as the template and TIP as the precursor for the formation of macroporous TiO_2 structures, as described earlier.[13] The resulting TiO_2 material was treated with basic solution (1 M sodium hydroxide aqueous solution), after which the macroporous TiO_2 was placed into 2 mL of a 0.5 mg mL^{-1} FITC-PAH solution containing 0.5 M NaCl, and 12 h was allowed for FITC-PAH adsorption. After removal of the FITC-PAH solution, the TiO_2 material was washed five times with 2 mL of water to ensure removal of FITC-PAH not electrostatically bound to the TiO_2. The adsorption of FITC-PAH changes the surface charge of the macroporous TiO_2 to positive due to charge overcompensation.[11] Subsequently, negatively charged CdTe nanocrystals were adsorbed from aqueous solution onto the surface and within the pores of the macroporous TiO_2 modified with FITC-PAH (the electrostatic interactions occur between the NH_3^+ groups of the FITC-PAH and the negatively charged hydroxy and thiol moieties on the surface of the nanocrystals[14]). This resulted in the sample turning red, suggesting a relatively high loading of the CdTe nanoparticles.[15]

The macroporous materials prepared were examined by scanning electron microscopy (SEM). Fig. 1 shows a SEM micrograph of a cross-section of the macroporous TiO_2 produced when using PS colloidal crystals as templates. The center-to-center average distance between the pores is 432 ± 10 nm, reflecting a linear shrinkage of 33% (compared to the diameter of the PS spheres, 640 nm). The round channels in the pore walls are clearly visible, and confirm that the pores in the structure are interconnected with each other. There are small openings in the middle of each of the triangular intersections of the macroporous TiO_2 (indicated by the arrow). These openings are likely caused by incomplete filling of the voids between the spheres.[16]

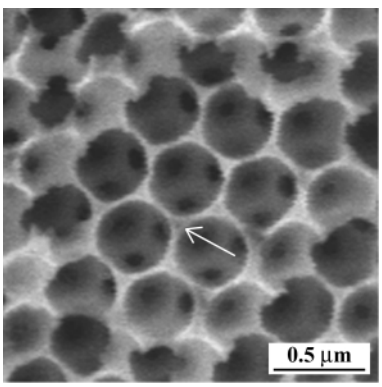

Fig. 1 SEM micrograph of the macroporous TiO_2 structure fabricated by templating pure PS colloidal spheres of diameter 640 nm. The arrow points to the small openings that are present in the middle of each of the triangular intersections of the macroporous TiO_2 material.

DOI: 10.1039/b009897n

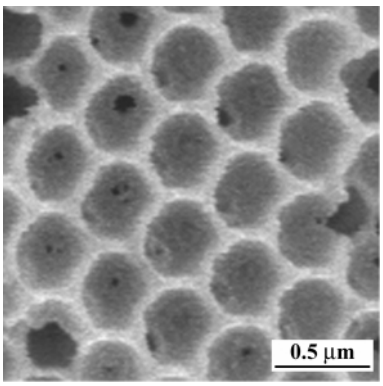

Fig. 2 SEM micrograph of the heterogeneous (TiO_2–FITC-PAH/CdTe) macroporous structure fabricated by the sequential electrostatic adsorption of FITC-PAH and CdTe nanocrystals onto macroporous TiO_2.

Fig. 2 displays a SEM micrograph of a cross-section of the macroporous TiO_2 structure modified with FITC-PAH and CdTe nanocrystals. The resulting heterogeneous (TiO_2–FITC-PAH/CdTe) macroporous material has the same structure as that of the original macroporous TiO_2 (Fig. 1). The center-to-center distance of 427 ± 10 nm is also the same (within experimental error) to that obtained for the unmodified TiO_2 structure. It is clearly observed that the pores are still interconnected with each other (round channels are seen). However, the small openings in the middle of each of the triangular intersections of the pure macroporous TiO_2 material (Fig. 1) are not observed. This suggests that the TiO_2 structure has been coated with the FITC-PAH/CdTe hybrid layer. Energy disperse X-ray (EDX) analysis of the heterogeneous macroporous material indicates the presence of Ti, O, Cd and Te [Fig. 3(a)], demonstrating that the CdTe nanocrystals were adsorbed on the TiO_2. Fig. 3(b) shows the luminescence spectrum of the heterogeneous macroporous material. The shoulder observed around 530 nm corresponds to the emission of the FITC molecules of the labeled PAH, confirming that FITC-PAH was also deposited. The maximum at 570 nm is attributed to the 'excitonic' emission of the 3–4 nm CdTe nanocrystals. It is important to note that the SEM, EDX and fluorescence experiments were conducted on cross-sections of the heterogeneous macroporous structures. The above results verify that the PAH-FITC and CdTe nanocrystals infiltrated the macroporous TiO_2 structure and coated the inside surface. In addition, all of the cross-sectioned samples showed a red color. Preliminary experiments revealed an intensified color for cross-sections of the heterogeneous material when additional FITC-PAH/CdTe nanocrystal multilayers were deposited. Characterization of the growth of FITC-PAH/CdTe nanocrystal multilayers on macroporous TiO_2 structures is currently in progress.

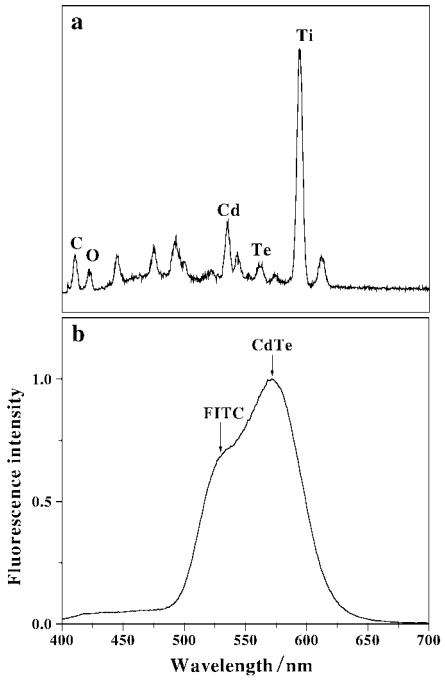

Fig. 3 (a) EDX and (b) luminescence spectra of the heterogeneous macroporous material shown in Fig. 2.

In this study, we have used FITC-PAH, CdTe nanocrystals and macroporous TiO_2 to demonstrate the feasibility of fabricating heterogeneous macroporous materials by using the sequential electrostatic deposition approach. This strategy provides a simple and versatile means to prepare novel macroporous materials, allowing control over their composition and functional properties. Given the general nature of the method, it is expected that complex and tailored structures can be produced with defined multilayers of polyelectrolytes, small organic molecules, inorganic nanoparticles, clays and proteins. Such studies are being undertaken. The creation of such structures should open up new and interesting possibilities for the applications of heterogeneous macroporous materials.

We thank Dangsheng Su and Gisela Weinberg (Fritz Haber Institute, Berlin) for assistance with SEM, and Andrey L. Rogach (Hamburg University) for the CdTe nanocrystals. This work was supported by the BMBF and the Volkswagen Foundation.

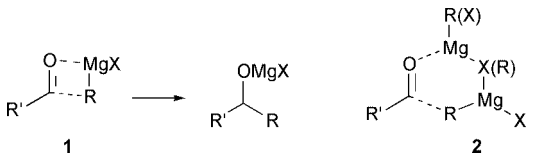
First published as an Advance Article on the web 20th February 2001

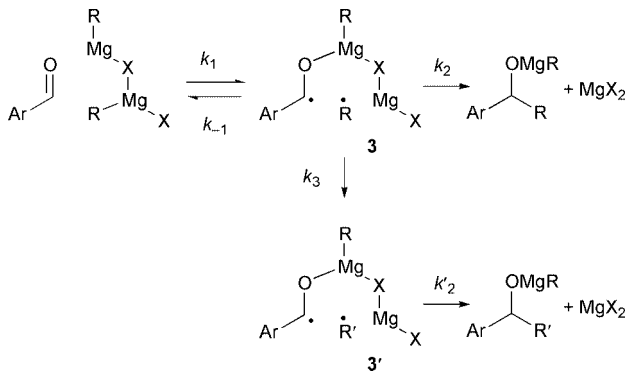
The Grignard reagent 6, in which the magnesium-bearing carbon atom is the sole stereogenic centre has been added to CO_2, PhNCO, PhNCS and certain aldehydes with full retention of configuration. Reaction with benzophenone, electron-deficient aldehydes and several allyl halides proceeded with partial or complete racemization. The findings are discussed with respect to a dichotomy between concerted polar and stepwise SET reaction pathways.

Grignard reagents are among the oldest organometallic reagents known.[1] Their chemistry has evolved as the prototype of polar organometallic compounds. Yet, despite the enormous body of polar addition reactions recorded,[2] the mechanism of these additions cannot be considered as settled.[3] Most textbooks describe the addition of Grignard reagents to aldehydes—being representative of carbonyl compounds—as a simple addition, *cf.* **1**. Evidence has however been provided[4] that it is a Grignard dimer (halogen-bridged or alkyl-bridged) that enters into the reaction with the carbonyl group, *cf.* **2**.



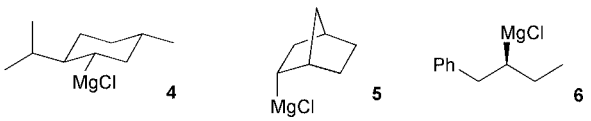
1 **2**

But still, this says little about the nature of the C–C bond forming step. At least in some cases it has been shown that electron transfer precedes the C–C bond formation, especially in addition reactions to carbonyl compounds with a low reduction potential, such as benzophenone.[5,6] While it is tempting to formulate[5,7,8] all polar additions as being initiated by an electron-transfer step, there is at the moment no meaningful way to address the question to what extent electron motion precedes nuclear motion in the formation of the new C–C bond. Rather we have to be content with the heuristic approach that a two-step process can be considered as established, if it is possible to prove the existence of an intermediate (likely the radical R· or radical pair **3**).[9]



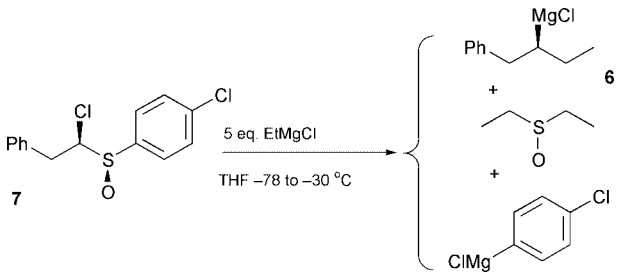
3 **3′**

This is usually done by diverting the radical R· to give another radical R′·, a process that becomes manifest if the rate of conversion (k_3) of R· into R′· is similar to or larger than the rate of collapse (k_2) of the postulated radical pair **3**. Radical rearrangements of known k_3 (radical clocks) have been studied in this context.[5] It is clear, that an ultrafast radical reorganization reaction would enlarge the scope of this approach.[10] This would hold *e.g.* for the conversion of a chiral carbon radical R· to its enantiomer R′·. The barrier to the inversion of the *tert*-butyl radical has been experimentally bracketed to be < 0.5 kcal mol^{-1}.[11] For most practical purposes alkyl radicals can be considered as being planar, that is prochiral. Therefore, the stereochemical probes such as **4**[12,13] and **5**[14] have been used to probe the mechanism of Grignard additions.[15,16]



4 **5** **6**

Yet in the case of **4** and **5** it is a moot point, to what extent the stereochemical outcome is influenced by the presence of the additional stereogenic centres (only one case of epimerisation[13] has been so far observed). The ideal probe would be a Grignard reagent such as **6**, in which the magnesium-bearing carbon atom is the sole stereogenic centre. We have recently described an access to such a species of *ca.* 90% ee by asymmetric synthesis.[17] We report here on the use of this reagent as a mechanistic probe in Grignard additions to carbonyl compounds and in Grignard-substitution reactions.



7

The reagent **6** is generated in *ca.* 90% ee from the enantiomerically and diastereomerically pure sulfoxide **7**.[17] Due to the mode of generation, the solution of **6** contains *ca.* 2 equiv. of EtMgCl, one equiv. of *p*-Cl-C_6H_4-MgCl and one equiv. of diethyl sulfoxide. The reagent **6** is configurationally stable in this cocktail in THF solution up to −30 °C; racemization proceeds with $t_{1/2}$ = 5 h at −10 °C.

Therefore those polar additions can be investigated that proceed readily at −30 °C or below. This holds *e.g.* for the addition of **6** to CO_2, PhNCO, or PhNCS which provides the adducts **8**, **9**, and **10**. The same level of enantiomeric purity of these adducts suggests that the value of 90 ± 2% ee represents the enantiomeric purity of **6** and that the addition proceeds without racemization (Table 1).

The absolute configuration of compounds **8**[18] and **10**[17] is known, that of **9** has been established by chemical correlation

DOI: 10.1039/b009678o

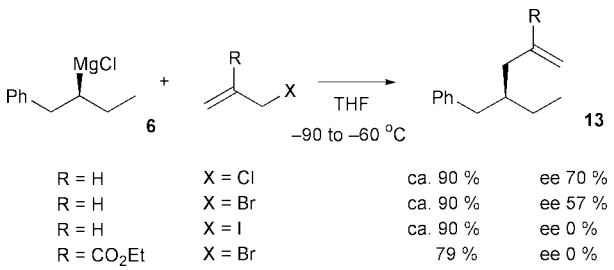
with compound **8**. This establishes that the addition reactions proceeded with retention of configuration. This is in line with the finding for the carboxylation of **5**.[14] As the addition of formaldehyde to **5** proceeded as well without epimerisation,[15] we looked at the addition of **6** to aromatic aldehydes, where the intervention of electron transfer steps is more likely. Addition of **6** to aldehydes generates two diastereomeric adducts (D1; D2), which were derivatized with Mosher's reagent and analysed by ^{1}H-NMR spectroscopy. Both for addition to benzaldehyde and *p*-methoxybenzaldehyde the formation of the major diastereomer proceeded without loss in enantiomeric purity. There is a slight decrease in enantiomeric purity of the minor diastereomer, a fact of uncertain significance. Addition to the more electron deficient pentafluorobenzaldehyde clearly led to partially racemized adducts. On addition to benzophenone, which has a reduction potential that is by +0.20 V more positive than that of benzaldehyde,[19] racemization is extensive but not complete.

The partial racemization observed in the addition to **11** and **12** can be interpreted in terms of a competition between a concerted polar addition and a SET initiated process. This would imply that even benzophenone undergoes a polar addition to the extent of 12%. One could also argue that all of these reactions proceed by SET[5,8] and that rotation of R· within the radical pair **3** is only in few instances faster than the collapse of the radical pair.

We then turned our attention to the reaction of Grignard reagent **6** with allylic halides, which proceeds in high yield even at −90 °C and therefore intuitively suggests an SET process.

While allylation with allyl iodide led indeed to racemic product **13** (R = H) we were surprised to find sizeable enantiomeric enrichment when allyl bromide or allyl chloride were allowed to react with **6**. We tend to interprete this as being caused by a competition between a polar S_N2-reaction and an SET process. This is in line with the ordering of the reduction potentials recorded for allyl chloride, bromide and iodide (−1.91; −1.29; −0.23 V *vs.* Hg).[20] The SET process should be faster with ethyl α-bromomethylacrylate and indeed, this gave rise to 79% of racemic product, **13** (R = COOEt).

Thus, with the chiral Grignard reagent **6** it was possible to probe the mechanism of Grignard addition to carbonyl compounds and Grignard substitution reactions with respect to the competition between polar concerted and stepwise SET pathways.



We are grateful to the Deutsche Forschungsgemeinschaft (SFB 260 and Graduiertenkolleg Metallorganische Chemie) as well as the Fonds der Chemischen Industrie for support of this study. We thank Dr O. Knopff for preliminary experiments in the racemic series.

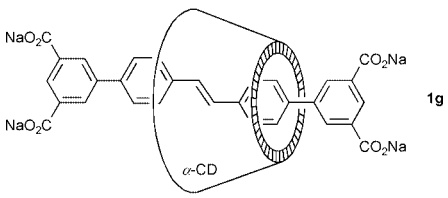
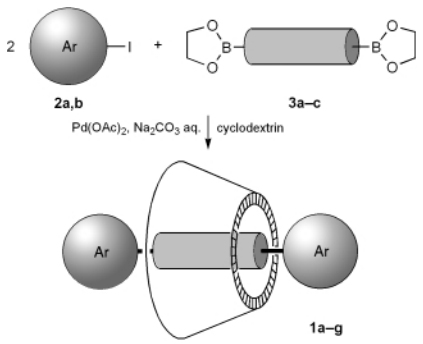
Received (in Cambridge, UK) 15th December 2000, Accepted 24th January 2001
First published as an Advance Article on the web 15th February 2001

Highly fluorescent stilbene and tolan cyclodextrin [2]rotaxanes have been synthesised in good yield using aqueous Suzuki coupling, and the crystal structure of one of these rotaxanes has been determined.

A rotaxane is a supramolecular assembly of a dumbbell locked through the cavity of a macrocycle.[1] The formation of rotaxanes provides a means of stabilising dumbbell-shaped chromophores, by shielding them from the external environment. This type of encapsulation can also enhance the fluorescence efficiency.[2] Hydrophobic binding is a convenient way of directing rotaxane formation, provided the dumbbell can be synthesised in water. Recently we reported the synthesis of poly-*p*-phenylene rotaxanes and polyrotaxanes using aqueous Suzuki coupling, although in this case the [2]rotaxane (**1a** in Table 1) was only obtained in low yield (4%).[3] While exploring the scope of this route to rotaxanes, we discovered that the right combinations of aryl iodide stopper, diboronic acid core and macrocycle components give highly fluorescent cyclodextrin encapsulated stilbenes and tolans, such as **1g**, in high yield. Previous stilbene rotaxanes have been prepared by aromatic nucleophilic substitution[4] and by slipping macrocycles over pre-formed dumbbells.[5]

Six new rotaxanes **1b**–**g** have been prepared by reacting bulky water-soluble aryl iodides **2a** and **2b** with diboronic acids **3a**–**c**[6] in the presence of cyclodextrins (α-CD and β-CD; *ca*. 5 eq.), in aq. sodium carbonate containing palladium(II) acetate, as summarised in Scheme 1 and Table 1.† As expected, the 5-iodoisophthalic acid stopper **2b** is too narrow to form rotaxanes with β-CD, and the biphenyl diboronic acid core **3a** is too bulky to form rotaxanes with α-CD. Apart from these exceptions, all combinations of aryl iodides, diboronic acids and macrocycles yield rotaxanes. The lower yields obtained with the 1-iodonaphthalene-3,6-disulfonate stopper **2a** can be attributed to an unfavourable interaction between the bound CD and the inwardly pointing H8 of the naphthalene. The tetracarboxylate





Scheme 1

Table 1 Yields for rotaxane synthesis, and fluorescence behaviour of rotaxanes and dumbbells[a]

Stopper	Diboronic acid core	Macrocycle	Rotaxane	Yield (%) Rotaxane	Φ_F Rotaxane	Φ_F Dumbbell	λ_{max}(em)/nm Rotaxane	λ_{max}(em)/nm Dumbbell
		β-CD	**1a**	4	1.04	0.67	394	418
		α-CD	**1b**	31	1.08	0.81	387	409
		β-CD	**1c**	16	0.98		390	
		α-CD	**1d**	25	1.03	0.30	416	445
		β-CD	**1e**	14	0.72		425	
		α-CD	**1f**	50	0.99	0.89	360, 378	359, 378
		α-CD	**1g**	73	0.94	0.67	387, 406	385, 405

[a]Yields are for isolated rotaxanes; reaction conditions were similar to those detailed for **1g**. Fluorescence spectra were measured in water; quantum yields (Φ_F) are relative to quinine bisulfate in 0.5 M H_2SO_4 (Φ_F = 0.546) and are reproducible to within ± 10%.

DOI: 10.1039/b010015n

rotaxanes **1f** and **1g** are easier to isolate than the sulfonates **1a**–**e**, because they precipitate from aqueous solution at low pH. The smaller isophthalic acid stopper is still large enough to prevent unthreading of α-CD. For example **1g** shows no sign of unthreading after 10 d in D_2O at 80 °C; even after 10 d at 120 °C in d_6-DMSO no unthreading was detected.

One objective of this investigation was to explore how encapsulation affects the fluorescence efficiencies of tolan and stilbene chromophores. Comparison of the fluorescence quantum yields of all seven rotaxanes **1a**–**g** with those of their free dumbbells (Table 1) demonstrates that encapsulation always enhances the fluorescence yield. In both cases where α- and β-CD rotaxanes can be compared (**1b**/**c** and **1d**/**e**) the α-CD is found to give greater fluorescence enhancement. The cyclodextrin probably reduces the rate of non-radiative decay by restricting the flexibility of the excited state, and by hindering the approach of quenchers. A similar effect has recently been reported for stilbenes bound to antibodies.[7] Epoxidation of rotaxane **1g** and its dumbbell analogue with dimethyldioxirane was explored, in order to test the shielding of the chromophore. Dimethyldioxirane (Me_2CO_2) was selected for this experiment because it is small and highly reactive. The dumbbell reacted with dimethyldioxirane in aqueous acetone over a few hours to form the epoxide, whereas no reaction was detected with the rotaxane under the same conditions, even after 24 h, demonstrating that the C=C double bond of the rotaxane is hidden from this reagent.

In order to understand in more detail how the cyclodextrin interacts with the chromophore in these rotaxanes, we have determined the crystal structure of **1g** (as the tetracarboxylic acid).‡ To the best of our knowledge, this is the first crystal structure determination of any cyclodextrin-based rotaxane, although many such rotaxanes have been synthesised[1b] and crystal structures have been reported for cyclodextrin-based pseudorotaxanes and pseudopolyrotaxanes.[9] The α-CD sits round the centre of the chromophore (as shown in Fig. 1a). The stilbene unit is essentially planar (deviation from mean plane < 0.2 Å), with slight twists about both biphenyl links (torsional angles: 29° near the 6-rim; 24° near the 2,3-rim). The CD is distorted into an elliptical conformation, to accommodate the flat π-system, and this distortion is most pronounced around the narrower 6-rim of the macrocycle (Fig. 1b). For example the cavity width defined by the van der Waals surfaces of the H5 hydrogens is 5.3 Å for the transannular H5–H5 distance in the plane of the stilbene, but 4.0 and 4.3 Å for the other two transannular H5–H5 distances. NMR spectra show that the rotaxane is dynamic in solution at 298 K. Only one set of ^{1}H and ^{13}C glucose resonances is observed, showing that the CD rotates rapidly relative to the dumbbell. The H5 protons of the α-CD show NOEs to all six stilbene resonances, indicating that there is significant lateral motion of the macrocycle.

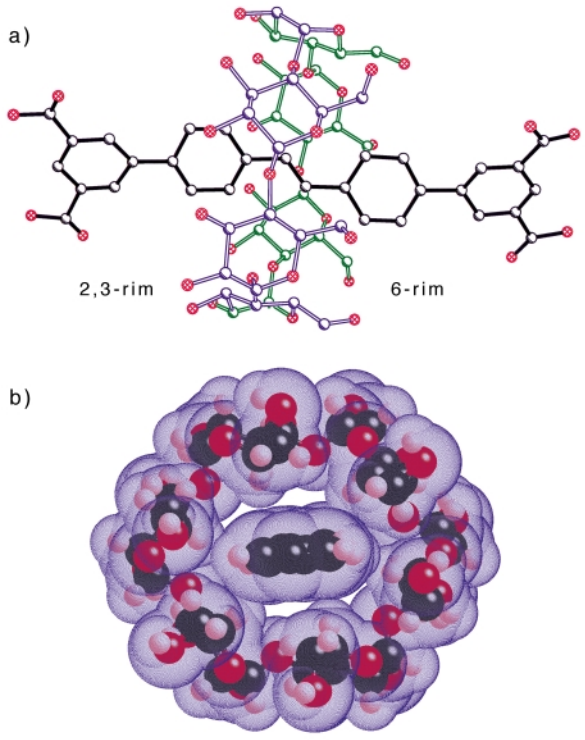


Fig. 1 Structure of rotaxane **1g** in the solid state: (a) view of whole molecule and (b) view of van der Waals surface, from the 6-rim end, with isophthalic acid units deleted for clarity.

In summary, we have shown that Suzuki coupling can be used to prepare cyclodextrin-based rotaxanes in good yield, and that this chemistry can be used to prepare stilbene and tolan rotaxanes with very high fluorescence quantum yields. The crystal structure of one of these compounds shows that the α-cyclodextrin clasps tightly round the centre of the stilbene chromophore.

This work was generously supported by the EPSRC and Avecia Ltd. We are grateful to Dr P. N. Taylor for valuable discussion, and to Dr M. G. Hutchings of DyStar UK Ltd. (Cheadle Hulme) for providing sodium 1-aminonaphthalene-3,6-disulfonate, for preparation of **2a**.

Notes and references

† Procedure for synthesis of **1g**: Water (8 cm^3), **2b** (151 mg, 0.63 mmol), **3c** (100 mg, 0.31 mmol), α-CD (1.6 g, 1.64 mmol), Na_2CO_3 (0.41 g, 3.9 mmol) and $Pd(OAc)_2$ (1.6 mg, 4 mol %) was stirred at 45 °C overnight. The mixture was diluted with Na_2CO_3 aq. (100 cm^3, 0.2 M), filtered, then acidified to pH 1 with HCl, to give a white suspension. The precipitate was separated by centrifugation, redissolved in Na_2CO_3 aq. (100 cm^3, 0.2 M), reprecipitated with acid, washed with water, dissolved in NH_3 aq. and evaporated to yield the ammonium salt of rotaxane **1g** (312 mg, 73%).

‡ Crystals of **1g** were grown over 2 weeks from aqueous solution in a 5 mm NMR tube by warming the lower region to 40 °C while the upper region was cooled to 20 °C. The structure was solved using synchrotron X-rays at Daresbury Station 9.8. *Crystal data* for **1g**: $C_{66}H_{80}O_{38}$, M = 1481.3, monoclinic, space group $I2$ (alternative setting of $C2$), a = 20.767(5), b = 13.960(3), c = 28.085(7) Å, β = 107.479(3)°; U = 7766(3) Å^3, Z = 4, λ = 0.6942 Å, μ = 0.11 mm^{-1}, T = 160 K, $R1$ = 0.164 for 9681 'observed reflections' [$F^2 > 2\sigma(F^2)$] and $wR2$ = 0.394 for all 10443 unique reflections ($\theta < 45°$). Methods and programs were as described elsewhere (ref. 8). Refinement included application of the SQUEEZE procedure (A. L. Spek, PLATON program, University of Utrecht, The Netherlands, 2000) to model diffuse electron density in two substantial voids per unit cell, presumably occupied by highly disordered solvent molecules. No H atoms were included, as they did not appear clearly in difference syntheses and those attached to oxygen atoms cannot be unambiguously placed from purely geometrical considerations. These limitations of the structural model and the weak diffraction due to disorder and crystal size and quality are reflected in the relatively high crystallographic residual factors, as is often found for cyclodextrin-containing materials. CCDC 156256. See http://www.rsc.org/suppdata/cc/b0/b010015n/ for crystallographic files in .cif format.

First published as an Advance Article on the web 19th February 2001

Linking of 'all chair' two-dimensional honeycomb networks, structurally analogous to CF_x, with the 4-aminopyridine ligand leads to a three-dimensional molecular framework.

The construction of porous hosts[1] through crystal engineering[2] is currently attracting a great deal of interest in pursuit of novel materials which may act as catalysts or selective sorbents. Approaches include construction of hydrogen bonded architectures,[3] pillared clay mimics,[4] zeolite analogues[5] such as the AlPOs and GaPOs, and coordination polymer chemistry.[6] A considerable challenge in the field is to achieve predictable combination of structural features, which we have effected by linking the two-dimensional honeycomb motif in three dimensions with a bidentate amine ligand, identified by simple chemical reasoning.

1,3,5-Benzenetricarboxylic acid, H_3btc, has received considerable interest as a tridentate ligand capable of forming coordination polymers.[7] The structures are controlled by the extent of deprotonation of the H_3btc and the nature of the auxiliary ligands coordinated to the metal centre. The graphene-like (6,3) net[8] is well matched to the molecular geometry of btc, and thus two-dimensional honeycomb sheets,[9] some with pyridine projecting perpendicular to the sheets,[10] are a common feature of this chemistry. This opens up the opportunity of linking together these honeycomb layers, thereby predictably generating a three-dimensional architecture, using a suitable bidentate auxiliary ligand.

A wide variety of potential linking ligands to combine these infinite two-dimensional building blocks may be envisaged. We reasoned that a bidentate linker chemically resembling pyridine but without the marked framework forming tendency of, for example, 4,4′-bipyridine, was required. These considerations led to the choice of 4-aminopyridine (4AP). The Cambridge Crystallographic Database‡ currently contains twelve examples where 4AP binds to metal cations through the pyridine function, but there are no examples in the current literature where it, or its *N*-methylated derivatives, act as bidentate ligands. Reaction of tridentate layer-forming and bidentate layer-linking components yields a phase with the desired structural features.

Controlled diffusion§ of 4AP into a butan-1-ol solution of nickel nitrate and H_3btc yields pure UOL-1, $Ni_3(btc)_2(\mu\text{-}4AP)_2(4AP)_4{\cdot}6C_4H_9OH{\cdot}2H_2O$. Analysis of single-crystal X-ray diffraction data collected using synchrotron radiation§ reveals that the structure consists of concertina sheets, shown in Fig. 1, composed of hexagonal 48-membered rings, linked by 4AP. Each ring is made up of six btc units joining six Ni^{II} cations and each sheet may be described topographically as a (6,3) net. In the present case the (6,3) net is not the ubiquitous flat graphene sheet but a topologically equivalent (6,3) net of chair conformation six-rings, which form a coordination polymer analogue of the puckered layers in graphite monofluoride, CF_x.[11]

Every btc is fully deprotonated and binds to three nickel cations: one carboxylate arm of the btc is monodentate to nickel, while the other two arms are bidentate with bite angles of 62.6(1) and 62.3(1)°. Two nickel cations (Ni2) act as linear connectors in the side of the concertina layer and these display

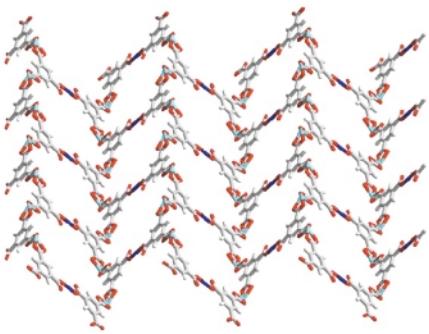

Fig. 1 A single concertina sheet composed of Ni^{2+} and 1,3,5-benzenetricarboxylate. The 'all chair' conformation of the six-membered rings generates a corrugated sheet which is structurally analogous to the layers in CF_x. 4-Aminopyridine ligands and encapsulated solvent have been omitted (colour scheme: Ni1, light blue; Ni2, dark blue; C, grey; O, red; H, light grey).

slightly distorted octahedral coordination. The other four Ni cations (Ni1) are each six-coordinate with an environment that may be described as an extremely distorted octahedron. Two btc units are linked together at Ni1 and the angle subtended between their mean planes is 81.7(9)°. This is reflected in the extreme puckering of the layers: adjacent corrugations subtend an angle of 76.4° to each other (Fig. 2). The coordination about the two crystallographically different nickel atoms is completed entirely by the btc described above and 4AP. Both monodentate (through the pyridine function) and bidentate 4AP are observed. Nickel cations (Ni1) at the peaks and troughs of each corrugated layer are linked by two bidentate 4AP molecules to nickel (Ni2) at the midpoints of the hexagons in adjacent layers, as shown in Fig. 2. To our knowledge this is the first crystallographic report of bidentate 4-aminopyridine.

While it might be possible to link plane (6,3) graphene nets using a bridging ligand with *linear* coordination geometry (such as pyrazine), this is not the case for 4AP. Unlike the pyridine function, which can bind a metal in the plane of the aromatic

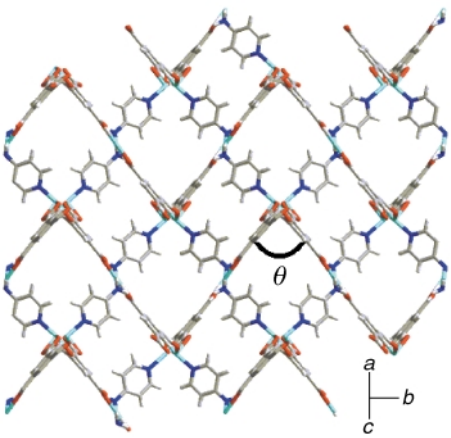

Fig. 2 Linking of ABAB stacked concertina sheets by bidentate 4-aminopyridine (4AP). The angle denoted θ is 76.4°. Monodentate 4AP and solvent are omitted (colour scheme: Ni, light blue; N, dark blue; C, grey; O, red; H, light grey).

† Electronic supplementary information (ESI) available: single-crystal and powder diffraction data and an ORTEP plot of UOL-1. See http://www.rsc.org/suppdata/cc/b0/b009455m/

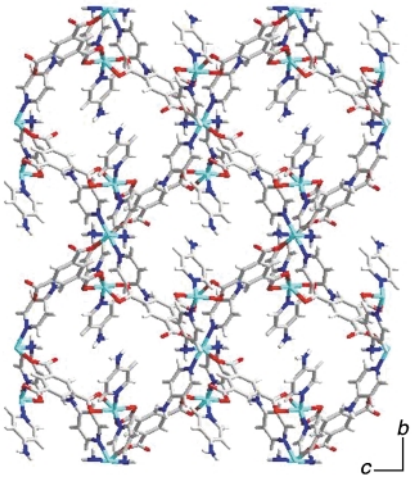

Fig. 3 View down ***a*** showing protrusion of monodentate 4AP into rectangular pores 15.4 × 7.7 Å in size. Pore solvent is omitted (colour scheme: Ni, light blue; N, dark blue; C, grey; O, red; H, light grey).

ring, the amino function can only bind a cation lying out of the plane of the ring because of the directionality of its coordination. Adoption of the graphite monofluoride layer allows the pyridine function of 4AP to bind in a linear mode, while the amino function can bind forming a C–N–Ni angle of 119.0(1)°. Thus the different geometric requirements of the two ends of the linker enforce the CF_x geometry on to the sheets: puckering must occur if the 4AP is to link the octahedral cations in adjacent layers.

The concertina sheets are stacked in an ABAB manner producing a three-dimensional architecture with pores running parallel to ***a*** (15.4 × 7.7 Å shortest van der Waals contacts) and ***c*** (15.1 × 6.0 Å). Monodentate 4AP protrudes into these pores forming necks where the pore is narrowed to *ca*. 3.4 Å, while providing an extremely hydrophilic lining to the cavities (Fig. 3). The program PLATON[12] reveals that the total solvent accessible volume within the crystal, summing voxels more than 1.2 Å away from the framework, is 42.2%. In the pristine material this pore volume is filled with butan-1-ol and water molecules, all engaged in hydrogen bonding with the framework. The hydroxyl groups of two of the three independent butan-1-ol molecules act as donors to btc carboxylates in the framework (O···O distances are 2.68(1) and 2.83(1) Å). The remaining butan-1-ol forms a hydrogen bond to water [2.70(1) Å] which in turn binds to a framework carboxylate [2.73(1) Å]. Removal of this solvent from within the pores may be effected thermally and leads to framework collapse.

The bidentate 4-aminopyridine ligand therefore allows the construction of molecular frameworks in which the infinite two-dimensional honeycomb building blocks characteristic of btc are linked to form a three-dimensional pore network. The (6,3) net unusually adopts the corrugated conformation of CF_x to allow connection of the layers, driven by the geometry of the connecting 4AP ligand. This systematic construction of a framework using linking units to join identifiable structural features may have wider application in coordination polymer chemistry.

We thank Dr S. J. Teat of the SRS, Daresbury Laboratories for help with data processing and the EPSRC for a studentship to T. J. P. and support from GR/N 08537.

§ 4-Aminopyridine (80 mg, 0.85 mmol) was allowed to mix with $Ni(NO_3)\cdot 6H_2O$ (17.4 mg, 60 μmol) and H_3btc (8.4 mg, 40 μmol) by diffusion through butan-1-ol in an H-cell (height 60 mm, crossbar 90 mm, circular cross-section diameter 15 mm). Extremely small single crystals were obtained after *ca*. 4 weeks. Single-crystal X-ray diffraction was carried out on a Bruker AXS SMART CCD area detector diffractometer at Station 9.8 of the CLRC Daresbury Laboratory Synchrotron Radiation Source, UK. A light green rod-shaped crystal of dimensions 15 × 15 × 40 μm was removed from the mother liquor and covered with a thin film of perfluoropolyether oil and mounted on the tip of a two-stage glass fibre. The crystal was cooled to 123 K in an Oxford Instruments nitrogen gas cryostream. Synchrotron radiation of wavelength 0.6923 Å was employed (determined by measurement of a known crystal). A sphere of data was collected in three series of ω-rotation exposure frames each with different crystal orientation φ angles: each 3 s exposure employs a 0.15° rotation in ω. Data were integrated using Bruker software[13] and semi-empirical corrections[14] were applied to account for beam decay and absorption. The structure was solved using direct methods within SHELXS-86.[15] Full-matrix least-squares refinement on F^2 was carried out with SHELXL-93.[16] Hydrogen atoms were located from the difference Fourier and fitted with a riding model.

UOL-1 crystallises in the centrosymmetric monoclinic space group $P2_1/n$ (no. 14): a = 13.1698(9), b = 19.1965(12), c = 16.6969(11) Å, β = 108.9670(11)°, V = 3992 Å^3. Using a single detector position, 14 214 intensities were recorded, producing 9505 unique data (θ_{max} 30.24 °), R_{int} = 0.0749, conventional R [$I > 2\sigma(I)$, all data] 0.0866 (0.1069), $wR2$ 0.2068 (0.2222). Received (in Cambridge, UK) 27th October 2000, Accepted 8th January 2001
First published as an Advance Article on the web 7th February 2001

This article deals with a coordination approach to three-dimensional assemblies *via* '*molecular paneling*'. Families of planar exo-multidentate organic ligands (molecular panels) are found to assemble into large three-dimensional assemblies through metal-coordination. In particular, *cis*-protected square planar metals, (en)Pd^{2+} or (en)Pt^{2+} (en = ethylenediamine), are shown to be very useful to panel the molecules. Metal-assembled cages, bowls, tubes, capsules, and polyhedra are efficiently constructed by this approach.

Introduction

The last decade has witnessed the syntheses of several complex 3D-molecules that are assembled by linking molecules *via* non-covalent bonds such as coordination and/or hydrogen bonds and has led to the development of a new paradigm denoted *non-covalent synthesis*.[1] This non-covalent synthesis has become a reliable approach to prepare 3D-complex molecules and has been considered as an alternative approach to organic synthesis. Earlier the important examples of metal-directed assembly of 3D structures, for example Saalfrank's M_4L_6 cages and Lehn's cylindrical cages, have been well documented.[2,3] Remarkable progress in the construction of 3D structures *via* metal coordination has been made by the groups of Raymond, Stang, Steels, Robson, Shinkai and others.[4–8] The focus of this article will be on our efforts in the construction of three-dimensional (3D) structures by linking two-dimensional (2D) planar organic components *via* metal-coordination. Before going into the main topic, we would like to brief the basic concept of the present study that prompted us to develop a concept of *molecular paneling* which points to a highly efficient approach for constructing large 3D molecules.

Makoto Fujita is a Professor of the Department of Applied Chemistry, Graduate School of Engineering, Nagoya University, Japan. He received his Ph.D. degree from Tokyo Institute of Technology in 1987. Then he joined Department of Applied Chemistry at Chiba University as an Assistant Professor in 1988 and was promoted to a Lecturer in 1991 and to Associate Professor in 1994. In 1997, he moved to Institute for Molecular Science (IMS) at Okazaki as an Associate Professor. Since 1999, he has been in the current position. He is currently a leader of the CREST (Core Research for Evolutional Science and Technology) project of Japan Science and Technology Corporation (JST). His current research interests include metal-assembled complexes, molecular recognition, and nanometer-sized molecules.

Takahiro Kusukawa is an Assistant Professor of the Department of Applied Chemistry, Graduate School of Engineering, Nagoya University. He received his Ph.D. degree from Tsukuba University in 1995. After working in Tsukuba for two years, he joined Fujita's group in 1997 as a Research Associate and moved to Nagoya in 1999 where he got the current position. His interests focus upon the synthesis, assembly, and structural analysis of giant molecules.

Kumar Biradha is also an Assistant Professor of the Department of Applied Chemistry, Graduate School of Engineering, Nagoya University. He received his Ph.D. degree from the University of Hyderabad, India in 1997. He was a postdoctoral fellow in Canada from 1997–1998. In 1998, he joined Fujita's group as a JSPS postdocotral fellow and got the current position in 2000. His interests focus upon the crystal engineering and supramolecular chemistry.

Norifumi Fujita and Kazuhiko Umemoto are doctoral students of the Graduate University for Advanced Studies and will soon receive Ph.D. degrees in March of 2001. Michito Yoshizawa is a doctoral student of Nagoya University.

A basic concept

It was more than a decade ago when we first had the idea to incorporate 90° coordination angles of transition metals into metal–organic frameworks.[9] We paid special attention to the geometry of square-planar metals since non-distorted 90° bond angles can not be afforded by the hybridization of organic elements. To exploit this angle, we designed a *cis*-protected square-planar metal as illustrated in Fig. 1. Accordingly, an

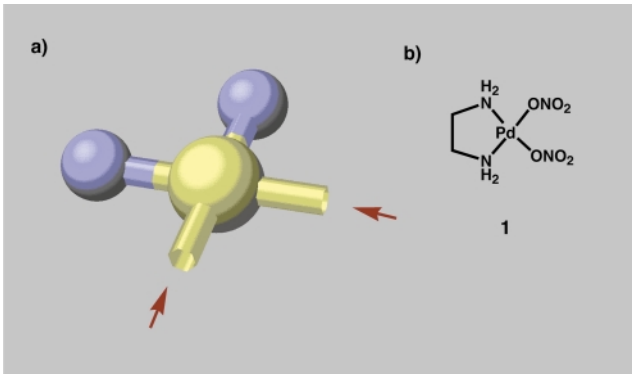

Fig. 1 (a) Cartoon representation of the *cis*-protected Pd(II) building block **1** and (b) structural drawing of **1**.

ethylenediamine-protected Pd(II) complex was prepared and successfully incorporated into a tetranuclear square framework by complexation with one of the simplest bridging ligands: 4,4′-bipyridine (Fig. 2). The design of the *cis*-protected Pd(II) as well as the formation of the square complex **1** cultivated the basic concept of our study which has been carried out over the last decade and can be dictated as follows:

Upon *cis*-protection, the coordination nature of the metal ion changes from divergent to convergent. Owing to the convergent nature, the discrete framework **1** was efficiently generated without formation of any oligomeric products, in striking contrast to the previous coordination chemistry of 4,4′-

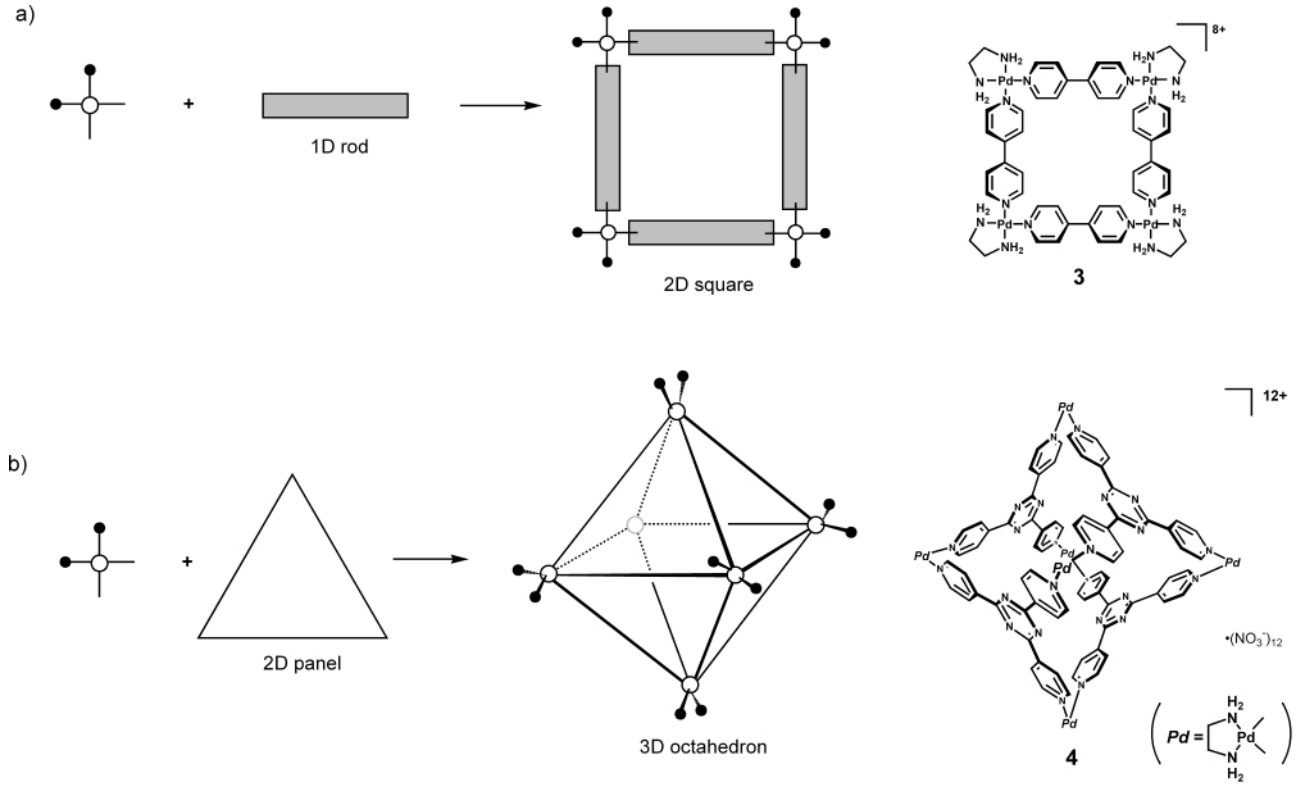

Fig. 2 (a) Schematic representation of molecular paneling: (a) from 1D-rods to 2D-molecules and (b) from 2D-panels to 3D-molecules.

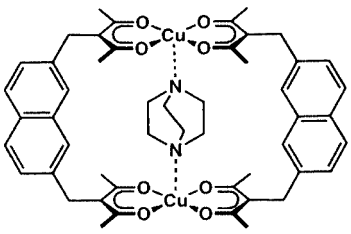
bipyridine where infinite complexes were afforded in most cases.[10] The Pd(II)–pyridine coordination bond is labile and hence the product is formed under thermodynamic control. Thus, under a set of appropriate conditions, the square molecule is spontaneously generated in quantitative yield.

A square molecule in which the transition metal provides a 90° angle at each corner of the square has been recently termed as a 'molecular square' by Stang.[11] The extensive studies by Stang and others stirred considerable current interest in such square molecules. Prior to our study, there have been some important studies on the synthesis of metal-linked macrocycles. One of the excellent examples is the Cu(II)-linked dinuclear complex **2** synthesised by Maverick *et al.*[12]



2

From 2D to 3D structures

A 1D molecular rod, 4,4′-bipyridine, upon linking with 90° coordination block **1** was assembled into a 2D square as discussed above. This molecular design was extended to the construction of 3D structures by considering 2D molecular components. Namely, instead of 1D rod, a 2D triangular panel was used as an organic component (Fig. 2). In 1995 this idea was first realized by the synthesis of an octahedral 3D structure **4** (Fig. 2b).[13] This example illustrates that the molecular paneling of a 2D organic component is undoubtedly an efficient method for the construction of large 3D entities. In the following sections, we will show a family of molecular panels that are successfully paneled into various 3D molecules *via* metal coordination. In addition to the coordination approach, 3D molecules are also accessible by hydrogen-bond directed self-assembly. The groups of Rebek[14] and Atwood[15] have demonstrated the efficient self-assembly of capsules through hydrogen bonding. The cavity volumes of these capsules range from 0.3 to 1.7 nm^3.[14,15]

Molecular panels

3D-molecular structures can be well designed by deducing the molecular components from polyhedra. For example, the basic components (polygons) to construct Platonic solids are equilateral triangles, squares and pentagons.[16] The common feature in these solids is that they are made up of regular polygons which are arranged in space such that the edges, vertices and three coordinate directions of each solid are equivalent. Here we have designed several molecular panels with the basic shapes of triangle, square and rectangle (Fig. 3). The assembling of these panels with the 90° *cis*-protected coordination block **1** can be considered as a new concept that we term as '*molecular paneling*'.

Paneling triangles

An important aspect of regular polygons is that they enclose space. In particular, four triangles enclose space, without the use of curved surface, and this is the lowest number of polygons which will do so.[16] Thus we first deal with a triangle which is a very basic building block of several polyhedra. For example out of five Platonic solids, three (tetrahedron, octahedron and icosahedron) are originated from equilateral triangles indicating the importance of triangular panels in the construction of polyhedra (Fig. 4). Accordingly we designed triangular molecular panels **5**–**9** to assemble them into several 3D-structures (polyhedra). The differences between these triangular panels is the number (varying from three to six) and position of the binding sites. Molecular panels **5** and **6** contain three binding

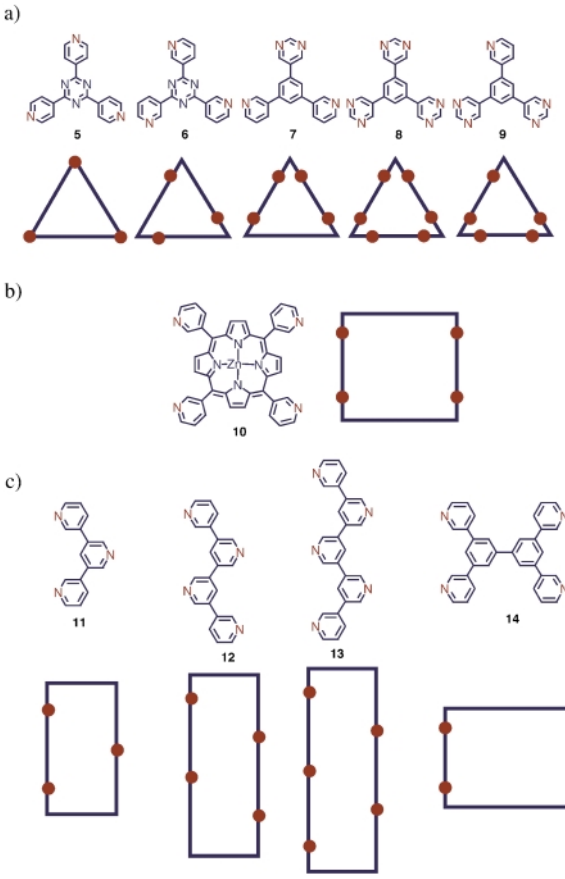


Fig. 3 Structural and cartoon representation of molecular panels: (a) triangular, (b) square and (c) rectangular. The filled circles represent the binding sites.

sites each but the position of the sites differs, whereas molecular panels **7**, **8** and **9** contain four, six and five binding sites each, respectively. The assembled architectures from these molecular panels include octahedra, square pyramids, tetrahedra and hexahedra.

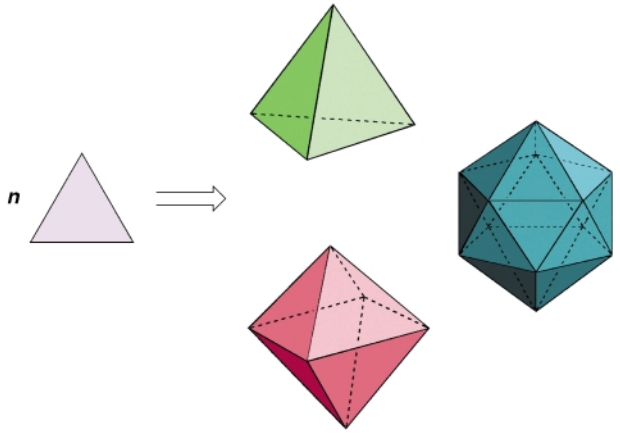

Fig. 4 Schematic representation of assembling of three types of Platonic solids from a triangular unit.

M_6L_4 octahedral cage

As discussed above, the first example of using the molecular panel approach to obtain a 3D discrete structure is an M_6L_4 octahedral assembly **4**, reported in 1995.[13] By treating **1** with **5** in 3:2 ratio, the octahedral complex **4** is assembled in quantitative yield (Fig. 5). In this complex, the four triangular panels are linked together at the corners of the triangles such that every alternate face of the octahedron contains either molecular panel or portal. Complex **4** is a thermodynamically stable product because the formation of the product is not affected by the presence of an excess of **1**. The synthetic procedure is so simple that a 10–50 g scale synthesis can be carried out in a laboratory.

It has been shown that the cage complex **4** effectively binds various organic guest molecules in its cavity. The structure of the clathrate complex of **4** with the adamantane carboxylate ion has been determined by X-ray crystallography (Fig. 5c), which showed that four guest molecules are tightly encapsulated inside the nano-sized cavity of **4**. The inclusion geometry of the guest in the cavity is interesting as the hydrophobic and hydrophilic groups (CO_2^-) are located inside and outside of the cavity, respectively. A space filling presentation of **4** shows that the

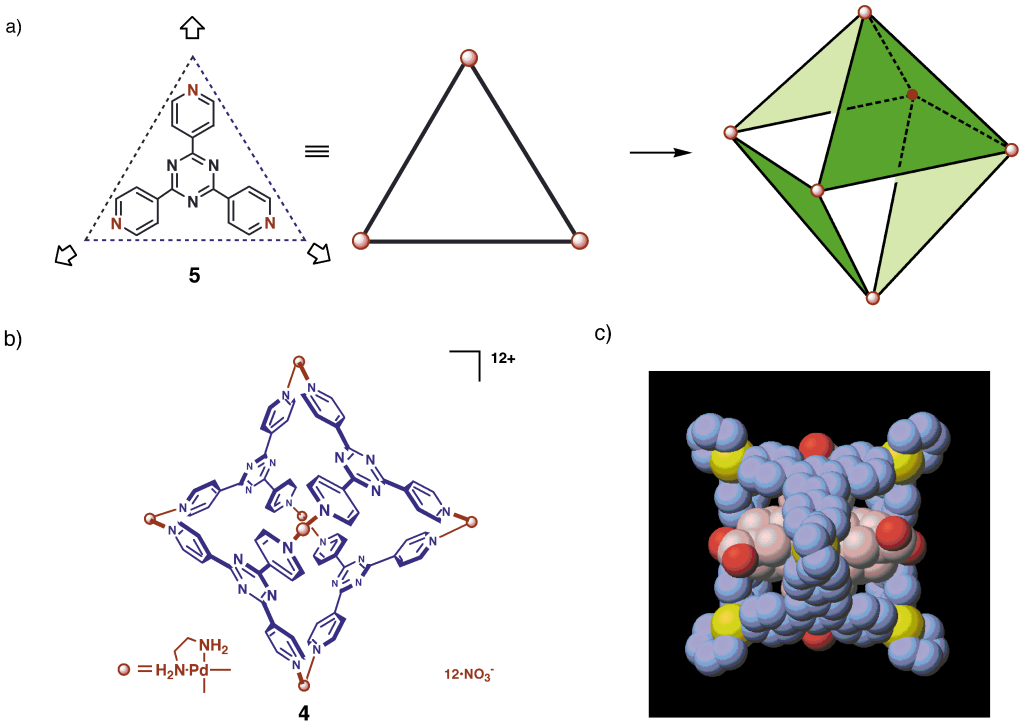

Fig. 5 (a) Schematic representation of molecular paneling of **5** to form **4**, (b) structural drawing of **4** and (c) X-ray structure of **4** with adamantane carboxylates in the cavity.

dimension of the portal of the cage is comparable to that of adamantane, whereas the interior space can hold as many as four guest molecules. The ^{1}H NMR study showed that the same host–guest aggregation was retained even in aqueous media.

A kinetically stable octahedral M_6L_4 cage

The Pd(II) self-assembly described above is a result of thermodynamical equilibration and the product is not stable under extreme conditions (*e.g.* acidic, basic or nucleophilic). In order to prepare a kinetically stable M_6L_4 complex, a Pt(II) analogue of **4**, **15** was used instead of **1**. In contrast to the Pd cage, the formation of Pt cage was quite slow to form in a reasonable yield. However, heating the solution and adding a guest molecule, adamantanecarboxylate, dramatically improved the reaction rate as well as the yield. The host–guest ratio and the guest inclusion geometry were found to be similar to those of Pd structure **4**. Usually, a receptor framework organized by guest induced fit will be lost when the guest is removed. In contrast, the assembled Pt cage did not lose its cage structure even after removal of the guest because of the locking, irreversible nature of Pt(II)–pyridine bond. As anticipated, the Pt(II) complex was very stable and did not decompose even in the presence of an acid (HNO_3), a base (K_2CO_3) or a nucleophile (NEt_3) owing to the inertness of a Pt(II)–pyridine coordinate bond.[17]

M_6L_4 square-pyramidal cone

The triangular molecular panel **6** was used to assemble a bowl-like M_6L_4 square-pyramidal cone. Although **6** has a similar structure as **5**, due to the different placement of N-atoms in the ligand this component formed a square-pyramidal cone **16** upon treatment with **1** (Fig. 6).[18a] The structure of **16** was characterized in solution by ^{1}H NMR spectroscopy and in the solid state by X-ray crystallography. The framework is held together by 10 molecular components (six metal ions and four ligands) having nanometer dimensions (*ca.* 3 × 2 × 2 nm) in spite of the small size of the molecular components.

In aqueous media the square-pyramidal cone **16** is expected to assemble into a dimeric capsule that contains a large hydrophobic pocket inside the framework because of its amphiphilic properties: hydrophobic inside and hydrophilic outside. In fact, such a dimeric structure does assemble in the solid state. That is, X-ray structures have been obtained for host–guest complexes with large guest molecules, all of which showed the dimeric capsule structure of the host accommodating as many as six neutral organic molecules.[18b] The solid structure of the complex with *o*-terphenyl (Fig. 7a) is recognized as a dimer of 1:2 host–guest complexes because the whole structure can be divided into two identical 1:2 complexes. On the other hand, the solid structure of the complex with *m*-terphenyl (Fig. 7b) can not be divided into two halves and thus the whole structure is regarded as a 2:4 complex rather than a dimer of 1:2 complex. With *cis*-stilbene, 1:6 complexation has been confirmed by X-ray analysis.

Dynamic assembly of an M_8L_4 cone and tetrahedron

Whilst molecular panels **5** and **6** contain C_3-symmetry, molecular panel **7** has C_2-symmetry, and therefore is expected to link in two different ways upon treatment with **1**: parallel and antiparallel fashions. Linking in parallel fashion is expected to generate the square-pyramidal cone **17** whereas linking in antiparallel fashion is expected to generate a closed tetrahedron **18** (Fig. 8). Interestingly, these two routes are found to be controlled effectively by the guest molecules.[19] Larger guest molecules such as dibenzoyl templated formation of the square-pyramidal cone **17** while small tetrahedral guests like CBr_4 templated formation of the closed tetrahedron **18**. Ligand **7** and dibenzoyl were suspended in aqueous solution of **1** and stirred for 24 h. The ^{1}H NMR spectra and ESI-MS of this solution revealed the formation of **17** which accommodated one molecule of dibenzoyl. In the ESI-MS, major peaks corresponding to $\{[\mathbf{17}(\text{dibenzoyl})_m\cdot(NO_3)_{16-n}]^{n+}$ (m = 0–2, n = 3, 4)$\}$ were observed suggesting the formation of a cone structure. In ^{1}H NMR spectra eight signals appeared corresponding to the C_2-symmetric environment of **7**. The signals of dibenzoyl were substantially upfield shifted suggesting its inclusion in the cone-shaped cavity. Other bulky guest molecules such as 1,2-dibenzoyl, ethane-1,2-diol and 1,1′-ferrocenedicarboxylic acid were also found to template the same square pyramidal cone **17**.

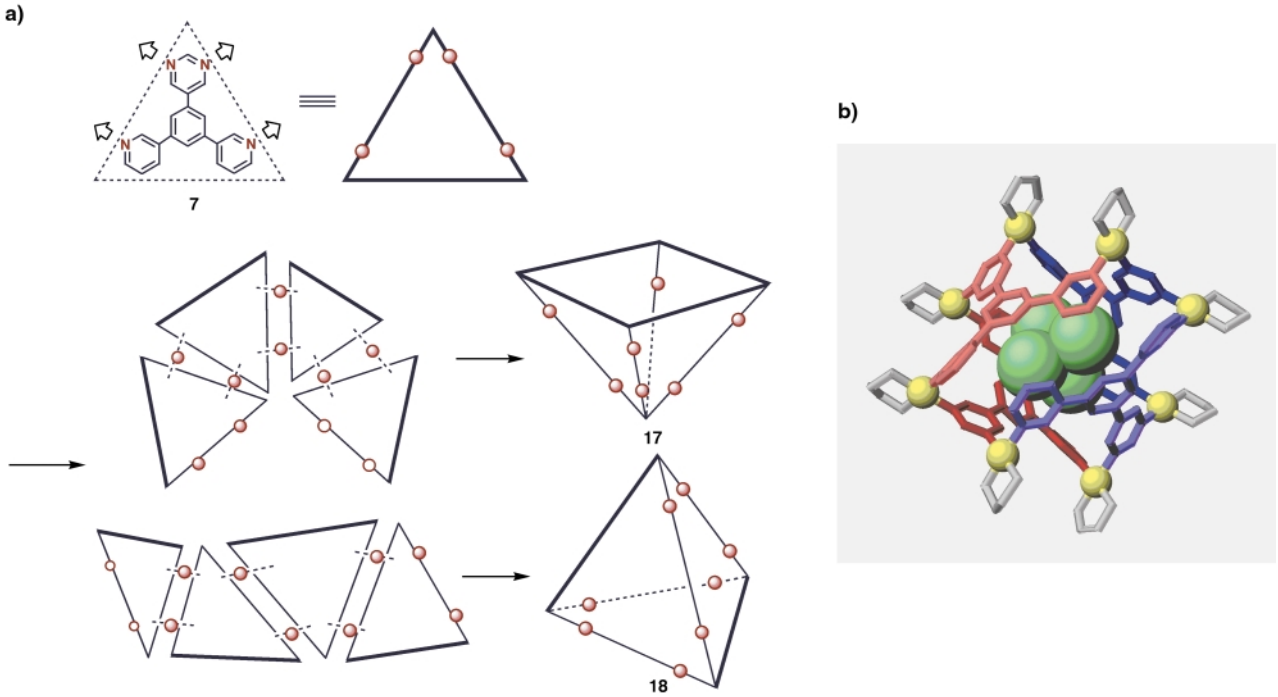

Fig. 8 (a) Schematic representation of molecular paneling of **7** to form **17** and **18** and (b) X-ray structure of the tetrahedron **18** (cylinder mode) with CBr_4 (space filling) in its cavity.

The closed tetrahedron structure **18** resulted when **1** and **7** were allowed to react in the presence of CBr_4 in D_2O. The antiparallel linking of the ligands was strongly supported by the observation of NOE between adjacent ligands. The complex was precipitated in 93% yield after adding an excess of EtOH and an elemental analysis supported a 1:1 host–guest ratio. Similarly $CHCl_3$ and $CBrCl_3$ were also found to template a similar type of structure. Further the assigned structure was supported by the single-crystal X-ray structure which showed the complete entrapment of CBr_4 in its closed tetrahedral cavity (Fig. 8b).

In the absence of guest molecules at 25 mM concentration, **1** and **7** were found to assemble into a 3:2 mixture of two products. According to ^{1}H NMR spectroscopy the minor product was identified as square-pyramidal cone **17** whereas an increase in the percentage of the major product was observed when the reaction was conducted at lower concentrations. This fact indicates that the major component could be a trimeric open-cone structure assembled from a lower number of molecular components than the tetrameric cone. These assembled trimeric and tetrameric cones and tetrahedron were found to reorganize from one structure to the other by the guest addition/exchange.

$M_{18}L_6$ hexahedron

Following the exotridentate ligands **5** and **6**, an exohexadentate ligand, 1,3,5-tris(3,5-pyrimidyl)benzene **8** was also designed as a triangular unit. As already discussed, the triangle is a basic unit for the self-assembly of polyhedra. Ligand **8** is an almost coplanar triangle and is expected to give an edge-sharing polyhedron when it is self-assembled with **1**. When ligand **8** is treated with **1** in D_2O, the predominant formation of a single component was observed, the ^{1}H NMR spectrum of which showed seven singlet-like signals in an integral ratio of 2:2:2:2:2:1:1. Of several possibilities, the assembly of the molecular hexahedron **19** was strongly suggested by ^{1}H NMR spectroscopy (Fig. 9).[20] This observation confirms that, after complexation, ligand **8** is placed in a less-symmetrical environment with one symmetry axis passing through a 3,5-pyramidyl (pym) ring and a core benzene ring. This symmetry is in good agreement with the trigonal-bipyramidyl structure of the

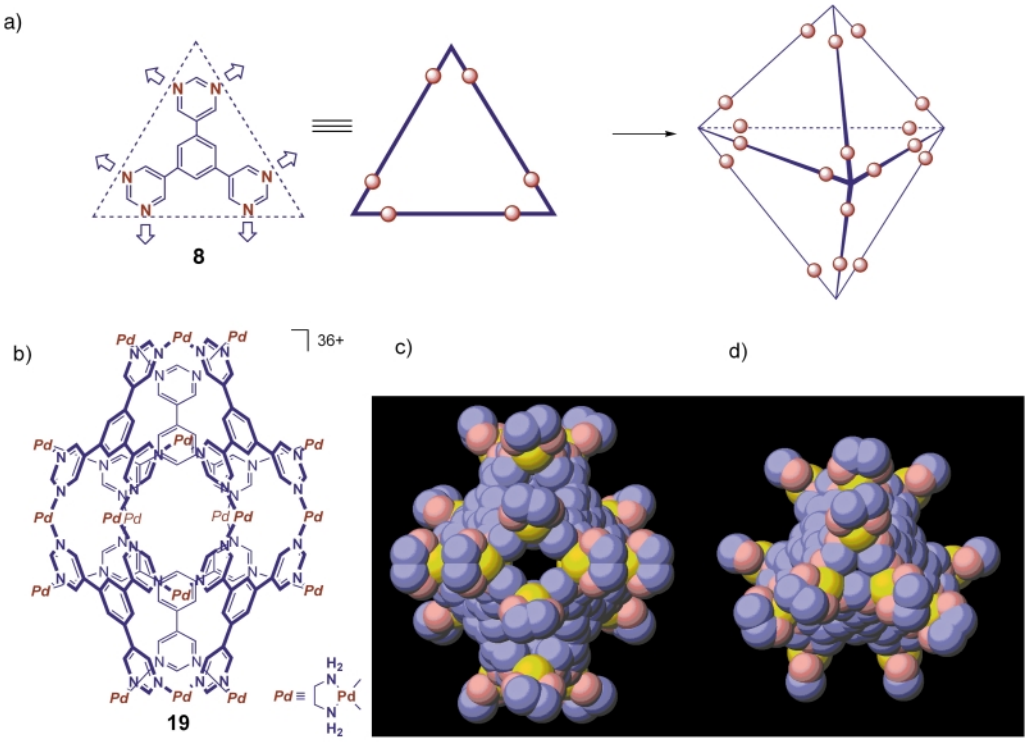

Fig. 9 Schematic representation of molecular paneling of **8** to form hexahedron **19**, (b) structural drawing of **19** and space filling representation of the X-ray structure of **19**: (c) equatorial and (d) apical views.

molecular hexahedron **19** in which the pym groups at the apical corners are not equivalent to those at equatorial corners. The metal-linked dimer and trimer of **8**, which are the possible intermediates for assembly process of **19**, were observed when ligand **8** was treated with **1** in D_2O in 1:1 and 3:4 ratios, respectively.

Reliable evidence for the hexahedron structure of **19** was provided by X-ray crystallography (Fig. 9c and d). The crystal structure clearly demonstrates that the assembly is a trigonal-bipyramidal capsule with a chemical formula of $C_{144}H_{216}N_{108}Pd_{18}$, a molecular mass of 7103 Da, and dimensions of 3 × 2.5 × 2.5 nm. Each equatorial corner of the hexahedron is the assembly of four triangle units, where [Pd(II)–pym]$_4$ leads to a small pinhole (2 × 2 Å). Only small molecules such as water and molecular oxygen may pass through these holes, whereas, ordinary organic molecules cannot enter or escape. The free volume inside the capsule, into which guests can be accommodated, is *ca.* 900 Å^3.

$M_{15}L_6$ hexahedron: reversible guest inclusion

As described above hexahedron **19** is a very closed and rigid structure making it difficult to encapsulate/exchange guest molecules. To prepare a hexahedron that has more flexibility to encapsulate/exchange guest molecules we designed another molecular panel **9**, which is similar to **8**, but has one binding site less than **8**. We found that the treatment of **9** with **1** in D_2O affords hexahedron **20** (Fig. 10). Interestingly as anticipated molecules of **20** can exchange the encapsulated encapsulates and small guest molecules.[21]

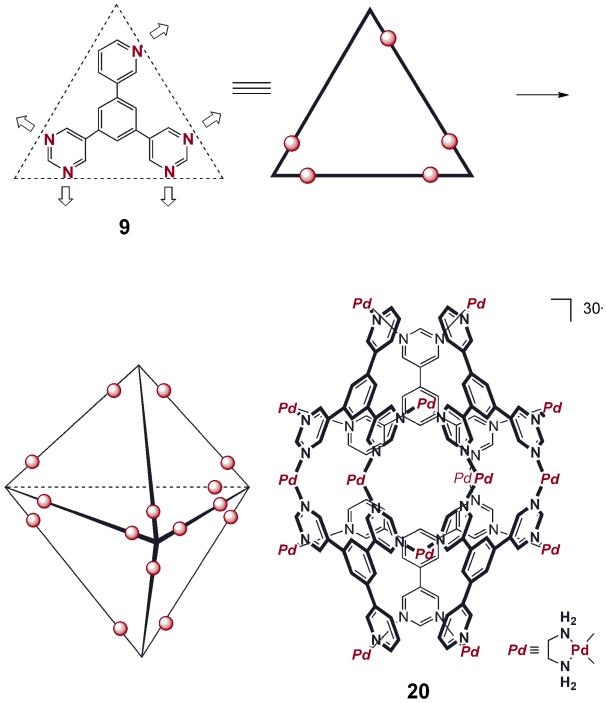

Fig. 10 Molecular paneling of **9** to form **20**.

Some functions of M_6L_4 octahedral cages

Cage compounds prepared by conventional covalent synthesis usually contain small cavities and can encapsulate only one or two small molecules. The *molecular paneling* approach gives us an opportunity to construct larger frameworks containing relatively large cavities. For example, the octahedral cage compound **4** has a very large cavity with a diameter of 1 nm and exhibited a remarkable ability to encapsulate large and neutral molecules. In the following sections we describe its abilities in molecular recognition, catalysis and condensation of trialkoxysilanes.

Molecular recognition

It has been already described that M_6L_4 can bind four molecules of aqueous guest such as adamantanecarboxylate. Further, it efficiently encapsulates neutral and spherical guest molecules such as adamantane, 1- and 2-adamantanol, *o*-carborane, and aromatic compounds such as 1,3,5-trimethoxybenzene, anisole and toluene in the cavity.[22] Interestingly, adamantane was found to transfer into the aqueous phase even in a solid–liquid

two-phase system. The very efficient guest binding by **4** can be ascribed to the amphiphilic nature of the cage: *i.e.* the inside of **4** is surrounded by 16 aromatic rings and thus hydrophobic, whereas the outside surface of the cage is hydrophilic due to the exposure of six charged Pd(II) centers.

Notably, complexation is faster with smaller guest molecules and slower with larger guest molecules. For example 1,3,5-tri-*tert*-butylbenzene which is slightly larger than the portal of **4**, was encapsulated very slowly. Tetrabenzylsilane required a few hours to be completely encapsulated by **4′** which is the 2,2′-bipyridine protected analogue of **4**. Crystallographic analysis showed a good fit for the tetrahedral symmetry of the guest in the octahedral cage (Fig. 11).[23]

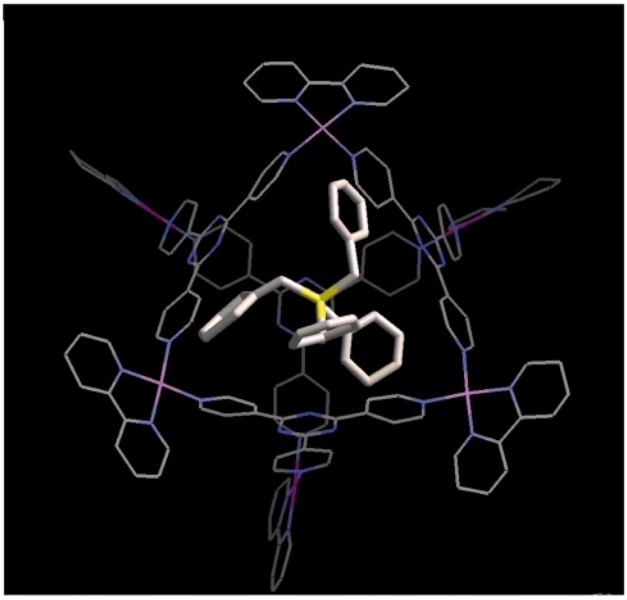

Fig. 11 X-Ray crystallographic structure of **4′** (stick mode) enclathrating tetrabenzylsilane (cylinder mode).

Compound **4** also exhibited a remarkable ability to encapsulate C-shaped molecules such as *cis*-azobenzene **21** and *cis*-stilbene **22**, derivatives.[24] These guest molecules are enclathrated in the cavity *via* the formation of a hydrophobic dimer with a topology reminiscent of a hydrogen-bonded tennis ball (Fig. 12a).[24] The formation of a hydrophobic dimer was

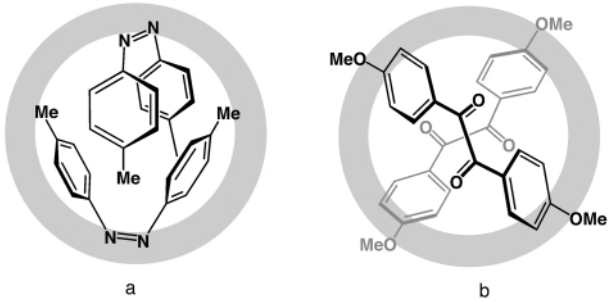

Fig. 12 Schematic drawing of formation of a hydrophobic dimer of (a) *cis*-stilbene and (b) 4,4′-dimethoxydibenzoyl within the cavity of **4** (shown as circle).

suggested by NOE and also by molecular dynamic simulation. Further the selective enclathration of only the *cis* isomer was observed when *cis–trans* mixtures of either **21** or **22** in hexane were stirred in a D_2O solution of **4**. The NMR spectra confirm the encapsulation of dimers of *cis*-isomers in the cavity. Notably, the *cis* isomer of **21** was significantly stabilized in the cavity and not isomerised to the *trans* isomer even after allowing the solution to stand for a few weeks under visible light at room temperature. Molecular modeling calculations suggest that the hydrophobic dimers are a perfect fit for cavity of **4**. Dimerization of the guests prior to enclathration is unlikely because the dimension of the spherical dimer (*ca.* 11 Å in diameter) is larger than that of the portals of **4** (*ca.* 7 Å diameter). Therefore, two guest molecules can subsequently, but not simultaneously, be enclathrated in the cavity leading *in situ* into the stable hydrophobic dimer.

A similar dimer formation was observed when 1,2-diketone **23** was employed as a guest (Fig. 12b). In the 1:2 complex, dissymmetrization of the host structure was observed by NMR spectroscopy: that is, before addition of guest the four ligands in host are equivalent, but after addition of guest, 12 protons on each ligand were observed independently. This observation was clearly revealed by X-ray crystallographic analysis. As shown in Fig. 13, two guest molecules are assembled in a similar way

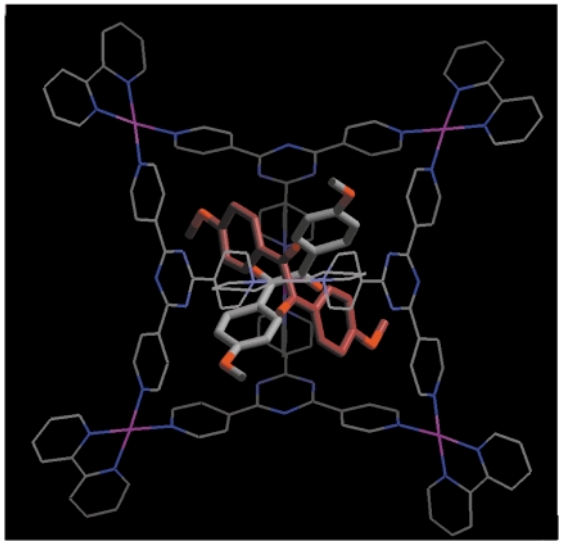

Fig. 13 X-Ray crystallographic structure of **4′** (stick mode) enclathrating the hydrophobic dimer of 4,4′-dimethoxydibenzoyl (cylinder mode).

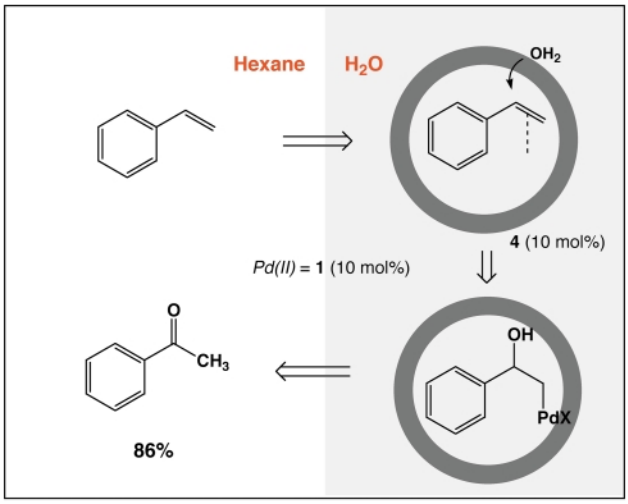
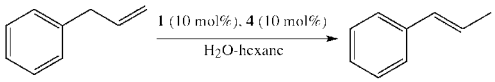
to that of **21** and **22**. However, each guest adapts a twisted conformation: one is *P*-form and another is *M*-form. As a consequence, the formed dimer has a *meso* configuration with no centrosymmetry making all protons on each ligand inequivalent.[22]

Catalysis in the cavity of M_6L_4 cage

Reactivity and catalysis represent one of the most important features of the functional properties of self-assembled molecular systems.[25] The existence of a large cavity in **4** motivated us to test its ability to catalyze the oxidation of styrene and isomerization of allylbenzene.[26] When **1** and **5** were mixed in D_2O in 2:1 ratio, formation of only **4** was observed and excess of **1** remained in the solution. Our strategy was to use the remaining amount of **1** as a mediator between organic and aqueous phases: that is to use **1** to transfer the substrate, cyclically and continuously, into a aqueous phase that contains **4** and then the formed product into the organic phase (Scheme 1). It was observed that **4** can accommodate nearly three molecules of styrene in its cavity. The oxidation of styrene at 80 °C in an aqueous solution of either **1** or **4** gave acetophenone only in 4% yield. Importantly, the presence of both **1** and **4** in an aqueous solution increased the yield of the reaction up to 86%. Similarly, the isomerization of allylbenzenes catalyzed by the presence of **1** and **4** in aqueous solution gave β-methylstyrene in 50% yield, whereas the reaction did not occur in the absence of either **1** or **4** (Scheme 2). The presence of trimethoxybenzene in the reaction media inhibited these reactions because the cavity of **4** was strongly occupied by this molecule. The yields of these reactions reveal that as the size and electron deficiency of the substrate increases the yield of the reaction decreases. These are



Scheme 1 Schematic representation of reversed phase-transfer catalysis of **4**. Wacker oxidation is promoted by a slight excess of **1**.

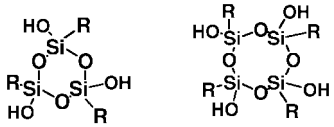


Scheme 2 Olefin isomerization in an aqueous phase with the aid of **1** (10 mol%) and **4** (10 mol%).

good examples of organic reactions in solutions but in the absence of organic solvents.

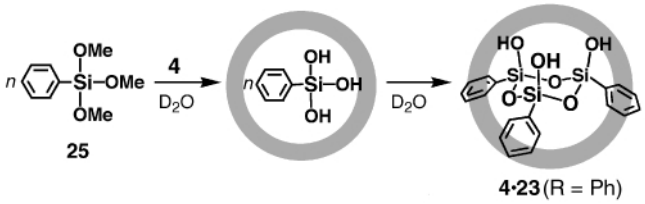
Condensation of trialkoxysilanes

Isolated cavities in molecular capsules are well known to stabilize labile molecules formed *in situ* by the reaction of smaller molecular components.[27] These components, being smaller in size, can enter into the cavity through the portals and react with each other to form a larger molecule that can not leave the cavity since it is larger than the portal. By using the same principles here we studied the condensation reaction of trialkoxysilanes in the cavity of an M_6L_4 cage.[28] Cyclic oligomers of silanols **23** and **24** are considered to be ephemeral



23 **24**

intermediates in the poly-condensation of trialkoxysilanes.[29] Cyclic tetramer **24** has been isolated in moderate yields whereas cyclic trimer **23** has never been isolated in a pure and stable form. Interestingly, when we conducted the condensation of trialkoxysilanes in the M_6L_4 cavity we observed the exclusive formation of cyclic trimer **23** as a stable form. In a typical reaction, phenyltrimethoxysilane **25** was suspended in D_2O solution of **4** at 100 °C. The ^{1}H NMR of the solution after 5 min showed the formation of complexes **4**·(**25**)$_3$ and **4**·(**25**)$_4$. After 1 h, the ^{1}H NMR spectrum showed the presence of only one complex **4**·**A**. The formation **4**·**A** was also evidenced by ESI-MS and single crystal X-ray crystallography (Scheme 3). We note the following important features of this reaction. First, the cyclic trimers are formed in a *ship-in-a-bottle* fashion. Secondly, the formed cyclic trimers, which are protected by the cavity, are very stable even in acidic aqueous solutions and isolable as pure clatharate compounds. Lastly, the stereochemistry of the condensation is highly controlled within the cage giving only all-*cis* isomers.



Scheme 3 Schematic representation of trimer formation in the cavity of **4** (shown as circle).

Paneling squares

The square is a basic unit for the construction of cubes and prisms (trigonal, square, pentagonal, hexagonal, *etc.*) Tetrakis(pyridyl)porphyrins are the most common and easily available square panels. Indeed tetrakis(4-pyridyl)porphyrin is already known to form coordination polymers and also some 2D-molecular squares with transition metal atoms.[30] However, 3D-discrete molecules using porphyrin molecular panels have not yet reported. We found the formation of a triangular prism **26** by the self-assembly of tetrakis(3-pyridyl)porphyrin **10** (Fig. 14).[31] The formation of the prism structure was confirmed by ^{1}H NMR ESI-MS and X-ray analyses.

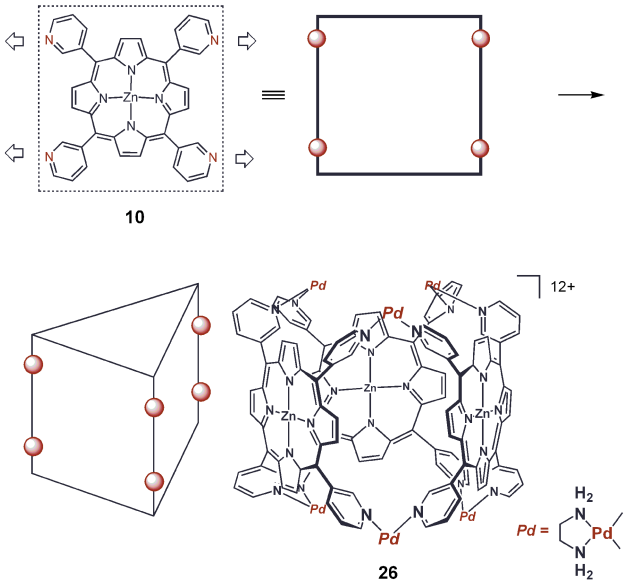


Fig. 14 Schematic representation of molecular paneling of **10** to form **26**.

Paneling rectangles

Similar to square panels, rectangular panels can also be used to construct prismatic structures of (triangles, squares, pentagonal, hexagonal *etc.*) However, depending on the length and width of the rectangular panel the assembled structures can be denoted as either tubes or boxes. Further a number of important topological surfaces such as torus, Möbius strip, Klein bottle and projective plane can also be constructed from rectangular panels. Here, we describe the self-assembly of a family of rectangular panels **11**–**13** to form molecular tubes, and that of **14** to form a molecular nano-box.

Coordination nanotubes

Molecular-based tubular structures have attracted considerable current interest because of their potential abilities for selective inclusion and transportation of ions and molecules and catalysis of specific chemical transformations.[32] Rectangular panels **11**–**13** were designed in anticipation of such tubular structures upon treatment with **1**.[33] For **13**, a coordination nanotube **27** is

expected from four molecules of **13** and 10 molecules of **1** (Fig. 15). However, the formation of coordination nanotubes were observed only in the presence of a rod-like template molecule

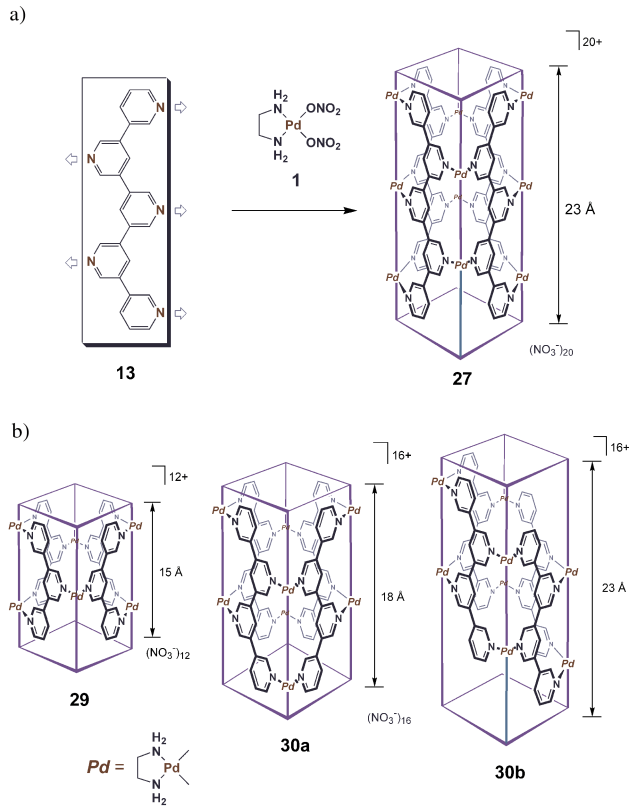

Fig. 15 (a) Schematic representation of molecular paneling of **13** and (b) structural drawings of **29**, **30a** and **30b**.

such as sodium 4,4′-biphenylenedicarboxylate **28**. Similarly, coordination nanotubes **29** and **30** were also obtained and characterized using NMR and ESI-MS. According to NMR spectroscopy, the protons of **28** were up-field shifted by up to 2.6 ppm indicating its encapsulation in the nanotube. A similar template effect was observed with two other rod-like molecules biphenyl and *p*-terphenyl. Spherical and large molecules such as adamantane carboxylate failed to template the nanotubes. Interestingly, it is found that the formation of these tubes is a completely reversible process. That is, the tube dissociates into its components by the removal of the guest molecule and again associates by the addition of guest molecule.

Shuttle movements of guest molecules were observed: at low temperatures the guest stays at a fixed position of the tube, shuttles on the NMR time scale at 60 °C, and rapidly moves or partially goes out at above 60 °C. NMR studies of nanotube **30** revealed that it is a 1 : 1 mixture of structural isomers **30a** and **30b**. In isomer **30a**, each ligand is placed on a C_2-symmetry site and only seven protons corresponding to half of **30a** were observed. On the other hand, in isomer **30b**, all 14 protons were observed as the C_2-symmetry of the ligands was removed. Tubes **29** and **30b** were characterized by X-ray crystallography. The crystal structures display tubular structures of **29** and **30b** efficiently assembled around template **28** *via* strong π–π and CH–π interactions (Fig. 16). The shape of the tube, which ideally should be square, is significantly distorted in order to maximize strong aromatic interactions. That is, the two faces which are interacting with **28** *via* π–π interactions, are squeezed towards the inside, while the remaining two faces, which interact with **28** *via* CH–π interactions, are pushed outwards. Another interesting feature of this crystal structure is the presence of a second molecule of **28** which is enclathrated between the nanotubes.

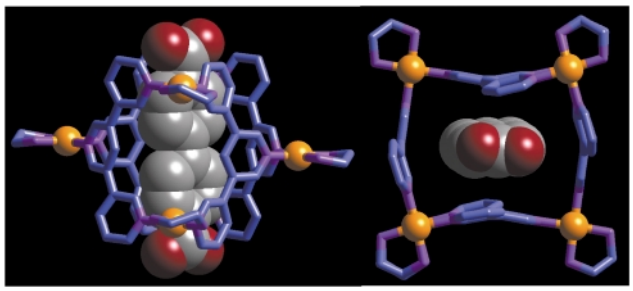

Fig. 16 The X-ray structure of **29**, side view (left) and top view (right).

Coordination box with dynamic property

A 1D rod-like ligand, such as biphenyl, upon treatment with **1** is known to be in equilibrium with two types of two-dimensional structures, namely square **3** and a triangle.[9] In order to extend this property into 3D structures we designed a rectangular molecular panel **14** which has four exodentate coordination sites. As anticipated the molecular panel **14** upon treatment with **1** was found to be in rapid equilibrium with several products which constitute a dynamic library of box structures. From the library we were able to isolate two box structures: namely trimeric box **31** and tetrameric box **32** which are minor products under normal conditions (Fig. 17).[34]

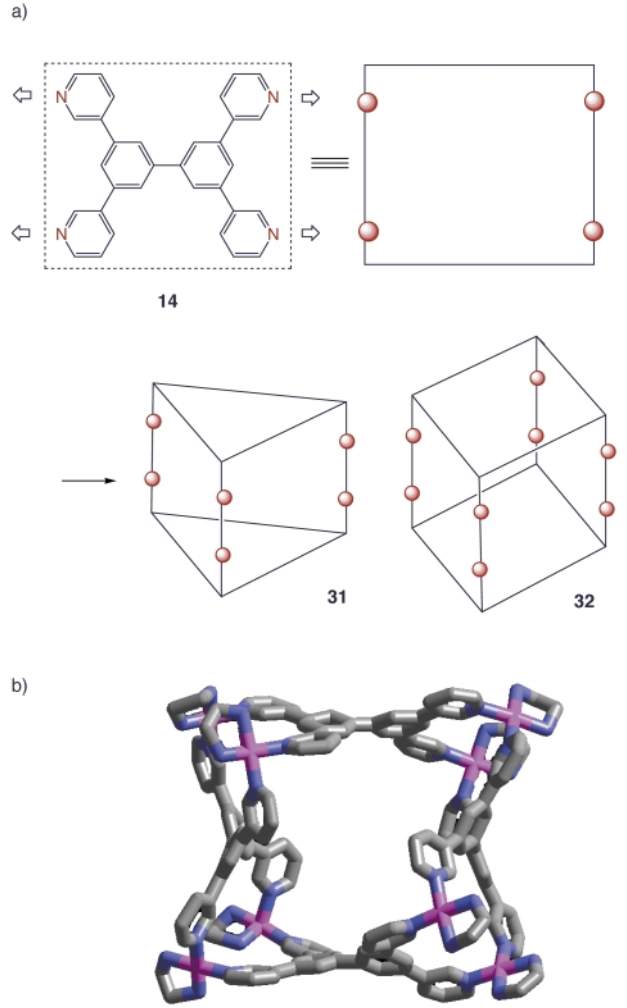

Fig. 17 Schematic representation of molecular paneling of **14** to form **31** and **32** and (b) X-ray crystal structure of an isomer of **32**.

The trimeric molecular box **31** was isolated quantitatively when a template such as biphenyl was suspended in a D_2O solution of **1** and **14** at 80 °C. The ^{1}H NMR of the solution showed two sets of signals: one set corresponds to triangular box **31** (δ 7–10) while the other set corresponds to biphenyl (δ

4.8–6.5). The biphenyl protons were significantly up-field shifted due to the inclusion in the box and the integration of the signals suggests that there are two biphenyl molecules per box. Moreover the proposed formula is in agreement with ESI-MS which shows five peaks at *m/z* 1502.9{[**31**·10NO_3]$^{2+}$}, 982.1{[**31**·9NO_3]$^{3+}$},720.8{[**31**·8NO_3]$^{4+}$},564.3{[**31**·7NO_3]$^{5+}$} and 460.3 {[**31**·6NO_3]$^{6+}$}.

Tetrameric box **32** was isolated as the major product when ligand **14** was treated with **1** at 50 °C for four days in D_2O–CD_3OD. In its ^{1}H NMR spectrum a set of six signals were observed in accord with D_{4h} symmetry of **32**, while CSI-MS of its PF_6 salt also supported the tetrameric box structure (*m/z* 1688.8 [**32**·13PF_6]$^{3+}$ and 1230.8 [**32**·12PF_6]$^{4+}$). Slow diffusion of THF vapor into an H_2O–CH_3CN solution of **1** and **14** for a few weeks resulted in single crystals suitable for X-ray analysis. The crystal structure revealed the formation of an unexpected structure that has the same composition as **32** but is composed of two structural isomers of **14**. The differences between solution and solid-state structures could be due to the presence of THF vapor that possibly shifted the equilibrium during the crystallization. However, the formation of a similar box structure in solution was not observed as it is rapidly isomerizes into box structure **32**.

The dynamic behavior of these box structures in solution was studied by ^{1}H NMR and CSI-MS. When the PF_6 salt of trimeric box **31**·2(biphenyl) was dissolved in CD_3CN the guest was liberated immediately leaving empty **31**. Interestingly monitoring of this solution by ^{1}H NMR and CSI-MS showed the reorganization of trimeric box **31** into tetrameric box **32** in 24 h and also revealed the presence of a pentameric box as a kinetic intermediate during the reorganization process.

Conclusions

Here we have described a highly successful strategy, which we term as *molecular paneling*, to construct various 3D-molecules that resembles several existing polyhedra. We note the following as advantages of using the concept of *molecular paneling* to construct 3D-architectures.

The syntheses are very facile: most of the compounds described here can be synthesized on a several gram scale in the laboratory simply by mixing the components in water, and the yield is quantitative in most cases.

This method provides the opportunity for the construction of larger cage-like molecules with larger cavities. Such larger cavities allow for the existence of isolated spaces which can be used for chemical transformations as described for octahedral cage **4**.

The involvement of transition metals in the molecular frameworks may lead to new properties (photo, redox, magnetic and/or thermal).

First published as an Advance Article on the web 28th February 2001

Tripodal, water-soluble thioethers based on 1,3,5-trismethylbenzene scaffolds are suitable ligands for the Au_{55} cluster.

The so called 'Schmid-cluster',[1] $Au_{55}(PPh_3)_{12}Cl_6$, has stimulated many different areas of chemistry ranging from catalysis research[2] to the concept of nanocrystals[3,4] and quantum electronics.[5] Monofunctionalized water-soluble derivatives of the cluster are commercially available and have found numerous applications as TEM markers for biomolecules.[6] We have recently reported on trisoligonucleotidyls,[7] a novel class of branched oligonucleotides that can be used for an informational self assembly of defined nanometer sized objects. TEM imaging of such objects proved to be successful in those cases where heating steps involving oligonucleotide gold conjugates could be avoided. The exploration of general strategies for the non-covalent synthesis of nanoobjects, however, requires sufficient thermal stability of the TEM markers, especially if one conceives a chemical replication of such nanoobjects.

We report here on the synthesis[8] and preliminary characterisation of water-soluble gold clusters bearing tripodal thioether based ligands **1**–**6** (Fig. 1). The rationale behind these ligands, shown in Fig. 2, relates to the general ideas of symmetry-based host design as outlined by MacGillivray and Atwood.[9] The Au_{55} cluster core may be described as a cuboctahedron whose surface

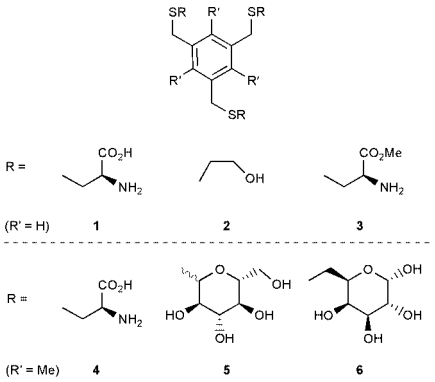

Fig. 1 Structures of examined thioethers.

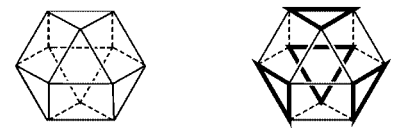

Fig. 2 Proposed cuboctahedron geometry of the Au_{55} cluster and some possibilities of coverage with multidentate ligands.

† Present address Soft Imaging System GmbH, Hammerstr. 89, 48153 Münster, Germany.

is composed of eight edge-connected triangles (111) and six squares (110). As such, Au_{55} is expected to bind four tripodal ligands if the binding mode of the ligands is comparable to the Schmid cluster where the 12 triphenylphosphanes most likely occupy the edges of the cuboctahedron. The affinity of C_3-symmetrical thioethers towards the (111) gold surface has already been reported in the context of self assembled monolayers.[10] Molecular modelling studies suggested that tris-thioethers derived from 1,3,5-trismethylbenzene scaffolds are suitable candidates for tripodal binding as they seem to match the geometric requirements for covering the (111) triangles of Au_{55}. A model of the Au_{55} core surrounded by ligand **1** is shown in Fig. 3.

Ligands **1**–**6** were tested for their ability to extract gold into the aqueous phase from a solution of the triphenylphosphane cluster in methylene chloride, a method used previously by Schmid *et al.*[11] to exchange the ligand into monosulfonated triphenylphosphane. The degree of phase transfer was monitored from the partition of the brown color after stirring the two-phase system for varying periods of time. Complete phase transfer resulting in an decolorization of the organic phase was achieved with ligand **6** after 16 h and with ligands **1** and **4** after 7 days (in buffered[12] solution or when using the sodium salt respectively). Extraction using the other ligands (**2**, **3** and **5**) did not show any phase transfer. The absence of remaining triphenylphosphane ligands was shown by NMR investigation of the precipitated and redissolved clusters with ligands **1**, **4** and **6** (in D_2O). In all cases neither signals of the phosphane aromatics (in ^1H NMR) nor P resonance signals could be detected. The clusters were precipitated from the aqueous phase by addition of propan-2-ol and purified by cycles of dissolution in water and reprecipitation with the alcohol. The solvent was

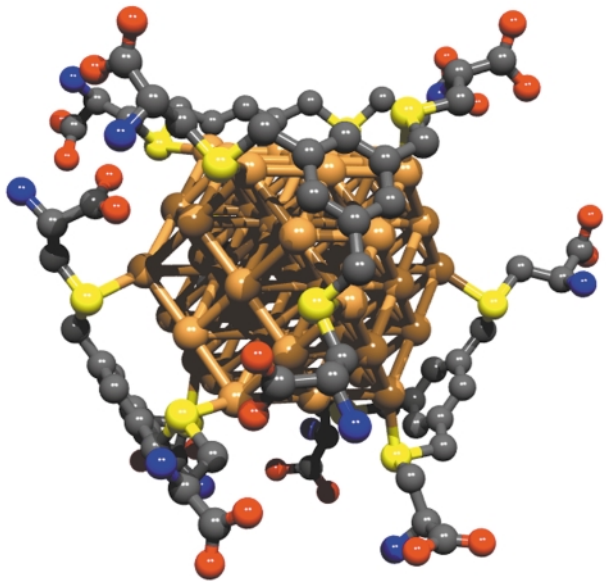

Fig. 3 Computational model structure of the ligand **1** cluster complex.

DOI: 10.1039/b008967m

evaporated *in vacuo* at room temperature, yielding a brownish powder. Elemental analyses were carried out with the cluster bearing ligand **1** as its sodium salt[13a] or with trishydroxymethylaminomethane (TRIS) as counter ion.[13b] The results suggest a ratio of four ligand molecules (with counter ions) per $Au_{55}Cl_6$ core.

Dynamic light scattering/photon correlation spectroscopy (PCS) proved to be a quick and comfortable method for studying the size distribution of the clusters. The mean diameters (and half value widths) were 2.6 ± 0.34 nm for clusters with ligands **1** and **4** and 2.8 ± 0.20 nm for ligand **6**, respectively. These data are not incompatible with the assumption of an Au_{55} core if one considers the hydrodynamic radius estimated from PCS is affected by the nature and solvation properties of the ligands. For ligand **1** the distribution of cluster core sizes was further monitored using high resolution TEM (400 kV). A fairly uniform size distribution with a mean diameter of 1.4 nm was found. The cluster preparations were stable in aqueous solution for weeks at ambient temperature, before slow aggregation to larger colloids and precipitation occurs, hinting at their high kinetic stability. A sample that was stored in aqueous solution at room temperature for 70 days still showed a very narrow size distribution (diameter *ca.* 1.4 nm) according to TEM (Fig. 4).

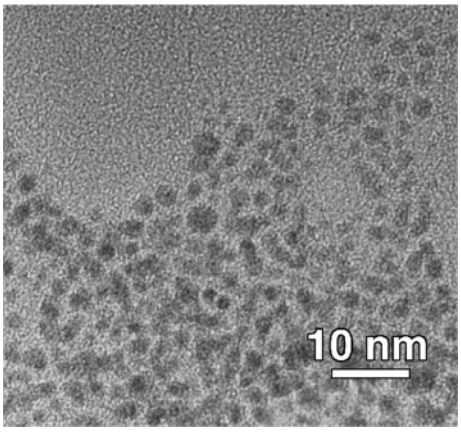

Fig. 4 HRTEM image of the Au_{55} cluster with ligand **1** after storing the sample solution for 70 days.

Gel electrophoresis using 1% agarose gel proved applicable to investigate the charge, uniformity and kinetic stability of the different clusters. The agarose gel of clusters with ligands **1** and **4** reveals a discrete brownish band moving to the anode. Its appearance in terms of broadness is comparable to bromophenyl blue hinting at its uniformity and proving the expected anionic character of the cluster. Under the same conditions, the clusters formed from ligand **6** did not show any mobility, as expected for neutral ligands, if the six chloride ions are tightly bound to the cluster core, with only diffusive broadening at the flanks of the gel pocket being observed. Furthermore, clusters from ligands **1** and **4** show only little smearing of the electrophoresis band so revealing their kinetic stability. All attempts to establish the molecular weight of the clusters by MALDI-TOF mass spectroscopy have failed so far.

To the best of our knowledge, this work represents the first examples of the utilisation of tripodal ligands and on the use of thioether ligands for the preparation of gold clusters. Future approaches towards the synthesis of stable, water soluble, biocompatible and monofunctionalizable gold clusters may now employ peptide chemistry for further sealing and packaging of Au_{55} cores.

We thank Deutsche Forschungsgemeinschaft (SFB 452) for support, Degussa-Hüls AG for the generous gift of tetrachloroauric acid, and G. Schmid for a sample of $Au_{55}(PPh_3)_{12}Cl_6$.

Treatment of planar-chiral cyclopentadienyl–phosphine ruthenium complexes with phosphine and phosphite induces metal-centered chirality with a high stereoselectivity (≥99 % de).

Planar-chiral cyclopentadienyl (Cp) complexes generated by coordination of unsymmetrically substituted Cp ligands to metal atoms have attracted much attention as novel asymmetric catalysts.[1] Although planar-chiral Cp complexes of early transition metals have been applied to asymmetric reactions with high selectivities, limited numbers of studies on such types of complex involving late transition metals are found in the literature. We have been investigating the synthesis, optical resolution and properties of planar-chiral organometallic complexes of Group 8 metals with trisubstituted Cp ligands.[2] Recently we prepared planar-chiral Cp–phosphine ruthenium complexes **1**,[3] which may serve as a good asymmetric environment around the ruthenium atom to prevent the rotation of the trisubstituted Cp ring by an anchor phosphine.[4] Now we examined the efficiency of the planar-chiral Cp–phosphine ligand on the induction of metal-centered chirality since the control of stereochemistry at a metal center is very important to develop highly enantioselective reaction using three-legged piano-stool complexes.[5]

Significant numbers of attempts to induce metal-centered chirality in three-legged piano-stool complexes have been found in the literature.[6] However, successive examples of the control of metal-centered chirality with a high selectivity are still limited. Very recently, with planar-chiral Cp and indenyl Rh and Ir complexes having anchor phosphine ligands it has been shown that the metal-centered chirality is induced by oxidative addition to the metal with high stereoselectivities.[7] Herein we report the thermodynamically or kinetically controlled induction of metal-centered chirality in the ligand exchange reactions of planar-chiral Cp–phosphine Ru complexes with various phosphines and phosphites.

Treatment of complex **1a** with 1.1 equiv. of PPh_3 in acetone at room temperature resulted in the replacement of one of the two MeCN ligands to give complex **2a** in quantitative yield. Resulting complex **2a** contained two diastereomers, each of which consists of a pair of enantiomers when racemic **1a** was used as the starting material (Scheme 1). Thus, the stereoselectivity at a chiral metal center was appraised by the ratio of the major diastereomer (**2a-1**) to the minor one (**2a-2**). ^1H and ^{31}P NMR spectra of **2a** clearly showed that the diastereoselectivity was 52% de. Fortunately, single crystals of **2a-1** were able to be grown in a CH_2Cl_2–ether solution of a mixture of the two diastereomers. The stereochemistry of **2a-1** was unequivocally identified by X-ray crystallography to be $S_{1C}S_{Ru}$/$R_{1C}R_{Ru}$ as shown in Fig. 1.‡

The stereoselectivity was then examined for the reactions of **1a**–**1c** with phosphines and phosphites (Table 1), and it was found that the selectivity depends upon the steric bulkiness of incoming phosphines and phosphites, and of the substituents on the Cp group. In the reactions with bulky phosphines, such as PPh_3 and PBu_3, the selectivities were higher than those with smaller ones such as PMe_3. The reaction of complex **1c** having a *t*-butyl group on the Cp ring gave products with a high selectivity relative to those for complexes **1a** and **1b**. Thus, the reactions of **1c** with bulky phosphines and phosphites (entries 11, 12 and 14) produced single diastereomers exclusively (> 99% de). The X-ray analyses of major products **2d-1**, **2f-1**, **2h-1**, **2m-1**, **2n-1** and **2o-1** revealed that all of them have the same stereochemistry as that of **2a-1**.†‡§ Similar reactions of planar-chiral Ru complexes **3** involving a $P(OMe)_3$ ligand instead of an anchor phosphine one were performed (Scheme 2, Table 2). Although the yields of products **4** were high, the

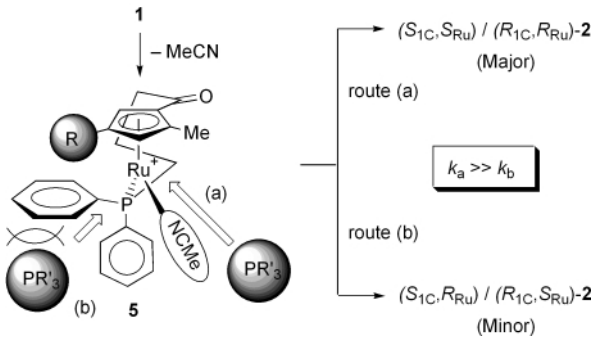
Table 2 Reactions of complexes **3a**–**3c** with phosphines

Entry	Complex	Product	Yield (%)[a]	% de[a]
1	**3a** (R = Me)	**4a**	92	28
2	**3b** (R = Ph)	**4b**	100	2
3	**3c** (R = Bu^t)	**4c**	100	34

[a] Determined by ^{1}H and ^{31}P NMR spectroscopy.

diastereoselectivities were very low (< 34% de) relative to those of **2**, suggesting that the anchor phosphine ligand has an important role in control of the stereochemistry at the metal center.

It should be noted that complexes **2a-1** and **2f-1** slowly isomerized into minor isomers **2a-2** and **2f-2**, respectively, in acetone at room temperature. For example, diastereomerically pure complex **2a-1** was converted into a mixture of complexes **2a-1** and **2a-2** in a 74:26 ratio (48% de), which is almost the same diastereoexcess as that observed for the reaction of **1a** with PPh_3. Since easy replacement of the MeCN ligands in **2a-1** and **2f-1** with CD_3CN was confirmed by means of ^{1}H NMR, the selectivities in these cases must be determined by the thermodynamic stability of the products. On the other hand, no epimerization at a metal center as well as no exchange of MeCN with CD_3CN were observed in other major products **2-1** in solution. These results strongly suggest that the selectivities of products **2**, except for **2a** and **2f**, were controlled kinetically. The kinetic preference of $S_{1C}S_{Ru}/R_{1C}R_{Ru}$ isomers to $S_{1C}R_{Ru}/R_{1C}S_{Ru}$ ones can be reasonably explained considering the stereochemistry of intermediate **5** as shown in Scheme 3. Ligand exchange reactions would proceed *via* unsaturated species **5**, which is generated by dissociation of MeCN from **1**. Coordination of incoming phosphines or phosphites from side (a) gives ($S_{1C}S_{Ru}/R_{1C}R_{Ru}$)-**2**, while coordination from side (b) produces ($S_{1C}R_{Ru}/R_{1C}S_{Ru}$)-**2**. The structures of planar-chiral ruthenium complexes with Cp–phosphine ligands including starting complex **1a**‡ clearly show that the attack of phosphines to the ruthenium center receives steric hindrance caused by the equatorial phenyl group and the substituent (R) on the Cp group. Thus, the attack from side (a) must be faster than that from side



Scheme 3

(b), resulting in the selective formation of ($S_{1C}S_{Ru}/R_{1C}R_{Ru}$)-**2**. This explanation is in good agreement with the steric influence of incoming phosphines and the substituents on the Cp group upon the selectivity of the reactions (*vide supra*).

In summary, we have disclosed here the first example of the kinetic control of metal-centered chirality by planar-chirality of the Cp group in the three-legged piano-stool complexes. Since the resulting complexes are conformationally stable, they may be applicable to novel asymmetric catalysts.

CCDC 147977–84. See http://www.rsc.org/suppdata/cc/b0/b009412i/ for crystallographic files in .cif or other electronic format.

§ In the reaction with PBu_3 and PMe_3, the assignments of configuration at a metal center (R_{Ru} or S_{Ru}) in resulting complexes **2b**, **2c**, **2g**, **2h**, **21** and **2m** are reversed relative to those of other complexes with the same conformation due to the change of the priorities of the anchor phosphine ligand and the incoming P ligands. Thus, the stereochemistries of **2b-1**, **2c-1**, **2g-1**, **2h-1**, **2l-1** and **2m-1** are $S_{1C}R_{Ru}/R_{1C}S_{Ru}$ whereas those of other major products are $S_{1C}S_{Ru}/R_{1C}R_{Ru}$.

First published as an Advance Article on the web 26th February 2001

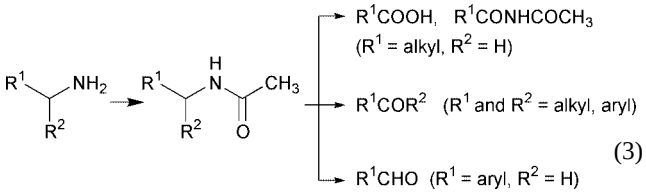
New procedures based on the oxidation by bromine-catalysed hydrogen peroxide in a two-phase system provide simple and cheap transformations of alkylamines to carbonyl derivatives (aldehydes, ketones, carboxylic acid, imides, lactams) through the corresponding acetamides.

Classical rearrangement reactions, such as the Hofmann[1,2] and Curtius[1,3] rearrangements, allow the transformation of carboxylic acids to amines through the corresponding amides or acyl azides [eqn. (1)], while the Beckmann[4,5] rearrangement involves the formation of amides from ketones through the oximes [eqn. (2)].

(1)

(2)

In this Communication we report a new simple oxidation procedure, which allows the reverse transformation of alkylamines to carboxylic acids, aldehydes, ketones and imides through the intermediates acetamides [eqn. (3)].



(3)

Recently we have reported[6,7] simple and highly selective methods for the oxidation of primary alcohols to either aldehydes or esters, depending on the benzylic or aliphatic nature of the alcohol, by bromine-catalysed H_2O_2 [eqns. (4) and (5)].

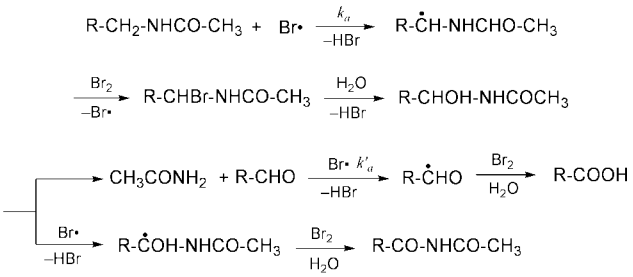
(4)

(5)

The selectivity of these reactions is determined by the relative rates of hydrogen abstraction by bromine atom from the alcohol (k_4) and from the corresponding aldehyde (k_5). For benzylic alcohols $k_4 > k_5$ and the reaction gives high selectivity in aldehyde with complete conversion, whereas for non-benzylic alcohols $k_4 << k_5$ and the oxidation gives high selectivity in esters even at very low conversion, without formation of a significant amount of aldehydes.

Aliphatic amines, in principle, should be more reactive, both for enthalpic and polar reasons, than the corresponding alcohols towards hydrogen abstraction by Br•. The acidic medium, however, deactivates the amines by protonation, which reverses the polar effect and increases the strength of the C–H bonds in the α-position. To avoid this limitation we have investigated the bromine-catalysed H_2O_2 oxidation of the corresponding acetamides.

With primary alkyl groups, the carboxylic acid was easily obtained, but when the primary alkyl group was benzylic the corresponding aldehyde was formed instead, with good selectivity at complete conversion. A free-radical chain is involved according to Scheme 1.



Scheme 1

Also in this case, as for alcohol oxidation, the selectivity was determined by the relative rates of hydrogen abstraction by Br• from the amide (k_a) or from the aldehyde (k'_a). Since $k_a > k'_a$ for R = aryl, while $k_a << k'_a$ for R = alkyl, an opposite behaviour is observed in the two cases. Polar and enthalpic effects, due to the different electronic configurations of the alkyl (π-type) and acyl (σ-type) radicals,[8] determine this different reactivity, as previously[6,7] discussed for the oxidation of alcohols.

With secondary alkyl groups the corresponding ketones were obtained, but under the reaction conditions a partial bromination of the ketones occurs; conversion and selectivity are low with cyclohexyl derivatives, due to the particular ease of bromination of cyclohexanone, compared to acyclic ketones.[9]

By-products of the oxidation according to Scheme 1 are the imides, formed by further oxidation of α-hydroxyamides before cleavage. In any case, imides can be easily hydrolysed, so that high overall yields of carboxylic acids can be obtained by refluxing the acidic reaction mixture; under the reaction conditions (room temperature) the imides are not substantially hydrolysed, supporting the mechanism of Scheme 1 for the formation of carboxylic acids.

With cyclic amines, such as **1** and **2**, the higher stability of α-hydroxyamides leads to the corresponding imides **3** and **4** with high yields and to the corresponding lactams **5** and **6** by hydrolysis [eqns. (6) and (7)].

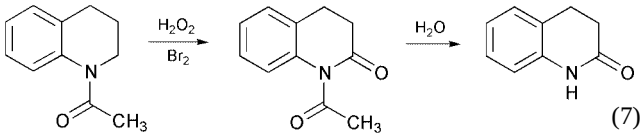
[a] DCE = 1,2-dichloroethane. [b] Procedure: the aqueous solution of H_2O_2 was added dropwise to the mixture of the other reagents and solvents reported in the Table, at rt and under effective stirring for 3 h. [c] Procedure: the mixture of the reagents and solvents reported in the Table 1 was effectively stirred for 3 h at rt. [d] Procedure: as in *c* but 2 mol of HBr and 1 mol H_2O_2 were used instead of 1 mol Br_2. All the reaction products were known and characterised by comparison with authentic samples (GLC-MS and NMR); quantitative yields were determined by GLC using as internal standards *n*-$C_7H_{15}COOH$ for carboxylic acids, *p*-MeO-C_6H_4-CHO for aromatic aldehydes, *n*-Pr-CO-Pr-*n* for ketones and *n*-$C_6H_{13}CONHCOMe$ for imides.



(7)

2 **4** **6**

The reactions, carried out in a two-phase system (H_2O–$ClCH_2CH_2Cl$), are initiated by ambient light and the active oxidant is Br_2, which acts in the organic phase; the formed HBr is extracted by the aqueous phase and oxidised to Br_2 by H_2O_2 making the process catalytic in Br_2. Two procedures were utilised as reported in Table 1. In both cases the overall process is catalytic in Br_2, but a higher concentration of Br_2 makes the overall process faster; an aqueous solution of HBr and H_2O_2 can be utilised instead of Br_2 in a two-phase system. Procedure a) gives better results for the synthesis of carboxylic acids because a higher concentration of Br_2 accelerates the oxidation of a-hydroxyamides to imides, while procedure b) is more suitable for the synthesis of ketones, which consumes the catalytic amount of Br_2 by electrophilic bromination and inhibits the free-radical oxidation.

Phosphide coupling in the reaction of $Sn(NMe_2)_2$ with MesPHLi; synthesis and structure of the Sn(II) phosphide dianion $[\{Sn(\mu\text{-}PMes)\}_2(MesP)_2]^{2-}$ (Mes = 2,4,6-$Me_3C_6H_2$)

In contrast to the reactions of other primary phosphides with $Sn(NMe_2)_2$, the reaction of MesPHLi with $Sn(NMe_2)_2$ results in partial coupling of MesP groups in the product (which contains the novel Sn(II) dianion $[\{(Sn(\mu\text{-}PMes)\}_2(MesP)_2]^{2-}$).

We recently showed that the heterometallic Sb(III) cage $[\{Sb(PCy)_3\}_3Li_6]$ (Cy = C_6H_{11}) decomposes at relatively low temperature (30–40 °C) into Zintl compounds containing the Sb_7^{3-} anion.[1] The isolation of $[CyP]_4$ from this 'cage-to-alloy' reaction suggests that the formation of P–P bonds (the strongest homonuclear Group 15 bond) provides the thermodynamic driving force.[1] In related studies it was shown that probable intermediates in the formation of E_7^{3-} Zintl ions (E = As, Sb) are cyclic anions of the type $[(RP)_nE]^-$.[2,3] A key observation was that the ease of formation of the Zintl compounds is dependent (among other factors) on the nature of the R substituent of the RP^{2-} groups.[3] Thus, reaction of MesPHLi with $As(NMe_2)_3$ at room temperature in the presence of TMEDA [= $(Me_2NCH_2)_2$] leads to rapid (1 h) formation of $As_7Li_3\cdot3$TMEDA, whereas prolonged reaction (12 h) of a range of aliphatic primary phosphides with $As(NMe_2)_3$ under similar conditions gives complexes containing $[(RP)_nAs]^-$ anions (n = 3 or 4), it being necessary to reflux these reactions in order to effect formation of Zintl compounds.[3] The synthesis and structure of $[\{(Sn(\mu\text{-}PMes)\}_2(MesP)_2]Li_2\cdot2$TMEDA **2** reported here provides the first evidence that the reactivity pattern established for Group 15 phosphides has broader implications to other p block elements.

In earlier studies we had observed that the reaction of $[SnNBu^t]_4$ with CyPHLi (1:6 equiv.) in thf gives the heterometallic complex $[\{Sn(\mu\text{-}PCy)_2\}_2(\mu\text{-}PCy)]_2Li_4\cdot4$thf **1**, containing the metallacylic tetraanion $[\{Sn(\mu\text{-}PCy)_2\}_2(\mu\text{-}PCy)]_2^{2-}$.[4] The impetus for further studies came with the surprising finding that the same complex is also produced by the reaction of $Sn(NMe_2)_2$ with CyPHLi in thf using a range of stoichiometries (from 1:1.5 to 1:3 equiv., respectively) (Scheme 1).[5] In fact other aliphatic primary phosphides react similarly with $Sn(NMe_2)_2$ in thf. For example, reaction of Bu^tPHLi with $Sn(NMe_2)_2$ gives $[\{Sn(\mu\text{-}PBu^t)_2\}_2(\mu\text{-}PBu^t)]_2Li_4\cdot4$thf **2** (in *ca.* 60% yield), whose structure is essentially identical to **1**.[5] However, the analogous reaction of MesPHLi (Mes = 2,4,6-$Me_3C_6H_2$) with $Sn(NMe_2)_2$ gives a radically different result. The product isolated in the presence of the bidentate donor TMEDA (addition of which was necessary to facilitate crystallisation) is $[\{(Sn(\mu\text{-}PMes)\}_2(PMes)_2]Li_2\cdot2$TMEDA **3** (in 96% yield).† Some indication of the different outcome of the reaction with MesPHLi is provided by room-temperature NMR studies. In contrast to **1** and **2** where the two ^{31}P NMR environments are markedly different (*e.g.* δ −180 and −249 in **1**), the P environments of **3** occur at very similar chemical shifts (δ −156.7 and −157.5). In addition, the electronic environment of the Sn centres in **3** (δ −154.6) is clearly vastly different from that found in **1** and **2** (*ca.* δ +690).[4] However, the Sn–P coupling was poorly resolved in the spectra of **3** so that no information concerning the connectivities of either nucleus within the core of the complex could be gleaned.

The low-temperature X-ray structure of **3**‡ shows that the complex is an ion-paired species, arising from the association of a $[\{(Sn(\mu\text{-}PMes)\}_2(PMes)_2]^{2-}$ dianion with two TMEDA solvated Li^+ cations (Fig. 1). In addition, there are two molecules of toluene in the lattice for each molecule of **3**. Although only a few Sn(II) and Pb(II) complexes containing RP^{2-} ligands have been structurally characterised,[4,6] (like **3**) the majority of these are ion-paired molecular species contain-

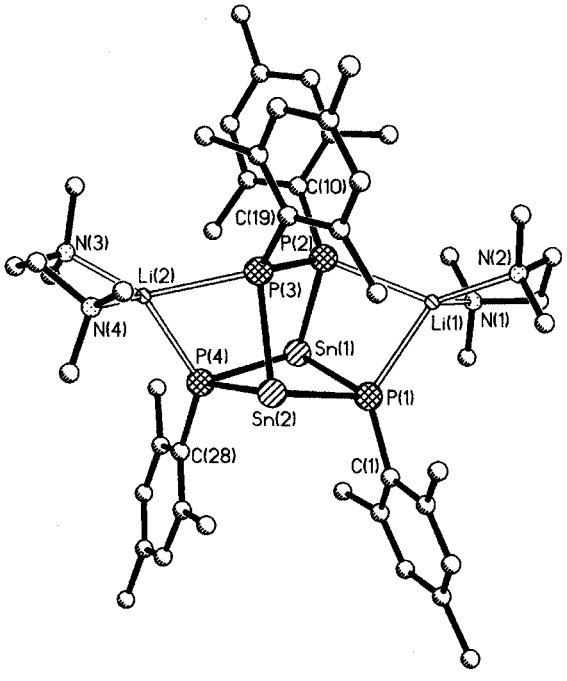

Fig. 1 The heterometallic cage structure of **3**. H atoms, lattice-bound toluene molecules and the disorder about the $-CH_2CH_2-$ groups of the TMEDA ligands have been omitted for clarity. Key bond lengths (Å) and angles (°); Sn(1)–P(1) 2.635(1), Sn(1)–P(2) 2.636(1), Sn(1)–P(4) 2.627(1), Sn(2)–P(1) 2.615(1), Sn(2)–P(3) 2.648(1), Sn(2)–P(4) 2.646(1), Li(1)–P(1) 2.518(8), Li(1)–P(2) 2.596(7), Li(2)–P(3) 2.609(7), Li(2)–P(4) 2.533(7), P(2)–P(3) 2.186(2), Li(1,2)–N(1,2,3,4) range 2.090(8)–2.118(8); Sn(1)–P(1,2)–Sn(2) mean 86.8, P(1)–Sn(1,2)–P(4) mean 90.6, P(1)–Sn(1)–P(2)/P(3)–Sn(2)–P(4) mean 75.8, P(4)–Sn(1)–P(2)/P(4)–Sn(2)–P(3) mean 93.7, Sn–{P(2)–P(3)} mean 99.8.

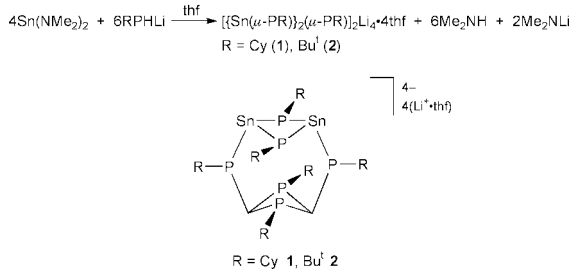

Scheme 1

ing Sn(II) phosphide anions coordinated to alkali or alkaline earth metal cations. However, in none of these previous examples has the formation of a P–P bond (*via* coupling of RP^{2-} anions) been observed. Of particular note in comparison with **3**, is the formation of $[(Me_3Si)PSn(\mu\text{-}PSiMe_3)]_2(Ca{\cdot}2thf)_2$ in the reaction of $[Ca\{PSiMe_3\}_2]$ with $SnCl_2$.[6b] The latter complex contains a $[(Me_3Si)PSn(\mu\text{-}PSiMe_3)]_2^{4-}$ tetraanion whose framework can be regarded as related to the $[\{(Sn(\mu\text{-}PMes)\}_2(PMes)_2]^{2-}$ dianion of **3** by 2e reduction and cleavage of the P–P bond.

Examination of the bond lengths and angles found in the bicyclic Sn_2P_4 core of **3** indicates that there is a considerable amount of strain in this arrangement. Thus, although the Sn–P bond lengths are similar to those found in the few structurally characterised Sn(II) complexes containing RP^{2-} ligands,[6] these bonds fall over a wide range of values [2.615(1)–2.648(1) Å]. In addition, the Sn(II) centres adopt highly irregular pyramidal geometries, with the P–Sn–P angles involved being in the range 75.75(3)–94.71(3)°. Clearly, the distortions found in the Sn_2P_4 core can be partly attributed to the geometric constraints involved in the coordination of the MesPPMes ligand to the two Sn centres of the $Sn_2(PMes)_2$ dimer unit. Some evidence for this view is seen in the compression of the P–P bond of the MesPPMes ligand [P(2)–P(3) 2.186(2) Å]; a value which is significantly shorter than that observed for the Bu^tPPBu^t groups in the Sn(IV) complex $[ClSn\{Bu^tPPBu^t\}_3SnCl]$[7] (2.237 Å). However, the highly distorted geometry of the Sn(II) centres in **3** is primarily the result of the chelation of each of the pseudo-tetrahedral Li^+ cations by a P centre of the MesPPMes group [Li(1,2)–P(2,3) mean 2.60 Å[7]] and by a MesP ligand [Li(1,2)–P(1,4) mean 2.53 Å[7]] of the $[\{(Sn(\mu\text{-}PMes)\}_2(MesP)_2]^{2-}$ dianion. This coordination to the Li^+ ions results in the compression of the associated P–Sn–P angles [P(1)–Sn(1)–P(2) and P(3)–Sn(2)–P(4) mean 75.8°; *cf*. 90.59(3)–94.71(3)° for the remaining P–Sn–P angles].

In summary, the reactions of $Sn(NMe_2)_2$ with RPHLi (R = Cy, Bu^t) and MesPHLi parallel those with Group 15 reagents $E(NMe_2)_3$ (E = As, Sb, Bi) and a range of lithium primary phosphides (RPHLi). In this context, the $[\{(Sn(\mu\text{-}PMes)\}_2(PMes)_2]^{2-}$ dianion core of **3** can be regarded as the Group 14 counterpart of the previously studied Group 15 $[(RP)_nE]^-$ anions. The $[\{(Sn(\mu\text{-}PMes)\}_2(MesP)_2]^{2-}$ anion of **3** has the potential to act as a multi-electron donor to a range of main group and transition metal complexes, yielding a variety of mixed-metal complexes. Furthermore, the thermolysis of **3** and similar complexes may lead to further P–P bond formation, providing a route to Sn Zintl phases.

† *Synthesis of* **3**: to a solution of $MesPH_2$ (0.94 ml, 6.0 mmol) in toluene (20 ml) at −78 °C was added Bu^nLi (4.0 ml, 6.0 mmol, 1.6 mol dm^{-3} in hexanes). Stirring at room temperature (1 h) produced a yellow precipitate of the monolithiate. To this suspension at −78 °C was added a solution of $Sn(NMe_2)_2$ (0.42 g, 2.0 mmol) in toluene (10 ml). Warming to room temperature led to the formation of a red–orange precipitate which was dissolved by the addition of TMEDA (1 ml, excess). Storage at 5 °C for 24 h gave orange crystalline blocks of **3**. Spectroscopic and analytical studies of **3** show that the toluene solvation found in the lattice is removed by placing crystalline samples under vacuum (*ca*. 15 min, 10^{-1} atm) during isolation. Yield 1.04 g (96%). ^{1}H NMR (400.16 MHz, d_8-toluene, +25 °C), δ 6.92 (S, 8H, aryl C–H), 2.90 (s, 12H, 4-Me of Mes), 2.65 (s, 24H, 2,6-Me of Mes), 1.97 (s, 24H, Me_2N of TMEDA), 1.83 (br s, 8H, $–CH_2CH_2–$ of TMEDA). ^{31}P NMR (161.98 MHz, d_8-toluene, +25 °C, rel. 80% H_3PO_4–D_2O), δ −156.7 (s), –157.5 (s). ^{7}Li NMR (155.55 MHz, d_8-toluene, +25 °C), δ 0.20 (s). ^{119}Sn NMR (141.21 MHz, d_8-toluene, +25 °C, rel. sat. $SnCl_2$–D_2O), δ −154.6 (br s). Satisfactory (C,H,N) analysis was obtained for **3**(−2toluene).

‡ *Crystal data* for **3**: $C_{62}H_{92}Li_2N_4P_4Sn_2$, M = 1268.54, monoclinic, space group $P2_1/c$, Z = 4, a = 21.4284(3), b = 13.5986(2), c = 22.9153(2) Å, β = 94.644(9)°, V = 6655.51(15) Å^3, μ(Mo-Kα) = 0.884 mm^{-1}, T = 180(2) K. Data were collected on a Nonius KappaCCD diffractometer. Of a total of 60891 reflections collected, 15148 were independent (R_{int} = 0.059). The structure was solved by direct methods and refined by full-matrix least squares on F^2. Final $R1$ = 0.053 [$I > 2\sigma(I)$] and $wR2$ = 0.174 (all data).[8] The $–CH_2CH_2–$ groups of one of the TMEDA ligands are disordered over two sites. This was modelled with 50% occupancy in each. Received (in Cambridge, UK) 23rd November 2000, Accepted 6th February 2001
First published as an Advance Article on the web 26th February 2001

The synthesis and characterization of zoned MFI films consisting of intergrown TPA-silicalite-1 and ZSM-5 crystals are described.

ZSM-5 is a zeolite which is used for shape selective acid catalysis. However, it is only the internal sites that are shape selective, the external sites are not. Various strategies have been used to improve the ratio of shape selective sites to non-selective sites. Large crystals have a higher ratio, but the increased diffusional length reduces activity, and deactivation can be more severe for larger crystals.[1] Chemical vapour deposition (CVD) of silica has been used to coat the external surface in order to eliminate the external sites.[2–5] However, the pore opening size and the activity may be reduced if this method is employed. A more elegant way to eliminate the external acid sites would be to prepare a compositionally zoned zeolite catalyst, *i.e*. to synthesize an inactive outer shell of aluminium free silicalite-1 on aluminium-containing ZSM-5 crystals. The pore openings would be unaffected if the channels propagate continuously from the interior of the ZSM-5 catalysts and through the external silicalite-1 shell. Materials that are claimed to be zoned have been evaluated previously by adsorption and catalytic testing.[5–7] It has been shown that at least some of the external acid sites of the materials were eliminated and shape selectivity increased. However, extensive characterization by means other than catalytic evaluation have not been carried out to determine whether such materials truly consist of a continuously propagating channel system through the compositionally zoned regions. The present communication describes the preparation and characterization of relatively thick zoned zeolite films consisting of TPA-silicalite-1 and ZSM-5 layers on quartz substrates. Such samples are well suited for characterization by techniques such as SEM, EDS and the preferred orientation of the crystals can be evaluated by XRD in order to elucidate the channel structure of the material. Additionally, these materials themselves possess a potential for various applications.[7]

A method employing seeding[8] was used for preparation of the zeolite films. TPA-silicalite-1 crystals with an average size of 60 nm were adsorbed on charge-reversed quartz substrates. The seeded substrates were further used to synthesize three different types of zeolite films (samples A, B, C). TPA-silicalite-1 films (A) were prepared by hydrothermal treatment of the seeded quartz substrate in a synthesis solution with a molar composition of 3 TPAOH : 25 SiO_2 : 1500 H_2O : 100 EtOH at 100 °C for 3 days.[8] After the first synthesis step, the samples were rinsed with a 0.1 M ammonia solution and a fresh synthesis solution with the same composition was used for further hydrothermal treatment. This sequence was repeated four times in total to reach a crystallization time of 12 days. ZSM-5 films (B) were prepared by hydrothermal treatment of the seeded quartz substrate in a synthesis gel free from organic templates at 180 °C for 18 h.[9] The molar composition of the gel was 30 Na_2O : 1 Al_2O_3 : 103 SiO_2 : 4000 H_2O. Zoned TPA-silicalite-1/ZSM-5 films (C) were prepared by a two-step crystallization procedure. In the first step, a TPA-silicalite-1 film was synthesized in the same way as for sample A. In the second step, the rinsed TPA-silicalite-1 film obtained from the first step was hydrothermally treated in the same way as for sample B. After completion of the two-step procedure the samples were rinsed with a 0.1 M ammonia solution to remove sediments and unreacted gel adsorbed on the film as described for sample B.

Fig. 1 shows SEM micrographs of the three samples. Fig. 1(a) and (b) show the top- and side-view images of sample A. The film thickness is *ca.* 2.8 μm and the texture is columnar. The surface of the film is relatively smooth. Fig. 1(c) and (d) show the top- and side-view images of sample B. The film consists of well intergrown crystals of ZSM-5 with very well developed crystal faces. The thickness of this film is *ca*. 3.4 μm. Fig. 1(e) and (f) show the top- and side-view images of sample C. After the second step, the morphology of the film has changed completely. The surface of the film is no longer smooth as for sample A, but well defined crystal faces constitute the surface, as in sample B. The thickness of film is *ca*. 6.3 μm, which agrees well with the sum of the film thickness of samples A and B. No border can be seen between the two different layers of silicalite-1 and ZSM-5 and the texture is still columnar.

The marker in Fig. 1(f) indicates the position of the EDS line scan shown in Fig. 2 which shows the Al Kα and Si Kα signals. The start of the EDS line scan at 0 μm in Fig. 2 corresponds to the dot in Fig. 1(a) on the quartz substrate. The Si signal is approximately constant over the quartz support and the zeolite, indicating an equal amount of Si in the zeolite and quartz. The Al signal from the support and the silicalite-1 film, (×5) is not

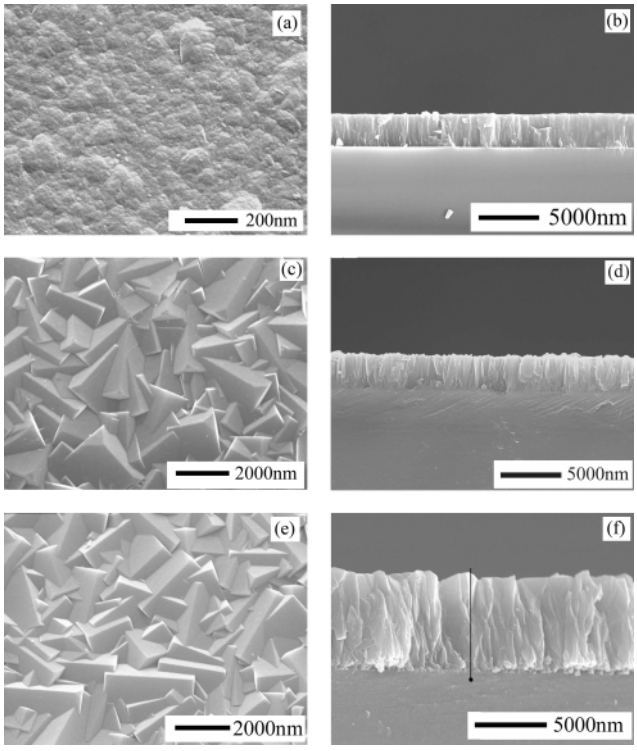

Fig. 1 SEM micrographs of the films. Top-view image of sample A (a), side-view image of sample A (b), top-view image of sample B (c), side-view image of sample B (d), top-view image of sample C (e) and side-view image of sample C (f).

DOI: 10.1039/b009414p

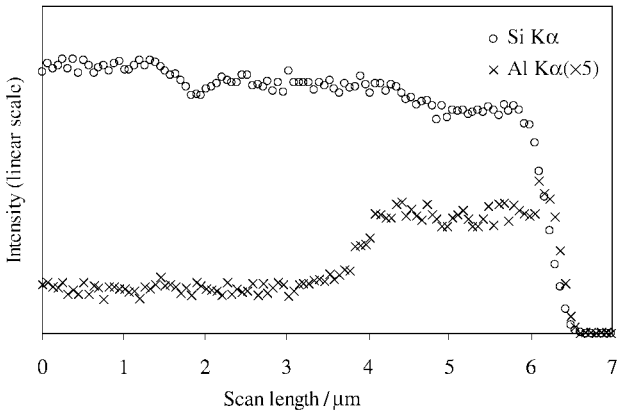

Fig. 2 Si Kα and Al Kα signals of the EDS line scan indicated by the line in Fig. 1(f), the scan starts at the position of the dot. The Al Kα signal was multiplied by 5.

zero owing to the continuous background signal (no Al atoms could be detected by EDS in sample A). The Al signal increases abruptly after *ca*. 3 μm which agrees well with the silicalite-1 film thickness of sample A of *ca*. 2.8 μm. From the EDS analysis the Si/Al ratio for the ZSM-5 layer was estimated to be *ca*. 10, which is a quite low value for ZSM-5 and identical to one reported previously.[9]

Fig. 3 shows X-ray diffraction patterns of samples A–C and a purified bulk product powder sample from TPA-silicalite-1 film synthesis. The powder sample [Fig. 3(d)] was used as a reference and considered to have a random orientation. It was reported previously that the (501) peak dominates in the pattern for TPA-silicalite-1 films with thickness of *ca*. 1.0 μm on silicon wafers.[8,10] However, in the pattern for sample A [Fig. 3(a)], the (303) peak dominates. This suggests that with increasing crystallization time not only the film thickness increases, but also the preferred orientation of the crystals changes so that the (303) peak dominates in films with a thickness of 2.8 μm. In the pattern for sample B [Fig. 3(b)], the (133) peak is dominant, which is in agreement with previous findings.[8] In the pattern for sample C [Fig. 3(c)], two (303) peaks, one from ZSM-5 and one from TPA-silicalite-1 dominate. Since the unit cell of ZSM-5 is larger than that of TPA-silicalite-1, the ZSM-5 peak occurs at lower 2θ.[11] The exact location of the (303) peaks was also determined by mixing silicon powder with TPA-silicalite-1 powder and ZSM-5 powder prepared from the synthesis mixtures used for film growth. The position of the (303) peak for ZSM-5 and for TPA-silicalite-1 was 23.86 and 23.98°, respectively. The fact that the (303) peak and not the (133) peak dominate in the zoned film indicates that the orientation of the crystals in the ZSM-5 part of the zoned films is controlled by the orientation of the TPA-silicalite-1 crystals in the first film. In other words, according to the XRD data, the TPA-silicalite-1 crystals in the first film continue to grow to form the ZSM-5 film, resulting in a zoned MFI film with a continuous channel system. Because the ZSM-5 layer covers the TPA-silicalite-1, based on the thickness, diffraction angle and absorption coefficient of the ZSM-5 film, about 20% of the signal from the silicalite-1 film should be absorbed by the ZSM-5 film. Also, the crystal size in the ZSM-5 film should be larger due to the continued growth of the crystals in the silicalite-1 layer. Therefore, the (303) peak from the ZSM-5 part should be more intense than from the TPA-silicalite-1 part since the films have similar thickness. However, Fig. 3(c) shows the opposite, *i.e*. the (303) peak from the ZSM-5 part is weaker than from the TPA-silicalite-1 part. This could be due to somewhat lower crystallinity of the ZSM-5 layer in the zoned film, which was also indicated by XRD data from powders of ZSM-5 and TPA-silicalite-1 with similar crystal size.

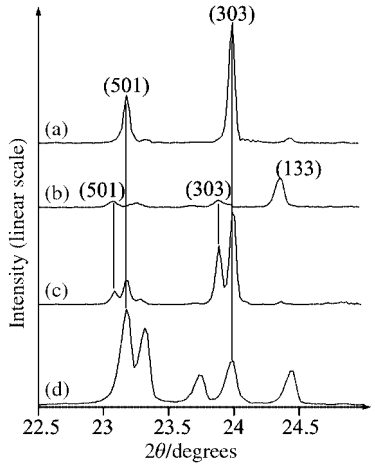

Fig. 3 XRD patterns of sample A (a), sample B (b), sample C (c) and TPA-silicalite-1 powder (d).

In summary, this communication presents a method for preparation of zoned MFI type films containing TPA-silicalite-1 and ZSM-5 layers. The most significant finding is that such films are not only compositionally zoned but also appear to consist of a continuously propagating channel system through the zoned regions, according to SEM/EDS and XRD data. In order to further verify that the channel system propagates continuously, TEM studies of the interface of zoned films on carbon fibres will be carried out and the results presented elsewhere. The same general method can be used for the preparation of zoned films with the reversed positioning of the layers, *i.e*. silicalite-1 covering ZSM-5, which is of more practical interest for preparation of catalysts free of external sites as discussed in the introduction. Also, the preparation method has been modified to synthesize zoned films with a non-continuous channel system. Characterization results for these zoned films will be presented in a subsequent publication.

The McMurry coupling of tris(5-formyl-2-thienyl)methanes affords novel cage molecules which are bicapped with tris(2-thienyl)methanes and where all the sulfur atoms of thienyl groups direct inward.

Cage molecules have been attracting increasing attention from the viewpoint of host–guest or supramolecular chemistry.[1] There are a number of types in the basic skeleton of cage molecules and one of such families is that of cage molecules bicapped with triphenylmethanes (triphenylmethanophanes).[2] Here we report on the first synthesis of cage molecules bicapped with tris(2-thienyl)methanes **1a** and **1b** (trithienylmethanophanes) where the thiophenes are bridged with etheno groups and the sulfur atoms are direct inward forming a three dimensional cavity. Related three or two dimensional sulfur-rich and unsaturated cyclophanes, macrobicyclic tetrathiafulvalene-bridged cage molecules or sulfur bridged annulenes have been reported.[3,4] Differing from triphenylmethanophanes, the thienyl groups in trithienylmethanophanes act as either π-electron donors, as aryl groups or electron-pair donors due to the sulfur atoms.

For the synthesis of **1a** and **1b** we chose tris(2-thienyl) methane **2** as the starting material because it has a number of favorable features such as easy lithiation–alkylation at the central methyl carbon (Cα-alkylation)[5] and possible metalation and functionalization at C5 of the thienyl groups in the Cα-alkylation products. It has been reported that treatment of **2** with BuLi–TMEDA in THF followed by addition of alkyl halides selectively yielded Cα-alkylation products.[5] In our case, however, C5-alkylation appreciably competed against Cα-alkylation under similar conditions and the separation of both the products was difficult. We have found that treatment of **2** with BuLi (1.2 equiv.) in THF in the presence of an excess amount (1.5 equiv.) of diisopropylamine (−70 °C then rt) followed by addition of alkyl halides provides a simpler procedure as well as excellent selectivity for Cα-alkylation with primary alkyl halides (Scheme 1).†[6]

Treatment of 1,1,1-tris(2-thienyl)ethane **3a**, thus obtained by methylation with methyl iodide, with five equivalents of BuLi in THF and subsequent addition of excess DMF afforded, after chromatographic purification on silica gel, trialdehyde **4a**‡ in 64% yield from **2**. Similarly hexyl compound **4b**‡ was obtained in 83% yield from **2** *via* **3b**. The McMurry coupling[7,8] of **4a** with low valent titanium in DME gave the trithienylmethanophane **1a**‡ in 5–8% yield as a sole, readily isolable, yellow crystalline substance. Trialdehyde **4b** also gave **1b**‡ in 7% yield. Although **1a** and **1b** are stable at solid state and in neutral solution, they slowly decomposed in $CHCl_3$–CF_3COOH (9 : 1 v/v) at rt when the effect of acid or encapsulation of proton in the cavity was examined by means of NMR spectroscopy.

^1H and ^{13}C NMR spectra show a high symmetry of **1a** and **1b** exhibiting only three proton-signals and six carbon-signals besides the signals of the alkyl groups. The vicinal coupling constants obtained from the ^{13}C satellite signals of the olefin protons of **1a** (δ 6.45, $J^{13}_{C\text{-}H}$ = 161.6 Hz, $J_{H\text{-}H}$ = 11.7 Hz) and **1b** (δ 6.50, $J^{13}_{C\text{-}H}$ = 161.4 Hz, $J_{H\text{-}H}$ = 11.9 Hz) indicate the *cis* configuration of the three etheno bridges. The UV-vis absorptions (325, 270 nm) are at slightly longer wavelengths than those of *cis*-1,2-bis(2-thienyl)ethene (322, 250 nm).[9] Inter-

DOI: 10.1039/b009811f

estingly, the mass spectra of the trithienylmethanophanes, in particular the EI spectrum of **1b**, suggest fair stability of dealkylated monocation and dication showing strong peaks at *m/z* 679 ([*M* − hexyl]$^+$, 100%) and 297 ([*M* − 2 × hexyl]$^{2+}$, 38%). Upon cyclic votammetry, **1b** shows an irreversible oxidation peak at +1.12 V (*vs*. Ag/Ag$^+$, in 0.1 M $Bu_4N^+ClO_4^-$/CH_3CN, ferrocene/ferrocene$^+$ = 0.33 V).

Recrystallization of **1a** from benzene–hexane afforded a single crystal suitable for X-ray structure analysis.§ The X-ray results establish the cage structure (Fig. 1) and reveal several structural features of **1a**. First, all the three etheno bridges have *cis* configuration, as ^{1}H NMR spectrum suggests, with considerably widened bond angles (av. 131.0°). Second, all the sulfur atoms of the six thienyl groups direct inward. Third, the molecule thus has a three dimensional cavity, though rather small, surrounded with six sulfur atoms, the cavity-size being about 0.7 Å in diameter. The cavity might encapsulate a Cu(II) ion. In a preliminary experiment, treatment of **1a** with $Cu(ClO_4)_2$·*n*AcOH in toluene–nitromethane precipitated dark green powder which was sparingly soluble in organic solvents.

In conclusion, the McMurry coupling of tris(5-formyl-2-thienyl)methanes affords novel cage molecules bicapped with tris(2-thienyl)methanes. The host–guest chemistry of **1a** and **1b**, further synthetic utility of trialdehyde **4**, and the synthesis of the cage cations suggested by the mass spectra are in progress. In addition, reductive desulfurization of trithienylmethanophanes **1** would form novel three dimensional hydrocarbons having a bicyclo[10.10.10]dotriacontane skeleton, and such attempts are also ongoing.

Notes and references

† Diisopropylamine mediates rapid equilibrium between Cα-lithio-species (thermodynamically more stable and hence less reactive) and C5-lithio-species (less stable and much more reactive) in nearly exclusive favor for the former which gives Cα-alkylation products with non-bulky, reactive alkyl halides. It is also important to add alkyl halides above 0 °C so as to keep the reactivity of the Cα anion high enough. The crude product from this procedure was used for the next step.

Received (in Cambridge, UK) 30th November 2000, Accepted 8th February 2001
First published as an Advance Article on the web 26th February 2001

Inclusion of hydration in atomistic simulations of the zeolite Goosecreekite allowed the determination of the most stable structure, including the distribution of Al in the framework and the position of extra-framework cations and water, and highlight how hydration appears to control the framework distribution.

The increasing use of zeolites in many branches of the chemical industry and, in particular, for environmental pollution control, demands a better understanding of the structure if we are to optimise their application. For catalysis and ion exchange, the number and location of aliovalent atoms in the framework and the charge balancing species govern the performance of a particular material. Thus, being able to determine and understand the location of such species will allow us to produce optimised compositions for specific applications. Whilst diffraction methods can identify extra-framework cation (efc) sites they often do not provide any accurate information on the spatial distribution of framework atoms. Similarly, NMR provides only short-range co-ordination of the framework Al and Si. Thus, whist there are established 'rules' of Al distribution in zeolites—Lowenstein's and Dempsey's rules—there is little further detail available from experiment.[1]

Computational methods, based on interatomic potentials, are well established in modelling the structure of zeolites:[2] for example, demonstrating an energetic basis for Lowenstein's rule.[3] Recently, we have developed a methodology to study the distribution of Al in the frameworks of low and medium Si/Al zeolites.[4–6] Whilst the results obtained are generally in excellent agreement with experimental data on the siting of Al atoms, we find that certain efcs shift away from experimental sites towards the framework – a consequence of the omission of water from our models. We now wish to determine the role of water in controlling both the distribution of Si and Al within the framework and the location of efcs. The limited number of theoretical studies of hydrated zeolites have considered only the location and dynamics[7–10] of water in fixed, ordered or 'random' distributions of Al.

Therefore, as a first step in modelling hydrated zeolites, we consider here the mineral Goosecreekite (IZA code GOO).[11] Experimentally, the material is found to have an ordered Al distribution with a Si/Al of 3, providing a rigorous test of our methodology[4–6] for identifying stable Al distributions. Goosecreekite has a three-dimensional channel structure with a maximum pore opening of 4.7 × 2.9 Å.

We employ lattice energy minimisation techniques[2] as implemented in the program GULP.[12] For the zeolite and efc interactions we used the potential parameters described by Jackson and Catlow,[13] while the water related interactions were taken from the work of de Leeuw *et al.*[14,15] These water potentials were originally derived for modelling of solvation at ionic mineral surfaces (*e.g.* $CaCO_3$). They are, therefore, more suitable for simulations of hydrated zeolites (where the most accurate models are also formally charged) than other water potentials such as those derived for the modelling of proteins and other biomolecules. They include a description of polarisation, which will be significant.

The Goosecreekite unit cell ($Ca_2Al_4Si_{12}O_{32}$) comprises eight unique tetrahedral sites,[11] each with a multiplicity of two. Six of the sites are found to be occupied by Si (labelled Si1, Si2,…Si6), the remaining two sites by Al (Al1 and Al2). We therefore considered a total of 1820 different framework configurations at the outset, with four Al distributed over the 16 sites. On the basis of our previous work[4–6] we applied Lowenstein's rule and eliminated those related by symmetry elements of the experimental[11] space group $P2_1$, reducing the number of structures considered to 89.

For the resulting minimised structures we calculated a Boltzmann distribution probability (Table 1) at 600 K, which is typical for volcanic mineral formation. We find that the most stable calculated configuration (C1§) possesses an ordered Al distribution, but that the Al is at the sites labelled Si3 and Si4. The second most stable configuration, C2, (Fig. 1) does have the experimental Al distribution, but is significantly less stable. We also find significant differences in the location of the efc sites.

Table 1 The calculated most stable configurations for Goosecreekite without water. Those configurations (of the 89 considered) with a Boltzmann population (*P*) greater than 5% at 600 K are shown

Configuration	E_{latt} per u.c./eV	*P* (%)	Al location
C1	−1936.389	53.2	2 at Si3, 2 at Si4
C2	−1936.345	22.5	2 at Al1, 2 at Al2
C3	−1936.308	11.0	Si1, Si3, Si4, Al1

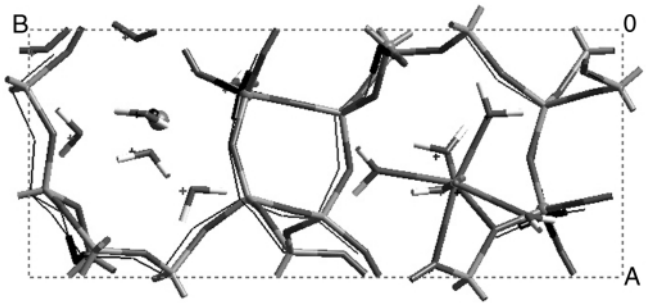

Fig. 2 The most stable calculated structure of Goosecreekite with water (C2) and the experimental unit cell (thin black lines with Al highlighted as tubes). Highlighted in the right channel is the co-ordination sphere of the Ca^{2+}. Also shown in the left channel are the experimental water oxygen (black crosses) and Ca^{2+} (black sphere) positions for comparison to the calculated sites (tubular water and larger spheres).

In the most stable calculated configuration, C1, we find that the Ca^{2+} are located along *a*, which are not observed experimentally, and coordinate strongly to four framework oxygens. Conversely, in C2 the Ca^{2+} are located close to the experimental sites in the channel along [001]. However, these cations can coordinate to only two framework oxygen atoms. We also note the reduced lattice parameters (Table 2) compared with experiment.

Although our methodology has successfully identified stable configurations that are indeed very similar to experiment, notable differences remain. In particular, the experimental framework structure is not sufficiently stabilised by the dehydrated cations (in the calculation) and as a consequence is not the most stable configuration calculated. It is also clear that there is considerable interplay between the location of Al and the siting of the efc sites. Thus, we now need to consider whether the omission of water from these calculations is significant and responsible for the observed discrepancies.

We placed 10 water molecules[11] in the unit cells of C1 and C2 and re-optimised the structures. On energy minimisation, we now find that C2 is more stable than C1 by 0.32 eV per unit cell (Table 2). Furthermore, the calculated structure is now in even better agreement with experiment (Fig. 2, Table 2), with a discrepancy of only 3.6% in the cell volume.

The cations in the calculated, hydrated C2 structure are now located very close to the experimental sites, being 7-fold co-ordinated to five H_2O and two framework oxygens (Fig. 2), as in experiment.[11] Whilst the position and co-ordination of Ca^{2+} in C1 are also in good agreement with experiment, the efcs are more distant from the AlO_4 tetrahedra, which destabilises this particular Al distribution. Thus, the role of water in influencing the Si/Al distribution in this zeolite can be considered as a combination of both electrostatic—screening the electrostatic interaction between the efc and the framework—and steric factors—preventing the efcs from occupying the smaller channels. These effects are reflected in the changes in cell volume (Table 2). A dramatic increase is seen in the cell volume of C2 upon hydration, where water screens the electrostatics and also occupies the same channels as the efcs. For C1, in contrast, the efcs are in the small channels in the dehydrated structure, whilst they move into the larger channels on hydration, resulting in only a small overall change in cell volume.

Our results show how, once solvation is considered, our methodologies and models are able to identify stable Si/Al distributions as well as reproducing the extra-framework structure of both cations and water. Agreement with the experimental structure is excellent. The work clearly demonstrates how water is critical, not only in stabilising the structure but also in actually determining the position of efc sites and framework Al distributions. The successful reproduction of the extra-framework structure also shows that the water potentials of de Leeuw *et al.*[14,15] are suitable for simulations of hydrated zeolites. Further evaluation of the water potential is underway, as are studies of cation exchange.

Dr N. de Leeuw is thanked for providing us with the water potentials prior to publication. Dr J. D. Gale is also thanked for the provision of GULP. A. R. R. S. acknowledges the Royal Society for a Postdoctoral Fellowship and the RSC for a Grant for International Authors. We also thank the University of Havana for an Alma Mater Research Grant.

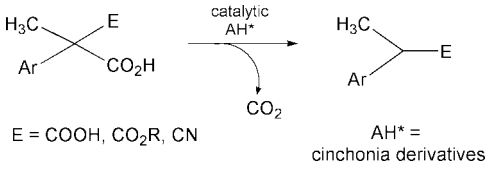
Benzyl 2-benzoyl-2-phenylpropanoate 1b subjected to heterogeneous hydrogenolysis conditions in the presence of catalytic amounts of commercially available cinchonia alkaloids as chiral protic source, led to (*R*)-1,2-diphenylpropanone with up to 71% ee, through a cascade reaction involving deprotection, decarboxylation and asymmetric tautomerization of enolic species.

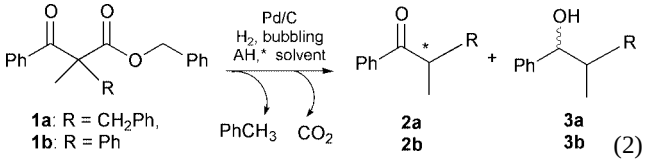
Numerous diastereoselective methods exist in enol chemistry to prepare linear ketones bearing an α-stereogenic centre: they use various protecting groups as chiral auxiliaries[1,2] or an alkylating reagent having a chiral leaving group.[3,4] Another efficient way involves the asymmetric protonation of metal enolates generated from ketones[5] or ketenes[6] by stoichiometric quantities of a chiral protic source. In some cases, these latter methods become catalytic in chiral inducing entity,[7,8] but meticulous adjustments of the experimental conditions are then required. The development of catalytic methods in asymmetric protonation of open chain ketone enolates can be complicated by two main factors: i) in contrast to ester or amide derivatives, these simple enolates have no additional chelation sites able to enhance the rigidity of a transition state in coordinating the chiral protic source[9] and ii) *Z*- and *E*-enolates can provide similar[10] or opposite[4] enantiomers. Currently no rule can predict the olefin configuration effect; thus, the preparation of a single enol geometrical isomer is required and is difficult to achieve.

We have shown that 2-carboxy-2-methyltetralone provided optically active 2-methyltetralone in a two step reaction consisting of a decarboxylation and an asymmetric protonation of the resulting enolic species assisted by catalytic amounts of enantiopure aminoalcohols.[11] In acyclic series, a similar methodology has been studied by Brunner's group and was also effective starting from malonic substrates[12] [eqn. (1)]; furthermore, this has been applied to the preparation of optically active naproxen derivatives, the selectivity being higher, starting from 2-cyano-2-arylpropionic acid[13] than from 2-ethoxycarbonyl-2-arylpropionic acid.[14]



(1)

Using this methodology, we envisaged to prepare aliphatic non racemic ketones. Since we have observed that solutions of 2-carboxy-2-methyltetralone where the acidic group is tertiary were not stable at rt,[11] we decided to start from protected β-ketoacids. The acidic group was protected as benzylic ester as the reductive cleavage of the benzyl group would allow a gradual generation of the acid and of the enolic species. The *in situ* generation of the intermediates under palladium–aminoalcohol catalysis[15] could improve both chemical and optical yields. We present here our results [eqn. (2)].



(2)

In the first experiments, we applied the conditions previously defined from cyclic substrates:[15] to an acetonitrile solution of substrate **1a**† and chiral aminoalcohol (0.3 eq.) was added palladium on charcoal (0.025 eq., Ref. 5011 from Engelhard Company), then, H_2 was continuously bubbled into the mixture for the time indicated in Table 1. From the results assembled in Table 1, it appears that ketone **2a** was obtained with good chemical yields but usually accompanied by alcohol **3a**,[16] which corresponds to an over-reduction of **2a**, the amount of **3a** increasing slowly with the reaction time (runs 1 and 2). As aminoalcohols, we used (−)-ephedrine (**4**) and aminoborneol (**5**) which gave satisfying results from cyclic substrates,[15] and also cinchonia alkaloids **6** or **7** which afforded good enantioselectivities from malonic substrates.[12–14] However these chiral inducing entities led to poor enantioselectivities even in varying the reaction temperature (Table 1); the results were not improved by modifying the nature of the supported palladium catalyst or the solvent (toluene and THF instead of acetonitrile).

[a] See Table 1. [b] Enantiomeric excess determined by HPLC (column Daicel, Chiralcel OD; n-hexane–*i*-PrOH = 99:1, 0.6 mL min^{-1}, t_r (*R*) = 11.8 min, t_r (*S*) = 13.9 min, α = 1.46); configuration determined by optical rotation comparison:[2,18] $[\alpha]_D^{20}$ = +167 (*c* 1.2 $CHCl_3$, ee_{HPLC} = 71%). [c] The suspension is prepared as following: the palladium on charcoal is added to a solution of **7** in chloroform; then the solvent is evaporated under reduced pressure and replaced by the solution of the substrate in MeCN or AcOEt. [d] Only 49% of conversion.

nia aminoalcohols; indeed we observed 49 and 56% ee with cinchonidine (**6**) (run 13) and cinchonine (**7**) (run 14) respectively. As these latter chirality inductors were insoluble in acetonitrile, we studied the effects of the amount of **7** and of its distribution in the medium. As expected, increasing the amount of **7** from 0.3 (run 14) to 0.5 eq. (run 15) did not change the selectivity. Dropping to 0.1 eq. the amount of **7** was not detrimental to both chemical yield and ee (run 16). Adsorbing **7** on the supported catalyst by its dissolution in chloroform followed by a solvent exchange allowed a slight increase of the enantioselectivity, but a concomitant decrease of the reaction rate (run 17). Switching from acetonitrile to THF led to a slower reaction and a decreased ee (run 18). The best solvent for both yield and ee was ethyl acetate, since ee could reach 71% for a quantitative chemical yield (runs 19); even in the presence of only 0.05 eq. of **7**, ee remained high (68%, run 20). In this solvent however, the adsorption of **7** on palladium on charcoal was detrimental to the conversion without change of the ee.

Thus we have shown that, in spite of their non-fixed geometry, enolic species corresponding to open chain ketones could be asymmetrically protonated in using a catalytic amount of commercial cinchonine, the one pot procedure starting from **1** being easily carried out.

We thank Eva Berssen for a few experiments and Socrates Institution for financial support to M. D. and E. B. who were on leave from Oldenburg University, Germany. Part of this work has been carried out in the framework of the COST D12/0028/99 program. We are grateful to the “Ministère de la Recherche et de la Technologie” for a PhD studentship to O. R. and to Engelhard Company for a loan of Pd catalysts.

Immobilisation of heteropoly anions in Si-MCM-41 channels by means of chemical bonding to aminosilane groups

Waldemar Kaleta and Krystyna Nowińska*

Faculty of Chemistry, A. Mickiewicz University, Poznań, Poland. E-mail: krysnow@main.amu.edu.pl

Received (in Cambridge, UK) 27th August 2000, Accepted 30th January 2001
First published as an Advance Article on the web 26th February 2001

Heteropoly acids (HPA) have been immobilised inside the channels of Si-MCM-41 mesoporous molecular sieve by means of chemical bonding with amine groups introduced into the system during a previous aminosilylation procedure, which resulted in the strong anchoring of heteropoly anions and prevented the HPA leaching when applied as a catalyst in polar solvent media.

The encapsulation of heteropoly compounds of Keggin structure into the pores of a molecular sieve may provide an active, stable catalyst. However, the anchoring of HPA into MCM-41 walls occurs by means of the interaction of the HPA acidic protons with the silanol groups and results in the formation of only very weak bonds between HPA and MCM-41. As a consequence, leaching of heteropoly acid was always observed when the HPA/MCM-41 system was applied in polar solvent media.[1–3] Our earlier reports[3] and those of others[4] have shown that the generation of insoluble non-stoichiometric caesium or ammonium salts of HPA inside the channels of the support prevents leaching of active phase.

In the following study we utilised modification of the silica gel surface with aminoalkoxysilanes, as reported by Vansant and coworkers,[5–7] in order to incorporate functional groups inside the channels of the mesoporous molecular sieve which would be able to react with heteropoly acid and form strong bonds. According to the mechanism proposed by Vansant and Van der Voort,[6,7] aminosilane molecules, initially connected to the silica surface *via* the amine groups, turn to display an amine-upward position as a result of the so-called flip mechanism.[6,7] It seems probable that the exposed basic amine groups might react with heteropoly acids to form the salt $\equiv Si(CH_2)_3NH_3 \cdot HPA$, which will be linked strongly to the modified surface.

Two samples of MCM-41 molecular sieves of different pore size were synthesised using $C_{14}H_{29}(CH_3)_3NBr$ [merystyltrimethylammonium bromide (MTMABr)] and $C_{16}H_{31}(CH_3)_3NBr$ [cetyltrimethylammonium bromide (CTMABr)] as surfactants according to ref. 8. These samples are denoted MCM-41-A and MCM-41-B, respectively.

After template removal the calcined materials were treated with the aqueous solution of ammonium nitrate to remove the sodium cations remaining after the synthesis. The samples were calcined again at 400 °C under nitrogen. The aminosilylation procedure was performed with γ-aminopropyltriethoxysilane (APTS) according to the procedure given in ref. 5 with some minor modification. MCM–41 dehydrated at 400 °C was contacted with a refluxing toluene solution containing 1% APTS for 5 h. The resulting materials were filtered off, washed with toluene and the remaining solvent removed under vacuum, firstly at RT and then at 140 °C for 20 h. MCM-41 modified by aminosilylation is denoted as ASIL/MCM-41 (A or B). The modified samples (1 g) were treated with 60 mL of a refluxing methanol solution containing 5% $H_6PMo_9V_3O_{40}$ for 3 h. After this time the samples were allowed to cool and the solids subsequently filtered off and washed four times with methanol. Finally, the filtered samples were heated *in vacuo* at 100 °C to remove the remaining methanol. The two resulting samples, HPMoV/ASIL/MCM-41-A and HPMoV/ASIL/MCM-41-B contained 10 and 30 wt% of HPMoV, respectively, the amount of heteropoly acid immobilised in the MCM-41 channels being estimated from analysis of the remaining methanol solution. The presence of heteropoly anions in the modified systems was also monitored by FTIR spectra.

We also introduced heteropoly acid (HPMoV) into MCM-41-B (unmodified with aminotriethoxysilane) using exactly the same procedure as for the modified sample. MCM-41-B after impregnation with HPMoV from methanol solution (denoted HPMoV/MCM-41-B) showed distinctive yellow colour indicating the introduction of heteropoly acid into the molecular sieve. Washing the sample with methanol (four times) resulted, however, in decoloration of the sample indicating removal of the HPMoV. By contrast, the aminosilane modified matrix releases very few Keggin units even after extraction with boiling methanol. Only 0.8 wt% of HPA anchored in APTS modified MCM-41 was removed after 2 h extraction with boiling methanol, while 95 wt% of HPA was removed from the unmodified support when treated with methanol at RT.

XRD patterns of MCM-41-A and MCM-41-B indicated that mesoporous materials were obtained (Fig. 1, curve 1). The APTS modified sample (ASIL/MCM-41-B) showed an XRD pattern which was almost unchanged relative to the parent MCM–41 matrix (Fig. 1, curve 2), while the XRD pattern of ASIL/MCM-41-B modified with 30 wt% heteropoly acid showed almost no reflectance in the low angle region (Fig. 1, curve 3). The disappearance of XRD patterns characteristic of the MCM structure has already been observed as a result of introduction of a relatively high number of HPA anions into MCM-48 channels.[9,10] The removal of heteropoly compound from unmodified MCM-41-B upon rinsing with methanol restored the XRD patterns characteristic of the MCM-41 structure (Fig. 1, curve 4). Considering that the heteropoly anions introduced into APTS modified samples are firmly connected to the MCM-41 by chemical bonds, destruction of the amine group by relatively high temperature treatment (320 °C) and subsequent removal of the HPA by washing with polar solvents (methanol and water) was performed. Removal of heteropoly anions from the MCM-41-B matrix restored the XRD pattern which were very similar to that of the parent MCM-41 sample (Fig. 1, curve 5).

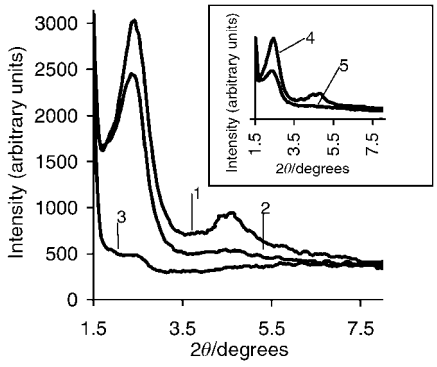

Fig. 1 XRD patterns of the MCM–41 samples before and after modification. 1, parent MCM–41; 2, ASIL/MCM-41 (aminosilylated MCM–41); 3, HPMoV/ASIL/MCM–41 (ASIL/MCM–41 modified with HPMoV); 4, HPMoV/MCM–41 (unmodified MCM–41 impregnated with HPMoV and subsequently rinsed with methanol); 5, HPMoV/ASIL/MVM–41 (after HPMoV removal).

Table 1 Catalytic activity of MCM-41 modified with heteropoly acid for cyclohexane oxidation

Catalyst	Catalyst loading/mg	HPMoV content		Cyclohexane conversion (mol%)	TON
		mg	mmol of KU		
HPMoV(30)/ASIL/MCM-41-B (first run)	50	15	0.009	14.6	24.6
HPMoV(30)/ASIL/MCM-41-B (second run)	50	15	0.009	13.5	23
HPMoV(30)/ASIL/MCM-41-B (after previous treatment with oxidative mixture)	50	14.8	0.0087	13.5	24
HPMoV(10)/ASIL/MCM-41-A (first run)	50	5	0.003	13.0	68
Free HPMoV dissolved in the reaction mixture	5	5	0.003	15.0	78

BET surface areas and pore distributions were calculated using N_2 adsorption at 77 K (ASAP equipment, Micromeritics). Aminosilylation and introduction of heteropoly anions affect the surface area and pore distribution of the modified samples significantly [Fig. 2(a) and (b)]. The parent MCM-41 samples (A and B) show a maximum of pore diameter at 22 and 25 Å and surface areas of 1330 and 1000 $m^2\ g^{-1}$, respectively. Aminosilylation of the molecular sieves results in a shift of the pore maximum to lower diameters and a decrease of the pore volume and surface area (*ca.* 720 $m^2\ g^{-1}$). Introduction of heteropoly anions leads to a further decrease in surface area and in pore volume. Taking into consideration the pore diameter of the MCM-41 modified with APTS (Fig. 2), and the diameter of the Keggin unit (12 Å), monolayer coverage can be expected at an HPMoV loading of *ca.* of 30 wt% (only one Keggin unit may be located along the ASIL/MCM-41 channels). It is unlikely that an ideal distribution of the Keggin units inside the channels, will be obtained, so encapsulation of *ca.* 30 wt% of HPMoV into the ASIL/MCM-41 matrix may result in partial blocking of the pores and makes some of the Keggin units inaccessible to reagents which should also affect the catalytic activity of the modified samples. The catalytic activity of heteropoly anions (HPMoV) anchored in the ASIL/MCM-41 channels (10 and 30 wt%) as well as of free HPMoV heteropoly acid was examined for cyclohexane oxidation reaction in the liquid phase (Table 1). 12–Molybdophosphoric acid modified with vanadium has been reported to be an active catalyst for liquid-phase oxidation of different organic and inorganic substrates with H_2O_2 or organic peroxides as oxidants.[11] The oxidation reaction was carried out in the liquid phase (sealed vials, 90 °C, 20 h, no stirring, 50 mg of ASIL/MCM-41 modified with HPMoV or 5 mg of free HPMoV) using *tert*-butyl hydroperoxide (TBHP) and acetonitrile as oxidant and solvent, respectively. A negligible cyclohexane conversion was observed in the presence of unmodified ASIL/MCM-41. Comparing the activity of samples containing different amounts of HPMoV, the TON (mol of reacted cyclohexane per KU) was calculated (Table 1). The results presented in Table 1 indicate that the heteropoly anions occupying the pores in ASIL/MCM-41-A (50 mg of sample, 10 wt% of HPMoV) show almost the same activity (TON) as 5 mg of free heteropoly acid dissolved in the reaction medium. This suggests that the distribution of the Keggin units in the HPMoV(10)/ASIL/MCM-41 is very close to monomolecular coverage and almost every heteropoly anion is accessible to the reagents. When the concentration of the Keggin units in the mesoporous material was increased to 30 wt%, the activity for cyclohexane oxidation (expressed as TON), decreased, which shows that a proportion of the heteropoly anions introduced may not be accessible to the reagents because of the pores being blocked.

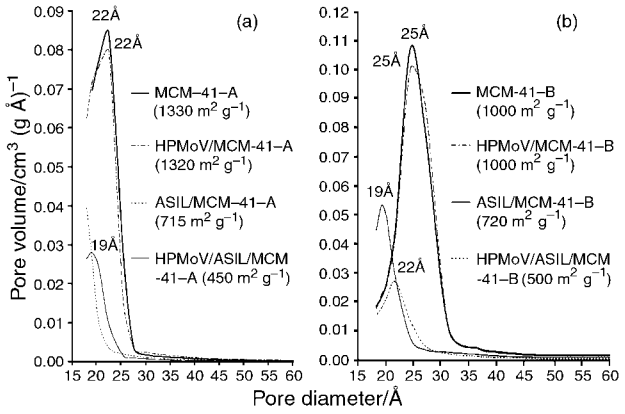

Fig. 2 Pore size distribution of the MCM–41 samples synthesised with MTMABr (a) and CTMABr (b) as surfactants before and after modification.

To investigate the stability of HPMoV/ASIL/MCM-41 system towards a powerful oxidant such as TBHP, two additional experiments have been carried out. The spent catalyst containing 30 wt% HPMoV (after cyclohexane oxidation process) was carefully separated from the products and reused for cyclohexane oxidation (second run, Table 1). The decrease in oxidative activity was insignificant. To check the effect of possible removal of HPMoV from the catalytic system as a result of potential oxidative degradation of aminopropyl groups, a fresh HPMoV(30)/ASIL/MCM-41 sample was treated with a mixture of TBHP and acetonitrile under exactly the same conditions as the oxidation process (90 °C, 20 h). The liquid phase was carefully separated and analysed for the presence of molybdenum. The remaining solid was treated again with the mixture of acetonitrile and TBHP under the same conditions with subsequent analysis for molybdenum. It was assumed that if partial decomposition of aminopropyl groups took place as a result of possible oxidation with TBHP it should result in some release of HPMoV. The first treatment resulted in the removal of 1.5 wt% HPMoV (anchored to ASIL/MCM-41) while the second treatment released an additional 0.8 wt% (ICP–AEC). These results indicate that 98 wt% of anchored HPMoV still remains in the HPA/ASIL/MCM-41 system and the leaching of HPA from this system is negligible even under drastic conditions. The HPA(30)/ASIL/MCM-41 sample was also used after the first treatment with a mixture of acetonitrile and TBHP as catalyst for cyclohexane oxidation. The decrease of oxidative activity was negligible.

The role of the 'glow phenomenon' in the preparation of sulfated zirconia catalysts†

Alexander Hahn, Thorsten Ressler, Rolf E. Jentoft and Friederike C. Jentoft *

During the calcination procedure that is necessary to obtain sulfated zirconia catalysts from hydroxide precursors an exothermic reaction occurs in the heat-up period which can lead to a rapid overheating ('glow') of the sample bed; the batch size is identified as a critical parameter that influences heat transfer and thus the extent of the temperature overshoot and the catalytic activity of the product.

Sulfated zirconia has attracted interest as a solid acid catalyst[1,2] because it is capable of isomerizing alkanes at temperatures below 373 K where the more valuable branched alkanes are thermodynamically favored. The activity of sulfated zirconia for *n*-butane isomerization increases 1–2 orders of magnitude upon addition of transition metal cations (Fe, Mn, typically *ca.* 2 wt%) as promoters,[3,4] whose function has not yet been clarified. For preparation of these materials, X-ray amorphous zirconium hydroxide is treated with sulfate solutions (*e.g.* ammonium sulfate, sulfuric acid) and, optionally, with solutions containing the respective cations (*e.g.* metal nitrates). The final step of the preparation is a thermal treatment at 773–973 K, typically conducted in air (calcination). Important catalyst properties such as sulfur content, surface area, phase composition and activity are seemingly correlated to the calcination temperature.[2,5–7] A number of reactions occur during calcination–typically already in the heat-up period–among them water loss, decomposition of species (*e.g.* ammonium, nitrate) and changes of morphology and structure (crystallization). Using thermal analysis, the heat of these reactions has been monitored, and for pure zirconium hydroxide typically a broad endothermic signal is found between 273–373 K, followed by a sharp exothermic signal around 725 K.[2,8] Not only is the origin of the exothermic signal–crystallization or a surface area reduction–still under debate,[6,8–11] the extent of the temperature increase has also never been accurately determined for catalyst precursor samples not of analytical (*ca.* 10 mg) but of preparative scale (*ca.*10 g). We measured the temperature in the sample bed when calcining gram amounts of zirconium hydroxide-based catalyst precursors and tested the activity of the obtained catalysts.

Zirconium hydroxide (ZH) and sulfated zirconium hydroxide with 5–6% SO_3 (SZH) (from MEL Chemicals) were used as starting materials. SZH was promoted by adding aqueous solutions of $Mn(NO_3)_2{\cdot}4H_2O$ or $Fe(NO_3)_3{\cdot}9H_2O$ (both Merck p.a.) under vigorous stirring, followed by room temperature drying (incipient wetness method[4]) to give *x*FSZH and *x*MSZH (*x* = nominal promoter content after calcination in wt% metal). For calcination, the powders were loaded into differently sized quartz boats (2.2, 8.4, 17.1 ml) providing different surface-to-volume ratios. Single boats were placed in a 29 mm i.d. quartz tube in a tubular furnace (Heraeus RO 4/25) with PID control. In order to monitor the bed temperature during calcination, an additional thermocouple was placed in the center of the bed. Sheath thermocouples with 0.5 mm o.d. were used for fast response and to minimize heat-sink effects. The quartz tube was continuously purged with 200 ml min^{-1} synthetic air and the oven was heated to 923 K at 3 K min^{-1}, held for 3 h at 923 K–a temperature recommended for best activity of promoted sulfated zirconia[7]–and then cooled to room temperature. Isomerization of *n*-butane to isobutane was conducted at atmospheric pressure in a once-through plug-flow fixed bed reactor employing 500 mg of catalyst. After a 30 min activation at 723 K in dry nitrogen, the isomerization was run at 338 K, feeding 80 ml min^{-1} of 1% *n*-butane in nitrogen mixture. Analysis was performed with on-line gas chromatography.

Fig. 1 shows the bed temperature *vs.* oven temperature during the calcination of ZH, SZH, 2FSZH, and 2MSZH in the largest boat. During the heat-up period, at oven temperatures of 650–850 K, a rapid temperature rise inside the bed was observed for all samples with maximum rates of 60 K s^{-1} (ZH). The bed temperature rose by up to 300 K (ZH) and exceeded the desired maximum temperature of 923 K in all cases. Increasing promoter content shifted the start of the temperature rise to higher oven temperatures, with Mn exerting a stronger effect than Fe. The position of the temperature rise was reproducible within 5 K, and the extent of the temperature rise was reproducible within 15 K.

Fig. 2(a) shows the bed *vs.* oven temperature for three differently sized batches (ESI†) taken from a single preparation of 2MSZH. The temperature rise in the large batch started first during the ramp, followed by the medium and the small batch. The largest batch produced the highest temperature rise and only this sample reached more than 923 K. These three batches underwent the entire calcination program as described above, the only difference being the batch size, and were then tested for *n*-butane isomerization. The sample taken from the large batch exhibited a significantly higher maximum conversion than the samples taken from the smaller batches [Fig. 2(b)]. For a number of samples with different promoter contents (Mn and/or Fe in the range 0.5–3.5%) calcination in a large batch led to higher activity *vs.* calcination in smaller batches. The BET surface area of Fe- or Mn-promoted samples increased with

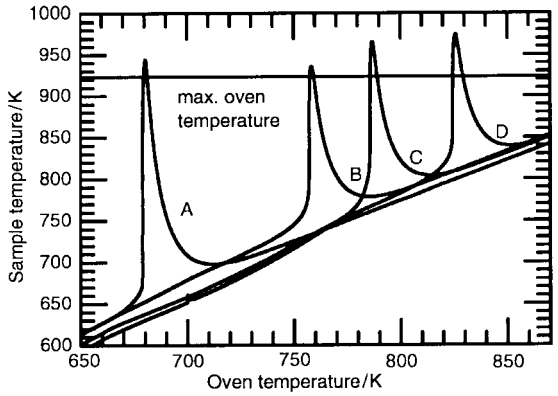

Fig. 1 Bed temperature *vs.* oven temperature during calcination of zirconium hydroxide (A), sulfated zirconium hydroxide (B), sulfated zirconium hydroxide promoted with 2 wt% Fe (C), and sulfated zirconium hydroxide promoted with 2 wt% Mn (D). Conditions: 17.1 ml boat (20–25 g sample), flowing air, nominal heating rate 3 K min^{-1}.

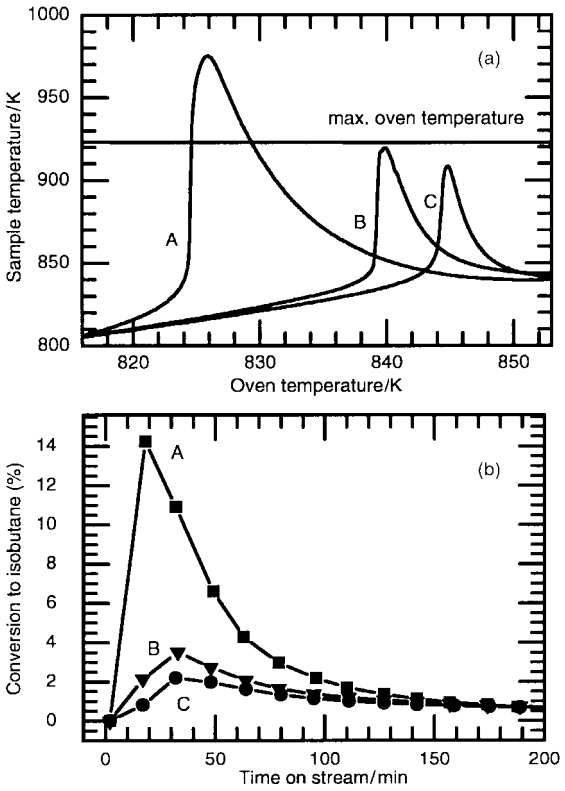

Fig. 2 (a) Bed temperature *vs.* oven temperature with the sample amount as parameter. Sample: sulfated zirconium hydroxide promoted with 2 wt% Mn. Conditions: flowing air, nominal heating rate: 3 K min^{-1}, holding time 3 h at 923 K. Large boat 25 g (A), medium boat 12 g (B), and small boat 3 g (C). (b) Butane isomerization reaction performance of the samples from Fig. 2(a). Reaction conditions: 500 mg sample, 1% *n*-butane in nitrogen, 80 ml min^{-1} total flow, $p = 1$ atm, $T = 338$ K.

increasing calcination batch size, covering a range of 85–115 $m^2\ g^{-1}$. Fe- or Mn-promoted samples consisted predominantly of tetragonal zirconia, and the size of the crystalline domains decreased with increasing calcination batch size, covering a range of 8–13 nm.

The spontaneous temperature rise in the sample bed during the heat-up phase corresponds to the reported thermal analysis data[2,6] in that an exothermic reaction occurs. Older literature gives some indication that the temperature rise may be considerable, depending on the amount and packing, *e.g.* Wöhler[11] heated as much as 0.25 g zirconium hydroxide and measured a *ca.* 60 K temperature rise. The effect has been observed for a number of different hydroxides and is also referred to as a 'glow phenomenon'[9,11,12] because it can lead to a visible light emission. In the presence of sulfate[6] or other hydroxides,[8,9] the 'glow'[9] or the thermal signals[6,8] were found to be subdued and/or shifted to higher temperature.[6,8,9] Our results are consistent with previous findings but additionally demonstrate how an extensive and typically not reported quantity, *i.e.* the mass to be calcined, influences heat transfer and thus the temperatures reached, and the catalytic properties of the final product. In sufficiently large and compact batches, the peak temperature may exceed the desired maximum calcination temperature; if this is the case, then for equally sized batches of differently promoted zirconium hydroxides, the nature and amount of additive (sulfate, Fe, Mn) may determine the true maximum temperature. Thus, the promoters have a systemic influence in that they alter the calcination chemistry. The start temperature correlates with the batch size, as does the catalytic activity. The series of events–rapid temperature increase, high peak temperature, rapid temperature decrease–allows for a chemistry that is reflected in the final product although the sample is subsequently treated for 3 h at 923 K.

Similar effects are potentially possible in the processing of other hydroxides that exhibit the 'glow', namely hydroxides of iron, chromium and titanium.[9,11] Certainly for the preparation and characterization of zirconia catalysts all details of the thermal treatment must be reported, *i.e.* the heating rate and any parameter influencing heat transfer such as sample size and shape. This applies particularly to experiments involving very small or large amounts (thermal analysis, scale-up) and *in situ* calcinations with the sample pressed into a pellet or wafer. Our results suggest that any two experiments involving thermal treatment of a zirconium hydroxide under non-identical conditions may not yield the same material and may not deliver related analytical data.

The authors thank Gisela Lorenz for preparing the catalysts and Robert Schlögl for continuous support. T. R. thanks the Deutsche Forschungsgemeinschaft, DFG, for financial support.

Easy formation of indium–silicon bonds: reaction of decamethylsilicocene with trimethylindium

Thorsten Kühler, Peter Jutzi,* Anja Stammler and Hans-Georg Stammler

Universität Bielefeld, Fakultät für Chemie, Universitätsstraße 25, 33615 Bielefeld, Germany. E-mail: peter.jutzi@uni-bielefeld.de

Received (in Cambridge, UK) 7th December 2000, Accepted 9th February 2001
First published as an Advance Article on the web 26th February 2001

The reaction of decamethylsilicocene 1 with trimethylindium yields the disilyl indium compound [Cp*$_2$Si(Me)]$_2$InMe (2) in nearly quantitative yield; 2 is characterised by ^{1}H, ^{13}C and ^{29}Si NMR and microanalytical data and by X-ray crystallography.

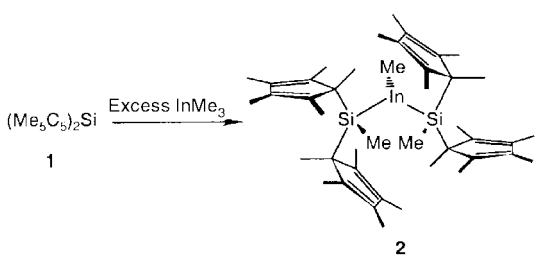
For the majority of main group elements a variety of silyl derivatives have been previously described in the literature. It is therefore somewhat surprising that silyl indium compounds are rarely known. Although $(Me_3Si)_3In$[1] has previously been synthesised by Bürger and Götze in 1969 it took nearly 20 years before a second representative of this class of compound, namely $[(Me_3Si)_3Si]_2InCl_2Li\cdot 2THF$, was reported by Cowley *et al.* in 1986.[2] It was not until the late 1990's that further silyl indium compounds were reported in the literature. Besides the silyl indium halides $(Bu^t_3Si)_nInHal_{3-n}$ (n = 1 and 2) prepared by Wiberg,[3] these were mainly examples of low valent indium compounds like the sterically crowded diindanes $\{[(Me_3Si)_3Si]_2In\}_2$ described by Weidlein *et al.*[4] and $[(Bu^t_3Si)_2In]_2$ synthesized by Wiberg.[5] The most recent examples are the indium cluster compounds $(Bu^t_3Si)_6In_8$[6] and $(Bu^t_3Si)_8In_{12}$[7] which were again prepared by Wiberg *et al.* Of the aforementioned compounds only the diindanes, the cluster compounds and the lithium indanate have been structurally characterised. It is of great interest to find new preparations for silyl–indium compounds and to structurally identify them.

In the course of our investigations on the reactivity of decamethylsilicocene[8] **1** we have already reported on the reactions of **1** with halides and organo halides of group 13 compounds.[9] Here we present the result of the reaction of **1** with trimethylindium (Scheme 1) where the disilyl indium compound **2** is formed by insertion of **1** into two of the three indium–carbon bonds.

When an excess of trimethylindium was added to **1** in pentane at low temperature a colourless solution was formed which turned yellow on warming to room temperature. Evaporation of all volatiles *in vacuo* gave **2** as a bright yellow, air and moisture sensitive solid in nearly quantitative yield.† Recrystallisation from pentane gave single crystals of **2** that were suitable for X-ray structure analysis. Fig. 1 shows the molecular structure of **2** in the solid state.‡

The indium atom is surrounded by the methyl group and the two silyl substituents in a trigonal planar fashion. The sum of the bond angles at the indium centre is 360°. The indium–silicon distances are 2.642(2) Å for In(1)–Si(1) and 2.640(3) Å for In(1)–S(2) and thus slightly longer than the sum of the covalent radii of 2.61 Å. However, they are decidedly shorter than the mean Si–In distances of 2.78 Å in the sterically crowded diindane $(Bu^t_3Si)_4In_2$[5] and of 2.68 Å in the somewhat less demandingly substituted conjuncto cluster $(Bu^t_3Si)_8In_{12}$.[7] Only in the indanate anion $[(Me_3Si)_3Si]_2InCl_2^-$ are shorter Si–In distances of 2.605(7) and 2.591(7) Å observed.[2] The widening of the C_{Cp}–Si–C_{Cp} angle (116° as compared to 109.5° for a perfect tetrahedral coordination) is due to the steric bulk of the Cp* groups. The Cp* moieties are in van der Waals contact with those on the other silicon centre as well as with the methyl groups on the silicon and indium atoms (for details see Fig. 1). This provides a tight organic wrapping of the inorganic core of the molecule.

This rigid structure of **2** is not retained in solution as is shown by the NMR spectra where conformational changes and sigmatropic rearrangements of the Cp* substituents are observed. In the room temperature ^{1}H NMR spectrum (500 MHz) of **2** in C_6D_6 the resonances for the methyl groups at indium and silicon are detected as singlets at δ 0.45 and 0.82, respectively. For the 60 methyl protons of the Cp* moieties the spectrum shows one broad signal of low intensity at δ 1.17 and a higher intensity broad signal at δ 1.82; only one broad signal at δ 1.66 is detected for the Cp* methyl protons in toluene-d_8 at 100 °C. The room-temperature ^{13}C NMR spectrum shows five signals for the ring carbon atoms of the Cp* groups and four broad signals for the Cp* methyl carbon atoms.[10] Owing to the prochiral character of the silicon centers five signals each would be expected. The observations described above are in accordance with the assumption that the Cp* groups perform rather slow sigmatropic shifts due to the steric interference of the Cp* groups as deduced from the molecular structure. In the ^{29}Si NMR spectrum one resonance at δ 20.6 can be detected for the two equivalent silicon centres. The mass spectrum (CI) of **2** shows no M^+ peak; however the $[M - Cp^*_2SiMe]^+$ ion is observed in low intensity at m/z = 443.



Scheme 1 Reaction of **1** with trimethylindium. *Reagents and conditions*: −90 °C → RT, pentane.

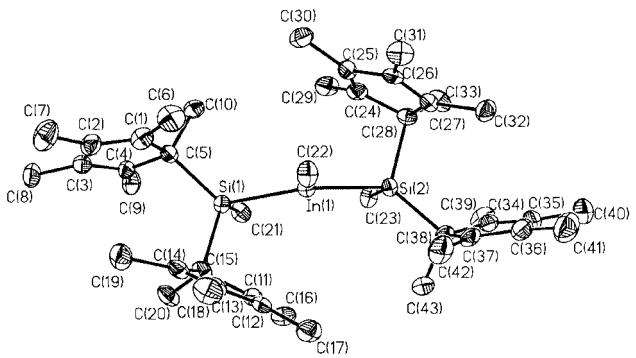


Fig. 1 Molecular structure of **2**. Selected interatomic distances (Å) and angles (°): In(1)–Si(1) 2.642(2), In(1)–Si(2) 2.640(3), In(1)–C(22) 2.172(6), C(10)–C(29) 3.7428(115), C(17)–C(42) 3.8451(119), C(22)–C(30) 3.9836(115), C(16)–C(21) 3.43, C(22)–In–(1)–Si(2) 120.40(18), C(22)–In(1)–Si(1) 120.87(18), Si(2)–In(1)–Si(1) 118.73(7), C(15)–Si(1)–C(5) 116.7(3), C(38)–Si(2)–C(28) 116.4(3).

DOI: 10.1039/b009839f

The thermal stability of **2** in solution and in the gas phase is limited. Thermal decomposition is observed to result in the formation of Cp*In. Evidence for this process can be found in the ^{1}H NMR spectrum of **2** at 100 °C which in addition to the aforementioned resonances shows a signal at δ 2.01 for the methyl groups of Cp*In[11] which grows on prolonged heating. No further defined decomposition products can be identified. As far as the stability of **2** in the gas phase is concerned the CI mass spectrum of **2** is very instructive. Here a very strong signal (rel. int. 94%) for the $[Cp^*In]^+$ ion is observed. This can also be explained as the result of thermal decomposition of **2** in the spectrometer. The thermolability of silyl indium compounds has been previously described.[4]

Concerning the mechanistic aspects of the formation of **2** we assume that the reaction is started by a nucleophilic attack of **1** on the Lewis acidic indium centre *via* the silicon lone pair. This attack is followed by a migration of one methyl group from indium to silicon accompanied by a rearrangement of the Cp* moieties from $\eta^{2/3}$ to η^1 thus forming an intermediate monosilyl substituted indium compound. This intermediate is again attacked by a silylene molecule in the way described above leading to the final product. The formation of **2** is one of the very few examples for the insertion of a silylene into a metal–carbon bond.[12]

Received (in Cambridge, UK) 24th January 2001, Accepted 12th February 2001
First published as an Advance Article on the web 1st March 2001

An ordered array of C_{70} single crystal nanowires was prepared by a sol–gel template method which is composed of three steps: generation of the C_{70} sol; deposition of C_{70} sol particles in the pores of the alumina membrane; and annealing of the resulting C_{70} composite in an argon atmosphere.

Fullerene-C_{70} chemistry[1] has been established since first detection of these species by Kroto *et al.*[2] and the subsequent macroscopic preparation by Krätschmer *et al.*[3] Photophysical properties,[4–7] conductivity,[8] photoconductivity[9] and optical limiting performance[10,11] of C_{70} have been reported frequently in the literature. Recently, C_{70} self-organization into short- and long-range order[12,13] has aroused great interest among scientists, but there has been little work on C_{70} nanostructures such as nanowires and nanotubules. As we all know, one-dimensional (1D) structures with nanometer diameters, such as nanotubes and nanowires, have a great potential for the testing and understanding of fundamental concepts about the roles of dimensionality and size in, for example, optical, electrical and mechanical properties and for applications ranging from probe microscopy tips to interconnections in nanoelectronics.[14] But developing the techniques for synthesizing and characterizing nanostructures is one of the grand challenges to chemists.

Here, we report the first generation of an ordered array of C_{70} single crystal nanowires obtained by a sol–gel template method. This is a key step for the construction of molecular devices.

A simple method to generate an aqueous colloidal solution has recently been developed by our group:[11] 8.0 mg C_{70} powder (99% purity), 100 mg Al–Ni alloy (excess) and 400 mg solid NaOH pellets were put in a bottle, which was evacuated and filled with argon; then 10 ml THF (distilled from sodium–benzophenone in a Schlenk system) were added with stirring. With the exception of C_{70}, which is slightly soluble in THF, the other starting materials do not dissolve. NaOH solid pellets dissolve with accompanying effervescence after the addition of 3 ml of deoxygenated water. The colour of the THF layer turned from slightly yellow to red–orange. After 1 h the red–orange THF solution was separated from the colourless aqueous caustic NaOH solution. Then, the solution of C_{70}^- in THF was added dropwise to 50 ml of undegassed distilled water. The THF was removed under reduced pressure to give an aqueous colloidal solution of containing 0.45 mg l^{-1} C_{70} (0.54 mM).[11]

An alumina template (Anodise®) made by Whatman Inc. (SEM images revealed a pore diameter ranges of 100–300 nm) was immersed in the C_{70} sol for 4–5 h under *ca.* 1.3 atm at ambient temperature. The template was then taken out from the C_{70} sol and dried at *ca.* 75 °C for 30 min. The deposits on both faces of the alumina membrane were removed by polishing with alumina powder, and annealed under argon atmosphere with the temperature ramping up to 500 °C for 5 h, before ramping back down to room temperature.

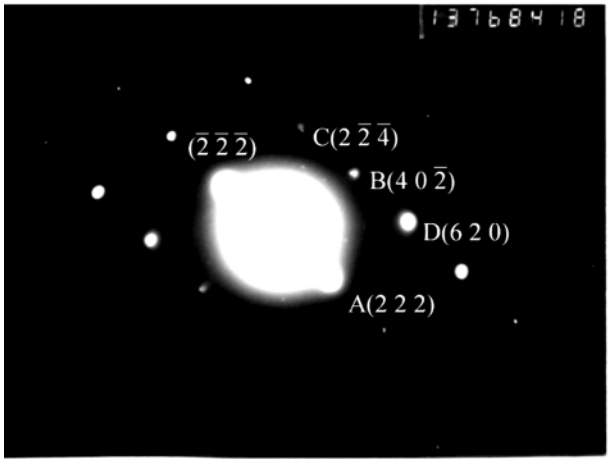
Fig. 1 shows scanning electron microscope (SEM)† images of the sample which was treated with a 6 M NaOH solution for *ca.* 3 min in order to dissolve the top layer of alumina. Without tetrabutylammonium hydroxide (TBAH) as catalyst, C_{70} cannot form C_{70} fullerol; also, without a reducing agent, C_{70} cannot form C_{70} anions in aqueous caustic solution. It can be seen that the C_{70} nanowires are well ordered and are perpendicular to the alumina template.

Fig. 2(a) is a transmission electron microscopy (TEM)† image of selected C_{70} nanowires. The diameter varies from 100 to 300 nm, which corresponds to the pore diameter of the alumina template. Bright field TEM images revealed that the

Fig. 1 Scanning electron micrograph of an array of C_{70} nanowires embeded in the alumina template matrix: (a) general cross-section view; (b) and (c) part view, magnifying power ×4000 and ×12 000, respectively.

DOI: 10.1039/b100863n

(a)



(b)

Fig. 2 (a) Transmission electron micrograph (TEM) images of a piece of *ca.* 150 nm diameter C_{70} nanowire after removing the alumina matrix, scale bar is 100 nm; (b) fcc [1$\bar{3}$2] zone axis electron diffraction pattern of corresponding C_{70} nanowires.

C_{70} nanowires were stable under the 200 keV electron beam. Fig. 2(b) is an electron diffraction pattern of the selected C_{70} nanowires. The ratio of $R_A^2:R_B^2:R_C^2:R_D^2 \approx 12:20:24:40$, R corresponding to the distance between the reflection spot and the reflection pattern center. These results suggest that the C_{70} crystal is of cubic structure, whose reflection spots may be indexed as A(222), B(40$\bar{2}$), C(2$\bar{2}\bar{4}$) and D(620), and the zone axis is [1$\bar{3}$2]. The sharp [1$\bar{3}$2] zone axis pattern contains D(620) reflections at *ca*. 44°, B(40$\bar{2}$) reflections at *ca*. 78°, and C(2$\bar{2}\bar{4}$) reflections at *ca*. 120° from A(222). Hence, the C_{70} single crystal samples prepared by this method, similar to the samples prepared by sublimation, are face-centered cubic, and thermal annealing is in favor of the fcc phase forming. This result is in accordance with the observation by Heiney and coworkers,[15] *i.e.* that the fcc phase is the equilibrium state of pure C_{70} above 300 K.

In conclusion, the sol–gel template method is a convenient and powerful method for generation the array of single-crystal C_{70} nanowires. The morphology and structure of the C_{70} nanowires array were studied by SEM and TEM. The C_{70} nanowires are single crystals with fcc structure and the zone axis is along the [1$\bar{3}$2] direction. The morphology of the array of C_{70} nanowires is brush-like and well ordered and is stable under a 200 keV electron beam.

Solid-state photolysis of sterically congested *cis*-1,2-dibenzoylalkenes: isolation and characterization of vinylketenes

Mithu Chanda, Dwijendralal Maji and Saswati Lahiri*

Department of Organic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700032, India. E-mail: ocsl@mahendra.iacs.res.in

Received (in Cambridge, UK) 8th November 2000, Accepted 12th February 2001
First published as an Advance Article on the web 28th February 2001

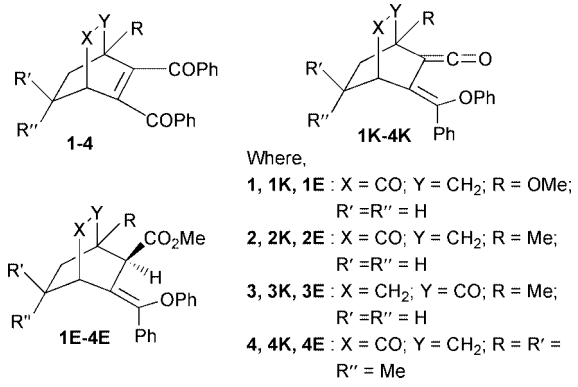
Hitherto non-isolable vinylketenes from the solid state photolysis of *cis*-1,2-dibenzoylalkene compounds have been isolated and characterized and their stabilities were found to be enhanced with the extent of steric congestion in the molecules.

Formation of vinylketenes from the photoreactions of *cis*-1,2-dibenzoylethylenes was first speculated in 1962[1] (Scheme 1). Its intermediacy was confirmed later from a strong peak for $\nu_{C=C=O}$ at 2103 cm^{-1} in the IR spectrum of the photolyzed reaction mixture.[2] Such photoinduced intramolecular phenyl migration from carbon to the proximate oxygen is a general reaction route for *cis*-1,2-dibenzoylalkene chromophore and has been observed in tetrabenzoylethylene[3] as well as in other *cis*-1,2-dibenzoylalkene derivatives.[4,5] In unsymmetrical derivatives, such migrations have been found to take place from the benzoyl group attached to the more crowded olefinic carbon atom.[1,4a,b,5] However, in our work with 5,6-dibenzoyl-4-methoxybicyclo[2.2.2]oct-5-en-2-one (**1**) such migration was observed to occur from both the benzoyl groups in solution, whereas in solid state, only the expected vinylketene (**1K**) was identified.[6] In all of these cases the intermediate vinylketenes have so far been neither isolated nor characterized fully because of their instability. The vinylketene **1K** was found to be fairly stable in cyclohexane solution at 20 °C. It took almost 48 h for the total disappearance of the ketene band at 2100 cm^{-1}. Such an observation encouraged us to take up the present project to enhance the steric congestion in such molecules and try to isolate the intermediate vinylketenes and characterize them.

In this attempt, the residue from the solid-state photoreaction of **1** was carefully chromatographed on a silica gel column.[7] Ketene **1K** as a pale-yellow solid (25%) and the starting compound **1** (70%) were separated from this reaction mixture. The spectral data of **1K** agreed well with the proposed structure. Since all attempts for recrystallization led to its decomposition, elemental analysis for **1K** could not be performed. However, its structure was finally confirmed by trapping it with MeOH which gave 4-methoxy-6-(phenoxyphenylmethylene)-5-*exo*-carbomethoxybicyclo[2.2.2]octan-2-one (**1E**).

To increase the persistency of such vinylketenes, we decided to enhance steric congestion in the molecule and hence prepared compound **2** with a methyl group at the bridgehead. Solid-state photolysis of **2** and chromatography of the photolyzed residue gave white crystals of the corresponding vinylketene **2K** (27%) whose analytical and spectral data were in agreement with the proposed structure. Further elution gave back unreacted starting material **2** (68%). The ketene **2K** was stable at rt and could be trapped with MeOH only at elevated temperature (~40 °C) to give 4-methyl-6-(phenoxyphenylmethylene)-5-*exo*-carbomethoxybicyclo[2.2.2]octan-2-one (**2E**) as the major product along with its 5-*endo* epimer (**2E′**) in minor yield.

The preference of photo-phenyl migration in *cis*-1,2-dibenzoylalkene chromophore from the more crowded olefinic carbon atom in the solid state, was further confirmed from the solid state photoreaction of compound **3**. Chromatography of the reaction mixture yielded the vinylketene **3K** (35%), unreacted starting material **3** (37%) and an unidentified gummy material (25%). The ketene **3K** was found to be less stable than its isomer **2K** and on stirring with MeOH at rt it yielded 1-methyl-5-(phenoxyphenylmethylene)-6-*exo*-carbomethoxybicyclo[2.2.2]octan-2-one (**3E**).



Addition of nucleophiles to ketenes is thought to occur in the plane of the ketene and the approach occurs from the least sterically hindered site of the ketene.[8,9] Increasing the steric congestion in a molecule thus could remarkably enhance persistency of vinylketenes and retard the nucleophilic addition to it. This was further confirmed from the solid state photolysis of 5,6-dibenzoyl-4,7,7-trimethylbicyclo[2.2.2]oct-5-en-2-one (**4**), which gave white crystals of the vinylketene **4K** (28%) along with the unreacted starting material (65%). Even under atmospheric conditions, solid **4K** could be stored without decomposition for a long time and its cyclohexane solution was stable at rt for more than 5 days. Addition of MeOH to **4K** took place only under refluxing conditions to yield 4,7,7-trimethyl-6-(phenoxyphenylmethylene)-5-*exo*-carbomethoxybicyclo-[2.2.2]octan-2-one (**4E**).

The ketene bands of **1K**–**4K** appeared near 2100 cm^{-1} in the IR spectrum. The ^{1}H-NMR spectra of these compounds were very similar to their parent molecules but their ^{13}C-NMR data were found to be much more useful (Table 1). In ^{1}H-NMR, the *endo*-protons around δ 3 ppm appeared as doublets for **1E, 2E** and **4E** and as a singlet for **3E** (Table 1).

3K	**3E** (158)	89[e]		3.3 (m)	3.6 (s)				
4K	**4E** (156)	90[e]		3.06 (s)	3.26 (d, *J* 1.5 Hz)				

[a] Compounds **1**–**4**, for the first time were prepared following reported procedures.[5,10] [b] Elemental analyses have been performed for all compounds excepting **1K**. [c] Unstable to prepare analytical sample. [d] Based on recovered starting materials. [e] Isolated yields.

In summary, we report here the first isolation and characterization of the intermediate vinylketene formed by photo-phenyl migration in *cis*-dibenzoylalkenes. In the solid state, the migration always occurred from the more crowded center to the less crowded one. By controlling the degree of steric congestion in the molecule, the stability of these vinylketenes can remarkably be enhanced.

Financial support from DST, India is gratefully acknowledged.

Received (in Cambridge, UK) 4th December 2000, Accepted 8th February 2001
First published as an Advance Article on the web 1st March 2001

A series of novel dinuclear copper(I) μ-chalcogenolate complexes is synthesized and their photophysics studied; the X-ray crystal structures of $[Cu_2(\mu\text{-dppm})_2(\mu\text{-SePh})]BF_4$ and $[Cu_2(\mu\text{-dppm})_2(\mu\text{-TePh})]BF_4$ are reported.

Increasing interest in the investigation of copper(I) complexes with chalcogenide ligands has emerged.[1,2] The closely related class of ligands, the chalcogenolates, has also attracted enormous attention owing to their importance in biological systems and their propensity to form metal complexes and clusters of various bonding modes and structural motifs.[3] In view of this and the ready functionalization of the chalcogenolate ligands *via* a change in the substituent on the heteroatom to effect steric and electronic control of the ligating ability, it would be of interest to synthesize and study the related copper(I) chalcogenolate complexes. Compared with copper(I) thiolates, reports on selenolate and tellurolate complexes are relatively rare.[4] Moreover, the luminescence properties of copper(I) chalcogenolate complexes are almost unexplored[5] and represent a challenging area of research. Here we report the syntheses and photophysics of a new class of dinuclear copper(I) chalcogenolates and the X-ray crystal structures of $[Cu_2(\mu\text{-dppm})_2(\mu\text{-SePh})]BF_4$ and $[Cu_2(\mu\text{-dppm})_2(\mu\text{-TePh})]BF_4$.

Reaction of $[Cu_2(\mu\text{-dppm})_2(MeCN)_2](BF_4)_2$ with the corresponding sodium chalcogenolate (prepared *in situ* from the diaryldiselenide or diarylditelluride and $NaBH_4$) in a molar ratio of 1:1 in THF and under anaerobic and anhydrous conditions afforded dinuclear copper(I) μ-chalcogenolate complexes, $[Cu_2(\mu\text{-dppm})_2(\mu\text{-EAr})]BF_4$ (EAr = SePh **1**, SeC_6H_4Cl-*p* **2**, TePh **3**, TeC_6H_4Me-*p* **4**) in *ca*. 19–62% yield. Single crystals of **1** and **3** suitable for diffraction studies were grown by layering of diethyl ether on concentrated solutions of the complexes in acetone. All of the newly synthesized dinuclear copper(I) complexes gave satisfactory elemental analyses, and have been characterized by ^1H and ^{31}P NMR spectroscopy, and positive FAB mass spectrometry.† The X-ray crystal structures of complexes **1** and **3** have also been determined.‡

Fig. 1 shows the perspective drawing of the complex cation of **3**. The two copper atoms of the dinuclear complexes are held in close proximity by three bridging ligands, two dppm ligands acting through the P atoms and one chalcogenolate ligand acting through the Se/Te atom. The Se/Te atom asymmetrically bridges the two copper atoms, with the Cu(2)–Se/Te distances [**1**, Cu(2)–Se(1) 2.485 Å; **3**, Cu(2)–Te(1) 2.608 Å] longer than those of Cu(1)–Se/Te [**1**, Cu(1)–Se(1) 2.371 Å; **3**, Cu(2)–Te(1) 2.532 Å]. In addition, a short non-bonded contact of *ca*. 2.4 Å is observed between the Cu(2) atom of the complex cation and an oxygen atom of the acetone solvent molecule, with a tendency to afford a distorted trigonal bipyramidal arrangement about Cu(2) [**1**, Cu(1)···Cu(2)···O(1) 150.5(3)° with Cu(2) deviated 0.43 Å towards O(1); **2**, Cu(1)···Cu(2)···O(1) 153.7(3)° with Cu(2) deviated 0.39 Å towards O(1)], while Cu(1) assumes a distorted tetrahedral arrangement. It is noted that the phenyl ring of the chalcogenolate is bent towards one side of the Cu_2E triangle (E = Se, Te) due to the sp^3 hybridization of the Se/Te atom. The Cu···Cu distances in **1** and **3** are in the range 2.723–2.739 Å. They are shorter than the sum of van der Waals radii for copper (2.8 Å)[6] and this may indicate weak metal–metal interactions in the complexes.

The electronic absorption spectra for complexes **1**–**4** in dichloromethane are characterized by absorption shoulders at *ca*. 250 and 260–295 nm (Table 1). Since the electronic absorption spectra were rather featureless, no further attempts were made to unambiguously assign the absorption bands. The emission spectra of the dinuclear complexes **1**–**4** in degassed acetone showed a low energy emission at *ca*. 600–630 nm, with emission energies in the order **4** ≥ **3** > **2** ≥ **1** (Table 1). Complexes **3** and **4** with tellurolate ligands show slightly higher emission energies than those with selenolate ligands **1** and **2**. Such an energy trend appears to depend upon the π-accepting ability of the chalcogenolate ligand, in which the areneselenolate is a better π-acceptor ligand than the arenetellurolate. This suggests that the low energy emission involves an excited state

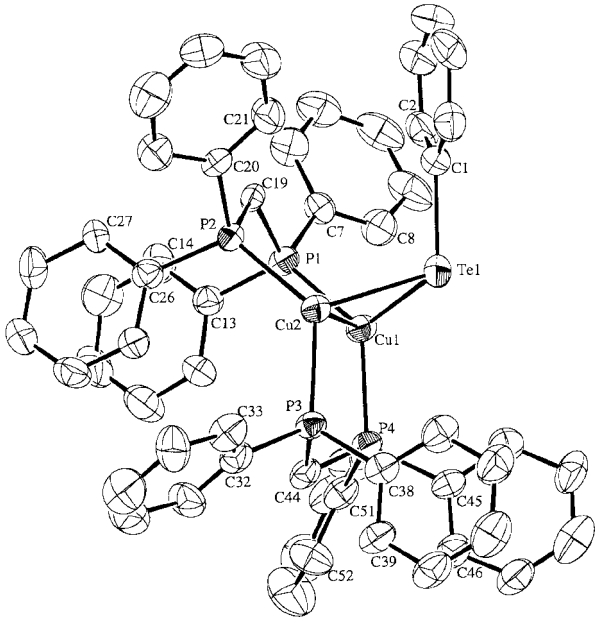

Fig. 1 Perspective drawing of the complex cation of **3** with the atomic numbering scheme. Hydrogen atoms have been omitted for clarity. Thermal ellipsoids are shown at the 40% probability level. Selected bond distances (Å) and bond angles (°) for complex **3**: Cu(1)···Cu(2) 2.723(1), Cu(1)–Te(1) 2.532(1), Cu(2)–Te(1) 2.608(1), Cu(1)–P(1) 2.243(3), Cu(2)–P(2) 2.283(3), Cu(2)–O(1) 2.36(1); Te(1)–Cu(1)–P(1) 116.80(8), Te(1)–Cu(2)–P(2) 112.40(8), Te(1)–Cu(1)–P(4) 112.44(9), Te(1)–Cu(2)–P(3) 111.01(8), P(1)–Cu(1)–P(4) 129.3(1), P(2)–Cu(2)–P(3) 128.46(10), Cu(1)–Te(1)–C(1) 110.7(3), Cu(2)–Te(1)–C(1) 107.1(3). Selected bond distances (Å) and bond angles (°) for complex **1**: Cu(1)···Cu(2) 2.739(2), Cu(1)–Se(1) 2.371(2), Cu(2)–Se(1) 2.485(2), Cu(1)–P(1) 2.241(4), Cu(2)–P(2) 2.296(3), Cu(2)–O(1) 2.39(1); Se(1)–Cu(1)–P(1) 118.3(1), Se(1)–Cu(2)–P(2) 112.91(10), Se(1)–Cu(1)–P(4) 111.1(1), Se(1)–Cu(2)–P(3) 108.9(1), P(1)–Cu(1)–P(4) 129.0(1), P(2)–Cu(2)–P(3) 128.0(1), Cu(1)–Se(1)–C(1) 113.5(3), Cu(2)–Se(1)–C(1) 106.4(3).

[e] $E_{1/2}$ is taken to be the average of E_{pa} and E_{pc}, where E_{pa} and E_{pc} are the anodic and cathodic peak potentials of the quasi-reversible couple, respectively.

of metal-to-ligand charge transfer (MLCT) [$Cu_2 \rightarrow ER^-$] origin. A related dinuclear copper(I) complex, [Cu_2(μ-dppm)$_2$(μ-O_2CMe)]$^+$,[7] in which the lowest lying excited state was suggested to be MLCT [copper → phosphine/acetate] in character, as supported by molecular orbital calculations, shows a relatively high energy emission at *ca*. 470 nm. However, low energy emissions at *ca*. 600–630 nm are observed for complexes **1**–**4** and the emission energy difference between the dinuclear copper(I) selenolate and tellurolate complexes is relatively small. This, together with the fairly short Cu···Cu contacts (*ca*. 2.7 Å) found in these dinuclear complexes, may be more suggestive of an assignment of the emission as having a metal-centered ds/dp origin. Thus, the low energy emission in the dinuclear copper(I) chalcogenolate complexes is tentatively assigned as derived from an excited state that is predominantly metal-centered ds/dp in origin, mixed with some MLCT [copper → chalcogenolate/phosphine] character.

The cyclic voltammograms of complexes **1**–**4** show quasi-reversible oxidation couples in the range 0.68 to 0.80 V *vs*. SCE (Table 1). A relatively small shift in the potential of the oxidation couples is observed. The oxidation couple is tentatively assigned as a copper(I/II) metal-centered oxidation. No reduction wave was observed even when the potential was scanned to −2.4 V *vs*. SCE. Further oxidation and reduction of the complexes resulted in decomposition, as suggested by the irreversibility of the couples at higher anodic and cathodic potentials.

The selective oxidation of benzyl alcohols by hypochlorite and a phase transfer catalyst has been successfully carried out in a membrane reactor.

Selective oxidation is one of the most important synthetic transformations in organic chemistry based on hydrocarbon resources. It is essential that these transformations are based on the principles of green chemistry and avoid heavy metal reagents, toxic solvents and the generation of large volumes of hazardous waste. The major source of waste in many organic reactions is commonly aqueous or salt effluent produced at the work-up stage when the organic and inorganic components are separated, often *via* an aqueous quench.[1]

Phase transfer catalysis (PTC) has been widely used to transfer inorganic anions into organic media by using catalytic amounts of lipophilic quaternary ammonium or phosphonium salts.[2] Sodium hypochlorite is a non-toxic oxidant, which has been reported to be transferred into the organic phase in the presence of quaternary ammonium salt[3–6] and is capable of oxidising alcohols including benzyl alcohol although it can be difficult to control selectivity.[7–9]

Most PTC reactions are carried out on an industrial scale in stirred tank reactors, which require the separation of products afterwards. Key criteria required in a PTC reactor are high interfacial area with little emulsification to enable easy phase separation. The use of a membrane reactor for a PTC reaction could fulfil these criteria as well as offering the advantages of easy product recovery. Furthermore, the organic-free reduced aqueous phase can be electrochemically regenerated while the organic phase remains uncontaminated with aqueous species thus facilitating continuous reactions. The use of a membrane reactor in a phase transfer catalysed reaction has been theoretically modelled before[10] and tested in a simple anion displacement reaction. It has been shown that the reactor performance depends on the flow rate ratio and conversions are slower than predicted due to mass transfer resistance. The membrane acts as a stable interface and no emulsification problems are involved.

Here we report the selective oxidation of benzyl alcohols using a porous PTFE membrane to separate the aqueous and organic phases. A flat sheet diaphragm reactor shown in Fig. 1, was used to carry out the reaction. In a typical reaction, a 13% aqueous solution of hypochlorite (25 ml), was adjusted to pH 9 and then added in the aqueous side of the reactor. Benzyl alcohol (3 mmol), and tetrabutylammonium hydrogen sulfate (0.3 mmol), were dissolved in DCM on the organic side. A hydrophobic microporous PTFE (0.2 μm) membrane was used and a slight pressure was applied to the aqueous side to avoid any transport of the organic phase into the aqueous phase. The hydrophobic PTFE membrane kept the aqueous phase from entering into the organic phase. The reaction could be run static or continuous with counter flowing aqueous and organic phases.

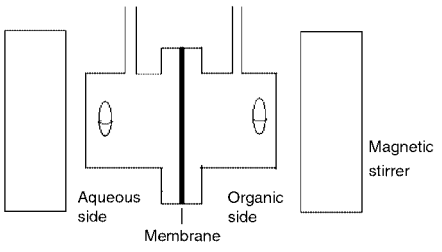

Fig. 1 Schematic diagram of flat sheet diaphragm cell.

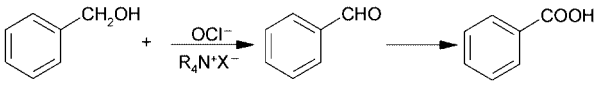
The influence of several parameters has been investigated so as to optimise the performance of the system and in particular to avoid further oxidation of the benzaldehyde to benzoic acid [eqn. (1)].



(1)

The effect of benzyl alcohol concentration on the reaction profiles was first investigated (Fig. 2). As the concentration of benzyl alcohol increases the rate of conversion increases slightly. For each reaction a small induction period is observed, due to slow mass transfer of hypochlorite although this is not observed if the system is allowed to equilibrate before the alcohol substrate is added. The rate of the reaction does not depend as much on the concentration of benzyl alcohol as expected, however the concentration of PTC increases the rate due to easier mass transfer. Selectivity to the aldehyde is also reduced at low concentrations of the PTC. Changing the counter anion in the PTC (HSO_4^-, Cl^-, Br^-) has little effect on reaction rate or selectivity but little reaction occurs in the absence of a PTC. While the hypochlorite concentration has only a small effect on the rate of conversion of benzyl alcohol, it strongly influences the selectivity of the reaction. The amount of hypochlorite transferred into the organic phase is dependant on both the concentration of quaternary ammonium in the organic phase and that of the hypochlorite in the aqueous phase. The optimum concentration of hypochlorite at which we obtain a good rate of conversion and very high selectivity to the aldehyde is 13%.

Toluene can be used as a solvent for the reaction, although it decreases the rate of conversion due to slower mass transfer and benzyl chloride was produced from its oxidation under the standard reaction conditions.

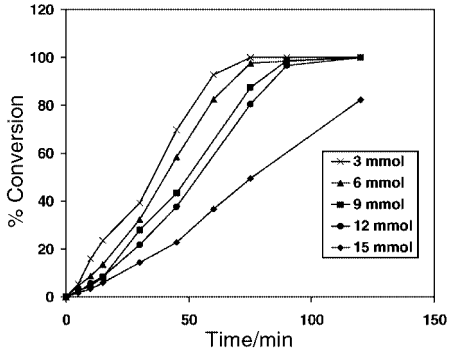


Fig. 2 Influence of the concentration of benzyl alcohol on the conversion of the reaction.

DOI: 10.1039/b009178m

Table 1 Oxidation of substituted benzyl alcohols to aldehydes under optimum conditions[a]

Substrate (benzyl alcohol)	Time/min	Product	Yield (%)[b]	Selectivity (%)
2-Methylbenzyl alcohol	60	2-Methylbenzaldehyde	97	98
4-Methylbenzyl alcohol	60	4-Methylbenzaldehyde	93	97
4-*tert*-Butylbenzyl alcohol	45	4-*tert*-Butylbenzaldehyde	90	95
4-Methoxybenzyl alcohol	120	4-Methoxybenzaldehyde	78	87
4-Chlorobenzyl alcohol	75	4-Chlorobenzaldehyde	75	84

[a] Reaction conditions: substrate (3 mmol), aqueous solution of NaOCl 13% (25 ml) at pH 9, $TBAHSO_4$ (0.9 mmol) and DCM (25 ml) at rt. [b] By quantitative NMR.

The optimised system was successfully used for the selective oxidation of a series of substituted benzyl alcohols (Table 1). It appears that moving the substituent away from the reaction centre did not affect the yield of the reaction. Insertion of an electron-withdrawing substituent on the benzene ring increases the reaction time and reduces the yield of the produced substituted benzaldehyde products.

In summary, we have shown that it is possible to develop a membrane reactor system for the static or continuous production of benzaldehyde as well as substituted benzaldehydes.

We thank the EPSRC for funding this work and we are grateful for valuable discussions with other members of the York–Newcastle Chemistry–Chemical Engineering collaboration. J. H. C. also thanks the RAEng-EPSRC for a Clean Technology Fellowship.

A Ru^{II}–based emission, while almost entirely quenched in a Ru^{II}/Os^{II} heterodimetallated DNA hairpin, is dramatically restored upon hybridization to a complementary oligonucleotide, while hybridization to an oligonucleotide that contains a single mismatch results in significantly lower emission intensity.

Luminescent polypyridine transition metal complexes have been gaining interest as molecular probes for bioanalytical applications.[1] Several important features distinguish emissive coordination compounds from their organic counterparts: (a) they are typically chemically inert and photostable, (b) their photophysical characteristics can be tuned while maintaining very similar structural features, (c) their photophysical properties are commonly insensitive to environmental changes (*e.g.* pH, ionic strength), although functional groups can be appended to affect sensing capabilities, (d) they exhibit rather large Stokes' shifts, and (e) their excited states are relatively long-lived, a feature that facilitates their utilization in polarization assays with relatively high molecular weight assemblies. Most of these traits can be attributed to their unique excited-state manifold, where the emission results from a metal-to-ligand-charge-transfer (MLCT) state.[2]

Oligonucleotides containing emissive transition metal complexes have become an important tool for the study of energy- and electron-transfer processes in nucleic acids.[3,4] In an early contribution, we have reported the synthesis of Ru^{II}- and Os^{II}-containing nucleosides **1** and **2** and their corresponding phosphoramidites (Fig. 1).[5] The Ru^{II} nucleoside exhibits a long-lived excited state in phosphate buffer pH 7.0 (τ = 1.08 μs) associated with a relatively high emission quantum efficiency (ϕ = 0.051). In contrast, the Os^{II}-containing nucleoside is quite non-emissive in an aqueous environment (τ = 0.027 μs, ϕ = 1×10^{-4}) and serves as a quencher of the Ru^{II} excited state.[6,7] Since this donor/acceptor interaction is distance-dependent,[5] we have envisioned its application for the detection of DNA hybridization events. In this contribution we demonstrate the utilization of novel metal-containing oligonucleotides as hybridization probes following the molecular beacons principle (Fig. 2).[8]

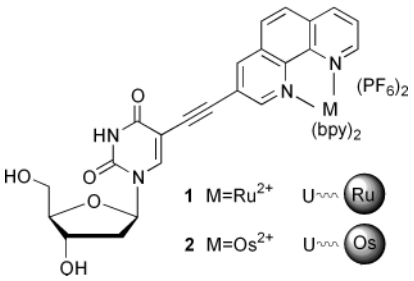

Fig. 1 Metal-containing nucleosides **1** and **2** serve as a donor and an acceptor, respectively.

† Electronic supplementary information (ESI) available: synthesis, enzymatic degradation, composition analysis and thermal denaturation studies of oligonucleotides. See http://www.rsc.org/suppdata/cc/b1/b100036p/

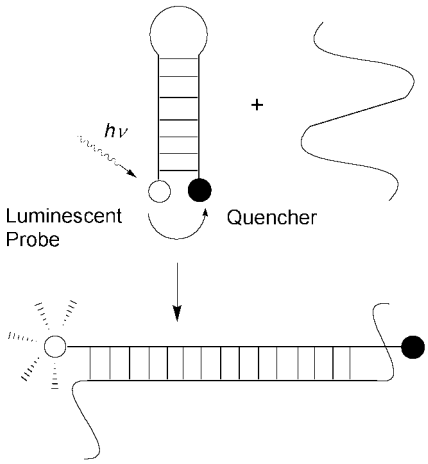

Fig. 2 General principle of molecular beacons technology: the quenched emission of a donor is restored upon hybridization to a target oligonucleotide.

The oligonucleotides used for this study are shown in Fig. 3.‡ The heterodimetallated hairpin **3**, which holds the donor and acceptor in close proximity, possesses a single mismatch in its 8-mer stem and a stable T_4 loop. Upon hybridization to its perfect complementary oligonucleotide **4a**, a 20-mer duplex **3·4a** with an additional six base pairs is formed, while placing the quencher away from the Ru^{II} donor (Fig. 3).§ Thermal denaturation studies confirm the enhanced stability of duplex **3·4a** when compared to the hairpin **3** (Table 1 and Fig. 4).

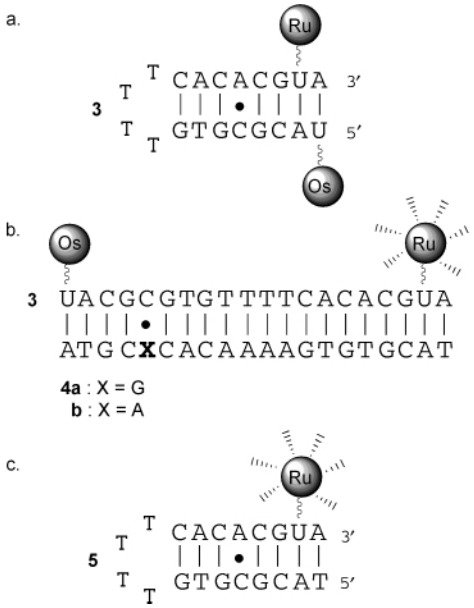

Fig. 3 Oligonucleotides used in this study: (a) Ru^{II}/Os^{II} heterodimetallated hairpin **3**, (b) duplexes **3•4a** and **3·4b** formed upon hybridization of **3** to the perfect (**4a**) and single-mismatch (**4b**) complement, respectively, and (c) a control Ru^{II}-containing hairpin **5**.

Table 1 Thermal denaturation and photophysical data

Sample	T_m/°C[ac]	I_{em} (arbitrary units)[bc]
3	69	5
3·4a	70	89
3·4b	70	38
5	69	100
5·4a	65	99
5·4b	69	98

[a] Melting temperature, ±1 °C. [b] Percent luminescence intensity (with respect to **5**), ±3%, 25 °C. [c] In 10 mM phosphate buffer pH 7.0 with 100 mM NaCl.

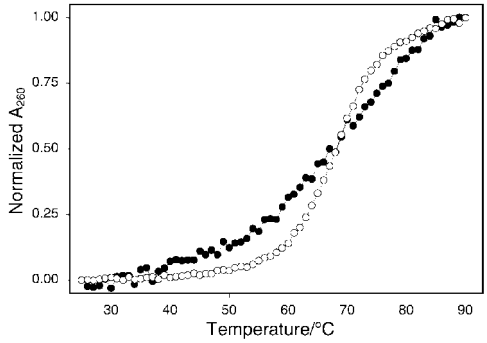

Fig. 4 Thermal denaturation curves of **3** (●) and **3·4a** (○).

Hybridization of hairpin **3** to oligonucleotide **4b** yields a less stable duplex **3·4b** that contains a single AC mismatch (Table 1 and ESI).

Steady-state emission spectra of iso-absorptive oligonucleotide solutions are shown in Fig. 5.§ The Ru-based emission intensity of the dimetallated hairpin **3** increases 17-fold when it hybridizes to its complementary strand to give duplex **3·4a**. The presence of a non-complementary strand **4b**, whose sequence differs from the perfect complement by merely one base, does not fully restore the Ru-based emission of the probe. The emission intensity of duplex **3·4b** is only 43% of the luminescence intensity of the perfect duplex **3·4a**. Hence, the hairpin hybridization probe **3** is able to distinguish between the target strand and a strand that contains a single mutation. We attribute this difference to the less favorable association between the unmatched oligonucleotides that is likely to lead to an equilibrium mixture of the quenched hairpin **3** and emissive

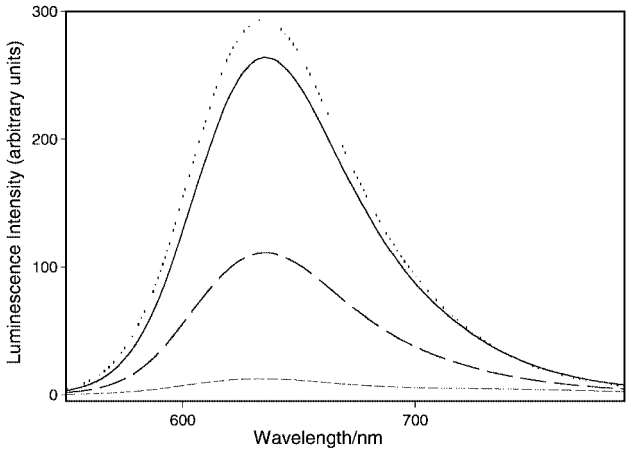

Fig. 5 Steady-state emission spectra of **3** (- - -), **3·4a** (—), **3·4b** (– – –) and **5** (···).

duplex **3·4b**.¶ Importantly, the luminescence of oligonucleotide **5**, the Ru^{II}-only control, does not significantly change in the presence of the complementary strand **4a** or the non-complementary strand **4b** (Table 1).‖

To the best of our knowledge, this is the first example of metallated hairpin oligonucleotides that serve as 'metallo-beacons'. The unique photophysical features of coordination compounds and their chemical compatibility with functional groups found on biomolecules hold great promise for future studies. In particular, advanced designs that include modulated emission and tailored quenchers that can undergo electron-transfer processes can further enhance the sensitivity and dynamic range of metal-based hybridization probes.

We thank the National Institutes of Health (Grant Number GM 58447) for generous support.

Notes and references

‡ Oligonucleotides were synthesized using the standard solid-phase phosphoramidite chemistry as previously described.[5] Purification was accomplished by preparative polyacrylamide gel electrophoresis and reversed-phase HPLC. The composition of each oligonucleotide was confirmed by enzymatic digestion followed by quantitative HPLC analysis of the resulting nucleosides. See ESI for experimental details.

§ Solutions of the oligonucleotides in 10 mM phosphate buffer, pH 7.0 containing 100 mM NaCl were heated to 90 °C for 5 min and slowly cooled to rt prior to measurements. Emission spectra of degassed solutions were measured upon excitation at 456 nm. The spectra were converted to an energy scale (cm^{-1}) and typically integrated between 520 and 850 nm.

¶ Supporting evidence can be found in the thermal denaturation curves of the corresponding oligonucleotides. See ESI.

‖ It is of interest to mention that the Ru-based emission in the Ru^{II}/Os^{II} perfect duplex **3·4a**, where the metal complexes are separated by 17 base pairs, is quenched by 10% in comparison to the Ru^{II}-only perfect duplex **5·4a**. This is consistent with the anticipated distance-dependent interaction between these coordination compounds.[5]

First published as an Advance Article on the web 28th February 2001

Inverse electron demanding Diels–Alder reactions of *o*-thioquinones with styrenes, followed by simple manipulations of the obtained cycloadducts, allowed the synthesis of polyphenolic 4-thiaflavans which showed antioxidant activity miming either flavonoid or tocopherol behaviour.

Flavonoids, natural products containing the 2-phenylchromane skeleton, are almost ubiquitous in higher plants and have been related to a huge number of biological effects[1] including anti-inflammatory, anti-viral and anti-cancer activity. Flavonoids bearing OH groups on A, B and C rings (Fig. 1) represent one of the most important families of natural antioxidants, able to prevent oxidation by oxyl radicals.[2] A high polyphenolic flavonoid content in the diet has been indicated as the reason why certain populations show statistically low levels of cardiovascular disease (the so-called *French paradox*) and most types of cancer.[3]

We have reported that *o*-hydroxy-*N*-thiophthalimides, prepared by *N*-phthalimidesulfenylation of activated phenols, are suitable precursors of *ortho*-thioquinones, a synthetically useful class of electron-poor heterodienes, which react with styrenes giving rise to the formation of aryl-substituted benzoxathiin cycloadducts with complete regioselectivity.[4]

This hetero Diels–Alder approach, can be involved in the preparation of 4-thiaflavan derivatives as shown in Fig. 1. Thus we decided to exploit this procedure for access to polyphenolic 4-thiaflavans with the aim of verifying their potential performance as antioxidants.

We focused our attention on the 5,7,3′,4′ and 5,7,4′ substitution patterns, two of the more common structural characteristics in natural flavonoids.[1]

The sulfenylation of 3,5-dimethoxyphenol and 3,5-(dimethyl-*tert*-butylsilyloxy)phenol with phthalimidesulfenyl chloride gave, as expected, the sulfenamide derivatives **1** and **2** as suitable precursors of the corresponding *o*-thioquinones.†

The reaction of compounds **1** or **2** with styrenes **3**–**5** in $CHCl_3$ at 60 °C, in the presence of TEA,[4] allowed the isolation of the required cycloadducts which were transformed into the hydroxy derivatives **6**–**12** by direct fluoro desilylation using wet TBAF in THF at 0 °C.‡ For sulfoxides **7**, **11** and **12** the oxidation with *m*CPBA of the corresponding sulfides was performed before the deprotection of the silyl ethers (Scheme 1).§

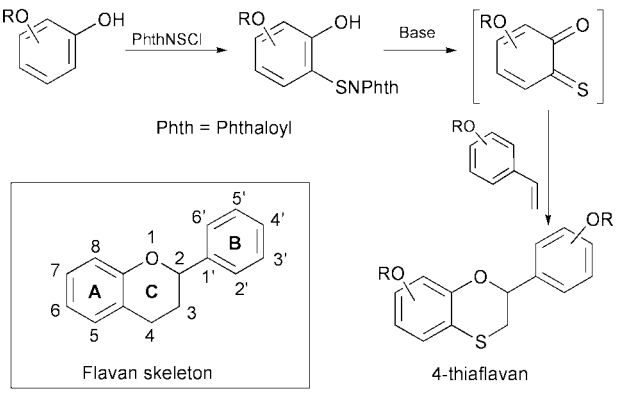

Fig. 1 Flavan skeleton and access to 4-thiaflavan structure.

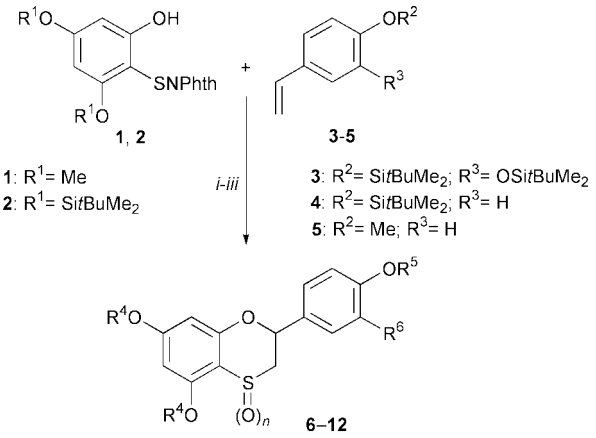
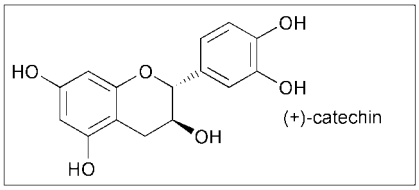
The antioxidant activity of compounds **6**–**12** was evaluated,[5] as fading of the purple colour of commercially available DPPH radical measured at 517 nm. Thus the value of the absorbance of a 10^{-4} M solution of DDPH in absolute ethanol (A_0) and the absorbance after 20 min from its mixing with an equimolar solution of the thiaflavans (A_1), were used for calculating the reducing activity ***RA*** as: $\boldsymbol{RA} = [(A_0 - A_1)/A_0] \times 100$. The obtained ***RA*** for derivatives **6**–**12** and the one measured for commercially available (+)-catechin hydrate are reported in Scheme 1.



Product	R^4	R^5	R^6	*n*	Yield (%)	***RA***
6	H	H	OH	0	36	***83***
7	H	H	OH	1	26	***83***
8	H	H	H	0	34	***85***
9	Me	H	H	0	38	—
10	H	Me	H	0	42	***83***
11	H	H	H	1	28	***23***
12	H	Me	H	1	30	***6***
(+)-catechin						***83***



Scheme 1 *Reagent and conditions. i*: TEA (1 equiv.), $CHCl_3$, 60 °C, 20–120 h; *ii* (only for **7**, **11** and **12**): *m*CPBA (1 equiv.) CH_2Cl_2, 0 °C, 0.5–2h; *iii*: TBAF (1–4 equiv.), THF, 0 °C, 1–2 h.

DOI: 10.1039/b100359n

Satisfactorily, derivatives **6** and **7** showed the same activity as catechin. The high efficiency as antioxidants of natural flavonoids showing a catechol-like ring B, has been explained on the basis of the formation of a stable *o*-quinone species arising from two consecutive hydrogen abstractions by the radical reagent.[2] Clearly thiaflavans **6** and **7** could show a similar behaviour demonstrating that the above mentioned catechol-like mechanism is maintained with the introduction of a sulfide or a sulfoxide sulfur into the C ring.

Surprisingly compound **8**, bearing only one hydroxy group on C4′ of ring B, was even more efficient than previously considered 4-thiaflavans and catechin. This is in sharp contrast with the literature data on antioxidant activity of flavonoids[2] and prompted us to envisage a different oxidation mechanism probably involving the A and C rings. This hypothesis was corroborated by the substitution of hydroxy by methoxy groups on the A ring which caused a complete loss of consumption of DPPH colour for derivative **9**, while compound **10**, bearing a methoxy group on the B ring but hydroxy groups on the A ring, exhibited the same activity as **8**. Moreover the transformation of sulfides **8** and **10** into the corresponding sulfoxides **11** and **12** gave rise to an almost complete loss of activity. Thus the observed antioxidant activity of compounds **8** and **10** requires both hydroxy groups on the A ring and a sulfide sulfur in the C ring (Scheme 1).

A simple rationalization of these results can be obtained by considering that a 5,7-dihydroxy-4-thiaflavan moiety, like in **8** or **10**, could behave as an antioxidant with the same mechanism operative in tocopherols and related compounds, which, with flavonoids, represent the most important families of natural antioxidants (Fig. 2).

Literature data regarding the activity of modified tocopherols[6] are in perfect agreement with the observed high efficiency of 4-thiaflavans **8** and **10**. Actually it is known that the introduction of electron donating groups in the aromatic ring (*i.e*. OH on C5) facilitates hydrogen abstraction by the oxyl radical, while the substitution of the oxygen by the sulfur atom, on the saturated condensed ring, increases the stability of the intermediate radical[7] (Fig. 2).

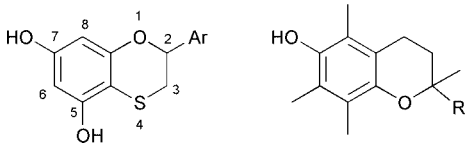


Fig. 2 4-Thiaflavan and tocopherol skeletons.

The oxidation of the sulfide sulfur causes the decrease of activity exhibited by sulfoxides **11** and **12** since it introduces an electron withdrawing group which, at the same time, is known to possess less ability in stabilizing radicals.[8]

These results seem to indicate that both the flavonoid-like and the tocopherol-like mechanisms are operative in compound **6**. Recent observations indicate that '*in vivo*' these two classes of natural polyphenols have to operate synergistically for a fast and safe protection against LDL (low density lipoprotein) damaging radicals.[9] Thus the possibility of joining in a single compound the very fast reaction of flavonoids with oxyl radicals and the high chain breaking ability of tocopherols, makes these thiaflavans very stimulating and promising new 'double-faced' antioxidant derivatives.

Moreover, since several 4-thiaflavans, including derivatives **8**–**10**, appeared active against *Staphylococcus aureus*, *Pseudomonas aeruginosa* and *Candida albicans* growth,[10] more detailed studies on the activity of 4-thiaflavans as antioxidants and antimicrobials are in progress in these laboratories.

This work was carried out under the auspices of the National Project: 'Stereoselezione in Sintesi Organica. Metodologie ed Applicazioni' supported by the Ministero dell'Università e della Ricerca Scientifica e Tecnologica, Rome, and by the University of Florence.

Notes and references

† 3,5-(Dimethyl-*tert*-butylsilyloxy)phenol was prepared by direct silylation of 1,3,5-trihydroxybenzene hydrate (fluorglucinol hydrate) with *t*-Bu-Me_2SiCl and imidazole in DMF.

‡ Representative experimental procedure: to a solution of **2** (150 mg, 0.28 mmol) and *p*-methoxystyrene (**5**) (38 mg, 0.28 mmol) in dry $CHCl_3$ (3 mL), TEA (28 mg, 0.28 mmol) was added and the mixture heated at 60 °C for 22 h. Evaporation of the solvent and flash chromatography afforded the required cycloadduct (145 mg, 60%), which was directly desilylated by reaction with TBAF hydrate (146 mg, 0.56 mmol) in THF (5 mL) for 35 min at 0 °C. Evaporation of the solvent and flash chromatography gave derivative **10** (57 mg, 70%) as a white solid; mp 169 °C.

§ Sulfoxides **7**, **11** and **12** were obtained, and tested, as 82 : 18, 86 : 14 and 93 : 7 mixtures of *trans* and *cis* isomers, respectively. For the synthesis and geometry of related sulfoxides see: G. Capozzi, P. Fratini, S. Menichetti and C. Nativi, *Tetrahedron*, 1996, **52**, 12 233. Using 1 equiv. of *m*CPBA the formation of sulfones is not observed, the latter can be easily prepared carrying out the oxidation with 2 equiv. of *m*CPBA at rt for 2–12 h.

Alkali metal-templated assembly of the tetrahedral cyanometallate cages $[M\subset Mo_4(\mu\text{-}CN)_6(CO)_{12}]^{5-}$ (M = Li, Na)

Stephen M. Contakes and Thomas B. Rauchfuss*

Department of Chemistry, University of Illinois at Urbana Champaign, Urbana, IL 61801,USA. E-mail: rauchfuz@uiuc.edu

Received (in Irvine, CA, USA) 11th December 2000, Accepted 16th January 2001
First published as an Advance Article on the web 28th February 2001

Acetonitrile solutions of (mesitylene)$Mo(CO)_3$, 1.5 equiv. Et_4NCN, and 0.25 equiv M^+ afford the inorganic tetrahedranes $(Et_4N)_5[M\subset Mo_4(\mu\text{-}CN)_6(CO)_{12}]$ (M = Na, Li), the strained nature of which is indicated by their ready reaction with CsO_3SCF_3 to give trigonal prismatic $(Et_4N)_8[Cs\subset Mo_6(\mu\text{-}CN)_9(CO)_{18}]$.

We have reported that the cyanometallate box $[Cp^*Rh]_4[Mo(CO)_3]_4(\mu\text{-}CN)_{12}^{4-}$ selectively binds Cs^+ (*vs.* K^+).[1] This mirrors behavior exhibited by solid state cyanometallates, which have been of interest for radiowaste separations.[2,3] We have recently discovered that in cyanometallate cages with labile M–CN bonds, Cs^+ and K^+ promote the formation of trigonal prismatic, not cubic, cages, *e.g.* $[Cs\subset Mo_6(\mu\text{-}CN)_9(CO)_{18}]$.[4] We now report that use of the smaller Na^+ (r_{ionic} = 116 pm[5]) and Li^+ (r_{ionic} = 90 pm) ions in place of Cs^+ (r_{ionic} = 181 pm) and K^+ (r_{ionic} = 152 pm) in the Mo–CO/CN^- system affords tetrahedral cages, a third member of the series $\{M\subset[Mo(\mu\text{-}CN)_{1.5}L_x]_n\}^{(1.5n-1)-}$. This result establishes that the alkali metal not only templates cage formation, but that *the size of the alkali metal ion determines the cage structure*. Of further interest, tetrahedral $M_4(\mu\text{-}CN)_6$ cages are unprecedented within the area of cyanometallates.[2]

Treatment of acetonitrile solutions of (mesitylene)$Mo(CO)_3$ with 1.5 equiv. Et_4NCN in the presence of 0.25 equiv. $NaSbF_6$ gives a yellow solution from which golden crystals, analyzed as $(Et_4N)_5[Na\subset Mo_4(\mu\text{-}CN)_6(CO)_{12}]$ ($Na\subset T^{5-}$), can be precipitated in 77% yield.†‡ 159 MHz ^{23}Na NMR spectroscopy indicates that this reaction is complete within 1 h. The IR spectrum shows that the anion is rather electron rich (ν_{CO} = 1997, 1876, 1745 cm^{-1}). X-Ray diffraction analysis revealed an anionic tetrahedrane with four $Mo(CO)_3$ vertices and six μ-CN edges (Fig. 1). Not unlike $[K\subset Mo_6(\mu\text{-}CN)_9(CO)_{18}]^{8-}$ ($K\subset TP^{8-}$),[4] each Mo atom is octahedral with acute CN–Mo–CN angles (82.1°) and 90° C–Mo–CO angles. The Na^+–C/N distance of *ca.* 2.56 Å is comparable to that in Na-alkyls.[6–10] The Mo–CN linkages are bent with Mo–C/N–N/C bond angles of 165.9°. In the molecular triangle $Re_3(\mu\text{-}CN)_3(CO)_{12}$, the M–C–N angles are *ca.* 180° with most of the bending occurring at the *ca.* 135° M–N–C angles.[11] A similar situation may apply to $Na\subset T^{5-}$ but the presence of four structurally similar linkage isomers, each of which can adopt four different orientations in the crystal structure, made this difficult to establish unambiguously. Evidence for the four different possible linkage isomers comes from ^{13}C NMR spectroscopy (Fig. 2), which shows the predicted 16 signals in the μ-CN region. The Li^+-containing tetrahedrane, $(Et_4N)_5[Li\subset Mo_4(\mu\text{-}CN)_6(CO)_{12}]$ ($Li\subset T^{5-}$), was prepared from (mesitylene)$Mo(CO)_3$, 1.5 equiv. Et_4NCN, and 0.25 equiv. LiO_3SCF_3.

The availability of two classes of cages of formula $M\subset[Mo(\mu\text{-}CN)_{1.5}(CO)_3]_n^{(1.5n-1)-}$ (M = Cs, K, *n* = 6 *vs.* M = Na, Li, *n* = 4) prompted a study of their interconversion. Cage interconversion is also relevant to cage assembly mechanisms, a topic that has only recently come under scrutiny.[12] The 233 MHz ^7Li NMR spectrum of $Li\subset T^{5-}$ in MeCN consists of a single signal at δ −0.28 (apparently the Na chemical shift is insensitive to the CN linkage isomerism). On addition of one equiv. of LiO_3SCF_3 to a MeCN solution of square $(Et_4N)_4[Cs\subset Mo_6(\mu\text{-}CN)_9(CO)_{18}]$ (**1**),[4] a broad signal at δ −1.8 as well as small amounts of $Li\subset T^{5-}$ (Fig. 3) were observed. Upon adjusting the CN^- : $Mo(CO)_3$ ratio to 1.5, the signal for $Li\subset T^{5-}$ becomes dominant. Further Et_4NCN, however, degrades the $Li\subset T^{5-}$ giving only $Mo(CO)_3(CN)_3^{3-}$ and free Li^+.[4] Similar observations were obtained by ^{23}Na NMR spectroscopy for the formation of $Na\subset T^{5-}$ from $NaSbF_6$ and **1**. These results confirm the ready formation of the tetrahedrane when $Mo(CO)_3$, CN^-, and the alkali metal are present in the appropriate ratio.

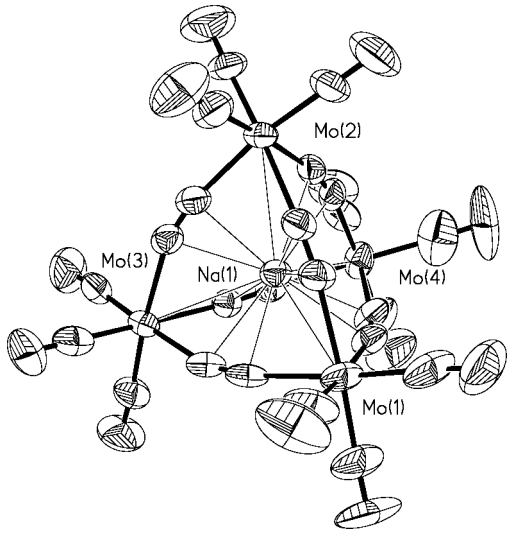

Fig. 1 Structure of the anion in $(Et_4N)_5[Na\subset Mo(\mu\text{-}CN)_6(CO)_{12}]\cdot 4MeCN$ with thermal ellipsoids set at the 50% probability level. Selected average distances (Å) and angles (°): Mo–C/N 2.25, Mo–CO 1.93, Na–C/N 2.56, C/N–Mo–C/N 82.1, OC–Mo–CO 90.0; Mo–C/N–Mo 165.9.

DOI: 10.1039/b010192n

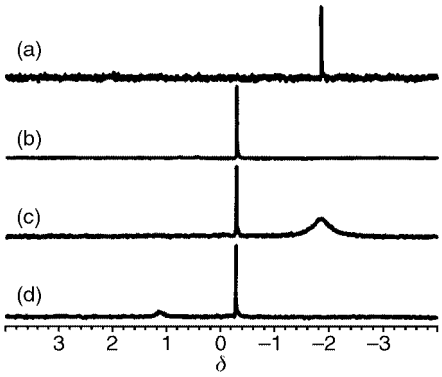

Fig. 3 233.2 MHz ^{7}Li NMR spectra illustrating the effect of Mo:CN ratio on cage synthesis (MeCN solutions): (a) 0.18 M LiO_3SCF_3; (b) 0.018 M $(Et_4N)_5[Li{\subset}Mo(\mu\text{-}CN)_6(CO)_{12}]$; (c) 0.019 M $(Et_4N)_4\{[Mo(CO)_3(NCMe)]_4(CN)_4\}$ and 0.019 M LiO_3SCF_3; and (d) 0.019 M $(Et_4N)_4\{[Mo(CO)_3(NCMe)]_4(CN)_4\}$, 0.019 M LiO_3SCF_3 and 0.038 M Et_4NCN.

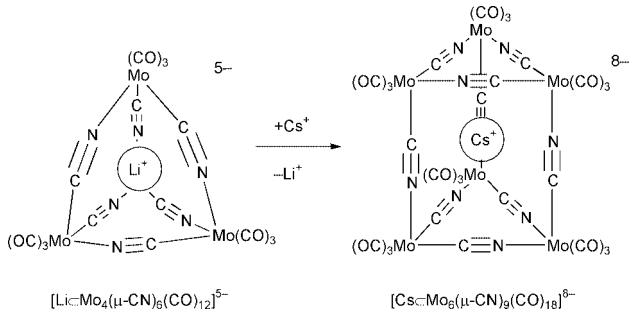
We also examined the effect of alkali metal stoichiometry. Addition of one equiv. $NaSbF_6$ to a solution of $Na{\subset}T^{5-}$ gave a broad ^{23}Na NMR signal for Na^+ centered at δ −4.5 along with undiminished signal for $Na{\subset}T^{5-}$, indicating that excess alkali metal does not degrade the cage. Using substoichiometric amounts of $NaSbF_6$ shows only formation of $Na{\subset}T^{5-}$. Thus, alkali metal is required for cage formation, only the tetrahedral cage forms at low stoichiometry, and excess alkali metal does not affect cage formation.

Experiments involving mixed alkali metals clarified the relative thermodynamic and kinetic stabilities of the new families of CN-based cages. LiO_3SCF_3 has no effect on the ^{23}Na spectrum of $Na{\subset}T^{5-}$ whereas one equiv of $NaSbF_6$ converts $Li{\subset}T^{5-}$ into $Na{\subset}T^{5-}$. This reaction is likely due to the better fit of the sodium ion within the cavity and may also be partially driven by the entropic advantage for encapsulation of $[Na(MeCN)_6]^+$ *vs.* $[Li(MeCN)_4]^+$.[13,14] ^{7}Li NMR measurements showed that one equiv. of CsO_3SCF_3 causes release of free Li^+ from $Li{\subset}T^{5-}$. Complementarily, 79 MHz ^{133}Cs NMR measurements showed that Cs^+ converts both $Na{\subset}T^{5-}$ and $Li{\subset}T^{5-}$ predominantly into $Cs{\subset}TP^{8-}$ (Scheme 1). Consistent with the greater stability of the larger cages, the ^{133}Cs NMR spectrum of $Cs{\subset}TP^{8-}$ is unaffected by the presence of Li^+, Na^+, and K^+. The higher reactivity of the tetrahedral cages is attributed to the weakened M-NC bonding associated with strained Mo–C–N–Mo angles (*vide supra*).



Scheme 1

The literature on tetrahedral cages is rapidly growing,[15–18] although the previously reported cages are guided by the directionality and denticity of organic ligands, whereas in the present case only CN^- is the linker and guidance is provided by the size of the encapsulated ion.

This research was supported by the Department of Energy. We thank Dr Paul Molitor for assistance with the NMR measurements.

The complexation *via* complementary hydrogen bonds, of three novel ferrocene receptors with barbital, ethylene urea and trimethylene urea is described with the binding mode and stoichiometry clearly shown by NMR spectroscopy and X-ray crystallography.

As part of the continued interest in the development of novel molecular switches and sensors, redox-active receptors for inorganic cations and anions have been studied in much detail,[1] although reports of similar receptors for organic molecules, be they charged or neutral, are less common.[2] Interest in the development of functional receptors for organic molecules such as barbiturates arises due to their importance as sedatives and anticonvulsants,[3] whilst the detection of ureas is important with regard to possible applications in dialysis. Previous studies concerning the binding of barbiturates and ureas have largely focused on organic receptors that bind the neutral guest through hydrogen bonds.[4] In particular, Hamilton and coworkers have reported the complexation of barbiturates by both macrocyclic and acyclic receptors (*e.g.* **1** and **2**) containing two 2,6-diaminopyridine units linked *via* an isophthaloyl group.[4a,b] Here we report that a similar binding motif can be constructed through the incorporation of the redox-active ferrocene unit into the receptor framework.

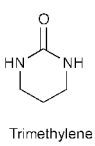
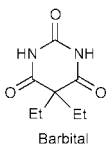
Ethylene urea



Trimethylene urea



Barbital

The synthetic strategy involved the synthesis of ferrocene-1,3-dicarbonylchloride,[5] which was then reacted, in the presence of triethylamine, with either two equivalents of 2-amino-6-methylpyridine or with an excess of 2,6-diaminopyridine, to yield compounds **3** and **4** respectively. Further reaction of **4** with propionyl chloride, again in the presence of triethylamine, yielded compound **5**. These reactions thus produced a series of ferrocene receptors containing either two hydrogen bond donor groups (D) with two hydrogen bond acceptor groups (A) (receptor **3**) or four hydrogen bond donor groups with two hydrogen bond acceptor groups (receptors **4** and **5**).

The interaction of each ferrocene receptor with a range of neutral guests was monitored by ^{1}H NMR spectroscopy in dry $CDCl_3$. Downfield shifts in the resonances corresponding to the amide protons and also the proton in the 2-position of the disubstituted ferrocene Cp ring were observed. For example, this Cp-H resonance in receptor **5** underwent a downfield shift of +0.25 ppm upon the addition of one molar equivalent of barbital. The stoichiometry of each of the complexes was confirmed as 1:1 *via* Job plots derived from the NMR data, which displayed a maximum at 0.5 mole fraction of the receptor. The values of the binding constants for each complexation experiment were then determined using the EQNMR program (Table 1).[6]

From Table 1 it is clear that there is a correlation between the number of the hydrogen bonds and the value of the binding constant. Receptor **3** forms the most stable complex *via* four hydrogen bonds with trimethylene urea, suggesting that ethylene urea is too small for the cavity formed by these receptors. Interestingly, **3** only forms a weak complex with barbital which is a similar size to trimethylene urea. This reflects the fact that there are two carbonyl groups on the barbital guest, which are not involved directly in hydrogen bonding but nevertheless are adjacent to a hydrogen bond, leading to unfavourable diagonal secondary electrostatic interactions.[7] In a related manner, trimethylene urea forms weaker complexes with receptors **4** and **5** compared to receptor **3**. The additional hydrogen bond donor groups on **4** and **5** are not directly involved in hydrogen bond formation but still contribute to unfavourable diagonal secondary electrostatic interactions with the adjacent hydrogen bonds. As expected, the highest binding constants, *via* the formation of six hydrogen bonds, are observed between barbital and receptors **4** and **5**. In fact, **4** binds more strongly than **5**, where the difference beween these two receptors arises at the hydrogen bond donor groups in position R, being amines or amides respectively. A related effect has previously been reported with ferrocene receptors used in anion recognition studies.[8]

Single crystals suitable for study by X-ray crystallography were obtained *via* the diffusion of diethyl ether into a chloroform solution of barbital and **5**.‡ The structures in Fig. 1 show that, as expected, barbital is complexed in a 1:1 stoichiometry through complementary hydrogen bonds. The hydrogen bond lengths in Table 2 show that the closest contacts are between barbital and the amide groups at the position R (*i.e.* N3 and N3′). The two bonds to the apical O3 atoms of the guest in fact are, in fact, very long for a hydrogen bond. However, it

Receptor	Ethylene urea	Trimethylene urea	Barbital
3	250 ± 5	600 ± 20	195 ± 6
4	—[a]	110 ± 2	3200 ± 242
5	—[a]	25 ± 2	2150 ± 127

[a] Weak binding with several complexes formed in solution.

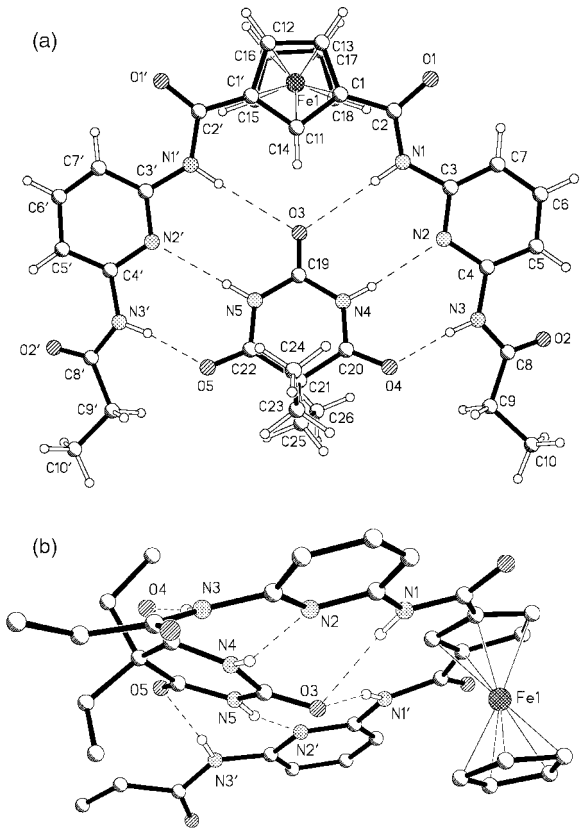

Fig. 1 (a) Top and (b) side views of the X-ray structure of [**5**:barbital].

Table 2 Hydrogen bond lengths and anglesin the X-ray structure of [**5**:barbital]

	Separation (D···A/Å	Angle (DHA)/°
N1–O3	3.434(7)	174.2
N1′–O3	3.494(7)	164.7
N4–N2	3.105(8)	156.6
N5–N2′	3.116(8)	165.3
N3–O4	2.865(7)	174.4
N3′–O5	2.892(8)	171.5

is clear that in solution, these two hydrogen bonds are formed since both resonances for the amide protons of the receptor undergo large downfield shifts upon addition of barbital. In fact, unambiguous assignment of the two resonances corresponding to these two pairs of amide protons was achieved through NOE experiments, allowing the observation that in the presence of 1.5 equiv. of barbital, the resonance for the amide protons adjacent to the Cp-ferrocene ring shifted by +0.9 ppm compared to a larger shift of +1.19 ppm for the resonance for the amide protons at position R. These findings are therefore in agreement with the solid state results in that the strongest amide hydrogen bonds are those that are the furthest away from the ferrocene unit. It is interesting to note that a similar trend in bond lengths was found in the crystal structure of the same guest with the macrocyclic host **1**.[4b] Furthermore, in both structures, the guest is oriented at an angle with respect to the plane formed by the 1,3-arms of the host (**1**:barbital = 27°,[4b] **5**:barbital = 38°).

The nature of the spacer group affects the binding constant with barbital. For Hamilton's analagous acyclic receptor **2**, where the spacer is a 1,3-isophthalic acid group,[4a] the binding constant with barbital in $CDCl_3$ is approximately one order of magnitude higher than that between **5** and barbital (K = 2.08 × 10^4 and 2.15 × 10^3 M^{-1} respectively). A likely explanation for this difference is that the angle between the 1,3-arms in the ferrocene host is larger (the angle geometry is 144 and 120° respectively for five and six-membered rings) which results in the guest having to position itself even closer to the spacer group, with its protuding Cp–H proton, to form hydrogen bonds of any reasonable length. However, additional electronic effects can not be completely ruled out since the Cp unit should lower the acidity of the proximate amide hydrogens, as it is more electron donating than benzene. To examine this effect further, electrochemical measurements were undertaken to assess the effect of oxidising the ferrocene unit on the binding strength. Receptor **5** undergoes a reversible oxidation in dry CH_2Cl_2 at 298 K [E = 0.41 V *vs.* ferrocene internal reference, where E = (E_{pa} + E_{pc})/2], corresponding to the Fe^{II}/Fe^{III} redox couple. Upon addition of excess barbital, a modest cathodic shift of −20 (±5) mV in this redox couple was observed, reflecting a slightly stronger binding of the guest upon oxidation of the ferrocene unit,§ as found previously with related hydrogen bonding ferrocene receptors.[2a] Therefore, the introduction of a positive charge and the resulting electron withdrawing effect from the spacer group would appear to increase the hydrogen bonding strength, although this effect is not as pronounced as when the guest is bridged between the two Cp rings.[2a,b] In conclusion, we have shown that a series of ferrocene compounds can form discrete complexes with a range of biologically relevant molecules through hydrogen bonding interactions. Further binding studies with these and other related receptors are currently underway.

We thank the EPSRC for the award of a PDRA grant (S. R. C.).

Received (in Cambridge, UK) 29th November 2000, Accepted 8th February 2001
First published as an Advance Article on the web 5th March 2001

Diarylurea-linked zinc porphyrin dimer and trimer were newly prepared: taking advantage of the structural characteristics of the diarylurea skeleton led to a convenient arrangement of the porphyrin chromophores in a cofacial manner.

Multi-porphyrin arrays and their photochemical properties have been attracting much attention from the viewpoint of the construction of suitable models for photosynthetic functions such as light gathering, excitation energy relay and long-range charge separation as well as their potential applications as molecular photonic devices such as solar cells, photon-gated molecular wires, and so on.[1] In multi-porphyrin arrays, photochemical processes, especially photo-induced energy and electron transfer are significantly affected by the inter-chromophore distance. Much effort has been devoted to regulating orientation among porphyrin chromophores by means of both covalent and non-covalent approaches,[2,3] but more convenient methods are still required to arrange the chromophores in various well-defined manners. In the present communication, we report the facile synthesis and conformational control of porphyrin dimer and trimer by using a diarylurea linkage, where the porphyrin chromophores are arranged in a cofacial manner.

As shown in Fig. 1a, *N*,*N*′-diarylurea predominantly adopts a *trans*,*trans*-conformation.[4] If porphyrin skeletons are introduced into the 5 and 5′ positions and the rotation of the N–C bonds (arrows a and a′ in Fig. 1a) is fixed by steric repulsion between the substituents introduced into the 2 and 2′ positions (*e.g.* methyls) and the carbonyl oxygen, the chromophores should be forced into a cofacial arrangement (Fig. 1b). In addition, diarylurea is easily obtained by the reaction of the corresponding amine and isocyanate in good yield. Thus, a diarylurea skeleton is a good candidate for the linkage in the construction of a cofacial porphyrin array. In Scheme 1 is shown the synthesis of diarylurea-linked zinc porphyrin dimer **1**, which is carried out in a similar manner to the preparation of urea-functionalized porphyrins reported by Collman.[5] Aminoporphyrin **3** was converted to the corresponding isocyanate **4** by treating with triphosgene in dry dichloroethane containing a small amount of dry pyridine. The reaction of **4** with another molecule of **3** followed by insertion of zinc(II) ions afforded zinc porphyrin dimers **1a** and **1b** in 73 and 49% yields from **3a** and **3b**, respectively. In the similar way, the reaction of 2 equiv. of **4a** with 1 equiv. of diaminoporphyrin **5** afforded trimer **2** in 44% yield from **3a**. The reference monomer **6** was also prepared from **3a** and aniline in 90% yield. Each compound was identified by ^{1}H NMR, ^{1}H–^{1}H COSY, electronic absorption, IR and FAB mass spectra and elemental analysis.†

† Electronic supplementary information (ESI) available: ^{1}H NMR, electronic absorption, IR and FAB mass spectra and elemental analysis data for **1a**, **1b**, **2** and **6**. See http://www.rsc.org/suppdata/cc/b0/b009578h/

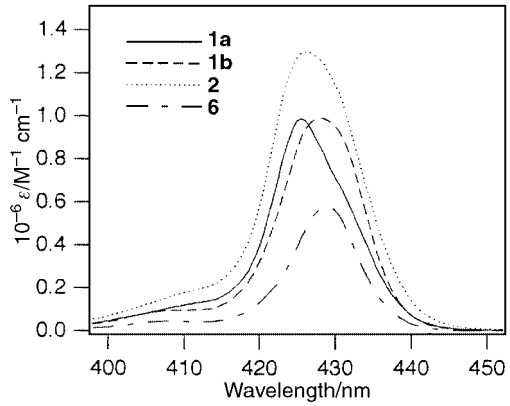

Fig. 2 Electronic absorption spectra of **1a**, **1b**, **2** and **6** in the Soret region in $CHCl_3$–DMSO (20/1, v/v) at 293 K.

Firstly, electronic absorption spectra gave us some information about the orientation between the chromophores in the zinc porphyrin oligomers **1** and **2**. The absorption spectra in the Soret region for **1**, **2** and **6** are shown in Fig. 2. The dimer **1b**, which possesses no substituents in the diarylurea skeleton except for the porphyrins, exhibited a similar absorption spectrum to **6**, whereas the absorption maximum of **1a** exhibited a slight blue shift of 4 nm compared to that of **6**, indicating an exitonic coupling between the transitions in the two porphyrin moieties adopting the cofacial arrangement.[6,7] The trimer **2** also exhibited the similar blue shift (λ_{max} = 426 nm), indicating a well-defined cofacial array of three porphyrin units, although the half band width is a little bit larger than that of **1a** (half band widths; 12 and 14 nm for **1a** and **2**, respectively).

The cofacial orientation between the porphyrin units in **1a** was also confirmed by formation of a complex with 1,4-diazabicyclo[2.2.2]octane (DABCO). The porphyrin face-to-face distance in **1a** estimated by a molecular modeling study was 7.0 Å,[8] suitable distance for binding of DABCO through two Zn–N coordination interactions. Addition of an equimolar amount of **1a** to a solution of DABCO in $CDCl_3$–DMSO-d_6 (20 : 1, v/v, 0.34 mM) induced a significantly large upfield shift of the $-CH_2CH_2-$ signal of DABCO from 2.80 to −4.75 ppm, which apparently originated from ring current anisotropy of the two porphyrin rings.[9] In Fig. 3 are shown absorption spectra of **1a** and **1b** in $CHCl_3$–DMSO (20 : 1, v/v) upon addition of varying concentrations of DABCO, and the titration data are summarized in Table 1. An isosbestic point observed in each spectral change (426 and 427 nm for **1a** and **1b**, respectively) indicates 1 : 1 complex formation in the present condition, which was supported by the Job plot. The spectra of **1a** and **1b** both exhibited blue shifts upon complexation with DABCO to

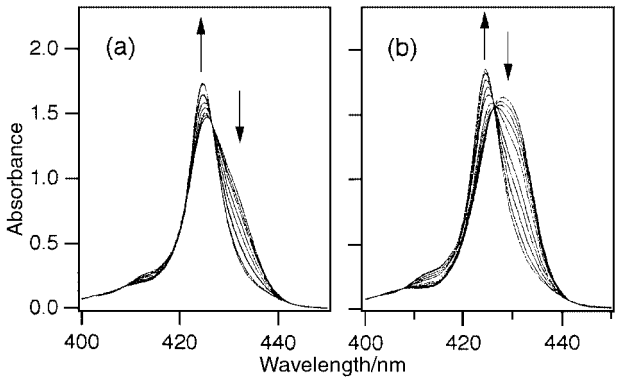

Fig. 3 Electronic absorption spectra of **1a** and **1b** in the presence of varying concentrations of DABCO in $CHCl_3$–DMSO (20/1, v/v) at 293 K. (a) [**1a**], 1.50 μM; [DABCO], 0, 1.22, 2.44, 4.83, 7.75, 11.7, 23.3, 34.8 μM. (b) [**1b**], 1.64 μM; [DABCO], 0, 0.0260, 0.0515, 0.0827, 0.125, 0.249, 0.372, 0.614, 2.50, 3.67 mM.

Table 1 Electronic absorption titration data for **1a**, **1b** and **6** with DABCO in $CDCl_3$–DMSO (20/1, v/v) at 293 K

Compound	λ_{free}[a]/nm	$\lambda_{complex}$[a]/nm	$\Delta\lambda$[b]/nm	K[c]/M^{-1} (s.d., %)
1a	425 (12)	424 (8)	−1	1.48×10^5 (11)
1b	428 (12)	424 (8)	−4	3.59×10^3 (7)
6	429 (10)	431 (9)	2	1.02×10^3 (5)

[a] Absorption maximum in the Soret region. λ_{free}; in the absence of DABCO, $\lambda_{complex}$; upon complexation with DABCO. Half band width in parenthesis. [b] $\lambda_{complex} - \lambda_{free}$. [c] Determined by computer-assisted least-squares analysis of the absorbance changes.

afford an identical narrow Soret absorption (λ_{max} = 424 nm; half band width, 8 nm), although monomer **6** exhibited a red shift upon complexation, induced by the coordination of DABCO's nitrogen to the central zinc of the porphyrin moiety.[10] This suggests that the blue shifts observed in **1a** and **1b** are due to the exitonic interaction between the porphyrin chromophores tightly fixed in a cofacial manner. It is emphasized that the binding constant K for **1a** was 41 times larger than that for **1b**, indicating that the introduction of methyl groups at the 2 and 2′ positions in the diarylurea skeleton of **1a** effectively forces the porphyrin moieties to adopt a cofacial orientation.

In summary, we have demonstrated here a facile method for construction of cofacial porphyrin oligomers by linking porphyrin units by a diarylurea linkage as well as the introduction of appropriate intramolecular steric interactions. As can be seen, alternative copolymerization of **5** with the corresponding porphyrin diisocyanate should afford a linear cofacial porphyrin array. This research is on going.

First published as an Advance Article on the web 5th March 2001

Calcined pure silica MCM-48 is modified by silylating its mesopores with trimethylsilyl chloride; such pore modification along with polymerization and carbonization of divinylbenzene as a carbon precursor is found to be a very efficient way of fabricating highly ordered carbon molecular sieves with three-dimensionally interconnected uniform pore arrays, greatly improving structural integrity and thermal stability.

Porous carbons have been greatly studied as adsorbents and electrode materials.[1,2] Since zeolites and other molecular sieves including mesoporous materials possess several attractive characteristics such as high surface area and periodic arrays of uniform pores, they can be used as synthesis templates for carbon with regular pore structures.[3,4] Polymerization and pyrolysis of acrylonitrile were demonstrated in zeolite Y and mordenite channels.[5] The formation of porous carbon by carbonization of poly(acrylonitrile) and poly(furfuryl alcohol) was reported in Y zeolite template.[6] The phenol–formaldehyde polymers and their carbons were also studied in Y, β and L zeolites.[7] However, the pore ordering was not well maintained in the porous carbon structure due to the non-rigidity of the carbon frameworks formed in the narrow pores of zeolites. Most recently, carbon frameworks with ordered pores were reported using mesoporous templates. Ordered porous carbon replicas of the MCM-48 template were reported by converting sucrose in the channels into carbon using an acid catalyst.[8] Mesoporous carbon was also synthesized by acid-catalyzed polymerization of phenol and formaldehyde in Al-implanted MCM-48 followed by carbonization.[9] Here we report the novel synthesis of highly ordered mesoporous carbon materials using a pure silica MCM-48 template with surface-modified pores and divinylbenzene as a carbon precursor. Particularly, this method provides the first example of mesoporous carbon with much improved structural integrity and thermal stability.

High quality silica MCM-48 was prepared using $C_{16}H_{33}N(CH_3)_3Br$ and Brij 30 as surfactants and colloidal silica Luodx HS40 as the silica source based on the modification of reported methods.[10] Calcined silica MCM-48 was first modified by a simple silylation using trimethylsilyl (TMS) chloride according to methods described in literature.[11] After such a silylation, more than 90% of the silanol groups in the pores were replaced with TMS groups [eqn. (1)].

$$(\text{silica})\equiv\text{SiOH} + (CH_3)_3\text{SiCl} \rightarrow (\text{silica})\equiv\text{SiOSi}(CH_3)_3 + \text{HCl} \quad (1)$$

This was confirmed by the decrease of a signal at 960 cm^{-1} corresponding to Si–O stretching in the Si–OH groups before silylation and by the concomitant development of two new signals at 845 and 2960 cm^{-1} ascribed to attached $OSi(CH_3)_3$ groups in the infrared spectra as reported in previous work.[11–13] We denote TMS-modified MCM-48 as TMS-MCM-48 in order to distinguish it from pure silica MCM-48. Such TMS-MCM-48 showed higher hydrophobicity and nonpolarity[11,13] which were confirmed by a marked decrease of a broad signal centered at 3450 cm^{-1} due to physically attached water in the mesopore. The modified pores in the templates were filled by soaking the TMS-MCM-48 template into a carbon precursor solution of 80% divinylbenzene (DVB) with a free radical initiator, azobisisobutyronitrile (AIBN) (DVB–AIBN mole ratio ≅ 10). Dissolved oxygen was removed by several freeze–pump–thaw cycles. Polymerization was performed by heating to 70 °C overnight. The resulting polymer was heavily cross-linked in the template pores. The template–polymer composites were then heated under N_2 gas flow at a heating rate of 1 °C min^{-1} to 750–850 °C and then held under these conditions for 7–10 h to carbonize the polymer. Porous carbon was obtained after subsequent dissolution of the silica framework in 48% aq. HF. The same procedures were also performed on calcined silica MCM-48 without any surface modification. The yield of obtained carbons was about 70–80% in both cases.

XRD patterns were measured at various stages during the course of synthesis (Fig. 1). Two intense peaks with about equal intensity at 2θ = 1.6 and 2.7 in synthesized carbon materials indicate long-range ordering of highly ordered uniform mesopores. It is interesting to note that the first intense peak not seen in parent MCM-48 template occurs in the synthesized carbons. The peak was suggested to occur due to the phase transition of MCM-48 with *Ia*3*d* space group to a new cubic phase with $I4_132$ space group due to shrinkage of the carbon walls upon removal of the silica framework.[8] Surprisingly, the overall XRD intensity for TMS-MCM-48 porous carbon was about two times higher than ones for the parent calcined silica MCM-48 template and for the MCM-48 carbon. Elemental analysis of the porous carbon replica shows a C:H mole ratio of about 23 (C 98.01 and H 0.35 wt%). Energy dispersive X-ray spectrophotometer analysis determined by field emission scanning electron microscopy also indicated a predominantly strong carbon signal at 0.270 keV with a weak residual undissolved silica signal at 1.752 keV.

TEM images from the thin edges of the porous carbon molecular sieves show a regular array of holes separated by walls (Fig. 2). The TMS-MCM-48 porous carbon showed much

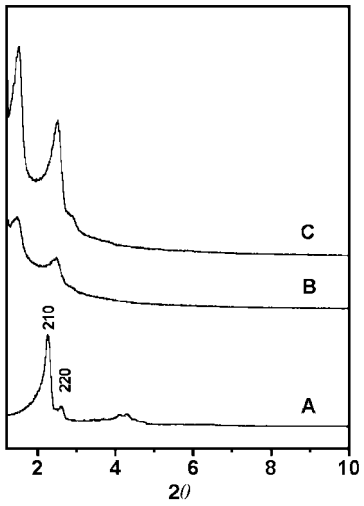

Fig. 1 X-Ray diffraction patterns of (a) calcined pure silica MCM-48 and mesoporous carbon obtained by using (b) silica MCM-48 and (c) TMS-MCM-48 as templates. These XRD patterns were obtained using a Rigaku D/MAX-III (3 kW). Each spectrum was measured under identical experimental conditions.

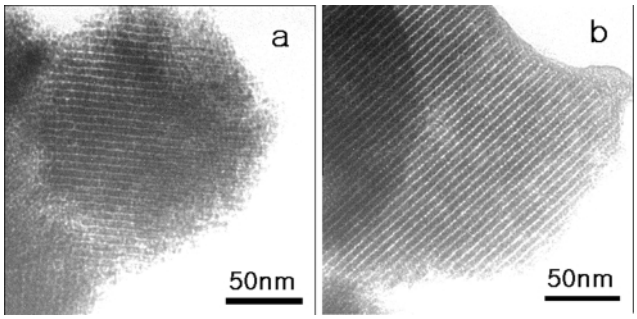

Fig. 2 Transmission electron micrograph (TEM) images of mesoporous carbon obtained by using (a) silica MCM-48 and (b) silica TMS-MCM-48 as templates.

better overall structural order than the MCM-48 porous carbon, which is also in good accordance with XRD results. The specific surface areas of the carbons were found to be 1200 ± 50 m^2 g^{-1} for nitrogen BET adsorption measurements. The pore size distribution data calculated from the adsorption branch of nitrogen adsorption–desorption curves by the BJH (Barrett–Joyner–Halenda) method showed that pores are uniform with quite narrow pore size distribution centered at 2.4 ± 0.2 nm.

Thermogravimetric (TG) weight change was recorded to study the thermal stability of carbons formed by carbonization of DVB in MCM-48 template under an O_2 atmosphere (Fig. 3). There was significant weight loss in a narrow temperature range at *ca.* 830 K for DVB carbon. The high temperature for DVB carbon, in good agreement with those for nanotubes and other graphitized carbons[14,15] indicates that the DVB carbon may have a graphitic nature. The corresponding TG temperature was near to 680 K for sucrose carbon in previous work.[8] This clearly indicates the DVB carbon with much improved thermal stability. Mechanical strength measured by monitoring XRD intensity changes after each pressurizing cycle of the pelletized carbon (100 mg and 1/2 inch diameter) for 1 min with gradually increasing pressure indicates that the DVB carbon was stable with no significant intensity change at pressures less than 4.0 ton cm^{-2} and above that, started decreasing its intensity slowly with 75% XRD intensity maintained at pressures of 4.8 ton cm^{-2} compared to the original intensity at atmospheric pressure. Calcined silica MCM-48 with high crystalline order and its silylated MCM-48 prepared here were stable at pressures of less than 2.4–2.7 ton cm^{-2} and *ca.* 3.0 ton cm^{-2}, respectively, but above these pressures, they started losing their crystallinity. This indicates that the mesoscopic porous carbon prepared here has much higher mechanical strength than the silica template.

In this work, we have obtained high quality mesoporous carbon with much better structural order for TMS-MCM-48 compared to those for MCM-48. This is unclear, but is perhaps due to the removal of oxygen sources in TMS-MCM-48 which are an effective quenching agent for DVB radical polymerization by replacing $Si(OH)_{1\text{ or }2}$ with $SiOSi(CH_3)_3$ *via* silylation. TMS-modified pores are also extremely hydrophobic compared to unmodified ones,[11,13] repelling more water molecules which can also be potential radical reaction quenchers and thus allowing more room for carbon precursors to fully fill the mesopore channels. Carbon prepared with phenol and formaldehyde was shown to have low thermal stability and lower structural ordering.[8] Also when we measure the XRD intensity ratios of the mesoporous carbon *versus* the parent calcined pure silica MCM-48 template as determined from a flat base line, our high quality carbon showed a much higher ratio of 2.2–2.5 than carbons prepared by carbonization of sucrose of about 1.3–1.6.[8] In addition, MCM-48 templated DVB carbon shows higher thermal stability than the corresponding sucrose carbon.

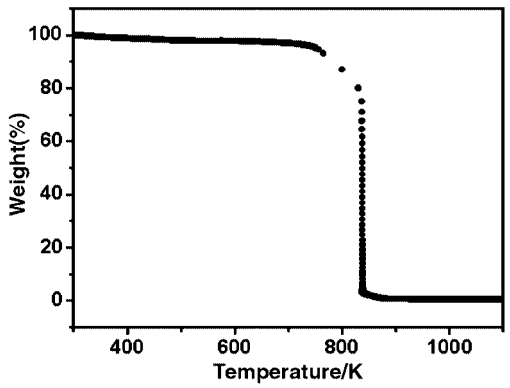

Fig. 3 Thermogravimetric weight change curve under an O_2 atmosphere for MCM-48 templated carbons prepared by the carbonization of DVB.

In summary, two major factors were considered in this work to improve the quality of mesoporous carbons: hydrophobicity of the template channels and the carbon precursor. The surface modification of the MCM-48 template and the use of DVB as a carbon precursor are considered to be a most efficient way of synthesizing highly ordered mesoporous carbons with greater structural integrity and thermal stability. We are currently carrying out further studies to evaluate this method which can be extended to the preparation of other high quality mesoporous carbons. We have synthesized carbons in the MCM-41 template using the same method. TEM pictures of the extracted carbon fibers showed continuous linear patterns due to carbon nanofibers, but in general not as orderly as the MCM-48 templated carbon because the fibers are not bound to each other in MCM-41. The highly ordered mesoporous carbon materials with superior structural integrity and thermal stability will find many new advanced applications in the future.

We thank the Korean Ministry of Science and Technology (I-01-03-A-073) and the Basic Science Institute (in Taejon) program (TEM images).

Received (in Cambridge, UK) 15th January 2001, Accepted 14th February 2001
First published as an Advance Article on the web 6th March 2001

The ethylenediamine functionalized quinacridone derivatives 3a–c display an orange fluorescence ($\lambda_{em\,(max)}$ = 558 nm) which is quenched upon addition of coordinating metal ions by formation of a macrocyclic chelate bringing metal ion and fluorophore in close proximity to one another.

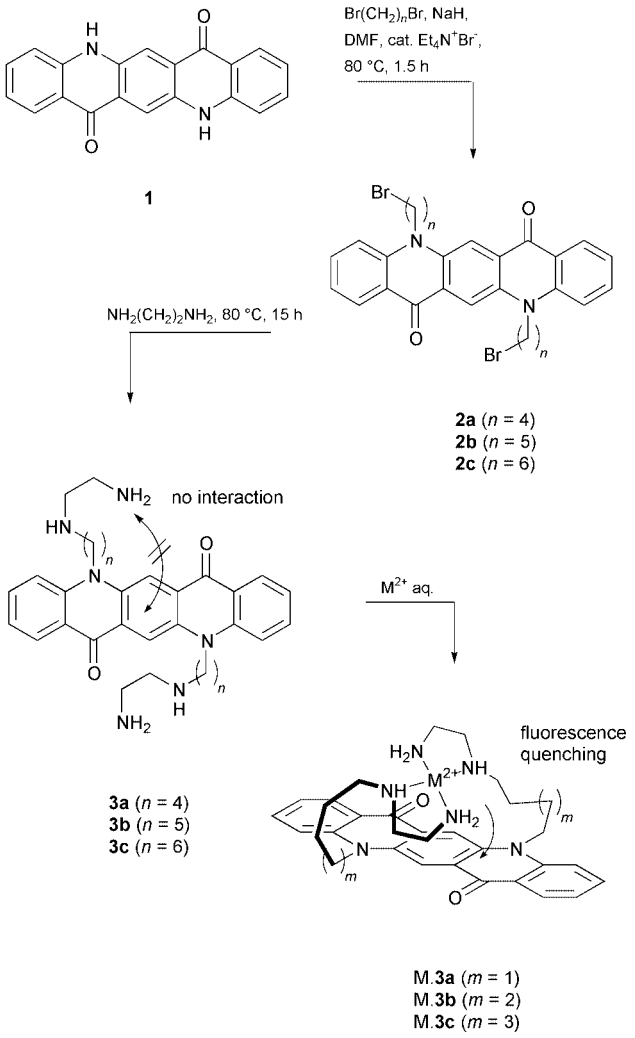
A number of small-molecule fluorescent sensors for metal ions have been developed in recent years, and find applications in trace-ion analysis and imaging. Fluorescence modulation upon metal binding is commonly observed whenever a fluorophore interacts directly with a non-bonding electron pair belonging to a metal-chelating group, typically placed one (phenols and anilines) or two (benzylic heteroatoms) bonds away from the fluorophore. This design forms the basis for the vast majority of fluorescent metal sensors described to date,[1–3] and usually implies that the metal sensors also operate as pH sensors. Herein we report a new type of fluorescent sensor in which a fluorescence quenching effect is obtained by formation of a macrocyclic metal chelate bringing metal ion and fluorophore in close proximity to one another. There is no direct interaction between the chelating group and the fluorophore, which avoids pH sensing.

Our sensor design is based on quinacridone **1**, a red organic pigment used in the dye industry and structurally related to acridone (Scheme 1).[4] A pair of chelating groups, such as ethylenediamines, are attached *via* a linker to each nitrogen atom of the symmetrical quinacridone. The linker is chosen long enough such that the protonation state of the chelating groups does not influence the fluorophore. Most importantly, the long linker now also allows a coordinating metal ion to bind simultaneously at both groups by forming a macrocyclic chelate in which the metal is in close proximity to the quinacridone chromophore. Such an arrangement should result in fluorescence quenching, in particular with energy-transfer quenching metal ions such as copper and nickel.[5]

Double alkylation of quinacridone **1** with dibromoalkanes gives dibromides **2a–c**. Further reaction with excess ethylenediamine then leads to ligands **3a–c** (Scheme 1). All ligands are obtained as trifluoroacetate salts after purification by reverse-phase HPLC.

As expected, the fluorescence spectra of ligands **3a–c** is independent of pH, with < 20% variation in intensity between pH 2 and pH 10. Fluorescence is directly proportional to concentration (0.1–100 μM, pH 7.2 or 9.0), showing that the ligands are not susceptible to auto-quenching. At pH 7.2, addition of Cu^{2+} to ligands **3a–c** induces almost complete quenching of fluorescence (98% quenching, $EC_{50} \approx 0.5$ μM at 1 μM ligand). There is no response with other divalent metal ions such as Hg^{2+}, Ni^{2+}, Co^{2+}, Zn^{2+}, Mg^{2+}, Ba^{2+}, Ca^{2+}, Mn^{2+}, Fe^{2+}, Pb^{2+}, Sr^{2+} (10^{-4} M of the chloride salts). At pH 9.0, quenching is observed for all three ligands with Cu^{2+} (Fig. 1), Ni^{2+} (96% quenching, $EC_{50} \approx 0.8$ μM), Co^{2+} (94% quenching, $EC_{50} \approx 8$ μM), and to a lesser extent with Hg^{2+} (70% quenching, $EC_{50} \approx 0.9$ μM) and Zn^{2+} (45% quenching, $EC_{50} \approx 0.7$ μM). The observed selectivity and pH-dependence of metal complexation with ligands **3a–c** corresponds to the stability constants of ethylenediamine metal complexes.[6] Fluorescence returns to its full intensity upon acidification of the metal–ligand solutions, as well as with high concentrations ($> 10^{-4}$ M) of Zn^{2+} or Hg^{2+}. In all cases the shape of the fluorescence spectrum is unaffected by quenching ($\lambda_{em\,(max)}$ = 558 nm). Remarkably, quenching has little effect on the visible absorbance spetrum or the wavelength of fluorescence emission. Thus solutions of free and complexed ligands **3a–c** show an indistinguishable red color in transparence. Under reflected light, however, the solutions of free ligands **3a–c** shine orange due to their fluorescence, while the metal-complexed ligands remain red (see ESI†).

Fluorescence titration curves at [L] = 1×10^{-5} M show a 1:1 stoichiometry of complexation for L = **3a–c** with Cu^{2+}, suggesting ML, M_2L_2 or M_nL_n modes of complexation.



Scheme 1 Synthesis of ligands **3a–c** from quinacridone **1**. Complexation with coordinating metal ions (M = Cu, Hg, Zn, Ni, Co) leads to a macrocycle in which the metal ion is placed above the aromatic nucleus.

† Electronic supplementary information (ESI) available: electrospray MS data and photographs of solutions of ligand **3c** in the absence and presence of Cu^{2+}. See http://www.rsc.org/suppdata/cc/b1/b100535i/

DOI: 10.1039/b100535i

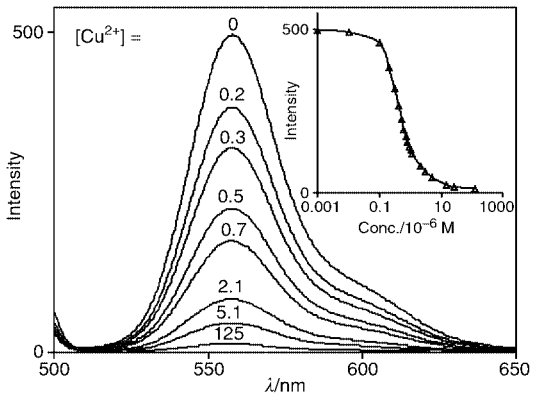


Fig. 1 Fluorescence emmission spectrum of 1×10^{-6} M ligand **3a** in the presence of increasing concentrations of Cu^{2+}. Insert: fluorescence intensity at λ_{em} = 558 nm as a function of copper concentration. Measured at 25 °C in H_2O–DMF 60 : 40, 1 mM Tris, pH 9.0, with λ_{ex} = 485 nm using a Perkin Elmer Luminescence spectrometer LS 50B.

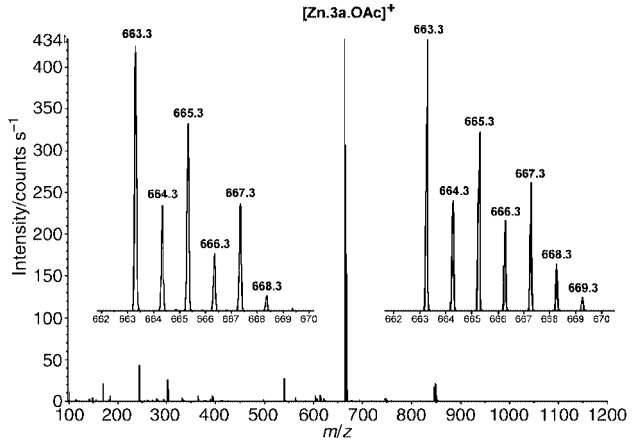

Fig. 2 Electrospray mass spectrum of the Zn.**3a** sample (10^{-3} M equimolar solution of **3a** and $Zn(OAc)_2$ in methanol). The spectrum exhibits an average mass resolving power of 10 000 (FWHM), which allows for full separation of the isotopic patterns. Insets show the measured (left) and calculated (right) pattern of the most abundant complex $[Zn.\mathbf{3a}.OAc]^+$, $C_{34}H_{46}N_6O_4Zn$, *m*/*z* = 663.264. Measured with a Sciex Q-Star Pulsar hybrid quadrupole-time-of-flight mass spectrometer (Applied Biosystems, Rotkreuz, Switzerland) equipped with a nanospray ion source (Protana, Odense, Denmark). A voltage of 1000 V was applied to the nanospray-needle and nitrogen was used as the drying gas.

Electrospray mass spectrometry shows that the ML complex is formed in equimolar solutions of metal ion and ligand **3a–c**. The ML complex disappears in favor of an M_2L species with excess metal [Fig. 2 and Table 1 (ESI)†].

In view of the MS-analysis, the fluorescence data is best interpreted in terms of the formation of an ML complex with a macrocyclic structure as shown in Scheme 1, where fluorescence is quenched by proximity of the coordinating metal.[7] The fact that quenching does not affect markedly either the aborbance (Fig. 2) or the fluorescence emmission spectrum is consistent with an energy-transfer mechanism for quenching. The quenching interaction disappears with the poor energy-transfer quenchers Zn^{2+} and Hg^{2+} when the M_2L complex is formed at high metal concentration, because the metal ions are not close enough to the fluorophore in this complex.[7] The continued quenching observed at high metal concentration with Cu^{2+}, Ni^{2+} or Co^{2+} can be explained by a transition to non-specific quenching by these strong energy-transfer quenchers.

The above experiments demonstrate that efficient fluorescent sensing of metal ions is possible by using a macrocyclic chelation effect. By contrast to standard metal sensors, there is no direct interaction between the metal-chelating groups and the fluorophore, which excludes pH-sensing. The fluorescence modulation obtained is directly visible by the eye since it occurs in the visible range. Remarkably, even weak quenching ions such as Hg^{2+} and Zn^{2+} produce an important fluorescence modulation by macrocyclic chelation. We are currently investigating the construction of macrocyclic chelation sensors with other fluorophores.

7 Molecular modelling (Spartan 5.1, semi-empirical calculations with PM3(tm)) shows that the metal ions (calculated for Cu^{2+} and Ni^{2+}) are placed at 5.5–6.5 Å above the quinacridone rings in all combinations of ligands **3a**, **3b** or **3c**, with tetrahedral, trigonal bipyramidal (+ 1 H_2O) or octahedral (+ 2 H_2O) coordination. In the M_2L complexes, the metal is placed on the side at 8.2 Å (with **3a**) to 11 Å (with **3c**) from the quinacridone.

Tandem reductive ring opening-retro-Bingel reactions of bismethano[60]fullerenes to give 1,2-dihydro[60]fullerylglycines

Bismethano[60]fullerene derivatives 1 and 3 give 1,2-dihydro[60]fullerylglycines 2 and 4 respectively by a novel tandem reductive ring opening-retro-Bingel reaction.

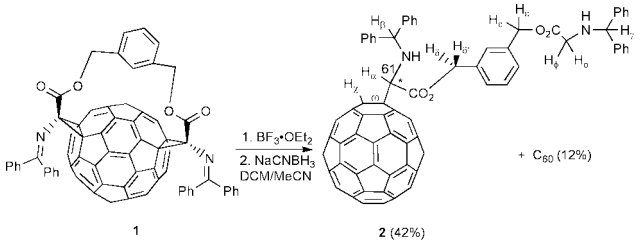
The addition of a single bis(ethoxycarbonyl)methylene unit [$C(CO_2Et)_2$] to [60]fullerene is readily achieved by treatment of C_{60} with diethyl bromomalonate under Bingel reaction conditions.[1] Sequential Bingel additions have been used to prepare the corresponding bis- and tris-adducts as mixtures of regioisomers.[2] The regiochemistry of these reactions however, improves as the fullerene becomes more substituted, as exemplified by the regioselective synthesis of $C_{60}[C(CO_2Et)_2]_6$ with the all-*e* addition pattern starting from *e-e-e*-$C_{60}[C(CO_2Et)_2]_3$.[3] The regioselective formation of bis- through to hexakis-adducts can now be realized using tethered-directed remote functionalization.[4] Anthracene and 9,10-dimethylanthracene have been employed as reversible covalent templates to regioselectively prepare tetrakis- and hexakis-derivatives ($C_{60}[C(CO_2Et)_2]_n$ n = 4,6).[5] Non-tethered bis-adducts ($C_{60}[C(CO_2Et)_2]_2$) can be isomerised under carefully controlled electrochemical conditions to afford predominantly a thermodynamically favoured mixture of bis-adducts ('walk-on-the-sphere rearrangements').[6] While one or more of the methano groups of higher adducts can be removed under reductive conditions (retro-Bingel reaction), either electrochemically[7] or chemically,[8,9] to give less substituted methano[60]fullerenes or C_{60} itself. The potential of using a malonate addend as a reversible directing group or a protecting group of more reactive double bonds on the fullerene sphere for the synthesis of functionalised fullerenes has been recently demonstrated.[7d,8]

Earlier we reported a method for preparing the protected cyclopropane amino acid fullerene derivative $C_{60}[C(N{=}CPh_2)(CO_2\,Bu^t)]$ from the reaction C_{60} and *tert*-butyl *N*-diphenylmethyleneglycinate under Bingel reaction conditions.[10] Treatment of this methano[60]fullerene derivative with sodium cyanoborohydride under protic conditions resulted in reduction of the C61 imino group and concomitant ring opening of the cyclopropane ring to give, after a further reduction step and protonolysis, the novel 1,2-dihydro[60]fullerylglycine derivative, $C_{60}H[C(NHCHPh_2)(CO_2Bu^t)]$.[10] More recently we have extended this study to the synthesis of the corresponding tethered *trans*-4 bismethano[60]fullerene derivative **1**.[11] Interestingly, the regiochemistry of this tethered reaction was different to that found using the analogous tethered bismalonate system. We report here our study on the reductive ring opening reactions of the bis-adduct **1** and that of its corresponding untethered diethyl ester analogue **3**.

Treatment of a solution of **1** in THF–MeOH at pH 4 with sodium cyanoborohydride at ambient temperature, as described by us previously,[10] resulted in only recovered starting material. However, after much experimentation, we discovered that treatment of a solution of **1** in DCM with 5 equiv. of boron trifluoride–diethyl ether, initially at 0 °C with warming to rt over 30 min (presumably to activate the imine by complexation to the imine nitrogen), followed by the addition of acetonitrile and 10 equiv. of sodium cyanoborohydride gave, after 90 min, a mixture of the 1,2-dihydro[60]fullerylglycine **2** and C_{60}. Separation of this mixture by column chromatography on silica gel gave pure samples of **2** and C_{60} in yields of 42 and 12%, respectively (Scheme 1).[12] These fullerene compounds arise formally from a tandem reductive ring opening-retro-Bingel reaction and a double retro-Bingel reaction, respectively. Interestingly, none of the double reductive ring-opened bisfullerylglycine adduct $\{C_{60}H_2[C(NHCHPh_2)(CO_2R)]_2\}$ was isolated. The structure of **2** was clearly evident from NMR spectroscopy. The UV-vis spectrum of **2** in DCM showed distinct absorbances at 430, 640 and 705 nm, similar to that found in the derivative $C_{60}H[C(NHCHPh_2)(CO_2Bu^t)]$.[10] The ^{1}H NMR spectrum of **2** revealed a one proton singlet at δ 6.84 that corresponded to the single fullerene proton (H_χ). An upfield shift of the aromatic protons of the benzhydryl moiety was consistent with the chemical transformation of the imine to the secondary amino functionality. The addend region of **2** revealed two doublets at δ 5.41 and 5.24 (J = 11.9 Hz) corresponding to the diastereotopic benzyl protons ($H_\delta/H_{\delta'}$). The other benzylic protons (H_ε) resonated as a two proton singlet at δ 5.08, whereas the two proton singlet at δ 3.40 was identified as corresponding to the methylene protons (H_ϕ). A singlet one proton resonance at δ 4.84 corresponded to the benzhydryl resonance (H_γ). A three proton coupled spin system was identified as H_α (δ 4.97, d, J 12.3 Hz), H_β (δ 5.24, d, J 2.5 Hz) and NH (δ 3.67, dd, J 12.3, 2.5 Hz).

The ^{13}C NMR spectrum of the fulleryl sp^2 region of **2**, like that of $C_{60}H[C(NHCHPh_2)(CO_2Bu^t)]$, revealed a structure lacking a plane of symmetry due to the newly formed stereogenic centre at C61. This centre gives rise to diastereotopic pairs of fulleryl sp^2 carbons that lie either side of the plane bisecting C1 and C2 of the fullerene sphere. A single set of fulleryl sp^3 resonances at C_χ (δ 58.9), and C_ω (δ 67.3) were observed in addition to resonances corresponding to the addend C_α (δ 70.4), C_β (δ 66.3) C_δ (δ 67.8), C_ε (δ 66.2), C_ϕ (δ 47.5) and C_γ (δ 66.5). These carbons were readily assigned from HSQC and HMBC experiments.

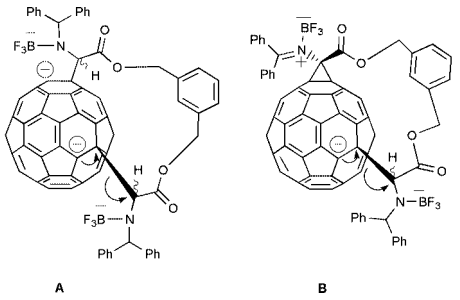
In principle, the product **2** could arise from the anionic intermediates **A** or **B**. The driving force for mono-elimination of the tether from **A** or **B** might be the relief of ring strain upon expulsion of one arm of the tether. In the case of **A**, a further driving force may be the conversion of a fulleryl dianion intermediate to a thermodynamic more stable fulleryl monoanionic system. Clearly the rate of mono-elimination of the



Scheme 1

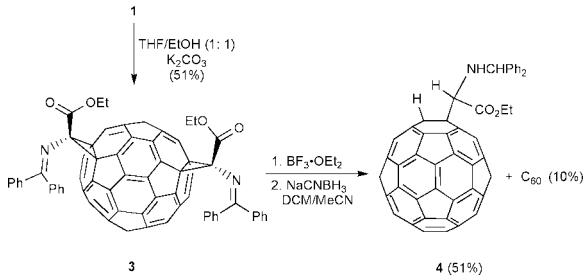
DOI: 10.1039/b100655j

addend is much faster than the rate of elimination of the entire addend as indicated by the relative isolated yields of **2** and C_{60}.



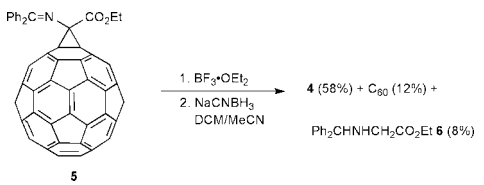
A B

To examine the influence of the tether on this ring opening-retro-Bingel reaction, the diethyl ester **3** was prepared from the base-catalysed trans-esterification of **1** with ethanol–THF–sodium carbonate as shown in Scheme 2. Treatment of **3** under similar reduction conditions to those described for **1** above also resulted in formation of a ring opened-retro-Bingel product, the ethyl ester **4**. This compound was obtained pure in 51% yield after column chromatography. A smaller amount of C_{60} (10%) was also isolated (Scheme 2). Compound **4** exhibited ^{1}H NMR and ^{13}C NMR resonances that were almost identical to those of $C_{60}H[C(NHCHPh_2)(CO_2Bu^t)]$[10] and **2**, except for those resonances associated with the different ester groups. The mono-ester **4** was also prepared in 58% yield from reductive ring opening of the methano[60]fullerene **5** (Scheme 3). In this case C_{60} (12%) and the reduced addend **6** (8%) were also isolated. The isolation of **6** supports our earlier proposed mechanism for these ring-opening reactions.[10,13]



Scheme 2

Thus we have demonstrated a general method for reductive ring opening of [60]fullerenes having a fused cyclopropane imino ester moiety. Both bis- and monomethano[60]fullerenes of this type give 1,2-dihydro[60]fullerylglycines, the latter by a novel tandem reductive ring opening-retro-Bingel reaction. In light of these results it can be concluded that the presence of the tether is not the driving force for the mono-elimination of one of the addends. While C_{60} is formed in all of these reactions it is only a minor component and thus the rate of elimination of one of these addends from the bismethanofullerene derivatives appears to be higher than the corresponding elimination of both addends. These results suggest that a dianion like **A** may be an intermediate in the tandem reductive ring opening-retro-Bingel reactions of **1** and **3**.



Scheme 3

The application of this chemistry to prepare more highly functionalised fullerenes is in progress. In principle, bis-cyclopropane imino esters can also function as directing and protecting groups for the synthesis of more highly functionalised fullerenes. For example, after the addition of further addends to the fullerene surface of **1** or **3** the bis-cyclopropane imino ester group could be then converted, under relatively mild conditions that would be compatible with a variety of other functional groups, to the mono-fullerylglycine moiety to give a variety of novel multifunctionalised fullerenes.

We thank the Australian Research Council for financial support and for a PhD scholarship to G. A. B.

12 Synthesis of **2**: Boron trifluoride–diethyl ether (0.104 g, 732.80 μmol) was added dropwise over 1 min to a solution of **1**[11] (0.095 g, 73.19 μmol) in DCM (100 mL) at 0 °C. The reaction mixture was allowed to warm to rt over a 30 min period when MeCN (50 mL) was added. Sodium cyanoborohydride (0.046 g, 732.80 μmol) was added to the reaction mixture which was stirred for 90 min and then concentrated *in vacuo*. The reaction mixture was redissolved in chloroform (100 mL) and washed with saturated ammonium chloride solution (10 mL), followed by saturated sodium bicarbonate solution (10 mL). The organic layer was dried ($MgSO_4$) and concentrated *in vacuo*. Column chromatography, eluting with DCM–hexane (90:10) provided [60]fullerene (0.006 g, 12%) and **2** (0.043 g, 42%) as a brown amorphous solid. UV/vis (DCM) 330 nm (sh, 15000), 435 nm (3000). ^{1}H NMR ($CDCl_3$ CS_2 (80 : 40), 600 MHz): d 3.37 (s, 2H), 3.66 (dd, 1H, J = 12.3, 2.7 Hz), 4.84 (s, 1H), 4.98 (d, 1H, J = 12.3 Hz), 5.07 (s, 2H), 5.24 (d, 1H, J = 11.9 Hz), 5.28 (d, 1H, J = 2.7 Hz), 5.41 (d, 1H, J = 11.9 Hz), 6.84 (s, 1H), 7.19 (t, 2H, J = 7 Hz), 7.23–7.38 (m, 14H), 7.41 (t, 2H, J = 7.9 Hz), 7.47 (t, 2H, J = 7.6 Hz), 7.64 (d, 2H, J = 7.8 Hz), 7.74 (d, 2H, J = 7.8 Hz). ^{13}C NMR ($CDCl_3$ CS_2 (80 : 40), 125 MHz): δ 172.39, 172.31, 154.03, 152.99, 152.17, 151.05, 147.50, 147.20, 147.07, 146.97, 146.43, 146.43, 146.42, 146.38, 146.33, 146.25, 146.19, 146.18, 146.16, 145.88, 145.75, 145.71, 145.58, 145.44, 145.42, 145.35 (2 × C), 145.31, 145.22, 144.74, 144.68, 144.38, 144.35, 143.17, 143.13, 143.11, 142.63, 142.58, 142.56, 142.43, 142.23, 142.14, 142.09, 142.06, 142.04, 142.01, 141.72, 141.70, 141.54, 141.49, 141.47, 140.39, 140.37, 139.62, 139.23, 137.34, 136.43, 136.32, 136.14, 135.45, 129.32, 129.12, 129.07, 129.04, 128.91, 128.71, 128.04, 127.68, 127.29, 127.26, 70.38, 67.74, 67.32, 66.56, 66.35, 66.09, 58.87, 49.08. MS(ES): *m/z* 1327 (M + 23), 720 (C_{60}).

13 The reduced addend was not isolated from the reactions involving **1** and **3** because of the small scales of these reactions.

Self-inclusion and paraffin intercalation of the *p-tert*-butylcalix[4]arene host: a neutral organic clay mimic†

Received (in Columbia, MO, USA) 6th November 2000, Accepted 18th January 2001
First published as an Advance Article on the web 6th March 2001

Two newly identified structures arise upon the crystallisation of the *p-tert*-butylcalix[4]arene host molecule from tetradecane: the guest-free, self-included host structure, and a 1:1 host–guest structure in which the paraffin guest is anchored in the bowl-shaped host cavity and intercalates layers of host molecules in a lamellar structure reminiscent of clays.

The crystal structures of inclusion compounds formed between the *p-tert*-butylcalix[4]arene host and small organic guest molecules have been studied extensively in order to understand guest-induced structural motifs, inclusion propensities and molecular recognition capabilities.[1] The bowl-shaped cavity of this relatively small supramolecular host molecule provides an excellent test site for isolating and probing the weak non-covalent host–guest interactions that prevail in much more complex supramolecular materials.[2] Essentially, three structural motifs have been observed with *p-tert*-butylcalix[4]arene inclusions with neutral guests: 1:1 and 2:1 host:guest structures,[3,4] and more recently, hydrogen-bonded structures formed with amine guests.[5] Herein we report two additional structures involving *p-tert*-butylcalix[4]arene that demonstrate the versatility of this host molecule to form multiple structural motifs under only slightly different synthetic conditions.

The host:guest ratio of compounds formed between linear hydrocarbon guests and *p-tert*-butylcalix[4]arene changes from 1:1 to 2:1 when the guest contains chains longer than six skeletal atoms, *e.g. n*-hexane or 1-chloropentane.[4,6] The longest paraffinic guest to form a 2:1 compound appears to be dodecane, with the alkane folded into a compact isomer in the double-sided host cavity.[6] With the next paraffin in the series, tetradecane, 2:1 host:guest inclusions no longer form, but rather two quite distinct motifs become apparent.

In the first instance, heating of *p-tert*-butylcalix[4]arene in a solution of tetradecane at 70 °C for three days yields guest-free crystals **1**,‡ since the solid-state ^{13}C CP MAS (cross-polarisation, magic angle spinning) NMR spectrum [Fig. 1(a)] of this compound shows tetradecane resonances to be absent. The multiplicity pattern of the host resonances is consistent with low-symmetry environments for the host molecule in the asymmetric unit.

The X-ray crystal structure of **1** (Fig. 2) shows that the host cavities are occupied by Bu^t groups of host molecules in the adjacent layer to form a self-included structure, such as seen with *p-tert*-butylcalix[5]arene.[7] The included Bu^t group is disordered over two positions with a site occupancy of 0.22/0.78. The shortest distance between the carbon atom of the included Bu^t group and the calixarene cavity wall is 3.4 Å. To transform the 1:1 structural motif, as seen with the pentane guest,[4] to the self-included bilayer structure, each calix is rotated off the 4-fold symmetry axis by 28° and moved towards the facing layer by 4.1 Å.

In the second instance, heating of the host molecule in tetradecane at 70 °C for eight days gives a structure with

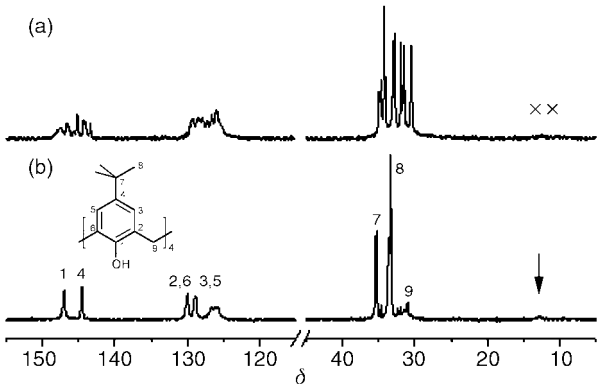

Fig. 1 Partial 50.3 MHz ^{13}C CP MAS NMR spectra: (a) self-included *p-tert*-butylcalix[4]arene **1**, (b) *p-tert*-butylcalix[4]arene–tetradecane inclusion/intercalation compound **1**·$C_{14}H_{30}$. Spinning sideband intensity is indicated by 'X'; the arrow indicates the tetradecane methyl resonance.

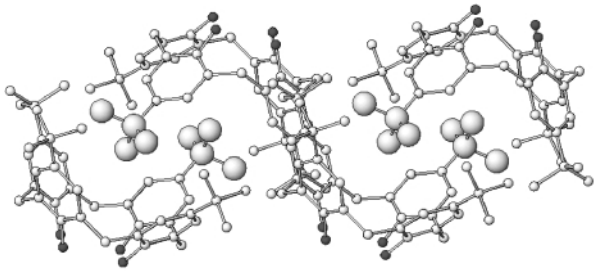

Fig. 2 Bilayer structure of the self-included *p-tert*-butylcalix[4]arene **1**. Hydrogen atoms are removed for clarity; oxygen atoms are black; cavity-filling *tert*-butyl carbons are shown at a larger radius for emphasis.

tetradecane present as guest‡ as indicated by the tetradecane resonances in the ^{13}C CP MAS NMR spectrum [Fig. 1(b)]. Whereas the guest methylene resonances are coincident with the host resonances, the tetradecane methyl line is distinct at δ 12.

Like inclusions formed with short-chain hydrocarbon guests,[2,4] the X-ray crystal structure of the second compound **1**·$C_{14}H_{30}$ shows a host:guest ratio of 1:1. The packing of the host layer (*ab* plane, $a \approx b$ with $\gamma \approx 90°$) is only slightly distorted from the tetragonal motif commonly observed in other 1:1 compounds. In all other aspects, the structure of the second compound is quite distinct. The most notable feature is the pillaring of the host layers by the guest molecules. The structural model from diffraction refines to give two coexisting structural schemes that are consistent with this pillaring. In the first, one end of the guest is tethered in a host cavity, and at the point where the chain leaves the cavity it bends into the interlamellar space in a pillaring fashion [Fig. 3(a)]. The second scheme has two guest positions. One guest has both ends of the molecule tethered in host cavities of two adjacent bilayers and the second occupies vacant interlamellar space between pillaring guests [Fig. 3(b)]. In both schemes the host positions are

DOI: 10.1039/b009133m

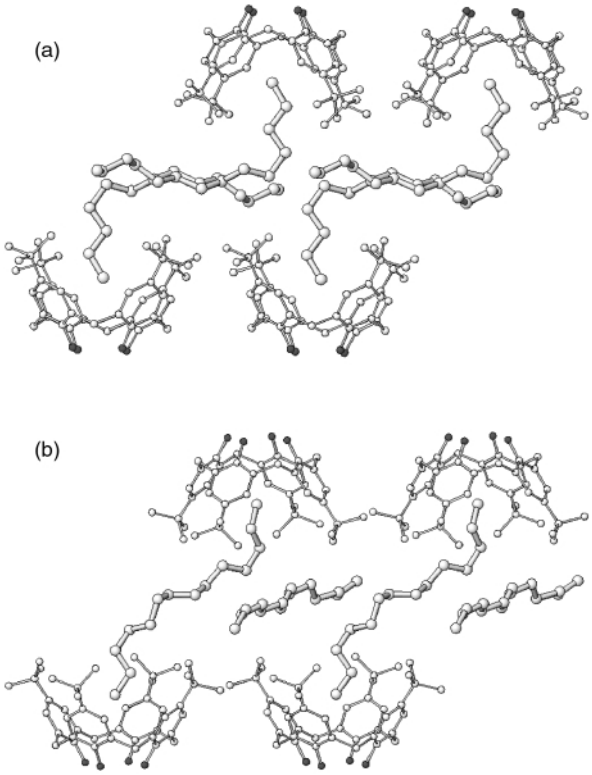

Fig. 3 Bilayer structure of the *p-tert*-butylcalix[4]arene–tetradecane inclusion/intercalation compound **1**·$C_{14}H_{30}$. (a) The end-to-interlayer spacing motif, (b) the end-to-end motif. Disordering in guest and host has been removed for clarity. Hydrogen atoms are removed for clarity; oxygen atoms are black.

identical, whereas the guest positions are disordered over two positions. The guest molecule in the interlayer space has a near all-*trans* conformation, but guest molecules that are included at either or both ends, are very different. All Bu^t groups in both structures are disordered over two positions with the site occupation *ca.* 0.5 , 0.4 to 0.6 and 0.3 to 0.7.

The bilayer structure of sodium calix[4]arenesulfonate, with the interlayer spacing occupied by water, has been compared to that of a clay.[8] The intercalated structure reported here shows a similar structure, although here it is a strictly neutral organic material, with lipophilic rather than hydrophilic regions. Examination of the bilayers of the 1:1 and 2:1 *p-tert*-butylcalix[4]arene–guest structural motifs suggests that the hydroxyl ends of the calixarenes are sufficiently polar to favour their mutual interaction in the bilayer, but allowing intercalation in the less polar interlamellar space. The present intercalated structure has well ordered layers separated by highly disordered interlayer regions giving a rather high diffraction *R*-value typical of clays. Clays also have the ability to tune the interlayer space by the intercalation of appropriate guests.[9] The *p-tert*-butylcalix[4]arene–tetradecane structure suggests that the distance between host bilayers may be tuned by intercalation of paraffins of appropriate length, and work to check this is currently in progress. Finally, noting that the self- and guest-included structures result from only slightly different crystallisation conditions, we anticipate that forming structures of *p-tert*-butylcalix[4]arene–tetradecane favouring only one of the two guest–host schemes (Fig. 3) may be possible by judicious choice of crystallisation conditions.

We have identified two new structural arrangements of supramolecular materials involving *p-tert*-butylcalix[4]arene. The self-included structure illustrates the collapsed lattice that likely occurs upon complete loss of guest from a *p-tert*-butylcalix[4]arene–guest inclusion compound. The structure formed with long paraffinic guests indicates synthetic access to a new class of calixarene-based lipophilic organic clay mimics. An upper limit to the length of the intercalating guests remains to be determined.

Homologous families of chloride-rich 4,4′-bipyridinium salt structures†

First published as an Advance Article on the web 6th March 2001

New layer and three-dimensional 4,4′-bipyridinium salts of Cl^-, $[MCl_6]^{2-}$ (M = Os, Pt) and $[FeCl_5]^{2-}$ contain $NH\cdots(Cl)_2\cdots HN$ interactions which form hydrogen bonded ribbons which in turn give one-, two-, or three-dimensional periodic networks; two related families of homologous motifs are present in these salts together with those of square planar, polymeric and tetrahedral $[MCl_4]^{2-}$ (M = Pt, Pd, Mn, Cd, Pb, Co, Zn, Hg), planar $[Cu_2Cl_6]^{2-}$ and square pyramidal $[SbCl_5]^{2-}$ dianions.

In the search for reliable strategies for crystal synthesis by design a key goal is the identification and exploitation of robust synthons[1] to control the relative orientation of the molecular components of the solid. While such local interactions (such as hydrogen bonds) may be necessary they may not be sufficient to afford control over the crystal structure or even the periodic network formed by synthons. Various possibilities may exist in which the same synthons are present but different although related structures form. In this paper we explore the relationships between the structures formed by complex salts containing similar molecular components and having closely related hydrogen bond-based synthon networks.

We have shown that chlorometallate anions and other metal chloride complexes are good hydrogen bond acceptors.[2] This has enabled preparation of three classes of tetrachlorometallate salts of stoichiometry $[4,4'\text{-}H_2bipy][MCl_4]$.[3] For square planar anions $[MCl_4]^{2-}$ (M = Pt, Pd), linear hydrogen bonded ribbons of type **A** are formed (see Scheme 1). When M = Pb, Mn or Cd the $[MCl_4]^{2-}$ moiety is polymerised and the zig-zag edge-sharing octahedral chains formed are cross-linked by hydrogen bonds to form **A**-type periodic motifs. The third family of structures has tetrahedral anions $[MCl_4]^{2-}$ (M = Zn, Co, Hg). Here we report that the simplest chlorine-containing salt of $[4,4'\text{-}H_2bipy]^{2+}$, $[4,4'\text{-}H_2bipy]Cl_2$ **1** itself, has a structure which presages the NH···Cl motifs in a large number of more complex chlorometallate salts. These more complex structures may be regarded as part of homologous families of structures formally derived from that of the chloride salt.

Treatment of metal chloride salts with aqueous HCl solutions of 4,4′-bipyridine led to isolation of crystalline salts **2**–**4**‡ whose single crystal structures were determined.§ Crystals of **2** and **3** are strictly isostructural and, as expected, have metal ions in essentially regular octahedral coordination. Compound **4** contains the rare trigonal bipyramidal $[FeCl_5]^{2-}$ ion, which has not apparently previously been obtained from aqueous media.[4] Presumably its isolation in this case is due to its stabilisation in the solid state through the network of hydrogen bonds formed (see below). The bipyridinium ions $[4,4'\text{-}H_2bipy]^{2+}$ in **1**–**4** have normal geometries.

All of these structures contain motif **B**, in a doubled form, **C**, as do the $[4,4'\text{-}H_2bipy]$ salts of the tetrahedral $[MCl_4]^{2-}$ anions (M = Zn, Co, Hg) **5**–**7**.[3c] The dimensions of units **B** are given in Table 1 for **1**–**4** and **5**–**7**[3c] and $[4,4'\text{-}H_2bipy][PtCl_4]$ **8**.[3c] They show some variation in geometry, notably for **5**–**7**, in which one of the NH···Cl contacts is *ca.* 3 Å. In **1**, ribbons of type **D** are formed because interaction **C** is present at both ends of the bipyridinium ion. The same **D**-type ribbons are present in the

[a] Only Cl···HN contacts < 3.15 Å are listed.[2] Other hydrogen bonds (notably Cl···HC)[5] are omitted for brevity. [b] Values quoted for hydrogen bonds are based on hydrogen atom positions determined by X-ray diffraction. [c] Two-centre interaction, not involved in **C**-type interaction.

structures of **2**, **3** and **4** albeit in a form in which the chloride is also bonded to a metal ion (*i.e.* as in **E**). Ribbons **A** are present in [4,4′-H_2bipy][MCl_4] for M = Pt, Pd, Mn, Cd and Pb,[3c] in which the pair of Cl^- ions in **D** are replaced by a planar MCl_4 moiety (see **F**). In [4,4′-H_2bipy][Cu_2Cl_6][6] (see **G**) the planar anion contains two square planar metals and takes the place of the two chlorides in **D**. Therefore, **G** may be regarded as the next higher homologue in the sequence **D**, **F**, **G**.

In **2**–**4** ribbons of type **D** are cross-linked by the metal ions (see **E** and **H**) so that *trans* chlorides at the metal belong to different ribbons. In the isostructural salts **2** and **3** these chains are parallel and coplanar and therefore neutral layers are formed (see Fig. 1). These contain a (4,4) network[7] with motif **E** at the nodes and equal numbers of organic (bipyridyl) and inorganic (metal) connections. In **4** the trigonal bipyramidal $[FeCl_5]^{2-}$ dianions link ribbons inclined at 55° to one another and a three-dimensional structure results in which there are two sets of criss-cross **D**-type ribbons (see Fig. 2) with every second ribbon parallel and coplanar. The network formed here is of the rare $CdSO_4$ type in which nodes of square-planar connectivity (here motif **E**) are linked in a three-dimensional manner.[8,9] Salts **5**–**7** also contain motif **C** but as part of a double-stranded chain (see **I**) in which only one end of the dication is engaged in a **C**-type interaction, the other forming a short, two-centre hydrogen bond with just one chloride ligand (see ref. 3*c* for further details on this interaction). Finally, it is striking that of the two known polymorphs[10] of the [4,4′-H_2bipy] salt of the square pyramidal anion $[SbCl_5]^{2-}$ one has layers of form **H** and the other contains ribbons of type **A**.

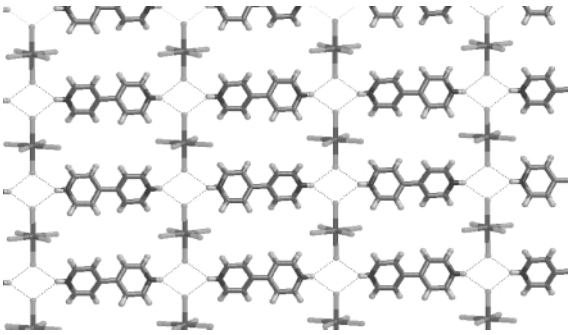

Fig. 1 A hydrogen bonded layer present within the crystal structure of [4,4′-H_2bipy][$OsCl_6$] **2**. Compound **3** is isostructural with **2**.

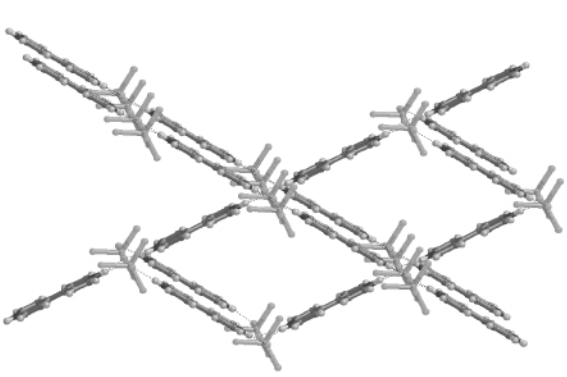

Fig. 2 A view of the crystal structure of [4,4′-H_2bipy][$FeCl_5$] **4**.

Indeed, all of the perchlorometallate [4,4′-H_2bipy] salts whose structures are known to us (as judged by the content of the current release of the Cambridge Structural Database[11] and as reported or cited here) incorporate motif **C**.

The recurrence of motif **C**, in periodic motif **D** and the derived **F**–**I** in this range of structures (and various analogous bromide salts)[3] implies that **C** is a robust feature of such salts.

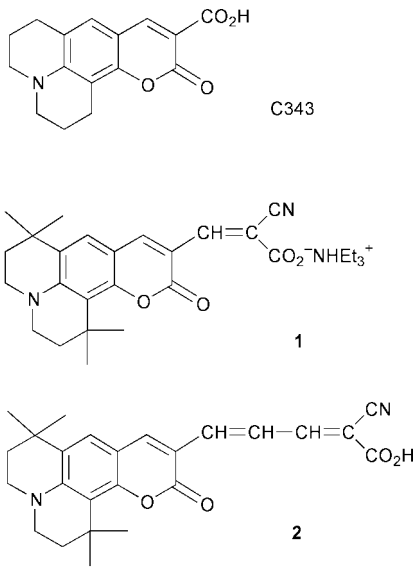
First published as an Advance Article on the web 6th March 2001

It is found that newly synthesized coumarin derivatives work as highly efficient photosensitizers for dye-sensitized nanocrystalline TiO_2 solar cells producing a 5.6% solar-light-to-electricity conversion efficiency, the highest efficiency so far among organic dye-sensitized solar cells, with a short-circuit current density of 13.8 mA cm^{-2}, an open-circuit photovoltage of 0.63 V, and a fill factor of 0.63 under standard AM 1.5 irradiation (100 mW cm^{-2}).

Dye-sensitized solar cells have been extensively investigated since Grätzel and coworkers reported a highly efficient solar-energy-to-electricity conversion efficiency, η, of 10%.[1] Transition metal complexes, *e.g. cis*-di(thiocyanato)bis(4,4′-dicarboxy-2,2′-bipyridine)ruthenium(II) [$Ru(dcbpy)_2(NCS)_2$], have been mainly applied, so far, in dye-sensitized solar cells as photosensitizers.[1–4] Organic dyes have been also used as photosensitizers for dye-sensitized solar cells.[5–9] Recently we reported a dye-sensitized TiO_2 solar cell, using special merocyanine dye aggregates as the photosensitizer, which showed a highly efficient η of 4.2%.[7] This result encouraged us to look for more efficient organic dye photosensitizers for dye-sensitized TiO_2 solar cells.

Coumarin dyes, *e.g.* coumarin 343 (C343) (Scheme 1), are recognized as good organic dye photosensitizers, injecting electrons effectively into the conduction band of semiconductors.[10,11] For example, Murakoshi *et al.* observed an ultrafast electron injection (< 20 fs) from C343 into the conduction band of TiO_2.[11] The η values of nanocrystalline semiconductor solar cells using conventional coumarin dyes such as C343 as the photosensitizer is, however, much lower than that of solar cells sensitized by Ru complex photosensitizers because of the narrow absorption area in the visible region. A wide absorption range in the visible region for the coumarin dye is required to attain highly efficient solar-energy-to-electricity conversion. We have synthesized new coumarin derivatives which are able to absorb visible light from 400 up to 700 nm and prepared highly efficient dye-sensitized nanocrysalline TiO_2 solar cells using such new coumarin photosensitizers. The value of η increased up to 5.6%, the highest efficiency among organic dye-sensitized solar cells so far, using 2-cyano-5-(2,3,6,7-tetrahydro-1,1,7,7-tetramethyl-11-oxo-1*H*,5*H*,11*H*-[1]benzopyrano[6,7,8-*ij*]quinolizin-10-yl)penta-2,4-dienoic acid **2** as the photosensitizer. It should be noted that the photocurrent performance of a TiO_2 solar cell composed of this dye (compound **2**) is almost equal to that of the $Ru(dcbpy)_2(NCS)_2$ system.



Scheme 1 Molecular structure of new coumarin derivatives.

Compound **1**† was synthesized by refluxing an acetonitrile solution containing 2,3,6,7-tetrahydro-1,1,7,7-tetramethyl-11-oxo-1*H*,5*H*,11*H*-[1]benzopyrano[6,7,8-*ij*]quinolizin-10-carbaldehyde **3** and cyanoacetic acid in the presence of piperidine, and purified by column chromatography using silica gel and a chloroform–methanol mixed solvent as the eluting solution. Recrystallization of **1** from acetonitrile solution in the presence of triethylamine afforded a red purple crystalline triethylammonium salt. 3-(2,3,6,7-Tetrahydro-1,1,7,7-tetramethyl-11-oxo-1*H*,5*H*,11*H*-[1]benzopyrano[6,7,8-*ij*]quinolizin-10-yl)propenal **4** was prepared from **3** by Wittig reaction and then Vilsmeier–Haack reaction. Compound **2**† was synthesized starting from **4** and cyanoacetic acid by a similar procedure for **1**. Resulting precipitates of **2** were dissolved in DMF and a bright purple crystalline compound was obtained upon recrystallization.

TiO_2 nanoparticles were prepared by hydrolysis of Ti tetraisopropoxide as described elsewhere.[12,13] TiO_2 thin films were prepared by screen printing on transparent conducting oxide (TCO, F-doped SnO_2) and then sintered at 500 °C for 1 h. Nanocrystalline TiO_2 films (10–13 μm thick) were coated with dyes by dipping the film in 3×10^{-4} mol dm^{-3} dye solutions in ethanol or *tert*-butyl alcohol–acetonitrile (1:1). The dye-coated TiO_2 electrode was incorporated into a thin-layer sandwich-type cell with a Pt sputtered TCO as the counter electrode, a spacer film, and an organic electrolyte solution to measure the solar cell performance. The electrolyte was 0.6 mol dm^{-3} 1,2-dimethyl-3-propylimidazolium iodide (DMPImI)–0.1 mol dm^{-3} LiI–0.05 mol dm^{-3} I_2 in methoxyacetonitrile. η Values for solar cells were measured using a standard AM 1.5 solar simulator and a digital sourcemeter.

Absorption spectra of C343, compounds **1** and **2** in ethanol and compound **2** adsorbed on a transparent TiO_2 film (4 μm thick) are shown in Fig. 1. The threshold wavelengths of absorption spectra for compounds **1** and **2** are 570 and 630 nm, respectively, while that for C343 was 500 nm, indicating that introducing the –CH=CH– unit into the coumarin framework expanded the conjugation in the dye resulting in wide absorption in the visible region. This wide absorption and red shift of absorption maximum in the visible region for photosensitizers is desirable for light harvesting of solar energy. The absorption spectrum of compound **2** adsorbed on a TiO_2 film is

DOI: 10.1039/b010058g

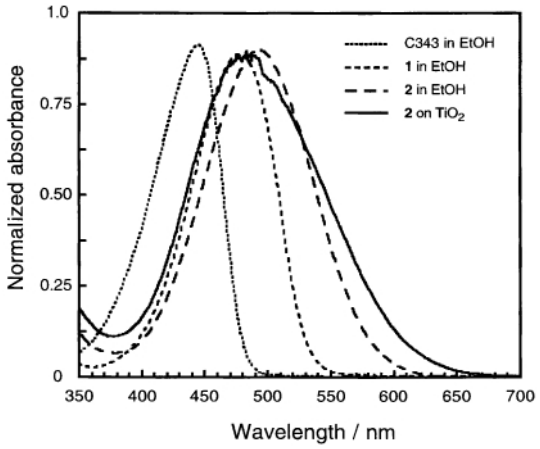


Fig. 1 Absorption spectra of C343, **1** and **2** in EtOH, and of **2** adsorbed on a TiO_2 film whose absorbance is normalized: (- - - - - -) C343, (– – –) **1** in ethanol, (— —) **2** in ethanol, (—) **2** adsorbed on TiO_2.

slightly expanded compared with that in ethanol. A long tail of absorption up to 670 nm was observed, indicating a strong electronic coupling between compound **2** and TiO_2. The absorption spectrum of compound **2** absorbed on TiO_2 films thicker than 10 μm gave an absorption band edge which tailed up to 750 nm, the deep purple film being similar to that of the Ru complex.

Fig. 2 shows typical action spectra of incident photon-to-current conversion efficiencies (IPCE) obtained from nanocrystalline TiO_2 solar cells sensitized by compound **2** as well as $Ru(dcpby)_2(NCS)_2(TBA)_2$. Visible light (400–750 nm) can be converted to current with a maximum of 76% at 470 nm by the solar cell composed of compound **2**, producing a large photocurrent.

Taking into consideration light absorption loss by TCO-coated glass, the light-to-current conversion efficiency is close to 100% from 450 to 550 nm. Both a large amount of compound **2** adsorbed on to a TiO_2 film (10 μm thick), 1×10^{-7} mol cm^{-2}, and the large absorption coefficient of dye (compound **2**) itself, *e.g.* 52 500 dm^3 mol^{-1} cm^{-1} at 504 nm in methnol, increased the light harvesting efficiency. The coverage of the TiO_2 surface with the dye was *ca.* 70% as derived from the roughness factor of the film, 1000, and the cross sectional area of one dye molecule, 1.2 nm^2. It should be noted that the IPCE performance of the solar cell with **2** is almost equal to that of the $Ru(dcbpy)_2(NCS)_2$ system, as shown in Fig. 2. The maximum short-circuit photocurrent density (J_{sc}) for a **2**-sensitized TiO_2 solar cell reached 15 mA cm^{-2} under AM 1.5 irradiation (100 mW cm^{-2}).

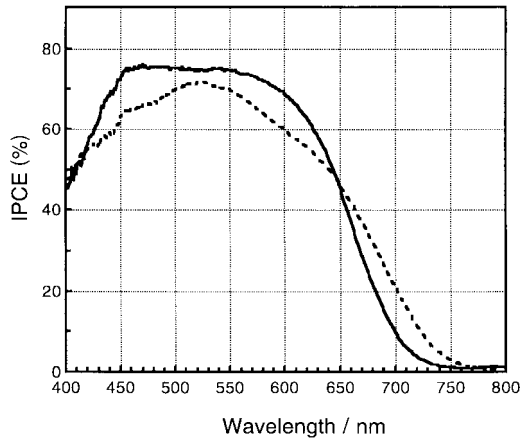

Fig. 2 Typical action spectra of incident photon-to-current conversion efficiencies (IPCE) obtained for nanocrystalline TiO_2 solar cells sensitized by **2** (—) and $Ru(dcbpy)_2(NCS)_2(TBA)_2$ (- - - -).

The lowest unoccupied molecular orbital (LUMO) of **2** (measured electrochemically) at −0.8 V *vs.* NHE, is able to inject electrons into the conduction band of the TiO_2 electrode (−0.5 V *vs.* NHE).[13] Good stability of the dye under irradiation for 2 days, with a turnover number of 100 000, was observed by a brief experiment using an opened cell, indicating effective cycling from the ground state of compound **2** to the oxidized form with efficient electron transfer from the dye to TiO_2 and from I^- ions to the oxidized dyes. Detailed investigation of the long term stability of the dye using a sealed cell will be carried out.

The maximum efficiency for the **2**-sensitized TiO_2 solar cell was 5.6% with a J_{sc} of 13.8 mA cm^{-2}, an open-circuit photovoltage (V_{oc}) of 0.63 V, and a fill factor (*ff*) of 0.63 under standard AM 1.5 irradiation, which is the highest solar cell performance, so far, among organic dye-sensitized solar cells. Our results strongly support the prospect for promising application of organic dye photosensitizers in dye-sensitized nanocrystalline semiconductor solar cells, and indicate the importance of molecular structure design for tuning photosensitizers to produce high efficiency dye-sensitized solar cells. If electron injection occurs through chemical bonding of the carboxyl group, the structures of compound **1** and **2**, whose carboxyl group is directly connected to the conjugated methine chain, is advantageous for improving the injection of electrons into semiconductors. In addition, the cyano group (–CN) connected to the methine chain and the carboxyl group might be effective for electron injection due to their strong electron acceptability. We are currently synthesizing new dyes absorbing in a wider visible region and studying solar cell performance and mechanisms in detail.

Hexadentate cluster anions $[Re_6S_8(CN)_6]^{4-}$ coordinate to Mn(II) centers to give a neutral 3D coordination network topologically related to the structure of Prussian Blue; the residual space is filled with isopropyl alcohol molecules, both ligated to Mn(II) and guest-solvated.

For three centuries, polydimensional metal cyanides have intrigued chemists with their diversity and unique properties.[1] Representatives include the oldest synthetic coordination compound Prussian Blue‡[2,3] which gives rise to a wide family of 'blues' and 'greens',[1–4] Hofmann and related clathrates,[5] and inclusion compounds formed by cadmium cyanide.[6] Today, cyanide complexes are important elements in crystal engineering.[7] Very recently, the cyanide cluster complexes $[Re_6X_8(CN)_6]^{4-}$ (X = S, Se, Te)[8] capable of acting as octahedral hexadentate ligands have become available. The first structural studies were performed for salts (usually hydrated) of these cluster anions, where pure ionic packing or H-bonded systems were found.[8] Incorporation of M(II) cations (Mn, Fe, Co, Zn, Cd)[9–12] resulted in layered coordination polymers. With M(II) (Mn, Co, Ni) and tetrapropylammonium cations 0D, 1D and 2D structures were obtained.[13] Salts reported with negatively charged 3D coordination frameworks include $Cs_2Mn_3[Q]_2\cdot 15H_2O$ [Q = $Re_6Se_8(CN)_6$], $(H_3O)_2Co_3[Q]_2\cdot 14.5H_2O$,[14] Cs_2[*trans*-$Fe(H_2O)_2]_3[Q]_2\cdot 18H_2O$ and its Mn, Co, Ni and Cd analogs,[9] $(H_3O)_2Zn_3[Q]_2\cdot 20H_2O$[15] and others,[11,12,16] with plenty of water molecules as well as metal or H_3O^+ cations filling the space of the open pore system.

In the course of our efforts to design novel porous materials with a high propensity for absorbing organic species[17] we have exploited cyanide cluster complexes as prospective building units. For this purpose the capability of the cluster anions to create weakly charged or electrically neutral 3D-bonded networks seems essential. The 3D phase $[Zn(H_2O)]_2[Re_6S_8(CN)_6]\cdot 7H_2O$ has been reported[9] but is of low inclusion capacity as it contains two interpenetrating neutral frameworks. Dehydrated $Ga_4[Re_6Se_8(CN)_6]_3\cdot xH_2O$ and $Fe_4[Re_6Te_8(CN)_6]_3\cdot xH_2O$,[16] $[Cd_2(H_2O)_4][Re_6S_8(CN)_6]_3\cdot 14H_2O$,[18] have been reported to absorb alcohols; $[Co_2(H_2O)_4][Re_6S_8(CN)_6]\cdot 10H_2O$ and $[Co(H_2O)_3]_4[Co_2(H_2O)_4][Re_6Se_8(CN)_6]_3\cdot 44H_2O$ have demonstrated vapochromic behavior during exposure to organic solvents. Structural studies showing included organic species are not available so far, however. We report here, for the first time, on a 3D polymer formed from Mn(II) cations bound to $[Re_6S_8(CN)_6]^{4-}$ cluster anions in molar ratio of 2:1 where the residual space is filled with organic molecules, in this case isopropyl alcohol.

Red octahedral crystals of the compound were grown in the course of slow diffusion of isopropyl alcohol vapor into a solution of 70 mg $K_4[Re_6S_8(CN)_6]$ [0.04 mmol; see ref. 8(*c*) for synthesis], 25 mg $MnSO_4\cdot 5H_2O$ (0.10 mmol), and 7 mL of water. A single crystal was maintained inside a sealed capillary filled with supernatant solution and studied by X-ray diffraction.§ The chemical formula derived therefrom was $\{[Mn(Pr^iOH)_2(H_2O)]_2[Re_6S_8(CN)_6]\}\cdot 2Pr^iOH$. A fine crystalline product was prepared by mixing saturated solutions of 170 mg $K_4[Re_6S_8(CN)_6]$ (0.1 mmol) and of 70 mg $MnSO_4\cdot 5H_2O$ (*ca.* 0.3 mmol) in water–isopropyl alcohol (1:3 v/v). A powder diffractogram of the bulky fresh product corresponded well to that calculated from single-crystal X-ray diffraction data, but the elemental analysis was not satisfactory because the compound readily lost isopropyl alcohol when exposed to air. The position of the ν(CN) band at 2143 cm^{-1} in the IR spectrum (in liquid paraffin) corresponded to a bridging cyanide group, values close to 2134–2138 cm^{-1} were found previously for cyanides bridging the 'Re_6S_8' core with Mn(II), Fe(II), Co(II) and Cd(II).[10]

The geometry of the anion fragment $[Re_6S_8(CN)_6]^{4-}$ found in the structure [Fig. 1(a)] is similar to those previously reported.[9–11,13,18] The Re_6 cluster is an almost ideal octahedron with Re–Re distances of 2.598–2.602 Å, the sulfur atoms capping each triangular face at Re–S distances of 2.399–2.414 Å. Six cyanide ligands coordinate to rhenium atoms through carbon with C–N distances of 2.117–2.118 Å, sticking out in pairs in a mutually perpendicular fashion.

The Mn(II) center has an 'N_3O_3' octahedral environment [Fig. 1(b)]. Three mutually perpendicular bonds extend to cyanide nitrogens, connecting each center to three neighboring cluster anions with Mn–N distances of 2.16–2.19 Å. The coordination octahedron is completed by three oxygen atoms from one water [at 2.220(7) Å] and two isopropyl alcohol molecules [2.230(7) and 2.259(6) Å for molecules A and B, respectively]. There is one further isopropyl alcohol molecule which is not chemically bound to the metal center, as it is H-bonded to ligand water with an O(water)–O(Pr^iOH) distance of 2.65(2) Å.

In the crystal structure, two Mn(II) centers are located about the inversion center, with an Mn–Mn distance of ≈5.3 Å. Isopropyl alcohol molecules attached to one center penetrate between isopropyl alcohol molecules attached to another center. The resulting packing associate $\{[Mn(Pr^iOH)_2(H_2O\cdots$

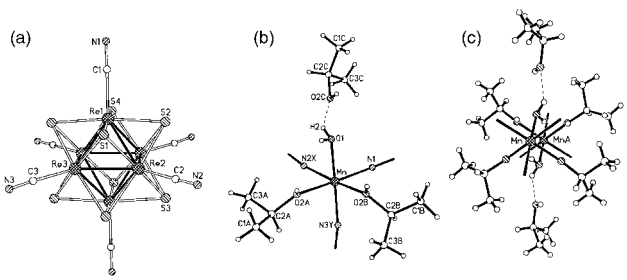

Fig. 1 The structure of the $[Re_6S_8(CN)_6]^{4-}$ cluster anion (a), coordination environment of Mn(II) (b), and the $\{[Mn(Pr^iOH)_2(H_2O\cdots Pr^iOH)]_2\}^{4+}$ associate. Hydrogen bonds are shown with dashes. N2X and N3Y arise from N2 and N3 atoms through $(-1/2 + x, 1/2 - y, 1 - z)$ and $(3/2 - x, -y, -1/2 + z)$ operations, respectively; the MnA atom rises from Mn through centrosymmetry.

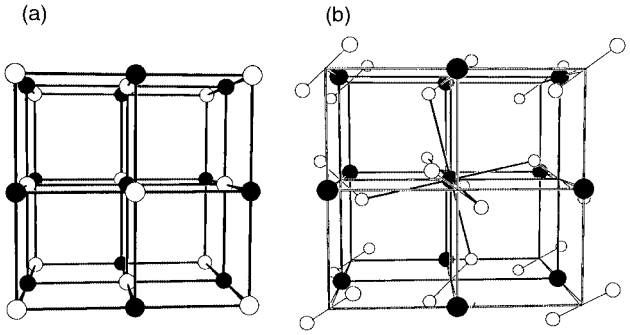

Fig. 2 3D coordination motif in Prussian Blue (a) [one unit cell is shown; black spheres show Fe(III) and open spheres show Fe(II) cations] compared to the 3D framework of the title compound (b) (one unit cell, schematic drawing: black spheres replace the cluster anions [Fig. 1(a)] and pairs of open spheres connected by single lines represent the associates [Fig. 1(c)]; coordination to manganese atoms is shown by solid lines for only the central cyanide cluster.

$Pr^iOH)]_2\}^{4+}$ is shown in Fig. 1(c). It should be noted that this fragment is complementary to the $[Re_6S_8(CN)_6]^{4-}$ cluster as it bears an equal but opposite charge and possesses six octahedrally disposed acceptor coordination sites (three about each Mn).

The 3D coordination framework in the structure shows profound parallels with the main structural motif of Prussian Blue; the latter is shown in Fig. 2(a).[2,3] In the structure of our work the $[Re_6S_8]^{10-}$ and $\{[Mn(Pr^iOH)_2(H_2O\cdots Pr^iOH)]_2\}^{4+}$ units play the role of Fe centers of two different types; each unit has six neighbors of another type attached approximately octahedrally through six cyanide bridges [Fig. 2(b)]. The unit cell of Prussian Blue is cubic with an *a*-parameter of 10.2 Å. The inner space within the smaller cubes is large enough to accommodate alkali metal cations and water molecules. The 3D framework of our structure also has a cubic motif distorted to orthorhombic. But the average unit cell parameter of 16.8 Å is dramatically larger than that in Prussian Blue. From the estimated volume of the $\{Mn_2[Re_6S_8(CN)_6]\}$ the framework occupies not more than 34% of the overall structure, with the residual empty space of 3120 Å^3 concentrated mainly in the eight smaller cubes of the unit cell. Moreover, the neutral charge of the framework makes it more hydrophobic. Such factors explain the filling of the inner space with isopropyl alcohol molecules, both as ligands and as solvating species. A cut-away layer of the 3D framework is shown in Fig. 3(a) and the packing of isopropyl alcohol solvate species inside the smaller cubes is shown in Fig. 3(b).

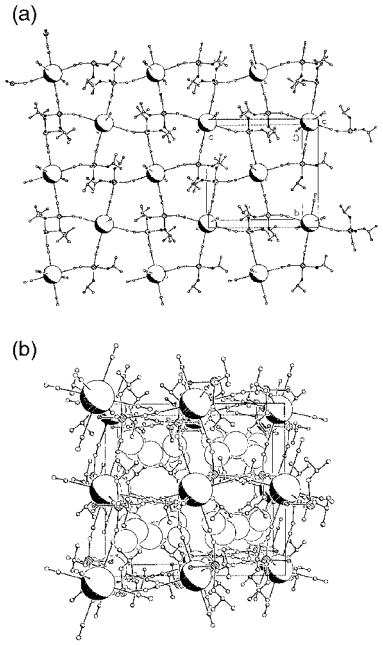

Fig. 3 Cut-away layer of the 3D framework in the title material (a) (coordinated water and isopropyl alcohol molecules are also shown) and packing of guest-solvated isopropyl alcohol molecules (van der Waals dimensions) in the small cube cavities (b). For clarity, cluster cores Re_6S_8 are replaced with 1.5 Å spheres.

Prussian Blue and related compounds form an extensive class of 3D coordination polymers revealing a remarkable stability of the main architecture and the ability to include small molecules and cations. This study demonstrates how utilization of cluster cyanides makes it possible to design analogous polymers but displaying a propensity to include species of larger size and lower polarity, thus making these useful materials for absorbing common organics.

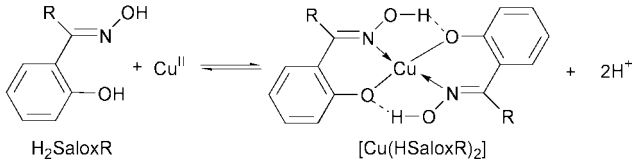
Received (in Cambridge, UK) 20th November 2000, Accepted 16th February 2001
First published as an Advance Article on the web 7th March 2001

Solvent extraction of Ni^{II} by phenolic oximes is enhanced significantly by addition of aliphatic diamines; octahedral [Ni(II)(phenolate-oxime)$_2$(diamine)] complexes have been characterised that contain a novel folded conformation, retaining intramolecular hydrogen bonding between the two oxime ligands.

Hydrometallurgical processes based on solvent extraction are becoming increasingly important[1] in the recovery of metals. Approximately 20% of the worldwide production of copper now involves solvent extraction using phenolic oximes (H_2SaloxR, Scheme 1) derived from salicylaldehydes (R = H) or *o*-ketophenols (R = alkyl). These reagents are able to transfer Cu^{II} from acidic sulfate media containing a high concentration of Fe^{III}.[2,3] An important aspect of the chemistry involved in this solvent extraction is the formation of square-planar [Cu(HSaloxR)$_2$] complexes, stabilised by interligand hydrogen bonding (Scheme 1).[4]



Scheme 1 The 'pH-swing' equilibrium for the acid leach/solvent extraction/electrowinning circuits for copper production; the phenolic oximes (H_2SaloxR) are derived from a salicylaldehyde (R = H) or an *o*-ketophenol (R = alkyl).[2,3]

Phenolic oxime reagents (H_2SaloxR) are not effective extractants for nickel in commercial solvent extraction processes because their $pH_{1/2}$ (the pH for 50% loading of the extractant as [Ni(HSaloxR)$_2$]) values are not sufficiently low to allow recovery from acidic feeds and the kinetics of the extraction process tend to be poor.[3] We have investigated the use of aliphatic acyclic polyamines (B) as agents for enhancing the solvent extraction of Ni^{II} by phenolic oximes. This approach was based on earlier observations that the extraction of Ni^{II} from aqueous media is enhanced when combinations of ligands are used, *e.g.* salicylic acid plus an aliphatic acyclic diamine[5] or salicylaldoxime plus a monodentate *N*-heterocycle.[6]

The extraction experiments accomplished and the results obtained are summarised in Table 1. The extent of the extraction of Ni^{II}, from H_2O into CH_2Cl_2, was significantly greater for H_2SaloxH plus a diamine, as compared with the extent of extraction by either reagent alone. The addition of a diamine (B) to a mixture of Ni^{II} and H_2SaloxH would be expected to favour extraction of the Ni^{II}, since B will act as a base and displace the equilibrium of Scheme 1 and, therefore, increase the amount of [Ni(HSaloxH)$_2$] **1** formed. However, the improvement in the efficiency of the extraction that we have observed may also involve two other contributing effects.

Firstly, we have obtained evidence for ligand assembly[7] between H_2SaloxH and representatives of the diamines listed in Table 1. In particular, the isolation and crystallographic characterisation of [(H_2SaloxH)$_2$(Me_4en)], plus ^{1}H NMR spectra recorded for a combination of these two reagents in $CDCl_3$ solution,[8] clearly demonstrate that H_2SaloxH and Me_4en form a 2:1 assembly. This ligand assembly would make a favourable contribution to the entropy of formation of [Ni(HSaloxH)$_2$(Me_4en)] **2** and related complexes.[7]

Secondly, the addition of each of the diamines (B) to a solution of **1** in CH_2Cl_2 (1:1) produced a colour change from the dark green of **1** to a shade of blue or red, depending upon the nature of B, and produced 1:1 complexes, [Ni(HSaloxH)$_2$B].† These processes have been followed by UV–VIS–NIR spectroscopy and the general result obtained is exemplified in Fig.1, for the addition of aliquots of pn to a solution of **1** in CH_2Cl_2. In each case, a stepwise increase in the absorbance at *ca.* 900 nm was observed, together with a concomitant decrease in the absorbance and a slight shift to higher energy in the λ_{max} at *ca.* 600 nm. An isosbestic point was observed in each titration, consistent with the reaction proceeding by a simple process. The variation of the absorbance at λ_{max} of 600 and 900 nm with the reagent ratio indicated that **1** and B interact with a 1:1 stoichiometry.

Isolation and recrystallisation of the solids formed by reacting [Ni(HSaloxR)$_2$] and B (1:1) in CH_2Cl_2 produced crystalline materials of composition [Ni(HSaloxR)$_2$B]. The compounds for which R = H, B = Me_4en (**2**)‡ or pn and R =

Table 1 Percentage of Ni^{II} extracted from an aqueous medium into CH_2Cl_2 using a base (B) plus salicylaldoxime (H_2SaloxH)[a]

N,*N*'-Me_2pn	32	98	100	100
Me_4en	37	59	86	100

[a] The extraction experiments were carried out using mechanically-shaken and stoppered vials containing $Ni(NO_3)_2 \cdot 6H_2O$ (1 mM) in H_2O (5 cm^3) and H_2SaloxH (2 mM) and B (1–3 mM) in CH_2Cl_2 (5 cm^3). Each system was equilibrated for 4 h at 25 °C and the concentration of nickel in the aqueous phase was then determined by atomic absorption spectroscopy. H_2SaloxH (2 mM) alone extracted 13% of the Ni^{II}. Each of the reported values is an average of three experiments and has an estimated error of ±3%. Abbreviations for B: *N*,*N*-Me_2en = *N*,*N*-dimethylethylenediamine; *N*,*N*'-Me_2en = *N*,*N*'-dimethylethylenediamine; pn = 1,3-diaminopropane; *N*,*N*'-Me_2pn = *N*,*N*'-dimethyl-1,3-diaminopropane; Me_4en = *N*,*N*,*N*',*N*'-tetramethylethylenediamine.

DOI: 10.1039/b009267n

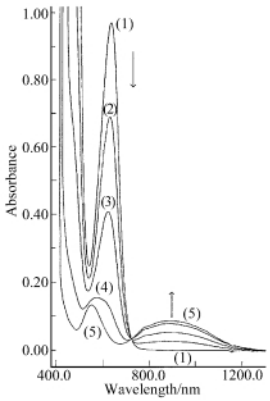

Fig. 1 The VIS–NIR absorption spectra for the addition of four [(2)–(5)] successive aliquots (2.4 mM) of pn to [Ni(HSaloxH)$_2$] (10 mM) in CH_2Cl_2; (1) is the spectrum of [Ni(HSaloxH)$_2$] prior to the addition of pn.

Me, B = *N*,*N*'-Me$_2$en have been characterised by X-ray crystallography.[8] Each compound is comprised of neutral mononuclear complexes with the Ni^{II} in a distorted octahedral environment, as exemplified by the molecular structure of **2** (Fig. 2). Each oxime is bound to the Ni^{II} *via* the phenolate *O*-atom and the oxime *N*-atom, to give a six-membered chelate ring that spans adjacent (*cis*) sites, and the diamine acts as a bidentate *cis*-*N*,*N*-chelate. Each [Ni(HSaloxR)$_2$B] compound that has been characterised by X-ray crystallography contains complexes exclusively in the form of the coordination isomer of the type shown in Fig. 2. An important structural feature of this isomer is that it involves retention of hydrogen bonding between the oximic hydroxyl groups and the phenolate oxygens. This type of hydrogen bonding is well established; *e.g.* in **1**[9] and [Cu(HSaloxH)$_2$],[4] it stabilises the *planar* complex (see Scheme 1). However, the [Ni(HSaloxR)$_2$B] complexes reported herein are the first examples that manifest the corresponding *folded* interligand, intramolecular H-bonding. Thus, in the octahedral [Ni(HSaloxR)$_2$B] complexes, *cis*-chelation of the diamine results in a folding about the phenolate–phenolate axis and the oxime N-atoms rotate to become mutually *cis*; the phenolate O-atoms remain mutually *trans*, but the O–Ni–O angle is reduced from 180 to 168.4(1)°. In **2**, the distances O1···O4 [2.670(4) Å] and O2···O3 [2.627(4) Å] are slightly (*ca.* 0.15 Å) longer than the corresponding distances in **1** (average 2.52 Å).[9] This difference is consistent with the increased span of the intramolecular H-bonding required to accommodate six-coordinate, high-spin, Ni^{II}, as compared to the planar four-coordinate, low-spin, Ni^{II} present in **1**.[10] Consistent with this view, the Ni–O and Ni–N$_{ox}$ bonds are longer by *ca.* 0.25 and 0.30 Å, respectively, in **2** than in **1**.[9] The oxime hydrogen atoms in **1** were located by Fourier techniques and the length of the hydrogen bonds to the phenolic oxygens (H2$_O$···O3 and H4$_O$···O1) are 1.70 and 1.88 Å, respectively. Given the importance of intramolecular H-bonding in stabilising [Cu(HSaloxR)$_2$] complexes, thereby aiding the efficacy and selectivity of the process employed for the commercial extraction of Cu^{II},[2,3] it is of considerable interest to observe that a similar, *but folded*, arrangement is present in the octahedral [Ni(HSaloxR)$_2$B] complexes.

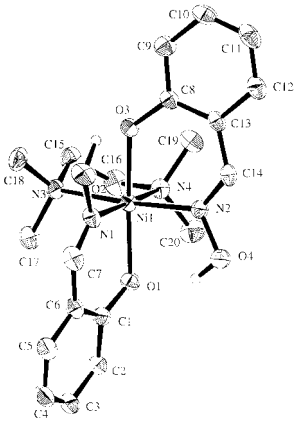

Fig. 2 ORTEP view and atomic labelling scheme for [Ni(HSaloxH)$_2$(Me$_4$en)]. Selected bond lengths (Å): Ni1–N1 2.065(4), Ni1–N2 2.057(3), Ni1–N3 2.171(4), Ni1–N4 2.170(4), Ni1–O1 2.050(3), Ni1–O3 2.041(3); selected interbond angles (°): O1–Ni1–O3 168.4(1), O1–Ni1–N1 85.4(1), O1–Ni1–N2 86.5(1), O1–Ni1–N3 97.7(1), O1–Ni1–N4 93.5(1), O3–Ni1–N1 85.8(1), O3-Ni1–N2 86.3(1), O3–Ni1–N3 90.1(1), O3–Ni1–N4 95.9(1), N1–Ni1–N2 91.7(1), N1–Ni1–N3 92.1(1), N1–Ni1–N4 175.0(1), N2–Ni1–N3 174.6(1), N2–Ni1–N4 93.1(1), N3–Ni1–N4 83.2(1); selected non-bonded distances (Å): O4···O4 3.175(7), O2···O3 2.627(4), O4···O1 2.670(4).

We consider that: (i) the displacement of the equilibrium of Scheme 1 by the presence of the basic diamine; (ii) the possible operation of a ligand 'assembly effect';[7] and (iii) the formation of [Ni(HSaloxR)$_2$B] with retention of the intramolecular H-bonding, could each contribute to the significant increase in the amount of Ni^{II} extracted by a combination of a phenolic oxime and a diamine, as compared with the amount of Ni^{II} extracted by either reagent alone.

We thank EPSRC and Avecia (formerly Zeneca Specialties) for the provision of a CASE studentship and travel funds to V. M. H. We also acknowledge the Australian Research Council for support.

First published as an Advance Article on the web 7th March 2001

Zincophosphate sodalites can be obtained by simple grinding of the substrate salts [$ZnCl_2$, $Zn(NO_3)_2$, Na_2HPO_4, Na_2CO_3] in a mortar, provided that at least one of the applied salts contains crystallization water.

The hydrothermal synthesis of zeolites or zeolite-like materials usually comprises forming an initial gel and its subsequent crystallization often at enhanced temperature and sometimes for extended times. Stucky and coworkers[1,2] demonstrated the unusual possibility to obtain faujasite (FAU) or sodalite (SOD) (zincophosphate, zincoarsenate, zincoantimonate) structures by means of spontaneous crystallization upon mixing aqueous solutions of the substrates at low temperatures. The above zeolite-like materials have been extensively studied by several research groups.[3] Such spontaneous crystallization can be useful for encapsulation of certain compounds inside the inner cages upon their formation. Our earlier attempts to prepare ultramarine analogs by introduction and further transformation of sodium polysulfides inside zincophosphate sodalite prepared according to the Stucky recipe[1] have not been successful[4] because of the low stability of the crystalline structure. The crystallization of zincophosphate with sodium polysulfide present in the initial mixture did not lead to formation of the sodalite structure. Another attempt to introduce polysulfides into the zincophosphate upon crystallization comprised simple grinding of the substrates without any water. Although mixtures containing polysulfides did not form a sodalite, it was interesting that a blank sample containing no sulfides formed the sodalite structure merely by grinding of the substrates.

The following study presents series of syntheses of zincophosphate sodalite by means of spontaneous, *dry* crystallization. The following principal substrates have been applied: $ZnCl_2$, $Zn(NO_3)_2{\cdot}6H_2O$, Na_2HPO_4, $Na_3PO_4{\cdot}12H_2O$, NaOH, Na_2CO_3, $Na_2CO_3{\cdot}12H_2O$ (all supplied by POCh, Poland). In some cases additional compounds (such as KBr, NaCl, CdS, elemental S) were admitted to the initial mixtures. The Zn/P ratio was always 0.85 and Na/Zn was 3.5, *i.e.* similar to that applied by Stucky and coworkers for synthesis of the SOD structure.[1,2] NaOH applied in preliminary experiments was replaced by sodium carbonate because of easier grinding of the latter. The procedure comprised grinding of the substrate mixture (usually *ca.* 2 g) in a ceramic mortar for *ca.* 10 min, then washing of the products with water and drying at 60 °C. The sequence of admittance of the substrates to the mixture varied. The obtained samples were characterized by means of XRD, IR, DTA, DTG and SEM.

The grinding of the mixture [*e.g.* $Zn(NO_3)_2{\cdot}6H_2O$, Na_2HPO_4, Na_2CO_3] led to release of water from the hydrated salts which made the sample wet. The evolution of CO_2 on grinding was noticeable due to Na_2CO_3 decomposition in the presence of Zn salts. Table 1 indicates the composition and sequence of adding the substrates as well as the structure and pH of the first drops of the filtrate on washing. Fig. 1 indicates high crystallinity SOD structures of the samples obtained from mixtures of Na_2HPO_4, Zn salts and Na_2CO_3 provided that one of components contains crystallization water. The as-made samples (before washing) usually contain a noticeable amount of NaCl or $NaNO_3$ (indicated in Fig. 1 for the sample ZnP-1*), which can then be washed out. It is remarkable that the sequence of substrate admittance affects the crystallinity and purity of the products. The sample obtained by merging all the substrates together (ZnP-0) contains more hopeite impurities than the samples ZnP-2 and ZnP-1, where either acidic (Zn) or alkaline (Na_2CO_3) components are admitted last. The SOD structure does not appear if Na_3PO_4 is used as the P source. The sequence of admittance as well as the P source influence the pH of the resulted products. It is likely that the pH of the mixture is an important factor for obtaining the SOD structure. The best results were achieved at pH ~ 7. The value of pH was as high as 11–12 for the samples prepared from Na_3PO_4 (with a similar molar ratio). The SOD structure was not formed on grinding when anhydrous salts were used (*e.g.* sample ZnP-4*), however, this sample attained the SOD structure upon washing with water

Table 1 Results of *dry* crystallization of zincophosphates

Sample	Substrates (order of admission)	pH	Structure
ZnP-SOD[1]	H_3PO_4 + NaOH + $Zn(NO_3)_2$ + H_2O	7.5	SOD + H
ZnP-0	Na_2HPO_4 + Na_2CO_3 + $Zn(NO_3)_2{\cdot}6H_2O$; all substrates mixed together	6.8	SOD + H
ZnP-1*	Na_2HPO_4 + Na_2CO_3 + $Zn(NO_3)_2{\cdot}6H_2O$		SOD + $NaNO_3$
ZnP-1	Na_2HPO_4 + Na_2CO_3 + $Zn(NO_3)_2{\cdot}6H_2O$	6.8	SOD
ZnP-2	Na_2HPO_4 + $Zn(NO_3)_2{\cdot}6H_2O$ + Na_2CO_3	6.8	SOD
ZnP-3	Na_2CO_3 + $Zn(NO_3)_2{\cdot}6H_2O$ + Na_2HPO_4	6.5	SOD + H
ZnP-4*	Na_2HPO_4 + Na_2CO_3 + $ZnCl_2$		NaCl
ZnP-4	Na_2HPO_4 + Na_2CO_3 + $ZnCl_2$	6.5	SOD
ZnP-5*	Na_2HPO_4 + $Na_2CO_3{\cdot}10H_2O$ + $ZnCl_2$	8.2	NaCl + SOD
ZnP-6*	$Na_3PO_4{\cdot}12H_2O$ + $Zn(NO_3)_2{\cdot}6H_2O$	12	$NaNO_3$
ZnP-7*	$Na_3PO_4{\cdot}12H_2O$ + $ZnCl_2$	11	NaCl

* The as made samples (not washed); H-hopeite; the pH was measured for the first drops of the filtrate on washing.

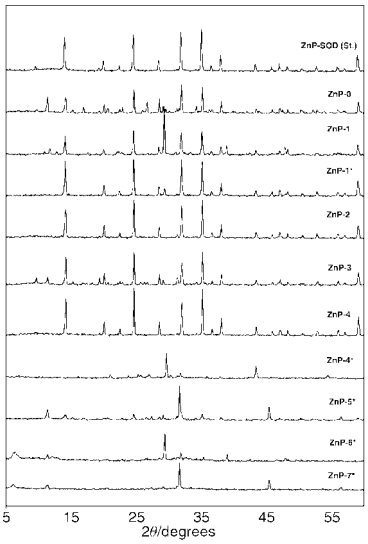

Fig. 1 XRD patterns of indicated samples. ZnP-SOD (St) indicates the sample prepared according to the Stucky recipe.[1] Samples indicated by asterisks were not washed before the diffraction measurements.

DOI: 10.1039/b100434b

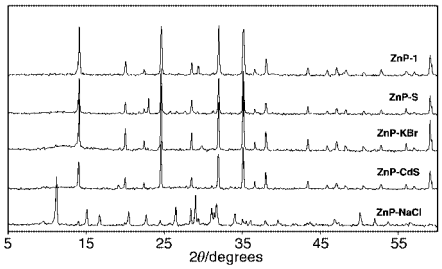

Fig. 2 XRD patterns of the indicated samples.

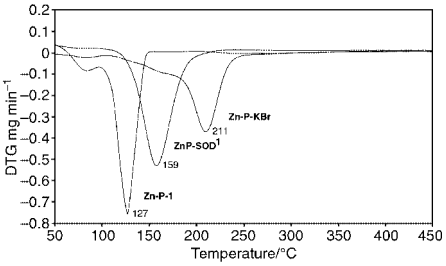

Fig. 4 Typical DTG curves (in air) for the indicated samples.

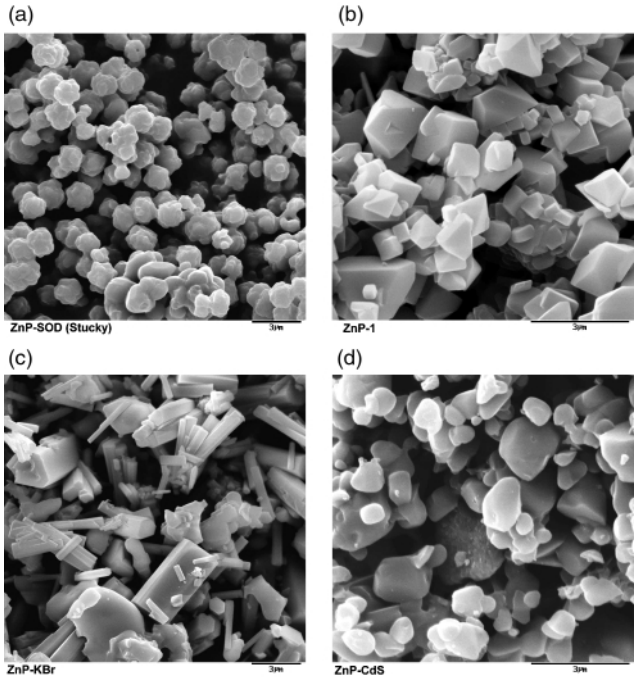

Fig. 3 SEM pictures of (a) sodium zincophospate sodalite prepared according to Stucky;[1] (b) sample ZnP-1; (c) sample ZnP-KBr; (d) sample ZnP-CdS.

(ZnP-4). The sodalite structure has also been attained when some additional compounds were admitted (KBr, S, CdS, see Table 2), whereas other salts (*e.g.* NaCl, Na_2S_n) impeded formation of the SOD structure (Fig. 2). No bromide was detected in the sample prepared with KBr, although its presence affected the morphology of the product (Fig. 3). The size of crystallites obtained using this *dry* method (*ca.* 2 μm) was similar to those prepared from solution as well as aluminosilicate sodalite (Fig. 3). CdS is most likely encapsulated inside the sodalite cages and only at high CdS loading (CdS/Zn > 0.2) do the SEM images indicate the presence of sulfide particles on the surface of sodalite crystallites.

The thermal properties of the samples obtained by grinding [examined by thermal (DTA) and gravimetric (TG, DTG) analyses (Fig. 4)] indicate the most significant effects attributed to removal of water. The dehydration temperatures differed for the samples prepared from different substrates or in the presence of additional components (*e.g.* KBr). It is interesting that regardless of the differences in dehydration temperatures, the amount of water removed is always the same (*ca.* 10%), which corresponds to empirical formula of the products: $NaZnPO_4{\cdot}H_2O$. For sample ZnP–CdS the weight loss on heating to 200 °C is only *ca.* 5%. This lower content of water results from encapsulation of CdS. The XRD data of the samples calcined at 200 °C indicate decomposition of the structure after removal of water which is not regenerated upon contact with atmospheric moisture.

Table 2 Syntheses with additional compounds (main procedure as for ZnP-1)

Sample	Additional reagents	Remarks
ZnP-S	S dissolved in CS_2 (Zn/S = 1,33)	SOD, yellow
ZnP-KBr	KBr ground with mixture (Zn/KBr = 0,35)	SOD, no Br^-
ZnP-CdS	CdS powder ground with mixture (Zn/CdS = 0,04)	SOD, yellow
ZnP-NaCl	NaCl (Zn/NaCl = 0,7)	Poor crystallinity

Another series of experiments with anhydrous substrate salts ground with a small admixture of various polar reagents such as ethanol, phenol, amines, acetone, nitrobenzene, acetonitrile, DMSO, DMF or liquid ammonia sometimes resulted in crystalline structures analogous to zeolites.[5]

The present preliminary results indicate a great affinity of zinc salts and phosphates to form a sodalite crystalline structure. Spontaneous crystallization of the sodalite structure can take place even upon grinding of substrate salts. The *dry* crystallization, however, requires some water, which is supplied from crystallization water present in at least one of the components of the substrate mixture. The sequence of adding the mixture components as well as the pH of the mixture affects the results of the syntheses. It seems that some additional compounds (*e.g.* S, CdS) can be encapsulated into the sodalite cages on *dry* crystallization. The admittance of a small amount of polar reagents (other than water) to an anhydrous substrate mixture can sometimes result in structures similar to zeolites.

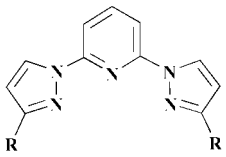
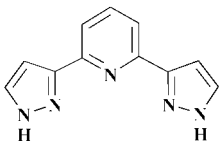
Received (in Cambridge, UK) 29th January 2001, Accepted 15th February 2001
First published as an Advance Article on the web 7th March 2001

The complex $[Fe(L^1H)_2][BF_4]_2$ exhibits an abrupt thermal spin-crossover which may be mediated by an order–disorder transition of the BF_4^- anions.

The spin-crossover phenomenon in Fe(II) complexes continues to be well studied,[1] reflecting their potential applicability as bistable materials for information storage.[2] For such applications, a thermally induced spin-state transition must occur over as small a temperature range as possible, and should exhibit a hysteresis loop.[2] These properties reflect intermolecular cooperativity within the sample, and are most often associated with a concomitant crystallographic phase transition and/or loss of long-range ordering. However, there are isolated examples where this is not the case, and intermolecular cooperativity in a thermal spin–spin transition is instead mediated by covalent pathways,[3] or *via* intermolecular hydrogen-bonding,[4] π–π interactions[5,6] or van der Waals contacts.[7] Following our studies of the electronic structures and solid state fluxionality of $[Cu(L^1R)_2]^{2+}$ (R = H, mesityl),[8–10] we wished to examine the Fe(II) complex chemistry of L^1R. This was of particular interest since several salts of $[Fe(L^2)_2]^{2+}$ {a structural isomer of $[Fe(L^1H)_2]^{2+}$} exhibit both thermal and light-induced spin-state transitions, whose physics has been extensively studied.[11]



L^1R



L^2

Complexation of $Fe(BF_4)_2 \cdot 6H_2O$ with 2 mol equivalents of L^1H[12] in acetone affords a mustard precipitate of $[Fe(L^1H)_2][BF_4]_2$ **1** in 70% yield, which can be recrystallised from MeCN–Et_2O.‡ Variable-temperature magnetic susceptibility measurements§ from polycrystalline **1** demonstrated a transition between high-spin ($S = 2$, $\chi_mT = 3.6$–3.7 cm^3 K mol^{-1}[13]) and low-spin ($S = 0$, $\chi_mT \leqslant 0.3$ cm^3 K mol^{-1}[13]) states centred at $T = 259$ K, with a transition width of 3 K and a 3 K hysteresis loop (Fig. 1). This change is reflected in the colour of the compound, which changes sharply from mustard yellow to dark brown upon cooling; this change is reversible upon rewarming to room temperature. Differential scanning calorimetry (DSC) experiments§ of **1** confirmed these results, showing a first-order transition centred at 260 K, with a hysteresis width of 4 K. Values of $\Delta H = 17.2(2)$ kJ mol^{-1} and $\Delta S = 66.2(8)$ J mol^{-1} K^{-1} for the transition were derived from the DSC data.

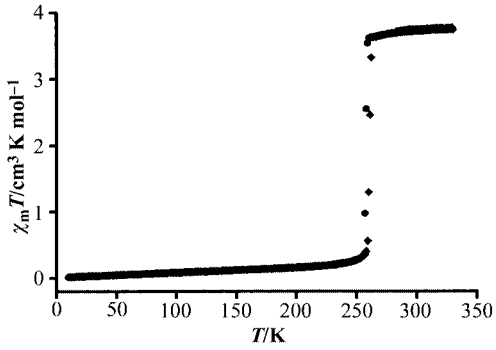


Fig. 1 Plot of χ_mT *vs.* T for polycrystalline **1** in cooling (●) and warming (◆) modes.

The temperature of the transition was also confirmed by measuring the crystallographic unit cell in the range 240–300 K, which demonstrated a discontinuity within the range 259–261 K in cooling and warming modes. No hysteresis was detected by this method, although this might reflect the less accurate temperature control at the diffractometer, which is estimated at ±2 K. There is no change in space group ($P2_1$) at these temperatures; rather, the transition is characterised by a decrease of 0.55 Å in the crystallographic *c*-direction, an increase of 0.05 Å in *b*, and an increase of 2.0° in β as the temperature is lowered (see ESI†). The decrease in unit cell volume associated with the phase transition (ignoring thermal contraction effects) is 35(5) Å^3 or 2.6%, the latter being a typical value for a spin state transition in an Fe(II) complex.[14] The temperature of the crystal can be cycled across the transition several times, although the crystal begins to decay noticeably after *ca.* five cycles.

Four datasets were collected from the complex, at 375, 290, 240 and 150 K.¶ The molecular structures of the complex dication at 290 and 375 K are crystallographically indistinguishable, as are the structures at 240 and 150 K (see ESI†). Therefore, only the structure analyses at 290 and 240 K will be discussed in detail. At both temperatures the six-coordinate Fe(II) ion in **1** has approximate local D_{2d} symmetry, with Fe–N bond lengths that are typical of a high-spin (290 K) and low-spin (240 K) Fe(II) centre (Fig. 2).[15] At 240 K the Fe–N distances are shorter than at 290 K by an average of 0.215(10) Å, which is a typical value for a high- to low-spin transition involving a Fe(II) complex with a hexa-nitrogen donor set.[15] As a result, the average ligand bite angle has increased at 240 K [80.0(3)°] compared to 290 K [73.47(18)°].

† Electronic supplementary information (ESI) available: tabulated and plotted unit cell dimensions for **1** between 240–300 K; tabulated magnetic susceptibility data between 10–330 K. See http://www.rsc.org/suppdata/cc/b1/b100995h/

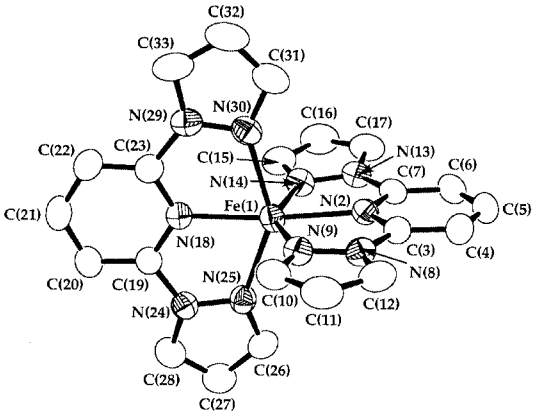

Fig. 2 View of the $[Fe(L^1H)_2]^{2+}$ dication in the crystal of **1** at 290 K, showing the atom numbering scheme employed for the complex cation. Thermal ellipsoids are at the 35% probability level. For clarity, all H atoms have been omitted. The complex at 240 K is visually indistinguishable. Selected distances (Å) and angles (°) at 290 K: Fe(1)–N(2) 2.1248(19), Fe(1)–N(9) 2.193(2), Fe(1)–N(14) 2.175(3), Fe(1)–N(18) 2.127(2), Fe(1)–N(25) 2.184(3), Fe(1)–N(30) 2.185(3); N(2)–Fe(1)–N(9) 73.47(8), N(2)–Fe(1)–N(14) 73.65(9), N(2)–Fe(1)–N(18) 173.15(10), N(2)–Fe(1)–N(25) 113.14(9), N(2)–Fe(1)–N(30) 100.21(10), N(9)–Fe(1)–N(14) 147.08(9), N(9)–Fe(1)–N(18) 104.24(8), N(9)–Fe(1)–N(25) 98.46(9), N(9)–Fe(1)–N(30) 92.88(9), N(14)–Fe(1)–N(18) 108.21(9), N(14)–Fe(1)–N(25) 95.95(9), N(14)–Fe(1)–N(30) 91.12(10), N(18)–Fe(1)–N(25) 73.44(9), N(18)–Fe(1)–N(30) 73.31(10), N(25)–Fe(1)–N(30) 146.58(9). Selected distances (Å) and angles (°) at 240 K: Fe(1)–N(2) 1.893(3), Fe(1)–N(9) 1.979(3), Fe(1)–N(14) 1.968(3), Fe(1)–N(18) 1.905(3), Fe(1)–N(25) 1.981(4), Fe(1)–N(30) 1.975(4); N(2)–Fe(1)–N(9) 80.22(14), N(2)–Fe(1)–N(14) 80.05(14), N(2)–Fe(1)–N(18) 178.25(18), N(2)–Fe(1)–N(25) 101.75(15), N(2)–Fe(1)–N(30) 98.34(15), N(9)–Fe(1)–N(14) 160.26(13), N(9)–Fe(1)–N(18) 100.50(14), N(9)–Fe(1)–N(25) 92.92(14), N(9)–Fe(1)–N(30) 92.24(14), N(14)–Fe(1)–N(18) 99.21(14), N(14)–Fe(1)–N(25) 91.57(15), N(14)–Fe(1)–N(30) 90.11(15), N(18)–Fe(1)–N(25) 79.83(15), N(18)–Fe(1)–N(30) 80.06(15), N(25)–Fe(1)–N(30) 159.82(13).

To conclude, we have shown that crystalline **1** undergoes a cooperative spin-state transition centred at 260(1) K, which does not involve a crystallographic phase change. It is not clear what mediates the cooperativity of this transition. However, one possibility is implied by the isomorphous complex $[Cu(L^1H)_2][BF_4]_2$ **2**, in which pseudo-Jahn–Teller cooperativity is mediated by rotation of the BF_4^- anions in the crystal.[10] It is therefore intriguing that there is an apparent change in the anion motion in **1** across the spin-state transition. At 290 K, all F atoms in both BF_4^- anions are badly disordered, implying that there is essentially free rotation of the near-spherical anions within their lattice cavity. In contrast, at 240 K one F atom in each ion appears to be crystallographically ordered, so that the anions are now disordered by rotation about one B–F bond. Experiments to further define the influence of anion motion on the spin-crossover in **1**, and to determine the magnetic properties of other $[Fe(L^1R)_2]^{2+}$ complexes, are in progress.

We would like to thank The Royal Society (M. A. H.), the EPSRC (J. A. M., Z. L.) and the University of Leeds for funding.

‡ *Analytical data* for **1**: Found C, 40.7; H, 2.8; N, 21.2. Calc. for $C_{22}H_{18}B_2F_8FeN_{10}$: C, 40.5; H, 2.8; N, 21.5%.

§ Susceptibility measurements were carried out in an applied field of 1000 G, with the sample being poised at each temperature for 1 min before measurement. DSC experiments were run using a temperature ramp of 10 °C min^{-1}.

¶ Four datasets were collected for **1** ($C_{22}H_{18}B_2F_8FeN_{10}$, M_r = 651.93, monoclinic, $P2_1$, Z = 2).

Crystal data: at 375 K: a = 8.5301(3), b = 8.5518(4), c = 19.1757(5) Å, β = 94.9043(24)°, U = 1393.70(9) $Å^3$, μ(Mo-Kα) = 0.628 mm^{-1}; 15873 measured reflections, 6039 independent, R_{int} = 0.035; $R(F)$ = 0.045, $wR(F^2)$ = 0.120, Flack parameter −0.001(17). The F atoms of both BF_4^- anions were badly disordered at this temperature. Each anion was modelled using three different disorder orientations, in a 0.50 : 0.25 : 0.25 occupancy ratio. All B–F distances were restrained to 1.37(2) Å, and non-bonded F···F distances within each disorder orientation to 2.24(2) Å. All non-H atoms with occupancy ⩾0.5 were refined anisotropically.

At 290 K: a = 8.4947(2), b = 8.5070(2), c = 19.0535(6) Å, β = 95.7050(18)°, U = 1370.07(6) $Å^3$, μ(Mo-Kα) = 0.639 mm^{-1}; 15406 measured reflections, 5442 independent, R_{int} = 0.043; $R(F)$ = 0.040, $wR(F^2)$ = 0.110, Flack parameter 0.022(15). Refinement details as for the 375 K structure.

At 240 K: a = 8.4977(3), b = 8.5665(3), c = 18.4299(8) Å, β = 98.0931(12)°, U = 3128.25(9) $Å^3$, μ(Mo-Kα) = 0.659 mm^{-1}; 10234 measured reflections, 5538 independent, R_{int} = 0.045; $R(F)$ = 0.046, $wR(F^2)$ = 0.124, Flack parameter 0.006(19). Both BF_4^- anions were disordered by rotation about one B–F bond. The disordered F atoms of the two anions were modelled over three orientations, with 0.50 : 0.25 : 0.25 and 0.40 : 0.30 : 0.30 occupancy ratios. All B–F distances were restrained to 1.39(2) Å, and non-bonded F···F distances within each disorder orientation to 2.27(2) Å. All non-H atoms with occupancy >0.5 were refined anisotropically.

At 150 K: a = 8.4575(2), b = 8.5233(2), c = 18.3756(4) Å, β = 98.2896(13)°, U = 1310.78(5) $Å^3$, μ(Mo-Kα) = 0.668 mm^{-1}; 19914 measured reflections, 5715 independent, R_{int} = 0.038; $R(F)$ = 0.031, $wR(F^2)$ = 0.079, Flack parameter −0.009(10). No disorder was detected at this temperature, and no restraints were applied. All non-H atoms were refined anisotropically.

First published as an Advance Article on the web 7th March 2001

Electrochemical oxidation of a titanium electrode in a solution of potassium amide in liquid ammonia resulted in the deposition of titanium nitride either as a thin film or as nanoparticles.

Titanium nitride is a technologically important material that exhibits excellent chemical stability, good wear resistance, and high electrical conductivity. As a thin film, titanium nitride finds uses as a hard coating for cutting tools,[1] as a diffusion barrier for microelectronic devices,[2] as an optical coating,[3] and as a gold-coloured surface for jewellery.[4] Conventional routes to thin films of TiN include heating titanium metal in a stream of ammonia,[5] reactive sputtering,[6] and chemical vapour deposition.[7] Many of these techniques require high temperatures and/or expensive equipment or precursors. Electrochemical synthesis is therefore an alternative route that has attracted significant interest. Previous studies have included anodisation of titanium in acetonitrile at an applied cell voltage of up to 1500–3000 V,[8] and nitridation of a titanium anode in an acetonitrile solution containing a primary amine and tetrabutylammonium bromide followed by heating at high temperatures.[9] Each of these routes produces TiN films, but incorporation of carbon-containing impurities is significant. A reduction in the level of carbon incorporation has been achieved by the use of NH_4Br–NH_3 electrolyte solutions. This resulted in an uncharacterised powder which on calcining at 1100 °C under flowing ammonia produced either small particles of TiN or could be used to coat substrates with TiN after calcining.[10] Electrochemical surface nitriding of titanium in a molten LiCl–KCl eutectic melt has been shown to produce TiN films, but the operating temperature of this process is 450 °C.[11] Titanium nitride powders have also attracted interest in the field of powder technology as precursors for the fabrication of sintered compact or thin films. A route describing the production of TiN particles by galvanostatic electrolysis using a titanium plate in a solution of *n*-butylamine in acetonitrile has recently been reported, but post-processing by heating to 200–1000 °C in the presence of ammonia was invariably required in order to generate TiN.[12]

In this work we describe an electrochemical process that operates at or below ambient temperatures to give, in one step, thin films or particles of TiN. Furthermore, the nature of the process favours nitride formation, with no incorporation of carbon, oxygen or halogen. This is because it involves liquid ammonia solutions containing the basic electrolyte KNH_2 rather than organic solvents containing the acidic NH_4Cl or NH_4Br electrolytes used previously.[9,10,12]

The apparatus for the electrochemical experiments is described below.† Sweeping the titanium electrode potential at sweep rates of 50–100 mV s^{-1} between 0.00 V and a negative potential limit, in excess of −1.50 V, produced a reduction current of several mA. During the reverse sweep to 0.00 V in the cyclic voltammogram (CV), an associated oxidation peak was observed at *ca.* −750 mV. On continued cycling, this oxidation peak was observed to diminish as the reduction wave shifted to more negative potentials. The CV recorded after 30 min showed little decrease in the negative sweep and no oxidation peak in the positive sweep at these potentials. It seems likely that this reduction reaction involves the reduction of the native titanium(IV) oxide with the loss of oxide from the titanium surface. The oxidation peak then corresponds to the reformation of the oxide surface. On repeated cycling, a fraction of the reduced oxide is lost to the bulk solution by diffusion. Thus the cycling eventually results in the production of an oxide-free titanium surface.

On stepping the potential of the cleaned titanium electrode from 0.00 to +3.00 V, a large positive current of several mA was initially observed, indicative of electrode oxidation, which fell slowly with time. Increasing the electrode potential (first to +4.00 V, then to +5.00 V) resulted in increases in the oxidation current, as did increasing the temperature of the solution from −78 to −33 °C, with no sign of gas evolution at the electrode. Stirring of the solution did not increase the current, indicating that the current is not limited by mass transport of solution species to the electrode. These results are consistent with the growth of a surface nitride film on the electrode surface by an oxidation that involves liquid ammonia and/or amide. Removal of the titanium electrode and washing with water revealed a golden coloured film.

CV sweeps to oxidising potential for clean titanium also showed an oxidation current due to nitride film growth. Each cycle resulted in the progressive shift of this oxidation current to more positive potentials. The increase by >1.00 V in the oxidative potential limit of this electrode, whilst retaining a similar pseudocapacitance, indicates that the deposited film is relatively inert and is conducting; this is a strong indication that the film is titanium nitride. The observed increase in current on raising the temperature of the ammonia solution from −78 to −33 °C allows one to calculate an activation energy for the process in the order of +20 kJ mol^{-1}. Extrapolation to 25 °C would predict an approximately 50-fold increase in the current compared with the current passed at −78 °C. For this reason, a pressure cell was constructed such that liquid ammonia at 25 °C could be safely contained. The predicted increase in current was indeed observed, but in this case small particles of a yellow–brown material grew on the surface of the titanium electrode. Evidence that these particles were electrically conducting was provided by the observations that (i) the particles grew as 'tendrils' towards the counter electrode, and (ii) when dislodged from the electrode surface by gentle tapping the current *decreased*, indicating a reduction of electrically conducting surface area. The small size of the particles caused them to be readily oxidised to TiO_2 in the presence of air and aqueous base. Hence it was essential to remove excess KNH_2 by washing the particles with portions of liquid ammonia, followed by removal of the last traces of ammonia *in vacuo* before handling in air. Glancing angle X-ray powder diffraction of the film and particles showed no peaks, but did show significant background scattering indicative of an amorphous or nano-crystalline phase.

DOI: 10.1039/b100713k

Attempts to anneal the film at 800 °C under argon resulted in some degree of sharpening, but were not conclusive. Subsequent characterisation involved a range of techniques that required as little processing of the film as possible.

The electrodeposited film showed a transition from metallic to superconducting behaviour at *ca.* 4.5 K in a field of 100 G; the magnitude of the transition, when correlated with the charge passed during synthesis, further indicated that titanium nitride was the major product of reaction. The temperature of the transition also suggested that the stoichiometry of the TiN_x film is such that x is very close to 1.[13]

The SEM-EDX spectrum also pointed to a nitride-containing film. Not surprisingly given the nature of the sample (TiN on bulk Ti) the spectrum was dominated by the strong Ti Kα line, but clearly discernible was the N 2p line (adjacent to the Ti Lα line). Quantitative assessment of the stoichiometry was not possible owing to the considerable contribution to the intensity from the titanium substrate. It is significant, however, that no peaks corresponding to either oxygen or potassium contaminants were observed.

Conclusive evidence for the identification of both the film and powder as TiN was provided by the Raman spectra. These display three broad bands, the positions of which were in extremely good agreement both with spectra described in the literature,[14] and with spectra obtained from authentic stoichiometric TiN powder. Previous Raman studies have shown that the relative intensities of the Raman bands at 550 and 235 cm^{-1} depend upon the stoichiometry of the titanium nitride.[14] The band at lower energy is ascribed to nitrogen vacancies in the lattice and its intensity relative to the band at 550 cm^{-1} increases rapidly with increasing nitrogen deficiency. When compared with published spectra, the Raman spectra of both film and powder suggest a value of x for the TiN_x that is close to unity.

Analysis of the films by X-ray photoelectron spectroscopy (XPS) was dominated by strong peaks for titanium (2p) and oxygen (1s) characteristic of TiO_2. This was not entirely unexpected given that several months elapsed between preparation and examination by XPS and points to aerial oxidation of the TiN film at its surface. After argon ion sputtering to an approximate depth of 50 nm, the Ti 2p peak shifted to a lower binding energy and a N 1s peak appeared at 397.2 eV, indicative of stoichiometric TiN.[15] The N 1s peak persisted to a depth of ~600 nm into the sample consistent with the expected film thickness based on the amount of charge passed. Transmission electron microscopy showed aggregates of approximately spherical particles of diameter *ca.* 5–10 nm (Fig. 1).

Electron diffraction from these particles produced distinct rings with the occasional appearance of spots. The separation of these rings corresponds to *d*-spacings in good agreement with those reported for the osbornite phase of TiN.[16]

We have demonstrated in this work that electrochemical oxidation of a titanium electrode in liquid ammonia/KNH_2 at temperatures between −78 and 25 °C, results in the deposition of TiN either as a thin film or as nanoparticles depending on the current density. A key step in the production of coherent thin films has been found to be repeated cycling of the titanium electrode to negative potentials such that a substantial negative current is observed. In this way, the native oxide layer is removed, thereby facilitating growth of chemically pure TiN when the electrode is subsequently held at positive potential. Furthermore, there is no requirement for post-processing of the films or particles at elevated temperatures. Preliminary results using other metal electrodes (*e.g.* Ta, Mo and W) suggest that this process is a general low-temperature route to metal nitrides.

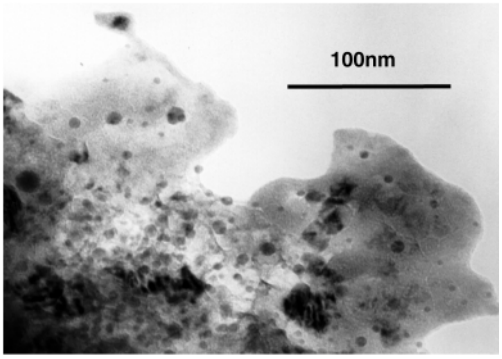

Fig. 1 TEM image of TiN particles mounted in epoxy resin.

We thank the EPSRC for a studentship (L. E. G.) and the British Council for a Monbusho Research Fellowship (L. E. G.). We dedicate this communication to the memory of the late Dr Marten Barker—a major contributor to the field of metal nitride chemistry.

Notes and references

† All operations were performed under dry, oxygen-free nitrogen. Saturated solutions of KNH_2 in liquid NH_3 at −78 °C were prepared by the addition of oxide-free potassium metal to dry liquid NH_3. Electrochemical experiments were performed using a three-electrode system; working electrode Ti foil (area ≈ 1 cm^2), counter electrode Pt coil (area >> 1 cm^2), pseudo-reference electrode (PRE) bright Pt wire. All potentials are reported with respect to this PRE. Electrochemical experiments at 25 °C involved a pressurised Pyrex vessel.

A linearly coordinated Hg(0) trapped in a gold(I) metallocryptand cage

Vincent J. Catalano,*[a] Mark A. Malwitz[a] and Bruce C. Noll[b]

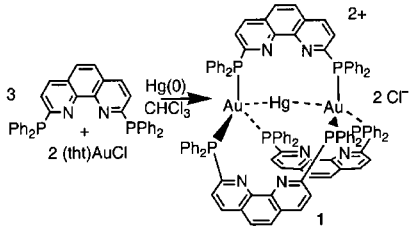
Received (in Irvine, CA, USA) 10th January 2001, Accepted 16th February 2001
First published as an Advance Article on the web 7th March 2001

Hg(0) is effectively encapsulated through strong, closed-shell metallophilic interactions by Au(I)-based metallocryptands using the multidentate P_2phen [2,9-bis(diphenylphosphino)-1,10-phenanthroline] ligand; synthesis, characterization and X-ray crystallography are presented.

Even though elemental mercury has found numerous uses and applications in many fields of chemistry, the coordination chemistry of Hg(0) remains extremely limited, and no stable compounds are known where a Hg(0) atom is coordinated to ligands forming a classical coordination compound. Rather, Hg(0) is often found as part of an electron-rich transition metal cluster[1,2] or as an adduct to the face of *triangulo* clusters.[3,4] For example, Puddephatt and coworkers[5] reported the reversible addition of Hg(0) to the trigonal face of $[Pt_3(\mu\text{-CO})(\mu\text{-dppm})_3]^{2+}$ (dppm = $Ph_2PCH_2PPh_2$) to form mixed-metal clusters that contain naked, triply bridging Hg(0) atoms. Similarly, Venanzi and coworkers[6] demonstrated that the addition of elemental Hg to $[Pt_3(\mu\text{-CO})_3(PPhPr^i_2)_3]$ produces a cluster containing two Pt_3 triangles bridged by a Hg_2 unit. More recently, Puddephatt and coworkers[7,8] extended this motif to generate cage complexes based on the triangular Pt_3 core that are capable of encapsulating metal ions including Hg(0) or Tl(I).

We too, have been investigating the encapsulation of metal ions by inorganic cage complexes denoted as metallocryptands and found a similar affinity for the incarceration of metals with s^2 electronic configurations.[9,10] Recently, we demonstrated that the Au(I)-based metallocryptand employing the ligand 2,9-bis-(diphenylphosphino)-1,10-phenanthroline (P_2phen) is a selective host for Tl(I) ion, and the resulting $[Au_2Tl(P_2phen)_3]^{3+}$ complex is intensely luminescent.[11] We have now extended this concept to the encapsulation of elemental Hg and report the structure of the resulting metallocryptate containing an Hg(0) atom in an unusually low coordination mode.

As shown in Scheme 1, the yellow $[Au_2Hg(P_2phen)_3](PF_6)_2$ **1** is readily prepared by reacting a chloroform solution containing 3 equivalents of colorless P_2phen with 2 equivalents of Au(tht)Cl (tht = tetrahydrothiophene) and a single drop of elemental mercury.† The chloride salt can be metathesized to the PF_6^- salt using excess $NaPF_6$. Alternatively, **1** can be synthesized by Hg(0) addition to the two-coordinate, gold macrocycle,[11] $[Au_2(P_2phen)_2](PF_6)_2$, and the free ligand in chlorocarbon solution. The $^{31}P\{^1H\}$ spectrum (CD_3CN) of **1** displays a singlet at δ 34.8 with ^{199}Hg satellites ($^2J_{PHg}$ 48 Hz, ^{199}Hg is 16.8% abundant, I = 1/2) and a heptet at δ −143.7 that integrates for two PF_6^- anions. The $^{199}Hg\{^1H\}$ NMR spectrum (Fig. 1) displays a septet at δ –1199.8 ($^2J_{HgP}$ 48 Hz) indicating a single Hg environment coupled to six chemically equivalent



Scheme 1

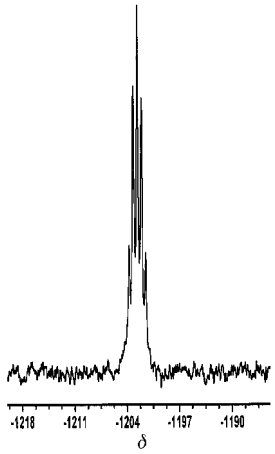


Fig. 1 89.312 MHz $^{199}Hg\{^1H\}$ NMR spectrum of $[Au_2Hg(P_2phen)_3](PF_6)_2$ in CD_3CN at 25 °C.

phosphorus atoms. For comparison, the phosphine environment in **1** is slightly more shielded than that observed in either $[Au_2Tl(P_2phen)_3](PF_6)_3$ or $[Au_2Na(P_2phen)_3](PF_6)_3$ which show resonances at δ 45.7 and 45.5, respectively. As probed by $^{31}P\{^1H\}$ NMR spectroscopy, the Hg atom appears to interact with the AuP_3 center in a fashion similar to the corresponding Tl(I) containing species, as the $^2J_{HgP}$ coupling constant in **1** is closely related to the $^2J_{TlP}$ of 186 Hz observed in $[Au_2Tl(P_2phen)_3](PF_6)_3$ by the simple ratio of the gyromagnetic ratios for ^{199}Hg and ^{205}Tl. Further, $^2J_{HgP}$ coupling constants ranging from 41 to 70 Hz were reported for Hg(0) trapped in the hexaplatinum clusters.[7] No comparable ^{199}Hg NMR chemical shifts could be found for genuine Hg(0) complexes. However, a chemical shift of δ −1310 was reported[12] for the low valent Hg cluster, $[Hg_4](AsF_6)_2$. The chemical shift dispersion for ^{199}Hg is quite large (> 5000 ppm) and is very sensitive to ligation, concentration and temperature.[13] Consistent with other metallocryptates[9] the ^1H NMR spectrum displays single resonances for the three magnetically distinct phenanthroline protons. These signals are only minimally shifted (±0.06 ppm) relative to the uncoordinated ligand. However, two sets of resonances corresponding to phenyl ring protons are observed in the metallocryptate suggesting that two phenyl ring environments exist: one along the metal–metal axis and one equatorial to this axis.

The structure of **1** as determined by X-ray diffraction‡ is presented in Fig. 2. The structure contains two trigonally-coordinated Au(I) centers capping a D_3 symmetric cage containing an Hg(0) atom. As can be seen in Fig. 2 the overall geometry of the complex is helical; however the bulk material is racemic as dictated by the centrosymmetric space group. The helicity is reflected in the large P(1)–Au(1)–Au(2)–P(2), P(3)–Au(1)–Au(2)–P(4) and P(5)–Au(1)–Au(2)–P(6) torsion angles of 91.2, 89.1 and 91.9°, respectively. This twisting of the trigonal planes compresses the metallocryptate to accommodate the requisite Au(1)···Au(2) separation of 5.546(1) Å. No attempt was made to resolve **1** into its chiral components.

The Au(1)–Hg(1) and Au(2)–Hg(1) separations are nearly identical at 2.7847(4) and 2.7804(4) Å, respectively. The three-

DOI: 10.1039/b100432h

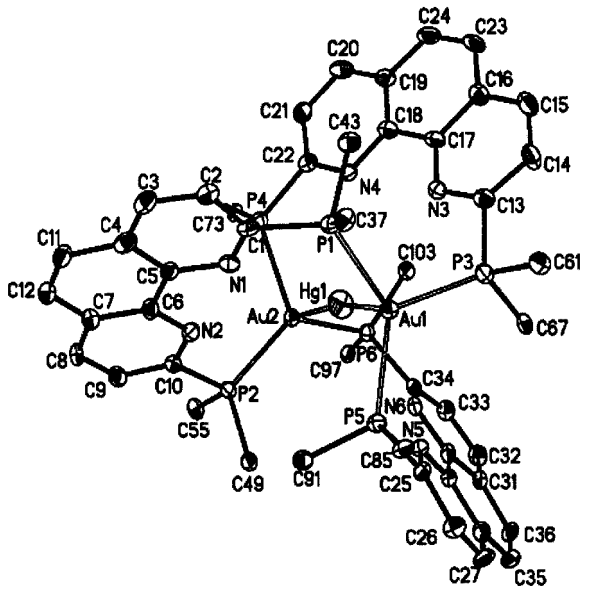

Fig. 2 Thermal ellipsoid plot for the cation of **1**. Hydrogen atoms and phenyl rings are removed for clarity. Selected distances (Å) and angles (°): Au1–Hg1 2.7847(4), Au2–Hg1 2.7807(4), Hg1–N1 3.589(2), Hg1–N2 3.636(2), Hg1–N3 3.374(2), Hg1–N4 3.378(2), Hg1–N5 3.659(2), Hg1–N6 3.604(2); Au1–Hg1–Au2 170.48(1), P1–Au1–P3 113.01(6), P1–Au1–P5 124.49(6), P3–Au1–P5 1217.63(6), P2–Au2–P4 116.01(6), P2–Au2–P6 125.32(5), P4–Au2–P6 113.44(6), P1–Au1–Hg1 98.14(4), P3–Au1–Hg1 94.74(4), P5–Au1–Hg1 98.90(4), P2–Au2–Hg1 98.61(4), P4–Au2–Hg1 95.72(4), P6–Au2–Hg1 98.31(4).

atom linkage is slightly bent with an Au(1)–Hg(1)–Au(2) angle of 170.48(1)°. The two Au atoms are distorted from their respective trigonal coordination planes towards the Hg atom by *ca*. 0.3 Å each. The Hg–N separations range from 3.374(1) to 3.659(1) Å (av. Hg–N 3.540 Å) and are considered non-interacting indicating that the attractive Au–Hg interaction is responsible for maintaining this assembly. The freedom of the Hg atom to move about the cage is reflected by its larger thermal ellipsoid as compared to the Au atoms, a trend noted in other metallocryptands.

The attractive Au–Hg interactions observed here can be rationalized using a simplified molecular orbital approach discussed elsewhere.[10] Although considered formally non-bonding, the metal–metal separations reported here are shorter than the sum of the respective covalent radii (Au = 1.34, Hg = 1.49 Å) indicating a significant attraction between these closed-shell metals. Similar associations with other closed-shell metal ions have been observed in other metallocryptates[9] and in the related trigonally coordinated Pt(0) and Pd(0) phosphine complexes.[14]

The Hg–Au separations described here are shorter than those found in $[Pt(AuPPh_3)_8(Hg)_2]^{4+}$ [3.0070(5) and 3.0011(5) Å][15] and those found in $[(PPh_3)Pt(AuPPh_3)_6(HgNO_3)](NO_3)$ [2.945(3)–3.636(2) Å].[16] Interestingly, in the former complex the Hg is added as Hg(II) while the latter complex is formed by the addition of Hg(0) to $[(PPh_3)Pt(AuPPh_3)_6](NO_3)$. However, to the best of our knowledge there are no reports of a genuine Hg(0) atom coordinating to two Au(I) centers in a linear fashion.

The electronic absorption spectrum (CH_2Cl_2) of **1** shows absorptions attributable to ligand π–π* transitions between 230 and 280 nm, a broad, unresolved band centered *ca*. 360 nm, and a low energy absorption at 390 nm which may be attributed to the $M_{d\sigma^*} \rightarrow M_{p\sigma^*}$ transition. Compound **1** is weakly emissive, and excitation into the low energy manifold produces an emission band centered at 580 nm. A similar, yet significantly more intense emission is observed in the isoelectronic Tl(I) containing species $[Au_2Tl(P_2phen)_3]^{3+}$ which was assigned to a metal-centered phosphorescence process. Unlike $[Au_2Tl(P_2phen)_3]^{3+}$ compound **1** exhibits an electrochemical oxidation (CH_2Cl_2, irreversible) at *ca*. 1.25 V *vs*. Ag/AgCl. No reversible reductions were observed out to the solvent limit.

The successful encapsulation of Hg(0) by the gold-based metallocryptand further demonstrates the applicability of these inorganic cage complexes as effective probes of closed-shell metal–metal interactions. This methodology may be applied to other d^{10}-based metallocryptands including Pd(0) and Pt(0) where similar metal–metal interactions are expected. Further, by careful ligand manipulation it may be possible to induce a stronger coordination environment around the encapsulated Hg(0) atom. We are actively pursuing these species.

A boron-substituted ZSM-11 (Si/B = 100, MEL structure) membrane was prepared and shown to selectively permeate methyl ethyl ketone, propan-1-ol, and propan-2-ol from aqueous solutions.

Zeolite membranes have the potential to continuously separate mixtures by both adsorption and molecular sieving because the zeolite pores are of molecular size. Most previous studies of zeolite membranes have focused on MFI (silicalite-1 and ZSM-5) membranes.[1,2] The MFI zeolites have a system of straight channels (pore size: 0.53 × 0.56 nm) interconnected by zigzag channels (pore size: 0.51 × 0.55 nm). Isomorphous substitution has been shown to be an effective method for modifying the MFI structure, and membranes with B substituted into the MFI framework membranes had higher n-C_4H_{10}/i-C_4H_{10} gas-phase selectivities than Al-ZSM-5 membranes.[3] In the current study, a B-ZSM-11 membrane was prepared that exhibited better pervaporation properties for organic/water mixtures than obtained for ZSM-5 membranes that were prepared by the same procedures. The ZSM-11 zeolite pore size is similar to that for ZSM-5, but it has intersecting straight channels (pore size: 0.54 × 0.53 nm).

The B-ZSM-11 membrane was prepared by *in situ* crystallization onto a tubular porous stainless steel support (500 nm pore size, Mott Corporation). The MEL structure can be hydrothermally synthesized from gels containing NaOH. den Exter[4] claimed that the MEL structure could not be synthesized as a pure phase, however, and they obtained a mixture of MFI and MEL structures.[4] Sano[5] prepared Al-ZSM-11 films on nonporous Teflon slabs, but did not show that these films were continuous membranes; no separations were reported for these films.

We prepared an alkali-free, ZSM-11 membrane that contained boron in the structure (Si/B = 100), and XRD of powder collected from the bottom of the tube indicated a MEL structure (Fig. 1). All peaks match those reported by Szostak[6] for MEL crystals, and no additional peaks were observed.

The synthesis was similar to alkali-free, MFI zeolite membranes, which showed higher separation selectivities than MFI membranes prepared from synthesis gels containing NaOH.[3] The molar composition of the gel was: 2.5 TBAOH : 0.195 $B(OH)_3$: 19.5 SiO_2 : 450 H_2O, where TBAOH (tetrabutylammonium hydroxide) was used as template, and silica sol (Ludox-AS40) was the Si source. Hydrothermal synthesis was carried out at 403 K for 72 h, and two synthesis layers were required. After synthesis, the membrane was washed, dried, and calcined at 753 K for 8 h with heating and cooling rates of 0.015 and 0.018 K s^{-1}, respectively.

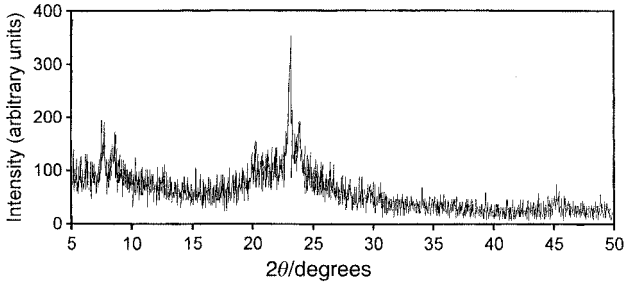

Fig. 1 XRD spectrum of the powder collected from the bottom of a B-ZSM-11 zeolite membrane.

The B-ZSM-11 membrane was used for separation of organic/water mixtures by pervaporation, using an apparatus described previously.[7] The membrane was calcined at 673 K for 3 h prior to each run at a given liquid feed composition in order to ensure that no species remained from previous experiments. The feed concentrations were 5 wt% organic. The permeate vapor was condensed by a liquid-nitrogen trap, and the downstream pressure was maintained below 0.5 kPa. The flux was measured by weighing the permeate, and permeate concentrations were measured by off-line GC.

Fig. 2 shows the steady-state total flux and the MEK/water separation selectivity as a function of temperature. A maximum flux of 0.69 kg m^{-2} h^{-1} and a maximum separation selectivity of 224 were obtained at 333 K. As the temperature increased, the fluxes increased because the diffusion rates increased, and the MEK diffusion rate increased slightly faster than the water diffusion rate. Since pure water permeated faster than pure MEK (Fig. 2), and the ideal MEK/water selectivity was *ca.* 0.8; the high MEK/water selectivity was due to the preferential adsorption of MEK. The separation selectivity was higher than the vapor–liquid equilibrium selectivity, which was 90 at 333 K.

Smetana *et al.*[8] separated a MEK/water mixture using a silicalite membrane and obtained a maximum MEK/water selectivity of 146 at 307 K with a MEK flux of 0.25 kg m^{-2} h for a 5 wt% MEK feed. Their results were similar to those measured for a silicalite-filled silicone composite membrane reported by Devine *et al.*[9] The ZSM-11 membrane has a similar flux and a higher selectivity.

Table 1 shows the pervaporation results for separation of propan-1-ol and propan-2-ol from aqueous solutions through the B-ZSM-11 membrane at 333 K. For comparison, fluxes and

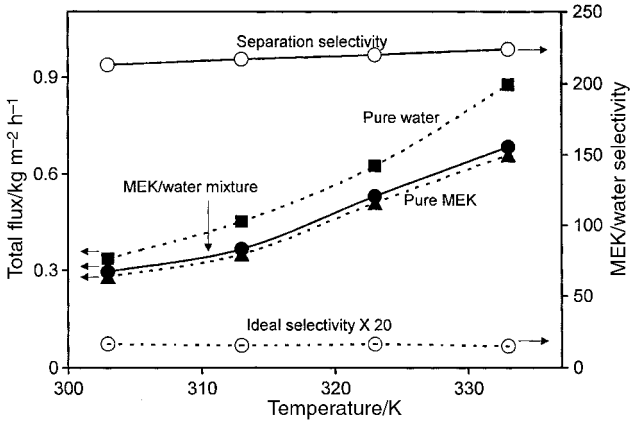

Fig. 2 Total flux and MEK/water selectivity as a function of temperature for pervaporation of a 5 wt% MEK aqueous solution through a B-ZSM-11 membrane. The flux of pure water and pure MEK are also shown. The ideal selectivity is the ratio of the fluxes.

DOI: 10.1039/b008547m

Table 1 Comparison of pervaporation results through B-ZSM-11 and B-ZSM-5 membranes for propanol/water mixtures at 333 K

Feed solution	Membrane	Total flux/ kg m^{-2} h^{-1}	Separation selectivity
Propan-1-ol/water	B-ZSM-11	0.25	25
	B-ZSM-5	0.072	7.8
Propan-2-ol/water	B-ZSM-11	0.31	16
	B-ZSM-5	0.068	7.0

selectivities are presented for a B-ZSM-5 membrane.[3] Both membranes had two zeolite layers prepared by similar procedures, but the fluxes and separation selectivities for the B-ZSM-11 membrane are approximately three times higher. Both propan-1-ol/water and propan-2-ol/water separation selectivities are higher than their ideal selectivities (0.21 and 0.18, respectively), and this indicates separations is due to preferential adsorption.

For MFI zeolites, the surface changes from hydrophobic (silicalite-1) to hydrophilic (Al-ZSM-5) when Si is replaced by Al in the framework. However, the substitution of B instead of Al in both MFI and MEL frameworks apparently does not make the membrane hydrophilic since high organic/water selectivities were obtained for the boron-substituted membranes, and the separations were due to preferential adsorption.

The development of scanning probe techniques has opened new ways to visualize and gain insight in chemical and physical processes with unprecedented spatial resolution. Scanning near-field optical microscopy combining high spatial topographic resolution and optical resolution surpassing the diffraction limit, has been applied for structure determination and manipulation studies of organic materials. With scanning tunnelling microscopy, photo-induced chemical reactions have been studied at the liquid/solid interface with subnanometer resolution.

Introduction

The birth of scanning probe techniques revolutionized the way small objects or domains can be visualized. Common to all scanning probe techniques is a tiny probe, which scans a surface at a very small distance from it and the interaction between probe and object is translated into a signal. The ultimate control in positioning has been achieved by using piezoelectric elements. Since the invention of the scanning tunnelling microscope (STM),[1] several experimental schemes have been developed which allow detection of a great variety of interactions between probe and surface. Among those techniques, scanning near-field optical microscopy (SNOM)[2,3] takes a special place due to its optical resolution below the diffraction limit.

In STM, a metallic tip is brought very close to a conductive substrate and by applying a voltage between both conductive media, a tunnelling current may result (Fig. 1A). The exponential distance dependence of the tunnelling current provides excellent means to control the distance between the probe and the surface. Very high resolution (atomic) can be achieved but in general, the use of this probe technique is limited to conductive substrates. In contrast, in atomic force microscopy (AFM) forces exerted by the sample on the tip are recorded and several detection schemes are possible. In addition, modification of tips with carbon nanotubes leads to supertips with enhanced spatial and mechanical properties[4] and chemically modified AFM tips provide chemical contrast and can allow the measurement of binding forces.[5]

SNOM combines both the possibilities of AFM and optical microscopy. On the one hand, it allows for probing the surface and obtaining information on the topography. On the other hand, in aperture SNOM, the probe contains an aperture and the sample can be illuminated very locally (Fig. 1B). The diameter of the aperture at the end of the probe is typically of the order of 50–100 nm and therefore the illuminating spot is not diffraction limited. Both transmission and fluorescence in combination with polarization provide appropriate contrast mechanisms. The high sensitivity of this technique has been demonstrated by its ability to detect even single molecules.[6,7]

Frans De Schryver obtained his doctoral degree at K.U.Leuven in 1964 and returned as staff member to his Alma Mater after a two-year postdoctoral stay as a Fulbright fellow at the University of Arizona with Speed Marvel. He became a Full Professor in 1975 working in the field of photochemistry and photophysics. He received a Humboldt research award in 1993 and stayed with G. Wegner and J. P. Rabe at the Max-Planck-Institute for Polymer Research in Mainz. As a result of this stay he combined space and time resolution in the study of organic molecules. He received the Porter medal in 1998 and the Havinga medal and Forster memorial lecture award in 1999.

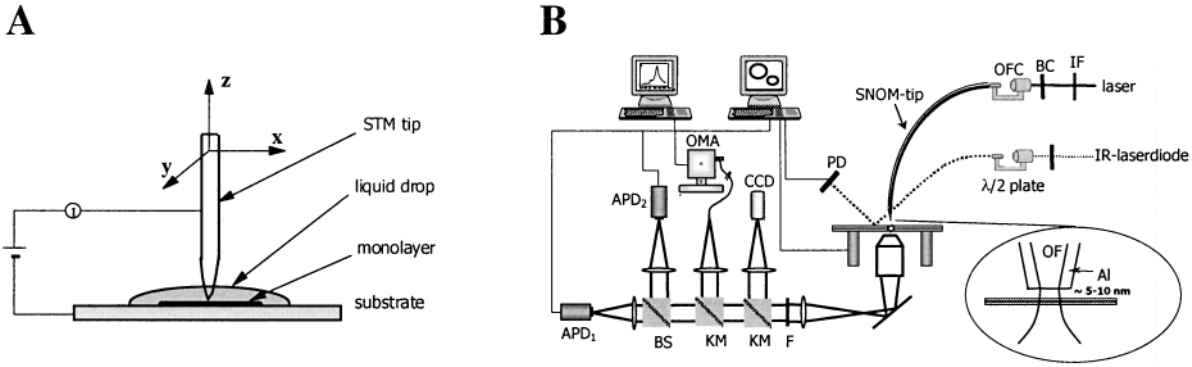

Fig. 1 (A) Scheme of a STM-setup. Note that during the experiments the tip is partially immersed in the fluid layer. (B) Scheme of the SNOM-setup. IF = interference filter, BC = Berek's compensator, OFC = optical fiber coupler, OF = optical fiber, PD = photodiode, F = filter, KM = kinematic mirror, BS = beam splitter, CCD = charge coupled device, APD = avalanche photodiode, OMA = optical multichannel analyser.

The high-resolution qualities of these techniques in addition to their local probing character make them very useful tools for the study of surface phenomena in various research fields. In our research group these techniques have been used to study several photo-induced processes at surfaces. In the first section here we will demonstrate how SNOM is useful in characterising and modifying the optical properties of materials on a sub-micrometer size. In the second, we will exemplify the use of STM for studying photo-induced reactions at the liquid/solid interface.

Scanning near-field optical microscopy

There are a number of excellent reviews on SNOM,[8–12] and its applications in the study of organic materials.[11,13–16] The reader is referred to these reports for detailed information on the technique and some of its applications. We focus on some of our results on the use of SNOM for the study of organic fluorescent materials and photo-induced local modifications in thin films or on substrates.

Single objects

Latex beads

As stated in the introduction, SNOM allows study of the optical properties of materials with subwavelength resolution. Thin poly(vinyl alcohol) (PVA) polymer films containing dye-labelled 100 nm beads were investigated.[17,18]

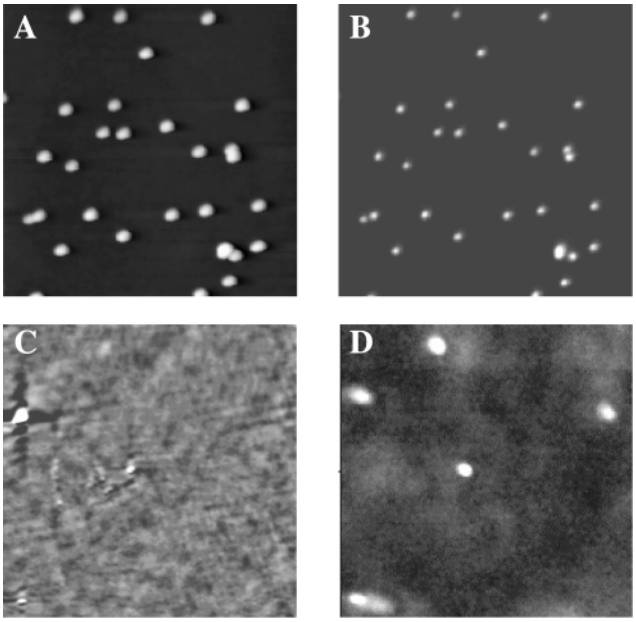

Fig. 2 SNOM image sets taken from a *ca*. 50 nm thin film (A topography, B fluorescence) and a *ca*. 10 μm thick film (C topography, D fluorescence) consisting of *ca*. 100 nm dye-labeled latex particles embedded in a PVA matrix. Image sizes: $10 \times 10\ \mu m^2$. The excitation wavelength is 488 nm for set A, B and 458 nm for set C, D.

Fig. 2 comprises a topographic (A) and a fluorescence map (B) of a thin polymer film (*ca*. 50 nm as measured by AFM) consisting of dye-labelled latex particles embedded in a PVA matrix. The image set was acquired while the polymer film was irradiated through the aperture probe at an excitation wavelength of 488 nm.[18] Based on their measured size the bead-like structures in the topography images can be attributed to single latex particles. The pattern of the black–white contrast in the topographic images corresponds to a diameter of 109 nm. In the fluorescence map in Fig. 2B, the particles displayed in the topographic image can be correlated with distinct spots of a fluorescence intensity exceeding the background intensity. Note that the size of the fluorescence spots is substantially smaller than the features in the topography image. In the latter, the signal is derived from the interaction of the tip end (including the Al coating surrounding the aperture) and the sample surface, while for the fluorescence measurement, the dimension of the aperture itself determines the optical resolution. The latex particles were also embedded in a film a few μm thick.[17] Fig. 2C,D shows one image set representing on the left side the topography and on the right side the fluorescence map. Where the topography shows only structures with a height substantially less than the size of a latex particle, fluorescence spots of high intensity appear in the fluorescence maps. Only some of these spots correlate with the topographic information. This finding reveals a unique capability of SNOM. In contrast to most scanning probe microscopies, SNOM is able to probe subinterface properties occurring in spatial domains that are located a few 10 nm beneath a sample–air interface. The luminescence properties of these domains can be addressed by the collimated radiation field generated by the aperture probe.

In order to gain insight in the distribution of functional groups and the distance between these functional groups in latex beads, energy transfer in latex beads has been investigated. Therefore, the shell of latex beads (core = polystyrene, shell = poly(acrylate) (PA), diameter *ca*. 100 nm) has been covalently labelled with two different dyes, Bodipy and TMR (Fig. 3). The beads are dispersed in a 10 nm thin PVA matrix. The spectral overlap between the emission spectrum of Bodipy (energy donor) and the absorption spectrum of TMR (energy acceptor) allows for efficient energy transfer between those dyes within individual latex beads. The energy transfer process has been 'visualized' by recording the wavelength dependent fluorescence intensity of individual beads obtained upon excitation of the Bodipy chromophores for different label concentrations. The fluorescence maps and spectra clearly show efficient excitation energy transfer within a single latex bead and energy transfer is more pronounced when the relative distances between donor and acceptor decrease. The efficiency of the energy transfer ranges from 85 to 57%, depending on the dye concentration (Fig. 3A). No significant differences have been found between different beads. When those beads are dispersed in a poly(acrylate) matrix, which has a lower T_g compared to PVA, the excitation energy transfer efficiency decreases (74% relative to 85%) and this is more pronounced (62%) when the samples are annealed (Fig. 3B). This has been attributed to 'swelling' of the PA latex shell, resulting in an increase of the distance between chromophores and a decrease in energy transfer efficiency.

SNOM not only allows investigation of photophysical properties of chromophore labelled latex beads, but also permits the visualization of a phototransformation leading to bleaching.[17] The latex particles in the topographic image of Fig. 4A are clearly correlated with fluorescence structures in the corresponding fluorescence map (Fig. 4B). The torus-like shaped fluorescence structures do not directly reflect the dye distribution on the particles, but result from the overlap of the intensity distribution of the radiation field beneath the aperture. In the course of the photobleaching experiment, the SNOM probe was positioned above the particle on the right, and the particle was raster-scanned while the particle was irradiated with the 458 nm light emanating from the probe. After 2 h, almost no fluorescence is observed from the denoted position in the fluorescence map (Fig. 4D), where the probe illuminated the latex particle. However, the topography image (Fig. 4C) indicates that the particle was not removed or destroyed during scanning. This experiment demonstrates that a photochemical reaction can be induced upon irradiation with the SNOM probe and that the photochemical reaction induced by the optical near-field is restricted to a nanometer length scale. Local photobleaching has also been demonstrated in molecular systems,[19] supramolecular systems[20] and polymers.[21]

Supramolecular structures

Porphyrin rings

In addition to the study of single objects, SNOM also helps to visualize parts of supramolecular structures. The formation of ring-like structures has been observed in the evaporation process of organic solutions containing a broad range of materials including metal particles,[22] polymers,[23] proteins[24] and organic molecules.[25–27] In particular, the deposition of these solutions on a substrate lead to micron scale ring-shaped arrangements of the solute/dispersed materials. Using SNOM, a deeper insight into the morphology and the local optical properties of solvent-evaporated porphyrin thin films has been reached. In particular, the effects of the concentration of the starting solution on the film morphology have been investigated.

Evaporation of a 10^{-6} M solution of PtP (Fig. 5A) in $CHCl_3$ on glass yielded symmetric rings for which the topography and fluorescence images are highly correlated.[25]

The ring diameter ranges between 100 nm and 10 μm, while the height of the rims, determined from the SNOM topographic image, varies between 10 and 300 nm. The fluorescence intensity measured inside the rings equalled the background value indicating the absence of porphyrin material at these positions. The use of a more dilute solution (10^{-7} M) resulted in the formation of incomplete ring-shaped assemblies that were made up from individual isolated structures which were observed both in the topography and the fluorescence image (Fig. 6B). In these conditions the rings had smaller diameters and the heights of the beads that comprise most of the rings were substantially smaller than the heights of the well formed rings prepared from more concentrated solutions.

A further characterization of the films in terms of the local optical properties and molecular organization was performed using fluorescence polarization imaging. From these data it

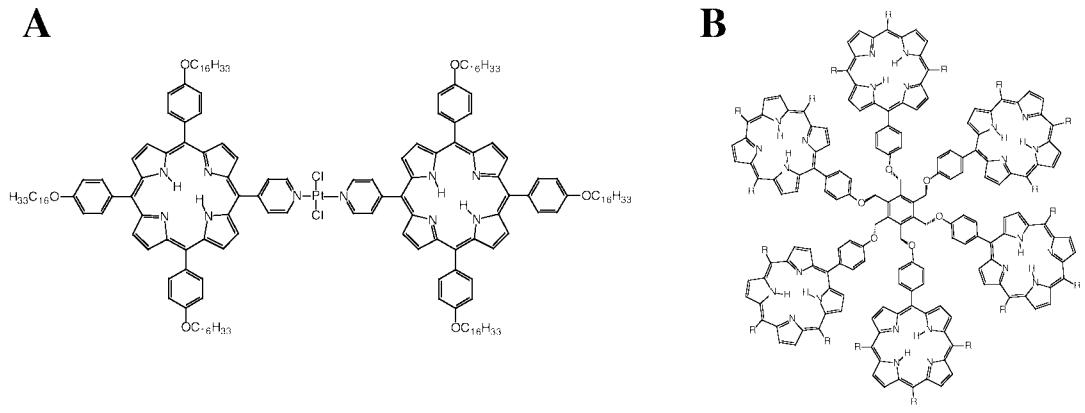

Fig. 5 Schematic representation of PtP (A) and BP_6 (B).

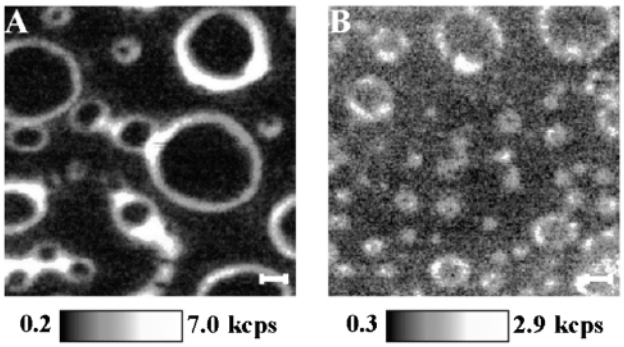

Fig. 6 SNOM fluorescence images of evaporated films of PtP/$CHCl_3$ solutions on glass. The scale bars represent 1 μm. (A, B) Fluorescence image taken on a sample prepared by solvent casting of a 10^{-6} M (A), and a 10^{-7} M (B) solution.

could be stated that in these films small, organized aggregates are present which, by using linearly polarized light for excitation, can be photoselected and that these aggregates show polarized emission. The length of these aggregates, as determined from the line profiles taken in the fluorescence polarization images, varies between 50 nm and *ca.* 300 nm. Annealing of the PtP ring samples leads to an increase in size, density and ordering of the aggregates.

Similar experiments were performed using samples prepared by evaporation of a $BP_6/CHCl_3$ (Fig. 5B) solution. For the samples studied before annealing, the images corresponding to the different polarization configuration were identical (images are not presented). On the other hand, the annealed samples exhibit strong polarization contrast. When the fluorescence intensity distributions in the rings are compared to what was found for PtP, a much smoother profile is observed. For the BP_6 samples the intensity distribution depends over a longer range on the excitation polarization with parallel emission polarization. When the excitation polarization is oriented horizontally in the image (Fig. 7B) the upper and lower parts of the rings have a relative higher intensity than the left and the right parts of the rings. Turning the excitation polarization 90 degrees (Fig. 7C) results in higher fluorescence intensity for the left and right parts of the ring. The different intensity distributions are not observed in the images taken with the excitation and the emission polarization oriented perpendicular with respect to each other. The observed fluorescence pattern can only be explained if there is a preferential orientation of the molecules in the rings. This would lead to a specific orientation of the absorption dipoles in the ring. Using polarized excitation results in a preferential absorption of the excitation light at the positions where the polarization and the absorption dipole of the chromophore are parallel. This results in higher fluorescence intensity at the respective positions. If the molecules are schematically presented as disks the orientation should be preferentially perpendicular to the sample plane. A possible arrangement of the disks in the rings could be one with the planes parallel or perpendicular to the radial of the ring.

These rings have been mechanically manipulated at the submicron scale with AFM. This manipulation was carried out by implementing an interface, called the nanoManipulator, on a combined AFM–confocal microscope.[28] A small amount of the fluorescent material from the ring could be displaced with the AFM tip. A special tool (sweep mode), in which the AFM tip is moved very fast perpendicular to the direction of the desired manipulation which creates a virtually broader tip, allowed a modification of 130 nm (Fig. 8A). The resolution attainable in these kinds of experiments could go down below 100 nm and is primarily determined by the tip and sample geometry. Besides the possibility of mechanically manipulating porphyrin rings using the force applied by an AFM tip, it is feasible to manipulate or modify locally the optical properties of these rings in terms of tip-induced photobleaching using the light coming from a SNOM-tip.[28] In such an experiment the dimensions of the manipulated area are related to the size of the SNOM probe used in the experiment (Fig. 8B).

J-Aggregates in polyelectrolyte layers

As an alternative to Langmuir–Blodgett (LB) film deposition,[29,30] self-assembly techniques based on covalent or coordination chemistry were developed.[31,32] In the beginning of the 1990s, Decher *et al.* demonstrated the alternate adsorption of cationic and anionic polyelectrolytes as a novel technique for the preparation of molecular multilayers.[33] This method was applied for the layer by layer fabrication of alternate assemblies containing J-aggregates[34,35] of a cyanine dye. J-Aggregates act as a multi-charged supramolecular ensemble, which promises a strong adsorption. Only a few papers report local properties of J-aggregates on a nanometer scale. The group of Barbara has applied SNOM to the investigation of J-aggregates, examining J-aggregates of 1,1′-diethyl-2,2′-cyanine iodide, pseudoisocyanine (PIC) which were formed in a solution with poly(vinyl sulfate) (PVS) and spin-coated onto quartz substrates.[20,36,37]

We have used SNOM for the investigation of J-aggregates of 3,3-disulfopropyl-5,5′-dichloro-9-ethylthiacarbocyanine (THIATS), formed in a layer by layer self-assembled multilayer when alternating with the cationic polyelectrolyte, poly-(allylamine) (PAH) The influence of the top layer and of ageing of the samples was studied.

Fluorescence images were obtained for a freshly deposited sample [glass/poly(styrene sulfonate] (PSS)/PAH/THIATS/PAH). The micrographs were obtained by excitation at 514 nm and collecting the total fluorescence. In the fluorescence micrograph, very short organized structures with an enhanced

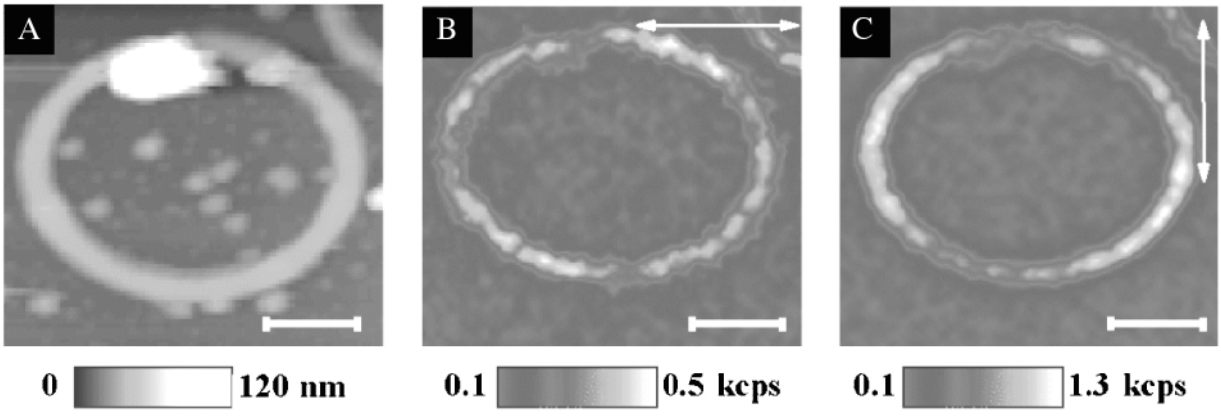

Fig. 7 A set of SNOM topographic and fluorescence polarization images acquired from a sample prepared by evaporation of a 10^{-6} M $BP_6/CHCl_3$ solution on glass after annealing in an oven at 75 °C for several days. The white scale bar on each image represents 1 μm. The orientation of the excitation polarization is indicated with the white arrows on the images. All fluorescence images are acquired with a parallel polarization configuration.

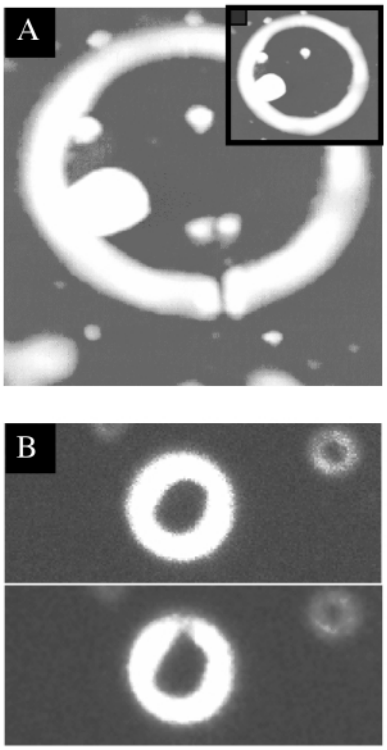

Fig. 8 (A) Mechanical and (B) optical manipulation of porphyrin rings at the submicrometer scale. (A) AFM image. The modification (cut through the ring) is around 130 nm. The insert is the intact ring before manipulation. (B) SNOM fluorescence images of a porphyrin ring before (upper half) and after (lower half) local photobleaching with a SNOM tip, leading to a modification of 280 nm wide.

fluorescence can be observed (Fig. 9A). Annealing of this sample at 70 °C induced structures in the fluorescence micrograph which resemble a needle-like pattern (Fig. 9B). The structures in the freshly deposited sample can be the nucleating sites for this pattern. The needle-like pattern was also observed in the fluorescence micrographs obtained for a multilayer which was kept at room temperature for 45 days after deposition (Fig. 9C). This suggests that a re-orientation and redistribution of the dye molecules into microcrystals does not happen immediately after deposition but that ageing of the sample is needed to obtain the needle-like pattern in the fluorescence micrograph. High-resolution images (not shown) reveal that the experimental width of the needles, measured in near-field, is about 80 nm, which corresponds to the lateral optical resolution of the experiment. The length of the needles exceeds a micron. We attribute the formation of needle-like structures to the PAH layer on top of the dye layer which must induce a redistribution and re-orientation of the dye molecules into microcrystals. The smoothness of topography suggests that the height of the microcrystals is small compared to the thickness of one polymer layer.[38,39]

In order to investigate to what extent the crystallites observed in the fluorescence image are oriented, polarized fluorescence images were obtained. Fig. 10 displays fluorescence images for a sample with PAH as top layer and for which the time between the deposition and the measurements was 45 days. Image 10A, B, C and D are the micrographs with 0°–0°, 0°–90°, 90°–0°, 90°–90° orientation of the polarizer and analyser, respectively. For different orientations of the emission polarizers different image contrasts were obtained. Fluorescence micrographs, obtained with the same orientation of the analyser but with different orientations of the polarizer, show the same fluorescent structures. The image contrast is furthermore independent of the excitation polarization at a fixed emission polarization. This indicates that the absorbing species is oriented randomly and that no photoselection occurs. One should realise that 514 nm, where the excitation occurs, is far from the absorption maximum of the J-aggregates situated at 623 nm. At 514 nm absorption is probably mainly due to residual monomers and sandwich dimers which transfer their excitation energy to the J-aggregates.

With a 'horizontal' orientation of the analyser, the emission of 'vertically' oriented needles was enhanced, while with a 'vertical' orientation of the analyser, the emission of 'horizon-

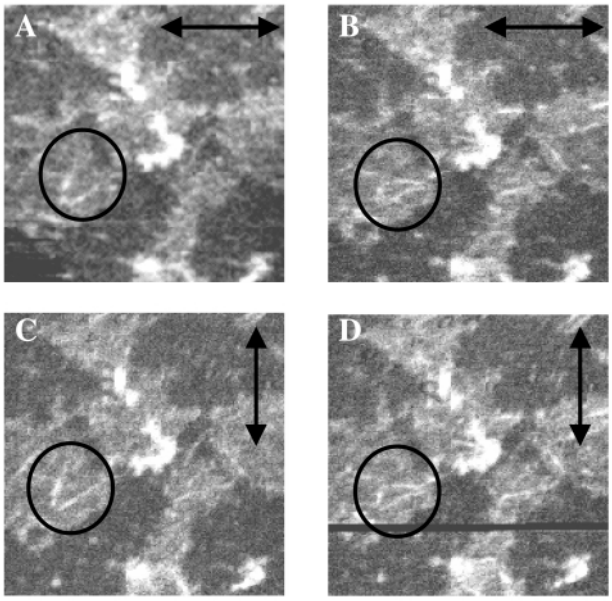

Fig. 10 Polarized SNOM measurements of a THIATS-containing multilayer covered by a layer of poly(allylamine) (PAH): Fluorescence micrographs with 0°–0° (A), 0°–90° (B), 90°–0° (C), 90°–90° (D) orientation of the excitation polarizer and fluorescence emission analyser respectively. The arrows indicate the excitation polarization. Excitation occurred at 514 nm.

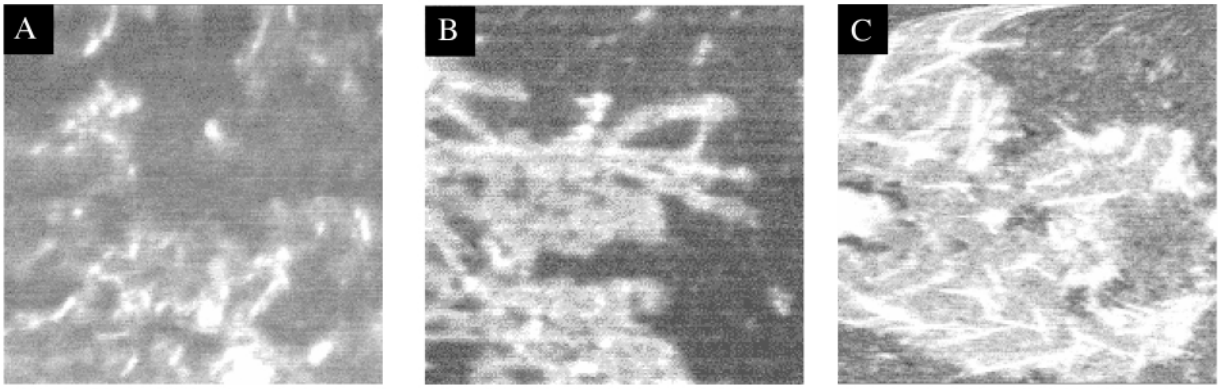

Fig. 9 SNOM fluorescence micrographs of a 10 μm × 10 μm sample with a PAH top layer: fresh sample (A), annealed sample (B), aged sample (C). Bright areas correspond to high fluorescence while dark areas correspond to low fluorescence relatively to each other.

tally' oriented needles was enhanced. This indicates that the transition dipoles of the emitting species have an orientation, which is highly correlated over several hundreds of nanometers to several microns. Furthermore in the 'horizontally' oriented needles, the emission dipole of the dye molecules will be oriented preferentially 'vertical' and *vice versa*. Needle-like structures, which are oriented at an angle of 45°, are visible in all the fluorescence micrographs. In Fig. 10, the area where the influence of the polarizers is clearly visible is marked with a white circle.

Excitation of residual monomers and dimers at 514 nm resulted in J-aggregate emission, which is polarized. The emission dipole of the dye molecules is oriented perpendicular to the needles. If a 2-D brickstone arrangement[40,41] is assumed for the aggregates their maximum π–π-interactions will occur perpendicular to the transition dipole and in the plane of the aggregate. Also the largest plane of the molecule is that parallel to both the long and the short axis. Hence packing along this plane will both be characterized by the largest π–π-interactions and reduce the hydrophobic interaction to a maximal extent. Therefore, the maximum growth rate of the microcrystals will be observed in those directions.

Scanning tunnelling microscopy and photochemistry

Where optical detection with SNOM is still limited to tens of nm, STM allows us to increase further the spatial resolution. In the last two decades, STM has proven to be a very valuable tool for the structure determination of surfaces at subnanometer resolution. The use of this technique is not restricted to a low temperature UHV environment but it has a wider application field and has also been applied successfully under ambient conditions and even in liquids. Moreover, the use of STM has been extended to the study of organic molecules physisorbed on conductive substrates at the liquid/solid interface.[42–47] In our research group, topics such as structure,[48] chirality,[49–51] dynamics[52–56] and light-induced reactions[57–59] are studied in physisorbed organic monolayers at the liquid/solid interface under ambient conditions.[60] The samples are prepared by applying a drop of a solution containing the compound under investigation on the basal plane of a freshly cleaved piece of highly oriented pyrolytic graphite (HOPG). The molecules are adsorbed on the graphite surface by physisorption. Adsorbate–substrate and adsorbate–adsorbate interactions lower the molecular mobility. This decrease in mobility (dynamics) is important for successful high resolution imaging with STM, which is often realized, in our group, by using molecules which display high affinity for the graphite substrate, for instance by having long alkyl chains. Intermolecular hydrogen bonding stabilises the two-dimensional network formed by the physisorbed molecules studied. In contrast to Langmuir–Blodgett films of fatty acids and their salts, the molecules are in most cases oriented parallel to the graphite substrate. It is important to note that during the measurements, the STM tip is immersed in the solution on top of the monolayer and that during the measurement molecules in the physisorbed monolayer might undergo desorption–adsorption dynamics. The presence of the solvent layer has some advantages. On one hand, it allows for the repair of defects in the monolayer by the desorption–adsorption dynamics and on the other hand, it lowers the force of the STM tip on the monolayer during scanning.

Using this experimental approach, we have investigated some photochemical reactions at the liquid/graphite interface. The aim of these studies was to demonstrate the feasibility of using STM for the study of photo-induced processes and on the other hand to learn more about these processes by STM.

A reversible reaction: *trans–cis* isomerization

With the aim of imaging the starting material and the reaction product of a reversible photoreaction, the *cis–trans* isomerization of an azo isophthalic acid derivative was investigated.[58] Upon irradiation with light of an appropriate wavelength, the *trans* to *cis* isomerization can be induced.

To achieve an efficient conversion of the *trans* to the *cis* isomer, the irradiation wavelength should match the absorption maximum of the *trans* isomer. The absorption maximum of the *cis* and *trans* isomer is situated at 317 and 360 nm, respectively. Upon irradiation at 366 nm, a photostationary mixture with a high *cis* isomer content is reached. When kept in the dark at room temperature the *cis* isomer spontaneously converts to the thermodynamically more stable *trans* isomer. For the STM experiments, an almost saturated solution of the azo compound in undecan-1-ol was applied on the surface of a freshly cleaved HOPG piece (Fig. 11). The solvent undecan-1-ol was selected

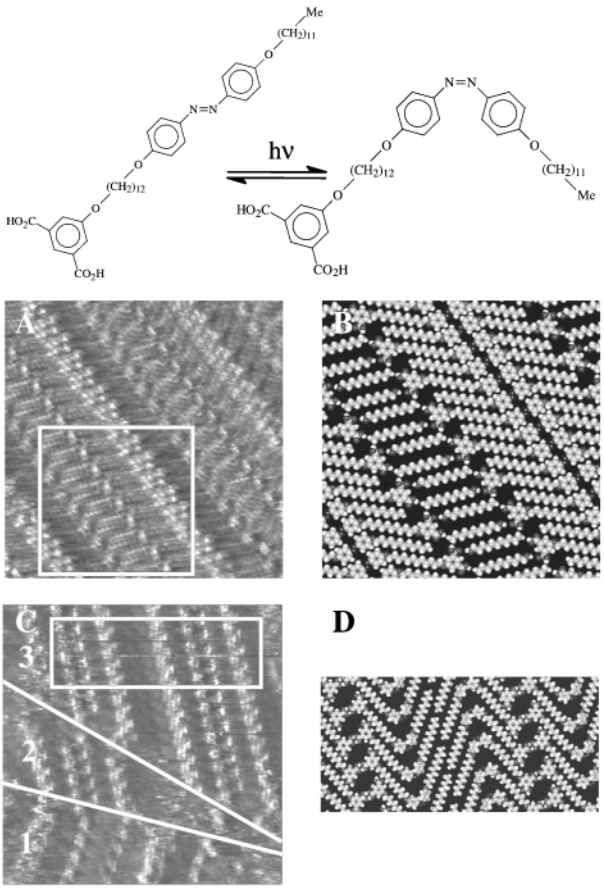

Fig. 11 *Cis* and *trans* isomer, reagent and product of a reversible photo-induced reaction. (A) STM image of an ordered monolayer of *trans* formed by physisorption from undecan-1-ol. Image size is 13 × 13 nm². White corresponds to the highest and black to the lowest measured tunnelling current in the image. (B) Molecular model for the two-dimensional packing of *trans*. The molecular model represents the area indicated in the STM image. (C) After illumination, STM image of an ordered monolayer of coexisting *cis*- and *trans*-domains. The domain boundaries are indicated by white lines. Image size is 13.4 × 13.4 nm². The molecular order in domain 1 corresponds to *trans*. The molecular order in domain 2 and 3 can be correlated with *cis*.

for its high boiling point (the solvent layer stays on top of the monolayer for several hours); in addition the solvent competes for intermolecular hydrogen bonding of the solute molecules which might disfavour physisorption.

Fig. 11A and 11B show an STM image and model of a monomolecular layer of the *trans*-form physisorbed from undecan-1-ol and shielded from light. The images are recorded in the constant height mode and the contrast is a function of the tunnelling probability as a function of *xy* coordinates. Bright and dark features in the images reflect a high and low tunnelling probability, respectively. Distinct bright spots corresponding to the isophthalic acid groups are easily recognized in the image. The somewhat broader bright bands represent the azobenzene moieties; in addition, the alkyl chains can be recognized in the image. Undecan-1-ol molecules are co-deposited in lamellae

separating lamellae of the azo-compound. Fig. 11C shows an STM image of a monolayer obtained by physisorption from a photostationary mixture after illumination of the solution in a cuvette (*ex situ*) at 366 nm. In addition to the regular monolayer structure characteristic for *trans* (domain 1), a new monolayer structure appeared which was not observed for *trans* monolayers (domains 2 and 3). Therefore, the patterns observed in these two domains must originate from a different molecular arrangement. Again, the bright spots correspond to the isophthalic acid groups and the broader bright bands to the azobenzene moieties. The measured lamellar distances and the observed molecular packing correspond to a monolayer of self-assembled *cis* isomers without solvent co-deposition. The absence of solvent co-deposition is probably due to the spatial orientation of the acid functions in the molecular arrangement of the *cis* isomer. It was not possible to form adlayers, which show solely *cis* structure. This can be attributed to the photostationary character of the mixture and to the larger affinity of *trans* compared to *cis* to form monolayers on the graphite surface. During imaging, the *cis* domains disappear with time. Finally, only *trans* domains could be observed, illustrating the reversibility of the reaction at the liquid/graphite interface. Similarly, *trans–cis* isomerization could be induced and their respective domains imaged by irradiating *in situ* a droplet of the *trans* isomer dissolved in undecan-1-ol directly on the graphite surface.

A possible mechanism for replacement of physisorbed 'reactant' molecules by the 'product' initiated by *in situ* illumination is the following. Irradiation of the system will lead to a change of the equilibrium composition and a concentration gradient in the supernatant solution. A decrease in *trans* concentration will induce desorption and enhance the adsorption of *cis* molecules. In addition, the isomerization reaction could also occur on the graphite surface itself and initiate the *cis*-product domain formation although this is expected to contribute only to a minor extent due to steric hindrance. During imaging (illumination off), these *cis* domains disappear with time until finally only *trans* isomer domains remain, due to the thermal back reaction (*cis* to *trans*).

The *cis–trans* isomerization has also been studied for another isophthalic acid derivative where one of the phenyl groups of the azobenzene moiety is the isophthalic acid group. Also for this compound the reaction could be visualized, however only after illumination *ex situ*.[60]

An irreversible reaction

In addition to a reversible *cis–trans* isomerization, an irreversible photoreaction was studied: the phototransformation of 10-diazo-2-hexadecylanthrone to 2-hexadecyl-9,10-anthraquinone.[57] Irradiation leads to the dissolution of the highly ordered molecular pattern of the reactant, starting at a domain boundary. When the irradiation is stopped, the highly ordered pattern reappeared and recrystallization of the reactant molecules occurred. As described in the previous section, the desorption must be the result of the formation of a concentration gradient induced by illumination. When irradiation is stopped, the system relaxes and the 2D crystal is reformed. Only when all reactant was transformed to product, which occurred after several illumination cycles were monolayers of 2-hexadecyl-9,10-antraquinone formed. Both phototransformations are believed to take place predominantly in the supernatant solution.

A topochemical reaction

To demonstrate the possibility of reactivity *within* the physisorbed monolayer, the study of a topological reaction was considered: the photopolymerization of a diacetylene[59] for which it is known that the relative orientation of the diacetylene monomer groups is critical as is shown in numerous studies in 3D crystals. The molecule chosen in this study is the diacetylene containing isophthalic acid derivative (Fig. 12).

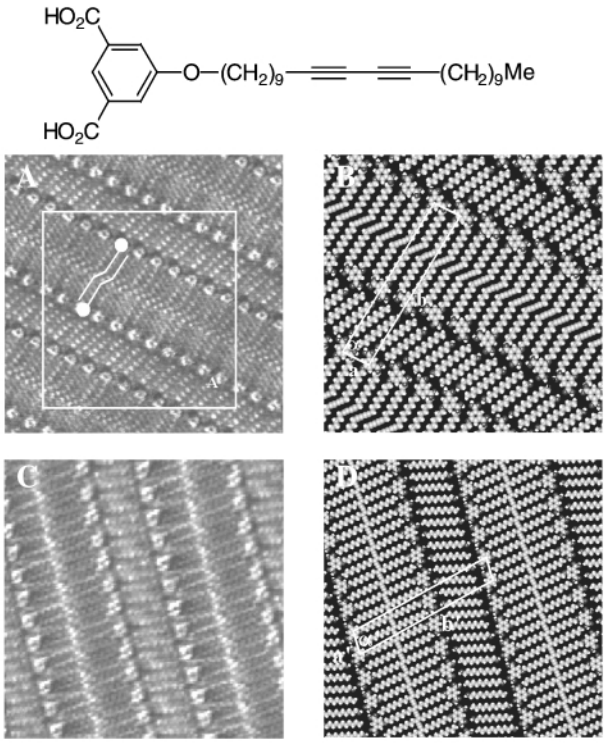

Fig. 12 Molecular structure of 5-(10,12-tricosadiinyloxy)isophthalic acid. (A) STM image of a physisorbed monolayer monomer from a solution in undecan-1-ol. Image size is 12.7 × 12.7 nm². The orientation of two molecules is indicated with a stick model. (B) Corresponding molecular model of the area indicated in the STM image in (A). (C) STM image of a polymerized monolayer structure. Image size is 10.8 × 10.8 nm². (D) Molecular model of the imaged area in (C).

This compound forms a physisorbed monolayer spontaneously at the liquid/graphite interface from a undecan-1-ol solution (Fig. 12A). The structure consists of lamellae of the diacetylene derivative alternated by solvent lamellae. The diacetylene moieties appear as bright spots in the middle of the lamellae. Within a lamella, the distance between isophthalic acid groups is 9.44 ± 0.09 Å. The alkyl chains are lying parallel to the substrate in the direction of one of the main graphite axes, and the orientation is modelled in Fig. 12B. After *in situ* illumination (254 nm, no scanning) of the monolayer film on graphite, the surface was re-examined, using the same scanning parameters as prior to the illumination, and again monolayer structures are observed (Fig. 12C). Isophthalic acid groups and solvent molecules are well resolved. The contrast in the middle of a lamella can be described by a series of bright spots, clearly distinct from the individual acetylene units, which suggests that the monolayer structure might be polymerized along the lamella direction. The most important change in the monolayer structure, however, is the change in spacing between the isophthalic acid groups. The distance was determined to be 9.81 ± 0.05 Å, in contrast to the unpolymerized repeating distance of 9.44 ± 0.09 Å. A molecular model for a polymerized monolayer structure is shown in Fig. 12D. The experimental value of 9.81 Å for the isophthalic acid group distance is in perfect accordance with the value of 9.82 Å obtained in a model optimized for the polymer chain. Consequently, the repeating distance in the polymer backbone is 4.91 Å which is in agreement with the three-dimensional crystal structure data of polymerized diacetylenes.[61] The structural parameters, describing the orientation of adjacent diacetylene units in unpolymerized monolayers, correspond to those values for which it was shown experimentally by X-ray crystallography of 3-D samples that crystallized diacetylene monomers could polymerize.[61]

Conclusions

The invention and development of scanning probe microscopy techniques has opened new ways to study surface phenomena with unprecedented resolution. The strength of these techniques is the very local nature of the probing mode and their general applicability even under ambient conditions, combined with the very high resolution. Both STM and SNOM have proven to be valuable tools in the study of thin organic films and photo-induced modifications on a very small scale. STM is for these kinds of systems used for the observation of the reactions while SNOM can optically modify material in an active way. Both techniques will continue to contribute in an important way to the study of photo-induced modifications on surfaces.

Acknowledgements

We thank the DWTC, through IUAP-IV-11, the F.W.O.-Vlaanderen and ESF SMARTON for financial support. We also gratefully thank Dr K. Grim, Dr P. Vanoppen, Dr K. Jeuris, A. Gesquière, M. Abdel-Mottaleb, E. Rousseau and P. Foubert for their substantial input in the realization of the experiments. S.D.F. and J.H. thank the Fund for Scientific Research–Flanders (FWO) for a postdoctoral fellowship. The collaborations were made possible thanks to the TMR project SISITOMAS.

The reaction of chiral *N*,*N*′-bis(aryl)tetrahydropyrrolo-[2,1-*c*][1,4]oxazine-3,4-diylidenediamines with carbon monoxide and ethylene in the presence of a catalytic amount of $Ru_3(CO)_{12}$ leads to the formation of spiro-lactams by a formal [2 + 2 + 1] cycloaddition reaction, whereas the imine double bond next to the oxazine nitrogen atom remains unreacted; the same spiro-lactams may be synthesized if iron carbonyl complexes of the *N*,*N*′-bis(aryl)tetrahydropyrrolo-[2,1-*c*][1,4]oxazine-3,4-diylidenediamines are introduced as the starting compounds.

Spiro-lactams have been described as the key intermediates in the total synthesis of several natural products[1] *e.g.* cephalotaxine or aldosterone antagonists, where the lactam ring system is attached to the D-ring of a steroid core.[2] Spiro[pyrrolidine-3,3′-indole] and spiro[pyrrolidine-3,3′-oxindole] derivatives are known as natural products with high cytostatic potential.[3] On the other hand, Murai *et al.* have synthesized functionalized γ-butyrolactones by a formal [2 + 2 + 1] cycloaddition reaction from a ketone, ethylene and CO.[4] It has also been described that the reaction of CO and/or olefins with unsaturated imines catalyzed by $Ru_3(CO)_{12}$ proceeds *via* C–H activation steps in the β-position with respect to the C–N double bond, followed by insertion reactions of CO and the olefins into the carbon metal bond. These reactions lead to functionalized imines or in some cases *via* intramolecular cyclization reactions to dihydropyrrol-2-one or dihydrobenzoisoindol-1-one derivatives, respectively.[5] Similar reactions have also been reported starting from N-heterocyclic compounds or aromatic ketones, respectively.[6]

If the cycloaddition reaction described by Murai and coworkers were also to work in the case of ketimines as starting compounds, one would formally end up with spiro-lactams if the organic substituents R and R′ of the ketimines formed a cyclic moiety (Scheme 1).

In addition, it would be of interest to perform this reaction with chiral ketimines in order to achieve stereoselective reactions, which in most cases are necessary in the synthesis of natural products. Therefore we chose the chiral *N*,*N*′-bis(aryl)-tetrahydropyrrolo[2,1-*c*][1,4]oxazine-3,4-diylidenediamines, which may be easily prepared from *N*,*N*′-bis(aryl)oxalimidoyl chlorides, and *S*-prolinol[7] as the starting compounds. In our earlier work we were able to show that these ligands react with $Fe_2(CO)_9$ to produce dinuclear iron carbonyl complexes in which the $Fe_2(CO)_6$ moiety is coordinated to the diimine ligand in an unsymmetrical fashion.[7c] One of the iron atoms is coordinated by both imine nitrogen atoms *via* their lone pairs whereas the second metal is coordinating the imine double bond next to the oxazine oxygen atom in side-on fashion (Scheme 2). This unsymmetrical coordination mode of a 1,4-diazadiene ligand has also been described in the literature.[8]

Scheme 2 shows the reaction of the diimine ligands **1**–**3** with CO and ethylene in the presence of a catalytic amount of $Ru_3(CO)_{12}$ to produce the spiro-lactams **4**–**6**. This reaction may be described as a formal [2 + 2 + 1] cycloaddition reaction of a ketimine with CO and ethylene to give a pyrrolidin-2-one system. Remarkably, only one of the imine moieties of the starting compounds does react. The cycloaddition only takes place at the C–N double bond neighboring the oxazine oxygen atom. This imine moiety is also the one that coordinates the second iron atom in a side-on fashion if **1**–**3** are reacted with stoichiometric amounts of $Fe_2(CO)_9$ (Scheme 2).[7c] So the reaction discriminates between the two imine subunits of the starting material whereas in principle both should be reactive.

Crystallization from toluene produced crystals of one of the diastereomers of **4** suitable for X-ray structure analysis.[9] The result is depicted in Fig. 1. The molecular structure shows the tetrahydropyrrolo[2,1-*c*][1,4]oxazine system which was already present in **1**. Now one of the former imine carbon atoms is the spiro-atom to which the pyrrolidone ring formed by the cycloaddition is attached (C6). The bonds from the pyrrolidone nitrogen atom (N2) towards the surrounding carbon atoms are in the single bond size-range with the bond to the carbonyl carbon atom (C10) being slightly shorter due to partial delocalization of π-electron density from the C–O double bond to the nitrogen. The bonds of C8 and C9 which represent the former ethylene molecule are also clearly single bonds. As expected, the planes through the oxazine and the pyrrolidone ring systems show a

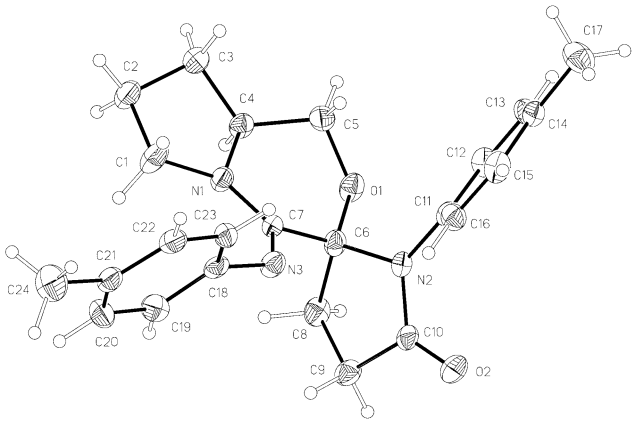

Fig. 1

nearly perpendicular arrangement. The second imine function of **1** did not react with CO and/or ethylene and thus the bond N3–C7 still shows a value typical for a double bond. **4** crystallizes in the chiral space group $P2_12_12_1$, so that in this crystal only the stereoisomer shown in Fig. 1 is present in which the *S*-configuration of prolinol still is preserved and the spiro-carbon atom (C6) shows a *R*-configuration.

NMR spectra of the crude reaction mixture of **4** show the presence of two isomers in a 1.5 : 1 ratio. The HMBC spectrum of the reaction mixture clearly proves that these isomers are diastereomers corresponding to the two different configurations possible at the new stereogenic center at C6. The spectra only show crosspeaks between the two different spiro-carbon atoms and the corresponding methylene protons at C5 (Fig. 1). If the second isomer was a regioisomer in which the reaction had taken place at the imine double bond next to the oxazine nitrogen atom, one would also expect to observe crosspeaks between the methylene moiety at C5 and the imine carbon atom next to the oxazine oxygen atom which then would have been preserved.

In the case of **4** the diastereomers may be separated by crystallization. NMR spectra of the crystals that were characterized also by X-ray diffraction show only one set of signals corresponding to the diastereomer which is the major component of the crude reaction mixture. The carbon resonances of the tetrahydropyrrolo[2,1-*c*][1,4]oxazine moiety do not differ very much from the corresponding signals in **1**,[6] with the exception, of course, of C6, which now is observed at δ = 94.3. The resonances of C8 and C9 give rise to signals at δ = 29.6 and 35.6, respectively.

The resonances of the second diastereomer show nearly identical chemical shifts compared to the one shown in Fig. 1. The most significant differences are the signals corresponding to the spiro-atom itself, which now is observed at δ = 95.5 and the resonances of the carbon atoms of C8 and C9, which are observed at δ = 35.5 and 21.3, respectively. The same observations can be made in the NMR spectra of the mixtures of diastereomers of **5** and **6**. For all compounds **4**–**6** the diastereomer which shows the signal of the spiro-carbon atom at higher field is the major component of the product mixture.

As mentioned previously, the reaction of **1**–**3** with $Fe_2(CO)_9$ yields dinuclear iron carbonyl complexes in which the two imine subunits are differently coordinated to the organometallic fragments (Scheme 1).[7c] In these complexes the imine double bond that is next to the oxazine oxygen atom is the one that is coordinated to both iron centers, whereas the other imine subunit is only bound to one $Fe(CO)_3$ moiety. So we tried to react the complex derived from **1** with CO and ethylene in the presence of a catalytic amount of $Ru_3(CO)_{12}$ under the same conditions as for the free ligands **1**–**3**. This reaction results in the quantitative formation of **4** also as a mixture of diastereomers in the same ratio as if the starting compound was **1**. This shows that the unsymmetrical coordination mode in the dinuclear iron complexes may well be of some relevance in the catalytic cycle leading to the spiro-lactams **4**–**6** and may also be responsible for the observed regioselectivity.

The authors gratefully acknowledge financial support by the Deutsche Forschungsgemeinschaft (SFB 436) and the fruitful cooperation with Professor R. Beckert, Institute of Organic Chemistry and Macromolecular Chemistry, Friedrich-Schiller-University, Jena.

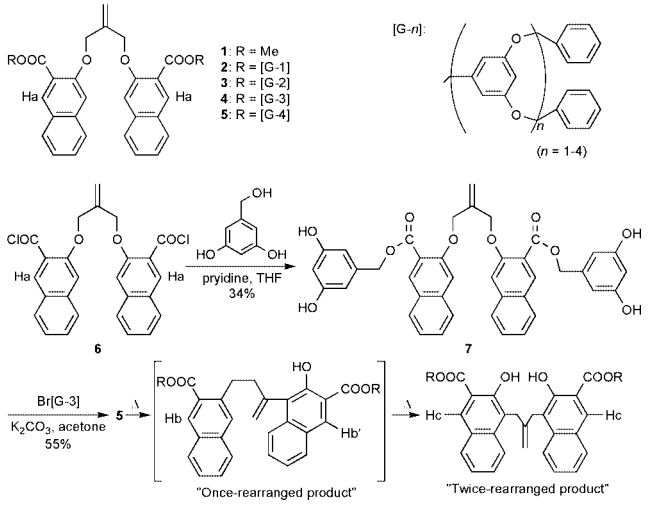
First published as an Advance Article on the web 8th March 2001

Fluorescent poly(benzyl ether) dendrimers containing an isobutenyl and two naphthoate units at the core have been synthesized; thermal reaction (tandem Claisen rearrangement) of the dendrimers took place quantitatively, resulting in the complete quenching of the fluorescence.

In recent years, dendrimers have been extensively employed for both basic and applied studies, principally owing to their well defined structures that enable functional groups to be accurately placed in dendrimer frameworks.[1] In particular, the light-harvesting function of dendrimers, one of the most unique and attractive dendritic effects, has recieved great attention in terms of biomimetic systems for photosynthesis.[2,3] Here we propose a fluorescent-controllable system using novel dendrimers with a reactive, fluorescent core that performs successive Claisen rearrangements.[4] Thermal Claisen rearrangement of high-generation dendrimers is expected to switch the emission property from 'on' to 'off' with a high contrast.

Dendrimers **2**–**4** were synthesized (Scheme 1) by a simple esterification of the corresponding dendritic wedges HO[G-*n*] with acid chloride **6** using triethylamine as base, and were isolated by preparative gel permeation chromatography (GPC), in moderate yields (18–69%). Polyether dendritic wedges HO[G-*n*] were obtained by following the convergent-growth method reported by Hawker and Fréchet.[5] However, esterification of the dendritic wedge HO[G-4] remarkably decreased the yield to 2.5% possibly due to the steric hindrance around the reactive site under these conditions. Hence, for the synthesis of the dendrimer **5**, we applied a divergent/convergent joint approach: **6** was first esterified with 3,5-dihydroxybenzylalcohol using pyridine to give **7** in 34% yield, followed by the etherification with a twice molar excess of the dendritic wedge Br[G-3] to obtain dendrimer **5** in 55% yield (Scheme 1). All dendrimers were characterized by ^{1}H and ^{13}C NMR, IR and MALDI-TOF mass spectra.†



Scheme 1

The absorption spectra of compounds **1**–**5** in CH_2Cl_2 are shown in Fig. 1, with spectral data summarized in Table 1. There are two clear absorption bands in all the spectra: one in the UV region (265–300 nm), due mainly to the dendritic wedges and the other in the near-UV region (305–385 nm), due only to the naphthyl moiety in the core. As the aromatic building unit of the dendritic wedges increases, the molar extinction coefficient (ε) at 280 nm increases almost proportionally, while the absorption at 345 nm remains unchanged, as expected, confirming the structure of the compounds (Scheme 1).

In order to investigate the light-harvesting effect of the dendrimers, steady-state emission spectra of the different generation dendrimers in CH_2Cl_2 were measured and the fluorescent quantum yields are summarized in Table 1. As the generation increases, there is a monotonic increase of the fluorescence intensity at 400 nm from the focal point upon excitation at 280 nm, where the dendritic wedges absorbed mostly in higher generation dendrimers. On the other hand, direct excitation of the naphthyl core at 345 nm gave a fluorescence at 400 nm without much difference in the quantum yields, 19–24% (Table 1). These results evidently demonstrate that this enhanced fluorescence is caused by an efficient energy transfer from the dendritic wedges to the naphthyl core in the higher generation dendrimer, in other words, the larger dendrimers serve as better antennae to collect photons, in accord with the report of Aida and coworkers on the light-harvesting effect of a poly(benzyl ether) dendron.[2] However, the energy transfer efficiency of the higher generation dendrimers **4** and **5**

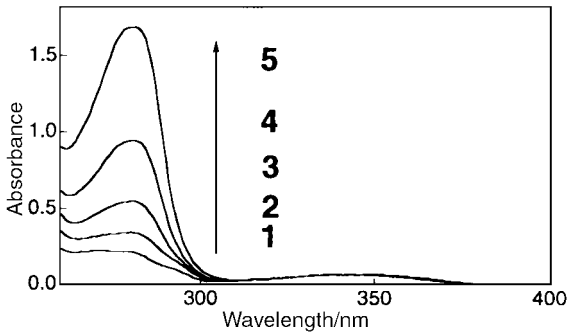


Fig. 1 UV–VIS absorption spectra of dendrimers **1**–**5** in CH_2Cl_2. The spectra are normalized to 1.98×10^{-5} M concentration.

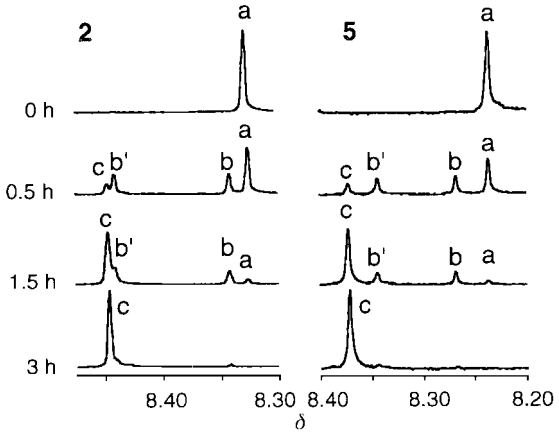

Fig. 3 ^{1}H NMR spectra of dendrimers **2** and **5** during the course of tandem Claisen rearrangement. Signals a, b, b′ and c arise from H_a, H_b, $H_{b'}$, and H_c in the naphthoates (Scheme 1).

decreases somewhat, taking into account the fact that the residual fluorescence at 308 nm from the dendritic wedges was observed and even increased for **5**. There are some reports on the loss in energy transfer efficiency for higher generation dendrimers, probably due to many factors based on Förster's mechanism.[3,6] We believe that the relatively small spectral overlap between the fluorescence of the dendritic wedges and the absorption of the core might be one of the key factors to decrease the energy transfer efficiency, although more data is required to discuss this point fully. Another noteworthy finding is that there was no red-shifted emission due to the excimer, expected to be formed between the two neighboring chromophores, in any spectra of the dendrimers in CH_2Cl_2. By contrast, the model compound **1** in the solid state showed a broad excimer emission around 500 nm while no additional signal or peak shift appeared for **5**, which suggests that inter- rather than intramolecular interactions between the chromophores cause excimer formation; the dendritic wedge of **5** shields the focal point so effectively as to prevent intermolecular collision.

We compared tandem Claisen rearrangement of the core unit among the dendrimers to investigate the steric effect on the reaction. Almost quantitative tandem Claisen rearrangement of all the dendrimers took place over 3 h in the absence of solvent at 150 °C. Indeed the rearrangement occurred even at 105 °C though 3 days were required to complete the reaction. Fig. 3 shows ^{1}H NMR spectra of dendrimers **2** and **5** during the course of tandem Claisen rearrangement at 150 °C. Surprisingly, there was no significant difference in the progress of the thermal reaction between the smaller and larger dendrimers. Indeed, the rate constants for this process were determined on the basis of the reasonable assumption that the rearrangement is a first-order successive reaction, to give almost identical rate-constants at 150 °C: $k_1 = 6 \times 10^{-4}$ s^{-1}, $k_2 = 4 \times 10^{-4}$ s^{-1} for **2**; $k_1 = 6 \times 10^{-4}$ s^{-1}, $k_2 = 5 \times 10^{-4}$ s^{-1}, for **5**. These results show that even for the dendrimer with 32 benzyl groups at the periphery there is no steric hindrance and enough space to form a chair- or boat-like conformation, thought to be adopted for the [3,3] sigmatropic rearrangement.[7]

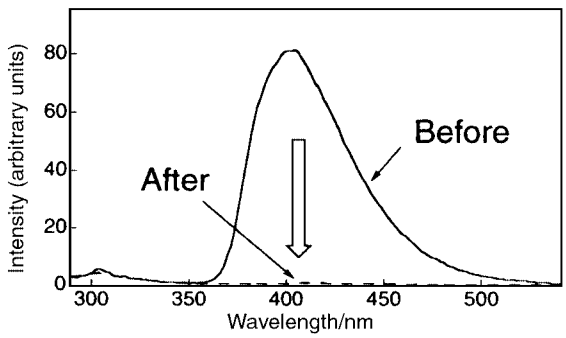

Fig. 4 Steady-state fluorescence spectra of dendrimer **5** in CH_2Cl_2 upon excitation at 280 nm before and after tandem Claisen rearrangement. The spectra are normalized to 0.99×10^{-6} M concentration.

Finally, the fluorescence spectra of the dendrimer **5** were compared before and after the rearrangement (Fig. 4). Interestingly, tandem Claisen rearrangement of the dendrimer resulted in complete quenching of the fluorescence around 400 nm with no change in the fluorescence at 308 nm arising from the dendritic wedge. We observed similar phenomena in the other dendrimers **1**–**4**. This indicates that the high generation dendrimers have potential to realize thermo- or photo-induced fluorescent images with high contrast.

In conclusion, we have demonstrated the light-harvesting effect of the fluorescent dendrimers having a reactive core for tandem Claisen rearrangement and their quenching by heating. Our finding that there is no steric hindrance on tandem Claisen rearrangement at the core of the dendrimers encourages us to incorporate other reactive groups into the core moiety such as carbamoyl, urea-type units in order to endow the dendrimer with new functions.

Nanofiltration-coupled catalysis to combine the advantages of homogeneous and heterogeneous catalysis

Koen De Smet, Sven Aerts, Erik Ceulemans, Ivo F. J. Vankelecom* and Pierre A. Jacobs

In a hybrid process that combines nanofiltration with homogeneous catalysis, the best possible reaction rates, chemoselectivities and enantioselectivities are obtained in a continuous operation mode while recycling the catalyst.

In industrial processes, heterogeneous catalysts are generally preferred as they facilitate removal of the catalyst after reaction[1] and allow a continuous operation mode. On the other hand, preparing a heterogeneous catalyst can be tedious and might demand a high preparative effort. In certain cases, mass or heat transfer limitations in the solid state catalyst may lead to decreased activities, and homogeneous reactions generally show higher chemo- and enantio-selectivities.[2]

In the reported hybrid process (Fig. 1), a reaction takes place in a continuously stirred tank reactor, thus reaching activities and selectivities as in homogeneous reactions. The liquid is contacted with a nanofiltration (NF) membrane that allows products to permeate but rejects the dissolved catalyst. This set-up is made possible by the recent development of solvent resistant NF membranes.[3] They have a molecular weight cut-off (MWCO) in the range of 200–700 Da and working conditions below 40 °C and 35 bar.

In related work by Giffels *et al.*,[4] the same membranes are used but they behave only like ultrafiltration membranes under the reaction conditions applied. This implies that an enlargement of their oxazaborolidines is still necessary to have them rejected by the membrane. Derivatisation of the catalyst in order to enlarge it—*e.g.* by linking it to polymers or by forming dendrimers—is avoided in our experiments by operating the membrane filtration under true nanofiltration conditions. The catalysts are thus retained by the membrane without the need to derivatise them first, and they can be used off the shelf in the form in which they are readily available.

In particular, chiral catalysts are among the preferred systems for this hybrid membrane/catalysis process due to their extremely high cost and their sensitivity towards traditional heterogenisation methods. Furthermore, most of these catalysts contain transition metal complexes with a molecular weight above 500 Da and high activities and selectivities under moderate reaction conditions. In the reported set-up, the hydrogen pressure needed for the hydrogenation of the substrates, forms—without any additional cost or equipment—the driving force for the membrane permeation. The whole hybrid process is operated in such a way that a sufficient amount of product with high purity is yielded in the catalytic process, while a good rejection of the the catalyst and reasonable fluxes are preserved in the NF.

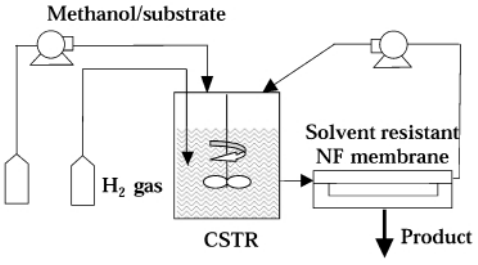

Fig. 1 Reactor set-up for NF-coupled catalysis.

The continuous enantioselective hydrogenation of dimethyl itaconate (DMI) with Ru–BINAP (MW 929 Da) and of methyl 2-acetamidoacrylate (MAA) with Rh–EtDUPHOS (MW 723 Da) (Fig. 2) were selected because of the excellent performance[5] of these catalysts and their industrial relevance.[6] Several ways to heterogenise these complexes have been reported already[7–9] but most did not equal the performance of the homogeneous catalyst, either in ee, activity or in the range of possible substrates.

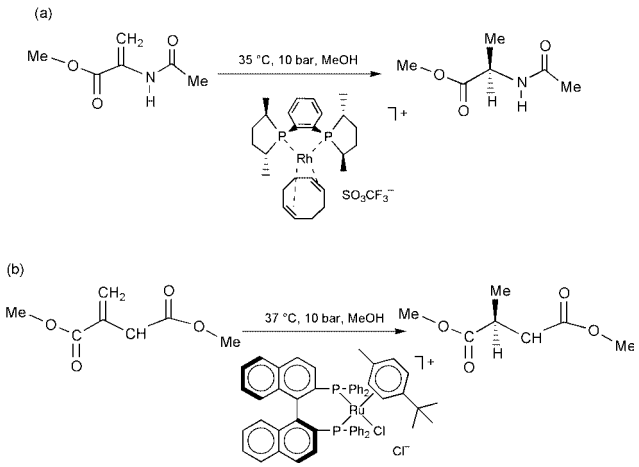

Fig. 2 Reactions with (a) Rh–EtDUPHOS and (b) Ru–BINAP.

Because the membrane fluxes in the NF part of the process are coupled *via* the hydrogen pressure to the reaction rates during catalysis, the reaction rate and enantiomer excess were determined first in a batch-wise reference reaction at pressures that fall within the range for nanofiltration (Table 1).

The homogeneous reactions were carried out in magnetically stirred 10 ml autoclaves. 0.35 g (2.5 mM) MAA was dissolved in 9 ml MeOH and flushed with N_2 before adding 1.7 mg Rh–EtDUPHOS (2.35 μM). For the homogeneous reaction with Ru–BINAP, 0.6 g (4 mM) DMI was dissolved in 9 ml MeOH, flushed with N_2 and subsequently mixed with 4.3 mg (4.6 μM) catalyst. The results[10] are shown in Fig. 1. For the hydrogenation of DMI with Ru–BINAP, no literature data could be found. The enantiomer excess and the activity for reactions with Rh–EtDUPHOS were lower than reported in the literature.[11]

Table 1 Hydrogenations of MAA and DMI with, respectively, Rh–EtDUPHOS and Ru–BINAP

	Substrate/ catalyst	Pressure/ bar	*T*/°C	TOF/ h^{-1}	Ee (%)
Rh–EtDUPHOS[a]	2000	2	22	> 2000	99.4
Rh–EtDUPHOS	1050	4	30	703	95
Ru–BINAP	850	10	37	330	93

[a] Burk *et al.*[11]

Table 2 Methanol fluxes at different temperatures and pressures for MPF-60 membranes (KOCH)

Pressure/bar	*T*/°C	Flux/kg m^{-2} h^{-1}
10	30	1.2
	40	1.6
	50	2.6
	60	3.2
15	30	1.7

This is believed to be due to a less thorough pre-treatment of solvents and reagents as compared with literature.

A NF membrane generally does not discriminate between reactants and hydrogenated products, given their negligible difference in MW, shape or polarity. This means that the conditions that determine the membrane flux—such as membrane type, membrane area, applied pressure gradient, temperature and type of solvent[12]—can be adjusted to the catalytic conditions that determine the conversion of the reactant. Methanol fluxes through the NF membrane (KOCH, MPF-60), are given in Table 2 for different temperatures and pressures: as expected, higher temperature and pressure are tools used to increase the flux through the membrane and thus realise a shorter residence time (τ) for a given reactor volume.

The continuous reactions were carried out in a stirred 100 ml autoclave containing an MPF-60 membrane at the bottom. The permeate was collected in a cooled flask (−78 °C). Both feed and permeate were analysed by GC and AAS to determine retention (retained concentration/feed concentration) of reactants, products and catalyst. For the hydrogenation of DMI with Ru–BINAP at 37 °C and 10 bar, the feed solution (C_0 = 0.4 μM) was pumped at a rate of 3.6 ml h^{-1} to the reaction mixture (V = 14 ml, C_0 = 0.4 μM and 33.7 mg Ru–BINAP). The hydrogenation of MAA was performed at 35 °C and 10 bar (V = 16 ml, C_0 = 0.13 μM and 8.5 mg Rh–EtDUPHOS) with the feed solution (C_0 = 0.13 μM) added at a rate of 3.5 ml h^{-1}.

To fully prove the concept, activities should remain unchanged after several refreshments of the reactor volume and the complex should be retained sufficiently. The hydrogenation of DMI shows a constant enantiomer excess as a function of time (Fig. 3). The very small decrease in conversion, becoming apparent after several hours, can be ascribed to the incomplete rejection of Ru–BINAP (> 98%). Nevertheless, this nanofiltration-coupled catalysis allowed the continuous hydrogenation of ten reactor volumes—as indicated by the vertical lines on the graph—with an enantiomer excess of 93%, which equals those reached under homogeneous conditions. For the hydrogenation of MAA with Rh–EtDUPHOS (Fig. 4), the decrease in enantiomer excess and conversion in the long term is slightly more significant. Since the 97% retention of this complex cannot alone account for this effect, a slow deactivation of the catalyst—possibly due to oxidation of the phosphine ligand—is assumed but still needs further investigation. The total TONs for the hydrogenation with Ru–BINAP and Rh–EtDUPHOS are, respectively, 1950 and 930.

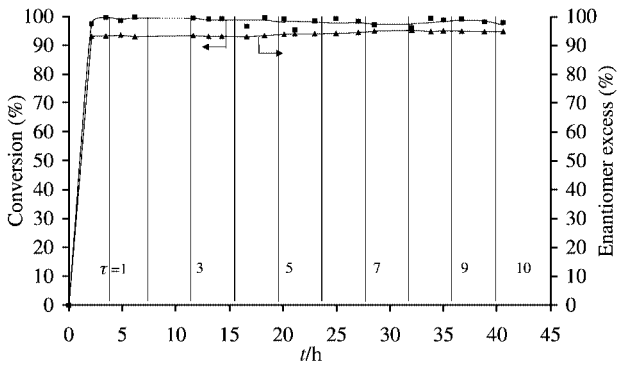

Fig. 3 Conversion and enantiomer excess as a function of time for the continuous NF-coupled hydrogenation with Ru–BINAP.

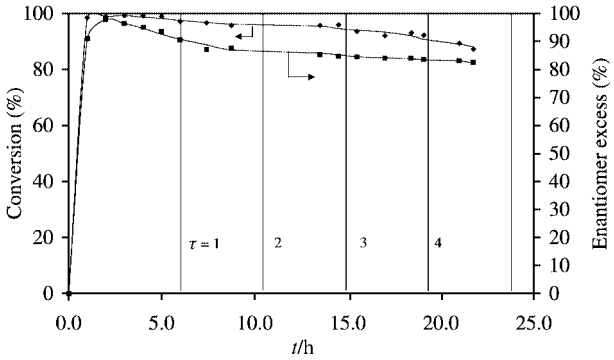

Fig. 4 Conversion and enantiomer excess as a function of time for the continuous NF-coupled hydrogenation with Rh–EtDUPHOS.

These two continuous reactions demonstrate the general concept of this hybrid process to perform homogeneous reactions in a continuous mode whenever the membrane is able to retain the catalyst and does not retain the products. Even though the system is limited by working conditions—like solvent, temperature and pressure—it is believed that the concept can be applied in many different types of reaction and for a wide range of catalysts and substrates, especially in the field of fine chemical synthesis.

Preparation of resin-bound amine *N*-oxides and demonstration of their use in synthetic carbonyl cluster chemistry†

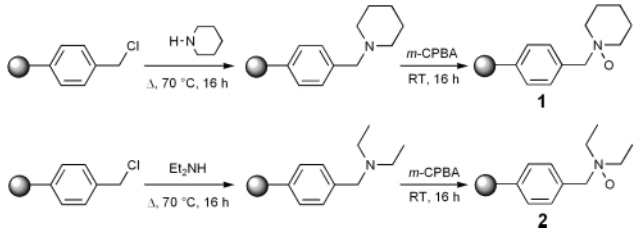
First published as an Advance Article on the web 13th March 2001

The preparation of two polymer-supported amine *N*-oxides is presented and their application as an improved methodology for synthetic metal carbonyl cluster chemistry is illustrated.

Amine *N*-oxides are readily deoxygenated by metal carbonyls. This mild reaction offers a general method for the activation of the complexes towards the substitution of a carbonyl with another ligand, avoiding the extreme temperatures and pressures normally required for direct substitution of carbonyl groups.[1,2] The main disadvantage of this route when applied to metal carbonyl clusters is that, in the case of unstable or highly-reactive complexes, it is often hard to remove all traces of amine *N*-oxide from the product. This has the drawback that, in subsequent reactions, a trace of *N*-oxide left in the starting material mixture can affect the reaction chemistry leading either to unwanted by-products or totally altering the course of the reaction.[3]

Within the organic chemistry community there is increasing interest in the development of polymer-supported catalysts and reagents for use in the synthesis of target molecules.[4] One of the key advantages of immobilizing a catalyst or reagent on a polymer support is the ease of separation from the product mixture at the end of a reaction and hence the greatly simplified work-up needed. To date, synthetic inorganic and organometallic chemists do not seem to have taken advantage of using supported complexes in their chemistry. Here, we report the simple synthesis of two polymer-bound amine *N*-oxides and demonstrate their use and applicability in organometallic cluster chemistry through the synthesis of the ruthenium and osmium trinuclear cluster complexes $M_3(CO)_{12-n}(MeCN)_n$ (M = Ru, Os; n = 1, 2).[5] The use of a supported *N*-oxide, as reported here, is significant since the cluster complexes can be prepared and purified very easily. These complexes have proven very useful as starting materials for a range of interesting cluster chemistry studies since their first reports in the early 1980s.[6,7]

The desired polymer-supported amine *N*-oxides were prepared in two steps from Merrifield's resin using modified literature procedures (Scheme 1).[8,9] Attention was focused on polymer-supported 'benzylpiperidine *N*-oxide' **1** and polymer-supported 'diethylbenzylamine *N*-oxide' **2**.§ The final loading of *N*-oxide on the polymer support was calculated at *ca.* 0.9–1.0 mmol g resin^{-1}. Like their homogeneous analogues, **1** and **2** are hygroscopic and are best stored under a blanket of dry nitrogen. Before use, water was removed by warming the beads gently (to no more than 35 °C) under vacuum.



Scheme 1 The synthesis of polymer-supported *N*-oxides **1** and **2**.

The applicability and activity of the resin-bound amine *N*-oxides **1** and **2** were assessed initially by using them in the synthesis of the mono- and bis-acetonitrile-substituted clusters $Ru_3(CO)_{11}(MeCN)$ **3a** and $Ru_3(CO)_{10}(MeCN)_2$ **4a** following the method of Johnson and Lewis (Scheme 2).[10]¶ Product yields are shown in Table 1.

The selectivity for **3a** or **4a** depends primarily upon the acetonitrile : $Ru_3(CO)_{12}$ ratio and upon the amine *N*-oxide : $Ru_3(CO)_{12}$ ratio but it is almost impossible to obtain 100% pure **3a** *via* any amine *N*-oxide route. In polymer-supported reagent chemistry it is often the case that a slight excess of the resin-bound species is required since not all the active sites on the polymer are readily accessible. However, in order to form the monosubstituted complex **3a** we prefer to use exactly one equivalent of **1** or **2**. Although traces of $Ru_3(CO)_{12}$ may then be present in the product, this compound is much less reactive and therefore less likely to perturb subsequent reactions than is **4a**, the impurity found if excess amine *N*-oxide is used.

The bis-substituted cluster is prepared in good yield using 2.5 equivalents of **1** or **2**. Again, the product can be easily separated from the amine *N*-oxide by filtering off the supported reagent.

We studied the effect of temperature on the synthesis of **3a** and **4a** using **1** and **2** and found that it is essential to perform the addition of the amine *N*-oxide at or below 0 °C. This is of interest when compared with other reports of resin-bound reagents which suggest that reactions that need low temperatures when using homogeneous reagents can often be performed at room temperature using heterogeneous analogues because of the rate retarding effects of immobilization.

We find that a small quantity of a ruthenium complex remains attached to the beads, even after thorough washing. One possibility is that a small proportion of the $Ru_3(CO)_{12}$ becomes tethered to the resin through more than one point of attachment. This is certainly possible given the close proximity of the amine *N*-oxide sites on the supported complex and the flexibility of the resin backbone. Once attached in this way, it may be difficult for the ruthenium complex formed to be removed from the support. This impacts on the recylability of the resins but work is currently underway to alleviate this problem by removal of the trace metal before re-loading the resin with *N*-oxide.

As a continuation of our studies, we used the resin-bound *N*-oxides for the synthesis of $Os_3(CO)_{11}(MeCN)$ **3b** and $Os_3(CO)_{10}(MeCN)_2$ **4b** (Scheme 2).[11] The *mono*-substituted complex was prepared by adding one equivalent of **1** or **2** to a dichloromethane–acetonitrile solution of $Os_3(CO)_{12}$. Yields are shown in Table 1. Again, although traces of $Os_3(CO)_{12}$ are

Table 1 Product yields

Product	Yield using **1** (%)	Yield using **2** (%)
$Ru_3(CO)_{11}(MeCN)$ **3a**	83	84
$Ru_3(CO)_{10}(MeCN)_2$ **4a**	85	92
$Os_3(CO)_{11}(MeCN)$ **3b**	80	85
$Os_3(CO)_{10}(MeCN)_2$ **4b**	73	86

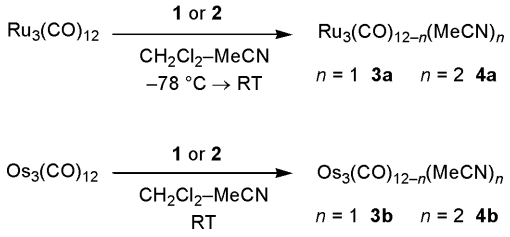
DOI: 10.1039/b100494h



Scheme 2 The use of **1** and **2** in synthetic cluster chemistry.

present in the product, this is less likely to be problematic in subsequent reactions than is **4b**. The bis-substituted cluster is formed in good yield when three equivalents of **1** or **2** are added to a dichloromethane–acetonitrile solution of $Os_3(CO)_{12}$.

With both the ruthenium and osmium clusters we find that **2** is a better reagent than **1**, giving higher yields and a more selective reaction. This could be due to the difference in steric bulk of the two amine oxides, the environment around the active centres in **2** being less crowded as compared with that around **1**. This is of key importance when considering the need for close encounter in the reaction between the clusters and the amine *N*-oxide.

In conclusion, the results presented here illustrate the applicability of **1** and **2** as reagents for the synthesis of substituted carbonyl clusters. They are particularly useful in the case of **3a** and **4a**, both of which are easily decomposed and where removal of the amine *N*-oxide from the reaction mixture is essential before performing further reactions.

We believe that it will be possible to use **1** and **2** as reagents for further chemistry and work is currently under way to confirm this assertion.

Experimental methods and spectroscopic data are presented as ESI.†

The Royal Society is thanked for a University Research Fellowship (N. E. L.). King's College London is thanked for funding.

Notes and references

§ Addition of an excess of amine (piperidine or diethylamine) to Merrifield's solid-phase resin (polystyrene crosslinked with 2% divinylbenzene; *ca.* 4.3 mmol Cl g resin^{-1}) in dioxane followed by heating overnight gives the resin-bound amine equivalent. Treatment of the resin-bound amines in chloroform with *m*-chloroperbenzoic acid at 0–25 °C gave the desired amine *N*-oxide.

¶ A dichloromethane–acetonitrile solution of $Ru_3(CO)_{12}$ was cooled to −78 °C before adding the resin-bound amine *N*-oxide. The reaction mixture was then allowed to warm up to room temperature. Filtration of the solution to remove the resin-bound reagent followed by removal of the solvent leads to isolation of the product. The exploratory reactions were performed using *ca.* 20 mg $M_3(CO)_{12}$ but can easily be scaled up to prepare larger quantities of product.

Boron-modified ZSM-5 zeolite membranes were effective for separating n-alkanes from 2,2-dimethylbutane, benzene and cyclohexane in binary mixtures, and enhanced selectivity was seen when both benzene and cyclohexane were mixed with n-hexane.

Zeolite membranes have high potential for separations owing to their unique pore structures and adsorption properties, and their superior thermal, mechanical and chemical properties. Zeolite membranes have been prepared with different zeolite structures, but the MFI structure has been studied most extensively. The MFI structure can be modified by isomorphous substitution of Si by trivalent elements into the zeolite framework. The zeolite surface can change from hydrophobic (silicalite) to hydrophilic (Al-ZSM-5) and from non-acidic (silicalite) to strongly acidic (Al-ZSM-5). Recently, we reported that B-ZSM-5 membranes have superior separation properties over silicalite or ZSM-5 with Al, Ge or Fe substitution.[1,2] For example, a B-ZSM-5 membrane had an n-C_4H_{10}/i-C_4H_{10} separation selectivity of 60 at 473 K. Here we report the separation of binary mixtures of n-hexane with branched, cyclic and aromatic hydrocarbon vapors using B-ZSM-5 membranes. The ternary n-hexane–benzene–cyclohexane mixture was also separated.

The B-ZSM-5 membranes used in this study were prepared by *in situ* crystallization from alkali-free gels onto tubular porous supports (stainless steel: 500 nm diameter pores, Mott Metallurgical; α-alumina: 200 nm diameter pores, US Filter). The molar gel composition was 4.44 TPAOH : 19.46 SiO_2 : 1.55 $B(OH)_3$: 500 H_2O, where TPAOH (tetrapropylammonium hydroxide) was used as the template. This corresponds to a Si : B ratio in the gel of 12.5. A previous study[2] has shown that the Si : B ratio in the zeolite is similar to that in the synthesis gel. Details of membrane preparation were reported elsewhere.[1] Membranes prepared for this study were characterized by single gas permeation and n-butane/i-butane ideal selectivity at 473 K. The results were similar to previous membranes that were characterized by SEM and XRD.[1] The SEM photos showed a continuous, intergrown layer that was 85–100 μm thick and was composed of randomly oriented crystals 5–10 μm in diameter. The XRD pattern of the membrane matched the MFI structure. The peak intensities in the patterns of all membranes were high and the background was low indicating a high degree of crystallinity.

Vapor permeation rates were measured in a continuous flow system that was described in detail elsewhere.[3] The hydrocarbon liquid was evaporated into a helium stream that flowed through the inside of the tubular membrane. The membrane was located in a stainless steel module that was heated by heating tapes. The binary hydrocarbon feeds were approximately 50 : 50, and the feed stream was *ca*. 10% hydrocarbon and 90% helium. Both sides of the membrane were at atmospheric pressure, and the He sweep gas provided a driving force across the membrane by removing the permeating components. The permeate stream was analyzed by a GC equipped with a flame ionization detector. A log-mean pressure driving force was used to calculate permeances, and permselectivity was calculated as the ratio of the permeances.

Fig. 1 shows that n-hexane can be separated from 2,2-dimethylbutane (DMB) using B-ZSM-5 membranes on α-alumina and stainless steel supports. The separation selectivities were highest (> 2000) at 373 K and they decreased with increasing temperature. The selectivity may decrease at high temperature because zeolite and non-zeolite pores expand with temperature. Since DMB (0.62 nm kinetic diameter) is larger than the MFI zeolite pore diameter, as measured by XRD (0.53–0.56 nm), its flux is expected to increase more with a slight increase in pore size. Even at 523 K, the stainless steel-supported membrane separated the n-hexane–DMB mixture with selectivity of 72.

The B-ZSM-5 membranes had much higher separation selectivities than a silicalite-1 membrane prepared by the same procedure (Fig. 2). The DMB permeances were lower and the n-hexane permeances were higher in the B-ZSM-5 membrane. The lower DMB permeances may be due to the narrowing of zeolite pores because either B^{3+} is smaller than Si or extra-framework boron deposited in the pores. According to the Pauling rule, B^{3+} cations are less stable in the framework due to their small size and they are partially removed from the framework during calcination. The gel composition for a B-ZSM-5 membrane is different from that for a silicalite-1 membrane and that could also change the quality of the membrane and reduce the number of non-zeolite pores.

Selectivities for n-hexane–DMB of 600–2000 at 360–373 K were reported by Coronas *et al.*[4] and Gump *et al.*,[5] but preferential adsorption of n-hexane rather than molecular sieving was responsible. In contrast, Ginoir-Fendler *et al.*[6] and Flanders *et al.*[3] observed selectivities of 1000 at 363 K and 70–250 at 473 K and separation was not due to preferential adsorption. Vroon *et al.*[7] obtained a selectivity of 600 at 300 K and of 2000 at 473 K. The separation selectivities were only 25–120 at 300 K for other ZSM-5 membranes.[8,9]

Separation of n-alkanes from cyclic and aromatic compounds has been studied less. Funke *et al.*[10] obtained a separation

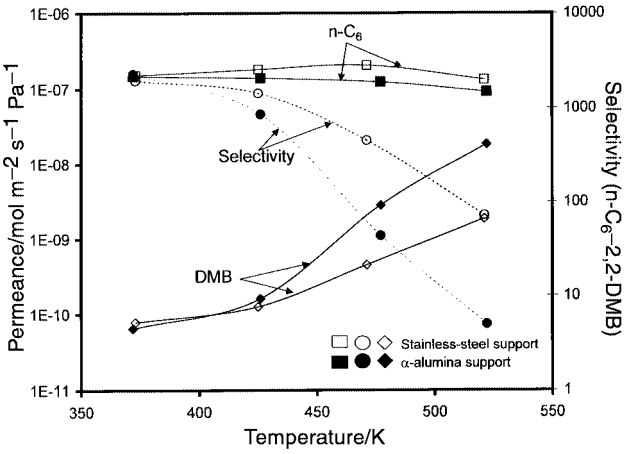

Fig. 1 n-Hexane–2,2-DMB permeances and separation selectivities as a function of temperature for B-ZSM-5 membranes on alumina and stainless steel.

Table 1 Permeances and separation selectivities for 50:50 n-hexane–organic mixtures through supported B-ZSM-5 membranes

	α-Alumina support			Stainless steel support		
	Permeance/mol m^{-2} s^{-1} Pa^{-1} (±15%)		Selectivity (±20%) n-Hexane–organic	Permeance/mol m^{-2} s^{-1} Pa^{-1} (±10%)		Selectivity (±14%) n–Hexane–organic
Organic	n-Hexane × 10^7	Organic × 10^{10}		n-Hexane × 10^7	Organic × 10^{10}	
DMB	1.5	0.65	2280	1.5	0.78	1950
Cyclohexane	2.4	3.3	720	1.3	2.2	570
Benzene	2.4	5.5	440	1.0	2.6	370
Benzene + cyclohexane (50:50)	2.2	2.8	790	1.5	1.8	800

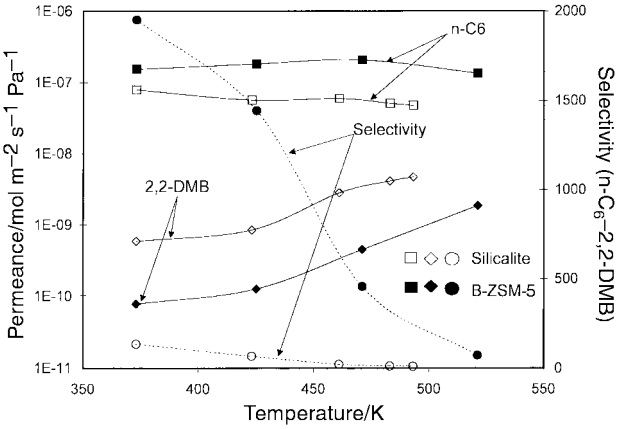

Fig. 2 n-Hexane–2,2-DMB permeances and separation selectivities as a function of temperature for silicalite-1 and B-ZSM-5 membranes on stainless steel.

selectivity of 25 at 373 K for a n-hexane–cyclohexane (50:50) mixture. Our B-ZSM-5 membranes had n-hexane–cyclohexane separation selectivities of 570 and 720 at 373 K (Table 1). Kita *et al.*[11] reported that a Y-type membrane separated n-hexane from benzene with a selectivity of 260 at 373 K. The n-hexane–benzene separation selectivities for B-ZSM-5 at 373 K were 370 on stainless steel and 440 on α-alumina supports. The B-ZSM-5 membrane also separated n-C_5 to n-C_8 alkanes from benzene, and the selectivities changed significantly with carbon number and temperature. At 373 K, the selectivities decreased from 660 to 16 as the carbon number of the alkane increased. In contrast, at 473 K, selectivities increased from 11 to 524 as the carbon number increased. For separations at 373 K, benzene permeances were almost constant but n-alkane permeances decreased as their carbon number increased. Apparently the coverages for all the alkanes were close to saturation at 373 K, so they all effectively inhibited benzene permeances. The benzene permeances in the mixtures were lower than the permeance of pure benzene. The diffusion rate of the alkane decreased with increasing carbon number, probably due to an increase in adsorption strength, and thus the selectivity decreased with carbon number. In contrast, at 473 K, the alkane permeances were almost constant because the permeances of the longer alkanes increased more with temperature. The benzene permeances at 473 K *decreased* as the alkane carbon number increased because the longer alkanes adsorbed more strongly and thus had higher coverages than the shorter alkanes. Thus, the longer alkanes more effectively blocked benzene and therefore the alkane–benzene selectivity was higher for the longer alkanes.

The separation selectivities of the ternary n-hexane–cyclohexane–benzene mixture (50:25:25) were 790–800 at 373 K, which are *significantly higher than those observed for the binary mixtures* (Table 1). The cyclohexane plus benzene permeances were lower than in the binary mixture, whereas the n-hexane permeances were similar. This increase in selectivity in the ternary mixture may be the result of competition for adsorption sites in the zeolite.

In summary, B-ZSM-5 zeolite membranes separated n-alkanes from branched, cyclic and aromatic hydrocarbons with high selectivities at elevated temperatures.

We gratefully acknowledge support by the NSF/IUCRC for Membrane Applied Science and Technology (MAST).

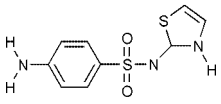
The sulfadrug sulfathiazole forms an extensive family of solvates and adducts, the crystal structures of which show a large variety of hydrogen-bonded frameworks.

In a recent communication, Nangia and Desiraju[1] analysed the relative solvate-forming propensities of fifty common solvates, and highlighted the need for systematic studies of the formation and structure of solvates. We have been engaged in such a study, largely based on one compound, the sulfadrug sulfathiazole, I,



I

with remarkable solvate forming abilities, which developed out of a detailed reinvestigation of the polymorphism of this compound[2]. We present here a preliminary report of our findings.

The sulfadrugs show extensive polymorphism.[2,3] They also crystallise erratically from solution, despite the contrary impression that might be gained from the literature. In the search for reliable crystallisation procedures for sulfathiazole polymorphs, several less common solvents were tried and in quite a number of cases solvates were obtained. This was surprising, since the only well-defined solvate encountered in over 40 papers[4] during 60 years of investigation was that from dioxane.[5] Shirotani *et al.*[6] have described 3 further solvates of sulfathiazole, but their work seems to have been subsequently overlooked. In the belief that a detailed preparative and structural study of solvate formation may give an insight into the crystallisation behaviour of the parent materials, we have explored this topic further. The first solvate we produced was that from cyclohexanone. Reasoning from the analogy between the structures of dioxane and cyclohexanone, we tried numerous other 6- and 5-membered saturated heterocyclic and carbocyclic rings possessing at least one polar group, the function of the latter being presumed to involve hydrogen bonding with one of the 5 acceptors and 3 donors in the sulfathiazole molecule. Single crystal X-ray determinations however showed a remarkable variety of structures with varying propensity for hydrogen bonding between the sulfathiazole and the solvent guest. The study was extended to a wider range of solvents with different molecular shapes and sizes, different polarities and different functional groups, and also to the preparation of mixed crystals with partners that are solids at ambient temperature. The solvates are easily made by crystallisation from the appropriate solvent, sometimes with the help of chloroform as a crystallisation aid. Sulfathiazole has a solubility at elevated temperatures of around 10% in typical solvate-forming solvents. It is very soluble (30–60%) in more polar solvents such as dimethylformamide or tetramethylurea but generally fails to form solvents from such solutions. It has a limited solubility in solvents of low polarity and usually only sulfathiazole polymorphs crystallise from these solutions. Surprisingly, we found that molecules with long aliphatic hydrocarbon chains can form solvates provided a solvatophilic group such as lactone or lactam is present. The two-component solid–solid adduct crystals can be made by fusion or sometimes by crystallisation of the components using an inert solvent. The presence of a third component is detrimental on thermodynamic grounds,[7] but in practice, as noted above for chloroform, may be favourable for kinetic reasons.

More than 100 solvates plus many related 2-component systems containing sulfathiazole have now been made, including inter-sulfa-drug combinations such as sulfapyridine with sulfathiazole.‡ All have been characterised by near- and mid-infrared spectroscopy, powder XRD and hot-stage microscopy, and studied, in some cases also by DSC/TGA, solid state NMR, Raman spectroscopy and microscopy. The crystal structures of more than 60 solvates and adducts have so far been determined; others are in progress. The existence of such a large collection of data allows a unique opportunity for the comparative investigation of the structural and spectral characteristics and of the factors determining solvate formation. Detailed consideration of this is beyond the scope of a Communication, and is the central theme of a series of full papers, now in preparation. However, the results obtained can be usefully summarised as follows.

No solvent containing an aromatic carbocyclic group has given a solvate. Virtually every saturated carbocycle or heterocycle of appropriate polarity, and of ring size 3 to 8 produces a solvate. Only the behaviour of aliphatic solvates is difficult to predict, although polarity can be distinguished as a key factor. A wide range of groups including cyano, ester, ether. keto, sulfonyl, and amido groups are capable of providing the necessary polar characteristics. A hydroxy group generally seems to be detrimental to solvate formation, although a very unstable solvate has been made from *n*-propanol. The identification of the latter solvate together with that of acetonitrile raises the question as to whether many of the outcomes of sulfathiazole polymorph preparation procedures are mediated by the intervention of unstable solvates. Competitive experiments, in which sulfathiazole is crystallised from mixed solvates, have shown a stability sequence of lactams > lactones > cyclic carbonates > cyclic ketones, which parallels the order of solvent polarity. The relative stabilities of adducts with different sized rings have not been determinable so far because the crystalline product from these competition reactions has often not been one of the expected products. Some of these may be polymorphs of solvates, since DSC shows that some of the solvates are di- or tri-morphic. (Fig. 1.) The infrared spectra of the solvates are almost always close to that of the highest melting polymorph I (mp 203 °C), (the structure of which contains two crystallographically independent molecules, and which we regard as a sulfathiazole solvate of sulfathiazole), and unlike those of the three mutually similar low-melting polymorphs, even though the solvates always desolvate to the lower melting polymorphs, especially polymorph IV.§ This may be explained by the fact that in the structures so far determined the

close amido–imido dimer present in sulfathiazole polymorph I but not in any of the others, features extensively in the solvate structures. The similarity of IR spectra for systems that are found to have quite different crystal structures is explained in terms of the presence of similar H-bonding associations but different supramolecular assemblies.

Terminology for the description of solid state molecular structures is unsatisfactory, even for single component systems.[8,9] Consideration of the multitude of structures displayed by the solvates listed in Nangia and Desiraju's paper raises the question as to whether nomenclature is even less adequate for the greater complexity resulting from two-component systems.

On the basis of the structure determinations so far completed in our study, we identify two types of structure which might provide a more generally useful classification—a) *clathrates*, or, more generally *inclusion phases*, in which the main function of the guest molecule is cavity filling, with or without additional weak H-bonding, in a host molecule assembly having a channel, layer or 3D framework structure, and b) *co-crystals* in which the partner molecule forms an essential part of the hydrogen bonded framework. In each class we have also found salts where proton transfer has occurred from the sulfathiazole molecule to a basic function on the guest. An example of each of the two main structure types is shown in Figs. 2a and 2b.¶

Multiple solvates have been reported for a variety of compounds, but these invariably show a large degree of isostructurality.[10] By contrast, our study has shown that sulfathiazole would appear to show more solid state structural versatility than any other organic molecule. We are investigating why this might be the case and whether other compounds form huge numbers of overlooked solvates or whether sulfathiazole is unique. To this end, the solvate forming propensities of other sulfadrugs are being examined. Preliminary experiments indicate that sulfapyridine forms many solvates, but not so extensively as sulfathiazole, and often with different solvates. The host–solvent relationship appears to be a very specific one even for such closely related hosts as the sulfadrugs, as might be expected from the huge variety of structures displayed by the sulfadrug polymorphs.

Notes and references

‡ A list of the solvates and adducts prepared so far, is given in the Supplementary Material.

Tandem ring-closing metathesis–radical cyclization based on 4-(phenylseleno)butanal and methyl 3-(phenylseleno)propanoate — a route to bicyclic compounds

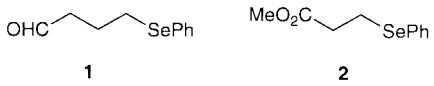
Derrick L. J. Clive* and Hua Cheng

Chemistry Department, University of Alberta, Edmonton, Alberta, Canada T6G 2G2

Received (in Corvallis, OR, USA) 4th January 2001, Accepted 7th February 2001
First published as an Advance Article on the web 13th March 2001

α,ω-(Phenylseleno) carbonyl compounds, such as 4-(phenylseleno)butanal (1) and methyl 3-(phenylseleno)propanoate (2), are easily converted by anionic reactions into substances that undergo sequential ring-closing metathesis and radical cyclization, affording bicyclic products.

The usefulness of radical cyclization is often determined by the ease with which the cyclization substrates can be made. In this regard, the nature of the homolyzable group is, of course, important, because this determines the stages at which it may be introduced. In particular, early introduction can avoid the extra steps involved in replacing a non-homolyzable group by one that is homolyzable. For radical generation, phenyl selenides have the distinct advantage that the PhSe group is usually inert to basic or nucleophilic reagents[1] and, among the common transformations, care need be exercised only in the choice of oxidizing agent[2,3] when selenium is present. We have found that the PhSe group is compatible with the Grubbs catalyst $(Cy_3P)_2Cl_2Ru{=}CHPh$,[4–8] and we report that α,ω-(phenylseleno) carbonyl compounds, such as 4-(phenylseleno)butanal (**1**[9]) and methyl 3-(phenylseleno)propanoate (**2**[10]) are useful for the



construction of substances that undergo sequential ring-closing metathesis[11] and radical cyclization. The PhSe group allows the use of anionic chemistry that would not be suitable in the

DOI: 10.1039/b100336b

presence of halogen or carboxy groups as the eventual source of radicals.[12] Several publications have reported that the catalyst is usually not compatible with sulfide substrates.[4,5]

The starting materials **3b**–**8b** (Scheme 1) for the metathesis–radical closure sequence were made as follows. Aldehyde **1** was converted into alcohols **3** (80%), **5** (87%), and **6** (60%) (Scheme 1) by reaction with vinyllithium, allylmagnesium bromide, and but-3-enylmagnesium bromide, respectively. Reaction of **1** with phenyllithium (50%), oxidation, using pyridine·SO_3 in DMSO[2] (87%), and treatment of the resulting ketone with vinyllithium afforded alcohol **7** (85%).

The alcohols **3**, **5**, **6** and **7** were easily converted into substrates for ring-closing metathesis by simple ionic reactions. Acylation of **3** and **5** with acryloyl chloride (Et_3N, DMAP, CH_2Cl_2) gave **3b** (64%) and **5b** (71%), respectively (Scheme 1), and the ethers **4b** (65%) and **7b** (73%) were made by alkylation (NaH, THF) of **3** with 2-chloromethyl-3-[(phenylmethyl)-oxy]prop-1-ene[13,14] and of **7** with allyl bromide, respectively.

The metathesis substrate **6b** was prepared by oxidation of **6** (87%), again using the pyridine·SO_3–DMSO system—which is an excellent reagent for selective oxidation of phenylseleno alcohols—and treatment with allylmagnesium bromide (78%).

The bis-allyl selenide **8b** was obtained directly from ester **2** by the action of allylmagnesium bromide (78%).

Each of the bis-olefins shown in Scheme 1 underwent ring-closing metathesis in the presence of $(Cy_3P)_2Cl_2Ru$=CHPh (8–12 mol%; 22% for **3b**), and the products were isolated by flash chromatography. The reactions were usually run in PhH at 50 °C for 12 h [**4b**, **6b** (65 °C), **7b**, **8b** (refluxing PhH,[15] 8 h)], or in refluxing CH_2Cl_2 in the presence of Ti(OPr-*i*)$_4$,[16] (42 h,[17] **3b**, 8 h, **5b**). In the case of the acrylates (**3b**, **5b**), Ti(OPr-*i*)$_4$ must be added to complex the ester carbonyl and prevent unproductive complexation of carbenoid intermediates.[18]

The radical cyclization step (see Scheme 2), leading to **3d**, **4d**,**e**, **5d**–**8d**, was carried out under standard conditions by syringe pump addition (over *ca*. 10 h) of a PhH solution of Bu_3SnH (1.4–2.2 equiv., 0.01–0.08 M) and AIBN (0.2–0.4 equiv., 0.006–0.03 M) to a refluxing solution (0.01–0.02 M) of the substrate (1 equiv.) in the same solvent. In the case of **6c** we isolated only the product of 6-*exo* cyclization, and not the isomeric alcohol resulting from 7-*exo* closure.[19]

The above experiments establish that the PhSe group, which serves as a very convenient radical source, can be introduced at an early stage in synthetic routes that involve ionic reactions and that end with sequential application of two powerful bond-forming processes, ring-closing metathesis and radical cyclization.

All new compounds were characterized spectroscopically, including high resolution mass measurements.

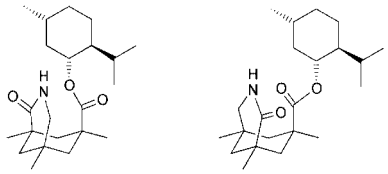
Received (in Cambridge, UK) 19th December 2000, Accepted 21st February 2001
First published as an Advance Article on the web 13th March 2001

The Norrish–Yang cyclisation of a prochiral imidazolidinone which was conducted in the presence of a chiral host afforded enantiomerically enriched (up to 26% *ee*) 1,3-diazabicyclo[3.3.0]octanones in good yields (73–86%) with a distinct preference for the *exo*-diastereoisomer (dr = 77/23–90/10).

The photochemical cyclisation of ketones *via* intramolecular hydrogen abstraction and subsequent ring closure is termed Norrish–Yang cyclisation.[1] It is a valuable C–C-bond forming reaction in the course of which two new stereogenic centres are formed. The facial diastereoselectivity of the reaction has been extensively studied[2,3] and applications of the Norrish–Yang cyclisation to natural product synthesis have been reported.[4] For the photocyclisation of amino acid derivatives a remarkable chirality transfer has been observed.[5] Enantioselective variants of the Norrish–Yang cyclisation have been investigated in the solid phase employing either precursors that crystallize in chiral space groups[6] or inclusion compounds of a prochiral substrate and a chiral host.[7] We have now attempted to achieve an enantioselective Norrish–Yang cyclisation in the liquid phase mediated by a chiral complexing agent[8] and report on the preliminary results of this work. The chiral host compounds **1** and **2** can be readily prepared from trimesic acid (1,3,5-



1 **2**

benzenetricarboxylic acid) *via* the well-known all-*cis*-1,3,5-trimethylcyclohexane-1,3,5-tricarboxylic acid (Kemp's triacid).[9,10] They are diastereomeric due to the chiral menthyl residue and can be separated by flash chromatography.

Lactams are attached to the host **1** or its diastereoisomer **2** *via* the carbonyl group and *via* the NH-group by two hydrogen bonds.[11] The lactam is fixed by the two-point binding in a chiral environment with the result that formerly enantiotopic faces become diastereotopic. As the menthyl residue acts simply as a sterically bulky substituent hosts **1** and **2** are expected to behave as if they were enantiomers. The prochiral imidazolidin-2-one **3** was selected as Norrish–Yang cyclisation substrate. It exhibits a lactam binding site which should allow for an association with the host compounds. The compound was readily prepared from the parent imidazolidin-2-one by monoacetylation,[12] 1,4-addition to phenyl vinyl ketone and deprotection. Upon irradiation (Rayonet RPR 3000 Å or Original Hanau TQ 150/duran filter) the ketone yielded four products which are depicted in Scheme 1.

The results of the preliminary study conducted with the easily accessible hosts **1** and **2** are summarized in Table 1. In general,

the conversion is complete and the yield of photocyclisation products are high (73–86%). The *exo*-isomers **4** and *ent*-**4** are the preferred diastereoisomers formed in toluene solution (entries 2–14)[13] whereas the *endo*-isomers **5** and *ent*-**5** are favored in the polar protic solvent *tert*-BuOH. It is reasonable to assume that *tert*-BuOH increases the size of the substituent OH by coordination[1,2] and leads to a reversal of the steric demand from Ph > OH to OH > Ph. The *exo*/*endo*-selectivity did not change (entries 3/7/11, 4/8/12, *etc*.) upon variation of the temperature. Contrary to that, the enantioselectivity was significantly influenced by this variation. The increase from 5% *ee* at 30 °C (entry 4) to 26% *ee* at −45 °C (entry 12) observed with 2.5 equiv. of host **1** exemplifies the typical temperature dependence which is partially due to an increased association. The increase in enantioselectivity upon increasing the host concentration (entries 3/4, 5/6, 7/8, *etc*.) undermines the crucial

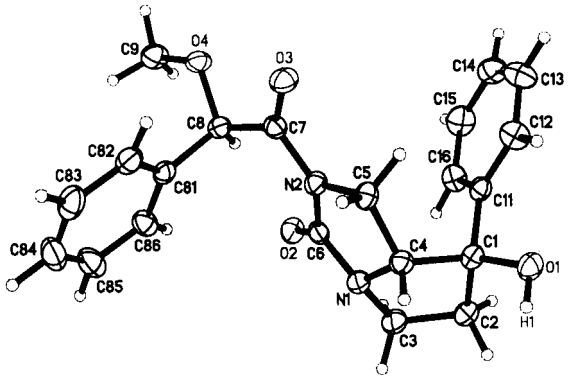

Fig. 1 A molecule of compound **6** in the crystal.

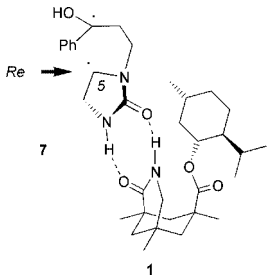

Fig. 2 The differentiation of enantiotopic sites at the C-5 radical center in the 1,4-biradical intermediate **7** associated to host **1**.

role the association plays in the enantioselective photocyclisation under scrutiny. The earlier assumption that the hosts **1** and **2** should behave as if they were enantiomers was proven experimentally. The opposite enantiomer was formed upon replacement of **1** with **2** (entries 3/5, 4/6, 5/7, etc.) resulting in a negative ee value. The minor diastereoisomers **5** and *ent*-**5** behaved similar to the major diastereoisomers with regard to the ee.

The absolute configuration of the major enantiomer *ent*-**5** obtained from the irradiation of compound **3** in the presence of host **2** was elucidated by single crystal X-ray crystallography. To this end, it was converted into its *N*-acyl derivative **6** by a sequence of *O*-silylation, *N*-acylation with (*R*)-(−)-*O*-methylmandelic acid chloride and desilylation.[14]

If host **2** delivers *ent*-**5** as major enantiomer host **1** delivers **5** with opposite optical rotation as was experimentally confirmed. The C–C-bond formation step which is decisive for the absolute configuration of products occurs from the C-5 *Re*-face of a 1,4-biradical intermediate **7** depicted in Fig. 2. The shielding of the *Si*-face by the menthyl group of host **1** is apparent although it is certainly not optimal. It is an obvious conclusion from this mechanistic picture that the absolute configuration of the major enantiomer **4** is also determined in the complex **7**–**1** (Fig. 2) and that the stereogenic centres within the imidazolidinone ring of diastereoisomers **4** and **5** have identical (*S*)-configuration. This assignment has already been implemented in Scheme 1.

Our preliminary study unequivocally demonstrates that a differentiation between the enantiotopic faces of radical centres are possible upon association to hosts of type **1**. Based on this observation enantioselective radical type cyclization reactions at chiral hosts are conceivable. Further studies are under way which will address this question in detail.

13 Representative procedure: A solution of the substrate **3** (0.1 mmol, 21.8 mg) and the chiral host **1** (0.25 mmol, 91.0 mg) in 20 ml of toluene was degassed for 30 min by a continuous stream of argon. The mixture was subsequently irradiated in a liquid cooled merry-go-round apparatus at −45 °C until the reaction was complete according to TLC (12 h). After evaporation of the solvent the diastereomeric ratio (dr) was determined from the crude product by integration of appropriate ^{1}H-NMR signals. The residue was purified by flash chromatography (eluent: EtOAc–MeOH = 98 : 2). The host **1** (R_f = 0.46; pentane–*tert*-butyl methyl ether = 25 : 75) was recovered and the products **4**/*ent*-**4** (R_f = 0.50; EtOAc–MeOH = 80 : 20) and **5**–*ent*-**5** (R_f = 0.52; EtOAc–MeOH = 80 : 20) were separated. The total yield was 16.8 mg (77%). The collected fractions of compounds **4**–*ent*-**4** were evaporated and the enantiomeric excess was determined by chiral HPLC (Table 1).

Received (in Cambridge, UK) 9th January 2001, Accepted 21st February 2001
First published as an Advance Article on the web 13th March 2001

Exposing oligodeoxynucleotide (ODN)-capped Au nanoparticles to a quartz crystal under shear oscillation resulted in the formation of a uniform monolayer containing these nanoparticles or multilayers with islands of the ODN-capped nanoparticles, which, in turn, improved the extent of DNA hybridization.

The development of sensitive and sequence-specific assays of nucleic acids in samples of biological origins has recently been a research area under active pursuit. Thiolated single-stranded oligodeoxynucleotides (HS-ss-ODNs) immobilized onto gold films[1–9] or gold nanoparticles[10] have received a great deal of attention. The use of DNA-capped gold nanoparticles was also shown as an attractive route for enhancing the sensitivities of several important techniques. For instance, a probe/target/probe-nanoparticle sandwich and a dendritic structure based on ODN-capped gold nanoparticles were developed by Zhou *et al.*[11] and by Willner and coworkers,[12] respectively, to amplify the weak quartz crystal microbalance (QCM), or more accurately, the thickness-shear mode sensor (TSM)[5,6] signals inherent in conventional ODN probe/ODN target hybridization based on the use of HS-ss-ODNs. The employment of gold nanoparticles in conjunction with other techniques [*e.g.* atomic force microscopy (AFM) and surface plasmon resonance spectroscopy[13,14]] were also demonstrated to improve other analytical 'figure of merits', such as selectivity and dynamic range.

We report here a simple procedure for attaching ODN-capped gold nanoparticles onto thin gold films for subsequent hybridization with target DNA molecules. The procedure is devised on the basis of a serendipitous discovery we made in performing a sandwich DNA assay described in ref. 11. We found that ODN-capped gold nanoparticles can be rapidly adsorobed onto a thin, polished gold film that is part of a quartz crystal undergoing shear oscillation (8 MHz fundamental frequency). Curve 1 in Fig. 1 depicts the dramatic frequency decrease resulting from attaching 30-mer-capped gold nanoparticles (*ca.* 890 Hz) upon injecting buffer solutions containing these ODN-capped nanoparticles. The attachment of the ODN-capped gold nanoparticles onto the gold-coated crystal must have arisen from the well known non-specific interaction between the DNA bases and the gold surface,[1,2] since the ODN-capped gold nanoparticles do not possess any affinity for the Au surface with a monolayer coverage of hexanethiol SAM (Curve 2), and the gold nanoparticles alone do not appear to adhere to the gold film (Curve 3). We believe that the shear motion of the thin gold film greatly facilitated a surface rearrangement of the adsorbed ODN-capped gold nanoparticles to form a robust film. The formation of the ODN-capped gold nanoparticle film appears to proceed layer-by-layer. AFM images revealed that a compact monolayer of the ODN-capped gold nanoparticle assembly was produced (Fig. 2a) after *ca.* 100 s of exposure of the crystal to an ODN-capped Au nanoparticle solution. The surface morphology of the crystal surface becomes much more uniform as the ODN-capped nanoparticles are within a smaller size distribution than the gold grains originally present at the crystal (not shown). Thus the surface of crystal was not rougher than the original polished gold film, suggesting that mass changes described below are unlikely to be caused by the effects due to the porosity and/or roughness of the new surface. Extensive exposure of the crystal surface under the shear motion to the solution, on the other hand, leads to the formation of multilayers of ODN-capped gold nanoparticles (Fig. 2b). Individual gold nanoparticles with a size around 13–15 nm can be resolved. Upon exposure for an extended period of time (*e.g.* 8000 s), a purple thin film can actually be visualized. Also notice that, beyond the first layer, it appears that the ODN-capped gold nanoparticles tend to agglomerate preferentially at certain sites to produce islands. These islands, together with the nanoparticle

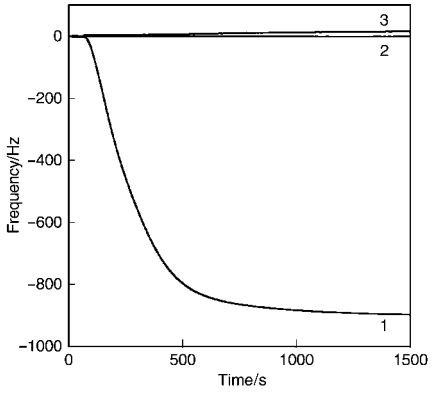

Fig. 1 QCM responses to the injections of 100 μL solutions containing Au nanoparticles and Au particles capped with HS-ss-DNA of different numbers of DNA bases. Curve 1 shows the response at the crystal surface to the injection of the Au nanoparticles capped with the 30-mer probe with the sequence of 5′-AGAGGATCCCCGGGTACCGAGCTC-GAATTC$(CH_2)_6$SH-3′. This sequence is complementary to the 47-mer target 5′-GAATTCGAGCTCGGTACCCGGGGATCCTCTACTGGCC-GTCGTTTTAC-3′ used in the follow-up hybridization experiment (shown in Fig. 3). Curves 2 and 3 correspond to the responses to a 0.15 μM 30-mer-capped Au nanoparticle at a crystal modified with a hexanethiol SAM and to a 0.15 μM Au nanoparticle solution at a crystal, respectively.

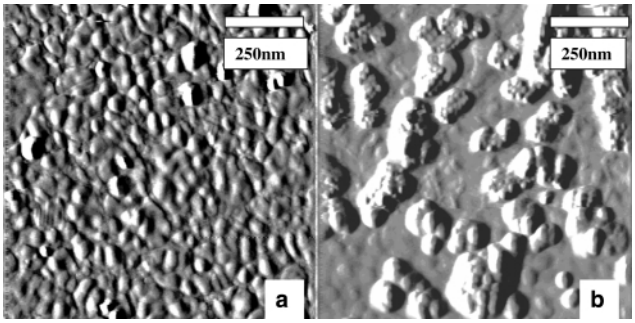

Fig. 2 AFM images of (a) a gold film covered with the 30-mer-capped gold nanoparticle assembly formed by exposing the gold film to the DNA-capped Au nanoparticle solution for 100 s, and (b) a gold film modified with the 30-mer-capped nanoparticle assembly formed upon an 8000 s exposure.

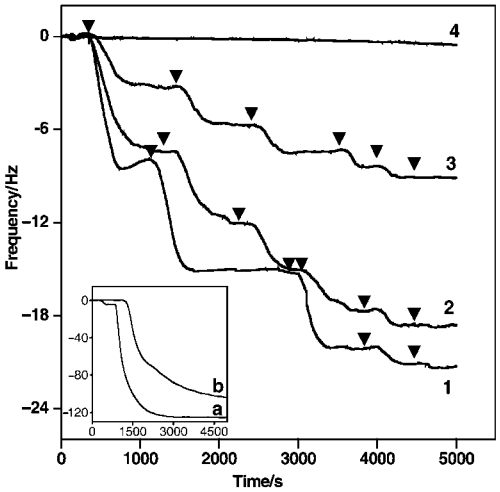

Fig. 3 QCM responses acquired after the injections of a 47-mer target (5′-GAATTCGAG CTCGGTACCCGGGGATCCTCTACTGGCCGTCGT-TTTAC-3′) at a crystal covered with a 30-mer-capped Au nanoparticle assembly (Curve 1), the 47-mer target at a crystal covered with a 16-mer (5′-$HS(CH_2)_6$GTAAAACGACGGCCAG3′)-capped Au nanoparticle assembly (Curve 2), the 47-mer target at a crystal covered with a sub-monolayer of 30-mer SAM (Curve 3), and a 47-mer target (5′-CTTGGAGAGCTCGG-TACCCGGGGATCCTCTACTGGCCGTCGTTTTAC-3′) with six of the bases mismatching the bases on the 30-mer probe that had been immobilized onto the gold nanoparticles (Curve 4). Inset: (a) hybridization of the 47-mer target with the 16-mer probe and the frequency change in a subsequent injection of the 30-mer-capped gold nanoparticle solution, and (b) the frequency change upon injecting the 30-mer-capped gold nanoparticle solution into the QCM cell housing a crystal covered with only the 16-mer probe. Arrows indicate the injection points.

terraces that are not covered, thus provide a unique 3-D ODN-capped gold nanoparticle assembly with many sites for DNA hybridization. Fig. 3 shows DNA hybridization at crystals covered with different ODN-capped gold nanoparticles (Curves 1 and 2) and the comparison of the results with those acquired at crystals modified with only HS-ss-ODN (Curve 3). As can be seen, the five consecutive injections of a 3.35 μg mL^{-1} 47-mer target solution resulted in a cumulative frequency decrease of *ca.* 22 Hz at a crystal covered with 30-mer-capped gold nanoparticles, whereas the injections of the same target solution at a crystal modified with 16-mer-capped gold nanoparticles produced a 19 Hz change. Both frequency decreases are greater than those observed from multiple injections of the target solution into a QCM housing a 30-mer SAM (*ca.* 9 Hz in Curve 3). Therefore, it seems that more probe molecules are present at the films containing ODN-capped gold nanoparticles since more target molecules can be detected at such films. Previous studies of gold films covered with different ODNs have shown that the surface density of a thiolated 32-mer is slightly less than 1.8×10^{-11} mol cm^{-2}.[3] We measured, with an inductively coupled plasma-atomic emission spectrometer, the average gold : sulfur ratio on the 30-mer-capped Au nanoparticles to be 1 : 87. Using a diameter of 13 nm for the Au nanoparticles,[14] we calculated the surface density to be 2.7×10^{-11} mol cm^{-2}. These values correspond to sub-monolayer coverages (*e.g.* 2.7×10^{-11} mol cm^{-2} corresponds to *ca.* 49% coverage)[9] and are consistent with those reported in many previous papers.[1,2,4-9] Obviously, the surface density associated with the sub-monolayer of HS-ss-ODN film would not lead to an extensive DNA hybridization at the surface. This contention is in line with the weak QCM signals observed by many research groups[11,15,16] without post-hybridization treatment or target derivatization. Thus, the formation of a multilayer of ODN-capped gold nanoparticles provides a unique means to increase the total number of probes per unit area by converting the ODN assembly at a 2-D surface to a 3-D network. Another implication of the incomplete HS-ss-ODN surface coverage at gold is that the non-specific interaction between ODN and the bare gold regions could lead to an overestimate of the DNA hybridization when ODN-capped gold nanoparticles were employed to amplify hybridization signals. Indeed, when we performed the sandwich assay using the 16-mer probe on the gold surface and the 30-mer-capped gold nanoparticle as the second probe for signal amplification of the hybridized 47-mer target, most of the frequency decrease appears to result from the non-specific adsorption of the gold nanoparticles onto the gold regions that were not occupied by the 16-mer. As seen in the inset of Fig. 3, Curve a, which shows the frequency change associated with the typical 'sandwich assay',[11] and Curve b, which shows the non-specific adsorption of the 30-mer probes immobilized to the nanoparticles onto the gold surface that has a partial coverage of 16-mer probes, have yielded similar frequency changes. In Curve a, the first step (*ca.* 4.5 Hz) corresponds to the hybridization of the 47-mer target with the 16-mer probe and the second step (*ca.* 126 Hz) is due to the combined effect of non-specific adsorption (*ca.* 108 Hz in Curve b) and the legitimate hybridization of the 30-mer on the gold nanoparticles with the surface-confined 47-mer target.

The comparison between the signal intensities of Curves 1 and 2 indicates that longer ODN probes would cause a larger extent of hybridization. While the longer probes tend to coil more extensively, and consequently impose a greater hindrance to target hybridization, the difference in binding energy between the two different strands should be more predominant for these short ODNs. To ensure that mass changes shown in Curves 1 and 2 in Fig. 3 did not originate from non-specific target adsorption onto the ODN-capped gold nanoparticles films, we conducted a control experiment. The absence of any appreciable frequency change at the 30-mer-capped gold nanoparticle film upon the injections of a target with six mismatched bases confirms that non-specific adsorption did not occur (Curve 4).

In closing, we have developed a method to modify a crystal surface with oligonucleotide-functionalized gold nanoparticles. The attachment of the ODN-capped gold nanoparticles increases the total number of ss-ODN probes available for DNA hybridization. An important point that merits attention is that caution should be exercized when ODN-capped gold nanoparticles are used in connection with the sandwich assay by QCM since non-specific adsorption of the DNA-functionalized gold nanoparticles could lead to an overestimate of the signal enhancement.

First synthesis of a phosphonothiashikimic acid derivative†

Montserrat Heras, Mihaela Gulea and Serge Masson*

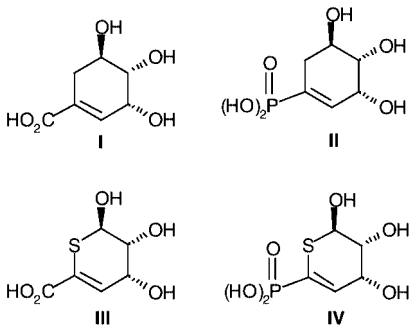
Laboratoire de Chimie Moléculaire et Thioorganique (UMR CNRS, 6507), ISMRA-Université de Caen et CNRS, 6 boulevard du Maréchal Juin, F-14050 Caen, France. E-mail: serge.masson@ismra.fr

Received (in Cambridge, UK) 30th January 2001, Accepted 21st February 2001
First published as an Advance Article on the web 13th March 2001

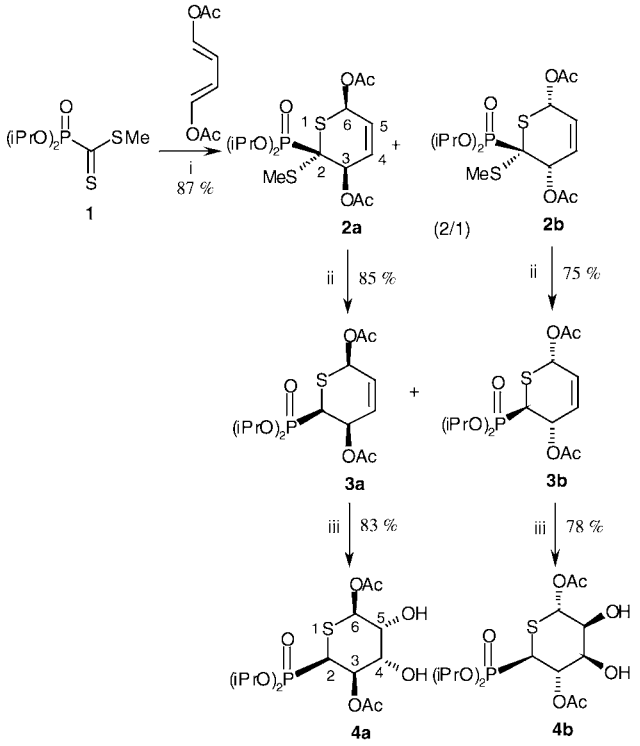
A new phosphono and thio analogue of shikimic acid ester has been synthesised from a thiopyranic derivative obtained *via* a [4 + 2] cycloaddition involving a phosphonodithioformate as heterodienophile.

Shikimic acid[1] **I** (Scheme 1) is an important intermediate in the biosynthesis of aromatic amino acids from carbohydrates in plants and microorganisms. Therefore, increasing effort has been directed towards the synthesis of its analogues as potential enzyme inhibitors in this biological pathway. Several modifications of the shikimic acid structure were described, including the functionalisation of the cyclohexene ring,[2] the substitution of the carboxylic function by a phosphono group[3] (phosphono shikimic acid **II**) or the replacement of the methylene group involved in the shikimate pathway by a sulfur atom (thiashikimic acid **III**). We report here the first synthesis of a new racemic derivative of compound **IV** which is both a phosphono and thio analogue of shikimic acid.

As for the preparation of thiashikimic acid ester,[4] we used a hetero Diels–Alder cycloaddition for the first step of our synthesis (Scheme 2). However, instead of the unknown and probably very unstable thioaldehyde-phosphonate (analogue of a thioxoacetate) we used a very stable and readily accessible phosphonodithioformate **1** (very recently described by our group as a new heterodienophile[5]). Although relatively slow (7 days), the reaction of (*E*,*E*)-1,4-diacetoxybutadiene with this dithioester in refluxing THF led to the functionalized dihydrothiopyranic derivative **2** as a mixture of diastereomers **2a** and **2b** in a 2 : 1 ratio and 87% yield (use of a Lewis acid to accelerate the reaction[5] was excluded because it induced some undesirable degradation of the cycloadduct). These isomers were easily separated by chromatography on silica gel. By comparison with the reaction of the thioxoacetate,[4] we could expect for the major isomer **2a** (58%) resulting from a preferential phosphonyl-*endo* cycloaddition, a *cis* configuration as far as the two acetoxy and the phosphono groups are concerned. The structures assumed for **2a** and **2b** were indeed found in accordance with the observed coupling constants between phosphorus and protons on C_3 and C_6: large equatorial–equatorial or axial–axial coupling (torsion angle $\Phi \sim 0$ or $\sim 180°$) and almost null equatorial–axial coupling ($\Phi \sim 90°$)[6] (Scheme 3).

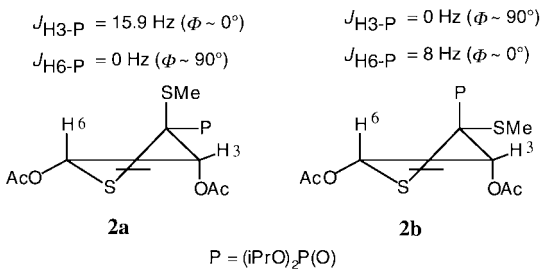


Scheme 1



Scheme 2 *Reagents and conditions*: i: THF, rt, 7 d; ii: Bu_3SnH–AIBN, refluxing benzene, 2 h; iii: OsO_4–Py, rt, 2 h.

Each isomer was then desulfanylated using Bu_3SnH–AIBN in refluxing benzene and, as expected from our preliminary study,[5] the heterocyclic sulfur atom is not affected by the reaction. A mixture of 2,3-*cis* **3a** and 2,3-*trans* **3b** isomers was respectively obtained in a 2 : 1 ratio from **2a** (85%) and in a 5 : 3 ratio from **2b** (75%). The favoured formation of isomer **3a** could be explained by the preferential reduction of the anomeric radical on the opposite side to the C_3 acetoxy groups through an axial attack.[7] The stereochemistry of these diastereomers was deduced from the $^3J_{H2–H3}$ = 6.1 (for **3a**) and 10.7 Hz (for **3b**) coupling constants.



Scheme 3 Relative configurations of cycloadducts **2** (one conformer of each isomer is represented).

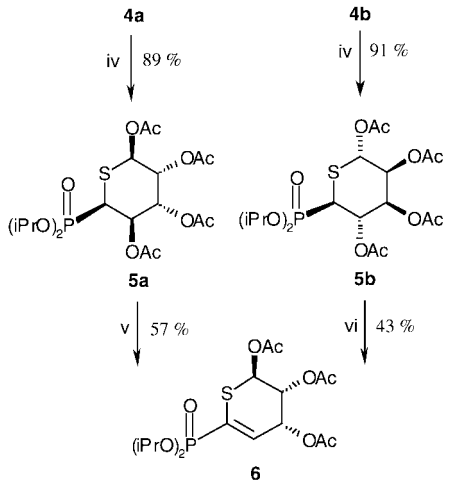
DOI: 10.1039/b101050f

After separation of these isomers by flash column chromatography on silica gel they were dihydroxylated by osmium tetroxide in pyridine. Compound **3a** gave the corresponding *cis*-diol **4a** (83%) as a single isomer, by attack from the less hindered side of the molecule. Under the same conditions, the dihydroxylation of isomer **3b** gave diol **4b** (78%). To avoid the possible 1,2-migration of an acetyl group[4] from O–C_3 to O–C_4, diols **4a** and **4b** were protected as acetylated derivatives **5a** and **5b** before performing a basic elimination of acetic acid (Scheme 4). From tetraacetate **5a**, this 1,2-elimination occurred in hot pyridine to give the phosphonothiashikimic derivative **6** in 57% yield after purification. As expected, for the epimer **5b**, in which the relevant proton and acetoxy group are not in a *trans* configuration, the elimination failed in similar conditions. However, using a stronger base (NaH in THF), **5b** led to the same expected compound **6** in 43% yield. In this way, both *Diels–Alder* isomeric cycloadducts were used for the synthesis of the target molecule **6**. The observed *J* values ($^3J_{H5–H6}$ = 4.6, $^3J_{H5–H4}$ = 3.3 Hz) for the acetoxy derivative of phosphonoshikimate **6** are consistent with the attributed structure and in good agreement with that of its carboxylic analogue.[4]



Scheme 4 *Reagents and conditions*: iv: $(AcO)_2O$–Py, 80 °C, 12 h; v: Py, reflux, 36 h; vi: 3 equiv. NaH, THF, rt, 36 h.

The search of an efficient enantioselective version of this synthesis is now under investigation. Besides, the preparation of other thiapyranic derivatives, from the phosphonodithioformate **1** and various functionalized dienes by the same sequence, cycloaddition–desulfanylation–dihydroxylation, are in progress and will be the subject of a full publication.

π-Conjugated polymer-protected gold nanoparticles of narrow size distribution in stable colloidal form have been prepared *via* reduction of $HAuCl_4$ by a π-conjugated poly(dithiafulvene) having electron donating properties.

Recently, hybrid systems consisting of inorganic nanoparticles with π-conjugated polymers as supporting matrices were found to display various interesting characteristics, particularly in the areas of dielectric properties, energy storage, catalytic activity, and magnetic susceptibility. The reason is that π-conjugated polymers as one-dimensional semiconductors have the advantage of being easy to process to form large-area devices. Their energy gaps and ionization potentials can readily be tuned by chemical modification of the polymer chains. The process of charge transfer at the contact between a metal nanoparticle and an organic (or polymeric) semiconductor plays an important role in many areas of technology.[1] The electronic structure of the polymer chain strongly influences the characteristic of the metal nanoparticles.[2,3]

This communication describes the first example of stable colloidal forms of nanocomposites consisting of metal nanoparticles protected with a π-conjugated polymer. Reduction of metal ions by the π-conjugated polymer leads to metal nanoparticles with the resulting oxidized polymer protecting the metal nanoparticles. It has already been reported that reduced forms of polymers such as polypyrrole and polyaniline are converted to the respective oxidized forms with simultaneous *in situ* reduction of metal ions, Pd(II) and Au(III) to their elemental forms.[4–6] However, these composites could not be dispersed in any solvents. Here we used a π-conjugated polymer containing the strong electron-donating dithiafulvene unit in the main chain, which was synthesized recently by our group.[7] We found that gold colloidal particles were formed with narrow size distribution *via* reduction of $HAuCl_4$ by the π-conjugated poly(dithiafulvene) (PDF). The oxidized polymer then protected and stabilized the gold nanoparticles.

In a typical preparation of π-conjugated polymer-protected gold nanoparticles, PDF† (5.44 mg, 2.86×10^{-5} mol by repeating unit) was dissolved in 5 ml of a dimethyl sulfoxide (DMSO) solution of $HAuCl_4$ (5×10^{-6} mol). The reaction mixture was stirred for 24 h at room temperature. The reaction mixture changed gradually from yellow to purple with stirring. A similar solution in the absence of PDF was also stirred for 24 h at room temperature. The solution remained yellow. These results indicate the reduction of $HAuCl_4$ to gold nanoparticles by PDF. The resulting DMSO solution of the polymer-protected gold nanoparticles was stable without precipitation for more than a month at room temperature under air. The sample showed film-forming properties when the DMSO solution was cast onto a glass slide.

Fig. 1(a) shows a transmission electron microscopy (TEM) image of the produced π-conjugated PDF-protected gold nanoparticles, which was deposited on a grid from a DMSO solution. It can be seen that spherical gold nanoparticles were produced with narrow size distribution and high dispersion. The histogram of the size distribution is shown in Fig. 1(b), which was obtained directly from an enlarged TEM image by counting 300 particles. The average size of the particles was 6 nm.

Fig. 2 shows the UV–VIS absorption spectrum of the PDF-protected gold nanoparticles in DMSO. An absorption band appears at 550 nm. It can be concluded that the band results from the surface plasmon resonance of the gold nanoparticles. A π–π* transition absorption band of PDF was observed around 400 nm.[7] The surface plasmon resonance band of gold colloids is calculated theoretically to be at 510–525 nm in an aqueous system.[8] It is clear that the absorption band of the PDF-protected gold nanoparticles was strongly red shifted compared with the theoretical value. It is well known that, for spherical

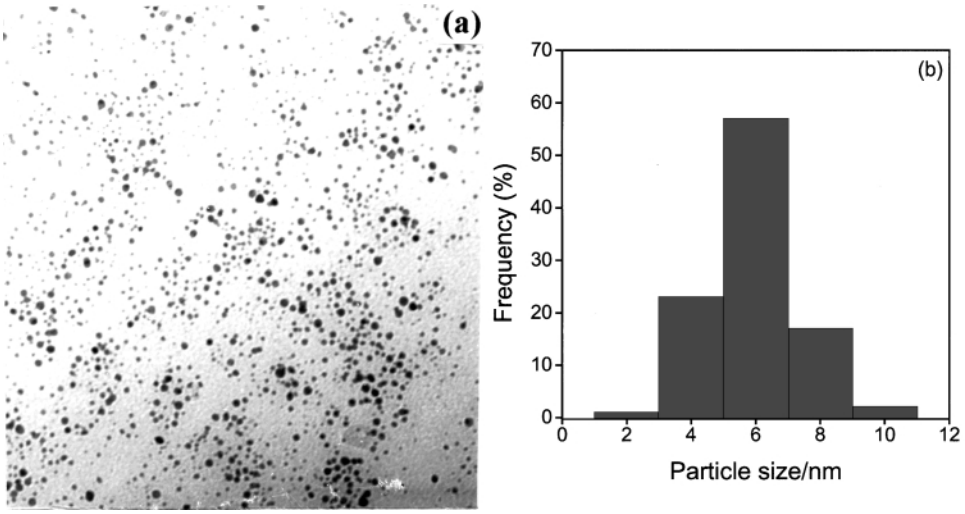

Fig. 1 (a) TEM image of the π-conjugated PDF-protected gold nanoparticles; (b) Histogram of the size distribution of the π-conjugated PDF-protected gold nanoparticles.

DOI: 10.1039/b100636n

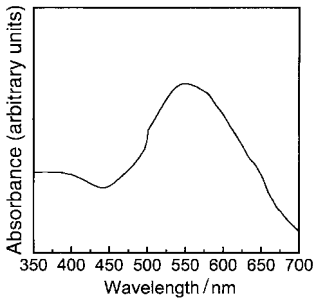

Fig. 2 UV–VIS absorption spectrum of the PDF-protected gold nanoparticles in DMSO.

colloidal metals of size 3–20 nm, there is not a strong dependence of the absorption spectrum on particle size.[8] This is because, for particle sizes below *ca*. 20 nm diameter the quadrupole and higher-order term in the Mie summation become significant.[9] In the present case, since the gold nanoparticles were of average size 6 nm, the red shift was not due to the size effect. However, the surrounding medium affects the absorption peak position of the metal nanoparticle by varying the interface conditions.[10] In this case, to study the influence of DMSO on the surface plasmon resonance band of the gold colloid, we used $NaBH_4$ as the reducing reagent and polyvinylpyrrolidone (PVP) as the protecting polymer for reduction of $HAuCl_4$ in DMSO. The absorption band of the gold nanoparticles of size 14 nm produced by this system was located at *ca*. 520 nm *i.e.* with no red shift. These results indicate that the red shift originated from the influence of the oxidized PDF. When protected by the oxidized PDF, the work function of the gold particle will decrease compared to that *in vacuo*, which lowers the energy of the surface resonance state,[11] leading to the red shift of the absorption band.[12]

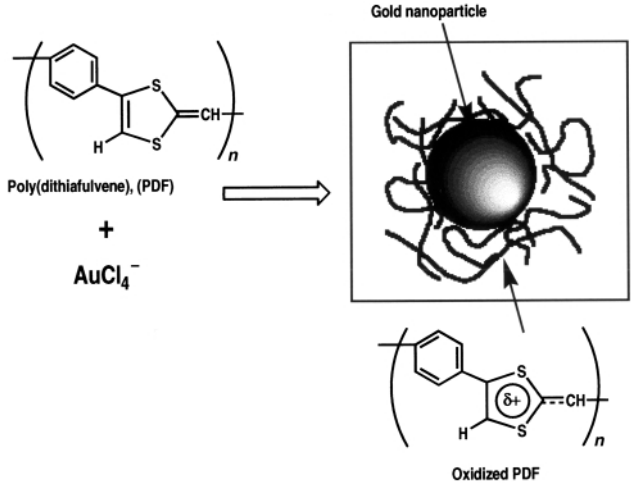

Fig. 3 Schematic illustration of the formation of the PDF-protected gold nanoparticles.

In conclusion, π-conjugated polymer-protected gold nanoparticles of narrow size distribution have been prepared in stable colloidal form *via* reduction of $HAuCl_4$ by the π-conjugated electron-donating PDF. Formation of the gold nanoparticle by the π-conjugated PDF is schematically shown in Fig. 3. The oxidized π-conjugated PDF induced a strong red shift of the absorption spectrum of the gold nanoparticles.

We thank Dr M. Tsujii, Dr S. Yamamoto and Professor T. Fukuda (Kyoto University) for the TEM micrographs. We also thank Dr T. Sato (Kyoto University) for helpful discussions.

Notes and references

† PDF was prepared from 1, 4-diethynylbenzene according to our previous report.[7] The number-average molecular weight (M_n) of PDF used here was 5440 as determined by ^{1}H NMR spectroscopy.

Received (in Irvine, CA, USA) 16th January 2001, Accepted 13th February 2001
First published as an Advance Article on the web 13th March 2001

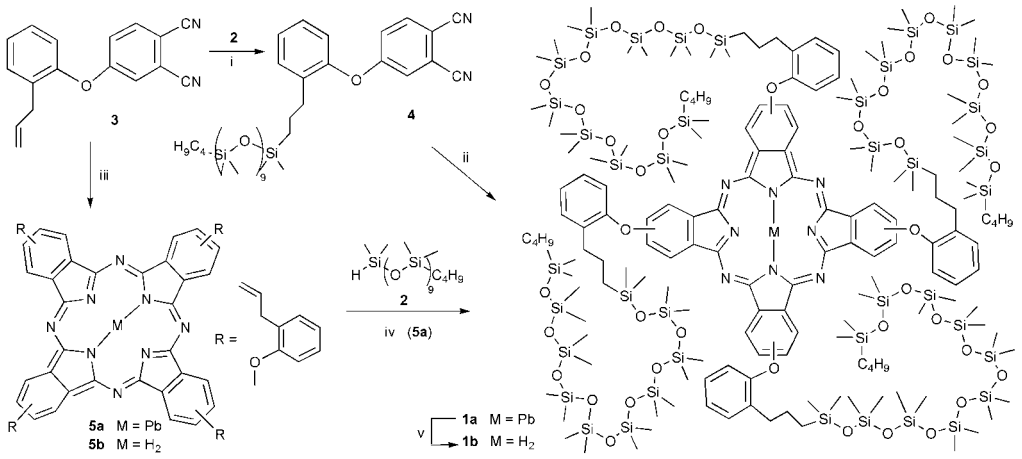
Isotropic liquid phthalocyanine compounds with peripheral polydimethylsiloxane oligomer substitution were synthesized and found to have a unique combination of thermorefractive and nonlinear optical properties along with unusual metal substitution reactivity and aggregation behavior.

Polydimethylsiloxane oligomer substitution at the periphery of a phthalocyanine ring generates a liquid material with exceptional optical properties and chemical behavior. This material is designed to have the rheological and thermorefractive properties of a silicone fluid[1] and the nonlinear optical properties characteristic of the phthalocyanine chromophore.[2] Structure **1** in Scheme 1 combines these molecular features coupled through an aromatic ether linkage. The motivation for this design is to combine two mechanisms important to an optical limiting application[2] into a single compound: a large fluence dependent, refractive index;[1] and a reverse saturable optical absorption.[2] The aromatic ether linkage further incorporates an enhanced photo-oxidative stability. Cloaking of the phthalocyanine ring in a silicone covering has important implications for the chemistries of aggregation and metal substitution. To our knowledge, no examples of peripheral silicone substituted phthalocyanines have been previously reported. In this communication we report synthesis and preliminary characterization of a new class of liquid phthalocyanine (Pcs) materials.

Two routes for the synthesis of the lead and metal-free phthalocyanine compounds are depicted in Scheme 1. Starting reagents for both routes are prepared in the first step. The butyl capped hydrosilyl terminated poly(dimethylsiloxane) (PDMS) oligomer (**2**) (DP = 9 in this example) is synthesized by an anionic ring opening polymerization of hexamethylcyclotrisiloxane.[3] The allylphenoxyphthalonitrile (**3**) is prepared by a nitroaromatic displacement reaction of 4-nitrophthalonitrile[4] with 2-allylphenol. In the preferred route, the PDMS oligomer is first coupled to the allylphenoxyphthalonitrile by a hydrosilylation reaction. Next the allylphenoxyphthalonitrile–PDMS adduct (**4**) is cyclotetramerized in the presence of lead oxide to yield the phthalocyanine **1a**. The alternate route is to first conduct the cyclotetramerization yielding the tetrakis(allylphenoxy)phthalocyanine (**5**) then to perform the hydrosilylation to yield the phthalocyanine product (**1**). This route has the disadvantage of a more arduous purification (as a consequence of a required large excess of **2** to ensure a quantitative conversion of the allyl groups) and the use of a heterogeneous non-acidic hydrosilylation catalyst (to avoid displacement of a labile metal from the phthalocyanine cavity).

Structures **1**–**5** are consistent with spectroscopic characterization.† The phthalocyanine materials have both a mixed isomer and polydisperse character. The phthalocyanine forming reaction produces a statistical mixture of four possible isomers.[5] The polydispersity is a result of the manner in which the butyl capped PDMS oligomer (**2**) is prepared.[6] These features are regarded as advantages in discouraging liquid crystal formation. In an analogous phthalocyanine system with polyethylene oxide oligomer substituents it was found that a monodisperse system is liquid crystalline[7] while that with a polydisperse system is an isotropic liquid.[8] Liquid crystallinity is detrimental for applications where optical transparency is required.

The PDMS chains determine the liquid character of these materials, which are viscous liquids at room temperatures. The glass transition temperatures, *T*g, for the Pb (**1a**), H_2 (**1b**) phthalocyanine compounds and the phthalonitrile precursor (**4**) are 3, 16, and 14 °C respectively. This narrow range of glass transition temperatures is a consequence of the dominant effect of the siloxane chains. A similar trend of a slightly increasing *T*g, when progressing from lead to metal-free phthalocyanine with epoxy substituted phthalocyanine glasses, has previously been observed.[9] This trend correlates with a greater tendency of the metal-free phthalocyanine to aggregate relative to the lead phthalocyanine.[10] At rt these phthalocyanine materials will fill short length (~4 μm) optical cells by capillary action over several hours. At elevated temperatures (~100 °C) the viscosity



Scheme 1 *Reagents and conditions*: i, 3 drops of 0.1 N solution of $H_2PtCl_6 6H_2O$ in isopropanol, 60 °C, 1 h; ii, PbO, 165 °C, 16 h; iii, PbO or hydroquinone, 165–180 °C, 16 h; iv, 8 drops of platinium-divinyl tetramethyldisiloxane complex, toluene, 20 h; v, toluene, F_3CCOOH, 10 min.

is much lower, the aggregation is reduced (spectroscopic detection), and the filling of the cell is much more rapid.

The refractive index of a thin film of the lead phthalocyanine compound (**1a**) was measured by ellipsometry and also by measuring the angle of total internal reflection for a thin film on a prism of known refractive index. Over a temperature range of 24 to 95 °C the refractive index at 1550 nm decreased from 1.492 to 1.465. This corresponds to a decrease of $4 \pm 1 \times 10^{-4}$ per degree Centigrade and correlates well with the dn/dT reported (4×10^{-4} °C^{-1}) for linear dimethylsiloxane oligomers.[1] This decrease also indicates that the temperature dependence of the refractive index of silicone substituted phthalocyanines is dominated by PDMS chains. Relative to other polymers, polydimethylsiloxane has an exceptionally large dn/dT,[11] and this combination with the phthalocyanine structure demonstrates a successful coupling of this property and this chromophore.

Z-scan and optical limiting measurements were performed on the lead phthalocyanine compound (**1a**) to characterize the nonlinear optical properties. The Z-scan of a 20.2 mM sample of **1a** in a 50.5 μm sample cell at 532 nm is shown in Fig. 1. The material is a strong reverse saturable absorber at 532 nm. An estimate of the excited state cross section from this Z-scan and from a nonlinear transmission experiment on the same sample gave a value of the excited state cross section of ~20 times that of the ground state at 532 nm. This implies that the material is a very good reverse saturable absorber. The nonlinear absorbing properties are similar to those found in lead tetrakis(cumylphenoxy)phthalocyanine, $PbPc(CP)_4$.[12] The strong nonlinear absorption, in combination with the large dn/dT reported above, makes this a superior optical limiter material.

Finally, the silicone chains covering the phthalocyanine chromophore impart some unusual chemical behavior, particularly with regard to metal substitution reactions and aggregate formation. When the siloxane–phthalonitrile precursor (**4**) is subjected to the Linstead conditions of lithium pentoxide–pentan-1-ol for conversion to lithium phthalocyanine,[13] a product with a Q-band diagnostic of the dilithium substituted phthalocyanine (675 nm) is obtained. However, it is very difficult to displace the normally very labile lithium with protons. Normally, this occurs under very mild acidic conditions. We find that normal and progressively more severe acid exchange conditions were unsuccessful.‡ Treatment with concentrated HCl and heating resulted in conversion being first observed at 90 °C which became quantitative after 2 h at this temperature. However, once the lithium ion is displaced by the proton, subsequent metal ion substitution reactions proceed under normal conditions.§

The other aspect of unique chemical behavior is in the aggregation tendency. Phthalocyanine compounds aggregate as a concentration dependent association of phthalocyanine rings. The dimerization constant is a useful measure of this aggregation tendency. Typical dimerization constants for phthalocyanine compounds range from 10^4 to 10^6 M^{-1}.[14] Preliminary analysis of concentration dependence of the Q-band absorption using a monomer–dimer equilibrium model indicates that the dimerization constant for **1b** is 150 ± 100 M^{-1}. This is significantly less than the range for phthalocyanine dimerization constants mentioned above. We attribute this result to the nature of the siloxane chain and the ortho substitution of the phenylene ether linkage to the phthalocyanine ring.

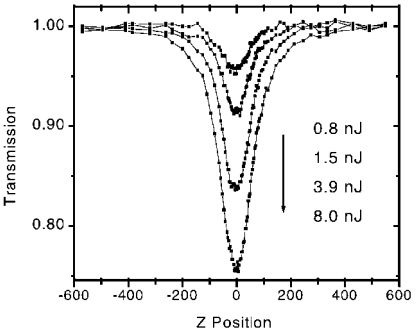


Fig. 1 A Z-scan of a 20.2 mM sample of **1a** at increasing input energy.

In summary, the incorporation of PDMS oligomers as phthalocyanine peripheral substituents combines the desirable rheological and refractive properties of a silicone fluid with the nonlinear optical properties associated with the phthalocyanine. The long silicone substituents further impart unique chemical behavior with respect to the phthalocyanine synthesis and aggregation.

First published as an Advance Article on the web 13th March 2001

Using a seed-mediated growth approach in a rodlike micellar media, silver nanorods of varied aspect ratio were prepared from nearly spherical 4 nm silver nanoparticles.

The physical and photophysical properties of metals on the nanometer scale are influenced by the shape of the nanoparticle.[1] Well defined silver nanorods and nanowires are desirable for their optical and electronic properties.[2,3] However, preparation of silver nanoparticles by chemical reduction methods generally yields a wide range of sizes and morphologies.[4] Silver nanorods and nanowires have been prepared by ultraviolet irradiation–photoreduction,[5] solid–liquid phase arc-discharge,[6] a pulsed sonochemical method,[7] templated by DNA,[8] with a carbon nanotube template,[9] in mesoporous silica,[10] in polymer films,[11] and in membrane templates.[12] Here, a new strategy is applied. A preformed silver seed was used to promote silver growth in solution, by chemical reduction of a silver salt. The presence of a rodlike micelle in solution promoted silver rod formation. We have been able to reproducibly make silver nanorods of aspect ratio 2.5–15 (10–15 nm short axes) and nanowires of 1–4 micrometer length with 12–18 nm short axes, and effectively separate the rods or wires from spheres and other shapes by centrifugation. Our method is not electrochemical and requires no nanoporous membrane, and thus may be more amenable to large-scale preparation of these materials.

The Ag seeds, 4 nm in diameter on average, were prepared by chemical reduction of $AgNO_3$ by $NaBH_4$ in the presence of trisodium citrate to stabilize the nanoparticles.‡ To make nanorods§ and wires¶ of varying aspect ratio, $AgNO_3$ was reduced by ascorbic acid in the presence of seed, the micellar template cetyltrimethylammoniun bromide (CTAB), and NaOH. The seed concentration and base concentration relative to the Ag^+ concentration are key to making larger aspect-ratio nanomaterials. CTAB is also necessary to produce a high yield of rods. Rods and wires can be separated from spheres by centrifugation.‖

The electronic absorption spectra of silver nanorod solutions show the conventional 400 nm peak observed for spherical silver nanoparticles and another peak at longer wavelengths, due to the longitudinal plasmon band of rod-shaped particles (ESI†).[1a,c,13–15] Decreasing the amount of seed in the nanorod preparation led to a further red shift of longer-wavelength longitudinal plasmon bands in the nanorod products, implying that the silver rods increased in average aspect ratio as the seed concentration decreased. Our optical data are in accord with what others have observed for metallic nanorods for transverse and longitudinal plasmon bands.[1a,c,13–15] In the absence of CTAB, spheroidal nanorods (aspect ratio < 2.5) were unstable and reverted to spheres (as judged by the disappearance of the long-wavelength absorption band) within 10 min. In the absence of seed, silver ion reduction by ascorbic acid in the presence of CTAB yielded only a few rods, which varied in aspect ratio.

Transmission electron microscopy (TEM) was performed on centrifuged solutions that had additional long wavelength peaks in their optical absorption spectra.** Figs. 1 and 2 show micrographs of particles prepared from 4 nm seeds after shape separation. The elongated rods shown in Fig. 1 were of uniform length (42 ± 3 nm) and aspect ratio (3.5). Interestingly, these rods self-assemble in a manner resembling a two-dimensional smectic liquid crystal upon gradual solvent evaporation. Depending on seed concentration, rods of aspect ratio 10–15 can also be seperated.§¶‖ Fig. 2 shows a micrograph of silver nanowires, 1–4 μm long with aspect ratio 50–350, mostly separated from spherical side-products. EDAX analysis of the samples confirmed that the particles were silver (not silver oxide) with a considerable amount of CTAB still present.

The only difference between the preparation of nanorods and the preparation of nanowires was the relative amount of NaOH in solution. For the nanorods, the pH of the reaction solution was slightly higher than the pK_a of the second proton of ascorbic acid (≈ 11.8), suggesting that the ascorbate dianion is a significant component of the solution. In the case of the nanowires, the pH of the solution was slightly lower than this pK_a, sugggesting that the monoanion of ascorbic acid (first $pK_a \approx 4.1$) is predominant in solution. It is reasonable that silver ion complexes of these two different forms of the reducing agent, in conjunction with their complexation with the cationic CTAB and silver seed in solution, are important in nanorod and nanowire formation. Mechanistic studies are in progress. Nonetheless, our new wet chemical synthetic method of silver

nanorods and nanowires is relatively simple to perform, and requires no nanoporous membrane.

Notes and references

‡ Preparation of 4 nm seed: a 20 mL solution with a final concentration of 0.25 mM $AgNO_3$ and 0.25 mM trisodium citrate in water was prepared. While stirring vigorously, 0.6 mL of 10 mM $NaBH_4$ was added all at once. Stirring was stopped after 30 s. This seed was used 2 h after preparation but could not be used after 5 h, as a thin film of particles appeared at the water surface. According to transmission electron microscopy, seed diameters were 4 ± 2 nm. For capping action of citrate see: A. Henglein and M. Giersig, *J. Phys. Chem. B*, 1999, **103**, 9533.

§ Procedure for Ag rods: first, six sets of solutions were prepared containing 0.25 mL of 10 mM $AgNO_3$, 0.50 mL of 100 mM ascorbic acid, and 10 mL of 80 mM CTAB. Next, a varied amount of 4 nm seed solution (2 mL, 1 mL, 0.5 mL, 0.25 mL, 0.125 mL or 0.06 mL) was added. Finally, 0.10 mL of 1 M NaOH was added to each set. NaOH must be added last to obtain the desired nanorods in decent yield. After adding the NaOH, the solution was gently shaken just enough to mix the NaOH with the rest of the solution. Within 1–10 min a color change occurred varying from red, to brown, to green depending on seed concentration. Each solution contained a mixture of rods and spheres with the aspect ratio of the rods increasing with decreasing seed concentration.

¶ Procedure for Ag wires: a solution containing 2.5 mL of 10 mM $AgNO_3$, 5.0 mL of 100 mM ascorbic acid and 93 mL of 80 mM CTAB was prepared. Next, 2.5 mL of the 4 nm seed solution was added. Finally, 0.5 mL of 1 M NaOH was added. After adding the NaOH, the solution was gently shaken just enough to mix the NaOH with the rest of the solution. A yellow color appeared within 15 min.

‖ Rods were concentrated and partially separated from spheres and surfactant by centrifugation. For solutions containing 0.25 mL of seed or more, 10 mL of solution was centrifuged at 6000 rpm for 30 min. The supernatant, containing mostly small spheres and platelets, was removed and the solid, containing some platelets and more rods with aspect ratio of 3–4, were redispersed in 0.5 mL of deionized water. For solutions containing 0.125 mL or 0.06 mL of seed, 10 mL of the solution was centrifuged at 2000 rpm for 6 min. The supernatant, containing short rods, spheres, and platelets, was separated from the solid which contained rods of aspect ratio 3–4 and a few larger rods (aspect ratio 10–15). Wires were partially separated from spheres and surfactant by centrifugation. For wires, 10 mL of the solution was centrifuged at 6000 rpm for 30 min. The supernatant was removed and the precipitate, containing silver nanowires, was redispersed in 0.5 mL of deionized water.

** All TEM grids were prepared from the solutions that were separated by centrifugation. 1.5 μL of solution was added to each grid. The grids and a small beaker of water were placed under a glass dish. The beaker of water provided a water vapor atmosphere to allow for slow drying (1–2 h) of the rod or wire solutions on the grid.

Synthesis, characterization and C–H activation reactivity of bis(ethylene) boratabenzene rhodium complexes†

David H. Woodmansee, Xianhui Bu and Guillermo C. Bazan*

Departments of Chemistry and Materials, University of California, Santa Barbara, CA 93106, USA. E-mail: bazan@chem.ucsb.edu

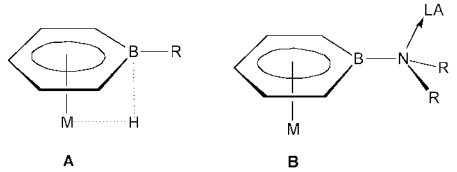
Received (in Irvine, CA, USA) 16th November 2000, Accepted 13th February 2001
First published as an Advance Article on the web 13th March 2001

Reaction of Li[C_5H_5B–Ph] with [$RhCl(C_2H_4)_2]_2$ gives [C_5H_5B–Ph]$Rh(C_2H_4)_2$ 1 in 91% yield; similarly, Li[C_5H_5B–NMe_2] with [$RhCl(C_2H_4)_2]_2$ gives [C_5H_5B–NMe_2]$Rh(C_2H_4)_2$ 2 in 85% yield; single crystal X-ray analysis studies of 1 and 2 show a molecular geometry analogous to those of the Cp and Cp* complexes; the use of 1 and 2 in promoting alkane boration was evaluated against the activity of Cp*$Rh(C_2H_4)_2$ 3; the boratabenzene complexes 1 and 2 show faster initiation, but yield less thermally stable catalysts than 3.

Advances in the chemistry of homogeneous transition metal complexes containing boratabenzene (Bb) ligands[1] have shown that it is possible to control the catalytic activity at the metal by choice of the boron substituent.[2] The dependence of significant elementary reactions on the electron density at the metal and how these parameters change as a function of Bb structure have also been studied.[3] Dialkylaminoboratabenzene is a considerably stronger donor than phenylboratabenzene, and both are considerably weaker than the isoelectronic cyclopentadienyl (Cp) or pentamethylcyclopentadienyl (Cp*) ligands.[4] Given a Cp or Cp*-based catalyst, it is possible to obtain a nearly isostructural complex by Bb substitution, however these species will display slightly different catalytic cycles.[5]

Cp* complexes of Group 9 metals have been intensely studied in C–H activation reactions.[6] Recently, Iverson and Smith[7] and Hartwig and coworkers[8] have demonstrated that complexes such as Cp*$Ir(PMe_3)H(Cy)$ (Cy = *c*-C_6H_{11}), Cp*$Rh(C_2H_4)_2$[9] **3** and Cp*Rh(η^4-C_6Me_6) mediate the selective functionalization of unactivated alkanes. In particular, the rhodium complexes are highly effective in catalyzing the reaction of 4,4,4′,4′,5,5,5′,5′-octamethyl-2,2′-bi-1,3,2-dioxaborolane (pinBBpin) to 2-(1-octyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane.[8] The importance of alkane functionalization is well appreciated and motivates considerable research.[10]

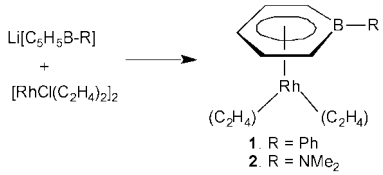
In view of the interest in these reactions, we decided to investigate whether boratabenzene complexes could participate in C–H activation processes. Three-center–two-electron interactions of type **A**[11] are known, which could weaken the M–H bond strength. It is also expected[12] that the nitrogen on aminoboratabenzene ligands will coordinate to Lewis acids, as in **B**. Precoordination of a diborane or a borane–hydride would



increase the local concentration of reactant near the vicinity of the metal center. Finally it is anticipated that in cycles that involve oxidative addition/reductive elimination sequences, the Bb counterparts will show more facile reductive elimination steps.[13]

In this contribution we report the synthesis and characterization of [C_5H_5B–Ph]$Rh(C_2H_4)_2$ **1** and [C_5H_5B–NMe_2]$Rh(C_2H_4)_2$ **2**. Phenyl and dimethylamino functionalities were chosen because they correspond to the weakest and strongest donors, respectively.[3] We also show that **1** and **2** can be used to catalyze C–H activation processes, that the boron substituent influences the reactivity of rhodium and that the relative stabilities of the resulting Bb catalysts are lower than that of the Cp* counterpart.

Reaction of Li[C_5H_5B–Ph][14] with [$RhCl(C_2H_4)_2]_2$, followed by standard workup, provides **1** in 85% yield as a red–orange powder [eqn. (1)].[15] A similar protocol, starting with Li[C_5H_5B–NMe_2], gives **2** in 91% yield.



(1)

Single crystal X-ray diffraction studies of **1** (Fig. 1) and **2** (Fig. 2)‡ confirm the isostructural relationship to **3**.[16] Three independent molecules are present in the unit cell of **2**, which differ slightly on the rotation of the Bb ring relative to the '$Rh(C_2H_4)_2$' base. The B–Rh distance is shorter for **1** (2.398 Å for **1**; av. = 2.516 Å for **2**) and the B–N distances in the three molecules of **2** are consistent with B–N π-bonding.[17] Interestingly, in both **1** and **2**, the Bb ring is rotated such that the boron atom sits above one of the ethylene ligands.

The ^{1}H NMR signals of the ethylene ligands in **1** and **2** show variable temperature behavior. Two doublets are observed at the

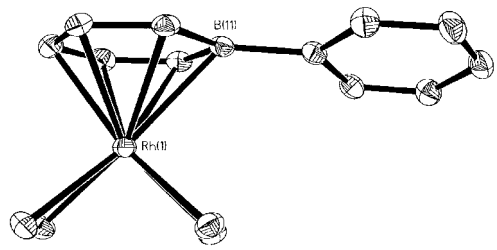


Fig. 1 ORTEP drawing of **1**; hydrogen atoms omitted for clarity.

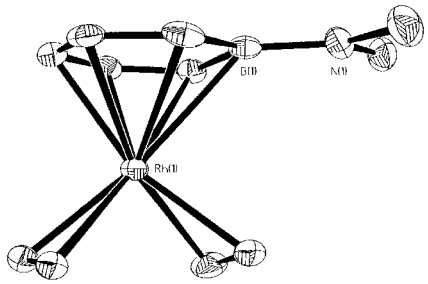

Fig. 2 ORTEP drawing of one of the three independent molecules in the crystal of **2**; hydrogen atoms omitted for clarity.

† Electronic supplementary information (ESI) available. Complete details for experimental procedures. See http://www.rsc.org/suppdata/cc/b0/b009246k/

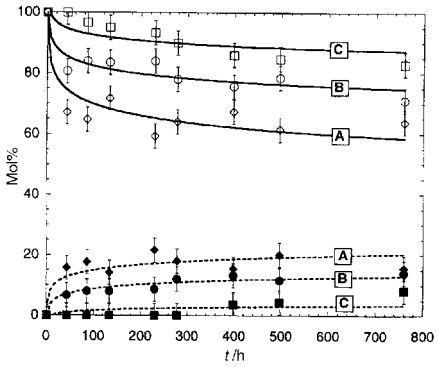

Fig. 3 Mol% of boron present as pinBBpin (——) and pinB–octyl (- - - -) as a function of time for reactions at 50 °C, containing (a) **1**, (b) **2** and (c) **3**; the lines are included to aid the eye.

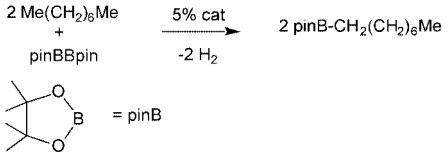
low-temperature limit, which coalesce into a single resonance as the temperature increases. These data indicate facile ethylene rotation about the axis joining the metal to the center of the C=C bond. This propeller-like motion is well known in the cyclopentadienyl counterparts such as **3**[18] and its rate depends on the back-bonding ability of the metal.[19] From ^{1}H NMR coalescence experiments, $\Delta G^{\ddagger}$ = 60(3) kJ mol^{-1} (T_c = 311 K) for **1** and 50(3) kJ mol^{-1} (T_c = 265 K) for **2**. Both barriers are lower than that observed for **3** (71.5 kJ mol^{-1} at 340 K),[19] and are consistent with less efficient back bonding to ethylene in the Bb complexes.

To compare how **1** and **2** catalyze C–H activation reactions relative to **3**, we examined the boration of octane[20] with pinBBpin [eqn. (2)], under the reagent ratios and conditions established by Hartwig and coworkers.[8] The progress of the reactions was monitored by ^{11}B NMR spectroscopy against an internal standard [B(C_6F_5)$_3$ inside a capillary]. Product identity was further confirmed by use of GC–MS analysis.



(2)

Fig. 3 shows the consumption of pinBBpin as a function of time using **1**, **2** or **3** with octane as the solvent at 50 °C, together with the molar percent of pinB–octyl. Mass balance is compensated by the formation of pinB–H (not shown). The reaction with **1** is most active at initial reaction times, followed by those of **2** and then **3**. As the reaction progresses, the activity quickly shuts down for the three cases. For **1**, the reaction yield of pinB–octyl is *ca*. 20% (assuming that one mole of pinBBpin yields two moles of pinB–octyl),[8] while for **3** the yield is only 7%. When the reaction temperature is 95 °C, the reactions mixtures containing **1** and **2** become inactive after 24 h and achieve only 15% conversion (Fig. 4). For the Cp* counterpart, the reaction continues until all starting material is consumed. The addition of mercury (300 and 3250 equiv. relative to Rh) does not affect the course of the reaction and suggests that the reactions are mediated by homogenous species.[21]

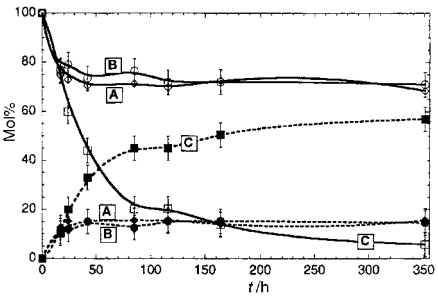


Fig. 4 Mol% of boron present as pinBBpin (——) and pinB-octyl (- - - -) as a function of time for reactions at 95 °C, containing (a) **1**, (b) **2** and (c) **3**; the lines are included to aid the eye.

In summary, we have shown that Bb complexes are capable of participating in catalytic C–H functionalization reactions. Under specific conditions these Bb complexes can initiate the reaction more quickly than their Cp* analogs. However, Bb compounds are less thermally stable and degrade before the reaction in eqn. (2) reaches completion. Compounds such as **1** and **2** may provide catalytic C–H activation possibilities for reactions that require milder conditions.

We are grateful to the Department of Energy, the ACS PRF and Equistar Chemicals LP for financial assistance.

First published as an Advance Article on the web 13th March 2001

The new heptadentate tripodal ligand tpaa containing three pyridinecarboxylate binding units reacts with Gd(III) in water to give a thermodynamically stable complex which displays high relaxivity.

In recent years there has been a rapid growth in the field of coordination chemistry of lanthanides(III) with polydentate ligands.[1,2] This development has been mainly spurred by the application of gadolinium complexes as magnetic resonance imaging (MRI) contrast agents[3–5] and of europium or terbium complexes as luminescent probes in time-resolved fluoroimmunoassays.[6,7] The key property of an efficient contrast agent is its ability to enhance the nuclear magnetic relaxation rate of solvent water protons. This can be achieved by the presence of a high number of inner sphere water molecules in combination with fast water exchange, long rotational correlation times and long electronic relaxation times. The current approach to achieve higher relaxivity consists in increasing the rotational correlation time (τ_R) by increasing the molecular weight of the contrast agent through the formation of macromolecular complexes by covalent or non-covalent linkage of Gd(III) chelates to large biomolecules. However the effective enhancement of the rotational correlation time attainable in these systems is limited by the residence lifetime (τ_M) of the coordinated water molecule. The relatively long τ_M of Gd complexes of octadentate ligands such as the currently approved contrast agents $[Gd(dtpa)(H_2O)]^{2-}$ and $[Gd(dota)(H_2O)]^{-}$† appears to be related to the dissociative exchange mechanism of the water molecule. This prevents dendrimeric Gd(III) derivatives[8] and non-covalent adducts of Gd(III) chelates with large bio-molecules[9] from attaining their potential relaxation enhancement.

Heptadentate ligands allow the coordination of two water molecules in the inner sphere of the metal and consequently yield higher relaxivity with respect to Gd(III) complexes of octadentate ligands. In addition Gd(III) complexes containing heptadentate[10,11] or hexadentate ligands[12] have shown faster water-exchange rates than complexes with octa-coordinating ligands. In spite of this, heptadentate ligands have seldom been used in the design of Gd(III) based contrast agents.[5]

Here we report the synthesis of the new tripodal ligand, tpaa (containing three pyridinecarboxylate arms connected to a nitrogen atom)‡ which acts an an heptadendate chelator thus allowing the coordination of at least two water molecules in its lanthanide(III) complexes. Moreover the ligand tpaa leads to an uncharged Gd(III) complex which should show reduced potential for osmotic cell damage.

As shown in Scheme 1, H_3tpaa **2** was prepared by hydrolysis of the heptadentate ligand tpa(trisamide) **1**, obtained from the condensation of the 6-aminomethyl derivative and the 6-chloromethyl derivative of 2-(*N*,*N*-diethylcarboxamido)pyridine in the presence of K_2CO_3. The protonation constants of H_3tpaa were determined by potentiometry [pK_{a1} = 2.5(2), pK_{a2} = 3.3(1), pK_{a3} = 4.11(6), pK_{a4} = 6.78(4)]. The $[Gd(tpaa)(H_2O)]_2$ complex **3**§ was obtained as colorless crystals suitable for X-ray diffraction¶ by slow evaporation of a 1 : 1 solution of $GdCl_3$ and H_3tpaa in water. Fig. 1 shows the structure of **3** in which two Gd(III) centers are joined by two bridging oxygens from the monodentate carboxylate groups of two different tpaa ligands to form a dimeric complex. The metal ion is nine-coordinated by four nitrogens and three carboxylate oxygens of tpaa, one water molecule and a carboxylate oxygen of the neighboring complexed ligand. The coordination geometry can be described as a distorted tricapped trigonal prism in which O(1), N(2) and N(3) occupy the capping positions in the rectangular faces. The average Gd–N(pyridyl) distance [2.56(4) Å] is shorter than the average Gd–N(tert) distances found in the neutral nonadentate complexes $(Gd(do3ma)(H_2O)]_2$[13]† (2.66 Å) and [Gd(dtpa-bea)(H_2O)][14]† [2.70(3) Å], while the distance Gd–N(apical) [2.7886(19) Å] in **3** is 0.222 Å longer than the sum of the ionic radii of Gd and N, probably due to the oligomerization. The Gd–O(water) distance [2.399(2) Å] is shorter than those found in the dimeric 9-coordinate complex $[Gd(do3ma)(H_2O)]_2$[13]† [2.451(5) and 2.56(4) Å] and in the eight-coordinate complex $[Gd(tren\text{-}Me\text{-}3,2\text{-}hopo)(H_2O)_2]$[15]† [2.446(5) and 2.436(4) Å], but is similar to the Gd–O(water) distances in the monomeric nine-coordinate complex [Gd(dtpa-bea)(H_2O)] [2.42(3) Å].[14] The tendency of the $[Gd(tpaa)(H_2O)_2]$ complex to oligomerize in the solid state, and in the conditions generated in the electrospray analysis arises from the presence of a relatively exposed metal face due to the flexibility of the unhindered tpaa ligand. This property of aminocarboxylate to oligomerize in water has only been observed before in the presence of macrocyclic ligands.

In order to avoid toxicity, Gd(III) complexes are required to be highly thermodynamically (and preferably also kinetically) stable for application as contrast agents. Potentiometric data

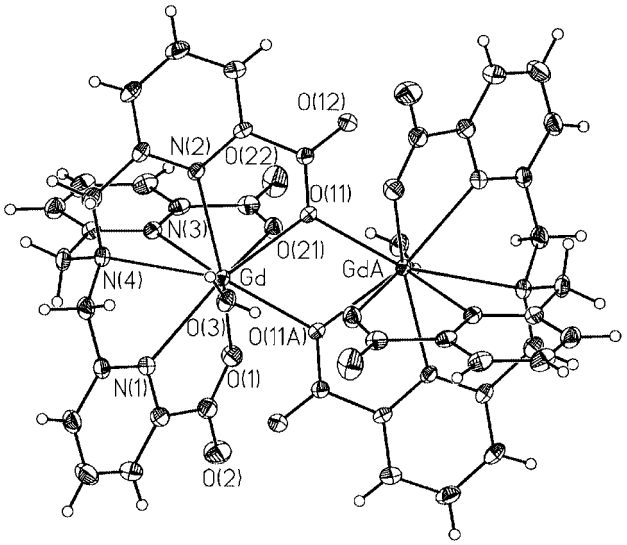

Fig. 1 Crystal structure of $[Gd(tpaa)(H_2O)]_2{\cdot}7H_2O$ **3** with thermal ellipsoids at 30% probability. Selected bond lengths (Å): Gd···GdA 4.125, Gd–O(11) 2.,4726(17), Gd–O(11A) 2.4010(15), Gd–O(1) 2.4414(17), Gd–O(21) 2.3783(17), Gd–O(3) 2.399(2), Gd–N(1) 2.546(2), Gd–N(2) 2.6051(19), Gd–N(3) 2.531(2), Gd–N(4) 2.7886(19) (symmetry transformation used to generate equivalent atoms A: $-x + 1$, $-y$, $-z$).

obtained by titration of 1:1 metal:H_3tpaa mixtures in the pH range 2.8–8 can be satisfactorily fitted to eqn. (1) leading to a

$$Gd^{3+} + tpaa^{3-} \rightleftharpoons [Gd(tpaa)] \quad \log\beta_{GdL} = 10.2(2) \qquad (1)$$

pM value of 11.2 for Gd(III) {$-\log[M]_{free}$ at pH 7.4, $[M]_{total}$ = 1 μM, $[tpaa]_{total}$ = 10 μM} which indicates a reasonable physiological stability of $[Gd(tpaa)(H_2O)]_2$ as compared to the lowest pGd value (15.8) found in commercially used MRI agents.[5] Only a small decrease of the physiological stability is observed for the Gd complex of the less rigid podate tpaa with respect to Gd complexes containing macrocyclic heptadentate ligands such as do3a (14.5).[5] Moreover we expect that the stability and the solubility of the gadolinium complex could be improved by suitable substitution of the pyridine rings.

The relaxivity r_{1p} is a critical property of a potential contrast agent which represents the increase in the water proton nuclear magnetic relaxation rate per millimolar concentration of the paramagnetic compound. At 60 MHz, r_{1p} was measured to be 13.3 $mM^{-1}\ s^{-1}$ at 25 °C (9.37 $mM^{-1}\ s^{-1}$ at 37 °C) for **3**. This value is higher than those found in the mono-aquo complexes $[Gd(dtpa)(H_2O)]^{2-}$ or $[Gd(dota)(H_2O)]^{-}$ (4.3 $mM^{-1}\ s^{-1}$ at 25 °C) and than the values found in bis-aquo complexes containing macrocyclic heptadentate ligands such as $[Gd(do3a)(H_2O)_2]$† (6.1 $mM^{-1}\ s^{-1}$ at 25 °C) and $[Gd(pcta[12])(H_2O)_2]$† (6.9 mM s^{-1} at 25 °C).[10,11] This high value cannot simply be explained by the presence in aqueous solution of two water molecules coordinated to the Gd(III) ion (each molecule makes a contribution to the relaxivity of *ca.* 2.5 $mM^{-1}\ s^{-1}$). A preliminary study of the temperature dependence of the relaxivity indicates that the inner sphere water molecules are involved in a fast exchange with the bulk water, in agreement with what is expected for complexes containing heptadentate ligands. More detailed NMR studies are in progress in order to elucidate the origin of this high relaxivity.

In summary we have described a new type of heptadentate ligand which leads to a gadolinium complex with unusually high relaxivity and fast water exchange.

Moreover the straightforward introduction of substituents on the pyridine rings allows us to envisage ligands with a higher water solubility, containing functional groups capable of non-covalent or covalent interactions with slowly moving substrates such as proteins or polysaccharides. This could lead to contrast agents with longer rotational correlation times and consequently higher relaxivities or to increased specific tissue affinity.

First published as an Advance Article on the web 14th March 2001

The total synthesis of 2,3-dihydroxytrinervitanes, 1a and 1b, was performed from secotrinervitane-type allyl chloride 2

More than two decades ago, characterization of 2,3-dihydroxytrinervitanes **1a** and **1b** (Fig. 1) was reported as the typical defensive substances from several species of termite soldiers inhabiting the tropics.[1] In spite of their unique structure and interesting biological activity, the total synthesis of **1a** and **1b** remained unpublished.[2]

We have been greatly interested in the biogenetic-type synthesis of diterpenoids secreted by termites and have explored the synthetic route of trinervitane **3** and kempane **5** skeletons through the intermediate, allyl chloride **2**, as illustrated in Scheme 1.[3] Our further effort led to completion of the synthesis of trinervitanes **1a** and **1b** as a *dl*-form. This paper reports the result of our study.

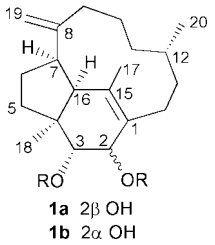

Fig. 1 Structure of 2β- and 2α-trinervitanes.

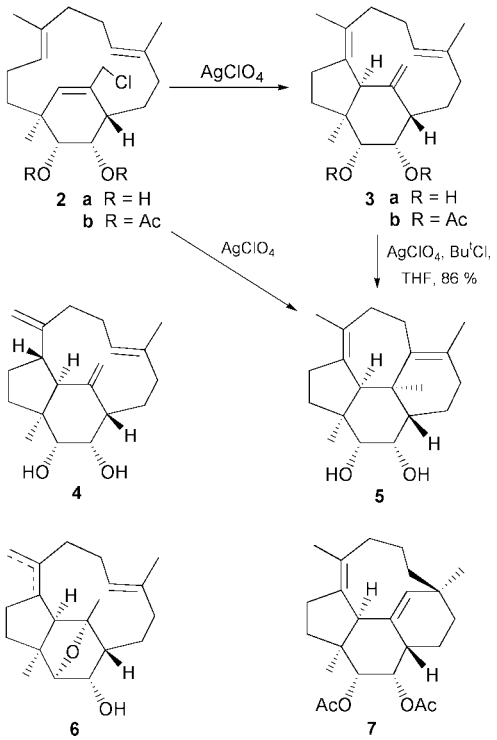

Scheme 1 Construction of trinervitane **3** and kempane **5** skeletons.

As reported previously,[4] the desired trinervitanes **3a** and **4** were provided in 68 and 5% yields, respectively, with accompanying formation of etheric compound **6** as unpurified minor product when **2a** was submitted to the reaction with $AgClO_4$ in THF at −20 °C. This ring-closure reaction depends largely on the reaction temperature, *i.e.* a completely different tetracyclic kempane diol **5** was formed in 50% yield when the reaction of **2a** with $AgClO_4$ was carried out at +20 °C. Treatment of **3a** at rt with $HClO_4$ in THF, prepared *in situ* by the reaction of *tert*-butyl chloride and $AgClO_4$, gave the kempane diol **5** in high yield. Based on this evidence, we first attempted to improve the yield of **3**.‡ We were surprised to find that completely different tetracyclic diacetate **7**[5] was isolated in high yield when diacetate **2b**, quantitatively prepared from **2a**, was treated with $AgClO_4$ in THF at rt. Eventually, **2b** was converted into **3b** in 91% yield by treatment with $AgClO_4$ (1.2 eq.) in the presence of pyridine (1.5 eq.) at rt.

The next step was focused on the regio- and face-selective hydrogenation of triene **3a** possessing three different types of double bonds. The PtO_2-catalyzed hydrogenation in MeOH afforded a 7:3 mixture of 11,12-dihydro derivatives, revealing the two remaining double bonds at 7(8) and 15(17) positions are inert under the employed conditions. The separation of the reduction products was unsuccessful at this stage since it forms prism-shaped mixed crystals, mp 92–94 °C and HPLC of the mixture showed the single peak under several conditions. As regards the reasonable conformation of the macro ring of the triene **3**, two gross structures are possible as shown in Fig. 2. The plane of the 11(12) double bond is perpendicular to the cyclohexane ring in one conformation (*perpendicular* conformation: PC) and horizontal in the other conformation (*horizontal* conformation: HC). The hydrogenation may occur from the opposite faces depending on the conformation, that is, the perpendicular conformation gives the 12β-methyl product by selective H_2 addition from the α-side. The horizontal conformation leads to the 12α-Me isomer by the preferential β-face attack, the opposite α-face being partly masked by the 15(17) double bond. The existence of **3a** as the horizontal conformation was deduced by the fact that **3a** is easily convertible to the cyclized products **5** and **7** under protonic conditions as mentioned in Scheme 1. The detailed NOESY experiments in the NMR spectrum of **3a** supported this deduction. Expecting the conformational change of the methylenecyclohexane moiety of **3a**, the five-membered carbonate ring was introduced at the 2 and 3 positions with carbonyldiimidazole to give **3c**. The 0.2 ppm up-field shift of 11-H of **3c** was observed, indicating the change of the chair-type cyclohexane ring of **3a** to the twisted form, in which the 15(17)

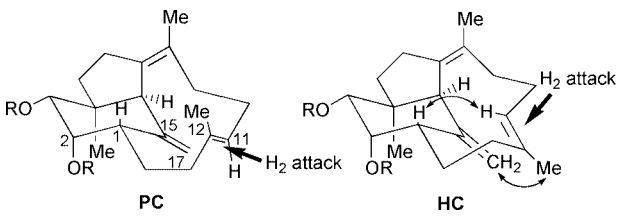

Fig. 2 Possible conformations of the triene **3**.

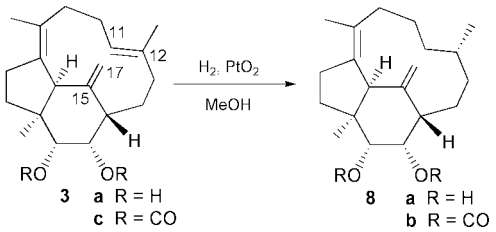


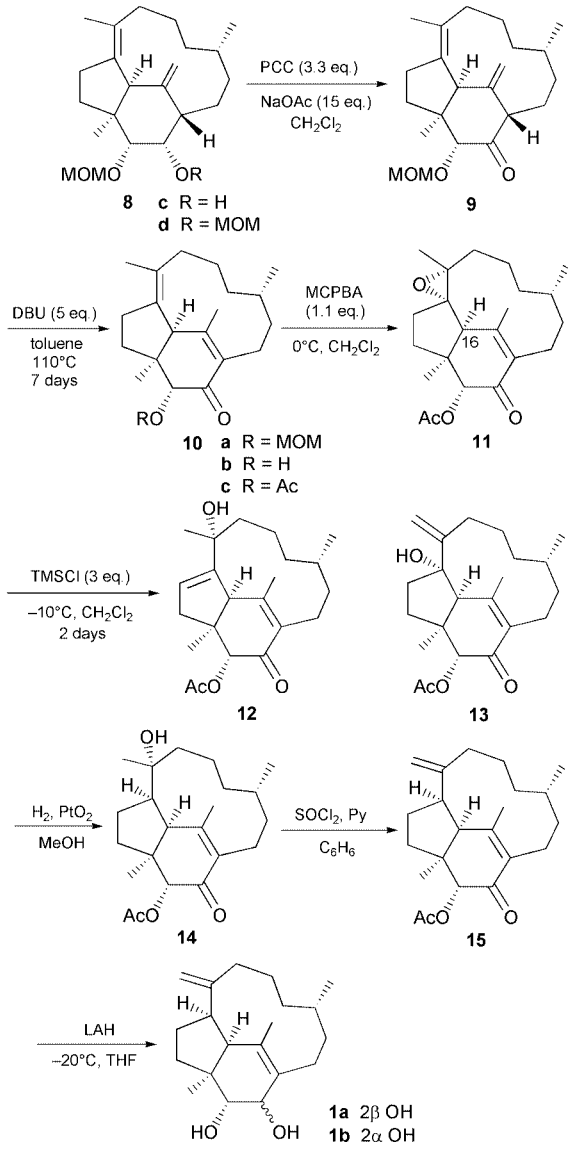
Scheme 2 Hydrogenation of triene **3**.

double bond locates more closely to the plane of the 11(12) double bond. The hydrogenation of **3c** in CH_2Cl_2 provided a 6:1 mixture of C_{12}-stereoisomers (Scheme 2). It was luckily found that both stereoisomers of the carbonate **8b** were easily separable by flash chromatography, affording the corresponding reduction products suitable for X-ray crystallographic analyses. The X-ray analyses demonstrated unequivocally the major product possessed 12α-Me configuration.

After removal of the carbonyl group of **8b**, the diol **8a** was treated with MOMCl (2 eq.) and diisopropylethylamine (4 eq.) in CH_2Cl_2 for 3 h at rt to furnish the 3-MOM ether **8c** in 74% yield accompanied with the 2-MOM ether (13%) and 2,3-diMOM ether **8d** (7%). The unnecessary minor products were converted to **8c** by hydrolysis (2 M HCl in MeOH), followed by etherification with MOMCl under the same conditions. The PCC oxidation of **8c** proceeded smoothly to give the corresponding ketone **9** in 91% yield (Scheme 3). For the isomerization of **9** to the conjugated enone **10**, we had to attempt several basic conditions[6] before finding the successful conditions of DBU in refluxing toluene for a week (89% yield). The convex face selective oxidation of **10c**, obtained from **10a** by the usual procedures, took place exclusively with MCPBA, affording the epoxide **11** in quantified yield.

The ring-opening conditions of the epoxide **11** were quite restricted since the 16-proton is labile under acidic and basic conditions. Of the reagents we examined TMSCl at −10 °C was the only choice and it gave a 1:1 mixture of **12** and its isomer **13** in 30% respective yields.[7] The hydrogenation of **12** afforded, as expected, a single product **14** (85%), the stereochemistry of the 7-position being assigned based on the convex selectivity as in the case of epoxidation of **10c**. The dehydration of the *tert*-alcohol **14** furnished a *ca.* 5:3:1 mixture of **10c**, **15** and trisubstituted isomer in total 83% yield. After separation with $AgNO_3$–SiO_2 column chromatography, **15** was reduced with LAH, giving an easily separable 1:1 mixture of 2,3-dihydroxytrinervitanes, **1a** and **1b**. The chemical shifts and coupling constants in the proton NMR of the synthetic materials were in complete accord with the reported values[1b] within experimental deviation due to the applied instruments.

Thus, we have accomplished the total synthesis of 2,3-dihydroxytrinervitanes in *dl*-form. Our recent study[8] on the enantiometrically pure synthetic intermediate may enable us to perform the enantiospecific synthesis of **1a** and **1b**.



Scheme 3 Synthesis of (±)-trinervitanes **1a** and **1b**.

Received (in Cambridge, UK) 19th December 2000, Accepted 21st February 2001
First published as an Advance Article on the web 14th March 2001

The treatment of alkyl ω,ω-bis(phenylthio)alkanoates with $Cp_2Ti[P(OEt)_3]_2$ produced enol ethers of 5-, 6-, 7-, and 9-membered cyclic ketones.

Intramolecular reactions of phosphorous ylides and related α-phosphorous carbanions with ketones and aldehydes have been used by a number of workers for the preparation of cycloalkenes, including complex natural products.[1] However, intramolecular carbonyl olefinations of esters using the phosphorous carbanions are generally unsuccessful because these reactions end up with the formation of acylation products.[2] Only the preparation of certain five- and six-membered cyclic compounds, in which the formation of a double bond is facilitated by π-conjugation with a carbonyl group or an aromatic ring, has been achieved.[3] Transition metal–carbene complexes and related reagents have been employed for this transformation. Stille and Grubbs have described the formation of titanium–carbene complexes by the ring-opening metathesis of strained norbornylene derivatives and their intramolecular reaction with an ester carbonyl.[4] Although tungsten–carbene complex promoted transformation of benzyl 2-benzylhex-5-enoate into 3-benzyl-2-benzyloxycyclopentene *via* olefin metathesis–carbonyl olefination was reported, the experimental details including the yield of the product were not disclosed.[5] Mortimore and Kociénski reported the cyclization of 4,4-dibromobutyl benzoate utilizing a $TiCl_4$–Zn–TMEDA system.[6] The olefination product, 6-phenyl-3,4-dihydro-2*H*-pyran, however, was obtained in only a poor yield. The intramolecular McMurry coupling of keto esters is regarded as a formal intramolecular olefination of esters, and various cyclanones have been prepared by this method.[7] Although this reaction is useful for the preparation of furans and benzofurans,[8] its application to the synthesis of alicyclic vinyl ethers has yet to appear. Formal intramolecular carbonyl olefination consisting of the intermolecular carbonyl olefination of esters and subsequent ring closing metathesis has been employed for the synthesis of cyclic vinyl ethers.[9] The studies described above indicate that the intramolecular carbonyl olefination of esters still remains a problem to be solved.

Recently we reported a new method for carbonyl olefination using a thioacetal–$Cp_2Ti[P(OEt)_3]_2$ **1** system.[10] Since this reaction is useful for the olefination of esters, we have studied its application to the synthesis of cyclic vinyl ethers. Unfortunately the attempt to prepare monocyclic vinyl ethers by

the titanocene(II)-promoted olefination of ω,ω-bis(phenylthio)alkyl alkanoates was unsuccessful owing to the concomitant formation of oligomers.[11] Herein we describe the intramolecular reaction of alkyl ω,ω-bis(phenylthio)alkanoates **2**. This reaction proceeds by way of the titanium–carbene complexes **3** to produce a wide variety of vinyl ethers of cyclic ketones **4** without formation of any oligomer (Scheme 1).

When methyl 2-phenyl-7,7-bis(phenylthio)heptanoate **2i** was treated with the low-valent titanium species **1** (4 equiv.) at room temperature for 1 h, the complete disappearance of the starting material was observed. Column chromatography using basic alumina gave the cyclic vinyl ether **4i** in 59% yield. The cyclization of **2i** in refluxing THF produced **4i** in better yield (Table 1, Entry 9). In a similar manner, the enol ethers of five-, six-, and seven-membered cyclic ketones were obtained in good yields by the reaction of alkyl α-substituted ω,ω-bis(phenylthio)alkanoates. The substituent α to the carbonyl group is not crucial for the present olefination. The reactions of the esters carrying a substituent at the β-position also produced the corresponding cyclic compounds **4d**–**f**.† It was found that the *tert*-butyl esters gave better yields than the corresponding ethyl esters in these reactions (see Entries 5 and 6). In some case, we observed the partial isomerization of the initial olefination product to the tetrasubstituted cycloalkene. This isomerization, however, was absolutely depressed when the reaction was carried out at 15 °C (Entry 2).

The advantage of the present preparation is that the starting materials are easily prepared by the use of organosulfur building blocks. Thus the esters **2k** and **l** were obtained by the Williamson ether synthesis utilizing ω,ω-bis(phenylthio)alkanols and were transformed into the nine-membered cyclic vinyl ethers **4k** and **l** with high stereoselectivity. The *E*-configuration of their double bonds was determined by NOESY.

All the experiments described above were carried out on a small scale (0.5 mmol). Since an intramolecular reaction generally requires high dilution conditions to prevent the competitive intermolecular reaction, decrease in the yield is sometimes a serious problem upon scale up. We examined a gram-scale reaction of **2i** to confirm the synthetic utility of the present reaction. Using a slightly modified procedure,[12] the cycloheptene **4i** was obtained in better yield (73%) than for the smaller scale reaction (Entry 9).

In conclusion, we have established the first versatile method for the regioselective preparation of vinyl ethers of cyclic ketones by the intramolecular carbonyl olefination of esters. Further study on the application of this methodology to the synthesis of a variety of heterocycles is currently in progress.

First isolation of *N*-alkoxyaminyl radicals

Yozo Miura* and Tatsuya Tomimura

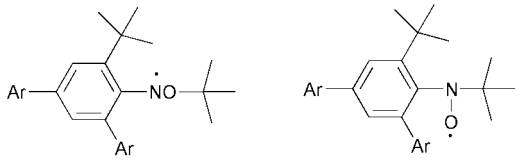
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558-8585, Japan. E-mail: miura@a-chem.erg.osaka-cu.ac.jp

Received (in Cambridge, UK) 17th January 2001, Accepted 22nd February 2001
First published as an Advance Article on the web 14th March 2001

***N*-(*tert*-Butoxy)-*N*-(2,4-diaryl-6-*tert*-butylphenyl)aminyls have been isolated; this is the first isolation of *N*-alkoxyaminyl radicals.**

Although a variety of *N*-alkoxyalkylaminyl (RṄOR),[1–3] *N*-alkoxyvinylaminy[4] and *N*-alkoxyarylaminyl radicals (ArṄOR)[1,2,5–10] have been investigated for a long period and persistent *N*-alkoxyaminyls have been found, there are no reports of isolation of *N*-alkoxyaminyls. This is in contrast to the chemistry of thioaminyl radicals (RṄSR). In the case of thioaminyls a variety of radicals have been isolated and their X-ray crystallographic and magnetic studies have been carried out.[11,12] Isolable stable free radicals have attracted much attention as spin sources or building blocks of organic magnetic materials.[13,14] In this communication we report on the first isolation of *N*-alkoxyarylaminyl radicals and their characterization.

N-(*tert*-Butoxy)-*N*-(2,4-diphenyl-6-*tert*-butylphenyl)aminyl (**1a**) was prepared by treating the lithium salt of 2,4-diphenyl-6-*tert*-butylaniline with two equiv. of *tert*-butyl peroxybenzoate



1 **2**

a Ar = Ph
b Ar = 4-FC_6H_4
c Ar = 4-ClC_6H_4
a-d_{10} Ar = C_6D_5

at −78 °C in THF.[15] The reaction mixture showed a deep red colour, and TLC analysis indicated formation of a red coloured product, along with the presence of the unreacted starting aniline and some minor products. Separation of the red zone by column chromatography (silica gel, 3 : 1 hexane–benzene) gave **1a** in 24% yield. In the same manner, **1b** and **1c** were isolated in 17 and 20% yields, respectively. Recrystallization of the isolated radical solid from MeOH afforded red plates (**1a**, **c**) or red needles (**1c**). The structures of radicals were confirmed by the IR spectra and elemental analyses. In the IR spectra no NH absorption was observed and the elemental analyses were in satisfactory agreement with the calculations in all cases. For **1a** single crystal X-ray crystallographic analysis was performed.

N-Alkoxyarylaminyls **1** were stable in solution, even in the presence of atmospheric oxygen and, although **1a** was heated at 80 °C in degassed benzene for 10 d, 80% of the radical survived and no rearrangement to the corresponding aminoxyl **2** was observed.[8,16] These observations indicate that **1** is an oxygen insensitive and thermally stable radical.

Since **1a** gave a single crystal suitable for the X-ray crystallographic analysis on recrystallization from MeOH, we performed an X-ray crystallographic study on **1a**.† The ORTEP drawing of the molecular structure is shown in Fig. 1. The X-ray crystallographic data shows the following structural characteristics. The N and O atoms are coplanar with the benzene ring A within 0.05 Å. While benzene ring C makes a dihedral angle of 41.5° with benzene ring A, benzene ring B makes a dihedral angle of 86.0° with benzene ring A, indicating that there is a large steric congestion around the radical center. Accordingly, it is likely that delocalization of the unpaired electron spin onto benzene ring B is very or negligibly small, and this means that the benzene ring B plays an important role in steric protection, but does not contribute to electronic stabilization of the radical. Since the N–O bond has the character of a two center–three electron bond where the unpaired electron is accommodated in the anti-bonding orbital,[17] its bond length in **1** [1.358(2) Å] is somewhat shorter than typical N(sp^2)–O bonds (1.397 Å).[18]

The EPR parameters are summarized in Table 1. All the EPR spectra of **1** were a simple 1 : 1 : 1 triplet signal (a_N = 0.997–1.01 mT, g = 2.0041–2.0042) with a large peak-to-peak linewidth (ΔH_{pp}) of 0.31–0.33 mT, and no hyperfine couplings due to protons were observed. The large ΔH_{pp} is attributed to the presence of many unresolved protons with very small

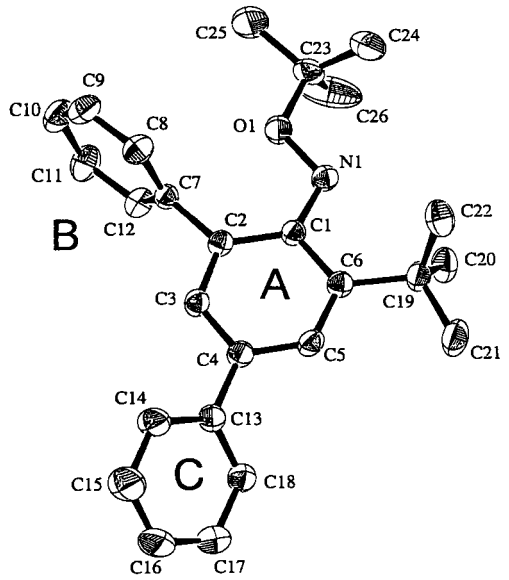


Fig. 1 ORTEP drawing of **1a**. Selected bond lengths and angles and torsion angles are as follows: C1–N1 1.368(3) and N1–O1 1.358(2) Å; C1–N1–O1 111.1(2) and N1–O1–C(23) 113.1(2)°; C2–C1–N1–O1 6.8(3), C6–C1–N1–O1 −175.4(2) and C1–N1–O1–C23 −173.9(2)°.

Table 1 EPR and UV-Vis spectroscopic data for **1**, **3** and **4** in benzene at 20 °C

Radical	a_N/mT	g	λmax/nm (ε/l mol^{-1}cm^{-1})
1a	1.01	2 .0042	545 (1230), 334 (28 600)
1b	0.997	2.0041	545 (1270), 334 (27 200)
1c	0.999	2.0042	553 (1120), 342 (29 900)
1a-d_{10}[ab]	1.00	2.0042	—

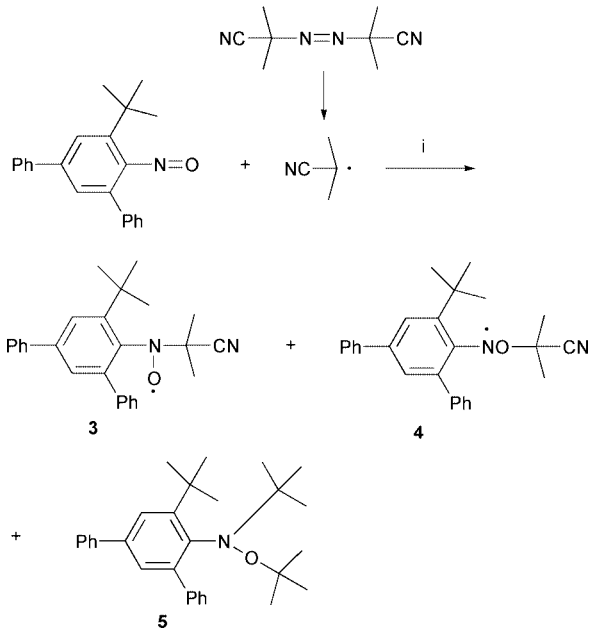

Scheme 1

hyperfine coupling constants. To reduce the ΔH_{pp} values, the two benzene rings of **1a** were deuterated. The deuterated radical **1a**-d_{10} was prepared from (2,4-diphenyl-d_5)-6-*tert*-butylaniline and *tert*-butyl peroxybenzoate in the same manner as for that of **1a**. As shown in Fig. 2, the EPR spectrum of **1a**-d_{10} is split into 1 : 2 : 1 triplets of a 1 : 1 : 1 triplet, and computer simulation gave a_N = 1.00 mT and a_H (2H) = 0.170 mT. The protons giving a_H of 0.170 mT are assigned to the anilino *meta* protons.

To compare the a_N and g values of **1** with those for the corresponding aminoxyls **3** was generated by addition of the 2-cyanoprop-2-yl radical to 2,4-diphenyl-6-*tert*-butylnitrosobenzene (Scheme 1). After a mixture of 2,4-diphenyl-6-*tert*-butylnitrosobenzene and 1,1′-azobis(propane-2-carbonitrile) in benzene was heated at 80 °C for 1 h, EPR spectra of the solution were measured at 20 °C. The spectra showed the presence of **3** and **4** in a ratio of *ca.* 3 : 1. While the a_N and g values for **3** are 1.27 mT and 2.0062, those for **4** are 0.989 mT and 2.0038, indicating that a_N of **3** are much larger than those for **1** or **4**, as well as the g value. Although **4** could be isolated as a red oil with a spin concentration of 89% in 3.9% yield by column chromatography, **3** could not be isolated in pure form. Since **5** is the main product and its mobility (R_f) in column chromatography was almost the same as that of **3**, **3** was separated as a mixture with **5**.

The UV-Vis spectra were measured using benzene as the solvent. The data are listed in Table 1. A λmax at 545–553 nm with ε of 1120–1270 l mol^{-1}cm^{-1} is observed, which is attributable to the characteristic red colours of **1**.

First published as an Advance Article on the web 14th March 2001

We present a convenient and safe one-pot route to capped 3 nm CdSe nanoparticles making use of common starting materials and inexpensive, low-boiling solvents under solvothermal conditions; H_2Se required for the reaction is generated *in situ* through the aromatization of tetralin by Se.

In semiconductor nanocrystals of materials such as CdSe, the happy union of bulk and molecular properties results in a rich photophysics that is not only interesting in its own right, but also lends itself to a number of applications.[1] One such application is the use of CdSe nanocrystals as fluorescent probes in biological imaging.[2] The key to all semiconductor nanoparticle research is the ability to prepare stable (typically through surface passivation – also referred to as capping) monodisperse particles that have very few defects. A number of techniques have been used to achieve this and have recently been reviewed in this journal.[3] Perhaps most widely used is the method introduced by Bawendi and coworkers[4] which involves the reaction of an organocadmium precursor with an Se source in a high temperature solvent such as trioctyl phosphine oxide (TOPO), which also doubles as a capping agent.

We have been interested in the preparation of chalcogenide nanoparticles from inexpensive starting materials of low toxicity. Cadmium stearate is easy to prepare† and dissolves in organic solvents such as toluene, in which it is known to react with H_2Se to yield chalcogenides. Since relatively high temperatures are required to prepare defect-free, monodisperse nanoparticles, we have carried out the synthesis in toluene using stainless steel bombs. H_2Se is not easily handled under these conditions, so we have employed the aromatization of tetralin to naphthalene by elemental Se in order to prepare H_2Se *in situ*. The addition of small amounts of dodecanethiol as a capping agent results in 3 nm nanoparticles with a narrow size distribution. The dark solution obtained from the reaction precipitates solid products when the solvent polarity is increased through the addition of propan-2-ol. The precipitated solid easily redissolves in toluene forming bright orange solutions.

Our procedure is inspired by the simple method of Mitchell and Morgan[5] who prepared $CuCr_2Se_4$ in mineral oil at 330 °C using stearate salts as the metal source and the aromatization of sitosterol as the H_2Se source. Qian and coworkers[6] have recently reported the preparation of 7 nm CdSe nanoparticles under solvothermal conditions using ethylenediamine at 120 °C.

Fig. 1 displays a TEM image of the nanoparticles. While a few large particles (*ca.* 10 nm) are occasionally seen, the vast majority of the particles are smaller; with a mean diameter of 3.0 nm and a standard deviation of 0.16 nm (*ca*. 5% of the mean). The powder XRD profile of the nanoparticles acquired in transmission mode is displayed in Fig. 2(a). We find that the profile is well fitted by the Rietveld[7] method to the cubic (a = 6.01(1) Å) zinc blende structure rather than the usual hexagonal wurtzite structure. Stacking 3 nm × 3 nm slabs of CdSe along the c axis in hexagonal and cubic (in different proportions) arrangements permits simulations using the DIFFaX[8] program, which confirms a cubic zinc blende structure relatively free from hexagonal defects. The Rietveld fit and cubic and hexagonal DIFFaX simulations (using a correlation length of about 3 nm in the c direction) are also displayed in Fig. 2(a).

The UV–VIS absorption spectrum in toluene [Fig. 2(b)] shows absorption peaks at 514 and 412 nm, consistent with quantum confinement. Bawendi, Steigerwald and Brus[9] have discussed the correlation of absorption spectra and particle diameter for various nanoparticles. According to their correlation, the particle size corresponding to the spectrum in Fig. 2(b) is close to about 2.5 nm and not 3.0 nm as obtained here from TEM. The discrepancy could arise from (i) the different crystal structure obtained in the present case and (ii) the difficulty in estimating sizes from the very small, low-contrast particles seen in the TEM image. Toluene solutions of the nanoparticles also show strong photoluminescence as seen from the emission spectrum displayed in Fig. 2(b) as a dashed line.

The presence of the thiol capping was verified from C–H stretches in the FTIR spectrum, as well as by thermogravimetry in air. We observe a weight loss of 35% before 400 °C which, if ascribed to the thiol cap, suggests that for 3 nm particles there is one thiol molecule for every 22 Å^2 of nanoparticle surface.

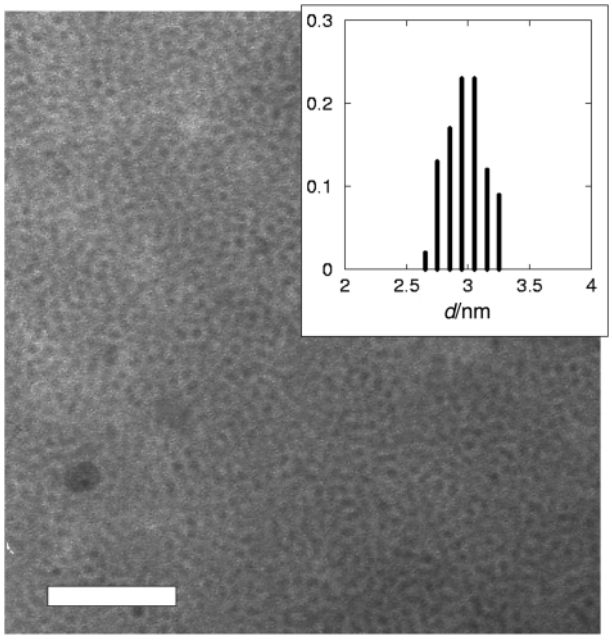

Fig. 1 TEM image of a relatively dense arrangement of CdSe nanoparticles showing a tendency to close packing in the plane (bar = 50 nm). The inset shows a histogram of particle sizes.

DOI: 10.1039/b009394g

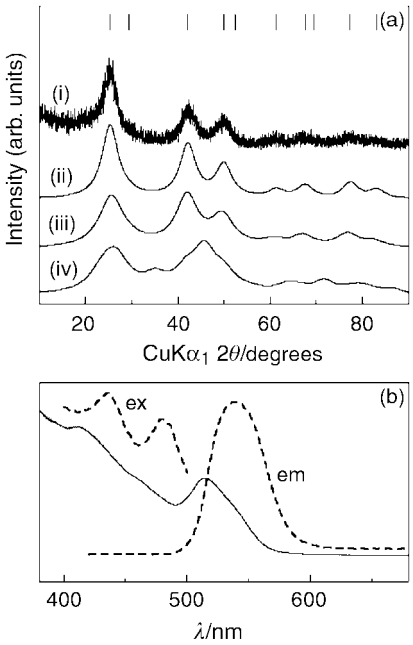

Fig. 2 (a) (i) Powder XRD pattern of CdSe compared with (ii) the background-subtracted Rietveld fit (R_{Bragg} = 6.4%), (iii) DIFFaX simulation of 3 nm cubic zinc blende stacking of CdSe, and (iv) DIFFaX simulation of a 3 nm hexagonal wurtzite stacking of CdSe. The vertical lines at the top are expected peak positions for the cubic zinc blende structure. (b) UV–VIS absorption spectrum of the nanoparticles in toluene. Dashed lines display luminescence spectra: emission (em) following excitation at 400 nm, and excitation (ex) following emission at 540 nm.

Energy dispersive X-ray analysis (EDAX) suggested that the Cd : Se ratio is nearly 1 : 1 (within 4%). When S is included in the analysis, the atomic ratios of S : Cd : Se are close to 20 : 40 : 40 (within a 5% error). Using a model of 3 nm particles with a thiol every 22 Å² of surface, we obtain a calculated S : Cd : Se of 120 : 260 : 260 (atoms) in reasonable agreement with the EDAX.

In conclusion, we present a new and convenient route to prepare large quantities of capped CdSe nanoparticles. The route can easily be extended to other nanoparticle chalcogenides of interest. The major advantages of the present route are that (i) there is no need to handle materials under inert conditions, (ii) inexpensive solvents can be used, and (iii) volatile, toxic organometallics can be avoided. Our method yields cubic (rather than hexagonal) CdSe nanoparticles, perhaps as a result of the autogenous pressure that develops during the preparative procedure.

This work has been supported by the Department of Science and Technology, India.

Notes and references

† Cadmium stearate [$Cd(St)_2$], prepared from the reaction of $Cd(OH)_2$ with molten stearic acid, could be reprecipitated from toluene and analyzed by FTIR and gravimetry. In a typical reaction 1.36 g (2 mmol) of [$Cd(St)_2$], 0.158 g (2 mmol) of Se, 0.2 g (1.5 mmol) of tetralin and 0.1 g (0.5 mmol) of dodecanethiol were taken in 50 ml of toluene in a stainless steel bomb (*ca.* 70% filling, Teflon gasket) and placed in an oven that had been preheated to 250 °C. After 5 h the bomb was removed and cooled to room temperature. The solid product obtained by precipitation as mentioned in the text was dried at 50 °C in air overnight. XRD patterns were acquired on a STOE STADI-P diffractometer in transmission geometry using a 0.02° step scan. Samples were prepared for TEM by placing a drop of the toluene solution of CdSe nanoparticles on a carbon-coated, Formvar-covered Cu TEM grid and subsequently drawing off excess solution. The grids were examined using a JEOL 2000EX TEM operating at 120 kV. The EDAX analysis used a Link ISIS system attached to a JEOL JSM 5600LV scanning electron microscope. UV–VIS spectra were recorded on a Hitachi U3000 spectrophotometer and photoluminescence on a Perkin Elmer L50 B spectrometer.

Received (in Irvine, CA, USA) 8th November 2000, Accepted 15th February 2001
First published as an Advance Article on the web 14th March 2001

Reaction of dioxygen with a dinuclear copper(I) complex of a new binucleating ligand is described, wherein a peroxo–dicopper(II) (Cu_2–O_2) intermediate leads to an oxo-transfer reaction to give an *N*-oxide of an *N*-benzyl internal ligand substrate; additionally observed regioselective oxidative *N*-dealkylation chemistry occurs.

Copper(I)–dioxygen reactivity studies,[1–6] particularly those involving actual substrate oxidations, are of interest as models for metalloproteins which effect oxidative transformations,[4,5,7,8] and may serve in the development of oxidation reagents. One type of chemistry which we have extensively examined involves O_2-binding and reactivity in the dinuclear complexes where two copper(I) ions each coordinate to a bis[(2-(2-pyridyl)ethyl]amine (PY2) tridentate moiety which is linked through the alkylamino nitrogens by a $–(CH_2)_n–$ (n = 3–5) (**N*n***),[9,10] or *m*-xylyl group (**XYL**);[5,11] in the former case reversible O_2-binding occurs, while in the latter situation, the Cu_2–O_2 intermediate effects xylyl aromatic hydroxylation chemistry. In our continuing effort to investigate the behavior of Cu_2–O_2 species and their reactivities toward internal substrates, we report here the use of a new ligand analogue **D**, with similarities to **N*n*** and **XYL** ligands, but possessing an *N*-benzyl internal moiety. We describe the nature of the O_2-binding to form Cu_2–O_2 species in the dicopper(I) complex of **D**, and novel oxo-transfer and oxidative *N*-dealkylation chemistry. Such reactions occur in copper proteins (*e.g.* peptidylglycine monooxygenase, PHM)[8,12] and heme cytochrome P-450 monooxygenases.[13]

The copper(I) complex $[Cu^I_2(\mathbf{D})]^{2+}$ (**1**) was synthesized by reaction of 2 equiv. of $[Cu^I(MeCN)_4]^+$ with **D**.† An X-ray structure of **1** was obtained (Fig. 1).‡ While both copper(I) ions possess distorted tetrahedral tetracoordination, the binding is highly unsymmetrical; Cu1 ligates to its PY2 tridentate plus the central benzylamine nitrogen atom N7. The other Cu atom (Cu2) has instead as its fourth ligand a perchlorate oxygen atom O5. We have previously observed related asymmetry utilizing trinucleating ligands, either for tricopper(I)[14] or tricopper(II)[15] complexes, wherein three copper ions bind a tridentate chelate, but only one coordinates to a similarly 'central' amine nitrogen. The copper ion moieties are well separated in **1**, with Cu1···Cu2 = 5.43 Å.

At −80 °C in dichloromethane, the dicopper(I) complex $[Cu^I_2(\mathbf{D})]^{2+}$ **1** reacts with excess dioxygen to give a Cu_2O_2 species $[Cu^{II}_2(\mathbf{D})(O_2)]^{2+}$ **2** which gradually decomposes (*vide infra*). Stopped-flow kinetic results show that the reversible (k_1/k_{-1}) formation of species **2** is first order in both **1** and O_2 with k_1 = (10 ± 0.3) $M^{-1}s^{-1}$ (183 K) [$\Delta H^{\ddagger}$ = (15.8 ± 0.8) kJ mol^{-1}, $\Delta S^{\ddagger}$ = (−135 ± 4) J K^{-1} mol^{-1} (183–206 K)}. The UV–VIS spectrum of **2** [λ_{max} = 360 (ε 12 500), 514 nm (ε 1220 dm^3 mol^{-1} cm^{-1})] shows features which are very similar to the Cu_2–O_2 peroxo–dicopper(II) complexes established with **XYL**[6,16] and **N*n***[9] ligands, $[Cu_2(\mathbf{XYL})(O_2)]^{2+}$ and $[Cu_2(\mathbf{N}n)(O_2)]^{2+}$, respectively, indicating that **2** also possesses a μ-η²:η² side-on peroxodicopper(II) core.

As mentioned, an *N*-benzyl moiety was designed into **D** as a potential oxidizable site. Indeed, analysis of products obtained when O_2 is reacted with $[Cu^I_2(\mathbf{D})]^{2+}$ **1** at 0 °C reveals that the *N*-oxide **D**–**O** is obtained (Scheme 1); a labeling experiment shows that the O atom is derived from dioxygen, suggesting an oxygen atom transfer reaction has occurred.§ However, $[Cu^{II}_2(\mathbf{D})(O_2)]^{2+}$ (**2**) is not directly responsible for the formation of **D**–**O**, since if it is allowed to stand at −80 °C, whereupon decomposition occurs, no **D**–**O** forms [kinetics of decomposition: k_2 = (4.5 ± 0.9) × 10^{-4} s^{-1} at 183 K; $\Delta H^{\ddagger}$ = (44 ± 2)

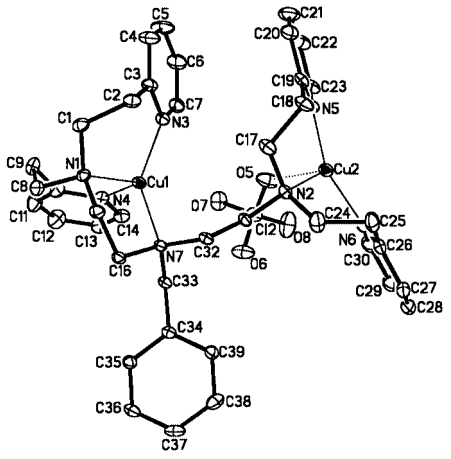

Fig. 1 ORTEP diagram of the cationic portion of complex **1**. Selected bond lengths (Å): Cu1···Cu2 5.432, Cu1–N1 2135(3), Cu1–N3 1.979(3), Cu1–N4 2.024(3), Cu1–N7 2.106(3), Cu2–N2 2.252(3), Cu2–N5 1.927(3), Cu2–N6 1.925(3), Cu2–N6 1.925(3), Cu2–O5 2.551(3).

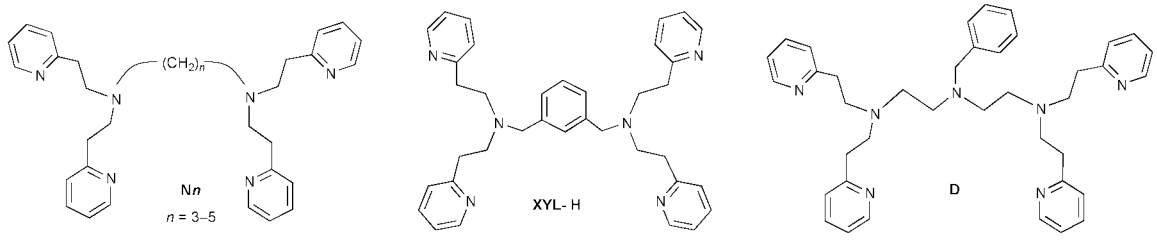

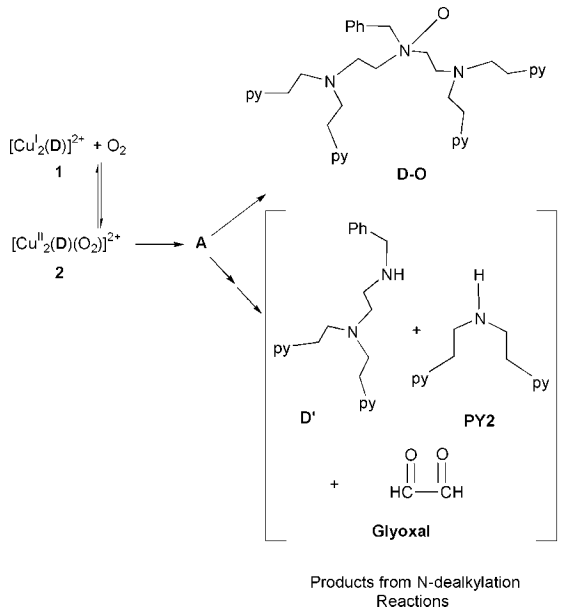

Scheme 1

kJ mol^{-1}, $\Delta S^{\ddagger}$ = (62 ± 8) J K^{-1} mol^{-1} (198–293 K)]. We suggest that the oxo-transfer reaction, having a relatively large activation energy (*i.e.* higher temperatures are required to see **D**–**O** product), is effected by a very reactive intermediate (**A**; Scheme 1) derived from **2**, which is formed in steady state. Direct formation of the different oxidation products, *i.e.* without formation of intermediate **A**, can be ruled out by the observation that the overall rate constant k_1k_2/k_{-1} shows a perfectly linear Eyring plot between 198 and 293 K. Differentiation between the various oxidation products thus must occur after the rate determining step k_2.

When the oxygenation of [Cu$^{I}_2$(**D**)]$^{2+}$ **1** is carried out at room-temperature and for longer reaction times (> 12 h), additional products derived from oxidative *N*-dealkylation chemistry are produced. **D′** is the amine byproduct from the hydroxylation of one of the non-benzylic methylene carbons adjacent to the middle nitrogen. The other fragment expected from this *N*-dealkylation, an aldehyde, is not isolable; it is further oxidized to yield glyoxal and **PY2** (Scheme 1). Overall, **D′**, glyoxal and **PY2** form in excellent yield and material balance.¶ The fact that this chemistry requires reaction times much longer than the lifetime of the peroxo species [Cu$^{II}_2$(**D**)(O$_2$)]$^{2+}$ **2** ($t_{1/2}$ = 0.01 s at 298 K) indicates that as for the **D**–**O** formation, **2** is not responsible for the oxidative *N*-dealkylation; in another case, a Cu$_2$-O$_2$ intermediate *is* known to effect such reactivity.[17] Here, other complexes derived from the decomposition of **2**, perhaps Cu^{II}–OH–Cu^{II} or Cu^{II}–O–Cu^{II} species, may be responsible. We note that anaerobic addition of 2 [Cu(H$_2$O)$_6$](ClO$_4$)$_2$ and base to **D**, followed by heating, does lead to similar oxidative *N*-dealkylation chemistry. The oxidative *N*-dealkylation chemistry here appears to be regioselective, as benzaldehyde (which would form by oxidation at the most easily oxidizable methylene group) is formed in trace amounts only.

In conclusion, a new dicopper(I) compound, **1**, has been synthesized with a built-in substrate and dissimilar copper(I) environments. [Cu$^{I}_2$(**D**)]$^{2+}$ **1** reacts with dioxygen yielding a peroxo species [Cu$^{II}_2$(**D**)(O$_2$)]$^{2+}$ **2** which decomposes leading to two different ligand transformation reactions: (1) a reactive species, which derives from **2**, is competent to effect an oxo-transfer reaction to give the *N*-oxide **D**–**O**. This appears to be a rare known copper–dioxygen mediated amine to *N*-oxide transformation. (2) With higher temperatures and over longer time periods, the Cu$_2$–O$_2$ species transforms to copper(II) products which effect biomimetic regioselective oxidative *N*-dealkylation chemistry. Additional studies will be directed towards further structural and mechanistic understanding of the chemistry described.

We are grateful to the National Institutes of Health (K. D. K., GM28962) and the Swiss National Science Foundation (A. D. Z.) for support of this research.

Notes and references

† Reaction of **D** with 2 equiv. of [Cu(MeCN)$_4$](ClO$_4$) gave **1**(ClO$_4$)$_2$, for which satisfactory C, H and N analyses were obtained.

‡ *Crystal data* for $C_{39}H_{47}Cl_2Cu_2N_7O_8\cdot 3CH_2Cl_2$. M = 1194.59, triclinic, $P\bar{1}$, a = 10.5816(2), b = 14.8247(2), c = 18.0045(2) Å, α = 112.4800(3), β = 97.2565(2), γ = 94.2666(2)°, V = 2565.53(6) Å^3, Z = 2, T = 173 K, $R(F)$ = 0.0469, $R(wF^2)$ = 0.1084. After accounting for the diCu cation and two ClO$_4^-$, a large void space of 644.8 Å^3 containing numerous, but chemically ill defined, difference peaks was resolved using SQUEEZE (A. Spek, PLATON library), which determined the presence of a total of 241 electrons, or *ca.* six molecules of the recrystallization solvent CH_2Cl_2 per unit cell. Due the collective nature of this treatment of solvent, the atom list does not contain individual atomic contributions. All other software was contained in the SHELXTL (5.1) library (G. Sheldrick, Bruker AXS, Madison, WI). CCDC 150146. See http://www.rsc.org/suppdata/cc/b0/b009053k/ for crystallographic data in .cif or other electronic format.

§ When the oxygenation reaction of **1** was carried out at 0 °C in CH_2Cl_2 for 10 min, **D**–**O** was isolated after workup in 47% yield. With an $^{18}O_2$ reaction, an ^{18}O atom is incorporated into **D**–^{18}**O** with 92% efficiency. *Characterization* of **D**–**O**: ^{1}H NMR ($CDCl_3$) δ 2.92 (m, 20H), 3.08 (m, 4H), 4.17 (s, 2H), 7.11–7.14 (m, 8H), 7.40–7.60 (m, 9H), 8.45 (d, 4H); positive ion FAB-MS: **D**–**O** *m/z*: 630.4 (MH$^+$), **D**–^{18}**O** *m/z*: 632.4 (MH$^+$).

Influence of pore wall thickness on the steam stability of Al-grafted MCM-41

Robert Mokaya

School of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: r.mokaya@nottingham.ac.uk

Received (in Cambridge, UK) 29th January 2001, Accepted 27th February 2001
First published as an Advance Article on the web 14th March 2001

Mesoporous aluminosilicate MCM-41 with improved steam stability may be prepared by grafting Al onto pure silica MCM-41 materials that possess thick pore walls.

Mesostructured aluminosilicates are currently attracting considerable research interest due to their potential use as heterogeneous catalyst.[1,2] Their main attraction is a well ordered mesostructure with uniform pores whose size is much larger than that of channels present in traditional microporous zeolites. They are therefore able to catalyse chemical transformations involving molecules too large to fit the pore channels of zeolites. The use of mesoporous aluminosilicates such as Al-MCM-41, in for example the cracking of heavy fractions in petroleum refining, is however hampered by their inadequate hydrothermal stability, which is lower than that of zeolites.[1,3] There have been several recent studies aimed at improving the hydrothermal stability of mesoporous aluminosilicates in boiling water and/or under steaming conditions.[4–7] It has been shown that Al-MCM-41 materials prepared *via* grafting routes are extremely stable in boiling water.[4–6] Directly prepared Al-MCM-41 has also been shown to exhibit considerable hydrothermal stability especially at relatively low Al contents.[8,9] More recently Liu *et al*. have shown that steam stable mesostructured aluminosilicates may be prepared using zeolite type seeds.[7] It has recently been suggested that a possible route to steam stable Al-MCM-41 is *via* the preparation of materials with thick pore walls.[1,3] However an attempt to prepare such steam stable (thick walled) Al-MCM-41 *via* direct (mixed-gel) synthesis was unsuccessful.[1,3] The direct mixed gel synthesis of Al-MCM-41 is known to be unpredictable and therefore it is to be expected that any attempt to carefully control the pore wall thickness will present considerable challenges. The pore wall thickness of pure silica MCM-41 can, on the other hand, be readily controlled by careful choice of synthesis conditions.[10,11] Here we report on the influence of pore wall thickness on the steam stability of Al-grafted MCM-41 and show that the stability of these materials can be remarkably improved by using thick-walled pure silica MCM-41 as 'starting material'. The improvement in structural steam stability is accompanied by a higher retention of acidity which is important for the use of these materials as solid acid catalysts. Mesostructured aluminosilicates prepared *via* grafting routes offer distinct advantages over directly synthesised materials with respect to accessibility to active (Al) sites and structural ordering;[12] their stabilisation is therefore desirable. Furthermore their preparation is not restricted by 'template synthesis' which can be expensive, irreproducible and in some cases inimical to the incorporation of Al. The starting point for Al-grafted materials is the purely siliceous mesoporous silica, which may take any form (hexagonal, cubic, lamellar) and can be prepared *via* a range of inexpensive synthesis routes employing cationic, neutral, non-ionic or even non-surfactant templates and cheap sources of silica.[13]

In order to vary the pore wall thickness of the starting pure silica MCM-41 materials, three different crystallisation regimes were used. This was achieved by varying the crystallisation temperature and duration. In brief the three purely siliceous MCM-41 materials were prepared by dissolving tetramethylammonium hydroxide (TMAOH) and cetyltrimethyammonium bromide (CTAB) in distilled water by stirring at 35 °C. The silica source, fumed silica (sigma), was then added to the solution under stirring for 1 h. After further stirring for 1 h the resulting synthesis gel of composition SiO_2:0.25 CTAB:0.2 TMAOH:40 H_2O was left to age for 20 h at room temperature following which the gel was transferred to a Teflon-lined autoclave and heated as follows; at 150 °C for 48 h (standard Si-MCM-41, designated sample A),[9] 140 °C for 96 h (sample B) and 145 °C for 96 h (sample C). In each case the solid product was obtained by filtration, washed with distilled water, dried at room temperature and calcined in air at 550 °C for 8 h. Al-grafted MCM-41 materials were prepared at a target bulk Si/Al ratio of 13 as previously described using aluminium chlorhydrol as the grafting reagent.[14] In all cases the final bulk Si/Al ratio was very close to the expected value and the proportion of tetrahedrally coordinated Al was similar. The Al-grafted samples were designated Al-MCM41-A, Al-MCM41-B and Al-MCM41-C where A, B and C represent the pure silica MCM-41 material from which they were derived. Hydrothermal stability was tested by heat treatment at 800 or 900 °C for 4 h in a flow of nitrogen saturated with water vapour at room temperature.

The textural parameters of the Al-grafted materials before and after hydrothermal treatment are given in Table 1. The basal spacing increases from sample Al-MCM41-A to Al-MCM41-C; this is consistent with previous results, which show that crystallisation at higher temperature and/or longer time favours larger basal spacing.[10,11] The surface area decreases from sample Al-MCM41-A to Al-MCM41-C while the pore volume remains constant. This is accompanied by an increase in pore size and pore wall thickness as shown in Table 2. The data in Table 2 is calculated using two methods, so as to clearly demonstrate the variation in pore wall thickness. Powder XRD and N_2 sorption isotherms obtained for the Al-grafted materials before hydrothermal treatment are given in Figs. 1 and 2 respectively. In all three cases well ordered aluminosilicate materials were obtained as indicated by the XRD patterns. All the samples also exhibit a N_2 sorption isotherm with a well developed step in the relative pressure (P/P_o) range 0.2–0.5 characteristic of capillary condensation into uniform mesopores.

Figs. 1 and 2 show the powder XRD patterns and N_2 sorption isotherms of the Al-grafted materials after hydrothermal treatment at 800 and 900 °C for 4 h. All the samples are

Table 1 Textural properties and acidity of the studied materials

Sample	d_{100}/Å	Surface area/ $m^2\ g^{-1}$	Pore volume/ $cm^3\ g^{-1}$	Acidity/ mmol $H^+\ g^{-1}$
Al-MCM41-A	42.2	907	0.78	0.83
steamed 800 °C	39.4	785	0.58	0.41
steamed 900 °C	35.0	224	0.19	0.16

Table 2 Comparison of pore diameter and corresponding pore wall thickness for Al-grafted materials

	Pore diameter/Å			Wall thickness/Å	
Sample model	a_o	$4V/S$	Geometric model[a]	$4V/S$	Geometric model[a]
Al-MCM41-A	48.7	34.4	38.1	14.3	10.6
Al-MCM41-B	58.5	40.6	45.6	17.9	12.9
Al-MCM41-C	64.2	42.5	50.2	21.7	14.0

[a] Pore diameter (PD) was calculated based on a geometric model according to the equation:[16] PD = $cd(\rho V_p/1 + \rho V_p)^{1/2}$, where c = 1.213, ρ (density of silica walls) = 1.6 g cm^{-3},[17] and d is basal spacing (d_{100}) and V_p is mesopore volume; a_o = the lattice parameter from the d_{100} spacing using the formula $a_o = 2d_{100}/\sqrt{3}$; wall thickness = a_o − PD.

relatively stable at 800 °C. The decrease in pore volume after treatment at 800 °C is 26% for sample Al-MCM41-A and 16% for sample Al-MCM41-B. In contrast the mesopore volume of sample Al-MCM41-C remains virtually unchanged while its total pore volume increases due to the presence of textural mesoporosity. The surface area follows the same trend. These observations imply that hydrothermal stability at 800 °C is, to some extent, influenced by the pore wall thickness. The influence of pore wall thickness is more clearly illustrated after the more severe hydrothermal treatment at 900 °C. From Fig. 1 and 2 it is clear that sample Al-MCM41-A, which has the thinnest pore walls, is severely degraded after treatment at 900 °C. The N_2 sorption isotherm of the resulting material exhibits virtually no mesoporous character. The surface area and pore volume decrease by 75%. Sample Al-MCM41-B shows better retention of structural ordering after treatment at 900 °C compared to sample Al-MCM41-A; its surface area and pore volume are reduced by *ca.* 65% although it still exhibits a N_2 sorption isotherm with some mesoporous character. When subjected to similar treatment, sample Al-MCM41-C shows considerable retention of structural ordering; the XRD pattern of Al-MCM41-C steamed at 900 °C is comparable to that of the parent material and its N_2 sorption isotherm still exhibits a relatively sharp mesopore filling step. The surface area and pore volume are reduced by only 32 and 38% respectively. It appears therefore that the steam stability of the Al-grafted MCM-41 materials increases with increasing pore wall thickness. It is worth pointing out that the steam stability of the pure silica 'starting' samples was very poor (in any case lower than that of the Al-grafted materials) and increased only marginally with increasing pore wall thickness. The surface area of pure silica samples A, B and C, after steam treatment at 900 °C for 4 h, was 69, 105 and 150 m^2 g^{-1} while the pore volume was 0.12, 0.15 and 0.21 cm^3 g^{-1}, respectively. The improved stability exhibited by the Al-grafted samples with thicker pore walls is therefore due to a combination of the strengthened framework and the presence of Al in the framework.[15] On stability of the core silica framework, we further note that the extent of silica condensation in the as-synthesised pure silica samples increased with pore wall thickness.[10] Consequently on calcination, the more polymerised (thicker walled) samples undergo less 'forced' condensation thus resulting in fewer strained siloxane bonds within the core silica framework. The greater stability of the thicker walled Al-grafted samples is accompanied by better retention of acidity as indicated by the data (determined using thermally programmed desorption of cyclohexylamine as previously described[4]) in Table 1. In brief samples saturated with cyclohexylamine (CHA) were pre-treated at 80 °C for 2 h and cooled under nitrogen prior to thermogravimetric analysis.[4] The weight loss between 300 and 450 °C was used to compute the acid content in mmol CHA g^{-1} assuming that each base molecule interacts with one acid site. Better retention of acidity may be an indication of lower levels of dealumination in the thicker walled Al-grafted samples. The findings reported here open new opportunities for the preparation of steam stable Al-MCM41 given that there are other methods that can be used to stabilise the pure silica starting material prior to Al grafting.

I am grateful to the EPSRC for an Advanced Fellowship.

Received (in Liverpool, UK) 15th December 2000, Accepted 5th March 2001
First published as an Advance Article on the web 16th March 2001

Monooxygenated terpenes are fine fragrance and flavouring chemicals, and active site mutants of the haem monooxygenase cytochrome P450$_{cam}$ which were designed to have improved complementarity between the substrate binding pocket and the monoterpenes (+)-α-pinene (1) and *S*-limonene (2) have been shown to have greatly enhanced activity for the oxidation of these two substrates, and the major products, verbenol and isopiperitenol from (1) and (2) respectively, were formed with high regioselectivity and near-total stereoselectivity.

Terpenes have the general formula $(C_5H_8)_n$ and are biosynthesized from isoprene units.[1] Terpenoid compounds, which mainly comprise the parent terpenes and their oxidation products such as the epoxides, alcohols, aldehydes and ketones, constitute one of largest class of organic compounds in biological systems. Many mono- and sesqui-terpenoid compounds are sought-after fragrances and flavourings due to their distinctive and pleasant odours.[2,3] For example isopiperitenol and carveol, which are intermediates in the biosynthesis of terpenoid compounds that give the characteristic flavours of different species of mint, are formed by the oxidation of (*S*)-limonene by highly specific cytochrome P450 enzymes in the plants.[4,5] As a result of their desirable properties, monooxygenated terpenoids are amongst some of the highest added value fine chemicals. Therefore the one step synthesis of these compounds by direct oxidation of the readily available parent terpenes could have important applications in synthesis. We report here the engineering of the haem monooxygenase cytochrome P450$_{cam}$ for the oxidation of the monoterpenes (+)-α-pinene (**1**) and (*S*)-limonene (**2**).

Cytochrome P450$_{cam}$ catalyses the oxidation of the bicyclic compound D-(+)-camphor to 5-*exo*-hydroxycamphor, the first step in the camphor metabolism pathway of the soil bacterium *Pseudomonas putida*.[6,7] The mechanism, structure, and substrate binding of P450$_{cam}$ have been extensively studied.[8] Since the bicyclic compound (**1**) is structurally related to camphor (Fig.1), we made the reasonable assumption that the two molecules might be bound in similar orientations within the P450$_{cam}$ active site. From the crystal structure the camphor carbonyl group forms a hydrogen bond with Y96 and is in van der Waals contact with F87.[9] Since this carbonyl group is absent from (**1**), the Y96F mutation should improve the binding of (**1**) by removing the polar phenol side-chain,[10] while the larger side-chain of the F87W mutation should improve the enzyme–substrate fit. The C_{10} methyl group of camphor contacts V247. Since the allylic methyl group of (**1**) is in a different position in the molecule, the V247L mutation should also improve the enzyme–substrate complementarity. The mutants Y96F, F87W–Y96F, Y96F–V247L and Y96F–F87W–V247L of P450$_{cam}$ were therefore examined for the binding and oxidation

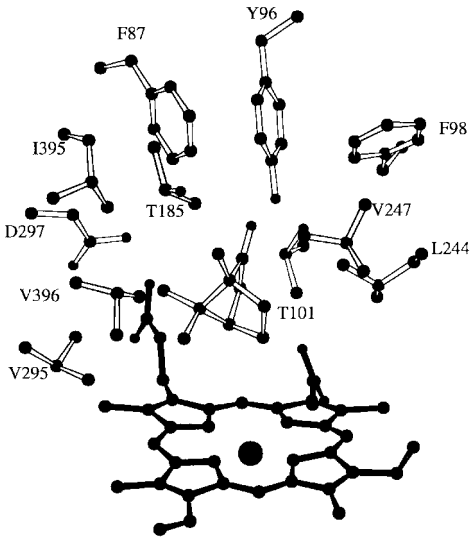

Fig. 1

Table 1 Binding and oxidation of (+)-α-pinene (**1**) and (*S*)-limonene (**2**) by wild-type (WT) cytochrome P450$_{cam}$ and active site mutants

	WT	Y96F	F87W–Y96F	Y96F–V247L	F87W–Y96F–V247L
(+)-α-Pinene (1)					
% High spin haem	85	95	95	95	75

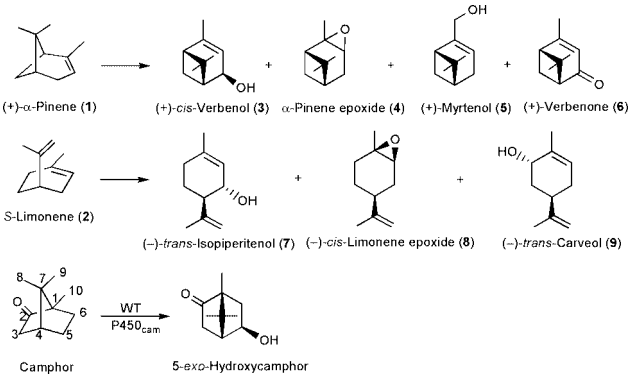

Scheme 1

of (**1**). The monocyclic compound (**2**) could also be bound in a similar orientation to camphor if it adopted the slightly higher energy conformation shown in Fig.1, and these mutants may also have higher activities for the oxidation of (**2**).

The substrate binding and catalytic parameters for the oxidation of (**1**) and (**2**) by wild-type $P450_{cam}$ and the mutants are given in Table 1. The monocyclic (**2**) was a very poor substrate for the wild-type compared to camphor (K_D = 0.25μM, rate = 400 min^{-1} under identical conditions, 100% coupling efficiency). However, the bicyclic (**1**) was bound much more tightly and oxidised at a faster rate with higher coupling than (**2**), in all likelihood reflecting the closer structure of (**1**) to camphor. As predicted the Y96F mutation strengthened the binding and also increased the rate and coupling for the oxidation of both substrates, particularly for (**2**). The addition of the F87W or V247L mutation further enhanced both the binding and oxidation activity for (**1**), suggesting improved enzyme–substrate fits in the F87W–Y96F and Y96F–V247L double mutants. Interestingly (**1**) was bound more tightly by the Y96F and these two double mutants than camphor was by the wild-type, and the fast substrate oxidation rate of 271min^{-1} and near total coupling efficiency of the Y96F–V247L double mutant almost matched the camphor oxidation activity of wild-type $P450_{cam}$. For (**2**) the addition of the F87W and V247L mutations slightly weakened substrate binding but substantially increased the rate and coupling, and so although (**2**) was less tightly bound it was located closer to the haem resulting in more efficient substrate oxidation. The F87W–Y96F–V247L triple mutant showed weaker monoterpene binding and lower activity compared to the double mutants, probably due to steric hindrance between (**1**) and (**2**) and the much smaller active site cavity in this mutant.

Since camphor is selectively oxidised at C_5 to give the *exo* alcohol, the major products from the proposed binding orientation of (**1**) should be (+)-*cis*-verbenol (**3**) and α-pinene epoxide (**4**) (Fig.1, Scheme1). GC co-elution experiments showed that (**3**) was indeed the major product (> 60%) for all the $P450_{cam}$ enzymes. The *cis* and *trans* isomers of (**4**) were minor products (total < 8%), and the enzymes showed little selectivity between the two. In addition (+)-myrtenol (**5**), which arose from oxidation of the allylic methyl group, and verbenone (**6**), the further oxidation product of (**3**), were also formed (Scheme 1). The most active mutant Y96F–V247L gave 70% (**3**) and 7% each of (**5**) and (**6**), while the less active triple mutant F87W–Y96F–V247L was the most selective, giving 85% (**3**).

The selectivity for the oxidation of (**2**) was more sensitive to the mutations. Chiral-phase GC analysis showed that the main products were (−)-*trans*-isopiperitenol (**7**), (−)-*cis*-limonene epoxide (**8**), and (−)-*trans*-carveol (**9**) (Scheme1). All the $P450_{cam}$ enzymes had very high diastereoselectivity (> 95% by GC) for the formation of all these products. Mutants containing the F87W mutation were more selective for (**7**) (82% for both the F87W–Y96F and F87W–Y96F–V247L mutants). The most active mutant Y96F–V247L gave 70% (**7**) but also the highest proportion (16%) of (**9**), while the less active wild-type and Y96F mutant gave the most epoxide (17 and 26% respectively). The predicted major product from the proposed binding orientation was (−)-*cis*-isopiperitenol, and some (*S*)-limonene epoxide was also expected. The observation of the *trans* isomer (**7**) and also some carveol product suggested that the more conformationally mobile (**2**) did not adopt the camphor binding orientation, and that there were multiple substrate binding modes. We note that the P450 enzyme from peppermint oxidises (**2**) with total selectivity to give the *trans*-isopiperitenol (**7**), while the spearmint enzyme gives only *trans*-carveol (**9**).[11,12]

In summary the results suggest that the strategy of designing mutations based on the structure of the monoterpenes and potential side-chain/substrate contacts to improve the enzyme–substrate fit was very successful in promoting monoterpene oxidation by $P450_{cam}$. In addition, with some further selectivity engineering, $P450_{cam}$ variants may have applications in the biotransformation of terpenes in fine chemical synthesis. Finally, since not all of the limonene and pinene oxidation products have been utilised by nature, the oxidation of these and indeed other terpenes by engineered P450 enzymes could give rise to novel fragrances and flavourings or new biologically active compounds.

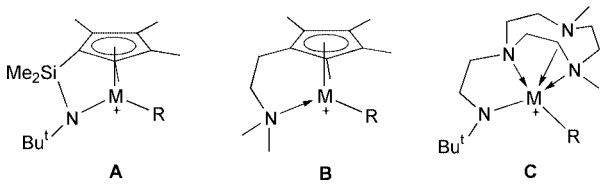
Received (in Cambridge, UK) 30th January 2001, Accepted 20th February 2001
First published as an Advance Article on the web 14th March 2001

Yttrium dialkyl complexes [*N*,*N*′-R_2-tacn-*N*″-$(CH_2)_2NBu^t$]-$Y(CH_2SiMe_3)_2$ (R = Me, Pr^i; tacn = 1,4,7-triazacyclononane) were prepared; when activated with $[PhNMe_2H][B(C_6F_5)_4]$ these complexes form cationic alkyl species that are active ethene polymerisation catalysts.

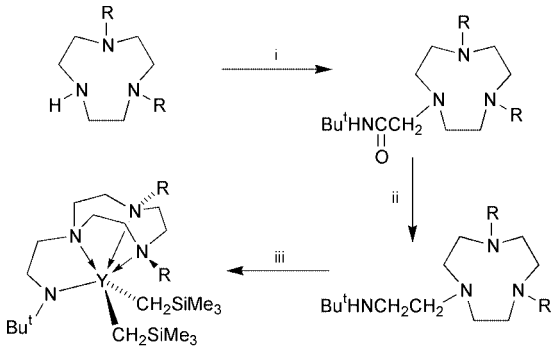
Cationic group 4 metal alkyl species with linked dianionic cyclopentadienyl-amide ancillary ligands, such as $[C_5Me_4SiMe_2NBu^t]M(alkyl)^+$ **A** (M = Ti, Zr), are highly efficient



catalysts for the polymerisation of alkenes.[1] The isoelectronic group 3 metal alkyl complexes with these ligands are neutral, and much less effective in alkene polymerisation.[2] One approach that might allow the generation of cationic group 3 metal alkyl species is to replace either one of the monoanionic moieties of the ancillary ligand (amide or cyclopentadienyl) by a neutral functionality. A recent patent showed that replacement of the amide group by an amine donor can lead to $[C_5Me_4CH_2CH_2NMe_2]M(alkyl)^+$ **B**, (M = Sc) species that are active in catalytic alkene polymerisation.[3] We have designed a ligand in which an amido functionality is attached to a substituted 1,4,7-triazacyclononane (tacn) group, and that allowed us to generate cationic tacn-amide group 3 metal alkyl complexes of type **C**. These species were found to be highly active in the catalytic polymerisation of ethene.

1,4,7-Triazacyclononane ligands have been successfully used as 6-electron *fac*-tridentate ligands on a wide range of transition metals, and various neutral and anionic tacn derivatives have appeared in the literature recently.[4] The new tacn-amine derivatives *N*,*N*′-R_2-tacn-*N*″-$(CH_2)_2NBu^tH$ (R = Pr^i, **1**; Me, **2**) were prepared in two steps from the known corresponding *N*,*N*′-dialkyl-1,4,7-triazacyclononanes[5] (Scheme 1). Reaction of these *N*,*N*′-dialkyltriazacyclononanes with *N*-*tert*-butylchloroacetamide in refluxing actonitrile, with a catalytic amount of NaI, yielded the corresponding *N*-*tert*-butyl-(4,7-dialkyl-1,4,7-triazacyclonon-1-yl)acetamides. These were then reduced with $LiAlH_4$ in refluxing diglyme and purified, after hydrolysis and acid–base extraction, by Kugelrohr distillation (**2**) or column chromatography (**1**).

Reaction of the amine **1** with the yttrium trialkyl $Y(CH_2SiMe_3)_3(thf)_2$[6] in C_6D_6 results in formation of $SiMe_4$, free thf, and the yttrium dialkyl complex [*N*,*N*′-Pr^i_2-tacn-*N*″-$(CH_2CH_2)NBu^t]Y(CH_2SiMe_3)_2$ **3**, (Scheme 1), as seen by NMR spectroscopy. The same reaction in pentane solvent (0.5 mmol scale), followed by crystallization, yielded analytically pure, white crystalline **3**. The isolated yield (28%) was rather modest, mainly due the high solubility of the product. An X-ray structure determination of **3**§ confirmed its identification as a monomeric, thf-free yttrium dialkyl (Fig. 1). As expected, the three nitrogens of the tacn moiety are bound in *fac* arrangement to the metal centre. There is considerable asymmetry in the structure of the complex, as seen *e.g.* in the angle N(1)–Y–C(19) 113.8(2)° *vs.* N(1)–Y–C(23) 95.9(2)°, and the groups are



Scheme 1 *Reagents and conditions*: i, *N*-*tert*-butylchloroacetamide, MeCN, cat. NaI, reflux, 1 h; ii, $LiAlH_4$, diglyme, reflux, 3 h (**2**) or 100 h (**1**), followed by hydrolysis and acid–base extraction; iii, $Y(CH_2SiMe_3)_3(thf)_2$, pentane, 14 h, 20 °C.

4	30	5.62	0.70	471	4.0
4	50	9.40	1.18	325	4.9
4	80	14.30	1.79	98	6.0
3[b]	30	11.95	0.96	—[c]	—[c]

[a] *Conditions:* toluene solvent (150 ml), 10 μmol Y dialkyl complex, 10 μmol activator, 5 bar ethene pressure, 10 min run time. [b] 15 min run time. [c] Not determined.

arranged in such a way as to prevent the eclipsing of the ligand Pr^i and Y–alkyl groups. The Y–N distances for the tacn nitrogens span a considerable range, the shortest being the distance to the bridgehead nitrogen Y–N(2), 2.541(5) Å, and the longest the Y–N(4) distance, 2.740(5) Å, N(4) being practically *trans* to C(23). This asymmetry appears to be retained in solution, as the ambient temperature ^{1}H and ^{13}C NMR spectra show resonances consistent with an asymmetric species (*e.g.* four resonances for the diastereotopic CH_2SiMe_3 methylene protons).[7] The alkyl methylene carbon resonances are found at δ 33.7 and 31.0, with rather large $^1J_{YC}$ coupling constants (*ca.* 38 Hz) and relatively small $^1J_{CH}$ coupling constants of 95 Hz.

Reaction of the amine **2** with $Y(CH_2SiMe_3)_3(thf)_2$ in pentane yielded the corresponding dialkyl complex [*N*,*N*′-Me$_2$-tacn-*N*″-(CH$_2$CH$_2$)NBu^t]Y(CH$_2$SiMe$_3$)$_2$ **4**, analytically pure in 86% isolated yield. The smaller size of the alkyl substituents makes the complex more fluxional, as the room temperature ^{1}H NMR spectrum of **4** shows broad resonances consistent with a species with an average C_s symmetry. Cooling a toluene-d_8 solution of **4** to −60 °C slows down this dynamic process, revealing spectra with four Y–alkyl methylene and two Y–C resonances, again consistent with an asymmetric ground state structure.[8]

The dialkyl complex **4** reacts cleanly with the Brønsted acid $[PhNMe_2H][B(C_6F_5)_4]$[9] in C_6D_5Br solvent to give $SiMe_4$, free $PhNMe_2$, and an ionic species formulated as {[*N*,*N*′-Me$_2$-tacn-*N*″-(CH$_2$CH$_2$)NBu^t]Y(CH$_2$SiMe$_3$)}[B(C$_6$F$_5$)$_4$] **6**.[10] The ^{1}H NMR spectrum shows a single resonance at δ −1.06 for the YCH_2 group (J_{YH} not resolved), and the ^{13}C NMR YCH_2 resonance at δ 37.0 (J_{YC} 40.7 Hz), shifted downfield and with a larger J_{YC} relative to the dialkyl **4**. The ionic species **6** is thermally relatively stable, and remains essentially unchanged over 1 h at ambient temperature in bromobenzene solution. In contrast, reaction of the dialkyl complex **3** with $[PhNMe_2H][B(C_6F_5)_4]$ leads to rapid formation of propene and 2 equiv. of $SiMe_4$ (as seen by ^{1}H NMR spectroscopy), and an ill-defined yttrium species. Apparently, an Pr^i substituent on the ancillary ligand is metallated on one of its methyl groups, followed by elimination of propene. When the reaction is performed in the presence of an excess of d_8-thf, the cationic alkyl species is trapped before ligand metallation occurs, giving a species formulated (based on its ^{1}H NMR characteristics) as {[*N*,*N*′-Pr$^i_2$-tacn-*N*″-(CH$_2$CH$_2$)NBu^t]Y(CH$_2$SiMe$_3$)(d_8-thf)}-[B(C$_6$F$_5$)$_4$] (**5**·d_8-thf), with YCH_2 resonances at δ −1.29 and −1.35 (dd, $^2J_{HH}$ 11.0 Hz, J_{YH} 3.0 Hz).[11]

Ethylene homopolymerisation experiments (toluene solvent) showed that the dialkyls **3** and **4**, in combination with the Brønsted acid activator $[PhNMe_2H][B(C_6F_5)_4]$, yield active ethene polymerisation catalysts, with observed productivities up to 1.79×10^3 kg(PE) mol(Y)$^{-1}$ h^{-1} bar^{-1}. Relatively short run times (10–15 min) were chosen to minimise inhomogeneity and mass transfer effects. Over the run period the catalysts show a modest (25–30%) decrease in ethene uptake rate. The results listed in Table 1 show that the productivity of the Me$_2$-tacn system is enhanced by increasing the reaction temperature, but that the polydispersity of the polyethene produced also increases substantially. One possible explanation for this is that the initial cationic alkyl catalyst is thermally transformed into another species that is also active in the polymerisation of ethene, thus leading to bimodal product distributions. The polymerisation behaviour of this type of catalyst and its dependence on various parameters (ligand substitution pattern, activator species, *etc.*) is subject of further study.

In conclusion, we have prepared new yttrium dialkyl species with monoanionic tetradentate triazacyclononane-amide ancillary ligands. Reactions of these dialkys with $[PhNMe_2H][B(C_6F_5)_4]$ generate the ionic species **5**·thf-d_8 and **6**, rare examples of spectroscopically characterised cationic group 3 metal alkyls.[12] These cationic alkyl species are active catalysts for the polymerisation of ethene.

This investigation was supported by ExxonMobil Chemical Company.

Competitive intramolecular nucleophilic aromatic substitution: a new route to coumarins

Concepción Alonso, Marilyn M. Olmstead, Michael H. Nantz and Mark J. Kurth*

Department of Chemistry, University of California, One Shields Avenue, Davis, CA 95616 USA. E-mail: mjkurth@ucdavis.edu

Received (in Corvallis, OR, USA) 10th November 2000, Accepted 17th January 2001
First published as an Advance Article on the web 14th March 2001

4-Hydroxy-3-(2′-pyridyl)coumarins (4) (R = 6-Cl, H, 6-NO_2, 8-NO_2) were prepared in moderate to good yields by the intramolecular nucleophilic aromatic substitution reaction of β-ketoesters (I) in refluxing xylenes; evidence for the reversible formation of benzo[*c*]quinolizinium III from I (X = 4-Cl), with eventual formation of 4 (R = 6-Cl), is also presented.

Cystic fibrosis (CF) results from defects in the gene encoding a cyclic adenosine monophosphate-dependent chloride ion channel known as the cystic fibrosis transmembrane conductance regulator[1] (CFTR) and is characterized by defective chloride transport across epithelia of the airways, exocrine ducts, and intestine as well as viscous epithelial mucous secretions.[2] Becq's recent report[3] that the benzo[*c*]quinolizinium derivative MPB-07 (**II**, Fig. 1) activates wild-type CFTR membrane protein[4] in a variety of cell systems, coupled with our interests[5] in developing small molecule drugs capable of modulating chloride-selective ion channels,[6] led us to explore the use of 3-oxo-2-(2′-pyridyl)(*o*-halophenyl)propanoates as precursors to CFTR-active compounds. The synthesis of benzo[*c*]quinolizinium salts *via* an intramolecular cyclization reported by Fozard and Bradsher[7] led us to consider cyclization of **I** to MPB-07 analog **III** by an intramolecular *ipso* substitution reaction. We report here a wider perspective on the intriguing and useful intramolecular nucleophilic aromatic substitution chemistry of these α-(2-pyridyl)-β-ketoesters.

Our work started with *C*-acylation of benzyl 2-(2-pyridyl)acetate (**1**, Scheme 1),† in turn generated by the transesterification of methyl 2-(2-pyridyl)acetate with lithium benzoxide.[8] Generation of the lithium salt of **1** and subsequent treatment with various *o*-halobenzoyl chlorides gave the corresponding 3-oxo-2-(2′-pyridyl)(*o*-halophenyl)propanoates (**2**). Yields for **1** → **2** are generally moderate (60–75%) for a variety of halobenzoyl chlorides.

Heating **2a** in xylenes at reflux for 2 h delivered a crystalline product which we initially assumed was benzo[*c*]quinolizinium salt **III** (82% yield, Scheme 2). However, single crystal X-ray crystallographic analysis‡ (Fig. 2) revealed that the product was in fact isolated as the neutral benzo[*c*]quinolizine **3a** replete with 1-carboalkoxy and 2-oxo substituents on the newly formed ring. The observation that **2a** → **3a** *via* **III**, which was consistent with the results reported by Fozard and Bradsher for cycloquaternization of *cis*-2′-chloro-2-stilbazole, suggested that *ipso* substitution in our 3-oxo-2-(2′-pyridyl)(*o*-halophenyl)propanoate series would provide a general route to the benzo[*c*]quinolizine ring system.

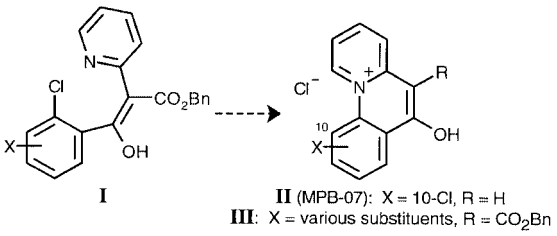

Fig. 1 3-Oxo-2-(2′-pyridyl)(*o*-halophenyl)propanoates as precursors to benzo[*c*]quinolizinium derivatives.

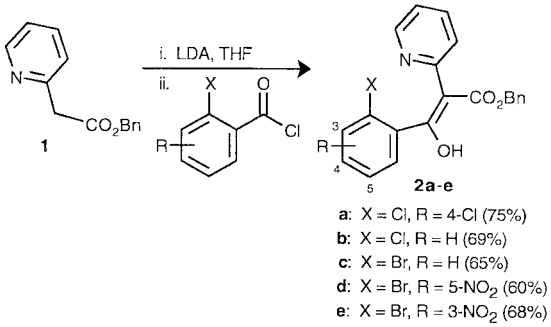
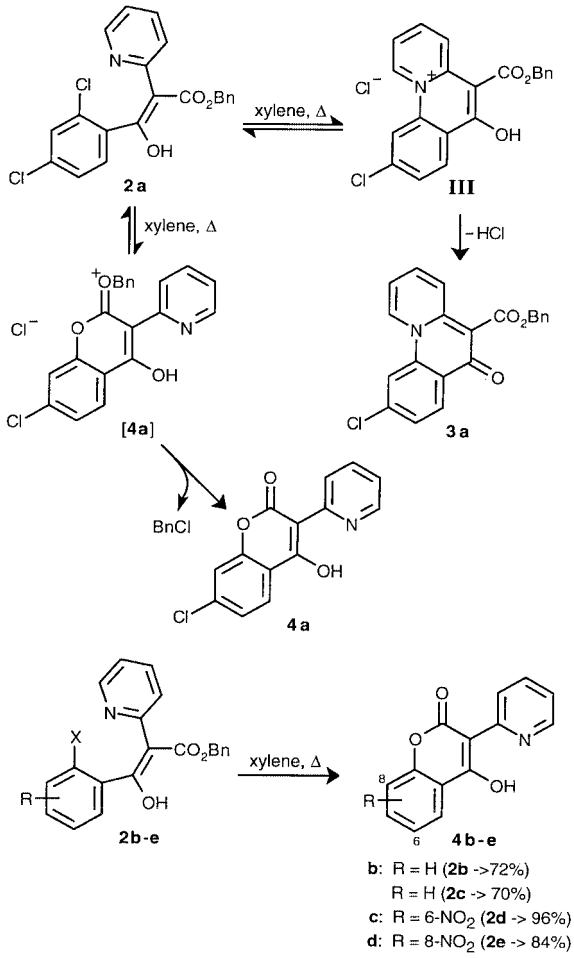


Scheme 1 Preparation of 3-oxo-2-(2′-pyridyl)(*o*-halophenyl)propanoates.



Scheme 2 Intramolecular *ipso* substitution in 3-oxo-2-(2′-pyridyl)(*o*-halophenyl)propanoates.

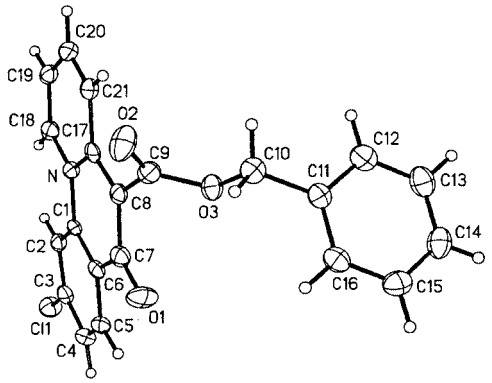


Fig. 2 X-Ray crystallographic structure of **3a**.

However, the next substrate investigated, **2b**, underwent ring-closing *ipso* substitution with loss of the benzyl ester moiety.† On closer inspection, it became apparent that *ipso* substitution of the *o*-chloro substituent in **2b** had occurred *via* nucleophilic attack of the carboalkoxy giving 4-hydroxycoumarin **4b** as the sole isolated product (72%). We speculate that **2** exists in a highly enolized, hydrogen-bonded (N···H–O) conformation[9] which biases the system to intramolecular carboalkoxy—rather than pyridyl—nucleophilic attack resulting in **2b** → **4b**. In the case of **2a**, the *p*-chloro substituent apparently deactivates the ring toward nucleophilic attack to the extent that only the 2-pyridyl moiety is nucleophilic enough to participate in *ipso* substitution, leading to formation of **3a**.

These observations led us to speculate that benzo[*c*]quinolizine **3a** might represent the kinetic product in this reaction and raised the question whether further heating of the **2a** → **3a** reaction mixture might lead to formation of the corresponding 4-hydroxycoumarin derivative. This would presumably occur by reversion of **III** to **2a** by intermolecular *ipso* attack by chloride followed by slow intramolecular ring-closing by carboalkoxy *ipso* attack to [**4a**]. Once formed, irreversible loss of BnCl from [**4a**] would deliver **4a**. To test this idea, the **2a** → **3a** reaction was performed in toluene-d_8 (110 °C) and intermittently monitored by ^{1}H-NMR. As anticipated, we observed the fairly rapid formation of **3a** (**2a** consumed in 72 h) followed by its slow disappearance and matched by the slow appearance of both benzyl chloride and 4-hydroxycoumarin **4a** (intermittent monitoring over 12 d). Moreover, when the laboratory scale reaction of compound **2a** was performed in refluxing xylene, formation of benzo[*c*]quinolizine **3a** was detected early on (monitored by TLC). Continued heating for 10 d afforded 4-hydroxycoumarin **4a** in 65% yield.

Three additional 3-oxo-2-(2′-pyridyl)(*o*-halophenyl)propanoates were also investigated (**2c**–**e**). In each of these, the *o*-halo substituent was a bromine and, in two of these, a strongly activating nitro group was incorporated at C5 (**2d**) or C3 (**2e**). In each of these cases, only carboalkoxy nucleophilic attack was observed. The yields for **2** → **4** are generally quite good (70–96%), with the more electron deficient C-ring systems affording higher yields.

The method reported here provides a general and useful route for the production of 4-hydroxy-3-(2′-pyridyl)coumarin derivatives. While both pyridyl and carboalkoxy moieties can participate in this reaction, reversible formation of the benzo-[*c*]quinolizinium coupled with irreversible loss of benzyl chloride during coumarin formation leads to the exclusive formation of the 4-hydroxy-3-(2′-pyridyl)coumarin derivative.

We thank the National Science Foundation and Cystic Fibrosis Foundation for financial support of this research as well as the National Science Foundation CRIF program (CHE-9808183) for Varian Inova 400 MHz and Mercury 300 MHz NMR instrument purchases. C. A. thanks the Departamento de Educación, Universidades e Investigación del Gobierno Vasco (Spain) for a Postdoctoral Fellowship.

Notes and references

† *General procedure for C-acylation of benzyl 2-(2′-pyridyl)acetate* (**1**): to a cold (0 °C) solution of diisopropyl amine (0.33 mL, 2.4 mmol) in dry ethyl ether (6.0 mL) under inert atmosphere was added dropwise n-BuLi (1.63 M in hexane, 1.47 mL, 2.4 mmol). The mixture was cooled to −78 °C and a solution of phenylmethyl 2-(2′-pyridyl)acetate (0.456 g, 2.0 mmol) in dry ethyl ether (2.0 mL) was added dropwise. This mixture was stirred at −78 °C for 60 min at which time a solution of the appropriate benzoyl chloride (2.0 mmol) in dry ethyl ether (1.0 mL) was added dropwise. Stirring was continued at 0 °C for an additional 30 min at which time the reaction was treated with 1 M aq. HCl and extracted with CH_2Cl_2. The organic layer was dried ($MgSO_4$), concentrated, and the oily residue was recrystallized from hexane.

General procedure for 4-hydroxycoumarin formation (**2** → **4**): a solution of phenylmethyl 3-aryl-3-oxo-2-(2′-pyridyl)propanoate **2** (0.2 mmol) in xylenes (2.0 mL) was stirred at reflux under N_2 for 2 h. After removal of the solvent in vacuum, the 4-hydroxycoumarin product was purified by silica gel chromatography (hexanes : EtOAc).

Steam-reforming of ethanol over ZnO gives highly effective production of CO-free H_2: 5.1 mol of H_2 per mol of reacted ethanol is formed at 723 K under 100% ethanol conversion.

There is growing interest in the use of H_2 as an alternative fuel mainly due to environmental aspects.[1,2] Alcohols could constitute a good supply of hydrogen, as they are efficient H_2-reservoirs and could avoid the difficulty of H_2-distribution. In this context, many efforts have been applied to the production of hydrogen from steam-reforming of methanol by using methanol synthesis-based catalysts;[3–5] however, there are fewer papers dealing with ethanol steam-reforming.[6] However, two considerations point to ethanol as an alternative to methanol: (i) the yield of H_2 is higher, (ii) ethanol is a renewable material which can be easily obtained from biomass. As regards the use of supported catalysts in the steam-reforming of ethanol, mainly copper- and cobalt-based catalysts have been studied.[7–9] In both cases the behaviour of supported catalysts was strongly affected by the support used. However, their role remains unclear and no exhaustive studies of transformations of ethanol over individual inorganic oxides under ethanol steam-reforming conditions have been reported.

Here we report the behaviour of several oxides, with a wide range of redox and acid–base properties, in the steam-reforming of ethanol. A high H_2O:ethanol ratio was used to explore the possibility of using ethanol as obtained from biomass (aqueous solutions of concentration *ca.* 15% in ethanol are obtained from sugar cane or starch-rich grains). In some cases total conversion of ethanol and high selectivity to the reforming reaction were attained.

The following oxides with the indicated BET surface area were used: MgO (prepared by adding ammonia to a $MgCl_2$ solution, 110 $m^2\ g^{-1}$), γ-Al_2O_3 (Girdler, 188 $m^2\ g^{-1}$), SiO_2 (Degussa–Hüls, 200 $m^2\ g^{-1}$), TiO_2 (Degussa–Hüls, 45 $m^2\ g^{-1}$), V_2O_5 (Merck, 22 $m^2\ g^{-1}$), ZnO (1) (Asturienne New Jersey, 11 $m^2\ g^{-1}$), ZnO (2) (prepared by decomposition of $3ZnO{\cdot}2ZnCO_3{\cdot}3H_2O$, 100 $m^2\ g^{-1}$), La_2O_3 (Merck, 11 $m^2\ g^{-1}$), CeO_2 (Aldrich, 17 $m^2\ g^{-1}$), Sm_2O_3 (Merck, 9 $m^2\ g^{-1}$). Steam-reforming of ethanol was carried out between 573 and 723 K, at atmospheric pressure, using a 1:13:70 C_2H_5OH:H_2O:Ar stream (molar ratio) and 0.1 g of the appropriate oxide diluted with inactive SiC, under a gas hourly space velocity (GHSV) of 5000 h^{-1}. After periods of 2 h at each temperature, the temperature was increased consecutively from 573 to 623, 673 and 723 K; at the final temperature the reaction was conducted over a period of 20 h. Products were analysed on-line by gas chromatography. Hydrogen was analysed with a TCD using Ar as a carrier gas, CO and CO_2 were analysed with an FID after passing through a methanizer, and hydrocarbons as well as oxygenated products were separated with a capillary column and analysed with an FID.

Conversion of ethanol increased with temperature for all samples (see Fig. 1). However, significant differences between

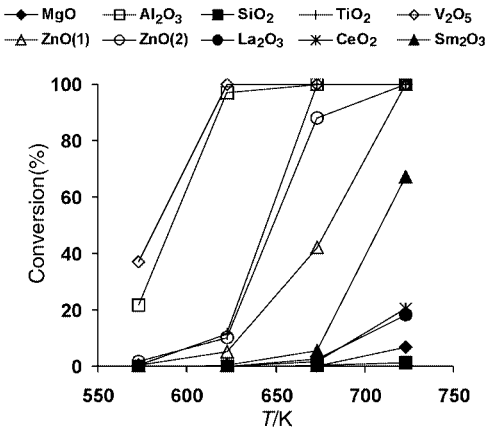

Fig. 1 Ethanol conversion as a function of temperature for different oxides. Reaction conditions: total pressure 1 atm, $C_2H_5OH:H_2O:Ar = 1:13:70$ (molar ratio), GHSV = 5000 h^{-1}.

them in terms of activity, stability and selectivity were found. The temperature required for total conversion was lower for V_2O_5 and γ-Al_2O_3 (623 K) than for the other oxides, and even at 723 K, conversions of $< 10\%$ were obtained over MgO and SiO_2 and were *ca.* 20% over La_2O_3 and CeO_2. A comparison between conversion values, after 20 h of reaction at 723 K and initial values (after 2 h of reaction at 723 K), shows a high deactivation process for TiO_2 and Sm_2O_3. Conversion diminished from 100% to 3.9% for TiO_2 and from 67.2% to 37.9% for Sm_2O_3. After reaction these two oxides appeared black, and carbon deposition during reaction could be responsible for the drop in activity. Table 1 shows the product selectivity and the ethanol conversion values after 20 h at 723 K (GHSV = 5000 h^{-1}) under the steam-reforming conditions mentioned above for catalysts with conversion $> 5\%$. The values of selectivity obtained with the different catalysts can be explained in terms of the contribution of the following reactions: ethanol steam-reforming (1), ethanol decomposition to CH_4 (2), ethanol dehydration (3), ethanol dehydrogenation (4), ethanol decomposition to acetone (5) and water–gas shift reaction (WGSR) (6).

$$CH_3CH_2OH + 3H_2O \rightarrow 2CO_2 + 6H_2 \quad (1)$$

$$CH_3CH_2OH \rightarrow CO + CH_4 + H_2 \quad (2)$$

$$CH_3CH_2OH \rightarrow C_2H_4 + H_2O \quad (3)$$

$$CH_3CH_2OH \rightarrow CH_3CHO + H_2 \quad (4)$$

$$2CH_3CH_2OH \rightarrow CH_3COCH_3 + CO + 3H_2 \quad (5)$$

$$CO + H_2O \rightarrow CO_2 + H_2 \quad (6)$$

Negligible steam-reforming of ethanol was observed over MgO and γ-Al_2O_3. Over γ-Al_2O_3 only the dehydration of ethanol to ethylene was observed and over MgO high selectivity to acetaldehyde was obtained. These findings are consistent with the acidic and basic characteristics of γ-Al_2O_3 and MgO respectively,[10] which in addition do not have redox properties.

† Dedicated to Professor Rafael Usón on the occasion of his 75th birthday.

[a] Water not included.

The product distribution for the remaining oxides indicates that the steam-reforming of ethanol took place. However, all samples in Table 1 except zinc oxides, showed significant yields in the dehydration of ethanol. For V_2O_5 the production of ethylene can be related to its acidic properties.[10,11] On the other hand, the dehydration of ethanol over La_2O_3 and Sm_2O_3 has been proposed to occur over basic centres,[11] with the production of ketones from alcohols also related to basic centres in the oxides. The high conversion values and high selectivity to CO_2 and H_2 obtained over ZnO (1) and ZnO (2) is of note. Over these oxides the main reactions under the experimental conditions used were the decomposition of ethanol to acetone, the reforming of ethanol and the WGSR. The decomposition of ethanol to acetone is well documented over ZnO-based catalysts.[12,13] This takes place *via* several successive reactions such as dehydrogenation and aldol condensation over basic centres. The performance of ZnO in the steam-reforming of ethanol could be a consequence of its basic and redox characteristics. The basic properties should be related to the dehydrogenation of ethanol to acetaldehyde and then, its specific redox characteristics could help to aid the steam-reforming reaction.

The yield of acetone is expected to be affected by the contact time. A deeper study of the transformations of ethanol over ZnO (2) as a function of contact time indicated that it is possible to have a very high yield in the reforming of ethanol and to minimize the yield of all the other ethanol transformations. Table 1 also compiles some results obtained for GHSV ranging from 22 000 to 2300 h^{-1}. Different space velocities were obtained by dilution of the C_2H_5OH–H_2O mixture (1 : 13 molar ratio) with Ar, after each change the system was stabilised for 2 h and then the products were analysed. In all cases total conversion of ethanol was obtained and no CO was detected (detection limit of CO 17 ppm). When the reaction was conducted at 22 000 h^{-1}, only 2.3% of the total products were other than H_2 or CO_2. Under these conditions, values of 5.1 mol H_2 and 1.7 mol CO_2 per mol of reacted ethanol were recorded representing 85% of the theoretical values that can be obtained from ethanol reforming. This finding, together with the absence of CO production (or at least < 17 ppm) indicate that a ZnO-based catalytic system may be used for H_2 production for fuel cells. Moreover, at a practical level, bioethanol could be used as raw material.

An expeditious solvent-free route to ionic liquids using microwaves

Rajender S. Varma* and Vasudevan V. Namboodiri

Received (in Corvallis, OR, USA) 9th February 2001, Accepted 22nd February 2001
First published as an Advance Article on the web 20th March 2001

A microwave-assisted preparation of a series of ambient temperature ionic liquids, 1-alkyl-3-methylimidazolium (AMIM) halides, that proceeds *via* efficient reaction of 1-methylimidazole with alkyl halides/terminal dihalides under solvent-free conditions, is described.

In addition to their role in electrochemistry[1] (electrolytes for battery, fuel cells *etc.*), heavy metal ion extraction,[2] phase transfer catalysis, and polymerization,[3] ionic liquids are emerging as a set of new green solvents, mainly as a replacement for conventional volatile organic solvents.[4] The use of a large excess of conventional volatile solvents required to run a chemical reaction is of ecological and economic concern. Ambient temperature ionic liquids encompassing 1,3-dialkylimidazolium cations (**A**) have shown great promise as an attractive alternative to conventional solvents.[5] The important properties of these ionic liquids are low volatility, negligible vapor pressure, ease of handling, accelerated reaction rates, potential for recycling, and compatibility with various organic compounds and organometallic catalysts.[6] Also, the products from reactions conducted in ionic liquids can be extracted very easily using various organic solvents. The preparation of 1,3-dialkylimidazolium halides *via* the conventional heating method in refluxing solvents requires several hours to afford reasonable yields and also uses a large excess of alkylhalides/organic solvents as the reaction medium.[7] In view of the emerging importance of the ionic liquids as reaction media[8] and our general interest in MW-assisted chemical processes,[9] we decided to explore the synthesis of ionic liquids using microwave (MW) irradiation under solvent-free conditions. Herein, we report an efficient method for the preparation of ionic liquids using microwave irradiation as the energy source by simple exposure of neat reactants in open containers to microwaves using an unmodified household MW oven. This solvent-free approach requires only a few minutes of reaction time in contrast to several hours needed under conventional heating conditions which uses an excess of reactants.

In an unmodified household MW oven it is not possible to vary the MW power. The reduction in power level simply entails that it operates at its full power but for a reduced period of time. A recently introduced household MW oven (Panasonic) equipped with inverter technology provides a realistic control of the microwave power to a desirable level. We examined the effect of microwave power on a set of reactions using 1-butyl bromide (1-BuBr) and 1-methylimidazole (MIM) as reactants (Table 1).† Upon microwave irradiation, the ionic liquid starts forming which increases the polarity of the reaction medium thereby increasing the rate of microwave absorption. The formation of ionic liquid could be monitored visibly in the reaction when it turns from clear solution to opaque and finally clear. It is observed that at elevated power levels evaporation of alkyl halide and partial decomposition/charring of the ionic liquid occurs possibly due to the localized heating of the ionic liquid, which eventually results in lower yields. To circumvent this problem, we conducted the reaction with intermittent heating and mixing at a moderate power level to provide better yields and cleaner ionic liquid formation.‡ After the first irradiation for 30 s at 240 W (~bulk temperature 70–100 °C) the homogeneity of the reaction mixture changes due to formation of a small amount of ionic liquid. The reaction mixture is then taken out, mixed again for 10 s and then heated at the same power level for an additional 15 s. This step is repeated until the formation of a clear single phase ionic liquid product. At this stage, the unreacted starting materials are removed by washing with ether and the product dried under vacuum at 80 °C.

A series of ionic liquids prepared by microwave heating and the protocol is then compared with the similar preparation using conventional heating (oil bath at 80 °C). The comparative results are summarized in Table 2. Most of the halides used in this study have higher boiling points and are converted efficiently to ionic liquids under microwave irradiation. The relatively less reactive and low boiling reactants such as butyl chloride and 2-bromobutane (entries 1 and 4, Table 2) incurred loss due to evaporation and hence are used in excess quantity. The reactivity trend of halides is found to be in the order $I^- > Br^- > Cl^-$. Due to the high reactivity of the iodides excellent yields are obtained in all cases with minimum exposure time. The conventional methods reported in the literature generally use a large excess of alkyl halide–THF as solvents. The present method is eco-friendly and uses only stoichiometric amounts of reactants.

The preparation of ionic liquids bearing polycations are of recent synthetic interest.[10] We have prepared novel dicationic compounds (**B**) utilizing alkyl dihalides. The butyl and hexyl dicationic salts (entries 11–15, Table 2) are solids at rt. The corresponding octyl analogues with bromide/chloride as the anions are viscous liquids (entries 16 and 17, Table 2) whereas the iodo compound (entry 18, Table 2) is a solid. From the NMR data the dicationic salts generated from chloro and bromoalkanes (entries 11, 13, 14 and 16, Table 2) are slightly contaminated with the corresponding monocationic intermediate (< 5%). However, the diiodoalkanes, being reactive, afforded pure products. The purity of ionic salts prepared *via* microwave heating are found to be superior to those prepared *via* conventional heating methods, presumably due to inefficient mixing in the later, once the solid product (**B**) begins to form.§

The thermogravimetric analyses (TGA) and differential scanning calorimetry (DSC) data show that all ionic liquids

Notes and references

† In a typical reaction, 1-bromobutane (2.2 mmol) and MIM (2 mmol) are placed in a test tube, mixed thoroughly on a vortex Mixer (Fisher, Model 231) and the mixture is heated intermittently in an unmodified household MW oven (Panasonic NN-S740WA-1200W) at 240 W (30 s irradiation with 10 s mixing) until a clear single phase is obtained. The bulk temperature recorded is in the range 70 to 100 °C. The resulting ionic liquid is then cooled, washed with ether (3 × 2 mL) to remove unreacted starting materials and product dried under vacuum at 80 °C to afford 86% of 1-butyl-3-methylimidazolium bromide, ^{1}H NMR (250 MHz; D_2O), δ_H: 0.72 (t, CH_3), 1.15 (m, CH_2), 1.81 (m, CH_2), 3.71 (s, N-CH_3), 4.09 (m, N-CH_2), 7.38 (s, NCH), 7.43 (s, NCH), 8.7 (s, N(H)CN); ^{13}C NMR δ_C: 12.89 (t, CH_2), 19.02 (m, CH_3), 31.51 (m, CH_2), 35.86 (N-CH_2), 49.51 (N-CH_3), 122.40 (NCH), 123.73 (NCH), 136.21 (N(H)CN). An experiment on a relatively large scale (22 mmol of 1-bromobutane and 20 mmol of MIM) afforded 87% yield.

‡ There are commercial microwave devices available that provide adequate mixing and control of reaction parameters such as temperature, pressure *etc.* For description see details at sites: http://www.cem.com; http://www.microcure.com and http://www.personalchemistry.com

§ The NMR spectra of the samples are recorded on a Brucker 250 MHz spectrometer using D_2O as solvent and CD_3OD/$CDCl_3$ as the standards. The new compounds are characterized by elemental analyses, ^{1}H and ^{13}C NMR. The data for a representative dicationic compound, entry 15, δ_H (250 MHz; D_2O) 1.29 (m, CH_2), 1.82 (m, CH_2), 3.71 (s, N-CH_3), 4.14 (m, N-CH_2), 7.38 (s, NCH), 7.43 (s, NCH), 8.7 (s, NC (H)N); δ_c: 24.99 (t, CH_2), 29.17 (m, CH_3), 36.18 (N-CH_2), 49.57 (N-CH_3), 122.35 (NCH), 123.64 (NCH), 135.97 (NC (H)N), (Calc. for $C_{14}H_{24}N_4I_2$: C, 33.49; H, 4.82; N, 11.16; Found. C, 33.69; H, 4.93; N, 11.68%).

¶ The TGA of the sample is performed by heating from 25 to 500 °C at a rate of 10 °C min^{-1} and DSC is conducted from 25 to 450 °C at a heating rate of 10 °C min^{-1}.

First published as an Advance Article on the web 20th March 2001

New PtdIns(3,4,5)P_3 binding proteins have been identified utilising PtdIns(3,4,5)P_3 modified affinity matrix 1 which was synthesised from *myo*-inositol derivative 2, phosphoramidite 9 and an agarose based solid support.

The role of *myo*-inositol phospholipids in cell signalling systems is well established.[1–4] One such signal transduction mechanism involves the *in vivo* production of PtdIns(3,4,5)P_3 *via* phosphorylation of PtdIns(4,5)P_2 mediated by PI3K.[5] Although PtdIns(3,4,5)P_3 binding proteins are known,[6] many of the cellular processes downstream of PI3K activation do not yet have a defined lipid binding protein mapped above them. For this reason we embarked on the preparation and evaluation of an affinity matrix based on PtdIns(3,4,5)P_3.

The phospholipid was attached to an agarose matrix by an amide linkage formed between a carboxylic acid-terminated side chain on the agarose and a 3-(ω-aminoacyl)glycerol derivative on the phospholipid (Scheme 1). The phospholipid **11** was prepared by coupling the alcohols **2**[7] and **3** (from the commercially available (*S*)-(+)-1,2-*O*-isopropylideneglycerol **4**) through a phosphodiester linkage.

We initially protected the primary alcohol **4** as the *tert*-butyldiphenylsilyl ether, but encountered difficulties in its removal at a later stage of the synthesis. A more efficient process involved 4-methoxybenzylation of the primary alcohol **4** (Scheme 2),[8] followed by acetonide removal to give the PMB-ether **5** (PMB = *p*-methoxybenzyl). Selective esterification of the primary alcohol in **5** with the Cbz-protected (Cbz = benzyloxycarbonyl) ω-amino acid **6**, followed by palmitoylation of the secondary alcohol **7** gave the diester **8**. Oxidative removal (CAN) of the PMB protecting group and phosphitylation of **3** with BnOP(N^iPr_2)$_2$[9] gave the phosphoramidite **9**.†

The lipid side chain, in the form of the phosphoramidite **9**, was then coupled with the enantiomerically pure alcohol (−)-**2** to afford the perbenzylated compound **10** (Scheme 3). Reductive debenzylation was readily effected using H_2 (50 psi) in the presence of Pd-black and $NaHCO_3$ in ^{t}BuOH–H_2O (6:1) as the solvent, to afford the amine **11** in good yield.† This was then coupled with the *N*-hydroxysuccinimide (NHS) activated ester resin, Affi-Gel 10,‡ to afford the PtdIns(3,4,5)P_3 modified matrix **1**. Excess resin (*ca*. 5 equiv.) was required to ensure the complete consumption of the amine which was determined by a negative Kaiser test.§

Pilot experiments showed that PKB (25 μM) [a known[6,10] PtdIns(3,4,5)P_3 binding protein] would bind to the matrix **1** and could be completely displaced by 10 μM D,D-PtdIns(3,4,5)P_3¶ but not at all by 10 μM L,L-PtdIns(3,4,5)P_3, thus establishing the potential specificity of the matrix. When applied to a pig neutrophil cytosol a number of proteins have been identified that bind to the resin **1** in a PtdIns(3,4,5)P_3 sensitive manner.

DOI: 10.1039/b101320n

Several novel proteins were identified and the full biological results will be disclosed in a separate publication. One of these proteins was subsequently shown to be identical to the recently characterised protein, DAPP1, possessing a Src homology (SH2) domain and a pleckstrin homology (PH) domain. This novel protein had been independently identified from a database search by comparison of the PH domain sequences with known PtdIns(3,4,5)P_3 binding proteins.[11] The fact that the 'functional screen assay' identified several proteins including DAPP1, which is involved in endosomal trafficking or sorting,[12] is noteworthy and exemplifies the strength of the approach. Very recently biotinylated PtdIns(3,4,5)P_3 has been used as an affinity ligand for the purification of recombinant PtdIns(3,4,5)P_3 binding proteins.[13]

In summary we have demonstrated a synthesis of a PtdIns(3,4,5)P_3-modified matrix and demonstrated its use as a tool for the identification of proteins binding to PtdIns(3,4,5)P_3.[14] The flexible nature of the methodology and the biological success of resin **1** warrants further investigation into the preparation and biological evaluation of other D-3 phosphorylated *myo*-inositol phospholipid modified matrices.[15]

Silica-bound copper(II) triazacyclononane: a robust material for the heterogeneous hydrolysis of a phosphodiester

Brett R. Bodsgard and Judith N. Burstyn*

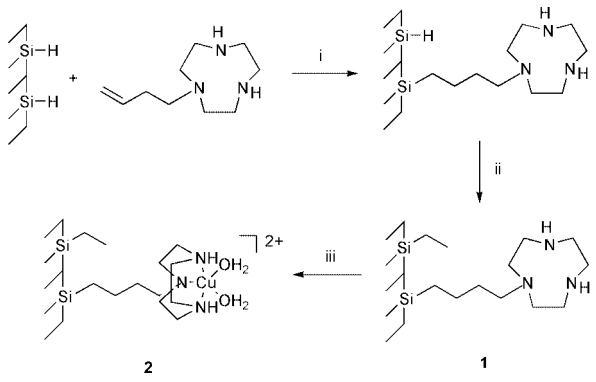
Department of Chemistry, University of Wisconsin, Madison, Wisconsin 53706, USA. E-mail: burstyn@chem.wisc.edu

Received (in Irvine, CA, USA) 28th June 2000, Revised manuscript received 16th January 2001, Accepted 13th February 2001
First published as an Advance Article on the web 16th March 2001

Copper(II) triazacyclononane, a catalyst for the hydrolysis of phosphate esters, has been covalently immobilized onto a silica surface and the resulting compound is a robust material that can effect heterogeneous phosphodiester hydrolysis.

The exceptional stability of phosphodiesters makes their cleavage a challenging task: at neutral pH and 25 °C, the half-life for the hydrolysis of dimethyl phosphate is estimated to be 130 000 years.[1] It is well documented, however, that a large range of metal ions and metal complexes are able to dramatically increase the rate of hydrolysis of phosphodiesters in aqueous solutions.[2] We have shown that in aqueous solution dichloro(1,4,7-triazacyclononane)copper(II) ($Cu[9]aneN_3Cl_2$) catalytically hydrolyzes the activated phosphodiester, bis(4-nitrophenyl)phosphate (BNPP).[3] A drawback of these homogeneous catalysis reactions is the inability to recover and reuse the catalyst. A heterogeneous catalyst, however, formed by immobilization of the active complex onto a solid support, can be easily separated from the reaction products and recycled continuously. Here we report the synthesis and characterization of silica-bound $(Cu[9]aneN_3)^{2+}$ and its reaction chemistry with BNPP.

Silica-bound $(Cu[9]aneN_3)^{2+}$ was prepared by a rhodium-catalyzed hydrosilation reaction between *N*-(4-but-1-enyl)-1,4,7-triazacyclononane[4] and hydride-modified silica,[5] both of which were prepared according to literature procedures. The chosen method of immobilization was favored because it produced more uniform and hydrolytically stable silicon–alkyl group linkages.[6] Conventional methods usually involve immobilization through an amide bond, which is not appropriate because $(Cu[9]aneN_3)^{2+}$ has been shown to hydrolyze amides.[7] *N*-(4-but-1-enyl)-1,4,7-triazacyclononane and hydride-modified silica were refluxed in toluene in the presence of Wilkinson's catalyst $[RhCl(PPh_3)_3]$ for 3 days, covalently linking the macrocycle to the silica surface (Scheme 1).[8] Unreacted hydrides were blocked with ethyl groups by charging the flask with ethylene (1 atm) and vigorously stirring the reaction solution for 15 h at room temperature.[9] After thorough washes with toluene, dioxane, and acetone, silica-bound triazacyclononane **1**, a pale yellow solid, was collected and dried at room temperature.



Scheme 1 *Reagents and conditions*: i, $RhCl(PPh_3)_3$, toluene, reflux, 3 days; ii, C_2H_4, $RhCl(PPh_3)_3$, toluene, 25 °C, 15 h; iii, $Cu(NO_3)_2$ (aq).

Characterization of **1** reveals that the silica surface has been modified with an organic layer. Elemental analysis was performed on **1**, yielding the following mass percentages: C 5.14%, H 1.54% and N 1.11%.[10] Based on the nitrogen value, it was calculated that the surface concentration of triazacyclononane was 0.264 mmol (g silica)$^{-1}$. Additionally, it was estimated that, of the original hydrides present on the silica surface, 24% had reacted with the *N*-(4-but-1-enyl)-1,4,7-triazacyclononane. Both of these values agree well with other reported values for silica-bound macrocycles.[11]

Metallation of **1** was achieved by mixing an aqueous solution of copper(II) nitrate with **1** and stirring vigorously for 30 min. The yellow material quickly became blue. The solid was isolated by filtration over a glass frit and was repeatedly washed with water until the washings were colorless. Finally, the material was washed twice with methanol and allowed to air dry, resulting in a pale blue solid, silica-bound copper(II) triazacyclononane **2**. EPR spectroscopy was used to probe the copper(II) environments in **2**. Spectra were recorded at both room temperature and 77 K.[12] The 77 K spectrum of **2** showed the characteristics of an axially symmetric d^9 copper complex.[13] The room temperature spectrum of **2** (Fig. 1) was essentially identical to its 77 K spectrum. A broadened spectrum was not observed, revealing that spin–spin interactions between the copper centers are minor or non-existent. Therefore, the conclusion can be drawn that the copper complexes anchored to the silica surface are well separated and non-interacting. This result demonstrates that dimerization of $(Cu[9]aneN_3)^{2+}$, an occurrence that contributes to rate reduction in the hydrolysis of phosphodiesters in aqueous solution,[3] will not be a factor for reactions with **2**.

Kinetic experiments showed that **2** was effective at hydrolyzing BNPP. Typical experiments began with the addition of 60 mg **2** to 50 mM HEPES [*N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid] buffer at pH 7.8. The solution was stirred

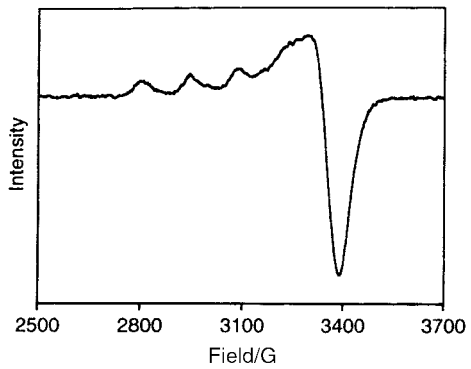


Fig. 1 X-Band EPR spectrum of **2** (undiluted powder sample). The spectrum was recorded at 298 K, 101 mW microwave power, 3.2×10^5 receiver gain, 5.88 G modulation amplitude, 9.6469 GHz microwave frequency, 100 kHz modulation frequency and a 163.84 ms time constant, using 10 averaged scans, each containing 4096 data points; $g_\perp = 2.065$, $g_\parallel = 2.283$, $A = 143$ G.

DOI: 10.1039/b005264g

vigorously for 15 min to wet the solid, followed by addition of 5 mM BNPP, to a total reaction volume of 3 mL. The solution was allowed to stir in the dark at 25 °C and was monitored by visible spectrophotometry, following the absorption at 400 nm due to the hydrolysis product 4-nitrophenolate.[14] Fig. 2(a) shows a plot of concentration of 4-nitrophenolate *vs.* time for a typical reaction. The plot shows an extended induction period where no hydrolysis was observed, and then a linear increase in product formation followed by a second linear region of product formation at a slower rate. The slowing of the reaction at relatively low (20%) conversion suggests that product inhibition may be significant. When **2** was allowed to stir with the buffer for 5 days prior to the addition of substrate, a significantly reduced induction period was observed, indicating that solvation of the solid surface is a limitation in this system. Negligible BNPP hydrolysis was observed in the absence of **2** or in the presence of **1** at the same temperature and pH over a two week period.

The same portion of **2** can be reused to hydrolyze additional samples of BNPP. In an initial reaction cycle, 60 mg **2** was combined with 5 mM BNPP in 50 mM HEPES, pH 7.8, as above. After *ca.* 700 h, by which time the reaction was proceeding at the slower rate, **2** was isolated from the suspension and repeatedly washed with 1 mL aliquots of 50 mM HEPES buffer (pH 7.8) until the washings were colorless (at least five washings). Fresh HEPES and BNPP (identical concentrations as in cycle 1) were added to **2** and the 4-nitrophenolate concentration was monitored as a function of time. In the second cycle, hydrolysis was again observed, following the same reaction profile as the first cycle with the exception of a shorter induction period (data not shown). This same portion of **2** was recycled a third time following the same procedure as for the second cycle, and identical hydrolytic activity was observed.

When **2** was recycled while the hydrolysis rate was maximal, after *ca.* 150 h, the higher reaction rate could be maintained through repeated reaction cycles. In the first reaction cycle 60 mg **2** and 5 mM BNPP were reacted at 25 °C, pH 7.8 (50 mM HEPES) for 300 h, and slow hydrolysis was observed. After isolation and washing by the procedure described above, **2** was combined with fresh substrate and buffer under the same conditions as in the first cycle. The reaction was followed for *ca.* 150 h. The rate of hydrolysis in the second cycle was significantly greater than in the first. The recycling procedure was repeated through 12 cycles over the course of 3 months: Fig. 2(b) shows data for cycles 1, 4 and 7. Cycles 1–5 proceeded with progressively increasing reaction rates. Once the maximal rate was achieved at cycle 5, all subsequent cycles exhibited the same rate of reaction. The maximal observed rate of hydrolysis was 7.5×10^{-10} M s^{-1}; this rate is significantly faster than the uncatalyzed rate, which cannot be measured at room temperature and neutral pH. These data reveal that if **2** is isolated, washed and recycled while reacting at its maximal rate, the high rate can be maintained through repeated cycles for an extended period of time.

The data presented herein demonstrate effective heterogeneous hydrolysis of a phosphodiester promoted by a surface-immobilized copper(II) macrocycle, $(Cu[9]aneN_3)^{2+}$. Importantly, **2** can be reused over many months to hydrolyze additional portions of BNPP, and a higher reaction rate can be maintained at low percentage conversion to product. The hydrophobic nature of the material is likely responsible for the long induction period and work is currently underway to promote the silica–substrate interaction.

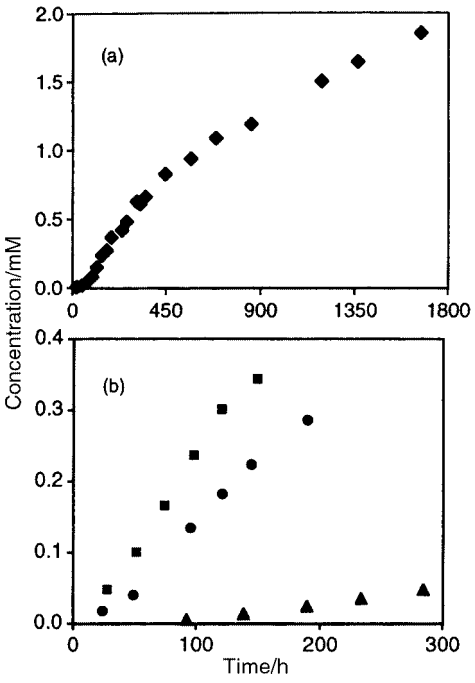

Fig. 2 (a) Single reaction time course. Plot of concentration of 4-nitrophenolate *vs.* time for **2**-mediated hydrolysis of BNPP. Reactions were carried out at pH 7.8, maintained by 50 mM HEPES, and 25 °C. The substrate (5 mM BNPP) was added to 60 mg **2**, and a suspension was maintained by constant stirring. Aliquots were clarified by centrifugation and filtration for absorbance measurements. (b) Multiple cycle, initial rate time course. Plot of concentration of 4-nitrophenolate *vs.* time for **2**-mediated hydrolysis of BNPP: see (a) for conditions. Each reaction after cycle 1 was allowed to proceed to *ca.* 6% conversion to product before recycling; (▲) cycle 1, (●) cycle 4, (■) cycle 7.

Salt-bridge formation may be used to stabilise the 3_{14}-helical conformation of β-peptides in aqueous solution, as shown by a 2D-NMR spectroscopic investigation.

The design, synthesis, and characterisation of artificial molecules capable of forming specific and predictable secondary structures offer new possibilities in the field of molecular recognition, catalysis, and protein folding.[1] Thus, it is not surprising that unnatural oligomers like β-peptides have received considerable attention, since these molecules are able to form stable secondary structures with as few as six residues.[2] Although we are starting to understand some of the factors influencing the folding of these molecules, much work remains until we are able to correctly predict how a particular sequence of unconstrained building blocks will fold, especially in aqueous media. To investigate if salt-bridge formation can be used to stabilise β-peptidic secondary structures we set out to synthesise the β-heptapeptide **1** (Fig. 1).

The sequence of **1** was selected based on the following design principles: (*i*) we expect an *all*-β^3 peptide to form a 3_{14}-helix[2]; (*ii*) use of charged residues will ensure high water solubility; (*iii*) residues with positively and negatively charged side-chains should be positioned in an *i*/*i* + 3 disposition so that they are in juxtaposition on the ternary 3_{14}-helix, allowing for the two desired salt-bridges to be formed; (*iv*) β^3-HOrnithine rather than β^3-HLysine residues were chosen since this brings the charges closer together and less entropy is lost upon salt-bridge formation; (*v*) one side of the helix is covered by aliphatic side-chains to allow for intramolecular hydrophobic interactions, Fig. 1.

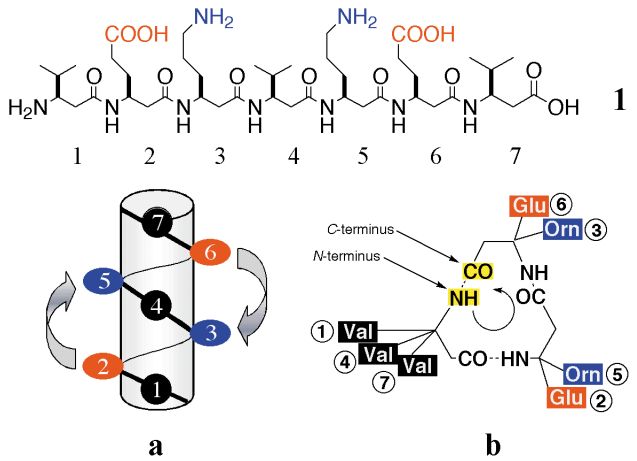

Fig. 1 Molecular formula of the β-heptapeptide **1** and schematic representations of a linear 3_{14}-helical structure from the side (**a**) and from top (**b**). Colour-code: Black = hydrophobic residues, Blue = positively charged residues, and Red = negatively charged residues.

† Electronic supplementary information (ESI) available: NMR spectroscopy and conc. dependent CD-spectra of **1**. See http://www.rsc.org/suppdata/cc/b1/b101085i/

The *all*-β^3-heptapeptide **1** was synthesised on *Wang* resin (0.25 mmol scale) using the standard *FastMoc* chemistry as implemented in an Applied Biosystem 433A automated peptide synthesiser. The protocol involved 45 min coupling times with four equiv. of the HBTU–HOBt activated β-amino acid (Fmoc-β^{3}HVal-OH, Fmoc-β^{3}HOrn(Boc)-OH, and Fmoc-β^{3}HGlu(OtBu)-OH prepared by Arndt-Eistert homologation),[3] 5 × 10 min deprotection, including NMP–DCM washings. The crude peptide was isolated in 78% purity, after TFA mediated removal of the protecting groups and cleavage from the resin. Purification by reverse phase HPLC (C18 column; MeCN–water gradient containing 0.1% TFA) afforded the pure peptide **1** in 65% yield, as characterised by its electrospray mass spectrum and complete assignment of the 500 MHz ^{1}H NMR spectrum. The main impurity (10%) was also isolated and characterised as *N*-Fmoc **1**, thus confirming previous observations that the standard Fmoc-cleavage, with 20% piperidine, is insufficient for complete Fmoc removal of β-peptides with chain-lengths exceeding six amino acids.[4] To the best of our knowledge, this is the first time a β-peptide was synthesised with standard coupling conditions on an automated synthesiser, suggesting that automated synthesis may be successfully applied for β-peptides of longer sequences and combinatorial libraries, especially if the deprotection protocol is modified according to our recently improved conditions.[4]

β-Peptide **1** exhibits excellent solubility in both water and MeOH. The far-UV circular dichroism (CD) spectra of **1** in MeOH and aqueous solution are shown in Fig. 2. As expected, the CD spectrum in MeOH displays a minimum at *ca*. 216 nm and a maximum at *ca*. 198 nm, characteristic of a 3_{14}-helix with (*M*)-chirality. Remarkably, when one compares the mean molar ellipticity of all β^3-peptides synthesised in our laboratory to date this peptide exhibits the strongest ellipticity of all in MeOH solution. The CD spectra recorded in aqueous solution also show the typical pattern of a 3_{14}-helical conformation.[4] Furthermore, the pH dependence study in Fig. 2 suggests that the two salt-bridges successfully increase the stability of the

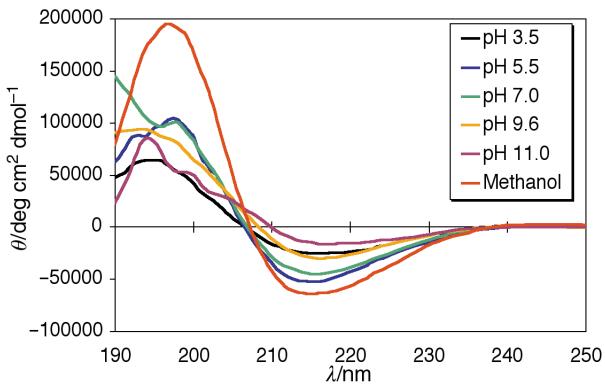

Fig. 2 CD-spectra of **1** in MeOH solution (red) and in aqueous solutions at different pH values (all measurements were done at 0.2 mM). The minimum near 215 nm, considered characteristic of a (*M*) 3_{14}-helical structure, shows maximal intensity at pH 5.5 (blue) consistent with a salt-bridge stabilisation.

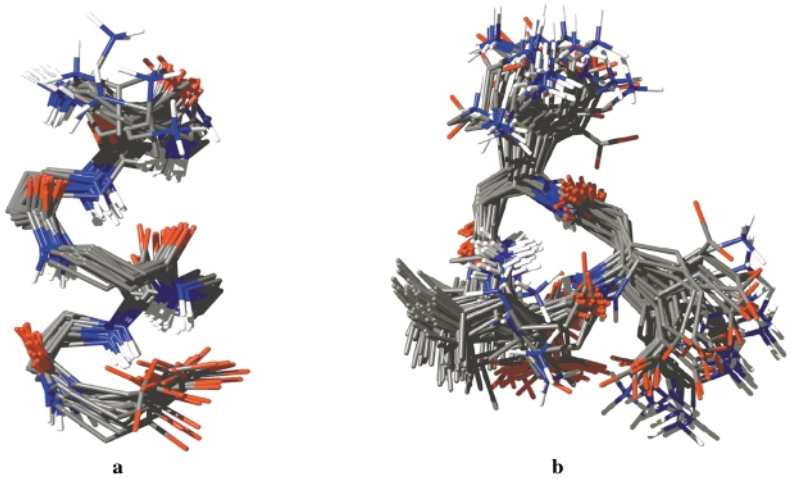

Fig. 3 Solution structure of the β-heptapeptide **1** in MeOH represented as a bundle of 25 lowest-energy structures obtained by simulated annealing, using NMR dihedral-angles and NOE-distance restraints, in the XPLOR programme. View along the (*M*) 3_{14}-helical axis with side-chains omitted (**a**), and top-view with side-chains (**b**).

helix since the strongest molar ellipticity is observed at pH 5.5, *i.e.* the pH value where the ornithine residues are expected to be protonated and the glutamic acid residues are still deprotonated. The CD spectra displayed only a slight change in the range 0.02 to 2 mM (see supporting information †), suggesting that no aggregation takes place in this concentration range. This observation is surprising if one considers the amphiphilic nature of the helix, and raises the question how to distribute the side-chains in order to achieve self-aggregation of 3_{14}-helical structures.

A detailed 2D-NMR spectroscopic study was undertaken to obtain high-resolution data on the actual conformation of **1** in water and in MeOH. The MeOH spectrum, recorded at 500 MHz, showed good separation of all signals and allowed complete assignment of all ^{1}H resonances in their respective spin system using DQF-COSY and TOCSY techniques; HSQC and HMBC experiments could then be used for sequence assignment. The large ^3J(NH; C(β)-H) coupling constants establish that the NH and C(β)-H protons are in an anti-periplanar arrangement. The diastereotopic CH_2(α) protons were assigned assuming that the axial protons exhibit a large, and the lateral protons a small, coupling with C(β), which is in agreement with the stronger NOEs observed from H-C(β) to the lateral H-C(α) protons than to the axial H-C(α) protons. ROESY spectra were acquired at three different mixing times (80, 150, and 300 ms), and a total of 72 NOEs were extracted from the spectra with mixing time 300 ms. Integration of the cross peak volumes followed by calibration allowed classification of the NOEs in three distance categories with the following upper bound distance limits: strong < 3.0 Å, medium < 3.5 Å, and weak < 4.5 Å. These distance restraints, together with 6 (NH, C(β)-H) dihedral angle restraints, derived from the coupling constants, were subjected to simulated annealing following the XPLOR protocol. The calculation produced a set of 25 structures with lowest restraint violations. These structures show a well-defined left-handed 3_{14}-helical conformation, Fig. 3. The side chains of β^3-HGlu and β^3-HOrn are on top of each other, thus allowing the designed salt bridges to form.

The NMR spectra recorded in aqueous solution at pH 5.5 showed more spectral overlap. Although it was possible to assign all resonances using a combination of the TOCSY, HMBC, and HSQC spectra, integration of the cross-peak volumes in the ROESY spectra was severely hampered by overlap. Nevertheless, the following NOEs could be unambiguously assigned: NH(2) and NH(4) to H-C(β) *i*+2 and *i*+3; NH(2) to NH(3); NH(3) to side chain protons of residue 6; H-C(β) of residue 4 to the lateral H-C(α) proton on residue 1. A qualitative treatment of these key NOEs, together with the large ^3J(NH; C(β)-H) coupling constants observed, imply the 3_{14}-helical conformation. Furthermore, no NOEs violating this conformation were observed. Based on the NMR spectroscopic data and the characteristic CD-spectra we conclude that the main conformation of β-peptide **1** is a 3_{14}-helix in MeOH as well as in water. Thus, since this is the first time a high resolution method supports the folding of a β-peptide without covalent constrains in water,[5] this study demonstrates that salt-bridge formation constitutes a valuable tool for the design of stabilised unnatural secondary structures in aqueous media.

P. I. A. gratefully acknowledges a postdoctoral fellowship from the Swedish Foundation for International Cooperation in Research and Higher Education (STINT). B. Brandenberg is acknowledged for recording the NMR-spectra.

Locked nucleic acid (LNA), a recently introduced nucleic acid analogue with a bicyclic 2′-*O*,4′-*C*-methylene linked furanose sugar, exhibits enhanced affinities for DNA and RNA relative to the corresponding oligodeoxyribonucleotides and oligoribonucleotides; we report the first crystal structure of an LNA unit incorporated in an oligonucleotide duplex. The structure at 1.4 Å resolution of the DNA–LNA decamer duplex with one LNA thymine monomer per strand provides a detailed view of the conformation and hydration of locked nucleic acid residues in a duplex A-form.

LNA (Fig. 1), exhibits stability of self-pairing that significantly exceeds those observed with DNA and RNA.[1–3] The UV melting temperatures of mixed DNA–LNA[1,4] and RNA–LNA[5] strands paired to DNA or RNA are increased by between 4 to 9 °C per modified residue compared to the corresponding unmodified duplexes. Increased RNA affinity, higher nuclease resistance and the observation that RNAs targeted by mixed DNA–LNA oligonucleotides are degraded by RNase H render LNA a promising third-generation antisense modification.[6]

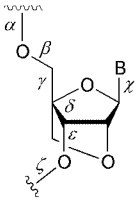

Fig. 1 Structure of LNA; torsion angles are labeled.

NMR solution structures of DNA–LNA[7–9] and RNA–LNA[10] duplexes containing either single or multiple LNA residues in one strand demonstrated the preference of the locked sugar for a C3′-*endo* conformation. Based on these experiments it was concluded that enthalpic (improved stacking) and entropic factors (conformational preorganization) may account for the unprecedented gains in the thermodynamic stabilities of LNA-modified duplexes. In order to examine the detailed conformation of LNA residues and the hydration of the bicyclic sugar moiety, we determined the single crystal structure of the DNA–LNA decamer duplex [GCGTA**T**$^{\mathbf{L}}$ACGC]$_2$ with a single LNA thymine **T**$^{\mathbf{L}}$ at high resolution.

The mixed DNA–LNA decamer was synthesized‡ using phosphoramidite chemistry as previously described[1] and purified to >98%. The modified decamer crystallizes§ in the A-form, the right-handed duplex geometry presumably preferred by an LNA–LNA duplex. The crystallographic model was refined¶ with simulated annealing and force field methods, using an initial orientation from Molecular Replacement.¶ The decamer duplex exhibits an average helical rise of 2.95 Å and the average values for helical twist and inclination are 31.2 and 17.8°, respectively. An overview of the crystal data and refinement parameters is shown in Table 1 and final electron density maps around LNA residues are depicted in Fig. 2.

The sugar conformations of the two locked thymines 6 and 16 are both C3′-*endo* (Fig. 3) and the respective values for the pseudorotation[17] angle *P* are 16.9 and 18.3° (calculated with the program CURVES[18]). All deoxyriboses in the decamer exhibit C3′-*endo* puckers and the average value of their *P* angles (17.9°; excluding the two LNA residues) is very similar to those of the modified thymines. Thus, the bicyclic sugar moieties fit seamlessly into an A-form double helix and the additional restraints appear to lock them in an A-type pucker.

In addition to the sugar–phosphate backbone torsion angle δ that is a characteristic of the ribose conformation (Fig. 1), the five other backbone torsions adopt values that are also consistent with the standard *sc*$^-$, *ap*, *sc*$^+$, *sc*$^+$, *ap*, *sc*$^-$ genus (α to ζ) of A-form double helices. A comparison of the backbone

DOI: 10.1039/b009447l

torsions in the modified thymines with those in the rest of the duplex does not manifest any notable deviations. Therefore the bicyclic modification in LNA is fully compatible with the A-form geometry adopted by both DNA and RNA. Similarly, the glycosidic torsion angles in both LNA residues are in the standard *anti* geometry and no significant changes appear to result from the chemical modification in the local helical parameters, such as slide and x- and y-displacement (Fig. 3).

Our findings here based on X-ray crystallographic data are consistent with those obtained from NMR solution studies of DNA and RNA duplexes with either single or multiple LNA residues in one of the strands.[7–10] According to those experiments, the exceptional thermodynamic stability gains seen with LNA-modified duplexes (both in the DNA and the RNA contexts) are a result of the conformational preorganization of modified single strands for the duplex state (entropic contribution) as well as of the improved stacking both in the single- and double-stranded states (enthalpic contribution).

Unlike 2′-deoxyribose sugars which lack a functionality for hydrogen bond formation at the C2′-position, the locked sugars contain a hydrogen bond acceptor in the form of O2′ (Fig. 1). In the crystal structure both 2′-oxygens are engaged in hydrogen bonds to water molecules (Fig. 3). Extensive hydration of individual hydrogen bond acceptors and donors in oligonucleotides is often accompanied by an increased thermodynamic stability of the corresponding duplexes (see, for example, references 19 and 20). However, it is difficult to draw conclusions as to the role of sugar hydration in the overall stability of LNA-modified DNA duplexes or all-LNA duplexes. The arrangement of water molecules around locked sugars observed here is reminiscent of the solvation in the case of the 2′-oxygen in 2′-*O*-methyl RNA.[21,22] Duplexes of 2′-*O*-methylated oligoribonucleotides exhibit thermodynamic stabilities that are increased by about 1 °C per modified residue relative to RNA. However, the precise contribution of hydration to the stability increase in the case of 2′-*O*-methyl RNA is not understood.

Our study provides a first look at the conformational properties of LNA in a crystal structure at relatively high resolution. The main characteristics of the structure are the standard A-type conformation induced by LNA residues and the capacity of the 2′-oxygen that is part of the bicyclic sugar framework to engage in a least two hydrogen bonds to water molecules. Circular dichroism spectra (CD) of LNA–LNA duplexes in solution indicated that such duplexes appear to adopt a conformation that closely resembles the A-form geometry of RNA–RNA duplexes. However, these spectra also manifested subtle differences between the two species (data not shown). The present analysis of a duplex with only a single LNA residue per strand does not provide any insight into potential conformational differences between LNA and RNA duplexes. Attempts to determine a crystal structure of a completely modified LNA–LNA duplex are underway.

Atoms of the sugar–phosphate backbone are colored green, red and magenta for carbon, oxygen and phosphorus, respectively. Water molecules within hydrogen bonding distance of O2′ atoms from **T**$^{\mathbf{L}}$ residues 6 (left) and 16 (right) are drawn as cyan spheres and hydrogen bonds are drawn as thin solid lines with their lengths indicated.

Notes and references

† Coordinates and structure factors have been deposited in the Protein Data Bank (pdb code 1i5w).

‡ The decamer was synthesized on a 2 μmole scale and the trityl-on strand was purified by RP-HPLC (C4, triethylammonium acetate pH 7–acetonitrile). Following detritylation the unprotected oligonucleotide was HPLC-purified a second time and then desalted.

§ Crystallization conditions were screened with a commercial sparse matrix kit (Nucleic Acid Miniscreen, Hampton Research, Laguna Niguel, CA), using the hanging drop vapor diffusion technique. Crystals suitable for diffraction experiments were obtained under the following conditions: 2 μl of a 2.8 mM decamer solution (single strand) were mixed with 2 μl buffer solution (10% 2-methylpentane-2,4-diol (MPD), 40 mM sodium cacodylate pH 6, 12 mM spermine tetrahydrochloride and 80 mM potassium chloride) and equilibrated against 1 ml of a 35% (v/v) MPD reservoir solution. A crystal was mounted in a nylon loop and shock-frozen in liquid nitrogen. Diffraction data were collected on the insertion device beamline (5-ID) of the DuPont-Northwestern-Dow Collaborative Access Team at the Advanced Photon Source (APS), Argonne National Laboratory (Argonne, IL). A total of 300 frames at high and low resolution ranges were recorded and reflections were integrated and merged in the DENZO/SCALEPACK suite.[11] A summary of amount and quality of the data is given in Table 1.

¶ The structure of the LNA-modified decamer was determined by the Molecular Replacement method using an A-form search model and the program AMORE.[12] The initial model was refined with the program CNS[13] setting aside 10% of the reflections for calculating the free R-factor.[14] Standard bond lengths and angles constraints[15] were employed for the DNA portion of the model and the geometric parameters for LNA residues were calculated with the program CHEM3D (CambridgeSoft Corporation, Cambridge, MA). The individual duplex models and the resulting Fourier electron density maps were visualized with the program TURBO-FRODO[16] on Silicon Graphics computers. Final refinement parameters and average root mean square (r.m.s.) deviations for bonds and angles from standard values are listed in Table 1. CCDC 156032.

Received (in Cambridge, UK) 3rd January 2001, Accepted 28th February 2001
First published as an Advance Article on the web 16th March 2001

A novel disodium 1,2-ethanediol bis(hydrogen sulfate) salt precursor-based solid acid catalyst is demonstrated to have significantly enhanced activity and high selectivity in producing methyl isobutyl ether (MIBE) or isobutene from a methanol–isobutanol mixture.

Methanol and isobutanol are the predominant products formed from CO/H_2 synthesis gas over alkali-promoted Cu/ZnO-based (low temperature) catalysts[1,2] and copper-free (high temperature) catalysts.[3,4] Since the two alcohols are produced together, their direct coupling to synthesize ethers for a number of applications is of interest. One such ether is the unsymmetrical methyl isobutyl ether (MIBE) which has desirable characteristics as a fuel additive (cetane number = 53),[5] and thus, can be employed as an additive to or as a neat fuel to substitute for current diesel fuels.[6,7] MIBE from direct coupling of methanol–isobutanol [eqn. (1)] was investigated over a number of solid acid catalysts.[8]

$$(CH_3)_2CHCH_2OH + CH_3OH \rightarrow (CH_3)_2CHCH_2OCH_3 + H_2O \quad (1)$$

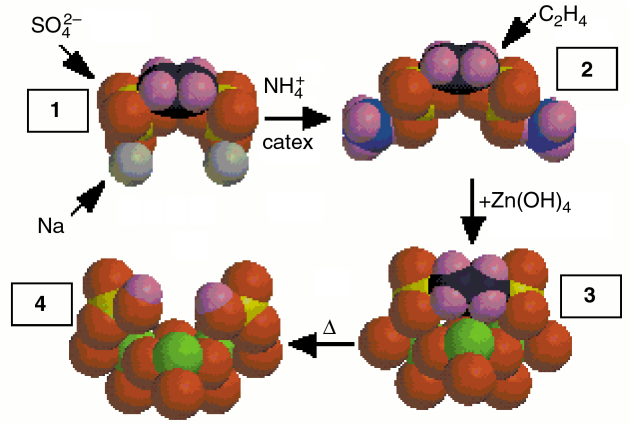
Improvement of yields, particularly over inorganic oxides, was found to be desirable. Furthermore, if new catalysts were found for selectively converting isobutanol to isobutene, eqn. (2),

$$(CH_3)_2CHCH_2OH \rightarrow (CH_3)_2C{=}CH_2 + H_2O \quad (2)$$

a chemical route to isobutene from natural gas or coal-derived synthesis gas would be provided.[5] Such a process would alleviate isobutene dependence on petroleum feedstock. Kinetic analyses,[8b,9] together with theoretical calculations,[10] suggest that the mechanism of reaction 1 is the S_N2 pathway involving competitive adsorption of reactants on proximal dual Brønsted acid sites on the catalyst surface, while that of process 2 has been proposed to be an E2 reaction.[8] Reactions 1 and 2 are a specific implementation of a general class of dehydrocondensations and dehydrations occurring in a mixture of a light alcohol and a heavier C_2-branched primary alcohol.

In the present work, we studied a novel heterogeneous catalyst derived from a $(HO)_3Zr–O_3SOCH_2CH_2OSO_3–Zr(OH)_3$ precursor which gave rise to proximal strong surface acid functionalities $(HOSO_2O–Zr–O–)_2$, as prompted by the requirement to activate the two alcohols.[8,10] High resolution X-ray photoelectron, near-infrared, and ^{13}C magic angle spinning nuclear magnetic resonance spectra confirmed the composition, structure and physicochemical properties of the catalyst. The results show that the 1,2-ethanediol bis(hydrogen sulfate) moiety was successfully grafted onto the surface of zirconium hydroxide, as will be reported elsewhere in detail.[11] The main features of the preparation sequence are presented in Scheme 1.

Here, the disodium 1,2-ethanediol bis(hydrogen sulfate) salt precursor $(NaOSO_3CH_2)_2$ **1** was converted to the ammonium form $(NH_4OSO_3CH_2)_2$ **2** by exchange over a catex column, an aqueous solution of compound **2** was combined with a zirconium hydroxide suspension to form the derivative $(–O_xZr–OSO_3CH_2)_2$ **3**, which was calcined in air at 773 K to remove the $–(CH_2CH_2)–$ residues, resulting in the surface-derivatized



Scheme 1 Atom colour codes are as follows: C, black; H, pink; O, red; S, yellow; N, blue, Zr, green; Na, gray.

species $(–O_xZr–OSO_3H)_2$ **4** with proximal acid sites. Upon calcination, this catalyst exhibited a surface sulfate-to-zirconium surface mol ratio of 0.84, corresponding to 0.72 mmol surface S/g catalyst, and all its carbon was removed. Thus the final composition corresponds to the formula $(HSO_4)_{0.84}$-$ZrO_{2,surf}$ on the surface of pure zirconia. This material simultaneously possessed a high thermal stability.

The dehydration of methanol–isobutanol (2-methyl-1-propanol, 99.9+%, Alfa) was investigated in a downflow stainless steel tubular reactor with controls of temperature (398–508 K), total pressure ($101.3–3.1 \times 10^3$ kPa, 1 atm = 101.325 kPa) and Bu^iOH/MeOH molar ratio (0/100–50/50) in a carrier gas of 5% N_2 diluted in He. Steady state activities were achieved within 2 h of initiation of alcohol injection or after altering a reaction variable such as temperature or pressure. Testing of the $(HO)_3Zr–O_3SOCH_2CH_2OSO_3–Zr(OH)_3$-derived catalyst under each condition was carried out for 8–12 h. No catalyst deactivation was observed over several hundred hours of testing.

At 448 K, the MIBE yield was 0.087 mol/kg cat/h (Table 1), which represented an enhancement of 78% compared with 0.049 mol/kg cat/h over previously reported SO_4^{2-}/ZrO_2,[9] and

Table 1 Product space time yields (mol/kg cat/h) in the reaction of MeOH/Bu^iOH (8.97 : 8.97 kPa) at 3.44 mol/kg cat/h alcohols, 16 mol/kg cat/h carrier gas and 101.3 kPa total pressure over $(HO)_3Zr–O_3SOCH_2CH_2OSO_3–Zr(OH)_3$-derived catalyst

of 200% compared with H-montmorillonite catalyst.[9] The isobutene yield of 1.43 mol/kg cat/h, also at 448 K, represented an increase of 11 and ~280% over the SO_4^{2-}/ZrO_2 and H-montmorillonite catalysts, respectively.[9] Other products involved dimethyl ether (DME) and traces of di-isobutyl ether (DIBE), di-*tert*-butyl ether (DTBE), methyl *tert*-butyl ether (MTBE) and octenes.

Table 2 demonstrates that MIBE yields increased, whereas isobutene yields decreased, with total alcohol pressure increasing from 7.8 to 240.7 kPa. For example, 0.156 mol/kg cat/h MIBE at 7.8 kPa kept increasing with pressure to 0.702 mol/kg at 240.7 kPa, while isobutene at 7.8 kPa (3.525 mol/kg cat/h) exhibited a decreasing trend to 0.335 mol/kg cat/h at 240.7 kPa. The data in Table 2 are consistent with the Langmuir–Hinshelwood kinetic laws,[8b] $v_{MIBE} = k_4K_Mp_MK_Bp_B/(1 + K_Mp_M + K_Bp_B)^2$ and $v_{Isobutene} = k_3K_Bp_B/(1 + K_Bp_B + K_Mp_M)^2$, which were derived on the basis of the reactions (1) and (2) occurring on the dual acid sites.[8b] The values of constants fitting the data of Table 2 were k_3 = 33.1 mol/kg cat/h, k_4 = 3.2 mol/kg cat/h, K_M = 0.035 kPa^{-1} and K_B = 0.086 kPa^{-1}.

Here, the ratio K_B/K_M = 2.46 shows that isobutanol adsorbed preferentially on the acid sites, agreeing with its greater basicity over methanol.[8b,12] When the partial pressure of isobutanol was increased in the range of 0–1.6 kPa while maintaining the partial pressure of methanol constant at 8.97 mPa, the MIBE space time yield increased from zero to 0.057 mol/kg cat/h, while the DME decreased from 0.040 mol/kg cat/h to zero. This distribution of DME and MIBE can be reasonably explained by kinetics previously observed on other catalysts,[8b] with $K_B > K_M$. The experimental data also show increasing yields of isobutene with increased molar ratio of Bu^{i}OH/MeOH. In addition, the enhancement of selectivity toward isobutene from 0% at 398 K to 94% at 448 K (Table 1) results from the increase of K_B/K_M with increasing temperature. The isobutanol dehydration to isobutene competed with MeOH/Bu^{i}OH coupling to MIBE. At relatively high temperatures, a large ratio of K_B/K_M resulted in an enhancement of the $\theta_{Bu^iOH}/\theta_{MeOH}$ ratio (θ, surface coverage), and favored the dehydration of the adsorbed isobutanol to isobutene [eqn. (2)]. The apparent activation energy for the formation of each product was determined from Arrhenius plots, yielding 22 kcal mol^{-1} for MIBE and 24 kcal mol^{-1} for isobutene. The activation energy of 19 kcal mol^{-1} for DME was obtained by theoretical calculations.[10]

The kinetic behavior of eqn. (1) showed that isobutanol partial pressure (p_B) promoted the MeOH/Bu^{i}OH coupling to MIBE, whereas the kinetic behavior of eqn. (2) indicated that increasing isobutanol pressure (p_B) very strongly suppressed its dehydration, and the kinetic order became negative at high p_B.[9] At low alcohol partial pressures, high selectivity of isobutene is ascribed to a significant fraction of unoccupied acid sites on the surface of the $(HSO_4)_2–2ZrO_2$ catalyst. These free acid sites are considered to promote the dehydration of adsorbed isobutanol to isobutene according to the dual site elimination mechanism of eqn. (2), whereby one site adsorbs the reacting alcohol and the second site is an acceptor for the product water.[8b,9] At high alcohol partial pressures, the fraction of acid sites occupied by alcohol molecules approaches unity, and the catalyst favors MIBE formation. The ratio of MIBE/isobutene increased with increasing alcohol pressure even at constant p_B/p_M. Moreover, the effect of pressure was found to be reversible, *i.e.* when alcohol pressure was decreased to its original value, isobutene production increased and MIBE decreased to their original rates.

The butene formed over the present $(HSO_4)_{0.84}–ZrO_{2,surf}$ catalyst was pure isobutene, whereas over other catalysts such as H-montmorillonite and H-ZSM-5, products involved isobutene, significant amounts of *n*-butene, and *cis*- and *trans*-2-butene. The highly concentrated Brønsted acid sites on this catalyst effectively catalyzed removal of OH from the alcoholic carbon and of H from the neighboring carbon, and resulted in isobutene formation. On the other hand, the single Brønsted acid site on the surface of other catalysts was associated with carbenium ion chemistry,[13] which leads to butene rearrangement in isobutanol dehydration.[13,14]

In conclusion, the novel heterogeneous catalyst derived from the $(HO)_3Zr–O_3SOCH_2CH_2OSO_3–Zr(OH)_3$ precursor effectively catalyzes MIBE formation at high pressures and favored isobutene production at low pressures.

Financial support from the US Department of Energy (DE-FG26-98FT40113-1) is appreciated. Special thanks go to Dr A. C. Miller at Lehigh University for the HR-XPS analyses.

First published as an Advance Article on the web 16th March 2001

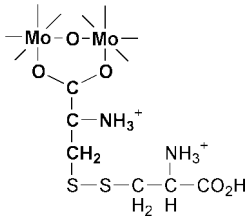
The reaction of an aqueous solution of sodium molybdate with cysteine hydrochloride acting as educt and reducing agent at rather low pH values (≈ 1.5) results in the formation of $Na_3[Mo_{154}O_{462}H_{14}(H_2O)_{48}(HO_2C–(NH_3^+)HC–CH_2–S–S–CH_2–CH(NH_3^+)–COO^-)_{11}]\cdot x\ H_2O$ 1 ($x \approx 250$) containing nanosized ring-shaped clusters which capture the oxidation product of cysteine, *i.e.* the diprotonated cystine ligands (H_2cystine$^+$) at the inner wall of their cavities; interestingly, the multiphilic ligands containing different types of functional groups (two $–NH_3^+$, one $–CO_2^-$, one $–CO_2H$ and one –S–S–) attach to the inner wall of the cluster through one of the two carboxylate groups thereby demonstrating the possibility to generate novel type surfaces within the cavity of a nanostructured ring-shaped cluster.

The design of multifunctional and especially of well ordered micro- and meso-porous materials which can incorporate guest molecules is a challenging task of modern chemistry.[1–3] Guests which may be reversibly and specifically bound at different appropriate sites of the host are of special interest. In particular this type of interaction may be significant for the synthesis of specially designed porous materials and may play a key role in catalysis and especially in separation methods. Polyoxometalates, formed by self-assembly processes are ideal systems in this respect as they can form crystalline materials with well-defined cavities and pores.[4]

Our recent interests in this field include the design of cavities within networks built up by giant wheel type species which can be opened and closed again as required.[5,6] Here we report a novel compound, in which cystine ligands (H_2cystine$^+$) are coordinated at the inner wall of a relevant nanosized car-tire shaped cluster anion.

If an aqueous acidified solution of Na_2MoO_4 is reduced with cysteine at *ca.* 55 °C, blue crystals of **1** precipitate after 1–2 days.† Compound **1** was characterized by elemental analysis‡ (including cerimetric titration to determine the formal number of Mo^V centers), thermogravimetry (for the determination of the crystal water content), bond valence sum (BVS) calculations[7] (to determine the positions of the H_2O ligands and to distinguish between Mo^{VI} and Mo^V centers), spectroscopic methods (IR, resonance-Raman, UV–VIS, XANES)§ and finally by single crystal X-ray structure analysis.¶ For the synthesis of **1**, cysteine acts as reducing agent at rather low pH values (≈ 1.5) resulting in the formation of the mixed-valent $\{Mo_{154}\}$ type cluster with 28 Mo^V centers (formal consideration) while the protonated form of the oxidized product, *i.e.* cystine, gets coordinated to the inner surface of the giant cluster through one of its carboxylate ends (Scheme 1).

The single crystal X-ray structure of **1** revealed the tetradecameric ring-shaped structure (Fig. 1) of the anion **1a** of **1**, which can be compared to that of the related parent host anion **2a**[5e] by substituting $2 \times 11 = 22$ H_2O ligands with 11 cystine (H_2cystine$^+$, see Scheme 1). According to the related building-block principle, **1a** and **2a** can be formulated generally as $[\{Mo_2\}_{14}\{Mo_8\}_{14}\{Mo_1\}_{14}]$ or specifically as $[\{(O)_2{=}Mo^{VI}(\mu\text{-}O)L_iMo^{VI}{=}(O)_2\}_{14}\{Mo^{VI/V}_8O_{26}(\mu_3\text{-}O)_2H(H_2O)_3\text{-}Mo^{VI/V}\}^{3-}_{14}]^{3-}$ **1a** and $[\{(O)_2{=}Mo^{VI}(H_2O)(\mu\text{-}O)(H_2O)Mo^{VI}{=}(O)_2\}^{2+}_{14}\{Mo^{VI/V}_8O_{26}(\mu_3\text{-}O)_2H(H_2O)_3Mo^{VI/V}\}^{3-}_{14}]^{14-}$ **2a** (ΣL_i = 11 μ-$HO_2C–(NH_3^+)HC–CH_2–S–S–CH_2–CH(NH_3^+)–CO_2^-$ + 6 H_2O).



Scheme 1 Atoms found in the crystal structure shown in bold.

While the basic $\{Mo_8\}$ and $\{Mo_1\}$ units are identical in both clusters, this is not the case for all of the $\{Mo_2\}$ groups because of the substitution of some H_2O ligands. The complete structure of the cystine ligands is—as expected—not found in the crystal structure due to the related high degree of disorder of the long chains which show an extreme flexibility and are attached to the inner wall through one of the two 'carboxylate ends'.‖ However, the experimental results of numerous carbon, hydrogen, nitrogen and sulfur analyses‡ together with spectroscopic data establish the fact that the cystine ligands are intact. The

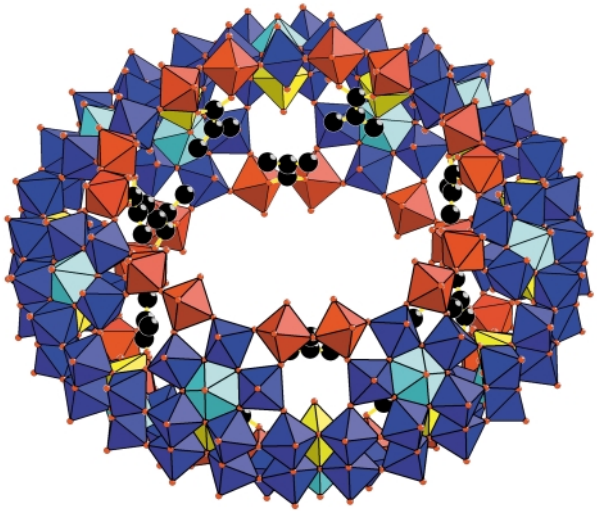


Fig. 1 Inclined view into the giant wheel type cluster anion **1a** in crystals of **1** in polyhedral (polyoxomolybdate part) and partly in ball-and-stick representation ($\{Mo_2\}$: red; $\{Mo_8\}$: blue (central pentagonal bipyramids: cyan); $\{Mo_1\}$: yellow; oxygen: small red circles; carbon and (disordered) nitrogen: enlarged black circles).

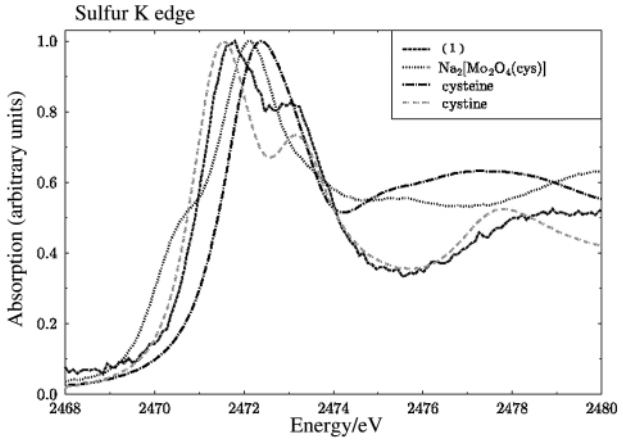

Fig. 2 S K-edge XANES spectra.

abundance of coordinated H_2cystine$^+$ is mainly supported by the IR and XANES spectral studies. In particular, a comparison of the S K-edge spectra of **1** (Fig. 2) and authentic cystine with those of cysteine and a cysteine molybdenum complex provides clear support for the presence of the former ligands. The absorptions at *ca.* 2472 eV are assigned to excitations of S 1s electrons to the first unoccupied electronic states of either the complexes or the free ligands. In the case of the complexes there are also unoccupied states centered on the molybdenum–oxygen part, but these are spatially significantly separated. Therefore, only ligand-internal transitions exhibit higher probabilities. The patterns for cystine and cysteine however, free or complexed, differ characteristically. The IR spectrum proves the abundance of cystinium cations which is indicated by the presence of a medium intensity band at 1495 cm^{-1} assigned to the $\delta(NH_3^+)$ mode of the cation as well as by the characteristic ν(C=O) band at 1730 cm^{-1} of the $-CO_2H$ group.[8] The diprotonation of the cystine ligands is supported by the experimental results of Na analyses since each replacement of a H_2O ligand by H_2cystine$^+$ reduces the negative charge of the original cluster **2a** by one unit. (However, the presence of one monoprotonated instead of diprotonated cystine in connection with four instead of three (highly disordered) Na^+ cations could not be excluded.) The resulting low charge is consistent with the very low solubility of **1**.

The 11 H_2cystine$^+$ ligands, coordinated to $\{Mo_2\}$ units through their carboxylate functions, are located quite disordered near the inner wall of the cavity (Fig. 1). Such a situation is also suggested by molecular modelling using the MM+ force field approach.** When all positions known from the crystal structure determination are kept fixed the remaining energy hypersurface turns out to be rather flat.

To summarize the interesting aspects: it is possible to place molecules at the inner wall of the cavity of a giant metal–oxide based wheel type cluster by replacing H_2O ligands. With the use of ambiphilic and/or multiphilic ligands, new characteristic surface structures inside the cavity can be generated. This process, which has been employed here with the cystine attached to the inner wall, creates an interesting type of (inner) surface with $-NH_3^+$, $-CO_2H$ and $-S-S-$ functions, which we are currently attempting to construct. This type of research work has special relevance for the construction of novel silica hybride materials containing these types of clusters.

† To an aqueous solution (35 mL) of $Na_2MoO_4 \cdot 2H_2O$ (3.0 g, 12.4 mmol) and hydrochloric acid (25 mL, 1.1 M) in a 100 mL Erlenmeyer flask, L-cysteine hydrochloride monohydrate (0.41 g, 2.3 mmol) was added and the reaction medium was stirred for 5 min at room temperature. The yellow color, which developed immediately after addition of cysteine, changed to bright green within 2–3 min and after a further 5 min to blue–grey. The suspension was subsequently heated in an oil bath at 55 °C under constant stirring for 2 h (flask covered with a watch glass) resulting in a dark blue solution which was kept at 20 °C for another 2 h. The amorphous blue material, separated after this time, was filtered off and the blue filtrate was kept at room temperature for 2 d in a 100 mL Erlenmeyer flask at 15–20 °C (note: the storing temperature should not exceed 20 °C). The precipitated blue crystals were filtered from the mother-liquor, washed with cold water and dried at room temperature. Yield: 0.9 g (≈ 37% based on Mo).

First published as an Advance Article on the web 19th March 2001

A novel and fundamental reaction system of matter following a type of 'supramolecular Darwinism' leads to the formation of giant spherical nano-sized cluster capsules as kinetically controlled destination having the highest possible symmetry (I_h) and formed directly from the decomposition products of the well known but less symmetrical Keggin anions (T_d) in aqueous medium in the presence of Fe^{III}– acting as a type of environmental influence–under conditions where Keggin anions are known to be extremely stable; remarkably the remaining non-decomposed Keggin anions finally get (non-covalently) encapsulated protected by the formed spherical capsules of the new supramolecular compound $[PMo_{12}O_{40} \subset \{(Mo^{VI})Mo^{VI}_5\}_{12}\ Fe^{III}_{30}O_{252}(H_2O)_{102}(MeCO_2)_{15}]\cdot xH_2O$ 1 ≡ 1a $\cdot xH_2O$ ($x \approx 120$).

The fact that self-assembly processes–based on simple (mainly highly symmetrical) building blocks or preorganized units–preferentially lead to higher symmetrical reaction products is an interesting phenomenon, *e.g.* in cluster chemistry which has not been explored in detail until now. Examples are the well known Keggin type anions, like $[PMo_{12}O_{40}]^{3-}$ (T_d) formed from molybdate and phosphate, models for the Fe_4S_4 type ferredoxin, like $[Fe_4S_4(SH)_4]^{2-}$ (T_d), the molybdenum-oxide-based giant wheels ($\approx D_{7d}$) as well as spheres (I_h). Therefore, the question arises as to why highest (possible) symmetrical species are the targets, and furthermore, whether we can elucidate this phenomenon or solve the problem by means of a model reaction system. In a novel fundamental type of reaction, which can be related to a type of '*Supramolecular Darwinism*' (see below), it can be shown that tetrahedral Keggin anions 'lose–at least partly–the competition' with higher symmetrical, *i.e.* icosahedral capsule type species as kinetic target in aqueous solution even under conditions where they are quantitatively formed. The formation of the latter occurs at the expense of the former.

In the presence of Fe^{III} ($FeCl_3\cdot 6H_2O$), *i.e.* formally in a kind of 'environmental attack', the Keggin anions[1] decompose in solution with the formation of the pentagonal $\{(Mo^{VI})Mo^{VI}_5O_{21}\}$ type building blocks which get linked by $\{Fe^{III}(H_2O)_2\}^{3+}$ groups. This leads finally to the formation of novel composites consisting of discrete icosahedral nanocluster capsules with the encapsulated Keggin anions $[PMo_{12}O_{40}]^{3-}$, which are abundant in the new compound $[PMo_{12}O_{40} \subset \{(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}O_{252}(H_2O)_{102}(MeCO_2)_{15}]\cdot xH_2O$ **1** ≡ **1a**$\cdot xH_2O$ ($x \approx 120$).† Upon drying, **1** shows a fast solid-state reaction with the consequence that the composites **1a** get covalently linked leading to the formation of $\{PMo_{12}O_{40} \subset H_4[(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}O_{254}(H_2O)_{98}(MeCO_2)_{15}]\cdot xH_2O$ **2** ≡ **2a**$\cdot xH_2O$ ($x \approx 60$), see refs. 2–4. This condensation process is only important in the present context as the relevant dry (!) product can be more easily structurally characterized compared to **1**. Using Fe^{II} instead of Fe^{III} the related compounds $[H_yPMo_{12}O_{40} \subset \{(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}O_{252}(H_2O)_{102}(MeCO_2)_{15}]\cdot xH_2O$ **3** ≡ **3a** $\cdot xH_2O$ ($x \approx 120$) and $\{H_yPMo_{12}O_{40} \subset H_4\{(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}O_{254}(H_2O)_{98}(MeCO_2)_{15}\}\cdot xH_2O$ **4** ≡ **4a**$\cdot xH_2O$ ($x \approx 60$) are obtained which contain the one- or two-electron reduced Keggin anions $[H_yPMo_{12}O_{40}]^{3-}$.‡ Compound **4** can be obtained not only by the present new fundamental type of reaction but also in a facile synthesis starting from the simple ingredients phosphate, molybdate, acetate, and Fe^{II}.[2]

Compound **2** with the cross-linked composites having core–shell topology and partly also **1**, *i.e.* the 'corresponding' non-dried crystals, were characterized by elemental analyses, thermogravimetry (to determine the crystal water content), single-crystal X-ray structure analysis§ [including the calculation of bond valence sums in order to distinguish between (terminal) O and OH_2 ligands] and spectroscopic methods (IR, Raman, UV–VIS, NIR) as well as magnetic measurements.¶ Whereas the complete structural characterization of **4**, obtained with another reaction, has already been reported (see ref. 2), the corresponding non-dried new compound **3** was characterized, like **1**, spectroscopically and by its crystal data (see below).‖ Compounds **1** and **3** with discrete cluster units (space group $P2_1/n$) as well as **2** and **4** with their corresponding layer structures (space group *Cmca*) are isostructural and have, as expected, practically the same unit cell dimensions. The crystal structures of **2** and **4** show the icosahedral capsule/nucleus type composites, abundant in **1** and **3,** cross-linked to 2D type assemblies *via* the formation of four Fe^{III}–O–Fe^{III} bonds per unit (see footnote ‖). Whereas the capsules of **1** and **2** have, as mentioned above, non-covalently bonded classical non-reduced Keggin anions $[PMo_{12}O_{40}]^{3-}$ (Fig. 1) those of **3** and **4** have the reduced Keggin anions $[H_yPMo_{12}O_{40}]^{3-}$ encapsulated. The acetate ligands, which are highly disordered, are located inside the spheres and coordinate as bidentate ligands bridging Mo and Fe sites. As the non-dried compounds **1** and **3** with the discrete cluster composites and different electron populations have, as expected, the same space group and practically the same unit cell dimensions as the compound $[\{(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}O_{252}(MeCO_2)_{10}\{Mo_2O_7(H_2O)\}\{H_2Mo_2O_8(H_2O)\}_3(H_2O)_{91}]\cdot xH_2O$ **5** ($x \approx 140$) containing the same $\{(Mo)Mo_5O_{21}\}_{12}Fe_{30}$ cluster capsules without Keggin ions, and for which the complete single crystal X-ray analysis has been performed,[8] **1** and **3** can easily be identified from the relevant crystal data.§ (Note that in the present case the non-dried crystals of **1** and **3** do not diffract sufficiently.)

The important result of this investigation is that the Keggin ions are not stable in the presence of Fe^{III} (or Fe^{II} and air) as they decompose, while $\{(Mo^{VI})Mo^{VI}_5O_{21}\}$ type pentagons are formed which are subsequently linked by $\{Fe^{III}(H_2O)_2\}^{3+}$ groups. The remarkable fact is that the remaining non-decomposed Keggin ions (reduced or not reduced) appear in the reaction product encapsulated. Interestingly, the Keggin ions even seem to accelerate the formation of their cage around them as templates. This models the observation that assembly processes of simple linkable units lead preferably to highly symmetrical species. The process can be correlated with a general symmetry formalism or symmetry-evolution principle for a quasi isolated (!) system; in this respect, the second law of thermodynamics and the symmetry-evolution principle are isomorphic (see ref. 6). The degree of symmetry cannot decrease as the system evolves, but either remains constant or

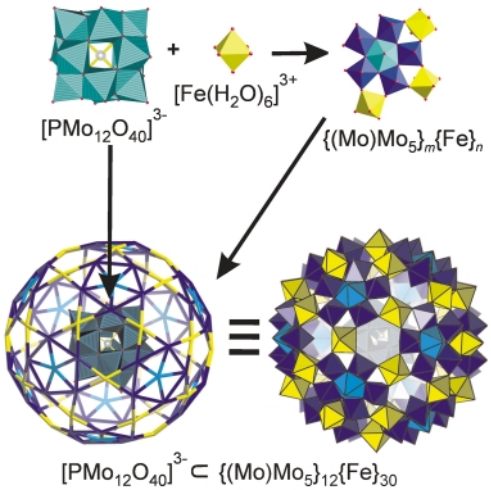

Fig. 1 Reaction scheme showing the decomposition of a part of the Keggin anions (top left, polyhedral representation) in the presence of Fe^{III} forming thereby fragments of the type $\{(Mo)Mo_5\}_m\{Fe\}_n$ which function as building blocks (top right, polyhedral representation) and leading finally to the formation of the $\{(Mo)Mo_5\}_{12}\{Fe\}_{30}$ type cage (bottom left with wire-frame representation of the capsule's metal atoms in blue and yellow (Fe part), and bottom right with polyhedral representation of the capsule), which subsequently encapsulates the remaining non-decomposed Keggin anions (polyhedral representation) to form the supramolecular species with core-shell topology: guest ⊂ (pentagon)$_{12}$(linker)$_{30}$ ≡ $[PMo_{12}O_{40}\subset\{(Mo)Mo_5O_{21}\}_{12}Fe_{30}(H_2O)_{102}(MeCO_2)_{15}]$ (colour code $MoO_{6/7}$ polyhedra: blue/turquoise, FeO_6 octahedra: yellow).

increases. (The effect is at least as symmetric as the cause.) This corresponds to the fact that causal relations exist between states of cause subsystems and states of effect subsystems, while states of the subsystems are determined by the states of the whole system. In other words, equivalent initial states must evolve into equivalent final states (see also ref. 5).

To express the related general aspect: two competing molecular systems model a type of '*Supramolecular Darwinism*' principle.** Spherical shell type molecules with highest possible (icosahedral) symmetry are for symmetry reasons the kinetically controlled destination and best adapted to the environment.

Notes and references

† *Syntheses*: **1**: to an aqueous solution (60 mL) of $H_3[PMo_{12}O_{40}]\cdot xH_2O$ (4.0 g, 2.2 mmol), $MeCO_2H$ (15 mL, 100%) and $FeCl_3\cdot 6H_2O$ (2.5 g, 9.2 mmol) 20 mL of NaOH solution (1 M) was added. The resulting clear brownish solution was kept in an open beaker for one week at 20 °C. Yellow plates of **1** precipitated during this time.

2: The wet crystals of **1** were filtered off, washed with water and kept at room temp. The condensation reaction was complete after *ca*. 1 h. Yield: 1.0 g (17.5% based on the starting Keggin type compound). (Note: single crystals suitable for X-ray structure analysis were obtained under more dilute conditions.)

3: To an aqueous solution (25 mL) of $H_3[PMo_{12}O_{40}]\cdot xH_2O$ (5.0 g, 2.7 mmol) and $MeCO_2H$ (10 mL, 100%), $FeCl_2\cdot 4H_2O$ (1.0 g, 5 mmol) was added (colour change to blue–green). 15 mL of NaOH solution (1 M) was subsequently added and the resulting clear solution was kept in an open flask for 2 weeks at 20 °C while greenish plates precipitated.

4: The wet crystals of **3** were filtered off, washed with water and kept at room temp. for the solid-state condensation reaction. Yield: 0.25 g (3.5% based on the starting Keggin type compound).

‡ For **3** or **4** it is difficult to distinguish between a one- and two-electron reduced system (even to position the electrons) which is mainly due to the presence of a large number (12 + 102) of metal atoms in connection with apparent analytical problems and due to disorder phenomena.

§ *Unit cell parameters for* **1**: monoclinic, space group $P2_1/n$, a = 26.548(4), b = 34.737(9), c = 28.910(4) Å, β = 97.194 (3)°, U = 26 452 (30) Å^3.

Crystal data for **2**: $C_{30}H_{365}Fe_{30}Mo_{84}O_{482}P$, M = 18 205.65, orthorhombic, space group *Cmca*, a = 36.847(1), b = 34.936(1), c = 34.859(1) Å, U = 44 874(3) Å^3 , Z = 4, D_c = 2.695 g cm^{-3}, μ = 3.328 mm^{-1}, F(000) = 34 896, crystal size = 0.22 × 0.12 × 0.02 mm. Dry crystals of **2** were measured at 183(2) K on a Bruker AXS SMART diffractometer (Mo-Kα, graphite monochromator). A total of 113 792 (1.71 < θ < 25.0°) reflections were collected of which 20 083 unique reflections (R_{int} = 0.155) were used. The structure was solved using the program SHELXS-97 and refined using the program SHELXL-97 to R = 0.073 for 10 583 reflections with $I > 2\sigma(I)$. Several crystal water molecules could not be located due to their disorder. For the encapsulated Keggin ion only the central P atom and (partly disordered) Mo atoms (but not the O atoms because of the disorder) could be detected for which the occupancy factors, however, add up to 12. These data together with the analysis, vibrational spectrum and the employed pH support the presence of a complete Keggin anion rather than a lacunary type one. Due to the disorder and related basic analytical problems in connection with the error limit of the number of acetate ligands, differently protonated Keggin ions cannot be completely excluded. CCDC 153129. See http://www.rsc.org/suppdata/cc/b0/b009518b/ for crystallographic data in .cif or other electronic format.

Unit cell parameters for **3**: monoclinic, space group $P2_1/n$, a = 26.388(8), b = 34.698(3), c = 28.852(1) Å, β = 96.958(4)°; U = 26 224(36) Å^3.

¶ *Selected physical and spectroscopic data* for **2**: IR (KBr pellet) (ν/cm^{-1}): 1618m {δ(H_2O)}, 1535m {$\nu_{as}(CO_2)$}, 1422m {$\nu_s(CO_2)$}, 1068w {ν_{as}(PO)}, 960m {ν(Mo=O)}, 775s, 623s, 567m, 433w. Raman (KBr dilution, λ_e = 1064 nm) (ν/cm^{-1}): 950s {ν(Mo=O)}, 836w, 512w, 371w, 241w. UV–VIS (solid state reflectance spectrum) λ_{max}/nm: *ca*. 285 (sh), *ca*. 370 (br). The magnetic susceptibility data are identical to those of **4** (see ref. 2).

‖ The crystals have to be taken from the corresponding mother-liquors and immediately investigated, because **2** and **4** with the characteristic layer structures are formed very fast even at room temperature due to a classical inorganic condensation process (see refs. 3 and 4). In the present case this corresponds to the following process (in schematic representation) which

$$\underset{\mathbf{A}}{-Fe^{III}(OH_2) + (H_2O)Fe^{III}-} \xrightarrow{-H^+} \underset{\mathbf{B}}{-Fe^{III}(OH) + (H_2O)Fe^{III}-} \xrightarrow{-H^+/-H_2O} \underset{\mathbf{C}}{-Fe^{III}-O-Fe^{III}-}$$

takes place after the capsules come closer together due to partial loss of crystal water. The related steps can be observed easily through the shrinking of the unit cell volumes. **A** denotes here the discrete composites and **C** the final product. Under the present mild conditions the content of each capsule remains of course unchanged.

** The term Darwinism is not only used in the literature in the sense of Darwin's *The Origin of Species by Means of Natural Selection*, but also for non-biological systems under (dissipative) stationary non-equilibrium conditions: (H. Haken uses it in his synergetics approach: H. Haken, *Synergetics*, Springer, Berlin, 1983; see especially: H. Haken, *Erfolgsgeheimnisse der Natur—Synergetik: Die Lehre vom Zusammenwirken*, Rowohlt, Reinbek, Hamburg, 1995, pp. 91, 94, 289 and H. Haken and A. Wunderlin, *Die Selbststrukturierung der Materie*, Vieweg, Braunschweig, 1991, p. 448 and additionally E. Ben-Jakob and H. Levine, *Nature*, 2001, **409**, 985 ['Pattening *via* competition']). In classical chemical reactions in general, a 'competition' between (molecular) species can be addressed. However, this is hardly detectable, in contrast to the present case where the different (kinetic) stabilities of two species can easily be referred to / explained by their different symmetry.

Received (in Cambridge, UK) 5th December 2000, Accepted 26th February 2001
First published as an Advance Article on the web 19th March 2001

Current-density maps for kekulene 1 computed using an *ab initio* all-electron distributed-origin method show global diamagnetic and paramagnetic circulations around outer and inner perimeters ('rim' and 'hub'), subsuming six local benzenoid diamagnetic π circulations, in qualitative agreement with the Hückel–London π model, but in contradiction of an [18]-in-[30] concentric-annulene description of 1.

Even before its synthesis in 1978 the cyclic polyacene kekulene (**1**, $C_{48}H_{24}$),[1] which consists of twelve annelated benzene rings, was already a subject of debate. Qualitative considerations suggest that **1** may be represented either as a D_{6h} Clar structure containing six benzenoid sextets[2] (**1a**) or an [18]annulene-within-a-[30]annulene corresponding to superposition of two D_{3h} Kekulé resonance structures (**1b**, Fig. 1). The proposal[3] that circularly conjugated **1** possesses superaromaticity, *i.e.* enhanced stabilisation energy, led to controversy[4] resolved by a recent *ab initio* study.[5] A comparison of the computed geometric, energetic and magnetic properties[6] of **1** with those of anthracene, phenanthrene, 1,2:7,8-dibenzanthracene and [18]annulene, showed no enhanced stabilisation energy, diamagnetic exaltation or magnetic anisotropy, all as would be expected from the qualitative graph theoretical analysis,[4] indicating that **1** is not superaromatic, and is realistically described by the D_{6h} structure **1a**.[5] These conclusions are compatible with the single-crystal X-ray structure of **1**. They also match the ^{1}H NMR data: the downfield-shifted $\delta(^1H)$ of the inner protons [H(3); 10.45/10.47][7] differs markedly from that of the corresponding protons in [18]annulene (−3.0[8]), as expected from the positive (paramagnetic; 5.0[5]) and negative (diamagnetic; −13.4[5]) NICS[6] values calculated for the geometric centres of **1** and [18]annulene, respectively (**III**, Fig. 1).

In a recent paper[9] the general picture of the 'annulene-within-an-annulene' model[10] for planar coronene (**2**, $C_{24}H_{12}$) and bowl-shaped corannulene (**3**, $C_{20}H_{10}$) was rejected on the basis of direct computation using *ab initio* all-electron distributed-origin methods and mapping of the current densities induced by a uniform magnetic field.† For **2** and **3**, two strong counter-rotating ring currents, a diamagnetic (anti-clockwise) and paramagnetic (clockwise) circulation around the rim and hub, respectively, were found.

To address the question of the electronic structure of kekulene **1**, *ab initio* all-electron current-density maps were calculated using the same distributed-origin methods.† Here we report the results, which support the Clar and Hückel pictures (*cf.* **1a**, Fig. 1).

The geometry of **1** was optimised using the 6-31G** basis set;[11] the planar, structure of **1** [D_{6h} symmetry (**1a**)] agrees with single-crystal X-ray data (Table 1).[3,5,7]

Fig. 2 shows the computed current-density maps† of **1a** for (a) the σ, (b) π and (c) total (σ + π) electrons at $1a_0$ above the molecular plane. The σ map demonstrates the characteristic superposition of diamagnetic circulations centred on σ bonds, giving rise to a cumulative net central paramagnetic circulation within each hexagonal ring. The π map shows a pattern of current density dominated by intense diamagnetic and paramagnetic circulations around outer and inner perimeters ('rim' and 'hub'), respectively. Residual benzenoid diamagnetic circulations within the central hexagons of the anthracene-like sub-units, are also visible (**1a**; rings **I**, Fig. 1). No diamagnetic circulations are observed in the hexagons at the six corner positions (**1a**; rings **II**, Fig. 1). This pattern is reminiscent of the computed *ab initio* current-density maps for anthracene and phenanthrene.[12] Thus, when placed in a perpendicular magnetic field, **1** has induced counter-rotating ring currents with a diamagnetic rim and a paramagnetic hub, in flat contradiction of the prediction of the [18]annulene-within-a-[30]annulene model, which would give diamagnetic rim and hub ring currents.[4]

The quality of the current-density maps is established by the calculated CTOCD-PZ2 integrated magnetic properties,† which are consistent with available experimental[7] and previous *ab initio* data acquired using different methods.[5]

The computed magnetic anisotropy $\Delta\xi$ (−153.9 a.u.) of **1a**, which tends to correlate[9] with the conventional exaltation of *isotropic* magnetic susceptibility Λ,[13] is *ca.* 10 times that of benzene. Thus, the CTOCD results support the conclusion that **1a** is not superaromatic.[3–5] The calculated $\Delta\xi$ is in qualitative agreement with an estimate of Λ (178×10^{-6} cm^3 mol^{-1} [14]).

The mean absolute shielding (σ) at the geometric centres of the distinct rings (**1a**; **I** 14.6, **II** 8.0 and **III** −3.2, Fig. 1), which with the required sign change are NICS[6] values (**I** −10.8, **II** −4.3 and **III** 5.0[5]), are consistent with the sense and strength of the calculated current densities (Fig. 2).

The computed mean absolute shieldings of the protons positioned on rim [H(1)/H(2)] and hub [H(3)] show good agreement with experiment (Table 1). The substantial downfield shift of H(3) with respect to H(1) [$\Delta\delta$ 1.62 (2.08/2.02[7])]

DOI: 10.1039/b009763m

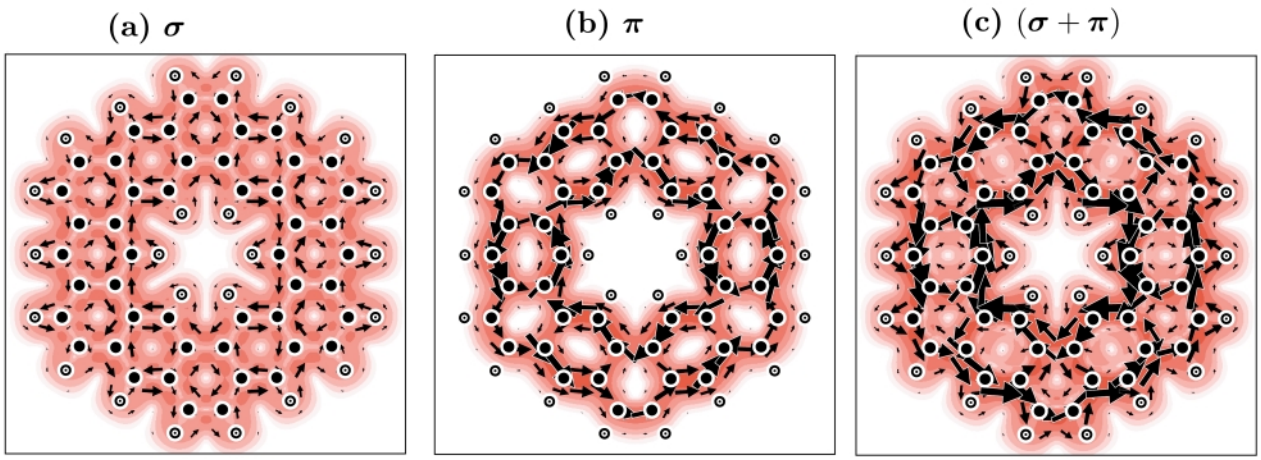

Fig. 2 Computed current-density maps of **1** [(a) σ, (b) π and (c) σ + π electrons].

and H(2) [$\Delta\delta$ 2.11 (2.50/2.46[7])] is in line with the strong paramagnetic hub ring current along the hub. Unfortunately, the extreme insolubility of **1** thwarted acquisition of its ^{13}C NMR spectrum. The $\delta(^{13}C)$ values of **1** compare with those of the corresponding position in anthracene and phenanthrene. We note that for C(3) an upfield shift of *ca.* 5 ppm is predicted (Table 1).

It is interesting to compare the results with the predictions of two simple models for the response of **1** to a uniform magnetic field. The annulene-within-an-annulene[10] picture of **1** (*cf.* **1b**, Fig. 1) considers the 48π-electron system as two separate $4n$ + 2 circuits, an outer 30π and an inner 18π cycle. As *disjoint* aromatic monocycles, each would therefore carry a uniform induced diamagnetic ring current, and hence **1** would have *con-rotating* currents. In contrast, when the Hückel–London model[15] is applied of **1**, a more complex pattern of induced currents in all 60 bonds is predicted. Application of symmetry constraints and current conservation at each vertex of the graph (as in electrical circuits[16]) shows that in fact all bond currents are functions of just three independent parameters, which govern the inner, outer and radial current flow. In the simplest version, where all bonds have equal resonance integrals, counter-rotating circulations on rim and hub are predicted,[4] in qualitative agreement with the *ab initio* π map, though with much weaker currents in the radial bonds connecting inner and outer perimeters (Fig. 3). If the resonance integral of the radial bonds is reduced to zero, the interior current slows down and reverses recovering the (physically incorrect) annulene-within-an-annulene model.‡

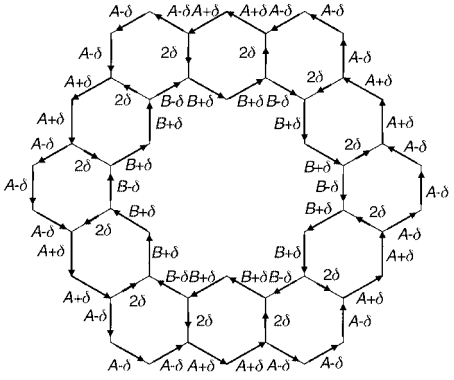

Fig. 3 Induced bond currents in the Hückel–London π model of **1**.‡

Notes and references

† For procedures see ref. 9.

‡ With all bond lengths set to 1.4 Å, perimeter resonance integrals set to the benzene β, and integrals for radial bonds to β', the variation $1 \geqslant \beta'/\beta \geqslant 0$ covers the range from **1** to a fully decoupled [18]-in-[30] annulene. All current strength parameters (Fig. 3) are monotonic: $1.18 \leqslant A \leqslant 3.64$, $0.18 \leqslant \delta \leqslant 0$, $0.99 \geqslant B \geqslant -2.24$, in units of the benzene ring current. The hub has a paramagnetic current for $0.424 < \beta'/\beta$, a diamagnetic current for $\beta'/\beta < 0.407$.

***Ab initio* simulations of the $CaZrO_3$ proton conductor predict that the transport mechanism involves proton transfer between adjacent oxygen ions (but predominantly inter-octahedra), and that the energetics of proton–dopant binding is favourable in accord with spectroscopic evidence.**

Metal oxides with the ABO_3 perovskite structure have received considerable attention as solid-state proton conductors,[1,2] with a range of promising electrochemical applications including fuel cells, gas sensors and hydrogen pumps. Most attention has focused on cerates[3] and zirconates[4] which possess varying levels of proton conductivity. An important example is the development of a potentiometric sensor for hydrogen in molten metal based upon doped $CaZrO_3$ as the proton-conducting electrolyte.[5] The $CaZrO_3$ material is typically acceptor-doped with trivalent ions (*e.g.* In^{3+}) at the Zr^{4+} site, which is crucial to proton dissolution.

It is acknowledged that the macroscopic behaviour of materials is often controlled by fundamental mechanisms acting on the microscopic scale. However, the information derived from most conductivity experiments is not sufficient to identify the precise mechanistic features of proton transport. There is also conflicting debate as to whether there is any significant interaction between the dopant ion and the protonic defect (hydroxyl ion at oxygen site), which may lead to defect clustering or proton 'trapping'.

In an attempt to gain further insight into these problems we have investigated the important $CaZrO_3$ material using quantum mechanical techniques based upon density functional theory (DFT), which are increasingly powerful tools for exploring solid-state properties. This preliminary account builds upon our previous atomistic modelling and X-ray absorption (EXAFS) studies, where we have already obtained valuable microscopic information on the defect chemistry of perovskite-type oxides.[6,7] Here we focus, for the first time, on the distorted orthorhombic phase of $CaZrO_3$, which extends earlier simulation work on ideal cubic perovskites.[8]

The present account of the computational techniques will be brief since more detailed reviews are given elsewhere.[9,10] The calculations are performed within the DFT framework, with the exchange-correlation energy being treated using the generalised-gradient approximation. The particular implementation of DFT employed here combines a plane-wave basis set with the total energy pseudopotential method (as embodied in the CASTEP code[9]) which is ideally suited to calculations on periodic systems. Our simulations are based upon ultrasoft pseudopotentials with the Brillouin zone sampled according to the Monkhorst–Pack scheme.[11] The DFT-pseudopotential approach can be utilised to perform *ab initio* dynamics which essentially combines the solution of the electronic structure with classical molecular dynamics (MD) for the nuclei. The MD simulations, which are highly computationally demanding, used a periodically repeated system of $Ca_4Zr_4O_{12}H$, a time-step of 0.5 fs and a total duration of 4000 time-steps at a temperature of 1000 K within the NVT ensemble; full computational details will be reported in ref. 12. It is worth noting that *ab initio* techniques of this kind have been applied successfully to other oxides including studies of molecular absorption on surfaces[13] and lithium intercalation.[14]

Table 1 Calculated and experimental structural parameters of orthorhombic $CaZrO_3$

	Experimental[a]	Calculated
Unit cell parameters		
a/Å	5.5912	5.5895
b/Å	8.0171	8.0550
c/Å	5.7616	5.7667
Mean bond lengths and angles		
Zr–O (×6)/Å	2.0964	2.1052
Ca–O (×4)/Å	2.3817	2.3742
Ca–O (×4)/Å	2.7616	2.7680
Ca–O (×4)/Å	3.5101	3.5345
Zr–O(1)–Zr/°	145.76	143.46
