Solution studies were undertaken in methanol and aqueous acetonitrile. The ^{1}H NMR spectrum of **1c** in methanol-d_4 measured at 295 K contains one singlet for the C–H protons of the aromatic rings and one triplet for the methine protons of the bridges. These features are characteristic of the C_{4v}-symmetric cone conformation. The addition of tropylium tetrafluoroborate **2a**$^+$BF$_4^-$ to the solution of **1c** in methanol-d_4 resulted in an intense red color, suggesting a charge-transfer interaction of the tropylium ion with the electron-rich pyrrogallol rings.[8] The UV spectrum showed a charge-transfer absorption maximum at λ = 407 nm. The NMR spectrum gives rise to a broad singlet for the tropylium ion, and its chemical shift depends on the ratio between the host and guest. The complexation equilibrium is fast on the NMR timescale at 295 K but becomes slow at 233 K. At host : guest ratios larger than 2 the ^{1}H NMR spectrum contains two signals for the protons of the bridges in the complexed and free **1c** [Fig. 3(a)]. The ratio between these signals depends on the amount of tropylium cation so that only the complex is detected at [**1c**]/[**2a**$^+$BF$_4^-$] = 2 [Fig. 3(b)]. A singlet at 5.2 ppm corresponds to the protons of the tropylium ion, shifted 4.3 ppm upfield by the shielding of the pyrogallol rings. Integration revealed that two molecules of **1c** complex one **2a**$^+$.[9] The slow exchange of the guest and the large upfield shifts of its resonances are typical for capsular assemblies.[10] Further addition of **2a**$^+$BF$_4^-$ results in a new set of signals for the protons of **1c** which grows at the expense of the set of the 2 : 1 complex [Fig. 3(c)]. After 4 equivalents of the salt were added, no dimeric complex remained. Remarkably, no signals

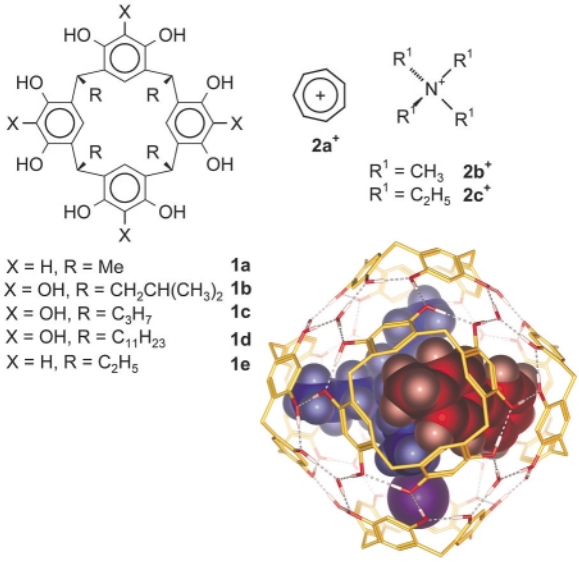

Fig. 1 Line drawings of the resorcinarenes and their guests. The specific complex shown has tetrabutylammonium bromide and *p*-phenyltoluene inside.

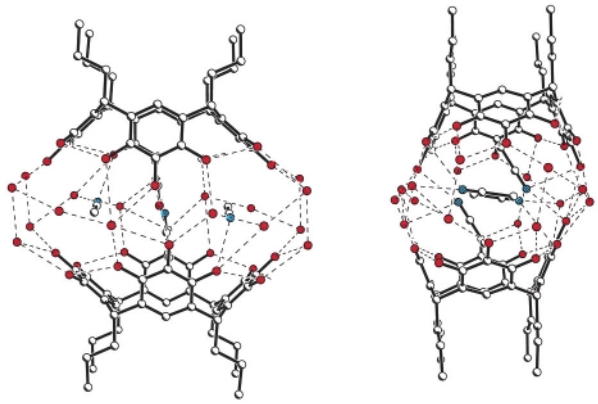

Fig. 2 X-Ray structure of **1c**·3MeCN·5H$_2$O. Symmetry-related water molecules are shown. Hydrogen atoms are omitted for clarity, heteroatoms are darkened and hydrogen bonds are indicated with dashed lines. Only one position of the encapsulated, disordered acetonitriles is indicated, while acetonitriles outside the cavity are not shown.

 DOI: 10.1039/b106793c

for the free tropylium cation were detected at host : guest ratios smaller than 2. Instead, the broad resonance emerged, whose chemical shift depended on the concentration of the tropylium salt [Fig. 3(c)]. This suggests that the new set of signals corresponds to an open, perhaps 1 : 1, complex between the tropylium cation and **1c**, which is in fast exchange with its components. The ESI mass spectrum showed peaks at *m/z* 722, 812 and 1533, corresponding to **1c**, **1c**·**2a** and 2**1c**·**2a**. The same behavior was observed in wet acetonitrile-d_3 (10% of D_2O) although the low temperature NMR studies were somewhat hampered by ice crystallization. The high stability of the dimer and its complicated behavior in the presence of excess **2a**$^+BF_4^-$ prevented the reliable determination of its stability constant.

The ^{1}H NMR spectrum of the more lipophilic resorcinarene **1d** in $CDCl_3$ shows sharp signals and contains one singlet for the aromatic rings and one triplet for the methine protons of the bridges. The addition of solid **2a**$^+BF_4^-$ does not lead to the formation of a lipophilic charge-transfer complex. Neither the color of the solution nor the ^{1}H NMR spectrum of **1d** changes. This is in sharp contrast to the behavior of resorcinarene tetrabenzoates, where encapsulation and charge-transfer take place.[9] However, the addition of methanol-d_4 (20%) results, again, in an intense red color of the solution which is a visual indication of a charge-transfer host–guest interaction. The NMR dilution experiments at 233 K revealed the same characteristics seen for **1c** in pure methanol-d_4. These results strongly suggest that a 2 : 1 complex forms between **1c**, **1d** and **2a**$^+BF_4^-$; in methanol-d_4, in wet acetonitrile-d_3 or in mixtures of $CDCl_3$ and methanol-d_4, the complex has a capsular structure – the methanol or water molecules act as linkers between two resorcinarene molecules in solution, as they do in the solid state (Fig 2).

Finally, the addition of the tetramethylammonium cation **2b**$^+$ gives a kinetically stable (*i.e.* slow exchange on the NMR timescale) 1 : 2 complex with **1c** at 233 K. The NMR signals of the guest's methyl groups are shifted upfield by 3.8 ppm, typical for an encapsulation complex. The octols **1a**, **1e** fail to show a kinetically stable complex with tropylium and tetramethylammonium cations under these conditions. [11] Apparently, the π-basicity and the expanded hydrogen bonding patterns available to the pyrogallol contribute to its more facile capsule formation.

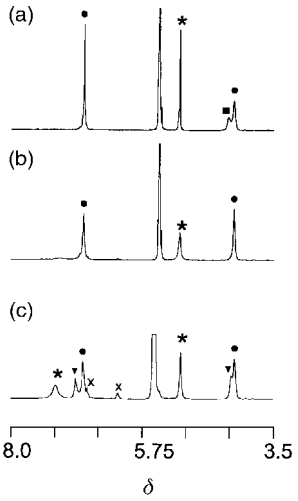

Fig. 3 ^{1}H NMR spectra at 233 K (methanol-d_4, 600 MHz, $[\mathbf{1c}]_{total}$ = 10 mM): (a) 3 **1c** + $C_7H_7^+BF_4^-$; (b) 2 **1c** + $C_7H_7^+BF_4^-$; (c) **1c** + $C_7H_7^+BF_4^-$; (*) tropylium cation; (■) free **1c**; (●) **1c** in a 2 : 1 complex; (▼) **1c** in an open complex; (×) products of methanolysis of the tropylium cation (established by control experiments with $C_7H_7^+BF_4^-$ in methanol-d_4).

In conclusion, the readily available tetrahydroxyresorcinarenes provide easy access to new molecular capsules, stable in protic solutions.[12] The repertoire of encapsulation complexes assembled from these molecules will be reported in the sequel.

We are grateful for support from the Skaggs Foundation and the National Institute of Health. A. S. is a Skaggs Postdoctoal Fellow.

Hydrogen-bonded molecular capsules are stable in polar media

Jerry L. Atwood,* Leonard J. Barbour and Agoston Jerga

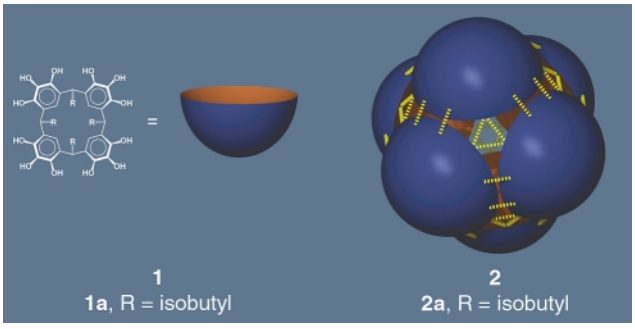
First published as an Advance Article on the web 19th October 2001

Robust, very large hydrogen-bonded capsules which are even stable in 50 : 50 water–acetone mixtures have been characterized both in solution and in the solid state.

For the spherical enclosure of space by means of hydrogen-bonded organic frameworks, two general approaches have emerged: covalent synthesis[1] and synthesis *via* self-assembly.[2] From our viewpoint, self-assembly has provided an attractive means for constructing large, highly organized chemical entities.[3–5] However, self-assembled capsules based on hydrogen bonding have not previously afforded robust structures, particularly in highly polar solvents. Here, we reveal spherical molecular capsules with outstanding stability in such media.

The synthesis of pyrogallol[4]arenes from the acid-catalyzed condensation of pyrogallol and aldehydes has recently been reported.[6,7] Mattay and co-workers noted that these entities typically crystallize as wave-like 2D polymeric structures held together by hydrogen bonds.[7] Of great interest was the revelation that *C*-isobutylpyrogallol[4]arene, **1a**, formed a spherical hexamer, **2a**, on one occasion. However, all attempts to form the hexamer a second time apparently failed.[7] This was attributed to an inherent instability of hexamer **2a** compared with [(*C*-methylresorcin[4]arene)$_6$(H$_2$O)$_8$], **3**, a very large synthetic molecular capsule.[3] This instability in solvents such as nitrobenzene or acetonitrile was especially noteworthy in view of the comment that hexamer **2** is stabilized by 72 hydrogen bonds.[7] A detailed inspection of **2a** shows that the hexamer, comprised of six molecular building blocks, is held together by 48 intermolecular hydrogen bonds, or by eight hydrogen bonds per molecule. For comparison, **3**, comprised of 14 entities (six resorcin[4]arenes and eight water molecules) is held together by 36 intermolecular hydrogen bonds, or 2.6 hydrogen bonds per molecule. The Rebek tennis balls, softballs, and related capsules are comprised of two identical molecules held together by eight hydrogen bonds, or four hydrogen bonds per molecule.[8] Thus, it seems to us that **2** should in fact be highly stable in solvents such as acetonitrile or nitrobenzene. We anticipate that conditions might be found such that hexamer **2** can enjoy a useful existence even in highly polar media. Surprisingly, even these high expectations for the stability of **2** have been exceeded.



The acid-catalyzed condensation of pyrogallol and isovaleraldehyde proceeded smoothly in 95% ethanol, as reported,[7] and, after stirring for 24 h, a precipitate consisting of *ca*. 25% yield of pure **1** was obtained. No evidence of any hexamer **2** was found in this material. Indeed, it is our view that the initial precipitate is comprised exclusively of the wave-like hydrogen-bonded polymer reported by Mattay.[7] It is possible to convert this material to hexamer **2** by dissolving the initial precipitate in Et$_2$O, acetone or methanol, with a few drops of nitrobenzene or *o*-dichlorobenzene added, followed by crystallization upon slow evaporation. The hexamer may also be obtained by thermal treatment of either the initial precipitate or the initial filtrate. The latter contains *ca*. 1–5% hexamer as determined by NMR analysis. The product in the initial filtrate may be converted to hexamer by extraction with Et$_2$O, followed by evaporation to dryness with subsequent dissolution in methanol. The methanol solution is then heated in a sealed tube to 120–150 °C for at least 12 hours. Methanol may be removed under vacuum to yield a red–brown solid. Colorless hexameric spherical capsules have been obtained utilizing the crystallization procedure described for the initial precipitate.

Conclusive proof for the existence of the hexamer in solution was obtained from an NMR spectroscopic investigation. A representative experiment afforded the ^{1}H NMR spectrum of the hexamer (thermally treated with methanol as described above) in deuterochloroform, which is shown in Fig. 1. For the purpose of this discussion, the most important features in the spectrum are the two methanol peaks labeled **b** and **c**, where **b** is the methyl proton resonance for methanol trapped within the hexameric sphere, and **c** is the methyl proton resonance for methanol in the bulk solvent. The identity of these peaks was proved by a spiking experiment in which additional methanol added to the NMR tube had the effect of increasing the intensity of peak **c**. Similar results were obtained in d^6-acetone, d^6-DMSO and d^8-toluene. It should also be noted that NMR spectra for hexamer **2** synthesized in ethanol or isopropanol also showed two sets of resonances for each inequivalent proton in the ethanol or isopropanol molecules. Indeed, in a pressurized NMR sample tube we observed no change in the intensities of peaks **b** and **c** at 150 °C. These results clearly demonstrate that

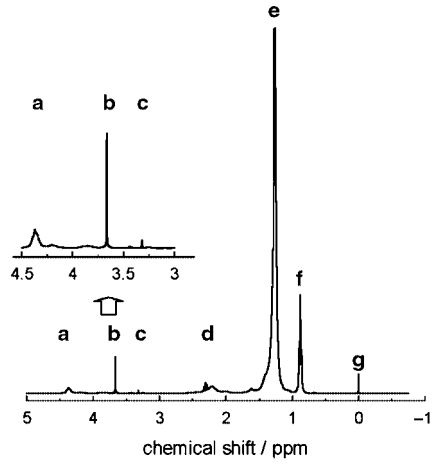


Fig. 1 ^{1}H NMR spectrum of *C*-tridecylpyrogallol[4]arene at room temperature in CDCl$_3$ with TMS. The region of the spectrum displaying the methanol resonances is enlarged in the inset. Peak assignments: **a**, diaryl C–H; **b**, CH$_3$ of guest methanol; **c**, CH$_3$ of methanol in the bulk solvent; **d**, CH$_2$ adjacent to CH in bridging group; **e**, remaining CH$_2$ groups; **f**, terminal CH$_3$ on R; **g**, TMS internal standard.

 DOI: 10.1039/b106250f

(1) methanol molecules within the hexameric sphere do not exchange with methanol in the bulk solvent, or with bulk solvent itself, and (2) the hexameric sphere is stable with methanol as a guest up to at least 150 °C in d^6-acetone.

Using the techniques described above, stable hexameric spheres have been obtained for R = *n*-propyl up to *n*-tridecyl, whereas for R = methyl or ethyl there is no evidence for the existence of hexameric spheres. The solubility of *C*-alkylpyrogallol[4]arenes is low in apolar solvents when the *C*-alkyl group is a short chain (*i.e.* C_3, C_4). Similarly, low solubility occurs in polar solvents when the *C*-alkyl chain is long (*i.e.* C_{10}, C_{13}). It is therefore possible, with the appropriate choice of R-group, to have stable hexameric spheres in polar or apolar solvents. Remarkably, these hexameric spheres are also stable in mixtures of acetone and water to the limit of their solubility. For example, the hexameric sphere for R = *n*-pentyl is stable in a 50% v/v mixture of d^6-acetone and D_2O (precipitation without decomposition occurs with a higher percentage of water). These results show the extraordinary stability of these hydrogen-bonded hexameric spheres in highly polar media. We refer here to the stability of the capsule both with regard to the structural integrity imparted by the hydrogen bonding arrangement, as well as to the failure of the entrapped methanol to exchange with the bulk solvent.

Thus far we have obtained and crystallographically characterized hexameric molecular capsules for R = *n*-propyl, *n*-butyl, isobutyl and *n*-pentyl. In the structure of the *C*-isobutylpyrogallol[4]arene capsule, **2a**,† the capsule completely encloses the space, Fig. 2. The interior volume[9] of the capsule is 1510 Å^3 and can be regarded as the total space available to the guest molecules. Indeed, the X-ray crystal structures reveal nothing more than smears of electron density within the cavity.

The hexameric structure **2** is the only type of capsule that we have observed in the solid state. Furthermore, the NMR experiments reveal that a capsule exists in solution and integration of the methyl proton signal **b** and the diaryl C–H signal **a** are consistent with the enclosure of *ca.* 18 methanol molecules. The free volume of 1510 Å^3, calculated from the solid-state structure, provides enough space for *ca.* 23 methanol molecules. This is based on a van der Waals volume of 36 Å^3 for a single molecule of methanol, and 55% guest-occupancy was recently put forward by Rebek and Mecozzi.[10] This clearly demonstrates that the capsule in solution encloses a comparable amount of space as the solid-state hexameric capsule. Therefore, the only reasonable interpretation is that the solid-state structure **2** is maintained in solution. The only other type of non-porous structure with precedent in this area of chemistry is a dimer.[5,11] While the dimer [*C*-alkylpyrogallol[4]arene]$_2$ has not been observed in the solid state, we modeled and calculated the volume that such a dimer would enclose, should it exist (*ca.* 140 Å^3). This is enough space to enclose two methanol molecules to give a 1 : 1 host : guest ratio, as opposed to the 1 : 4 ratio expected for the hexamer. The 1 : 3 ratio observed in the NMR experiments rules out any structure which provides less available space, such as the dimer. While 23 molecules provide 23/6 or a 1 : 4 host : guest ratio, the observed 18 methanol molecules (1 : 3 host : guest ratio) is quite reasonable, since other unaccounted guests may also be present (*e.g.* non-hexameric **1**, unreacted starting material, colored reaction by-products, other solvents, all in low concentration).

In summary, very large spherical capsules with outstanding stability in highly polar media have been synthesized and characterized reproducibly.

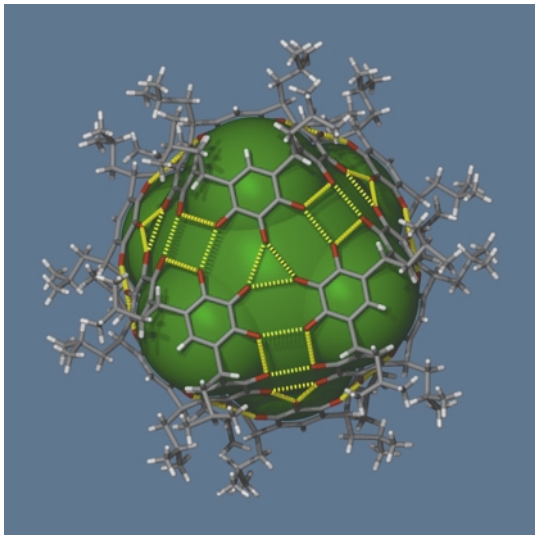

Fig. 2 Stick-bond representation of hexameric capsule with the enclosed space represented in green. Hydrogen bonds are shown as broken yellow cylinders. Orientation is the same as that shown in **2**.

Notes and references

† *Crystal data* for *C*-isobutylpyrogallol[4]arene: M = 905.06, rhombohedral, space group $R\bar{3}$ (the space group for the hexameric capsule reported by Mattay[7] was $P\bar{1}$), $a = b$ = 34.84(2), c = 24.04(3) Å, V = 25268(4) Å^3, Z = 18, μ (Mo-Kα) = 0.066 mm^{-1}. A colorless crystal of dimensions 0.35 × 0.30 × 0.20 mm was used. Intensity data were collected at 173 K on a Bruker SMART CDD diffractometer. Owing to extensive disorder of the contents of the supramolecular cavity as well as the nitrobenzene molecules embedded in the propyl chains, the structure is very poorly resolved. Final refinement converged with R_1 = 0.1482 for 6890 unique reflections [$I > 2\sigma(I)$, $2\theta_{max}$ = 46°]. CCDC reference number 167522. Received (in Purdue, IN, USA) 30th July 2001, Accepted 28th September 2001
First published as an Advance Article on the web 31st October 2001

$[(C_2H_5)_2NH_2]_2[(UO_2)_5(PO_4)_4]$ was prepared from U_3O_8, $HONEt_2$ and phosphoric acid under hydrothermal conditions (180 °C, 5 days) and represents the first three-dimensional open-framework uranium phosphate prepared to date.

Microporous phosphates are an important class of materials that are well studied for their use in catalysis and their ability to selectively sorb guest molecules.[1,2] Interest in the preparation of open-framework and porous transition metal phosphates, in particular, has heightened in recent years.[1,3–8] These materials can provide many of the same benefits as traditional zeolites such as accessible internal micropores, size and shape selectivity, rigid frameworks and chemical/thermal stability, and in addition, incorporate potentially catalytically active sites. Uranium phosphates are of interest in areas such as ion exchange[9,10] and protonic conduction.[11,12] Uranium-containing materials, such as uranium oxides, are also known to be effective catalysts.[13,14] The synthesis of 3-D open-framework uranium phosphates is a desirable goal in this regard but there are currently no examples of such materials. Uranyl (UO_2^{2+}) phosphates tend to form 2-D layered structures in both mineral phases and synthetic compounds.

The pentagonal bipyramidal (PBP) geometry common to the uranyl complexes could be combined with the tetrahedral phosphate ion to form a new class of PBP-tetrahedral framework structures. Recent studies have yielded new uranium-(IV) and -(VI) compounds of variable dimensions containing phosphate,[15] molybdate[16] and fluoride;[17–21] including the first two organically templated layered uranyl phosphate compounds.[15] These two-dimensional structures form with charge-balancing organic cations interacting through hydrogen bonds between the layers. Clearfield and co-workers have been investigating the formation of uranium-containing molecular solids incorporating phenylphosphonates and phenylphosphinates to produce linear, layered and tunnel-type frameworks.[22,23] The three-dimensional inorganic uranium frameworks prepared to date are limited to uranium(IV) fluorides.[17–21]

As part of a systematic search for novel uranium phosphate phases, we have employed hydrothermal methods to prepare an organically templated three-dimensional open-framework uranium phosphate. We report here the synthesis and structural characterization of the first example in this class: $[(C_2H_5)_2NH_2]_2[(UO_2)_5(PO_4)_4]$ (**1**). In a concurrent study, O'Hare and coworkers have prepared the first organically templated 3-D uranium phosphite.[24]

The title compound was prepared† from U_3O_8, $HONEt_2$ and phosphoric acid under hydrothermal conditions (180 °C, 5 days, autogenous pressure). The reaction produced a large amount of brown powder and a small amount of tiny, translucent gold-colored crystals of **1**. X-Ray powder diffraction showed the brown powder to be a mixture of U_3O_8 and other unidentified components. The largest of the plate-like crystals measured 0.02 × 0.04 × 0.08 mm^3. The compound is air-stable and has been characterized by single crystal X-ray diffraction.‡ The small size of the crystals and the low crystalline yield of the reaction have hindered further characterization.

$[(C_2H_5)_2NH_2]_2[(UO_2)_5(PO_4)_4]$ is monoclinic, space group *I*2/*m*, and contains a 3-D network of U(VI) distorted octahedra, U(VI) PBPs and phosphate tetrahedra. These vertices form an open-framework structure (Fig. 1) in which the channels are filled with $Et_2NH_2^+$ cations. The structure contains parallel chains of edge-shared PBPs (containing U(1)) that are linked into $UO_2PO_4^-$ sheets in the *xz* plane by virtue of bridging phosphates (Fig. 1). The PBP is defined by two axial uranyl oxygen atoms (U(1)–O = 1.76(1), 1.74(1) Å) and five

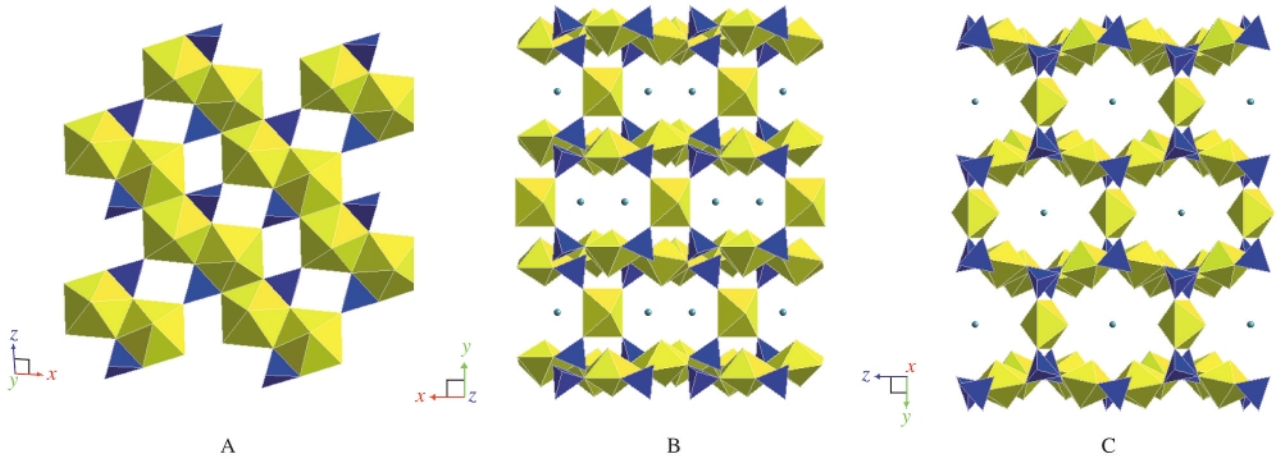

Fig. 1 The 3-D structure of $[(C_2H_5)_2NH_2]_2[(UO_2)_5(PO_4)_4]$ as viewed down (A) the crystallographic *b* axis, (B) the crystallographic *c* axis, and (C) the crystallographic *a* axis. Only nitrogen atoms of $[(C_2H_5)_2NH_2]^+$ are shown for clarity. The yellow polyhedra represent the uranyl distorted octahedra and PBPs. The blue tetrahedra represent phosphate groups and the light blue balls the nitrogen atoms.

 DOI: 10.1039/b106916k

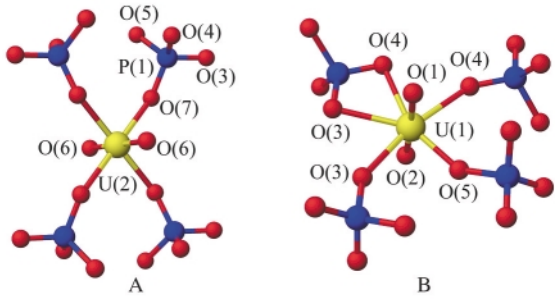

Fig. 2 Ball-and-stick drawings of (A) the distorted octahedron, U(2), and (B) the pentagonal bipyramid, U(1). Selected bond distances (Å): U(1)–O(1) 1.756(14), U(1)–O(2) 1.736(13), U(1)–O(3) 2.348(10), U(1)–O(3′) 2.513(10), U(1)–O(4) 2.382(11), U(1)–O(4′) 2.484(12), U(1)–O(5) 2.225(12), U(2)–O(6) 1.72(2), U(2)–O(7) 2.266(13).

equatorial phosphate oxygens that form the pentagonal plane (Fig. 2B). These five uranium–oxygen bonds are formed by sharing corners with three phosphate tetrahedra and an edge with a fourth tetrahedron. Each PO_4 tetrahedron shares corners with four uranyls and an edge with a fifth.

The $UO_2PO_4^-$ sheets stack along the *y*-axis and are linked into a rigid 3-D structure by the bridging U(2) distorted octahedra (Fig. 1B). The distorted octahedra (Fig. 2A) are defined by two axial uranyl oxygens and four phosphate oxygens from two adjacent $UO_2PO_4^-$ layers. The U(2)–O uranyl distance of 1.72(2) Å is typical of distorted U(VI) octahedra of this type. The U(2) distorted octahedra create a pillaring effect with intersecting tunnels that run along the crystallographic *a* and *c* axes. The 3-D $[(UO_2)_5(PO_4)_4]^{2-}$ uranyl phosphate framework is charge balanced through inclusion of two $Et_2NH_2^+$ cations per formula unit that reside in the tunnels (see Fig. 1B and 1C).

The $UO_2PO_4^-$ sheets of **1** are similar to those of the mineral β-uranophane, $Ca(UO_2)_2(SiO_3OH)_2{\cdot}5H_2O$.[25] In this layered structure, chains of uranyl PBPs are linked into sheets by SiO_3OH^{3-} tetrahedra. The silicate oxygens that are not involved in bonding within the sheet are all protonated and on one side of the sheet whereas the corresponding phosphate oxygens of **1** alternate, pointing above and below the sheet, and are not protonated. The layers of β-uranophane are intercalated with Ca^{2+} ions in contrast to the rigid 3-D framework structure of **1**. The layers of **1** are reminiscent of those in the 2-D uranyl phosphates prepared by O'Hare and co-workers[15] and α-uranophane.[26] The presence and mode of connectivity of the inter-layer uranyl octahedra in **1** also appear in phosphuranylite, $KCa(H_3O)_3(UO_2)_7(PO_4)_4O_4{\cdot}8H_2O$.[27] However, the sheet portion of this mineral contains hexagonal bipyramids and PBPs and is very different from that in **1**.

The formation of the $Et_2NH_2^+$ cations from Et_2NOH presumably occurs through a redox process involving U_3O_8. The use of Et_2NH instead of Et_2NOH in the synthesis of **1** under identical conditions results in smaller crystallites that are not suitable for single-crystal studies by conventional methods.

This work was supported by the LDRD program at Los Alamos National Laboratory.

Notes and references

† Hydrothermal reactions were carried out in Teflon lined 23 mL stainless steel, commercially purchased Parr brand pressure autoclaves. Water was purified in a Millipore MilliQ Ultra-pure water system. U_3O_8, phosphoric acid (85%), diethylhydroxyamine and deionized water were combined in the mol ratio of 1.0:8.0:4.0:496 and reacted under autogenous pressure at 180 °C for 5 days, then ramp cooled at the rate of 5 °C h^{-1}. Single crystals were manually isolated for analysis.

‡ *Crystal data* for $[(C_2H_5)_2NH_2]_2[(UO_2)_5(PO_4)_4]$: $C_8H_{24}N_2O_{26}P_4U_5$, M = 3748.58, monoclinic, *I*2/*m*, a = 9.4442(17), b = 15.449(3), c = 9.5719(17) Å, β = 93.268(3)°, V = 1394.3(4) Å^3, Z = 2, D_c = 4.464 g cm^{-1}, λ = 0.71073 Å, T = 193 K, $5 < 2\theta < 50°$, R (R_w) = 0.0619 (0.1133) for refinement on F^2 using all 1243 unique reflections. The structure was solved and refined using the SHELXTL software package.[28] All atoms were refined anisotropically except for the N and C atoms of the $Et_2NH_2^+$ cation, which were refined isotropically. Hydrogen atoms were placed in idealized positions. There was large thermal motion but no apparent disorder associated with the Et groups.

First published as an Advance Article on the web 31st October 2001

The reaction of equimolar amounts of $Cu(NO_3)_2$ and bdc-5-OH (bdc-5-OH = benzene-1,3-dicarboxylate-5-hydroxy) affords hydroxylated nanoballs with high solubility and an ability to form microcrystals on surfaces.

The design and generation of nanoscale polyhedral structures *via* self-assembly represents an approach to synthesis that offers new horizons in the context of synthetic chemistry and its possible impact upon nanotechnology.[1–9] In this context, we have recently reported a design strategy for the one-step synthesis of nanoscale molecules[10] and frameworks[11,12] that are based upon self-assembly of structure building units (SBUs),[13] $M_2(O_2CR)_4$ molecular squares, at their vertices. The discrete structures, which we have termed 'nanoballs', are molecular versions of faceted polyhedra,[14] namely *small rhombihexahedra*, and are depicted schematically in Fig. 1. The key to obtaining 'nanoballs' cleanly and in high yield is that the square SBUs are linked at a 120° angle using the angular bifunctional ligand benzene-1,3-dicarboxylate, bdc. They are distinguished by their nanoscale size, their facile synthesis and the potential for functionalisation at multiple sites: the inner or outer metal centres, the interior cavity, or the bridging ligand. In this contribution we report the first example of a small rhombihexahedron that is functionalised at the bridging ligand, bdc-5-OH serving as the ligand.

The small rhombihexahedron $[(DMSO)(MeOH)Cu_2(bdc\text{-}5\text{-}OH)_2]_{12}$, **1**, formed spontaneously upon the addition of 2,6-dimethylpyridine (2 equivalents) to a methanolic solution of $Cu(NO_3)_2$ (1 equivalent) and H_2bdc-5-OH (1 equivalent). Addition of diethyl ether precipitated a crude product, recrystallization of which from DMSO afforded single crystals of **1** suitable for X-ray crystallography.† The crystal structure of **1** is illustrated in Fig. 2. **1** has DMSO ligands axially bonded to the metal ions that lie at the exterior surface of the nanoball, and MeOH ligands axially bonded to the metal ions that lie at the interior surface of the ball. It has a molecular volume, including solvent sphere, > 17 nm^3 and a molecular weight of 7.43 kDa. The internal cavity has a volume of *ca.* 1 nm^3. Crystals of **1** appear to be stable indefinitely if in contact with the mother-liquor but are highly deliquescent if removed from mother-liquor.

The presence of 24 hydroxy groups on the surface of the nanoball predictably alters the chemical and physical properties when compared to the unsubstituted analogues. For example, **1** is readily soluble in a variety of organic solvents, including methanol, ethanol, *iso*-propyl alcohol, DMF and hot acetonitrile. This has allowed us to grow microcrystals of **1** on mica or glass, *via* evaporation of methanol solutions of **1**.

Atomic force microscopy (AFM) has become one of the most widely used tools for the study of crystal growth and behaviour on surfaces,[15–20] examples include size control of nano-crystals on Langmuir–Blodgett films,[15] protein crystal growth,[16] molecular and nanotribology,[17] statistical analysis of 2-D crystal sizes,[18] dopant effects on crystal growth[19] and annealing effects on crystallisation.[20] AFM studies‡ revealed that the microcrystals of **1** are of quite uniform dimensions and that they are stable even after mild heating.

The images obtained on a mica surface, without thermal treatment, show increasing density of microcrystals with increasing concentration. The micocrystals have an average height of 140 nm with a variation of 30 nm; the roughness (RMS) is 56 nm. The average size is 1.3 μm with a variation of 0.4 μm. In the case of the films prepared on glass, observation on samples not thermally treated gave poor image quality even in the non-contact mode due to the presence of residual solvent forming a strongly bound contamination film. This contamination layer can be removed by heating to 37 or 75 °C during 24 h. The corresponding images are shown in Fig. 3(a) and (b), respectively; the roughness (RMS) is 236 nm and 261 nm. Image analysis shows an average size of 1.4 μm for the sample annealed at 37 °C and again 1.4 μm for that annealed at 75 °C, the variance is 0.4 μm. It is interesting that there is no apparent difference in the crystal sizes either on different substrates or under different thermal treatment. The average heights are 500 and 600 nm, respectively. For the sample treated at 37 °C the height values are randomly distributed about this average. However, for the sample treated at 75 °C there is a clear statistical distribution of heights at 300, 600 and 900 nm. Whilst it is apparent that annealing at higher temperature leads to a higher density of crystals, it is of interest that there is apparently non-crystalline material present between the microcrystals in Fig. 3(a). This situation is analogous to that observed for thermally treated thin films of *tert*-butylcalix[4]arene.[21] It would appear that annealing at the higher temperature gives rise

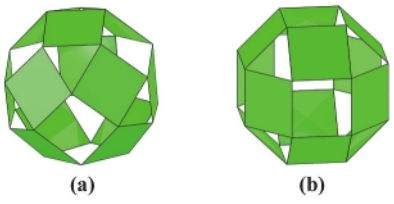

Fig. 1 Schematic representations of the small rhombihexahedra that exist for $[(MeOH)_2Cu_2(bdc)_2]_{12}$, **a**, and $[(Py)(MeOH)Cu_2(bdc)_2]_{12}$, **b**. The two polyhedra differ in the connectivity of the SBUs.

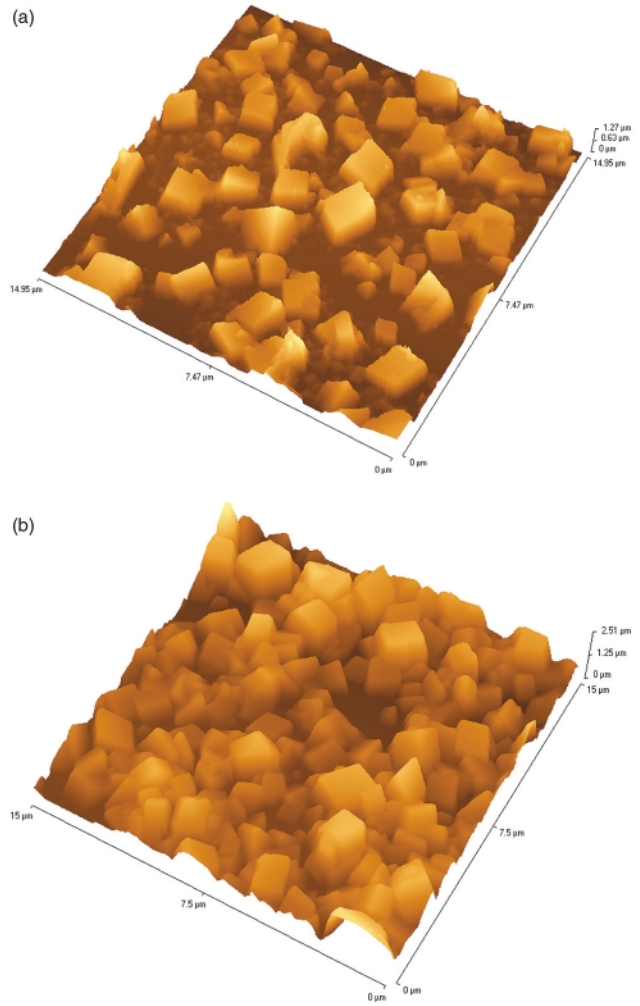

Fig. 3 (a) Non-contact mode AFM image of microcrystals of **1** on glass after annealing at 37 °C for 24 h. (b) Non-contact mode AFM image of microcrystals of **1** on glass after annealing at 75 °C for 24 h.

to a complete crystallisation of the film and that there is a definite self-organisation producing structures for which the heights are multiples of 300 nm. The existence of nanoscale channels in the crystal structure of **1** is a consequence of the inability of spheres to close-pack efficiently and the inherent open structure that must occur for a faceted polyhedron. We are therefore evaluating **1** for possible use in sensors.

Notes and references

† *Crystallographic data*: intensity data for **1** were collected at 200 K on a Bruker SMART-APEX diffractometer using Mo-Kα radiation (λ = 0.7107 Å). The data were corrected for Lorentz and polarization effects and for absorption using the SADABS program. The structure was solved using direct methods and refined by full-matrix least-squares on $|F|^2$. All non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed in geometrically calculated positions and refined with temperature factors 1.2 times those of their bonded atoms. The calculated density is very low and a reflection of the large amounts of space in the unit cell that are occupied by disordered solvent molecules.

Crystal data for **1**: tetragonal, space group *I*4/*mmm*, $a = b = 31.111(4)$, $c = 35.999(6)$ Å, $V = 34844(8)$ Å^3, $Z = 2$, $D_c = 0.708$ g cm^{-3}, $\mu = 0.778$ mm^{-1}, $F(000) = 7366$, $2\theta_{max} = 42.08°$ ($-30 \leqslant h \leqslant 31$, $-31 \leqslant k \leqslant 31$, $-36 \leqslant l \leqslant 21$). Final residuals (for 296 parameters) were $R1 = 0.1531$ for 5170 reflections with $I > 2\sigma(I)$, and $R1 = 0.2128$, $wR2 = 0.4702$, GOF = 1.679 for all 49928 data. Residual electron density was 1.051 and -0.592 e Å^{-3}.

CCDC reference number 169279. See http://www.rsc.org/suppdata/cc/b1/b106592k/ for crystallographic data in CIF or other electronic format.

‡ *Atomic force microscopy data*: films of **1** were prepared by deposition of 20 µL of a solution of **1** in methanol, at varying concentrations, onto either freshly cleaved mica or freshly cleaned glass slides. Images of deposited films of **1** on mica or glass were collected using a Thermomicroscopes Explorer AFM. Scan sizes from 80 to 5 µm were collected in amplitude detection in the non-contact mode. Cantilevers were HRF with a resonance frequency of 270 kHz, scan rates were 1 Hz. Image resolution was 500 × 500. Images are unfiltered.

M_2 δ-to-oxalate π* conjugation in oxalate-bridged complexes containing M–M quadruple bonds†‡

Bruce E. Bursten,* Malcolm H. Chisholm,* Christopher M. Hadad,* Jun Li and Paul J. Wilson

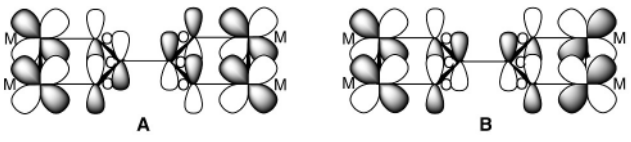
Department of Chemistry, The Ohio State University, Newman and Wolfrom Laboratory, 100 W. 18th Avenue, Columbus, OH 43210-1185, USA. E-mail: chisholm@chemistry.ohio-state.edu

Received (in Cambridge, UK) 1st May 2001, Accepted 27th September 2001
First published as an Advance Article on the web 18th October 2001

The electronic structures of oxalate-bridged, quadruply-bonded dimolybdenum and ditungsten compounds have been investigated by a variety of computational methods employing density function theory (gradient corrected and time-dependent) which reveal the consequences of strong mixing of M_2 δ and oxalate π orbitals within extended chains and cyclic structures.

Recently, Cotton and others have reported the solid-state and molecular structures of a wide variety of dinuclear complexes linked by dicarboxylate groups, including dimers, cyclotrimers and cyclotetramers.[1–10] Lehn and coworkers have also reported alkynyl-linked tetranuclear complexes incorporating Ru_2 units.[11] In our earlier work, we have prepared several linked dimolybdenum and ditungsten complexes supported by pivalate ligands and noted the strong electronic communication between the metal centres that arises for oxalate-bridged complexes of the type $(Bu^tCO_2)_3M_2(\mu\text{-}O_2CCO_2)M_2(O_2CBu^t)_3$, where M = Mo and W.[12] We have now investigated the electronic communication in these complexes. These investigations have involved electronic structure calculations employing density functional theory (DFT) using both the Gaussian 98 and the ADF 2000 packages, and use has been made of the rapidly emerging time-dependent density functional theory (TDDFT) method to predict excitation energies for both the cyclic and linear forms. We report here the highlights of these findings.

When two quadruply-bonded M–M groups are linked by a bridging oxalate ligand, the primary interactions between the metals and dicarboxylate unit (aside from the formation of the M–O σ bonds) involve the filled δ orbitals and two of the oxalate π orbitals. There is a filled–filled interaction between the M_2 δ orbitals and one of the filled oxalate π orbitals, shown in **A**, and a donation from the M_2 δ orbital to one of the empty π* orbitals of oxalate, shown in **B**.



A **B**

The calculated molecular structures of the compound $(HCO_2)_3Mo_2(\mu\text{-}O_2CCO_2)Mo_2(O_2CH)_3$, which we have thus far used to model the previously reported hexa-pivalate complexes, are shown in Fig. 1.

For this work, molecular and electronic structure determinations were performed under either rigid D_2, D_{2h} or D_{4h} symmetry using both the Gaussian 98 and ADF 2000.01 programs, which gave comparable results.[13] It is notable that the oxalate ligand is essentially planar even though the symmetry of the molecule was relaxed to allow twisting about the oxalate C–C bond; and furthermore, the oxalate ligand has a relatively short C–C distance (1.50 Å) compared with 1.57 Å as seen in $K_2C_2O_4\cdot H_2O$.[14,15] Based on the oxalate-based LUMO being C–C π bonding, the planar D_{2h} structure is favoured by the back-bonding that results from the orbital interaction shown in **B**. The geometrical parameters shown in Fig. 1 for the central $Mo_2(\mu\text{-}O_2CCO_2)Mo_2$ core compare well with those recently reported by Cotton and Murillo for formamidinate-supported, oxalate-bridged complexes of Mo_2 and Rh_2.[1,2] The calculations also predict that the 'twisted' D_{2d} structure is not much higher in energy than the D_{2h} form, with an energy difference calculated to be 3.0 (Gaussian 98) and 3.7 (ADF 2000) kcal mol^{-1}. Slightly larger (6–8 kcal mol^{-1}) D_{2h}–D_{2d} energy differences are found in preliminary calculations for the analogous tungsten systems. The small conformational differences seem to correlate well with the observed thermochromism of the low-energy electronic transitions of the oxalate-bridged molecules. The energy of the transition from the b_{2g} HOMO to the b_{3u} oxalate π* orbital will be particularly sensitive to small changes in the C–C torsional angle that can be induced upon cooling. (These symmetry labels refer to D_{2h} symmetry. Under D_2 symmetry, b_{2g} transforms as b_2, and similarly, b_{3u} transforms as b_3.) The calculated energy of that vertical transition for $(HCO_2)_3Mo_2(\mu\text{-}O_2CCO_2)Mo_2(O_2CH)_3$ using TDDFT[13] is 2.76 eV (449 nm) and 2.41 eV (515 nm) as determined by Gaussian 98 and ADF 2000, respectively, which compares reasonably well to the λ_{max} observed for the pivalate complex $(Bu^tCO_2)_3Mo_2(\mu\text{-}O_2CCO_2)\text{-}Mo_2(O_2CBu^t)_3$, namely 2.70 eV (460 nm) at room temperature.[12]

In reactions employing $M_2(O_2CBu^t)_4$ (M = Mo or W) with one equivalent of free oxalic acid, replacement of two pivalate ligands per dinuclear unit occurs leading to higher oligomers, which have yet to be structurally characterized. If substitution proceeds to give *trans* products, a series of compounds can be anticipated which may be conveniently represented as $[M_2]_n(OXA)_{n-1}$, whereas if substitution proceeds in a *cis* manner, as recently seen in the substitution reactions of $Rh_2(O_2CMe)_4$ with a dicarboxylic acid,[4] then molecular squares $[M_2]_4(OXA)_4$ could result. Indeed, Cotton and Murillo, who have employed formamidinate ligands, have shown that squares, cyclotetramers, as well as cyclotrimers can be formed.[2,5–9] There, the *cis*-disposition of the ligands around the

M_2 core may be anticipated based on the *trans*-influence order N > O. Irrespective of the substitution pattern, the important electronic and structural features of the resulting compounds arise from extensions of the key orbital interactions shown in **A** and **B**. For D_{2h} planar $[M_2]_n(OXA)_{n-1}$ systems, if n is even the M_2 δ orbitals transform as $n/2$ b_{2g} and $n/2$ b_{3u}, and by contrast, when n is odd they transform as $(n + 1)/2$ b_{2g} and $(n - 1)/2$ b_{3u}. The filled and empty oxalate π orbitals also transform as b_{2g} and b_{3u}, which allows for the formation of a filled δ band and a vacant oxalate π* band. Irreducible representations spanned by the δ and oxalate orbitals are given in Table 1 (ESI†) for all values of n. On the other hand, for a D_{4h} square $[M_2]_4(OXA)_4$ system, the M_2 δ orbitals transform as a_{1g}, b_{2g} and e_u, and the filled and empty oxalate π orbitals transform as a_{2g} b_{2g} e_g and a_{1g} b_{1g} e_u, respectively.

In order to investigate the growth of the band structure in the linear compounds, we examined the electronic structure of the model compound $[Mo_2]_4(OXA)_3$ supported by formate ligands, and also, for comparison, that of the formate-supported cyclic tetramer, $[Mo_2]_4(OXA)_4$. The calculated optimised geometries of the model systems are illustrated in Figs. 2 and 3, respectively, and a comparative description is given in the frontier molecular orbital energy level diagram, Fig. 4.

For both D_{2h} $[Mo_2]_4(OXA)_3$ and D_{4h} $[Mo_2]_4(OXA)_4$, the HOMO is a b_{2g} δ-based orbital, which is raised in energy by interaction with the filled b_{2g} oxalate π orbital. The LUMO for $[Mo_2]_4(OXA)_3$ has b_{3u} symmetry, and that for $[Mo_2]_4(OXA)_4$ has b_{1g} symmetry, and in each case is an oxalate-localised π* orbital which is *totally* uninvolved with the metal atoms. Throughout, the M_2 δ*, π and σ orbitals are largely unperturbed by the oxalate ligands. Plots of the key frontier molecular orbitals for the linear $[Mo_2]_4(OXA)_3$ and the square $[Mo_2]_4(OXA)_4$ system are given as ESI in Fig. S1.†

The lowest energy electronic bands of $M_2(O_2CR)_4$ 'monomers' are due to metal-localised δ → δ* transitions. The presence of the oxalate ligands in $[M_2]_n(OXA)_{n-1}$ chains and $[M_2]_4(OXA)_4$ squares provides a significant electronic perturbation and hence the electronic transitions in these systems will be dominated by M_2 δ → oxalate π* MLCT transitions. In the linear chains, there is a low-energy allowed $b_{2g} \rightarrow b_{3u}$ or $b_{3u} \rightarrow b_{2g}$ transition for all values of n. By contrast, the highly symmetric square $[M_2]_4(OXA)_4$ system has a smaller number of allowed, low-energy transitions. The lowest energy MLCT transition ($b_{2g} \rightarrow b_{1g}$) is rigorously forbidden, but the next lowest transitions are expected to be intense MLCT transitions. The bonding in the formamidinate square $[(HNCHNH)_2M_2(\mu\text{-}O_2CCO_2)]_4$ is qualitatively very similar, underlining the importance of the oxalate ligands in determining the ultimate electronic structure of these systems.

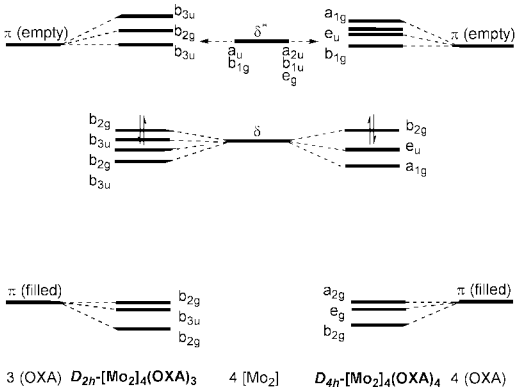

Fig. 4 Qualitative schematic frontier molecular orbital energy level splitting diagram for the D_{2h} linear $[Mo_2]_4(OXA)_3$ system (left), and the D_{4h} square $[Mo_2]_4(OXA)_4$ system (right).

From the above example of perpendicularly linked M–M quadruple bonds, the qualitative features of conjugation involving M_2 δ orbitals and vacant ligand π* orbitals can be anticipated. By contrast, for an axially aligned linear arrangement ~(M_2–bridge–M_2)~, such as found in Lehn's acetylene linked diruthenium chains,[11] the primary conjugation involves the metal π or π* orbitals except when the bridge spans the M_2 unit as in 2,7-dioxynaphthyridine or 1,8-anthracenyldicarboxylate. Thus, investigations of these complexes should also prove most fascinating.

We thank the National Science Foundation for financial support and the Ohio Supercomputing Center for computational resources.

First published as an Advance Article on the web 23rd October 2001

Utilization of double aromatic π-stacking interactions on a 2,3-diaminobutane framework provides a new motif for structurally rigid C_2-symmetrical propeller-shaped chiral 1,2-diamines.

Catalytic asymmetric carbon–carbon bond forming reactions have emerged as one of the most active areas of research in organic synthesis.[1] In this field, standard reactions such as the addition of diethylzinc to benzaldehyde are investigated as benchmarks upon which to evaluate the relative efficiency of different ligands. Chiral, C_2-symmetrical 1,2-diamines are valuable scaffolds both as auxiliaries and ligands in catalytic asymmetric reactions.[1,2] In particular, sulfonamide derivatives of the ligands 1,2-diaminocyclohexane **1** and 1,2-diamino-1,2-diphenylethane **2** (Fig. 1) have been utilized extensively over the last few years in a large variety of catalytic asymmetric processes.[1]

Kobayashi *et al*. have demonstrated that derivatives of **1** are highly efficient (maximum 99% yield and 99% ee) in promoting the addition of diethylzinc to benzaldehyde.[3] However, applications to other systems involving functionalized aldehydes and/or functionalized organozincs are generally not as efficient. For example, Marshall reported an elegant approach to annonaceous acetogenins employing the addition of a functionalized organozinc reagent to an aliphatic aldehyde, using the Kobayashi catalyst, in 90% ee[4] This result appears to be quite general for functionalized variants of the reaction[5] highlighting the need for the design of new types of chiral ligand incorporating new defined structural motifs.

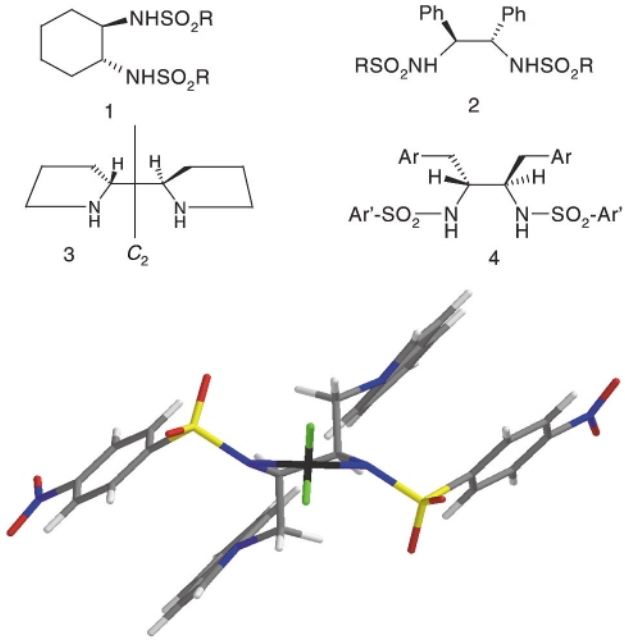

Fig. 1 Design of propeller shaped catalyst **5** as the minimized $ZnCl_2$ complex of ligand **4**.

† Electronic supplementary data (ESI) available: colour figure showing π-stacking in compound **12**. See http://www.rsc.org/suppdata/cc/b1/b106641b/

A central theme of our research is the investigation of novel scaffolds for chiral ligand design.[6] This led us to the concept of developing a new class of chiral ligand having a C_2-symmetrical 1,2-diamine core encompassed within a 2-bladed propeller-shaped architecture exemplified by the 2,2′-bipyrrolidine **3**. Such a structure has analogy with axially chiral 1,4-bidentate ligands (*e.g.* BINAP, BINOL) but is connected *via* sp^3 hybridized atoms and has the stereogenic centre in closer proximity to a coordinated metal. Propeller[7] and helical[8] shaped motifs have found application as ligands in the area of asymmetric catalysis.[1] Current difficulties with the incorporation of a propeller motif into ligand design centre on devising a molecular assembly which will retain a rigid propeller shaped conformation.

We considered that two important factors in the design of such a ligand would be the chemical nature and the control of conformational mobility of the 'blades' of the ligand. One possible molecular assembly which emerged from modelling studies‡ consisted of the incorporation of two different aromatic rings on each 'blade' of the propeller, conformationally restrained by utilization of double intramolecular π-stacking secondary orbital interactions (**4**, Fig. 1). These studies indicated that an arylsulfonamide moiety (Ar′) on each nitrogen would be correctly positioned for donor–acceptor interactions with a second aryl residue (Ar) on the diamine core provided that a methylene spacer was positioned between. Under these constraints, the two Ar residues of **4** could be envisioned to form a π-stack with each arylsulfonamide having an approximate interplanar separation of about 3.5 Å. Complexes of such a ligand **5** would result in the desired conformationally rigid propeller structural motif.[9,10] We chose the electron-rich heterocycle indole as the Ar-substituent at the 1,4-positions in this model study. It was considered advantageous to install the bis-*N*-sulfonamide late in the synthesis allowing for steric or electronic manipulation of the Ar′ π-acceptor and for the introduction of diversity within the ligand set. We now report the synthesis and characterization of ligand **12** from tartaric acid (Scheme 1), confirming the rigid double π-stack both in solution and in the solid state, as well as preliminary application of **12** and analogs **13** and **14** as promoters for the addition of diethylzinc to benzaldehyde. Tartaric acid **6** was converted to the bis-mesylate **7** following literature protocols.[11] Interestingly, substitution using the lithium salt of indole proceeded in refluxing THF to provide only the monosubstituted product while the use of THF–HMPA 4 : 1 gave the desired bis-*N*-alkylated product **8** in high yield. The acetonide was cleaved and the resulting 2,3-diol converted to the bis-mesylate derivative **9**. Conversion to the 2,3-bis-azide was achieved following the protocol of Mosset *et al*.,[11b] reduction of which, using Adam's catalyst, provided the key diamine **11**. Standard

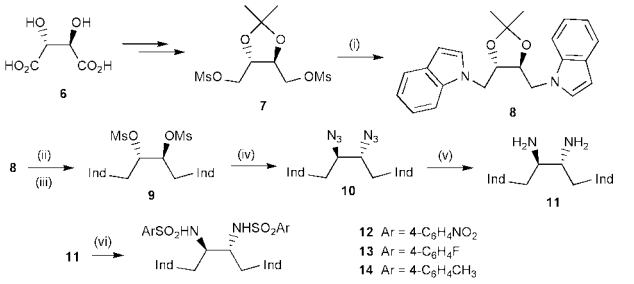
 DOI: 10.1039/b106641b

sulfonylation of the diamine using 4-nitrobenzenesulfonyl chloride gave ligand **12**.

The UV spectra of ligand **12** in CH_3CN exhibited both a bathochromic as well as a significant hyperchromic shift in comparison to indole and 4-nitrobenzenesulfonyl chromophores attributable to a charge-transfer interaction in solution.[12] Further evidence for the π-stacking in solution was provided by the ^{1}H-NMR spectrum. For example, the average chemical shift of the indole C-2 proton of **8**–**11** was δ 6.55 ppm in sharp contrast to that of **12** (δ 6.23 ppm). This shielding is ascribed to the neighbouring ring current anisotropy exerted by the nitrosulfonamide on the stacked indole.[13]

Crystals of **12** suitable for X-ray diffraction were grown from MeOH,§ the molecular structure is shown in Fig. 2. The unit cell consists of two molecules of **12** each of which are doubly intramolecularly π-stacked with an interplanar separation of approximately 3.5Å. The two molecules of **12** are bonded through a rarely observed intermolecular hydrogen bond between the oxygen lone pairs of a nitro substituent and a sulfonamide NH on the other ligand.

Other sulfonamide derivatives such as **13** (4-FC_6H_4-) and **14** (4-MeC_6H_4-) were also readily obtainable from diamine **11**. The addition of diethylzinc to benzaldehyde was investigated in toluene under conditions similar to Kobayashi using these ligands.[3] The adduct (*S*)-1-phenylpropan-1-ol was obtained in ee's of 99% (**12**), 71% (**13**) and 31% (**14**) respectively. Consumption of benzaldehyde was generally complete, however in all cases 5–15% of benzyl alcohol was also produced through competitive β-hydride reduction which may be attributed to steric crowding in the catalysts derived from **12**–**14**.



Scheme 1 Synthesis of ligands **12**–**14**. *Reagents and conditions*: (i) indole, LiHMDS, THF–HMPA 4 : 1, −78 °C, 2 h then to 22 °C, 6 h, 81% (ii) MeOH–THF 2 : 1, 0.1 N HCl, 68 °C, 1 h, 86%. (iii) MsCl, Et_3N, CH_2Cl_2, 0 °C, 5 h, 90%. (iv) NaN_3, DMSO, 80 °C, 24 h, 89%. (v) MeOH–H_2O 3 : 2, PtO_2, 1 atm H_2, 22 °C, 8 h, >99%. (vi) $ArSO_2Cl$, Et_3N, CH_2Cl_2, 0 °C, 6 h, 62%. Note: Ind = 1′-indolyl.

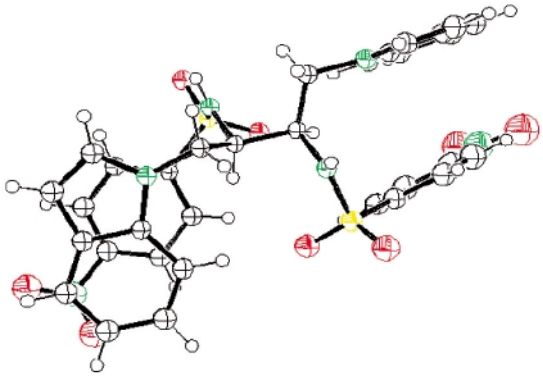


Fig. 2 ORTEP diagram of one molecule of **12** verifying the double intramolecular π-stacking.

In conclusion, we have experimentally confirmed the structure of the double π-stacked chiral 1,2-diamine ligand **12** as a model system for obtaining the C_2-symmetrical propeller motif as well as the preparation of propeller shaped catalysts. An inspiring agreement between the molecular modelling studies‡ and eventual structure of ligand **12** was observed. Preliminary investigations have demonstrated the viability of this structural motif in asymmetric catalysis. Further modifications to the ligand structure based on models **3** and **4** incorporating various donor–acceptor partners as well as applications to functionalized variants of the reaction are in progress.

Received (in Cambridge, UK) 24th July 2001, Accepted 9th October 2001
First published as an Advance Article on the web 31st October 2001

Direct visualisation of induced current density in clamped benzenes 1–4 distinguishes between saturated clamping groups, for which the central benzene ring retains a conventional diamagnetic ring current, and strongly interacting, unsaturated clamps, for which the central ring supports only the localised circulations expected of a 1,3,5-cyclohexatriene with fully fixed double bonds.

Synthetic chemists have been tantalised for many years by the target of a molecular realisation of 1,3,5-cyclohexatriene (CHT). A popular strategy for conversion of benzene to CHT has been to attempt to tilt the energy balance in favour of the localised form by imposition of geometric constraints.[1] Annelation with rigid clamping groups has produced rings having various degrees of bond alternation, ΔR. If bond equalisation is the signature of aromaticity, then structures such as tris(bicyclo-[2.1.1]hexano)benzene (**1**) and tris(benzocyclobutadieno)benzene (**2**), with ΔR(**1**) = 0.089 Å and ΔR(**2**) = 0.154 Å (X-ray[1]), are *de facto* non-aromatic forms of benzene and hence realisations of CHT.[1] If, on the other hand, magnetic criteria for aromaticity[2] are used, the conclusion is different. From IGLO calculations, it is known that the benzene ring can tolerate a wide range of geometric distortion (*e.g.* $\Delta R \leq 0.165$ Å[2a]) whilst maintaining exaltation of diamagnetisability. We will show here by direct visualisation of the current density maps that **1** retains the ring current of benzene, whereas **2** has the localised magnetic character expected of a CHT ring with fixed double bonds. It will be seen that the same dichotomy in magnetic response is exhibited by simpler model systems[3] tris(cyclobuteno)benzene (**3**, de-localised) and tris(cyclobutadieno)benzene (**4**, localised), and we will give a systematic explanation in terms of an orbital model[4] for sizes and signs of ring currents.

A distributed-origin, coupled Hartree–Fock method such as CTOCD-DZ (continuous transformation of origin of current density, diamagnetic zero[5]) is particularly suited to visualisation and interpretation of ring currents.[6] As the current density at any point is calculated with that point as the origin of vector potential, this *ipsocentric* formulation gives numerically well converged results[5] and lends itself to physically based analysis.[4]

Optimised geometries (RHF/6-31G**) show bond alternations of ΔR(**1**) = 0.096 Å, ΔR(**2**) = 0.152 Å, ΔR(**3**) = 0.015 Å and ΔR(**4**) = 0.182 Å. The SYSMO program[7] was used to calculate current densities (Fig. 1) as in ref 6. In all plots, diamagnetic circulation is shown anti-clockwise.

The computed map (Fig. 1a) for the π current density in **1** exhibits a strong central diamagnetic current in the benzene ring. Despite significant bond alternation imposed by clamping, the D_{3h} benzene moiety of **1** retains the classical π ring current. In contrast, the central ring of **2**, also of D_{3h} symmetry, has only localised π currents (Fig. 1b). Thus, attachment of the unsaturated benzocyclobutadieno clamps to the benzene ring has completely destroyed its delocalised character, and hence on magnetic criteria, removed its aromaticity. Compound **2** does have delocalised currents (π diamagnetic in outer benzene rings, σ paramagnetic[6a] in square rings) but no central ring current.

As Figs. 1c and d show, retention and destruction of a central π ring current can be reproduced in simpler model systems, **3** and **4**. To explain the opposite effects of saturated and unsaturated clamping groups, it is useful to consider orbital contributions to the current density maps. In an ipsocentric formulation, the total current density is partitioned into paramagnetic and diamagnetic orbital contributions, that depend on accessibility of excited states *via* rotational and translational transitions,[4] respectively. In the Hückel picture of the benzene ring, the *sole* active transition is that from HOMO (e_{1g}) to LUMO (e_{2u}), which is translationally allowed and produces four-electron diamagnetism.[4b] In a full, *ab initio* treatment this transition remains overwhelmingly dominant in the diamagnetic π ring current.[4a]

Fig. 2 illustrates the π orbital systems of the molecules **3** and **4**, and reveals the essential difference between the two. Clamping of the benzene ring with saturated groups as in **1** and **3**, imposes a purely geometric constraint, producing bond alternation and lowering the molecular symmetry. The HOMO–LUMO transition is then formally both translationally and rotationally allowed, but as the changes to the orbitals are first-order in ΔR, the transition moments are hardly changed, so that the pattern of currents remains essentially that of free benzene.

On the other hand, an *un*saturated clamping group introduces an extra set of π orbitals around the Fermi level. In **4** the interaction between central and perimeter π systems leads to a manifold of 5 orbitals in which significant but cancelling current density in the central ring arises from a mixture of translational and rotational $\pi \rightarrow \pi^*$ transitions. The $2e''$ HOMO pair gives a strong paramagnetic circulation in the central ring, the $2a_2''$ HOMO-1 gives con-rotating paramagnetic circulations in all three four-membered rings, and the $1e''$ HOMO-2 gives a diamagnetic circulation outside the central ring. The result is the island pattern of circulation on formal double bonds seen in the π map (Fig. 1d), dominated by 10 of the 12 π electrons.

A similar interaction diagram can be constructed for the benzene-annelated derivative **2**. The $2e''$ set corresponding to the HOMO of benzene contributes a diamagnetic current that is quenched by the paramagnetic contribution from $3e''$. A further 8 π electrons in the highest lying occupied orbitals ($4e''$, $3a_2''$, $1a_1''$) account for the discrete diamagnetic circulation on the outer benzene rings.

Orbital analyses also account for the different nucleus-independent chemical shifts[2b] in **1** (−8.0 ppm (0.0 Å)[8] and **2** (−1.1 ppm (1.0 Å)).[9] The strongly diatropic value for **1** and the equivocally diatropic value for the central ring of **2** arise from integrations over distinctly different patterns of total current.

Two general comments can be made. The first concerns bond alternation, used as an indication of benzenoid character of a

Nuclear positions are projected into the plotting plane, $1a_0$ above molecular plane.

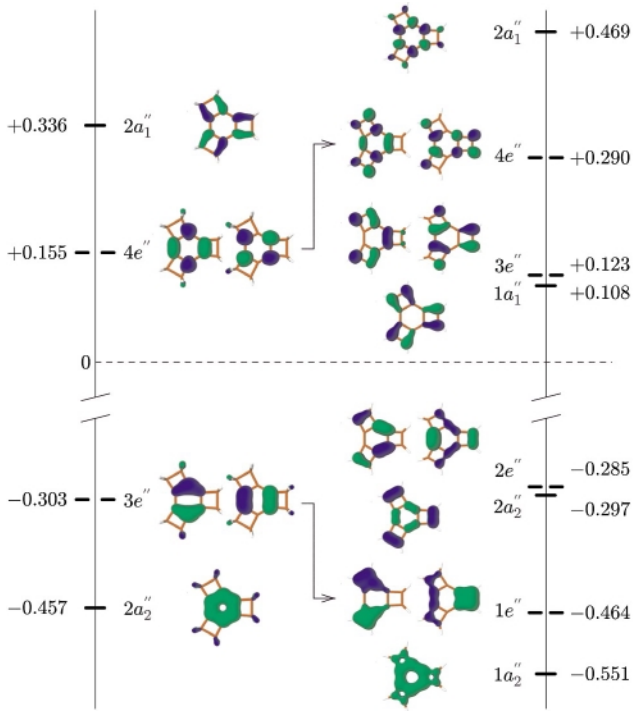

Fig. 2 Highest occupied and lowest unoccupied π molecular orbitals of **3** and **4**, with energies (au) and symmetries. In D_{3h}, translational (diamagnetic) π-π* transitions are $a_1'' \rightarrow e''$, $a_2'' \rightarrow e''$, $e'' \rightarrow (a_1'', a_2'', e'')$ and rotational (paramagnetic) transitions $a_1'' \rightarrow a_2''$, $a_2'' \rightarrow a_1''$, $e'' \rightarrow e''$.

clamped ring. It is clear from the orbital picture that the electronic effect of the clamping groups rather than their rôle as geometrical constraints determines whether the central current will be quenched. Strong bond alternation may be a symptom of either a rigid saturated clamp without significant effect on ring current, or of a strongly interacting unsaturated clamp which, by pushing HOMO and LUMO apart, quenches the current. The (benzo)cyclobutadieno clamp belongs to this latter class, whereas, for example, a set of 3,4-dimethylenecyclobuteno clamps,[3a] with localised π bonds *exo* to the four-membered rings, would be expected not to affect the central benzene current. Calculated maps (not shown here) confirm this expectation.

The second comment is that the orbital picture gives a unified account of both diatropic and paratropic central rings. For example, annelation[8] of cyclooctatetraene (COT) either retains or quenches the central paratropic current,[10] accordingly as the clamps do or do not push apart the closely separated HOMO–LUMO pair of the COT subunit.

Successive intramolecular transiminations in an iron(II) complex with chiral tridentate ligands

Tulio Enrique Chavez-Gil,† Mizuomi Yasaka, Tomoko Senokuchi, Masamitsu Sumimoto, Hiromasa Kurosaki and Masafumi Goto*

Received (in Cambridge, UK) 23rd August 2001, Accepted 9th October 2001
First published as an Advance Article on the web 24th October 2001

Two molecules of *S*-2-pyridylmethylidene-1-(2-pyridyl)-ethylamine coordinated to an iron(II) undergo successive transiminations yielding bis[1-(2-pyridyl)ethylidene-2-pyridylmethylamine]iron(II) in acetonitrile.

Biochemical transformations such as transamination and racemization of α-amino acid are mediated by pyridoxal (vitamin B_6).[1] Pyridoxal converts one amino compound to an aldimine by providing aldehyde followed by transimination of the aldimine to a ketimine, a precursor of a keto acid. Metal ions assist these reactions, though the details of their participation *in vivo* is a matter of controversy.[1] 2-Pyridinecarbaldehyde has been reported to promote the transimination by forming an imine bond with aliphatic α-amino acids in the presence of Zn^{II} and Cu^{II}.[2]

Imines, on the other hand, are useful functional groups for the construction of metal chelates because imines are easily derived from carbonyl groups (aldehyde or ketone) and primary amines.[3] Although much attention has been paid to the mechanism for the formation of imine bonds in the presence of metal ions,[3,4] less is known about the conversion of imines thus formed.[5] A translocation of the imine bond in a macrocyclic tetraimine coordinated to Fe^{II} has been described but the nature of the reaction remains ambiguous.[6]

Here, we describe the occurrence and kinetics of a smooth transimination on a low-spin iron(II) with *S*-2-pyridylmethylidene-1-(2-pyridyl)ethylamine, *S*-PMPE. The bis(*S*-PMPE)Fe^{II} perchlorate was isolated as a diastereomeric mixture.‡ The UV–Vis spectrum of CD_3CN solution is almost identical to {Fe[1-(2-pyridyl)ethylidene-2-pyridylmethylamine]$_2$}$^{2+}$, [Fe(PEPM)$_2$]$^{2+}$, but a significant negative Cotton effect at 550 nm and positive-to-negative exciton band around 330 nm were observed in CD spectroscopy. The Cotton effects are in agreement with the Λ-[Fe(phen)$_3$]$^{2+}$ or Λ-[Fe(bpy)$_3$]$^{2+}$.[7] (The assignment of the absolute configuration is based on the chirality of two 1,2-diimine chromophores of the tridentate ligands.) From the ^{1}H NMR spectrum the ratio of the amount of the two diastereomers is 1.0 to 0.8. Based on these, the major and minor compounds are tentatively assigned to the Λ-*mer*- and Δ-*mer*- isomers respectively.

Changes on the ^{1}H NMR spectrum of [Fe(*S*-PMPE)$_2$]$^{2+}$ in CD_3CN at 45 °C are shown in Fig. 1. At first, the spectra (Fig. 1(a)) are composed of two sets of signals because [Fe(*S*-PMPE)$_2$]$^{2+}$ is a mixture of two diastereomers, each of which has C_2 symmetry. In the early reaction stage, the magnitudes of two doublet methyls at δ = 2.42 (peak 1) and 2.57 (peak 4) and two azomethine signals at δ = 10.32 (peak 11) and 10.39 (peak 14) decreased, while those of the two new doublet methyls at δ = 2.44 (peak 2) and 2.48 (peak 3) and azomethine signals at δ = 10.33 (peak 12) and 10.34 (peak 13) increased along with new singlet methyls at δ = 3.40 (peak 6) and 3.43 (peak 7) and AB pattern signals at *ca*. 6.43–6.30 ppm. In the successive stage, the magnitudes of the new signals diminished after reaching maxima and new signals followed, in which only one methyl signal at δ = 3.37 (peak 5) emerged and an AB pattern centered at δ = 6.37 (peak 8) appeared. The final spectrum coincided with that of [Fe(PEPM)$_2$](ClO$_4$)$_2$.[8] These changes are accounted for by consecutive reactions shown in Fig. 2. There are two tridentate ligands, *S*-PMPE, co-ordinated to Fe^{II}. The transimination on one of the ligands of Λ-[Fe(*S*-PMPE)$_2$]$^{2+}$ (**1**) and Δ-[Fe(*S*-PMPE)$_2$]$^{2+}$ (**2**) yields intermediates, Δ-[Fe(*S*-PMPE)(PEPM)]$^{2+}$ (**3**) and Λ-[Fe(*S*-PMPE)(PEPM)]$^{2+}$ (**4**) respectively. In the successive transimination, the remaining *S*-PMPE is converted to PEPM thus forming Λ- and

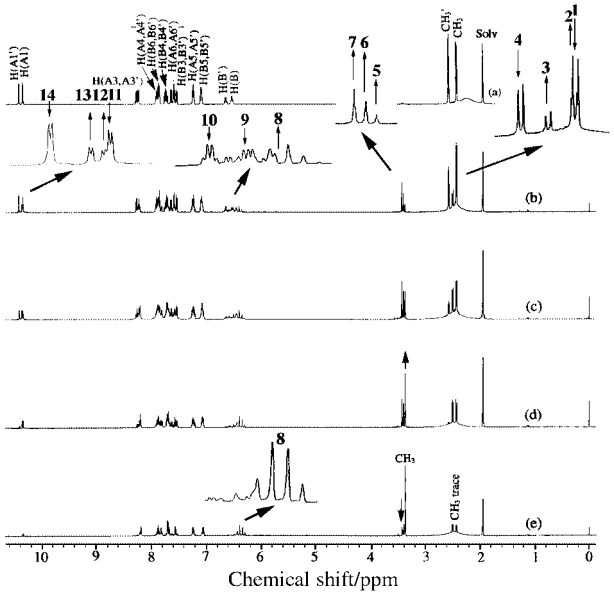

Fig. 1 ^{1}H NMR change of [Fe(*S*-PMPE)$_2$](ClO$_4$)$_2$ in CD_3CN.

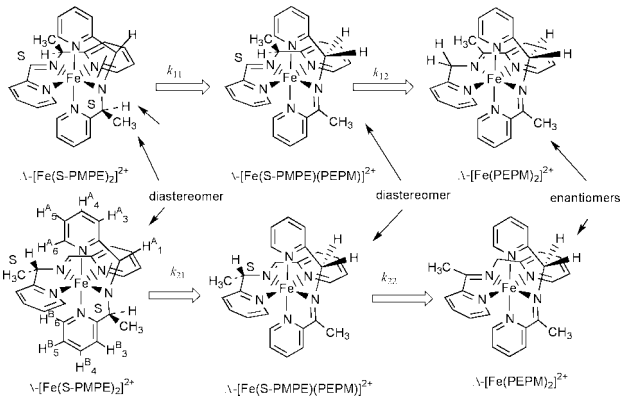

Fig. 2 Pathway of transimination of Λ- and Δ-[Fe(*S*-PMPE)$_2$]$^{2+}$ as detected by NMR and CD spectra in CD_3CN and proton labels.

† A JSPS Foreign Researcher Postdoctoral Fellow from Nov 1997 to Nov 1999. Present Address, University of Puerto Rico, Mayaguez Campus, Department of Chemistry, P.O.Box 9019, Mayaguez, PR 00681.

 DOI: 10.1039/b107502k

Δ-[Fe(PEPM)$_2$]$^{2+}$ (**5** and **6**) which are enantiomers to each other and indistinguishable by NMR spectroscopy.

The CD spectrum of the final stage showed Cotton effects which are very similar to those of [Fe(*S*-PMPE)$_2$]$^{2+}$. This finding supports that the optical activity stems from the configurational effect of two 1,2-diimine chromophores co-ordinated to Fe^{II} because the asymmetric centres in the ligands were lost in the final product and that this reaction proceeds without disruption of the Fe–N bonds.

This conversion was slow in CD_3CN, and the presence of water accelerated the reaction. The reaction was investigated with varying solvents, *i.e.* 90% CD_3CN–H_2O, 90% CD_3CN–D_2O. In the presence of D_2O, however, the intensity of the AB signals (peak 8) due to –CH_2 diminished. These findings support that the product [Fe(PEPM)$_2$]$^{2+}$, undergoes a facile H–D exchange at the methylene hydrogen in the presence of D_2O.

The reaction was accelerated by the presence of organic base. The time course of the reaction was followed by ^{1}H NMR measurements with CD_3CN solution of 2,6-dimethylpyridine and an example is shown in Fig. 3, the curves are drawn based on the first-order consecutive reactions using rate constants derived from a non-linear least-squares method. Increase in the concentration of 2,6-dimethylpyridine resulted in the increase of the rate constant as shown in the inset of Fig. 3. The abscissa, $k_{0,\,obs}$, for each reaction can be ascribed to a small amount of water in the solvent. From the slope of the lines in the inset, second order rate constants are derived: k_{11} = 41.7 ± 0.1; k_{12} = 24.1 ± 0.1; k_{12} = 10.7 ± 0.1; k_{22} = 10.1± 0.1 M^{-1} min^{-1} at 45 °C.

The driving force of this transimination will be the difference in the enthalpy between N(py)=C–CH=N–CH(CH_3)–CH(py) and N(py)=C–CH_2–N=C(CH_3)–C=N(py) co-ordinated to Fe(II). This reaction could occur *via* H$^+$ dissociation by a base yielding a 1,3-diiminate intermediate, N(py)=C–CH=N(Fe^{II})$^-$=C(CH_3)–CH(py), followed by reprotonation from the conjugated acid of the base to the 1,3-diiminate because the rate of each step is proportional to the base. It is noteworthy that the doublet methyls did not show any indication of singlet formation in 10% D_2O–CD_3CN solution due to an H–D exchange at the –CH(CH_3)– site. This will be the consequence of the unidirectional nature of this reaction, *i.e.* reprotonation to the deprotonated species occurs exclusively at the ethylidene site.

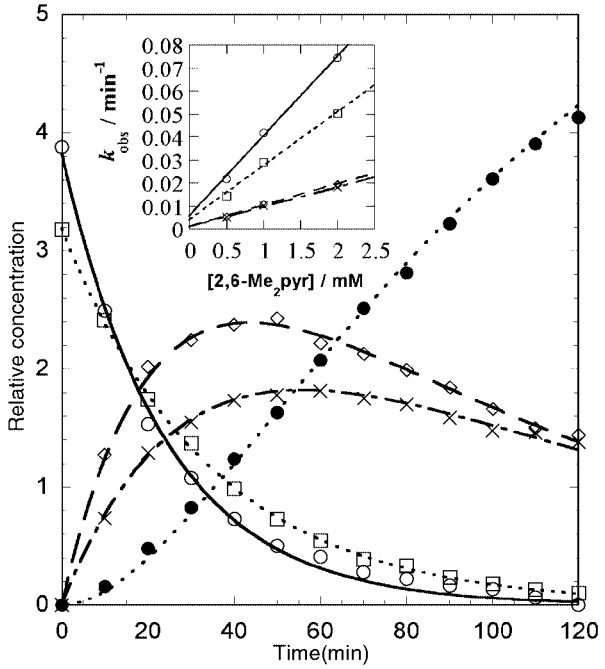

Fig. 3 Time course of transimination of Λ- and Δ-[Fe(*S*-PMPE)$_2$]$^{2+}$ in 1.0 mM 2,6-dimethylpyridine CD_3CN solution at 45 °C: ○, 1; □, 2; ◇, 3; ×, 4; ●, 5 + 6. Inset shows the dependency of first-order rate constants on the concentration of 2,6-dimethylpyridine: ○, k_{11}; □, k_{21} ◇, k_{12}; ×, k_{22}.

These observations led us to measure the rate of H–D exchange in {Fe[pyridylmethylidene-1-(2-pyridyl)methylamine]$_2$}$^{2+}$. This compound has been known for several decades but there seems no report on the H–D exchange on the ligand.[9] In a 10% D_2O–CD_3CN solvent, the H–D exchange occurred at the methylene and azomethine in the presence of 5 mM 2,6-dimethylpyridine at 45 °C. The H–D exchange at the methylene followed successive first-order consecutive reactions (exchange of one of the methylene hydrogens in the initial stage followed by exchange of the remaining hydrogen) with the rate constants of 0.04 min^{-1} and 0.025 min^{-1}. The decay of the azomethine signal occurred more slowly and did not follow simple first-order rate law. The decay was described by two-phase first-order reactions as rate = $A_1\exp(-k_1t)$ + $A_2\exp(-k_2t)$, with k_1 = 0.014 min^{-1} and k_2 = 0.0015 min^{-1}. These results are in accordance with the reaction paths where the H$^+$ is removed from the methylene (or deuterated methylene) solely and reprotonation occurs to a 1,3-diiminate intermediate.

Notes and references

‡ *Experimental procedure*: *S*-2-(1-ethyl)pyridine was synthesized as described in the literature.[10] Λ- and Δ-[Fe(*S*-PMPE)$_2$](ClO_4)$_2$. An acetonitrile solution of Fe(ClO_4)$_2$·6H_2O (0.5 g, 1.4 mmol) in 50 cm^3 was mixed with 3 cm^3 of acetonitrile containing 0.29 g (2.7 mmol) of pyridine-2-aldehyde under argon. After 10 minutes, 0.33 g (2.7 mmol) of *S*-2-(1-ethyl)pyridine in 5 cm^3 of acetonitrile was added dropwise. The mixture was warmed at 60 °C for 10 minutes followed by cooling; addition of 15 cm^3 of diethyl ether yielded violet microcrystals. Yield 0.89g (96.7%). Anal. Calc. for $C_{26}H_{26}N_6FeCl_2O_8$: C, 46.1; H, 3.8; N, 12.4. Found: C, 46.7; H, 3.8; N, 12.1%. FAB-mass *m/z*: $C_{13}H_{13}N_3FeClO_4^+$ requires 366.5; found: 366.5. The signals of the ^{1}H NMR spectrum were assigned as indicated in Fig. 1a on the basis of ^{1}H–^{1}H COSY, ^{1}H–^{13}C HMQC, and ^{1}H–^{13}C HMBC spectra. For the 2,6-dimethylpyridine accelerated reactions, the iron complex was weighed into 2 mm φ NMR tubes and air was eliminated by argon flow through a serum cap. The CD_3CN solution of 2,6-dimethylpyridine was added with a syringe through the serum cap. The sample was mounted to an NMR probe and the measurement was started immediately at 45 °C. The isolated peaks were chosen to measure the peak areas; peak 4 as **1**, peak 14 as **2**, peaks 6, 7, 5 as intermediates and the final product. The relative concentration of each species was calculated based on the area.

Selective binding and reversible release of riboflavin by polymer-bound zinc(II) azamacrocycles†

Burkhard König,* Hans-Christoph Gallmeier and Roland Reichenbach-Klinke

Institut für Organische Chemie, Universität Regensburg, Regensburg, Germany. E-mail: Burkhard.Koenig@chemie.uni-regensburg.de; Fax: (+49)941-943-1717; Tel: (+49)941-943-4576

Received (in Cambridge, UK) 23rd August 2001, Accepted 9th October 2001
First published as an Advance Article on the web 31st October 2001

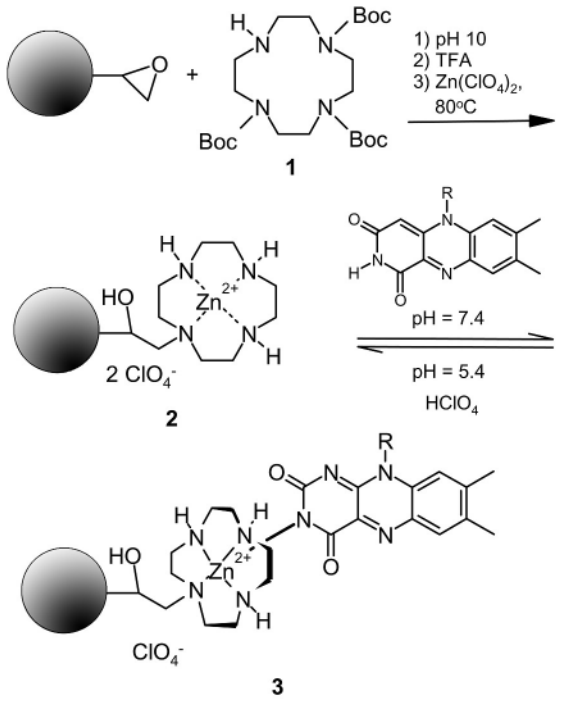
The reversible formation of a coordinative bond between a polymer-bound Lewis-acidic metal complex and a flavin imide moiety allows complete extraction of riboflavin from aqueous solution at physiological pH and its quantitative release at pH 5.

Vitamin B2 (riboflavin) is an important biological redox cofactor and essential for human and animal health. Riboflavin is produced biotechnologically and used in vitamin enriched food and food supplements. This calls for methods that allow the quantitative and selective isolation of riboflavin from aqueous solutions. We report here the synthesis and the properties of a functionalized polymer which reversibly and selectively binds flavins at physiological pH in aqueous solution.[1]

From the work of Kimura[2,3] and others[4] the ability of Lewis-acidic zinc(II)–cyclen complexes to reversibly coordinate imide moieties with high binding strengths is well documented. The binding motif has been used in artificial receptors for barbiturates,[5] thymine[6] and flavins.[4] To immobilize zinc(II)–cyclen as a binding site on a polymer surface we have reacted the protected cyclen derivative **1**[7] with Fractogel® EMD epoxy, a tentagel phase which is derivatized with epoxy groups.[8] Remaining epoxide groups on the polymer were deactivated with excess glycine, the BOC protecting groups of the azamacrocycle were removed by standard methods with trifluoroacetic acid (TFA) and treatment with aqueous zinc(II) perchlorate solution gave the target material, as a stable, white powder (Scheme 1). A loading of 15 mmol of zinc(II) complex per gram of the polymeric material was determined by elemental analysis.‡

Due to the large number of binding sites, high affinity of the polymer to imide-containing molecules was expected even in water. A simple experiment revealed the predicted properties. Buffered aqueous solution of riboflavin (c = 4.9 × 10^{-5} mol L^{-1}) was passed through a column which was filled with the polymer material. For comparison an identical second column was filled with Fractogel® EMD epoxy, which was derivatized with glycine only. As easily observed by the naked eye the flavin was fully retained on the material with zinc(II)–cyclen binding sites (see supporting information† Fig. 3b, left column), while no retention is observed on the reference polymer (Fig. 3b, right column). The flavin is retained on the polymer upon washing with aqueous buffer pH 7.4, but is quantitatively released with aqueous buffer at pH 5.4 (Fig. 3c, left column). Fig. 1 shows the UV spectra of the solutions before and after passage through the column.

Apoproteins of riboflavin-binding proteins, *e.g.* the riboflavin-binding protein of egg white, have been used to determine the amount of riboflavin in mixtures with other compounds.[9] Such proteins show up to nanomolar affinities for the analyte and distinguish between flavin derivatives.[10]



Scheme 1 Synthesis of a zinc(II)–cyclen loaded polymer **2** and binding equilibrium with riboflavin (R = ribityl) or its tetraacetate [R = $CH_2CH(OAc)CH(OAc)CH(OAc)CH_2OAc$].

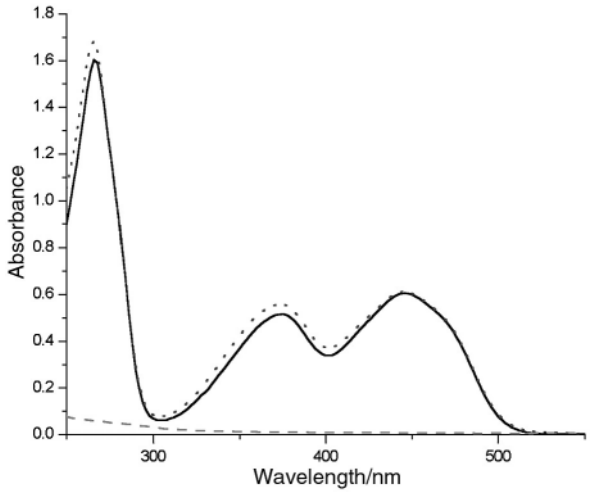


Fig. 1 Absorption spectra of a buffered aqueous solution (pH = 7.4; Tris–HCl) of riboflavin (c = 4,9 × 10^{-5} mol L^{-1}) before passage through the column filled with **2** (——); absorption spectra of the eluate after passage through the column (– – –); absorption spectra of the buffered aqueous solution (pH 4.4; acetate buffer) used to wash the column (· · ·). Solutions to load and to wash the column have the same volume.

† Electronic supplementary information (ESI) available: selective binding and reversible release of riboflavin, Figs. 3 and 4. See http://www.rsc.org/suppdata/cc/b1/b107605a/

 DOI: 10.1039/b107605a

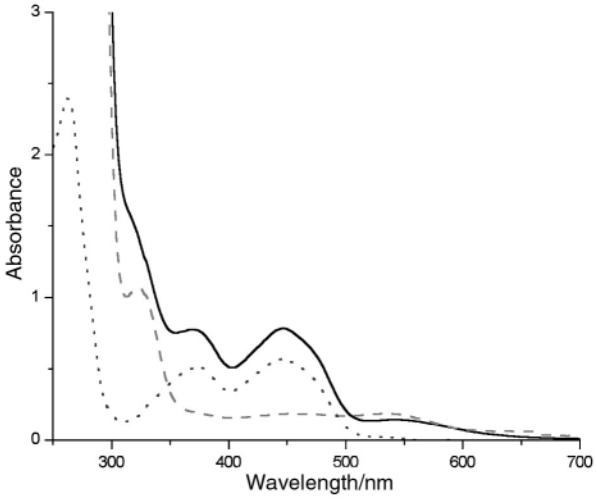

Fig. 2 UV spectra of vitamin drink: (——) before passage through a column filled with **2**; (– – –) filtrate after passage; (· · ·) eluted with aqueous buffer pH 4.4.

Polymer **2** shows an apparent binding constant to riboflavin in the millimolar range at pH 7.4 and its selectivity is restricted to imide recognition.§ However, for many practical purposes this might be sufficient to replace an apoprotein. To demonstrate the ability of **2** to remove riboflavin selectively and quantitatively from a mixture of compounds, the polymer was treated with a solution of a commercial vitamin dietary supplement.[11] The tablets, which have to be dissolved in water to prepare a vitamin drink, contain vitamins B1, B2, B6, B12, C, E, folic acid, biotin, pantothenic acid and nicotinamide in amounts corresponding to the recommended daily amount (RDA) for adults. Additional ingredients are citric acid, sodium bicarbonate, fructose, colour from beetroot, starch, sodium cyclamate and sodium saccharine. The composition of ingredients of this product is typical for similar dietary supplements of this kind. Passage through the column filled with **2** removes riboflavin, as indicated by the disappearance of the typical absorptions in the UV spectra of the filtrate (Fig. 2). Elution of the column with aqueous buffer at pH 4.4 gave a solution of pure riboflavin in the concentration exactly corresponding to the total amount of riboflavin the mixture (tablet) had contained.[12] As verification, 0.21 mg of riboflavin were added to the filtrate which had passed the column and the resulting solution was passed through a second column filled with **2**. The retained riboflavin was eluted with aqueous buffer pH 4.4. From the absorption an overall isolated amount of 0.20 mg was determined, showing within the experimental error a quantitative reisolation.

The functionalized polymer **2** introduced in this paper facilitates the isolation of riboflavin from natural sources[13] and its analytical determination in mixtures.[9] Moreover, it is another example of selective binding of a biological important compound under physiological conditions using artificial receptors within the concept of polyvalence binding sites.

Notes and references

‡ *Preparation of zinc(II)–cyclen loaded Fractogel® EMD epoxy polymer.* Fractogel® EMD epoxy (4.0 g) and **1** (600 mg, 1.27 mmol) were suspended in 80 mL of water buffered to pH 10 with carbonate, and mechanically stirred for 4 d at 40 °C. The polymer was collected by filtration, suspended in 40 mL of aqueous Tris–HCl buffer (pH 8) which contains 0.2 mol L^{-1} glycine and stirred for 2 h at 40 °C. The material was collected by filtration, treated with 20 mL of trifluoroacetic acid for 10 min at rt, filtered and washed with aqueous NaOH (2 M, 50 mL) and water (100 mL) to yield 4.01 g cyclen-loaded polymer. Elemental analysis (C: 53.32, H: 8.02, N: 0.80%) corresponds to 0.14 mmol cyclen for 1 g of material.

A suspension of $Zn(ClO_4)\cdot 6H_2O$ (1.34 g, 3.6 mmol) and the prepared polymer (2.02 g) in 10 mL of water was heated to 80 °C for 3 h, the polymer was collected by filtration and was washed with water and methanol to yield after drying 1.9 g of zinc(II)–cyclen-loaded polymer. Elemental analysis (C: 51.45, H: 7.6, N: 0.85%) corresponds to a polymer loading of 0.15 mmol zinc–cyclen complex for 1 g of polymeric material.

§ The binding constant was determined from the UV absorption of a buffered aqueous solution of riboflavin ($c = 10^{-5}$ mol L^{-1}) after incubating it with a specific amount of **2** for 30 min at room temperature. $K_{app} = 1.2 \times 10^{-3}$ mol L^{-1} (average of several measurements).

1 The use of reversible coordinative bonds for the binding of substrates to polymeric support has very recently been reported by Ley *et al*. in the context of organic synthesis. S. V. Ley, A. In the lamellar architecture of the title crystal structure mediated by C–H···O hydrogen bonds, 1,2-dimethoxyethane and *n*-hexane are included in the hydrophobic galleries; isostructurality of these clathrates is a unique case of guest mimicry.

Host–guest inclusion compounds provide opportunities for the design of novel open architectures for diverse applications such as chemical separation, reactions and catalysis in a microcavity, and for electrooptic, nonlinear and magnetic materials.[1] Crystal engineering of 2D and 3D robust metal–organic and soft molecular open frameworks offer the promise of tailoring specific structures, functions and properties through functionalised organic molecules.[2] For example, 4-tritylbenzoic acid crystallises *via* a carboxylic acid dimer (O–H···O hydrogen bond) with wheel–axle topology, 4-halophenoxy triazines self-assemble through triangulo halogen synthons (Cl···Cl, Br···Br interaction) as hexagonal channel hosts, and ligands such as 1,3,5-benzenetricarboxylic acid, 4-aminopyridine and 4,4′-bipyridine continue to be exploited in coordination polymer networks.[3] We report herein the construction of a lamellar, C–H···O hydrogen bonded host lattice which includes guest species in the interlayer region, thereby expanding the family of newly emerging neutral, organic clay mimics.[4]

Molecule **1**† [5] (Scheme 1) was designed as a tecton[6] with hydrogen bonding donor–acceptor groups in the quinone ring and biphenyl spacers oriented in the third dimension. It was expected that tecton **1** will self-assemble in a layer motif *via* C–H···O hydrogen bonded tape **2** and the biphenyl groups will constitute the pillars in the resulting 3D open framework. While implementing this molecule → crystal synthetic strategy for a potential host, we are aware that interpenetration[7] competes with guest inclusion during crystallisation and that the latter phenomenon (the goal of this study) occurs in only *ca.* 15% cases.[8] Recrystallisation of **1** from various solvents afforded diffraction quality crystals from 1,2-dimethoxyethane (DME). The X-ray structure of **1**·DME (2:1 stoichiometry, *C*2/*c* space group)‡ contains a C–H···O hydrogen bond chain along [001] (H···O 2.66 Å, C–H···O 160.6°; C–H distance neutron-normalised to 1.083 Å). The second C–H···O bond of the tape is long (3.05 Å, 175.6°) but at the accepted distance limit advocated by Desiraju and Steiner.[9] What is significant from a crystal engineering objective is that the target synthon **2** has been obtained (Fig. 1). The biphenyl groups do not engage in the usual herringbone T-motif or π–π stacking interactions,[10] possibilities that would have resulted in a self-inclusion crystal through interdigitation. Instead, inversion-related biphenyl groups form parallelepiped channels of 8 × 5 Å down the *c*-axis which are occupied by ordered DME guest species (Fig. 2). Host–host and host–guest (Ph)C–H···O hydrogen bonds (2.71, 137.2; 2.57 Å, 159.5) further stabilise the ordered supramolecular structure of **1**·DME. The advantage of building host networks with weak interactions was highlighted in a recent paper on 14 inclusion compounds of tetrakis(4-nitrophenyl)-methane.[11] Open architectures assembled with C–H···O hydrogen bonds have a degree of both stability and flexibility, a combination that results in adaptability and versatility towards guest inclusion.

Continuing further, **1** was recrystallised from *n*-hexane, a solvent isosteric with DME but devoid of hydrogen bonding groups. The crystal structure of **1**·*n*-hexane (2:1) is iso-

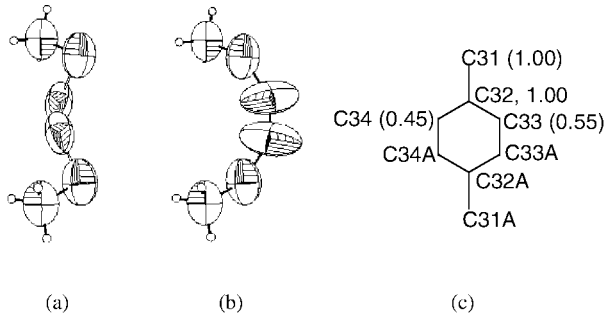

Fig. 3 Displacement ellipsoids at 50% probability of *n*-hexane in **1**·*n*-hexane (2:1). (a) Conformation with 45% occupancy of C34, (b) conformation with 55% occupancy of C33, (c) superposition of both conformers to show the mimicry with 1,4-dimethylcyclohexane (sof of atoms).

morphous‡ with identical arrangement of host atoms in the crystal. The metrics of quinone tape C–H···O bonds are 2.67, 161.9 and 2.99 Å, 175.1°; the (Ph)C–H···O is 2.71 Å, 137.2°. In the channel, *n*-hexane is disordered over two orientations with 55% and 45% occupancy (Fig. 3). The slightly elongated displacement ellipsoid of the C33 atom in a low temperature crystal structure implies that there are other minor conformations that contribute to guest disorder, but it is difficult to assign their exact position because of very low electron density. Using our refinement model, the structure converges (*R* factor 0.0675) with site occupancy factor (sof) of 0.55 and 0.45 for C33 and C34 guest atoms. Notably, neither of the conformations of *n*-hexane trapped in the microcavity correspond to the one in the crystal structure of pure solvent.[12] Superposition of the two conformers (Fig. 3c) suggests that host **1** may be able to separate a mixture of *cis*- and *trans*-1,4-dimethylcyclohexane.§ The guest is present in folded conformations because dimensions of the host cavity (8 × 5 Å) force it to adopt a compact shape.[13] The end-to-end C···C distance in the folded conformations of *n*-hexane is 5.5 Å (5.3 Å in DME) while it is 6.4 Å in the extended zigzag conformation.[12] Energy of the three conformations of *n*-hexane (RHF-631G*)¶ is −235.2718 au (55% population), −235.2933 au (45% population) and −235.3678 au (zigzag). A survey of the Cambridge Structural Database[14] (version 5.21, April 2001 update) shows that this is the first example of structural mimicry between DME and *n*-hexane in a host channel. The host cavity of **1**, which also includes 1,4-dibromobutane,‖ is highly selective towards these guest species. Co-solvents such as EtOAc, Et_2O, $CHCl_3$, CH_2Cl_2 are not included, even when present in large excess.

Finally, we note that while polymorphs of phenyl benzoquinone **3** were found to have divergent, even abstruse, crystal packing in $P\bar{1}$ (Z = 8) and $P2_1$ (Z = 2) space groups,[15] pseudopolymorphs of biphenyl analogue **1** are isostructural. Therefore replacement of geminal phenyl group with biphenyl steers crystal packing towards a recurring (robust) supramolecular synthon[16] and yields a novel, organic host material with clay-like properties. Metric engineering[2] of the lamellar–pillar molecular framework of **1** is a current goal in our studies.

We thank Professor W. T. Robinson and Dr R. Kadirvelraj (University of Canterbury, New Zealand) for X-ray data collection on a Bruker SMART diffractometer. Financial assistance from the DST in the form of a research project (SP/S1/G29/98) and for supporting the Enraf-Nonius X-ray diffractometer facility is acknowledged. VSSK thanks the CSIR for fellowship.

First published as an Advance Article on the web 2nd November 2001

X-Ray crystallographic analyses of fluorocyanides *anti*-1 and 2 revealed a novel *intramolecular through-space interaction between F and CN* in an acyclic system, which was applied to a stereoselective protonation of acyclic fluorocyanides 2 having flexible conformation.

The discovery of interactions between functional groups, such as hydrogen-bonding, π–π stacking, and CH–π interactions, is a pivotal area of investigation in organic and bioorganic chemistry. In organic synthesis, these interactions have controlled the stereochemistry in Diels–Alder and ene reactions.[1] Based on theoretical studies of the 'Bürgi–Dunitz trajectory' in nucleophilic additions to carbonyl groups,[2] Dunitz *et al*., discovered in 1978 the interaction between the ethereal oxygen and the carbonyl group in 8-methoxy-1-naphthyl methyl ketones.[3a] The newly coined 'nucleophilic–electrophilic interaction' was also found between the nitrogen and the carbonyl carbon and between the oxygen and the cyanide carbon.[3] Recently, intramolecular nonbonded interactions between oxygen and sulfur or selenium in heterocycles have also been observed.[4] Because of their unique characteristics of metabolic inhibition and high lipophilicity, organofluorine compounds are widely used in pharmaco- and agrochemistry. However despite their extensive use, the interaction of fluoride with organofunctional groups has remained virtually unexplored,[5] whereas interactions between fluoride and metals[6] and hydrogen-bonding interactions with fluoride[7] are often observed. We report herein the discovery of *a novel through-space interaction between F and CN*, which serves as a conformational regulation of a flexible acyclic carbon chain.

A molecule having two functional groups with large dipole moments in an acyclic system usually adopts a stable conformer in which the dipole moments oppose each other. However, we have observed the unusual phenomenon in which two functional groups in an acyclic system align to give the maximum dipole moment. Namely, during studies on ferroelectronic crystals,[8] a large spontaneous polarization was observed in liquid crystals doped with optically active 3-fluorocyanide derivatives. It is possible that in this case the two functional groups with large dipole moments aligned in the same direction to make a large spontaneous polarization; therefore, we postulated the existence of a novel through-space interaction between F and CN, as depicted in Fig. 1. In order to prove this hypothesis, we carried out X-ray crystallographic analyses of the crystalline fluorocyanides **1** and **2**.

The crystallographic analysis[9] (see ESI†) of optically active *anti*-**1**, which was prepared from 4-methoxyphenylacetonitrile and (*R*)-epoxyoctane,[10] is shown in Fig. 2. The distance between F and C(1) was found to be 2.890 Å, which is 0.28 Å shorter than the sum (3.17 Å) of their van der Waals radii. The angle between these atoms when projected in the C2–C4 plane was 8.6°. These two functional groups formed an envelope-shaped *pseudo* five-membered ring which includes the three carbons C2–C4. The F moiety of the *pseudo* five-membered ring was distorted toward the CN group. Among the angles concerned with the *pseudo* ring, θ_1 and θ_2 were shorter than a right angle, and θ_4 was found to be less than 180°, unlike the usual cyanide having the linear sp configuration. These data suggest that the lone pair of the fluorine (n_F) is being donated to the π* orbital on the cyanide carbon (π^*_{CN}).

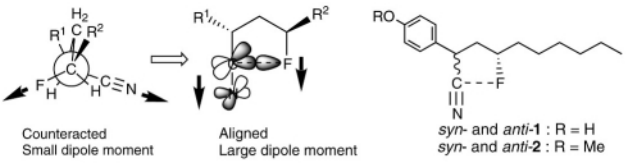

Fig. 1 Novel through-space $n_F \rightarrow \pi^*_{CN}$ interaction to freeze the conformation in an acyclic system.

Unlike the *anti*-**1**, the crystallographic analysis[11] (see ESI†) of the other diastereomer *syn*-**1** has revealed that the angle between these atoms when projected in the C1–C3 plane is −118.6°. Instead of a through-space interaction, an intermolecular hydrogen-bonding between phenolic hydrogen and cyano nitrogen was observed in the packing structure. This suggests that the observed through-space interaction between F and CN is weaker than the hydrogen-bonding interaction. Since the phenol moiety of the *syn*- and *anti*-**1** had drastically affected their conformation through the hydrogen-bonding interaction, we next decided to investigate the conformation of their methyl ethers *syn*- and *anti*-**2**.

The crystallographic analysis[12] (see ESI†) of *anti*-**2** has shown that the distance between F and C(9) is 2.872 Å, which is 0.30 Å shorter than the sum of their van der Waals radii. The conformation of *anti*-**2** was found to be almost the same as that of *anti*-**1**; therefore, the novel through-space interaction was

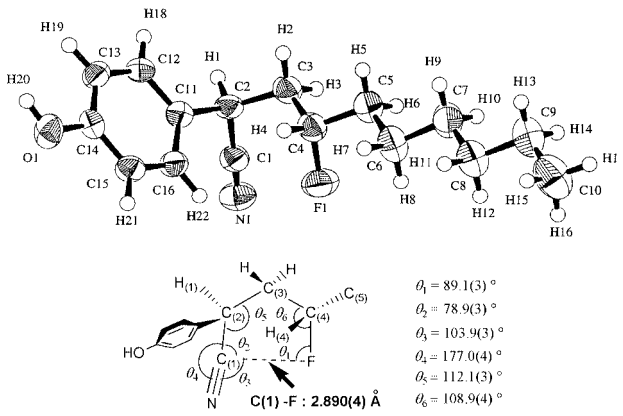

Fig. 2 Crystal structure of *anti*-**1**.

† Electronic supplementary information (ESI) available: experimental procedure for the syntheses of *syn*- and *anti*-**1** and **2**, spectroscopic data for all compounds, a procedure for the stereoselective protonation of **2**, full crystallographic data of *syn*- and *anti*-**1** and *anti*-**2**. See http://www.rsc.org/suppdata/cc/b1/b107213g/

 DOI: 10.1039/b107213g

proved to be independent of the intermolecular hydrogen-bonding of the phenol moiety. However, conformational data on *syn*-**2** in solid state could not be obtained because it is an oil.

Since the through-space interaction between F and CN had been established in the crystal, we turned our attention to the existence of this new interaction in solution. The ^{1}H-NMR signals of the methylene protons (ABXX′ type) in *syn*-**1** were observed at 1.98 and 2.34 ppm in $CDCl_3$, whereas those of *anti*-**1** were at 1.94–2.13 (2H). These chemical shift values and the coupling patterns in *syn*- and *anti*-**1** were very similar to those of the corresponding *cis*-γ-lactone (1.99 and 2.72) and the *trans*-γ-lactone (2.35 and 2.46), respectively.[8a,b] This observation suggests that the through-space interaction also occurs *via* a *pseudo* five-membered ring in both the *syn* and *anti*-fluorocyanides **1** in solution. To demonstrate the conformational control of an acyclic system utilizing this interaction, we investigated the stereoselective protonation of the α-anion of the cyanide derived from an equimolar mixture of *syn*- and *anti*-**2**. Our working hypothesis is that the diastereoselective protonation of the naked anion intermediate[13] with a bulky proton source would give *syn*-**2** preferentially by 1,3-asymmetric induction, based on a chiral carbon bearing a fluorine atom, if the through-space interaction between F and CN existed in the naked anionic molecule in solution. Our results are summarized in Table 1. Bulky phenols as proton sources gave products with higher diastereoselectivity than benzoic acid derivatives. 2,5-Dichlorobenzoic acid gave a product with lower selectivity than did benzoic acid, probably due to its higher acidity. The major diastereomer obtained was *syn*-**2**, with a very significant diastereoselectivity (5.3 : 1). We interpret this result as follows: the 1,3-asymmetric induction would arise from the *pseudo* five-membered ring intermediate formed by the through-space interaction between a lone pair of F and an sp-carbon of the naked α-anion of the cyanide, as in the control experiment under the same reaction conditions using an equimolar mixture of the corresponding *cis*- and *trans*-γ-lactones to give predominantly the *cis*-γ-lactone (94% yield, *cis* : *trans* = 10.6 : 1). From the above experiments, this through-space interaction, even in a solution containing the carbanion, is able to affect the conformational regulation of an acyclic carbon chain, but the ring formed by the interaction is not completely fixed as in the γ-lactone. However, this novel conformational regulation in an acyclic compound is valuable because of (1) the diastereoselective reaction of the α-anion of the 3-fluorocyanide and (2) the stereochemical prediction of the product, both of which are usually difficult in acyclic systems.

In conclusion, we have observed for the first time *a novel intramolecular through-space interaction between F and CN* by X-ray crystallographic analyses of the 1,3-fluorocyanides *anti*-**1** and **2**. Although this through-space interaction is weaker than the hydrogen-bonding interaction, acyclic compounds having flexible conformations were conformationally controlled by this interaction to form the distorted *pseudo* five-membered ring. However, it is particularly noteworthy that the existence of this novel interaction can not be predicted by the semiemperical PM3 calculation of *anti*-**1**, and by *ab initio* MP2 6-31G* and density functional df 6-31G* calculations of the simplified model compound of *anti*-**1**.[14] We also demonstrated the utility of the through-space interaction by a stereoselective protonation of an anion in solution. Further studies on through-space interactions between the functional groups are underway in our laboratory.

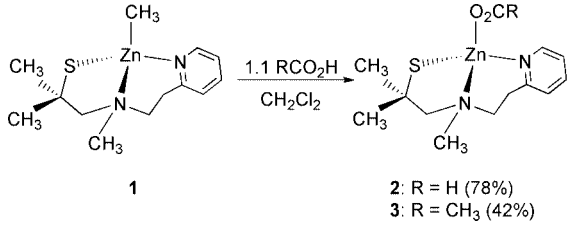
Received (in Cambridge, UK) 30th July 2001, Accepted 27th September 2001
First published as an Advance Article on the web 2nd November 2001

The synthesis and crystallographic characterization of a new (N_2S)zinc–alkyl complex and (N_2S)zinc–formate complex is described; the bonding mode of the formate complex has implications for the mechanism of action of the enzyme peptide deformylase.

The zinc ion is the active metal in a considerable number of metalloenzymes, and the details of its catalytic function are of great interest to a continually expanding audience.[1,2] In many of these enzymes (*e.g.* carbonic anhydrase, thermolysin, carboxypeptidase A), a tetrahedral zinc(II) center is bound by an N_xO_y ligand set and a fourth catalytically active H_2O/OH^- ligand.[2] Much less commonly found, however, is the presence of a cysteinate sulfur ligand as part of a mixed N,S environment. One example of this uncommon coordination environment comes from the bacterial enzyme peptide deformylase (PDF), which has a [(His_2Cys)$M^{II}(OH_2)$] active site.[3] Intriguingly, PDF is the first example of a metallopeptidase that utilizes an iron(II) ion *in vivo*,[4] although its structural and functional characteristics indicate that it rightfully belongs in the mononuclear zinc(II) enzyme family.[5] Even more interestingly, the Zn(II) form of the enzyme is remarkably less active ($k_{cat}/K_m \sim 10^2$ smaller for the same substrate) than the Fe(II) form.[6]

Through a synthetic analogue approach, we intend to address the underlying principles that may be responsible for the unusual selection of iron(II) by PDF and the low reactivity found for Zn(II)–PDF. Also of interest is the role that the unusual thiolate donor plays. The effect of a thiolate donor on the structure and reactivity of model compounds capable of hydrolysis[7] is essentially unknown because of a dearth of well-defined N_xS_y-M(II)X (X ≠ N,S) complexes.[8] Herein is described the synthesis and structural characterization of a new reactive N_2S(alkythiolate)zinc(II)–alkyl complex [(PATH)-Zn(CH_3)] **1** (PATH = 2-methyl-1-[methyl-(2-pyridin-2-yl-ethyl)amino]propane-2-thiolate)[8] which serves as a useful synthon for the preparation of the carboxylate complexes [(PATH)Zn(O_2CH)] **2** and [(PATH)Zn(O_2CCH_3)] **3**. Complex **2** represents the best model to date of a PDF–formate species, which may be an important intermediate in the mechanism of deformylation.[3] Also, to our knowledge **2** is the first crystallographically characterized four-coordinate zinc(II)–formate complex. Intriguingly, the bonding mode of the formate ligand in **2** provides a plausible rationale for the strikingly low reactivity of the Zn(II) form of PDF.‡

As shown in Scheme 1, the synthesis of the zinc alkyl complex **1** proceeds smoothly by the addition of $Zn(CH_3)_2$ to PATH-H (thiol form) in toluene. Recrystallization of **1** from toluene at −20 °C resulted in X-ray quality crystals,§ and the molecular structure is shown in Fig. 1. Compound **1** is a discrete zinc–alkyl species with the zinc bound in a distorted tetrahedral geometry. The PATH–Zn(II) bond distances and angles in **1** are similar to those previously observed in [(PATH)ZnBr] and [(PATH)Zn(NCS)].[8] A search of the Cambridge Crystallographic Database shows that **1** is the first reported structure of an (N_2S)zinc–alkyl complex.[9] The Zn–C bond length of 1.987(2) Å for **1** is not much different from that observed for the four-coordinate (N_3)Zn–CH_3 compounds [N_3 = substituted tris(pyrazolyl)borate, Tp^R], *e.g.* *d*(Zn–C) = 1.971(4) Å in [($Tp^{t\text{-}Bu}$)Zn(CH_3)][10] and 1.981(8) Å in [($Tp^{Me,Me}$)Zn(CH_3)],[10] or the NS_2 complex [($pzBm^{Me}$)Zn(CH_3)], [$pzBm^{Me}$ = bis(mercaptoimidazolyl)(pyrazolyl)hydroborato] with *d*(Zn–C) = 1.988(4) Å.[11] Thus the Zn–C distance appears to be insensitive to the other ligands in the coordination sphere.



1 **2**: R = H (78%) **3**: R = CH_3 (42%)

Scheme 1

One might expect the thiolate donor of PATH to make the zinc(II) ion more electron-rich as compared to an N_3 donor ligand. Although this effect is not reflected in a comparison of Zn–C bond lengths, an examination of the ^{1}H NMR data is

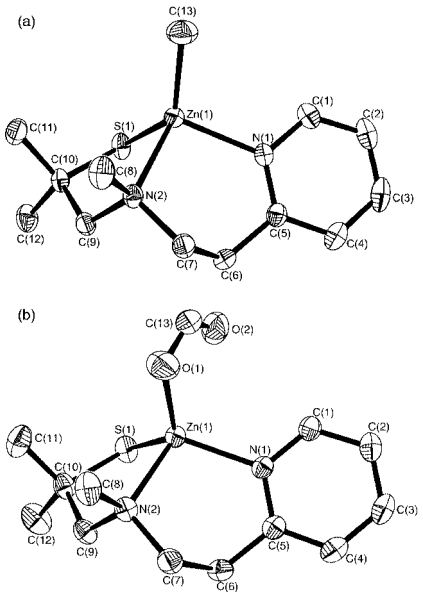


Fig. 1 (a) Thermal ellipsoid plot of [(PATH)Zn(CH_3)] showing 50% probability level. Hydrogen atoms have been omitted for clarity. (b) Thermal ellipsoid plot of [(PATH)Zn(O_2CH)] showing 50% probability level. Hydrogen atoms have been omitted for clarity.

 DOI: 10.1039/b106865m

enlightening. The ^{1}H NMR spectrum of **1** reveals an upfield shift of δ −0.19 in C_6D_6 (δ −0.82 in $CDCl_3$) for the Zn–CH_3 group, as compared to [(Tp^{Me,Me})Zn(CH_3)] [δ +0.28 (C_6D_6)], or [(Tp$^{t\text{-}Bu}$)Zn(CH_3)] [δ +0.54 (C_6D_6)].[10] These data are in line with **1** having a more electron-rich zinc(II) ion than the analogous N_3 complexes. In addition, the Zn–CH_3 peak of **1** is significantly further upfield in comparison to the only other (N_2S)zinc(II) alkyl complex, [(L3S)Zn(CH_3)] [δ −0.55 ($CDCl_3$)],[9] or even the (NS_2) complex [(pzBm^{Me})Zn(CH_3)] [δ −0.63 ($CDCl_3$)].[11]

Addition of 1 equivalent of either formic or acetic acid to **1** in CH_2Cl_2 gives the formate complex **2** and the acetate complex **3**, respectively, *via* protonolysis of the terminal methyl ligand. The ^{1}H NMR spectrum of **2** in $CDCl_3$ reveals a downfield singlet at δ 8.44 for the formate ligand, and that of **3** shows an O_2CCH_3 resonance at δ 2.02. Peaks due to the PATH ligand in **2** and **3** retain the diastereotopic pattern seen for **1** as well as for other [(PATH)ZnX] (X = Br, NCS) complexes,[8] indicative of a monomeric complex with a pseudo-tetrahedral zinc center. Recrystallization of **2** from CH_2Cl_2–hexanes led to the X-ray structure shown in Fig. 1, which reveals the expected monomeric zinc structure.§ Although a crystal structure of **3** has yet to be obtained, the NMR data suggest it has the same monomeric structure as **2**. It is clear that the PATH ligand has a remarkable ability to favor the formation of biologically relevant, monomeric zinc model complexes without the steric encumbrance or constrained tripodal platform of other 'tetrahedral enforcer' ligands.[1]

The most interesting feature of the structure of **2** is revealed in an examination of the bonding mode of the formate ligand, which can be classified as bidentate (or more strictly anisobidentate), as opposed to monodentate, based on the differences in the Zn–O distances (Δd = 0.605 Å) and the M–O–C(13) angles ($\Delta\theta$ = 27.8°).[12] In contrast, the related N_2S complex [(L3S)Zn(O_2CCH_3)], which has recently been prepared,[9] contains an O_2CCH_3 ligand which is bonded in a monodentate fashion (Δd = 0.947 Å, $\Delta\theta$ = 44.2°). The N_2S ligand in [(L3S)Zn(O_2CCH_3)] provides more steric encumberance near the zinc ion than does the PATH ligand, and therefore steric constraints may be the cause of the monodentate bonding in [(L3S)Zn(O_2CCH_3)].[13,14]

The enzyme carbonic anhydrase (CA) contains a $(His)_3$-Zn(II)(OH_2) site, and the reactivity of metal-substituted derivatives follows the order: Zn > Co >> Cu ~ Cd ~ Hg.[15] Data from biochemical[16] and model compound studies[15] indicate that the low reactivity of the latter metals correlates with a bidentate bonding mode of the product molecule (HCO_3^- anion). Bidentate bonding likely makes the displacement of HCO_3^- by H_2O in the final step of the mechanism of action of CA more difficult when compared to a monodentate-bound species. It was suggested that the presence of the thiolate ligand in [(L3S)Zn(O_2CCH_3)] favors monodentate coordination, and hence a cysteinate-containing CA may be inherently more reactive.[9] The bidentate structure of **2** clearly conflicts with these findings.

Importantly, the bidentate motif of **2** correlates nicely with the low reactivity of Zn(II)-PDF. Based on the electron-rich nature of the zinc ion in **1** as indicated by the ^{1}H NMR data, one might expect that **2** would exhibit a monodentate bonding mode. However, the structure of **2** suggests that the inherent (*i.e.* purely electronic) preference of an N_2S(alkylthiolate)–zinc(II) center is to coordinate a carboxylate ligand *via* a more *bidentate* mode. In analogy with CA, it may be more difficult for an incoming water molecule to displace a bidentate-bound formate ligand in Zn(II)–PDF, resulting in the inhibition of the mechanism of action of the enzyme. In fact, the existence of a PDF–formate complex was implicated in the mechanism of PDF and experimental evidence for it has been described.[3]

In conclusion, we have prepared the new (N_2S)zinc alkyl compound **1** as a useful synthetic precursor to other N_2S–Zn(II) complexes. A good model of an enzyme-formate complex has been prepared, and the X-ray structure reveals a rather unexpected anisobidentate bonding mode for the formate ligand. These results imply that this bonding mode may be operative in Zn(II)–PDF, providing a possible explanation for its low reactivity. Further model studies to address this point, including the synthesis of an analogous (N_2S)iron(II)–formate complex, are warranted.

Financial support from the NIH (Grant GM 62309) is gratefully acknowledged.

Catalytic reactions in ionic liquids

Roger Sheldon

Laboratory of Organic Chemistry and Catalysis, Delft University of Technology, Julianalaan 136, Delft BL-2628, The Netherlands. E-mail: secretariat-ock@tnw.tudelft.nl

Received (in Cambridge, UK) 10th August 2001, Accepted 11th September 2001
First published as an Advance Article on the web 18th October 2001

The chemical industry is under considerable pressure to replace many of the volatile organic compounds (VOCs) that are currently used as solvents in organic synthesis. The toxic and/or hazardous properties of many solvents, notably chlorinated hydrocarbons, combined with serious environmental issues, such as atmospheric emissions and contamination of aqueous effluents is making their use prohibitive. This is an important driving force in the quest for novel reaction media. Curzons and coworkers,[1] for example, recently noted that rigorous management of solvent use is likely to result in the greatest improvement towards greener processes for the manufacture of pharmaceutical intermediates. The current emphasis on novel reaction media is also motivated by the need for efficient methods for recycling homogeneous catalysts. The key to waste minimisation in chemicals manufacture is the widespread substitution of classical 'stoichiometric' syntheses by atom efficient, catalytic alternatives.[2] In the context of homogeneous catalysis, efficient recycling of the catalyst is a *conditio sine qua non* for economically and environmentally attractive processes. Motivated by one or both of the above issues much attention has been devoted to homogeneous catalysis in aqueous biphasic[3,4] and fluorous biphasic[5] systems as well as in supercritical carbon dioxide.[6] Similarly, the use of ionic liquids as novel reaction media may offer a convenient solution to both the solvent emission and the catalyst recycling problem.[7,8]

Historical development

What are ionic liquids? Quite simply, they are liquids that are composed entirely of ions. Molten sodium chloride, for example, is an ionic liquid but a solution of sodium chloride in water is an ionic solution. The term molten salts, which was previously used to describe such materials, evokes an image of high-temperature, viscous and highly corrosive media. The term ionic liquid, in contrast, implies a material that is fluid at (or close to) ambient temperature, is colourless, has a low viscosity and is easily handled, *i.e.* a material with attractive properties for a solvent. Room temperature ionic liquids are generally salts of organic cations, *e.g.* tetraalkylammonium, tetraalkylphosphonium, *N*-alkylpyridinium, 1,3-dialkylimidazolium and trialkylsulfonium cations (Fig. 1).

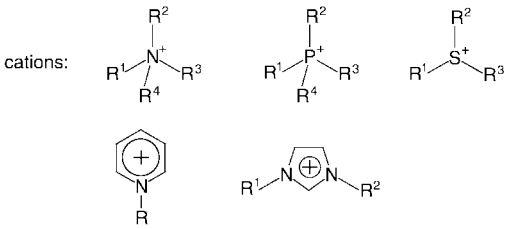

Fig. 1 Structures of ionic liquids.

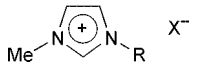
In order to be liquid at room temperature, the cation should preferably be unsymmetrical, *e.g.* R^1 and R^2 should be different alkyl groups in the dialkylimidazolium cation. The melting point is also influenced by the nature of the anion (see Table 1).

Table 1 Melting points of some dialkylimidazolium salts



R	X	mp/°C
Me	Cl	125

Et	CF_3SO_3	−9
Et	$(CF_3SO_3)_2N$	−3
Et	CF_3CO_2	−14
n-Bu	CF_3SO_3	16

Room temperature ionic liquids are not new. Ethylammonium nitrate, which is liquid at room temperature (but usually contains 200–600 ppm water) was first described in 1914.[9] In the late 1940s, *N*-alkylpyridinium chloroaluminates were studied as electrolytes for electroplating aluminium. These systems were reanimated by the groups of Hussey,[10] Osteryoung[11] and Wilkes[12] in the late 1970s. The first examples of ionic liquids based on dialkylimidazolium cations were reported in the early 1980s by Wilkes and coworkers.[12] They contained

Roger Sheldon was born in Nottingham (UK) in 1942. After receiving a PhD in Organic Chemistry from Leicester University (1967) he spent two years as a postdoc with Professor Jay Kochi in the USA. From 1969–1980 he was with Shell Research in Amsterdam and from 1980–1990 he was R&D Director of DSM Andeno. In 1991 he moved to his preent position as Professor of Organic Chemistry and Catalysis at the Delft University of Technology. His research interests are focused on the application of catalytic methodologies—homogeneous, heterogeneous and enzymatic—in organic synthesis, particularly in relation to fine chemicals production. He has widely promoted the concepts of E factors and atom efficiency for assessing the environmental impact of chemical processes. He is the author of ca. 300 scientific publications, numerous patents and three books on the subject of catalysis and chirotechnology. He is the Editor-in-Chief of Journal of Molecular Catalysis B: Enzymatic and Chairman of the Editorial Board of Green Chemistry. Among other distinctions he was recently awarded a Doctor Honoris Causa from the Russian Academy of Sciences.

DOI: 10.1039/b107270f

chloroaluminate anions ($AlCl_4^-$ or $Al_2Cl_7^-$) and proved to be useful catalysts/solvents for Friedel–Crafts acylations.[13] However, a serious obstacle for widespread use of these ionic liquids is the high reactivity of the chloroaluminate anion towards water.

The first example of the new ionic liquids, that currently are receiving so much attention as novel media for homogeneous catalysis, ethylmethylimidazolium tetrafluoroborate (emimBF_4)† was reported by Wilkes *et al.* in 1992.[14] The synthesis of the corresponding hexafluorophosphate followed shortly thereafter.[15] In contrast to the chloroaluminate salts the fluoroborates and hexafluorophosphates are stable towards hydrolysis. Subsequently, 1,3-dialkylimidazolium salts containing a wide variety of anions, *e.g.* $CF_3SO_3^-$, $[CF_3SO_2]_2N^-$, $CF_3CO_2^-$, $CH_3CO_2^-$, $PhSO_3^-$ and many more have been prepared.[16]

Ionic liquids can be prepared by direct quaternisation of the appropriate amine or phosphine. Different anions can subsequently be introduced by anion exchange. It is beyond the scope of this review to discuss in detail the synthesis of ionic liquids and the reader is referred to excellent reviews for many details.[17–20] It is important to note, however, that ionic liquids, owing to their non-volatile nature, cannot be purified by distillation. Consequently, they should be produced in high purity. For example, if synthesis involves exchange of chloride ions it is important that no chloride ions remain in the product as they may seriously impede catalysis by strongly coordinating to low valent transition metal complexes.

The hydrophilicity/lipophilicity of an ionic liquid can be modified by a suitable choice of anion, *e.g.* bmimBF_4 is completely miscible with water while the PF_6 salt is largely immiscible with water. The lipophilicity of dialkylimidazolium salts, or other ionic liquids, can also be increased by increasing the chain length of the alkyl groups.[21]

Ionic liquids containing 'fluorous ponytails' have even been described.[22] When these are added to conventional ionic liquids they facilitate emulsification with perfluorocarbons. This provides the possibility of performing (catalytic) reactions in ionic liquids/perfluorocarbon biphasic systems.

Catalysis in ionic liquids: general considerations

Room temperature ionic liquids exhibit many properties which make them potentially attractive media for homogeneous catalysis:

- They have essentially no vapour pressure, *i.e.* they do not evaporate and are easy to contain.
- They generally have reasonable thermal stability. While tetraalkylammonium salts have limited thermal stability, owing to decomposition *via* the Hoffmann elimination, emimBF_4 is reportedly stable up to 300 °C and emim-$(CF_3SO_2)_2N$ up to 400 °C.[16a] In other words many ionic liquids have liquid ranges of more than 300 °C, compared to the 100 °C liquid range of water.
- They are able to dissolve a wide range of organic, inorganic and organometallic compounds.
- The solubility of gases, *e.g.* H_2, CO and O_2, is generally good which makes them attractive solvents for catalytic hydrogenations, carbonylations, hydroformylations, and aerobic oxidations.
- They are immiscible with some organic solvents, *e.g.* alkanes, and, hence, can be used in two-phase systems. Similarly, lipophilic ionic liquids can be used in aqueous biphasic systems.
- Polarity and hydrophilicity/lipophilicity can be readily adjusted by a suitable choice of cation/anion (see earlier) and ionic liquids have been referred to as 'designer solvents'.[7]
- They are often composed of weakly coordinating anions, *e.g.* BF_4^- and PF_6^- and, hence, have the potential to be highly polar yet non-coordinating solvents. They can be expected, therefore, to have a strong rate-enhancing effect on reactions involving cationic intermediates.
- Ionic liquids containing chloroaluminate ions are strong Lewis, Franklin and Brønsted acids. Protons present in emim$AlCl_4$ have been shown to be superacidic with Hammett acidities up to −18.[23] Such highly acidic ionic liquids are, nonetheless, easily handled and offer potential as non-volatile replacements for hazardous acids such as HF in several acid-catalysed reactions.

Faced with these numerous potential benefits one may wonder if ionic liquids have any problems associated with their use. Atmospheric emissions may not be an issue but, when used on an industrial scale, small amounts of ionic liquids will inevitably find their way into the environment *via* the proverbial 'mechanical losses'. So, what is known about their potential environmental impact? A cursory examination of the literature reveals a dearth of information regarding the biodegradability and toxicity of ionic liquids. A prerequisite for industrial use is, therefore, the generation of appropriate data to enable the assessment of the potential environmental impact of ionic liquids.

Another question which arises in any discussion of ionic liquids as reaction media pertains to the isolation of soluble reaction products. Volatile products can be separated by distillation. Non-volatile products, on the other hand, can be separated by solvent extraction. Although this seems paradoxical—using an ionic liquid to avoid atmospheric emissions and subsequently using a volatile organic solvent to extract the product—it could have environmental benefits. For example, substituting an environmentally unacceptable solvent by an ionic liquid as the reaction medium, followed by extraction with a more benign organic solvent would constitute an environmental benefit. In this context it is worth noting the use of supercritical carbon dioxide to extract products from ionic liquids, which is currently the focus of attention.[24] Quite remarkably, $scCO_2$ is highly soluble (up to 60 mol%) in bmimPF_6 while the latter is insoluble in $scCO_2$. Naphthalene, for example, was recovered quantitatively from bmimPF_6 by $scCO_2$ extraction, without any contamination of the extract by the ionic liquid.

One can envisage various scenarios for catalysis in and/or by ionic liquids:

- Monophasic systems in which the catalyst and substrate are dissolved in the ionic liquid.
- Monophasic systems in which the ionic liquid acts as both the solvent and the catalyst, *e.g.* dialkylimidazolium chloroaluminates as Friedel–Crafts catalysts (see later).
- Biphasic systems in which the catalyst resides in the ionic liquid and the substrate/product in the second phase or *vice versa*.
- Mono- or biphasic systems in which the anion of the ionic liquid acts as a ligand for the homogeneous catalyst, *e.g.* a sulfonated phosphine ligand (see later).
- Triphasic systems comprising, for example, an ionic liquid, water and an organic phase in which the catalyst resides in the ionic liquid, the substrate and product in the organic phase and salts formed in the reaction are extracted into the aqueous phase, *e.g.* in Heck reactions (see later).

The first example of homogeneous transition metal catalysis in an ionic liquid is the platinum catalysed hydroformylation of ethene in tetraethylammonium trichlorostannate, described by Parshall in 1972.[25] This ionic liquid (referred to as a molten salt back in those days) has a melting point of 78 °C. These results were largely ignored for two decades. The potential of ionic liquids as novel media for homogeneous catalysis became more widely appreciated largely due to the pioneering studies and extensive promotion of the groups of Seddon[17] and Chauvin and Olivier-Bourbigou[18] and, more recently, the groups of Welton[19]

and Keim and Wasserscheid.[20] In the last five years their use as novel media for, *inter alia*, catalytic hydrogenations, hydroformylations, isomerisations, olefin dimerisations, oligomerisations and polymerisations and Heck couplings, has been rapidly expanding. The salient features of these studies will be reviewed in the ensuing discussion, with emphasis on their potential as clean synthetic methodologies.

Hydrogenation

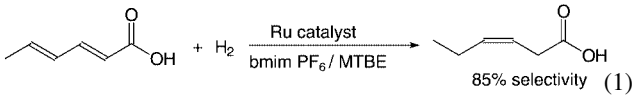
The first example of catalytic hydrogenation in an ionic liquid was reported by Chauvin *et al*. in 1995.[26] A solution of the cationic [Rh nbd(Ph_3P)$_2$]PF_6 complex [nbd = norbornadiene (bicyclo[2.2.1]hepta-2,5-diene)] in bmimPF_6 or bmimSbF_6 was shown to be an effective catalyst for the biphasic hydrogenation of pent-1-ene. Reaction rates were up to five times higher than in acetone as solvent which was attributed to the formation of an unsolvated cationic rhodium(III) dihydride complex with two free coordination sites in the nonsolvating ionic liquid. In contrast, poor results were obtained with bmimBF_4 which was ascribed to the presence of trace amounts of strongly coordinating chloride ions in their sample of this ionic liquid. The catalyst solution in the ionic liquid could be reused with rhodium losses below the detection limit of 0.02%.

Similarly, advantage was taken of the biphasic system to perform the selective hydrogenation of cyclohexadiene. The solubility of cyclohexadiene in bmimSbF_6 is about five times that of cyclohexene and, hence, the latter was obtained in 98% selectivity at 96% conversion.

Dupont and coworkers[27] performed the biphasic hydrogenation of cyclohexene with Rh(cod)$_2BF_4$ (cod = cycloocta-1,5-diene) in ionic liquids. They observed roughly equal rates (turnover frequencies of *ca*. 50 h^{-1}) in bmimBF_4 and bmimPF_6 (presumably their bmimBF_4 was chloride-free).

The same group showed that $RuCl_2(Ph_3P)_3$ in bmimBF_4 is an effective catalyst for the biphasic hydrogenation of olefins, with turnover frequencies up to 540 h^{-1}.[28] Similarly, (bmim)$_3$-Co$(CN)_5$ dissolved in bmimBF_4 catalysed the hydrogenation of butadiene to but-1-ene, in 100% selectivity at complete conversion.[28]

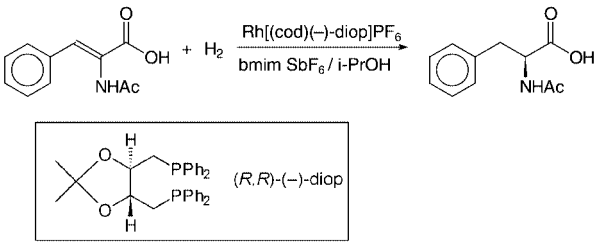
More recently, the ruthenium-catalysed hydrogenation of sorbic acid to *cis*-hex-3-enoic acid (Reaction 1) was achieved in a biphasic bmimPF_6–methyl *tert*-butyl ether system.[29]



85% selectivity (1)

The ruthenium cluster, $[H_4Ru(\eta^6\text{-}C_6H_6)_4]$ $[BF_4]_2$ in bmimBF_4 was shown to be an effective catalyst for the hydrogenation of arenes, to the corresponding cycloalkanes, at 90 °C and 60 bar.[30] The cycloalkane product formed a separate phase which was decanted and the ionic liquid phase, containing the catalyst, could be repeatedly recycled.

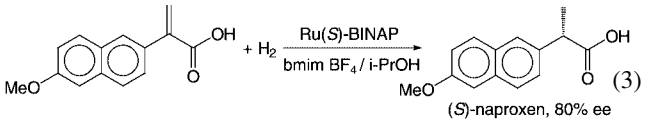
Enantioselective hydrogenation in ionic liquids is of particular interest as it could provide a means for facile recycling of metal complexes of expensive chiral ligands. In their original study Chauvin *et al*.[26] reported that [Rh(cod)(−)-(diop)]PF_6 catalysed the enantioselective hydrogenation of α-acetamidocinnamic acid to (*S*)-phenylalanine, in 64% ee, in a biphasic bmimSbF_6–isopropyl alcohol (Reaction 2). The observed



(2)

enantioselectivity is what one would expect with diop which is not a particularly good ligand for this reaction. The product, contained in the isopropyl alcohol, could be separated quantitatively and the recovered ionic liquid, containing the catalyst, reused.

Similarly, Dupont and coworkers[31] extended their studies of ruthenium-catalysed hydrogenations in ionic liquids to enantioselective reactions. The chiral [$RuCl_2$(*S*)-BINAP]$_2NEt_3$ complex was shown to catalyse the asymmetric hydrogenation of 2-phenylacrylic acid and 2-(6-methoxy-2-naphthyl)acrylic acid in bmimBF_4–isopropyl alcohol. The latter afforded the anti-inflammatory drug, (*S*)-naproxen, in 80% ee (Reaction 3). The

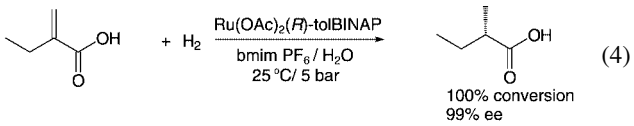


(*S*)-naproxen, 80% ee (3)

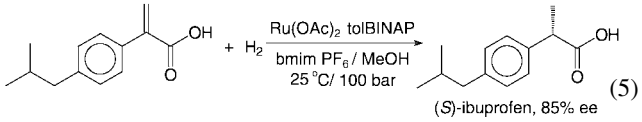
product could be quantitatively separated and the recovered ionic liquid catalyst solution recycled several times without any significant change in activity or selectivity.

An interesting recent development is the use of a biphasic ionic liquid–supercritical CO_2 for catalytic hydrogenation[32,33] and other processes (see later). Tumas and coworkers[32] showed that the catalytic hydrogenation of olefins could be conducted in a biphasic bmimPF_6–scCO_2 system. The ionic liquid phase containing the catalyst was separated by decantation and reused in up to four consecutive batches.

Jessop and coworkers[33] extended this concept to the asymmetric hydrogenation of tiglic acid (Reaction 4) and the precursor of the antiinflammatory drug ibuprofen (Reaction 5) using Ru$(OAc)_2$(tolBINAP) as the catalyst.



100% conversion
99% ee (4)



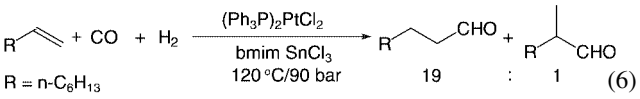
(*S*)-ibuprofen, 85% ee (5)

They found that Reaction 4 was more selective in a bmimPF_6–water biphasic mixture while Reaction 5 gave poor enantioselectivities in the wet ionic liquid. In this case the best result (85% ee) was obtained using methanol as cosolvent at 100 bar H_2 pressure. In both cases the product was separated by scCO_2 extraction when the reaction was complete. The different solvent effects observed with the two substrates was assumed to be due to the solubility of H_2 in the reaction mixture. The hydrogen concentration dependence of asymmetric catalytic hydrogenation with ruthenium BINAP complexes is known to be dependent on the substrate.[34] Class I substrates such as the ibuprofen precursor give higher enantioselectivities at high H_2 concentration while class II substrates, exemplified by tiglic acid, give higher enantioselectivities at low H_2 concentrations.

Hydroformylation

Hydroformylation of propene in an aqueous biphasic system, using a water-soluble rhodium complex of the sodium salt of trisulfonated triphenylphosphine (tppts) forms the basis of the Ruhr Chemie Rhone Poulenc process for the manufacture of butanal.[35] Unfortunately this process is limited to C_2 to C_5 olefins owing to the very low solubility of higher olefins in water. Hence, one can envisage that the use of an appropriate ionic liquid could provide the basis for biphasic hydroformylation of higher olefins.

As noted earlier, Parshall showed, in 1972, that platinum-catalysed hydroformylations could be performed in tetraethylammonium trichlorostannate melts.[25] More recently, Waffenschmidt and Wasserscheid[36] studied the platinum-catalysed hydroformylation of oct-1-ene in bmimSnCl$_3$ (Reaction 6)



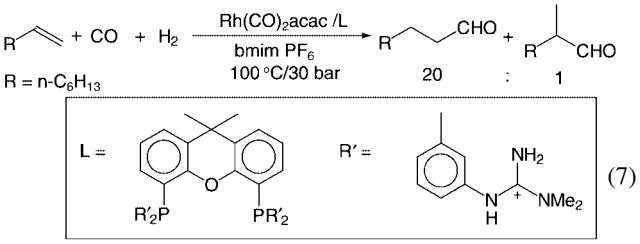
(6)

which is liquid at room temperature. Despite the limited solubility of oct-1-ene in the ionic liquid, high activities (TOF = 126 h^{-1}) were observed together with a remarkably high regioselectivity (n/iso = 19). The product was recovered by phase separation and no leaching of platinum was observed.

The ruthenium- and cobalt-catalysed hydroformylation of internal and terminal olefins in molten tetra-*n*-butylphosphonium bromide was reported by Knifton in 1987.[37] More recently, the rhodium-catalysed hydroformylation of hex-1-ene was conducted in molten phosphonium tosylates, *e.g.* Bu$_3$PEt$^+$TsO$^-$ and Ph$_3$PEt$^+$TsO$^-$ having melting points of 81–83 °C and 94–95 °C, respectively, at 120 °C and 40 bar.[38] Advantage was taken of the higher melting points of these 'ionic liquids' to decant the product from the solid catalyst medium at room temperature.

Chauvin and coworkers[26] investigated the rhodium-catalysed biphasic hydroformylation of pen-1-tene in bmimPF$_6$. High activities (TOF = 333 h^{-1} compared with 297 h^{-1} in toluene) were observed with the neutral Rh(CO)$_2$(acac)–Ph$_3$P as the catalyst precursor but some leaching of the catalyst into the organic phase occurred. This could be avoided by using Rh(CO)$_2$acac with tppts or tppms (monosulfonated triphenylphosphine) as the catalyst precursor, albeit at the expense of rate (TOF = 59 h^{-1} with tppms). Higher activities (TOF = 810 h^{-1}) and high regioselectivity (n/iso = 16) were observed in the biphasic hydroformylation of oct-1-ene in bmimPF$_6$ using cationic cobaltocenium diphosphine ligands but some catalyst leaching (< 0.5%) was observed.[39]

Better results were obtained with cationic guanidine-modified diphosphine ligands containing a xanthene backbone.[40] Xanthene-based diphosphine ligands with large bite angles (P–metal–P ~ 110°) are known to give high selectivities (≥98%) towards the linear aldehyde.[41] Biphasic hydroformylation of oct-1-ene, using rhodium complexes of these ligands in bmimPF$_6$ (Reaction 7), afforded high regioselectivities (*ca.* 20)



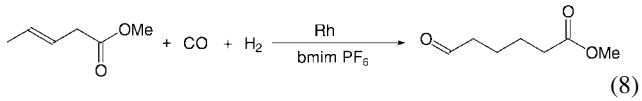
(7)

and the catalyst could be recycled ten times (resulting in an overall turnover number of 3500) without detectable (< 0.07%) leaching of Rh to the organic phase.

The group of Olivier-Bourbigou[42] has recently explored the use of a wide range of ionic liquids, based on imidazolium and pyrrolidinium cations and weakly coordinating anions, for the biphasic hydroformylation of hex-1-ene catalysed by rhodium complexes of modified phosphine and phosphite ligands. The latter are, in contrast, unstable in aqueous biphasic media. The rate and regioselectivity could be optimized by choosing a suitable combination of cation, anion and phosphine or phosphite ligand. Rhodium leaching was minimised by modification of the ligands with cationic (guanidinium or pyridinium) or anionic (sulfonate) groups.

Another interesting recent development is the rhodium-catalysd biphasic hydroformylation of oct-1-ene in bmimPF$_6$–scCO$_2$ in a continuous flow process.[43] Because of the low solubility of Rh–tppms and Rh–tppts complexes in the ionic liquid, [pmim]$^+$Ph$_2$PC$_6$H$_4$SO$_3^-$ (pmim = 1-propyl-3-methylimidazolium) was synthesised and used together with Rh$_2$(OAc)$_4$ as the catalyst precursor. Aldehydes were produced at a constant rate for 72 h albeit with moderate regioselectivity (n/iso = 3.8). Analysis of recovered products revealed that < 1 ppm Rh is leached into the organic phase.

The monophasic hydroformylation of methylpent-3-enoate in bmimPF$_6$ has been reported.[44] The linear aldehyde product (Reaction 8) is a precursor of adipic acid in an alternative

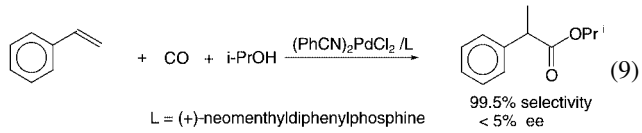


(8)

butadiene-based route. The product was removed by distillation (0.2 mbar/110 °C) and the ionic liquid recycled ten times without significant loss in activity.

Alkoxycarbonylation

Much less attention has been focused on carbonylation reactions in ionic liquids. The biphasic palladium-catalysed alkoxycarbonylation of styrene (Reaction 9) in bmimBF$_4$–cyclohexane has been reported.[45] Very high regioselectivities (≥99.5% iso) were obtained, using PdCl$_2$(PhCN)$_2$ in combination with (+)-neomenthyldiphenylphosphine and toluene-*p*-sulfonic acid, under mild conditions (70 °C and 10 bar).



(9)

More recently, the palladium-catalysed alkoxycarbonylation and amidocarbonylation of aryl bromides and iodides in bmimBF$_4$ and bmimPF$_6$ has been described.[46] Enhanced reactivities were observed compared to conventional media and the ionic liquid–catalyst could be recycled.

Olefin dimerisation and oligomerisation

The nickel-catalysed dimerisation of lower olefins in ionic liquids containing chloroaluminate anions is probably the most investigated reaction in ionic liquids.[18,26,47–49] As early as 1990 the group of Chauvin at the Institut Francais du Petrole (IFP) reported the nickel-catalysed dimerisation of propene in bmimAlCl$_4$.[47] The catalyst precursor consisted of L$_2$NiCl$_2$ (L = Ph$_3$P or pyridine) in combination with EtAlCl$_2$ (bmimCl–AlCl$_3$–EtAlCl$_2$ = 1 : 1.2 : 0.25). The active catalyst is a cationic nickel(II) complex, [LNiCH$_2$CH$_3$]$^+$AlCl$_4^-$, formed by reaction of L$_2$NiCl$_2$ with EtAlCl$_2$. Since ionic liquids promote the dissociation of ionic metal complexes it was envisaged that they would have a beneficial effect on this reaction.[18]

This proved to be the case: at 5 °C and atmospheric pressure productivities (> 250 kg dimers per g Ni) much higher than those observed in organic solvents were achieved.[18,47,48] The mixture of dimers obtained, containing 2,3-dimethylbutene as the major component (83%), has commercial importance as the precursor of octane boosters for reformulated gasoline. It has been produced since the mid-seventies by the IFP 'Dimersol' process (25 units worldwide with a production of 3.4 × 10^6 tons per annum) in a single-phase solvent-free medium.

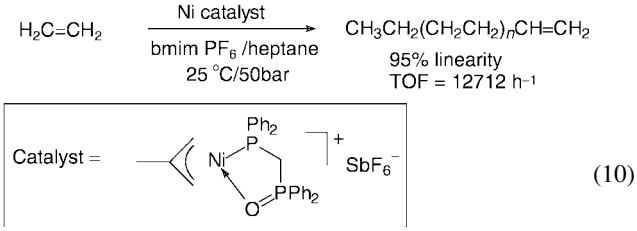
The methodology was subsequently extended to the dimerisation of butenes. The isooctene product constitutes the feedstock for the manufacture of isononanols (plasticizers) by

hydroformylation. A productivity of > 100 kg dimers per g Ni was obtained at 10 °C.

Conducting these dimerisations as biphasic reactions in ionic liquids affords several benefits:[18] a better selectivity to dimers (owing to their low solubility in the ionic liquid), a better use of the catalyst components and, hence, reduced disposal costs, substantially reduced reactor size, no corrosion and broader scope (to less reactive, higher olefins).

The nickel-catalysed biphasic dimerisation of olefins in ionic liquids is being offered for licensing by IFP under the acronym 'Difasol process' and is likely to be the first large scale application of biphasic catalysis in ionic liquids.

Wasserscheid and Keim[20,50] have developed alternative, alkylaluminium-free nickel catalysts for the linear dimerisation of but-1-ene. A turnover frequency of 1240 h^{-1} and a dimer selectivity of 98% (64% linearity) was observed at 25 °C. More recently, the same group reported[51] the use of cationic nickel complexes for the biphasic oligomerisation of ethene to higher α-olefins in bmimPF_6 (Reaction 10). The products separated as

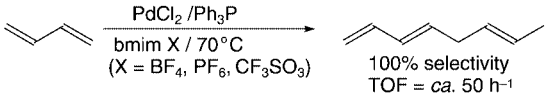


(10)

a clear and colourless layer and the catalyst-containing ionic liquid could be recycled with leaching below the detection limit (0.1%).

The palladium-catalysed dimerisation of butadiene to octa-1,3,6-triene and octa-1,3,7-triene is industrially important as the products have a wide range of applications, *e.g.* as comonomers and in the synthesis of plasticizers, adhesives and fragrances. Since these octatrienes rapidly polymerise in the presence of air, separation of the product from the homogeneous catalyst, *e.g.* by distillation, presents a serious problem. This would seem, therefore, to be an attractive target for biphasic catalysis in an ionic liquid.

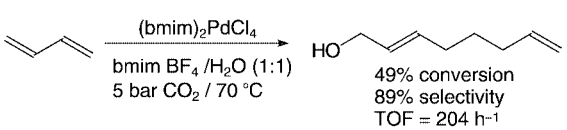
Dupont and coworkers[52] have reported that $PdCl_2$–Ph_3P (1:4) catalyses the biphasic dimerisation of butadiene (Reaction 11)



(11)

in bmimX (X = BF_4, PF_6 or CF_3SO_3) at 70 °C, affording octa-1,3,6-triene in 100% selectivity.

The same group reported[53] that when the reaction is performed with $(bmim)_2PdCl_4$ in bmimBF_4–H_2O (roughly 1 : 1 v/v) selective telomerisation resulted to afford octa-2,7-dien-1-ol (Reaction 12). As is also observed in other mono- and

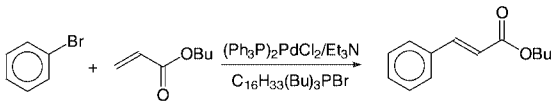


(12)

biphasic telomerisations of butadiene, the presence of carbon dioxide was essential for high activity. Using 5 bar CO_2 a turnover frequency of 204 h^{-1} and a selectivity of 89% (11% octa-1,3,6-triene) at 49% conversion was observed at 70 °C. Interestingly, the reaction is monophasic under the reaction conditions but cooling the mixture to 5 °C produces two phases and the ionic liquid phase can be separated and recycled. This methodology is a potentially attractive alternative to the aqueous biphasic telomerisation of butadiene developed by Kuraray.[3,4]

Heck reactions

The Heck and related C–C coupling reactions are of major importance in organic synthesis and are finding wide application in the manufacture of fine chemicals.[54] The first example of a Heck coupling in an ionic liquid was reported by Kaufmann *et al.* in 1996.[55] Butyl *trans*-cinnamate was produced in high yield by reaction of bromobenzene with butyl acrylate in molten tetraalkylammonium and tetraalkylphosphonium bromide salts (Reaction 13). No formation of palladium metal was observed



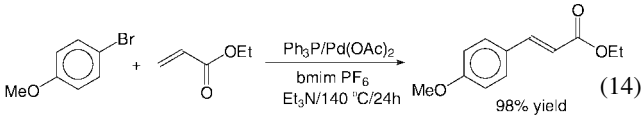
(13)

and the product was isolated by distillation from the ionic liquid.

Herrmann and Böhm[56] subsequently showed that molten Bu_4NBr (mp 103 °C) is a particularly suitable reaction medium for Heck reactions, affording superior results compared with commonly used organic solvents such as DMF. For example, in the reaction of bromobenzene with styrene, using diiodobis(1,3-dimethylimidazolin-2-ylidine)palladium(II) as the catalyst, the yield of stilbene was increased from 20% in DMF to 99% in Bu_4NBr under otherwise identical conditions. The product was separated by distillation and the catalyst containing ionic liquid recycled up to 13 times without significant loss of activity.

Seddon and coworkers[57] performed Heck couplings in bmimPF_6 or *n*-hexylpyridinium PF_6 using $PdCl_2$ or $Pd(OAc)_2$–Ar_3P as the catalyst and Et_3N or $NaHCO_3$ as the base.

For example, $Pd(OAc)_2$–Ph_3P-catalysed coupling of 4-bromoanisole with ethyl acrylate (Reaction 14) in bmimPF_6 at 140 °C, afforded ethyl 4-methoxycinnamate in 98% yield.



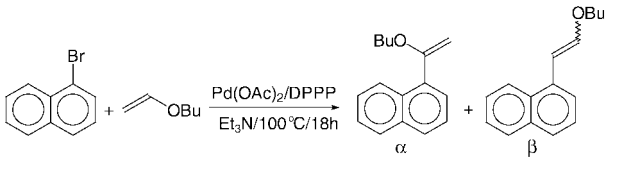
(14)

The high solubility of the catalyst in the ionic liquid allows for product isolation by extraction into a hydrocarbon, *e.g.* hexane or toluene. Furthermore, if water is added a triphasic system is obtained in which the salt formed in the reaction, Et_3NHBr, is extracted into the aqueous phase.

It was also noted that palladium complexes of imidazolylidene carbenes, formed by reaction of the base with the imidazolium cation, may be implicated in these reactions.[57]

This was later confirmed by Xiao and coworkers[58] who observed a significantly enhanced rate of the Heck coupling in bmimBr compared to the same reaction in bmimBF_4. This difference could be explained by the formation of the corresponding palladium–carbene complexes (which were isolated and characterised) in the former but not in the latter. The isolated carbene complexes were shown to be active catalysts when redissolved in bmimBr. Presumably, the formation of the carbene in bmimBr can be attributed to the stronger basicity of bromide compared to tetrafluoroborate.

The Heck arylation of electron-rich enol ethers generally leads to a mixture of regio isomers owing to competition between cationic and neutral pathways, leading to α- and β-arylation, respectively (Reaction 15). The ionic pathway is favoured with aryl triflates but these are less available and much more expensive than the corresponding chlorides and bromides. The ionic pathway would also be expected to be favoured by conducting the reaction in an ionic liquid and this proved to be the case. Thus, Xiao and coworkers[59] achieved > 99% selectivity to the α-arylation product in the Heck coupling of 1-bromonaphthalene to butyl vinyl ether in bmimBF_4 (Reaction 15). In contrast, the same reaction in toluene, acetonitrile, DMF or DMSO afforded mixtures of the α- and β-regio isomers. A range of 4-substituted bromobenzenes were similarly shown to give α-/β-regioselectivities of > 99%.



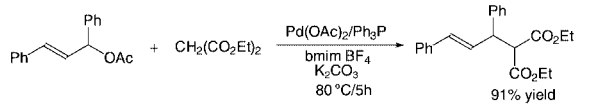
Solvent	Conv. (%)	α/β
bmim BF_4	50	> 99/1
toluene	23	46/54
acetonitrile	36	69/31
DMF	100	60/40
DMSO	100	75/25

(15)

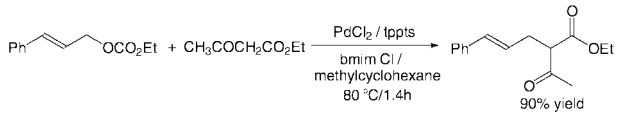
Similarly, palladium-catalysed Stille[60a] and Negishi[60b] couplings and nickel-catalysed coupling of aryl halides[61] in $bmimBF_4$ and $bmimPF_6$, respectively, have also been described.

Palladium-catalysed allylic substitution

Palladium-catalysed allylic substitution by carbon nucleophiles constitutes another synthetically useful method for the generation of C–C bonds. These reactions have also been performed in ionic liquids, both in a mono- and biphasic system, using $Pd(OAc)_2$–Ph_3P (with K_2CO_3 as base) in $bmimBF_4$ (Reaction 16)[62] and $PdCl_2$–tppts in bmimCl–methylcyclohexane (Reaction 17),[63] respectively. In the latter case distinct advantages



(16)



(17)

compared to the corresponding aqueous biphasic system were noted: an order of magnitude higher activity and improved selectivity owing to suppression of the competing reaction with water as a nucleophile and a much decreased phosphonium salt formation (by reaction of tppts with the Pd–allyl complex).

Reaction (16) has also been performed using chiral ferrocenylphosphine complexes of palladium, in $bmimPF_6$.[64] The product was obtained in moderate enantioselectivity (62–74% ee), which was higher than that observed in conventional solvents.

Catalytic oxidations

Considering the commercial importance of catalytic oxidations, and the fact that ionic liquids are expected to be relatively inert towards autoxidation with O_2, surprisingly little attention has been devoted to performing such reactions in ionic liquids. The $Ni(acac)_2$-catalysed aerobic oxidation of aromatic aldehydes, to the corresponding carboxylic acids, in $bmimPF_6$ has been described.[65] However, rather high (3 mol%) catalyst loadings were used and this can hardly be considered a challenging oxidation.

The methyltrioxorhenium (MTO)-catalysed epoxidation of olefins with the urea–H_2O_2 adduct (UHP) in $emimBF_4$ has been reported.[66] Both the UHP and the MTO are soluble in $emimBF_4$ and the medium remains homogeneous throughout the reaction. It should be noted, however, that the substrates were generally highly reactive olefins and when the more challenging dec-1-ene was used, a long reaction time (72 h) was needed for moderate conversion (46%) using 2 equivalents of oxidant. When 30% aq. H_2O_2 was used as the oxidant this led to ring opening of sensitive epoxides.

Asymmetric Jacobsen-Katsuki epoxidation, with NaOCl catalysed by a chiral Mn Schiff's base complex has been conducted in $bmimPF_6$.[67] However, dichloromethane was required as a cosolvent, as the ionic liquid solidifies at the reaction temperature (0 °C), which nullifies one of the primary incentives for using an ionic liquid. The ionic liquid, containing the catalyst, could be recovered and recycled 4 times albeit with a significant loss in yield.

A more recent, and very exciting development, is the electroassisted biomimetic activation of molecular oxygen by a chiral Mn Schiff's base complex in $bmimPF_6$ described by Gaillon and Bedioui.[68] Evidence was provided for the formation of the highly reactive oxomanganese(v) intermediate that could transfer its oxygen to an olefin. This would appear to offer potential for clean, electrocatalytic oxidations with molecular oxygen in ionic liquid media.

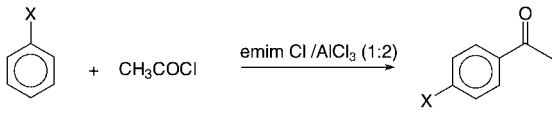
Lewis and Brønsted acid catalysis in ionic liquids

Ionic liquids containing chloroaluminate ($AlCl_4^-$, $Al_2Cl_7^-$) anions are strong Lewis acids and if protons are present they are superacidic (see earlier). Coupled with the fact that they are relatively easy to handle this makes these materials attractive non-volatile alternatives for standard Lewis acid catalysts, such as $AlCl_3$, and hazardous Brønsted acids such as HF. The ionic liquid can function as both a catalyst and a solvent for acid catalysed processes. Since Lewis and Brønsted acid-mediated processes generally involve cationic intermediates, *e.g.* carbenium and acylium ions, one would also expect to see substantial rate enhancements in ionic liquids. Indeed, some of the first reactions to be studied in ionic liquids were Friedel–Crafts alkylations and acylations. Wilkes and coworkers[69] showed that ionic liquids derived from the reaction of emimCl with $AlCl_3$ exhibit a wide range of Lewis acidity depending on the molar ratio of reactants. A 1:1 mixture affords the tetrachloroaluminate, $emimAlCl_4$, which is referred to as being neutral and is not active as a Friedel–Crafts catalyst. In contrast, the 2:1 adduct, $emimAl_2Cl_7$ is strongly acidic and was shown to be very active in Friedel–Crafts alkylations and acylations.[69] For example, a mixture of benzene, acetyl chloride and $emimAl_2Cl_7$ in the molar ratio 1.1:1.0:0.5 (*i.e.* less than a stoichiometric amount of the ionic liquid) afforded complete conversion to acetophenone in less than 5 minutes at room temperature. Spectral evidence suggested the formation of the free acylium cation, CH_3CO^+, in the ionic liquid medium.

The Friedel–Crafts alkylation of benzene with long chain α-olefins is used industrially for the manufacture of more than two million tons of linear alkylbenzenes worldwide. The products are the precursors of the corresponding alkylbenzene sulfonates which are widely used as surfactants. Traditionally the reaction is performed using liquid HF or $AlCl_3$ as the catalyst. The production of linear alkylbenzenes using chloroaluminate ionic liquids has been described.[17a] The potential to retrofit existing installations with the ionic liquid catalyst offers enormous benefits with regard to reduced catalyst consumption, ease of product separation and elimination of caustic quenching associated with catalyst leaching. Chloroaluminate ionic liquids modified with HCl were recently shown[70] to give higher rates and more favourable product distributions in Friedel–Crafts alkylations, which was attributed to the superacidities of these media. In this context it is also worth mentioning the work of Hölderich *et al.*[71] who showed that ionic liquids immobilised on inorganic supports (SiO_2, Al_2O_3, TiO_2, ZrO_2) are effective catalysts for Friedel–Crafts alkylation of aromatics. Activities

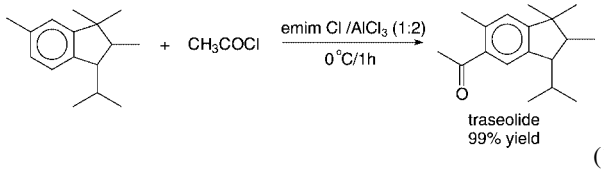
were higher than those observed with a conventional zeolite catalyst and no leaching of the ionic liquid from the surface was observed. Reactions were performed in batch, continuous liquid-phase and continuous gas-phase operation. For example, alkylation of benzene with dodecene afforded the mono-alkylated product in 98% selectivity at 99% conversion at 80 °C.

Seddon and coworkers[72] studied the Friedel–Crafts acylation of toluene, chlorobenzene and anisole with acetyl chloride in emimAl_2Cl_7 and obtained excellent regioselectivities to the *para* isomer (Reaction 18). Similarly, the fragrance chemical, traseolide, was obtained in 99% yield as a single isomer (Reaction 19). It should be noted, however, that the question of



R	Temp/°C	Time/h	Yield(%)
MeO	−10	0.25	99
Me	20	1	98
Cl	20	24	97

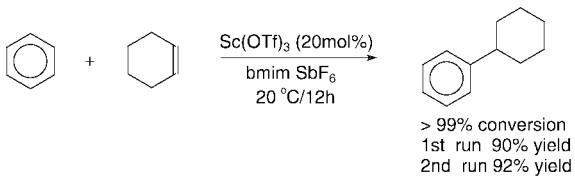
(18)



(19)

product recovery from the reaction medium still needs to be addressed in these systems. As in conventional $AlCl_3$-promoted acylations the ketone product forms a strong complex with the chloroaluminate ionic liquid.

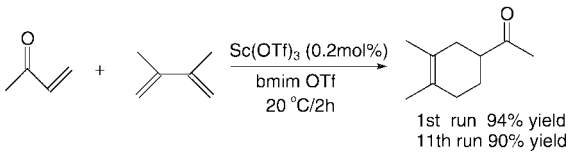
Lanthanide triflates, in particular $Sc(OTf)_3$, have been widely studied as water-tolerant Lewis acids in a variety of transformations, including Friedel–Crafts alkylations and acylations.[73] Song and coworkers[74] have recently shown that $Sc(OTf)_3$ catalyses the Friedel–Crafts alkylation of aromatics with olefins in hydrophobic ionic liquids, *e.g.* bmimPF_6 and bmimSbF_6. In contrast, no reaction was observed in common organic solvents, water or hydrophilic ionic liquids such as bmimBF_4 or bmimOTf. For example, reaction of benzene with cyclohexene (Reaction 20) afforded cyclohexylbenzene in 92% yield at



(20)

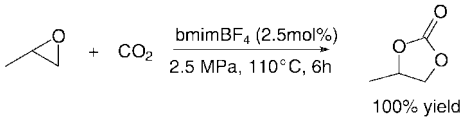
> 99% cyclohexene conversion in bmimSbF_6 at 20 °C for 12 h. The product formed a separate layer and, after phase separation, the ionic liquid phase, containing the catalyst, was recycled to afford 92% yield of cyclohexylbenzene at > 99% conversion. Although high catalyst loadings (20 mol%) were used the ease of separation and recycling of the catalyst offers potential environmental and economic benefits.

The same group has recently reported[75] that $Sc(OTf)_3$ catalyses Diels–Alder reactions in bmimX (X = BF_4, SbF_6 or OTf), in this case at much lower catalyst loadings (0.2 m%). In contrast to the Friedel–Crafts alkylation (see above) the product did not form a separate phase and was recovered by extraction with ether. It was shown, however, that the ionic liquid containing the catalyst could be recycled eleven times without loss of activity (Reaction 21). Furthermore, improved *endo*/*exo* selectivities were observed with cyclic dienes.



(21)

Another reaction catalysed by Lewis acids is the cycloaddition of carbon dioxide to epoxides, affording cyclic carbonates. It was recently reported that this reaction is catalysed by bmimBF_4.[76] When propene oxide was allowed to react with CO_2 (2.5 MPa) at 110 °C for 6 h in the presence of bmimBF_4 (2.5 mol%), propene carbonate was obtained in 100% yield (Reaction 22).



(22)

The propene carbonate was distilled from the reaction mixture and the ionic liquid catalyst recycled four times with only a minor loss in activity.

Protons in acidic ionic liquids have acidities greater than those of H_2SO_4 or liquid HF.[8,17,18] They are, for example, able to protonate benzene to the cyclohexadienyl cation. The acidic ionic liquid, bmimAl_2Cl_7, catalyses the alkylation of ethene with isobutane[18] whereas neither HF nor H_2SO_4 is effective for this reaction. The major product is 2,3-dimethylbutane (75–86%) which has a higher octane number than the products of alkylation of higher olefins. The product forms a separate upper phase and the ionic liquid is readily recycled.

Olefin oligomerisation and polymerisation is also promoted by these strongly acidic ionic liquids, *e.g.* high molecular weight polyisobutene is readily obtained from isobutene.[17] The catalytic activity and degree of polymerisation is determined by the chain length of the alkyl group in the 1-alkyl-3-methylimidazolium or *N*-alkylpyridinium cation which provides a convenient mechanism for controlling the product distribution. Polyisobutene is a commercially important lubricant and the ionic liquid process has several advantages compared with the conventional process which employs a supported or dissolved $AlCl_3$ catalyst. The polymer forms a separate phase and is readily separated and reused which obviates the need for an aqueous wash and, hence, reduces waste and costs. Moreover, the process can be easily retrofitted into existing production facilities.

The electrophilic nitration of aromatics, using a variety of nitrating agents, has also been investigated in ionic liquid solvents.[77] It was noted that nitration in ionic liquids constitutes a useful alternative to classical methods owing to easier product isolation and recovery of the ionic liquid and avoidance of problems associated with the neutralisation of large quantitities of acid.

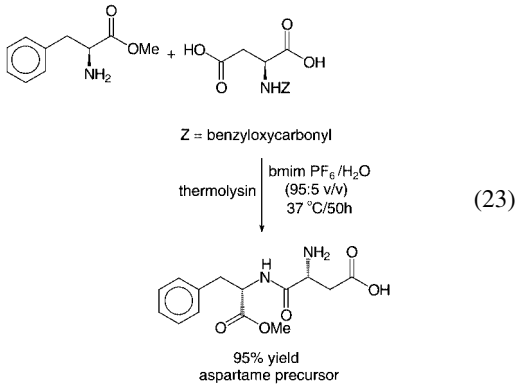
Many synthetically important rearrangement reactions are catalysed by Brønsted or Lewis acids and, hence, may benefit from using acidic ionic liquids as solvents and/or catalysts. For example, the Beckmann rearrangement of ketoximes in ionic liquids, in the presence of catalytic amounts (20 mol%) of phosphorus compounds (*e.g.* P_2O_5) was recently reported.[78]

The ionic liquid tributylhexylammonium bis(trifluoromethylsulfonyl) amide was shown[79] to be a useful solvent for the acid-catalysed cyclotrimerisation of veratryl alcohol. The methodology obviates the need for large quantities of organic solvent and strongly dehydrating acids and provides the cyclotriveratrylene (CTV) in high yield and purity. CTV is of interest as a supramolecular host compound that complexes a variety of guest molecules.

Biocatalysis in ionic liquids

Attention has recently been focused on the use of enzymes in ionic liquids. It was already noted in 1984[80] that the enzyme alkaline phosphatase is relatively stable in a 4:1 (v/v) mixture of triethylammonium nitrate and water. More recently, Lye and coworkers[81] reported a two-phase biotransformation in which $bmimPF_6$ acts as a reservoir for the substrate while the biocatalyst—whole cells of *Rhodococcus* R312—is present in the aqueous phase. Shortly thereafter two reports of enzymatic conversions in an ionic liquid medium appeared.[82,83]

Erbeldinger *et al.*[82] reported the thermolysin-catalysed synthesis of *Z*-aspartame (Reaction 23) in $bmimPF_6$ containing

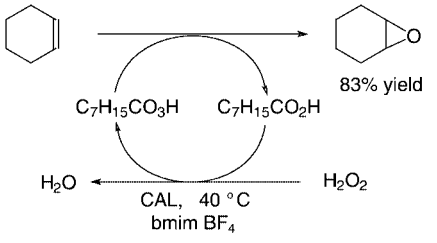


(23)

5% (v/v) water. The enzyme displayed excellent stability when suspended in the ionic liquid and the activity was equal to that observed in ethyl acetate–water. A small amount of the enzyme (< 3.2 mg mL^{-1}) which dissolved in the ionic liquid was completely inactive.

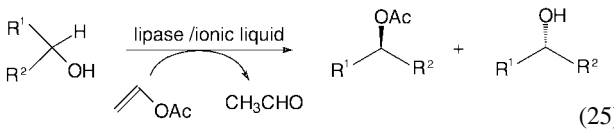
We showed[83] that *Candida antarctica* lipase is able to catalyse a variety of transformations—transesterification, ammoniolysis and perhydrolysis—in $bmimBF_4$ or $bmimPF_6$ in the absence of water. Reactions were performed with the free (NOVO SP525) or immobilized enzyme (Novozyme 435). Reaction rates were comparable with or better than those observed in conventional organic media. For example, the reaction of octanoic acid with ammonia, in $bmimBF_4$ at 40 °C, gave complete conversion to octanamide in 4 days compared to 17 days for the same conversion using ammonium carbamate in methyl isobutyl ketone.[84]

The epoxidation of cyclohexene by peroxyoctanoic acid, generated *in situ* by Novozyme 435-catalysed reaction of octanoic acid with 60% aqueous H_2O_2, proceeded smoothly in $bmimBF_4$ (Reaction 24).



(24)

Subsequently, other groups have reported on lipase-catalysed enantioselective transesterification of chiral alcohols (Reaction 25) in ionic liquids.[85–87] Kragl and coworkers[85] investigated the



(25)

kinetic resolution of 1-phenylethanol with nine different lipases in ten different ionic liquids. Good activities and, in many cases, improved enantioselectivities were observed compared with the same reaction in MTBE (methyl *tert*-butyl ether). Rates and/or enantioselectivities were dependent on the anion as was also observed by Itoh and coworkers.[86] It was also shown that the product could be extracted with ether and the ionic liquid ($bmimPF_6$), containing the suspended enzyme, could be recycled.[86] Similarly, Kim and coworkers[87] observed markedly enhanced enantioselectivities in *Candida antarctica* and *Pseudomonas cepacia* lipase-catalysed transesterifications of chiral alcohols in $bmimBF_4$ and $bmimPF_6$.

Based on these initial studies the use of enzymes in ionic liquids would appear to open up a new field of nonaqueous enzymology. Ionic liquids could have added benefits for performing biotransformations with highly polar substrates, *e.g.* carbohydrates and amino acids, which are sparingly soluble in common organic solvents. We are currently investigating the scope with regard to type of enzyme, transformation and the effect of the structure of the ionic liquid.

Concluding remarks

Catalysis in ionic liquids is an exciting and burgeoning area of research (many of the references in this review are from 2000 and 2001) which holds considerable potential for industrial application. The use of ionic liquids as reaction media for catalytic transformations or, in some cases, as the catalyst itself can have a profound effect on activities and selectivities. Furthermore, precision tuning of reactions can be achieved by a suitable combination of cation and anion, *i.e.* they are truly 'designer solvents'. In the majority of cases studied the ionic liquid, containing the catalyst could be readily recycled. They provide a medium for performing clean reactions with minimum waste generation. As was remarked by Seddon[8] they could, quite literally, revolutionise the methodology of synthetic organic chemistry.

A surprisingly mild and versatile method for palladium-catalyzed Suzuki cross-couplings of aryl chlorides in the presence of a tri*aryl*phosphine†

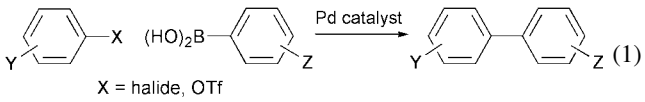
Shih-Yuan Liu, Michael J. Choi and Gregory C. Fu*

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139 USA. E-mail: gcf@mit.edu

Received (in Corvallis, OR, USA) 30th August 2001, Accepted 21st September 2001
First published as an Advance Article on the web 8th November 2001

In the presence of new air-stable triarylphosphine 2, palladium-catalyzed Suzuki reactions of a wide array of aryl chlorides can be accomplished in uniformly good yield, including couplings of very sterically demanding and electronically deactivated substrates; activated aryl chlorides can be coupled at room temperature. In terms of scope and mildness, Pd–2 compares well with other catalyst systems that have been described for Suzuki reactions of aryl chlorides, thereby establishing that triarylphosphines should be regarded as fertile ground for future ligand-design efforts for palladium-catalyzed couplings of aryl chlorides.

The palladium-catalyzed cross-coupling of organic halides/triflates with organoboron reagents [Suzuki reaction; *e.g.*, eqn. (1)] is a powerful and widely used method for carbon–carbon



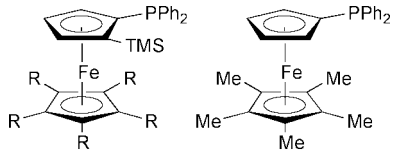
(1)

bond formation.[1] Until recently, aryl chlorides, an attractive class of substrates due to their low cost and ready availability,[2] were generally not suitable coupling partners in palladium-catalyzed Suzuki reactions.[3] However, during the past few years this deficiency has been remedied through the use of ligands such as electron-rich, sterically hindered phosphines[4] and carbenes.[5,6]

The low reactivity of aryl chlorides in palladium-catalyzed coupling reactions is often ascribed to their reluctance to oxidatively add to palladium, and the unusual effectiveness of strongly electron-donating ligands in achieving Suzuki cross-couplings of aryl chlorides is consistent with this hypothesis. Thus, at the time that we initiated our studies, there were no examples of Suzuki reactions of unactivated aryl chlorides by palladium catalysts that bear tri*aryl*phosphines,[7,8] which are generally significantly less electron-rich than tri*alkyl*phosphines.

In this communication, we describe our discovery that a wide array of palladium-catalyzed Suzuki reactions of aryl chlorides can be achieved through the use of a new ferrocene-derived triarylphosphine (**2**). In the presence of this air-stable, sterically demanding ligand, we can effect the Suzuki cross-coupling of activated aryl chlorides at rt, and we can accomplish reactions of unactivated aryl chlorides, including sterically hindered and electron-rich substrates, at 70 °C.

Phosphine **1**, previously reported by Price and Simpkins,[9] serves as a moderately efficient ligand for the palladium-catalyzed coupling of *p*-chlorotoluene with *o*-tolylboronic acid (37% yield by GC after 24 h at 70 °C; Table 1, entry 1). An increase in the steric demand of the bottom ring of the ligand (Cp → Cp*; **2**) leads to a substantial increase in reactivity (entry 2 *vs.* entry 1).[10] The TMS group is an important contributor to



the unusual reactivity of **2**, as demonstrated by the slow coupling that we observe when we employ the corresponding non-silylated ligand (**3**; entry 3). Entry 4 establishes that PPh_3 is not useful under these conditions.

New triarylphosphine **2**, which is air- and moisture-stable both in the solid state and in solution, serves as a remarkably versatile ligand for Suzuki cross-couplings of aryl chlorides. As shown in Table 2, a variety of chlorides, including hindered (entries 2–5) and electronically deactivated (entry 6) ones, react with a range of boronic acids in very good yield. The sterically demanding coupling that is illustrated in entry 5, which furnishes a tri-*ortho*-substituted biaryl in 93% yield, is especially worthy of note.[11,12]

We have determined that, in the presence of triarylphosphine **2**, Suzuki cross-couplings of activated aryl chlorides can be accomplished at rt. To date, only a few other ligands have achieved this objective.[13] For room-temperature couplings, use of $Pd(OAc)_2$ as the palladium source and an ~1:1 ratio of Pd:ligand provide the highest reactivity among the conditions that we have examined. With these conditions, we can effect Suzuki cross-couplings of a range of activated aryl chlorides, including heteroaryl (entry 2) and *ortho*-substituted (entry 3) substrates, with arylboronic acids in excellent yield (Table 3).

In summary, we have prepared a new, air-stable triarylphosphine (**2**), and we have established that it serves as an

effective ligand in palladium-catalyzed Suzuki couplings of aryl chlorides. In the presence of Pd–**2**, a diverse array of substrates, including hindered, heteroaryl, and electronically deactivated chlorides, react in uniformly good yield. The ability of this system to achieve cross-couplings of activated aryl chlorides at rt is particularly noteworthy. Because **2** is a tri*aryl*phosphine, the high reactivity of Pd–**2** (in terms of scope and mildness, comparable to sterically demanding trialkylphosphines and greater than carbene ligands) is unexpected. In view of the ease with which the structure of **2** can be modified, we anticipate that further enhancements in reactivity will be possible, as well as the design of effective ligands for asymmetric catalysis.

Support has been provided by Bristol-Myers Squibb, Merck, the National Institutes of Health (National Institute of General Medical Sciences, R01-GM62871), Novartis, and Pfizer. We thank Frontier Scientific for donating arylboronic acids.

7 For a single example of a Suzuki coupling of an *activated* aryl chloride by a Pd–triarylphosphine catalyst, see: P. Kocovsky, S. Vyskocil, I. Cisarova, J. Sejbal, I. Tislerova, M. Smrcina, G. C. Lloyd-Jones, S. C. Stephen, C. P. Butts, M. Murray and V. Langer, *J. Am. Chem. Soc.*, 1999, **121**, 7714.

8 As our investigation was nearing completion, Richards described one Suzuki coupling of an unactivated aryl chloride (*p*-chlorotoluene) and one reaction of an activated aryl chloride (*p*-chloronitrobenzene) that proceed in good yield by GC at 60 °C, using a Pd–tris(2-methylferrocenyl)phosphine catalyst: T. E. Pickett and C. J. Richards, *Tetrahedron Lett.*, 2001, **42**, 3767. This catalyst furnishes modest yields in couplings of deactivated and *ortho*-substituted aryl chlorides (< 50% by GC).

9 D. Price and N. S. Simpkins, *Tetrahedron Lett.*, 1995, **36**, 6135.

10 For a related observation of a change in reactivity upon conversion of a remote Cp group to a C_5Ph_5 group, see: Q. Shelby, N. Kataoka, G. Mann and J. Hartwig, *J. Am. Chem. Soc.*, 2000, **122**, 10 718.

11 Suzuki cross-couplings that efficiently generate tri-*ortho*-substituted biaryls are very uncommon, especially with aryl chlorides as substrates. For a discussion, see ref. 3.

12 This catalyst system is also very active for Suzuki reactions of aryl bromides. For example, in the presence of 0.25% Pd_2dba_3–0.5% **2**, the cross-coupling of 2-bromo-*m*-xylene with *o*-tolylboronic acid proceeds in 99% isolated yield after 24 h at rt. To the best of our knowledge, only P(*t*-Bu)$_3$ has been shown to effect a room-temperature Suzuki reaction of an unactivated aryl bromide to generate a tri-*ortho*-substituted biaryl (ref. 3).

13 Only Buchwald's aryldialkylphosphines are effective for room-temperature couplings of unactivated aryl chlorides: ref. 4*a*. See also: ref. 4*b* (six examples); D. Zim, A. L. Monteiro and J. Dupont, *Tetrahedron Lett.*, 2000, **41**, 819 (two examples); P. Kocovsky, S. Vyskocil, I. Cisarova, J. Sejbal, I. Tislerova, M. Smrcina, G. C. Lloyd-Jones, S. C. Stephen, C. P. Butts, M. Murray and V. Langer, *J. Am. Chem. Soc.*, 1999, **121**, 7714 (one example).

First published as an Advance Article on the web 8th November 2001

Flow linear dichroism is shown to be able to detect single base mismatches in a polymerase chain reaction (PCR) amplimers from exon 10 of the human β-glucocerebrosidase gene (associated with Gaucher disease) over a kilobase long with no post PCR manipulation.

The need to detect sequence variations in human genes has increased with the continuing identification of disease-causing mutations and the use of DNA polymorphisms, especially single nucleotide polymorphisms (SNPs), to assist genetic mapping strategies.[1] Despite improvements in technologies available for detecting and identifying SNPs, all suffer from either expense (reagents and time) or low sensitivity/accuracy.[2–6] We aimed to identify an inherent optical signal from DNA that is sensitive to distortions in DNA structure, and to demonstrate that this signal can be used to detect point mutations in PCR products. Existing absorbance (on thermal denaturation) and circular dichroism methods are of value for oligonucleotides,[7,8] but not for polynucleotides (100's of bases). Here we present data describing the use of flow linear dichroism[8,9] (LD) to detect structural distortions caused by mismatching of base pairs in DNA helices.

An LD signal is produced by measuring the difference in absorbance of light linearly polarised parallel and perpendicular to an orientation direction. LD signals are positive for transitions whose polarization is along the direction of orientation and negative for those perpendicular to it. In this case, the dichroic signal is generated by aligning DNA fragments in solution by induced laminar flow. The signal from the π–π* transitions of the DNA bases is expected to be negative as the bases lie more perpendicular than parallel to the DNA helix axis which is also the orientation axis. However, an additional factor that must be considered when analysing the data below is that all absorbance spectroscopic measurements involve measuring what light the sample causes not to reach the photomultiplier tube. These are a combination of true absorbance and apparent absorbance—scattering. In most cases the true absorbance dominates the scattering effects as is the case for calf thymus DNA linear dichroism. However, with the PCR products that form the subject of this paper, the total LD signal is three orders of magnitude smaller than with the calf thymus DNA so the scattering effect dominates. With flow LD the scattering effect is always positive.[10]

In this study we have used two mutations within the human gene β-glucocerebrosidase that are associated with Gaucher disease. These mutations were found in 32/92 and 15/92 alleles respectively from UK patients diagnosed with Gaucher disease.[11] This large, clinically relevant, gene spans 7 kilo bases of genomic DNA and is comprised of 11 exons. At least 138 different types of mutation have been found to be associated with Gaucher disease, and the UK population is particularly heterogeneous for these. DNA-based diagnosis and family screening for this disease is currently limited by available methodology.

Genomic DNA was prepared from peripheral leucocytes of patients previously confirmed to be a compound heterozygote (h1/h2) for the L444P and R463C point mutations (A to C and G to T, see Fig. S1 ESI for full details) in the β-glucocerebrosidase gene (Entrez AF023268), from patients heterozygous for each mutation (h1/wt and h2/wt), and a control without either mutation (wt/wt), using conventional methods.[12] A 1353 bp amplimer encompassing these mutations was generated by PCR. Mutations were confirmed using restriction digestion and cycle sequencing (ABI big dye cycle sequencing reagents and an ABI 310 capillary zone sequencer) using the previously published primers and methods.[11]

Heteroduplexes were generated by re-heating each PCR reaction to 95 °C for 5 min, incubating at 72 °C for 20 min and allowing to cool to 25 °C over 3 h. As the patients were heterozygous for these mutations heteroduplices of each mutant (h1/wt and h2/wt) with the normal sequence were produced from the single heterozygous patients and a heteroduplex containing two mismatches (h1/h2) from the compound heterozygous patient.

The LD spectra of the samples were measured using a JASCO J-715 spectropolarimeter. The sample was aligned within the light beam using a custom made stirred cell.[13] The stirred cell consists of a cylindrical cross section stainless steel sleeve with opposing quartz apertures embedded in the cylinder walls. A cylinder of quartz is mounted centrally (with a 0.5 mm annular gap) with respect to its circular face on a rotating spindle within the sleeve. The speed of rotation of the spindle and hence the quartz cylinder is controlled electronically to allow the sample solution to be maintained with the highest possible degree of alignment without inducing turbulent flow. LD measurements were made directly in PCR buffer. The signals derived from the PCR amplimers are corrected for concentration, as determined by PICO green binding (Molecular Probes, Oregon), and are directly comparable (50 μg mL^{-1}); the calf thymus DNA (Sigma) was at a concentration of 300 μM (determined using the extinction coefficient at 258 nm of 6600 cm^{-1} mol^{-1} dm^3).

LD spectra of wt/wt, h1/wt, h2/wt and h1/h2 are shown in Fig. 1a. All 4 samples showed a negative maximum of similar magnitude at 260 nm that is characteristic of the signal from the lowest energy π–π* transitions of the DNA bases when the bases are oriented approximately perpendicular[14] to the DNA helix axis. The spectra of the short PCR amplimers also show *positive* maxima at 230 nm that is of a greater magnitude relative to the 260 nm band and of a different sign from the LD signal of the much larger DNA fragments obtained from calf thymus (Fig. 1b). The amplitudes of the 230 nm peak observed from the PCR derived amplimers show a trend related to the number of mismatched base pairs in each sample, h1/h2 having the lowest amplitude. Upon addition of 50% glycerol to the DNAs to increase the sample viscosity, the flow orientation increases the true absorbance LD signal by an order of

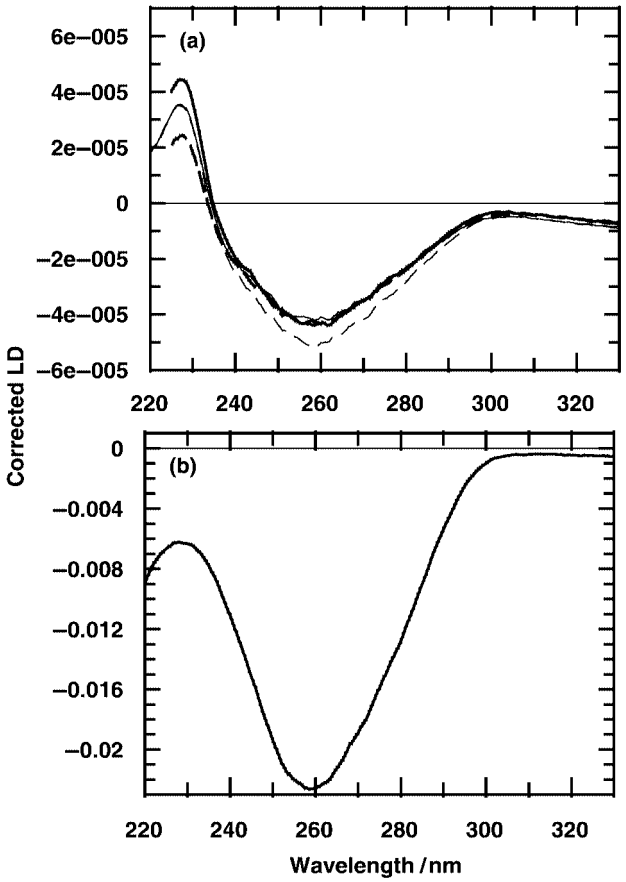

Fig. 1 (a) Flow LD spectra of wt/wt (*thick solid line*), h1/wt (*thin solid line*), h2/wt (*thin dashed line*), and h1/h2 (*thick dashed line*) at 50 μg mL^{-1} in Bio-extract PCR buffer at 1750 rpm. The maximum at 230 nm changes in intensity with respect to the number of mis-matches present. (b) Flow LD spectra of Calf thymus DNA. Corrected LD denotes the signal is corrected for concentration differences. The units for the LD are the absorbance readings directly from the instrument. Pathlength is 1 mm.

magnitude making LD absorbance signal dominant over the scattering signal (see Fig. S2 ESI). Residual primers have no LD signal and the starting genomic DNA sequence has an incredibly small (2–3 orders of magnitude smaller than the PCR products) signal (data not shown). The effect of flow rate is given in Figs. S3 and S4 of the ESI.

The effect of single base pair mismatches on the conformation of linear sections of DNA is most likely due to induced local flexibility around the mismatched region. Existing techniques for detecting single mutations such as Differential Gradient Gel Electophoresis[3] and denaturing HPLC[4] rely on the fact that the local disruption in structure is propagated through the DNA molecule and effects hydrodynamic behaviour. The limitation of these techniques is that as the length of the DNA molecule increases the difference in behaviour of the mismatched and complementary DNA is reduced. By way of contrast our data show that linear dichroism relies on changes in hydrodynamic properties having an effect on the spectroscopy of the DNA itself. We have demonstrated that, although the 260 nm minimum is essentially unaffected by base pair mismatches, the amplitude of the maximum at 230 nm is sensitive to such changes and these can be detected in a DNA amplimer of greater than a kilobase in length. This exceeds the length at which previous techniques have been shown to be effective.

As 230 nm corresponds to an absorbance minimum for DNA and we see a positive maximum in the LD signal, these observations imply that light scattering is dominating the 230 nm signal whereas at 260 nm the intrinsic LD signal dominates the scattering. The intensity of the 230 nm signals is therefore dominated by the volume of the DNA. wt/wt is largest and h1/h2 the smallest. If the 230 nm signals are normalised by dividing by the 260 nm signal we have:

$$LD_{230\ nm}: \text{wt/wt} > \text{h1/wt} > \text{h2/wt} > \text{h1/h2}$$

The h1 mutation involves replacing an A:T base pair with C:T which could retain two hydrogen bonds if the helix were pulled in. The h2 mutation can retain at most one hydrogen bond and needs to accommodate an extra N–H bond within the base-pairing region. These differences presumably result in h1/wt being stiffer than h2/wt (so having a larger intrinsic LD) and less bent (so having a larger scattering term).

Increasing the viscosity of the sample also has the effect of increasing alignment of the DNA molecules, so increasing the intrinsic LD signal. The heteroduplex and homoduplex DNA appear equivalent in glycerol, the increased viscosity overriding the differences in flexibility seen in less viscous solutions and the larger LD signal swamps the scattering effects.

These data provide evidence for the exciting prospect that LD spectroscopy may be a powerful tool for use as a pre-screen to detect base pair mis-matches, and even distinguishing different mismatches, in comparatively long pieces of DNA. The major advantage of this technique is that it exploits an inherent optical property in combination with the hydrodynamic properties of the DNA helix. This allows the information derived from LD spectra to be less dependent on the length of the DNA (and may even be enhanced for longer DNAs in contrast to other techniques) and hence allows the possibility that the technique will be applicable to whole gene searches. These experiments were deliberately designed to use PCR products directly demonstrating that no post-amplification modification is necessary. For these particular mutations no other technique can distinguish between these disease-causing mutations so efficiently. How widely applicable this technique is to other mutations awaits the results of further studies.

Visible light-induced photoepoxidation of propene by molecular oxygen over chromia–silica catalysts

Chizu Murata, Hisao Yoshida* and Tadashi Hattori

Department of Applied Chemistry, Graduate School of Engineering, Nagoya University, Nagoya 464-8603, Japan. E-mail: yoshidah@apchem.nagoya-u.ac.jp

Received (in Cambridge, UK) 5th September 2001, Accepted 9th October 2001
First published as an Advance Article on the web 8th November 2001

Highly dispersed chromate species on silica catalyse the selective epoxidation of propene to propene oxide (PO) by molecular oxygen under visible light irradiation with the same quantum yield as that under UV light irradiation.

Currently propene epoxidation is performed by two liquid phase processes: the chlorohydrin process and the hydroperoxide process.[1] These processes have some problems of by-products, wastes, *etc*. The direct gas phase epoxidation of propene by molecular oxygen, which is the most simple process without these problems, is desirable. Recently some workers reported new approaches for propene epoxidation using O_2 and H_2.[2] However, it is evident that using only O_2 is more advantageous, and many researchers have attempted epoxidation of propene using only O_2.[3]

On the other hand, 'photoepoxidation' of propene using only O_2 over TiO_2,[4] Ba-Y type zeolite,[5] Nb_2O_5/SiO_2,[6] MgO/SiO_2 and SiO_2[7] has been reported. However, these activities were low and it was not clear whether the reaction proceeded catalytically. We have found that isolated tetrahedral Ti species on titania–silica catalytically promoted the selective photoepoxidation of propene by molecular oxygen.[8] However, the isolated tetrahedral Ti species absorb only UV light ($\lambda < 250$ nm), and the reaction proceeded only under UV irradiation. Artificial UV light sources tend to be expensive, and the UV light component in sunlight reaching the surface of the earth is relatively small. Thus, it is significant to develop a visible light-driven photocatalyst for epoxidation of propene. It is known that Cr species have LMCT absorption in the visible light region, and recently NO decomposition and propane oxidation over Cr-containing mesoporous silica molecular sieves (Cr-HMS) under visible light irradiation have been reported.[9,10] In our previous screening study of silica-supported metal oxide catalysts for propene photoepoxidation, CrO_x/SiO_2 (1.5 mol% as Cr) showed high propene conversion, but low selectivity for PO.[11]

In the present study, we prepared chromia–silica catalysts containing a very small amount (0.1 mol%) of Cr by the sol–gel method or impregnation method, and examined the propene photoepoxidation activity and the dependence of the activity on the wavelength of photoirradiation.

CrO_x–SiO_2 binary oxide was prepared by hydrolysis of a mixed solution of $Si(OC_2H_5)_4$ and $Cr(NO_3)_3{\cdot}9H_2O$ dissolved in ethylene glycol followed by calcination at 773 K in flowing air for 5 h.[12] CrO_x/SiO_2 supported oxides were prepared by impregnation method with amorphous silica and $Cr(NO_3)_3{\cdot}9H_2O$ aqueous solution, followed by calcination in the same way.[11] CrO_x–SiO_2 and CrO_x/SiO_2 are denoted as Cr–Si(x) and Cr/Si(x) respectively, where x is mol% of Cr; $n_{Cr}/(n_{Cr} + n_{Si}) \times 100$. Prior to each reaction test and spectroscopic measurement, the sample was treated with 100 Torr oxygen at 773 K for 1 h, followed by evacuation at 673 K for 1 h. The photoepoxidation of propene was performed with a conventional closed system (123 cm^3) and 200 W Xe lamp in the same manner as previously reported.[8]The wavelength of photoirradiation light was limited by using TOSHIBA UV-cut glass filters: UV-31 and Y-43, which allow the transmission of light with $\lambda > 310$ nm and 430 nm, respectively. The distribution of the intensity of light from the Xe lamp was measured using a Hamamatsu Photonic Multi-Channel Analyzer C7473 with a CCD sensor. Diffuse reflectance UV-vis spectra of the pretreated samples were measured *in vacuo* on a JASCO V-570 spectrophotometer at room temperature.

Fig. 1 shows diffuse reflectance UV-vis spectra of Cr/Si(0.1), Cr–Si(0.1) and Cr/Si(1.5). All samples showed three absorption bands centred around 245, 330 and 460 nm, which were assigned to the LMCT (from O^{2-} to Cr^{6+} charge transfer) transitions of chromate species.[9] Cr/Si(1.5) and Cr–Si(0.1) showed an additional absorption band in the 580–800 nm region assigned to the d–d transition of octahedral Cr^{3+} in Cr_2O_3 clusters.[9] Weckhuysen *et al*. reported that monochromate and dichromate species existed over Cr/SiO_2 0.2 wt% (0.23 mol%), and, with increasing Cr loading, additional polychromate (trichromate, tetrachromate, *etc*.) species and Cr_2O_3 clusters were formed.[13] Since Cr/Si(0.1) contained 0.09 wt% of Cr and exhibited a spectrum without an absorption band at 580–800 nm, Cr/Si(0.1) would have dispersed chromate species (monochromate and/or dichromate) most abundantly. The additional very weak absorption band at 580–800 nm in the spectrum of Cr–Si(0.1) indicates that a very small amount of polychromate species and Cr_2O_3 clusters would also be formed on Cr–Si(0.1). Over Cr/Si(1.5), larger amounts of polychromate species and Cr_2O_3 clusters would exist, illustrated by the stronger band at 580–800 nm in the spectrum.

Table 1 shows the results of photooxidation of propene over chromia–silica catalysts. The major products were propene oxide (PO), ethanal, CO and CO_2. Small amounts of propanal, acetone, acrolein, 2-propanol, ethene and butene were also observed. Cr/Si(1.5) showed very high selectivity for CO_x and low selectivity for PO (run 1) as previously reported.[11] Cr/Si(0.1) and Cr–Si(0.1) showed much higher selectivity for PO than Cr/Si(1.5) when they were compared at similar conversion (runs 2 and 3). This indicates that chromia–silica catalysts containing a very small amount (0.1 mol%) of Cr were efficient for the photoepoxidation of propene. Cr–Si(0.1) showed slightly lower selectivity for PO and higher selectivity for ethanal than Cr/Si(0.1). These results on the photoreaction and the UV-vis spectra indicate that dispersed chromate species on SiO_2 should be effective in the photoepoxidation of propene, while polychromate species and Cr_2O_3 clusters should promote

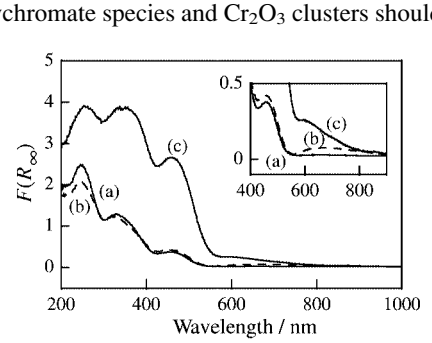

Fig. 1 Diffuse reflectance UV-vis spectra of chromia–silica catalysts. (a) Cr/Si(0.1), (b) Cr–Si(0.1) (broken line) and (c) Cr/Si(1.5). The samples were evacuated at 673 K.

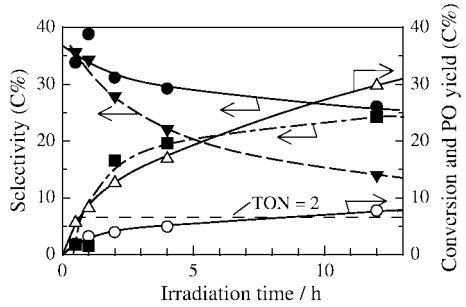

Fig. 2 Time course of photooxidation of propene over Cr–Si(0.1). Conversion (△), PO yield (○), and selectivity to propene oxide (●), ethanal (▼) and CO + CO_2 (■).

the oxidation of propene to by-products such as ethanal and CO_x. In addition, the turnover number, TON = (the amount of produced PO) / (the amount of Cr on sample), exceeded 2 after 12 h irradiation over Cr–Si(0.1) (Fig. 2), which indicated that this reaction proceeded catalytically.

The effective wavelength for photoepoxidation of propene over the Cr–Si(0.1) catalyst was examined using UV cut-off filters (Table 1, runs 4 and 5). Even under visible light ($\lambda > 430$ nm) irradiation (run 5), the conversion and PO yield almost reached half of the run without the filter (run 3). This means that visible light is sufficient to promote photoepoxidation of propene over chromia–silica catalysts. By using the UV cut-off filters, selectivity for PO was not significantly changed, but ethanal selectivity increased and CO_x selectivity decreased. As shown in Fig. 2, in the range of conversion 7–18% (1–4 h) ethanal selectivity decreased and CO_x selectivity increased with increasing conversion, but selectivity to PO was not so affected by the conversion. The differences in ethanal and CO_x selectivity among runs 3–5 can be attributed to the difference in conversion, not in the wavelength of light. In other words, the product distribution would not be affected by the wavelength of light, which suggests that the chromate species excited by UV or visible light catalyse the photoepoxidation of propene *via* the same mechanism, regardless of the absorbed wavelength. The relative amount of photons absorbed by Cr–Si(0.1) was estimated from summing the products of absorption intensity of

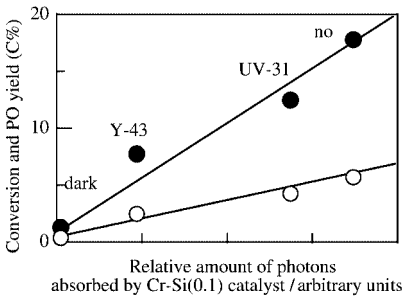

Fig. 3 The plot of conversion (●) and PO yield (○) in photooxidation of propene over Cr–Si(0.1) against the relative amount of photons absorbed by Cr–Si(0.1).

Cr–Si(0.1) and light intensity irradiated from the Xe lamp through UV cut-off filters at each wavelength. With increasing the relative amount of photons absorbed by Cr–Si(0.1), the conversion and PO yield increased linearly (Fig. 3). This result means that chromate species excited by UV or visible light would be equally efficient in the photoepoxidation of propene; that is, the quantum yield of photoepoxidation under visible light would be equal to that under UV light. Thus, exclusion of UV light changed neither the selectivity nor the quantum yield of propene photoepoxidation over chromate species. Therefore, it is suggested that chromate species excited by UV or visible light identically catalyse the photoepoxidation of propene, although the energy of photons was different at each wavelength. This should mean that the energy of visible light is sufficient to promote photoepoxidation of propene, that is, to activate oxygen and/or propene on the catalyst.

In conclusion, highly dispersed chromate species on SiO_2 were found to catalyse propene epoxidation by molecular oxygen under photoirradiation, and even under visible light irradiation. Chromate species excited by visible light would promote propene epoxidation identically to those excited by UV light.

This work was partly supported by a Grant-in-Aid for Encouragement of Young Scientists from the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan.

Reactivity in polynuclear transition metal chemistry as a means to obtain high-spin molecules: substitution of μ_4-OH^- by η^1,μ_4-N_3^- increases nine times the ground-state *S* value of a nonanuclear nickel(II) cage

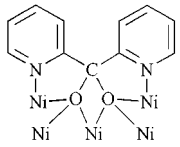
The reaction of di-2-pyridyl ketone, $(2\text{-py})_2CO$, with $Ni(O_2CMe)_2{\cdot}4H_2O$ yields the cage $[Ni_9(OH)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]$, which reacts further with N_3^- ions to give the structurally similar cluster $[Ni_9(N_3)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]$ containing extremely rare η^1,μ_4-N_3^- groups; magnetic studies reveal that the spin ground state of the latter is nine times the ground state of the former.

The study of molecules with unusually large numbers of unpaired electrons has taken on added impetus in the last five years,[1–3] since it has been realised that a fairly large ground-state *S* value is one of the necessary requirements for molecules to be able to function as magnetizable magnets (single-molecule magnets, SMMs) below a critical temperature.[4] In most polynuclear clusters, magnetic exchange interactions are mainly propagated by bridging OH^-, O^{2-}, RO^- or RCO_2^- ligands, or a combination of two or more of these groups.[4] These ligands often cause antiferromagnetic interactions and, thus, it is necessary to arrange the metal ions and the bridging groups in an appropriate manner so that they can give a high-spin ground state for the system.[4] No systematic attempts have been made to replace the above mentioned bridging ligands in a known cluster with other groups that are more prone to ferromagnetic coupling, for example end-on N_3^-, and, in general, the reactivity chemistry of polynuclear 3d-metal complexes is practically unexplored. We herein describe a novel OH^--bridged, nonanuclear nickel(II) cluster with an $S = 1$ ground state and its reaction with azide ions, which leads to substitution of the μ_4-OH^- ligands and yields a structurally similar cluster with an $S = 9$ ground state.

Reaction of di-2-pyridyl ketone, $(2\text{-py})_2CO$, with 2 equivalents of $Ni(O_2CMe)_2{\cdot}4H_2O$ in DMF under reflux resulted in a green solution from which $[Ni_9(OH)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]{\cdot}19H_2O$ **1**† precipitated within 4 days in *ca.* 60% yield. The double deprotonation of the *gem*-diol form of di-2-pyridyl ketone (formed *in situ* in the *presence* of the metal ions) is a consequence of the high $MeCO_2^-$ to $(2\text{-py})_2C(OH)_2$ ratio (4 : 1) used in the reaction. The $RCO_2^-/(2\text{-py})_2CO_2^{2-}$ ligand 'blend' has resulted in a variety of high-nuclearity species in cobalt(II)[5] and copper(II)[6] chemistry.

Complex **1**‡ (Fig. 1) has a fourfold axis passing through Ni(1). The nine Ni^{II} atoms adopt the topology of two square pyramids sharing a common apex at Ni(1) and are held together by four $\eta^1:\eta^3:\eta^3:\eta^1:\mu_5$ (**A**) $(2\text{-py})_2CO_2^{2-}$ ligands. Each Ni···Ni edge of the bases of the pyramids is further bridged by one *syn, syn* $\eta^1:\eta^1:\mu_2$ acetate. The four acetate ligands create a concave cavity in each pyramid's base, into which a very rare μ_4-OH^- is effectively trapped capping the square base. A



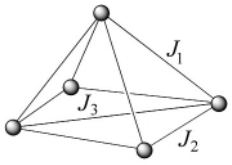
A

salient feature of the structure is the coordination number eight (square antiprismatic geometry) around Ni(1).

The dc $\chi_M T$ product of **1** shows a continuous decrease from the room temperature value of 11.47 cm^3 K mol^{-1} down to 0.40 cm^3 K mol^{-1} at 2 K (Fig. 2), indicating a dominant antiferromagnetic superexchange pattern. A first approach to quantify the magnetic exchange interactions in **1** has been performed by means of the full-matrix diagonalisation program CLUMAG,[7] applying the Hamiltonian (1):

$$H = -J_1(S_1S_2 + S_1S_3 + S_1S_4 + S_1S_5 + S_1S_6 + S_1S_7 + S_1S_8 + S_1S_9) - J_2(S_2S_3 + S_3S_4 + S_4S_5 + S_5S_2 + S_6S_7 + S_7S_8 + S_8S_9 + S_9S_6) - J_3(S_2S_4 + S_3S_5 + S_6S_8 + S_7S_9) \quad (1)$$

in which S_1 corresponds to the central metal site [Ni(1)], and S_2, S_3, S_4, S_5 and S_6, S_7, S_8, S_9 correspond to the Ni^{II} atoms placed at the two square bases [Ni(2), Ni(2b), Ni(2c), Ni(2d) and Ni(3), Ni(3b), Ni(3c), Ni(3d), respectively]. In this scheme (**B**), J_1



B

relates the central with the peripheral spins, whereas J_2 and J_3 relate the neighboring and the opposite spins, respectively, in each base. To reduce the deviation of the data due to the zero field splitting effect, the fit was performed in the 300–12 K temperature range. The best fit parameters obtained are $J_1 = 6.0$ cm^{-1}, $J_2 = 18.0$ cm^{-1} and $J_3 = -57.0$ cm^{-1} for a *g* value of 2.30. The strong antiferromagnetic interaction J_3 is consistent with the large Ni–O–Ni angles of *ca.* 140°, whereas the weak to moderate ferromagnetic interactions J_1 and J_2 were expected for the observed Ni–O–Ni angles that are slightly larger than 90°.[8] The ground state of **1**, obtained from the low temperature data and magnetization measurements ($M/N\beta$ value of 1.05 under an external field of 5 T at 2 K) is $S = 1$.

We have wondered whether the end-on azido ligand, a well known ferromagnetic coupler, would be incorporated into the

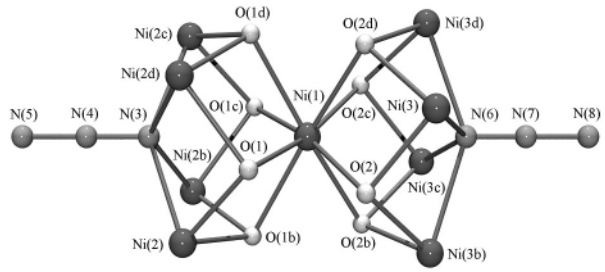

Fig. 3 The molecular structure of complex **2**. For clarity, only the Ni^{II} atoms, nitrogen atoms of the azido ligands and triply bridging oxygen atoms of $(2\text{-py})_2CO_2^{2-}$ are shown. Symmetry transformations used to generate equivalent atoms: b: *x*, $-y + 1/2$, *z*. c: $-x + 1/2$, $-y + 1/2$, *z*. d: $-x + 1/2$, *y*, *z*.

Ni_9 cage skeleton replacing the hydroxo ligands, which cause the strong antiferromagnetic interaction J_3 (see **B**). This has, indeed, turned out to be the case. Reaction of **1** with 2–3 equivalents of NaN_3 in DMF–MeOH (2 : 1 v/v) gave green crystals of $[Ni_9(N_3)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]\cdot 4DMF\cdot 4.5H_2O$ **2**† in 80% yield.

Complex **2**‡ (Fig. 3), which also has a fourfold axis passing through Ni(1), bears striking structural similarity to **1**, the main difference being the replacement of the μ_4-OH^- ligands of the latter by the η^1,μ_4-N_3^- ligands in the former. Such η^1,μ_4 azido ligands had been totally unknown and were first observed in the recently reported[9] nonanuclear cage $[Co_9(N_3)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]$ **3**.

Complexes **1** and **2** join a handful of structurally characterized discrete, non-organometallic nonanuclear Ni^{II} complexes with O,N-ligation.[10–13]

The dc $\chi_M T$ product of **2** increases from the room temperature value of 10.87 cm^3 K mol^{-1} to a maximum of 13.88 cm^3 K mol^{-1} at 24 K, and then decreases continuously down to 2 K (Fig. 2). This behaviour is compatible with a moderate ferromagnetic coupling; the low-temperature decrease of the magnetic moment is associated with the anisotropy of the Ni^{II} ions. Magnetization data collected for **2** show a rapid increase of $M/N\beta$ upon increasing the external field, reaching a value of 9.59 at 5 T. Thus, the magnetic data for **2** should be associated with ferromagnetic coupling mediated by the η^1,μ_4-N_3^- ligand (giving a total *S* value of nine times the local spin), assuming ferromagnetic coupling between the central and the peripheral Ni^{II} ions (as in **1**); this assumption is reasonable because the structural parameters of complexes **1** and **2** do not differ much. The low temperature fall in $\chi_M T$ might be very exciting and the study of the relaxation behaviour of **2** is in progress.

In conclusion, the structures of both **1** and **2** feature very rare characteristics, such as the coordination number 8 for the central Ni^{II} ion, the μ_5 coordination mode of $(py)_2CO_2^{2-}$, and the η^1,μ_4 coordination mode of both the hydroxo and azido ligands. However, the most remarkable result of this work is the fact that rational reactivity chemistry of a polynuclear complex results in a new cluster of the same nuclearity, which retains the structural identity of and has much more attractive magnetic properties than the starting material. The described N_3^- for OH^- substitution has the potential for general application in the area of high-spin molecules.

First published as an Advance Article on the web 29th October 2001

The stoichiometric splitting of water into H_2 and O_2 (H_2/O_2 = 2) under visible light irradiation (λ > 420 nm) took place for the first time using a mixture of Pt-WO_3 and Pt-$SrTiO_3$ (Cr–Ta-doped) photocatalysts and an IO_3^-/I^- shuttle redox mediator.

The construction of an efficient artificial photosynthesis system for solar energy conversion and storage is one of the fascinating goals to solve the global energy problem. The splitting of water into H_2 and O_2 stoichiometrically (H_2/O_2 = 2) is the most fundamental and important reaction in artificial photosynthesis. So far, many semiconductor photocatalysts such as Pt-TiO_2 have been reported for water splitting under UV light irradiation.[1,2] However, development of a photocatalyst system working under visible light irradiation (λ > 400 nm) is indispensable from the viewpoint of efficient solar energy utilization. Unfortunately, such a reliable and reproducible photocatalyst system has not been established yet.

Recently, we reported a unique synergy effect of two different TiO_2 photocatalysts suspended in NaI aqueous solution for the water splitting reaction under UV light in a one-pot cell.[3] In this system, H_2 was formed on Pt-TiO_2(anatase) accompanied by the oxidation of I^- to IO_3^-, and O_2 was formed on TiO_2(rutile) accompanied by the reduction of IO_3^- to I^-, therefore, I^- and IO_3^- ions acted as electron carrier shuttles between two photoexcitation systems, as shown in the following equations:

$$6H^+ + 6e^- \rightarrow 3H_2 \text{ (conduction band of Pt-}TiO_2\text{(anatase))} \quad (1)$$

$$I^- + 6OH^- + 6h^+ \rightarrow IO_3^- + 3H_2O \text{ (valence band of Pt-}TiO_2\text{(anatase))} \quad (2)$$

$$IO_3^- + 3H_2O + 6e^- \rightarrow I^- + 6OH^- \text{ (conduction band of } TiO_2\text{(rutile))} \quad (3)$$

$$6OH^- + 6h^+ \rightarrow {}^3/_2O_2 + 3H_2O \text{ (valence band of } TiO_2\text{(rutile))} \quad (4)$$

Here, we report the first stoichiometric decomposition of water into H_2 and O_2 under only visible light (λ > 420 nm) using a mixture of two different photocatalysts, Pt-WO_3 and Pt-$SrTiO_3$(Cr–Ta-doped) in NaI aqueous solution.

Commercial WO_3 powder (99.999% purity), supplied from Kojundo Chemical Co., was used as one of the photocatalysts. $SrTiO_3$ powder doped with Cr and Ta ions was prepared by the calcination of a mixture of Cr_2O_3 (Cr: 1 mol% of Ti), Ta_2O_5 (Ta: 1 mol% of Ti), $SrCO_3$ and TiO_2 at 1100 °C in air.[4] Pt-loaded catalyst was prepared by the photodeposition of H_2PtCl_6 on the catalysts in aqueous solution. The photocatalytic reaction was performed in a one-pot Pyrex glass cell connected to a closed gas-circulating system. A suspension of catalyst powder (0.2 g) in NaI (100 mmol l^{-1}) or $NaIO_3$ (4 mmol l^{-1}) aqueous solution (250 ml) in the cell was degassed completely. The visible light irradiation was performed using a Xe lamp (300 W, CERMAX-LX-300) through a 420 nm cutoff filter (HOYA Glass Co.). The evolution of H_2 and O_2 was detected by on-line gas chromatography (TCD, molecular sieve 5A, argon carrier). The I^-, IO_3^- and I_3^- ions were analyzed by ion-chromatography and UV-vis spectroscopy.

There are some reports on unique mixed-oxide semiconductor photocatalysts that could produce H_2 under visible light irradiation using methanol as a sacrificial reagent,[4–6] suggesting a negative conduction band potential compared to the H^+ reduction potential to H_2. First, we investigated these mixed-oxide semiconductors such as $SrTiO_3$(Cr–Ta-doped),[4] $In_2Zn_9O_{12}$,[5] $InNbO_4$,[6] *etc.* for H_2 formation using I^- ion as a reversible electron donor. Pt-loaded $SrTiO_3$(Cr–Ta-doped) showed catalytic activity, with H_2 evolution from NaI aqueous solution. The initial rate of H_2 evolution was 0.8 μmol h^{-1}, but the evolution rate decreased gradually and stopped after 20 h from the start of irradiation, as shown in Fig. 1(a). No H_2 evolution was observed without NaI. In the case of Pt-TiO_2(anatase), the IO_3^- ion was mainly produced by the oxidation of I^-.[3] The IO_3^- ion was also observed in solution after the photoreaction on Pt-$SrTiO_3$(Cr–Ta-doped). O_2 evolution was not detected. This catalyst had a broad absorption band in the visible light region and the absorption edge extended to more than 700 nm. H_2 evolution was observed under visible light even through a 500 nm cutoff filter. The catalyst itself was stable after a long reaction time, and the activity of the used catalyst was recovered by replacing the reaction solution with a new NaI aqueous solution. The H_2 formation was significantly suppressed (< 0.1 μmol h^{-1}) when a small amount of $NaIO_3$ (0.1 mmol l^{-1}) was added to the initial NaI reaction solution (100 mmol l^{-1}). Therefore, it is speculated that the decrease in

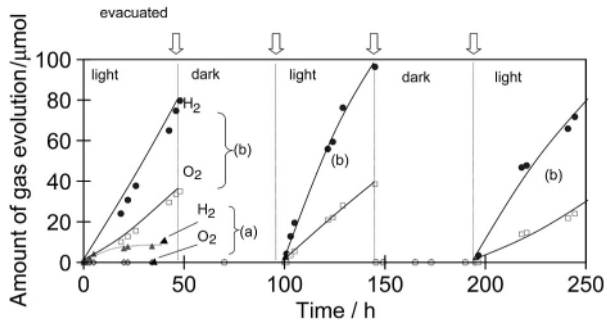

Fig. 1 Reaction time course of the photocatalytic splitting of water into H_2 and O_2 under visible light (λ > 420 nm, 3.1 W, window area: 16 cm^2). (a) 0.2 g of Pt(0.3 wt%)-$SrTiO_3$ doped with Cr and Ta (both 1 mol% of Ti) was suspended in the NaI aqueous reaction solution (100 mmol l^{-1}, 250 ml, pH = 7.0). (b) Both 0.2 g of Pt(0.3 wt%)-$SrTiO_3$ doped with Cr and Ta (both 1 mol% of Ti) and 0.2 g of Pt(1 wt%)-WO_3 were suspended in the NaI aqueous reaction solution (100 mmol l^{-1}, 250 ml, pH = 7.0). The magnetic stirring was continued during the light irradiation and in the dark.

 DOI: 10.1039/b107673f

H_2 evolution rate was caused by the accumulation of IO_3^-. By analogy with the mixed system of Pt-TiO_2(anatase) and TiO_2(rutile) described in reference 3, we added TiO_2(rutile) powder as an O_2 evolution photocatalyst into the Pt-$SrTiO_3$(Cr–Ta-doped) suspension in NaI aqueous solution. TiO_2(rutile) had the ability to reduce IO_3^- to I^-, resulting in O_2 evolution. After TiO_2(rutile) addition it was found that both H_2 and O_2 gases were evolved (H_2: 3.1 μmol h^{-1}, O_2: 1.5 μmol h^{-1}) under UV irradiation for a long time.

Next, in order to utilize visible light for photocatalytic O_2 evolution, we investigated various kinds of narrow bandgap semiconductor photocatalysts (WO_3, In_2O_3, Bi_2O_3, Fe_2O_3, $BiVO_4$, $CuWO_4$, $NiWO_4$, $SrWO_4$ *etc*.) instead of TiO_2(rutile), using the IO_3^- ion as an electron acceptor. It was found that the Pt-loaded WO_3 catalyst showed the best activity for O_2 evolution under visible light irradiation in $NaIO_3$ aqueous solution. No H_2 gas evolution was observed. The initial O_2 evolution rate was very high (84 μmol h^{-1}), and the rate decreased gradually with decreasing levels of the IO_3^- ion and with increasing I^- ions. More than 96% of the IO_3^- ions were reduced to I^-, accompanied by O_2 evolution, after a reaction time of 70 h. The O_2 evolution continued until most of the IO_3^- ions were consumed even if an excess of I^- was present in the solution during the reaction. Therefore, it is considered that the undesirable backward reaction, oxidation of I^- to IO_3^- by holes in the valence band, was very slow on this catalyst under these reaction conditions compared to the oxidation of water to O_2. The band gap of the WO_3 was *ca*. 2.7 eV, and the catalyst absorbed visible light up to 460 nm. O_2 gas was evolved under visible light even through a 440 nm cutoff filter but was negligible through a 460 nm cutoff filter, suggesting that the dependence of the activity on the wavelength of the incident light was in accord with the absorption spectrum.

Finally, we added the Pt-WO_3 photocatalyst into the Pt-$SrTiO_3$(Cr–Ta-doped) suspension in NaI aqueous solution. It was found that both H_2 and O_2 gases evolved under visible light, as shown in Fig. 1(b). The stoichiometric ratio of evolved H_2 and O_2 (2 : 1) was constant from the start of irradiation to more than 250 h. For the mixed catalysts, the H_2 evolution rate over Pt-$SrTiO_3$(Cr–Ta-doped) (1.8 μmol h^{-1}) was higher than that over Pt-$SrTiO_3$(Cr–Ta-doped) alone (0.8 μmol h^{-1}), suggesting that the added Pt-WO_3 effectively eliminated the IO_3^- ion from the solution by reduction to I^-. Both H_2 and O_2 gases were evolved using a 440 nm cutoff filter, but only H_2 evolution was observed using a 460 nm cutoff filter because the Pt-WO_3 catalyst could not work at $\lambda > 460$ nm. The concentration of introduced I^- ion (100 mmol l^{-1}) did not change, and formation of the IO_3^- ion was negligible during the reaction. For the first time, stoichiometric water splitting has taken place over oxide semiconductor photocatalysts under visible light irradiation, and the presence of three components, Pt-$SrTiO_3$(Cr–Ta-doped), Pt-WO_3 and NaI, was essential. The rates of H_2 and O_2 evolution under monochromatic light through a bandpass filter (420.7 nm, 57 mW) were 0.21 and 0.11 μmol h^{-1}, respectively. Therefore, the quantum efficiency was estimated to be *ca*. 0.1% at 420.7 nm.

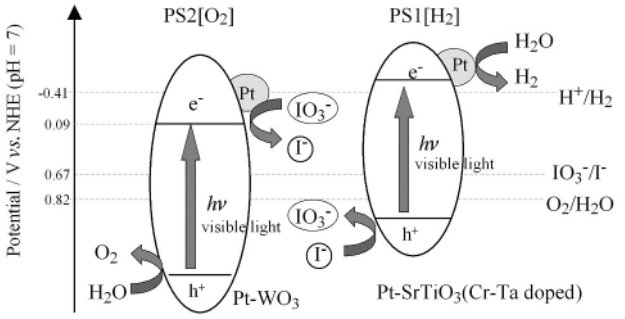

Fig. 2 Speculated reaction mechanism for the water splitting using a mixture of Pt-$SrTiO_3$, Pt-WO_3 and NaI aqueous solution.

Fig. 2 shows the speculated reaction mechanism. By analogy with the Pt-TiO_2–NaI system described in reference 3, it is considered that the IO_3^-/I^- redox pair may act as an electron carrier between two photocatalysts because it has an appropriate redox potential (0.67 V (*vs*. NHE, pH = 7)). The conduction band potential of WO_3 is +0.09 V (*vs*. NHE, pH = 7),[7] and the redox potential of H^+/H_2 is −0.41 V (*vs*. NHE, pH = 7). Therefore, the electron in the conduction band of WO_3 has the ability to reduce IO_3^- to I^-, but it cannot reduce H^+ to H_2. Though the I_3^-/I^- redox pair also seemed to be suitable as an electron carrier from its redox potential, it did not contribute to this reaction because any gas evolution on Pt-WO_3 or on Pt-$SrTiO_3$(Cr–Ta-doped) did not take place in I_3^- aqueous solution. The details of the band structure of Pt-$SrTiO_3$(Cr–Ta-doped) and the reaction mechanism are under investigation by means of photoelectrochemical measurement.

A low cost route to hexagonal mesostructured carbon molecular sieves

Seong-Su Kim and Thomas J. Pinnavaia*

Department of Chemistry and Center for Fundamental Materials Research, Michigan State University, East Lansing, MI 48824, USA. E-mail: pinnavai@cem.msu.edu

Received (in Columbia, MO, USA) 30th July 2001, Accepted 2nd October 2001
First published as an Advance Article on the web 29th October 2001

A mesoporous carbon molecular sieve with a hexagonal framework structure (denoted C-MSU-H) has been prepared using a MSU-H silica template that can be assembled from a low cost soluble silicate precursor at near-neutral pH conditions.

Porous carbons with high surface areas, large pore volumes, and chemical inertness are useful in many materials application areas, including water and air purification, adsorption, catalysis, and energy storage.[1,2] It has been recently demonstrated that a new class of carbon molecular sieves can be prepared through the use of mesostructured silica[3] as a host to template the carbon structure. The subsequent removal of the silica host by dissolution methods allowed the carbon replica to be recovered intact. A number of carbons with hexagonal,[4] cubic,[5] wormhole[6] and foam-like[7] framework mesostructures have now been reported. Zeolites also have been used to form microstructured carbon replicas.[8] Among these templated carbons, the CMK-3 materials[4] templated in the mesopores of hexagonal SBA-15 silicas[9] are especially attractive for catalytic and adsorption applications, in part, because they possess very large mesopores, thick framework walls and an interconnected channel structure. Although SBA-15 can be assembled using readily available and biodegradable tri-block copolymers of propylene oxide and ethylene oxide as the structure director, the structure is formed under strongly acidic conditions from cost intensive silicon alkoxides as the silica precursor. Since the silica mesostructure is destroyed in the preparation of a templated carbon, it is desirable to develop more efficient synthetic routes to the mesostructured silica templates.

In an effort to replace the silicon alkoxides with low-cost sodium silicate for the synthesis of SBA-15, we recently achieved the high-yield synthesis of highly ordered mesoporous silica molecular sieves (denoted MSU-H) with large framework mesopores (7.6–11.9 nm) under near neutral pH conditions using sodium silicate as the silica precursor.[10] MSU-H mesostructures are isostructural with SBA-15, although the fundamental particle size of MSU-H (300–500 nm) is somewhat small in comparison to SBA-15 (>1.0 μm). Also, we have shown that the framework pore size, intraparticle textural porosity, and interconnected channel size of MSU-H silicas can be tailored by a favorable choice of the initial synthesis temperature and post-synthesis hydrothermal treatment methods.[11]

In the present work we demonstrate the preparation of a mesostructured carbon molecular sieve (denoted C-MSU-H) using MSU-H silica as the nanoscale template. For comparison purposes, we compare the textural properties of the C-MSU-H carbon with those of CMK-3 templated by SBA-15.

MSU-H and SBA-15 silicas were synthesized as reported previously.[9,10] MSU-H was prepared at 60 °C from Pluronic P123 surfactant and sodium silicate (27% SiO_2, 14% NaOH) using a reaction stoichiometry of 1 SiO_2:0.016 P123:0.8 CH_3COOH:0.76 NaOH:230 H_2O and a reaction time of 20 h. SBA-15 was assembled under acidic conditions and a reaction stoichiometry of 1.00 TEOS:0.017 P123:6.0 HCl:195 H_2O. The mixture was allowed to react at 35 °C for 20 h, then at 100 °C for 24 h. The surfactants were removed from the as-made MSU-H and SBA-15 mesostructures by calcination at 600 °C for 4 h and 500 °C for 6 h, respectively. Carbon replication of the MSU-H mesostructure was performed at 900 °C using sucrose in the presence of sulfuric acid as the carbon source, as described by Ryoo and coworkers.[4,5b] The carbon/silica composites were washed twice with 5 wt% hydrofluoric acid at room temperature to remove the silica templates. Elemental analysis of C-MSU-H and CMK-3 gave C/H molar ratio of 7.9 and 6.8, respectively.

Fig. 1 illustrates the powder X-ray diffraction patterns of calcined MSU-H and SBA-15 silicas and the corresponding C-MSU-H and CMK-3 carbon replicas. The calcined MSU-H and SBA-15 silicas exhibited resolved *hkl* reflections consistent with two-dimensional hexagonal symmetry and unit cell dimensions of 122 and 116 Å, respectively. The C-MSU-H and CMK-3 carbons also exhibited hexagonal structural order and unit cell dimensions of 109 and 100 Å, respectively. Interestingly, the structural shrinkage experienced in the replication of a mesostructured silica into a mesostructured carbon is somewhat smaller for the MSU-H system ($\sim$10% shrinkage) than for the SBA-15 system ($\sim$13% shrinkage).

Fig. 2 illustrates the N_2 adsorption–desorption isotherms and BJH pore size distribution plots (insert) determined from the adsorption branch of the N_2 isotherms for the calcined silicas and carbon replicas. The values of the BET surface area, total pore volume, pore diameter, and wall thickness are listed in Table 1. The adsorption–desorption isotherm for the C-MSU-H carbon is similar to that of CMK-3 carbon. The pore volume is 1.26 $cm^3\ g^{-1}$ and the BET surface area is 1228 $m^2\ g^{-1}$ for the C-MSU-H carbon. The values are a little higher than a pore volume of 1.10 $cm^3\ g^{-1}$ and a BET surface area of 1190 $m^2\ g^{-1}$ for CMK-3 using SBA-15. The pore size distribution obtained for the C-MSU-H carbon from N_2 adsorption is compared with that for CMK-3. The result indicates that the C-MSU-H is mesoporous with a quite narrow pore size distribution centered at 39 Å, while the distribution for CMK-3 is centered at 35 Å.

Thermogravimetric weight changes were recorded to determine the thermal stability and phase purity of the mesostructured carbons in air. As can be seen in Fig. 3, the C-MSU-H and CMK-3 carbons exhibited nearly identical weight change

 DOI: 10.1039/b107896h

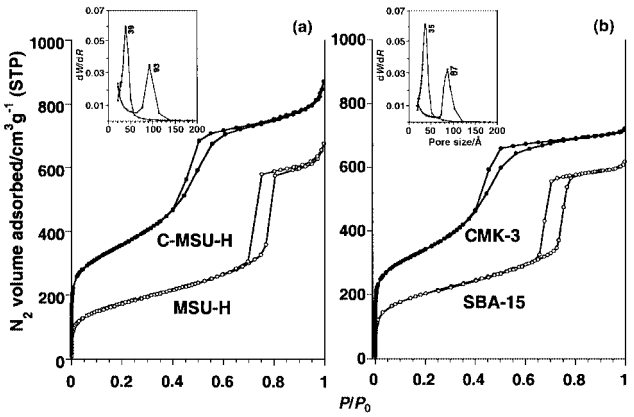

Fig. 2 N_2 adsorption–desorption isotherms for (a) MSU-H silica and C-MSU-H carbon replica and (b) SBA-15 silica and CMK-3 carbon replica. The insert provides the BJH pore size distribution calculated from the adsorption branch of the N_2 isotherm.

Table 1 Structural properties of MSU-H and SBA-15 silica templates and the corresponding mesostructured C-MSU-H and CMK-3 carbon replicas

Sample	*d* Spacing/ nm	Pore size[a]/ nm	Wall thickness[b]/ nm	S_{BET}/m^2 g^{-1}	Total pore volume/ cm^3 g^{-1}
MSU-H	10.6	9.3	2.9	625	0.97
SAB-15	10.0	8.7	2.8	718	0.93
C-MSU-H	9.5	3.9	7.1	1228	1.26
CMK-3	8.7	3.5	6.5	1190	1.10

[a] Calculated from the adsorption branch of the N_2 isotherm. [b] Determined from the difference between the unit cell parameter ($a_0 = 2d_{100}/\sqrt{3}$) and the framework pore size.

profiles. A significant loss in weight loss corresponding to the oxidation of the carbon occurred in a narrow temperature range between 550 and 650 °C. Thus, the oxidation temperatures for these carbons are significantly higher than the reported burning temperature of C_{60} (425 °C), but lower than those of multiwalled carbon nanotubes (700 °C) and highly graphitized carbon fibers (up to 800 °C).[12]

In summary, a new route to templated carbon molecular sieves (C-MSU-H) has been developed using MSU-H silica as the template without compromising the textural properties of the carbon replica. Thus, C-MSU-H carbons should be considerably more cost-efficient to prepare on an industrial scale in comparison to CMK-3 carbons, because the silica template is easily assembled from readily available sodium silicate.

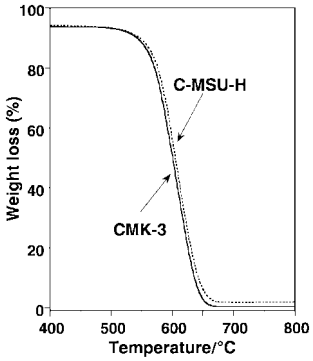

Fig. 3 Thermogravimetric curves for the calcination of C-MSU-H and CMK-3 carbons in air. The heating rate was 5.0 °C min^{-1}.

Tuning the recovery of an Rh-containing catalyst with silica-based (poly) amine ion exchangers

Jurjen Kramer, Ana Ríos García, Willem L. Driessen* and Jan Reedijk

Leiden Institute of Chemistry, Leiden University, P.O. Box 9502 2300 RA. Leiden, The Netherlands. E-mail: driessen@chem.leidenuniv.nl

First published as an Advance Article on the web 29th October 2001

Highly efficient Rh-recovery from different adsorption media has been effected with silica-based (chelating) ion exchangers containing (poly) amine functionalities; recoveries have been found to correlate well with the stability of the metal-to-ligand complexes.

Rh-containing homogeneous catalysts play an important role in the improvement of many important industrial processes, such as hydroformylation and hydrogenation reactions.[1] As these catalysts are widely used and since Rh is a very scarce element, the efficient separation of the used metal-containing catalyst from product streams is of paramount importance. However, the complete recovery of the often very low concentration of catalyst is a difficult task. A highly efficient technique for the recovery of low concentrations of metal ions is ion exchange, due to the ease of separation of the adsorbed metal ions from the product stream. Earlier findings indicated that silica is a very suitable backbone, due to its high chemical and thermodynamical stability and fast recovery kinetics.[2]

One of the difficulties is to find optimal binding. This means, the ligands′ binding capacity should be sufficiently strong. On the other hand, if the coordination is too strong, the desorption becomes very difficult, as previous studies on the recovery of two Rh-containing model catalyst with ion exchangers that possessed ligands with both N and S donor atoms already pointed out.[3]

Amine ligands are known to coordinate well to platinum group metals and a number of studies have focussed on their application, mainly as anionic extractants for hydrometallurgical purposes.[4,5] The efficient recovery of Rh almost always proved to be the bottleneck, though. The Rh extraction is complicated due to its chemical behaviour in chloride media, and desorption of the loaded ion exchangers is often incomplete or only possible under very harsh elution conditions.[6,7]

This communication describes our first investigations on the tuning of the recovery of $RhCl_3$, which is both used as a catalyst precursor and as a real catalyst,[8–11] with silica-based ion exchangers containing (poly) amine functionalities.

The ion exchangers used for this investigation contain a monoamine (**1**), ethylenediamine (**2**), diethylenetriamine (**3**)[12] and propylenediamine (**4**) functionalities (Table 1).†

In order to gain insight into the stability of the binding of the different ligands with the Rh metal-ions, distribution coefficients have been measured at different pH values (Fig. 1).[3] Clearly, the log *D* values of ion exchangers **1** and **4** are much lower than of **2** and **3**. The stability of Rh-complexes with the latter two ion exchangers proved to be some 3–10 times higher over the entire tested pH range (Fig. 1).

An explanation for the observed behaviour lies in the ability of **2** and **3** to form highly stable chelate rings with Rh, whereas **1** can only coordinate in a monodentate fashion. Another striking feature is the observed log *D* difference between **2** and **4**. The experiment clearly demonstrates, that the complex formation of ligands that contain five-membered chelate rings with Rh metal-ions is favoured over those forming six-membered rings. This is in agreement with previous findings on metal ion selectivity, that already indicated the preference of relatively large metal ions to coordinate with chelating ligands *via* five-membered rings whereas relatively small transition metals prefer larger, six-membered rings.[13]

At low pH (< 2), the amines are protonated[14] and binding will probably proceed *via* an ion association way, with positively charged amine ligands binding in an ionic fashion to a negatively charged Rh complex of the type $[RhCl_{6-n}(H_2O)_n]^{(3-n)-}$ (with *n* generally 0–2).[6] The somewhat lower log *D* values at pH 1–2, are caused by the presence of Cl^- ions from the HCl/NaCl buffers which compete with the metal ions for binding to the ion exchangers. At higher pH, HOAc/NaOAc buffers have been used, and these coordinate less strongly to the Rh metal-ions. Still, the acetate ions, present in increasing amounts with increasing pH, also compete when the ligand to metal complexes are weaker (Fig. 1, **1** and **4**).

For the recovery of Rh, ion exchangers **1**–**4** were added to a fresh solution of $RhCl_3{\cdot}3H_2O$‡ in water, 1 M HCl or EtOH (absolute), to study the effect of the adsorption medium on the stripping possibility. The desorption was done in 2 M HNO_3, as it proved to be the most effective stripping agent. The results are depicted in Fig. 2. Since the ligand concentrations vary significantly between the different ion exchangers (see Table 1) it is more correct to not only look at the uptake capacity (*C*, mmol g^{-1}) but to compare the ligand occupation (*L*, %) as well. This value is defined in the following way: *L* (%) = [uptake capacity (*C*) for M^{n+} (mmol g^{-1})]/[ligand concentration (mmol/g silica)].

The maximum ligand capacities have been found to increase with increasing ligand concentration. A maximum of over 0.5 mmol g^{-1} ion exchanger could be extracted (> 50 mg Rh/g ion exchanger). The extraction percentage is clearly very dependent on the adsorption medium; the Rh adsorption in water and ethanol proved to be much more efficient (about 40–70%) than

Table 1 Ion exchanger characteristics

Ion exchanger	Grafted group	Ligand conc./ mmol g^{-1}[a]
1	$-(CH_2)_3NH_2$	1.14
2	$-(CH_2)_3NHCH_2CH_2NH_2$	1.02
3	$-(CH_2)_3NH(CH_2CH_2NH)_2H$	0.63
4	$-(CH_2)_3NH_2CH_2CH_2CH_2NH_2$	0.68

[a] Based on the N content.

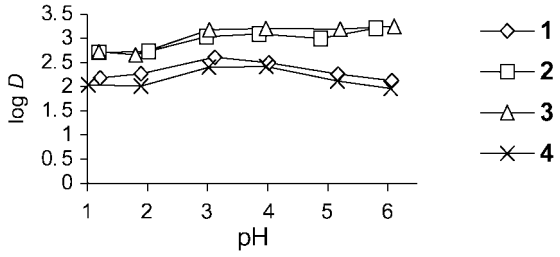

Fig. 1 The distribution coefficients for Rh^{3+} uptake using ion exchangers **1**–**4**. *D* = (mmol M^{n+}/g of dry ion exchanger)/(mmol M^{n+}/ml of solution). The ligand to metal ratio is 5 : 1.

 DOI: 10.1039/b108457g

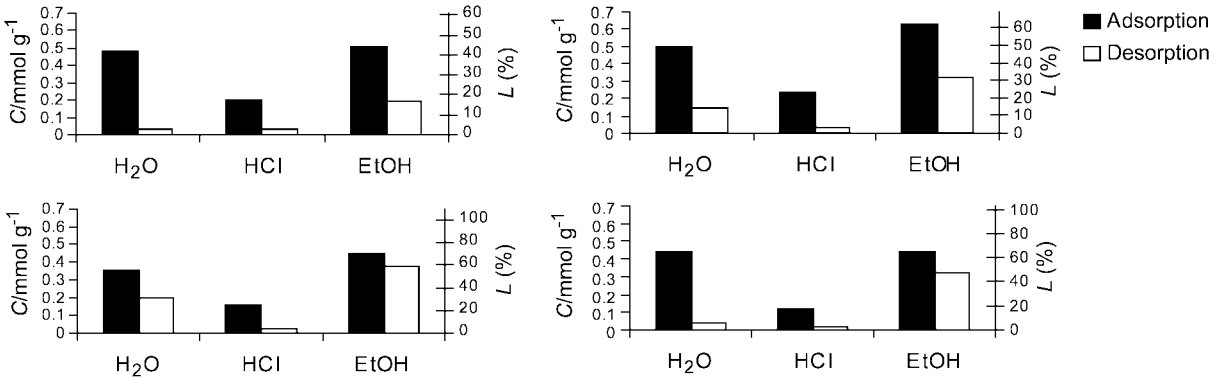

Fig. 2 Recovery experiments of Rh^{3+}-loaded ion exchangers **1** (top left), **2** (top right), **3** (bottom left) and **4** (bottom right).§ Black bars indicate the loaded ion exchangers after adsorption of Rh^{3+} in H_2O, 1 M HCl or absolute EtOH for 48 h. White bars indicate the amount of Rh^{3+} left on the ion exchanger after desorption in 2 M HNO_3 for 48 h. *Reagents and conditions*: adsorption: $RhCl_3{\cdot}3H_2O$ (an amount, corresponding to a ligand to metal ratio of 1 : 1) in 50 ml of solvent (H_2O, 1 M HCl or absolute EtOH), 200 mg ion exchanger, agitation for 2 days. Desorption: 100 mg loaded ion exchanger, 50 ml 2 M HNO_3, agitation for 2 days.

in 1 M HCl (maximum 25%). The difference can be explained by a different extraction mechanism under the adsorption conditions, as discussed above. The large amounts of chloride ions strongly compete with the metal ions for the positively charged binding sites. The possible coordination of more than one ligand to a single Rh metal-ion might be an explanation for the inability of any of the ion exchangers to attain a 100% ligand occupancy.

The desorption possibility (Fig. 2, right bars), after Rh adsorption in water, increased in the following way: **3** ≪ **2** ≪ **4** = **1**

The stripping percentages range from 45% when the diethylenetriamine ion exchanger **3** is used to >90% for the monoamine ion exchanger **1**. Evidently, the formation of five-membered chelate rings has a strongly negative effect on the desorption. This effect already becomes clear with ethylenediamine but is more strongly displayed when multiple chelate rings are formed. Apparently, the six-membered chelate rings, that ion exchanger **4** forms with the metal ions, are stable enough for good adsorption (64%), but not too stable, to prevent easy desorption.

These desorption differences are absent when the adsorption was performed in 1 M HCl, demonstrating the absence of binding in a chelate fashion under these conditions. Although the adsorptions were much lower, a good desorption was obtained with all the ion exchangers (>80%).

The desorption, after adsorption in ethanol, proved to be very difficult for all the ion exchangers used. This has most probably to do with partial reduction of the Rh metal ions in this solvent, as reported by Hernan *et al.*[15] and Kriek *et al.*[16]

In conclusion, it is shown that very efficient recovery of Rh^{3+} has been achieved with amine-containing ion exchangers that form complexes with log *D* values lying roughly between 2.0 and 2.5. Both the ligand capacity and the elution percentage of the metal ion have proven to be very dependent on the adsorption conditions.

The work is currently being extended to the possible application in a continuous system. This implies that important factors such as adsorption and desorption kinetics, successive recovery and the use of other Rh-containing catalysts will be investigated.

Financial support comes from the IOP (Innovation Oriented Research Programme, The Netherlands) Environmental Technology/Heavy Metals cluster Separation, project number IZW97411. Dr W. Buijs (DSM-Research) is acknowledged for stimulating discussions. Mr J. J. M. van Brussel is thanked for his technical assistance.

Notes and references

† A mixture of 3-chloropropyltrimethoxysilane (83 mmol) and 1,3-diaminopropane (250 mmol) was heated under argon at 150 °C for 6 h. After cooling, the white solid phase was filtered off and the liquid phase was purified by vacuum distillation (bp 112–114 °C/1 mm Hg). Yield 5.18 g (22%).^{1}H NMR (300 MHz, $CDCl_3$): δ 0.61 (t, 2H, $SiCH_2$) 1.00 (br s, 2H, NH_2), 1.21 (t, 9H, OCH_2CH_3), 1.55–1.65 (m, 4H, $SiCH_2CH_2$, $NHCH_2CH_2CH_2NH_2$), 2.59–2.64 (2 × t, 4H, CH_2NHCH_2), 2.74 (t, 2H, CH_2NH_2), 3.80 (q, 6H, OCH_2CH_3). Subsequent immobilisation was performed similarly to ion exchangers **1**–**3**.[12]

‡ As $RhCl_3$ shows extensive aquation (the formation of kinetically rather inert aquochloro complexes) with time, freshly prepared $RhCl_3$-solutions (<10 min old) were always used. Furthermore, hardly any variation in the pH has been observed.

§ The determinations of the uptake capacities and desorption, are based upon the metal content on the ion exchangers, established by concentrated acid digestion as previously described.[3]

Received (in Cambridge, UK) 13th September 2001, Accepted 12th October 2001
First published as an Advance Article on the web 30th October 2001

The first use of silicon-29 diffusion-ordered NMR spectroscopy (DOSY) is reported, in a study of the speciation of aqueous silicates.

Aqueous silicate solutions are extensively used in industry, with applications in the preparation of detergents, adhesives and coatings. The diversity of silicate chemistry familiar from the solid phase extends also to solution, with alkaline solutions of silica forming a wide range of species from the silicate monomer through small oligomers up to colloids.[1] Silicon-29 NMR is a useful tool in the study of such species,[2–6] although the modest (negative) magnetogyric ratio, low natural abundance (4.7%) and long spin–lattice relaxation times of this spin-1/2 nucleus pose some experimental obstacles. At natural abundance of ^{29}Si, there are difficulties also in attempting to link together different signals for the same species. The dependence of the rate of self-diffusion on molecular size, shape and solvation makes high-resolution diffusion-ordered NMR spectroscopy (DOSY),[7–9] in which pulsed field gradient spin–echo experiments are used to construct a two-dimensional plot of signal strength as a function of chemical shift and of diffusion coefficient, a natural candidate as a method of studying silicate speciation.

Experiments were carried out at room temperature (21 °C) and 99.34 MHz using a 5 mm broadband probe (Nalorac Corporation) equipped with a 0.6 T m^{-1} actively shielded gradient coil in a 500 MHz Varian Unity spectrometer. To enable field-frequency locking, solutions were made up in H_2O–D_2O mixtures; samples were stored in plastic vials to avoid contamination with ions leached from glassware. Spectra were measured using the bipolar pulse pair stimulated echo (BPPSTE) pulse sequence,[9] with a 90° pulse duration of 20 μs.

Fig. 1 shows the DOSY spectrum of a sample of 0.5 mol kg^{-1} ^{29}Si enriched silicate in 1 mol kg^{-1} aqueous (90% H_2O/10% D_2O) tetramethylammonium hydroxide (TMAOH), prepared by dissolving enriched silica ($^{29}SiO_2$, 99.35%, Cambridge Isotope Laboratories, Inc.) in TMAOH (Aldrich) at 70 °C overnight. Two-parameter exponential fitting of peak height as a function of gradient strength squared was used to extract a diffusion coefficient D for each detected peak. The DOSY spectrum was then constructed by taking the NMR lineshape from the lowest gradient spectrum in the NMR (horizontal) dimension for each peak and giving it a Gaussian shape, with a width determined by the estimated standard error in D, centred on the fitted diffusion coefficient D in the diffusion (vertical) dimension.

The result is clear resolution of the four principal species found in this system, the monomeric silicate unit **1** (the Q^0 species, where the superscript indicates the number of siloxane bridges to a given silicon centre), the cyclic trimer **3** (Q^2), the prismatic hexamer **7** (Q^3) and the cubic octamer **8** (Q^3). As

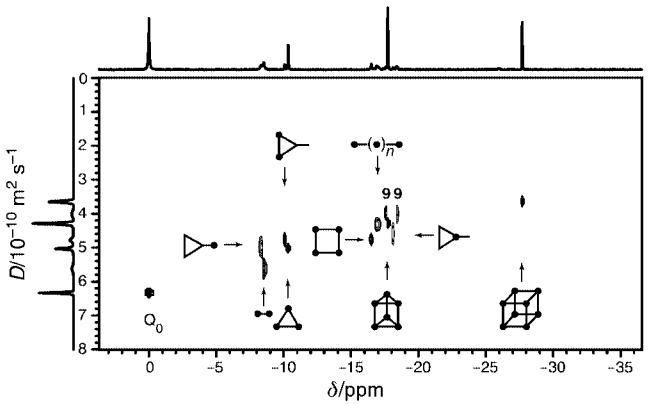

Fig. 1 99.34 MHz ^{29}Si DOSY spectrum of 0.5 mol kg^{-1} ^{29}Si-enriched silicate in 1 mol kg^{-1} aqueous tetramethylammonium hydroxide, measured as described in the text, with (top) the normal ^{29}Si spectrum and (side) the integral projection onto the diffusion axis. 10 BPPSTE spectra of 320 transients each were measured in a total time of 7 h, using gradient pulses of duration 1.5 ms and amplitude from 0.1 to 0.6 T m^{-1}, and a diffusion time Δ of 0.5 s. Chemical shifts are referenced to the Q^0 signal at 0 ppm.

expected, the diffusion coefficients decrease as the number of silicate units in the species increases, with the cubic octamer having the slowest diffusion of these species. Magnetic equivalence causes each of the species to display a single line, making their signals the most prominent in the spectrum. The dimer **2** and cyclic tetramer **6** are also seen, at lower concentration, as are signals from several species displaying multiplet structure due to scalar (Si,Si) coupling. Here the ability of the DOSY technique to identify signals from the same species is apparent, all three signals from species **5** appearing, as expected, at similar positions in the diffusion domain. Similarly, the two signals marked '9' in Fig. 1 appear at the same diffusion coefficient, and at the chemical shifts tentatively assigned in ref. 5 to the pentacyclic heptamer **9** (though the Q^2 signal cannot be identified). One limitation of the technique is illustrated by the remaining peak, from the inner silicate units of linear oligomers **4**, where a number of signals from different species coincide in the NMR dimension and hence show an averaged diffusion coefficient (the terminal silicate signals of the linear oligomers are obscured by the terminal silicate signal of **5**).

 DOI: 10.1039/b108325m

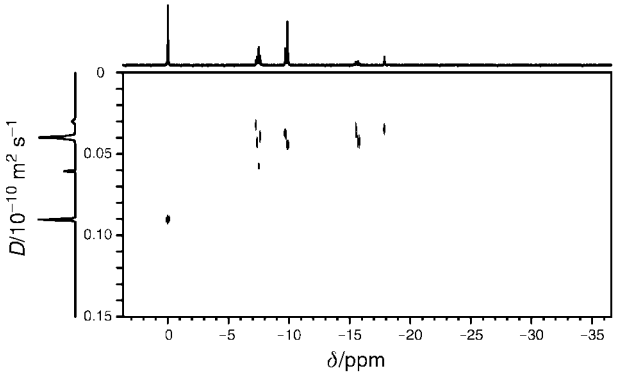

Fig. 2 99.34 MHz ^{29}Si DOSY spectrum of 13 mol kg^{-1} natural abundance silicate in 13 mol kg^{-1} aqueous NaOH. 10 BPPSTE spectra of 480 transients each were measured in a total time of 10 h, using gradient pulses of duration 5.8 ms and amplitude from 0.1 to 0.6 T m^{-1}, and a diffusion time Δ of 1.3 s.

Fig. 2 shows the DOSY spectrum at natural abundance of a sample containing 13 mol kg^{-1} silicate (34% SiO_2 by weight) and 13 mol kg^{-1} NaOH (Aldrich) in HDO, again prepared by dissolution of silica (produced by hydrolysis of silicon tetrachloride (99.8% purity; Janssen Chemical Co.) using doubly distilled water) in alkaline solution at 70 °C overnight. Here, once again, well-resolved signals are seen, but without multiplet structure, and at diffusion coefficients almost two orders of magnitude lower. The spectrum is dominated by low coordination species (Q^0, Q^1 and Q^2), and signal intensities are broadly consistent with the known silica content, suggesting that most if not all of the silicate species are NMR visible. The chemical shifts and DOSY correlations are consistent with a mixture of species **1**, **2**, **3**, **4** and **5**; such assignments could be tested by homonuclear correlation on an enriched sample. The sharp lines suggest short rotational correlation times, whereas such slow diffusion is normally associated with large (colloidal) particles. In practice Stokes' law, which represents the solution as a continuous medium and from which size estimates are generally derived *via* the Stokes–Einstein relation, is not applicable to such concentrated solutions of strongly interacting particles, in which obstruction effects outweigh viscous drag. The unrealistic radii which this relation produces for species in concentrated sodium silicate solutions have been noted previously.[6]

^{29}Si DOSY is potentially a highly effective tool for studying speciation in silicate solutions, where sensitivity permits, allowing the separation of signals of different species and the estimation of their relative sizes. The principal limitations of the technique are the difficulty of extracting useful diffusion data for strongly overlapping NMR signals, the limited receptivity of the ^{29}Si nucleus, and the complications (line broadening, diffusional averaging) caused by chemical exchange. As comparison between Figs. 1 and 2 shows, a wide range of different sizes of aggregate is accessible to study.

Reversible encapsulation of multiple, neutral guests in hexameric resorcinarene hosts

Alexander Shivanyuk and Julius Rebek, Jr*

Received (in Columbia, MO, USA) 6th August 2001, Accepted 2nd October 2001
First published as an Advance Article on the web 8th November 2001

A variety of aromatic guest molecules are co-encapsulated with Bu_4SbBr in an assembly of six resorcinarene subunits.

Resorcinarenes are known to form huge, hexameric hydrogen bonded capsules in the crystalline state.[1] The hexamer of **1a** reported by MacGillivray and Atwood[1a] resembles a cube with six resorcinarenes as its sides and eight water molecules at its 'corners' (Fig. 1). Through NMR studies in water-saturated $CDCl_3$, we recently showed that six molecules of **1b** assemble to encapsulate appropriately sized tetraalkylammonium or phosphonium salts.[2] Here we report that covalent antimony(v) bromides **2**[3] also induce capsule formation and leave enough room inside to reversibly co-encapsulate various aromatic guests.

The ^{1}H NMR spectrum of resorcinarene **1b** in *water-saturated* $CDCl_3$ is shown in Fig. 2A. The expected sets of signals for the protons of resorcinol rings, methine bridges, hydroxy groups and water (at 3.0 ppm) are present.[4] Addition of Bu_4SbBr results in the formation of a complex having high kinetic stability (Fig. 2B): separate signals for bound and free guest are present and the exchange rates are slow on the NMR timescale (600 MHz, 313 K). The large upfield shifts of the guest signals are the earmarks of encapsulation. Integration of the appropriate signals at different host–guest ratios clearly shows that one molecule of **2a** is complexed by six(!) molecules of **1b**. The broadened resonance of water is found at 3.0 ppm and indicates that it, too, is an integral component of the assembly.[5] A similar complex is formed between **1b** and the tetraphenyl derivative **2b**, but the less polar Bu_4Si and Bu_4Ge are not encapsulated within **1b**.

Reversible encapsulation in the liquid state occurs optimally when ~55% of the space in the host is occupied by guests.[6] One molecule of Bu_4SbBr (V = 314 Å^3) or Ph_4SbBr (V = 340 Å^3) leaves enough space in the cavity of **6**$\cdot$$8H_2O$ (V = 1375 Å^3) for occupancy by appropriate smaller guest molecules. This co-encapsulation was confirmed by NMR spectroscopy.

The addition of benzene to the complex resulted in splitting of the signals for the methylene protons of encapsulated Bu_4SbBr and the appearance of a broadened singlet at 5.9 ppm (Fig. 3A). The 1D-GOESY experiment established that the latter peak corresponds to the protons of encapsulated benzene molecules (Fig. 3B). The relatively small upfield shift of −1.2 ppm suggests that, on average, the benzene molecule(s) are situated at some distance from the magnetically anisotropic regions of the hexameric capsule.[7] At higher concentrations of benzene the protons of encapsulated Bu_4SbBr emerge as three sets of signals (Fig. 3C).[8] The set **c** appears at the expense of the set **b** and the original set **a**. Analogous behavior was observed on the addition of toluene and *p*-xylene. No encapsulation of benzene, toluene or *p*-xylene could be detected in absence of Bu_4SbBr; the principal guest determines the properties of the inner space of the capsule.

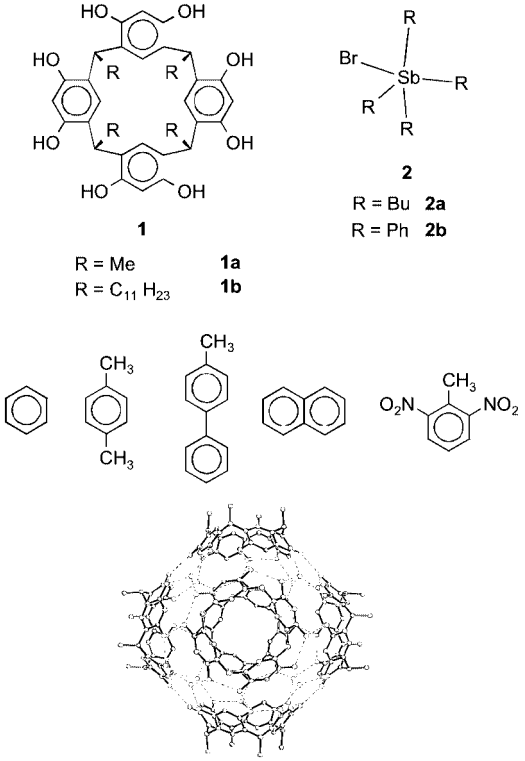

Fig. 1 Resorcinarenes, their guests and the crystal structure of the hexameric capsule **6**$\cdot$$8\ H_2O$.[1a]

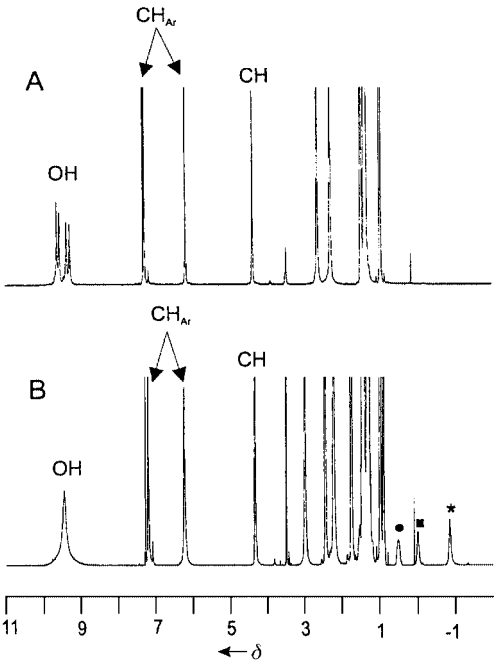

Fig. 2 The ^{1}H-NMR spectra in $CDCl_3$ saturated with H_2O (600 MHz, 313 K): A) **1b**; B) **1b** + Bu_4SbBr. The signals of encapsulated Bu_4SbBr are marked with an asterisk (methyl groups) and solid square and circle (methylene groups).

 DOI: 10.1039/b109464p

Addition of 4-phenyltoluene to the complex 6**1b**·Bu_4SbBr gives rise to an additional set of signals for the methylene groups of encapsulated Bu_4SbBr (Fig. 3D). Further addition of 4-phenyltoluene increases the new set of signals at the expense of the original set (Fig. 3E). Through 1D-GOESY-experiments it was shown that the singlet at −0.75 ppm corresponds to the methyl protons of encapsulated 4-phenyltoluene $\Delta\delta = -3.05$ ppm.

To probe the dimensions and the character of the remaining space in the Bu_4SbBr complex, a range of guests were added. Amongst those also encapsulated were ethylbenzene, *p*-xylene, propylbenzene, amylbenzene, nitrobenzene, 4-nitrotoluene, 2,6-dinitrotoluene, naphthalene, biphenyl, anthracene and azulene. Those not encapsulated include heptylbenzene, 1,4-dimethyl-2,6-dinitrobenzene, hexamethylbenzene, trans-stilbene, azobenzene, *p*-terphenyl. The longest guest co-encapsulated with Bu_4SbBr appears to be 4-phenyltoluene, since the slightly longer 4,4′-dimethylbiphenyl was not encapsulated under the same conditions. Hexafluorobenzene, cyclohexane and pentane were also not encapsulated suggesting that not only the size and shape of the aromatic guest but also its polarity and polarizability determines its co-inclusion with Bu_4SbBr.

Hexameric capsule encapsulating tetraphenylantimony bromide **2b** is also able to include benzene, toluene, *p*-xylene, however no encapsulation of *p*-phenyltoluene occurred. This difference in binding properties of 6 : 1 complexes of **2b** and **2a** is caused most probably by a larger volume of **2b** which does not leave enough space for the co-encapsulation of *p*-phenyltoluene.

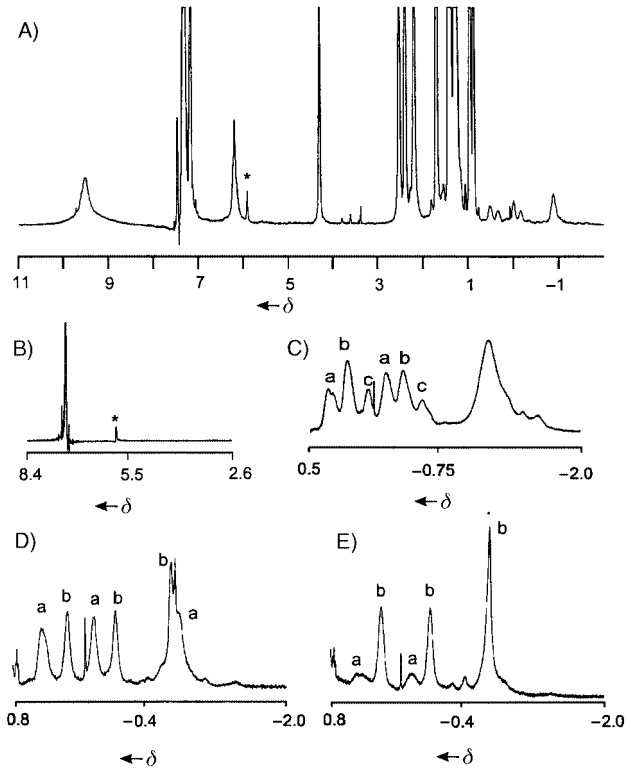

Fig. 3 (A) The ^{1}H-NMR spectrum of **1b** + Bu_4SbBr + 60 equiv. benzene; (B) 1D-GOESY spectrum with saturation of the benzene signal; the signal of encapsulated benzene is indicated by an asterisk. (C) Up-field window of the spectrum in the presence of 20% of benzene-d_6. (D) **1b** + Bu_4SbBr + 13 equiv. 4-phenyltoluene; (E) **1b** + Bu_4SbBr + 42 equiv. 4-phenyltoluene. The signal of the methyl protons of the encapsulated guest is marked by an asterisk.

The resorcinarenes hold a special place among modules for molecular recognition: their chemical modifications provided the first cavitands,[9] then carcerands[10] and hydrogen bonded capsules.[11] More than a decade ago Aoyama and co-workers[12] described the formation of *stoichiometric* (1 : 1) complexes of **1b** (Fig. 1) with dicarboxylic acids, sugars and even steroids in $CDCl_3$ solution. We now see that the resorcinarene **1b** is capable of hexameric assembly and encapsulates sizable molecules, independent of their hydrogen bonding abilities but dependent on the presence of water. The principal guest **2** fine tunes the binding properties of the hexameric cavity, and is essential for further encapsulation of smaller, aromatic guests.

We are grateful to the Skaggs Research Foundation and The National Institutes of Health for financial support. A. S. is a Skaggs Postdoctoral Fellow.

5 Carefully dried resorcinarene 1b is *insoluble* in $CDCl_3$ dried over molecular sieves, but heating the mixture gives a gel that dissolves immediately after addition of water. In $CDCl_3$ with a little water, resorcinarene **1b** shows a very broad and featureless spectrum characteristic of ill-defined hydrogen bonded aggregates. The addition of guests **2** to this solution results in very broad signals for the complexed species; these sharpen when water is added.

Received (in Cambridge, UK) 6th September 2001, Accepted 11th October 2001
First published as an Advance Article on the web 30th October 2001

The first unsymmetrically substituted polyfluorene bearing a bulky poly(benzyl ether) dendron and less bulky 3,6-dioxaoctyl groups in the 9-position was designed and synthesized, which gives almost a pure bluish photoluminescence with negligible weak greenish excimer emission around 520 nm even in a thermally annealed thin solid film.

Recently, π-conjugated polyfluorene (PF) has been attracting intensive interest due to its bluish photo/electro-luminescence properties with high quantum yield.[1] However, greenish excimer emission and significant fluorescence quenching generally occur for this blue light emitter in a solid film.[2] Among the methods to avoid the detrimental π-aggregation behavior,[3] much effort has been made to introduce bulky dendrons like poly(benzyl ether) (Fréchet-type) or polyphenylene into the conjugated polymer backbone, *i.e*., end-capping of poly[2,7-(9,9-di-*n*-hexyl)fluorene][4] and symmetrically 9,9-bis-substituting PFs.[5] The resulting PFs have been found to significantly suppress the excimer emission even in their thermally annealed solid films. In addition to these symmetrically 9,9-bis-substituted PFs, the unsymmetrically substituted PF having two different side groups in the 9-position has also attracted much attention.[6] As an example, a PF bearing two different methyl and 4-cyanobutyl groups in the 9-position was designed and synthesized towards water-soluble conjugated polymer.[6b] Based on the assumption that a regio-random PF bearing two different substituents in the 9-position may significantly suppress the π-aggregation in a solid film to decrease the greenish excimer emission and the combination of bulky dendrons with less bulky groups will increase the luminophore density, thereby producing a strong luminescence, we have designed and synthesized a new unsymmetrically substituted PF **4** (Scheme 1) bearing semiflexible bulky poly(benzyl ether) dendrons and linear 3,6-dioxaoctyl groups in the 9-position. We now report that **4** emits almost a pure blue color photoluminescence even in a thermally annealed thin solid film, while the greenish excimer emission was drastically suppressed even compared to the corresponding 9,9-bis-dendron-substituted **5**.

The synthetic procedures are outlined in Scheme 1. The resulting 2,7-dibromo-9-lithiofluorene from 2,7-dibromofluorene (**1**) (Aldrich) and 2-fold lithium diisopropylamide (LDA) (Aldrich) was reacted with an equivalent amount of 1-bromo-3,6-dioxaoctane (Lancaster) at −60 to 25 °C in THF, yielding 2,7-dibromo-9-(3,6-dioxaoctyl)fluorene (**2**).[7] Using the phase transfer catalyst, triethylbenzyl ammonium chloride (Kanto), the monomer **3** was synthesized from **2** and 3,5-bis[3,5-bis(benzyloxy)benzyloxy]benzyl bromide (**R-Br**) (TCI). The conversion was almost quantitative, which was evidenced by the complete disappearance of the triplet signal of 9-H at 4.10 ppm in the ^{1}H NMR spectrum. Polymerization was carried out using the zero-valent nickel reagent, bis(1,5-cyclooctadiene)-nickel(0) ($Ni(COD)_2$) (Kanto), and the end-termination was accomplished using 2-bromofluorene (Acros).[8] For a comparison of the photophysical properties with **4**, the two corresponding symmetrically 9,9-bis-substituted **5** and **6** were also synthesized using previouly reported method.[8] The structures of all the synthesized monomers and PFs were confirmed by NMR and elemental analysis.†

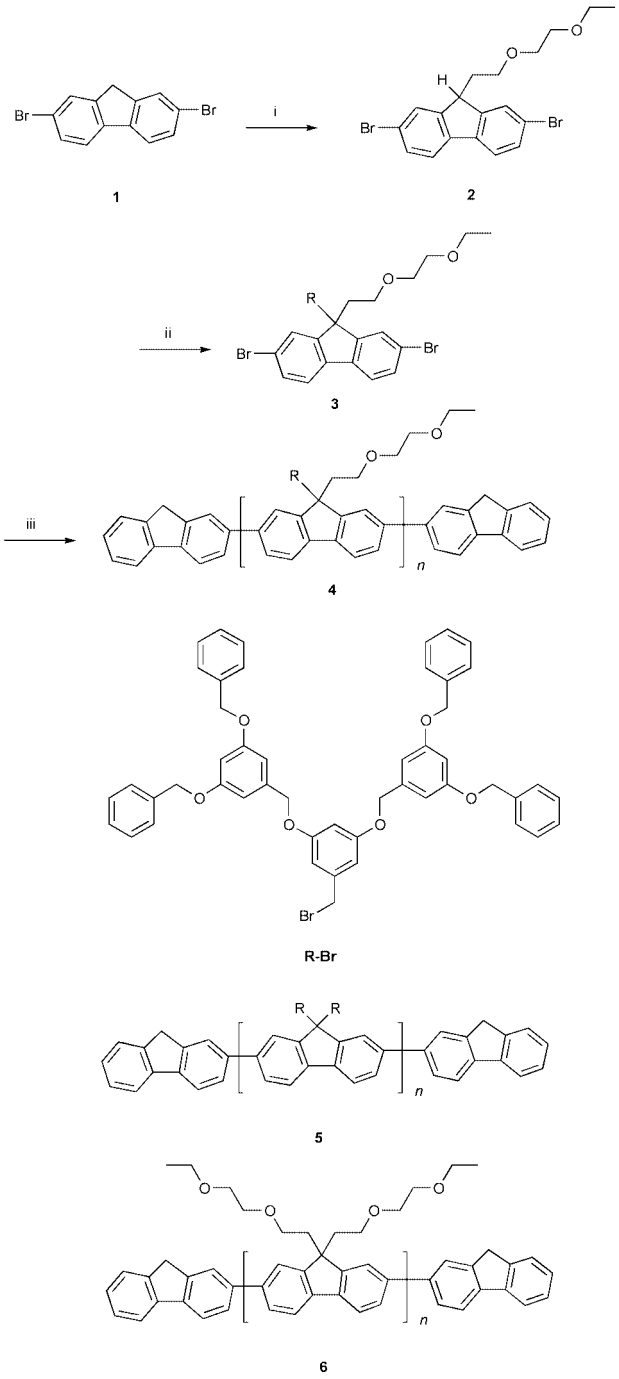
PF **4** as well as **5** is highly soluble in common organic solvents, *e.g*., THF, toluene and chloroform, but **6** has limited solubility in THF and toluene although it is readily soluble in chloroform. The molecular weights of **4**, **5** and **6** (soluble part in THF) estimated by gel permeation chromatography (GPC) *versus* the polystyrene standards in THF at 30 °C are M_w = 26,300 (M_w/M_n, 2.0), M_w = 32,700 (M_w/M_n, 1.7), and M_w = 381,300 (M_w/M_n, 2.6), respectively. Differential scanning calorimetry (DSC) (heating at 10 °C min^{-1} at the second run) revealed that **4** and **5** have softening points at around 58 °C and 62 °C, respectively, evidenced by the endothermic peaks, while **6** exhibits a melting point of 182 °C.

As shown in Fig. 1, the UV-vis spectrum of **4** in THF solution exhibits two absorption bands at 386.0 nm (ε = 3.1 × 10^4 (fluorene-repeating-unit)$^{-1}$ dm^3 cm^{-1}) and 284.0 nm (ε = 1.1 × 10^4 (fluorene-repeating-unit)$^{-1}$ dm^3 cm $^{-1}$), probably ascribed to the π–π* transition of the conjugated polymer backbone and the phenylene in the side dendrons, respectively. The $\lambda_{max,abs}$ of **4** exhibits only a slight red shift of 2 nm compared to that of **5** ($\lambda_{max,abs}$, 384.0 nm), implying that the number of bulky dendron side chains does not affect the torsion angle in the conjugated polymer backbone, but shows a large blue shift of 8.5 nm compared to that of **6** ($\lambda_{max,abs}$, 394.5 nm), probably due to the larger steric hindrance impacted by the bulky dendrons than the two less bulky 3,6-dioxaoctyl groups. The photoluminescence (PL) spectrum of **4** in THF solution exhibits the two characteristic sharp peaks at 415.0 and 437.0 nm and a low energy shoulder near 470.0 nm, almost identical to those of the corresponding **5** ($\lambda_{max,emi}$, 414.0 nm, excited at 384.0 nm) and **6** ($\lambda_{max,emi}$, 417.0 nm, excited at 394.5 nm). The quantum yield of **4** in THF is estimated to be 58%, comparable to 54% of **5** and 53% of **6**.†

Fig. 2 compares the UV-vis and PL spectra of **4**–**6** in the thermally annealed thin solid films. The UV-vis spectrum of **4** in the film exhibits no absorption band broadening except for the $\lambda_{max,abs}$ showing a minute red shift of 2.5 nm in comparison to that in THF solution. This is similar to **5** in the film and THF solution. On the other hand, **6** in the solid film gave a UV-vis spectrum with a significantly broadened absorption band and a new absorption peak around 399 nm compared to that in THF solution, indicating that a specific intensive aggregation formed. The PL spectrum of **4** in the film shows two characteristic $\lambda_{max,emi}$s at 423.0 and 447.5 nm and a tail in the range 500 to 700 nm. On the other hand, **5** gave a PL spectrum with a featureless long wavelength emission (excimer emission)

† Electronic supplementary information (ESI) available: characterization data for **2**, **3**, and **4**, and measurement details of the quantum yield in THF solution. See http://www.rsc.org/suppdata/cc/b1/b108097k/

 DOI: 10.1039/b108097k



Scheme 1 *Reagents and conditions*: i, 2-equimolar LDA, THF, 1-bromo-3,6-dioxaoctane, −60 to 25 °C, 3 h, 60%; ii, **R-Br**, 50% aq. NaOH, DMSO, triethylbenzyl ammonium chloride, 25 °C, overnight, ~100%; iii, $Ni(COD)_2$–1,1′-bipyridyl (1 : 1, mol/mol), COD, DMF–toluene (1 : 4, v/v), 80 °C, 4 d; 2-bromofluorene in toluene, 4 h, 80%.

band around 520 nm, which is much weaker than that for **6**, indicating that the steric impact of the dendritic substituents significantly suppresses the intermolecular π-stacking of the polymer backbone. The weak excimer emission for **5** could be due to the liquid crystalline property already reported for the poly(phenylenevinylene)s having poly(benzyl ether) dendron side chains.[9] The almost negligible weak excimer emission for **4** in the film might result from an amorphous structure caused by the regio-random backbone structure, which is possibly related to the lower softening point than that of **5**. Thus, the replacement of one dendron with a less bulky substituent in the 9-position enables almost pure blue photoluminescence.

In conclusion, the first well-defined unsymmetrical-substituted **4** bearing bulky poly(benzyl ether) dendron and less bulky 3,6-dioxaoctyl substituents in the 9-position gave almost a pure bluish photoluminescence with negligible weak greenish excimer emission around 520 nm even in the thermally annealed thin solid film, showing the great potential for the construction of large-area blue light emitters.

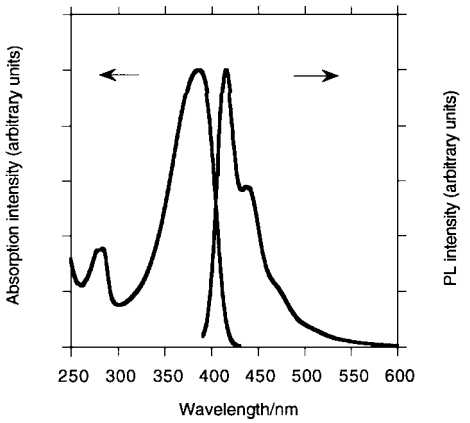


Fig. 1 UV-vis absorption (3.0×10^{-5} mol L^{-1} of the fluorene-repeating-unit) and PL (1.4×10^{-6} mol L^{-1} of the fluorene-repeating-unit) spectra of **4** (excited at 386.0 nm) in THF solution at 25 °C.

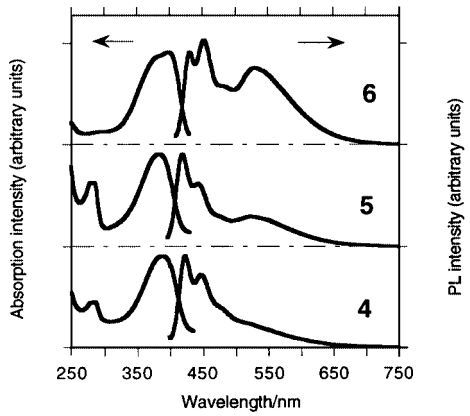

Fig. 2 Normalized UV-vis absorption and PL spectra of **4** (excited at 388.5 nm), **5** (excited at 384.5 nm) and **6** (excited at 399.0 nm) in thin solid films prepared by the spin-coating method from chloroform solution ($\sim 10^{-2}$ mol L^{-1} of the fluorene-repeating-unit) on a quartz substrate upon annealing at 200 °C for 3 h *in vacuo* followed by slow cooling to 25 °C.

We gratefully thank Dr Hideaki Takayanagi for his continuing support. CREST-JST is acknowledged for funding at NTT.

New fluorocarbon iodides†

Richard D. Chambers,* Julian A. Cooper, Elodie Copin and Graham Sandford*

University of Durham, Department of Chemistry, South Road, Durham, UK DH1 3LE.
E-mail: R.D.Chambers@durham.ac.uk; Graham.Sandford@durham.ac.uk

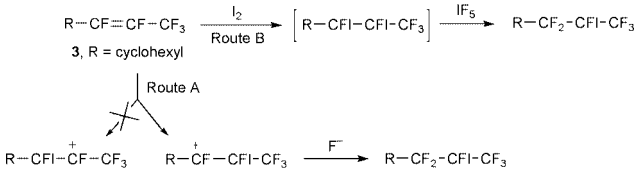
Received (in Cambridge, UK) 21st August 2001, Accepted 16th October 2001
First published as an Advance Article on the web 8th November 2001

A general, efficient approach for the synthesis of fluorocarbon iodides and di-iodides bearing hydrocarbon groups is described and the synthetic utility of these new systems is demonstrated in reactions with thiols.

Perfluorocarbon iodides (R_FI) have been important for many years as 'building blocks' for the synthesis of various organic compounds containing fluorine.[1–3] For example, they are crucial components in the synthesis of highly efficient surfactants on the industrial scale.[4] Here, we report an approach to the synthesis of fluorocarbon iodides that bear hydrocarbon end-groups and demonstrate the potential of these systems for further synthesis of fluorinated derivatives.

We are exploring the use of the carbon–hydrogen bond as a functional group in efficient free radical chain reactions with fluorinated alkenes,[5] *e.g.* formation of **1** and **2** from cyclohexane,‡ and have begun to explore the chemistry of the resultant fluorinated adducts. It has been demonstrated that stereospecific elimination of hydrogen fluoride[5] from **1** and **2** leads to unsaturated derivatives **3** and **4** respectively. We now find that alkene derivatives **3** and **4** react with a stoichiometric mixture of iodine pentafluoride and iodine, that corresponds to iodine monofluoride, giving fluorinated iodide **5** and di-iodide **6** respectively in efficient processes (Scheme 1).

The mechanism of iodine monofluoride addition is of interest because the process is regiospecific, to the limits of detection by ^{19}F NMR. In principle, we could envisage two possible mechanisms for addition of I–F to **3** (Scheme 2). Route B involves first addition of iodine to the double bond, but the next step would then require selective replacement of iodine at the R–CFI site by fluorine and we see no convincing reason for this to occur. Furthermore, we have been unable to add iodine to **3** to give a di-iodide. In contrast, we find that other additions to **3** involving bromine, iodine monochloride and iodine monobromide are efficient processes and moreover, additions involving ICl and IBr are regiospecific. It is surprising that these electrophilic additions proceed so readily with electron deficient double bonds but the regioselectivity is entirely consistent with an electrophilic process. The developing carbocationic site in intermediate **7a** is stabilised by cyclohexyl and by fluorine, whereas **7b** would be strongly destabilised by the attached trifluoromethyl group and so, consequently, we favour Route A.



Scheme 2

Novel iodides **5** and **6** react with thiols and di-thiols, most likely *via* an $S_{RN}1$ mechanism,[6] giving thioethers **8a–d**[7] and di-thioethers **9**, mostly in high yields (Scheme 3) and oxidation of the thioether products to the corresponding sulphones was possible using chromium trioxide in acetic acid.

These preliminary results demonstrate that these unusual fluorocarbon iodide 'building blocks' could be used for approaches to a variety of new systems containing fluorinated groups.

Received (in Cambridge, UK) 6th September 2001, Accepted 10th October 2001
First published as an Advance Article on the web 30th October 2001

A new polyimide with covalently incorporated 4,4′-bis-(dialkylaminostyryl)-2,2′-bipyridine chromophores is described which allows the synthesis of the corresponding NLO octupolar metallo-polymer.

Polymers featuring nonlinear optical (NLO) chromophores are of particular interest due to potential applications in electro-optic devices.[1] A current approach for the design of NLO materials is the covalent attachment of NLO-phores to a polymer backbone, and increasing numbers of side-chain, main-chain and cross-linked polymers have been recently designed.[2] Among them, aromatic polyimides appear to be very promising materials due to their high thermal stabilities and high glass transition temperatures.[3]

Beyond the dipolar approach, recognition in the early nineties of the enlarged potential for nonlinear optics of octupolar chromophores has opened a new field of research.[4] Metal bipyridyl complexes offer many possibilities for the design of non-centrosymmetric octupolar molecules.[5] For instance, large nonlinearities have been demonstrated for octahedral metal complexes[6] and tetrahedral copper(I) complexes[7] possessing 4,4′-bis(dialkylaminostyryl)-2,2′-bipyridines. Despite their interesting properties, so far only the third-order optical nonlinear properties of one polymer containing a substituted 1,3,5-triazine octupole has been reported.[8] We now describe the synthesis, characterisation and preliminary solution NLO activity of the first polyimide functionalised by an octupolar ruthenium trisbipyridyl complex.

To achieve the synthesis of the desired polymer, the preparation of the proper monomer was required. Our approach began with the synthesis of dihydroxy-substituted 4,4′-bis-(dialkylaminostyryl)-2,2′-bipyridine **1a** (x = 1).[9] In order to get more soluble polymers, **1b** (x = 2) was prepared in 74% yield by the same route, *i.e.* from 4,4′-dimethyl-2,2′-bipyridine and *p*-(*N*-butyl-*N*-tetrahydropyranyloxybutyl)aminobenzaldehyde **b** (Scheme 1).[10] NLO polyimides are generally prepared *via* the condensation of a diamino functionalised chromophore with dianhydrides. Therefore, the bis-diamino substituted 4,4′-bis(dialkylaminostyryl)-2,2′-bipyridines **2a** and **2b** were readily prepared (81 and 74% yield, respectively) from **1a** and **1b** using the Mitsunobu reaction and followed by the cleavage of the phthalimido protecting groups with hydrazine. The diamine derivatives were then reacted with hexafluoroisopropylidene diphthalic anhydride (6FDA) in NMP at 25 °C, followed by chemical imidization with Ac_2O–pyridine,[11] to yield the expected polyimides **3a** and **3b**. It is worth noting that the presence of butyl end groups and C_4 linkers in **3b** leads to enhanced solubility in organic solvents (NMP, THF and dichloromethane), as compared to the poor solubility of **3a** in the same solvents. The structure of **3a** and **3b** was confirmed by IR, UV-visible and NMR (^{1}H, ^{19}F) spectroscopies.† In the IR spectra, the polyimides display characteristic absorptions at *ca.* 1780, 1720 and 740 cm^{-1}, attributed to the imide rings, and all the resonance peaks in the ^{1}H NMR spectra can be assigned to the protons of the bipyridine moieties and polymer backbone. Their UV-visible spectra are characterised by a broad intramolecular charge-transfer absorption band at *ca.* 400 nm, comparable to that of the monomer precursors (Table 1). Gel permeation chromatography gave relatively low molecular weights [M_w (**3a**, 9300; **3b**, 19300 Da); M_n (**3a**, 6600; **3b**, 14100 Da)] indicating an average of *ca.* 7 and 14 bipyridine units in **3a** and **3b**, respectively. These polyimides possess excellent thermal stability, with 5% weight losses (Td_5 determined by TGA) occurring above 370 °C. Thermal analysis by DSC also shows that the glass transition temperature (T_g) of **3b** is significantly lower ($\triangle T_g$ = 45 °C) than that of **3a**, in agreement with the more flexible structure of **3b** (Table 1). The metallo-polyimide **4b** was obtained in 92% yield by refluxing **3b** and $(DBAS\text{-}bpy)_2RuCl_2$ (DBAS-bpy = 4′4′-bis(dibutylamino-styryl)-2,2′-bipyridine) in DMF, followed by an exchange of the

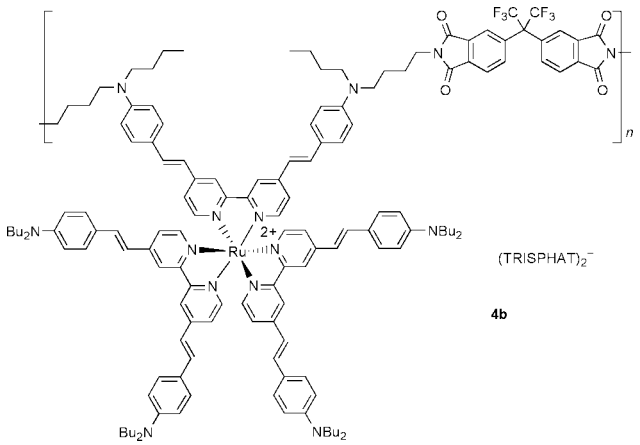
chloride counterions with tris(tetrachlorobenzenediolato)phosphate (TRISPHAT) anions and precipitation in Et_2O (Scheme 2). The use of this anion was found to greatly enhance the solubility of the resulting polymer in solvents such as THF and dichloromethane.[12] The complete coordination of all bipyridine units was confirmed by ^{1}H NMR, which showed an upfield shift of the H_6 protons by *ca*. 1 ppm upon complexation.[12] The UV-visible spectrum is similar to that of the Ru(DBAS-bpy)$_3^{2+}$ monomer with two maxima at 445 and 513 nm due to the overlapping metal to ligand (MLCT) and intra-ligand (ILCT) charge-transfer transitions. This new polymer also displays high thermal stability (Td_5 = 358 °C).

The molecular hyperpolarisability β of the metallo-polyimide **4b** was measured by means of the harmonic light scattering technique (HLS).[13] To circumvent the problems associated with reabsorption of the second harmonic and enhancement of β by two-photon absorption fluorescence, the experiment was performed at a fundamental wavelength of 1.91 μm in dichloromethane.[14] The β value of **4b** is 1300 × 10^{-30} esu, which is approximately 4 times larger than that of the parent octupolar



Scheme 2

monomer Ru(DBAS-bpy)$_3^{2+}$ [β(monomer) = 320 × 10^{-30} esu].[15] According to the HLS principle, the number N of individual monomers in **4b** can be inferred from the following relationship $<\beta^2(\text{polymer})> = N <\beta^2(\text{monomer})>$. Thus, a number of *ca*. 16 ruthenium trisbipyridine monomers can be deduced, and it worth noting that this value fits almost perfectly with the average number of 14 obtained from the GPC analysis of **3b**.

In conclusion, we have reported an efficient synthesis of a highly thermally stable octupolar NLO polyimide which exhibits large solution second-order nonlinearity. The designed approach described here also opens the way for the preparation of new push–pull polyimides featuring dipolar chromophores upon complexation of the bipyridyl-polymer ligands to metal complexes.[16] We are continuing to explore the second- and third-order NLO bulk susceptibilities on thin films.

The authors thank the CNET (France-Telecom) and the Conseil Régional de Bretagne for financial support.

Ferrocene-modified bis(spiropyridopyran)s as synthetic signaling receptors for guanine–guanine dinucleoside derivatives

Masayoshi Takase[a] and Masahiko Inouye*[b]

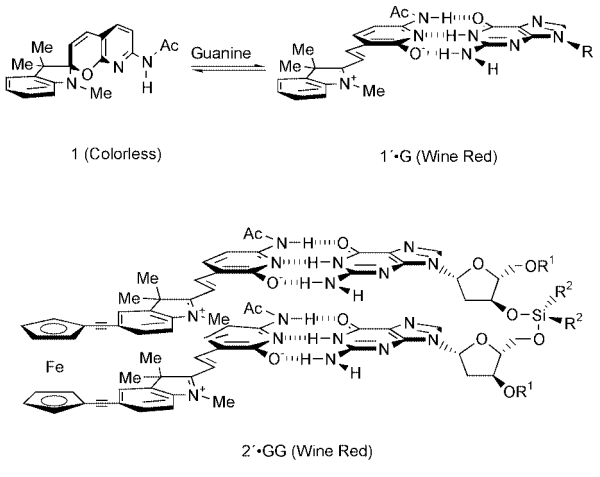
[a] *Department of Chemistry, Graduate School of Science, Kyoto University, Kyoto 606-8502, Japan*
[b] *Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Toyama 930-0194, Japan. E-mail: inouye@ms.toyama-mpu.ac.jp*

Received (in Cambridge, UK) 13th August 2001, Accepted 16th October 2001
First published as an Advance Article on the web 30th October 2001

A ferrocene-linked bis(spiropyridopyran) was designed and synthesized, that recognized guanine–guanine dinucleoside derivatives *via* complementary hydrogen bonds in CH_2Cl_2, resulting in the isomerization of the colorless spiropyridopyran as self-indicating receptors.

The recognition and selective binding of nucleobases play essential roles in entire living systems. For example, complementary hydrogen bonds arise in a very specific fashion between purine and pyrimidine bases of the two strands of double-helical DNA in order to store genetic information.[1] Thus, the synthetic models that recognize specific nucleobases and that read-out the recognition event are attracting much attention from the viewpoint of their uses in biological sciences.[2] In this connection, we have reported spiropyridopyrans **1**,[3] isomerization of which to the colored merocyanines **1′** was induced by recognition of guanosine derivatives.[4] To extend this approach to more challenging projects, we focused on the recognition of oligonucleotides. Here we describe the molecular recognition ability and its recognition-induced coloration of a ferrocene-modified bis(spiropyridopyran) **2** for guanine–guanine dinucleosides (Scheme 1).

The choice of ferrocene as a linker was based on the inter-ring spacing of the two Cp rings (0.33 nm),[5] which is near to the spacing between the stacked base pairs.[6] Another advantageous point of the ferrocene skeleton is its restricted conformational flexibility. This may result in the decrease of the entropy loss of **2** upon complexation with dinucleotides.[7] To evaluate the recognition abilities of **2** for dinucleotides in less-polar solvents, lipophilic dinucleoside derivatives were chosen (Fig. 1b). The bulky silyl groups at the 5′ and 3′ ends and the di-*n*-hexylsilylene internucleoside linkage make the dinucleoside soluble in such solvents and prevent their deoxyribofuranoside residues from interacting with the hydrogen-bonding motif of **2**. The decision for utilizing the silylene linkage was based on the similarity of covalent bond radius of tetrahedral silicon (0.117 nm) to that of tetrahedral phosphorus (0.110 nm).[8]



Scheme 1

The 3*H*-indole derivative bearing ethynyl groups at the 5 position was prepared from 4-bromophenylhydrazine by using the Fischer-indole synthesis followed by Sonogashira reaction.[9] Further Sonogashira reaction of the indole with 1,1′-diiodoferrocene[10] gave ferrocene-linked bis(3*H*-indole),[7c] which was methylated at the nitrogen and condensed with 6-acetamido-2-pyridone-3-carbaldehyde[4a] to yield desired bis(spiropyridopyran) **2** (Scheme 2).† The lipophilic dinucleoside derivatives were prepared according to a literature procedure.[8]

The ferrocene-linked bis(spiropyridopyran) **2** showed wine-red color in CH_2Cl_2, indicating that it exists at least partly as the open merocyanine form. This was demonstrated by the ^{1}H NMR spectrum of **2**, in which 10% or less of **2** is present as **2′** on the basis of the integration of the spectrum.‡ Futhermore, the UV-vis spectrum of **2** revealed an absorption maximum around 580 nm ($\varepsilon = 6.9 \times 10^3$) that is unambiguously attributed to the merocyanine chromophore (Fig. 1a; a line of 'none').[4a] In CH_2Cl_2, addition of the guanine–guanine dinucleoside derivative **GG** (10 equiv.) to **2** produced changes in the absorption spectra, and strong absorption bands appeared ($\lambda_{max} = 575$ nm, $\varepsilon = 3.8 \times 10^4$). The change was clearly seen visually, as the wine-red color of **2** dramatically darkened. Unfortunately, the ^{1}H NMR spectrum of the mixture of **2** and **GG** in $CDCl_3$ gave no useful information for the increment of the merocyanine

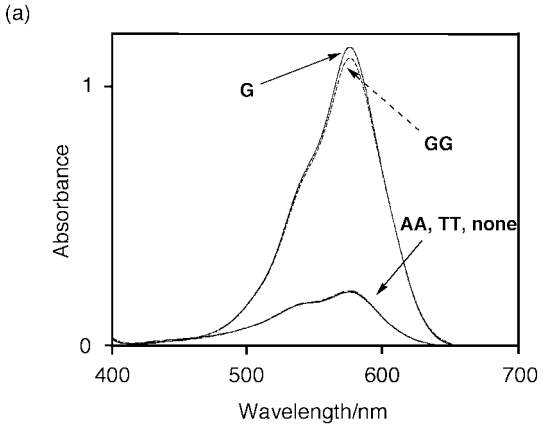


Fig. 1 (a) Electronic absorption spectra of **2** (3.0×10^{-2} mM) in the presence of the lipophilic nucleoside derivatives (3.0×10^{-1} mM) in CH_2Cl_2 at 25 °C. (b) The structures of the dinucleoside derivatives. The guanine–guanine dinucleoside (**GG**) was used as a mixture with 3′–3′ and 5′–5′ homo-coupling dimers. The guanine mononucleoside (**G**) is 3′,5′-bis-*O*-(*tert*-butyldimethylsilyl)deoxyguanosine.

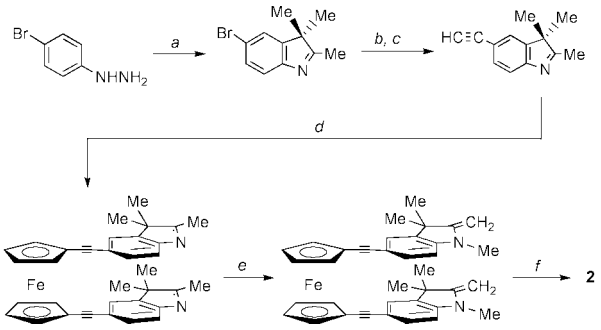
 DOI: 10.1039/b107306k



Scheme 2 *Reagents*: (*a*) butan-2-one, AcOH; (*b*) 2-methylbut-3-yn-2-ol, $(Ph_3P)_2PdCl_2$, CuI, Et_2NH; (*c*) NaOH, toluene; (*d*) 1,1′-diiodoferrocene,[10] $(Ph_3P)_2PdCl_2$, $Cu(OAc)_2$, *i*-Pr_2NH; (*e*) MeI, MeCN, then NaOH, H_2O; (*f*) 6-acetamido-2-pyridone-3-carbaldehyde,[4a] EtOH.

form **2′** because of much overlap of the peaks between **2′** and **GG**. The guanine mononucleoside **G** resulted in similar changes to the absorption spectrum, while other mononucleoside (**A**, **T**, **C**) and dinucleoside (**AA** and **TT**) derivatives had absolutely no influence on it (Fig. 1a). These findings indicated that the complementary triple hydrogen bond between the acetamidopyridone anion part of **2′** and guanine bases is critical for selective coloration.

The binding constants were estimated by UV titration at 25 °C using an iterative least-squares curve-fitting with weighting of data points according to the error analysis of Deranleau.[11] The absorbances of the merocyanine forms (575 nm) were monitored as a function of the concentration of guanosine derivatives assuming that all the complexed-spiropyrans exist as merocyanine forms. The association constant between **1′** and **G** displayed 2.4×10^4 M^{-1} ($-\Delta G_{298} = 25.0$ kJ mol^{-1}), while that of **2′** and **GG** was 4.2×10^5 M^{-1} ($-\Delta G_{298} = 32.0$ kJ mol^{-1}). The increment of the binding energy was lower than that predicted by the doubled recognition sites; this may partly result from the electrostatic repulsion between the two zwitterionic merocyanines.

In summary, a ferrocene-modified bis(spiropyridopyran) was developed as a synthetic signaling receptor for guanine–guanine dinucleoside derivatives. The high selectivity for the coloration of the receptor is governed by the hydrogen-bonding complementarity between them. In the future, design and synthesis of the receptors that bind native nucleotides will be expected to show significant practical value.

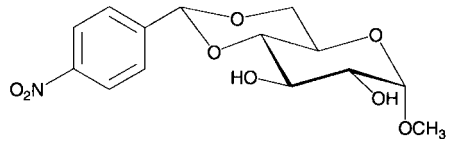
Gelator–catalyst interactions allow the transcription of the organogel structure of methyl-4,6-*O*-(*p*-nitrobenzylidene)-α-D-glucopyranoside (1) into its silica analogue, even in the absence of positive charges or H-bonding sites on the gelator molecule which, until now, were considered indispensable.

Inorganic materials can be shaped into a variety of structures using organic, supramolecular assemblies as templates.[1] Vesicles,[2] organic crystals[3] and phospholipid fibers[4] are just some of the organic templates that have successfully been employed to create interesting silica constructs. In addition, we have found that superstructures formed by organogelators act as excellent templates because of their stable, 'solid-like' aggregation behavior. The growth of helical silica is one of the most striking examples of what can be achieved by using organogel fibers as the template for sol–gel polycondensation of tetraethylorthosilicate (TEOS).[5] It has, however, been shown that the presence of some attractive force between the superstructures and TEOS is indispensable for efficent sol–gel transcription. Therefore, up till now, transcription into silica *via* TEOS polycondensation has been limited to superstructures of molecules that possess a cationic charge in the form of a quaternary ammonium moiety[6] or a metal cation,[5,7] and molecules that possess a H-bonding site in the form of primary amines or combinations of primary and secondary amines.[2,8] The design of new gelators for organogel transcription into silica has, therefore, been strongly limited to molecules containing either positive charges or amino groups.[8] In this paper we show the first example of an organogel that can be successfully transcribed into silica although it does not possess either a positive charge or a H-bonding amino group. We have found that the catalyst for silica formation, *i.e.* benzylamine, can interact with the molecular aggregates of **1**[9] in



1

the gel fibers, thus providing the driving force necessary for the transcription process. Clear evidence for the gelator–catalyst interaction has been obtained from transmission electron microscopy (TEM), circular dichroism (CD), ^{1}H NMR and FT-IR spectroscopy measurements.

In water, gelator **1** forms a clear gel consisting of a three-dimensional network of curved fibers[9] (Fig. 1a). An aqueous solution containing **1** (0.5 wt%) and benzylamine (ba) in a 1 : 1 ratio also yields a clear gel. However, this particular gel consists of a network of much straighter fibers (Fig. 1b) than those observed for the gel of **1** without benzylamine. The structure of the organogel of **1** is, therefore, altered, to some degree, by the interaction with benzylamine. To transcribe this organic superstructure into silica, polycondensation of TEOS was carried out using an aqueous solution of **1** + ba.[10] After calcination of the sample,[11] TEM images (Fig. 1c and d) showed tubular structures of similar diameter (50–100 nm) and appearance to those observed in the gel samples of **1** + ba, indicating that the transcription was successful. In a sample containing only **1** and TEOS, *i.e.* no catalyst, no silica formation was observed even after several weeks. Apparently, benzylamine can interact with the molecules of **1** in the gel fibers, most likely *via* hydrophobic and/or π–π stacking interactions, making transcription of the organogel possible.

To elucidate the gelation process of **1** with benzylamine, experiments were carried out replacing benzylamine with different catalysts: hydrazine and 3,5-dimethoxybenzylamine. Although an aqueous solution of **1** (0.5 wt%) and hydrazine (in a 1 : 1 ratio) did form a gel, the transcription experiment carried out by adding TEOS to this system yielded only granular silica particles. This result indicates that there is no particular interaction between **1** and hydrazine which can lead to the transcription of the organogel. This observation is in accordance with the assumption that hydrophobic and/or π–π stacking interactions between benzylamine and **1** play a key role in the

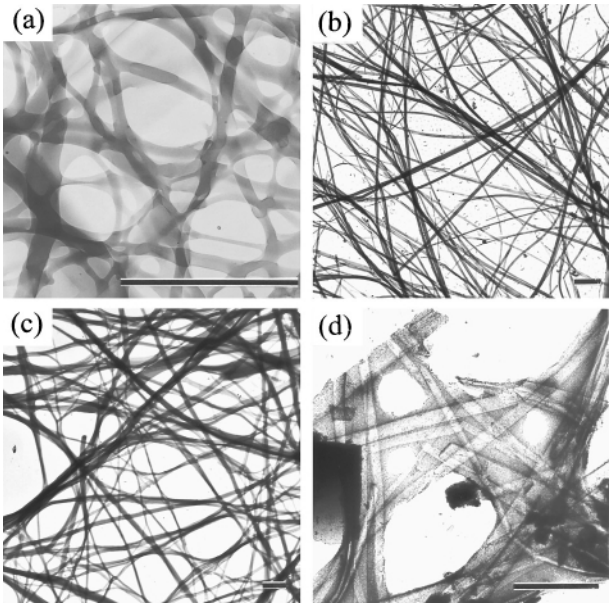


Fig. 1 TEM images of (a) the gel of **1** (scale bar = 0.75 μm), (b) the gel of **1** + ba, (c) the xerogel of **1** + ba + TEOS and (d) the xerogel after calcination (scale bars = 1.50 μm).

† Electronic supplementary information (ESI) available: CD, FT-IR and temperature dependent ^{1}H NMR spectra. See http://www.rsc.org/suppdata/cc/b1/b108148a/

 DOI: 10.1039/b108148a

transcription process. The structure of 3,5-dimethoxybenzylamine is similar to that of benzylamine, however, its bulky methoxy substituents should disturb the stacking of **1** and, therefore, prevent organogel formation. Indeed, an aqueous solution of **1** (0.5 wt%) and 3,5-dimethoxybenzylamine (in a 1 : 1 ratio) did not form a gel upon cooling, but a precipitate and, thus, could not be transcribed. These results strongly indicate that benzylamine interacts with **1** *via* aromatic π–π stacking, without considerable disruption of the gel structure. Such interactions bring a number of amino moieties (from the benzylamine) onto the gel fiber surface thereby providing the stimulus for organogel transcription.

CD spectra of a gel of **1** and of a gel of **1** + ba show slight differences which can be attributed to interactions of the catalyst with **1**. The decrease in spectral intensity for the gel of **1** + ba implies that the chiral superstructure originating from the H-bonding interactions among the sugar moieties of **1** is partially destroyed by bound benzylamine molecules. Furthermore, the appearance of a shoulder (215 nm) on the peak at 212 nm suggests the presence of benzylamine in proximity of, or perhaps even intercalated in the gel fibers.

Additional evidence for the interaction of benzylamine with the gel fibers of **1** was obtained from FT-IR measurements (KBr pellet) of the xerogel of **1** and the xerogel of **1** + ba. The spectrum of the xerogel of **1** shows only a rather broad peak (3750–3100 cm^{-1}) corresponding to H-bonded OH and NH moieties. However, more signals can be distinguished in the spectrum of **1** + ba, *i.e.* shoulders at 3482 cm^{-1} and 3254 cm^{-1}, in comparison with the spectrum of the xerogel of **1** alone. These signals most likely arise from the partial disruption of the H-bonding network of the OH groups in the gel fibers by the interaction of the amino moieties of the catalyst with the gelator molecules within or between the fibers.

To obtain a more detailed picture of the gel of **1** + ba in water, temperature-dependent ^1H NMR spectroscopy was performed. The peaks of the gelator and of the benzylamine appear broadened in the spectrum of the gel at 298 K. This line-broadening effect for the gelator molecules is typical of organogel samples due to the restricted molecular motion in the gel state with respect to the solution state.[12] Moreover, broadening of the benzylamine peak can be attributed to a decreased mobility of some of the benzylamine molecules, deriving from their intercalation in the gel fibers of **1**.[13] However, the integrals for the peaks of the benzylamine and the gelator protons show a 1 : 1 ratio of both components only in the solution state (343 K), while in the gel state (298 K) the amount of benzylamine appears to be approximately 3 times larger than the amount of **1**. This shows that in the gel, the benzylamine molecules are, on average, more mobile than the molecules of **1** and, therefore, only some are incorporated in the gel fibers, while most are probably situated between the fibers. To determine the actual amount of benzylamine trapped in the gel fibers of **1**, xerogels of **1** + ba were prepared by freeze drying the aqueous samples for 8, 14, 18, 24 and 36 h. The samples were then dissolved in CD_2Cl_2 and the ratio of benzylamine to gelator was determined by measuring the integrals of the corresponding aromatic proton peaks in the NMR spectra. The amount of benzylamine in the samples decreased with freeze drying time, to reach a steady value of 10–20% after approximately 14 h (Fig. 2). No further decrease was observed even after freeze drying for 36 h. As a reference, a sample containing only benzylamine and water, but no gelator, was subjected to the same treatment and after 24 h no benzylamine could be detected by NMR spectroscopy. Therefore, the amount of benzylamine intercalated/trapped in the gel fibers of **1** seems to be approximately 10–20% of the total number of gelator molecules. These results are in agreement with the temperature-dependence NMR experiments, which showed only a partial broadening of the signals of the benzylamine protons in the gel state, as well as an increase in the integral ratio of benzylamine to gelator.

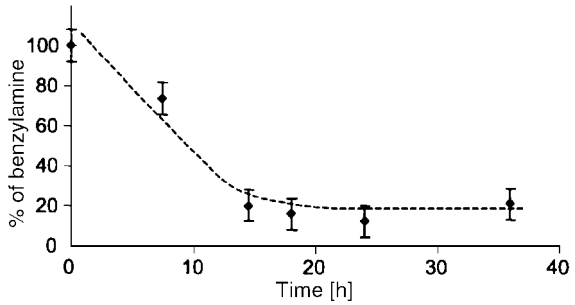

Fig. 2 Percentage of benzylamine in samples of **1** + ba as a function of freeze drying time (---- line to guide the eye).

In conclusion, we have shown that the organogel of a compound which does not contain a positive charge or an amino group can still be transcribed into a silica structure, as long as the catalyst for the polycondensation process can interact with the gelator molecules. Preliminary results using other gelators that do not contain positive charges or amino groups either,[14] indicate that this phenomenon is of a general nature. As a consequence, the transcription of a much broader range of organic superstructures, such as proteins, neutral vesicular aggregates or polysaccharides, *via* the polycondensation of TEOS can now be taken into consideration. Being able to transcribe such entities will undoubtedly lead to a greater variety of inorganic materials with interesting new shapes and properties.

A cascade of reactions involving anchimeric assistance leads to a highly 'crowded' hexa(alkylcarboxy)benzene†

Gunther Hennrich, Vincent M. Lynch and Eric V. Anslyn*

Received (in Columbia, USA) 26th June 2001, Accepted 15th October 2001
First published as an Advance Article on the web 8th November 2001

The substitution of hexabromomethylbenzene with 1-adamantyl carboxylate quantitatively leads to the corresponding hexacyl derivative *via* anchimeric assistance by the alkylcarboxy substituents.

Currently, considerable effort is being devoted to the synthesis of hexasubstituted benzene derivatives with a 1,3,5-, 2,4,6-substitution pattern, leading to characteristically preorganized systems.[1] Based on this type of scaffold, we recently presented various receptor molecules for the recognition of small, biologically relevant anions.[2] Such preorganized systems are also useful in the synthesis of macrocycles. By virtue of the alignment of functional groups of a reactant, the closure to the desired ring is facilitated.[3]

Lately, we have been exploring the substitution of the halogen atoms of hexabromomethyl benzene (**1**)[4] in order to create molecules with alternating groups on the phenyl ring. By reacting **1** with equimolar amounts of a bulky, weak nucleophile, we expected to obtain in a first step the respective, monosubstituted pentabromomethyl benzene and/or statistical mixtures of other substitution products.

To our surprise, the reaction of 1-adamantylcarboxylic acid (1-adca) with **1** in a 1 : 1 stoichiometry using caesium carbonate as the base, gave the hexa(alkylcarboxy)benzene **2** in a quantitative yield (Scheme 1), along with the recovery of **1**.[5] There are several effects to explain this result. The use of potassium carbonate instead of caesium carbonate as the base did not significantly affect the yield of the product. Accordingly, we can exclude a caesium induced effect, by which the caesium cation templates a benzene intermediate and brings a carboxylate reactant in proximity to the reaction center.[6] Further, there is no obvious inductive effect that can be invoked as a reason for this results. Therefore, we sought a different explanation.

Hexasubstituted benzenes have been studied extensively, with particular attention having been paid to their distinct conformations, *i.e.* the orientation of the substituents around the benzene core.[7] It was found by X-ray and NMR investigations that the alternation of substituents at the phenyl ring is thermodynamically favoured in persubstituted benzenes, with significant energetic barriers for the rotation of a substituent around the respective *C*(aryl)–*C*(methylene) bond.[8]

As determined for **2** by X-ray crystallography, the molecule lies on a crystallographic inversion center at ½, ½, ½ (Fig. 1).‡ Three molecules of benzene solvate co-crystallize along with **2**. Each molecule of benzene is also situated around a different crystallographic inversion center located at the center of the aromatic ring in the **ab** plane. As can be seen in the figure, the six bulky substituents alternate above and below the plane of the central benzene ring.

The stoichiometry used in the reaction, the mass balance of the products, as well as the identity of the product itself dictates kinetic control of the substitution reaction. The most apparent explanation is anchimeric assistance. Anchimeric assistance by acetoxy groups is a known and well-investigated phenomenon in substitution reactions, involving cyclic dioxonium intermediates,[9] but has so far been disregarded in the syntheses of hexasubstituted benzene derivatives.[10]

Although most commonly 5- or 6-membered rings are invoked in anchimeric assistance reactions, the formation of 7-membered heterocyclic intermediates has been reported.[11]

In our case, we propose that the introduction of a first adamantylcarboxy substituent leads to the monosubstituted adduct, which due to the alternation of the groups around the benzene ring is perfectly poised for an S_N2 displacement of a neigbouring bromide. This forms a 1,3-cycloheptadienium ring, which should be relatively free of ring strain due to the ring size and the *cis*-orientation at the benzene double bond and that of the carboxy group.[12] The attack of each additional carboxy nucleophile is thereby accelerated. Each neighbour group effect is 'handed over' from one carboxy group to the next one (Scheme 2).

However, Siegel has found S_N2 mechanisms are operative in similar systems,[13] and also at this stage we cannot rule out the formation of other intermediates, such as a cyclic bromonium cation.

As a control experiment, trisbromomethyl benzene **3**,[14] which does not allow the formation of the proposed 7-membered ring was subjected to the same reaction as **1**. After 3 h the reaction was still incomplete, *i.e.* starting material was still present, and the main product was identified as the mono-

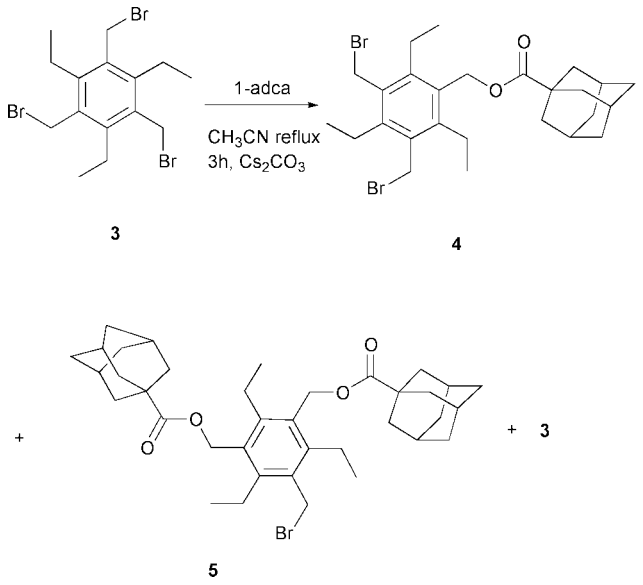

Scheme 3

adamantylcarboxy-derivative with traces of bis-substituted product being present in the reaction mixture (Scheme 3). After a further 5 h of heating, a complex mixture of the expected products was found.

The results reported herein support the necessity of adjacent bromomethyl functions to be present in the starting material, and therefore substantiate a mechanism involving the formation of cyclic intermediates, controlled by anchimeric assistance. Also, the clean and quantitative reaction of **1** giving **2** as the only detectable product points to a mechanism that involves an initial, rate determining step, and the subsequent fast conversion of the remaining bromomethyl groups as with energetically less demanding reactions.

We gratefully acknowledge the financial support by from the Beckman and Welch Foundation.

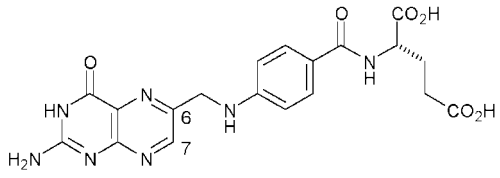
First published as an Advance Article on the web 13th November 2001

The one-pot cyclocondensation of 2,6-diaminopyrimidin-4-one, an aromatic or aliphatic aldehyde and a β-ketoester in acetic acid, or dimethyl sulfoxide in the presence of zinc(II) bromide, under thermal conditions provided dihydropyrido[2,3-*d*]pyrimidin-4(3*H*)-ones in good yield and with total regiocontrol.

Since the isolation and characterisation of wing pigments of European butterflies at the end of the nineteenth century, the pterins have distinguished themselves as heterocycles of profound chemical and biological significance.[1] The discovery that the pyrazino[2,3-*d*]pyrimidine core of the pterin pigments was shared by the vitamin folic acid[2] caused a dramatic increase

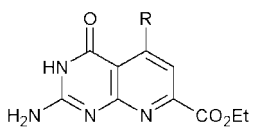


folic acid (*N*-pteroyl-L-glutamic acid)

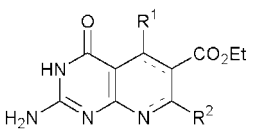
in interest in this heterocycle in an effort to understand its role in the prevention of disease.[3] Structurally-related folate antagonists[4] have been shown to possess a diverse range of biological properties and they elicit highly species-specific responses as antitumour,[5] antibacterial,[6] anti-inflammatory,[7] and antifungal agents.[8]

Uracil derivatives have been reported in the literature to be versatile building blocks for the synthesis of a wide range of heterocyclic motifs,[9] including pyrazolopyridines,[10] pyrimido- and pyridopyrimidines[11] and pyrazolopyrimidines.[12] Kajino has reported the synthesis of dihydropyrido[2,3-*d*]pyrimidines using 6-aminouracils, but as a one-pot three-component cyclocondensation reaction this procedure suffered from very poor yields and limited substrate tolerance.[13] Since our own studies on this topic, Quiroga revealed the successful three-component cyclocondensation of a 6-aminouracil derivative, benzoylacetonitrile and aldehyde, but this process was only reported for aromatic aldehydes and required microwave irradiation as thermal conditions gave only a poor yield of the pyridopyrimidine product.[14]

As part of our interest in the synthesis of simple nitrogen-containing heterocycles[15] we established a new approach towards the 5-deaza-7-folate heterocycle **1**,[16] based upon a



1



2

modification of the Bohlmann–Rahtz pyridine synthesis,[17] for the rapid assembly of a targeted library of folate antagonists from uracil derivatives. This communication describes a complementary approach towards the 5-deaza-6-folate motif **2** using a new three-component condensation reaction of an aldehyde, β-ketoester and 2,6-diaminopyrimidin-4-one **3**. This novel process prepares the target heterocycle with total regiocontrol, is successful for both aromatic and aliphatic aldehydes, utilises simple experimental conditions and incorporates a number of points of diversity for application in the synthesis of antifolate combinatorial libraries.

A mixture of 2,6-diaminopyrimidin-4-one **3**, benzaldehyde **4a** and ethyl acetoacetate **5** or ethyl benzoylacetate **6** was heated to 110 °C in dimethyl sulfoxide (DMSO) in the presence of zinc(II) bromide. After 72 hours, water was added and the precipitated solid was filtered to give dihydropyrido[2,3-*d*]pyrimidine **9** or **10** in 65 or 53% yield, respectively, as the only isolated reaction product.

In an effort to optimise this process, a range of different temperatures, solvents and acid catalysts were investigated. The choice of solvent for this reaction was limited by the solubility of diaminopyrimidinone **3** but reactions conducted in ethanol or DMSO at room temperature in the absence of a Lewis acid failed completely and gave only unreacted starting material **3**. Other Lewis acids, such as ytterbium(III) trifluoromethanesulfonate or scandium(III) trifluoromethanesulfonate were found generally not to be as efficient in this reaction. However, when a mixture of pyrimidinone **3**, benzaldehyde **4a** and ethyl acetoacetate **5** was stirred in acetic acid at 110 °C 5-deaza-5,8-dihydropterin **9**† was generated in 86% yield (Scheme 1).

Evidence on the mechanistic course of this reaction was obtained by the isolation of intermediate **7**, from a three-component reaction conducted in acetic acid at room temperature, that when stirred with ethyl acetoacetate **5** in acetic acid at 110 °C gave the same product **9**, albeit in only 43% yield. These findings indicated that initial addition to aldehyde **4a** was followed by acetoacetate **8** cyclodehydration in what appeared to be a totally regioselective process. The product **9** or **10**, obtained as a single regioisomer, was identified by ^{1}H and ^{13}C NMR spectroscopic techniques, the former of which clearly

indicated the presence of the NH (position 8) and deshielded methine (position 5) protons.

In order to examine the scope of this new three-component cyclocondensation reaction, 2,6-diaminopyrimidin-4-one **3**, a range of aromatic and aliphatic aldehydes **4** and ethyl acetoacetate **5** or ethyl benzoylacetate **6** was stirred at room temperature or heated to 110 °C in DMSO with zinc(II) bromide or in acetic acid for 72 hours to give dihydropyrido[2,3-*d*]pyrimidine **9**–**20**, usually in good to excellent yield (Scheme 2, Table 1). Although aromatic aldehydes gave slightly disappointing results in DMSO, it was found that conducting these reactions in acetic acid or in the presence of zinc(II) bromide usually improved the reaction and gave yields routinely in excess of 70%. Aliphatic aldehydes proved the most predictable, generating the product in reasonable yield as a single regioisomer after 72 hours at 110 °C in DMSO.

This new one-pot three-component cyclocondensation reaction generated 5-deaza-5,8-dihydropterins, bearing a range of different functional groups, under thermal and, where necessary, Lewis acid catalysed conditions. Efforts are now underway to apply this new procedure, that is simple, appropriate for combinatorial methodology and avoids the use of microwave irradiation, to the synthesis of deazapterin libraries and other targeted libraries of inhibitors of folate-dependent enzymes.

Notes and references

† *General experimental procedure for the 3-component cyclo-condensation reaction*. A mixture of 1,3-diaminopyrimidin-4-one **3** (0.20 g, 1.6 mmol), benzaldehyde **4a** (0.15 g, 1.5 mmol) and ethyl acetoacetate **5** (0.18 g, 1.5 mmol) in glacial acetic acid (5 mL) was stirred at 110 °C for 72 h. The mixture was allowed to cool, water (15 mL) was added and the solution was left to stand for 5 h. The precipitate that formed was filtered to give pure *5-deaza-5,8-dihydropterin* **9** (0.41 g, 86%) as a pale yellow solid.

First published as an Advance Article on the web 5th November 2001

The tandem action of a homogeneous chiral Pd(II) catalyst and a heterogeneous Co/C catalyst leads to a two-step one-pot highly enantioselective Pauson–Khand-type reaction.

Much success has been achieved in the field of transition-metal-mediated (or catalyzed) synthesis of cyclopentenones from readily available substrates;[1] however, catalytic asymmetric synthesis is still surprisingly underdeveloped. The use of a chiral titanocene complex (EBTHI)Ti(CO)$_2$ (EBTHI = ethylene-1,2-bis(η^5-4,5,6,7-tetrahydroinden-1-yl)[2] and Co,[3] Rh,[4] and Ir[5] complexes with chiral diphosphines have been recently reported. Demand for the development of a catalytic and enantioselective Pauson–Khand type reaction remains high.

Recently, the tandem use of two kinds of homogeneous catalyst in a one-pot multistep transformation of substrates to products has been reported.[6] The report by Jeong's group has attracted our attention. They used a combination of Pd and Rh catalysts in the preparation of bicyclopentenones from propargyl malonates. The use of Pd-catalyzed asymmetric allylic alkylation[7] to generate enantioselective enynes appears to be quite promising. However, the use of *in situ* generated enantiomerically enriched enynes as substrates in the Pauson–Khand reaction has not been reported even though increasing efforts are being devoted to the development of practical enantioselective versions of the Pauson–Khand reaction.[8]

In this connection, we decided to use the Pd(II)-catalyzed asymmetric allylic alkylation in the synthesis of enantiomerically pure enynes. We report herein that the tandem action of homogeneous chiral Pd(II) catalyst and heterogeneous catalyst Co/C[9] leads to a 'two-step one-pot' highly enantioselective Pauson–Khand-type reaction. The efficiency of this two-step one-pot reaction was studied for **3(Me)** as shown in Scheme 1. Thus, we screened several chiral ligands (Chart 1) to find the best chiral ligand (Table 1).[10] The same reaction was conducted in the presence of dppe to obtain racemic products. All the chiral ligands were effective for Pd-catalyzed asymmetric allylic alkylation. The ee values of **4(Me)** ranged from 83 to 95% at room temperature. As expected, the best ligand was phosphinooxazoline ligand **b**. The best ee value of 96% was obtained when the reaction was conducted at 0 °C in the presence of **b** (entry 3 in Table 1). The absolute configuration of **3(Me)** was easily established by comparison of the observed [α] values with those of the known reactions. The absolute configuration (3*R*,4*S*,5*R*) of the bicyclic enone **4(Me)** was determined by an NMR study. When the reaction in Scheme 1 was carried out stepwise to determine whether the ee value was changed during the carbonylative cyclization, the ee value of the final product was the same as that of the first step and no other diastereomer was found in the second step. Thus, the ee value of the first asymmetric allylic alkylation reaction was maintained during the second cycloaddition reaction. This suggests that the first step is a stereoselective reaction and the second a stereospecific one. The enantioselectivity of this tandem cycloaddition was absolutely dependent on the Pd-catalyzed asymmetric allylic alkylation. This could be a good advantage of this combination of catalysts because the palladium-catalyzed allylic alkylation is one of the most thoroughly and intensively studied catalytic transformations. High yields were observed for all reactions. The yield of the second step was always quantitative. Thus, the turnover number was completely dependent upon the Pd-catalyzed allylic alkylation. For convenience, we used 2.5 mol% of Pd(II) catalyst for studying the reactions.

The success of this tandem catalytic reaction is primarily due to the use of Co/C. In the Pd(II)-catalyzed allylic alkylation reaction, acetic acid was generated. The acid would interact with cobalt species in the solution. When $Co_2(CO)_8$ (20 mol%) instead of Co/C was used as a catalyst, only 2% of the product

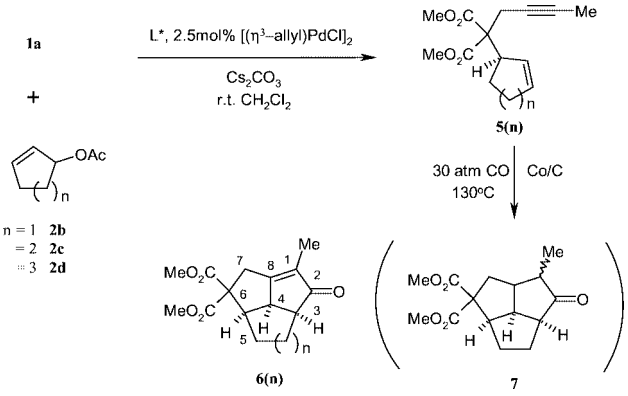
[a] Reaction conditions: 6.0 mol% L* , 2.5 mol% $[(\eta^3\text{allyl})PdCl]_2$, 0.2 g Co/C, and THF. Condtions for the 2nd step: 130 °C, 18 h, and 30 atm CO.[b] Reaction time of the first step at rt.[c] Isolated yield.[d] Diacel OD column was used.[e] CH_2Cl_2 as a solvent.

was isolated (entry 4 in Table 1). However, the Co/C was found to be insensitive to acid or base. Generally, for good enantioinduction, low temperatures are required. However, our reaction conditions in the second step seem to be quite harsh, nevertheless no racemization occurred under these reaction conditions. We also examined the catalytic asymmetric carbonylative cyclization of **3(R)** (R = Ph, *n*-Bu) (entries 2 and 3 in Table 2). Under our reaction conditions, **4(R)** were obtained in high yields (84–95%) with high ee values (84–95%). The usefulness of this combination catalyst is highlighted by the



Scheme 2

synthesis of various tricyclic enones **6(*n*)** (*n* = 1–3) (Scheme 2 and entries 4–6 in Table 2).

The intramolecular Pauson–Khand reaction of cyclic enynes having cyclopentenes or cyclohexenes with pendant alkynes has been well studied.[11] Chiral ligand **d** developed by Trost[12] was selected since it is one of the best ligands in the Pd(II)-catalyzed asymmetric reaction of 2-cyclopentenyl, -hexenyl, or -hepenyl acetate with the anion of dimethyl malonate.[13] The reaction was quite sensitive to the base and the solvent used. The best results were obtained when Cs_2CO_3 and dichloromethane were used as a base and a solvent, respectively.[13] Interestingly, substrates **5(2)** and **5(3)** were known not to be cyclized with (EBTHI)-$Ti(CO)_2$.[1] However, fairly high yields (89–97%) were obtained in our case. In the cyclization of **5(1)**, the reduced **7** was obtained as a byproduct provided the generated acetic acid was not removed. In contrast to the high yields, the ee values (31–94%) were quite sensitive to the ring size. As the ring size increases, the ee values decrease. A fairly high ee value of 94% was obtained for **6(1)**. The absolute configuration (3*R*,4*R*,5*S*) of the tricyclic enone **6(*n*)** was determined by comparison with the known reactions.[13] The fused tricyclic systems such as **6(1)** and **6(2)** had been used in the synthesis of natural products.[14]

In summary, we have demonstrated that the tandem action of a homogeneous chiral Pd(II) catalyst and a heterogeneous Co/C catalyst leads to a two-step one-pot highly enantioselective Pauson–Khand-type reaction. The enantiomeric purity of the product depends upon the optical purity of the *in situ* generated enyne. Further synthetic applications of the tandem action of two different catalysts in other reactions are now in progress.

A synthetic unsymmetrical 1-galactosamide bolaamphiphile self-assembles in methanol to form a multilayer structure comprising unsymmetrical monolayer lipid membranes linked *via* a sugar–carboxylic acid H-bonding interface.

Bolaamphiphiles having a hydrophilic group at each end are able to form monolayer lipid membrane (MLM) structures.[1,2] When the bolaamphiphiles are unsymmetrical with two headgroups of different sizes, the resulting MLMs are classified into two categories, 'unsymmetrical' and 'symmetrical', depending on a parallel or antiparallel molecular packing within the layer as shown in Fig. 1. In multilayer structures (such as in the crystalline state), a further two kinds of membrane stacking motifs can be defined depending on the interface between the two surfaces termed 'head-to-head' or 'head-to-tail' (with the larger of the two hydrophilic groups termed the 'head'). Since the dipole moment and spatial void arising from the bulky headgroup are best compensated by an antiparallel packing motif, most synthetic bolaamphiphiles exhibit this kind of packing in the solid phase[3] or (excepting a few examples)[4] form MLMs with random molecular orientation in the disperse phase.[1,5] Even in those cases where unsymmetrical MLMs are formed,[6] each membrane stacks with the head-to-head interface to give the multilayer structures for the same reason. Some attempts have been made to combat this tendency to form unsymmetrical MLMs by the introduction of the multiple H-bonding functional groups into both ends of an unsymmetrical bolaamphiphile.[7]

Recently, we have found that the bolaamphiphilic 1-glucosamide **2** or 1-galactosamide **3** self-assembled to form MLM-based structures in the crystal lattice *via* the formation of multiple sugar and amide H-bond networks,[8,9] with the stereochemistry of the sugar headgroups strongly affecting the intra- and interlayer H-bonding scheme. Our results suggested that similar unsymmetrical sugar-based bolaamphiphiles might be able to self-assemble to form an unsymmetrical MLM with a head-to-tail interface, forming multiple H-bonds between hetero surfaces. In this communication we report the crystal structure obtained from the synthetic unsymmetrical bolaamphiphile **1** having a 1-galactosamide headgroup at one end and a carboxylic acid group at the other (Scheme 1). This bolaamphiphile self-assembled in methanol to form an unsymmetrical MLM-based structure with the formation of intralayer H-bonds between the sugar headgroups and between amide groups. In addition, these MLMs stacked together with a head-to-tail interface directed *via* the formation of interlayer H-bonds between the 1-galactosamide hydroxy and carboxylic acid groups. To the best of our knowledge, only three crystal structures have so far been reported for unsymmetrical bolaamphiphiles with spacers longer than a decamethylene chain[3,6] and only one[6] forms an unsymmetrical MLMs-based structure with a head-to-head interface.

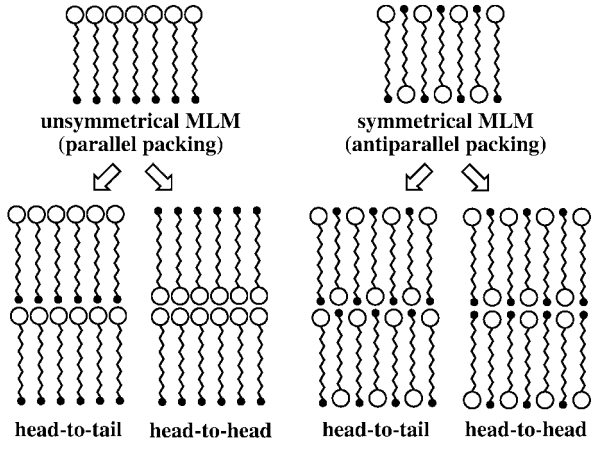

Fig. 1 Monolayer lipid membrane (MLM) formation from unsymmetrical bolaamphiphiles and resultant multilayer structures formed by the stacking of the MLMs.

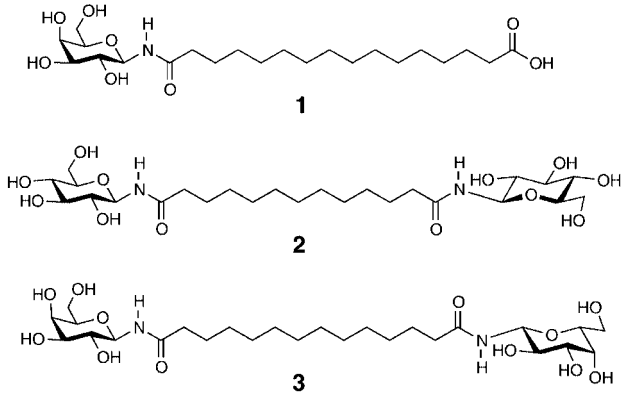

Scheme 1

Single crystals of the unsymmetrical bolaamphiphile **1** suitable for X-ray measurements† were obtained on cooling of a hot methanolic solution (6.1 g ml^{-1} at 40 °C) and the crystal structure is shown in Fig. 2. The bolaamphiphile **1** packed in the parallel arrangement to form the unsymmetrical MLM-based structure in the crystal, with the 1-galactosamide headgroups adopting the same $^4C_1$ chair conformation as reported previously for the symmetrical analogue **3**.[9] The alkylene chain adopts an all-*trans* zigzag conformation which has an inclination of 52° with respect to the normal to the layer plane, again in a similar fashion to that previously reported for the 1-glucosamide **2** and 1-galactosamide **3** bolaamphiphiles.[8,9] The two hydrophilic surfaces of the each unsymmetrical MLM arising from this parallel orientation, one comprising sugar and the other carboxylic acid groups, come into contact and form a complementary H-bonded interface along the *ac* plane.

Among the eleven H-bonds per molecule in crystals, intralayer H-bonds between the sugars and amides stabilize the parallel molecular arrangement within the unsymmetrical MLM structure, whilst interlayer H-bonds between the sugar hydroxy and the carboxylic acid groups stabilize the head-to-tail

 DOI: 10.1039/b106581p

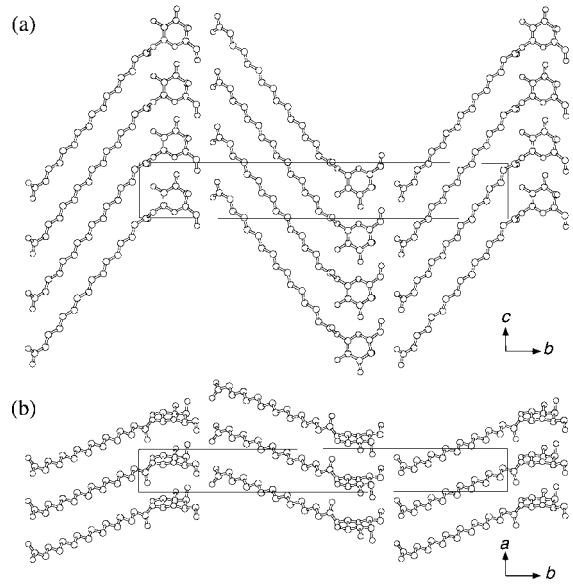

Fig. 2 Molecular packing of **1**, viewed along (a) the *a* axis and (b) the *c* axis. Hydrogen atoms have been omitted for clarity.

membrane interface as shown in Fig. 3. The intralayer H-bonding scheme of **1** exhibited '*N*'-type H-bonds (O-4···H–(O-6)···O-3···O-5) and amide H-bonds (O-2–H···O-7···H–N-1) similar to those characteristic of the pyranose headgroup with 1-amide group found in **2**.[8] The carboxylic and sugar hydroxy groups form interlayer H-bond arrays of O-8···H-O-4 and O-9-H···O-6 resulting in a finite H-bonded chain (O-8···H–O-4···H–O-6···H–O-9) which stabilizes the stacking of unsymmetrical MLMs at the head-to-tail interface. In general, carboxylic acids tend to form cyclic dimers with bifurcated H-bonds[2] and there have been so far very few examples of sugar–carboxylic acid H-bonds except for a carbohydrate-binding protein.[10] Since the axial O-4 hydroxy group seems to be buried under the hydrophilic surface, it forms H-bonds with the less bulky carboxylic acid to form a head-to-tail interface rather than the hydroxy groups of the 1-galactosamide which would give a head-to-head interface. This can be supported by the existence of clathrated water around the O-4 axial group for the head-to-head interface of the symmetrical 1-galactosamide **3**.[9] In contrast, no clathrated water can be found in the solid state structure of the 1-glucosamide **2**.[8] These results indicate that the predominant driving forces for the unsymmetrical MLM structure are the side-by-side aggregation of the 1-galactosamide headgroups *via* H-bond formation between the hydroxy groups and amides and a hydrophobic interaction between tetradecane spacers. The resultant unsymmetrical MLMs stack with a head-to-tail interface, forming H-bonding arrays between residual hydroxy groups of the 1-galactosamide and carboxylic acid groups.

***In-situ* deposited thin films of the conducting polymer poly-3,4-ethylenedioxythiophene (PEDOT) have been prepared on hydrophilic and hydrophobic substrates and characterized by UV–Vis spectroscopy, atomic force microscopy and resistivity measurements.**

Conducting polymers have been widely discussed for their potential applications in molecular electronics. The recent development of the highly conductive, stable, and transparent polythiophene derivative poly-3,4-ethylenedioxythiophene (PEDOT) by Jonas *et al.*[1] and its commercialization by Bayer Corp. ('Baytron M, C, P', Bayer Corp.) has resulted in multiple patents, suggesting a new era of electronics based on this class of organic compounds and their derivatives.[2] Even though thin films of various conducting polymers have been extensively studied, the reliable deposition of such films on different surfaces is a continuing challenge due to the poor solubility of many of these polymers in common solvents.[3]

Recently, high quality thin films of conducting polymers have been prepared on substrates by *in-situ* deposition of the polymer from a polymerizing solution of the monomer and an oxidant.[4,5] *In-situ* deposited films of polyaniline and polypyrrole have been shown to be applicable for electronic devices, *e.g.* liquid crystal displays[5] and capacitors.[6] Given the limited solubility of PEDOT, the *in-situ* deposition method would seem to provide an effective means of preparing high quality thin films of this new material. The enhanced transparency of PEDOT to visible wavelengths could lead to new transparent electronic and photonic devices.

Here we report the first example of PEDOT thin films *in-situ* deposited from an acetonitrile solution of the ethylenedioxythiophene (EDOT) monomer and iron(III) chloride oxidant. The PEDOT films, deposited on hydrophilic and hydrophobic substrates, are characterized by UV–Vis–NIR spectroscopy, surface resistivity and atomic force microscopy (AFM).[7]

Commercially available glass microscope slides were rinsed with deionized water and then dipped into a mixture of 100 ml concentrated sulfuric acid and 50 ml 30% hydrogen peroxide ('piranha solution') for 2 h. The fresh hydrophilic surfaces were thoroughly rinsed with deionized water, dried and stored under vacuum. Hydrophobic glass surfaces were obtained by immersing piranha solution-cleaned substrates in a 0.1 wt% solution of dodecyltrichlorosilane in hexane for 5 s, drying and storing under vacuum. Hydrophilic slides were then coated with a composition of 1 ml ethylene glycol and 6 ml 1.3 wt% water dispersion of poly-3,4-ethylenedioxythiophene–polystyrenesulfonic acid (PEDOT–PSS, 'Baytron P', Bayer Corp.) by a single roller application wetted by the PEDOT–PSS. The slides were then dried in a stream of hot air for 2 min to obtain PEDOT–PSS pre-coated substrates. Pieces of a polyethyleneterephtalate (PET) transparency film (Nashua xf-20, Nashua Corp., NH) were cut to the same size as the glass slides and used as substrates without further treatment.

Separate solutions of 0.1 M EDOT ('Baytron M', Bayer Corp.) and 0.2 M iron(III) chloride·$6H_2O$, were prepared in acetonitrile and stirred for at least 20 min until completely clear. In most solvents, EDOT does not polymerize or does so very slowly (*e.g.* water or tetrahydrofuran). Acetonitrile was found to be the only highly polar solvent allowing fast reaction.[8] Each of the four substrates (hydrophilic glass, hydrophobic glass, PEDOT–PSS pre-coated glass, and PET) was suspended in a beaker with 125 ml of the stirred EDOT solution. At room temperature, 125 ml of the $FeCl_3$ solution was added with gentle stirring. The clear solution darkened rapidly (< 20 s) as the oxidative polymerization began, Scheme 1. After 2, 5, 10, 15 and 20 min, one substrate of each type was removed from the polymerizing solution and immersed in de-ionized water for 30 min to stop polymerization and remove residual reactants and un-bound oligomers. These PEDOT covered substrates were dried under air at room temperature for 30 min.

The characteristic electronic transitions for PEDOT on the four different substrates after a 15 min *in-situ* deposition are shown in Fig. 1. Regardless of the substrate, all UV-Vis-NIR absorption spectra exhibit the same general shape with relatively sharp absorptions in the UV at 300–450 nm and an intense, broad absorption at longer wavelengths. The higher energy transitions can be assigned to n–π* transitions in the polymer backbone. The band starting at 700 nm has been described as the free carrier tail.[10] In general, the absorbance of the film increases as a function of the deposition time, indicating continuous growth of the film. This has also been observed for polypyrrole and polyaniline films where maximum absorbances were observed at deposition times of 10–20 min.[5]

Table 1 Surface resistivity in kΩ cm^{-2} of *in-situ* deposited PEDOT films as a function of substrate type and deposition time

	Deposition time [minutes]				
	2	5	10	15	20
Hydrophilic glass	—[a]	—[a]	4.95 ± 3.6	18.0 ± 4.5[b]	1.8 ± 1.0[b]
Hydrophobic glass	—[a]	—[a]	—[a]	90.0 ± 4.5[b]	4.5 ± 1.35
PET	—[a]	9000 ± 2250	8.1 ± 1.35	1.35 ± 0.18	0.945 ± 0.135
Pre-coated glass	18.0 ± 9.0[c]	1.8 ± 0.45	0.765 ± 0.135	0.585 ± 0.225	0.405 ± 0.045

[a] Measurement out of range (> 13,000 kΩ cm^{-2}).[b] Resistivity measured on extended spots (islands); the majority of the slide showed no measurable resistivity.[c] Initial value of the PEDOT–PSS coating.

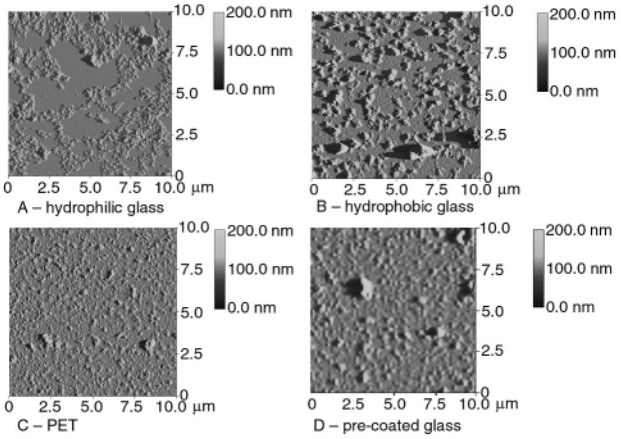

Fig. 2 Amplitude images of the surface morphology of PEDOT films on (A) hydrophilic, (B) hydrophobic, (C) PET, and (D) pre-coated glass substrates after 15 min *in-situ* deposition.

Although there is no significant shift in the spectra as a function of the substrate, there is a large difference in intensity. PEDOT on hydrophilic glass (A) shows the weakest absorption, suggesting the thinnest films, relative to the other three substrates. This result is consistent with the highly polar surface of the glass, which would be expected to interact weakly with the PEDOT polymer during deposition. In fact, following 20 min deposition cycles, the polymer was found to 'flake off' the surface. The three hydrophobic surfaces should facilitate deposition of a thicker, more uniform film, consistent with the absorption spectra (Fig. 1).

Shown in Table 1 are the resistivity values for each film–substrate combination obtained with a Pt 'four-in-line' probe with a constant current source and digital voltmeter.[11] In some cases insufficient surface coverage by PEDOT prevented resistivity determination. The lowest resistivity values were obtained for the PEDOT films *in-situ* deposited on PEDOT–PSS glass slides. A steady decrease of resistivity with increasing deposition time was observed on both PET and PEDOT–PSS pre-coated substrates, indicating continuous and stable film growth. This result is consistent with the stronger UV–Vis absorption for films grown on the pre-coated substrate.

Atomic Force Microscopy (AFM) in 'tapping mode' was used to analyze the surface morphology and film thickness of the *in-situ* deposited PEDOT thin films. Fig. 2 shows the different substrates after a 15 min *in-situ* deposition.

Deposition on hydrophilic glass (A) leads to islands of PEDOT, with only ~50% coverage of the glass surface. The average film thickness, determined by scoring the film with a razor to expose the underlying substrate, was found to be 50 ± 22 nm. In contrast, PEDOT on hydrophobic glass (B) exhibits larger grains, with film thickness of 118 nm ± 36 nm. The particulate nature of these *in-situ* deposited films contrasts with the successful 4-probe measurements on these two samples. While it is possible that a very thin (< 25 nm) surface layer of PEDOT exists, it is more likely that connectivity occurs through adjacent grains on the surface.

The deposition of PEDOT on PET (C) and PEDOT–PSS pre-coated glass (D) leads to uniform films of similar quality, as can be seen in Fig. 2. The thickness of the films deposited on pre-coated glass (D) was 228 ± 32 nm, whereas the thickness of the film on PET (C) could not be measured due to the softness of the plastic substrate. By comparison to the UV–Vis absorption spectra, both films are expected to be nearly the same thickness. PEDOT films on PET and on pre-coated glass showed moderate adhesion with respect to a 'Scotch-tape' test. Surface roughness of both films, calculated as the average variation in height across each sample, was ~60 nm.

In conclusion, we have successfully prepared thin, conducting films of PEDOT by the *in-situ* deposition method, bypassing common application problems associated with low polymer solubility. By varying the substrate on which the deposition occurs, we have identified the importance of surface hydrophobicity in obtaining uniform, highly conducting thin films. A simple and inexpensive method has been developed to reproducibly deposit highly conducting films of PEDOT with uniform thickness on organic substrates such as PET. Further it was observed that pre-coating insulating glass substrates with PEDOT–PSS resulted in highly conducting and uniform, ~230 nm thick films after only 15 min of deposition.

This work was financed jointly by the Office of Naval Research, the Army Resarch Office under the Multidisciplinary University Research Institute (MURI) program, and the National Institute of Health (Grant No. 1RI5ES10106-0).

A novel way to prepare ultra-thin polymer films through surface radical chain-transfer reaction

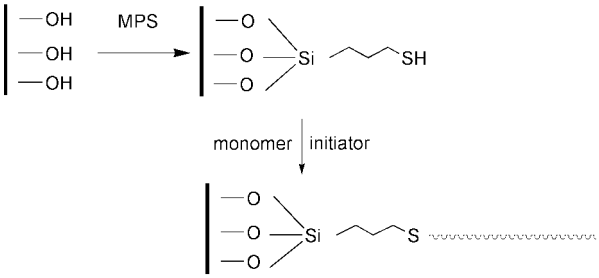
Radical chain transfer to bonded thiol groups and surface re-initiated polymerization resulted in ultra-thin polymer films.

In-situ grafting polymer films through surface initiated polymerization (SIP) from inorganic substrates are gaining increasing interest in recent years.[1] The key step is to introduce initiating points on substrates surfaces, which can be carried out through the assembly of self-assembly-initiators or the *in-situ* modification of end group functionalized surfaces by using self-assembling techniques.[2] Therefore, most polymerization techniques including conventional free radical polymerization,[3] 'living' radical polymerization based on 'iniferter',[4] 'TEMPO'[5] and 'ATRP',[6] ionic polymerization,[7] ROMP,[8] *etc*. have been realized on surfaces. However, most of these SIPs require the synthesis of self-assembly-initiator molecules with complex structures. Thus, the formation of initiating points on surfaces often involves many reaction steps. Radical chain-transfer reaction is widely used in molecular weight control, synthesis of end group functionalized polymers and macromonomers, *etc*.[9] and has once been used for the modification of solid substrates *via* the so-called radical transfer addition of olefin derivatives.[10] Here we report that it may also serve as the intermediate reaction for surface induced polymerization to fabricate covalently attached polymer films with the emphasis on planar substrates.

Surface bonded thiol groups were used as the radical chain transfer agents because of their relative high chain transfer constant. A widely used silane coupling reagent, mercaptopropyltrimethoxylsilane (MPS), was used to prepare thiol-terminated silica or silicon wafer (denoted as HS–silica and HS–silicon) according to the corresponding published procedures[11] using toluene as the solvent. The grafting amount of MPS on silica surface (S_{BET}, 250 $m^2\ g^{-1}$) was about 0.9 mmol g^{-1} from elemental analysis. HS–silicon had a water contact angle of 70°, which indicated a complete coverage of thiol-terminated monolayer. *In-situ* polymerization was carried out in a 20 ml mixture of methyl methacrylate (MMA), azodiisobutylnitrile (AIBN) as the initiator and toluene at 60 °C for a certain time in the presence of HS–silica or HS–silicon. The molar ratio of MMA : AIBN (100 : 1) and the volume ratio of MMA : toluene (1 : 2) were kept constant. The thiol terminated silica or silicon wafers and the polymer film modified silica/silicon (denoted as polymer-silica or polymer-silicon) were extracted with CH_2Cl_2 to ensure the removal of all unbonded species. The basic strategy of this novel process is depicted in Scheme 1.

The obvious Raman shift at 2577 cm^{-1} for HS–silica was attributed to the stretching vibration of S–H (Fig. 1a). After polymerization, its intensity decreased dramatically but still could be detected, indicating that radical chain transfer to (a part of, but not all) thiol groups occurred. The other absorbance bands characteristic of PMMA proved that MMA was grafted onto silica surface. The normalized transmittance FTIR of HS–silicon, PMMA–silicon and spin-cast PMMA film as a control for the selected region between 3200 and 1500cm^{-1} also indicated that a layer of PMMA was formed on silicon wafer (Fig. 1b).



Scheme 1 Reaction procedures of *in-situ* grafting polymer film through radical chain transfer reaction.

The role of silica-carried thiol groups as the potential chain-transfer agents was verified by measuring the molecular weight of the free polymers formed simultaneously in the bulk solution. As is shown in Fig. 2, increasing the amount of HS–silica

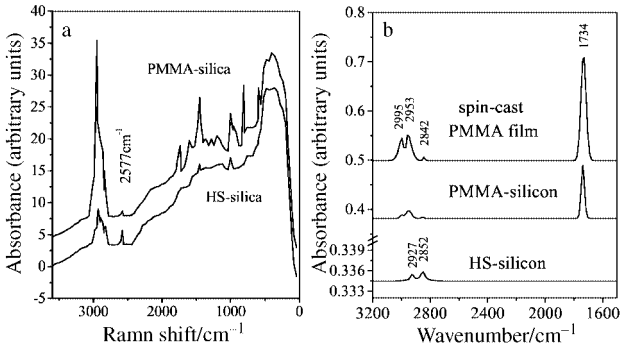


Fig. 1 (a) Raman spectra of HS–silica, PMMA–silica and (b) normalized transmittance FTIR of HS–silicon, PMMA–silicon as well as spin-cast PMMA film.

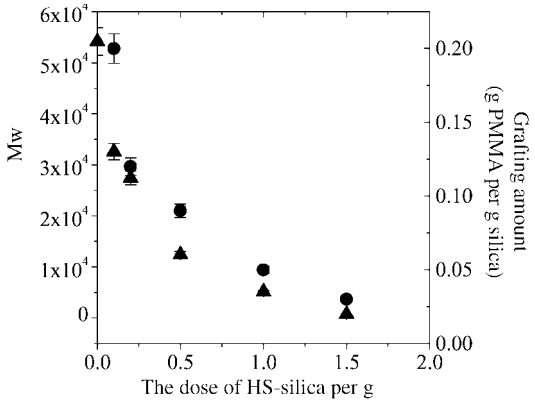

Fig. 2 Weight average molecular weight (▲) of free PMMA and the grafting amount (●) of PMMA *versus* the dose of HS–silica.

 DOI: 10.1039/b107831n

reduced the weight-average molecular weight of the free polymer. The results confirmed that silica-carried thiol groups played a similar role as the other thiol compounds, of being effective chain-transfer agents in polymerization. The grafting amount[12] of polymer also decreased with increasing the dose of HS–silica, closely resembling the variation of the molecular weight of the free polymer.

Our hypothesized reaction procedures were also confirmed by XPS. After polymerization of MMA for 24 h on silicon wafers, no peaks characteristic of Si_{2p} and S_{2p} were detected. This indicated that the substrate was completely covered by a polymer layer of at least 5 nm. (In fact, the film thickness was about 27 nm.) But this is not the case with the silica surface. The evaluation[13] of the film thickness from the attenuation of Si_{2p} of PMMA–silica (even the sample having the maximum grafting amount in Fig. 2) showed a very thin polymer film of less than 2 nm. We attributed the ineffectiveness of the method on silica surfaces, against that on silicon wafers, to the different rate of termination. Propagating chains on silica surfaces were easily formed and simultaneously terminated by the chain transfer reaction because of the relatively high contents of thiol groups in polymerization systems and also the mobility of silica-carried thiol groups. But on planar substrates, the possibility of radical chain transfer could be reduced because of the two-dimension restriction of thiol groups and also the absence of effective chain transfer agents in bulk solution, which made the propagating chains on planar substrates less likely to be terminated.

Grafting polymerization on silicon wafers was found to occur during the first two hours, resulting in more than 90% of the thickness obtained with 24 h of polymerization time. The contact mode AFM topography of a 27 nm thick PMMA film revealed a homogeneous and smooth polymer film with an rms roughness of 0.207 nm.

The advantage of this method was its capability to realize polymerization of a wide range of monomers in both non-aqueous and aqueous solutions. Table 1 lists several examples of the obtained polymer films and the corresponding contact angles and film thicknesses. We aimed to fabricate surfaces with different lypohydrophilic characters by co-polymerization of monomer pairs using different molar ratios. Fig. 3 shows that the method was effective. By simply varying the composition of the monomer pairs, the wetting behavior of the resulting copolymer films could be changed in a highly controlled fashion. Therefore, radical chain transfer reaction and surface re-initiated polymerization provides a means to control the physical properties of polymer films.

In conclusion, we have demonstrated for the first time that (1) radical chain transfer to thiol-terminated self-assembled monolayer and (2) surface re-initiated radical polymerization on both silica surface and silicon wafers truly occurred and ultra-thin polymer films with nanometer dimensions resulted. The method is a new addition to SIP, applicable to the polymerization of a wide range of monomers (especially functionalized monomers) and workable in situations where other SIPs are inconvenient to use. The method has potential applications in tailoring the chromatographic properties of solid supports, enhancing the biocompatibility of substrate surfaces, lubricating microelectromechanical systems (MEMS), the chemical modification of electrodes, *etc*.

Table 1 The static contact angles of water and thicknesses of the obtained polymer films

Film	Solvent	Contact angle	Thickness (Å)
PMMA	Toluene	70	274
PSt	Toluene	90	225
PTDMA	Toluene	94	62
PBuA	Toluene	96	134

Dissociative cycloelimination, a new selenium based pericyclic reaction

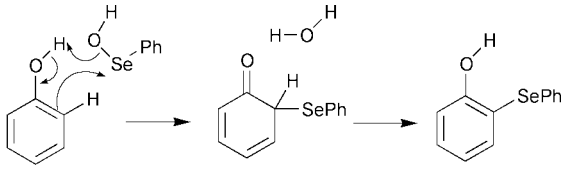
Lars Henriksen* and Søren Jakobsen

Department of Chemistry, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark. E-mail: larsh@kiku.dk

Received (in Cambridge, UK) 24th August 2001, Accepted 19th October 2001
First published as an Advance Article on the web 13th November 2001

The stereospecific oxidation of hydrazine into *cis*-diimide and the catalytic disproportionation of hydrogen peroxide effected by selenoxides are suggested to involve a dissociative cycloelimination from an intermediary selenurane.

One consequence of the high polarizability of the selenium nucleus is the occurrence under mild conditions of pericyclic reactions involving selenium. Three reactions of this type, *i.e.* the [2,3]-sigmatropic shift,[1] the ene-reaction[2] and the cycloelimination,[3] were described shortly after the recognition of the concept of pericyclic reactions. More recently[4] we have found evidence for a dissociative analogue of the ene-reaction (Scheme 1) in the *ortho*-specific substitution in phenols effected by neutral benzeneselenenic acid (while more reactive phenylselenenium ion equivalents attacks a variety of donor-activated aromats with high *para*-selectivity).[5] In consequence, a dissociative analogue of the cycloelimination reaction might also be feasible. The selenuranes formed from a selenoxide and a nucleophile having a labile hydrogen atom in a vicinal position, *e.g.* hydrogen peroxide, hydrazines and hydroxylamines, are the most obvious substrates for this type of reaction (Scheme 2). In fact, all three types of compound react with selenoxides at ambient temperature. The present paper discusses the evidence for a dissociative cycloelimination step in the reactions of phenyl methyl selenoxide (**1a**) and phenyl anisyl selenoxide (**1b**)[6] with hydrazine and hydrogen peroxide as substrates.

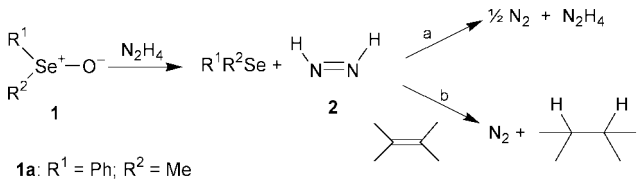


Scheme 1

The reaction of hydrazine with a variety of oxidants has been shown to proceed *via* diimide (**2**) which exists in *cis* and *trans* isomeric forms with a high barrier for interconversion. Only the thermodynamically less stable *cis*-**2** can transfer a pair of hydrogen atoms to a double bond through a pericyclic transition state. Therefore exhaustive alkene hydrogenation with **2** normally requires a large excess of hydrazine and oxidant. (See ref. 7 for a review of diimide chemistry.) Only one previous example of the specific generation of *cis*-**2** has appeared.[8]

Since the dissociative cycloelimination path (Scheme 2, Y = Z = NH) predicts a stereospecific formation of *cis*-**2**, the hydrazine oxidation furnishes a test of our hypothesis. We found that the reaction of **1a** with hydrazine in methanol (Scheme 3) produced 1 mol of N_2 per 2 moles of selenoxide (path **a**) while the same reaction in the presence of an excess of alkene (prop-2-en-1-ol) gave 1 mol of N_2 per mol of selenoxide

Scheme 2

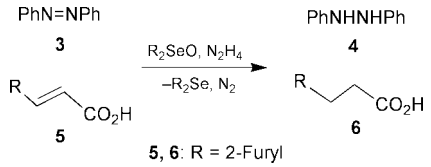


1a: R^1 = Ph; R^2 = Me
1b: R_1 = Ph; R_2 = 4-MeOC$_6$H$_4$

Scheme 3

(path **b**). The observed quantitative transfer of hydrogen to the alkene shows that *cis*-**2** is produced specifically. The rate of evolution of nitrogen does not follow a simple reaction order but is approximately constant during the first 60% of the reaction indicating the presence of an intermediate, presumably **2**, at a steady-state concentration. Plots of the reaction fraction against time for cases **a** and **b** are almost superimposable, showing that the bimolecular disporportionation of **2** into hydrazine and dinitrogen is fast even at a very low concentration.

The preparative use of *cis*-**2** generated by the hydrazine–selenoxide reaction is illustrated by the examples shown in Scheme 4. The reaction of **1a** (2.3 mmol) and hydrazine hydrate (5 mmol) with azobenzene (**3**) (2.1 mmol) in ethanol (3 ml) at 300 K gave complete decolourisation in 14 min. 1,2-Diphenylhydrazine (**4**) (93%) was isolated from the reaction mixture. This result confirms the specific formation of *cis*-**2**. It further demonstrates that a nucleophilic addition to the selenoxide precedes the elimination step. While **4** is very readily oxidized and is, in fact, slowly converted into **3** by selenoxides it is not sufficiently nucleophilic to compete with hydrazine in the initial addition step. The conversion of 3-(2-furyl)propenoic acid (**5**) into 3-(2-furyl)propanoic acid (**6**) with **1** and **5** in the molar ratio 1 : 1 is included as a model for the reduction of a less reactive hydrogen acceptor. In this case the reduction yields increase with an increasing reaction period (Table 1) in accord with a disproportionation (second order in **2**) competing with the hydrogen transfer to the alkene (first order in **2**). The rate of diimide generation qualitatively displays the same dependence



5, **6**: R = 2-Furyl

Scheme 4

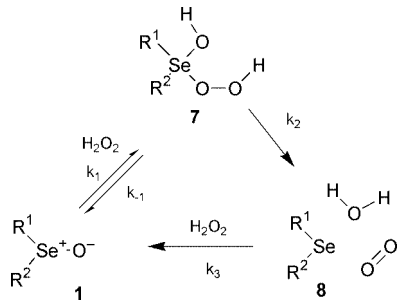
upon the identity of **1** and the solvent composition as found in the hydrogen peroxide reaction (see later). It may thus be regulated by varying the identity of the selenoxide and/or changing the composition of the medium to suit the hydrogenation of alkenes with varying reactivities.

Since the kinetics of the hydrazine oxidation are not simple we turned to the reaction of **1** with hydrogen peroxide in order to obtain additional information on the medium dependence of the addition–cycloelimination sequence. It has been reported[9] that hydrogen peroxide is disproportionated into water and dioxygen with selenoxides as catalysts. We suggest that the catalytic cycle involves a reversible addition of hydrogen peroxide to **1** with formation of selenurane (**7**), a cycloelimination giving dioxygen and selenide (**8**) and a reoxidation step (Scheme 5). This sequence is supported by the observation[10] that *tert*-butyl hydroperoxide lacking the vicinal hydrogen atom necessary for the elimination does not give a similar reaction and by our observation that **8** is present in the reaction mixtures at steady-state concentrations depending on the identity of the medium. The rate of oxygen evolution is first order in hydrogen peroxide with an apparent rate constant proportional to the concentration of the selenoxide. Some representative second order rate constants are given in Table 2. This type of kinetics can be reconciled with either of three situations: (i) rate determining addition to give **7** (k_1); (ii) rate determining elimination to give **8** (k_2) preceded by the formation of **7** in a rapid equilibrium, (iii) rate determining reoxidation to **1** (k_3). The three steps appear to have comparable rates and depending upon the medium either one may be rate determining. The concentration of **8** is very low in neutral or acidic methanol showing that k_3 cannot be rate determining. Addition of triethylamine gives an unchanged initial rate which subsequently falls off to about one third. At the latter stage ^{77}Se NMR shows **8** and **1** in the approximate ratio 2:1 thus indicating a slow reoxidation. The reaction of **1b** in methanol is acid catalysed while that of **1a** is not. This indicates a rate determining addition step for **1b**, at least in the absence of acid, in accord with the report that the racemization of optically active **1b**, assumed to occur by reversible selenurane formation, requires acid catalysis[6] while **1a** is racemized by water alone.[11,12]



Scheme 5

Table 2 Second order rate constants[a] (10^2 k/s^{-1} M^{-1} = 10^2 k_{obs} [**1**]$^{-1}$) for the selenoxide catalyzed decomposition of hydrogen peroxide at 300 K

Selenoxide	**1a**		**1b**	
Conditions	Neutral	4M AcOH	Neutral	4M AcOH
Solvent:				
94% MeOH	3.7	3.7	0.60	5.2
80% MeOH	1.5	1.7	0.43	1.5
60% MeOH	0.5	0.5	0.18	0.55
96% THF	2.0	5.8	0.36	0.95
90% THF	2.0	4.2		0.50
84% THF	2.0	3.2		

[a] Reproducibility ± 20%.

In THF the reactions of both **1a** and **1b** are acid catalysed. This is hardly surprising. The formation of **7** is not an elementary process but also involves a proton transfer step which requires a proton donating component in the medium. Two observations suggest that the elimination step may be rate determining at high reaction rates. The reactions of **1a** in neutral and **1a** and **1b** in acidic methanol are more strongly inhibited by water than the reactions of **1b** in neutral methanol and **1a** in THF. Moreover, the order of reactivities **1a**:**1b** is reversed in acidic 94% methanol.

While the three-stage mechanism of hydrogen peroxide decomposition seems established it cannot in the absence of stereochemical information be finally shown that the elimination step is pericyclic. However, the observation that triethylamine does not increase the initial rate in the reaction of **1a** is a strong argument against an acyclic, base or solvent assisted reaction. The dissociative cycloelimination step calls for the oxygen molecule to be produced in the singlet state. We were unable to detect oxygen consumption by singlet oxygen acceptors such as furanes. However, this cannot be taken as an argument against the pericyclic reaction. The oxygen molecule is generated in a solvent cage together with a molecule of **8** which, in analogy with diethyl sulfide[13] is expected to be a powerful quenching agent for singlet oxygen.

In conclusion, a dissociative cycloelimination reaction is indicated by the stereospecific oxidation of hydrazine with **1** to give *cis*-**2**. The same mechanism is compatible with the features of the selenoxide (or selenide) catalysed disproportionation of hydrogen peroxide in which case the disproportionation releases no reactive intermediates into the reaction medium, a feature of possible interest in selenium biochemistry.

Regiocontrolled deprotonative-zincation of bromopyridines using aminozincates

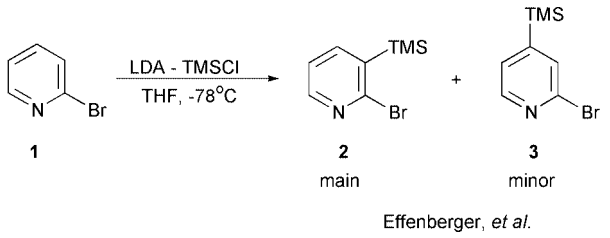
Tatsushi Imahori, Masanobu Uchiyama, Takao Sakamoto and Yoshinori Kondo*

Graduate School of Pharmaceutical Sciences, Tohoku University, Aobayama, Aoba-ku, Sendai 980-8578, Japan. E-mail: ykondo@mail.pharm.tohoku.ac.jp

Received (in Cambridge, UK) 11th September 2001, Accepted 19th October 2001
First published as an Advance Article on the web 13th November 2001

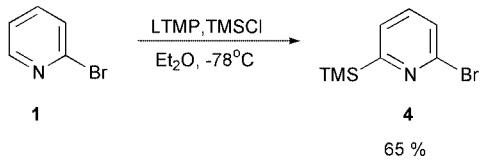
Regiochemistry in the deprotonation of bromopyridines was found to be greatly influenced by the choice of metal amide base, and DA-zincate and TMP-zincate turned out to be excellent complementary practical agents for regioselective metalation of bromopyridines.

Deprotonative metalation has been widely used as a facile method for regioselective functionalization of various aromatic compounds.[1] Regioselective metalation has also been important in pyridine chemistry and pyridine derivatives have been employed as attractive functional molecules for supramolecular chemistry.[2] Much work has been done on selective lithiation using lithium diisopropylamide (LDA) and other bases,[3] including investigations by Effenberger and co-workers who reported that the lithiation of 2-bromopyridine proceeds mainly at the 3-position together with partial lithiation at the 4-position using LDA in THF at −78 °C. These lithiospecies were trapped by trimethylsilyl chloride using an *in situ* method (Scheme 1).[4]



Scheme 1

In order to investigate regiochemistry in the deprotonative metalation of pyridine, we screened metalating agents and solvents in the lithiation of 2-bromopyridine. To our surprise, when we carried out the reaction of 2-bromopyridine (**1**) with LTMP and TMSCl using an *in situ* method at −78 °C in Et_2O, the 6-TMS derivative (**4**) was obtained exclusively in 65% yield (Scheme 2). Related to this unique regioselectivity, Fort and co-workers recently reported a unique selective lithiation at the 6-position of 2-chloropyridine or 2-methoxypyridine using a n-BuLi and lithium dimethylaminoethoxide mixed reagent in hexane;[5] however their method is considered to be difficult to apply to the lithiation of 2-bromopyridine due to the likely competition with the bromine–lithium exchange reaction. To the best of our knowledge, the reaction described above is the first example of the regioselective deprotonative-lithiation of 2-bromopyridine at the 6-position. This complete reversal of the regioselectivity by changing only the amide base and solvent (LDA in THF *vs.* LTMP in Et_2O) is noteworthy.



Scheme 2

In some cases, pyridinyllithiums with a bromo substituent are known to be unstable due to the formation of pyridyne,[4b,6] lithium migration[7] and so on. In order to overcome these side reactions, the *in situ* method is effective by the existence of an electrophile in the metalation process, but the range of electrophiles has been limited. We therefore focused our interest on the use of organozincate chemistry in the metalation of bromopyridines, seeking a wider scope of direct functionalization. We recently disclosed that TMP-zincate is a highly chemoselective base for aromatic metalation in the presence of electrophilic substituents such as alkoxycarbonyl or cyano groups and that it has also been found to be effective for α-metalation of N-heteroaromatics[8] in connection with our recent studies on selective aromatic metalation.[9]

Intrigued by the above result on regioselective lithiation, we turned our interest to the selective zincation of bromopyridines using TMP-zincate (lithium di-*tert*-butyltetramethylpiperidinozincate) and DA-zincate (lithium di-*tert*-butyldiisopropylaminozincate). The reaction of 2-bromopyridine (**1**) with TMP-zincate in Et_2O proceeded at room temperature and treatment with I_2 gave 2-bromo-6-iodopyridine (**6**) in 86% yield together with a trace amount of 2-bromo-3-iodopyridine (**8**). In contrast, when DA-zincate was employed as a metalating agent and the reaction was carried out at −20 °C, the metalation proceeded at the 3-position preferentially and 2-bromo-3-iodopyridine (**8**) was obtained in 72% avoiding the formation of 2,3-pyridyne (Scheme 3). The intermediary bromopyridinylzincates **5** and **7** are relatively stable under those reaction conditions, and thus the selective conversion without side reactions to the corresponding bromoiodides was achieved.

The zincation of 3-bromopyridine was also examined and it was found that TMP-zincate and DA-zincate show completely different regioselectivity (Scheme 4). Namely, the reaction of 3-bromopyridine (**9**) with TMP-zincate in THF at room temperature proceeded at the 2-position exclusively and treatment with I_2 gave 3-bromo-2-iodopyridine (**11**) in 68% yield, whereas the zincation of **9** with DA-zincate occurred predominantly at the 4-position and treatment with I_2 gave 3-bromo- 4-iodopyridine (**13**) in 66% yield together with a trace amount of **11**. It is noteworthy that these results suggest that the pyridinylzincates **10** and **12** cause no formation of pyridyne[4b,6] throughout the reactions, even at room temperature.

Limited examples of the preparation of these bromoiodopyridines using conventional methods are known but they sometimes require tricky steps or multi steps and particularly no report on the preparation of 2-bromo-6-iodopyridine from 2-bromopyridine has appeared so far.[10] The present regioselective zincation is considered to provide a new effective direct methodology.

In summary, regiocontrolled deprotonative metalation of pyridine was achieved with excellent regioselectivity by choosing one of the tunable aminozincates, and highly regioselective transformation of bromopyridines was accomplished. Further studies are underway for understanding the origin of the regioselectivity by the change of amide bases[11] and

also for applying the methodology for the preparation of unique functional molecules using new carbon–carbon bond forming reactions.

Received (in Cambridge, UK) 30th August 2001, Accepted 22nd October 2001
First published as an Advance Article on the web 7th November 2001

An ionophore assisted metal-ion transport across block copolymer membranes has been used to control the local Ca^{2+} concentration during precipitation of calcium phosphate in giant block copolymer vesicles.

The controlled formation of inorganic minerals within organic or polymeric matrices is successfully used by nature to design biological composite materials such as bone or teeth.[1] Many of the mineralized tissues formed by organisms have superior mechanical properties. Therefore it has been tempting for a long time to mimic their design principles during fabrication of synthetic (so-called 'biomimetic') materials. Although the detailed mechanisms of biomineralization are still not clarified various models have been suggested that increase our understanding of these biological processes.[2] A key step in the control of mineralization employed by almost all organisms is an initial allotment of space. This is usually achieved by cellular membranes, predeposited macromolecular matrix frameworks or vesicles. Subsequently minerals are precipitated under controlled conditions within the individual compartments. Vesicular structures are one of the most investigated *in vitro* templates in biomimetic mineralization. Furthermore they also play a crucial role in biological processes such as epiphyseal cartilage or embryonic bone growth.[1] Phospholipid vesicles have been successfully used to mineralize and precipitate inorganic solids, such as *e.g.* calcium phosphate[3] or iron oxide[4] within their interior.

Ion transport across the membranes of lipid vesicles can be controlled by lipophilic ion carriers. This allows control of the local ion concentration inside the vesicles during mineralization.[5] Similar to biological systems, also during biomimetic mineralization, specific interactions between the matrix forming material and the crystal planes of the growing nuclei are of crucial importance[6] for the structure and morphology of the newly formed minerals. The high diversity of block copolymer chemistry (*i.e.*, the ease to modify their chemical constitution or attach certain functionalities) makes the self assembled superstructures of amphiphilic block copolymers ideally suited as templates for biomimetic mineralization.[7] Recently we could show that even membrane proteins can be functionally reconstituted in block copolymer membranes.[8] Similar to nature, such membrane proteins could potentially be used to tune, for example, the interactions between the matrix and minerals or to control the local ion concentration during precipitation in block copolymer vesicles. The latter could be achieved by incorporating ion carriers or specific ion channels or pumps into the membrane. As a preliminary example of this, we report here on ion carrier-assisted precipitation of calcium phosphate in giant poly(2-methyloxazoline)–poly(dimethylsiloxane)–poly(2-methyloxazoline) (PMOXA–PDMS–PMOXA)[9] triblock copolymer vesicles. In this work, phosphate anions are encapsulated within the vesicles during their formation. Since the Ca^{2+} ions from the external solution are not able to permeate the triblock copolymer membranes, precipitation of calcium phosphate in the vesicle interior requires a transport system (see Fig. 1 for a schematic representation). As representative model systems we used three different ionophores that should enable selective or unselective calcium transport from the bulk medium into the intravesicular space. Lasalocid A (X537A, from Fluka)[10] and *N*,*N*-dicyclohexyl-*N*′,*N*′-dioctadecyl-3-oxapentane-1,5-diamide (ETH5234, from Buchs)[11] transport cations *via* a carrier mechanism, where the former shows no specific selectivity and the latter is highly selective for calcium ions. Alamethicin (U22324, from Sigma)[12] is a channel forming peptide that transports cations and anions unselectively.

To facilitate observation of the precipitated calcium phophate we used giant unilamellar PMOXA–PDMS–PMOXA triblock copolymer vesicles prepared by electro-formation. Here, usually a thin film of polymer is phoresed from conductive glasses or adjactent platinum electrodes by an alternating current into the aqueous solution.[13] To obtain giant vesicles in higher yields we used a slightly modified set-up based on a two-electrode cell that had originally been designed for EPR studies.[14] The cell consists of a helically wound (0.5 mm diameter) gold wire electrode and a 0.5 mm diameter straight platinum wire supported by two Teflon holders. 2 ml (concentration: 10 g L^{-1} polymer) of a chloroformic PMOXA–PDMS–PMOXA solution was sprayed onto the gold electrode and the polymer formed a thin film which was dried by blowing a stream of nitrogen over the wire for about 1 min. Afterwards the electrodes were immersed in 2.2 ml phosphate buffer (50 mM K_3PO_4, 10 mM Hepes, 10 mM KCl; pH adjusted to 7.4 with KOH). Giant vesicles were prepared by applying an ac voltage of 5 V at a frequency of 10 Hz for 2 h followed by 30 min at 5 V and 5 Hz. Phase contrast microscopy investigations indicated that the resulting dispersion contained giant vesicles with diameters between 1 and 2 μm in a very high density. Subsequently non-encapsulated phosphate ions can be removed by dialysis against buffer solution (10 mM Hepes, 110 mM KCl, pH = 7.4). After addition of 2 ml of a calcium chloride solution (50 mM $CaCl_2$, 10 mM Hepes, 35 mM KCl; pH adjusted to 7.4 with KOH) the sample was divided into four aliquots of 1 ml. The first aliquot was mixed with 18 μl of a U22324 solution (1.28 mM in ethanol), the second with 18 μl of an X537A solution (0.44 mM in ethanol) and the third with 18 μl of an ETH5234 solution (0.41 mM in ethanol). As a control experiment we added 18 μl

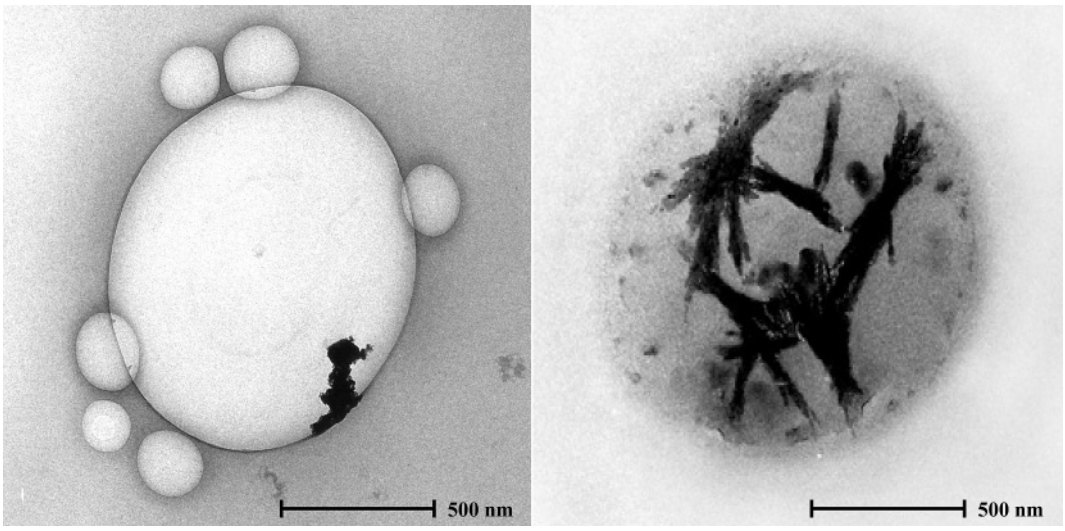

Fig. 2 Transmission electron micrograph of phosphate loaded PMOXA–PDMS–PMOXA triblock copolymer giant vesicles after 1 (left) and 24 h (right) of incubation with $CaCl_2$-solution in the presence of the ion carrier ionophore U22324.

of pure ethanol to the fourth aliquot. All samples were incubated at 4 °C and investigated after 1 and 24 h by transmission electron microscopy. To avoid rupturing of the vesicles the samples were kept in a hydrated state during the preparation procedure. In the control experiment without ionophore no precipitation of calcium phosphate occurred. This is in contrast to observations with any of the three used ionophores in which formation of crystals could be observed within the vesicular structures. This clearly shows that the ionophores play a crucial role for the transport of Ca^{2+} ions across the polymer membranes. Fig. 2 shows a representative transmission electron micrograph of phosphate containing triblock copolymer vesicles after 1 and 24 h of incubation with $CaCl_2$-solution in the presence of U22324. As can directly be seen already after only 1 h calcium phosphate crystals start to grow at the inner surface of the polymer membrane. After 24 h a considerable fraction of the vesicle interior is filled with needle-like calcium phosphate crystals. Longer incubation times did not lead any detectable further growth of the crystals. Obviously after 24 h the encapsulated phosphate ions have already been consumed. This is also reflected by the fact that the volume of the minerals was always in reasonable agreement with the starting concentration of phosphate in the vesicle. Moreover, the inorganic crystals are clearly confined to the inner cavity of the vesicles thus indicating that crystal growth is limited by the shells of the block copolymer vesicles.

In conclusion, we have successfully applied ionophores to control ion concentration within ABA triblock copolymer vesicles during mineralization of calcium phosphate. Although the ionophores are still rather simple ′vehicles′ to transport ions across polymer membranes we believe that the concept of combining artificial block copolymer membranes with natural membrane proteins holds great potential for biomimetic mineralization.

The possibility to incorporate additional design criteria to the block copolymers is straightforward, *e.g.*, functional groups that lead to special surface characteristics of the resulting vesicles which could be used to control the morphology of the resulting minerals. In this context it is also interesting to note that nature provides many more specific, unspecific and ligand gated channels or pumps (that can additionally be genetically modified!) which can be reconstituted in block copolymer superstructures thus providing a unique tool to control the permeation of ions across polymer membranes. Moreover, the resulting combination of the enormous mechanical stability of block copolymer aggregates with the specifity and efficiency of naturally occurring membrane proteins could even be a helpful tool to get a closer insight into the principles of biomineralization.

A composite catalyst comprising a physical mixture of a zeolite and a cobalt/manganese oxide Fischer–Tropsch catalyst decreases the formation of methane in the hydrogenation of carbon monoxide without significantly affecting conversion.

The Fischer–Tropsch synthesis, in which carbon monoxide is hydrogenated to linear C_{2+} hydrocarbons, continues to attract considerable research attention.[1,2] Part of this revival in interest has been due to the commercialisation of the Shell Middle Distillate Synthesis in Malaysia in 1993,[3] as well as the recent interest in the use of air blown methane partial oxidation technology which eliminates the requirement for pure oxygen in the overall process.[4] However, the main interest concerns the utilisation of remote natural gas reserves using the Fischer–Tropsch synthesis as a liquefaction process. In this process, methane is partially oxidised to CO + H_2 which is then converted to liquid hydrocarbons.[1,2] It is essential that the yield of methane, which can be a significant by-product in the Fischer–Tropsch synthesis, is minimised. Previously, catalysts that favour carbon–carbon bond formation have been preferred for minimisation of methane, but the products produced are typically waxes which require further processing.[1–3] Use of chain limiting Fischer–Tropsch catalysts,[1,5,6] *e.g.* Fe/MnO or Co/MnO, can produce liquid hydrocarbons with decreased methane formation and, in particular, the Co/MnO catalyst gives propene as the major product. Previously, many studies[7–10] have attempted to modify the product distribution of Fischer–Tropsch catalysts by supporting them on zeolites, but this approach did not lead to a marked decrease in methane yields, and most emphasis has concerned the synthesis of C_{6+} products. In these earlier studies, the catalysts were typically prepared by impregnation of the zeolite and the use of a composite of the zeolite with a chain limiting Fischer–Tropsch catalyst as a simple physical mixture has been largely neglected. We have now addressed this type of catalyst and, surprisingly, we have observed that methane formation is significantly decreased with the composite catalyst Co/MnO:H-ZSM-5. Furthermore, we show the active sites present in the composite catalyst can be formed reversibly, indicating that new catalyst sites are formed at the interface between the zeolite and Co/MnO particles.

Carbon monoxide hydrogenation (CO:H_2 = 1:1 mol ratio) was investigated using a Co/MnO catalyst (Co:Mn = 1:1, prepared by coprecipitation[5]) physically mixed with boron nitride (Co/MnO:BN = 1:1 by wt) using a standard laboratory microreactor operating at atmospheric pressure. Under these reaction conditions (Table 1, experiment 1) the formation of methane as a by-product is the preferred reaction. No reaction was observed for CO hydrogenation over boron nitride or H-ZSM-5 in the absence of Co/MnO. The catalyst performance was found to be stable for ≥100 h time-on-stream. In a subsequent experiment (Table 1, experiment 2), a physical mixture of pellets (600–1000 μm) of Co/MnO and zeolite H-ZSM-5 (Si:Al ratio = 80) was tested under identical reaction conditions and it is apparent that the selectivity of methane is decreased by a factor of 2, without any significant effect on conversion being observed. Use of the sodium-exchanged form of zeolite (Table 1, experiment 3) also decreased the selectivity to methane but, in this case, the conversion of carbon monoxide was significantly decreased. Use of zeolite H-ZSM-5 with a higher concentration of acid sites (Si:Al = 30) also showed decreased methane formation (Table 1, experiment 4). Interestingly, a physical mixture of Co/MnO with silicalite (the aluminium-free form of ZSM-5) did not give any marked reduction in the formation of methane (Table 1, experiment 5). This indicates that the acidity of the zeolite is an important factor with respect to the reduction in methane formation. Similar effects of decreased methane formation were observed when the Co/MnO catalyst was mixed as a physical mixture with zeolite β and, to a lesser extent, with zeolite Y (Table 1, experiments 6 and 7). This indicates the effect can be observed with several zeolites.

In a subsequent set of experiments, we demonstrate that the active sites responsible for the decreased methane formation can be produced reversibly. In this experiment, a physical mixture of pellets of the Co/MnO catalyst (600–1000 μm) with zeolite H-ZSM-5 powder (Si/Al = 80) were reacted for *ca.* 100 h and the product selectivities by carbon number are given in Fig. 1. Following reaction, the catalyst was cooled in dry N_2 and the

[a] *Reaction conditions*: 206 °C, CO : H_2 = 1 : 1 mol ratio, GHSV = 4400 h^{-1}, P = 2.2 MPa.

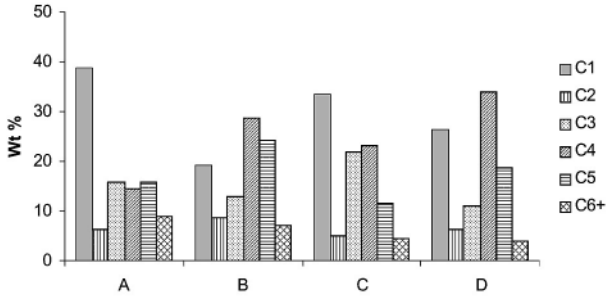

Fig. 1 Selectivity for C_1–C_{6+} hydrocarbons for the hydrogenation of CO. (a) Co/MnO : BN (1 : 1 by wt) physical mixture, (b) Co/MnO:H-ZSM-5 (Si/Al = 80, 1 : 1 by wt) physical mixture, (c) Co/MnO recovered by sieving following experiment (b) mixed with fresh boron nitride as physical mixture (1 : 1 by wt), (d) Co/MnO recovered by sieving following experiment (c) mixed with fresh H-ZSM-5 (Si/Al = 80) as physical mixture (1 : 1 by wt). Reaction conditions: 206 °C, CO = H_2 = 1 : 1 mol ratio, GHSV = 200 h^{-1}, 101 kPa.

Co/MnO catalyst was separated by sieving from the H-ZSM-5 and the catalyst was tested again for CO hydrogenation following mixing with boron nitride powder (1 : 1 physical mixture) and it is clear that, in the absence of the zeolite, the methane selectivity is significantly enhanced and is similar to that observed for the fresh Co/MnO:BN catalyst mixture (Fig. 1). It is, of course, possible that not all the H-ZSM-5 has been removed by the sieving procedure and this may account for the small differences observed. After reaction for a further 100 h, the Co/MnO catalyst was cooled in dry N_2 and was again separated by sieving and it was then mixed with fresh zeolite H-ZSM-5 (Si/Al = 80) in a simple physical mixture (Co/MnO:H-ZSM-5 = 1 : 1 by wt). The results (Fig. 1) clearly show that the methane selectivity is significantly decreased and the higher hydrocarbons, particularly C_3, are enhanced.

The effect was also observed when the catalysts were tested at a higher pressure using the same contact time (Table 2). At the higher pressure, methane formation is much lower when the Co/MnO catalyst is tested alone (Table 2, experiment 1). This is because carbon–carbon bond formation is favoured as the reaction pressure is increased.[1,2] However, the methane selectivity is still decreased when zeolite H-ZSM-5 (Si/Al = 80) is physically mixed with the Co/MnO catalyst. Although the effect is much less marked, it was observed over extended catalyst testing for periods of up to 1000 h.

It is interesting to consider the origin of this effect. We consider that the physical interaction of the Co/MnO and the zeolite particles creates new active sites at the interface. These sites comprise a combination of a strong acid together with a CO hydrogenation catalyst. The origin of the effect may be similar to the reduction in methane formation that is observed when ethene is added to CO hydrogenation when Co/MnO is used as catalyst[11] and may involve the activation of the C–H bonds of hydrocarbon, including methane, by polarisation at the interface between the zeolite and the Co/MnO.

We thank Dr S. Jones for useful discussions and Advantica Technologies Ltd. and the EPSRC for financial support.

Synthesis of cyclopentadienones catalyzed by methylidynetricobalt nonacarbonyl

Takumichi Sugihara,* Akihito Wakabayashi, Hiroko Takao, Hiroshi Imagawa and Mugio Nishizawa

Faculty of Pharmaceutical Sciences, Tokushima Bunri University, Yamashiro-cho, Tokushima 770-8514, Japan. E-mail: taku@ph.bunri-u.ac.jp; Fax: +81-88-655-3051; Tel: +81-88-622-9611

Received (in Cambridge, UK) 4th September 2001, Accepted 23rd October 2001
First published as an Advance Article on the web 7th November 2001

Easily prepared and air-stable methylidynetricobalt nonacarbonyl could be used as a catalyst for the intramolecular [2+2+1]-cocyclization of diynes and carbon monoxide producing cyclopentadienones.

Cyclopentadienones are anticipated versatile building blocks in synthetic organic chemistry due to the formal ease in introduction of a variety of functionalities at all positions on the ring.[1,2] Since the compounds have *anti*-aromatic nature, availability would seem to be troublesome. The assistance of transition metal complexes in the [2+2+1]-cocyclization of alkynes and carbon monoxide appears as a promising method to prepare cyclopentadienones.[3] In most cases, however, a stoichiometric amount of complex is required, since the newly formed cyclopentadienone tends to remain coordinated onto the metal.[4,5] Unexpectedly we were led to discover that the cocyclization of alkynes and carbon monoxide can be catalysed by certain polynuclear cobalt carbonyl complexes.

At first, we chose **1** as a substrate and investigated the cyclization catalyzed by polynuclear cobalt carbonyl complexes under various conditions. The results are shown in Table 1.

Since some alkylidynetricobalt nonacarbonyls[6] **4** were known to catalyze the Pauson-Khand reaction without any additive,[7,8] we first chose these clusters as catalysts for the cyclization. When the structurally simplest methylidynetricobalt nonacarbonyl (**4a**) was used, the desired **2**[9] was produced in 24% yield along with **3** even under an argon atmosphere (Entry 1). More than half of the carbon monoxide in the cluster was incorporated into the products. Whereas the catalytic activity was not increased dramatically under 1 atm pressure of carbon monoxide (Entry 2), the reaction under 20 atm of carbon monoxide proceeded in a good yield (Entry 3). It should be mentioned that **4a** was also recovered in 70% yield by silica gel column chromatography (Entry 3). Since the reaction of **1** in the presence of 0.01 equiv. of **4a** produced **2** in 32% yield, a certain amount of **4a** was required to complete the reaction and **4a** was recyclable under these conditions. Among the solvents investigated (such as THF, DME, CH_2Cl_2, MeCN, DMF, and EtOH) toluene seemed to be the best for this reaction in terms of the yield of **2** and the recovery of **4a**. When the reaction was carried out at 120 °C for 48 h, only **3** was obtained and **4a** was not recovered at all (Entry 4). The prolonged reaction time at higher temperature brought about the decomposition of the cluster, which might have promoted isomerization of one of the alkenes to produce **3**. A variety of clusters was also investigated. Whereas the thermally stable clusters, such as **4b–e**, did not catalyze the cyclization (Entries 5–8), ones having hydrogen and bromine brought about fruitful results (Entries 3 and 9). While it is known that treatment of **4f** in refluxing toluene gave **4g**, **4g** itself also catalyzed the cyclization but the yield was lower than the case of **4f** (Entry 10). Finally, dicobalt octacarbonyl **5** and tetracobalt dodecacarbonyl **6** also catalyzed the cyclization (Entries 11 and 12), although the catalytic activity was less than **4a**. The difference of reactivity between **4a**, **5**, and **6** was also observed in the cyclization of **7** (Scheme 1). When **4a** was used as a catalyst, the desired **8** was produced in 48% yield along with the recovery of **7**, whereas the reaction with **5** or **6** was not fruitful. Since the cluster is more stable against auto-oxidation than the binary cobalt carbonyl complexes such as **5** and **6**, placing one carbon unit in the core brings stability and reactivity. Methylidynetricobalt nonacarbonyl showed the best catalytic activity in the cyclization.

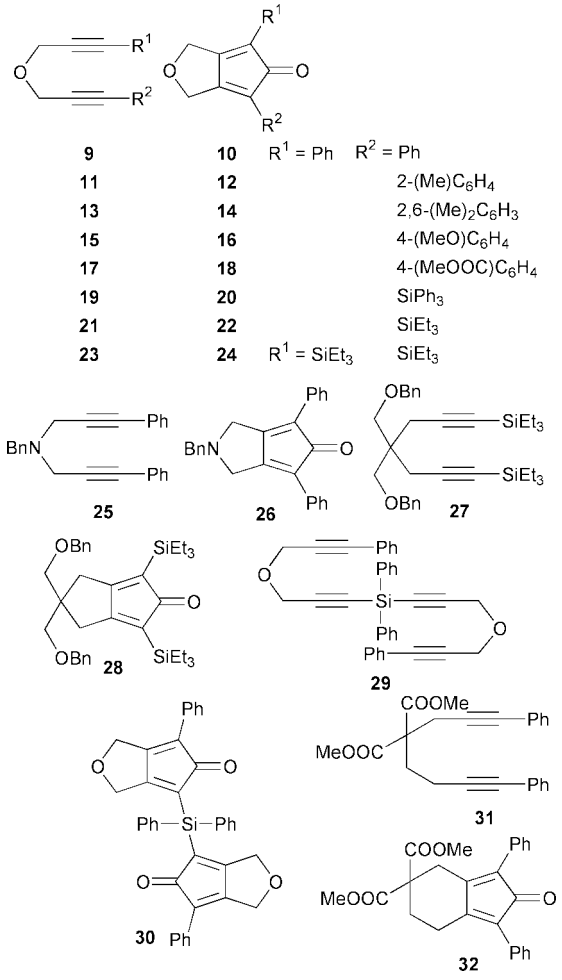
[a] All reactions were carried out in a 0.125 M solution of toluene at 95 °C under 20 atm of carbon monoxide in the presence of **4a**.



(triphenylsily)acetylene did not produce the cyclopentadienones and recovered the starting alkynes and **4a**. When oct-4-yne was treated under the same conditions, hexa(*n*-propyl)benzene was produced in 99% yield.[10] The cyclization could proceed only when the diynes with three or four atoms' tether had an aromatic or silyl group on both termini of the alkynes (Table 2). In all cases shown in Table 2, the desired cyclopentadienones[9] were produced in good yields.

In conclusion, we have developed a method for catalytic synthesis of cyclopentadienones by methylidynetricobalt nonacarbonyl. The cluster combines the advantages of being both easy to handle and catalytically active.

This work is supported in part by grants from the Asahi Glass Foundation and the Ministry of Education, Science, Sports, and Culture, Japan. TS gratefully thanks Professor Masahiko Yamaguchi at the Graduate School of Pharmaceutical Sciences, Tohoku University, Japan for his helpful discussion.

EPR and NMR spectroscopic studies of $[MoL_2(MeC{\equiv}CMe)Cp]^z$ (L = P-donor ligand, z = 0 and 1): fluxionality in a metal–alkyne redox pair

Christopher J. Adams,[a] Neil G. Connelly[a] and Philip H. Rieger[b]

Variable temperature NMR and EPR spectroscopic studies provide rates and activation parameters for alkyne rotation and oscillation, respectively, in the fluxional redox pair $[Mo\{P(OMe)_3\}_2(MeC{\equiv}CMe)Cp][BF_4]$ (diamagnetic) and $[Mo\{P(OMe)_3\}_2(MeC{\equiv}CMe)Cp]$ (paramagnetic).

Although 'piano-stool' alkyne complexes of molybdenum[1–4] were first formulated as 16-electron species, with the alkyne acting as a two-electron donor, it was soon recognised that this ligand could act as a four-electron donor, thus bringing the formal electron count to 18.[5] The crystal structures of $[Mo\{P(OMe)_3\}_2(\eta^2\text{-}HC{\equiv}CBu^t)Cp]^+$ [6] and $[Mo\{(MeO)_2PO\text{-}BF_2OP(OMe)_2\}(\eta^2\text{-}PhC{\equiv}CPh)Cp]^+$ [7] show the alkyne aligned parallel to one of the metal–phosphorus bonds, as in isoelectronic tungsten and vanadium species.[8,9]

If maintained in solution this geometry would lead to different environments for R′ and R″ in an alkyne R′C≡CR″ and, therefore, separate signals in the ^{1}H NMR spectrum even when R′ = R″. At room temperature, however, only one signal is often observed due to a propeller-like rotation [Fig. 1(a)] of the alkyne ligand rendering R′ and R″ equivalent. In some cases this rotation process is frozen out at low temperature, and an activation energy, $\Delta G^{\ddagger}$, can be estimated from the coalescence temperature of the appropriate signals in the ^{1}H NMR spectrum, *e.g. ca.* 60 and 47 kJ mol^{-1} for $[Mo(dppe)(\eta^2\text{-}MeC{\equiv}C\text{-}Me)Cp][PF_6]$[1] and $[Mo(dmpe)(\eta^2\text{-}MeC{\equiv}CMe)Cp][BF_4]$,[4] respectively.

We have recently described the effects of electron-transfer on the structures of metal–alkyne complexes *via* single crystal X-ray diffraction studies of the redox pairs $[Cr(CO)_2(\eta\text{-}PhC{\equiv}CPh)(\eta\text{-}C_6Me_6)]^z$, $[Mo(CO)_2(\eta\text{-}PhC{\equiv}CPh)Tp']^z$ [10] and $[WX(CO)(MeC{\equiv}CMe)Tp']^z$ (X = Cl and Br; z = 0 or 1).[11] This communication reports the *solution* behaviour of the redox pair $[Mo\{P(OMe)_3\}_2(\eta^2\text{-}MeC{\equiv}CMe)Cp][BF_4]$, $\mathbf{1}^+[BF_4]^-$, and $[Mo\{P(OMe)_3\}_2(\eta^2\text{-}MeC{\equiv}CMe)Cp]$, **1** (and related complexes) where NMR and EPR spectroscopic studies allow the fluxional behaviour of the diamagnetic and paramagnetic species respectively to be quantified and compared.

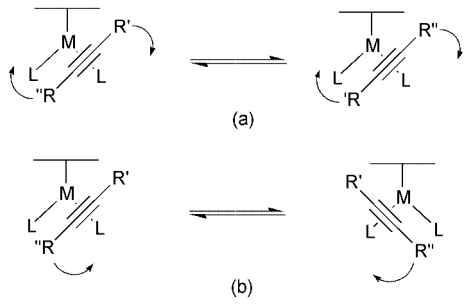

Fig. 1 (a) Propeller-like rotation, and (b) oscillation, of the coordinated alkyne of $[ML_2(R'C{\equiv}CR'')Cp]$ (L = PR_3). The horizontal line denotes the Cp ligand.

Variable temperature ^{1}H NMR spectroscopic studies of $\mathbf{1}^+[BF_4]^-$ in CD_3OD show that the room temperature singlet (δ 3.03) attributable to the alkyne methyl groups becomes two signals (δ 2.93, 3.11) below about 200 K. Line shape analysis[12] of spectra recorded at 2 K intervals between 208 and 188 K gives $\Delta H^{\ddagger}$ = 40.9(2) kJ mol^{-1} and $\Delta S^{\ddagger}$ = 9(1) J mol^{-1} K^{-1}, and (at 298 K) a rate constant, k, of 1.2 × 10^6 s^{-1} for the propeller-like rotation. Similar values in CD_2Cl_2 show that there is relatively little solvent effect on this intramolecular process (Table 1).

These results do not, however, show that the alkyne is stationary at 188 K as the ^{1}H NMR spectrum still shows the two $P(OMe)_3$ ligands to be equivalent; a stationary alkyne aligned with one of the M–P bonds, as in the crystal structures noted above[6,7] would create different environments for the two phosphite ligands, as well as for R′ and R″. Thus, a second fluxional process, namely an oscillation of the alkyne [Fig. 1(b)] which renders the two phosphite ligands magnetically equivalent while R′ and R″ remain inequivalent, still operates at this temperature.

Cyclic voltammetry shows that $\mathbf{1}^+[BF_4]^-$ undergoes reversible reduction at −1.25 V *vs.* SCE at a platinum electrode in dichloromethane. Accordingly, complex **1** was generated by adding solid $[Co(\eta\text{-}C_5Me_5)_2]$ ($E^{o\prime}$ = −1.48 V)[13] to a frozen solution of $\mathbf{1}^+[BF_4]^-$ in a 2:1 mixture of thf–CH_2Cl_2 and allowing the mixture to thaw slowly. Surprisingly, the EPR spectra of the resulting solution of **1** are similar to the NMR spectra of $\mathbf{1}^+[BF_4]^-$ in that they too reveal a temperature-dependent fluxional process. (The observation of fluxional behaviour for paramagnetic organometallic complexes on the EPR timescale is very unusual.[14,15])

At 280 K the EPR spectrum of **1** [Fig. 2(a)] shows a triplet ($<A^{31}P>$ = 11.25 G), resulting from coupling of the unpaired electron to two equivalent phosphorus nuclei and arising from either alkyne oscillation or rotation. As the temperature is lowered to 160 K the triplet gradually becomes a doublet due to

Table 1 Activation parameters for, and rates of, fluxional processes for metal–alkyne complexes

Complex	$\Delta H^{\ddagger}$/kJ mol^{-1}	$\Delta S^{\ddagger}$/mol^{-1} K^{-1}	k/s^{-1}[a]
$[Mo\{P(OMe)_3\}_2(\eta^2\text{-}MeC{\equiv}CMe)Cp]^+$, $\mathbf{1}^{+b}$	40.9(2)	9(1)	1.2 × 10^6
$[Mo\{P(OMe)_3\}_2(\eta^2\text{-}MeC{\equiv}CMe)Cp]^+$, $\mathbf{1}^{+c}$	39.5(4)	−2(2)	6.0 × 10^5
$[Mo\{P(OMe)_3\}_2(\eta^2\text{-}MeC{\equiv}CMe)Cp]$ **1**	13.2(3)	−14(2)	1.0 × 10^9
$[Mo\{P(OMe)_3\}_2(\eta^2\text{-}PhC{\equiv}CPh)Cp]$	21.6(4)	−4(2)	1.3 × 10^9
$[Mo\{P(OMe)_3\}_2(\eta^2\text{-}DC{\equiv}CBu^t)Cp]$	24.7(7)	−5(3)	3.2 × 10^8

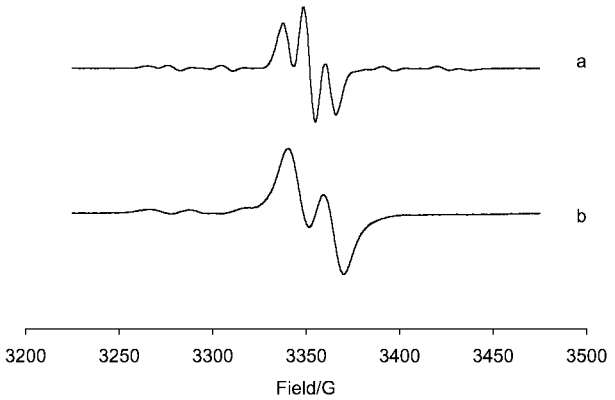

Fig. 2 The EPR spectra of **1** at (a) 280 K and (b) 160 K.

coupling to only one phosphorus nucleus ($<A^{31P}>$ = 18.8 G) [Fig. 2(b)], now implying a stationary alkyne ligand. Line shape analysis[14] of spectra recorded at 10 K intervals from 240 to 160 K gives values for the fluxional process of $\Delta H^{\ddagger}$ = 13.2(3) kJ mol^{-1} and $\Delta S^{\ddagger}$ = −14(2) J mol^{-1} K^{-1}, and a rate constant k (at 298 K) of 1.0 × 10^{9} s^{-1}. {Similar results were obtained for [Mo{P(OMe)$_3$}$_2$(η^2-PhC≡CPh)Cp] and [Mo{P(OMe)$_3$}$_2$(η^2-DC≡CBu^t)Cp] (in toluene) (Table 1)}.

Given that EHMO calculations, based on the crystal structure of [Mo{P(OMe)$_3$}$_2$(η^2-HC≡CBu^t)Cp]$^+$, show that the barrier to alkyne oscillation is significantly lower than the barrier to rotation we conclude that the fluxional process observed for **1** involves alkyne oscillation. It is therefore apparent that the fluxional behaviour involving the metal–alkyne units of **1**$^+$ and **1** involve different processes, *i.e.* alkyne rotation in the monocation and a much faster oscillation process in the neutral species.

The EHMO calculations also indicate that although the SOMO of **1** is based largely on the metal, there is a significant amount of unpaired electron density on the alkyne. In agreement, coupling to the alkyne H atom ($<A^{1H}>$ = 4.2 G between 210 and 310 K) as well as to the phosphorus atoms ($<A^{31P}>$ *ca.* 18.4 G at lower temperatures, for the single P coupling) is observed in the EPR spectrum of [Mo{P(OMe)$_3$}$_2$(η^2-HC≡CBu^t)Cp]. Thus, *C*-based radical-like behaviour is anticipated for **1** and related paramagnetic alkyne complexes.

We thank the EPSRC for a Postdoctoral Research Associateship (to C. J. A.).

Received (in Cambridge, UK) 14th September 2001, Accepted 15th October 2001
First published as an Advance Article on the web 15th November 2001

A variety of cyclic and acyclic allylic alcohols undergo efficient chemo-, regio- and/or stereoselective epoxidations in neutral aqueous solutions of amphiphilic carbohydrates (sucrose, L-arabinose, methyl or ethyl β-D-fructopyranoside) by using dilute hydrogen peroxide in the presence of molybdic or tungstic salts.

Epoxides are versatile building blocks for organic synthesis, because the epoxide group can be readily opened to produce vicinal functionalities. Chemo-, regio-, diastereo- and enantioselective processes have therefore been developed over the last decades for the synthesis of oxiranes.[1] Traditionally, the conversion of an alkene into an epoxide is performed by using peroxycarboxylic acids or *tert*-butyl hydroperoxide in conjunction with transition metal catalysts in organic solvents.[1] Nevertheless the need for reducing the amounts of toxic waste from chemical processes requires the use of environmentally friendly solvents and reagents. In this context, intensive efforts have been developed in the field of organic synthesis in water.[2,3] In this communication, we report a novel and very simple route for epoxidation of allylic alcohols by aqueous hydrogen peroxide[4] in the presence of molybdic or tungstic salts[5] in neutral aqueous solutions of non surfactant amphiphilic carbohydrates.

Reactions were carried out in water solutions of selected carbohydrates, *e.g.* sucrose **1**, α-L-arabinopyranose **2** and methyl or ethyl β-D-fructopyranoside **3a**,**b** (Fig. 1). Recent reinvestigation of sucrose conformation in water reveals the existence of an interresidue water-bridge.[6] This conformation resembles that found in the crystal[7] and in polar aprotic solvents.[8] Applying the Oxford Molecular MAD program[9] to that conformation of sucrose revealed the outside section of the fructose moiety to be hydrophobic in type.[10]

The composition of an equilibrated mixture of L-arabinose **2** in water greatly favours pyranoses (60% α, 35% β) over furanoses (3% α, 2% β) at 25 °C.[11] In the most abundant α-pyranose form, L-arabinose **2α** is characterised by an arrangement of hydroxy, methine and methylene groups which divides the molecule into hydrophobic and hydrophilic surfaces. This expectation is clearly corroborated by computation of the hydrophilicity potential. Moreover, we have synthesised methyl and ethyl β-D-fructopyranosides **3a** and **3b**, respectively, according to a procedure recently developed in our laboratory.[12]

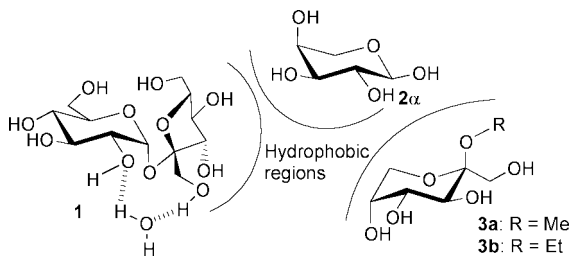

Fig. 1 Structure and hydrophobic areas of amphiphilic carbohydrates **1**–**3**.

Carbohydrates **1**–**3a**,**b** display therefore facial amphiphilicity and apolar organic compounds are expected to interact in aqueous media with the hydrophobic regions of these sugars in order to minimise unfavourable interactions with water. Aqueous solutions of amphiphilic carbohydrates are therefore expected i) to enhance the solubility of allylic alcohols and ii) to localise and to orientate the organic substrates.

Epoxidations of allylic alcohols (Fig. 2, 1 mmol) were performed with 30% hydrogen peroxide (10 mmol) in the presence of molybdic acid or sodium tungstate (0.1 mmol) in aqueous buffered solutions (20 mL, pH7, phosphate buffer)

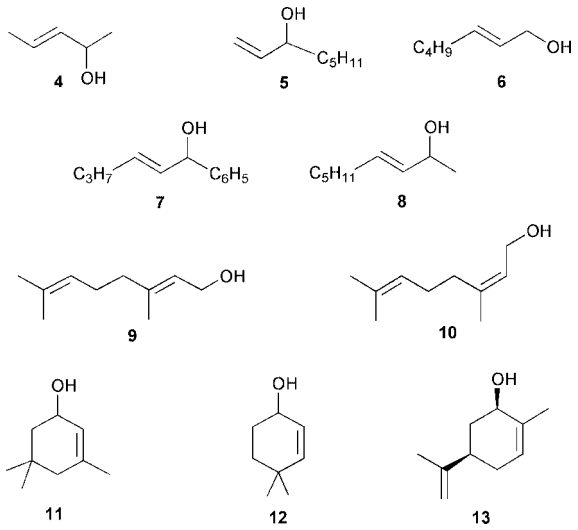

Fig. 2 Selected allylic alcohols **4**–**13**.

containing 20 mmol (molar solutions) of sugar additives. Indeed epoxidations were therefore carried out in dilute ~2% aqueous hydrogen peroxide. The reactions were stirred for 12–72 h (Table 1) at +2 °C and the products were then easily extracted with diethyl ether and their purity was determined by capillary GLC analysis. To compare our system with previously described aqueous solutions of surfactants,[13] some epoxidations were carried out under the same conditions without any amphiphilic carbohydrate.

Results of the epoxidation of a number of acyclic and cyclic allylic alcohols are reported in Table 1. Simple allylic alcohols **4**–**8** (entries 1–6) afforded the corresponding epoxides in high conversion yields when reactions were performed in the presence of carbohydrates **1** or **2**. It is noteworthy that no enone formation was observed[14] (see for example entry 2) and that conversion of the less reactive terminal olefin **5**[1] was dramatically enhanced in the presence of sucrose additive (entries 2, 3). Moreover, under the present conditions, no triol, resulting from oxirane opening, could be detected.

In order to extend our investigation on the regioselectivity of the reaction, geraniol **9** and nerol **10** were chosen as typical polyolefinic substrates that are sparingly soluble in pure water

but highly soluble in 1 M sucrose solutions. A site-selective epoxidation occurred at the least electron-rich allylic double bond and pure 2,3-epoxy-geraniol and -nerol were isolated in high yields (entries 7, 8). Unfortunately, epoxidation of geraniol **9** in the presence of sucrose gave 2,3-epoxygeraniol with modest enantioselectivity (ee = 10% determined by polarimetry). Our results obtained in neutral media therefore compare favourably with previous work performed with peracids in strongly alkaline media[13] or with transition metal catalysed epoxidations in organic solvents.[15,16]

Oxidations of six-membered cyclic substrates (Table 1, entries 9–15) indicated that enone formation competed with epoxidation. The ratio of oxirane to ketone showed a pronounced dependence on both substrates and reaction conditions as exemplified by entries 14 and 15. The best chemoselectivities were attained by using tungsten(VI) catalyst in the presence of sugar additives. Moreover, it is important to mention that solutions containing fructosides and catalyst could be recycled for further experiments without loss of conversion yield, chemoselectivity and stereoselectivity (entry 12).

The results presented here suggest OH-assisted epoxidation of allylic alcohols, presumably related to the formation of an intermediate in which the olefinic alcohol is most likely coordinated to the metal *via* the hydroxy group. Such an intermediate was previously suggested for tungsten catalysed epoxidations in protic media.[16,17] The next step was therefore to ascertain whether sugar–substrate and/or intermediate interactions were strong enough to promote stereodiscrimination in the epoxidation reaction. Some significant results for the epoxidation of representative cyclic and acyclic allylic alcohols are listed in Table 2. The data indicate that acyclic alcohols **4–8** gave mixtures of *erythro*/*threo* epoxides. Nevertheless, epoxidation in glycosidic aqueous media generates stereoselectively *erythro* enriched epoxy alcohols. This outcome is the same as for metal catalysed systems in organic solvents but is opposite to that obtained using peroxyacids in organic media.[16]

Table 2 Diastereoselective epoxidations of allylic alcohols in aqueous neutral solutions of carbohydrates **1–3**

Entry	Substrate	Additive	Metal catalyst	dr[a] *erythro* : *threo* (*cis* : *trans*)	mCPBA or analogues (lit.)
1	**4**	**1**	Mo^{+6}	68 : 32	30 : 70[13]
2	**5**	**1**	Mo^{+6}	68 : 32	38 : 62[14]
3	**8**	**1**	Mo^{+6}	62 : 38	36 : 64[14]
4	**11**	**2**	Mo^{+6}	(99 : 1)	(95 : 5)[18]
	11	**3a** or **3b**	W^{+6}	(>99 : 1)	(95 : 5)[18]
5	**12**	**1**	W^{+6}	(95 : 5)	
6	**12**	**3a** or **3b**	W^{+6}	(>99 : 1)	
7	**13**	**2**	Mo^{+6}	(94 : 6)	(90 : 10)
8	**13**	—	Mo^{+6}	(89 : 11)	

[a] dr: diastereoisomeric ratio were determined by GLC. *erythro*/*threo* refers to acyclic substrates whereas *cis*/*trans* to cyclic products.

In the case of cyclohex-2-enols **11–13** the epoxidation was highly stereoselective when compared with the results obtained by a peracid epoxidation (Table 2). In particular, allylic alcohols **11–12** gave exclusively the product where epoxide and OH functions are *cis* to each other when the reactions were performed in aqueous solutions of D-fructose derivatives **3a** or **3b** in the presence of Mo^{+6} or W^{+6} catalyst. Once again, comparison of *cis* : *trans* ratio underlines the role played by arabinose as additive (entries 7 and 8).

The predictable sense of the addition to cyclic olefins can be rationalised by means of a model where hydrophobic interactions are probably involved between the most hydrophobic face of the cyclic alcohol and that of sugar additive. These interactions may account for the enhanced stereoselective hydroxy directed epoxidation of cyclic allylic alcohols observed herein.

In conclusion, it was shown that dilute hydrogen peroxide together with molybdenum(VI) or tungsten(VI) salts is an efficient system for the chemo-, regio- and stereoselective epoxidation of allylic alcohols in aqueous solutions of carbohydrates characterised by a facial amphiphilicity.

Exploiting modularity in template-controlled synthesis: a new linear template to direct reactivity within discrete hydrogen-bonded molecular assemblies in the solid state

Giannis S. Papaefstathiou, Alex J. Kipp and Leonard R. MacGillivray*

Department of Chemistry, University of Iowa, Iowa City, Iowa 52242-1294, USA. E-mail: len-macgillivray@uiowa.edu

Received (in Columbia, MO, USA) 14th May 2001, Accepted 30th September 2001
First published as an Advance Article on the web 7th November 2001

Co-crystallization of 1,8-naphthalenedicarboxylic acid (1,8-nap) with *trans*-1,2-bis(*n*-pyridyl)ethylene (*n,n′*-bpe) (*n* = 2 or 4) yields a discrete four-component molecular assembly, 2(*n,n′*-bpe)·2(1,8-nap) 1, that is held together by four O–H···N hydrogen bonds where the dicarboxylic acid, serving as a linear template, directs alignment of olefins in the solid state for [2 + 2] photoreaction.

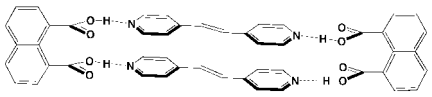
Molecules that function as linear templates[1,2] are emerging as tools for applying principles of molecular recognition,[3] supramolecular chemistry,[4] and self-assembly[5] for the control of covalent-bond-making processes that lead to the design of molecules,[6] oligomers,[7] and polymers[8] in solution[6a,d,7] and the solid state.[6b,c,8] In addition to facilitating stereo- and regiocontrolled positioning of reactive sites with atomic-level precision, linear templates are promising tools for gaining control of reactivity that approaches the nanometer-scale level, and beyond (*i.e.* > 10 Å),[9] owing to an ability of such molecules to enforce predetermined topologies upon reactants, circumventing problems of molecular entanglement[10] that can lead to poor selectivities and product yields. Indeed, to extend linear templates beyond the reach of current synthetic methodologies,[1] it will be necessary to exploit the inherent modularity of such a template approach[9] by devising templates, reactants, and reactions that may be readily interchanged. Moreover, by establishing such synthetic flexibilities, ready access to molecules and materials not accessible using traditional approaches to synthesis may be realized.[6–8]

We are utilizing linear templates to control reactivity in molecular solids.[6b] In particular, we have revealed the ability of resorcinol, and derivatives, to function as linear templates in the solid-state by organizing, by way of hydrogen bonds, olefins attached to symmetrically substituted bipyridines in position for [2+2] photoreaction.[11] By enforcing reaction to occur within a discrete molecular assembly,[5] this approach eliminates many vexatious problems of intermolecular forces that have made such topochemical designs unreliable,[11] providing a reliable means to make covalent bonds in solids. Such an ability to deliberately control chemical reactivity offers a prospect of eliminating waste organic solvent in molecular synthesis (*i.e.* green chemistry)[12] and gaining access to molecules less obtainable, or completely inaccessible, in solution.

We are currently identifying molecules that function as linear templates. Owing to the modularity of the approach, we reasoned that it should be possible to engineer molecules that possess structures largely preorganized,[13] in a similar way to resorcinol, to align olefins within discrete assemblies, giving rise to template libraries.[8] Here, we reveal the ability of 1,8-naphthalenedicarboxylic acid (1,8-nap), in 2(4,4′-bpe)·2(1,8-nap) **1a** and 2(2,2′-bpe)·2(1,8-nap) **1b** (where 4,4′-bpe = *trans*-1,2-bis(4-pyridyl)ethylene, 2,2′-bpe = *trans*-1,2-bis(2-pyridyl)ethylene), to function, in a similar way to resorcinol, as a linear hydrogen bond donor template. Following work of Feldman and Campbell,[14] we anticipated that co-crystallization of 1,8-nap with either 4,4′-bpe or 2,2′-bpe would yield a four-component molecular assembly held together by four O–H···N hydrogen bonds (Scheme 1) where 1,8-nap, owing to the proximity of the carboxylic acid groups along the naphthalene scaffold,[14] would juxtapose two bipyridines in the solid for [2 + 2] photoreaction. To our knowledge, 1,8-nap represents the second example of a molecule that functions as a linear template by controlling reactivity within a discrete hydrogen-bonded molecular assembly in the solid-state.[6b]† In addition to increasing the synthetic flexibility of this approach, such observations provide structure criteria for controlling reactivity that approaches the nanometer-scale level,[6–8] which is of growing interest.

Addition of 1,8-nap (0.017 g) to methanol (2 mL) in the presence of either 4,4′-bpe (0.015 g) or 2,2′-bpe (0.015 g) yielded, upon slow cooling, colorless crystals of **1a** and **1b**, respectively, suitable for X-ray analysis. The formulations of **1a** and **1b** were confirmed by ^{1}H NMR spectroscopy and single-crystal X-ray diffraction.‡

ORTEP perspectives of **1a** and **1b** are shown in Fig. 1. The components of **1a** and **1b** have assembled, in a similar way to 2(4,4′-bpe)·2(resorcinol) and 2(2,2′-bpe)·2(resorcinol),[6b] to form discrete molecular assemblies, of dimensions ~5.5 × 6.4 × 26.3 and 5.5 × 11.1 × 19.3 Å, respectively, held together by four O–H···N hydrogen bonds. In addition to a primary O–H···N interaction, each carboxylic acid group, each of which is twisted out of the plane of the naphthalene unit, participates in a C–H···O hydrogen bond with each pyridyl ring.[15,16] In this arrangement, two molecules of 4,4′-bpe and 2,2′-bpe lie stacked adjacent to 1,8-nap where the olefins of each complex are separated by 3.73 and 3.91 Å, respectively. These separations



2(4,4'-bpe)·2(1,8-nap)

Scheme 1

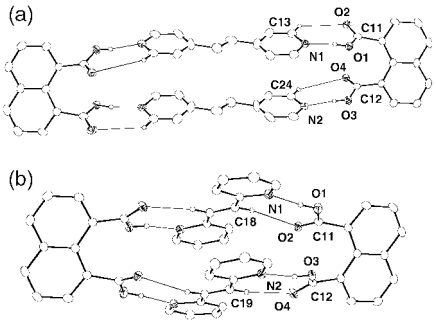


Fig. 1 ORTEP perspectives of molecular assemblies: (a) **1a** and (b) **1b**. Selected interatomic distances (Å) for **1a**: O(1)···N(1) 2.598(4), O(3)···N(2) 2.612(4), C(13)···O(2) 3.497(5), C(24)···O(4) 3.562(4); for **1b**: O(1)···N(1) 2.658(2), O(3)···N(2) 2.601(2), C(18)···O(2) 3.396(2), C(19)···O(4) 3.287(2). Twist angles of carboxylic acid groups (°): **1a**, 51.2 (C11), 50.9 (C12); **1b**, 53.0 (C11), 52.2 (C12).

 DOI: 10.1039/b106584j

are within the distance criterion of Schmidt for [2 + 2] photoreaction.[11] Notably, in the case of **1a**, the olefins are disordered across two sites (occupancies: 70 : 30) while the olefins of **1b** are ordered and parallel. Olefins of nearest-neighbor molecular assemblies of **1a** and **1b** are offset and separated by 4.81 and 4.09 Å, respectively. Indeed, UV irradiation of powdered crystalline samples of **1a** and **1b**, each for a period of 7 h (Rayonet reactor, 300 nm Hg lamp), produces, stereospecifically (100% yield), *rctt*-tetrakis(4-pyridyl)cyclobutane (4,4′-tpcb) and *rctt*-tetrakis(2-pyridyl)cyclobutane (2,2′-tpcb), respectively, as determined by ^{1}H NMR spectroscopy.

To confirm the structure of each product, a portion of each photolyzed solid (0.0010 g) was dissolved in methanol (5 mL) and single crystals of (4,4′-tpcb)·2(1,8-nap) **2a** and (2,2′-tpcb)·2(1,8-nap) **2b** were grown, after a period of approximately three days, by way of slow solvent evaporation. The formulations of **2a** and **2b** were confirmed by ^{1}H NMR spectroscopy and single-crystal X-ray diffraction.‡

ORTEP perspectives of **2a** and **2b** are shown in Fig. 2. As in the case of **1a** and **1b**, the components of **2a** and **2b** assemble by way of O–H···N and C–H···O hydrogen bonds, the carboxylic acid groups being twisted out of the plane of the naphthalene unit. For **2a**, one carboxylic acid group participates in an O–H···O hydrogen bond, in the form of a carboxylic acid dimer, with a neighboring diacid. As a consequence of these forces, the components of **2a**, in contrast to **1a**, assemble to form a one-dimensional hydrogen-bonded polymer along the crystallographic *a*-axis. This contrasts (4,4′-tpcb)·2(resorcinol)[6b] where the template, owing to the flexibility of the hydroxy groups, forms a discrete assembly with 4,4′-tpcb. We attribute the formation of the polymer **2a** to the rigidity of the diacid which, presumably, is less able to participate, in a similar way to (4,4′-tpcb)·2(resorcinol), in two O–H···N interactions with two *cis*-pyridyl groups of the product. In the case of **2b**, the components assemble, in a similar way to **1b**, to form a discrete molecular assembly held together by four O–H···N and four C–H···O hydrogen bonds where the O–H···N forces involve, in contrast to **1b**, two *trans*-pyridyl groups of the photoproduct.§

In this report, we have identified the ability of 1,8-nap to function as a linear template in the solid state, controlling reactivity within a discrete molecular assembly held together by hydrogen bonds. With these observations realized, we are currently utilizing the molecule as a template for conducting solid-state synthesis by design.[6b] With a library of linear templates now emerging,[8] it may be possible to utilize this approach for the designed synthesis of molecules of increasing complexity (*e.g.* nanosystems).[7] In the case of the solid state, our observations suggest an ability to organize molecules with precision and flexibility that rivals the liquid phase, providing routine access to molecular species less available in solution.[9]

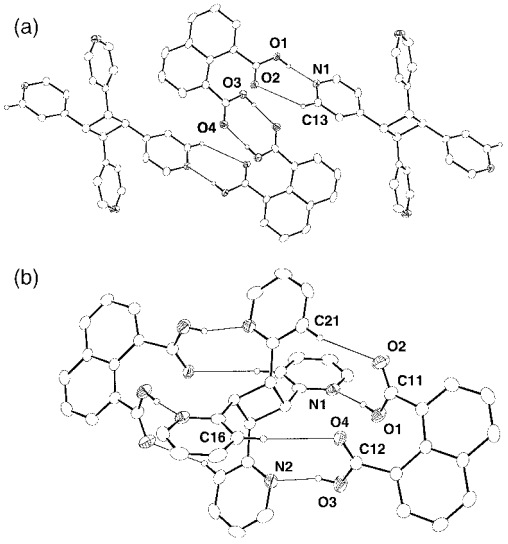

Fig. 2 ORTEP perspectives of the photoproducts: (a) **2a** and (b) **2b**. Selected interatomic distances (Å) for **2a**: O(1)···N(1) 2.607(3), O(3)···O(4) 2.619(3), C(13)···O(2) 3.474(4); for **2b**: O(1)···N(1) 2.651(2), O(3)···N(2) 2.667(2), C(21)···O(2) 3.196(3), C(16)···O(4) 3.722(3). Twist angles of carboxylic acid groups (°): **2a**, 48.5 (C11), 50.2 (C12); **2b**, 41.0 (C11), 48.8 (C12).

We are grateful for financial support from the University of Iowa. We thank Dr Michael J. Zaworotko (University of South Florida) for collection of the X-ray data for **2a**.

Notes and references

† A conceptually similar approach has been described that has involved infinite assemblies (see ref. 6*c*).

Synthesis and DNA-binding properties of dinuclear platinum(II)–amine complexes of 1,7-dicarba-*closo*-dodecaborane(12)†

Susan L. Woodhouse and Louis M. Rendina*

Department of Chemistry, The University of Adelaide, Adelaide 5005, Australia. E-mail: lou.rendina@adelaide.edu.au

Received (in Cambridge, UK) 6th September 2001, Accepted 19th October 2001
First published as an Advance Article on the web 7th November 2001

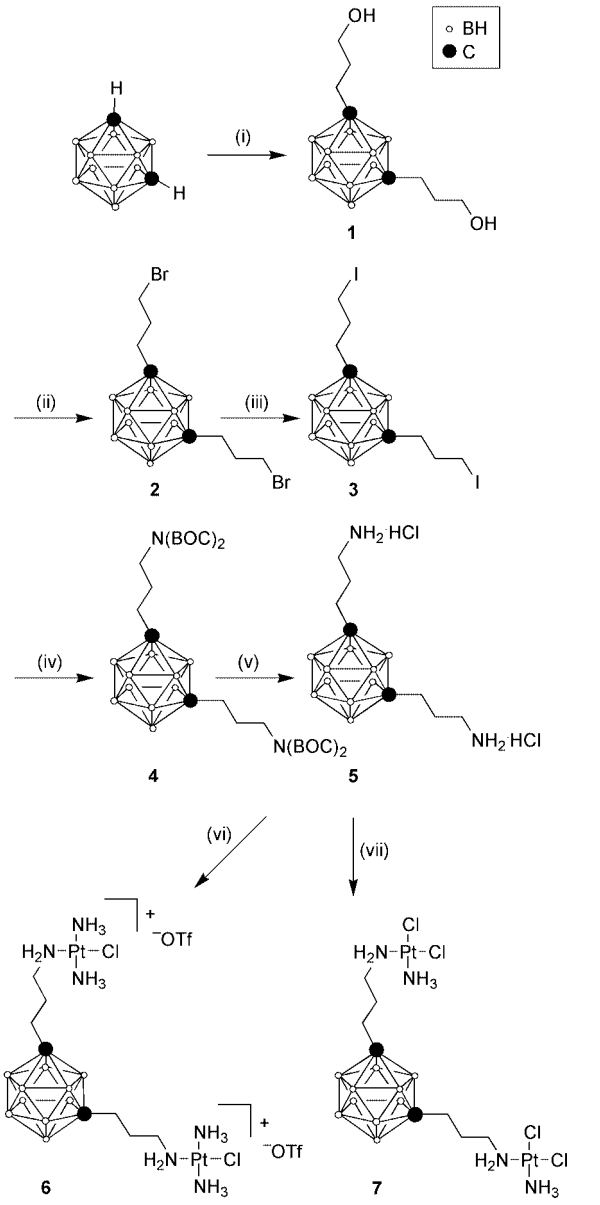
The first examples of platinum(II)–amine complexes containing a dicarba-*closo*-dodecaborane(12) (carborane) moiety are described; preliminary *in vitro* DNA-binding experiments indicate that the complexes are capable of targetting plasmid DNA.

Boron Neutron Capture Therapy (BNCT) is a bimodal cancer treatment that is currently undergoing clinical trials in several countries, including the US, Japan, Sweden, The Netherlands and Finland.[1] The therapy makes use of thermal neutrons of low kinetic energy (<0.025 eV) and ^{10}B-containing drugs, and it exploits the unusual capacity of the ^{10}B nucleus (natural abundance = 19.8%) to undergo neutron capture (NC) reactions as a consequence of its extremely large effective nuclear cross-section (3837 barns). The immense amount of kinetic energy (*ca*. 2.4 MeV) that accompanies the primary fission products ($^{7}Li^{3+}$ and $^{4}He^{2+}$) is dissipated in a very small volume, and the potential application of the NC reaction to the selective destruction of cancer cells is the subject of intensive research. Previous studies have demonstrated that if ^{10}B-compounds are localized near the nucleus of a cell, then cellular damage is maximized.[2] To date, a number of organic compounds tethered to boron-rich moieties such as dicarba-*closo*-dodecaboranes(12) (carboranes), *e.g*. alkylating agents,[3] bibenzimidazole groove binders,[4] acridine dyes,[5] and polyamines,[5a,6] are known to target DNA, but their success in BNCT has yet to be demonstrated.[1a] To our knowledge, the use of boron-containing metal complexes as potential DNA-targetting agents in BNCT is without any precedent. Herein we describe the synthesis and DNA-binding properties of novel, dinuclear platinum(II)–amine complexes of 1,7-carborane that are related to the DNA cross-linking agents reported by Farrell and co-workers.[7]

The synthetic methodology employed in the preparation of the bridging 1,7-bis(3-aminopropyl)-1,7-carborane ligand and its platinum(II) derivatives **6** and **7** is presented in Scheme 1. The protocol for the ligand synthesis was based upon that reported by Sjöberg and coworkers for the preparation of 1,12-bis(3-aminopropyl)-1,12-carborane.[8] The reaction of ^{n}BuLi with 1,7-carborane in THF solution at −78 °C, followed by the addition of oxetane and subsequent hydrolysis with $HCl_{(aq)}$, afforded the dipropanol **1** in 62% yield. Bromination of **1** using CBr_4 and PPh_3 in CH_2Cl_2 solution at 0 °C gave the dibromo compound **2** (86%), which was readily converted to the diiodo species **3** (92%) by means of a metathesis reaction employing NaI in acetone solution. Alkylation of di-*tert*-butyliminodicarboxylate, $HN(BOC)_2$, with **3** was carried out under basic phase-transfer conditions and afforded the di-substituted, BOC-protected amine **4** (75%). Treatment of **4** with 3 M HCl in ethyl acetate solution gave the amine **5**·2HCl as a white crystalline solid in 69% yield. Addition of $K_2CO_{3(aq)}$ to **5**·2HCl afforded the free amine **5** as a slightly unstable, white solid (76%). All compounds were fully characterised by ^{1}H, ^{13}C{^{1}H} and ^{11}B{^{1}H} NMR spectroscopy and microanalysis.

† Electronic supplementary information (ESI) available: experimental section. See http://www.rsc.org/suppdata/cc/b1/b108081d/

Treatment of **5** with two equivalents of the labile precursor complex *trans*-$[PtCl(dmf)(NH_3)_2]OTf$ led to the formation of **6** as an off-white solid.‡ Alternatively, use of the mixed-halogeno species *cis*-$[PtCl_2I(NH_3)]^-$, formed *in situ* from the reaction of $[PtCl_3(NH_3)]^-$ and KI in aqueous solution,[9] afforded the chloro–iodo analogue of **7**.‡ Subsequent treatment of this



Scheme 1 *Reagents*: (i) ^{n}BuLi, oxetane, H_3O^+; (ii) CBr_4, PPh_3; (iii) NaI; (iv) $HN(BOC)_2$, NaOH, Bu_4NHSO_4; (v) 3 M HCl in EtOAc; (vi) $K_2CO_{3(aq)}$, *trans*-$[PtCl(dmf)(NH_3)_2]OTf$; (vii) $K_2CO_{3(aq)}$, *cis*-$[PtCl_2I(NH_3)]^-$, $AgNO_3$, $HCl_{(aq)}$.

 DOI: 10.1039/b108081d

complex with $AgNO_3$ in DMF solution, followed by the addition of $HCl_{(aq)}$ to the resulting tetra(nitrato) species gave the target complex **7** as a bright-yellow solid. The new complexes were fully characterised by ^{1}H, $^{13}C\{^{1}H\}$ and $^{11}B\{^{1}H\}$ NMR spectroscopy and microanalysis. Furthermore, **6** and **7** exhibited singlet $^{195}Pt\{^{1}H\}$ NMR resonances that lie in the range observed for complexes with a PtN_2Cl_2 and PtN_3Cl coordination sphere, respectively.[10]§

In order to assess the DNA-binding characteristics of **6** and **7**, preliminary plasmid DNA-binding experiments were conducted using a well-established *Eco* RI restriction endonuclease assay that monitored platinum binding at (or near) its unique restriction site in linearized pBR322 DNA.[11] For comparative purposes, we also investigated the DNA-binding characteristics of the archetypal, cross-linking agent *cis*-$[PtCl_2(NH_3)_2]$. These experiments confirm that **6** (Fig. 1) and **7** are capable of targetting plasmid DNA. The concentration of platinum complex required to achieve 20% inhibition of DNA cleavage by the enzyme is 3, 14 and 49 μM for **6**, *cis*-$[PtCl_2(NH_3)_2]$, and **7**, respectively. The inhibition of *Eco* RI activity by **6** at a concentration that is considerably less than *cis*-$[PtCl_2(NH_3)_2]$ and **7** is most likely the result of its rapid kinetics of DNA-binding. Similar effects have been reported previously with dinuclear platinum(II) complexes bridged by α,ω-diaminoalkane ligands.[12] At platinum concentrations greater than *ca*. 3.3 μM for **6**, considerable streaking of the DNA is observed (Fig. 1). This effect is also consistent with the rapid and effective (covalent¶) binding by the dicationic complex to the polyanionic DNA molecule, resulting in extensive charge neutralization. Further work to elucidate the nature of the Pt–DNA adduct(s) formed by **6** and **7**, including their quantification, is in progress.

In conclusion, **6** and **7** are the first examples of platinum(II)–amine complexes containing a carborane moiety, and they represent a new class of boron-containing DNA-binding agents for potential application in BNCT. The NC properties and biological studies involving selected platinum complexes will be reported in due course.

We thank Mr D. Sykiotis (The University of Adelaide) for assistance with the DNA-binding studies, Dr N. E. Dixon (Australian National University) for advice regarding the DNA-binding experiments, Prof. N. P. Farrell (Virginia Commonwealth University, US) for advice regarding the synthesis of **7** and DNA-binding studies, Prof. S. Sjöberg (Uppsala University, Sweden) for advice regarding the ligand synthesis, and Prof. B. J. Allen (Cancer Care Centre, Sydney, Australia) for many useful discussions. We are grateful to Johnson Matthey for the generous loan of $K_2[PtCl_4]$. We also thank the Australian Research Council and the Anti-Cancer Foundation of South Australia for financial support.

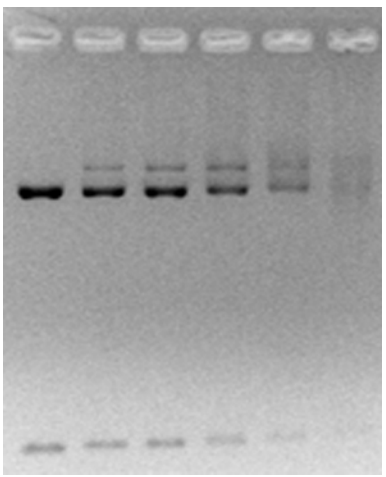


Fig. 1 Gel electrophoresis experiment. Lanes correspond to linear pBR322 DNA samples that were incubated with increasing concentrations of **6** (0, 1.2, 1.6, 2.3, 3.3 and 4.0 μM) for 2 h at 37 ± 0.1 °C, followed by spin dialysis and treatment with *Eco* RI restriction endonuclease.

Notes and references

‡ Note that the use of the isomeric 1,2-carborane derivative in the complexation reactions with platinum(II) precursors resulted in extensive decomposition accompanied by the formation of platinum metal. We are now in the process of investigating the various factors that may contribute to the reduction process, and the results of this study will be reported in due course.

§ $^{195}Pt\{^{1}H\}$ NMR data (d_7-DMF): δ −2410 and −2156 for **6** and **7**, respectively.

¶ Note that electrostatic interactions alone are unlikely to account for the strong binding of **6** to DNA. These would be reversed with the high NaCl concentrations used in the quenching of the Pt–DNA reactions, and under the conditions of the gel electrophoresis experiment.

How van der Waals bonds orient molecules in zeolites

Ewout Kemner,* Ignatz M. de Schepper and Gordon J. Kearley

Interfaculty Reactor Institute, Mekelweg 15 2629 JB, Delft, The Netherlands.

First published as an Advance Article on the web 9th November 2001

We show that weak bonds are responsible for the way a molecule is held in a zeolite, and for its reactivity.

How is a guest molecule held in a zeolite cage? What is the bonding? How does this affect the reactivity of the guest? To answer these questions in a coherent manner we must examine the topology of electron density between the host and the guest, and then reconsider what we mean by 'bonding'. Using the approach pioneered by Bader,[1] we reveal only weak H-bonds and even weaker van der Waals bonds between the host and the guest. Yet the reactivity of the guest (ferrocene in the present case) is dramatically increased when it is in the zeolite.[2,3] The popular concept is that the increased reactivity of the guest arises from changes in its electronic structure is incorrect in the present case, and it is the orientation in which the guest ferrocene molecule is held that renders it vulnerable to attack. Analyses of this type in which we separate the electronic and steric effects may have a general impact on the study of catalytic systems. In the current study the guest molecule is ferrocene, $Fe(C_5H_5)_2$, (an iron atom 'sandwiched' by two identical parallel cyclopentadienyl C_5H_5 rings) held within the host lattice of NaY zeolite, $Na_x(AlO_2)_x(SiO_2)_{192-x}$. The original interest in this system stems from its use as a preparative route by which iron may be included in the zeolite. The ferrocene molecules occupy 'supercages' (shown in Fig. 1) in the zeolite which have a diameter of about 12 Å, and each of these contains four sodium ions on its walls (see Fig. 1). We have recently determined the position of the ferrocene molecule in the supercage of NaY zeolite to be 0.87 Å above a line joining two sodium ions, using powder X-ray and neutron diffraction[4] (see Fig. 1). The question immediately arises as to why the ferrocene molecule does not lie on the line joining two sodium ions since then it would optimize the Coulombic interaction between the π-systems of the aromatic rings and the sodium ions. Such a position would also lead to considerably shorter hydrogen bonds between the cyclopentadienyl hydrogen atoms and the oxygen atoms of the zeolite. Where is the energy-gain in leaving the ferrocene molecule almost 1 Å above the Na^+–Na^+ vector, and how can we quantify this? One possibility would be to map out the potential-energy hypersurface of the ferrocene along its normal-mode vectors. A subsequent examination of this map for all atom pairs would reveal the origin of the observed ferrocene position. A far more convenient approach is a direct examination of the electron density for evidence of bonds between the ferrocene molecule and the zeolite cage. An analysis of the electron density should be able to account for the observed location of the ferrocene molecule, and more important, the increased reactivity with respect to the pure compound.

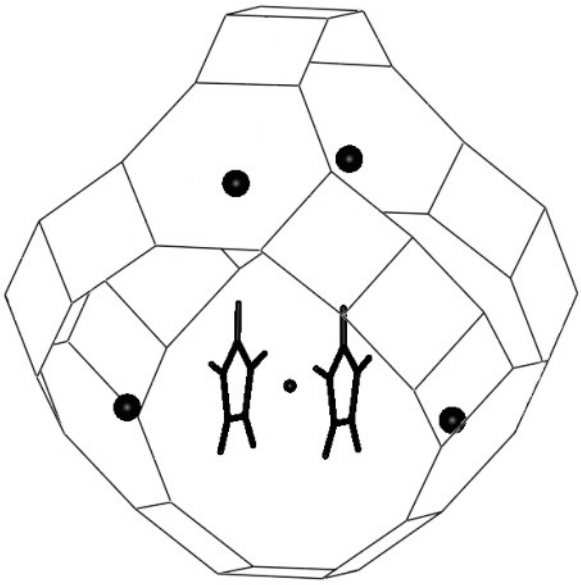

Fig. 1 Location and orientation of a ferrocene molecule (bold) inside a NaY zeolite supercage. The four spheres show the positions of the sodium ions on the walls of the zeolite supercage.

The first step in the analysis is to ensure that the atomic positions derived from crystallography do indeed correspond to the energy minimum, and that there is consistency between observation and calculation. We achieve this by modelling a realistic fraction of the zeolite containing the ferrocene (Fig. 2). Various constraints are possible which would allow relaxation in the immediate environment around the ferrocene molecule. For convenience we chose the outer H-atoms (which had been introduced artificially) as a rigid container for the model. The energy of the system is then minimised with respect to the ferrocene position using *ab initio* density functional theory (Dmol[3] within the suite Cerius[2]).[5] We use the local density approximation, Perdew Wang functionals, the DND basis set,[5] and an atomic cutoff radius of 5.5 Å. After optimization of the geometry we find that there is no significant difference in the atomic positions from diffraction experiments and DFT calculations.

The DFT calculations also provide the total electron density $\rho(\boldsymbol{r})$ map for the model, which we use to perform a topological analysis, and hence obtain a straightforward definition of bonds between atoms. We start by locating the critical points in the electron density, that is, where the gradient of the electron density $\nabla\rho(\boldsymbol{r})$ vanishes. In addition to the maxima associated with atom positions, there are also saddle points where the curvature is positive in one direction and negative in the two

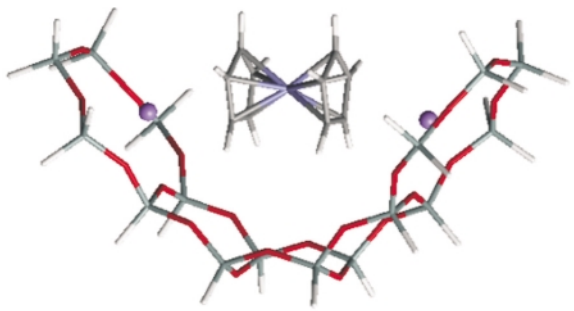

Fig. 2 Illustration of the zeolite fragment consisting of oxygen (red) and silicon (grey) atoms and the ferrocene molecule as used for DFT calculations. Sodium ions are represented by purple spheres. The oxygen atoms adjacent to the zeolite framework have been replaced by hydrogen atoms (white).

 DOI: 10.1039/b105611p

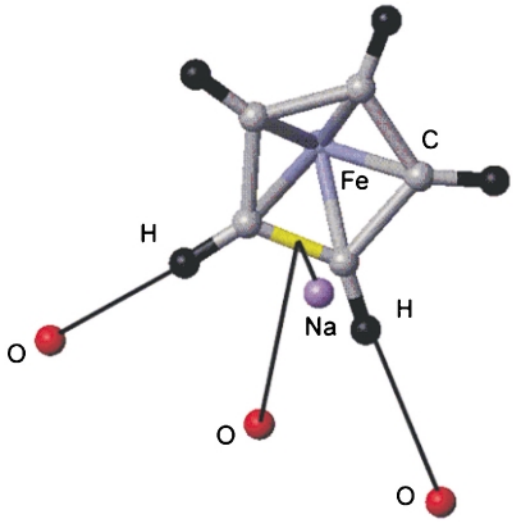

Fig. 3 Interaction paths between a ferrocene-C_5H_5 ring and atoms in the zeolite framework. We find two paths from a hydrogen atom (black) of the ring to an oxygen atom (red) of the framework. There are also two paths from a sodium ion (purple) and an oxygen atom to the centre of a carbon-carbon bond in the ring (yellow).

others. Saddle points are located somewhere in between the nuclei and are usually termed 'bond critical points'. The next step is to identify 'gradient paths', *i.e.* curves such that the gradient vector $\nabla\rho(\boldsymbol{r})$ is tangent to it in every point. These paths are roughly analogous to ridges in a mountainous landscape. Some of these originate at a bond critical point and lead to atoms (peaks, in our analogy), and these correspond to bonds. We perform this topological analysis on the electron density with the program FAST,[6] the results for the bond critical points and paths for the model being shown in Fig. 3.

All of the bonds that one normally would expect in the zeolite framework and in the ferrocene molecule, are found as expected, but what is of interest here are the bonds that we find between the ferrocene and the zeolite framework. These go *via* the cyclopentadienyl rings. There are four connecting each cyclopentadienyl ring of the ferrocene molecule and the zeolite framework (see Fig. 3). Two of these are between a hydrogen atom of the ring and an oxygen atom of the framework, and these correspond to weak hydrogen bonds. The other two paths are somewhat unusual, and to our knowledge, unique. Essentially, these join both a sodium ion and an oxygen atom of the zeolite to the same point, that point being the center of a bond between two carbon atoms. These bonds lie in a mirror plane of the system, and if this symmetry is broken the van der Waals bonds go to one of the carbon atoms, and the real situation at room temperature corresponds to fluxionality of bonding to the alternative carbon atoms. These bonds are not artefacts of the basis set in that although the details of the density maps vary with the level of calculation, even the most basic calculations still show the van der Waals bonds.

It seems clear that the unexpected position of the ferrocene molecule arises from an interaction of the carbon atoms of the ferrocene with the sodium ions and the oxygen atoms of the zeolite. It should be emphasised that many gradient paths in the electron density eventually flatten out, and hence disappear, but in the present case they actually continue as bond-paths. This makes it possible to express these arguments in more chemical terms. The energy associated with the formation of these new bonds more than compensates for the weakening of the hydrogen bond and the weaker interaction of the aromatic π-system with the sodium ion. The length of these bonds and the charge density in the bond critical points are collected in Table 1, and these allow a quantitative comparison of the different types of bond. For example, the electron density at the critical point of the strong covalent bond between two carbon atoms in benzene amounts to 0.33 e/a_0^3, and of the bond between oxygen and hydrogen in a water molecule 0.39 e/a_0^3.[1] An ionic bond has a rather lower value, for example 0.036 e/a_0^3 in case of NaCl,[1] whilst hydrogen bonds normally have a values for the electron density between 0.001–0.035 e/a_0^3.[7] In the present case the hydrogen bond between the ferrocene hydrogen and the zeolite oxygen is also within this range, 0.0081 e/a_0^3, and further, the C···O distance is comparable with that found in C–H···O hydrogen bonds.[7] Similar values for the electron density at bond critical points are found in van der Waals molecules, for example 0.0077 e/a_0^3 between Ar and HF and 0.0099 e/a_0^3 between Ne and HF. These are comparable with the values we find for the interaction between the sodium and oxygen and the center of the C–C bond of 0.0057 e/a_0^3. However, we find distances that are >3 Å, which is somewhat longer than the corresponding distances in Ne/HF (2.11 Å) and Ar/HF (2.56 Å).

Table 1 Pathlength and electron density ρ at the bond critical points for the interaction lines between a cyclopentadienyl ring and the zeolite framework

	Pathlength/Å	ρ (e/a_0^3) at bond critical point
H–O	2.63	0.0081
Ring–O	3.49	0.0057
Ring–Na	3.15	0.0057

Bonds between π-bondings and positive ions have been observed before,[8] and a Bader analysis has been reported for hydrogen bonds with a π-bond.[9] However, to our knowledge the binding between the π-cloud of an aromatic ring and an ion always involves the centre of the ring. In the present case the iron atom may well distort the π-cloud in such a way that two edge-bonds plus the involvement of an extra oxygen atom is energetically more favourable. We stress that these novel bonds should not be thought of as the primary interaction between the ferrocene and the zeolite. They are secondary to the main Coulomb and hydrogen bond interactions, which play the primary role in holding the ferrocene molecule in its place. It follows that rather long weak bonds are responsible for the displacement of the ferrocene molecule from the expected position. All bonds between the ferrocene and the zeolite are weak and the bonding within the ferrocene itself is virtually unchanged from that of the isolated molecule. Inspection of Fig. 1 reveals a large 'free volume' on the side of the ferrocene molecule furthest from the cage fragment as shown in Fig. 2, which is an attractive site for any potential reactants. It is even conceivable that without the van der Waals bonds, the ferrocene would be held deeper in the zeolite cage where it would be less accessible to attack, and in this way very weak bonds could play a crucial role in catalysis.

Silver(I) carboxylates: versatile inorganic analogs of carboxylic acids for supramolecular network formation†

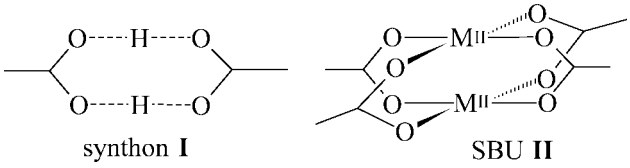
Lee Brammer,*‡ Michael D. Burgard, Colin S. Rodger, John K. Swearingen and Nigam P. Rath

Department of Chemistry and Biochemistry, University of Missouri–St. Louis, 8001 Natural Bridge Road, St. Louis, MO 63121-4499, USA

Received (in Cambridge, UK) 18th September 2001, Accepted 16th October 2001
First published as an Advance Article on the web 15th November 2001

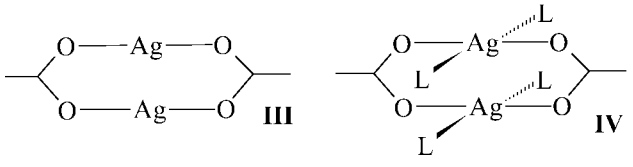
Dimeric motifs formed by silver(I) carboxylates, illustrated here by the unit $Ag_2(CF_3CO_2)_2$, resemble the well known dimerization of carboxylic acids, *i.e.* '$H_2(RCO_2)_2$', but exhibit greater flexibility, while permitting further elaboration into neutral coordination networks through linkage of the silver centres *via* ditopic ligands.

The molecular level design of new materials, synthetic receptors and biomimetic systems has proceeded apace in the past decade under the banner of the multidisciplinary fields of supramolecular chemistry[1] and crystal engineering.[2] Fundamental to such an approach is the need for interactions between molecular building blocks that are sufficiently reliable to permit some degree of predictability and control over the formation of supramolecular assemblies and networks.[3] To convey this idea Desiraju has introduced the term supramolecular synthon,[4] often applied to structural units comprising weaker, and thus inherently *flexible*, non-covalent linkages. The carboxylic acid dimer, the archetypal synthon, illustrated as **I** in its symmetric

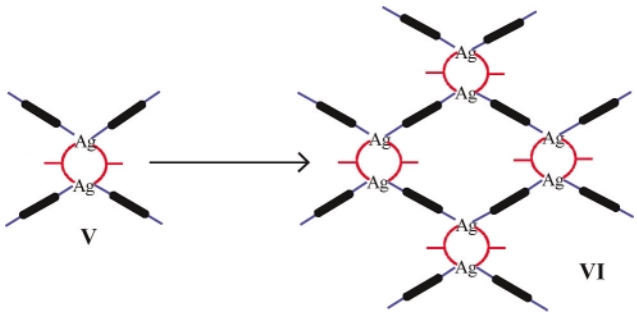


form, is a mainstay of organic crystal engineering[2a] and is beginning to see some applications in organometallic systems.[2b,5] A related concept conveyed by Yaghi is that of the secondary building unit (SBU),[6] as exemplified by the square 4-connected unit **II**. SBU **II** is known for a variety of divalent transition metals, M^{II}, and has been applied to the synthesis of *rigid* metal–organic frameworks.[6]

In this report, we highlight a middle ground in the form of a versatile inorganic analog of synthon **I** in which the hydrogen-bonded protons that link the two carboxylate groups are replaced by Ag^+ ions, an idealised symmetric example of which is shown as **III**. However, in contrast to protons, the



coordination sphere of the Ag^+ ions is not satisfied by the two oxygen atoms, and additional bridging by the oxygen atoms typically leads to polymeric or oligomeric structures for simple silver(I) carboxylates.[7] Thus, we surmised that the silver carboxylate dimers might serve as a useful new building block through occupation of these additional coordination sites at each silver center by neutral polytopic ligands (**IV**). Here we illustrate the case where L is a ditopic ligand capable of forming a linear linkage between two metal centers. This leads to a new SBU (**V**) with approximately square connectivity about the central $Ag_2(RCO_2)_2$ unit, self-assembly of which generates a 2D-network (**VI**).



The three examples presented herein, $Ag(O_2CCF_3)L$ [L = 1,4-diazabicyclooctane (DABCO) **1**, tetramethylpyrazine (TMP) **2**, pyrazine (pyraz) **3**] (ESI†),[8] are archetypes for this approach using a small carboxylate anion. In each compound, pairs of silver centers are linked *via* carboxylate bridges. Each silver ion is further coordinated by two neutral ditopic ligands that provide linkages to two further silver centers resulting in assembly of the SBUs into a 2D grid of tiled rhomboids with an Ag_2 dimer at each node [Fig. 1(a)–(c)]. The structures of **1** and **2** adopt a staggered arrangement of layers [Fig. 1(d) and (e)] in which the anions occupy the interlayer space with each CF_3 group oriented toward the center of a rhomboid in an adjacent layer. The pairs of silver ions in **1** and **2** are bridged by a slipped version of the idealised synthon **III**, employing only one oxygen atom from each carboxylate anion. The structure of **3** differs in that the layers are now aligned to give a channel structure. This alignment appears to be permitted due to the stacking of the planar pyrazine ligands (face-to-face separation 4.34 Å). The versatility of the silver carboxylate bridge is further illustrated in **3** by its adaptation from the discrete linkage seen in **1** and **2** to an infinite linkage that lies mid-way between the ring [$R^2_2(8)$] and chain [C(4)] arrangements[9] well known for the (organic) carboxylic acid analog. This permits cross-linking of the 2D network [Fig. 1(c)] into a 3D network [Fig. 1(f)]. In contrast to **1** and **2**, the anions in **3** are oriented parallel to the layers.

Importantly, it is apparent that the integrity of the silver(I) carboxylate dimer, and thus its structure-directing role, can be maintained within a variety of related bridging carboxylate coordination modes.[10] This offers the prospect of both control and reliability of the overall structural arrangement while maintaining some flexibility. These traits are often cited as being advantages offered by hydrogen bonds rather than by coordination bonds in supramolecular chemistry.[11] It should also be emphasized that the approach described here differs from the predominant approach to coordination networks, especially those involving silver(I) ions.[12] Rather than using

Dimensions: Ag–Ag (bridged), vertical (Ag···Ag) and horizontal (Ag_2···Ag_2) dimensions of rhomboids, and interlayer separation, respectively. **1**: 3.75, 10.63, 12.58, 6.20 Å; **2**: 3.82, 10.83, 13.02, 6.47 Å; **3**: 4.00, 8.95, 13.22, 7.01 Å.

weakly coordinating anions to avoid disruption of a cationic network formed from Ag^+ centers and neutral polytopic ligand connectors, as is the common practice, here we have deliberately used the anions as an integral part of the final *neutral* network.[13] Therein, this approach provides a new avenue to the construction of neutral frameworks that complements the recent approaches of the groups of Yaghi[6] and Cotton[14] in linking pairs of *divalent* transition metal ions *via* polycarboxylate units to yield a variety of networks, polygons and polyhedra. Thus, this approach utilizes what might be considered a 'soft' or adaptable SBU (**V**) that appears to offer reliable 2D network formation coupled with flexibility of the silver(I) carboxylate linkage, permitting accommodation of the specific packing demands of the network for a given ditopic ligand, L.

We are currently exploring a variety of extensions of this approach including changing the length of the linkages, the use of polytopic connectors, and the provision of additional network links through use of polycarboxylate anions, with a view to developing adaptable cavity and channel-containing network solids.

Support for this work from the NSF (CHE-9988184) is gratefully acknowledged.

First published as an Advance Article on the web 7th November 2001

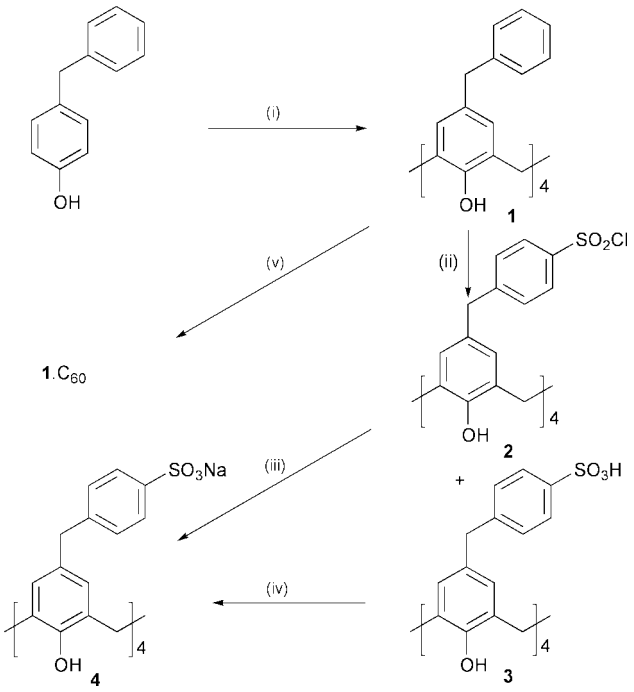
p-Benzylcalix[4]arene is formed in good yield by a direct "one pot" reaction involving *p*-benzylphenol and formaldehyde, selectively converted to the corresponding chlorosulfonyl and sulfonate analogues.

There is a growing interest in cyclooligomeric compounds called calix[*n*]arenes.[1] These bowl shaped (usually $n = 4, 5$) or more flexible ($n \geqslant 6$) macrocycles can form a diverse range of molecular assemblies. The synthesis of calixarenes has been widely investigated by Gutsche *et al.* and others, leading to well-established procedures for their preparation in reasonable yields.[2,8] However, these focus mainly on *p*-^{t}Bu- calix[*n*]arenes derived from base or acid catalysed condensation of *p*-^{t}Bu-phenol and formaldehyde, leading to the major calixarenes (n = 4, 5, 6, and 8) and other higher calixarenes.[2,3] In contrast, the direct syntheses of calixarenes derived from other *p*-alkylphenols are not extensively investigated and are generally formed in low yields;[6] this is an impediment to developing their chemistry. Base catalysed condensation of *p*-benzylphenol and formaldehyde, for example, leads to a mixture of *p*-benzylcalix-[5,6,8]arenes in 33%, 16% and 12% yields respectively,[5–7] as well as *p*-benzylcalix[7 and 10]arenes,[4,9,10] with no evidence for the formation of the *p*-benzylcalix[4]arene. Herein we report the synthesis of *p*-benzylcalix[4]arene as the first 'major' calixarene of the *p*-benzylcalix[*n*]arene family now available in good yield. The calix[4]arene is new and its availability offers scope for further elaboration such as *O*-alkylation, aromatic substitution of the benzyl groups, and as a receptor molecule, both aspects being established herein with the synthesis of the water soluble sulfonated *p*-benzylcalix[4]arene and the formation of a discrete 1 : 1 complex of the calixarene with C_{60} (Scheme 1).

The rigid cone structure of the phenolic-containing array with the flexibility of the benzyl moieties, offers scope for complexation of a range of substrates, of varying shape and electronic characteristics.

The base induced condensation reaction of *p*-benzylphenol and formaldehyde, proceeds smoothly and quickly relative to the similar condensation of its *p*-^{t}Bu-phenol analogue.[2] Oligomerization of *p*-benzylphenol formed at 120 °C using aqueous formaldehyde as the reaction medium with a catalytic amount of sodium hydroxide, affording a clear beige glass, consisting exclusively of *p*-benzylcalix[8]arene as the sole calixarene formed (TLC, NMR), with the consumption of all the starting phenol. Other products presumably are linear oligomers, noting that corresponding oligomers are formed in the condensation of *p*-^{t}Bu-phenol. Upon addition of diphenyl ether to this material and increasing the temperature quickly to 260 °C over half-an-hour and holding the temperature at reflux for 3 hours affords *p*-benzylcalix[4]arene, **1** in 60% isolated yield.†

It is noteworthy that the outcome of the reaction changes dramatically when either the ramping period or the reflux temperature is altered. For instance when the ramping is over one hour instead of half-an-hour and the reflux temperature is 220 °C instead of 260 °C and even over an extended period of reflux (10 h) the conversion to *p*-benzylcalix[4]arene accounts for only 16% of the starting material.



Scheme 1 Reagents and conditions: (i) Ph_2O, NaOH, H_2CO, 260 °C, 3 h; (ii) Anh. DCM, $ClSO_3H$, rt, 5 h, Argon; (iii) Py–H_2O, $NaHCO_3$, 100 °C; (iv) NaOH; (v) C_{60}, Tol.

The organic free solvent condensation to give the *p*-benzylcalix[8]arene also depends on the reaction conditions, notably, the molar ratio of the base to *p*-benzylphenol and the amount of formaldehyde used. Interestingly, this reaction always gives *p*-benzylcalix[8]arene in varying amounts which is easily separated, precipitating from the reaction mixture upon addition of acetonitrile. The mother liquor contains a mixture of *p*-benzylcalix[4,5,6,7]arenes which can be recycled and, if desired, separated (Table 1).

The ready availability of compound **1** allowed the preparation of the water soluble sulfonated derivative. This adds a novel lipophilic and highly charged calixarene to the expanding

Table 1 Product distribution of solvent free base induced condensation of *p*-benzylphenol (10 g) and formaldehyde (15 ml) using different molar ratios of base to *p*-benzylphenol at 110 °C

Molar ratio	*p*-Benzylcalix[*n*]arene distributions
0.045 NaOH	$n = 8$, 30%[a]
0.045 KOH	$n = 8$, 30%[a]
0.26 NaOH	$n = 8 > 6 > 4 > 7$

0.34 NaOH	$n = 8 > 5 > 4$
0.34 KOH	$n = 6 > 5 > 8$

[a] Isolated yield, no other calixarenes present.

 DOI: 10.1039/b106161p

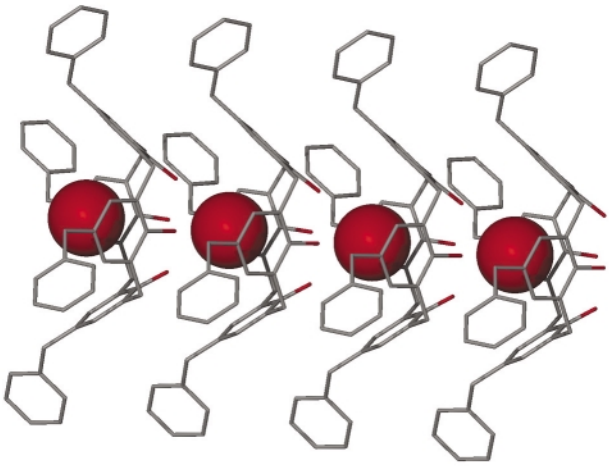

Fig. 1 Molecular structure of *p*-benzylcalix[4]arene showing the inclusion of water (space filling) within a self inclusion leading to a columnar array (hydrogen atoms have been removed for clarity).

chemistry of the water soluble calixarenes. The sulfonated *p*-benzylcalix[4]arene was prepared using the chlorosulfonation approach, isolated either in 60% yield as the sulfonic acid **3**, which slowly absorbs moisture as a deliquescent solid or as the sodium salt **4**. The chlorosulfonyl analogue, **2** can be intercepted and isolated in 30% yield (this yield can be improved under dry forcing reaction condition).†

The structure of *p*-benzylcalix[4]arene (Fig. 1) was established using diffraction data,‡ and shown to be an inclusion complex with water sandwiched between calixarenes in a columnar array, Fig. 1. The water resides deep in the cavity of the cone conformation, hydrogen bonded to the lower rim hydroxy groups. This is different to the water inclusion complex of sulfonated calix[4]arene with water in the cavity whereby the O–H groups are H-bonded (H$\cdots\pi$) to adjacent aromatic rings.[11,12] Another structural feature is the columnar π-stacking of the 1 : 1 supermolecules.

The C_{60} inclusion complex of **1** was prepared by slow evaporation of an equimolar toluene solution of both components. While crystals suitable for X-ray-diffraction studies were available, solution of the structure has proved elusive. Nevertheless, the structure is likely to be similar to those reported by Atwood *et al.*[13,14] where the fullerenes form columnar arrays. Indeed the cell dimensions are remarkably similar for the 1 : 1 complex of C_{60} with *C*-ethylphenylcalix[4]resorcinarene (tetragonal, $a = b = 18.9296(7)$, $c = 27.2702(13)$ Å,[13] and tetragonal, $a = b = 19.2183(3)$, $c = 27.7911(6)$ Å for **1**.C_{60}). Moreover, the similarity of the two cells supports the assignment of the 1 : 1 ratio of the two components.

In conclusion, we have demonstrated the accessibility of *p*-benzylcalix[4]arene in good yield and its water soluble sulfonated derivatives, opening the challenge to expand and diversify the chemistry. Moreover, the results give insight into the advantage of organic solvent free oligomerisation reactions.[15,16]

We are grateful to the Australian Research Council for support of this work.

Notes and references

† *Synthesis* of compound **1**. *p*-Benzylcalix[4]arene was prepared by an adapted method described in ref. 2. A mixture of *p*-benzylphenol (20.1 g, 0.109 mol), 13 ml of formaldehyde solution and (0.19 g, 0.0049 mol) of 10 M sodium hydroxide was stirred and heated at 120 °C for *ca.* 2 h forming a gummy beige material. 165 ml of warm diphenyl ether was added and the contents were heated first for 2 h at 120 °C, before ramping the temperature to 260 °C over half-an-hour. Refluxing at 260 °C was maintained for 3 h forming a dark amber solution, and the mixture then allowed to cool to rt. Diphenyl ether was evaporated and the viscous material obtained was washed and dried *in vacuo* affording an amber oil which crystallized slowly on standing, and upon addition of acetone (150 ml), *p*-benzylcalix[4]arene, **1** was obtained as a micro-crystalline white powder. Yield 60%, mp 204.5–205.6 °C, MS (ESI$^+$): *m/z* 807.34 [M.Na$^+$], 844.44 [M(H_2O).K$^+$], $C_{56}H_{48}O_4$ (784.34). ^{1}H NMR ($CDCl_3$, 300 MHz) δ 3.39 (d, 4H, Ar-CH_2-Ar), 3.76 (s, 8H, Ar-CH_2-Ph), 4.18 (d, 4H, Ar-CH_2-Ar), 6.78 (s, 8H; Ar-H), 7.11–7.30 (m, 20H, Ph), 10.13 (s, 4H, OH), ^{13}C NMR: ($CDCl_3$, 300 MHz) δ 32.1 (Ar-CH_2-Ar), 41.3 (ArCH_2-Ph), 126.2 (Ar), 128.4 (Ar), 128.6 (Ar), 129.0 (Ar) 129.5 (Ar), 134.7 (Ar), 141.3 (Ar), 147.2 (Ar-OH). *Synthesis* of compounds **2** and **3**. To a solution of *p*-benzylcalix[4]arene (0.4 g, 0.51 mmol) dissolved in 20 ml of dry dichloromethane, 1 ml of chlorosulfonic acid was added dropwise. The biphasic mixture was stirred at rt for *ca.* 5 h with formation of a viscous amber coloured material. The reaction mixture was poured over ice, and the organic phase was separated, treated successively with 1 M sodium bicarbonate ($\times$ 2), brine solution ($\times$ 2), water and dried ($MgSO_4$) affording the tetrachlorosulfonyl of *p*-benzylcalix[4]arene, **2**. Yield 56%, decomp. 180–195 °C, MS (ESI$^+$): *m/z* 1201.9 [M.Na$^+$], 1218.1 [M.K$^+$], $C_{56}H_{44}O_{12}S_4Cl_4$ (1179.01). ^{1}H NMR ($CDCl_3$, 300 MHz) δ 3.45 (d, 4H, Ar-CH_2-Ar, J_{AB} 13.2 Hz), 3.87 (s, 8H, Ar-CH_2-Ph), 4.24 (d, 4H, Ar-CH_2-Ar), 6.79 (s, 8H, Ar-H), 7.36 (AA′XX′, 8H, Ph-H), 7.94 (AA′XX′, 8H, Ph-H), 10.15 (s, 4H; OH), ^{13}C NMR ($CDCl_3$, 300 MHz) δ 32.1 (Ar-CH_2-Ar), 41.3 (ArCH_2-Ph), 127.4 (Ar), 128.7 (Ar), 129.8 (Ar), 130.1 (Ar) 132.7 (Ar), 142.4 (Ar), 147.9 (Ar), 149.7 (Ar-OH). The aqueous phase was filtered and treated with activated charcoal ($\times$ 2) leaving a clear light amber solution. Water was evaporated affording a deliquescent light gray solid, which crystallized from acetone to afford the sulfonic acid of *p*-benzylcalix[4]arene, **3**. Yield 80% decomp. 166–170 °C, MS (ESI$^+$): *m/z* 1105.2 [M.H$^+$], 1127.2 [M.Na$^+$], $C_{56}H_{48}S_4O_{16}$ (1104.2). ^{1}H NMR (d_6-DMSO, 300 MHz) δ 3.68 (s, 8H; Ar-CH_2-Ph), 4.08 (br s, 8H, Ar-CH_2-Ar), 6.25 (br s, COH/SOH, shifts downfield with increasing [H_2SO_4]), 6.88 (s, 8H, Ar-H), 7.15 (AA′XX′, 8H, Ph-H), 7.53 (AA′XX′, 8H, Ph-H), ^{13}C NMR (d_6-DMSO, 300 MHz) δ 49.2 (Ar-CH_2-Ar), 49.5 (ArCH_2-Ph), 126.2 (Ar), 128.7 (Ar), 129.1 (Ar), 129.7 (Ar) 134.2 (Ar), 143.2 (Ar), 145.3 (Ar), 148.2 (Ar-OH). Compound **4** was prepared by titration of compound **3** with 1 M sodium hydroxide to neutral pH. Treatment with methanol afforded sodium sulfonates of *p*-benzylcalix[4]arene, **4**, decomp. 200–210 °C. ^{1}H NMR (CD_3OD, 300 MHz) δ 3.65–3.95 (m, 8H, Ar-CH_2-Ar), 3.81 (s, 8H, Ar-CH_2-Ph), 4.82 (s, 4H, COH), 6.90 (s, 8H, Ar-H), 7.22 (AA′XX′, 8H, Ph-H), 7.73 (AA′XX′, 8H, Ph-H).

‡ *Crystal data*. Crystals of **1** for X-ray structural determination were grown from a moist acetone–propan-2-ol solution of *p*-benzylcalix[4]arene affording [*p*-benzylcalix[4]arene]·[H_2O]$_{0.5}$: $C_{56}H_{48}O_{4.5}$, space group *P*4/*n*, $a = b = 19.0703(3)$, $c = 5.6631(11)$ Å, $V = 2059.4(6)$ Å^3, $T = 173(2)$ K, $\rho_{calc.} = 1.279$ g cm^{-3}, $\mu = 0.080$ cm^{-1} (no correction), $Z = 2$, Mo-K$_\alpha$ radiation, $2\theta_{max} = 50°$ (1484 observed, $I > 2\sigma(I)$, 139 parameters, no restraints, $R_1 = 0.0455$, $wR_2 = 0.1245$ (all data), Data were collected at 173(1) K on an Enraf-Nonius Kappa CCD diffractometer. The structure was solved by direct methods (SHELXS-97) and refined with a full matrix least-squares refinement on F^2 (SHELXL-97), hydrogens included at calculated positions, $S = 1.079$. An extended chain structure formed by covalently linking polyoxovanadate cages with tetrahedral six rings

Xiqu Wang, Lumei Liu, Ge Zhang and Allan J. Jacobson*

Department of Chemistry and Materials Research Science and Engineering Center, University of Houston, Houston, TX 77204-5641, USA. E-mail: ajjacob@uh.edu

Received (in Cambridge, UK) 13th September 2001, Accepted 24th October 2001
First published as an Advance Article on the web 15th November 2001

The compound $Cs_{10.5}[(V_{16}O_{40})(Si_{4.5}V_{1.5}O_{10})]\cdot 3.5H_2O$ is the first example of an extended structure in which a polyoxometallate anion is linked by an extended tetrahedral unit.

A promising approach to the synthesis of new microporous compounds is to connect nanoscale 'cores' with extended linking groups *via* covalent bonds. Yaghi and coworkers have used this concept in the synthesis of a number of microporous phases in which metal–oxo cores have been connected with multifunctional organic linking groups. The compound $(benzenedicaboxylate)_3Zn_4O$ is a recent example.[1] We have explored a similar approach using preformed vanadium borophosphate anions linked by metal cations into three-dimensional structures.[2] Others have synthesized compounds where polyoxovanadate ions are linked in a similar way.[3–5] A combination of both approaches in which polyoxoanion clusters are *covalently* linked to form stable microporous structures would be of special interest since polyoxovanadates are known to adopt a wide variety of structures with shapes ranging from cages to bowls, baskets, and belts.[6–8] A great diversity of framework topologies is therefore possible. Precedents for this strategy are found in the known compounds based on $Mo_4O_4^{4+}$ and $V_5O_9^{2+}$ 'cores' linked by single phosphate anions[9,10] and in the related structures of the minerals pharmacosiderite[11] and phosphovanadylite.[12] Here, we report the first example (to our knowledge) of an extended structure in which a polyoxovanadate ion is linked covalently by an extended tetrahedral linking unit. We note that chains of oxobridged cluster units have been previously reported.[13,14] The compound $Cs_{10.5}[(V_{16}O_{40})(Si_{4.5}V_{1.5}O_{10})]\cdot 3.5H_2O$ **1** contains a linear chain of $V_{16}O_{40}^{16-}$ anion shells linked by $(Si_{4.5}V_{1.5}O_{10})^{5.5+}$ six-rings and represents a first step towards the synthesis of three-dimensional expanded structures based on polyoxoanions.

In a typical synthesis of compound **1**, a mixture was prepared by mixing 0.14 g fumed silica, 0.26 g $VOSO_4\cdot 3H_2O$ and 1 ml H_2O. The mixture was then sealed together with 0.5 ml CsOH 50 wt% aqueous solution in a flexible Teflon bag in air. The bag was subsequently sealed in a steel reaction vessel filled with water to about 60% volume, and heated at 240 °C for 3 days. After cooling to room temperature over 3 h, the products were filtered off, washed with water, and dried in air. Dark-brown plate-like crystals of **1** were recovered as a minor phase together with blue crystals of $Cs_2(VSi_4O_{11})\cdot 3H_2O$ (VSH-2),[15] and were characterized with electron microprobe analysis, IR spectra† and single crystal X-ray diffraction.‡

In the crystal structure of **1**, two eight-membered rings of VO_5 tetragonal pyramids that share basal edges are fused together perpendicularly to form a cage. Two opposite windows of the cage are each capped by an additional VO_5 pyramid forming a spherical shell of composition $[V_{16}O_{40}]$ (Fig. 1).

The shell can be considered as a derivative of the α-Keggin cluster shell $[V_{12}O_{36}]$. The six square windows of the α-Keggin shell can be capped by V=O groups to form a $[V_{18}O_{42}]$ shell.[16] Substitution of two VO_5 pyramids of the $[V_{18}O_{42}]$ shell by Si_2O_7 dimers leads to the $[V_{16}Si_4O_{46}]$ unit of **1**. The spherical

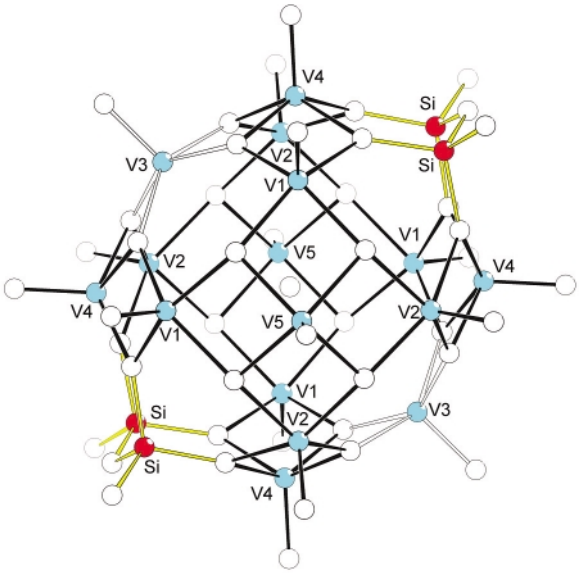

Fig. 1 The spherical shell $[V_{16}Si_4O_{46}]$ in **1**. Empty circles are oxygen atoms. The two eight-rings of square pyramids (vertical and horizontal) are plotted with black solid bonds.

shell $[V_{16}Si_4O_{46}]$ in **1** has the symmetry 2/*m* and has a water molecule located at the shell center. The shortest distances from the water oxygen to the shell oxygen and vanadium atoms are 3.52 and 3.57 Å, respectively. Neighboring $[V_{16}Si_4O_{46}]$ shells are linked together by $(V_{1.5}Si_{0.5})O_4$ tetrahedra to form infinite chains running along [001]. The $(V_{1.5}Si_{0.5})O_4$ tetrahedra share corners with the SiO_4 tetrahedra of the shells to form a six-membered ring that has the symmetry 2/*m* (Fig. 2). Alternatively the chain may be described as made up of $[V_{16}O_{40}]$ cluster anions that are linked by single six-rings of composition $[Si_{4.5}V_{1.5}O_{10}]$. Efforts to solve the V,Si cation disorder in the $(V_{1.5}Si_{0.5})O_4$ tetrahedra by refinements in lower symmetry space groups were unsuccessful. Caesium cations and water molecules occupy the space between the chains.

The SiO_4 tetrahedron in **1** has regular Si–O bond lengths 1.604–1.630 Å and O–Si–O angles 105.8–112.3°. The $(V_{1.5}Si_{0.5})O_4$ tetrahedron has an average V–O bond length of 1.69 Å and a bond valence sum (bvs) of 5.45 v.u. calculated using bond valence parameters for V^{5+}–O bonds.[17] The high bvs value is a result of the partial substitution of Si^{4+} for V^{5+}. The chemical composition was confirmed by electron microprobe analysis and is consistent with the occupancies refined

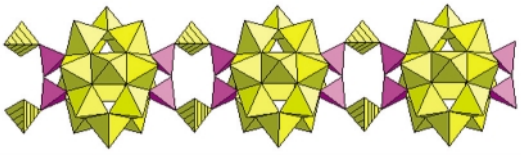

Fig. 2 The one-dimensional chain in **1**; $(V_{1.5}Si_{0.5})O_4$ tetrahedra are hatched.

 DOI: 10.1039/b108303a

from the X-ray data. The VO_5 pyramids have apical V=O bond lengths 1.602–1.633 Å and basal V–O bond lengths 1.908–2.017 Å. Bond valence sums calculated for the V atoms of the pyramids are in the range 4.03–4.20 v.u., in agreement with their V^{4+} characters.

The $[V_{16}Si_4O_{46}]$ unit of **1** has four silicate tetrahedral corners available for further covalent bonding, and therefore, can readily be linked into a chain. In contrast, in the related Keggin cluster derivatives $[As^{III}_{2n}V^{IV}_{18-n}O_{42}]^{4-}$, n = 3, 4 where n VO_5 pyramids of a $[V_{18}O_{42}]$ shell are replaced by As_2O_5 trigonal pyramid dimers, the clusters cannot link because of the presence of the electron lone pairs on As(III).[18,19] The tetrahedral configuration of the four As_2O_5 groups in $[As^{III}_8V^{IV}_{18}O_{42}]^{4-}$, however, points to possibilities for similar substitution by Si_2O_7 groups to form, for example, clusters of composition $[Si_8V_{14}O_{50}]$. Such clusters could favor formation of three-dimensional framework structures in which each cluster functions as a super-tetrahedron.

In summary, we have synthesized hydrothermally a novel one-dimensional silicovanadate that demonstrates the possibility of decorating cage-like polyvanadate clusters with silicate tetrahedra and linking them covalently into extended structures. This example suggests a synthetic route to novel microporous materials by using polymetalate nanoclusters as building units.

Received (in Columbia, MO, USA) 14th August 2001, Accepted 2nd October 2001
First published as an Advance Article on the web 15th November 2001

The complexation of Bovine Serum Albumin with sulfonatocalix[*n*]arenes has been demonstrated by means of electrospray mass spectrometry, dynamic light scattering and atomic force microscopy; with sulfonatocalix[4]arene one strong and two weaker binding sites are detected; the effects on the structure of thin films formed by surface deposition of BSA show that the sulfonatocalix[*n*]arenes act to reticulate the films and produce essentially planar systems.

During the last few years there has been a rising interest in the application of *p*-sulfonatocalix[*n*]arenes as bioactive molecules, reports on the action of these molecules include chloride ion-channel blocking,[1] anti-thrombotic[2] and anti-viral effects,[3] the lack of cell cytotoxicity[4] and the inhibition of enzymatic activity of lysyl-oxidase.[5] These effects have been measured *in vitro* or on the pure proteins themselves. However in order to cross over to *in vivo* activity one interesting experiment remains; do these molecules interact with the most common of the physiological proteins, the Serum Albumins? The Serum Albumins are a class of globular circulating proteins with a molecular mass of 67 kDa and molecular size of $4 \times 4 \times 14$ nm.[6] A major role of these proteins is their adhesion at surfaces forming anchors for subsequent formation of protein films. In addition it has been demonstrated that the Serum Albumins possess a wide number of different binding sites for cations and anions. In the case of anion binding three strong binding sites for fatty acids are located at Arg117, Lys351 and Lys475,[7] three weaker anion binding sites have also been identified, these may include the salicylate binding sites, Lys199 and Arg 222.[8] We have previously studied the formation of films at surfaces by the Serum Albumins and have demonstrated that molecular recognition of cations plays a determinant role in the structuring of such films.[9] In this communication we report on the complexation of Bovine Serum Albumin by the sulfonatocalix[*n*]-arenes.

Fig. 1 shows the mass spectrum† of BSA in the presence of sulfonatocalix[4]arene **1** at a molar ratio of 1:4. The observed molecular mass of BSA at 66.5 kDa is in agreement with literature.[6] Additional peaks showing specific complexation[10] and corresponding to the 1:1 (67.2 kDa), 1:2 (68.1 kDa) complexes and a very weak peak due to a 1:3 (68.8 kDa) complex are observed, the intensity of the 1:1 being the greatest. For **2** (not shown) with BSA only a weak signal for the 1:1 complex is observed and for **3** no complexation is observed by ES–MS. The steric hindrance for **2** and **3** reduces their access to the anion binding sites and inhibits complexation, in contrast to **1** for which one strong binding site is sterically available.

Surface plasmon resonance studies show that the complexation of BSA with **2** has no effect on the adhesion properties of the protein (data not shown).‡

Sulfonatocalixarenes **1**, **2** and **3** in aqueous solution cause precipitation of BSA at 2.36 mM concentration with molar rations above 1:6, 1:4 and 1:3 respectively, in the presence of a Tris buffer at 10 mM, pH 7.4 and 150 mM NaCl such precipitation is not observed. Indeed dialysis§ showed complexation of 36 molecules of **2** (5.0 mL at 9.1×10^{-4} mol L^{-1}) to BSA (1.0 mL at 2.9×10^{-5} mol^{-1}, and hence **2**/BSA = 157). This higher number of molecules of **2** bound to BSA in comparison with the distribution found by ES–MS shows either the occurrence of additional non-specific complexation which cannot be detected by mass spectrometry or an effect due to the variation in ionic strength. Microcalorimetry§ titration of BSA with **2** shows an exothermic interaction with a standard enthalpy of interaction equal to (-8600 ± 200) kJ mol^{-1} at 304 K in the presence of 10 mM Tris and NaCl 150 mM at pH 7.4 indicating an average enthalpy of -239 kJ mol^{-1} per bound **2**. The measurement of the titration curve of BSA by **2** is in progress.

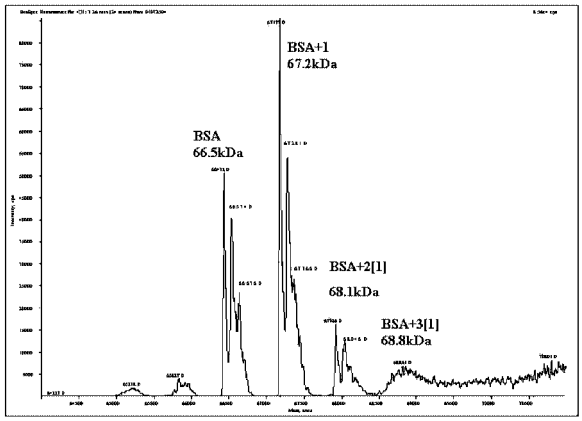

Fig. 1 ES–MS spectrum of the BSA–**1** complexes at a molar ratio of 1:4.

The results of studies using photon correlation spectroscopy¶ are given in Fig. 2(a) and (b).

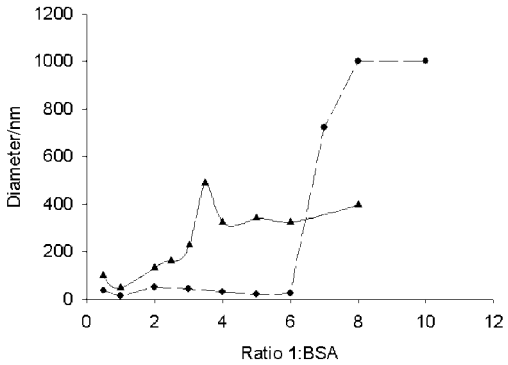

Fig. 2 PCS titration curves for BSA:**1**, (a) in buffer (●) and (b) in the absence of buffer (▲).

 DOI: 10.1039/b109190p

It appears clearly that the average size reaches a maximum at a **2**/BSA ratio of about 3 in the presence of water and that the Tris–NaCl buffer delays the occurrence of strong aggregation. However, at high **2**/BSA ratios in the presence of tris–NaCl, a large increase in size is also observed in possible correlation with the high number of bound **2** and the high observed exothermicity observed under these conditions. Hence the Cl^- counter ions delay the complexation. In pure water a specific binding of three calixarenes per BSA is hence detected both by ESMS and PCS, however higher **2**/BSA ratios also induce non-specific binding and finally protein precipitation. This suggested that mixtures of **2** and BSA dissolved in water should be contacted with mica surfaces after drying of the solutions. The effect of **2** on the structure of films prepared by deposition of a 1 : 1 solution on mica were studied by non-contact mode AFM.‖ The images for BSA alone and in the presence of **2** are shown in Fig. 3(a) and (b), respectively. For BSA alone a highly irregular cracked surface with large linear structures is observed with an rms roughness of 1236 nm. In the presence of **2** a planar unfractured film with rms roughness of 2.8 mn is observed.

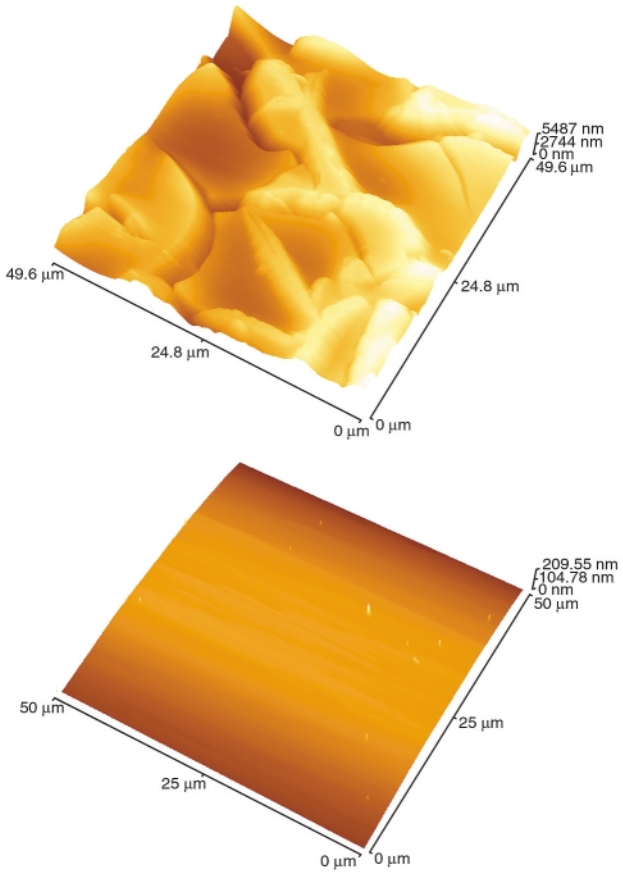

Fig. 3 (a) AFM image of a film of BSA at 50 µm scan range and (b) AFM image of a BSA–sulfonatocalix[4]arene film at 50 µm scan range.

Optical measurements have shown that the films are typically 4–6 µm in thickness.

From the above it has been shown that BSA complexes with sulfonatocalix[*n*]arenes; this involving multiple binding for sulfonatocalix[4]arene, complexation of which leads to aggregation of the protein and in the case of film formation to stabilisation of the film. We plan also to study the structure of films like those shown in Fig. 3 by means of small angle X-ray scattering. Indeed, it cannot be totally excluded that the sulfonatocalix[*n*]arenes induce some crystallisation of the proteins since high concentrations of sodium sulfate are used to crystallise a number of proteins with acidic isoelectric points, such as albumins.[11]

We thank the Fondation pour la Recherche Medicale for support for the AFM.

Notes and references

† Electrospray mass spectrometry was carried out on a Sciex API 165 spectrometer, the solvent was H_2O–MeOH–HCO_2H (50 : 50 : 0.1), with a BSA concentration of 10 pmol μl^{-1}. The spectra were deconvoluted to obtain the molecular masses.

‡ Surface plasmon resonance was carried on a Texas Instruments SPREETA 256 channel system at 20 °C using a flow cell.

§ Non-contact mode imaging was performed using a Themomicroscopes Explorer system; using a 11 µ linearised scanner, Si cantilevers with resonant frequencies of 159 kHz were used, the scan rate was 1.2 Hz.

¶ Photon correlation spectroscopy was carried out on a Malvern 4700C spectrometer equipped with a Siemens 40mW laser at 633 nm, values were measured at 90 °C in 10 mm cells using a thermostated bath at 25 °C.

‖ Equilibrium dialysis experiments were performed at 298 K with Spectra R Cellulose Ester membranes (cut off: 10000 Da) for a duration of 45 h. Unbound **2** was quantified by UV spectroscopy at λ = 300 nm.

The microcalorimetry experiments (Microcal Omega MC-2, Microcal) were performed in presence of a huge excess of **2** (3.3 mM) in the cell so allowing the assumption that all the added protein is bound to **2**. The small dilution heat of BSA (-20 kJ mol^{-1}) is taken into account in the quoted reaction enthalpy.

Formation of a novel porphyrin–gold nanoparticle network film induced by IR light irradiation

Mami Yamada, Akiyoshi Kuzume, Masato Kurihara, Kenya Kubo and Hiroshi Nishihara*

Department of Chemistry, School of Science, The University of Tokyo, Tokyo 113-0033, Japan. E-mail: nisihara@chem.s.u-tokyo.ac.jp

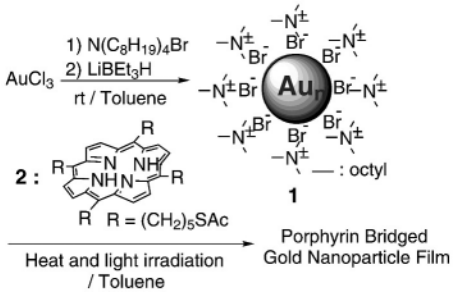
Received (in Cambridge, UK) 24th July 2001, Accepted 30th October 2001
First published as an Advance Article on the web 15th November 2001

IR light irradiation of a mixed toluene solution of ammonium salt-stabilized gold nanoparticles with 3.8 ± 0.8 nm core diameter and a porphyrin thioacetate derivative affords a thin photoactive film of the cluster–porphyrin network.

Many attempts to construct 2D/3D structures of nanometer-scale metal particles[1] have been made in order to attain more advanced properties brought about by collective interaction among the assembled metal particles for use in electronic and photochemical devices.[2] Current research is moving into a new stage of functionalization by introducing redox and photoactive species into metal nanoparticle arrays so that the specific properties of metal nanoparticles associated with the electronic state of surrounding functional molecules are changeable upon an applied potential[3] or light.[4] From this viewpoint, we previously reported on an electrochemical procedure effective in fabricating redox-active gold[1e,5] and palladium[6] nanoparticle films.

In this report, we present a new approach by which a photofunctional nanoparticle film is constructed. The system consists of a combination of an octylammonium bromide-covered gold nanoparticle (**1**) and a new porphyrin derivative, mesotetra(5-thioacetylpentyl)porphyrin, with four alkyl chains terminated with a thioacetate group (**2**) (Scheme 1). It is expected that heat activation can produce aggregation of **1** bridged by **2** based on the fact that the adsorption force of the ammonium salt on the gold nanoparticle surface is weaker than that of thiolate. Heating a toluene solution of the mixture caused substantial coagulation, and resulted in precipitation at the bottom of the vessel. In this study, we successfully introduced an extra perturbation of 'light irradiation' in addition to heating, in order to control the cohesion process of the nanoparticles to form a film on a specific part of the substrate. The film formation process, along with the morphological and photochemical properties of the constructed film, is reported.

A toluene solution of **1** was prepared by use of the single-phase method employed in our previous report.[6] In brief, $AuCl_3$ (29 mg, 0.097 mmol) dissolved in a micelle solution of tetraoctylammonium bromide (0.53 g, 0.97 mmol) in degassed toluene (90 cm^3) was reduced by 1.0 mol dm^{-3} lithium triethylborohydride (0.73 mmol) in THF (0.73 cm^3), and stirred for 2 h. The mixture was diluted with 150 cm^3 toluene and then dried with a requisite amount of Na_2SO_4 to give a dark red solution of **1**, which was used without isolation, in order to avoid irreversible aggregation, for further experiments. The core diameter of the particles determined by transmission electron micrograph (TEM) images was 3.8 ± 0.8 nm. The core size was sensitive to the total concentration used in the synthetic procedure; *e.g.* it was diminished to 2.9 ± 0.8 nm in a ten times more dilute solution with the same mol ratio of the starting materials. The solution was stable for a few weeks in the absence of air, water and light. The porphyrin derivative **2**[7] equipped with four adsorptive units around a rigid planar porphyrin moiety to generate a chemically tight combination with **1**, was synthesized by a nucleophilic substitution reaction between potassium thioacetate and mesotetra(5-chloropentyl)porphyrin[8] in a yield of 87%.



Scheme 1

Fig. 1A displays time-resolved UV–VIS spectra of a mixed solution of **1** (15 cm^3) and **2** in toluene (38 μmol dm^{-3}/5 cm^3) with incident light of D_2 + W lamps for 2 h with simultaneous heating at 50 °C.[9] The formation of a purple thin film on the inner wall of the UV quartz cell was observed, and corresponded to a gradual increase of the absorption in the range of 500–900 nm (Fig. 1A). A film is formed in a circle where the irradiated light strikes indicating that the irradiation process is essential for formation of this film. The thus prepared film exhibits a red-shifted surface plasmon band of assembled **1** at 576 nm, and a sharp Soret band due to the porphyrin moiety of **2** at 420 nm (ε_{max} = 2.4 × 10^5 dm^3 mol^{-1} cm^{-1}), confirming that the film is essentially composed of porphyrin-bridged gold nanoparticles (Fig. 1A inset). Assuming that the molar absorp-

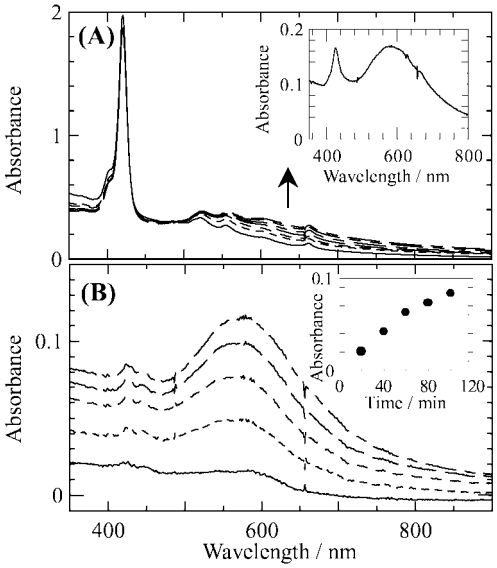


Fig. 1 (A) UV–VIS spectral changes of a mixture of **1** and **2** with incident light at every 20 min intervals for 2 h with simultaneous heating at 50 °C (from bottom to top). (Inset) The UV–VIS spectrum of the prepared film after the measurement. (B) UV–VIS spectrum of the porphyrin-bridged gold nanoparticle film on the wall of the UV cell prepared using an a Xe lamp (from bottom to top for 20, 40, 60, 80 and 100 min) with simultaneous heating at 50 °C in a mixture of **1** and **2**. (Inset) Correlation between the absorption intensity at 420 nm of the film and the irradiation time.

 DOI: 10.1039/b106682j

tion coefficient of the synthesized gold nanoparticles, ε_{max}, is *ca.* 1.2×10^7 dm^3 mol^{-1} cm^{-1},[10] the molar ratio of **1** to **2** in the film is calculated to be 1 : 19. The coverage of **1** is 1.6×10^{-11} mol cm^{-2}, corresponding to 4 layers having a total thickness of 25 nm based on an inter-particle spacing of 6.2 nm, as estimated from scanning tunneling microscopy (STM) (*vide infra*).

Fig. 1B shows the UV–VIS spectra of the films stuck on the inside of the cell prepared using an Xe lamp with different irradiation times.[11] The spectra present two bands, derived from **1** and **2**, respectively, similar to those shown in Fig. 1A, and the intensity of the absorption bands grows almost linearly with increase in irradiation time (Fig. 1B inset). The molar ratio of **1** to **2** is 1 : 7.5, indicating that the film contains fewer porphyrin moieties than that prepared using the D_2 + W lamps, as noted above, and in addition the film formation process depends on the light source.

Additional experiments were carried out for a detailed elucidation of the mechanism of film formation, and the following results were obtained: (i) the film cannot be constructed without a binding ligand of **2**, and insoluble black precipitates were collected at the bottom of the cell; (ii) there is no dependence of film formation on the wavelength of irradiated light between 360 and 840 nm; and (iii) light blocked by an infrared cut filter cannot produce a film. These results indicate that the main factor involved in film formation is 'the thermal energy of molecular vibration' in the quartz of the UV cell provided by IR light irradiation, which generates a specifically heated area of the inner wall. Consequently, the isolated and/or partially gathered nanoparticles are stuck on the irradiated spot, connected by a thioacetate group of porphyrin ligands, and the nanoparticle networks grow gradually in a three-dimensional direction.

The top of Fig. 2 shows an STM image of the porphyrin-bridged gold nanoparticle film prepared by photoirradiation with an Xe lamp for 1 h. It can be seen that many spherical particles are closely packed to cover the HOPG surface over an area *ca.* 100 nm^2. The average inter-particle distance shown in Fig. 2 (bottom) is 6.2 nm, which is reasonable compared with the expected value (6.0 nm) when **1** is bridged with **2** (the core diameter of the nanoparticle is 3.8 nm and the porphyrin linker length is 2.2 nm). This finding proves that the gold nanoparticles exist individually in the film without decomposition or flocculation by light irradiation.

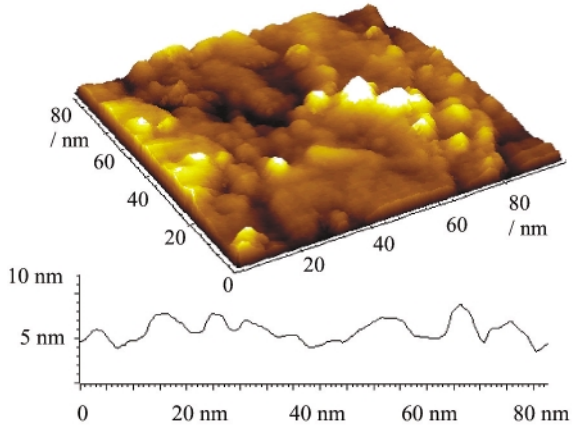

Fig. 2 STM image of a multilayer porphyrin-bridged gold nanoparticle film on HOPG (top), and a cross-sectional profile of the film (bottom). The image was taken at a current of 0.3 nA and a bias of 0.5 V with a Pt/Ir tip.

Film formation also occurs for larger gold nanoparticles with a 5.6 nm core diameter prepared by the method of Fink *et al.*[12] This demonstrates that this technique is possibly useful for film formation in a designated area. We also examined the photochemical properties of the film using an interdigitated array microelectrode,[13] which shows that the photocurrent response is switchable by light irradiation, and involves a reliable increase of conductivity in 30%. It can be deduced that the excited electrons of the porphyrin units induce faster electron transfer through the film.

In conclusion, we have synthesized a new porphyrin thioacetate derivative that can connect to ammonium salt-covered gold nanoparticles. The porphyrin-bridged gold nanoparticle films were formed on the substrate in a mixed toluene solution of the porphyrin and nanoparticles, and formation was induced by IR light irradiation.

This work was supported by Grants-in-Aid for Scientific Research (Nos. 11309003 and 12874085) from the Ministry of Culture, Education, Science, Sports, and Technology, Japan, and the Tokyo Ohka Foundation.

Si-BEZA – catalytic pyridinium triflate: a mild and powerful agent for the silylation of alcohols

Tomonori Misaki, Minoru Kurihara and Yoo Tanabe*

School of Science, Kwansei Gakuin University, 1-1-155 Uegahara, Nishinomiya, Hyogo 662-8501, Japan

Received (in Cambridge, UK) 16th August 2001, Accepted 9th October 2001
First published as an Advance Article on the web 5th November 2001

A highly efficient method of silylation using a novel agent, *Si*-BEZA (silylbenzamide), together with a pyridinium triflate catalyst was developed, wherein a variety of silyl groups can be introduced into sterically crowded alcohols under mild conditions.

The silylation of alcohols is indispensable for organic syntheses as the most reliable protective method.[1–3] Despite the well-established method, there still remains a strong need for improved efficiency. In view of the restrictions involved during elaborate syntheses of complex compounds, the development of mild and efficient silylation methods has become increasingly important for: (1) smooth silylation against sterically crowded and functionalized alcohols under mild conditions, (2) introduction of bulky silyl groups into unreactive alcohols, and (3) mild alternatives to some bulky-sized silyl triflates, one of the most powerful agents, because the preparation of silyl triflates sometimes requires tedious procedures.

Thus, we were prompted to explore a more efficient system. Consistent with the interest in the mild and effective silylations,[4,5] we wish to introduce here a novel, efficient, and powerful silylation agent, *Si*-BEZA [**1**, *O*-(trisubstituted silyl)benzamide] together with catalytic $PyH^{+}\cdot OTf^{-}$ (**2**, pyridinium triflate). The present method is of general interest, because it covers several types of silylations [TMS, TES, TBMDS, TIPS (triisopropylsilyl), and TBDPS (*tert*-butyldiphenylsilyl)] against sterically crowded, functionalized, aliphatic, allylic, and phenolic hydroxy groups under mild conditions.

Preparation and handling of both *Si*-BEZA (**1a–e**) and $PyH^{+}\cdot OTf^{-}$ (**2**) are quite easy (Table 1).† Compared with the

corresponding silyl triflates (especially, TBDMS, TIPS, and TBDPS), **1c–e** are considerably moisture-insensitive. Without catalyst **2**, the reaction did not proceed. Namely, *Si*-BEZA (**1**), itself, is adequately stable and **2** acts as a useful trigger. An analogous pyridinium salt, PPTS did not promote the silylation. Diphenylammonium triflate[6] is also a good catalyst, we chose **2** due to its convenience. Careful NMR experiments of **1c** revealed that the structure was not an *N*-TBDMS amide but a *O*-TBDMS imidate. The high silylation potential originated from the strong driving force of the reactive *O*-silyl imidate transformed into thermodynamically stable benzamide with the release of the silyl moiety. Table 2 lists the results of the silylation of sterically crowded (silylation-resistant) and/or functionalized alcohols.‡ Indeed, silylation-resistant terpinen-4-ol (**3**), linalool (**4**), and 2,4-di-*tert*-butylphenol (**5**) were successfully silylated in excellent yield under mild conditions. In the case of **5**, BTF solvent was more suitable than THF. Several functionalized alcohols, *i.e.*, allylic **4**, tetrahydropyranyl **6**, ester **7** and aldol **8** tolerated the present conditions. To our knowledge, this is the first example of the bulky TBDPS group being practically introduced into a tertiary alcohol **9**.[7]

The present method has another practical merit of easy work-up procedure. After the reaction was completed, solid benzanilide was easily filtered from the mixture containing the desired silyl ester and/or separated by standard column chromatography. Two parallel experiments for silylations using TIPS-BEZA (**1d**) with linalool (**4**) and *o*-cresol (**10**) demonstrate that the ability of **1d** is considered to rival or surpass the most powerful method using *Si*OTfs–2,6-lutidine[8] under standard conditions (Figs. 1 and 2). Small amounts of polymerization

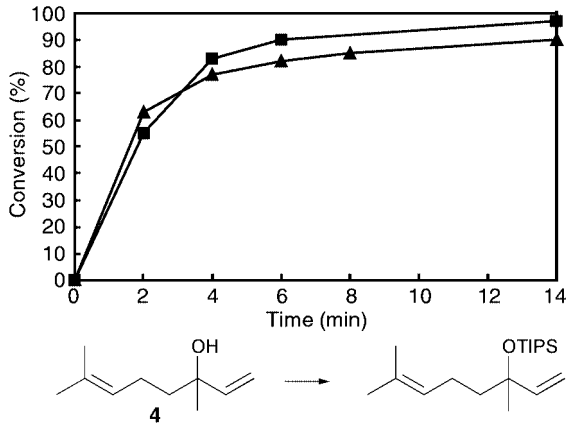

Fig. 1 Comparable experiments of triisopropylsilylation of linalool (**4**) conversion (GC%) ■: TIPS-BEZA (**1d**; 1.5 equiv.)–PyH$^+$·OTf$^-$ (**2**; 0.2 equiv.)–THF, 50 °C. ▲: TIPSOTf (1.5 equiv.)–2,6-lutidine (2.5 equiv.)–DMF, 50 °C.

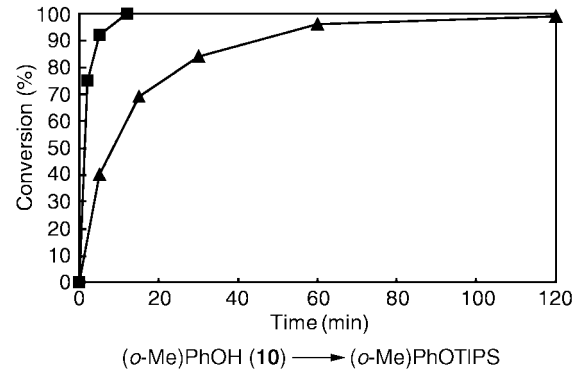

Fig. 2 Comparable experiments of triisopropylsilylation of *o*-cresol (**10**) conversion (GC%) ■: TIPS-BEZA (**1d**; 1.5 equiv.)–PyH$^+$·OTf$^-$ (**2**; 0.2 equiv.)–BTF, 25 °C. ▲: TIPSOTf (1.5 equiv.)–2,6-lutidine (2.5 equiv.)–CH_2Cl_2, 25 °C

was found to occur, when linalool (**4**) was subjected to silylation using TIPSOTf–2,6-lutidine (Fig. 1).

In conclusion, this original reagent, *Si*-BEZA (**1**), with catalytic PyH$^+$·OTf$^-$ (**2**) is structurally simple, yet, exhibits powerful and highly efficient silylations.

The first example of a diazaarsolyl anion: structure and coordination polymerisation of the aromatic metallacycle benzo[1,3,2]diazaarsolyl lithium·2THF

Michael A. Paver,* Jonathan S. Joy and Michael B. Hursthouse

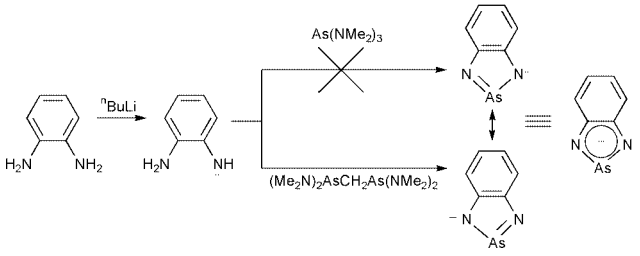
First published as an Advance Article on the web 15th November 2001

The first example of an aromatic diazaarsolyl anion 1 has been synthesised and structurally characterised; the X-ray crystal structure of 1 exhibits planar metallacyclic fragments which link together to generate a coordination polymer *via* bridging lithium cations.

Over the past few years the chemistry of metal–imido species and anionic ligand systems based on p block element imido frameworks have received much attention.[1,2] As part of our recent research into the reactivities of distibine-dimethylamido derivatives we reported the synthesis and structural characterisation of 1,3-[(RNLi)Sb]$_2$(μ-NR)(CH$_2$)$_3$·RNHLi, a chiral bimetallic imido-/amido-bridged cage structure of interlocking six-membered rings, incorporating the co-complexation of primary lithium amide.[3] In relation to this work we have also investigated the chemistry of (Me$_2$N)$_2$AsCH$_2$As(NMe$_2$)$_2$. In contrast to the iminophosphanes, compounds containing an As–N double bond are very rare.[4–7] The first stable compound containing an As^{III}N double bond to be structurally characterised was reported by Lappert, Hitchcock and coworkers, namely As(=NAr)(NHAr) where Ar = C$_6$H$_2$^{t}Bu$_3$-2,4,6. In this case the As–N p_π–p_π bond is stabilised by both steric bulk and electronic factors.[5] Subsequently, Roesky and coworkers reported bis[2,4,6-tris(trifluoromethyl)phenyl]iminoarsane which is only kinetically stabilised by bulky groups,[6] as is the very recently reported (2,4,6-^{t}Bu$_3$C$_6$H$_2$)N=As–N(SiMe$_3$)$_2$.[7]

Here we report the unexpected outcome of the reaction between (Me$_2$N)$_2$AsCH$_2$As(NMe$_2$)$_2$ and 1,2-H$_2$N(C$_6$H$_4$)NHLi (1 : 4 equiv.) which instead of generating the expected diarsine-based polyimido anion, yields the aromatic metallacycle, benzo[1,3,2]diazaarsolyllithium·2THF, [C$_6$H$_4$N$_2$As·Li(THF)$_2$]$_\infty$ **1** (Scheme 1).†

Clearly the reaction involves cleavage of the bridging methylene group, the by-product presumably being an, as yet unidentified, methyl arsine species. Attempts to prepare **1** by an alternative route, namely the reaction of As(NMe$_2$)$_3$ with 1,2-H$_2$N(C$_6$H$_4$)NHLi (1 : 1 equiv.), have failed indicating that the methylene bridged diarsine plays an important role with a differing pattern of reactivity to its mononuclear counterpart. Previous studies indicate that the reactivity of As(NMe$_2$)$_3$ towards primary lithium amides differs markedly from that of Sb(NMe$_2$)$_3$, requiring acid catalysis from an excess of primary amine in order to react, *e.g.*, in the synthesis of {As(N^{t}Bu)$_3$}$_2$Li$_6$.[8] However, all attempts to prepare **1** utilising various stoichiometries of lithium amide and free amine have also failed.‡



Scheme 1

The X-ray structure of **1** reveals planar anionic C$_6$H$_4$N$_2$As metallacycles that are linked together *via* bridging Li(THF)$_2^+$ units to form a two-dimensional coordination polymer (see Fig. 1). This is the first example of an aromatic diazaarsolyl anion to be structurally characterised. The neutral phosphorus analogue of **1**, 1*H*-benzo[1,3,2]diazaphosphole, has been reported, but readily oligomerises to a tetrameric form requiring Lewis acid stabilisation or thermolysis to retain the monomeric unit.[9] As a result of a direct synthesis of the (more synthetically useful) anion, we believe that the aromatic nature of **1**, leads to its inherent stability with respect to oligomerisation without the need for any steric protection.

Unlike As(=NAr)(NHAr) (Ar = C$_6$H$_2$^{t}Bu$_3$-2,4,6)[5] and (2,4,6-^{t}Bu$_3$C$_6$H$_2$)N=As–N(SiMe$_3$)$_2$[7] [As=N 1.714(7), 1.708(3); As–N 1.745(7), 1.822(2) Å, respectively] where there are clear distinctions between the arsenic–nitrogen single and double bonds (even though some conjugation is evident), in **1** the As–N bonds are virtually identical [As(1)–N(1) 1.786(3), As(1)–N(2) 1.789(3) Å]. Thus there is complete delocalisation within the N$_2$As unit, with the bond order being intermediate between single (calculated at 1.87 Å[10]) and double bond character {av. 1.71(1) Å for the previous two compounds, *cf.* 1.73 Å[11] in [(Me$_3$SiO)$_2$AsN]$_3$}. The sum of the angles about N(1) and N(2) (av. 359.7(5)°) are also consistent with the planar nature of the metallacycle, indicating a sp^2 hybridisation. Within this ring the C–N distances (av. 1.36 Å) are also consistent with comparable literature aromatic systems.[12] The angle about As [93.87(12)°] indicating predominant use of p-orbitals in bonding, is in line with those found in arsole derivatives, *e.g.*, 86.96° in η^5-(Me$_4$C$_4$As)Li·TMEDA.[13]

The coordination polymerisation of **1**, caused by N–Li–N bridging of Li(THF)$_2^+$ units with neighbouring metallacyclic anions is comparable to that seen in the anionic phosphorus cyclen complex, [(C$_8$H$_{16}$P)(Li·THF)]$_\infty$.[14] The Li–N distances

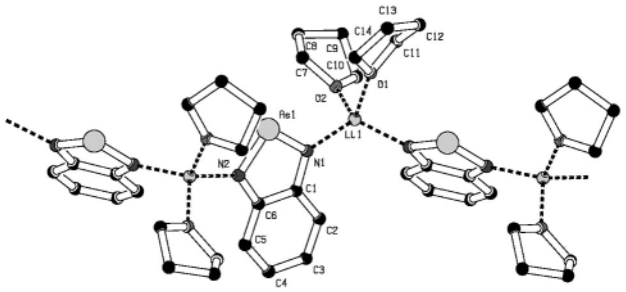


Fig. 1 Selected bond lengths (Å) and angles (°) for compound **1**. Hydrogen atoms have been omitted for clarity: As(1)–N(1) 1.786(3), As(1)–N(2) 1.789(3), C(1)–N(1) 1.364(4), C(6)–N(2) 1.363(4), Li(1)–N(1) 2.003(6), Li(1)–N(2) 2.043(6), Li(1)–O(1) 1.992(6), Li(1)–O(2) 1.974(5); N(1)–As(1)-N(2) 93.87(12), N(1)–C(1)-C(6) 115.6(3), N(2)–C(6)–C(1) 115.6(3), C(1)–N(1)–As(1) 107.4(2), C(6)–N(2)–As(1) 107.4(2), O(2)–Li(1)–O(1) 97.1(2), O(2)–Li(1)–N(1) 108.3(2), O(1)–Li(1)-N(1) 112.8(3), O(2)–Li(1)–N(2) 112.3(3), N(1)–Li(1)–N(2) 121.3(3).

 DOI: 10.1039/b108593j

[range 2.003(6)–2.043(6) Å] are within the expected values.[15] The preparation of **1** *via* such a pathway to directly generate a stable anion may allow the syntheses of heavier metal homologues, which would otherwise be unstable with respect to oligomerisation in the protonated form. Additionally, the ligand chemistry of **1** is currently being investigated with a range of metal centres.

‡ *Synthesis* of **1**: all manipulations were undertaken under an inert nitrogen atmosphere. 1,2-Diaminobenzene (0.43 g, 4 mmol) was dissolved in dry toluene and ^{n}BuLi (4 mmol) added to give a white precipitate which was stirred, with gentle warming, for *ca*. 30 min. Subsequently $(Me_2N)_2$-$AsCH_2As(NMe_2)_2$ (0.34 g, 1 mmol) was added and the mixture stirred at 100 °C for 2 h to yield a pale green precipitate. The toluene was removed *in vacuo* and the mixture dissolved in 30 cm^3 of THF to yield a blue solution. Reduction to *ca*. 15 ml and storage at 5 °C overnight yielded a crop of colourless plates of **1** in 30% yield (relative to 1,2-diaminobenzene, 1st batch). ^{1}H NMR (300 MHz; DMSO-d_6; 25 °C) δ 7.51–6.85 (m, 4H, ArH), 3.61 (m, 8H, –CH_2CH_2O–), 1.75 (m., 8H, –CH_2CH_2O–); ^{13}C NMR (75 MHz; DMSO–d_6; 25 °C) δ 114.6–135.1 (Ar), 67.1 (–CH_2CH_2O–), 25.2 (–CH_2CH_2O–). Satisfactory analyses (C, H, N) were obtained for all samples of **1**.

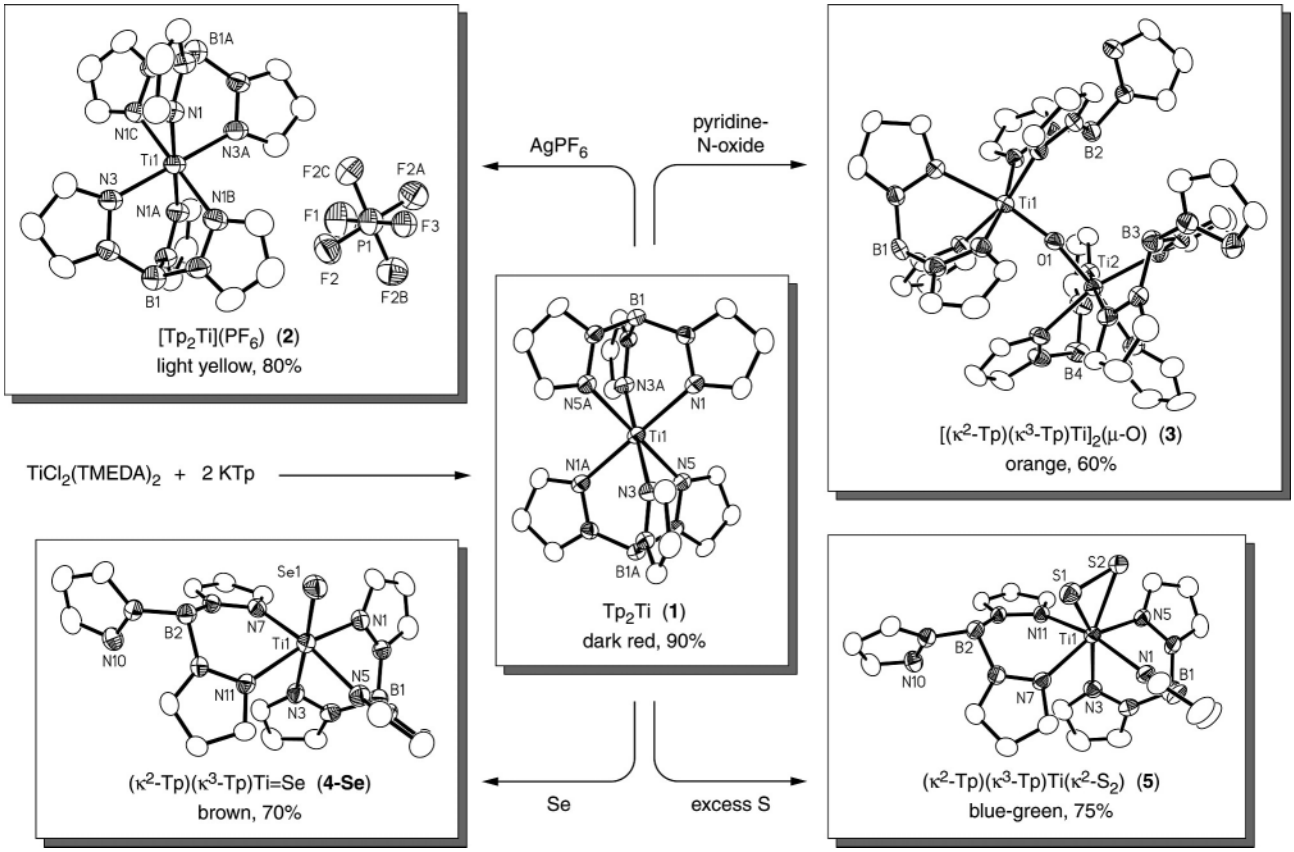
First published as an Advance Article on the web 15th November 2001

Tp_2Ti [Tp = hydrotris(pyrazol-1-yl)borate] is a stable hard donor complex of divalent titanium that shows controlled reaction chemistry with simple chalcogen oxidants.

The homoleptic bis-complexes of hydrotris(pyrazol-1-yl)borate ($[Tp_2M]^{0,+}$) are founding compounds in the expansive metal chemistry of polypyrazolylborate ligands.[1] The first of these simple, symmetric species date back to Trofimenko's disclosure of the ligand class,[2] and neutral Tp_2M complexes of divalent metal ions (or equivalently substituted pyrazole homologues) are now known for almost all of the 3d (V to Zn) and three 4, 5d elements (Ru, Cd, Hg), as well as for a number of alkaline earths (Be–Ba), rare earths (Sm, Eu, Yb) and metalloids (Sn, Pb).[1,3] We report here the extension of this chemical series to the uncommon, reactive divalent oxidation state of titanium.†

The reaction of $TiCl_2(TMEDA)_2$[4] with 2 equivalents of potassium hydrotris(pyrazol-1-yl)borate (KTp) in benzene immediately affords a deep red solution from which Tp_2Ti (**1**) can be isolated as a dark red, analytically pure, microcrystalline solid in excellent (>90%) yield (Scheme 1). A crystal structure analysis‡ reveals the expected bis(κ^3-Tp) structure, with approximate molecular D_{3d} symmetry and octahedral microsymmetry about the Ti(II) center; the average Ti–N bond distances§ are comparable to values previously observed for Ti(II)–N(aromatic) contacts.[5–7] Compound **1** is paramagnetic and, as a polycrystalline solid, obeys the Curie–Weiss law (30–300 K) for an $S = 1$ state ($\mu_{eff} = 2.62\ \mu_B$). Under rigorously anaerobic, aprotic conditions, the complex is soluble, stable, and well-defined in a variety of solvents. The ^{1}H NMR spectrum of **1** consists of four paramagnetically shifted signals (C_6D_6: δ −43.1 (6H), 1.2 (6H), 13.1 (2H), 16.1 (6H)), as expected for a D_{3d} symmetric structure, that can be fully assigned to corresponding hydrogens through ^{1}H{^{11}B} NOE difference spectroscopy. The intense purple–red color of the complex arises from broad charge-transfer bands in the near UV and visible regions of its electronic absorption spectrum (CH_2Cl_2: λ_{max} = 256, 390 (sh), 513, 590 (sh) nm, with ε_M = 7400, 1650, 3170, 1610 dm^3 mol^{-1} cm^{-1} respectively). Complex **1** exhibits two reversible electrochemical oxidations at −1.28 and +1.20 V *vs.* SCE (MeCN, 0.1 M (n-Bu_4N)ClO_4). Oxidation with $AgPF_6$ in CH_2Cl_2 allows chemical access to the trivalent state as crystalline, transparent yellow $[Tp_2Ti](PF_6)$ (**2**) (Scheme 1). The cyclic voltammogram of the oxidized complex

† Electronic supplementary information (ESI) available: synthetic details for compounds **1**–**5**. See http://www.rsc.org/suppdata/cc/b1/b108115b/



Scheme 1

 DOI: 10.1039/b108115b

shows one reversible reduction and one reversible oxidation at potentials matching those of the two oxidative couples measured for **1**; this allows definite assignment of the lower potential as the Ti(II)/Ti(III) couple. We are aware of only one other report of a reversible Ti(II)/Ti(III) couple, measured for $Ti(OAr)_2(bipy)_2$ (Ar = 2,6-diisopropylphenyl) in THF at −0.86 V *vs.* SCE.[7,8] Although a precise comparison is not possible due to the use of different electrochemical solvents, the aryloxide complex appears to have a moderately higher oxidation potential,[8] perhaps as a result of π-acidity in its bipyridyl ligands.

Stable, isolable complexes of divalent titanium typically require the presence of π-acceptors and/or soft donor ligands to support the reduced metal ion;[9] Ti(II) centers ligated solely by hard donors (as in **1**) are rare[4–7] and often undergo progressive, spontaneous decomposition in solution.[4] We ascribe the exceptional stability of complex **1**, which remains unchanged in toluene solution even after prolonged heating (90 °C, 1 week, dinitrogen atmosphere), to the effectiveness of the bis(κ^3-Tp) ligation in maintaining a coordinatively saturated metal center. This intrinsic stability of the bis-chelate structure might be expected to preclude further chemistry, and indeed, we know of no documented reactivity in transition metal Tp_2M complexes other than electron transfer.[10] Studies with simple chalcogen reagents, however, establish the Tp_2Ti environment as an effective platform for metal-centered chemistry.†

Exposure of **1** in benzene solution to atmospheric dioxygen results in an immediate color change and eventual separation of oxo-bridged Ti(III) dimer $[(\kappa^2\text{-Tp})(\kappa^3\text{-Tp})Ti]_2(\mu\text{-O})$ (**3**) as light orange crystals (Scheme 1). The same product can be obtained by treatment of **1** with 0.5 equivalents of pyridine *N*-oxide in benzene; excess pyridine *N*-oxide (to 6 equivalents) has no effect on the reaction outcome. Analogous oxidations with elemental sulfur and selenium are marked by more varied, stoichiometry-dependent behavior. Complex **1** reacts with 0.5 equivalents of yellow sulfur or gray selenium to form as yet unidentified but homologous paramagnetic species.[11] At 1 equivalent of sulfur, a rapid (minutes) reaction yields the terminal sulfido Ti(IV) monomer (κ^2-Tp)(κ^3-Tp)Ti=S (**4-S**) along with limited amounts of the disulfido Ti(IV) complex (κ^2-Tp)(κ^3-Tp)Ti(κ^2-S_2) (**5**); although the two products co-crystallize inseparably, crystal structure and NMR analyses allow unambiguous identification of the individual components. The use of excess sulfur (12 equivalents) also generates a mixture of **4-S** and **5** at first, but in this case the terminal sulfide ligand slowly (hours) transforms to disulfide, allowing isolation of pure **5** (Scheme 1). Finally, reactions of **1** with 1–20 equivalents of selenium lead exclusively to the selenium homologue of **4-S**, (κ^2-Tp)(κ^3-Tp)Ti=Se (**4-Se**) (Scheme 1). The reaction chemistry of complex **1** is well-behaved, with spectroscopically clean conversions and high isolated yields (60–80%) of pure crystalline products.

In solution, the terminal chalcogenido complexes **4-S** and **4-Se** present nearly identical $^1H\{^{11}B\}$ NMR spectra with 2 B–H and 12 sharp, well-resolved pyrazole-H resonances in a 2:2:1:1 pyrazole ratio; this signal pattern is consistent with the C_s symmetric structures found in the solid state (*vide infra*). The spectra also display weak, broad features (< 5% of the total signal intensity) that have been linked through variable-temperature EXSY experiments to intermediates in dynamic processes which exchange all pyrazole positions of the parent structure. The room-temperature NMR spectra of the other reaction products are also characteristic, but less interpretable due to line broadening from paramagnetism (Ti(III) dimer **3**) and pronounced fluxionality (disulfido complex **5**).

Despite differences in their solution NMR spectra, the solid-state structures of the chalcogen reaction products all share the same distinctive (κ^2-Tp)(κ^3-Tp)TiL architecture, where bidentate binding of one Tp chelate allows incorporation of the entering ligand within an octahedral coordination sphere. (For comparative purposes, the κ^2-S_2 fragment of seven-coordinate **5** is regarded as one ligand of a six-coordinate metal center.) The unbound pyrazole arm and the chalcogen ligand are *trans*-oriented in the (κ^2-Tp)Ti metallocycle, indicating that the change in Tp binding mode is not a simple substitution of one donor for another, but reflects a more substantive rearrangement of the coordination sphere. The *trans*-influences of bridging oxo and terminal selenido ligands give rise to long Ti–N(*trans*) bonds in complexes **3** and **4-Se**; increased Ti–N distances are also evident for the three meridional pyrazole donors coplanar with the κ^2-disulfido ligand of complex **5**, due presumably to non-orthogonal, '*trans*-like' orbital interactions as well as steric effects that exist when five ligands occupy the same coordination plane. The structural metrics of these complexes are otherwise typical for their respective donor sets.‡§

In conclusion, the venerable Tp_2M structure type offers new, extensible chemistry as a stabilizing yet reactive coordination environment for divalent titanium.

We thank Drs A. K. Verma and I. Pelczer for experimental assistance and helpful discussions, and the Arnold and Mabel Beckman Foundation (Beckman Young Investigator Award) and the NSF (CAREER CHE-9984645) for their generous support.

8 The Ti(II)/Ti(III) redox potential of $Ti(OAr)_2(bipy)_2$ was measured at −0.95 V *vs.* Ag/AgCl using 0.1 M (n-Bu_4N)PF_6 in THF, and referenced against the ferrocene/ferrocinium couple at +0.47 V;[7] this can be adjusted to −0.86 V *vs.* SCE, since Fc/Fc^+ = +0.56 V *vs.* SCE under the same conditions. The solvent effect can be approximated by comparing the Fc/Fc^+ couple in MeCN (+0.40 V *vs.* SCE) and THF (+0.56 V *vs.* SCE) to give an estimated Ti(II)/Ti(III) potential of *ca.* −1.0 V *vs.* SCE in MeCN. Hydrophobic ionic liquids incorporating *N*-alkylisoquinolinium cations and their utilization in liquid–liquid separations

Ann E. Visser, John D. Holbrey and Robin D. Rogers*

Department of Chemistry and Center for Green Manufacturing, The University of Alabama, Tuscaloosa, AL 35487, USA. E-mail: rdrogers@bama.ua.edu; Fax: +1 (205) 348 0823; Tel: +1 (205) 348 4323

Received (in Columbia, USA) 4th September 2001, Accepted 8th October 2001
First published as an Advance Article on the web 6th November 2001

The first examples of Room Temperature Ionic Liquids (RTIL) containing fused polycyclic *N*-alkylisoquinolinium cations ([C$_n$isoq]$^+$) in combination with the bis(perfluoroethylsulfonyl)imide anion ([BETI]$^-$) have been synthesized, characterized, and utilized in liquid–liquid partitioning from water; these salts have unexpectedly low melting points and give high distribution ratios for aromatic solutes, especially chlorobenzenes, between the RTIL and water.

The growth in recent attention given to Room Temperature Ionic Liquids (RTIL) stems from the unique properties inherent to this new class of solvents and their potential to replace volatile organic solvents. RTIL may exhibit miniscule vapor pressure, high thermal stability, unique miscibilities,[1] and a wide temperature range for the liquid phase. In addition, the composite RTIL cations and anions significantly affect the IL miscibility with other solvents (*e.g.*, water), and also the solubility of these solvents in the IL.[2] For aqueous–organic separations, relatively hydrophobic RTIL can be considered as replacements for traditional VOCs while maintaining the basis for biphasic separation.[3–8] Solute partitioning studies indicate that organic solutes have an affinity for the RTIL phase, correlating with their octan-1-ol–water log *P* values,[2,5] or hydrophobicity.

The range of hydrophobic RTIL has, until recently, been limited and largely focused on systems containing imidazolium and pyridinium cations,[9] imidazolium cations have exceptional advantages for electrochemical applications.[10] The number of available RTIL systems has increased due to the incorporation of a large range of different weakly coordinating anions.[11,12] Using perfluorinated anions has led to ionic liquids with attractive properties (hydrophobicity and low viscosity) for applications beyond electrochemistry.[13] Clearly, however, new classes of RTIL are needed, both to further our understanding of RTIL in general and also to find the appropriate combination of physical properties and performance geared towards industrial application.

In this work, a homologous series of *N*-alkylisoquinolinium salts containing linear alkyl substituents from butyl to octadecyl were prepared with the bis(perfluoroethylsulfonyl)imide ([BETI]$^-$) anion. It was hoped that the extended aromatic system present in these RTIL would lead to specific interactions with other aromatic species that could improve specific separations, *e.g.* in the removal of aromatics from hydrocarbon feedstocks.[1]

The salts were prepared by metathesis from the corresponding chloride salts and were isolated as colorless liquids that separated from aqueous solution. The physical properties for the [C$_n$isoq][BETI] RTIL are summarized in Table 1. The thermal properties are of particular interest. TGA results show the onset of thermal decomposition begins around 400 °C from where they decompose in the liquid state with a single continuous weight loss with little variation with increasing alkyl chain length. The salts displayed DSC cooling and heating profiles typical for ionic liquids[14] showing a glass transition on cooling and an exothermic transition on heating (corresponding to crystallization) followed by a sharp melting transition of the crystalline phase. The variation in glass transitions and melting point with chain length and anion are shown graphically in Fig. 1. Glass transition temperatures generally increase progressively with increasing alkyl-chain length (*n*) owing, perhaps, to the additional energy required to reorient larger cations in the glassy state.

Table 1 Characterization of the [C$_n$isoq][BETI] RTIL[a]

n	Water content (wt%)	Mole fraction water	Melting point (T_g/°C)	Glass transition (T_g/°C)	Density/ g cm^{-3}
4	1.77	0.36	−62.0	−85.2	1.23
6	1.62	0.35	−77.3	−84.0	1.20
8	1.49	0.35	−68.1	−79.4	1.17
10	0.69	0.20	−59.3	−77.8	1.09
12	0.66	0.20	−51.0	−75.4	1.08
14	0.61	0.20	−49.7	−66.7	1.07
16	0.47	0.16	−48.6	−61.8	1.05
18	0.41	0.15	−47.2	−59.3	1.05

[a] Data measured for RTIL equilibrated against water.

For the series [C$_n$isoq][BETI], melting points are affected by the alkyl chain length and decrease from n = 4 to 6. This observation may be associated with a possible destabilization of the crystalline state. With further lengthening of the alkyl chain, the melting point increases monotonically, associated with the increasing stability of the crystal state through alkyl–alkyl interactions.

The observed decrease in melting points with increasing alkyl chain length to a minimum for the C$_6$-derivatives and then increasing melting point for longer alkyl chain derivatives has been observed as a general feature of organic salts containing an alkyl-chain substituent.[15] The reasons behind this trend are not well understood but it is believed to be a combination of competing factors which influences the stability of the crystal lattice and therefore the melting point; destabilization of cation packing on increasing chain length, and increased chain–chain packing stabilization through microphase separation.

All the [C$_n$isoq][BETI] RTIL prepared were relatively hydrophobic and separated from water upon metathesis from the Li[BETI] salt as colorless liquids containing around 1%

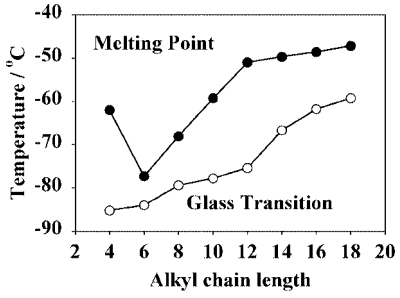

Fig. 1 Glass transition temperatures (○) and melting points (●), for [C$_n$isoq][BETI] RTIL determined on cooling and heating cycles respectively, by differential scanning calorimetry.

 DOI: 10.1039/b109340c

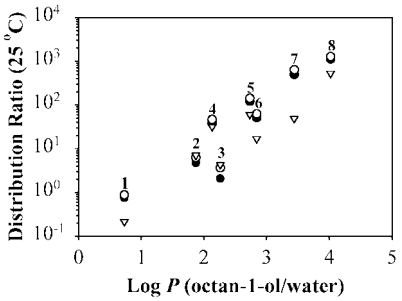

Fig. 2 Distribution ratios for ^{14}C-labeled organic solutes (1, phthalic acid; 2, benzoic acid; 3, salicylic acid; 4, benzene; 5, toluene; 6, chlorobenzene; 7, dichlorobenzene; 8, trichlorobenzene) in [C_8isoq][BETI]–water (●), [C_{14}-isoq][BETI]–water (○), or [C_4mim][PF_6]–water (∇) as a function of the solutes' octan-1-ol–water log *P* value.

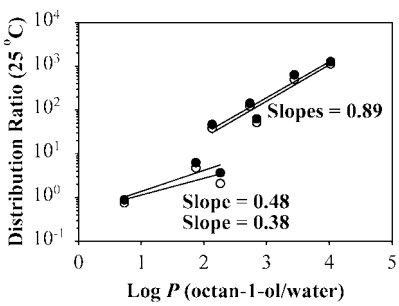

Fig. 3 Linear regression of the distribution ratios from Fig. 2 for the sets of acid (lower points 1–3) and aromatic (upper points 4–8) solutes partitioned between [C_8isoq][BETI]–water (●) or [C_{14}isoq][BETI]–water (○).

(wt.) of water. The water content of the RTILs corresponds to approximately 0.35–0.15 mole fraction. With increasing chain length, the salts become less dense and increasingly hydrophobic (see Table 1) as the contribution from the alkyl-chain to the liquid structure increases.

The octyl- and tetradecyl-substituted RTIL were used in liquid–liquid separation for a series of aromatic solutes and the results are compared to [C_4mim][PF_6]–water systems in Fig. 2. As the solute hydrophobicity increases (as noted by the octan-1-ol–water partition coefficient, log *P*), the general trend is for an increase in the distribution ratios for the organic solutes. Using log *P* provides at best only a general parameter for comparing solute partitioning behavior in these systems since, the environment in an ionic liquid is clearly different from that in octan-1-ol. Certain solutes, (*e.g.*, benzoic and salicylic acids) may interact *via* hydrogen bonding and partition as complex species, hence the break in the trend for those solutes.

The data in Table 1 indicate that the [C_{14}isoq][BETI] RTIL is the most hydrophobic and, in fact, the data in Fig. 2 show a slight increase in the distribution ratios for most hydrophobic solutes in liquid–liquid systems with that RTIL. It is of particular interest to note that the distribution ratios for substituted aromatics with the isoquinolinium systems are higher than with [C_4mim][PF_6] as the extracting phase.[2] With [C_{14}isoq][BETI], the distribution ratio for 1,2,4-trichlorobenzene is 1280 compared to 524 with [C_4mim][PF_6].[2] For the series of solutes (*e.g.*, carboxylic acids or substituted aromatics) examined here, the slope of the carboxylic acid partitioning data (0.44) is approximately half that of the aromatic hydrocarbons and halogenated aromatic solutes (0.89), as shown in Fig. 3. It is not yet clear whether the enhanced distribution ratios, particularly for aromatic species, are due to the hydrophobicity in the isoquinolinium RTIL or to increased aromatic interactions.

This series of new, hydrophobic ionic liquids based on the *N*-alkylisoquinolinium† cation and the [BETI]$^-$ anion has been characterized and the thermal properties of the salts have been described. All the salts are hydrophobic and are liquids at room temperature, prompting the investigation of their use as a component for aqueous-IL two-phase separation systems. The availability of ionic liquids containing a conjugated aromatic core in particular, offers significant potential opportunities for the separation of aromatic compounds from aqueous or hydrocarbon sources.

This research has been supported by the U. S. Environmental Protection Agency's STAR program through grant number R-82825701-0. Additional support was provided from the PG Research Foundation.

Notes and references

† Chloride salts were prepared by *N*-alkylation of isoquinoline with the respective alkyl chloride. The *N*-alkylisoquinolinium salts were prepared by metathesis in aqueous solution from the respective chloride salts with Li[BETI] (3 M). Distribution ratios are measured as the radioactivity in the lower(RTIL) phase divided by the radioactivity in the upper (aqueous) phase, the standard radiochemical assay utilized is described elsewhere.[2] Water content, melting point, thermal decomposition, and density measurements were perfomed as described in the literature.[2]

Received (in Purdue, IN, USA) 30th August 2001, Accepted 23rd October 2001
First published as an Advance Article on the web 15th November 2001

Hollandite with Cr(III) in both tunnel and framework sites has been prepared hydrothermally from layered manganese oxide precursors.

Hollandite-type manganese oxides are one-dimensional tunneled materials that consist of 2 × 2 arrangements of edge-shared MnO_6 octahedra with cations occupying the interstitial voids. They have been widely studied for potential applications in catalysis, cation sorption, chemical sensing, and rechargeable battery technology.[1,2] By far, the most common and easily prepared member of this class is cryptomelane, a specific hollandite with K^+ in the tunnels. The prevalence of cryptomelane can be attributed to the widespread use of potassium salts in manganese oxide syntheses and stabilization from an excellent fit of K^+ in the 2 × 2 tunnels.[3] Hollandite-type manganese oxides have been prepared with other alkali and alkaline earth cations in the tunnels,[4,5] but similar routes have not been developed for hollandites with interstitial transition metal cations. Here we report the hydrothermal synthesis of the transition-metal-containing Cr-hollandite from a layered manganese oxide precursor. The formation of the 2 × 2 hollandite material is unusual because previous studies have found this route to yield the related 3 × 3 tunneled manganese oxide, todorokite.[6–8]

The overall synthetic scheme for Cr-hollandite is shown in Fig. 1. A 1.69 g (10.0 mmol) sample of $MnSO_4{\cdot}H_2O$ was dissolved in 20 mL of water in a plastic bottle and treated with 30 mL of aqueous 6 M NaOH to produce tan-colored $Mn(OH)_2$. A solid mixture of 1.89 g (7.0 mmol) $K_2S_2O_8$ and 0.38 g (1.4 mmol) pulverized $CrCl_3{\cdot}6H_2O$ was then added very slowly with stirring over a 45 min period. The resulting grey–black slurry of Cr-doped Na-birnessite was aged for two days before being isolated by filtration and washed three times with water. The Na-birnessite was then immediately slurried with 100 mL of 0.25 M $Cr(NO_3)_3$ and stirred overnight to yield Cr-buserite, which was isolated in a very slow filtration step. Hydrothermal

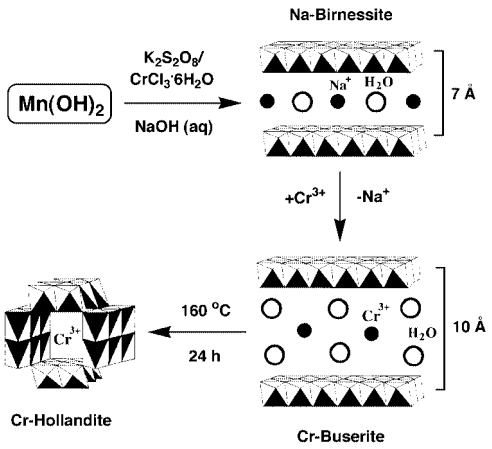

Fig. 1 Synthetic scheme for Cr-hollandite.

treatment of Cr-buserite at 160 °C for 24 h ultimately led to the transformation into Cr-hollandite, of which *ca.* 0.8 g (*ca.* 70% based on Mn) could be isolated.

The structures of Na-birnessite and Cr-buserite were confirmed by powder X-ray diffraction data collected on a Scintag PDS 2000 diffractometer using Cu-Kα radiation. The diffraction pattern for Na-birnessite displayed characteristic peaks at 7.14 and 3.57 Å, which correspond to the interlayer spacing. In the pattern of Cr-buserite, peaks were observed at 9.63, 4.81 and 3.21 Å due to interlayer expansion from a second layer of water molecules being established in the gallery region. Scanning electron microscopy images reveal plate-like morphologies for both Na-birnessite and Cr-buserite, which are typical of these layered materials.

The Cr^{3+} ion was introduced in the synthesis of Na-birnessite as an isomorphous dopant in the manganese oxide framework. Similar modifications with other transition metal cations have been applied to birnessite and buserite materials to promote the formation of 3 × 3 tunneled todorokite materials.[6–8] Elemental analysis of the Cr-doped Na-birnessite revealed a Cr/Mn ratio of 0.13, which compared favorably to the 0.14 ratio used in the reactants and was taken to indicate that most of the Cr^{3+} became incorporated in the manganese oxide structure. After ion exchange, a Cr/Mn ratio of 0.32 was determined for Cr-buserite. No soluble Mn was detected from the reaction, which suggested that the ion exchange process occurred topotactically without contributions from redox reactions involving the manganese oxide framework.[3,9] From the Cr : Mn ratios in Cr-doped Na-birnessite and Cr-buserite, it was determined that 44% of the total Cr^{3+} was doped into the manganese oxide framework while 56% was contained between the layers.

Hydrothermal treatment of Cr-buserite resulted in the collapse of the layered framework and formation of tunneled Cr-hollandite. The hollandite-type manganese oxide structure was confirmed by X-ray diffraction, Fig. 2. The peaks were indexed to a tetragonal structure, which is analogous to the observed patterns for cryptomelane (K-hollandite).[4] Scanning electron microscopy revealed needle-like formations of Cr-hollandite with thickness in the range 100–400 nm. By comparison, cryptomelane also has a fibrous morphology, but with thinner particles that are much less than 100 nm.[10,11] A thermogravimetric profile showed essentially no weight loss (< 0.5%) up to 300 °C, indicating a lack of interstitial water. A weight loss of 7% from 400 to 620 °C was assigned to the formation of M_2O_3 while a further weight loss of 4% from 620 to 800 °C was due to the appearance of Mn_3O_4.

The chemical formula of $Cr_{0.30}MnO_{2.41}$ was determined for Cr-hollandite using data from elemental analysis (14.4% Cr, 50.3% Mn) and the thermogravimetric results which showed the absence of water. There was no detectable Na in the material. The 0.30 Cr/Mn ratio indicated some loss of interstitial chromium during the hydrothermal treatment of Cr-buserite (Cr/Mn = 0.32). This was verified by an observed light yellow color in the Cr-holladite filtrate and detection of soluble Cr by atomic absorption spectroscopy. There was no detectable Mn in

 DOI: 10.1039/b107887a

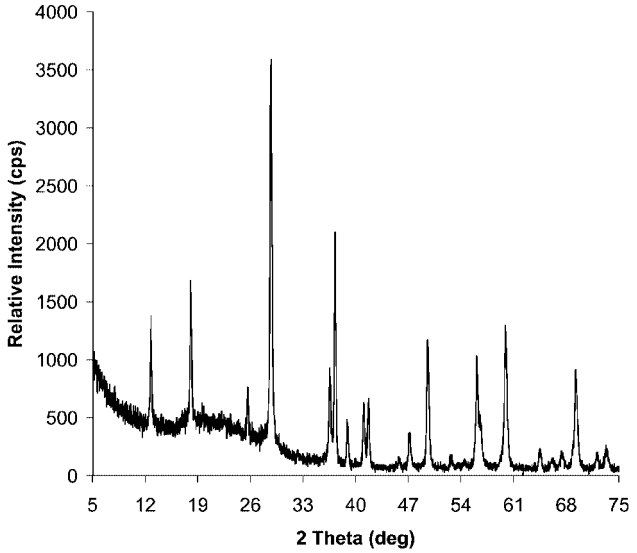

Fig. 2 Powder X-ray diffraction pattern for Cr-hollandite. The *d*-spacings in Å and indices (*hkl*) are provided: 6.95 (110), 4.92 (200), 3.48 (220), 3.12 (310), 2.46 (400), 2.42 (211), 2.32 (330), 2.20 (420), 2.17 (301), 1.93 (510), 1.84 (411), 1.64 (600), 1.63 (431), 1.54 (521), 1.44 (002), 1.36 (640).

the filtrate, indicating that Cr^{3+} was expelled from the interstitial region rather than from the manganese oxide framework. Thus, the Cr-hollandite formula can be expressed as $Cr_{0.16}(Cr_{0.14}Mn)O_{2.41}$ to show the distribution of chromium between tunnel and framework sites. Difficulties in sample preparation prevented a standard analysis of the average Mn oxidation state, but a value of 3.9 could be obtained indirectly from the chemical formula determined for Cr-hollandite. Cryptomelane samples have similar oxidation states. Considering the presence of Cr(III) in the $Cr_{0.14}Mn$ composition of the tunneled framework, the average oxidation state on each metal center in the framework is 3.8.

The synthesis of Cr-doped Na-birnessite is the key step in the overall preparative scheme for Cr-hollandite. The degree of crystallinity in Na-birnessite, as determined by X-ray diffraction peak intensities, correlates well with the crystallinities of buserite and hollandite obtained in subsequent steps. Slow addition of the $K_2S_2O_8/CrCl_3{\cdot}6H_2O$ oxidant/dopant mixture is critical to achieving high quality Na-birnessite, as rapid addition produced amorphous manganese oxide. In related birnessite syntheses, rapid addition of $K_2S_2O_8$ and divalent cation dopants (Mg^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}) resulted in the formation of feitknechtite, a layered MnOOH material.[8] A number of other oxidants have been used to prepare Na-birnessite and these can presumably be substituted for $K_2S_2O_8$ in this synthesis.[1] $CrCl_3{\cdot}6H_2O$ was chosen as the other solid reagent with $K_2S_2O_8$ because it was less hygroscopic than other water-soluble Cr(III) salts. The effect of aging on Cr-doped Na-birnessite was interesting, since aging has been typically used to promote greater crystallinity in birnessites.[12,13] However, in this case the most crystalline birnessites were obtained when aging was carried out between zero and three days, with the optimum time being about two days. Prolonged aging yielded birnessite with poorly crystallinity or amorphous manganese oxide.

Successful syntheses of Cr-hollandite were dependent on having Cr^{3+} both as an isomorphous framework dopant and a gallery cation in the birnessite and buserite precursors. Na-birnessite with Cr^{3+} as a framework dopant could be ion exchanged with divalent cations such as Mg^{2+}, Co^{2+}, Ni^{2+} and Cu^{2+}. However, the resulting buserites were converted to feitknechtite (layered MnOOH) upon hydrothermal treatment, as determined by the appearance of a prominent X-ray diffraction peak at 4.70 Å.[8,12,13] Similar results were obtained when divalent cations were doped in the manganese oxide framework and Cr^{3+} was exchanged into the interlayer gallery. Interestingly, there was no evidence of the 3 × 3 tunneled todorokite phase from the hydrothermal reaction, even though

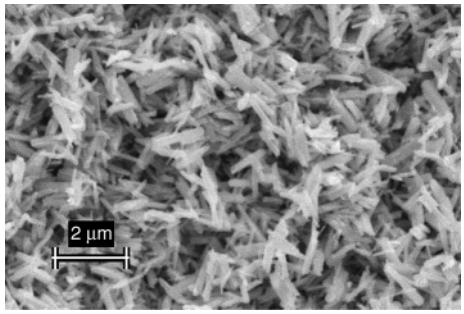

Fig. 3 Scanning electron microscope image of Cr-hollandite.

this phase is favored when the divalent cations occupy both framework and interlayer sites in buserite.[8] Attempts were also made to prepare Cr-hollandite in the absence of framework dopants. In these cases, some conversion of undoped Cr-buserite to Cr-hollandite was observed, but the process was slow and incomplete.

In addition to presenting the first example of a Cr-containing hollandite, the hydrothermal synthesis also provides a route to 2 × 2 tunneled manganese oxides that contain a high level of framework dopant. The cryptomelane framework has been doped with a variety of foreign cations, but the amounts are typically low (0.01–0.5% substitution of total manganese) using redox precipitation methods.[11] Significant improvement of up to 16% has been reported for Fe^{3+} in cryptomelane through calcination of Fe-doped K-birnessite.[14] The framework doping of Cr^{3+} in Cr-hollandite represents a 12% substitution of total manganese.

Overall, the hydrothermal synthesis of Cr-hollandite from Cr-buserite is very unusual, especially given all the precedents that show buserite acting as a precursor to todorokite. Hydrothermal routes to todorokite are known with a variety of tunnel cations, including alkali metals (Li^+, Na^+),[15] alkaline earth metals (Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}),[15] transition metals (Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}),[6–8,15] and even lanthanides (Eu^{3+}, Tb^{3+}).[15] It is not yet clear why Cr^{3+} is able to direct this reaction toward the hollandite structure, but such information would undoubtedly be valuable in designing syntheses of tunneled manganese oxides.

Non-centrosymmetric structures are promoted through the use of perfluoroaromatics containing structure-directing CN···X (X = Br, I) supramolecular synthons.

There has been considerable interest over a number of years in the design of organic molecules for non-linear optic (NLO) applications, particularly frequency doubling through second harmonic generation (SHG).[1] For materials to exhibit SHG a (macroscopically) non-centrosymmetric crystal is required.[1] Considerable efforts in crystal engineering have led to the design of well defined polar molecular chains[2] but the antiparallel alignment of these supramolecular dipoles tends to generate centrosymmetric structures.[3] An approach to favour the co-parallel alignment of molecular chains is inclusion into channel-like hosts such as PHTP.[4] In this case molecules in separate channels are essentially non-interacting and crystal polarity evolves through a stochastic process (Markov theory).[3,4] A natural development of this concept is the design of molecular chains bearing lateral substituents which minimise interactions between chains, favouring co-parallel or non-centrosymmetric structures.[3] Here we report the structures of *p*-XC_6F_4CN (X = Cl, Br, I) in which the CN···X interaction is utilised as a structure-directing synthon[5] and the fluorinated substituents reduce inter-chain interactions.

The nitrile *p*-BrC_6F_4CN is commercially available (Lancaster). The related nitriles, *p*-ClC_6F_4CN and *p*-IC_6F_4CN were prepared according to literature methods.[6] C_6F_5CN is a liquid at room temperature and its low-temperature crystal structure has been reported recently.[7] The other halo-derivatives are solids and were crystallised by slow sublimation (1 atm, 45–28 °C).

The CN···X interaction (X = Br, I) is a well characterised supramolecular synthon[5] but is less structure-directing for the less polarisable more electronegative halogens (F, Cl). The structures of *p*-BrC_6F_4CN and *p*-IC_6F_4CN are isomorphous (space group $Pna2_1$) and exhibited some tendency for racemic twinning. Amongst the samples, single crystals of both compounds were found which did not exhibit twinning (on the basis of their Flack parameter). Both *p*-BrC_6F_4CN and *p*-IC_6F_4CN contain a single molecule in the asymmetric unit of unexceptional geometry.‡ The solid state structures of both derivatives exhibit characteristic chain motifs, with molecules linked *via* CN···X interactions [$d_{N\cdots X}$ = 3.157(7) and 3.128(7) Å for Br and I analogues]. Within error (3 esd's), these are close to the sum of the van der Waals radii (3.14–3.44 Å in the case of *p*-BrC_6F_4CN and 3.36–3.73 Å for the iodo derivative). The chain-like motif for *p*-BrC_6F_4CN is illustrated in Fig. 1. There appear to be no significant directional intermolecular interactions between molecules in different chains, with N···F, F···F and C···F contacts all greater than the sum of the van der Waals radii. The shortest of the intermolecular Br···F contacts [at 3.413(5) Å] and the corresponding I···F contacts [at 3.521(5) Å] falls beyond or at the longer end of the range expected for an X···F non-bonded contact (2.84–3.22 Å for Br···F and 3.06–3.51Å for I···F).

The chains run co-parallel across the unit cell diagonal and lie approximately in the *bc* plane, with Br···N–C angles of 164.8°. A second set of co-parallel chains run across the unit cell diagonal, approximately bisecting the *b* and *c* cell edges (Fig. 2). These two planes form acute angles of 75.9° and 73.4° for *p*-

 DOI: 10.1039/b107665p

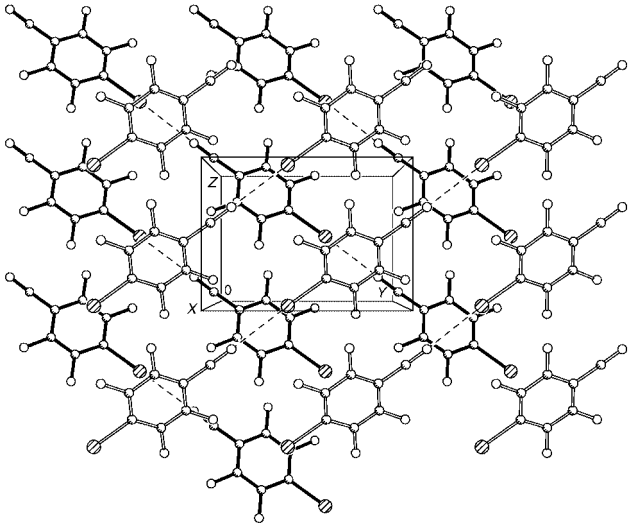

Fig. 2 View of *p*-IC_6F_4CN viewed in the *bc* plane, illustrating the non-colinear alignment of molecular chains.

BrC_6F_4CN and *p*-IC_6F_4CN respectively, generating a macroscopically polar structure. This is in marked contrast to the hydrogenated analogue, *p*-IC_6H_4CN which crystallises in the centrosymmetric space group *I*2/*a* [*p*-BrC_6H_4CN crystallises in the non-centrosymmetric space group *Am*, but exhibits some structural disorder].[5]

In contrast to the bromo and iodo derivatives, the fluoro[7] and chloro analogues adopt rather different structures, consistent with the less structure-directing nature of the CN···X interaction for the lighter halogens. In both these cases the cyanide prefers close contacts with the π system of the aromatic ring rather than the polarisable electron density of the heavier halogens (Fig. 3). The CN···centroid contacts in *p*-FC_6F_4CN and *p*-ClC_6F_4CN are 3.071 and 3.110 Å respectively.

For the current series of derivatives, *p*-XC_6F_4CN (X = F, Cl, Br, I), the structures of the heavier halogens are dictated by CN···X interactions similar to those reported elsewhere,[5] whereas for the lighter halogens a tendency for CN···π type interactions are observed. The structure-directing CN···X interactions generate polar chains in both bromo and iodo derivatives. The inclusion of the perfluorinated aromatic substituent leads to minimal inter-chain interactions (as exemplified by all major interchain interactions greater than or equal to the sum of the van der Waals radii). The CN···X interaction (X = Br, I) faciliates a co-parallel alignment of chains forming polar molecular sheets. In the current systems, the sheets do not align co-parallel but are oriented at approximately 75° with respect to each other but, nevertheless, render the structures non-centrosymmetric and macroscopically polar.

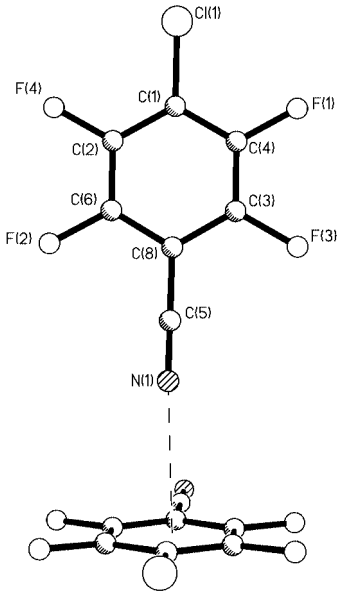

Fig. 3 Crystal structure of *p*-ClC_6F_4CN, illustrating the CN···π interaction.

Confirmation of acentric packing in *p*-BrC_6F_4CN was obtained from an SHG test using a Continuum SLI-10 nanosecond pulsed Nd:YAG laser (1064 nm). The qualitative measurement of frequency doubling utilised single crystals, crushed between two glass slides at a peak power of 30 MW cm^{-2}. Previous studies have indicated that there is no clear trend in the molecular second order susceptibility, β, on perfluorination of the aromatic ring.[8] Further experiments are underway to characterise fully the NLO activity of these materials.

The present studies indicate that perfluorinated aromatics containing structure-directing CN···X synthons can be utilised to generate macroscopically polar structures which we have shown to be SHG active. The current series of molecules are not particularly rod-like in nature and perfect co-parallel alignment of molecular chains is not observed. We are currently persuing perfluorobiphenyl derivatives and related systems in which the co-parallel alignment of molecular chains should be preferred.

We thank the EPSRC for financial support (A. D. B., J. G.).

Received (in Cambridge, UK) 4th September 2001, Accepted 19th October 2001
First published as an Advance Article on the web 15th November 2001

Synthesis and characterisation of organochalcogens has demonstrated a high correlation between their electrochemical oxidation potential on the glassy carbon electrode, their activity in bioassays and an unprecedented antioxidant activity in neuronal cell culture (EC_{50} ~ 20 nM) making electrochemical methodology a valuable tool in drug design for Alzheimer's and related diseases.

Oxidative stress is a biochemical condition present in several human disorders, including Alzheimer's disease.[1] It is the manifestation of an imbalance in an organism's biochemical redox-processes that results in the production of high concentrations of reactive oxygen (ROS), nitrogen and sulfur species. Various antioxidant strategies are used to treat oxidative stress related disorders, *e.g.* by supplementation with artificial 'one shot' antioxidants (vitamin C, penicillamine) that react *stoichiometrically* with stressors to form non-toxic species.[2] Recent studies have indicated that catalytic antioxidants that mimic the action of the selenium enzyme glutathione peroxidase (GPx) are considerably more effective. GPx catalyses the reaction of toxic peroxides with glutathione (GSH) to form oxidised glutathione (GSSG) and water. Most synthetic GPx mimics incorporate a Se or Te atom within an organic framework and their catalytic redox cycle consists of the initial oxidation of a chalcogen atom, in the process reducing peroxide to water, followed by regeneration of the catalyst *via* reduction with two equivalents of thiols.[3–5]

Only a few attempts have so far been made to link the electrochemical redox potentials of these agents with antioxidant activity, among them cyclic voltammetry (CV) to characterise tellurides and selenides in organic solvents and polarography of diselenides on mercury electrodes.[6,7] A fast, widely applicable and reliable method to *predict* biochemical and biological activity is, however, still lacking and a requirement for an accurate prediction is that antioxidants are compared under conditions closely resembling a biological environment. The results presented in this communication show that oxidation potentials can be obtained in aqueous media on the glassy carbon graphite electrode (GE) for both mono- and di-chalcogens and that there is a good correlation between these potentials and biochemical activity in oxidation assays. This data can be used to predict antioxidant activity in cell culture experiments indicative of Alzheimer's disease.

The redox-behaviour of a number of structurally related mono- and di-chalcogens has been investigated (Table 1). Compounds **1** and **2** were purchased from Aldrich and **3**–**6** and **10** were synthesised according to established procedures.[8] **7** and **9** were synthesised by the reduction of **6** with sodium borohydride followed by the addition of either a stoichiometric amount of 1,3-dibromopropane (**7**) or an excess of the reagent (**9**). Compound **8** was synthesised by stirring **10** in excess acetic anhydride over 20 h. Cyclic voltammograms of organochalcogens (50 μM) were recorded in 50 mM potassium phosphate buffer (pH 7.4) containing 30% methanol (due to the limited solubility of the organochalcogens in aqueous media) using a standard Ag/AgCl reference electrode, a Pt counter electrode and a GE (BAS) that was thoroughly cleaned and polished (Al_2O_3) after each scan.

Most chalcogen compounds studied displayed only one irreversible oxidation peak between 0 and +1200 mV *vs.* Ag/AgCl (Table 1) with the exception of **10**, which also exhibited a reduction peak at +270 mV and a second oxidation peak at +820 mV. The value for the first oxidation potential (*E*pa) ranged from +300 to +1400 mV with a clearly observable trend, the tellurides having the lowest potential averaging around +400 mV, increasing to approximately +900 mV for the selenides and +1200 mV for the sulfides. Interestingly, both mono- and di-chalcogens displayed an oxidation peak, allowing comparison of the two species. In aqueous solution anodic oxidation of these chalcogens is an irreversible process that involves the formation of the intermediate radical species rapidly followed by reaction with water to form the chalcogen- or dichalcogen oxide.[4,9] The formation of such species (*e.g.* disulfide *S*-oxides, selenoxides) is frequently observed in biochemical studies[3] and has been implicated in catalytic antioxidation (*e.g.* oxidative activation of ditellurides, selenylsulfides).[4] On the assumption that the ease of radical formation correlates with the ease of oxidation of the

Table 1 Correlation between *E*pa and the biochemical activity of compounds **1**–**10**. Cyclic voltammograms were recorded at a scan rate of 200 mV s^{-1}. MT (0.5 μM) was incubated with *t*-BuOOH (500 μM) and catalyst (200 nM, 100 nM for **7** to allow for the presence of two tellurium catalytic sites) in the presence of PAR (100 μM) in 20 mM HEPES-Na^+, pH 7.5 at 25 °C (N_2 purged). The reaction was continuously monitored for 60 min at 500 nm (Cary50/Varian). Initial rates (*r*) were calculated between 0 and 10 min

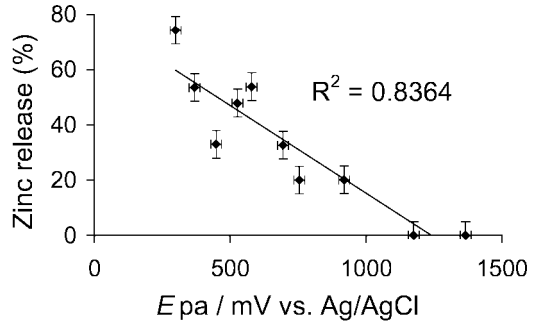

Fig. 1 Correlation between *E*pa and % zinc transfer from MT (experimental details given in legend of Table 1). A value for the maximum zinc release was obtained by incubation with 10 μM ebselen. The value for zinc release after 60 min was expressed as a percentage of the maximum zinc release and plotted as a function of the catalyst's (separately determined) oxidation potential. Experiments were repeated (N = 3) and error bars (SD) applied for zinc release as well as *E*pa.

chalcogen *in vivo* *E*pa has the potential to be used as a predictor of biological activity.

Organochalcogens were evaluated for GPx-like activity *via* their ability to catalyse the reaction of *tert*-butyl hydrogen peroxide (*t*-BuOOH) with the thiol protein metallothionein (MT) (this redox assay is increasingly used since it provides excellent reproducibility).[10,11] Zinc release from MT occurs upon oxidation of the thiol ligands and is detected spectrophotometrically in the presence of the chromophoric dye 4-(2-pyridylazo)resorcinol (PAR). Agents catalysing this process can be evaluated according to both the initial rate and the total extent of zinc release. Maximum zinc release from 0.5 μM MT was calculated by incubation with 10 μM ebselen (2-phenyl-1,2-benzisoselenazol-3[2*H*]-one) and the amount of zinc release for different antioxidants compared to this theoretical maximum.[11] Table 1 and Fig. 1 indicate that *E*pa correlated well with the activity in the bioassay, with the lowest potentials associated with the highest activity. A similar correlation was observed in a standard GPx assay monitoring thiophenol oxidation by hydrogen peroxide in methanol (data not shown).[12] Among the agents tested, **10** had the lowest *E*pa and also one of the highest activities. It was therefore tested in PC12 cell culture indicative of Alzheimer's disease and compared with other antioxidants.

PC12 cells were cultured as previously described.[13,14] 24 h prior to study aliquots were exposed to 100 nM amyloid beta peptide (residues 1–40) ($A\beta P_{(1-40)}$) and varying concentrations of antioxidants. $A\beta P_{(1-40)}$ causes dramatic and selective enhancement of Ca^{2+} channel activity in these cells *via* a mechanism which involves increased production of ROS.[13,14] Ca^{2+} channel currents were recorded using the whole-cell patch clamp technique, with 20 mM Ba^{2+} as charge carrier. Currents were evoked by applying 200 ms ramps (−100 mV to +100mV, 0.2 Hz) from −80 mV holding potential, measured at the peak of the current–voltage relationship (+20 mV) and corrected for cell size to yield current densities (p*A*/p*F*, means ± sem).[14] Cell viability was determined using a standard 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay and at this dose of $A\beta P_{(1-40)}$ does not result in cell kill. The antioxidants tested reversed the current augmentation induced by $A\beta P_{(1-40)}$ without any detectable loss of cell viability (Fig. 2). The naturally occurring antioxidant melatonin exhibited the least potency (EC_{50} ~30 μM), whereas the commonly used selenium based anti-inflammatory agent ebselen (*E*pa determined as +1044 mV) showed increased potency (EC_{50} ~1 μM). In line with a variation in *E*pa of approximately 700 mV, compound **10** by far exceeded the activity of ebselen and, astonishingly, was active in nanomolar concentrations (EC_{50} ~20 nM). The diselenide **4** was also found to be highly active in cell culture, albeit considerably less active than **10**, in line with its higher oxidation potential (+ 1000 mV) and lower bioassay activity (EC_{50} ~160 nM). In accordance with a high oxidation potential (*E*pa = +1155 mV) the commonly studied Se-compound selenocystamine proved rather inactive (EC_{50} ~10 μM).

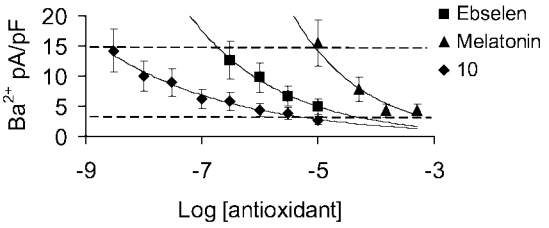

Fig. 2 Effect of antioxidant concentration on current augmentation of PC12 cells with $A\beta P_{(1-40)}$. The plot shows the preventive effect of different concentrations of antioxidants. The lower dashed line indicates current density in control cells, whilst the upper dashed line represents currents observed following 24 h incubation with 100 nM $A\beta P_{(1-40)}$.

These experiments have demonstrated that antioxidants selected on the basis of electrochemical redox-behaviour and their activity in bioassays are also likely to be highly active in cell cultures. Compound **10** exhibited the lowest *E*pa and the most promising antioxidant activity in the *in vitro* bioassays. It also showed a remarkable activity when compared to ebselen and melatonin in cell culture while showing little cell toxicity, demonstrating that this compound is among the best antioxidants available to date in cultured cells mimicking Alzheimer's disease. It is expected that this combination of chalcogen-electrochemistry with organoselenide and organotelluride catalysts will provide a new methodology for innovative antioxidant research in Alzheimer's disease.

Novel mixed catalysts systems have been developed using a platinum tetraammine complex with a cobalt or nickel quinolyldiamine complex supported on graphite powder and heat treated at 600 °C in argon atmosphere, for the methanol oxidation reaction in direct methanol fuel cells.

The methanol oxidation reaction (MOR) is of great technological interest because of its potential application to direct methanol fuel cells (DMFCs).[1] DMFCs have an advantage over polymer electrolyte fuel cells utilizing hydrogen gas generated through a methanol reformer, because the system can be made much simpler. However, in order to accomplish the DMFC reaction, the methanol fuel should undergo the six-electron oxidation process on the electrode catalyst given by eqn. (1).

$$CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^- \quad (1)$$

This is extremely difficult to control, and therefore leads to a high overpotential. Moreover, the reaction is strongly hindered by adsorbed CO, which occurs on the catalyst surface when Pt based catalysts are used.[2,3] Electrode catalysts free from CO poisoning are thus desired in order to realize high conversion efficiency in the DMFC.

Several types of MOR electrocatalysts have been proposed including platinum based alloy catalysts[4,5] or platinum finely dispersed on oxides such as TiO_2, MoO_2, WO_3, *etc*.[6] New base catalysts have also been proposed, *e.g*. mixtures of nickel–tungsten alloy and WC prepared from nickel tungstate.[7] The best catalyst known so far is Pt–Ru alloy (50/50), the function of Ru being as sites of oxygen containing species, and capable of CO elimination by oxidation.[8–11] However, a low natural abundance of Ru is a drawback of this catalyst for practical uses.

Here, the possibility of constituting a new class of catalysts is pursued using new components that may possess novel functions. We select organic metal complexes as candidates, because these could provide the possibility to generate new functions such as CO removal by selective oxidation or strong coordination, compared to metal alloy catalysts *etc*., by manipulating molecular structures.

An aqueous mixture of 8-hydroxyquinoline (2.90 g, 0.02 mol), *o*-phenylenediamine (1.08 g, 0.01 mol) and sodium disulfate (3.08 g, 0.02 mol) was refluxed for a week at 110 °C. Recrystalization from methanol gave *N*-8-quinolyl-*o*-phenylenediamine (mqph) as an amber colored crystals (ESI†). Equimolar amounts of mqph and cobalt acetate tetrahydrate were added at room temperature in ethanol under nitrogen atmosphere in a glass flask, and the resulting solution was concentrated and refrigerated to obtain cobalt *N*-8-quinolyl-*o*-phenylenediamine diacetate [Co(mqph)] as a claret or reddish purple powder.

Mixed catalysts were prepared from the platinum precursor, platinum tetraammine chloride $Pt(NH_3)_4Cl_2{\cdot}xH_2O$, and the cobalt complex Co(mqph) in various mixing ratios. Mixing ratios used were $Pt(NH_3)_4Cl_2{\cdot}xH_2O$/Co(mqph) = 100/0, 80/20, 60/40, 50/50, 40/60, 20/80 and 0/100 (on a weight basis). 10 mg of the mixed catalyst and 40 mg of graphite powder (1–2 μm, Aldrich) were mixed in 0.5 cm^3 of ethanol in a mortar, dried in air at 80 °C for 60 min and then heat-treated in Ar atmosphere at 600 °C for 2 h in a furnace. 5 mg of the powder thus obtained (denoted Pt–Co(mqph)/C] was mixed with 100 mg of 5% Nafion solution (Aldrich) together with 0.1 cm^3 of ethanol, to obtain an ink of the mixture. 0.01 cm^3 of this mixture was transferred to the disk electrode [6 mm diameter, basal plane of high-density pyrolytic graphite (BHPG)]. The overall loading of the mixed catalyst was 1.8×10^{-4} g cm^{-2}, for the apparent electrode area of BHPG.

Electrochemical measurements were conducted in a glass cell consisting of a three-electrode system in 1 mol dm^{-3} CH_3OH–0.05 mol dm^{-3} H_2SO_4 at 25 °C, in deaerated conditions under N_2. The working electrode was the catalyst supported BHPG disk, the counter electrode was a platinum plate and a saturated calomel electrode (SCE) was used as the reference electrode. The electrode was pretreated by cyclic potential scanning between −300 and 1200 mV *vs*. SCE (+316 mV on the RHE scale) at 100 mV s^{-1}. Potentials were scanned in the anodic direction at a scan rate of 1 mV s^{-1} for the polarization measurement in the potential range −200 to 1000 mV.

Fig. 1 shows the polarization curves of MOR for mixed catalysts Pt–Co(mqph)/C of various mixing ratios. The total catalyst amount corresponds to 12% Pt/C in the case of 100/0 mixing ratio. The polarization curves were reproducible to within 10%. Compared with Pt/C or Co(mqph)/C alone, 40/60 → 60/40 mixtures revealed extraordinarily high MOR current density indicating cooperative phenomena between two components.

On the other hand, using the organic complex $Co(NH_3)_6Cl_3$ in place of Co(mqph) as a precursor material led to no MOR activity. In this system, the activity did not exceed that of pure Pt. The initial structure of the complex thus clearly affects the catalytic function after the heat treatment.

XRD showed evidence of inter-metallic compounds between Pt and Co for the mixed system of Pt and $Co(NH_3)_6Cl_3$ after heat treatment, but not for the mixed system of Pt and Co(mqph). According to X-ray photoelectron spectroscopy (XPS), Co 2p and N 1s peaks for Pt–Co(mqph)/C mixed catalysts were identified as Co coordinated by N ligands. As anticipated from the temperature of heat treatment of the catalyst, only a small extent of demetallation of the Co complex was observed after the heat treatment, but major peaks indicated coordinated states between Co and N. The particle size of the

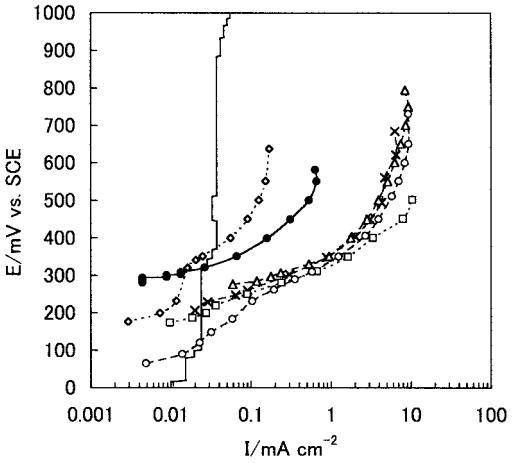

Fig. 1 Polarization curves of methanol oxidation on mixed catalysts Pt–Co(mqph)/C with various mixing ratios. Solution: 1 mol dm^{-3} CH_3OH–0.05 mol dm^{-3} H_2SO_4 at 25 °C, under deaerated conditions (N_2). $Pt(NH_3)_4Cl_2{\cdot}xH_2O$/Co(mqph) ratios: (●) 100/0, (×) 80/20, (△) 60/40, (□). 50/50, (○): 40/60, (◇) 20/80, (——) 0/100.

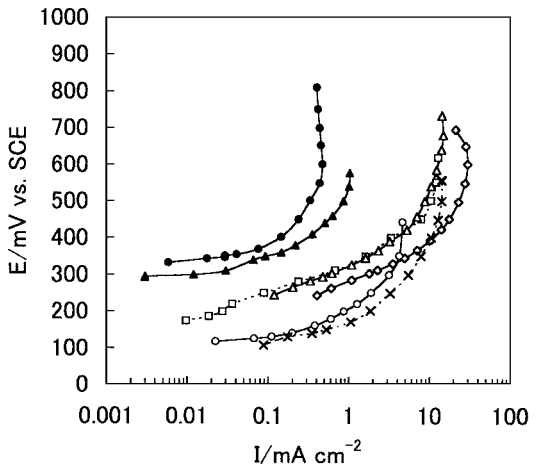

Fig. 2 Comparison of performances of methanol oxidation electrocatalysts: (□) 50/50 Pt–Co(mqph)/C, (◇) 50/50 Pt–Ni(mqph)/C, (△) 50/50 Pt–Fe(mqph)/C, (▲) 50/50 Pt–$Co(NH_3)_6Cl_3$/C, (●) 10% Pt/C (Aldrich), (○) 10% Pt–Ru/C (Shinshu Univ.), (×) 20% Pt–Ru/C (E-TEK).

mixed catalysts tended to be smaller than for pure Pt/C after the heat treatment, but did not solely account for the difference in observed MOR activity. The role of the graphite supporting material may be important for the stability of complexes at high temperature.

In Fig. 2, MOR performances are compared for several types of mixed catalysts of platinum and M(mqph) (M = Fe^{3+}, Co^{2+} and Ni^{2+}) complexes. Results for 10% Pt/C (Aldrich), 10% Pt–Ru/C (Shinshu University) and 20% Pt–Ru/C (E-TEK) are also included. The amount of mixed catalyst corresponds to 10% on C. Among the three central metals of the M(mqph) complex prepared as precursors, Ni showed the best MOR activity. The MOR activity of Pt-Ni(mqph)/C of 50/50 ratio is very promising far exceeding the performance of Pt–Ru in terms of current density.

To our knowledge, there have been no reports concerning methanol oxidation utilizing organic metal complexes in acidic media. Only methanol oxidation on a nickel porphyrin complex has been reported in basic media for methanol sensors, with polymerized nickel porphyrin functioning as 3-D Ni(II)/Ni(III) redox centers.[12] It is discovered for the first time that mixed catalysts of platinum and organic metal complexes exhibit very high catalytic ability for MOR, which could have very high potential considering the wide variety and applicability of such organic complexes. The function and mechanism of the organic complex in promoting the reaction is not clear at this stage, but some concerted process is likely. Further study on the detailed mechanism, the longevity of the catalysts and search for other combinations of platinum (or other metals) and organic complex mixed catalysts is now under progress.

We thank Professor Yoshio Takasu of Shinshu University for supplying Pt–Ru/C catalysts.

Deep desulfurization of diesel fuel by extraction with ionic liquids

A. Bösmann, L. Datsevich, A. Jess,* A. Lauter, C. Schmitz and P. Wasserscheid

Institut für Technische und Makromolekulare Chemie, RWTH Aachen, Sammelbau Chemie, Worringer Weg 1, D-52074 Aachen, Germany, E-mail: jess@itmc.rwth-aachen.de

Received (in Cambridge, UK) 17th September 2001, Accepted 24th October 2001
First published as an Advance Article on the web 15th November 2001

A new approach for the deep desulfurization of diesel fuels by extraction with ionic liquids is described.

In recent years deep desulfurization of diesel fuel has attracted much attention due to the gradual reduction of the statutory sulfur content in most western countries. In 2005 the max. S-content will be limited down to 10–50 ppm compared to today's value of 500 ppm S. These efforts aim to limit SO_2 emission from diesel engines and to protect equipment from corrosion. Moreover, lower sulfur content of diesel fuels would allow the use of other catalysts for the reduction of NO_x emissions.

In industry, desulfurization of diesel is actually carried out by hydrotreating. Generally, this allows the elimination of aliphatic and alicyclic sulfur compounds.[1] However, dibenzothiophene (DBT) and especially 4,6-alkyl-substituted DBTs are difficult to convert into H_2S due to the sterically hindered adsorption of these compounds on the catalyst surface.[2–4] The expenses (hydrogen pressure, reactor size) to meet future legal specifications with classical hydrotreating processes are therefore high. Thus, alternative ways for the production of low or even ultra-low sulfur contents in diesel oil are attractive.

In the present paper, the use of ionic liquids (ILs) for the selective extraction of sulfur compounds from diesel fuel is described for the first time. ILs are low melting (< 100 °C) salts which represent a new class of non-molecular, ionic solvents.[5,6] Up to now, ILs have been mainly studied with respect to biphasic homogeneous catalysed processes. The range of known and available ILs has been expanded so that many different candidates are accessible today.[7,8]

In a first set of experiments, the desulfurization of a model diesel oil obtained by dissolving 500 ppm DBT in *n*-dodecane was investigated. Based on the initial idea to extract the sulfur compound by chemical interaction, the extraction with Lewis- and Brønsted-acidic ILs was studied. As Lewis-acidic ILs, acidic mixtures of 1-*n*-butyl-3-methylimidazolium ([BMIM]) chloride and 1-ethyl-3-methylimidazolium ([EMIM]) chloride[8] with $AlCl_3$ (molar ratio [cation]Cl/$AlCl_3$ = 0.35/0.65) were investigated. A 1 : 1 (mol/mol) mixture of two trialkylammonium methanesulfonate salts was tested as Brønsted-acidic ILs. All ILs formed a biphasic system with the model oil at room temperature. Application of the methanesulfonate melt had the additional advantage of having an easy analytical control of IL leaching into the (for this specific experiment S-free) oil, although this was never observed.

For the extraction experiments, the IL was added to an excess of model oil in a mass ratio of 1/5. The obtained biphasic mixture was then stirred at room temperature. Samples were taken every 5 min. However, it was found that the extraction process proceeded quickly. Consequently, the final sulfur concentration was reached after 5 min and longer stirring did not result in lower sulfur contents. All sulfur contents presented were determined with an Antek Pyroreactor 771, which was equipped with an Antek UV-sulfur-detector 714. Repeated measurements indicated an average error of this method of ± 5 ppm.

The results of a single extraction step with selected Lewis- and Brønsted-acidic ILs are presented in Table 1. All ILs under investigaton showed good properties to extract DBT out of the model oil. The comparison of the extraction experiments with the two different chloroaluminate melts suggests a certain influence of the ionic liquid's cation (compare entries a and b in Table 1). The relatively good extraction properties of the Brønsted-acidic methanesulfonate mixture indicates both good extraction power for DBT and no (or at least not measurable) leaching of the ionic liquid into the model oil. The solubility of hydrocarbons in ILs compared to S-compounds is very low.

Table 1 Desulfurization of model diesel fuel (500 ppm sulfur in *n*-dodecane) by extraction with Lewis- and Brønsted-acidic ionic liquids[a]

Entry	Ionic liquid	Sulfur content/ ppm
a	[BMIM]Cl/$AlCl_3$ = 0.35/0.65[b]	275
b	[EMIM]Cl/$AlCl_3$ = 0.35/0.65	335
c	[HN(C_6H_{11})Et_2][CH_3SO_3]/[$HNBu_3$][CH_3SO_3] = 1/1	310

[a] *General conditions*: room temperature, mass ratio model oil/IL = 5/1, extraction time: 15 min, initial sulfur content 500 ppm. [b] Mol/mol.

In order to understand in more detail the observed DBT extraction, the extraction with the neutral methanesulfonate mixture [N(C_6H_{11})Et_2Me][CH_3SO_3]/[NBu_3Me][CH_3SO_3] = 1/1 (C_6H_{11} = cyclohexyl) under otherwise identical conditions was investigated. The latter was obtained in a simple manner by mixing equimolar amounts of N(C_6H_{11})Et_2 and NBu_3 with a stoichiometric amount of methanesulfonic acid methylester. Surprisingly, the sulfur content of the model oil was found to be as low as 300 ppm after a single extraction step. This demonstrates—at least for the methanesulfonate melts under investigation—that the ionic liquid's extraction power for DBT is not uniquely based on chemical interactions involving the acid proton.

Encouraged by these results, different cation/anion combinations of neutral ILs in the extraction of DBT were tested. Selected results of an anion variation with ILs of the general type [BMIM][anion] are given in Table 2.

The data indicate that the desulfurization is hardly affected by the chemical nature of the anion. Only the IL with the somewhat bigger octylsulfate ion showed significantly better extraction properties. From these results it can be concluded that the size of the ions is rather important for the extraction effect. This

Table 2 Comparison of different anions in the desulfurization process of a model diesel oil (500 ppm sulfur in *n*-dodecane) by extraction with neutral ionic liquids of the general type [BMIM][anion][a]

Entry	Anion	Sulfur content/ppm
a	$[PF_6]^-$	440
b	$[CF_3SO_3]^-$	430
c	$[BF_4]^-$	420
d	Cl^-	410
e	$[MeSO_4]^-$	410
f	$[MeSO_3]^-$	410
g	$[OcSO_4]^-$	350

[a] *General conditions*: 60 °C (except entry d: 80 °C), mass ratio model oil/IL = 5/1, reaction time 15 min, initial sulfur content: 500 ppm.

 DOI: 10.1039/b108411a

Table 3 Comparison of different cations in the extraction of DBT from *n*-dodecane with different tetrafluoroborate ionic liquids[a]

Cation	Sulfur content/ppm
[EMIM]	450
[BMIM]	420
[OMIM]	380

[a] *General conditions*: 50 °C, mass ratio model oil/IL = 5/1, reaction time 15 min, initial sulfur concentration 500 ppm; [OMIM] = 1-methyl-3-*n*-octylimidazolium.

Table 4 Multistage desulfurization of predesulfurized (real) diesel oil[a]

Stage	[BMIM]Cl/$AlCl_3$	$[HN(C_6H_{11})Et_2]$-$[CH_3SO_3]$/$[HNBu_3]$-$[CH_3SO_3]$ = 1/1	[BMIM]-[octylsulfate]
1	375	375	375
2	220	330	320
3	160	300	280
4	130	270	260
5	75	240	235

[a] 60 °C, mass ratio diesel oil/IL = 5/1, reaction time: 15 min.

assumption was further supported by extraction experiments with different tetrafluoroborate salts (Table 3).

In this context, it is important to note that the comparison of different ILs in Tables 2 and 3 is based on equal mass ratio model oil/IL. A comparison on the base of equal molar levels would show an even more pronounced effect of the cation's/anion's size on the extraction power of the ILs. A possible explanation for this behaviour may be that the physical solubility of DBT in the IL is dependent on steric factors in the IL.

In order to check the feasibility of our concept for a deep desulfurization process, we tried to reach very low sulfur levels by application of a multistage extraction process (mixer–settler-system). For these experiments the best IL candidate [BMIM]Cl/$AlCl_3$: 0.35/0.65 was chosen as extraction medium. The desulfurized model oil from the first extraction step was again treated with fresh ionic liquid. This process was repeated up to four times. The results with different mass ratios model oil/IL are presented in Fig. 1.

As expected, Fig. 1 shows that a lower mass ratio of model oil to ionic liquid results in lower sulfur contents. However, sulfur contents below 50 ppm can be reached for all mass ratios if the number of extraction steps is high enough. The almost linear relationship of log(S-content) *vs*. the number of extraction steps indicates that the extraction can be formally described by a partition coefficient according to Nernst's law. This is confirmed by re-extraction experiments (mixture of IL with extracted S-compound and S-free *n*-dodecane): The same distribution of sulfur (ratio of concentration in IL to concentration in *n*-dodecane) is obtained, which was tested by the re-extraction of DBT from the loaded ionic liquid $[HN(C_6H_{11})Et_2][CH_3SO_3]/[HNBu_3][CH_3SO_3]$ = 1/1 with in this case S-free *n*-dodecane. In this context NMR measurements of the used ILs confirm also that the extracted DBT remains unreacted. Thus regeneration of the ILs should be generally achievable, although more systematic experiments are needed.

In a technical extraction process, the IL, which has been loaded with organic sulfur components in the extraction column (or mixer–settler-system), would be continuously regenerated in a second column, and then pumped back into the extraction unit. Thus the potential to regenerate the IL is an important aspect. Interesting re-extraction media are probably light alkanes (C_2–C_5) or supercritical CO_2, as these solvents can be easily recovered and separated from the higher boiling sulfur compounds by evaporation. The organic sulfur would than be converted into elemental sulfur by the common Claus-process.

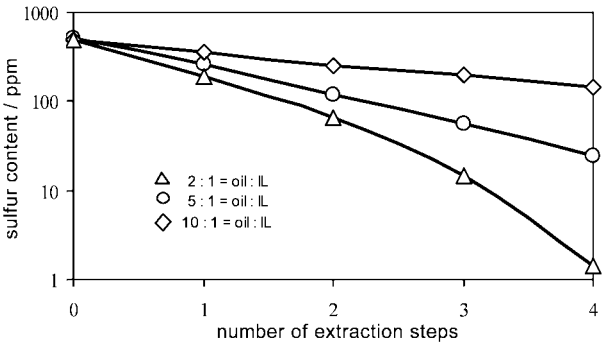

Fig. 1 Multistage desulfurization of model diesel oil (500 ppm sulfur in *n*dodecane) by the IL [BMIM]Cl/$AlCl_3$ (0.35/0.65; different mass ratios oil/IL) at room temperature.

Subsequently, the new desulfurization concept was tested by additional experiments with a 'real' predesulfurised diesel oil (without additives, sulfur content: 375 ppm). As expected, the extraction of real diesel oil is much more complicated due to its complex chemical composition including many different sulfur compounds and other impurities like organic nitrogen and oxygen compounds.

Nevertheless, the results of experiments with predesulfurized diesel are also promising. As shown in Table 4, the Lewis-acidic ionic liquid [BMIM]Cl/$AlCl_3$: 0.35/0.65 showed much higher efficiency in the sulfur extraction from real diesel in comparison to the methanesulfonate and octylsulfate melts.

This indicates that Lewis acid–base interactions enhance the extraction power of the IL here. Nevertheless, the extraction power of the neutral methanesulfonate and octylsulfate melts is still remarkable. However, more extraction steps are necessary in case of 'real' diesel oil to reach future technical sulfur content specifications (< 50 ppm). The use of $AlCl_3$-free ILs is particularly promising as the use of $AlCl_3$ in desulfurization is probably unlikely to be accepted by refiners.

In conclusion, the presented results show a new approach for the deep desulfurization of diesel oil, especially with regard to those sulfur compounds that are very difficult to remove by common hydrodesulfurization techniques. Traces of such sulfur compounds could easily be removed. The new method is based on the extraction of the sulfur compounds with ILs. The application of very mild process conditions (low pressure and temperature) is an additional advantage of this new approach in comparison to traditional HDS.

Generally the extraction of polarizeable compounds by ionic liquids may be a possibility to isolate valued products which reside in complex mixtures of a multitude of different organic substances as is likely to occur in aromas and scents.

Present work is directed towards a deeper understanding of the extraction properties of ILs, and to identify inexpensive, unchlorinated IL systems with enhanced extraction power.

The authors acknowledge Miro refinery/Karlsruhe, Germany for the donation of the predesulfurized diesel oil.

Design of silica-coated microcapsules for bioencapsulation

Thibaud Coradin, Emilie Mercey, Laurent Lisnard and Jacques Livage*

Laboratoire de Chimie de la Matière Condensée, CNRS-UMR 7574, 4 place Jussieu, F-75252 Paris cedex 05, France. E-mail: livage@ccr.jussieu.fr

Received (in Cambridge, UK) 13th September 2001, Accepted 24th October 2001
First published as an Advance Article on the web 15th November 2001

Alginate-based microcapsules are coated with silica, providing enhanced mechanical resistance, protein diffusion and allowing enzyme immobilization.

The design of microcapsules for cell encapsulation is a major challenge for tissue transplantation.[1] The most popular device is based on alginic acid, a copolymer of guluronic and mannuronic acids, that can be prepared as gel beads in the presence of divalent metals such as Ca^{2+}.[2] Additional coating with poly(L-lysine) and liquefaction of the inner-core alginate by complexing Ca^{2+} (*i.e.* with citrate) leads to the formation of hollow capsules with a semi-permeable membrane.[3] The strengthening of this membrane is made possible by using other polycationic systems[4] or adding a second alginate layer.[5]

The possibility to coat alginate/poly-lysine capsules with silica was studied in order to improve their mechanical properties. This strategy was based on our recent work showing that poly-lysine is able to favor the condensation of silica.[6]

The principle of preparation of the microcapsules is illustrated in Scheme 1. Ca^{2+}/alginate beads, *ca.* 4 mm in diameter, were prepared by the dropwise addition of an aqueous solution of alginic acid (1.5 wt%) to a solution of $CaCl_2$ (0.1 M). Beads were then placed into a solution of poly-lysine, alginate or silica (0.1 w/v%) with a Tris·HCl buffer (0.05 M, pH = 7.2) and citrate (0.05 M).

Alginate/poly-lysine coated with alginate (APA), with sodium silicate (APS) and colloidal silica (APC) were prepared.† The sodium silicate concentration was limited to 30 mM to avoid solution gelation during the coating process. APC beads could be prepared with a concentration up to 60 mM from Ludox sols (Aldrich). The contact time between the poly-lysine/alginate beads and silica solutions was optimized at 2 h in order to obtain a complete and homogeneous coating.

The presence of silica was ascertained by IR spectroscopy showing the appearance of a band at 1100 cm^{-1}, corresponding to the stretching vibration mode of $[SiO_4]$ tetrahedra, and confirmed by energy dispersive X-ray analysis.

Scanning electron micrographs of dried APA, APS ([Si] = 30 mM) and APC ([Si] = 60 mM) are shown in Fig. 1. Sodium silicate condensation leads to a smooth coating whereas silica particles lead to a more granular surface. Fig. 1 also shows the homogeneous 10 μm thick membrane of APS.

The mechanical strength of the hollow capsules was investigated by stirring 100 beads at 300 rpm in 50 mL Tris·HCl buffer and counting fractured capsules at selected intervals of time. As shown in Fig. 2, sodium silicate coating enhances membrane resistance when compared to alginate whereas colloidal silica does not appear to be suitable for long-term use. This is consistent with SEM studies and suggests that sodium silicate is highly condensed at the poly-lysine interface whereas the colloid coating consists of silica particles adsorbed on the polyamine chain with only weak interparticle bonding.

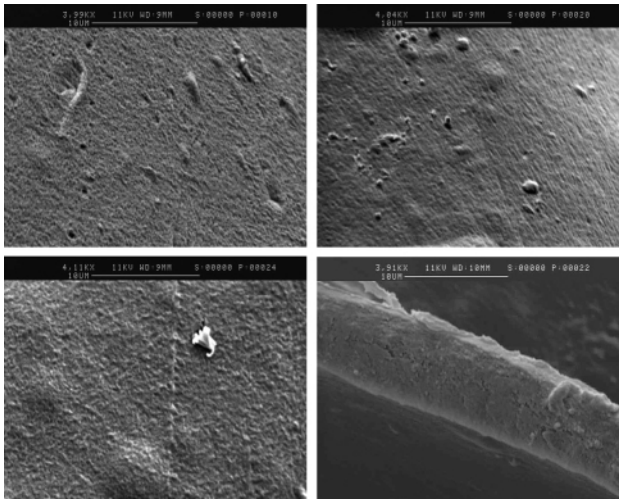

Fig. 1 Scanning electron micrographs of (top left) APA, (top right) APS, (bottom left) APC surfaces and (bottom right) APS membrane (bar = 10 μm).

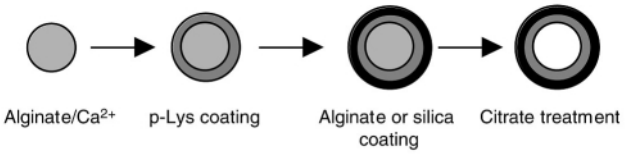
The existence of a molecular weight cut-off for diffusion through the membrane is a key feature for cell transplantation since small substrates or products should be able to diffuse through the membrane, whereas larger molecules such as antibodies should not be able to interact with the immobilized species.[1] The diffusion of myoglobin (≈20 kDa) in the beads was followed by the intensity decrease of its absorption band at λ = 409 nm. Fig. 2 shows that protein diffusion is easier in silica coated beads. In contrast, following the same procedure, no diffusion of a larger protein, Bovine Serum Albumin (≈70 kDa) could be observed after 2 h.‡ Differences in diffusion properties arise from the porosity of the external coating. Silica gels obtained from sodium silicate or Ludox have been shown to be in the mesoporous range (50–100 Å).[7] Layer-by-layer coating by polyelectrolytes of opposite charge can lead to dense membranes if the charge density of both polymers is optimized.[8] This is the case at pH 7 where carboxylate groups from



Scheme 1 Schematic representation of the step-by-step formation of hollow beads.

 DOI: 10.1039/b108324b

alginic acid ($pK_a \approx 5$) and amino groups from the poly-lysine side chains ($pK_a \approx 9$) are mostly ionised.

The final issue to be raised is the biocompatibility of these materials. Sol–gel silica has already been demonstrated to be suitable for cell encapsulation.[9] We have recently reported that encapsulation of *E. coli* bacteria within sol–gel matrices obtained from sodium silicate and Ludox precursors led to a limited lysis of the cell membrane.[10] This effect was assigned to the confinement of the cell within the silica network rather than to the reaction conditions which were very similar to those used in this work (pH ≈ 7, ionic strength < 0.2 M, room temp., low silica content). As a first step, we have studied the encapsulation of β-galactosidase in APS beads. The catalytic activity of this enzyme can be measured *via* the hydrolysis of 4-nitrophenyl-β-D-galactopyranoside that yields the formation of *p*-nitrophenol, a yellow compound that can be easily titrated by UV–VIS spectroscopy.[10] Moreover, the enzyme should be too large (≈ 135 kDa) to be leached out of the beads. The enzyme was introduced in the initial alginate solution before the formation of Ca^{2+}/alginate beads. The enzymatic activity§ of β-galactosidase in filled and empty APS beads was found to be 1.2 ± 0.2 U mg^{-1} and 1.0 ± 0.2 U mg^{-1}, respectively. A comparison with the activity of a solution of β-galactosidase in Tris·HCl buffer (1.8 ± 0.2 U mg^{-1}) shows that enzymes are not severely denaturated during the entrapment process. After rinsing the beads, they could be re-used, leading to similar enzymatic activities, therefore demonstrating that no leaching occurs during the activity measurements. Therefore, it suggests that partial leaching of β-galactosidase took place during the gelation of alginate droplets in aqueous $CaCl_2$. Moreover, it was observed that adding β-galactosidase leads to weakening of the membrane. Beads could be partially damaged during the citrate treatment, a fact that could account for the difference between filled and empty capsules.

Such an association of mineral and bioorganic components, mimicking Nature's strategy to design composite materials,[11] appears therefore very promising. Further work will now focus on size reduction of capsules and cytocompatibility investigations.

Notes and references

† 10 mL of a 1.5 wt% alginic acid solution (Fluka) was added dropwise through a 0.9 mm needle to 100 mL of a 0.1 M solution of $CaCl_2$. After 1 h stirring, *ca*. 600 beads were recovered and washed with 0.05 M Tris·HCl (pH = 7.2) buffer. They were then placed in contact for 30 min with a 0.01 w/v% poly-lysine (≈ 30 kDa) solution prepared in 0.85 wt% NaCl. After recovering and washing, beads were added for 6 min to a 0.03 wt% solution of alginic acid (APA) or 2 h in a dilute solution of sodium silicate (Riedel-de Haen) (APS) or Ludox sols (Aldrich) (APC). The dissolution of the inner-core alginate was performed by complexing Ca^{2+} ions with citrate (0.05 M). After washing, beads were kept in Tris·HCl buffer.

‡ It was checked that similar experiments using fractured beads led to a very small decrease in the protein content of the solution. This therefore indicates that the observed decrease is due to the diffusion of the proteins inside the beads and not to adsorption on their surface.

§ Enzymatic activity is given in U per mg of enzyme in the starting alginate solution. 1 U corresponds to the hydrolysis of 1 μmol of 4-nitrophenyl-β-D-galactopyranoside per minute.

Diastereo- and enantioselective synthesis of α,β-disubstituted γ-nitro methyl sulfonates†

Dieter Enders,*[a] Otto Mathias Berner,[a] Nicola Vignola[a] and Jan Willem Bats[b]

[a] *Institut für Organische Chemie der RWTH Aachen, Professor-Pirlet-Strasse 1, D-52074 Aachen, Germany. E-mail: enders@rwth-aachen.de; Fax: +49-241-8092 127*

Received (in Cambridge, UK) 24th September 2001, Accepted 22nd October 2001
First published as an Advance Article on the web 15th November 2001

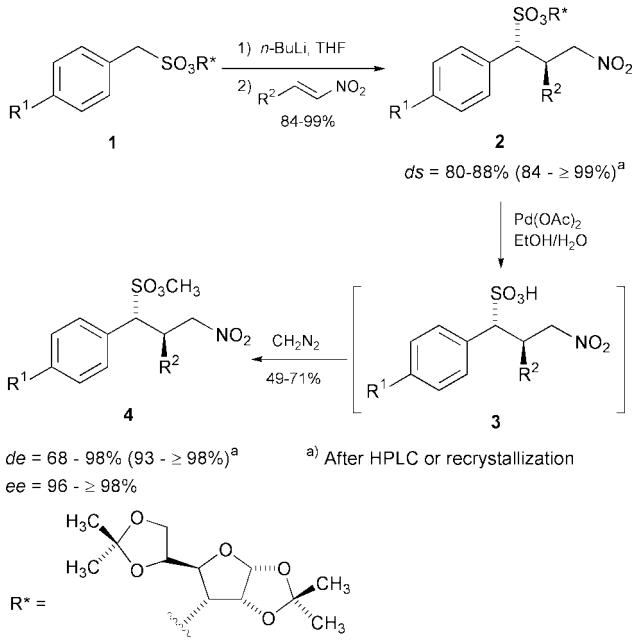
A novel asymmetric synthesis of highly enantioenriched homotaurine precursors has been developed *via* diastereoselective Michael addition of lithiated enantiopure sulfonates to nitroalkenes by using 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose as chiral auxiliary.

Recently, we have reported a highly efficient asymmetric synthesis of α-substituted methyl sulfonates by α-alkylation of lithiated enantiopure sulfonates using 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose as easily available chiral auxiliary.[1] We have now extended this new methodology to asymmetric Michael additions using nitroalkenes as acceptors leading to α,β-disubstituted γ-nitro methyl sulfonates.

Homotaurine (3-aminopropanesulfonic acid) is the sulfonic acid equivalent of γ-aminobutyric acid (GABA), which is of great importance in the regulation of neurological disorders.[2] Consequently, homotaurine possesses many pharmacological effects, increasing for example the synthesis of dopamine in the brain.[3] Furthermore, the γ-aminosulfonic acids can provide interesting applications in the area of peptide mimetics. We envisioned to gain access to γ-aminosulfonic acid precursors *via* an asymmetric Michael reaction to nitroalkenes. In recent years, a great variety of asymmetric Michael additions have been developed,[4] including nitroalkenes as excellent acceptors, which are easily obtained *via* the Henry reaction[5] and subsequent dehydration. In addition to being very reactive, the nitro group can be converted into a broad range of functionalities such as the amino group.[6] Although several reports of enantioselective Michael additions to nitroalkenes do exist,[7] no asymmetric 1,4-additions of metalated sulfonates bearing a chiral auxiliary have been reported so far.

As is depicted in Scheme 1, the enantiopure sulfonates **1**[1] were metalated with *n*-butyllithium in tetrahydrofuran and allowed to react with nitroalkenes[8,9] at −(90–95) °C to obtain the highest diastereoselectivity. In addition, any side reactions are minimized by using low temperatures, mainly the attack of *n*-butyllithium on the sulfonate moiety. For this reason, exactly one equivalent of base must be utilized. After the reaction is quenched, the aqueous phase must be extracted several times with dichloromethane (TLC control) to ensure high yield, as some of the Michael adducts have a solubility in water. The Michael adducts **2** were obtained in very good to excellent yields (84–99%) and high diastereoselectivities of 80–88% (Table 1). Only three of the possible four diastereoisomers could be detected. In the case of **2a**, for example, a ratio of 88.5:7.5:4 was obtained. Further increase in diastereoselectivity could be achieved either *via* preparative HPLC or recrystallization (ds = 84–≥ 99%). In the case of compound **2d**, preparative HPLC purification resulted in a mixture of the two major diastereomers. If the two diastereomers would remain as such rather than enantiomers *after* the cleavage of the auxiliary, then a possible separation at a later stage would still provide enantiomerically pure products (*vide infra*).

† Dedicated to Professor Helmut Zahn on the occasion of his 85th birthday.



Scheme 1

Originally, the removal of the chiral auxiliary to form the corresponding sulfonic acids **3** was achieved by refluxing the Michael adducts in an EtOH–H_2O solution containing 20 mol% $Pd(OAc)_2$ for 12 h. In contrast to the alkylation products,[1] care must be taken when the reaction is performed. The liberated sulfonic acid can cause a Meyer reaction[10] to occur, which converts the primary nitro group into a carboxylic acid. The yields could be significantly increased if additional H_2O was added to the reaction. This reduces the side reactions allowing an increase of reaction time which results in higher yields (Table 2). In analogy, it has been reported that additional H_2O slows the related Nef-reaction.[11] Also elementary Pd^0 can be used to achieve cleavage of the auxiliary indicating that

elementary palladium may be required for the reaction. To obtain the final product in a more accessible form, the sulfonic acids **3** were converted with diazomethane to the corresponding methyl sulfonates **4**. The methyl groups can be considered as suitable 'protecting groups' due to their ability to be easily cleaved under mild conditions. The title methyl sulfonates **4** were obtained in moderate to good yields and as virtually pure stereoisomers (Table 2).

[a] Yields in paranthesis are obtained by using an EtOH–H_2O-solution as solvent. [b] Measured by ^1H NMR and ^{13}C NMR. [c] Based on de values of the Michael adducts. [d] All optical rotations were measured in Uvasol grade $CHCl_3$ at rt. [e] After recrystallization.

NOE-studies of the products revealed that the protons at the α and β positions are *anti* to each other. The absolute configuration of the newly formed stereogenic centers was established unambiguously as *R*,*R* by X-ray crystallography.‡ The stereochemistry of the major diastereomer of other Michael adducts is expected to be also *R*,*R* and is based on the assumption of an uniform mechanism operating in the addition to nitroalkenes. Further evidence is obtained for this assumption by the fact that the related electrophilic substitution under α-alkylation[1] shows the same relative topicity.

To confirm that the cleavage of the auxiliary occurs in the presence of a nitro group without epimerization of the α-position of the sulfonyl group, compound **2d**, which consists of only the two major diastereomers in a ratio of 84:16, was chosen as a case study. If the reaction is truly epimerization free, then the ratio should be identical after the cleavage reaction. After treatment with $Pd(OAc)_2$ and diazomethane the ratio remained the same. Indeed, the result is in accordance with the reported racemization-free cleavage of the auxiliary in the case of the alkylated products.[1] This also proves that the two major diastereomers of the Michael addition are in an *anti* and *syn* relation to each other. The diastereomeric ratio could be easily increased to 97:3 *via* recrystallization from an ether–pentane mixture.

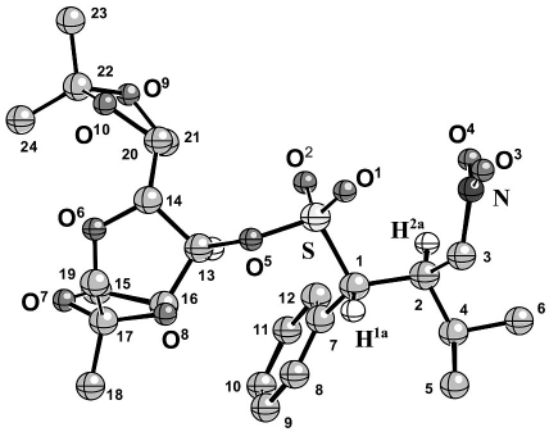

Fig. 1 X-Ray crystal structure of **2c**.‡

In conclusion, the described asymmetric Michael addition provides an efficient route to optically active α,β-disubstituted γ-nitro methyl sulfonates in good overall yields as well as excellent diastereomeric and enantiomeric excesses. The title compounds are valuable bifunctional building blocks and constitute highly enantioenriched precursors of pharmacologically interesting homotaurine derivatives.

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 380) and the Fonds der Chemischen Industrie. We thank Degussa AG, BASF AG, Bayer AG and Aventis for the donation of chemicals. The NOE-measurements by Dr J. Runsink are gratefully acknowledged.

Notes and references

‡ *Crystal data* for **2c**: single crystals were obtained by recrystallization from a diethyl ether–petrol ether mixture (6:4). The substance ($C_{24}H_{35}NO_{10}S$ M_r = 529.59) crystallized in the orthorhombic space group $P2_12_12_1$, a = 9.7493(9), b = 15.7940(15), c = 17.251(2) Å, V = 2656.4(5) Å^3, Z = 4, ρ_{calcd} = 1.324 g cm^{-3}, $F(000)$ = 1128, T = 143(2) K. Data collection: A single crystal (colorless transparent block with dimensions 0.32 × 0.40 × 0.60 mm) was measured on a SIEMENS SMART diffractometer at a temperature of about −130 °C. Repeatedly measured reflections remained stable. An empirical absorption correction was made using the program SADABS. The correction factor ranged from 0.973 to 1.000. Equivalent reflections were averaged. Friedel opposites were not averaged. $R(I)$internal = 0.040. The structure was determined by direct methods using the program SHELXS. The H atoms were placed at calculated positions and were treated as riding atoms. The segment containing atoms O9, C22, C23 and C24 was found to be disordered over two possible conformations. Atoms in this group were refined with a split atom model. The occupancy factor of atoms O9, C22, C23 and C24 refined to 0.644(4). The occupancy factor of atoms O9′, C22′, C23′ and C24′ was 0.356(4). The structure was refined on F^2 values using the program SHELXL97. The final difference density was between −0.34 and +0.54 e Å^{-3}. The absolute configuration of the structure was confirmed by the value of the Flack x-parameter (x = 0.04(5)). CCDC 167504. Phosphatidylethanolamine and -choline derivatives equipped with fluorescent donor–acceptor pairs of dyes connected to the tips of the fatty acids were synthesised and shown to be suitable substrates for phospholipase A_2.

Phospholipase A_2 is a central enzyme in intracellular signal transduction and digestion and a major constituent of various venoms.[1] The Ca^{2+}-dependent cytosolic phospholipases A_2 ($cPLA_2$) regulate the biosynthesis of eicosanoides by specifically cleaving off arachidonic acid from the *sn*-2 position.[2] Because of the involvement of both cytosolic and secretory isoenzymes in diseases like inflammation and allergies,[3] the monitoring of PLA_2 enzyme activity is crucial for the development of PLA_2 inhibitors as drug candidates. We aim towards the preparation of probes that allow real-time monitoring, that are concentration-independent due to ratio measurements of two emission wavelengths, and which exhibit significant specificity in favour of PLA_2 over other phospholipases. We therefore looked for a pair of matching fluorophores that would allow fluorescence resonance energy transfer (FRET) with an excitation wavelength close to common laser bands, a large difference in emission wavelengths and a good match of the donor emission and the acceptor excitation spectra. We chose the pair consisting of 7-nitrobenz-2-oxa-1,3-diazole amine (NBD-amine) and Nile red, because NBD can be excited with the 458 or 488 nm argon-ion laser lines and the membrane stain Nile red emits above 600 nm in lipophilic environment and is more lipophilic than other red dyes like rhodamine. The fatty acid of the *sn*-1 position was altered to an ether to avoid PLA_1 substrate properties. The fatty acid chain length was held above C_{10} for favorable substrate properties when treated with secretory PLA_2.[4] Previously published probes relied on interdye quenching or excimer formation. A choline compound had two identical BODIPY® dyes attached as esters and served to monitor $cPLA_2$ activity during zebra fish development.[5] A similar probe relied on the excimer formation of two pyrene dyes. After separation of the dyes due to enzymatic ester hydrolysis, the pyrenes emit at much shorter wavelengths.[6] However, the short excitation wavelength required is often not favourable in microscope applications.

In order to synthesize phospholipid derivatives equipped with two matching dyes we started from the commercially available 2,3-isopropylidene-*sn*-glycerol **1** which was treated with sodium hydride in DMF and subsequently alkylated with 1,12-dibromododecane. After acidic hydrolysis of the acetonide the Nile red 2-*O*- or 3-*O*-hydroxy derivative[7] was coupled to the alkyl chain, respectively, to give the diol **2** in an overall yield of 58%. Regioselective *tert*-butyldimethylsilyl (TBDMS) protection of the primary hydroxy group of **2** was achieved in moderate yield. 11-NBD-aminoundecanoic acid was linked with the help of triisopropylphenylsulfonyl nitrotriazole (TPSNT)† and three equiv. of methylimidazole in dichloromethane to give the fully protected glycerol derivative **3** in excellent yield (86%).[8] For this reaction the method appears to be clearly superior to esterifications with carbodiimides like DCC or DIC (35–75% yield). Deprotection of the *sn*-3 position was achieved best with 10% aq. HCl in a dichloromethane–ethanol mixture at rt (78% yield plus 12% recovery of **3**).[9] Under these conditions acyl migration could be limited to a minimum (Scheme 1). Several attempts to introduce ethanolamino phosphate or choline phosphate headgroups *via* phosphorous(v) reagents failed probably due to the sensititvity of the dyes under the reaction conditions. We then employed several ethanolamine-containing phosphorous(III) reagents which required intermediate protection of the latter negatively charged phosphate oxygen and the amino group. An approach with an

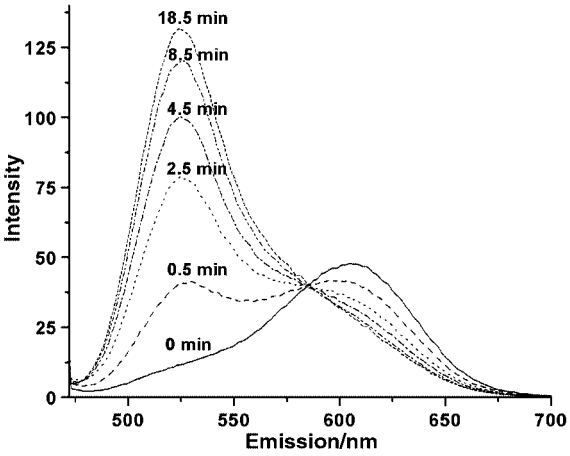

Fig. 1 Rapid change in the emission spectra of probe **6a** after the addition of honey bee PLA_2.

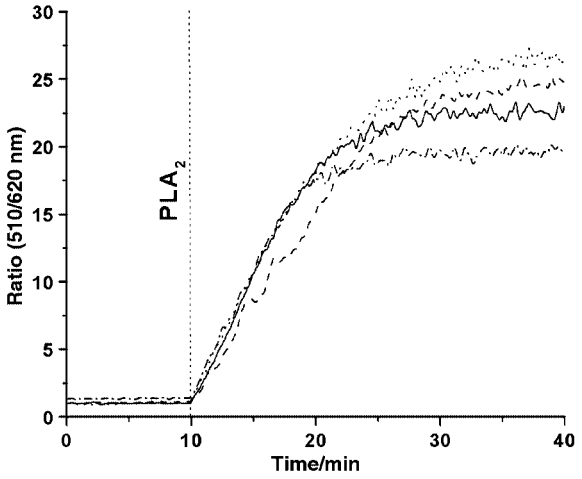

Fig. 2 Emission ratio change 510/620 nm over time, depicted for the four probes **6a** (solid line) and **6b** (dot dash line), as well as **9a** (dotted line) and **9b** (dashed line). (n = 3 for each trace).

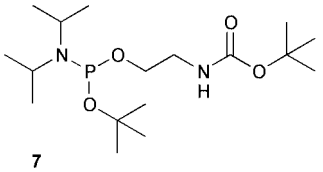
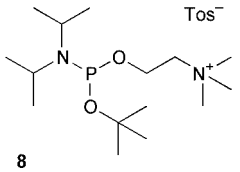
allyl group on the phosphate and Fmoc protection of the amino group failed, because under deprotecting conditions (piperidine, followed by palladium(0)), the ethylamino group was presumably lost. More successful was the use of a novel reagent: *tert*-butyl *tert*-butyloxycarbonylaminoethyl *N*,*N*-diisopropyl phosphoramidite (**7**) which was prepared for the first time from the commercially available *tert*-butyl *N*,*N*,*N*′,*N*′-diisopropyl phosphordiamidite and Boc-protected ethanolamine in the presence of ½ equiv. diisopropyl ammonium tetrazolide.[10] The phosphitylation with **7** and subsequent oxidation with *t*-BuOOH was successful, but due to some instability of the protected phospholipid **5** on silica we decided to remove the protecting groups without further purification. A sample of **5** was purified for analysis. The final phosphatidyl ethanolamines **6a** and **6b** were generated after treatment with TFA in dichloromethane and purification on silica (DCM–MeOH–H_2O, 80:20:1.5, v/v/v). In order to introduce the choline phosphate head group, we prepared *tert*-butyl trimethylammomiumethyl *N*,*N*-diisopropyl phosphoramidite as its tosylate (**8**). Phosphitylation and oxidation proceeded as described above and the *tert*-butyl protecting group was removed instantly to give the phosphatidylcholine (**9a**) and (**9b**), respectively. Purification on silica (DCM–MeOH–H_2O, 65:35:3, v/v/v) was successful to give homogenous **9** in 40% yield.



7



8

The ethanolamine and choline derivatives **6** and **9**, each with the 2- (**a**) and 3-*O*-linkage (**b**) of the Nile red dye, respectively, were dispersed with the help of micelles from Triton X-100 in the presence of calcium chloride (100 mM) and the mixture was buffered with Tris–HCl to pH 7.5 at 37 °C. Addition of one unit of PLA_2 from honey bee venom led to a rapid increase in NBD fluorescence at 520 nm and a decrease of the Nile red fluorescence at 600 or 610 nm (Fig. 1, 2-*O*-linked **6a** shown), respectively. After about 20 min no further change was monitored, indicating that the hydrolysis was complete. Consequently, TLC analysis showed NBD fluorescence only for the NBD-labelled undecanoic acid. The overall change in the emission ratio 520/620 nm was 20- to 30-fold (Fig. 2), depending on the dye linkage (2-*O*-linkage gave slightly better separated emission maxima and hence larger ratio changes).

Equimolar concentrations (1 μM) of the competitive PLA_2 inhibitor MJ33 (ref. 11) reduced the hydrolysis rate by about 40% (data not shown) indicating that inhibitor and fluorescent probe bound to the enzyme with similar kinetics.

In conclusion, the PLA_2 probes presented here fulfil all criteria of a true FRET probe for real-time monitoring. Future experiments in vesicles and living cells and particularly the use of a membrane-permeable derivative to non-disruptively load the dye into cells will allow interesting experiments for drug searches, including high throughput screening in living cells.

We thank the Deutsche Forschungsgemeinschaft (Schu 943/3-1) and the Fonds der Chemischen Industrie for financial support.

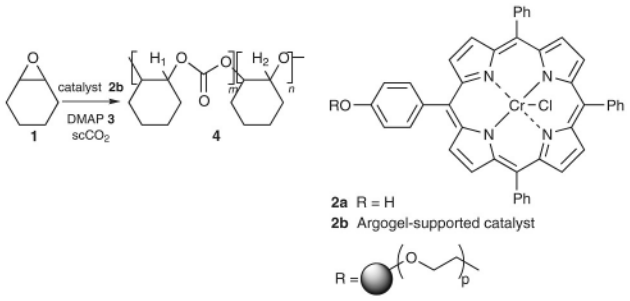
A new polymer-supported chromium porphyrin has been prepared and fully characterised; its catalytic activity and recyclability were investigated for the ring-opening copolymerisation of 1,2-cyclohexene oxide (CHO) and carbon dioxide (CO_2).

The synthesis of polycarbonates by copolymerisation of carbon dioxide and epoxides, was first reported in 1969 by Inoue *et al.*[1] More recently, Darensbourg *et al.*[2] synthesised these polymers using supercritical carbon dioxide ($scCO_2$) as both a solvent and a reactant, thereby eliminating the need for toxic volatile organic solvents in this process. Beckman and colleagues[3,4] have also prepared polycarbonates, including products that were found to be soluble in $scCO_2$. The physical properties of compressed carbon dioxide make it an attractive alternative solvent and reagent for application in polymer synthesis owing to its high diffusivity, low viscosity and readily attainable supercritical region (T_c of 31 °C, P_c of 73 atm).[5] The plasticisation effects of CO_2 on polymeric materials also make it an interesting choice as a solvent for polymer supported reactions.[6] The use of supported catalysts in supercritical CO_2 is an emerging field.[7,8]

In recent years, many supported catalysts have been developed for use in organic synthesis[9] and for polymer-assisted solution-phase parallel synthesis.[10] Furthermore, in the drive towards the development of more environmentally friendly or Green Chemistry,[11] supported transition metal catalysts offer many advantages over their homogeneous counterparts. Herein we report the synthesis of an Argogel® supported chromium porphyrin **2b** and the study of its catalytic activity in the copolymerisation of 1,2-cyclohexene oxide (CHO) **1** and CO_2 (Scheme 1) and compare our results with previously investigated systems.[12]

The attachment of the porphyrin onto Argogel chloride beads, *via* an ether linkage, was achieved in 75% yield, following three treatments of the beads with a phenol-functionalised porphyrin **2a**.[13] (using potassium carbonate as base and catalytic potassium iodide in DMF, at 80 °C for 3 days). The metallation using chromium(II) chloride (in DMF, at 45 °C for 3 days) proceeded in 67–78% yield to give the new polymer-bound chromium porphyrin catalyst **2b**.



Scheme 1 Copolymerisation of CHO **1** and $scCO_2$ using the supported chromium porphyrin catalyst **2b** and DMAP **3**.

Before testing this catalyst, control experiments were carried out (in the absence of catalyst), using Argogel chloride beads, to probe for any unexpected activity of the blank resin. The beads were therefore exposed to reaction conditions in $scCO_2$ (90 °C, 200 bar, 72 h) analogous to those to be used for the polymerisations. These control experiments were carried out with and without stirring using 100 mg of the polymer support. The beads were analysed by Scanning Electron Microscopy (SEM), which showed that they remained intact except when stirring was applied. A breakdown of the spherical morphology of the particles was observed due to stirring. Further control experiments determined that the presence of both the supported catalyst **2b** and 4-dimethylaminopyridine (DMAP **3**) was essential for polymerisation (Table 1, entries 1–3).

After these control experiments were completed, the ring opening copolymerisation of 1,2-cyclohexene oxide (CHO) **1** and CO_2 to form the copolymer poly(cyclohexene carbonate-*co*-cyclohexene ether) **4** was investigated using catalyst **2b** under various reaction conditions (Table 1).

The number average molecular weight (M_n) (determined by conventional polystyrene-calibrated gel permeation chromatography (GPC) in chloroform) and the yield of the polymer varied greatly according to the conditions applied. It appeared that the polymerisation was near to completion after 24 hours as indicated by both the M_n and the yield (even though an improvement to 78% was observed after 120 h; Table 1, Entry 8). In addition, it was observed that increasing the temperature and the pressure of the CO_2 led to greater molecular weights and higher yields. This is probably due to the fact that, although a constant volume of CHO **1** and a constant amount of the catalysts **2b** and **3** were used in all cases, the effective mole fraction of CHO **1** decreased, since more moles of CO_2 were present in reactions at elevated pressures.

Variation of the reaction conditions appeared to have little effect on the percentage of CO_2 incorporated into the polymer backbone (determined by the ratio of H_1 to H_2 using ^{1}H NMR spectroscopy) which always remained $m > 90$ % (Scheme 1, **4**). Very low polydispersities (determined by GPC) were observed, ranging between 1.2 and 1.7. However, there was no obvious trend observed relating to the increase of the temperature, pressure and the reaction time. Average molecular weights and yields varied according to the batch of beads used for polymerisation (Table 1, entries 11 and 16). This can be attributed to the variable loading of the porphyrin attachment onto the polymer support as well as the variation of the amount of chromium introduced during metallation, which was determined by microanalysis.

Experiments were also carried out in order to investigate the recyclability of the solid supported chromium porphyrin catalyst **2b** (Table 2, entries 1–6). After a reaction,† the polymer

[a] Conditions: χ(CHO) (volume fraction of monomer) = 25 %w/v, N_{cat} (amount of catalyst) = 100 mg (average loading = 0.14 mmol g^{-1}). [b] Relative to polystyrene (PS) standards. [c] Recovered monomer. [d] Chromium porphyrin beads (batch 1, loading 0.14 mmol g^{-1}). [e] Chromium porphyrin beads (batch 2, loading 0.06 mmol g^{-1}).

4 was solubilised in acetone allowing the beads to be filtered, washed and dried for re-use.

Polymerisations were also carried out using an Irori Kan™ reactor[14] to encapsulate the porphyrin beads (Table 2, entries 7–10). This not only allowed the use of a stirrer bar, thereby preventing damage to the beads, but also facilitated their recovery.

Table 2 shows that the chromium porphyrin beads **2b** can successfully be recycled, although a decrease in molecular weight and yield is observed. This may be due to leaching of the metal from the porphyrin or decomposition of the beads leading to loss of porphyrin. Mild colouration of the polycarbonate also suggested minor leaching of the chromium metal. However, the solid supported catalyst appeared to prevent the polymer products becoming intensely green as was observed when the soluble chromium perfluorinated porphyrin was used.[12] The use of an Irori Kan™ reactor[14] to encapsulate the beads appeared to result in higher molecular weights and yields of the polycarbonate. This is likely to be due to thorough mixing of the reagent in the vessel.

In summary, we have presented a new supported chromium porphyrin **2b** as a catalyst in the ring opening copolymerisation of 1,2-cyclohexene oxide **1** and CO_2. The results are comparable to those reported for a CO_2-soluble tetra(pentafluorophenyl)chromium porphyrin catalyst. However, as well as being recyclable, the supported catalyst showed efficiencies of up to 5.5 kg of polymer/1 g of chromium, thus demonstrating this new system to be superior to those previously reported.[12]

Notes and references

† In a typical experiment a 10 cm^3 stainless steel reactor was charged with CHO **1** (2.4 g), DMAP **3** (5 mg) and supported catalyst **2b** (100 mg). The reactor was filled to capacity with liquid CO_2 and heated to the desired temperature. Then the reaction mixture was pressurised with further CO_2. After the allotted time the reaction was allowed to cool and then vented into acetone (50 cm^3). The remaining contents of the reactor were added to this solution and the beads were collected by filtration. The polymer solution was concentrated to 10 cm^3 and precipitated into hexane, filtered and dried to constant weight. The polymeric products were characterised by ^{1}H NMR spectroscopy and GPC.

Intramolecular addition of acyl radicals to α-substituted vinylogous carbonates: demonstrating the effect of ring size on acyclic stereocontrol†

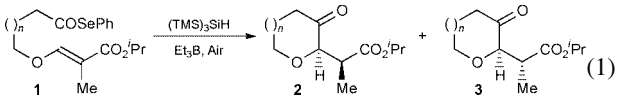
P. Andrew Evans,*[a]‡ Sushil Raina[b] and Khalid Ahsan[a]

[a] *Department of Chemistry, Indiana University, Bloomington, IN 47405, USA. E-mail: paevans@indiana.edu; Fax: +1(812) 855-8300*
[b] *Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716, USA*

Received (in Corvallis, USA) 14th July 2001, Accepted 18th September 2001
First published as an Advance Article on the web 9th November 2001

The level of stereocontrol obtained in the reduction of the free radical derived from the intramolecular addition of an acyl radical to an α-branched vinylogous carbonate is dependent upon the ring-size of the cyclic ether.

The stereoselective construction of cyclic ethers remains an important area of interest due to the ubiquity of this structural motif in biologically significant natural and unnatural molecules.[1] In the course of our studies focused on the intramolecular addition of acyl radicals[2] to vinylogous carbonates[3,4] and sulfonates,[5] we anticipated that we could expand the synthetic utility of the former through the examination of α-branched derivatives, which should provide access to an additional stereogenic center.[6,7] The ability to control the relative and absolute configuration of acyclic stereogenic centers in free radical addition reactions represents an important method in asymmetric synthesis.[8] Herein, we report that the level of stereocontrol in the intramolecular addition of acyl radicals, derived from the selenoesters **1a–c** (n = 0–2), to α-substituted vinylogous carbonates, is directly dependent upon the ring size of the resulting cyclic ether **2/3a–c** (eqn. 1).



(1)

Table 1 outlines the results for the preliminary study. Treatment of **1a–c** with tris(trimethylsilyl)silane[9] and triethylborane in the presence of air, furnished the cyclic ethers **2/3a–c** in excellent yield. Interestingly, the tetrahydrofuran-3-one **2a/3a** and tetrahydrooxepin-3-one **2c/3c** were furnished with only modest diastereocontrol irrespective of reaction temperature (Entries 1/2 and 5/6). This trend in selectivity was somewhat surprising given the precedent for this type of free radical reduction in tetrahydrofuran derivatives.[5–7] Conversely, the tetrahydropyran-3-ones **2b/3b** were afforded with excellent diastereoselectivity, favoring the *syn*-isomer **2b** (Entry 3). Furthermore, the diastereoselectivity could be further improved by lowering the reaction temperature (−20 °C), which is in sharp contrast to the tetrahydrofuran-3-one **2a/3a** and tetrahydrooxepin-3-one **2c/3c** derivatives (Entry 4 *vs* 2/6).§ The origin of the stereoselectivity may be rationalized using the static model for allylic strain,[7] in which the ketone is responsible for promoting *re*-face reduction of the radical (Fig. 1). The difference in selectivity between the various ring sizes may be attributed to conformation, which presumably alters the relative orientation of the carbonyl relative to the incipient radical. This observation is likely to provide a useful guide in understanding the factors that influence stereocontrol in acyclic radical reductions involving the intramolecular addition of acyl radicals.

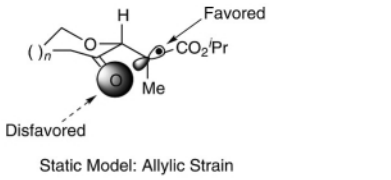

Fig. 1

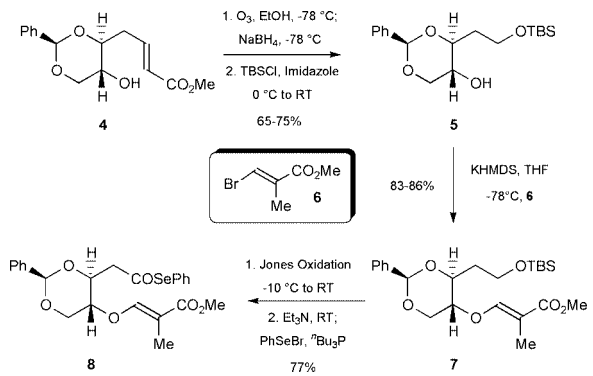
The ability to undertake the stereoselective synthesis of tetrahydropyran-3-ones in this manner prompted the extension of this study as outlined in Scheme 2. The benzylidene acetal **8** was expected to promote the formation of *cis*-2,6-disubstituted tetrahydropyran-3-one **9a** in accord with previous studies and thus determine whether the more conformationally rigid system would deviate from the excellent stereoselectivity obtained in the simple acyclic radical reduction in eqn. 1.

The acyl selenide **8** required for this study was prepared from the secondary alcohol **4** derived from deoxy-D-ribose (Scheme 1).[10] Ozonolysis of the α,β-unsaturated ester **4** followed by *in situ* reductive work-up furnished the diol, which was selectively



Scheme 1

† Electronic supplementary information (ESI) available: spectral data (IR, ^{1}H and ^{13}C NMR) and high resolution MS for **1/2a-c**, **7–10**. See http://www/rsc.org/suppdata/cc/b1/b106766b/

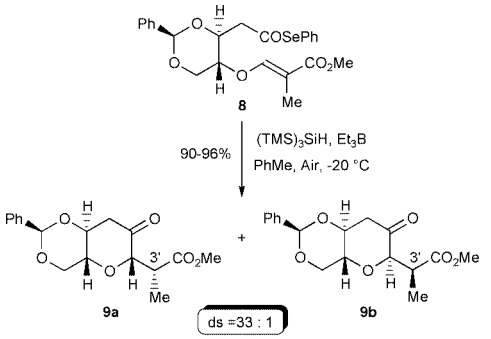
 DOI: 10.1039/b106766b

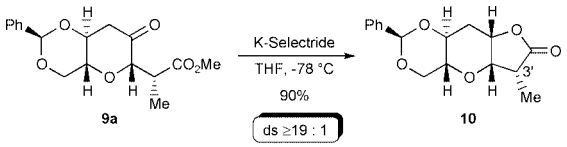
protected as the primary *tert*-butyldimethylsilyl ether **5** in 65–75% overall yield from **4**. Treatment of **5** with potassium hexamethyldisilazide followed by the β-bromomethacrylate **6**, furnished the vinylogous carbonate **7** in 83–86% yield. Oxidation of the primary *tert*-butyldimethylsilyl ether **7** with Jones reagent afforded the carboxylic acid,[11] which was then converted to the acyl selenide **8**, using the Crich protocol in 77% yield from **7**.[12] The chemoselectivity of the oxidation is pertinent given that the benzylidene acetal and vinylogous carbonate are susceptible to acid-catalyzed hydrolysis.



Scheme 2

The acyl selenide **8** was then subjected to the optimized cyclization conditions, as outlined in Scheme 2. Treatment of the acyl selenide **8** in an analogous manner to **1b**, at −20 °C, furnished the cyclic ethers **9a**/**b** in 90–96% yield, with 33 : 1 diastereoselectivity (by HPLC) at C-3′ favoring **9a**. The stereochemical outcome is consistent with the model outlined in Fig. 1.

The relative configuration of the radical cyclization–reduction was proven unequivocally through X-ray crystallography of the tricyclic lactone **10** (Fig. 2).¶ Reduction of the cyclic ketone **9a** with K-Selectride at −78 °C resulted in an *in situ* lactonization, to afford **10** in 90% yield with ⩾19 : 1 diastereoselectivity for the *cis*-lactone (eqn. 2).



(2)

In conclusion, we have demonstrated that the level of stereocontrol in the reduction of the insipient radical derived from the *intra*molecular addition of an acyl radical to a α-substituted vinylogous carbonate is dependent on the relative ring-size of the cyclic ether. The ability to achieve excellent acyclic stereocontrol in 6-*exo* acyl radical addition reactions is likely to have considerable synthetic utility, particularly for the construction of *C*-glycosides.

The promotion of hydrolysis of acetylsalicylic acid in AOT/near-critical propane microemulsion

Zameer Shervani* and Yutaka Ikushima

Supercritical Fluid Research Center, National Institute of Advanced Industrial Science and Technology, 4-2-1 Nigatake, Miyagino-ku, Sendai 983-8551, Japan. E-mail: z.shervani@aist.go.jp

Received (in Cambridge, UK) 24th August 2001, Accepted 22nd October 2001
First published as an Advance Article on the web 8th November 2001

A significant acceleration of the hydrolysis of acetylsalicylic acid was accomplished by the introduction of an AOT/near-critical propane microemulsion at lower W_0 values; the rate constant at W_0 = 1 was found to be 54 times that in aqueous buffer medium in the presence of imidazole catalyst.

In recent years, high pressure microemulsions prepared in near-critical and supercritical hydrocarbons or carbon dioxide have been applied to various fields such as organic synthetic reactions[1,2] and synthesis of nanometer-sized metal and metal oxide particles[3,4] from industrial and scientific points of view. It is well known that the advantages of near-critical (NC) and supercritical fluids (SCFs) as the dispersed phase for microemulsion preparation are their higher diffusivities and lower viscosities compared to conventional solvents.[5] In addition, their physical properties such as density,[6,7] viscosity,[8] diffusivity and dielectric constant[9] can be varied widely by simply changing the temperature and pressure of the system. In this communication we demonstrate for the first time that the introduction of a sodium bis(2-ethylhexyl) sulfosuccinate (AOT) microemulsion into near-critical propane leads to a significant acceleration of hydrolysis even at low W_0 compared with aqueous buffer solution in the presence of catalyst.† *In situ* UV-vis was employed for the determination of the rate constant of the reaction as a function of the water content of the microemulsion at a fixed temperature and pressure of 310 K and 25 MPa, respectively. The appearance of a band at 298.6 nm has been assigned to the expected hydrolysis product salicylic acid and the absorbance of this band was followed as a function of time for kinetics measurement, with spectra being recorded at different reaction times, for the determination of the degree of conversion.

Fig. 1 shows the pseudo first-order rate constant (k) of hydrolysis of acetylsalicylic acid carried out in various reaction media. A dramatic enhancement in the rate constant is observed in an AOT/NC propane microemulsion containing imidazole compared to a micoemulsion without imidazole or an aqueous buffer media. The reaction in the microemulsion containing imidazole at W_0 = 1 is 54 times faster than in aqueous buffer. The rate constant in aqueous buffer remains unchanged on addition of imidazole catalyst, whereas in the microemulsion system it greatly increased in the presence of catalyst. In a separate experiment monitoring percentage conversion *vs.* reaction time, it was noticed that the conversion of acetylsalicylic acid into salicylic acid in the microemulsion at W_0 = 1 reached 100% after 33 min while in aqueous buffer it took 61 h for 100% conversion in the presence of imidazole catalyst. The W_0 dependence of the rate constant shows that the reaction is significantly accelerated (Fig. 2) by decreasing the W_0 value in the microemulsion system, especially in the region below W_0 = 4, which is contrary to the W_0 dependence on the reaction rate for enzyme catalyzed hydrolysis or esterifications.[10,11] In the AOT/propane microemulsion medium in the presence of imidazole, a considerably higher reaction rate was observed at low water content (W_0 = 1) since the small water soluble imidazole and acetylsalicylic acid molecules can be solubilized inside the smaller cores of microemulsion droplets consisting of a small amount of water W_0 = 1. As the water content is increased in the microemulsion, the concentration of imidazole and acetylsalicylic acid is decreased and therefore the rate of reaction decreases. The higher values of the rate constant observed in the microemulsion compared to that in aqueous solution is attributed to the compartmentalization of water soluble imidazole and acetylsalicylic acid in the aqueous core of the microemulsion droplets as a result of which the local concentration of reactants is increased compared to that in neat aqueous medium. The enhancement of the reaction rate due to compartmentalization of imidazole catalyst and substrate acetylsalicylic acid was confirmed after conducting the concentration dependent hydrolysis reaction in AOT/propane microemulsion and aqueous buffer media. In both media, the rate constant increased with increasing the concentration of imidazole and acetylsalicylic acid (Fig. 3). This shows that the compartmentalization of solutes in the core of microemulsion droplets is responsible for the higher reaction rate and decreased reaction time. The mechanism of the hydrolysis reaction using

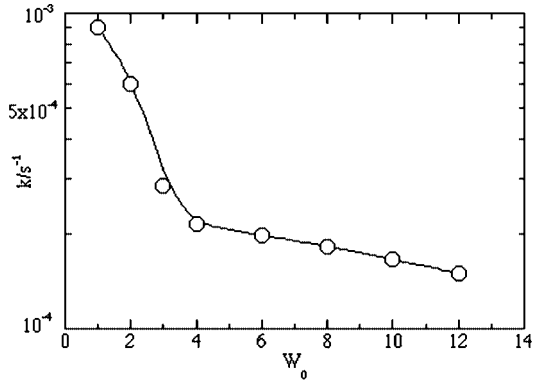

Fig. 2 W_0 dependence of the rate constsnt of hydrolysis of acetylsalicylic acid in AOT/NC propane microemulsion at 25 MPa and 310 K.

 DOI: 10.1039/b103695p

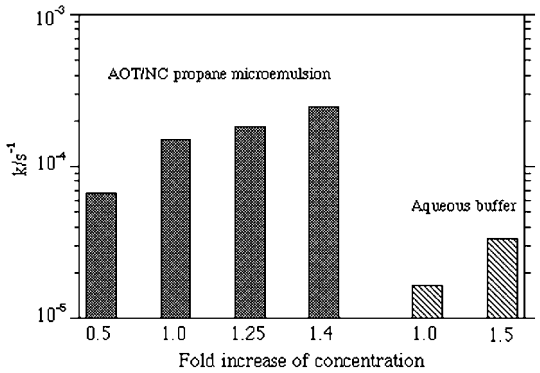

Fig. 3 Rate constant (k/s^{-1}) *vs*. fold increase in the concentration of acetylsalicylic acid and imidazole in AOT/NC propane microemulsion (W_0 = 12, P = 39.2 MPa) and in aqueous buffer at 310 K.

imidazole catalyst has been proposed to be a general acid–base catalysis reaction involving the transferral of a proton in the transition state.

Fig. 4 compares the rate constants of the hydrolysis of acetylsalicylic acid in AOT/NC propane and AOT/hexane microemulsions. The rate constant in the propane system is higher than in hexane. This can be be attributed to the decrease in the microviscosity of the water/AOT interface in the NC propane system similar to the reduced microviscosity observed in a perfluoropolyether ammonium carboxylate (PFPE-$CO_2^-NH_4^+$)/carbon dioxide microemulsion.[12]

In conclusion, high pressure microemulsion systems can be used as reaction media for hydrolysis reactions leading to the enhancement of catalytic activity as compared to aqueous buffers and normal microemulsion systems. The water content of the microemulsion has a strong influence on the hydrolysis of acetylsalicylic acid in presence of imidazole catalyst. The reaction is faster in low water containing microemulsions than in microemulsions of larger water content. The promotion of the hydrolysis in the microemulsion has been proved to be due to the compartmentalization of the water soluble catalyst and substrate in the cores of microemulsion droplets which also explains the dependence of the rate constant on the water content of the system. Increasing the amount of water in the microemulsion dilutes the reactants so lowering the rate constant and slowing the reaction.

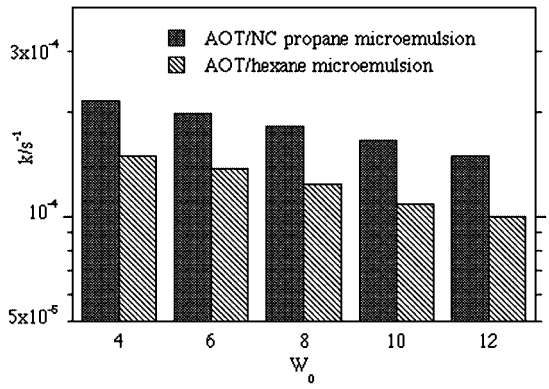

Fig. 4 A comparison of pseudo-first order rate constant (k/s^{-1}) of hydrolysis of acetylsalicylic acid in the presence of imidazole in AOT/hexane and AOT/propane (25 MPa) systems at 310 K.

Notes and references

† *Experimental procedure*: a high pressure UV cell of 2.2 ml volume fitted with a pair of sapphire windows was used as the reactor. After adding AOT, acetylsalicylic acid, imidazole and water the high pressure cell was closed and propane at 25 MPa was pressurized inside the cell. The concentrations of AOT, acetylsalicylic acid and imidazole was estimated as 0.1, 2.5×10^{-4} and 2.5×10^{-2} M, respectively. The temperature of the reaction was controlled within ±0.2 °C with a temperature controller attached to the cell. The reaction mixture was stirred continuously during the measurement by a Teflon-coated bar driven by an outside magnet. A schematic diagram of the high pressure cell used as the reactor has been given elsewhere.[13] The increase in the absorbance was recorded *vs*. the reaction time with a Jasco V-570 spectrometer. The percentage conversion was determined by the intensity of 298.6 nm band. W_0 represents the water content of the microemulsion and is the molar ratio of water to AOT. 100 mM phosphate buffer was used to adjust the water content of the microemulsion and also as the aqueous reaction medium. The reactions in aqueous buffer and in AOT/hexane microemulsions were carried at 310 K and at ambient pressure.

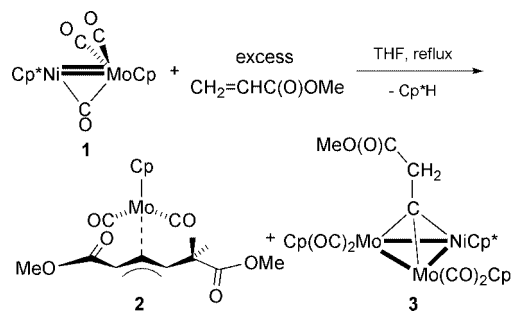
Received (in Cambridge, UK) 30th August 2001, Accepted 19th October 2001
First published as an Advance Article on the web 7th November 2001

An organometallic complex resulting from tail-to-tail dimerization and C–H activation of methyl acrylate (MA), $[Mo(CO)_2Cp\{\eta^3\text{-}(MeO_2C)CH{=}CH{=}CHCH_2(CO_2Me)]$ 2, has been fully characterized from the reaction of the heterobimetallic complex $[Cp^*Ni{=}Mo(\mu\text{-}CO)(CO)_2Cp]$ with MA and an exclusively η^3-allyl bonding mode of the coupled ligand was established for the first time by X-ray diffraction; formation of 2 is accompanied by that of the μ_3-alkylidyne-capped cluster $[NiMo_2(\mu_3\text{-}CCH_2CO_2Me)(CO)_4Cp^*Cp_2]$ 3 which results from a double C–H activation of the CH_2 group of MA; none of these reactions occur with the corresponding homodinuclear complexes.

Methyl acrylate (CH_2=CHC(O)OMe = MA) plays an increasingly important role in the copolymerization of olefins[1] and its catalytic tail-to-tail dimerization represents an attractive alternative route to adipic acid from C_3 feedstocks. Its activation by metal complexes is therefore of significant current interest.

Reaction of the paramagnetic heterobimetallic complex $[Cp^*Ni{=}Mo(\mu\text{-}CO)(CO)_2Cp]$ **1** (Cp = η-C_5H_5, Cp* = η-C_5Me_5)[2] with an excess of MA (THF, reflux) afforded the new compounds **2** (20% yield) and **3** (18% yield based on Ni) (Scheme 1).†

The structure of **2** (Fig. 1)§ revealed that the organic ligand MeOC(O)CH=CH=CHCH$_2$C(O)OMe (*i*) has formed by C–C coupling and C–H bond activation of two methyl acrylate moieties leading to their tail-to-tail dimerization and (*ii*) that it is only η^3-allylically *exo*-bound to a $CpMo(CO)_2$ fragment. The methoxycarbonyl group bonded to the sp^2-hybridized carbon is essentially coplanar with the allylic carbon atoms while the other is perpendicular. One H is lost from one molecule of MA and a formal 1,2-hydrogen migration takes place in the other. The H atom is likely eliminated with a Cp* ligand to form isolated Cp*H.



Scheme 1

The other complex isolated (Scheme 1)† is the μ_3-alkylidyne capped mixed-metal cluster $[NiMo_2(\mu_3\text{-}CCH_2CO_2Me)(CO)_4Cp^*Cp_2]$ **3** (Fig. 2).§ In this 48e cluster, each Mo atom is bonded to a Cp ligand and to two CO ligands, and the Ni to its Cp* ligand. The cluster has no (C_1) symmetry. The Ni–Mo bonds (2.63 Å, av.) and the Mo–Mo bond (2.9343(4) Å) are in the range for normal single bonds between these metals. As in **2**, the C(O)OMe group in **3** is not involved in any bonding interaction with any metal. The asymmetry observed in the solid-state for **3** is maintained in solution, as is reflected in the NMR spectra.†

The organic ligand in **3** is derived from MA by activation of both CH_2 protons: again 1,2-migration of one H and loss of the other have occurred, generating the triply-bridging $\equiv CCH_2C(O)OMe$ fragment. There appears to be no precedent in the literature for such activation of MA to afford structures like those of **2** and **3**.

MA dimerization has been observed with complexes of Ni,[3] Pd,[4] Rh,[5] Ru[6–8] and Sm,[9] but few organometallic intermediates have been isolated. An Rh(III) complex which contains a dimerized MA ligand was characterized but both an allylic interaction and chelation *via* a carbonyl function were noted; the latter was thought to be responsible for its inactivity towards excess MA.[5c] Carbon–carbon bond formation at polynuclear metal centers has been much investigated but fewer studies have targeted alkenes as compared to alkynes[10] and we are not aware of any complexes similar to **2** that were isolated from such reactions. The potential of multicenter activation of organic substrates is further illustrated by the recent thermal cleavage (in contrast to our case of C–C coupling) of the C=C double

Only the alkylidyne ligand hydrogen atoms are shown; selected bond lengths (Å) and angles (°): Ni–Mo(1) 2.6282(5), Ni–Mo(2) 2.6309(5), Mo(1)–Mo(2) 2.9343(4), Ni–C(1) 1.891(3), Mo(1)–C(1) 2.090(4), Mo(2)–C(1) 2.131(3); Mo(1)–Mo(2)–Ni 56.04(1), Mo(1)–Ni–Mo(2) 67.83(2), Ni–Mo(1)–Mo(2) 56.13(1), Ni–C(1)–C(2) 119.6(2), Mo(1)–C(1)–C(2) 131.4(3), Mo(2)–C(1)–C(2) 134.6(3), C(10)–Mo–C(11) 87.6(2), C(17)–Mo–C(18) 87.5(2).

bond of methyl acrylate mediated by a triruthenium pentahydride cluster which afforded a μ_3-alkyne, μ_3-methylidyne cluster.[11]

To address the need for a heterometallic species, we examined the reactivity of MA separately with each of the closely related metal–metal bonded homodinuclear complexes $[Cp^*Ni(\mu\text{-}CO)]_2$ and $[CpMo(CO)_3]_2$ and with the triply bonded, unsaturated complex $[Cp(OC)_2Mo{\equiv}Mo(CO)_2Cp]$ under similar reaction conditions. In all cases the metal complexes and ligand were recovered essentially unchanged. Since the reaction of Scheme 1 occurs under thermal conditions, we do not believe that the paramagnetic nature of **1** is responsible for its reactivity. Furthermore, the multiple metal–metal bond character of **1** alone is not sufficient, as shown by the lack of reaction of the Mo≡Mo complex. The coordinatively saturated complex $[Cp^*(OC)Ni\text{–}Mo(CO)_3Cp]$ was not investigated as it decarbonylates under these thermal reaction conditions to generate **1**.

Although the detailed reaction mechanism leading to the C–H activations of MA and C–C bond formation observed here remains unknown, the reactions observed here could occur at the heterometallic core or, alternatively, fragmentation of the Ni–Mo multiple bond could generate reactive species not readily acccessible from the Ni_2 or Mo_2 complexes. Nevertheless, pure **1** is thermally stable in refluxing THF. This study represents a clear example of a heterobimetallic complex showing enhanced reactivity as compared to that of its homodinuclear congeners.[12]

This work was supported by the CNRS and the Ministère de la Recherche (also *via* an associate research position to M. J. C.) and we are also grateful to the COST D-17 programme of the European Commission (DG-XII).

Efficient heterogeneous catalytic intramolecular Tishchenko reaction of *o*-phthalaldehyde to phthalide with alkaline earth oxides

Tsunetake Seki and Hideshi Hattori*

Center for Advanced Research of Energy Technology, Hokkaido University, Kita-13, Nishi-8, Kita-ku, Sapporo 060-8628, Japan. E-mail: hattori@carbon.caret.hokudai.ac.jp

Received (in Cambridge, UK) 10th October 2001, Accepted 30th October 2001
First published as an Advance Article on the web

The heterogeneous catalytic systems realized by alkaline earth oxides are successfully applicable to the highly efficient intramolecular Tishchenko lactonization of *o*-phthalaldehyde to phthalide.

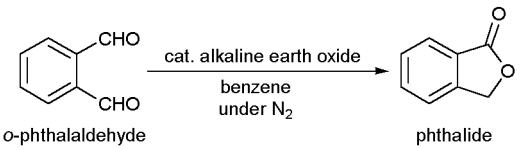
The heterogeneous catalytic Tishchenko reaction using solid bases involves the dimerizarion of aldehydes yielding the corresponding esters initiated by the interactions of polarized carbonyl groups of aldehydes with surface acidic and basic sites of solid bases. The adaptability of solid base catalysts to the Tishchenko reaction has been demonstrated in several investigations.[1] Most of previous development of efficient catalysis for Tishchenko reaction, however, has been confined to homogeneous catalytic systems. Recent articles dealing with homogeneous catalyses have reported considerable improvements in activities for the dimerization of aldehydes in comparison with traditional aluminium alkoxides catalysts.[2,3] Solid base catalysts, unlike these homogeneous catalysts, can be easily separated from the reaction mixture after carrying out the reaction, and are inexpensive and environmentally benign. These excellent properties emphasize the importance of the replacement of homogeneous catalyses with heterogeneous ones both in the laboratory and in industrial processes utilizing Tishchenko esterification.

Although several studies have been conducted on the *intermolecular* Tishchenko reaction over solid base catalysts as mentioned above, there have been no reports of the *intramolecular* Tishchenko reaction which results in cyclization.[2,4] In addition, to our knowledge, in the field of heterogeneous basic catalysis, there has been only one report dealing with intramolecular cyclization (dehydration of monoethanolamine to ethylenimine).[5] Here we report the intramolecular Tishchenko reaction of *o*-phthalaldehyde to phthalide using alkaline earth oxides as powerful and highly selective heterogeneous catalysts. The general reaction equation is shown in Scheme 1.

Experimental procedures are as follows: MgO, CaO, SrO and BaO were prepared from $Mg(OH)_2$, $Ca(OH)_2$, $SrCO_3$ and $BaCO_3$, respectively, by thermal decomposition at elevated temperatures *in vacuo*. The pretreatment temperatures and surface areas of the catalysts examined are listed in Table 1. To a Schlenk tube containing the alkaline earth oxide pretreated (10 or 50 mg) was added a benzene (1 mL) solution of *o*-phthalaldehyde (1 mmol) under N_2 at room temperature. Then the reaction mixture was warmed to 313 K and stirred for a prescribed reaction time. The resulting solution, after alkaline earth oxide was separated, was analyzed by GC equipped with a DB-1 column (total length: 60 m; diameter: 0.25 mm) to determine the yield (%) of phthalide. The product was identified by ^{1}H NMR and GC–MS analysis.

The catalytic activities of alkaline earth oxides for the intramolecular Tishchenko reaction of *o*-phthalaldehyde to phthalide are given in Table 1. To compare the activities of alkaline earth oxides, *o*-phthalaldehyde was treated with 10 mg of each alkaline earth oxide at 313 K for 60 min (entries 1, 3, 5 and 7). Barium oxide did not furnish the corresponding lactone at all (entry 7). Magnesium oxide and SrO showed almost equal moderate activities (entries 1 and 5). In contrast, however, CaO exhibited an excellent activity (entry 3). It should be emphasized that MgO, CaO and SrO yielded phthalide selectively (intermolecular Tishchenko dimerization products were not observed by GC–MS analysis). In an attempt to attain a synthetically satisfactory level of yield, the amount of MgO, CaO, and SrO was increased without changing the reaction temperature. Thus, when the reaction was carried out at 313 K with 50 mg of CaO, the reaction proceeded instantaneously, and phthalide was obtained quantitatively in a short time of 15 min (entry 4). Under the same conditions, MgO and SrO also furnished pthalide in excellent yields of 91 and 86%, respectively (entries 2 and 6).

In summary we have shown that efficient heterogeneous catalytic lactonization of dialdehydes can be realized by using alkaline earth oxides through the intramolecular Tishchenko reaction of *o*-phthalaldehyde to phthalide.



Scheme 1 Heterogeneous catalytic intramolecular Tishchenko reaction of *o*-phthalaldehyde to phthalide with alkaline earth oxides.

Table 1 Activities of alkaline earth oxides for the intramolecular Tishchenko reaction of *o*-phthalaldehyde to phthalide[a]

Entry	Catalyst	Catalyst weight/mg	Pretreatment temperature/K	Surface area[b]/m^2 g^{-1}	Reaction time/min	Reaction temp./K	Yield[c] (%)
1	MgO	10	873	267	60	313	15
2	MgO	50	873	267	15	313	91
3	CaO	10	873	48	60	313	59
4	CaO	50	873	48	15	313	Quantitative
5	SrO	10	1273	12	60	313	15
6	SrO	50	1273	12	15	313	86
7	BaO	10	1273	2	60	313	0

[a] Reactant: 1 mmol of *o*-phthalaldehyde; solvent, 1 mL of benzene. All reactions were carried out under N_2. [b] Surface areas were determined by the BET method. [c] Yield was determined by the GC analysis of the resulting solution and was calculated by the equation: yield (%) = {(mol% of phthaide)/[(mol% of *o*-phthalaldehyde) + (mol% of phthalide)]} × 100.

Thermal stability of an SiO_2-coated Rh catalyst and catalytic activity in NO reduction by CO

Masanori Ikeda,* Teruoki Tago, Masahiro Kishida and Katsuhiko Wakabayashi

Department of Materials Process Engineering, Graduate School of Engineering, Kyushu University, 6-10-1 Hakozaki, Higashi-ku, Fukuoka 812-8581, Japan. E-mail: mikeda@chem-eng.kyushu-u.ac.jp

Received (in Cambridge, UK) 1st August 2001, Accepted 25th August 2001
First published as an Advance Article on the web

An SiO_2-coated Rh catalyst with SiO_2 thickness of 13 nm has much higher stability against sintering of Rh and SiO_2 than sol–gel and impregnation Rh/SiO_2 catalysts; it exhibits the highest activity in the NO–CO reaction among these catalysts after thermal treatment.

The efficiency and life-time of a supported metal catalyst is influenced by the thermal stability of the metal particles. At high temperatures, sintering of metal particles causes deactivation of the catalyst. Sintering is a serious problem especially for automotive catalysts because they are exposed to exhaust gases at high temperatures. There is no method that completely inhibits sintering. However, it is considered that physical prevention of the migration of metal particles can effectively restrain sintering. For instance, sol–gel catalysts are known to have high resistance to the sintering of metal particles.[1–3] Such catalysts have metal particles that are incorporated into the framework of the support or partially embedded in the support.[1,2] Such a structure restrains the migration of metal particles, leading to inhibition of sintering.

We developed a preparation method for supported metal catalysts using a water-in-oil microemulsion (ME method) and reported that Rh particles of an Rh/SiO_2 catalyst prepared by this method were partially embedded into SiO_2 supports.[4] Furthermore, we successfully synthesized Rh nanoparticles wholly coated by a nanometer-scale SiO_2 layer using a specific microemulsion system.[5] It is expected that such a structure results in high resistance to sintering since the migration of the Rh particles is prevented by the SiO_2 layer. In the present study, we compared the sintering behaviors of SiO_2-coated Rh particles (SC) with catalysts prepared by the microemulsion (ME) method, sol–gel (SG) method and the impregnation (IMP) method. In addition, the catalytic activities of the particles in NO reduction by CO were also compared with those of the other catalysts before and after thermal treatment. It has been reported that similar silica-coated metal particles have been synthesized,[6–8] but the present report is the first to describe SC particles used as a catalyst.

The starting materials for Rh and SiO_2 were $RhCl_3{\cdot}3H_2O$ and tetraethyl orthosilicate (TEOS), respectively for all the catalysts. The SC and ME catalysts were prepared using the same procedure as reported previously.[4,5] A microemulsion system of polyoxyethylene (n = 15) cetyl ether (226 g, 0.5 M)/cyclohexane and polyoxyethylene (n = 5)–*p*-nonylphenyl ether (22 g, 0.5 M)/hexan-1-ol were used for the preparation of the SC and ME catalysts, respectively. The molar ratios of surfactant to water (for hydrolysis of TEOS) were 3 and 6 for the SC and ME catalysts, respectively.

The SG catalyst was prepared using the following procedure. A mixture of TEOS (37 g) and ethanol (20 ml) were stirred at 70 °C for 10 min. A solution of $NH_3{\cdot}H_2O$ (1 ml) and distilled water (20 ml) were added to the mixture and stirred at 70 °C for 30 min. An aqueous $RhCl_3$ solution (0.38 M, 2.6 ml) was added to the mixture and stirred at 70 °C for 1 h to obtain a gel containing the Rh precursor. The gel was then dried at 70 °C for 12 h. The IMP catalyst was prepared by the usual procedure. The SiO_2 support was prepared using the ME method employing a microemulsion system of polyoxyethylene (n = 15) cetyl ether/cyclohexane.

In all methods, the dried samples were calcined under an air flow at 500 °C for 2 h and reduced at 450 °C for 1 h. The Rh loading was 1 wt% for the ME SG and IMP catalysts and 10 wt% for the SC catalyst. For the NO–CO reaction, the SC catalyst was mixed with silica (the same silica as the support of the IMP catalyst) to 1 wt% Rh content.

To investigate the thermal stability of Rh particles against sintering, air calcination of all the catalysts was conducted at 900 °C for 12 h under air flow. The mean Rh particle size of the Rh/SiO_2 catalysts was determined by powder X-ray diffraction (XRD) using a Rigaku RINT 2500 instrument. BET surface areas were measured by nitrogen adsorption at −196 °C using a Shimadzu Tristar 3000 instrument at 55 °C. The amount of CO uptake by the Rh particles was measured by CO chemisorption. Transmission electron microscopy (TEM) images of the catalysts were taken with a JOEL JEM 2000FX.

Catalytic activity was measured using a quartz tubular reactor. The reactant gas mixture was composed of 10 000 ppm NO, 10 000 ppm CO and He as a balance, while the gas-flow rate was 100 ml min^{-1} (SV = 30000 ml $g\text{-}cat^{-1}$ h^{-1}). The effluent gas was directly routed to a gas chromatograph (Shimadzu GC-8A) for on-line analysis.

Table 1 shows the Rh particle sizes determined by XRD before and after thermal treatment. Both the Rh particle size after the thermal treatment and the difference in the Rh particle size before and after the thermal treatment, $\triangle D$, could be ranked in the following order according to size: SC < ME < SG < IMP. Fig. 1 shows TEM photographs of these catalysts after thermal treatment. The sequence of mean Rh particle sizes determined by TEM photographs was the same as that determined by XRD. In the IMP catalyst [Fig. 1(a)], several Rh particles of size >20 nm were observed. In the SG catalyst, most Rh particles remained small (*ca.* 5 nm) after thermal treatment, which indicates that the SG catalyst has a higher resistance to sintering than does the IMP catalyst, although some Rh particles were as large as those of the IMP catalyst. In the ME catalyst [Fig. 1(c)], most of Rh particles remained small (*ca.* 4 nm) after thermal treatment while a few Rh particles of size *ca.* 15 nm were observed. Therefore, the ME catalyst has a higher resistance to the sintering than does the SG catalyst. In

Table 1 Rh particle sizes and BET surface areas of catalysts prepared *via* different routes

	Rh particle size/nm			BET surface area/m^2 g^{-1}	
Cat.	Before[a]	After[b]	ΔD[c]/nm	Before[a]	After[b]
SC	3.4	5.7	2.3	246	170
ME	3.8	6.8	3.0	24	18
SG	6.8	10.1	3.3	231	34
IMP	6.6	11.0	4.4	73	51

 DOI: 10.1039/b106797d

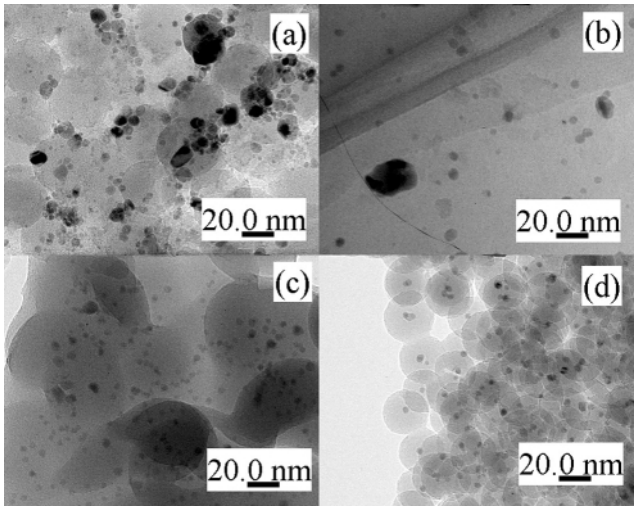

Fig. 1 TEM photographs of the Rh/SiO_2 catalysts after thermal treatment at 900 °C for 12 h: (a) IMP, (b) SG, (c) ME, (d) SC.

the SC catalyst [Fig. 1(d)], however, all the Rh particles were covered by the SiO_2 layer and remained small even after the thermal treatment. It is concluded that migration of Rh particles of the SC catalyst was restrained by the SiO_2 layer, resulting in the highest resistance to sintering.

Fig. 2 shows the temperatures for 50% NO conversion in NO reduction by CO, T_{50}, before and after thermal treatment. The sequence of relative activity before thermal treatment was IMP < SC < ME < SG. It was noted that the SC catalyst showed an activity as high as that of the IMP catalyst although the Rh particles of the SC catalyst were fully covered by the SiO_2 layer. This result indicates that the reactant gases were accessible to the Rh particles. The amount of CO uptake of the SC catalyst (13.9 μmol g^{-1}) was of the same order as found for the IMP catalyst (16.5 μmo g^{-1}).

The IMP catalyst was considerably deactivated by the thermal treatment as can be seen from Fig. 2. The main reason for the deactivation is due to the sintering of the Rh particles as shown in Table 1. T_{50} of the ME and SG catalysts also considerably increased despite their high resistance to sintering. In contrast to these catalysts, T_{50} of the SC catalyst having the highest resistance to sintering increased only slightly and was the lowest after the thermal treatment. Accordingly, the SC

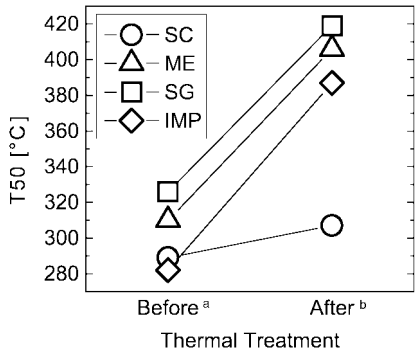

Fig. 2 T_{50} values in the NO–CO reaction over the Rh/SiO_2 catalysts. [a] Values before thermal treatment; [b] Value after thermal treatment at 900 °C for 12 h.

catalyst had the highest activity of these catalysts after the thermal treatment. As to the difference in activity between the three types of catalysts, this is difficult to explain in terms of Rh particle size since the difference is attributable to changes in several physical and physico-chemical factors. One of the most important factors may be metal–support interactions. It was reported that sol–gel catalysts with metal particles embedded in silica supports showed stronger metal–support interaction than impregnation catalysts,[9] leading to the existence of $M^{\delta+}$ species in the catalyst. In another report, it was shown that the presence of $Rh^{\delta+}$ in the catalyst improved catalytic activity in the NO–CO reaction.[10] Rh–SiO_2 interactions might differ between the catalysts causing the differences in catalytic activity.

In addition, we considered that the thermal stability of the SiO_2 support might affect the catalytic activity since the reactant gases are accessed on the Rh surface through the SiO_2 pores. The BET surface areas of these catalysts are given in Table 1. For the SG catalyst, the area was drastically decreased upon thermal treatment while for the ME catalyst the initial low surface area was further lowered upon thermal treatment. On the other hand, the area of the SC catalyst after thermal treatment was still substantial. The CO uptake of these catalysts were 3.1, 0.2 and 0.2 μmol g^{-1} for the SC, ME and SG catalysts, respectively. These results suggest that the SiO_2 pores of the ME and SG catalysts are decreased upon thermal treatment while the pores are less affected in the SC catalyst. It is clear that the SC catalyst has a high SiO_2 thermal stability. The reason for this is not clear, but such high thermal stability may be derived from the thin SiO_2 layer. The thickness of SiO_2 layer of the SC catalyst used in the reactions is *ca.* 13 nm [Fig. 1(d)]. The BET surface area of this SC catalyst decreased upon thermal treatment from 246 to 170 m^2 g^{-1} (Table 1). On another SC catalyst with an SiO_2 thickness of 22 nm, however, the BET surface area drastically decreased upon thermal treatment from 91 to 3 m^2 g^{-1}. The difference suggests that the thinner SiO_2 layer shows a higher resistance to blockage of silica pores upon thermal treatment. Such high thermal stability of SiO_2 in the SC catalyst as well as high resistance to sintering of Rh particles led to high activity after thermal treatment.

In conclusion, the SiO_2-coated Rh catalyst with SiO_2 thickness of 13 nm showed a much higher stability against sintering of Rh and SiO_2 than sol–gel and impregnation Rh/SiO_2 catalysts. As a result, this catalyst had the highest activity in NO reduction by CO after thermal treatment at 900 °C for 12 h.

A new, highly fluorescent terpyridine which responds to zinc ions with a large red-shift in emission†

Wendy Goodall and J. A. Gareth Williams*

Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE. E-mail: j.a.g.williams@durham.ac.uk

Received (in Cambridge, UK) 17th September 2001, Accepted 24th October 2001
First published as an Advance Article on the web

A sequence of three metal-catalysed aryl coupling reactions leads to the new ligand 4′-(4-*N*,*N*-diphenylaminophenyl)-2,2′:6′,2″-terpyridine, the intense ICT emission of which undergoes a large red-shift upon binding of zinc ions, providing a unique response over other common metal ions.

Sensitive and selective fluorescent probes for metal ions are important in clinical analyses, including the study of the physiological roles of metal ions.[1] With a large number of cellular functions having been identified for zinc over the past decade, probes of cellular Zn^{2+} concentration are of increasing interest.[2] The luminescence of some transition metal complexes of terpyridines is well established including applications to chemical sensing (*e.g.* for pH, halide and metal ions[3,4]). On the other hand, terpyridine ligands themselves have generally not been considered for use as fluorescent sensors, possibly owing to an expected lack of selectivity (given the diverse range of metal ions they are able to bind) and perhaps also to the fact that few terpyridines are strongly emissive at wavelengths other than in the UV, with short-wavelength excitation being required. We report here on the use of palladium-catalysed cross-couplings of aryl boronates with 4′-bromoterpyridine, to construct novel, 4′-substituted terpyridines in high yield.[5] In particular, this methodology has been used to prepare the compound 4′-(4-*N*,*N*-diphenylaminophenyl)-2,2′:6′,2″-terpyridine, a highly fluorescent new ligand whose emission is affected very distinctively upon binding of zinc ions.

4-Bromo-*N*,*N*-diphenylaniline was prepared by a copper(I)-catalysed Ullmann coupling of diphenylamine with 4-bromoiodobenzene in the presence of 1,10-phenanthroline (Scheme 1, ESI†). Under these conditions, substitution occurs specifically at the iodine atom. Conversion to the neopentyl boronate was accomplished by a palladium-catalysed reaction with bis(neopentyl glycolato)diboron. Finally, a Suzuki-type coupling of the boronate with 4′-bromoterpyridine, (readily accessible in multigram quantities†), led to the desired compound in 66% yield. The use of cross-coupling reactions in this way offers an attractive, divergent route to new 4′-aryl-substituted terpyridines and, indeed, the *N*,*N*-dimethyl analogue (designated L^2) was prepared similarly from 4′-triflate-terpyridine upon reaction with commercially available 4-(dimethylamino)benzeneboronic acid.

The lowest energy absorbance maxima of the two compounds in solution (Table 1) display a very small red-shift with increasing solvent polarity. In contrast, the fluorescence maxima undergo very large shifts to longer wavelengths. Such behaviour is strongly indicative of intramolecular charge transfer (ICT) character in the emissive excited states of these compounds. The fluorescence of L^2 and its non-methylated ($-NH_2$) analogue has been interpreted in this way in a contemporary report, where a semi-empirical MO calculation revealed that the amino substituent raises the energy level of the pendent phenyl to such an extent that the lowest energy excited state corresponds to an ICT (π_{Ph}–π^*_{tpy}) transition, as opposed to the locally excited states (π_{tpy}–π^*_{tpy}) of other 4′-aryl-substituted terpyridines.[6] The present results indicate that the diphenylamino substituent has a similar effect, with comparable emission wavelength maxima in each solvent. However, whereas the emission intensity of L^2 is greatly reduced in polar solvents such as ethanol, L^1 is strongly fluorescent in all solvents investigated. This difference is strikingly clear upon comparing the fluorescence quantum yields in ethanol: 0.009 and 0.25, respectively. Given that the fluorescence lifetimes of the two compounds in this solvent are the same within experimental error (Table 1), the much smaller quantum yield of L^2 is most likely due to a reduction in the efficiency of formation of the emissive ICT state in L^2, following excitation to the initially populated excited state, rather than enhanced non-radiative deactivation. It is well-established that ICT emission from dialkylamino-substituted aromatics of the 'push–pull' type (for example, the classic compound dimethylaminobenzonitrile), requires a dynamic relaxation of the initially populated state through twisting of the dialkylamino group, coupled with electron transfer from the amino nitrogen to the remote π* orbital of the acceptor moiety. In alcohol solutions which can hydrogen bond to the N atom of the donor, it has been shown that the twisting process may be partially inhibited owing to the requirement for simultaneous breakage of such a hydrogen bond.[7] Given the basicity of dimethylaniline compared to non-basic triphenylamine (pK_a values of the conjugate acids are 5.15 and *ca.* −5 respectively), such hydrogen bonding is to be expected in L^2 but may be absent (or only very weak) in

Table 1 Photophysical properties of ligands L^1 and L^2 in solvents of varying polarity

	Cyclohexane	THF	DCM	EtOH
L^1				
λ_{max}[a]/nm (absorbance)	356	360	361	362
λ_{max}[b]/nm (emission)	392 (414 sh)	453	472	513

 DOI: 10.1039/b108408a

L^1, such that formation of the ICT state may be inhibited in the former but not in the latter.

Acidification of an ethanolic solution of L^1 led to a change from colourless to yellow, with a substantial hypochromic shift in the longest wavelength absorption band to 430 nm (Fig. 1). The fluorescence emission band underwent a comparable red-shift (from 513 to 642 nm, Fig. 2), but the integrated emission intensity was enormously decreased, by a factor of >200 when excited at the isosbestic point (387 nm). The red-shift in emission may be attributed to the stabilisation of the charge-transfer state which is expected to occur upon protonation of the terpyridine, as the electron acceptor properties of the latter are enhanced. Monitoring of the emission intensity at 513 nm in the presence of increasing concentrations of trifluoroacetic acid led to a pH profile with a single inflection point at 3.3, probably associated with diprotonation of the terpyridine. Ligand L^2 behaved similarly, but with a smaller change in intensity and with a subtle displacement of the profile to higher pH.†

Addition of zinc(II) ions (as zinc triflate) to a solution of L^1 in ethanol–water (9/1) led to an effect on the absorbance and emission maxima comparable to that of acid, namely a large shift to longer wavelengths (Figs. 1 and 2). In this case, however, the fluorescence intensity was not reduced to the same extent. Terpyridines are well-known to possess quite high affinity for Zn^{2+}, although the 2:1 complexes they form are kinetically more labile than those of transition metal ions with partially-filled d sub-shells such as iron(II). That the binding of zinc to L^1 leads to red-shifts similar to those induced by protonation is not surprising, since the positive charge on the metal ion will similarly promote the ICT process from pendent amine to terpyridine. On the other hand, the markedly higher emission intensity of the zinc complex is intriguing (Fig. 2). It is likely that this is due to the greater rigidity of the zinc complex, compared to the diprotonated terpyridine, which will serve to reduce the efficacy with which C–C stretching vibrations are able to act as energy accepting modes for deactivation of the excited state.[8] Although fluorophores with ICT excited states have been considered previously for pH and metal ion sensing,[9] the system described here is very unusual in that the proton or metal ion binds to the moiety which acts as the acceptor (rather than the donor) in the charge transfer process.

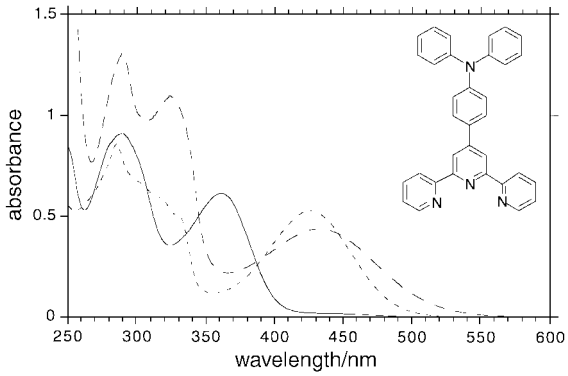

Fig. 1 UV–VIS absorbance spectra of L^1 (——); L^1 after addition of trifluoroacetic acid to pH 0.7 (— —); after addition of Zn^{2+} (5 equivalents of zinc triflate) (- - -). [L^1] = 6.7 μM in ethanol.

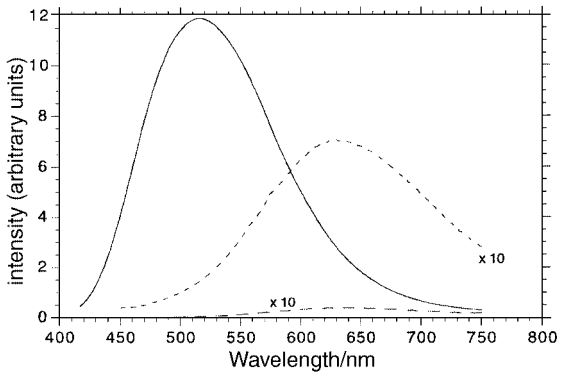

Fig. 2 Fluorescence emission spectra of L^1 (——), L^1 in the presence of H^+ (— —) (×10), and L^1 in the presence of Zn^{2+} (- - -) (×10) at the concentrations in ethanol given in the caption to Fig. 1. Samples were excited at the isosbestic point (387 nm) with excitation and emission band-passes set to 2.5 nm. Spectra shown are corrected for the wavelength dependence of the photomultipler tube.

The fluorescence responds sensitively to zinc ions; preliminary estimates indicate an apparent 2:1 (ligand:Zn^{2+}) association constant of $(4.3 \pm 0.6) \times 10^9$ dm^6 mol^{-2}.† However, although the emission profile changes dramatically (Fig. 2), excitation at the isosbestic point actually leads to a net decrease in the intensity at the new maximum (630 nm), owing to the higher emissivity of the ligand and the broadness of its fluorescence band. On the other hand, the changes in the absorption spectra which accompany formation of the zinc complex are synergistic, such that excitation at 415 nm (close to the absorbance maximum of the zinc complex) allows a 5-fold increase in the emission intensity at 630 nm to be achieved. The *ratio* of the emission intensity at 630 nm to that at 513 nm increases by a factor of 12 under these conditions; such ratiometric fluorimetry, where the ratio of signals at two emission or excitation wavelengths is monitored, is highly desirable in practical sensors, in order to cancel out variations in intensity arising from background changes in the analytical environment.[1]

The response to zinc is unique among the metal ions investigated (with the single exception of Cd^{2+}).‡ The addition of calcium and magnesium ions (competing ions when zinc sensors are used in physiological studies[2]) gave no change in the fluorescence of L^1, probably owing to the low affinity of these metal ions for terpyridines. On the other hand, paramagnetic transition metal ions such as Fe^{2+}, Ni^{2+} and Cu^{2+}, led to quenching of the fluorescence of both bands, as did the heavy metal ion Pb^{2+}. Thus, ligand L^1 offers a set of responses which render it encouraging for study as a potential sensory system for zinc, although a water-soluble analogue would be required in order to allow use in physiological studies.

We thank the University of Durham, EPSRC and the Royal Society for support.

Notes and references

‡ The effect of other metal ions was tested at concentrations equal to that required to bring about the maximum response for zinc(II). Cd^{2+} induced similar changes to that of Zn^{2+}, binding significantly more strongly.

First published as an Advance Article on the web

Bond covers based on substructures can be used to guide retrosynthetic analysis and give greater insight into the principle of convergence.

Topology is of growing interest in chemistry.[1] It has been proposed that molecular topology might have a significant effect on chemical synthesis;[2,3] thus, Corey and Cheng posited, 'The existence of alternative paths through a molecular skeleton as a consequence of the presence of cyclic subunits gives rise to a topological complexity which is proportional to the degree of internal connectivity.'[4] The concept of topological complexity has been generalized to include all the structural features that contribute to skeletal complexity, *e.g.* multiple bonds and branching in addition to rings.[5] Herein we address the problem of finding a measure of topological complexity by introducing an approach to chemical topology based on mathematical entities known as edge covers.[6–8] For chemical applications we call them bond covers.

A *substructure* of a molecule is a structure that has all its atoms and bonds in the molecule. For our applications the substructures are *connected*, meaning all pairs of atoms are the termini of at least one path. (The methane subgraph is trivially connected to itself by a path of length 0.[6]) We follow the precedent of Gordon and Kennedy,[9] who named substructures after the molecules they become when any incomplete valences are satisfied by hydrogen. For example, butane has four methane substructures, three ethane, two propane and one butane. (It follows from the above definition that a molecule is a substructure of itself.) We also adopt the common practice of representing molecules and substructures as hydrogen-suppressed structural formulas,[5] in which hydrogen atoms and the bonds to them are omitted.

We define a *bond cover* of a molecule as a set of substructures such that every bond in the molecule is in at least one of the substructures. In a *minimal bond cover* (or simply *minimal cover*) each substructure is essential, *i.e.* the removal of any substructure results in a set that no longer contains all the bonds in the molecule. A special case of minimal cover is a *partition*, in which each bond in the molecule is in exactly one of the substructures, so that no two substructures have a bond in common. The total number of covers K_T, minimal covers K_T^{min} and partitions P_T follow the order, $K_T > K_T^{min} > P_T$, except for ethane ($K_T = K_T^{min} = P_T = 1$) and propane ($K_T = 5$, $K_T^{min} = P_T = 2$). The corresponding numbers of kinds of covers are K_S, K_S^{min} and P_S, respectively.

These definitions are illustrated for cyclopropane **1** with the aid of Fig. 1. The minimal bond covers are 1{3 ethane}, 3{propane + ethane}, 3{2 propane} and 1{cyclopropane}, where the coefficient of a pair of braces gives the number of covers of that kind. (Henceforth, a 1 will not be shown explicitly.) Bond covers are the same kind when they contain the same substructures in equal numbers; they do not have to be isomorphic.[5–8] In this example $K_S^{min} = 4$ and $K_T^{min} = 8$. They are all partitions except 3{2 propane}, which have overlapping bonds; consequently, $P_S = 3$ and $P_T = 5$. An example of a bond cover of **1** that is not minimal is {cyclopropane + ethane}, since the ethane substructure can be removed and {cyclopropane} is also a cover. As far as all possible covers are concerned, $K_S = 28$ and $K_T = 109$ (*cf.* ESI†).

The values of K_T, K_T^{min} and P_T increase monotonically with the numbers of atoms, bonds, rings and branches, *e.g.* K_T^{min} (P_T) = 1 (1) for ethane, 2 (2) for propane, 5 (4) for butane, 13 (8) for pentane and 34 (16) for hexane, members of the homologous series of *n*-alkanes; 8 (5) for cyclopropane **1**, 30 (12) for cyclobutane **2**, 97 (27) for cyclopentane and 285 (58) for cyclohexane, members of a homologous series (cycloalkanes) which have an additional bond and ring compared to the corresponding *n*-alkanes; and 8 (5) for 2-methylpropane, 49 (15) for 2,2-dimethylpropane and 522 (52) for $K_{1,5}$ (the graph in which one point is joined to five other points, *i.e.* the hypothetical '2,2,2-trimethylpropane'), members of a homologous series (stars) where branching is greater than in the corresponding *n*-alkanes (except for methane, ethane and propane, which are *n*-alkanes and stars). Also, it can be shown that these indices increase with the introduction of multiple bonds; therefore, they are general indices of topological complexity. As a more sophisticated example, the [2]catenane of **1** has $K_T^{min} = 8 \times 8 = 64$ and $P_T = 5 \times 5 = 25$, compared to $K_T^{min} = 8 + 8 = 16$ and $P_T = 5 + 5 = 10$ for two isolated molecules of **1**. Minimal covers grow in number much less rapidly than covers, and partitions are particularly easy to enumerate.

Indices based on bond covers can be used to infer that topology has a significant role in synthesis, *e.g.* in the case of strategic bond disconnections. *Strategic bonds* are those that give a significant simplification when disconnected in the retrosynthetic (antithetic) direction.[4,10,11] When chosen on the basis of experience, they are *heuristic strategic bonds*, and when identified by using mathematical methods like the ones discussed here, they are *topological strategic bonds*. The question is, to what extent are they the same? According to Corey *et al.*,[10] 'the most desirable bond disconnections in the antithetic manipulation of structure are those in which the following structural features are minimized: (i) appendages, (ii) appendages carrying chiral centers, (iii) rings of medium or large size, and (iv) bridged rings.'

For any complexity index C, a change in complexity ΔC is calculated as the sum of index values for the products minus the sum for the starting materials, ΔC(reaction) = ΣC(products) − ΣC(starting materials). A negative value indicates overall simplification in a reaction or disconnection. Construction reactions are characterized by significant increases in complexity,[12] and their retrosynthetic transforms and disconnections by significant decreases. Several transforms can have the same

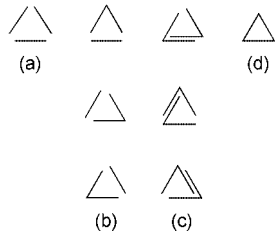

Fig. 1 Minimal bond covers of cyclopropane **1**: (a) {3 ethane}, (b) {propane + ethane}, (c) {2 propane}, and (d) {cyclopropane}.

† Electronic supplementary information (ESI) available: all possible covers for cyclopropane and 2-methylpropane. See http://www.rsc.org/suppdata/cc/b1/b107339g/.

 DOI: 10.1039/b107339g

disconnection, and the advantage of the latter is functional groups do not have to be included explicitly, unless they contain bonds that are made or broken. Thus, disconnections most clearly reveal topological changes. (We follow Corey *et al.*,[4,10] and differentiate 'transform' and 'disconnection'; some authors use them synonymously.)

Cyclobutane **2** (P_T = 12, K_T^{min} = 30) and methylcyclopropane **3** (P_T = 13, K_T^{min} = 39) are the results of the two possible 1-bond disconnections of bicyclobutane **4** (P_T = 43, K_T^{min}(**4**)). (*Cf.* Fig. 2.) For **4** ⇒ **2**, which breaks the fusion bond, ΔP_T(fusion) = ΔP_T(**4** ⇒ **2**) = P_T(**2**) − P_T(**4**) = −31, and for **4** ⇒ **3**, which breaks one of the four equivalent 'exendo'[4] bonds, ΔP_T(exendo) = ΔP_T(**4** ⇒ **3**) = P_T(**3**) − P_T(**4**) = −30. (Whereas $\Delta\Delta P_T$ = ΔP_T(**4** ⇒ **2**) − ΔP_T(**4** ⇒ **3**) = –1 is small, $\Delta\Delta K_T^{min}$ = [30 – K_T^{min}(**4**)] − [39 − K_T^{min}(**4**)] = −9 is substantial.) We conclude that the fusion bond is the topological strategic bond, as it gives the larger simplification. It was eliminated as the heuristic strategic bond in the general case, owing to the difficulty of forming the synthetic precursors when they are medium or large rings (*vide supra* iii, *cf.* rule 2A).[10]

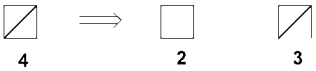

Fig. 2 The 1-bond retrosynthetic disconnections of bicyclobutane **4** to cyclobutane **2** and methylcyclopropane **3**.

The changes in the indices for the 1-bond and 2-bond disconnections of **3** are summarized in Table 1 (*cf.* Fig. 3). Since all the disconnections proceed from the same molecule, they are named according to the result, *e.g.* (a) stands for **3** ⇒ butane. Of the 1-bond disconnections (a)–(c), the one (a) that breaks the bond adjacent to the methyl substituent to afford butane gives the greatest simplification (ΔP_T = −9, ΔK_T^{min} = −34). Disconnection (b) to 2-methylpropane does not minimize appendages (*vide supra* i), and it gives less simplification (ΔP_T = −8, ΔK_T^{min} = −31).‡ The 2-bond disconnections (d) and (e) cannot be ranked by minimal covers, since the resulting systems have the same number of them (ΔP_T = −11, ΔK_T^{min} = −37); nevertheless, (d) and (e) are more efficient than the 1-bond disconnection (c) into two pieces (ΔP_T = −8, ΔK_T^{min} = −31).‡ The tie between (d) and (e) can be broken by considering the total number of covers K_T for the disconnected products. For propane they are {2 ethane}, {propane}, 2{propane + ethane} and {propane + 2 ethane}, and K_T = 5. For ethane K_T = 1, and for methane K_T = 0.§ Both disconnections have the same starting material **3**; thus, for (d) ΔK_T = 5 − K_T(**3**) and for (e) ΔK_T = 2 – K_T(**3**). Since K_T(**3**) > K_T^{min}(**3**) = 39, the latter is the negative number with the larger absolute value, indicating greater simplification ($\Delta\Delta K_T$ = −3). Therefore, the disconnection that results in two pieces of equal complexity is the most efficient. This is the topological basis for the heuristic of convergence.[11,12] Overall, the order of simplification is (e) > (d) > (a) > (b) > (c).¶

Table 1 Index values for the molecules of Fig. 3[a]

System	P_T	K_T^{min}	K_T
3 (methylcyclopropane)	13	39	K_T(**3**)
Butane (a)	4 (−9)	5 (−34)	46 (46 − K_T(**3**))
2-Methylpropane (b)	5 (−8)	8 (−31)	109 (109 − K_T(**3**))
1 + methane[b] (c)	5 (−8)	8 (−31)	109 (109 − K_T(**3**))
Propane + methane[b] (d)	2 (−11)	2 (−37)	5 (5 − K_T(**3**))
2 Ethane (e)	2 (−11)	2 (−37)	2 (2 − K_T(**3**))

[a] The values in parentheses are the changes in the indices for the disconnections (a)–(e) of **3** into the other systems. [b] For methane every index is 0.§

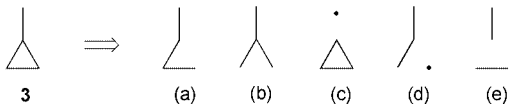

Fig. 3 The 1-bond (a)–(c) and 2-bond (d)–(e) retrosynthetic disconnections of methylcyclopropane **3**: (a) butane, (b) 2-methylpropane, (c) cyclopropane + methane, (d) propane + methane, and (e) 2 ethane.

For large molecules it is very difficult to determine all possible covers or even all possible minimal covers. Fortunately, there are subsets of all possible substructures that can be used to construct novel covers. For example, Bone and Villar[13] limited substructures to maximal ones (*cf.* induced subgraphs[6]), *i.e.* two atoms are bonded in a substructure whenever they are bonded in the structure. Another approach is to use substructures that are cliques or bicliques.[8] In a clique each atom is bonded to every other atom. In a biclique the atoms can be labeled with an asterisk or left unlabeled (*cf.* alternant hydrocarbons[5]) in such a way that each labeled atom is bonded to every unlabeled atom, and *vice versa*.

Bertz and Sommer proposed the number of kinds of subgraphs (substructures) of the molecular graph (structure) as a measure of diversity,[2] and Bone and Villar used the number of kinds of maximal substructures.[13] The number of kinds of covers or partitions might also be useful in this regard.

The author thanks C. Zamfirescu (CUNY) for assistance with checking the calculations, T. Sommer (Brandeis) for helpful discussions and W. F. Wright for valuable literature searches.

Notes and references

‡ When methane is ignored, disconnections (b) and (c) cannot be distinguished, since **1** and 2-methylpropane have the same number of bonds and the same symmetry (Supplementary Information). If methane is assigned K_T = 1,§ then (b) is more efficient.

§ Following Harary,[6] we generally do not include the trivial graph K_1 (methane) as a subgraph (substructure) in covers, hence K_T = 0 for methane. Some mathematicians include it,[7] in which case K_T = 1.

¶ Disconnection (d) represents two isomorphic disconnections, *i.e.* they have the same initial and final states. They can be differentiated by labeling the bonds that are broken in **3**. In the first, the bond joining the methyl and cyclopropyl groups is broken, along with the distal cyclopropane bond. In the second, the distal cyclopropane bond and one of the bonds adjacent to it are broken. The latter corresponds to the reaction of methylene and propene. (Disconnection (d) is drawn to suggest this reaction.) The former corresponds to the (theoretical) reaction of methane with allene, *e.g. via* cyclopropylidene.[14]

A novel core–shell gold colloid–silk fibroin (SF) bioconjugate was prepared by the protein *in situ* redox technique at room temperature, in which the tyrosine (Tyr) residue of the SF, having strong electron donating properties, *in situ* reduced Au(III) ions to Au colloids showing a stable and highly monodispersed nature.

Recently, the immobilization of proteins and enzymes on nanocolloidal substrates has received much attention in biotechnology, biochemistry and medicine. The general route to protein–metal colloid conjugates involves a simple solution-mixing process of proteins with metal colloidal sols formed prior to the mixing.[4] The thiol or amine functional groups in the protein bind with the metal nanoparticle surface, leading to the formation of the bioconjugate. However, due to the inhomogeneous dispersion between the protein and the metal colloid, the resulting conjugates always show large aggregated structures either in solution or in dried state, which is not a promising indication for the application of such bioconjugates. To the best of our knowledge, until now, no definite core–shell nanostructured metal colloid–protein bioconjugates have, as yet, been reported.

Here, we report, for the first time, the preparation of a novel core–shell nanostructured gold colloid–silk fibroin (SF) bioconjugate by the protein *in situ* redox technique at room temperature. The tyrosine residue (Tyr) component in the SF, having strong electron donating properties, *in situ* reduced Au(III) ions to Au colloids displaying a stable and highly monodispersed nature. The SF is secreted from the silk gland of the silkworm *Bombyx mori*. The SF possesses many special properties that are desirable for food, cosmetics, medical and biological materials, which attracts the wide interest of scientists in many disciplines including biology, polymer materials, iatrology, the chemical industry *etc*., and has led to a recent upsurge in researching SF.[5] With the incorporation of colloidal gold nanoparticles, the present SF will be expected to exhibit new bioactivity and applications in biotechnology.

In a typical preparation of the core–shell nanostructured gold colloid–SF bioconjugate by the protein *in situ* redox technique, 5 ml of an SF aqueous solution (10 mg ml^{-1}) (ESI†) was added dropwise to 5 ml of an aqueous solution of $HAuCl_4$ (2 mmol l^{-1}). The pH of the mixture solution was adjusted to 9–10 with KOH to prevent cross-linked aggregation of the SF [the isoelectric point (pI) of the SF is *ca*. 4.58–5.00].[5] The solution was stirred for 6 h at room temperature and the reaction mixture changed gradually from yellow to purple with stirring, indicating the formation of the gold colloid *via* oxidation of the SF. The resulting aqueous solution of the Au colloid–SF bioconjugate was stable with no precipitation being observed for more than three months at room temperature under air. A similar SF aqueous solution in the absence of $AuCl_4^-$ was allowed to stand at room temperature under air and flocculent precipitates appeared in the solution after a week. This result indicates that the presence of a large number of *in situ* produced Au colloids rendered high stability of the protein against aggregation.

Fig. 1 shows a typical transmission electron microscopy (TEM) image of the core–shell nanostructured Au colloid–SF bioconjugate produced by the present protein *in situ* redox technique at room temperature. It is evident that the gold nanoparticles are evenly coated with the SF to form core–shell nanostructrured bioconjugates. The spherical core–shell Au–SF nanostructures of 45 nm average size were essentially monodispersed. No large aggregation structure of the protein was observed in the present Au colloid–SF bioconjugate. The nanostructured bioconjugate particles were in contact with each other, a consequence of the solvent evaporation process required for TEM analysis, and not due to performed aggregation in solution. The gold nanoparticle cores of 15 nm average size with a narrow size distribution are well separated from each other *via* the coating of the SF. The thickness of the SF was *ca*.

15 nm. The oxidized SF stabilized the gold nanoparticles and prevented the close approach of the particles *via* both steric and electrostatic stabilization mechanisms.[6] Mulvaney and coworkers have also reported similar interesting core–shell nanostructures of silica-coated gold particles.[7]

It has been reported that three conformations occur for silk fibroin: random coil, α-helix form (silk fibroin I) and β-sheet form (silk fibrion II).[5] The α-helix form is a crankshaft pleated structure while the β-sheet form is an antiparallel pleated sheet structure. Previous atomic force microscopy (AFM) measurements revealed that a single SF molecule is rod shaped with length 60 nm, width 15 nm and height 0.3 nm with long smaller chains extending from the ends.[8] The rod shape can be ascribed to the α-helix form of the SF. The SF molecule with a random-coil conformation has a hydrodynamic radius of *ca.* 20 nm.[9] Many factors can induce the transformation of the SF conformation. Bhat *et al.*[10*a*] and Tsukada *et al.*[10*b*] investigated the conformation transition induced by solvents and other treatments *via* infrared (IR) spectroscopy and X-ray diffractometry. Yu and Li studied the conformation change of a single silk fiber in different parts of silkgland under stress and provided a relevant model.[11] They found that under stretching, the α-helix form can be completely destroyed and partially turned into a random coil conformation. In the present reaction system, the TEM image demonstrates that the SF employed displayed a rod shape, which may be associated with the α-helix fibroin conformation. During the formation of the core–shell Au–SF nanostructured bioconjugate, the oxidation of the SF may promote the transformation of the SF conformation from the α-helix form to the random-coil form. The random-coil form is expected to facilitate the attachment of the SF molecular chain onto the gold nanoparticle to form the core–shell nanostructure. Based on the thickness of the SF of *ca.* 15 nm, it is deduced that one shell may be constructed by one SF molecular chain; this requires clarification by AFM measurements.

The SF is composed of 18 types of amino acid residues, which arrange in a specific sequence in the SF molecular chain.[5] The total content of glycine (Gly, 44.60 mol%), alanine (Ala, 29.40 mol%), serine (Ser, 12.10 mol%) and tyrosine (Tyr, 5.17 mol%) comprised more than 90 mol% of the whole composition of the SF (ESI†).[12] In the preparation of the present core–shell nanostructured Au colloid–SF bioconjugate at room temperature, according to the molecular structures and contents of various amino residues in the SF, the most probable amino acid residue which contributed to the reduction of $AuCl_4^-$ is believed to be the Tyr residue. It is well known that the cresol component of the Tyr residue is very easily oxidized into the quinone in air, displaying strong electron donating properties. In addition, in the present solution of pH 9–10, the cresol components may be transformed partially to phenoxide anions, increasing the electron density in the π–π* transition of the Tyr residues, favorable for electron transfer from Tyr to Au(III). Although the Ser residue contains a methanol group, widely used as a reducing agent for the preparation of metal nanoparticles, this reduction process proceeds only at elevated temperatures. To confirm our assumption, two model compounds, *p*-cresol and methanol, were added to two similar $AuCl_4^-$ solutions in the absence of the SF. The results show that the *p*-cresol can reduce $AuCl_4^-$ ions into gold nanoparticles very quickly within 30 s at room temperature while methanol did not. As a result, it can be concluded that the Tyr residue in the SF molecular chain was responsible for the reduction of the $AuCl_4^-$ in the preparation of the present core–shell nanostructured Au colloid–SF bioconjugate.

For further corroboration of the role of the Tyr residue in reduction of Au(III), UV–VIS absorption spectra (ESI†) were measured. The UV–VIS absorption spectra of an aqueous solution of pure SF displayed a strong absorption band at *ca.* 276 nm, assigned mainly to the π–π* transition of the Tyr residue in the SF molecular chain.[13] This band strongly red shifted to 288 nm with the reduction of the $AuCl_4^-$ and formation of the core–shell nanostructured Au colloid–SF bioconjugate. Further results demonstrate that the partial conversion of the cresol components of the Tyr to phenoxide anions at pH 9–10 did not induce the red shift. Therefore, the most probable reason for the red shift would be electron transfer from the residue to the Au(III) ions. A similar red shift, from 258 to 269 nm, was also observed in the UV–VIS absorption spectra of *p*-cresol (as a model compound) before and after the reduction of Au(III) ions. The strong absorption band at 521 nm in the core–shell nanostructred Au colloid–SF bioconjugate can be assigned to the surface plasmon resonance of the produced gold colloid. The absorption band maximum of the present Au colloid in the bioconjugate is well consistent with results for Au sols of 3–20 nm in size.[14] It has been demonstrated that adsorbate-induced aggregation of metal colloids leads to increased absorption at longer wavelengths and broadening of the primary absorption band, and often to the appearance of a secondary absorption peak that is red-shifted relative to the primary absorption band.[15] In the present study, no absorption at longer wavelength was observed, and the absorption band was symmetrical. The absorption spectrum of the Au colloid–SF bioconjugate did not change in shape, absorption maximum or intensity even after three months, indicative of the high stability of the gold nanoparticle in the bioconjugate.

In summary, a novel core–shell nanostructured gold colloid–silk fibroin (SF) bioconjugate has been prepared by the protein *in situ* redox technique at room temperature. The tyrosine (Tyr) residue in the SF *in situ* reduced $AuCl_4^-$ to Au colloids showing a stable and highly monodispersed nature. Simultaneously, the oxidized SF molecular chain attached to the surface of the Au nanoparticle forms the core–shell nanostructured bioconjugate. The present protein *in situ* redox technique may be extended to prepare other core–shell nanostructured metal colloid–SF bioconjugates.

We thank Professor T. Fukuda and Dr M. Tsujii (Kyoto University) for the TEM measurements.

Lanthanide ions and complexes occupy a special position in developing synthetic nucleases capable of catalyzing the hydrolytic cleavage of RNA or DNA. Stimulated by a number of serendipitous lanthanide complexes that feature the common active-site structure of dinuclear metallo-phosphodiesterases, rational design and synthesis of polynuclear lanthanide–hydroxo species *via* ligand-controlled hydrolysis of the lanthanide ions were attempted. The efforts yielded a series of highly sophisticated yet structurally well-defined lanthanide–hydroxo complexes. These materials are potentially applicable to the study of biomimetic catalysis of phosphate diester cleavage. Research highlights are described in this Feature Article.

Introduction

Polynuclear metal complexes exhibit a fascinating variety of unusual symmetries and structural patterns.[1] The biological relevance of some of these compounds and their potentially important applications as advanced materials add to their interest and significance.[2,3] Ligand-controlled hydrolysis is a time-honored approach to these unique chemical entities.[4] In this method, auxiliary ligands occupy part of the metal coordination sphere, thereby reducing the number of sites available for water coordination and preventing extensive hydrolysis from occurring. As a result, finite-size polynuclear complexes rather than intractable metal hydroxides and/or oxides can be crystallized and structurally characterized. Several classes of ligands have been utilized in this capacity, among which carboxylates, polyketonates, polyamines, polyols, pyridonate and alkoxides are prominent.[5–10] Spectacular examples in transition metal chemistry, such as molecular cages and wheels, have been reported.[11,12] These novel complexes exhibit rather interesting magnetic properties owing to the presence of a large number of unpaired electrons.[3–12]

Despite the impressive progress in the preparation of polynuclear complexes of the d-block elements, the number of large, polynuclear lanthanide complexes is still rather limited.[13,14] Lanthanide elements, bearing special electronic and spectroscopic properties mainly associated with their 4f electronic configurations, represent a unique series of metals in the Periodic Table. The position of mononuclear lanthanide complexes in a number of important areas has been firmly established,[15] but polynuclear lanthanide complexes are expected to find such niche applications as precursors in sol–gel technology,[16] new radiographic agents,[17] and metalloenzyme mimics.[18] Great prospects notwithstanding, the high expectations have been compromised by our current limited synthetic ability; the formation of polynuclear lanthanide complexes cannot yet be controlled and is frequently characterized by random self-organization.[13,14,19]

The story begins

Our efforts to create structurally well-defined polynuclear lanthanide complexes were stimulated by the potential to develop synthetic nucleases that are capable of hydrolyzing RNA or DNA through the cleavage of the phosphate diester bonds.[20] X-Ray analysis of many phosphodiesterases indicates that these important metalloenzymes possess two or three divalent metal ions, such as Zn^{II}, in the active site.[20] It is generally agreed that the catalysis occurs *via* substrate activation by the electropositive metal ions, followed by nucleophilic attack by the activated hydroxo ligands (Fig. 1). Numerous

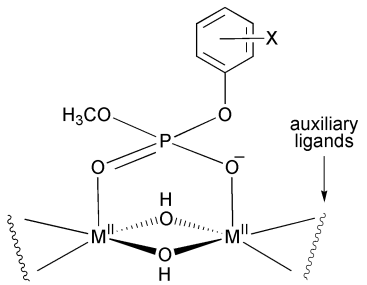

Fig. 1 A possible activation mechanism of a phosphate diester substrate by the dinuclear active site of a metallo-phosphodiesterase.

synthetic models have appeared in the literature in mimicking the dinuclear structural motif, most of which utilize transition metal ions, most notably Zn^{II}, Cu^{II} and Co^{III}, to activate the substrate.[21] Trivalent lanthanide ions (Ln^{III}) are expected to be more effective in this capacity due to their strong Lewis acidity and the kinetic lability of their complexes. Elegant studies in this vein have been carried out by Chin, Schneider, Martell and others.[18] However, the ease of lanthanide ion hydrolysis and the propensity for lanthanide–hydroxo species to form polynuclear aggregates in solution render unambiguous identification of the catalytically active species extremely difficult, if at all possible. There exist, nevertheless, a number of structurally characterized dinuclear[22] and tetranuclear[23] lanthanide–hydroxo complexes

Zhiping Zheng received his B.S. (1987) and M.S. (1990) in Chemistry from Peking University, Beijing, China. He obtained his Ph.D. from UCLA (1995) with Professor M. Frederick Hawthorne. After conducting postdoctoral research with Professor Richard H. Holm at Harvard University, he joined the faculty of The University of Arizona in 1997. His current research is focused on supramolecular inorganic chemistry and its materials applications, which involves the elaboration of polynuclear lanthanide complexes, transition metal clusters, dendrimers, and nanocrystallites.

DOI: 10.1039/b107971a

whose core components (Fig. 2) feature the desired diamond-shaped dinuclear lanthanide–hydroxo motif. However, these species were either synthetic serendipity or accidents, and general synthetic guidelines are lacking, and not surprisingly, there were no studies of their catalytic potentials.

Toward the ultimate goal of achieving non-enzymatic hydrolysis of phosphate diesters using *structurally well-defined* lanthanide catalysts, we have recently embarked on a design and synthesis tour of lanthanide–hydroxo complexes whose core structure resembles that of the active site of phosphodiesterases. We were particularly interested in the tetranuclear species whose constituent lanthanide ions and triply bridging hydroxo groups occupy the alternate vertices of a distorted cube. Structurally, it may be viewed as the dimeric form of the dinuclear species. More importantly, a complex featuring this core may be catalytically more potent on per molecule basis due to the extra Lewis acidic metal ions. The three seemingly unrelated literature precedents[23] further stimulated our interest. That distinctly different routes yielded the common structural motif led to our suspicion that the cubane-like core may actually be a standard feature of this type of chemistry, analogous to its extensively studied d-block counterparts.[24]

The presence of the hydroxo ligands suggests that these tetranuclear clusters may be synthesized *via* hydrolytic reactions of the lanthanide ions. However, hydrolysis of the lanthanide ions is commonly perceived as rather limited and unpredictable with intractable precipitates of lanthanide hydroxides and/or oxohydroxides as the end products.[25] Probably due to this very concern of extensive and uncontrollable hydrolysis, aqueous lanthanide coordination with organic ligands have been carried out almost exclusively under acidic conditions, typically below pH 5.[26] However, in light of the increasing number of unexpected and structurally characterized polynuclear lanthanide–oxo/hydroxo species,[13,14*a*,19,22,23] we deemed a systematic investigation of the hydrolytic reactions of these unique metal ions to be not only worthwhile, but also important.

Providing further inspiration for this endeavor is the great success of creating polynuclear transition metal complexes using the hydrolytic approach.[4] In such an approach, certain types of supporting ligands are necessary to control the hydrolysis in order to avoid the possible formation of intractable products. It is the subtle balance between the hydrolysis of a transition metal ion and its coordination with a chelating ligand that affords the novel high-nuclearity complexes. *We submit that an analogous ligand-controlled hydrolytic approach should be applicable to the lanthanide ions, provided that suitable supporting ligands are identified.* Our efforts have been concentrated on utilizing α-amino acids as auxiliary ligands to control the hydrolysis.[27] This exploratory synthesis has produced a number of spectacular and unprecedented polynuclear lanthanide–hydroxo complexes which may find important applications in biotechnology and chemotherapy. Research highlights are summarized in this Feature Article.

The story of α-amino acids – self-assembly of complexes featuring the $[Ln_4(\mu_3\text{-}OH)_4]$ core

The specific choice of α-amino acids as hydrolysis-limiting auxiliary ligands is mainly based on their biological relevance. It is reasonable to hypothesize that the metal coordination environment of the native enzyme can be better modeled by using such biological building blocks. In addition, lanthanide coordination with α-amino acids has been extensively investigated.[28] These studies have been conducted almost exclusively under low-pH (below 5) conditions. Typically, only the carboxylate group coordinates the lanthanide ion, as shown by more than 50 crystal structures of such complexes.[28*a*] The great variety of α-amino acids due to the presence of different side-group(s), some of which being potentially lanthanide-coordinating, is especially beneficial for systematic studies of lanthanide complexation with this unique class of ligands.

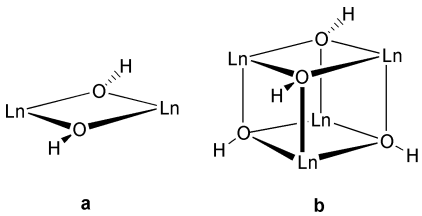

Fig. 2 Core components of crystallographically characterized dinuclear (a) and tetranuclear (b) lanthanide–hydroxo species.

The validity of this ligand-controlled hydrolytic approach was tested in a series of proof-of-concept syntheses, using a variety of α-amino acids, including glycine, alanine, valine, phenylalanine, tyrosine, proline, glutamic acid and aspartic acid as the supporting ligands.[29–34] The zwitterionic structures of these amino acids are shown in Fig. 3.

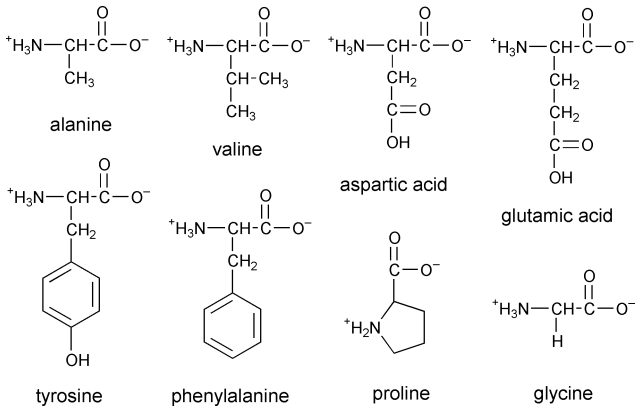

Fig. 3 Zwitterionic structures of the α-amino acids discussed in this article.

In a representative synthesis, a lanthanide chloride or perchlorate is mixed with an α-amino acid in aqueous solution. The mixture is subjected to hydrolysis with dilute NaOH. The end point of the reaction is indicated by the formation of an incipient but permanent precipitate, presumably of lanthanide hydroxide and/or oxohydroxide. Although the addition of base is seemingly arbitrary, lanthanide–amino acid (other than tyrosine) complexes composed of a cubane-like $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ core have invariably been obtained as crystalline solids upon slow concentration of the supernatant at room temperature. The ORTEP drawing of the cationic complex[35] formed by $Yb(ClO_4)_3$ and phenylalanine (Phe), representative of all the single-cubane complexes, is depicted in Fig. 4.†

The cluster core is 'camouflaged' by six phenylalanine ligands through bridging carboxylate groups, and the metal coordination sphere is completed by aqua ligands. The amino groups remain protonated, presumably affecting lanthanide complexation *via* electrostatic and steric effects. Because the amino groups do not participate in direct coordination with the lanthanide ion, the interaction of an α-amino acid with a lanthanide ion is structurally reminiscent of that of a carboxylic acid.[36] However, with carboxylic acids as supporting ligands, lanthanide acetates are typically obtained. These well-studied lanthanide materials exist in polymeric forms in the solid state, often featuring carboxylate-bridged dinuclear lanthanide units as the fundamental building blocks.[36] It is thus of interest to note that finite-size cluster-type polynuclear lanthanide–hydroxo complexes are generally isolated with the use of N-containing supporting ligands,[37] including α-amino acids. It is reasonable to assume that the higher water-solubility of lanthanide complexes with such ligands is due to possible hydrogen bonding interactions involving the N atom(s). In the case of α-amino acids, the zwitterionic character of these unique ligands

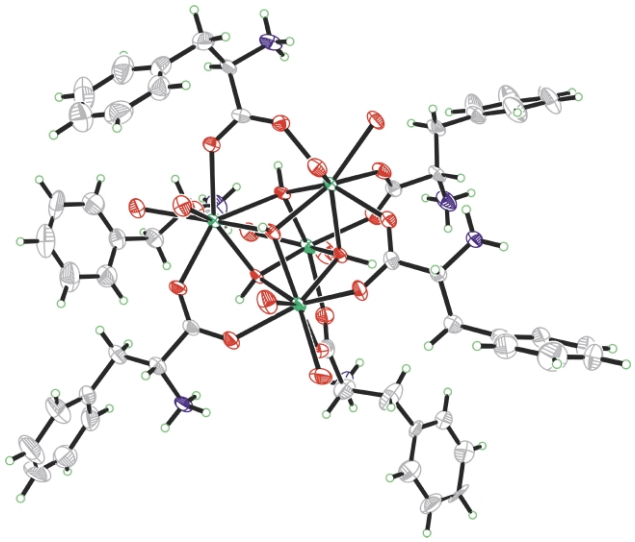

Fig. 4 An ORTEP representation of the cationic complex $[Yb_4(\mu_3\text{-}OH)_4(Phe)_6(H_2O)_7]^{8+}$. The cubane-like tetranuclear Yb^{III}-hydroxo core is apparent.†

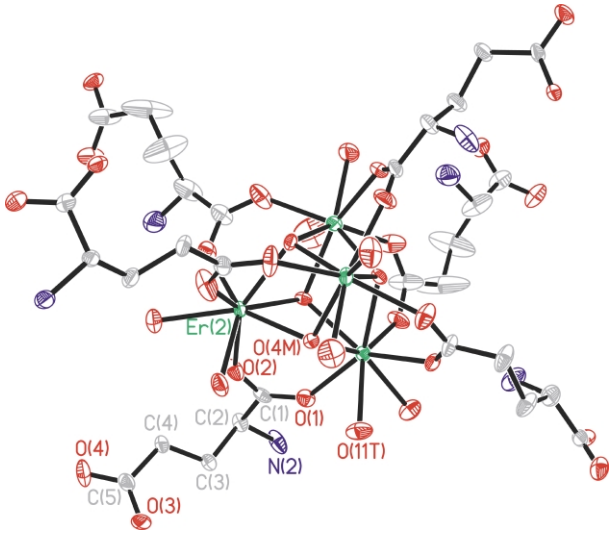

Fig. 5 An ORTEP drawing of the elementary building unit of $[Er_4(\mu_3\text{-}OH)_4(Glu)_3(H_2O)_8]^{5+}$. Three symmetry-related glutamic acid "arms" are included to complete the coordination of the cuboid $[Er_4(\mu_3\text{-}OH)_4]^{8+}$core.

is expected to further contribute to the better water solubility of their complexes. As a result, a lanthanide complex with such ligands remains soluble in solution instead of precipitating out as less soluble coordination polymers. Addition of base to such a solution is expected to deprotonate the aqua ligands. Condensation of the lanthanide–hydroxo species thus generated eventually leads to the formation of the cluster-type lanthanide–hydroxo complexes.

The story of the networking glutamic acid

Having established that the cuboid $[Ln_4(\mu_3\text{–}OH)_4]^{8+}$ cluster is a common structural motif in lanthanide complexes, we entertained the idea of using this motif as a secondary building unit[38] for the creation of supramolecular assemblies with porosity. The practice of constructing such open framework structures is stimulated by the hope that these porous materials will display a range of molecular sieve, ion exchange and catalytic properties that are comparable to (or perhaps more extensive than) those observed in zeolites. As compared with the large amount of work concerning the construction of coordination networks of d-block metal ions with polydentate ligands, crystal engineering involving lanthanide ions remains relatively unexplored at the present time,[39] and the use of lanthanide clusters as building blocks is unknown. Nevertheless, by employing appropriate supporting ligands, it may be possible to assemble the $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ cluster units into zeolite-like polymeric forms, whereby the high coordination requirement and Lewis acidity of the lanthanide ions may be of important use for both laboratory research and industrial processes.

In this effort, an α-amino acid with more than one carboxylate group is necessary in order to support the hydrolytic formation of the $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ cluster and to bridge individual cluster units. A three-dimensional (3-D) network may be anticipated from such extended interactions between the carboxylate ligands and the lanthanide–hydroxo cluster core. As expected, by treating a mixture of $Er(ClO_4)_3$ and L-glutamic acid with aqueous NaOH to the point of incipient precipitation, a 3-D porous network comprised of discrete $[Er_4(\mu_3\text{-}OH)_4]^{8+}$ units and cluster-linking glutamate ligands, $[Er_4(\mu_3\text{-}OH)_4(Glu)_3(H_2O)_8][ClO_4]_5$ (Glu = glutamate), was obtained.[30] The structure of the complex was determined by single-crystal X-ray diffraction, and the elementary constituent of the open framework is depicted in Fig. 5. The cubane-like $[Er_4(\mu_3\text{-}OH)_4]^{8+}$ building block is apparent, resembling its previously reported analogues. The six carboxylate groups ligating a particular cube are of two different types, one being α and the other (of the side chain) being γ to the amino moiety; each glutamate ligand contributes one carboxylate group for the coordination of one $[Er_4(\mu_3\text{-}OH)_4]^{8+}$ cluster while using the remaining one to coordinate an adjacent lanthanide cluster cube. The 3-D open framework exhibits nearly parallelogram-shaped pore apertures with approximate dimensions of 4.4 × 9.1 Å for channels in the *c* direction (Fig. 6). Although the network structure is the result

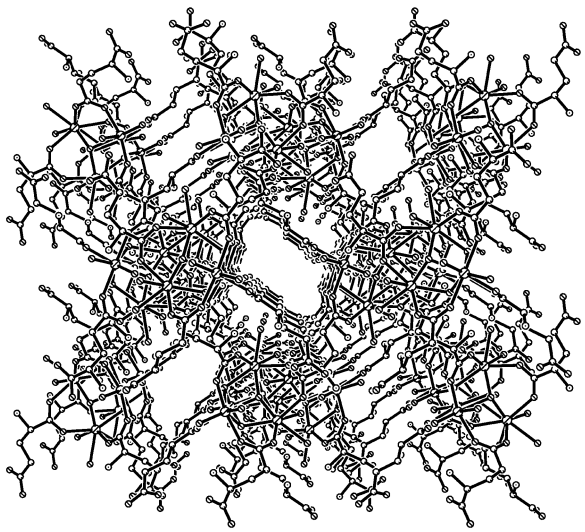

Fig. 6 3-D porous framework structure of $[Er_4(\mu_3\text{-}OH)_4(Glu)_3(H_2O)_8]^{5+}$, shown along the *c* axis. The channel dimensions are approximately 4.4 × 9.1 Å.

of self-assembly, the $[Er_4(\mu_3\text{-}OH)_4]^{8+}$ core may be *formally* considered as a *prefabricated* and *transferable* building block for the assembly of the extended structure. An analogous extended channel structure has also been obtained by the hydrolytic reaction of $Dy(ClO_4)_3$ using L-aspartic acid as supporting ligand,[34] which further supports our synthetic design in using the cubane-like units as building blocks for the extended solid state materials.

The unique story of tyrosine – anion-templated self-assembly of multi-cubane complexes

Using lanthanide perchlorates, analogous hydrolytic reactions with tyrosine as the supporting ligand were carried out in an effort to evaluate the possible effect(s) of the side-group of an α-amino acid has on the metal coordination.[29,32] To our great surprise, complexes featuring a single lanthanide–hydroxo

cluster core were not obtained. Instead, the reactions produced a series of pentadecanuclear lanthanide–hydroxo complexes.

As a representative of these pentadecanuclear complexes, the sophisticated structure of an Eu^{III} complex is described in detail below. As shown in Fig. 7, the complex, containing 15 Eu^{III} ions

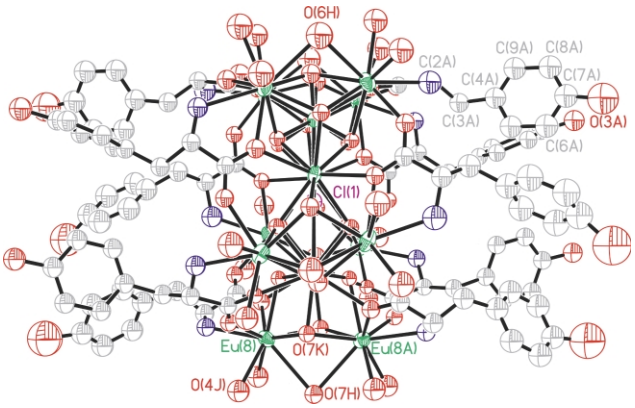

Fig. 7 A perspective view of the pentadecanuclear Eu^{III}–hydroxo complex with tyrosinato ligands. The cationic complex is formulated as $[Eu_{15}(\mu_3\text{-}OH)_{20}(\mu_5\text{-}Cl)(\mu_3\text{-}Tyr)_{10}(OH)_2(\mu\text{-}H_2O)_5(H_2O)_{18}]^{12+}$ (Tyr = tyrosinato ligand). Color legend: chlorine (purple).

and 10 tyrosinato ligands in addition to the hydroxo and aqua ligands associated with the hydrolysis, crystallizes as discrete barrel-shaped molecular units with space between these barrels filled with solvent water. The core component of the complex, formulated as $[Eu_{15}(\mu_3\text{-}OH)_{20}(\mu_5\text{-}Cl)]^{24+}$, consists of five vertex-sharing $[Eu_4(\mu_3\text{-}OH)_4]^{8+}$ cubane units centered on a μ_5-Cl^- 'axle' (Fig. 8). The metal ions are assembled into a layered

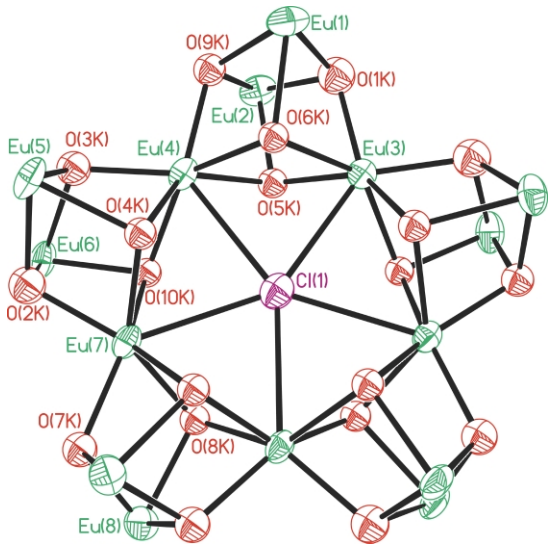

Fig. 8 An ORTEP drawing of the wheel-like core structure showing five vertex-sharing cuboid $[Eu_4(\mu_3\text{-}OH)_4]^{8+}$ units centered on a μ_5-Cl^- ion.

arrangement; each of the three parallel layers contains five Eu^{III} ions that occupy the vertices of a nearly perfect pentagon. The average Eu–Eu separation within the two outer layers is 6.331 Å, while that in the middle layer is 3.896 Å. The average Eu–Cl distance of 3.314 Å is significantly longer than the sum of the van der Waals radii of Cl^- (1.81 Å)[40] and Eu^{III} (0.95 Å),[40b] reflecting the primarily ionic interactions between the halide and the lanthanide ions. The coordination sphere of the Eu^{III} ion is completed by hydroxo and aqua ligands. Thus, each of the 10 Eu^{III} ions in the outer layers has a coordination number (CN) of nine, and the coordination polyhedra can be best described as monocapped square antiprismatic, while the inner-layer Eu^{III} centers also have a CN of nine, forming irregular square antiprisms monocapped by the central chloride ion.

The tyrosinato ligands can be divided into two equivalent groups, each of which extends their 4-hydroxybenzyl side-chains in the direction perpendicular to the crystallographically imposed C_2 axis. The side-chains do not participate in the coordination. The coordination mode of the tyrosinato ligand with Eu^{III} is significant: each acts as a tridentate ligand by utilizing both its amino and carboxylate groups. The ligand can be described as a $\mu_3:\eta^1:\eta^2:\eta^1$ anion (Fig. 9), not only linking

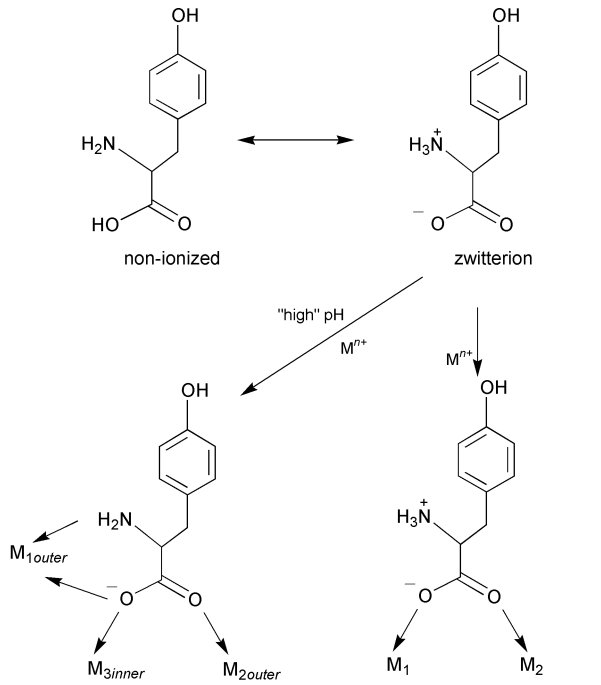

Fig. 9 Comparison of the lanthanide-coordination modes of tyrosine-based ligands under different pH conditions.

two neighboring Eu^{III} within the same (outer) layer, but also coordinating a third Eu^{III} ion in the middle layer through one of the carboxylate oxygen atoms. Such a mode has not been observed prior to our work.

The formation of the pentadecanuclear complex was unexpected, as only complexes containing discrete cubane unit(s) were obtained with other supporting α-amino acids,[30,33–35] including the closely related phenylalanine.[35] It is not yet understood why tyrosine is so unique in this capacity, but work is in progress to elucidate the possible causes. The incorporation of a μ_5-Cl^- ion was even more surprising because no Cl^- was utilized in the original synthesis which involved only $Ln(ClO_4)_3$, tyrosine and NaOH. A possible source of the mystifying Cl^- was an impurity present in the perchloric acid used for the digestion of lanthanide oxides. Template effects exerted by Cl^-, presumably in minute amount in the original synthesis, were thus suspected, and subsequently corroborated by the improved synthesis, in both product yield and purity, with the presence of added Cl^-. Thus, *the formation of the pentadecanuclear complex may be best understood as chloride-templated self-assembly of the lanthanide ions with the assistance of tyrosinato ligands.*

Stimulated by these findings, the potential roles of other anionic species in promoting the assembly of similar or distinct complexes were explored.[32] It has since been found that the composition of the resulting complex is profoundly affected by the anionic species present in the reaction mixture, but is independent of the lanthanide ions. For example, analogous pentadecanuclear complexes featuring a μ_5-Br^- were obtained when Br^- was involved. Except for the substitution of Br^- (van der Waals radius, 1.96 Å)[40] for Cl^-, the cationic complexes are isostructural to their Cl^--containing cognates. The Br^- simultaneously coordinates the five inner-layer Ln^{III} ions in a perfectly planar and previously unknown fashion (Fig. 10). The Ln–Br distances are also significantly longer than the corresponding sum of the van der Waals radii.

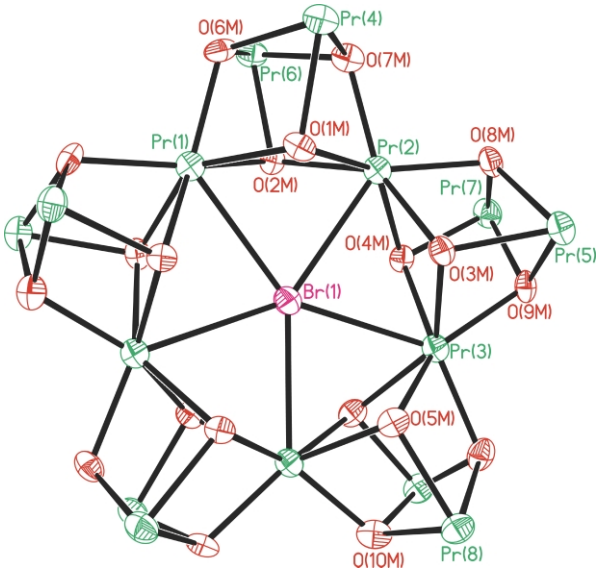

Fig. 10 An ORTEP drawing of the wheel-like core structure of the pentadecanuclear Pr^{III}–hydroxo complex showing five vertex-sharing $[Pr_4(\mu_3\text{-}OH)_4]^{8+}$ units centered on a μ_5-Br^- ion. Color legend: bromine (purple).

When I^- was employed, however, dodecanuclear complexes were isolated; the surprising product featured a cyclic core composed of four vertex-sharing $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ cubanes and two I^- guests (Fig. 11). In contrast to the single Cl^- or Br^- that

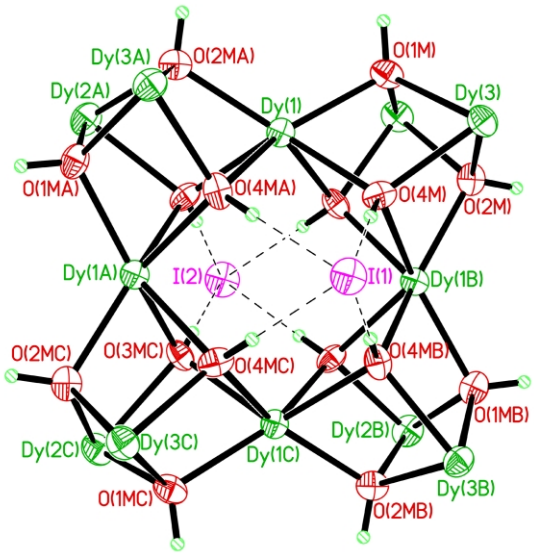

Fig. 11 An ORTEP representation of the core component of the dodecanuclear Dy^{III}–hydroxo complex showing four vertex-sharing $[Dy_4(\mu_3\text{-}OH)_4]^{8+}$ units in a square-shaped arrangement. Two I^- ions are found in the complex, one on each side of the square and interacting with the μ_3-OH groups in a μ_4-I^- fashion. Color legend: iodine (purple).

was situated in the center of the five-cubane wheel, the I^- ions were located on both sides of wheel plane formed by the lanthanide ions. The distances between the iodide ion and the hydrogen atoms of the μ_3-OH groups are almost the same as the corresponding sum of the van der Waals radii, indicating a very compact core structure and likely a hitherto unknown supramolecular motif. Eight tyrosinato ligands cap the wheel structure, four on each side (Fig. 12). The coordination mode of the tyrosinato ligands is identical to that in the Cl^- and Br^--containing complexes. Although the formation of a smaller cubane-wheel is counterintuitive, this observation may be understood in terms of the energetically insurmountable constraints between adjacent cubane units if a larger wheel were formed.

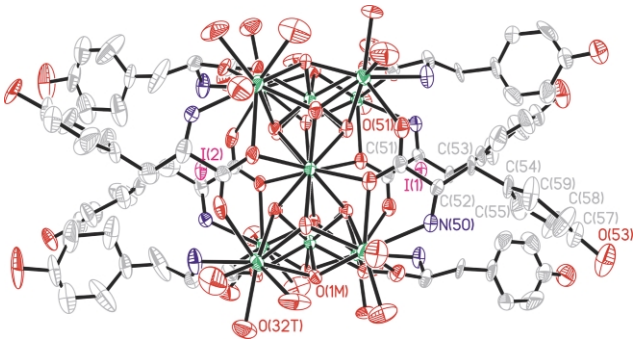

Fig. 12 A perspective view of the cationic dodecanuclear Dy^{III}–hydroxo complex, $[Dy_{12}(\mu_3\text{-}OH)_{16}(I)_2(\mu_3\text{-}Tyr)_8(H_2O)_{20}]^{10+}$.

The identity of the multi-cubane complex is clearly dependent on the nature of the halide ion utilized. However, the templating roles of these spherical anions in establishing the wheel-like complexes remain to be confirmed because the key criterion of a legitimate template is the influence of both of its size and shape on the product distribution.[41] Specifically, can one expect a different product with the presence of a non-spherical anion? Further, what outcome may one anticipate when two different types of anions coexist in the reaction mixture? To answer these questions, a reaction with the trigonal planar NO_3^- (1.79 Å),[40] which is of similar size to Cl^-, was executed.[32,42] The analogous hydrolytic reaction using $Er(NO_3)_3$ and tyrosine produced a known and structurally characterized, tyrosine-free cationic complex $[Er_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8(NO_3)_6(H_2O)_{12}]^{2+}$ (Fig. 13) which was obtained pre-

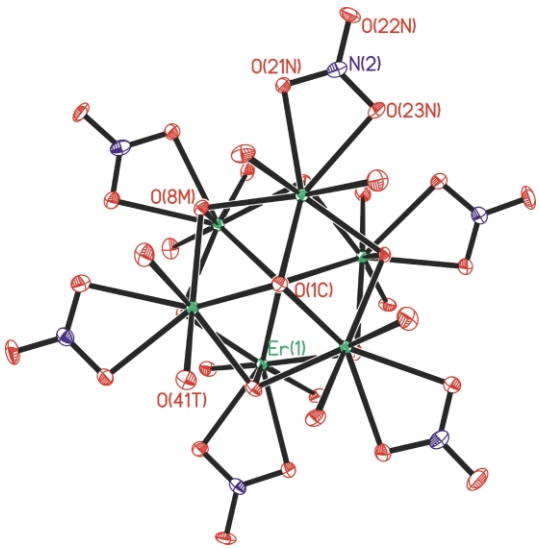

Fig. 13 An ORTEP representation of the cationic complex $[Er_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8(NO_3)_6(H_2O)_{12}]^{2+}$.

viously by the thermal decomposition of hydrated $Er(NO_3)_3$ followed by hydrolysis of the decomposition products.[43] The core component of this compound is a face-capped octahedral $[Er_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8]^{8+}$ unit with an interstitial μ_6-oxo group. Its assembly is presumably templated by the μ_6-oxo group whose origin is unclear, but is probably from hydroxide or water. These results clearly indicate the general importance of spherical anionic species in governing the formation of polynuclear lanthanide complexes.[13,14a]

The most convincing evidence supporting the halide template effects was provided by the tyrosine-limited hydrolytic reaction of $Gd(NO_3)_3$ in the presence of competitive Cl^-: Structural determination by X-ray crystallography established that the pentadecanuclear Cl^--containing complex was the sole product with non-coordinating NO_3^- as counter ions. This finding, coupled with the inability to produce a multi-cubane complex in the absence of a halide ion suggests that the halide ion must be

a stabilizing factor along the reaction coordinate to the 'wheel'-structured complexes, and hence, a kinetic template.[41]

It has long been recognized in the chemistry of lanthanide alkoxides that the presence of a 'central spherical negative charge density' accounts for the driving force for product formation.[13] However, the exact roles played by these anionic species have not yet been investigated. We have discovered several lines of evidence that point convergently to the superior ability of halide ions in templating the formation of unprecedented lanthanide–hydroxo complexes. Our work thus provides a stimulating demonstration of the under-appreciated templating roles of anions in self-assembly processes,[44] and should aid in future work in assembling novel lanthanide complexes by utilizing templating anions of different *size* and *geometry*.

Controlled or not? Direct hydrolysis of lanthanide nitrates and perchlorates

The isolation of polynuclear complexes containing the cubane-like $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ unit firmly establishes the critical importance of the organic ligands in controlling the hydrolysis of the lanthanide ions. However, the isolation of the tyrosine-free complex, $[Er_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8(NO_3)_6(H_2O)_{12}](NO_3)_2$, from a hydrolytic reaction involving $Er(NO_3)_3$, tyrosine and NaOH was unexpected and intriguing. Admittedly, this and related hexanuclear complexes[43,45] are structurally drastically different from the cubane-like tetranuclear species. But are tyrosine or any organic ligands really necessary in controlling the hydrolysis of the lanthanide ions? Is the equivalent polyoxometalate chemistry[46] of the lanthanide ions a reasonable conceptual stretch? If so, how extensive is this chemistry?

The answers to these interesting questions were provided by the isolation of the same hexanuclear complex from the direct hydrolysis of $Er(NO_3)_3$ [eqn. (1)]:[42]

$$Er(NO_3)_3 + NaOH(aq) \rightarrow [Er_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8(NO_3)_6(H_2O)_{12}](NO_3)_2 \quad (1)$$

Insolubility of this and analogous nitrate-containing complexes[43] in organic solvents and the strong coordination of nitrato ligands to the lanthanide ions preclude the potential use of these clusters in further research. Our efforts have therefore concentrated on the direct hydrolysis of lanthanide perchlorates. Although these starting materials are potentially explosive, they have been utilized extensively in lanthanide research because of their water solubility and the weakly coordinating nature of ClO_4^-. The latter is essential for the preparation of novel oxo–hydroxo lanthanide precursors for future work.

Indeed, the direct hydrolysis of $Nd(ClO_4)_3$ and $Gd(ClO_4)_3$ afforded two new molecular oxo–hydroxo clusters.[42] Shown in Fig. 14 is the structure of the cationic cluster complex obtained from the reaction of $Nd(ClO_4)_3$ with aqueous NaOH. Established by X-ray diffraction, the cationic cluster core, formulated as $[Nd_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8(H_2O)_{24}]^{8+}$, is comprised of an octahedron of Nd^{III} centered on a μ_6-oxo ligand. Each of the triangular metal faces is capped by a μ_3-OH ligand. The metal coordination sphere is completed with four aqua ligands. Thus, each Nd^{III} is coordinated to nine oxygen atoms: one interstitial oxo unit, four face-capping hydroxo groups, and four terminal aqua ligands. Overall, the complex is structurally similar to the Lindquist-type hexametalates of transition elements with the distinction of having eight face-capping hydroxo groups instead of 12 edge-bridging oxo ligands. To the best of our knowledge, this is the first molecular lanthanide cluster with *only coexisting* oxo, hydroxo and aqua ligands. Such hydrous species are the simplest and most fundamental forms of $[Ln_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8]^{8+}$ core-containing clusters and may be useful precursors for various substituted clusters in future work, including the construction of open framework structures using the octahedral clusters as building blocks. In fact, the octahedral core appears to be another common structural motif in lanthanide oxo-

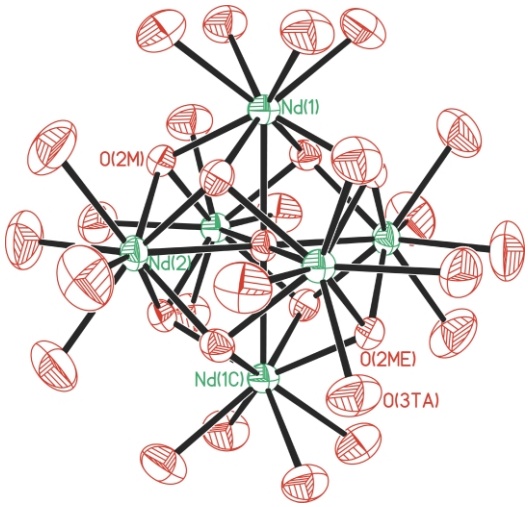

Fig. 14 An ORTEP drawing of $[Nd_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8(H_2O)_{24}]^{8+}$, a cationic complex featuring a face-capped hexanuclear cluster core and containing only water-based ligands.

hydroxides, as demonstrated by our group[42] and others.[43,45] Its presence has also been recognized in a polymeric cyanide-bridged lanthanide-transition metal complex reported by Shore and coworkers.[47]

In stark contrast to the extensive chemistry of the closely related lanthanide oxo–alkoxides,[16a,48] the closely related chemistry of lanthanide oxo–hydroxides has essentially been unexplored. Thus, our demonstration of the direct hydrolysis of the lanthanide ions leading to hexanuclear lanthanide oxo–hydroxo complexes is significant. The structural integrity, the highly ordered arrangement of paramagnetic centers and the anticipated substitutional lability of the cluster terminal aqua ligands portend their applications as structural and functional building blocks for a variety of lanthanide-containing materials.

New tricks for an old dog – unusual lanthanide–EDTA coordination under high-pH conditions

Prompted by the close relationship between polyaminopolycarboxylic acids (PAPCs) and α-amino acids, we set out to re-evaluate, under much higher pH conditions however, the classical coordination chemistry of the lanthanide ions with PAPCs. If the solution pH condition can have such significant influence on the outcome of the well-established lanthanide–amino acid coordination chemistry, one should not be surprised if some new but admittedly hard-to-predict results are to be obtained with this venerable class of ligands[49] under similarly altered pH conditions.[50] In this section, we illustrate how the otherwise well-established chemistry can be profoundly affected by simply increasing the pH of the reaction mixture.

Our initial foray has been focused on ethylenediamine-*N,N,N′,N′*-tetraacetic acid (H_4EDTA), one of the most studied PAPCs. Lanthanide–EDTA complexes, represented by the general chemical formula $M[Ln(EDTA)(H_2O)_m]\cdot nH_2O$ (M = an alkali metal ion), have invariable 1 : 1 (EDTA : Ln) composition.[51] Structural analyses always reveal a hexadentate EDTA ligand with two coordinating nitrogen atoms and four oxygens of the unidentate carboxylate groups (**A**, Fig. 15). The O(aqua)–Ln–O(aqua) bond angles range from 70.0 to 83.3°, which are very close to the corresponding O(μ_3–OH)–Ln–O(μ_3–OH) angles (ranging from 68.1 to 76.8°) in the $[Ln_4(\mu_3\text{–}OH)_4]^{8+}$ unit. An intriguing question then arises: *Can a cubane-like tetranuclear lanthanide–hydroxo cluster be assembled from a mononuclear trisaqua lanthanide complex with EDTA?*

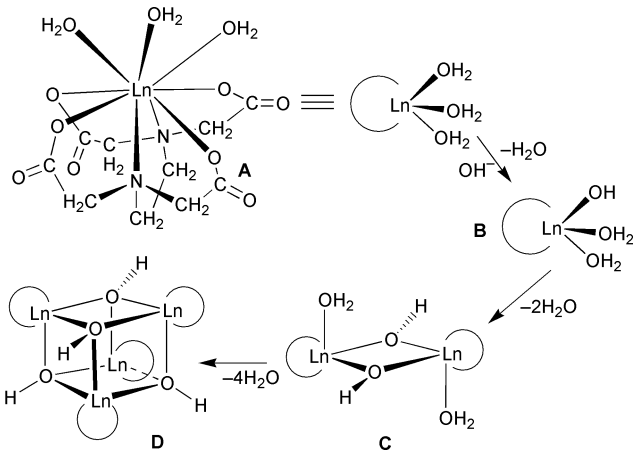

Fig. 15 A proposed mechanism for the self-assembly of a tetranuclear lanthanide–hydroxo complex with EDTA from its corresponding mononuclear aqua complex.

It seemed plausible that if the pH of a lanthanide-EDTA reaction mixture is raised, the aqua ligand(s) of the initially formed nine-coordinate complex would be deprotonated, giving rise to a hydroxo complex of lanthanide with EDTA (**B**, Fig. 15). Bimolecular reactions of species **B** leads to the formation of the μ_2-OH bridged, diamond-shaped intermediate (**C**, Fig. 15), for which a number of literature precedents exist.[22] Subsequent condensation of two of such dinuclear units would afford a tetranuclear lanthanide cluster, bearing the familiar cuboid $[Ln_4(\mu_3\text{–}OH)_4]^{8+}$ unit whose metal centers are capped by EDTA ligands (**D**, Fig. 15).

This hypothesis was validated: The La^{III}–EDTA complex, formulated as $Na_{10}[La_4(\mu_3\text{–}OH)_4(EDTA)_4](ClO_4)_2$, was obtained by mixing $La(ClO_4)_3$ and $Na_2H_2EDTA{\cdot}2H_2O$ in an aqueous solution and subsequently adjusting the pH of the reaction mixture to about 13 with dilute aqueous NaOH.[31] The molecular structure of the anionic cluster was established by X-ray diffraction and is shown in Fig. 16, wherein the presence of

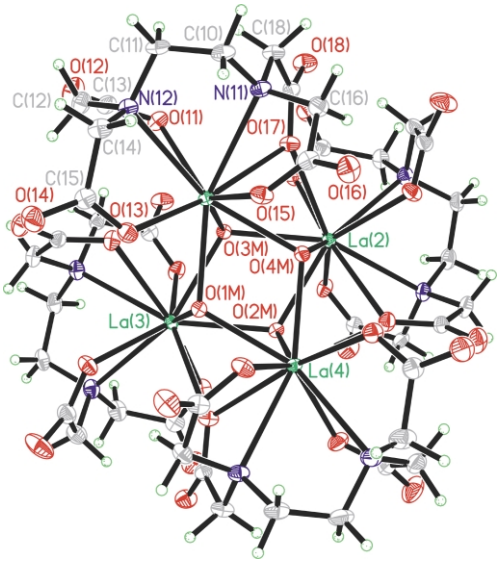

Fig. 16 An ORTEP representation of the anionic complex $[La_4(\mu_3\text{-}OH)_4(EDTA)_4]^{8-}$ featuring the familiar cubane-like $[La_4(\mu_3\text{-}OH)_4]^{8+}$ core.

a cubane-like $[La_4(\mu_3\text{–}OH)_4]^{8+}$ core is quite clear. Each metal vertex is capped by an EDTA ligand whose coordination mode is unusual: the EDTA ligand is hexadentate (a, Fig. 17), but with one of its four coordinating oxygen atoms bridging a second La^{III} ion. The two non-bridged La^{III} pairs (La1–La4 and La2–La3) correspond to a metal–metal separation of 4.278 Å, which is significantly longer than the other four (3.975 Å). Each La^{III} ion has a CN = 10, and its coordination polyhedron may be best described as a bicapped square antiprism. Although the

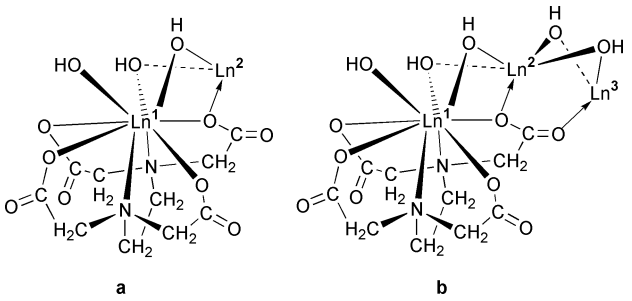

Fig. 17 The well-known hexadentate mode of an EDTA ligand to Ln^1 with the unprecedented bridging modes to additional lanthanide ions (Ln^2 and Ln^3).

complex is not exactly the one originally targeted, its formation can be readily rationalized based on the proposed condensation mechanism. An isostructural tetranuclear hydroxo complex of Pr^{III} with EDTA has been obtained;[52] the Pr^{III} ion in this complex is also 10-coordinate.

Since one EDTA ligand contributes six coordinating atoms, only two aqua ligands would be possible for a lanthanide ion that prefers a coordination number of eight. A complex featuring the diamond-shaped lanthanide–hydroxo core would be the expected product, and the reaction would terminate at the stage of **C** upon increasing the pH of the reaction mixture. Indeed, a dinuclear Er^{III}–hydroxo complex was isolated from a reaction mixture of $Na[Er(EDTA)(H_2O)_2]$ (formed at pH 6) with KOH at pH 13–14.[52] The structure of the complex, formulated as $K_4[(EDTA)Er(\mu\text{-}OH)_2Er(EDTA)]$, has been determined by X-ray diffraction, and that of the anionic core component is depicted in Fig. 18.

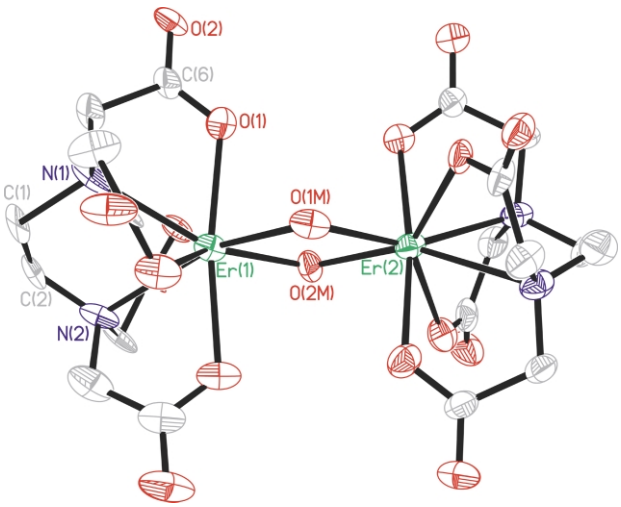

Fig. 18 An ORTEP representation of the diamond-shaped dinuclear Er^{III}–hydroxo complex with EDTA, $[(EDTA)Er(\mu\text{-}OH)_2Er(EDTA)]^{4-}$.

The observation of ten-coordinate La^{III} and Pr^{III} in both of the tetranuclear complexes merits further discussion. While the high coordination number is not so unusual for La^{III}, ten-coordinate Pr^{III} is rather rare. It appears that the previously unknown bridging interaction by one of the EDTA carboxylato oxygens is a prerequisite for the formation of the cubane-like structure. What can one anticipate when a lanthanide ion preferring a CN = 9 is utilized in an analogous reaction? On the one hand, since a CN = 10 is very unlikely, it is a reasonable assessment that the tetranuclear complex will not form. On the other hand, since such a lanthanide ion may not be satisfied with a CN = 8, one may expect a coordination environment different from that of the dinuclear Er^{III} complex (Fig. 18). Once again, our efforts to seek answer to this question yielded pleasantly surprising results. A dodecanuclear complex composed of four vertex-sharing $[Nd_4(\mu_3\text{–}OH)_4]^{8+}$ cubanes and eight EDTA

ligands was isolated from an aqueous mixture of EDTA and $Nd(ClO_4)_3$ at pH 14.[27,31]

The crystal structure of the anionic cluster complex, formulated as $\{[Na(H_2O)_2]_4[Nd_{12}(\mu_3\text{–}OH)_{16}(EDTA)_8]\}^{8-}$, is shown in Fig. 19. Its skeletal structure is identical to those of the

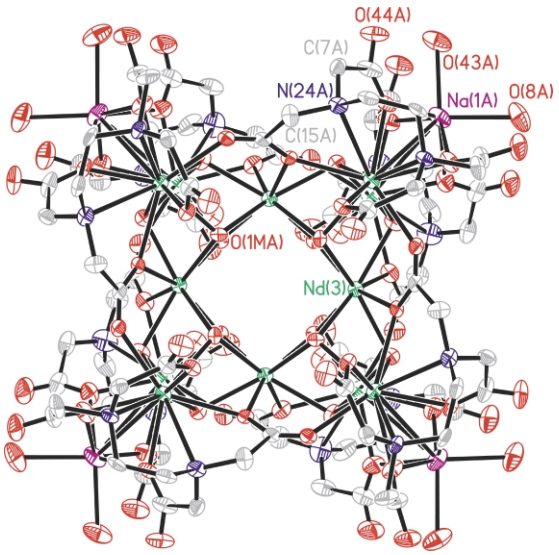

Fig. 19 An ORTEP representation of the dodecanuclear Nd^{III}–hydroxo complex featuring four vertex-sharing $[Nd_4(\mu_3\text{-}OH)_4]^{8+}$ units in a square-shaped arrangement. The anionic complex is formulated as $\{[Na(H_2O)_2]_4[Nd_{12}(\mu_3\text{–}OH)_{16}(EDTA)_8]\}^{8-}$. Color legend: sodium (purple).

diiodide complexes obtained from the tyrosine-supported hydrolytic reaction of $Ln(ClO_4)_3$ (Ln = Dy^{III}, Er^{III}) with templating I^-.[32] The EDTA ligands occupy the vertices of a perfect tetragon, each capping one of the eight non-shared Nd^{III}. One may alternatively view the structure as a sandwich made with a four-cubane 'patty' and two slices of EDTA 'bread'. The coordination mode of EDTA ligands in this complex is significant: each EDTA molecule acts as a *heptadentate* ligand (b, Fig. 17) as opposed to the well-known hexadentate one. One of the carboxylate groups together with the nitrogen atom to which it is bound can be described as $\mu_3:\eta^1:\eta^2:\eta^1$, a coordination mode first observed in the aforementioned lanthanide-tyrosine complexes,[29,32] but unprecedented for EDTA. Hydroxo ligands complete the Nd^{III} coordination sphere. Thus, each inner-layer Nd^{III} ion has a CN of 8, forming an irregular square antiprism, while each outer layer Nd^{III} ion has a CN of 10, and its coordination polyhedron may be best described as a bicapped square antiprism. Both eight- and ten-coordinate Nd^{III} are uncommon; the metal ion is predominantly nine-coordinate with tricapped trigonal prism being the most frequently observed structure. Even more intriguing are the unprecedented co-existence of these rare coordination numbers and the accompanying absence of the commonly observed nine-coordination.

The square opening, clearly shown in Fig. 19, could potentially permit entry by a guest molecule or ion. The strong preference of Nd^{III} for nine-coordinate geometry coupled with the high affinity of a lanthanide ion for F^- suggests that a fluoride-containing complex with the anionic guest species sitting in the square-shaped opening is possible.[53]

What the story tells us

The research described here was initially stimulated by the observation of several aesthetically pleasing polynuclear lanthanide–hydroxo complexes that were characterized as synthetic serendipity or accidents. The ultimate goal of making high-nuclearity lanthanide complexes aimed at potential applications in biomedical science and advanced technologies drove us to study the lanthanide coordination with biologically relevant ligands under near physiological and even high pH conditions. A variety of novel lanthanide–hydroxo complexes have been isolated and structurally characterized. The results clearly illustrate that otherwise well-established chemistry can be profoundly affected by simply altering the reaction pH.

The following are the principal results and conclusions from the research described above.

1. Ligand-controlled hydrolysis of the lanthanide ions is a new avenue in lanthanide coordination chemistry. It is a valid and highly efficient approach to the assembly of finite-size polynuclear lanthanide–hydroxo complexes.
2. α-Amino acids are a novel class of supporting ligands for controlling the hydrolysis of the lanthanide ions. Under near physiological pH conditions, lanthanide complexation with amino acids may be achieved *via* only the carboxylate group or simultaneous coordination by both the carboxylate and amino moieties.
3. Lanthanide–amino acid complexes generated under near neutral conditions typically exist as discrete polynuclear lanthanide–hydroxo clusters, whereas their low-pH counterparts are in mononuclear, dinuclear or noncluster polynuclear forms. It is the high-pH conditions that promote the formation of the large molecular clusters. These complexes may be viewed as the precursors to stepwise, controllable sol–gel materials syntheses.
4. The cuboid $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ cluster, complementing its *d*-block counterparts, is a common structural motif in lanthanide coordination compounds. Extended supramolecular structures can be assembled by using the $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ cluster cores as building blocks.
5. Octahedral $[Ln_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8]^{8+}$ core-containing clusters with an interstitial μ_6-O ligand can be assembled *via* direct hydrolysis of lanthanide nitrates and perchlorates in the absence of any organic supporting ligands.
6. Spherical anionic species are important in templating the formation of wheel-like lanthanide cluster complexes.
7. pH conditions exert a strong and general influence on the outcome of lanthanide coordination chemistry, as demonstrated by the isolation of unprecedented EDTA–lanthanide complexes from otherwise well-established chemistry.

The story continues with an open end

The results detailed above suggest extensive and promising coordination chemistry of the lanthanide ions under physiological or higher pH conditions. Many important questions, both fundamental and practical, remain to be answered. For example, why is tyrosine so unique in that it uses both amino and carboxylate groups for simultaneous lanthanide coordination? Why are pentadecanuclear or dodecanuclear complexes composed of corner-sharing cuboid $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ cluster units formed with tyrosine ligands while monocluster complexes are generated with carboxylate-only coordination when other amino acids are utilized? Although the steric effect due to the side group of the amino acid may play an important role, answers to these questions are not yet available. Further, how extensively applicable to other metals and ligands is the hydrolytic approach to polynuclear complexes? What properties may be expected of these novel lanthanide-containing materials? From the work discussed herein, it is clear that 'high'-pH lanthanide coordination chemistry represents a rich field of research that can be exploited to create novel lanthanide-containing materials with desirable properties. There are ample opportunities for investigation and high expectation for a broad range of applications of these novel polynuclear lanthanide complexes, including the well-characterized structural platform for potential development of lanthanide-based synthetic phosphodiesterases.

A hierarchically structured composite ion conductor film (AgI nanorod/γ-Al_2O_3) was chemically prepared using nanoporous anodic aluminium oxide (AAO) as a template, where ion conducting AgI nanorods (av. diameter = 75 nm) are periodically aligned within a hexagonally organized insulating Al_2O_3 matrix.

Composite solid electrolytes, where ion conducting solids (such as AgI, AgCl, AgBr, LiI, CuCl, *etc.*) are heterogeneously mixed with an insulating solid dispersant (such as γ-Al_2O_3, SiO_2, MgO, *etc.*), have attracted much research attention due to their markedly enhanced conductivity with respect to pristine ion conducting solids themselves.[1–3] Among many composite ion conductor systems, AgI/γ-Al_2O_3 composite solid electrolytes have been extensively studied and impedance measurements revealed a maximum conductivity enhancement by a factor of 10^3–10^4, even at room temperature, compared with pristine β-AgI.[3] It is generally accepted that interface interactions between the ionic conductor (AgI) and insulator (γ-Al_2O_3) play a key role in governing the transport behaviour.[2] Although it has been suggested quite recently that such an enhanced conductivity is a consequence of the formation of an interfacial conducting phase (*e.g.*, 7H polytype of AgI with stacking fault arrangement), the microscopic mechanism or the origin of the enhancement in ionic conductivity is, as yet, not clear.[4] The interfacial interaction between particles could be maximized by reducing the size of particles down to 140 nm, since the surface of fine particles with high specific surface area are not only structurally unsaturated but also chemically labile and so can be easily converted to metastable phases. Previously, the fabrication of such composite ion conductors have been simply achieved by mechanically mixing and grinding the constituent materials (*i.e.* AgI and γ-Al_2O_3) and then hydrostatically pressing the resulting solid mixture, which does not, however, ensure homogeneous mixing of the components.[4,5]

Herein we report the synthesis and characterization of a hierarchically structured composite ion conductor film (AgI nanorod/Al_2O_3), where ion conducting AgI nanorods are homogeneously and periodically aligned within an insulating Al_2O_3 matrix with hexagonally organized configuration. A novel composite conductor was realized using porous anodic aluminium oxide (AAO) as a template, the structure of which is characterized by a closely packed regular array of hexagonal columnar cells with uniform nanoholes each of which contains a long cylindrical nanochannel.[6] The synthetic procedure for the preparation of the AgI nanorod/AAO composite is schematically presented in Fig. 1.

The nanoporous anodic aluminium oxide (AAO) template was prepared by a two-step anodization technique as described previously.[7] A field emission scanning electron microscopic (FE-SEM; Hitachi S-4300) image of the as-prepared AAO indicated that the template contained a well-organized hexagonal array of cylindrical pores with an average pore diameter of 75 nm and a pore density of 1×10^{10} cm^{-2} (Fig. 2(a)). According to XRD (Philips PW3710) pattern of the as-prepared AAO, the nanoporous AAO turned out to be X-ray amorphous, showing a broad spectral feature over the 2θ range 15–35°. However, the corresponding FT-IR (Bomem DA 8) spectrum showed a characteristic Al–O vibration of γ-Al_2O_3 with a shoulder at *ca.* 1180 cm^{-1} and strong absorption bands at 600–900 cm^{-1}.[8]

The Ag nanorod/AAO composites were fabricated *via* the electrodeposition of silver within the pores of the alumina template. A through-hole AAO membrane was used in the preparation of the Ag nanorod array. Initially, a layer (*ca.* 120 nm thick) of Ag was thermally evaporated onto one side of membrane to make the surface electrically conductive. This

 DOI: 10.1039/b108230m

conducting layer functions as the working electrode in the electrodeposition of silver. After this, Ag was electroplated using a commercial plating solution (Technic silver 1025A and B) at room temperature. Electrodeposition of silver on the nanoporous AAO membrane produced large arrays of silver nanowires with a uniform diameter and a very large aspect ratio. As evidenced by FE-SEM investigation, the average diameter of the resulting metal nanowires is highly consistent with the average pore diameter (75 nm) of the alumina template used in the electrodeposition (Fig. 2(b)).

Fabrication of the silver iodide nanorod array was readily achieved by utilizing the solid–gas reaction between metallic silver nanorods and gaseous iodine. This reaction is known as iodization or iodination of silver;[9] a typical metal oxidation process where iodine serves as an oxidant. The net reaction can be expressed by eqn. (1):

$$2\ \mathrm{Ag(s)} + \mathrm{I_2(g)} \rightarrow 2\ \mathrm{AgI(s)} \qquad (1)$$

Typically, iodination was carried out by heating a vacuum sealed Pyrex tube containing 2 g of elemental iodine and a piece (0.5×1 cm^2) of Ag nanorod/AAO composite film in a constant temperature furnace (150 °C) for 24 h. After completion of the reaction, the resulting AgI nanorod/AAO composite was isolated after subliming the excess iodine, thoroughly washing with acetone and water to remove the residual elemental iodine, and finally drying under vacuum.

A representative cross-sectional FE-SEM image of the AgI nanorod/AAO is shown in Fig. 2(c). Some of the nanochannels (white triangle marks in Fig. 2(c)) of AAO were not filled with AgI nanorods probably due to the mechanical force applied to the film in order to obtain the cross-sectional image of the AgI nanorod/AAO composite film. An FE-SEM image of AgI nanorods freed from alumina by dissolving the oxide matrix with 0.5 M NaOH solution is shown in Fig. 2(d). Unlike the image of Ag nanorods in Fig. 2(b), the direction of the rod axis of individual AgI nanorods is rather arbitrary and the length of each nanorod is relatively short. Such morphological evolution can be attributed to the brittle nature of ionic AgI nanorods compared to metallic Ag nanorods and to the external stress exerted during the processes of eliminating the alumina matrix and drying the resulting AgI nanorods. Each of AgI nanorods in the nanochannels of the AAO matrix, however, is expected to have a high aspect ratio aligning its rod axis perfectly orthogonally with respect to the surface of AAO.

The phase of the synthesized nanorods was checked by TEM and X-ray diffraction (XRD). A selected area electron diffraction (SAED) pattern of the present AgI nanorods indicated that the sample is polycrystalline showing diffuse ring patterns. According to the estimated lattice spacings from the diffraction rings, the sample is mainly composed of a hexagonal wurtzite type β-AgI and this assignment was confirmed by XRD. Typical XRD spectra of Ag nanorod/AAO and AgI nanorod/AAO composites are presented in Fig. 3, together with the spectrum of commercial AgI for comparison. Broad spectral features in the 2θ range 15–35° were observed for the Ag nanorod/AAO and AgI nanorod/AAO composite samples, which originated from amorphous alumina (Al_2O_3). The XRD spectrum of the Ag nanowire/AAO composite showed well defined (111), (200) and (220) lines at 2θ = 38.8, 44.1 and 64.7°, respectively, revealing pure metallic silver (JCPDS code # 03-0931). On the other hand, it is evident from the present XRD patterns that the iodination reaction on the Ag nanorod/AAO composite gives rise to significant changes in the diffraction patterns. According to our XRD analysis, the observed diffraction peaks in the AgI nanorod/AAO composite could be indexed to the β-AgI structure with lattice parameters a = 4.6 Å and c = 7.5 Å (JCPDS code # 09-0374), consistent with the analytical result of the SAED pattern.

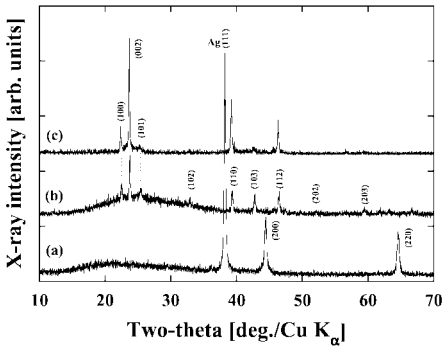

Fig. 3 Cu-Kα powder X-ray diffraction (XRD) pattern of (a) Ag nanorod/AAO, (b) AgI nanorod/AAO composite film, and (c) commercially available AgI.

Our preliminary results on ionic conductivity measurements revealed that the present AgI nanorod/AAO composite showed a three orders of magnitude enhanced ionic conductivity ($\sigma_{(28\ ^\circ\mathrm{C})} = (1.67 \pm 0.03) \times 10^{-3}\ \Omega^{-1}\ \mathrm{cm}^{-1}$) compared with pristine β-AgI, which is comparable with the previously reported maximum values in physically prepared AgI/Al_2O_3 composite ion conductors.[3]

It has been pointed out that the interfacial effect together with size and texture are responsible for conductivity enhancement in composite ion conductors. Unlike the inhomogeneous structure of physically prepared conventional composite ion conductors, the present sample has a novel geometric structure, where ion conducting nanorods with high aspect ratio are periodically embedded in the nanochannels of porous anodic aluminium oxide (AAO). Moreover, the interfaces formed by the AgI nanorods and the walls of cylindrical nanochannels of AAO are expected to act as well defined, isolated, and discrete conduction channels, leading to a markedly enhanced ionic conductivity. Therefore, the present AgI nanorods/AAO composite film might provide a good model system for elucidating the origin of the conductivity enhancement as well as the mechanism governing the transport behaviour in composite conductors.

We are quite certain that our underlying concept to develop novel nanostructured composite ion conductors can be readily extended to other solid electrolyte systems such as LiI and CuCl. We are at present investigating the transport properties of the present composite conductor with variation of the physical dimensions of the AgI nanorods, such as rod diameter and length.

This work was supported by the grant from the Interdisciplanary Research Program (Grant No. 1999-2-121-004-5) of the KOSEF. W. Lee is grateful for the award of a BK21 fellowship.

1,4-Benzenedicarboxylate derivatives as links in the design of paddle-wheel units and metal–organic frameworks

Matthew E. Braun, Cory D. Steffek, Jaheon Kim, Paul G. Rasmussen and Omar M. Yaghi*

Department of Chemistry, University of Michigan, Ann Arbor, MI 48109-1055, USA.

Received (in Columbia, MO, USA) 5th September 2001, Accepted 6th November 2001
First published as an Advance Article on the web 30th November 2001

The square grid structure of MOF-2, constructed from paddle-wheel units of Zn(II) and 1,4-benzenedicarboxylate (BDC) links, persists for 2-amino-1,4-benzenedicarboxylate (ABDC) links but not for the sterically demanding 2,3,5,6-tetramethyl-1,4-benzenedicarboxylate (TBDC); the dihedral angle between planes of the benzene and carboxylate groups play a determining role in the formation of the paddle-wheel motif.

Extensive progress has been achieved in the synthesis of metal–organic frameworks (MOFs).[1–6] In particular MOFs of carboxylates have been designed to have permanent porosity in the absence of guests.[7–10] The first such material was constructed from paddle-wheel secondary building units (SBUs) and ditopic benzene links.[7a] Namely, Zn(BDC)·(DMF)(H_2O) (termed MOF-2) in which the benzene ring of BDC (1,4-benzenedicarboxylate) (Fig. 1a) is essentially in the same plane as the carboxylates (dihedral angle, Θ = 5.5°), a feature that allows the formation of a porous 4^4 square network with one dimensional channels of 7.8 Å cross-section (Fig. 1a–c). Our interest in design of MOFs led us to consider whether other derivatives of BDC can form this structural motif. In particular we focused on 2-amino-1,4-benzenedicarboxylate (ABDC) and 2,3,5,6-tetramethyl-1,4-benzenedicarboxylate (TBDC), since the substituents on benzene were expected to result in rotation of the carboxylates out of the plane containing the benzene ring to give larger Θ. In this report, we show that the size of substituents, and Θ are critical parameters in the formation of paddle-wheel units and ultimately their reticulated MOFs.

The ABDC and TBDC compounds were prepared using identical procedures: slow diffusion of a mixture containing chlorobenzene–trimethylamine (700:1 v/v) into an *N*,*N*′-dimethylformamide (DMF)–chlorobezene (5/5 mL) solvent mixture containing $Zn(NO_3)_2·6H_2O$ (55 mg, 0.185 mmol) and H_2ABDC (1 equiv.) or H_2TBDC (1 equiv.) at room temperature results after 4–7 days in the formation of Zn(ABDC)(DMF)·$(C_6H_5Cl)_{0.25}$ (MOF-46) or $Zn_2(TBDC)_2(H_2O)_{1.5}(DMF)_{0.5}$·(DMF)($H_2O$), (MOF-47). These compounds were formulated and characterized by elemental microanalysis† and single crystal X-ray diffraction.‡

To fully appreciate the structures of MOF-46 and -47, it is important to consider first the structure of MOF-2 in which the paddle-wheel M–O–C core cluster is considered a square SBU (Fig. 1b) that is polymerized into square grids by benzene ditopic links (Fig. 1c). We sought to learn whether the paddle-wheel and thus the square grid can be produced from other BDC derivatives. Our approach required relating the dihedral angle, Θ of the benzene ring of the ligand to the distance, *d* between the

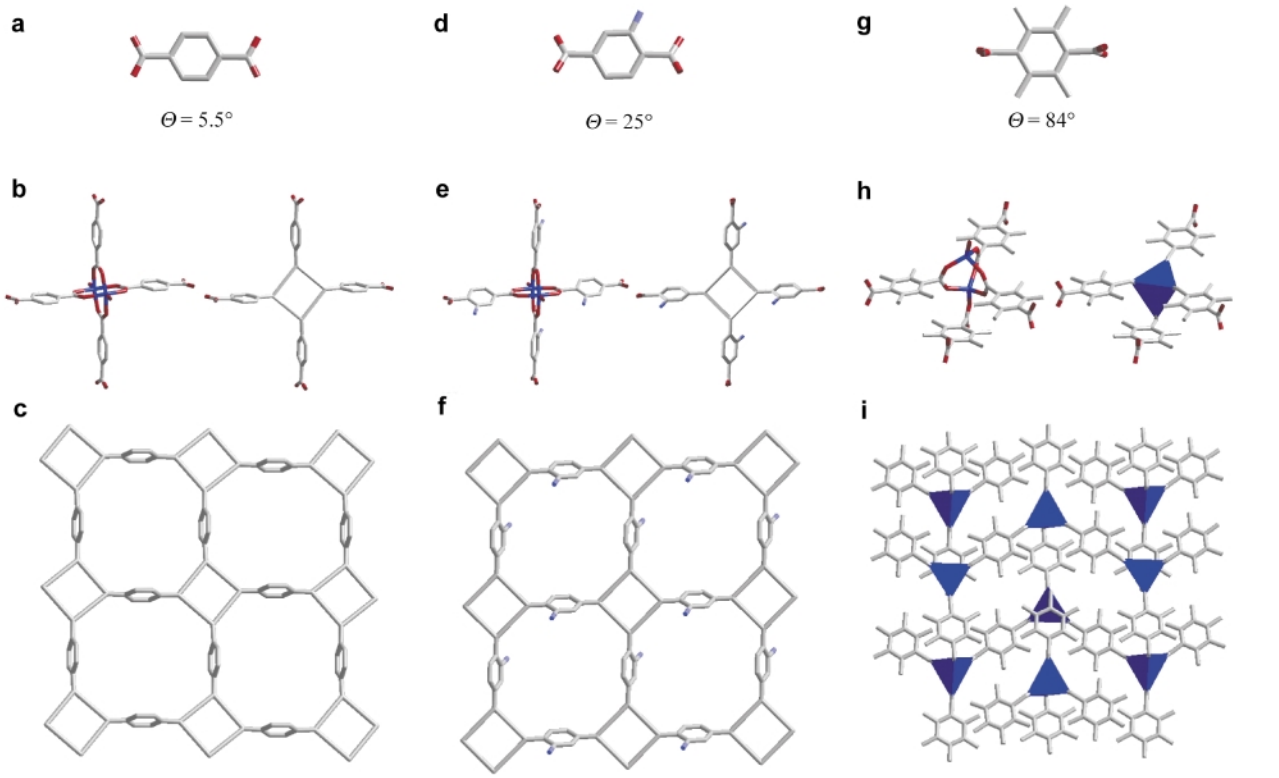

Fig. 1 The assembly of Zn(II) with BDC derivatives having a dihedral angle Θ to produce MOF-2 (a–c), MOF-46 (d–f) and MOF-47 (g–i). Zn(II) (blue) is connected to carboxylate O (red) with carboxylate C (gray) forming square (MOF-46) and tetrahedral (MOF-47) SBUs, which are linked by functionalized benzene units (N, light blue in d–f). All hydrogen atoms have been omitted for clarity.

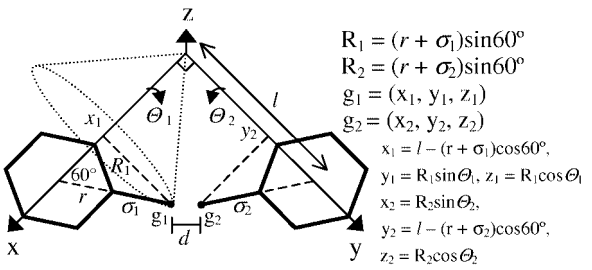
 DOI: 10.1039/b108031h

substituent groups (g_1 and g_2) of contiguous BDC units of the same paddle-wheel. This is illustrated below and d is derived accordingly.

The general equation for d can be obtained by using $d = \{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2\}^{1/2}$ with the limiting condition, $\{l(1 + \tan 15°)\}/2 \geqslant R$. In case when g_1 and g_2 are the same functional groups and $(180° - \Theta_1) = \Theta_2$, this equation is simplified to $d = [2(l - (r+\sigma)/2 - \{3^{1/2}(r+\sigma)/2\}\sin\Theta_1)^2 + 3(r + \sigma)^2\cos^2\Theta_1]^{1/2}$.



Here l = the distance between the center of the SBU and the center of the benzene ring, R = the radius of the trajectory of the circle generated by rotating the substituent group along the x- or y-axis by the dihedral angle, Θ. Thus to obtain a square grid structures as in MOF-2, functionalization of BDC should use groups that do not allow d to have value less than the summation of the van der Waals radii of g_1 and g_2.

For ABDC, $\Theta_1 = 25°$, $\Theta_2 = (180 - 25)°$, $l = 5.495$ Å, $r = 1.342$ Å and $\sigma = 1.40$ Å result in $d = 6.17$ Å which is enough to accommodate the $-NH_2$ groups. Then in principle, a paddle-wheel and an MOF-2 type structure can form. Reactions that are known to yield the paddle-wheel were utilized to make MOF-46. Indeed, the single crystal structure of the amino-benzene allows the formation of the expected motif (Fig. 1d–f), where the square layers are stacked along the c-axis, and DMF axial ligands fill the space in between adjacent layers. Due to the larger size of DMF relative to water (present in MOF-2 as an axial ligand), the $(CH_3)_2N$– groups pertrude into the channels of MOF-46. In this way, the pores have periodic arrays of $(CH_3)_2N$– and $–NH_2$ functionalities decorating the internal walls.

On the other hand, for TBDC, $\Theta_1 = 84°$, $\Theta_2 = (180 - 84)°$, $l = 5.309$ Å, $r = 1.398$ Å and $\sigma = 1.50$ Å result in $d = 2.00$ Å which is smaller than twice the van der Waals radii of the $–CH_3$ groups, 4.0 Å. Therefore it is not possible to produce an analogous framework. This is essentially a consequence of having methyl groups on both *ortho*-C atoms which inhibit the formation of the paddle-wheel structure at such a large dihedral angle. In fact, the van der Waals distance across the pores is 8.076–6.771 Å in MOF-2; well below that needed (9.329 Å) for TBDC units to replace BDC in that structure. Instead, MOF-47 is constructed from tetrahedral SBUs (Fig. 1g–i), a geometry known to be best in spacing apart sterically demanding groups.

Three carboxylate groups from three TBDC units are bound in a dimonodentate fashion to two Zn centers. One zinc center is also bound to a terminal water molecule, while the other is linked by an additional carboxylate in a monodentate fashion. Following the SBU structure analysis scheme, the carboxylate C atoms in the M–O–C cluster of MOF-47 forms a tetrahedral SBU. A closely related SBU is known in molecular complexes and other MOFs.[11,12] However, in this case, where it is expected that a tetrahedral SBU leads to the formation of a tetrahedral 4-connected 3-D network such as diamond, we find that the structure forms a double layer motif. Two TBDC units are bound entirely through dimonodentate coordination to Zn centers, and the remaining two units are each bound to Zn in both dimonodentate and monodentate fashion. One water and one DMF molecule per formula unit fill the space between the layers.

Thermogravimetric analysis on MOF-46 and -47 show that the DMF ligands in MOF-46, and the guests in MOF-47 can be removed upon heating to >50 °C: a weight loss of 41% was observed for MOF-46 in the range 50–310 °C corresponding to the loss of one DMF and 0.25 C_6H_5Cl (Calc.: 41%), and a sharper weight loss of 21% was measured for MOF-47 in the range 50–90 °C, which is attributed to the loss of 1.5 DMF and one water (Calc.: 21%). Both frameworks completely decompose above 350 °C.

This study demonstrates that the pores in MOFs can be functionalized with potentially reactive groups ($–NH_2$) without changing the SBU or the underlying framework topology (MOF-46). It is clear from the structure of MOF-47 that TBDC is too bulky to have the paddle-wheel arrangement or the square grid structure observed in MOF-2.

First published as an Advance Article on the web 30th November 2001

Two crystalline metal–organic frameworks formulated as $Zn_6(NDC)_5(OH)_2(DMF)_2{\cdot}4DMF$, MOF-48, and $Zn_7(m\text{-}BDC)_6(OH)_4(H_2O)_2{\cdot}6DMF{\cdot}4H_2O$, MOF-49, (NDC = 1,4-naphthalenedicarboxylate; *m*-BDC = 1,3-benzenedicarboxylate) have been synthesized and fully characterized by single crystal X-ray diffraction studies, which reveal that the frameworks are constructed from pentagonal antiprismatic (MOF-48) and cuboctahedral (MOF-49) secondary building units respectively, however, both are reticulated into 3-D structures having the B network of CaB_6.

In the chemistry of metal–organic frameworks (MOFs), especially where metal ions have been joined by polytopic carboxylate links, M–O–C clusters generally result in which the carboxylate C atoms define the shape of what is referred to as a secondary building unit (SBU).[1–4] Such entities have been recognized and used as tools for simplifying complex structures,[5] and in cases where reaction conditions can be directed to give specific SBU geometries; they have the potential to allow for the assembly of MOFs by design.[6–8] Furthermore, the size of SBU constructs is directly related to achieving optimal porosity and rigidity of MOFs including the design of periodic arrays of open metal sites within their voids.[6–10] With the long-term goal of understanding the factors affecting the composition, topology, shape and size of SBUs, we have begun to explore synthetic routes that may lead to new SBUs. Here we report two 3-D metal carboxylate frameworks prepared by linking Zn(II) with 1,4-naphthalenedicarboxylate (NDC), and *m*-benzenedicarboxylate (*m*-BDC) to give MOF-48 and MOF-49, respectively. We find that these MOFs are constructed from pentagonal antiprismatic and cuboctahedral SBUs; however, both form 6-connected CaB_6 type networks rather than 10- and 12-connected networks that one might expect to find based on the geometry of their respective SBUs. We show that pairwise connections between SBUs in MOF-48 and 49 provide the means for these frameworks to adopt networks of lower connectivity.

Vapour diffusion from a mixture of H_2O_2 (0.40 mL, 40% in water) and chlorobenzene–triethylamine (20 mL/1 mL) into a clear solution of *N*,*N*′-dimethylformamide (DMF)/chlorobenzene (5 mL/5 mL) containing $Zn(NO_3)_2{\cdot}6H_2O$ (0.029 g, 0.097 mmol) and NDC acid (0.015 g, 0.069 mmol) gives, after 7 d, cube-like crystals of MOF-48 in 33% yield (based on NDC acid). MOF-49 was prepared by dissolving $ZnCl_2$ (0.060 g, 0.44 mmol) and *m*-BDC acid (0.040 g, 0.261 mmol), in that order, in DMF (5 mL). This solution was subjected to dropwise addition of a mixture of 0.6 M aqueous methylamine–acetonitrile (2 mL/5 mL). The resulting clear solution was left undisturbed for three days at room temperature to give hexagonal shape crystals in 27% yield (based on *m*-BDC acid). MOF-48 and 49 were formulated and characterized by elemental microanalysis† and X-ray single crystal diffraction studies.‡

MOF-48, $Zn_6(NDC)_5(OH)_2(DMF)_2{\cdot}4DMF$, is constructed from hexameric units composed of four tetrahedral and two octahedral Zn(II) centres, where a total of ten NDC links doubly bridge the zinc atoms in a dimonodentate fashion (Fig. 1a). Each cluster has an inversion centre, which relates two zinc trimer units in which the zinc centres are further joined by a triply bridging μ_3–OH group. One terminal DMF ligand is bound to each of the octahedral zinc centres. The assignment of μ_3-OH was based on the near tetrahedral angles around the central O (110.8(6), 114.0(4), 114.0(4)°), which are in the range of those found in molecular complexes.[11]

It is useful to connect the points-of-extension (the carboxylate C atoms) in the hexameric units, a process that leads to SBUs having pentagonal antiprismatic geometry (Fig. 1b). Each SBU is connected to six other SBUs to give a 3-D framework having 6.2 Å diameter[12] 1-D channels where four DMF guests per formula unit reside (Fig. 1c). It is important to note that in addition to two single NDC connections along [001] between SBUs, there are eight pairwise connections (Fig. 1c). Here each pair of NDC links connecting two SBUs can be considered topologically as a single ditopic link, in essence a doubly reinforced link. Since each SBU acts as a six connector, the structure of MOF-48 has the topology of a decorated B network of CaB_6.[13]

The crystal structure of MOF-49, $Zn_7(m\text{-}BDC)_6(OH)_4(H_2O)_2{\cdot}6DMF{\cdot}4H_2O$, is constructed from a unit composed of four tetrahedral and three octahedral Zn(II) centres in which two identical units, each composed of two tetrahedra and one octahedron, are joined together by an octahedron (Fig. 2a). Within each such unit, the carboxylates of four *m*-BDC links bridge the zinc centres in a dimonodentate fashion, and an additional two links bind as monodentate to the tetrahedral zinc

 DOI: 10.1039/b108684g

centres. Each unit also contains two μ_3-OH groups (their identity was confirmed as in MOF-48) and only one terminal water ligand bound to each octahedral centre.

In the crystal structure of MOF-49, a total of twelve carboxylates per formula unit in which carboxylate C atoms are found to lie on the vertices of a large, distorted cuboctahedral SBU (Fig. 2b). Here each SBU is bridged to six others *exclusively* through pairwise connections resulting in an extended framework having a topology similar to MOF-48, in that it is also related to the B network of CaB_6. MOF-49 contains a 3-D porous system with 3.5–5.5 Å diameter voids, where six DMF and four water molecules per formula unit reside as guests.

It is instructive to note that although the SBUs observed in MOF-48 and -49 have overall geometries generally associated with higher coordination (10 and 12), their large size combined with the short link do not allow for high coordination of the SBU in the solid state, as that would be sterically disfavoured. Instead the SBUs are reticulated into frameworks having six-coordination around each SBU; this made possible by the pairwise binding of links. Another factor that may be operating here was revealed upon close examination of distances between benzene rings of pair members: distances in the ranges 3.246–3.634 Å (MOF-48) and 3.315–3.725 Å (MOF-49) were found—values that indicate strong π–π intermolecular forces, and point to the possibility of their relevance in achieving lower coordination SBUs. It will be necessary to use *branched* links in order to attain SBUs with higher coordination as recently demonstrated for seven coordinated SBUs in MODF-1.[14]

Calculations of the space occupied by guests in MOF-48 and -49 indicate that it represents 50% of the crystal volume. The mobility of guests within their frameworks was assessed by thermal gravimetric studies: Here, 8.711 mg (MOF-48) and 17.23 mg (MOF-49) were heated over a range of 30–400 and 30–650 °C, respectively. For MOF-48, 25.8% weight loss was observed in the range 50–380 °C, which is equivalent to the loss of six DMF molecules per formula unit (calc.: 22.6%) representing four DMF guests and two DMF ligands. While for MOF-49, 16.95% weight loss was observed in the range 30–140 °C, which is equivalent to the loss of 3.5 DMF guests and four water guests per formula unit (calc.: 17.34%) representing the 3.5 DMF guest molecules and four water guest molecules found in the air-dried samples subjected to elemental microanalysis.† Experimentation is currently underway to examine whether the evacuated forms of MOF-48 and -49 can maintain their porosity in the absence of guests.

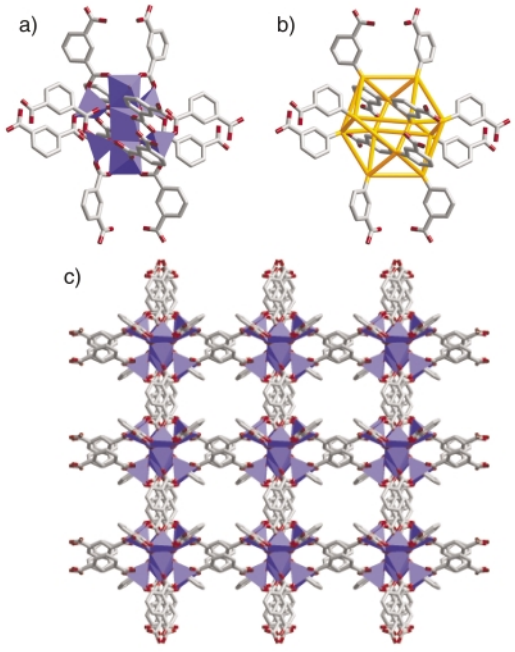

Fig. 2 MOF-49: (a) $Zn_7(m\text{-}BDC)_6(OH)_4(H_2O)_2$ unit showing the coordination around four tetrahedral and three octahedral zinc atoms. (b) A cuboctahedron SBU is shown in orange. (c) Extended structure along [001], DMF and water guests and all hydrogen atoms have been omitted for clarity (same colour scheme and drawing conditions as in Fig. 1).

This study has prompted us to focus on examining the role of intermolecular forces and the geometry of the link on the symmetry, size and coordination number of SBUs, aspects central to design of MOFs.

We acknowledge support of this work by the National Science Foundation.

First published as an Advance Article on the web 9th November 2001

Macroporous α-Al_2O_3 hollow fibers are used as supports for thin dense Pd membranes; these membranes show a high and stable H_2 flux in permeance studies.

The increasing demand for H_2 as an energy carrier or chemical in the petroleum industry has promoted research interest in H_2 production, purification and utilization all over the world.[1] As an advanced technology with a compact apparatus and high efficiency, metallic Pd-based membranes have occasionally been applied to separate and purify H_2 for electronic, metallurgic and fine chemical applications.[2] However, the commercialization of Pd-based technology on a large scale does not appear to be likely in the near future, although this technology has been shown to have great potential[3–5] in last four decades. The high cost of membranes, still too low permeability and long-term stability and low separation area/volume ratios are some of most important obstacles[6,7] to wide acceptance in industry.

Hollow fibers (HFs) are known for their much higher separation area/volume ratios, in comparison to other geometries such as plates, discs, tubes and multichannels.[8] The objective of this work was to deposit ultrathin dense Pd membranes on macroporous α-Al_2O_3 HFs since thin membranes can reduce the cost and improve H_2 permeability.

α-Al_2O_3 HFs are produced by a spinning-extrusion technique.[9] Typical HFs have an outer diameter of 700–800 μm, an inner diameter of 500–600 μm and an average pore size of 0.2 μm. Boehmite sol was modified with palladium complexes.[10] A modified sol prepared in this manner was coated on HF surfaces by a dip-coating process, based on capillary forces of the support pores,[11] while applying a vacuum on the inner side of the HFs. The particle size of the sol was 60–100 nm, which was smaller than the size of support pores. Therefore with the aid of the vacuum on the inner side of the HFs, there was some penetration of sol particles into the pores, which improved the adhesion between the top layer and the support. After calcination at 750 °C in static air, the average pore size of Pd/γ-Al_2O_3 was determined by the N_2 adsorption–desorption technique to be around 5.7 nm. SEM micrographs of these porous Pd/γ-Al_2O_3 membranes showed a very smooth surface. No defects or pinholes were observed in the scanned area. Both the narrow pore size distribution and smooth surface of the substrate make it possible to deposit ultrathin Pd membranes without defects.[12] After reduction in flowing H_2 at 200 °C, substrates with palladium species uniformly distributed in γ-Al_2O_3 were used for electroless plating.

The electroless plating process was developed by Rhoda,[13] which is based on an autocatalytic reaction between $[Pd(EDTA)]^{2-}$ and hydrazine. The palladium seeds introduced during modification of the boehmite sol act as catalysts for the chemical reaction and as nuclei for deposition and growth of Pd membranes. Fig. 1 shows SEM micrographs of a thin dense Pd membrane supported on a porous Pd/γ-Al_2O_3/α-Al_2O_3 HF. The surface of the porous substrate was fully covered by a continuous Pd membrane, which grew by nucleation at and growth of the small palladium crystals. No defects or pinholes were observed on the surface. The Pd membrane was around 0.6 μm thick after 1 h deposition, as can be seen from Fig. 1(b).

Gas permeation through dense Pd/ceramic HFs were measured at 335–400 °C with the permeate side set at atmospheric pressure. These membranes are composed of a 2–3 μm thick Pd membrane and a porous substrate, comprising of a mesoporous Pd/γ-Al_2O_3 layer (3–4 μm thick) supported on α-Al_2O_3. Each layer contributes some resistance to gas transport, which is defined as the reciprocal of H_2 permeance. The substrate has an H_2 permeance of 170–200 $m^3\ m^{-2}\ h^{-1}\ bar^{-1}$ while that of the dense Pd membrane is 8.8 $m^3\ m^{-2}\ h^{-1}\ bar^{-1}$ at 400 °C. Therefore the resistance of the substrates can be neglected, since it represents only 5% of the total resistance. H_2 transport through the composite membranes can thus be essentially discussed in terms of the Pd membrane itself.

H_2 transport through a Pd membrane follows a solution–diffusion mechanism, which involves several steps: (1) reversible dissociative adsorption of H_2 on the membrane surface; (2) diffusion of atomic hydrogen in the bulk metal under the driving force of concentration gradients; (3) recombination of hydrogen atoms to molecules on the opposite surface and desorption into the gas phase. The H_2 flux can be described by the integration of Fick's law [eqn. (1)]:

$$J = (D/l)(P_h^n - P_l^n) \quad (1)$$

where D is the diffusion coefficient, l is the membrane thickness, P_h and P_l are the pressures on each side of membrane

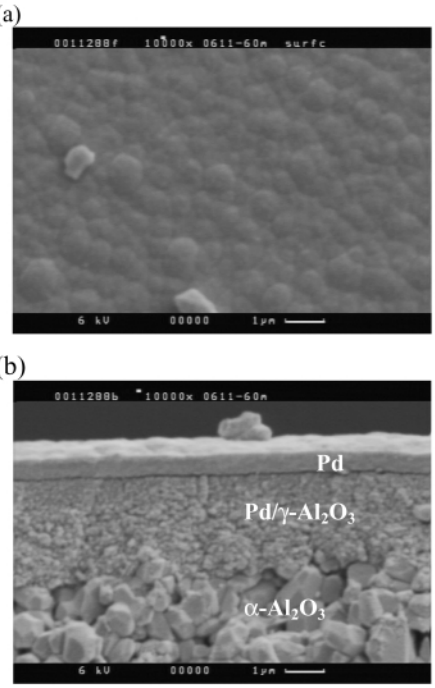

Fig. 1 SEM micrographs of a dense Pd membrane on a ceramic hollow fiber: (a) surface view; (b) cross-sectional view.

 DOI: 10.1039/b108395c

and n is the pressure exponent, which reflects the mechanism of H_2 transport. In thick membranes, the surface process of H_2 adsorption and desorption is very fast compared to the bulk diffusion and H_2 transport is often controlled by the bulk diffusion. In this case, $n = 0.5$, so that H_2 permeance is proportional to the square root of H_2 pressures on either side of the membrane.[3] With a decrease of membrane thickness, the resistance of the bulk diffusion reduces, so that the resistance of the surface process becomes increasingly significant. When both the surface process and bulk diffusion control H_2 transport, $0.5 < n < 1$. With a further decrease of membrane thickness, the surface process dominates, and n tends to unity.

As seen in Fig. 2(a), the H_2 permeance shows a linear relationship with the pressure difference across the membranes in the temperature range 335–400 °C, indicating that $n = 1$. This implies that the reaction of hydrogen with the Pd surface is the rate-determining step rather than bulk diffusion.[14] The thin Pd membrane (2–3 μm) reduces the resistance of bulk diffusion of hydrogen in the metal, so that the surface process becomes the rate-determining step. Moreover, Fig. 2(a) shows that the H_2 permeance increases with temperature: from 6.5 $m^3\ m^{-2}\ h^{-1}\ bar^{-1}$ at 335 °C to 8.8 $m^3\ m^{-2}\ h^{-1}\ bar^{-1}$ at 400 °C. These membranes have a fairly high permance compared to thick membranes previously investigated.[15,16] Fig. 2(b) shows the Arrhenius relation of H_2 permeance as a function of the temperature in the range 335–400 °C. The activation energy for H_2 transport was calculated to be 15.8 kJ mol^{-1}, similar to a recently reported value.[17]

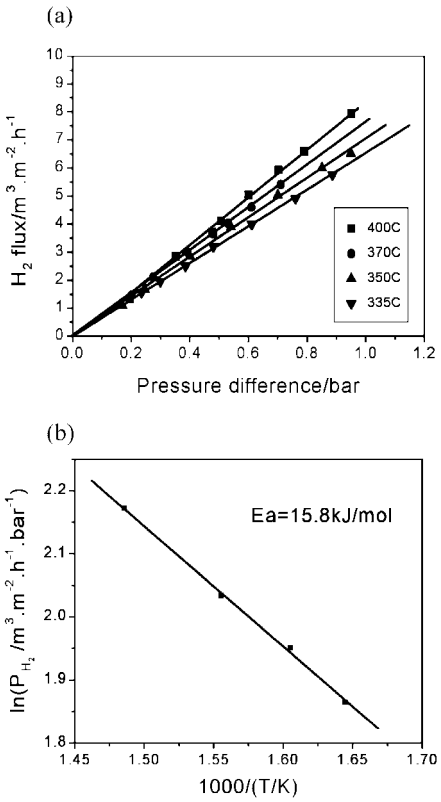

Fig. 2 H_2 transport through ultrathin Pd/ceramic hollow fiber membranes: (a) influence of the temperature and pressure difference; (b) Arrhenius relation between the H_2 permeance and temperature in the range 335–400 °C.

For applications in industry, membranes should have a good long-term stability, which was tested here for H_2 permeation at 430 °C for 660 h. Before applying high temperatures, no He flux was detected at a pressure difference of 1.2 bar at room temperature. This implies that these membranes are fairly gas-tight. At 430 °C, N_2 permeance was detected as 0.019 $m^3\ m^{-2}\ h^{-1}\ bar^{-1}$. This might be attributed to some leakage through the sealing at high temperatures or formation of defects during heating. There is probably some stress in the ultrathin Pd layer after the electroless deposition which may be released during heating, which might cause small defects. Either possible defects or possible leakage through the sealing will lead to transport of inert gases. After 660 h H_2 permeation, there was only a slight decrease in H_2 permeance, which remained > 11 $m^3\ m^{-2}\ h^{-1}\ bar^{-1}$. The ideal separation factor $\alpha(H_2/N_2)$ (defined as the ratio of permeances of pure H_2 to pure N_2) was > 1000. Such membranes are applicable in catalytic reactions to enhance conversions and/or selectivities.[18]

In conclusion, ultrathin dense Pd membranes have been successfully deposited on hollow fiber substrates. The resulting composite membranes not only provide high separation area/volume ratios, but also reduce the cost and improve the permeability with a high separation factor. These membranes show a good durability in H_2 permeation, which is important for industrial applications in H_2 separation and membrane catalysis.

We gratefully acknowledge Mr N. Specognia for SEM measurements and Dr A. Goldbach for many discussions and constructive suggestions in this work.

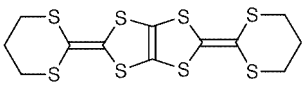
First published as an Advance Article on the web 9th November 2001

The title charge-transfer (CT) salt exhibits metallic conducting behavior with a metal-to-insulator (MI) transition at 113 K, and its magnetic properties reveal that it is an antiferromagnet below the Néel temperature, T_N = 8.5 K.

Recent studies on the development of molecular magnetic conductors by combining organic π-electron donors and inorganic magnetic anions have resulted in a new class of CT salts with multifunctional properties such as antiferro- and ferro-magnetic organic metallic behavior,[1,2] and antiferromagnetic organic metals exhibiting superconductivity.[3] However, these CT salts, in which magnetic order and metallic conductivity coexist, are derived from tetrachalcogenafulvalene (TCF) donors. Meanwhile, the successful formation of metallic or superconducting CT materials consisting of non-TCF donors and magnetic anions remains as a challenging subject in this research area.[4] The Fe-containing BDA-TTP salts in this regard would be promising candidates, because we have already found that BDA-TTP, a sulfur-based π-donor containing no TTF functionalities, produces superconducting salts with relatively large anions, such as SbF_6^-, AsF_6^-, and PF_6^-.[5] In this paper we report on the preparation and crystal structure of β-(BDA-TTP)$_2$FeCl$_4$ and also on its electrical conducting and magnetic properties.

Electrocrystallization of BDA-TTP (0.08 mmol) with Et_4N-$FeCl_4$ (0.43 mmol) in 5% EtOH–PhCl (60 mL) by the controlled-current method[6] gave two types of crystals; preliminary X-ray analyses revealed that the black plate crystals had a β-type structure [designated as β-(BDA-TTP)$_2$FeCl$_4$] while the more pale black plate-like crystals are solvated with composition (BDA-TTP)$_3$FeCl$_4$·PhCl.†

Fig. 1(a) shows the crystal structure of β-(BDA-TTP)$_2$FeCl$_4$, which consists of one $FeCl_4^-$ anion and two crystallographically independent BDA-TTP molecules. In this salt, the BDA-TTP molecules and the $FeCl_4^-$ anions are arranged in alternating layers along the *b* axis, so that the Fe···Fe distance between the most adjacent anions along the *b* axis [19.535(6) Å] is significantly longer than those along the *a* and *c* axes [6.227(3) and 7.731(4) Å]. Two independent BDA-TTP molecules have similar molecular structures, in both of which the two outer dithiane rings adopt nonequivalent chair conformations: their respective dihedral angles around the intramolecular sulfur-to-sulfur axis in one BDA-TTP molecule are 38.6 and 13.0°, and the corresponding angles in the other are 39.1 and 13.0° (Fig. 2). Thus one dithiane ring of each independent BDA-TTP molecule is much flatter than that of each BDA-TTP molecule in the superconducting BDA-TTP salts.[5] The BDA-TTP molecules form slipped stacks along the



BDA-TTP

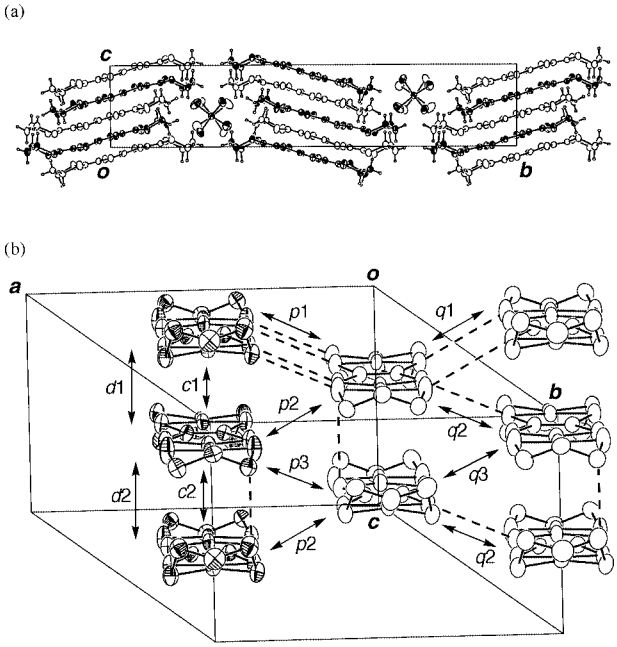


Fig. 1 (a) Crystal structure of β-(BDA-TTP)$_2$FeCl$_4$ viewed down the *a* axis; open circles indicate the back molecules. (b) Donor arrangement of β-(BDA-TTP)$_2$FeCl$_4$. Hydrogen atoms are omitted for clarity. The interplanar distances of the BDA-TTP column are 3.56 (*d*1) and 3.89 (*d*2) Å. Intermolecular S···S contacts (< 3.70 Å) are drawn by broken lines. The values of intermolecular overlap integrals ($\times 10^{-3}$) *c*1, *c*2, *p*1, *p*2, *p*3, *q*1, *q*2 and *q*3 are 14.4, 13.5, 1.88, −7.34, 3.44, 6.99, −5.62 and 5.49, respectively.

c axis with some dimerization (average interplanar distances of 3.56 and 3.89 Å), so as to avoid the steric hindrance of the less flat dithiane ring. There is only one S···S contact shorter than the sum of van der Waals radii (3.70 Å) within the stack, while several short intermolecular S···S contacts exist between stacks (Fig. 1(b)). These S···S contacts, however, do not always reflect the magnitude of the intermolecular overlap integrals, calculated on the donor layer in the *ac* plane by the extended Hückel method.[7] It is noteworthy that the largest overlap integral (14.4 $\times 10^{-3}$) is almost equal to those found in the superconducting

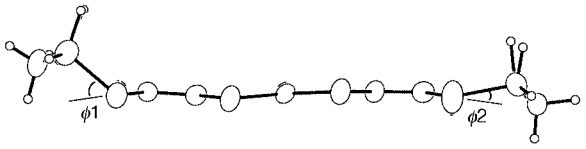

Fig. 2 Molecular structure of one BDA-TTP unit in β-(BDA-TTP)$_2$FeCl$_4$. The dihedral angles ϕ1 and ϕ2 are 38.6 and 13.0°, whereas the corresponding angles in the other BDA-TTP are 39.1 and 13.0°.

 DOI: 10.1039/b105264k

BDA-TTP salts,[5] suggesting that the BDA-TTP molecules in this salt are also packed loosely.

The four-probe resistivity of β-(BDA-TTP)$_2$FeCl$_4$ as a function of temperature indicated that this salt, with a room-temperature conductivity (σ_{rt}) of 9.4 S cm^{-1}, is metallic from room temperature down to 113 K, at which temperature it undergoes a sharp MI transition (Fig. 3). Although the reason of this MI transition is not clear, the charge separation between two independent donors in the column may be considered as a cause. Fig. 4 shows the temperature dependence of the magnetic susceptibility of this salt measured by using a SQUID magnetometer at 1000 Oe from 300 to 2 K. The susceptibility can be well fitted to the Curie–Weiss law over the whole temperature range 40–300 K, and the values of the Curie and Weiss constants are 4.48 emu K mol^{-1} and −15.1 K, respectively. The fitted Curie constant is close to the value of 4.38 emu K mol^{-1} calculated for a high-spin Fe^{3+} ion (S = 5/2, g = 2.0), so that the Fe in the anion certainly dominates the measured magnetization. Below 40 K, the susceptibility increased to a maximum near 8.5 K, after which it decreased rapidly. As shown in the inset of Fig. 4, the susceptibilities, which were measured under magnetic fields (1000 Oe) applied along the directions approximately parallel to the *a*, *b* and *c* axes, were anisotropic below near 8.5 K, indicating antiferromagnetic ordering with T_N of near 8.5 K. Below T_N, the easy spin axis seems to lie close to the intrastacking *c*-direction of the donor molecules. So, considering that the shortest Fe···Fe distance along the *c* axis is longer than 6 Å, the donor molecules could mediate the observed antiferromagnetic order between the Fe^{3+} ions.[8]

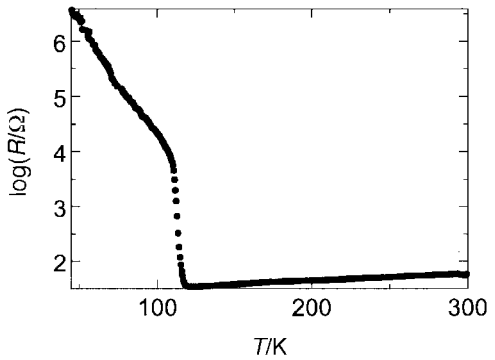

Fig. 3 Temperature dependence of the resistance of β-(BDA-TTP)$_2$FeCl$_4$.

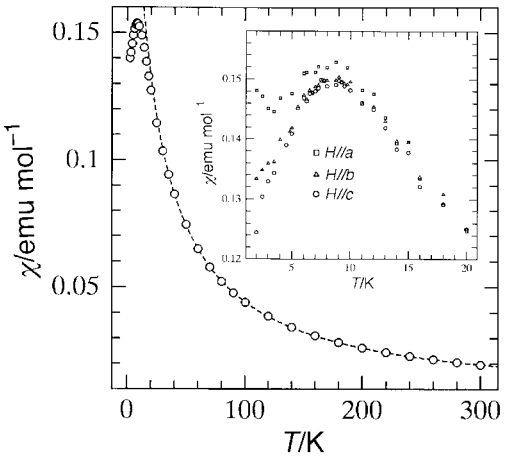

Fig. 4 Temperature dependence of the susceptibility of β-(BDA-TTP)$_2$FeCl$_4$. The dashed line is a Curie–Weiss fit (see text). The inset shows magnetic anisotropies in magnetic fields approximately parallel to the *a*, *b* and *c* axes (*H*//*a*, *H*//*b*, and *H*//*c*).

On the other hand, the solvated (BDA-TTP)$_3$FeCl$_4$·PhCl salt is a semiconductor with a thermal activation energy of 0.11 eV (σ_{rt} = 2.0 × 10^{-2} S cm^{-1}) and exhibited Curie–Weiss behavior from 300 to 2 K. The fitted Curie constant is 4.42 emu K mol^{-1} and the Weiss constant is –0.35 K, suggesting very weak antiferromagnetic interaction between the Fe moments. The structural characteristics of this salt will be report elsewhere.

In conclusion, following the discovery of superconducting BDA-TTP salts, we found a new BDA-TTP salt that displays metallic conductivity as well as antiferromagnetism. To search for a new system capable of enhancing further the interaction between conduction π-electrons of donors and localized d-spins of anions, the preparation of CT salts composed of BDA-TTP or related π-donors and other magnetic anions is currently underway.

Received (in Cambridge, UK) 10th September 2001, Accepted 26th October 2001
First published as an Advance Article on the web 8th November 2001

A new chloro-bridged single-helical chain has been constructed from a ferrocenyl-containing tetranuclear double-helical architecture *via* self-assembly

Helical complexes have elegantly illustrated how the specific formation of architecturally complex assemblies are directed by the interplay between relatively simple parameters such as the stereoelectronic preference of the metal and the disposition of the binding sites of the helicands (helicating ligands).[1] While the basic features of the design necessary to assemble a double helix are now fairly well established,[2] the design and control of assembly of the helical unit into a multi-helical array represents a considerable synthetic challenge.[3,4] Sophisticated supramolecular targets will require the ability to assemble small molecular units which may be further aggregated in a controlled fashion. To achieve this, a five-coordinated copper(II) ion is chosen to build the unsaturated double helicate, which contains binding sites on its interior. It is suggested that the five-coordinate geometry of the copper(II) ion may prevent the formation of a triple helicate and that the metal centers incorporated into the helicate framework will not use all of their coordination sites in the construction process. We reasoned that these unused coordinated sites might then be bound by additional mono- or bi-dentate coordinated ligands such as bridging groups or anions. Here we report what we believe to be a unique helical structure motif in inorganic supramolecular architectures through self-assembly, where single-helical 1D chains are constructed from double-helicates *via* chloro-bridging.

The chosen ligand designed here is an easy-to-prepare ferrocenyl-containing imine-based bis-bidentate system. The introduction[5] of a ferrocenediyl unit as a spacer to separate the two metal binding sites is chosen not only because such a spacer is suitable to assemble double-helices, but also because molecules containing metallocene units can retain a particular metal ion at its coordination site whilst undergoing a concurrent redox change.

An ethanol solution of $CuCl_2{\cdot}2H_2O$ was added to a mixture of diacetylferrocene and 2-hydrazinopyridine in absolute methanol followed by addition of NH_4BF_4; after 24 h, dark-red crystals of **1** were obtained.† In the electronspray mass spectrum of **1**, a peak at *m/z* 1066.5, corresponding to the $[Cu_2(L - H)_2Cl]^+$ cation, in which one of the hydrogen atoms attached to the imine nitrogen atom in each ligand is lost, indicates the formation of a 2:2 (ligand:metal) coordination stoichiometry. An X-ray crystallographic study‡ has unequivocally confirmed the existence of a tetranuclear cationic unsaturated double helicate.

Fig. 1 shows one of the two enantionmers of the double helicate. Each ligand wraps around the two copper(II) cations with a copper–copper separation of 8.4 Å and the two iron centers are separated by a distance of 6.4 Å. The four metal centers are co-planar and form a slightly distorted rhombus with sides of 5.2 and 5.3 Å. Each copper center is coordinated to two pyridyl imine units, one from each ligand, to form the unsaturated double helicate while the fifth coordination site is occupied by a chloride ion. The value of the topological parameter[6] τ of *ca.* 0.6 indicates an intermediate structure between square pyramidal and trigonal bipyramidal for copper but more towards the trigonal bipyramidal limit. The EPR spectrum of the complex also indicates a trigonal bipyramidal stereochemistry.[7] The pyridines are twisted by *ca.* 39° from the Cp rings to which they are attached with dihedral angles between the two pyridine rings in each ligand being *ca.* 38° on average. It is interesting that the helicate is also stabilized by intramolecular π–π stacking interactions between the pyridine rings of one ligand and the Cp rings of the other. The dihedral angles of the stacked pairs lie in the range 17.4–33.5° with center-to-center separations of the stacked pairs in the range 3.47–3.81 Å.

The most distinctive structural feature of the complex in the solid state is that each enantiomer of the double helicate links to its symmetry-related equivalents to form an infinite monochiral helical polymer (Fig. 2) *via* single chloro-bridges. The bridging chloride coordinates to two copper centers with a Cu–Cl–Cu angle of 124.6(1)° and Cu···Cu separation of *ca.* 4.29 Å. It is particularly striking that the helices in one chain are all of a single enantiomer. Each chain exhibits a crystallographic 2_1 single helix with a pitch twice that of the crystal cell *b* axis. The chains lie parallel to each other and align themselves along

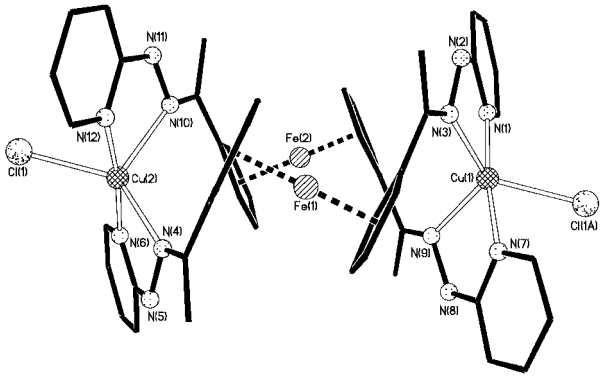

Fig. 1 Molecular structure of the double helicate with hydrogen atoms omitted for clarity. (Symmetry code A: $-x$, $-0.5 + y$, $0.5 - z$).

 DOI: 10.1039/b108206j

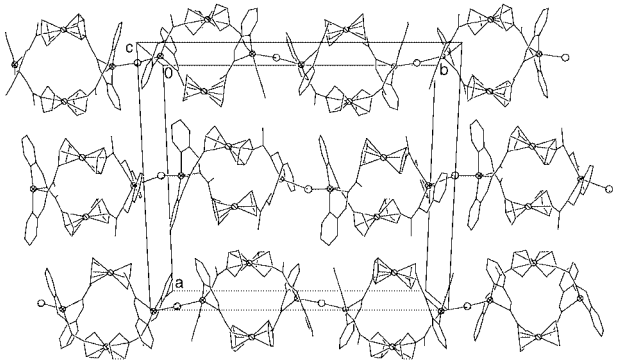

Fig. 2 Molecular packing along the *b*–*c* plane showing the one-dimensional mono-helical chains; solvent molecules, hydrogen atoms and anions are omitted for clarity.

the (0,1,0) direction. It is interesting that the pyridine ring containing nitrogen atom N(1) is almost parallel to the related pyridine ring containing nitrogen atom N(6A) (symmetry code A: $-x$, $-0.5 + y$, $0.5 - z$) of an adjacent double-helicate in an adjacent chain (dihedral angle between the two planes is *ca.* 6.4°) with a close intermolecular separation between the stacked pair of *ca.* 3.5 Å. Although these stacking interactions are weak compared to the metal–nitrogen and metal–chlorine coordination bonds,[8] such interactions may well be important in the molecular assembly of double helicates and mono-helical chains.

Bridged biferrocenes have been proven to be good candidates for mixed-valence compounds. Differential pulse voltammetry of **1** (Fig. 3) shows two peaks with half-wave potentials ($E_{1/2}$) at 0.75 and 0.58 V, respectively, corresponding to the two single-electron oxidations of the ferrocene moieties. The ΔE value of *ca.* 0.17 V indicates strong interactions between two ferrocene moieties. A similar separation ΔE has also been found for the two single electron reductions (Cu^{II}/Cu^{I}) with two peaks at 0.29 and 0.14 V, respectively.

The assembly of helical units into a multi-helical array is interesting in terms of controlled aggregation of helices. The generation of a helical motif derived from an inexpensive and readily prepared ferrocene containing ligand enables extension of self-assembly through the use of helicates as building blocks by judicious design and control. The development of new ligand systems containing functional ferrocene groups and the application to aggregation of small supramolecular units into large multi-helical arrays are in progress.

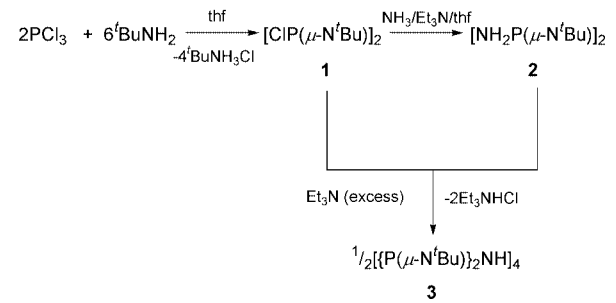
Received (in Cambridge, UK) 28th August 2001, Accepted 25th October 2001
First published as an Advance Article on the web 22nd November 2001

The 1:1 reaction of the symmetrical dimers $[ClP(\mu\text{-}N^tBu)]_2$ 1 and $[H_2NP(\mu\text{-}N^tBu)]_2$ 2 in thf–Et_3N gives the tetrameric macrocycle $[\{P(\mu\text{-}N^tBu)\}_2NH]_4$ 3 (67%); consisting of four $P_2(\mu\text{-}N^tBu)_2$ rings linked by *endo* N–H groups.

Although the study of macrocyclic organic ligands, such as crown ethers, calixarenes and cyclophanes,[1] is an ever-growing field of research, in comparison there are very few counterparts based on frameworks other than those of carbon. A major problem in such inorganic systems is establishing general and selective synthetic strategies to cyclic inorganic frameworks that avoid polymerisation or other undesired modes of aggregation. Mercuracarborands[2] and cyclic s-block amides[3] are two recently explored classes of inorganic ligands that behave as Lewis acids in their coordination of various anions. Particularly rare, however, are inorganic macrocycles which have the ability to act as Lewis bases; for example certain cyclophospha(v)zenes, such as $[P(NMe_2)_2N]_6$,[4] and Si/N macrocyles of the type $[(R_2Si)NH]_4$.[5] In earlier work we characterised the neutral Group 15 macrocycle $[\{Sb(\mu\text{-}NR)\}_2(\mu\text{-}NR)]_6$ (R = 2-$MeOC_6H_4$), composed of six $[Sb(\mu\text{-}NR)]_2$ rings linked into a cyclic structure by μ-NR groups.[6] Owing to the more robust nature of P–N bonds compared to other Group 15 element–nitrogen bonds, we have more recently begun to extend studies in this area to related cyclophospha(III)zanes,[7,8] with the aim of producing more generally useful and (possibly) air-stable ligand arrangements. We report here the selective, high yielding synthesis of a neutral cyclophospha(III)zane macrocycle $[\{P(\mu\text{-}N^tBu)\}_2NH]_4$ **3**, *via* the reaction of $[ClP(\mu\text{-}N^tBu)]_2$ **1** with $[NH_2P(\mu\text{-}N^tBu)]_2$ **2** (Scheme 1).

The dimer $[ClP(\mu\text{-}N^tBu)]_2$ **1** is readily prepared by the 1:3 stoichiometric reaction of PCl_3 with $^tBuNH_2$ in thf (67%).† This method is different from that reported in the literature, involving the reaction of $^tBuNH_2$, PCl_3 and Et_3N (3:2:3 equivalents, respectively).[8] However, very little of the monochloride $[^tBuNHP(\mu\text{-}N^tBu)PCl]$[7,8] is isolated after distillation of **1** from the reaction, despite the use of excess of $^tBuNH_2$. The slow addition of **1** to a saturated solution of NH_3 in thf–Et_3N at −78 °C produces $[NH_2P(\mu\text{-}N^tBu)]_2$ **2**.† Very few impurities are present in the ^1H and ^{31}P NMR spectra of the crude product (obtained in 48% yield), which can be used without further purification. The 1:1 stoichiometric reaction of **1** with **2** in thf–Et_3N was followed by variable-temperature ^1H and ^{31}P NMR spectroscopy. This study showed that the conversion to the macrocyle $[\{P(\mu\text{-}N^tBu)\}_2NH]_4$ **3** is *ca.* 100% efficient (with only minor traces of other products being generated). The selectivity of this reaction and the almost quantitative formation of **3** can be attributed to the known preference for the phosphazane dimers $[XP(\mu\text{-}NR)]_2$ to adopt the *cis* isomer in solution and in the solid state,[8,9] *i.e.* pre-organisation of the precursors. Indeed, the *cis* isomer of **1** has previously been shown to be preferred[10] and, although the structure of **2** is not known at this stage, the relatively low ^{31}P chemical shift observed (δ 100.2) is strongly indicative of a *cis* conformation (normally in the range δ 96–108; *cf.* δ 166–185 for *trans* isomers).[11] Subsequent scaling up of the reaction allows **3** to be obtained in 67% (crude) yield (the overall conversion of PCl_3 and $^tBuNH_2$ to **3** being *ca.* 30%).† Again, ^1H and ^{31}P NMR studies reveal that the crude product is extremely pure (estimated 95–100%, over several reactions). The ^{31}P NMR spectrum of **3** shows that a single species exists in solution, with a singlet resonance being observed at δ 129.5 over a wide temperature range. This chemical shift compares to δ 117.2 for the related dimer $[\{P(\mu\text{-}N^tBu)\}_2N^tBu]_2$.[12] Compound **3** is relatively air-stable, air-exposure for greater than *ca.* 6 h leading only to slight decomposition, with the appearance of minor new resonances in both the ^{31}P and ^1H NMR spectra.



Scheme 1

The low-temperature X-ray structure of **3** shows that its macrocyclic backbone arises from cyclic tetramerisation of four $[\{P(\mu\text{-}N^tBu)\}_2NH]$ units [Fig. 1(a)].‡ Although these units are crystallographically independent, the pattern of bond lengths and angles in **3** is very regular. As a result, the twelve atoms of the $(P\cdots P\text{–}N)_4$ fragment defining the macrocycle deviate by only *ca.* 0.07 Å from their mean plane, and the transannular N···N separation between opposite pairs of N centres differ by only *ca.* 0.067 Å (mean 5.221 Å). The planes of the four $[P(\mu\text{-}N^tBu)]_2$ rings are aligned almost exactly perpendicular to the macrocyclic plane (the associated dihedral angles with respect to the macrocyclic plane being in the range 87.0–93.2°), giving the ligand periphery of **3** an overall torus-shape. The only noticeable distortion in the structure of **3** arises from the steric crowding of the ^{t}Bu groups above and below the macrocycle. As a consequence, two of the four ^{t}Bu groups on either side [attached to N(1) and N(5), and N(4) and N(8)] are forced out of the planes of their P_2N_2 rings. However, this distortion has only a marginal effect on the P–N bonding within the P_2N_2 ring units; resulting in small variations in the associated P–(μ-N) bond lengths (by *ca.* 0.03 Å) and P–N–P angles (by *ca.* 2°).

The closest relatives to **3** are cyclophosphazanes of the type $[\{P(\mu\text{-}NR)\}_2NR]_2$, consisting of two $P_2(\mu\text{-}NR)_2$ rings linked into a cyclic arrangement by bridging NR groups.[12,13] The formation of a tetrameric macrocyle for **3** (as opposed to a cyclic dimer, $[\{P(\mu\text{-}N^tBu)\}_2NH]_2$) primarily results from the presence of sterically undemanding NH groups linking the $[P(\mu\text{-}N^tBu)]_2$ units; this allows the *cis* conformation of the constituent units to be retained in **3**, without producing steric congestion at the centre of the macrocylic cavity. It is interesting in this regard that the increased steric effects associated with the NR groups linking the $[Sb(\mu\text{-}NR)]_2$ units in $[\{Sb(\mu\text{-}NR)\}_2(\mu\text{-}NR)]_6$[6] (R = 2-$MeOC_6H_4$, Ph) results in the adoption of a *trans* conformation

Key bond lengths (Å) and angles (°); P–N(9–12) mean 1.703 [range 1.697(2)–1.709(2)], ring P–N mean 1.725 [range 1.710(2)–1.740(2)], N(9)···N(11) 5.255(4), N(10)···N(12) 5.188(4), P–N(9,10,11,12)–P mean 127.8, endocyclic N–P(1–8)–N mean 81.4, exocyclic N–P(1–8)–N mean 103.5, P–{μ–N(1–8)}–P mean [range 97.6(1)–99.6(1)]; (b) Space-filling diagram (top view).

for these constituents. This *trans* conformation provides the most probable reason for the greater size of the macrocyles obtained in these cases, since the formation of a smaller ring composed of *trans* constituents would be more strained.

The presence of four N–H protons within the macrocyclic structure of **3** is reminiscent of a tetraazacyclotetradecane (*i.e.* based on $[CH_2CH_2NH]_4$),[14] while the molecules possess a ligand periphery that is analogous (spatially) to calixarenes.[1] Although the macrocyclic cavity of **3** is apparently sterically crowded [Fig. 1(b)], the rearrangement of the ligand framework to accommodate metal centres (upon deprotonation) may well be anticipated. This is suggested by the observed flexibility of the μ-N^{t}Bu groups within **3**. Studies of the coordination behaviour of **3** and of related P/N ligands are underway.

We gratefully acknowledge the EPSRC for financial support.

Notes and references

† *Syntheses*: **1**: to a solution of freshly distilled PCl_3 (16.6 ml, 0.190 mol) in thf (300 ml) at −78 °C was added dropwise ^{t}BuNH$_2$ (60 ml, 0.571 mmol) (the addition taking *ca.* 1 h). The mixture was stirred for a further 4 h at this temperature, then allowed to stir at room temperature for 12 h. The solvent was removed under vacuum and the colourless, crystalline mass formed was carefully distilled through a 10 cm Vigreaux column under vacuum (since the product rapidly solidifies, the condenser should not be cooled). The major fraction (86 °C, 2.0 mmHg) was collected (the minor 96 °C fraction is $[^tBuNHP(\mu\text{-}N^tBu)]_2$). Yield 17.6 g (67%, based on P supplied). ^{1}H NMR (d_6-benzene, +25 °C, 400.16 MHz), δ 1.25 (s, ^{t}BuN). ^{31}P NMR (d_6-benzene, +25 °C, 161.98 MHz), δ 207.6 (s).

2: A concentrated solution of NH_3 in thf–Et_3N was produced by condensing NH_3 gas into a mixture of thf (450 ml) and Et_3N (40 ml) at 25 °C for *ca.* 40 min. To this solution (at −78 °C) was added a solution of **1** (10.0 g, 36.4 mmol) in thf (250 ml) at −78 °C. After stirring at this temperature (3 h), the mixture was allowed to warm to room temperature and stirring was continued (12 h). The solvent was removed under vacuum and to the dried solid was added *n*-pentane (400 ml). The insoluble ammonium salts were removed by filtration and the filtrate reduced under vacuum to *ca.* 120 ml, whereupon precipitation of **2** occurred. This first batch was filtered off and dried under vacuum. A second batch was obtained by further reduction of the solvent to *ca.* 50 ml. Total yield 4.15 g (48%). Mp 110–115 °C. IR (Nujol, NaCl), ν/cm^{-1} 3402 (doublet, m), 3291 (doublet, m) (N–H str.). ^{1}H NMR (d_6-benzene, +25 °C, 400.16 MHz), δ 2.41 (d, $^2J_{^{31}P-H}$ 7.9 Hz, 2H, NH_2), 1.46 (s, 9H, ^{t}BuN). ^{31}P NMR (d_6-benzene, +25 °C, 161.98 MHz), δ 100.2 (s). ^{13}C NMR (100.1 MHz, d_8-toluene, rel. 80% H_3PO_4–D_2O), δ 51.33 (t, $^1J_{C-^{31}P}$ 13.3 Hz, C_α of ^{t}Bu), 31.17 (t, $^2J_{C-^{31}P}$ 6.8 Hz, Me of ^{t}Bu). Found C 40.1, H 9.2, P 25.5, Cl 0.2; Calc. C 40.8, H 9.3, P 26.3, Cl 0.0% (satisfactory N analysis could not be obtained, despite repeated attempts). The crude reaction product is of high purity and can be used in further reactions without purification.

3: A solution of **1** (0.50 g, 2.12 mmol) in thf (20 ml) was added dropwise to a solution of **2** (0.58 g, 2.12 mmol) in thf (100 ml) and Et_3N (1 ml) at −78 °C. The mixture was stirred for 3 h at this temperature and allowed to warm to room temperature before being stirred further (12 h). The solvent was removed under vacuum and the solid extracted with *n*-pentane (100 ml) and filtered. The filtrate was reduced to dryness under vacuum to give **3** as a white powder (0.62 g, 67%). Crystals of **3** were obtained from *n*-pentane–thf at 25 °C. The following data refer to the crude material. Partial melting *ca.* 130 °C, decomp. *ca.* 170 °C. IR (Nujol, NaCl), ν/cm^{-1} 3582 (sharp, w) (N–H str.). ^{1}H NMR (d_6-benzene, +25 °C, 400.16 MHz), δ 4.86 (s, 1H, N–H), 1.54 (s, 18H, ^{t}BuN). ^{31}P NMR (d_6-benzene, +25 °C, 161.98 MHz), δ 129.5 (s) (minor impurities may be seen at *ca.* δ 120, 75 and 0). Electrospray MS (+ve ion), *m/z* = 877.4 (tetramerH$^+$) (dominant), 658.4 (trimerH$^+$) (minor) (no dimerH$^+$). Satisfactory C, H and P analysis were obtained. ^{1}H and ^{31}P NMR spectroscopy indicate that the crude product obtained from the reaction without further purification is *ca.* 95–100% pure.

‡ *Crystal data* for **3**: $C_{32}H_{76}N_{12}P_8$, M = 876.81, orthorhombic, space group $P2_12_12_1$, Z = 4, a = 13.3936(2), b = 17.1372(4), c = 21.7137(5) Å, V = 4983.92(18) Å^3, μ(Mo–Kα) = 0.315 mm^{-1}, T = 180(2) K. Data were collected on a Nonius Kappa CCD diffractometer. Of a total of 25299 reflections collected, 8699 were independent (R_{int} = 0.040). The structure was solved by direct methods and refined by full-matrix least squares on F^2.[15] Final $R1$ = 0.036 [$I > 2\sigma(I)$] and wR 2 = 0.079 (all data).

Stacking of a benzenehexacarboxylic acid core in the crystal structure of benzenehexacarboxylic acid α-aminomethyl isobutyrate amide (MA-Aib$_6$)–sodium nitrate complex†

Subramania Ranganathan,*[ab] K. M. Muraleedharan,[a] C. H. Chandrashekhar Rao,[a] M. Vairamani,[c] Isabella L. Karle[d] and Richard D. Gilardi[d]

Received (in Columbia, MO, USA) 20th August 2001, Accepted 4th October 2001
First published as an Advance Article on the web 22nd November 2001

MA-Aib$_6$ forms discrete stacks with sandwiched water, sodium and nitrate ions, presenting a novel profile, where nine out of the 12 binding sites, of the six amides present, are involved in bonding with water, sodium and nitrate ions, with no inter-amide hydrogen bonding. This is the first example of the stacking of a benzenehexacarboxylic acid core.

The design and synthesis of conformationally constrained organic scaffoldings/templates that can potentiate controlled growth to protein secondary structure motifs, is of current interest.[1] Such structural mimics are important for the design of simple, low molecular weight pharmaceutical agents.[2] The present communication reports the synthesis of benzenehexacarboxylic acid α-aminomethyl isobutyrate amide (MA-Aib$_6$, $C_6[CONHC(CH_3)_2COOMe]_6$ (**1**) and the determination of its structure by X-ray crystallography. The choice of α-aminomethyl isobutyrate as the first spacer was logical because of the known ability of the Aib residue to control the growth of secondary structures.[3]

The tertiary carbon center present in Aib resisted the introduction of all the six units in a single step. The best conditions afforded only MA-Aib$_5$ mono imide (**2**), which, on *in situ* treatment with further Aib gave **1**. Thus, the reaction of hexamellitoyl chloride[4] with Aib-OMe under carefully defined conditions followed by chromatography on silica gel column and elution with ethylacetate–hexane afforded nearly pure MA-Aib$_6$ in 41% yield.[5] Re-chromatography under the same conditions afforded fine needles, mp 256–258 °C, that separated from the eluent (Fig. 1).

The crystal structure[6] of MA-Aib$_6$ (**1**) (Fig. 2) shows its assembly to layered stacks along a two-fold screw axis where molecules of MA-Aib$_6$ on the one hand and water and sodium nitrate on the other, form alternate layers (Fig. 2). The ester groups, projected vertically, do not participate in the assembly. The twelve α-methyl groups from each molecule form a neat ring around the stack. The pattern of the stack is repeated every 14.3 Å. Each stack is quite independent of the others and there are no hydrogen bonds between stacks or any interdigitation.

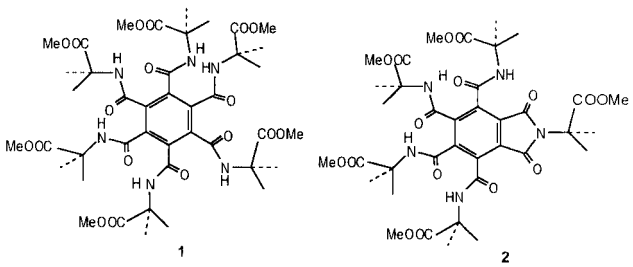

Fig. 1 Structure of **1** and **2**.

† Respectfully dedicated to Darshan Ranganathan, who passed away on June 4, 2001, her sixtieth brithday.

In the stack, shown with a central MA-Aib$_6$ flanked by two neighbors as presented in Fig. 2, the aromatic rings are tilted slightly along the two-fold screw axis by 2.9°. The sodium ion is penta-coordinated to two proximate carbonyls of the upper layer (Na···O30, 2.472 Å; Na···O40, 2.488 Å) and a single carbonyl from the middle layer (Na···O0, 2.255 Å), as well as to both water molecules (Na···W3, 2.463 Å, Na···W4, 2.415 Å). The short Na···O0 distance of 2.255 Å is found in penta-coordinated Na^+ complexes[7] but not for tetra- or hexa-complexes. The water molecules are, in addition, bonded to carbonyls from the middle layer (W3···O10, 2.872 Å; W4···O50, 2.813 Å), the NH of the upper layer (W3···N21, 3.011 Å; W4···N51, 2.996 Å) and the nitrate ion (W3···O1S, 3.102 Å; W4···O2s, 2.824 Å). In turn, the nitrate ion is an acceptor for the NH of the middle layer (N31···O1s, 2.984 Å) and NH in the upper layer (N1···O2S, 2.805 Å). Thus, of the twelve binding sites available in the hexa-amide **1**, five carbonyl groups and four NH units are used in a unique manner; while N11 and N41 do not participate in any manner. The absence of any inter amide hydrogen bonding and the strong involvement of the nitrate counter ion in the assembly are particularly noteworthy.

A schematic profile of the stacking is presented in Fig. 3.

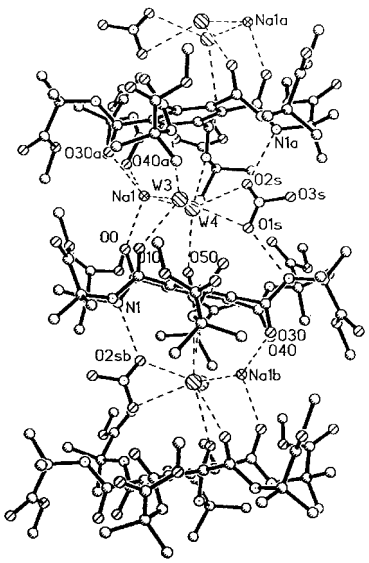

Fig. 2 The crystal structure of **1**. A Na^+ ion, NO_3^- ion and two water molecules (W_3 and W_4) are also indicated. The columnar stacking of molecules **1** alternating with Na^+ and NO_3^- ions and two water molecules. The dashed lines indicate the five ligands to Na^+ and hydrogen bonds between water molecules, the NO_3^- ion and **1**.

 DOI: 10.1039/b109465n

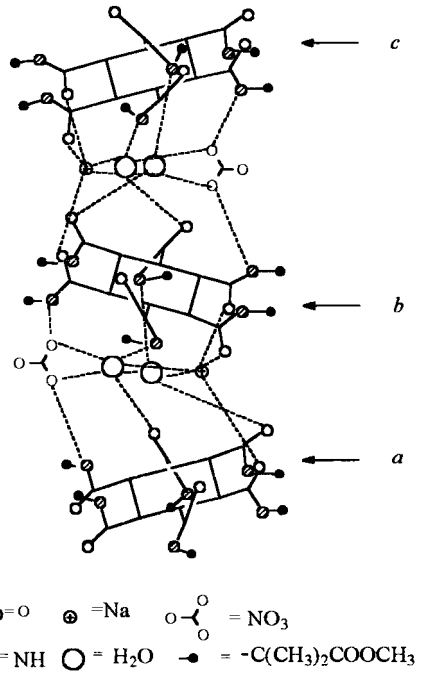

Fig. 3 Schematic drawing of the layered structure in a stack.

Using a sample of the crystal, the presence of sodium nitrate was confirmed by using positive and negative ion mass spectrometry. By negative ion mass spectrometry, the source of sodium nitrate was traced to the silica gel used for chromatography.[8] Chromatographically pure MA-Aib$_6$, freed of nitrate[9] when allowed to stand in ethyl acetate with dissolved sodium nitrate, deposited needles identical to that used for crystallographic studies.[10]

Futher experiments have shown that in the complexation of **1**, the nature of the metal ion is important. Thus, under identical conditions lithium nitrate formed the complex whereas potassium nitrate did not.[11] However it is very likely that in the assembly of **1** the nitrate ion, being large and with dispersed charge, plays a controlling role to the extent that the expected hydrogen bonding involving the amide bonds is not seen.

To the best of our knowledge, this is the first report of achieving the stacking of a benzenehexacarboxylic acid core. Crystallographic data currently available relating to mellitic acid, its esters and metal salts are unexceptional.[12]

Financial support was provided by the National Institutes of Health Grant GM-30902, the Office of Naval Research and the Department of Science and Technology, New Delhi.

4 Mellitic acid [1.62 g, 4.73 mmol] was digested with PCl_5 [9.8 g, 47 mmol] at 150 °C for 24 h, excess reagent and $POCl_3$ distilled off, the residue triturated with dry benzene [5 × 10 ml] and dried to give 1.8 g [84%] of hexamellitoyl chloride mp 245–247 °C, whose structure was confirmed by methanolysis to mellitic acid hexamethyl ester and comparison with an authentic sample.

5 A solution of hexamellitoyl chloride [0.48 g, 1.1 mmol] in dry CH_2Cl_2 (20 mL) and triethylamine (1 mL, 6.7 mmol) were simultaneously added, in drops, over a period of 0.5 h to an ice cooled and stirred solution of α-amino isobutyric acid methyl ester, generated *in situ* by addition of triethylamine (1 mL, 6.7 mmol) to an ice cooled and stirred solution of α-amino isobutyric acid methyl ester hydrochloride (1.48 g, 9.67 mmol) in dry CH_2Cl_2 (65 mL). The reaction mixture was left sitrred at room temperature for two days. After this period another batch of α-amino isobutyric acid methyl ester, precisely generated as described above from the hydrochloride (1.48 g, 9.67 mmol) in dry CH_2Cl_2, was introduced, the mixture left stirred for 2 d at rt, washed successively with saturated $NaHCO_3$ (2 × 15 mL), 2 N H_2SO_4 (2 × 15 mL), water (2 × 15 mL), dried ($MgSO_4$) and the residue chromatographed on silica gel. Elution with hexane–EtOAc = 8:2 afforded 0.420 g (41%) of nearly pure MA-Aib$_6$ (**1**), mp 247–250 °C; δ_H (200 MHz, DMSO-d$_6$) 1.68 (s, 36H), 3.71 (s, 18H), 7.00 (br, 6H); FAB-MS (*m/z*) (%) 959 (M + Na$^+$) (60), 820 (M + H$^+$ − Aib) (44), 703 (M + H$^+$ − 2Aib) (100), 586 (M + H$^+$ − 3Aib) (8). Further elution gave 0.100 g (11%) of **2**, mp 203–205 °C. When the second batch was not added, work up afforded exclusively 33% of **2**, mp 203–205 °C; δ_H (200 MHz, $CDCl_3$) 1.66, 1.77, 1.88 (s, s, s, 30H), 3.68, 3.73, 3.78 (s, s, s, 15H), 7.13 (br, 4H); FAB-MS (*m/z*) (%) 842 (M + Na$^+$) (77), 703 (M + H − Aib) (100%), 586 (M + H$^+$ − 2Aib) (24).

6 *Crystal data* for **1**: $C_{42}H_{60}N_6O_{18}\cdot 2H_2O\cdot NaNO_3$, space group *Pna*2$_1$, a = 14.286(1) Å, b = 14.614(1) Å, c = 24.800(5) Å, V = 5177.9 Å^3, D_c = 1.352 g cm^{-3}, Cu-Kα radiation, λ = 1.54178 Å. Least squares refinement on F^2, R_1 = 0.0512 for 4480 data [$|F| > 4.0\sigma(F)$] and wR_2 = 0.1388 for all data. Data collection at 293 °C. CCDC 173157. See http://www.rsc.org/suppdata/cc/b1/b109465n/ for crystallographic files in .cif or other electronic format.

7 I. L. Karle, *Biochemistry*, 1974, **13**, 2155.

8 Silica gel (2.0 g), used for chromatography, was triturated with ethyl acetate (5 mL), filtered and the clear filtrate evaporated. Negative ion Ms of the residue clearly showed presence of nitrate and the positive ion Ms that of sodium ion.

9 Chromatographically pure MA-Aib$_6$ (0.005 g, mp 247–250 °C) was triturated with distilled water (3 × 2 mL), centrifuged and dried *in vacuo* to afford sample, mp 238–239 °C which was shown to be totally free of sodium nitrate by Ms.

10 Sodium nitrate (0.005 g) in water (2 mL) was shaken with ethyl acetate (2 mL), the layers separated and the organic layer filtered through cotton to give a clear solution in which salt freed MA-Aib$_6$ from the above experiment was dissolved and left aside. Fine needles, mp 256–258 °C, identical to that used for crystallographic studies were slowly deposited. These were demonstrated to contain sodium nitrate by positive and negative ion mass spectrometry.

11 The conditions used were similar to that described above. Unlike sodium nitrate, crystals were not deposited with lithium nitrate and potassium nitrate, on standing. Solvents were evaporated, the residue washed with water to remove uncomplexed salts, centrifuged, dried and the resulting fine powders, when analyzed by both positive and negative ion mass spectra, clearly showed complexation with lithium nitrate and the absence of this with potassium nitrate. In view of the exclusive preference of the amide groups for hydrogen bonding with nitrate ions seen with **1**, the lithium nitrate complex is likely to have a structure similar to that with sodium nitrate.

First published as an Advance Article on the web 22nd November 2001

A periodic structured organosilica solid of the MCM-41 type containing 4,4′-bipyridinium presumably inserted on the walls that is stable after surfactant removal has been prepared; the ability of bipyridinium units to act as electron acceptor termini has been demonstrated by observation of the radical cation in the photochemical and thermal activation of the as-synthesized material.

Since the first report describing the preparation of periodic mesoporous silica of the MCM-41 type[1] there has been considerable amount of work aimed at exploiting the possibilities of these materials to host organic guests. The target was to produce hybrid solids with functional properties derived from the response of the organic guest confined in a regular compartmentalised space provided by the MCM-41 silicate. In this regard, recent reports have described the preparation of periodic mesoporous organosilica (PMO) in which the organic component occupies framework positions in the walls rather than in the empty voids of the hexagonal channels.[2–5] This paves the way for the preparation of a new type of innovative organic–inorganic hybrid materials for which a vast potential can be foreseen. In the present communication we describe a new PMO incorporating 4,4′-bipyridinium units that implemented the solid with unique electron acceptor ability as well as photo- and thermo-chromic responses characteristic of viologen derivatives.[6]

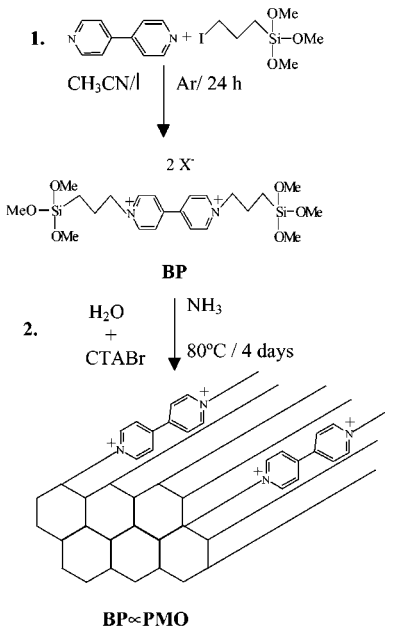
Viologens are the most widely used electron acceptor units in a variety of charge transfer complexes and electron transfer processes. The corresponding radical cations are very well documented and have as the most characteristic properties a relatively high stability and an intense blue–green colour.[7]

The preparation of the solid of the MCM-41 type incorporating 4,4′-bipyridinium units (BP∝PMO) was accomplished following basically the same procedure described in the literature for similar solids having methylene groups covalently linked to the walls.[5]

Our strategy to attempt the covalent binding of viologen to the silica walls consisted in the attachment of trimethoxysilylpropyl groups to the nitrogen atoms of 4,4′-bipyridine by nucleophilic substitution as indicated in Scheme 1.† Subsequently, the silyilated viologen precursor (BP) was used in combination with TEOS in the synthesis of the BP∝PMO, using cetyltrimethylammonium bromide (CTABr) as the structure directing agent. The molar proportions of the precursor gels used in a preferred preparation are: 1.00 Si: 114 H_2O: 8.0 NH_3 (20 wt%): 0.12 CTABr. TEOS as the silica source and BP were used in the following mol ratios: 0.85:0.15, 0.95:0.5 and 0.99:0.01. The formation of the solid was carried out at 80 °C in a closed 25 ml polyethylene container.

Thermogravimetric analysis coupled with differential scanning calorimetry conducted in air shows three distinctive peaks. The first between 150 and 250 °C corresponding to a loss of 30% in weight was attributed to the decomposition of the CTABr surfactant based on the reports on analogous PMO materials.[8] A second exothermic jump between 250 and 450 °C (11.5% weight, for the BP∝PMO with the maximum BP content) probably corresponds to the concurrent loss of residual surfactant and viologen. The final peak in the thermogravimetry (4% weight) is most probably due to desorption of water generated by condensation of silanol groups.

The presence of viologen in BP∝PMO is clearly revealed in the IR spectrum of the solid (Fig. 1). The strongest band characteristic of BP appears at 1650 cm^{-1}. Its intensity remains unaltered upon outgassing at 200 °C under 10^{-2} Pa for 1 h, conditions under which a large part of the template has been desorbed [see Fig. 1(b)]. Other characteristic bands of weak to medium intensity also appear in the aromatic region of the IR spectrum corresponding to BP.[9]



Scheme 1

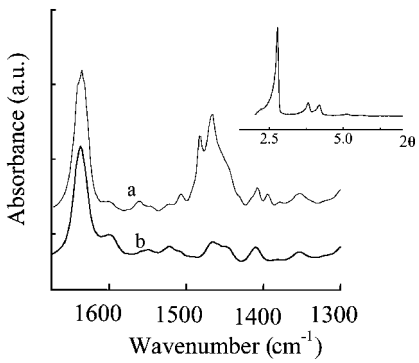


Fig. 1 FT-IR spectra of as-synthesised BP∝PMO (TEOS:BP 0.85:0.15) recorded at r.t. (a) and after outgassing at 200 °C for 1 h at 10^{-2} Pa (b). The decrease in the intensity of the 1470 cm^{-1} band corresponds to the desorption of the structure directing agent. The inset shows the powder X-ray diffraction spectrum of as-synthesized BP∝PMO.

 DOI: 10.1039/b108964c

The periodic structure of the as-synthesized BP∝PMO was assessed by powder X-ray diffraction wherein a sharp peak appearing at $2\theta = 3°$ characteristic of the d_{100} reflection is clearly observed[8] (inset of Fig. 1). Removal of the structure directing agent was accomplished by solid–liquid extraction using dilute acid in ethanol. The resulting solid exhibits the same characteristic X-ray diffraction peak as the as-synthesised powder and a BET surface area of 930 m^2 g^1 having a mononodal pore distribution around 3.8 nm and a total pore volume of 0.88 ml g^{-1}. These values are within the expected range for a typical MCM-41 solid. The fact that BP is not removed in the extraction treatment that removes CTA^+ and the ordering evidenced by X-ray diffractogram indicates that BP is strongly bound to the solid walls.

Of note in the observation in the UV–VIS spectrum of as-synthesised BP∝PMO, together with a sharp peak at 280 nm due to the pyridinium rings, was the presence of a featureless, broad band $\lambda_{max} = 400$ nm. This weak, broad band is characteristic of the formation of a charge transfer (CT) complex between the bipyridinium units and accompanyging halide as electron acceptor and donor components, respectively. This type of CT complex between viologen and halides has been reported in the literature[7] and evidences the ability of this new BP∝PMO material to promote the formation of CTC complexes.[10]

The novel opportunities of our BP∝PMO can be exemplified considering the efficiency of the generation of the $BP^{\cdot+}$ radical cation. Thus 308 nm laser excitation of powdered BP∝PMO in a sealed cell gives rise to the formation of the corresponding radical cation as assessed by diffuse reflectance UV–VIS spectroscopy (Fig. 2). The intensity of the band grows gradually upon irradiation until a maximum is reached. An estimation of the maximum percentage of radical ion generation can be obtained by comparing the intensity of the reflectance corresponding to the residual neutral viologen precursor at 280 nm with that of 600 nm characteristic of the radical ion, both corrected by the relative extinction coefficient of the bands. From this data it can be concluded that the transformation of the neutral BP into $BP^{\cdot+}$ radical cation is in practice complete $[(I_{280}/\varepsilon_{280})/(I_{600}/\varepsilon_{600})] < 0.1$. Concerning the nature of the electron donor site, we can conclusively rule out I^- as the electron donor, since none of the corresponding oxidised I_2 and $I_2^{\cdot-}$ species were observed in the optical spectrum.[11] In this context, the fact that a silicate framework can provide an electron to the excited state of viologens is not without precedent.[12] Importantly, not only has such high efficiency of $BP^{\cdot+}$ generation in aluminosilicates not been reported previously, but also the $BP^{\cdot+}$ does not significantly decay even one month after generation.

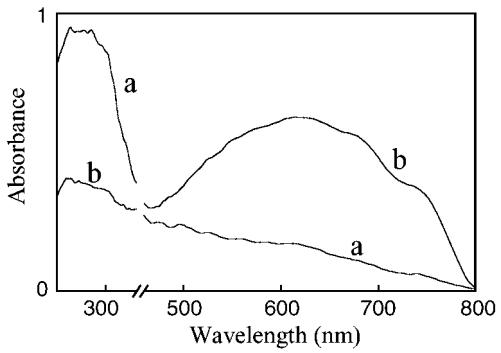

Fig. 2 Diffuse reflectance UV–VIS spectra of as-synthesized BP∝PMO (TEOS : BP 0.85 : 0.15) in a sealed cell before (a) and after 10 min (b) 308 nm laser irradiation. The sharp band at 290 nm is characteristic of BP while the broad band in the region 500–800 nm is due to the corresponding radical cation. Note that the increase of the latter upon irradiation is accompanied by a decrease of the 290 nm band.

The other unprecedented observation, that can give an idea of the potential of our BP∝PMO material, derived from its ability to stabilize $BP^{\cdot+}$, is thermal generation of the viologen radical cation. As far as we are aware, the only related precedent claiming the thermal generation of a viologen radical cation included in a porous aluminosilicate was published by Yoon as a note in his review on CT complexes in zeolites, which appeared in 1993.[7] No later confirmation of this interesting observation has been ever reported. In our case, just the simple outgassing of the BP∝PMO at room temperature develops a slight blue tint visually indicating the spontaneous generation of some $BP^{\cdot+}$. Upon heating at increasing temperatures (25–150 °C) under an Ar stream the intensity of the color increases and the diffuse reflectance UV–VIS spectrum provides evidence for the formation of the radical ion together with an enhancement of the CT complex. Upon cooling at room temperature apparently the radical cation decays but an enhanced concentration of CT complexes remains. This cycling can be repeated without noticeable loss in the ability to generate $BP^{\cdot+}$ radical cations.

In summary, our contribution derives from the seminal reports on PMO[2–5] that we have shown it can be applicable to covalently insert viologen in MCM-41 walls. While we describe the synthesis of the BP∝PMO and some properties of the as-synthesised material concerning its ability to stabilise radical cations, it is obvious that a range of further possibilities will be available after removal of the surfactant, emptying the channels of BP∝PMO. Preliminary experiments have shown that the template can be extracted from the solid without removing BP^{++}, as expected according to its covalent bonding. The empty voids of this BP∝PMO material could then be used to assemble different types of CT complexes having viologen imprinted in the walls as the acceptor unit.

Cooperative directing effect of OH anions and polymerized DABCO cations in the formation of the $Ge_{16}O_{32}(OH)^{-}(C_6H_{12}N_2H)^{+}(C_6H_{12}N_2)\cdot 1.125H_2O$ zeotype

Received (in Cambridge, UK) 24th July 2001, Accepted 30th October 2001
First published as an Advance Article on the web 22nd November 2001

$Ge_{16}O_{32}(OH)^{-}(C_6H_{12}N_2H)^{+}(C_6H_{12}N_2)\cdot 1.125H_2O$ results from a simultaneous cation and anion templating effect during the zeotype formation; the structure shows a linear arrangement of the organic species along the channels as well as the existence of Ge_4O_8 tetramers with confined OH^- anions in the middle of large germanium cages.

The possibility of designing new open frameworks increases greatly for germanium zeotypes. The co-existence of different coordination polyhedra around the Ge atom (tetrahedron, octahedron and trigonal bipyramid) implies different charged frameworks.[1–8] The hydroxy group is involved in the formation of some new germanium zeotypes but not much attention has been paid to its role. In the previously reported ICMM3[7] the OH^- group was confined inside a six germanium cage, and the templating effect of this group was suggested.

The use of $(DABCO)^{+}(C_6H_{13}N_2)$ and DABCO derivatives as structure-directing agents (SDA) for zeolite synthesis has resulted in many high-silica products. The occurrence of a polymerization process has also been shown in solutions of DABCO at temperatures $\geqslant$ *ca.* 170 °C in the presence of an 'initiator', for instance ammonium salts.[9] In the synthesis of the beta zeolite a similar process has been suggested.[10] High-germanium compounds, zeotypes such as ASU-9,[2] or ICMM4[11] have been obtained by using DABCO as an SDA. In these compounds DABCO molecules or *dabconium* cations are isolated without any evidence of polymerization processes. Following our studies on this subject, we focus our attention on the effect of both OH^- and *dabconium* ions in zeolite formation, as well as on the acid–base bifunctional character that these templates confer to the zeotype.

ICMM5 was synthesized hydrothermally, and variations in the procedure were explored especially to avoid the presence of ASU-9[2] and ICMM4[11] the synthesis of which also involves DABCO (Table 1). Finally, by tuning the amount of water as a reactant and optimizing the reaction conditions ICMM5 was obtained as the sole product of the reaction. The purity of the resulting solid product was confirmed by PXRD.

TGA–DTA in N_2 atmosphere (50 ml min^{-1}) shows that the compound is stable up to 250 °C. A progressive weight loss of 12.5%, was then observed between 250 and 600 °C accompanied by an endothermic effect corresponding to the loss of both DABCO molecules, the OH group and water molecules, to give crystalline GeO_2 at 600 °C. PXRD and IR spectra show that the structure is maintained after heating to 400 °C for 1 h in air and collapses into amorphous GeO_2, after prolonged heating.

Table 1 Variation in gel composition and obtained products; Temp. = 150 °C and time = 5 days; EG = ethylene glycol

GeO_2	DABCO	H_2O	$PrNH_2$	EG	pH	Products
1	2.8	112	—	14	8.5	ASU-9[2]
1	2.8	112	—	—	9.5	ASU-9 + ICMM4
1	2.8	112	1.3	—	11	ICMM4[11]
1	2.8	2.9	25	—	12	ICMM5
1	2.8	0.14	25	—	12.6	GeO_2
1	2.8	—	25	—	—	GeO_2

Upon determining the crystal structure,† the composition was found to be $Ge_{16}O_{32}(OH)^{-}(C_6H_{12}N_2H)^{+}(C_6H_{12}N_2)\cdot 1.125H_2O$ [ICMM5]. In ICMM5 there are nine unique Ge sites, all exhibiting tetrahedral coordination [Ge–O 1.715(9)–1.784(8) Å; O–Ge–O 99.2(4)–119.9(4)° Ge–O–Ge 123.4(4)–147.0(6)°]. Connections among tetrahedra give rise to cages formed by 24 Ge atoms. The cages are made up of three different kind of rings (eight 6R, eight 5R and three R4). Linkages among cages along the *a* and *b* directions produce cubane 4–4 units which are displaced relative to each other in the *c* direction as required by the $I4_1/amd$ spatial group symmetry. The zeolite framework can be thought to consist of a combination of 5–3 + 4–4 SBUs that gives rise to a 3-D system of 12R intersecting tunnels (Fig. 1).

Inside each cage, one O atom is situated on a twofold axis, and corresponds to a confined OH^- anion (H atom located by difference Fourier synthesis. The O weakly interacts with the four Ge atoms of the central 4R of the cage at distances of 2.32(1) and 2.52(1) Å ($r_{Ge} + r_O$ = 1.9 Å).

This framework, that has been also described[10] for $(Me_3N)_6[Ge_{32}O_{64}]\cdot 4.5H_2O$ (FOS-5), is very similar to that of beta zeolite, both showing tetragonal symmetry, with 5–3 and single 4R SBUs and a 3-D system of 12R channels. Nevertheless, there are some important differences: (1) besides the 5–3 and 4R, ICMM5 bears double 4–4 cubane units. (2) Due probably to the templating effect of the OH^- anion,[7] cages of 24 Ge atoms, which do not exist in beta zeolite, are formed. (3) In ICMM5 the 12R channels are circular and equally sized in the three directions, while in beta zeolite, they are smaller in the [001] than in the [100] direction.

It is important to note the role of the OH^- anion on these new germanium cages. During the zeotype formation, some GeO_5

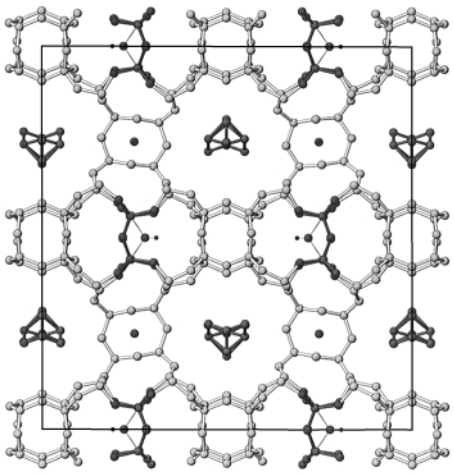

Fig. 1 View of the structure of $Ge_{16}O_{32}(OH)^{-}(C_6H_{12}N_2H)^{+}(C_6H_{12}N_2)\cdot 1.125H_2O$ [ICMM5] along the [010] direction, where the Ge_4O_8 tetramers and confined OH^- anions in the middle of the cages as well as the rows of DABCO molecules and dabconium cations, are in black. Thin lines do not indicate an actual bond but the shorter OH^-–Ge distances.

 DOI: 10.1039/b106671b

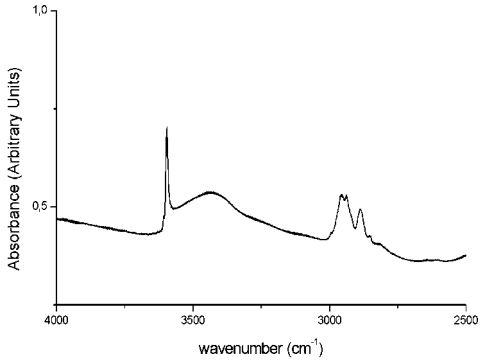

Fig. 2 Infrared spectrum of ICMM5.

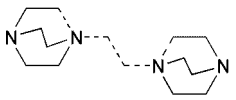

Scheme 1

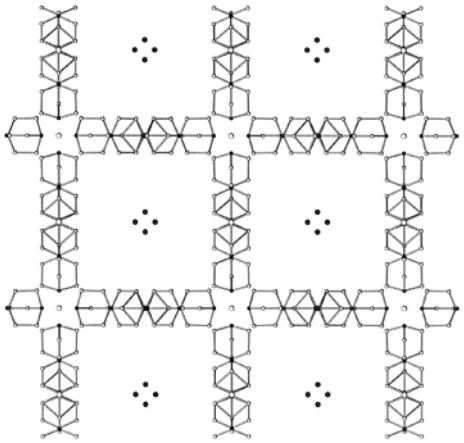

Fig. 3 View of the templates along [001] showing the disposition of the DABCO molecules and dabconium cations along the channels. Black and grey circles are the OH^- anions and water molecules respectively.

pentacoordinate species are formed, in which the fifth coordination position is occupied by an OH^- anion. In some cases this OH^- is only bonded to one Ge atom, usually giving laminar structures as in ICMM4 where the OH^- clearly forms part of a charged framework. Frequently hydroxy groups interact with more than one Ge, creating around it clusters of GeO_4 tetrahedra that give rise to new cages. When the zeotype is built up these OH^- anions remain confined inside the cages. Depending on the distances between the oxygen atom and the surrounding Ge atoms the tetrahedra become distorted to a greater or lesser degree, distortion ranging from the nearly regular tetrahedra as in the current ICMM5, to what can be considered trigonal bypiramids when including the fifth Ge–O interaction.[7,11] It seems quite probable that the presence of these hydroxy groups stabilizes the formation of new cages in gemanium zeotypes, but the point is to know to what extent they are either mere templates or anions belonging to the framework and thus, giving charged structures. Anyway, their existence implies the presence of cations, in this case, protonated molecules of DABCO.

Probably due to the difficulty of obtaining this compound free of ASU-9, in FOS-5, no total characterization of the material is reported. It could be that in that compound, the oxygen atoms inside the cages belong to OH^- anions instead of water molecules. ICMM5 was finally obtained as the sole product of the reaction. The presence of both OH^- anions and dabconium cations are clearly observed in the IR spectrum. Besides the characteristic C–N, C–C and C–H bands, it exhibits a very sharp peak at 3580 cm^{-1} and a band at ~2700 assigned to the stretching vibrations of the OH groups and to the characteristic N–H vibrations of an amine in its protonated form, respectively (Fig. 2); $\delta(NH^+)$ at ~1530 cm^{-1} is also observed.

We propose that in the reaction mixture for preparing ICMM5 the DABCO molecule might behave as in the beta zeolite synthesis.[10]

In fact in the single crystal structure solution of ICMM5 we have found, apart from the thermal some positional disorder around these molecule (Scheme 1). This model of disorder assumes the coexistence of both dabconium cations and polyethylene piperazine and does not allow a determination of the number of polymerized monomers in the crystal.

Although propylamine is probably involved in the polymerization process, perhaps as the 'initiator', its role is not fully clear. The arrangement of the DABCO molecules (Fig. 3) is in accord with a certain degree of polymerization and indicates clearly the directing effect of these molecules in the formation of the 3-D system of straight large rings.

The acid–base bifunctional character of ICMM5 has been tested in reactions catalyzed by basic sites (Michael addition) and acid sites (isomerization of epoxides). ICMM5 catalyzes the Michael addition of acrolein or methyl vinyl ketone and nitroethane at 313 K, in toluene yielding, after 20 h reaction, 62–54% Michael adduct. The rearrangement of styrene oxide over ICMM5, in acetone at 313 K was successful, giving 50% of phenylacetaldehyde after 20 h. XRPD spectra of the material after the catalytic tests, show in both cases that the structure remains unchanged.

If abstraction of the nearest environment of the OH^- (black part in Fig. 1), and of the deformation that it provokes in the framework is made, the result is a more symmetric zeolite with double the amount of equivalent 12R channels along the [100] and [010] directions. The *a* and *b* cell parameters would be one half of their value, as occurs in beta zeolite. In the actual ICMM5, rows of dabconium cations run along one half of these channels and the other half is occupied by the $Ge_4O_8(OH)^-$ tetramers giving rise to the 24 Ge cages. The result can be considered a 2×2 superstructure derived from the beta zeolite.

In view of this, we conclude that in the initial steps of the zeotype constitution, the hydroxy group induces $Ge_4O_8(OH)^-$ tetramer formation, which could take part in an anion templating effect, similar to that of the organic cations (dabconium cations in ICMM5) in the structural building formation.

First published as an Advance Article on the web 22nd November 2001

Two pyrimidine (6-4) pyrimidone photoproduct derivatives, highly valuable to probe the substituent influence during polymerase replicative bypass, were prepared; one (1a) by diastereoselective Raney nickel reductive desulfurization of the s[5](6-4) adduct of TpT (3) and the other (1b) by alkaline treatment of 1a.

Pyrimidine (6-4) pyrimidone photoproducts are one of the major mutagenic UV-induced DNA damage produced at adjacent pyrimidine sites.[1] These photoproducts are formed by a [2 + 2] cycloaddition between the 5,6-double bond of the 5′-pyrimidine and the carbonyl (thymine) or imine (cytosine) of the 3′-pyrimidine yielding an unstable four membered heterocycle (oxetane or azetidine) that spontaneously rearranges to transfer the heteroatom onto the C5 position of the 5′-pyrimidine base (Scheme 1). Among the four possible bipyrimidine sites, 5′-thymine-containing-sequences (TC and TT) are the most reactive.[2] Comparison of the mutagenic properties of (6-4) adducts produced at these sites, when embedded in a same sequence context, allowed some insights into structure–mutagenicity relationships.[3,4] It appeared that the 5′-pyrimidine base retained its coding properties (95% A insertion) whereas incorporation of G opposite the 3′-pyrimidone was favoured (89% for the TT (6-4) adduct, and 71% for the TC (6-4)). However, the 18% variation could not be attributed to any substituent since photoproduct structures differed at more than one position (X_2 at C5 of the saturated thymine and R_2 at C5 of the pyrimidone) (Scheme 1). Thus, neither the influence of the 5′-pyrimidine C5 substituent, and *a fortiori* nor its stereochemistry, on nucleotide insertion during trans-lesion synthesis (TLS) could be established from these experiments.

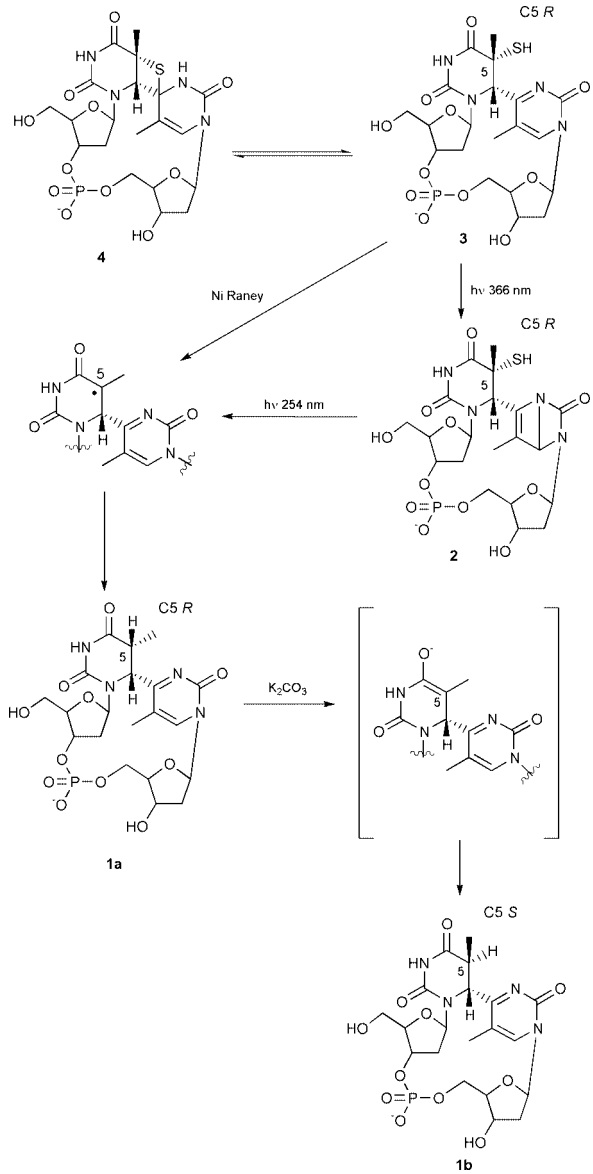
Analogues of the (6-4) photoproducts, differently substituted at the C5 position of the saturated thymine base portion, when incorporated into oligonucleotides, would be highly valuable to study in detail structure–mutagenicity relationships. In a first approach, we considered that analogues of the (6-4) TpT adduct bearing an hydrogen atom instead of the hydroxy group at the dihydropyrimidine 5-position (**1a** or **1b**) would be very useful to study the impact of this latter group during TLS. We envisaged that such analogues could be obtained by reductive desulfurization of the known s[5](6-4) adduct of TpT (**3**).[5]

	X_1	X_2	R_1	R_2
TT	O	O	CH_3	CH_3
TC	O	NH	CH_3	H
CT	NH	O	H	CH_3
CC	NH	NH	H	H

Scheme 1

Raney nickel is a reagent of choice to reduce sulfur compounds.[6] Thus, treatment of a methanolic solution of the thietane **4**,[5] in equilibrium with its opened form **3**, with Raney nickel led rapidly to the formation of a major product (**1a**) together with a minor compound (**1b**) (Scheme 2) in a *ca.* 9 : 1 ratio as judged by ^{1}H NMR and HPLC analysis.[7] ^{1}H NMR signals of **1a** were strictly superimposable to those of the product that we previously obtained upon 254 nm irradiation of the s[5]Dewar photoproduct **2**.[8] The tentatively assigned *R* stereochemistry at C5 of **1a** was herein confirmed from a set of NMR data. The configuration of Tp C6 is retained since H6 gives an NOE with Tp H3′. It is known that dihydropyrimidines adopt half chair conformations, N1–C2–N3–C4 atoms in the plane and the C5 and the C6 atoms on each side of the plane (Fig. 1).[9] The 7 Hz coupling constant between H6 and H5, a value typical of an ax/eq coupling, could accommodate only with a C5 *R* configuration. NOEs between the two methyl groups and between Tp H6 and pT CH_3 showed the conformation of the 5′-thymine ring to be in an half chair with C5 atom above and C6 atom below the N1-C4 mean plane (Fig. 1, B). It is worth mentioning that this conformation is the same as the one recently observed by X-ray crystallography of the (6-4) adduct of TpT[10] and obtained by molecular modelling.[11] The ^{13}C NMR spectrum of **1a**, compared to the one of the natural (6-4) photoproduct of TpT,[12] ascertained the proposed structure and its stereochemistry at C5. All the ^{13}C NMR chemical shifts matched those of the (6-4) TpT adduct except C5, C6 and the methyl of the Tp part. In particular, carbon C5 (40 ppm) experienced a shielding of 34 ppm in agreement with removal of the α-effect produced by C5 hydroxy substitution in 5,6-dihydropyrimidine derivatives.[13] The methyl (δ 10.5 ppm) was also shielded compared to the corresponding one of the TpT (6-4) adduct (δ 26.4 ppm). This difference cannot be attributed solely to the removal of a β-effect due to OH substitution which is around 9 ppm (comparison between 5-hydroxy-5,6-dihydropyrimidine and 5,6-dihydropyrimidine) but is due to a *gauche* relationship with the bulky pyrimidone C6 substituent, confirming a *cis* relationship between the Tp methyl and the pyrimidone.[13] Carbon C6 (δ 53.3 ppm) experienced a 5.8 ppm shielding when compared to the corresponding one in the (6-4) adduct of TpT, a β-effect magnitude in agreement with that observed between 5-hydroxy-5,6-dihydrothymidine and 5,6-dihydrothymidine.[13] Interestingly, upon storage in D_2O, the H-5 atom of **1a** experienced an isotopic exchange that occurred with retention of configuration.

 DOI: 10.1039/b107773m



Scheme 2

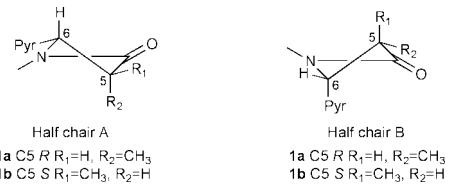


Fig. 1

Compound **1b** also belongs to the pyrimidone type as attested by its UV chromophore (absorption at 322 nm). Its ^{1}H NMR spectrum displayed two methyl signals at 2.23 and 1.51 ppm, one of which being a doublet, evidencing that this compound was either a conformer or a diastereoisomer of **1a**. Its saturated H6 proton (5.02 ppm) appeared as a singlet indicating an eq/eq relationship between H6 and H5, fitting the half chair B with methyl in β position and ruling out **1a** in the half chair A conformation. Finally, deshielding of the ^{13}C NMR methyl signal (17.7 ppm) compared to the corresponding one of **1a** confirmed the *trans* substitution and hence that **1b** is the C5 diastereoisomer of **1a**.

The reductive desulfurization step proceeded not only in high yield (73%) but also with an excellent diastereoselectivity. Attempts to fully explain the observed diastereoselectivity are, at this stage, premature since the stereochemical course of desulfurization, in cyclic systems, using Raney nickel is not fully understood[14] and would require additional experiments which are beyond the scope of this work. Moreover, our case is particularly complex for the reduction occurs at a potentially isomerizable center. However we propose, to interpret the observed diastereoselectivity, that the major C5 *R* diastereoisomer **1a** could result from a stereoselective hydrogen atom transfer on the less hindered face of the C5 radical (Scheme 2).

Raney nickel desulfurization of **3** yielded **1a** in good yield, we then attempted to define conditions affording **1b** on a preparative scale. Since it is known that 5,6-dihydrothymine derivatives isomerize at C5 under alkaline conditions,[15] we thought that **1a** could be converted into **1b** at high pH. Treatment of the water solution of the **1a**–**1b** 9 : 1 mixture with K_2CO_3 (0.15 M) at rt indeed led to the full conversion of **1a** into **1b**. C5 epimerization of **1a** is likely to proceed through an enol intermediate (Scheme 2). Our results seem to indicate that at neutral pH, this enol preferentially equilibrates with its kinetic form **1a** (protonation on the less hindered side of the dihydropyrimidine) whereas at basic pH, the thermodynamic species (**1b**) is highly favoured. This hypothesis could explain the 10% formation of **1b** since the desulfurization reaction was achieved using crude Raney nickel reagent.

In conclusion, we have developed a straightforward method to prepare either the C5 *R* or *S* h^5(6-4) photoproduct of TpT sites at the dinucleotide level. This result is extremely important since **1b**, when incorporated into oligonucleotides, could directly probe the impact of the C5 hydroxy group of the (6-4) dithymine lesion on its mutagenic properties. Oligonucleotides containing **1a**[16] would be also very important to examine the stereochemical effect of the methyl group on mutagenesis. We are confident that these (6-4) analogues will find a number of other applications in the biophysical and biological fields of (6-4) photolesions.

We thank CONACYT (Mexico) for a doctoral fellowship to S. K. A. M.

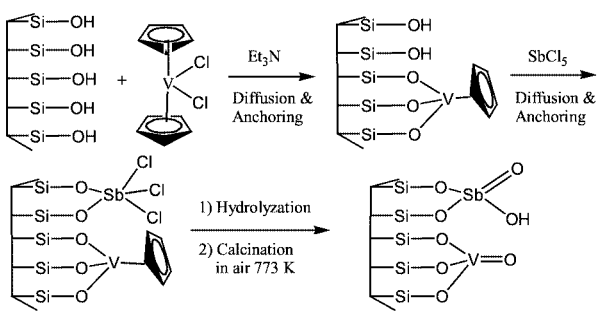
First published as an Advance Article on the web 22nd November 2001

Bi-metallic VO_x–SbO_x/SBA-15, which may be used as a site-isolated model catalyst, is successfully prepared by a two-stage grafting method using a vanadium matallocene and $SbCl_5$ as precursors.

SBA-15[1,2] is a purely siliceous mesoporous molecular sieve with high thermal and hydrothermal stabilities and is a potential support in catalysis. Grafting methods are widely used to prepare catalysts on supporting materials. The catalysts prepared in this way are often highly active and selective. In mesoporous molecular sieves the active metal species are dispersed evenly on the inner walls of the pores and appear to be less likely to form large clusters at reaction temperatures as they are usually bonded with the surface silanols. Although single metals are relatively easy to graft on the support, there are only a few reports on grafting bimetallic clusters as they are difficult to prepare.[3–6] V–Sb mixed oxide catalysts have been extensively studied for their activities of propane ammoxidation to acrylonitrile. However, the surface areas of these materials are still no more than 21 $m^2\ g^{-1}$.[7] Mixed-oxide catalysts have been rationalized in terms of the site isolation theory, *i.e.* the isolation of active V moieties in the structure is a key factor for obtaining a catalyst with high selectivity.[8] Here we present a two-stage grafting method to prepare V–Sb bimetallic oxide on the support of mesoporous SBA-15 with isolated V and Sb active centers. Our aim is to obtain a new type of catalyst to further study its catalytical activities and reaction mechanisms in comparison with conventional mixed-oxide catalysts.

The synthesis of SBA-15 was carried out using the literature method.[1–2] Prior to grafting, SBA-15 was calcined to remove the surfactant, resulting in *ca.* 15% Si atoms remaining as silanols as detected by ^{29}Si MAS NMR spectroscopy. The amount of the two precursors, bis(cyclopentadienyl)vanadium dichloride and $SbCl_5$ was calculated according to the molar ratio of SiOH:V:Sb = 5:1:1, *i.e.* utilizing all silanols (Scheme 1). The grafting process was conducted in a similar method as used by Maschmeyer *et. al.*[9] and Kang *et al.*[10] for grafting Ti and V, respectively, on other mesoporous silicates. SBA-15 was dehydrated at 423 K for 2 h under vacuum and then added to chloroform containing 10 wt% bis(cyclopentadienyl)vanadium dichloride under dry nitrogen. The sample was kept in chloroform solution for 2 h under stirring to enable the V species to diffuse into the SBA-15 pores. Triethylamine was then added to activate the grafting reaction. After 3 h, a 10 wt% $SbCl_5$ chloroform solution was added to the now brown mixture and allowed to react for 3 h. The grafted sample was washed with chloroform and filtered off, and then washed with water to hydrolyse and to remove HCl. The sample was finally dried and calcined in air at 773 K for 3 h, to form VO_x–SbO_x/SBA-15 (Scheme 1). SbO_x/SBA-15 and VO_x/SBA-15 were prepared in a similar manner.



Scheme 1

XRD patterns of all grafted SBA-15 samples (Fig. 1) show well-resolved patterns with a prominent peak at *ca.* 1.0° and two weak peaks at *ca.* 1.6 and 1.7°, confirming that the SBA-15 structure was maintained.

The N_2 adsorption isotherms of all materials (Fig. 2) give typical type IV adsorption isotherms with a H1 hysteresible

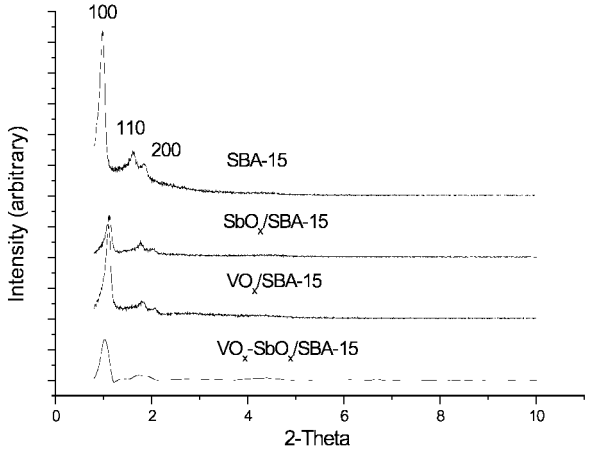


Fig. 1 X-Ray powder diffraction patterns for SBA-15, SbO_x/SBA-15, VO_x/SBA-15 and VO_x–SbO_x/SBA-15.

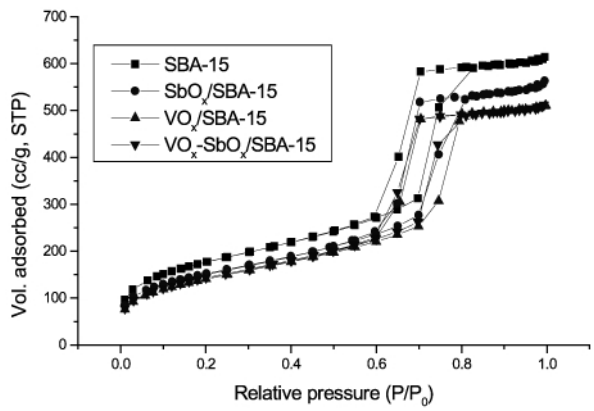

Fig. 2 N_2 adsorption isotherms for SBA-15, SbO_x/SBA-15, VO_x/SBA-15 and VO_x–SbO_x/SBA-15.

 DOI: 10.1039/b107487n

Table 1 Pore structural parameters of SBA-15, SbO_x/SBA-15, VO_x/SBA-15 and VO_x–SbO_x/SBA-15 calculated from the desorption branch of the nitrogen adsorption isotherms and the molar compositions by ICP

Sample	A_{BET}/ $m^2\ g^{-1}$	A_{BJH}/ $m^2\ g^{-1}$	V_{BJH}/ $cm^3\ g^{-1}$	D_{BJH}/ Å	Si/metal
SBA-15	706	716	1.10	61.3	
SbO_x/SBA-15	512	578	0.81	56.0	15.3
VO_x/SBA-15	548	600	0.89	59.4	21.9
VO_x–SbO_x/SBA-15	520	584	0.81	55.6	53.6(V) 44.1(Sb)

loop. The BET surface area of SBA-15 was 706 $m^2\ g^{-1}$, and decreased to 512, 548 and 520 $m^2\ g^{-1}$ for the samples SbO_x/SBA-15, VO_x/SBA-15 and VO_x–SbO_x/SBA-15, respectively (Table 1). This decreasing trend is also shown by the mesopore surface areas (A_{BJH}). Such a trend can be explained by two factors: the addition of the metals increases the density of the samples and decreases the pore size, as shown by the decreasing trend of V_{BJH} and D_{BJH}. The BJH pore size distribution is narrow, indicating that the pore structure remains regular and unchanged after the grafting process. The elemental content of each sample was determined by ICP (Table 1). The values of Si/metal indicate that in all three grafted samples not all of the precursor molecules reacted with the available silanols.

Fig. 3 shows the UV Raman spectra of the four samples. The bands at *ca*. 490 cm^{-1} are assigned to three Si siloxane rings.[11] For both VO_x–SbO_x/SBA-15 and VO_x/SBA-15 the bands at *ca*. 1035 cm^{-1} arise from the (support–Si–O–)$_3$V=O species[11] illustrated in the final product (Scheme 1). Bands at 930 cm^{-1} assignable to dinuclear vanadium complexes[12] were not observed, since the cyclopentadienyl ring prevents vanadium from bonding with other metal centers. The XPS binding energies of Sb $3d_{3/2}$ for SbO_x/SBA-15 and VO_x–SbO_x/SBA-15 are 540.0 and 540.5 eV, respectively. The former is the same as that reported previously by Benvenutti *et al.*,[13] for the Sb structure is shown in the final product (Scheme 1). The latter is slightly higher which may be caused by the weak interaction between the V and Sb species.

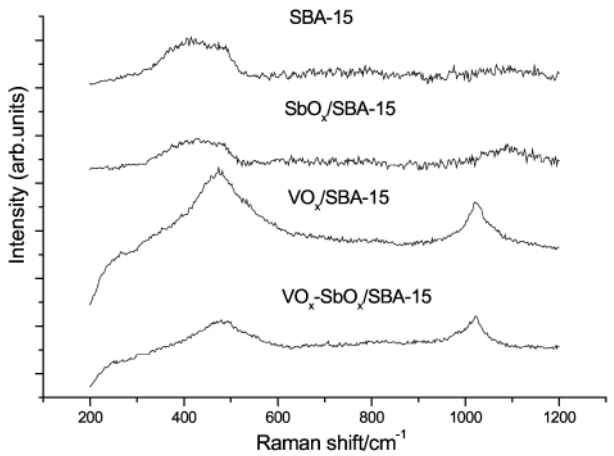

Fig. 3 UV Raman spectra for SBA-15, SbO_x/SBA-15, VO_x/SBA-15, and VO_x–SbO_x/SBA-15.

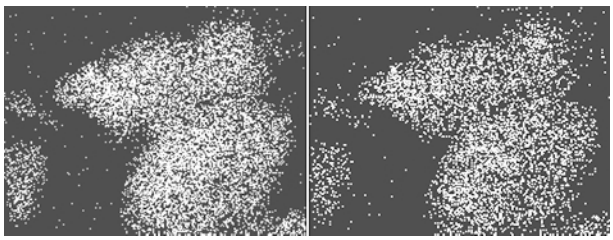

Fig. 4 Elemental mapping images of VO_x–SbO_x/SBA-15; left: Sb, right V.

VO_x–SbO_x/SBA-15 was also studied by elemental mapping. Fig. 4 shows that the grafted metals are evenly spread in the support. In the preparation of VO_x–SbO_x/SBA-15 the amount of two precursors was calculated to react with all silanols. However, the ICP analysis shows that V and Sb had not reacted completely. Therefore, all these results indicate that the metal species do not associate together during the calcination process at 773 K and confirm our expectation of isolated metal centers in the grafted samples (Scheme 1).

In conclusion, bimetallic VO_x–SbO_x/SBA-15 has been successfully prepared by a two-stage grafting method using the vanadium matallocene and $SbCl_5$ as precursors. SbO_x/SBA-15 and VO_x/SBA-15 were also synthesised and characterized for comparison. The structure of SBA-15 is retained after the grafting and calcination processes. The material may be used as a site-isolated model catalyst, *e.g.* for the ammoxidation of propane.

Received (in Cambridge, UK) 29th August 2001, Accepted 23rd October 2001
First published as an Advance Article on the web 9th November 2001

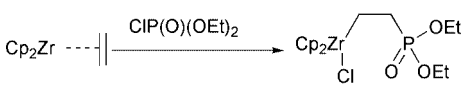
Zirconocene–ethylene complex Cp_2Zr ($CH_2=CH_2$) reacted with chlorophosphate to form zircono-ethylphosphonate, which could be converted into various functionalized ethylphosphonates.

Introduction of a heteroatom to multiple carbon–carbon bonds is attractive from the synthetic viewpoint.[1] In this regard, a particularly attractive and interesting subject is the simultaneous introduction of a metal and another heteroatom to multiple carbon–carbon bonds, since it is a more versatile and elegant synthetic elaboration. While the related carbometallation of multiple carbon–carbon bonds has been extensively studied,[2] only a few reactions for the preparation of such a complex, which contains a metal and a heteroatom to a carbon–carbon bond, have been studied. In this paper, we would like to report a novel reaction of zirconocene–ethylene complex $Cp_2Zr(CH_2=CH_2)$ with chlorophosphate to form zircono-ethylphosphonate **(1)** (Scheme 1), which can be converted into various functionalized ethylphosphonates.

A typical experiment was carried out as follows. To a solution of zirconocene–ethylene complex $Cp_2Zr(CH_2=CH_2)$,[3] generated by the reaction of Cp_2ZrCl_2 with 2 equiv. of EtMgBr in THF, was added one equiv. of diethyl chlorophosphate. The reaction mixture was kept at room temperature for 24 hours, and then it was quenched with 2M HCl. Purification of crude product was carried out by column chromatography on silica gel (ethyl acetate–petroleum ether = 2:1). Ethylphosphonate **(2a)** was obtained in 87% yield.

The product ethylphosphonate did not come from the reaction of EtMgBr with chlorophosphate: hydrolysis was replaced by iodination of the reaction mixture and 2-iodoethylphosphonate **(2b)** was obtained in 85% yield, which suggested that the intermediate of the reaction of zirconocene–ethylene complex with chlorophosphate contains a Zr–C bond before hydrolysis.

Zircono-ethylphosphonate could be converted into functionalized ethylphosphonate by coupling with various electrophiles such as I_2, NBS, acyl chloride and allyl bromide. The various reactions are summarized in Table 1. The reaction of zircono-ethylphosphonate with I_2 or NBS gave 2-iodoethylphosphonate or 2-bromoethylphosphonate **(2c)** in 85% and 73% yields, respectively. Moreover, treatment of zircono-ethylphosphonate with allyl bromide obtained **(2d)** in 77% yield, in which the new carbon–carbon bond was formed. It is noteworthy that without CuCl the reaction of zircono-ethylphosphonate with acyl chloride did not proceed. The zircono-ethylphosphonate requires initial reaction with CuCl to give the alkylcopper reagent,[4] which then undergoes smooth reaction with acyl chloride to give **(2e)**. This is due to the different reactivity of the carbon attached to zirconium in the zircono-ethylphosphonate.



(1)

Scheme 1

The reaction of zirconocene–ethylene complex Cp_2Zr ($CH_2=CH_2$) with various unsaturated compounds such as alkynes,[5] alkenes,[3] ketone, and nitriles,[6] in which the reactions afforded five-membered zirconacycles was investigated. To elucidate the intermediate of this reaction, the reaction of $Cp_2Zr(CH_2=CH_2)$ with chlorophosphate was followed by ^{31}P NMR spectroscopy. Immediately following the addition of chlorophosphate at −78 °C, the reaction mixture was analysed by ^{31}P NMR. The ^{31}P NMR spectrum showed only one peak at 3.2 ppm, which was confirmed to be due to the phosphorus of the chlorophosphate. Then, the reaction mixture was stirred for 10 minutes from −78 °C to room temperature. Three peaks appeared in the ^{31}P NMR spectrum. One appeared at 3.2 ppm and another at −3.8 ppm. The latter signal is consistent with phosphorus of coordination number five.[7] The third signal was at 33.7 ppm and was assigned to the phosphorus of zircono-ethylphosphonate **(1)**. Following continuous stirring of the reaction mixture for 30 minutes at room temperature, the peak at 3.2 ppm completely disappeared and the peak at 33.7 ppm increased. Finally, the peak at −3.8 ppm disappeared after the reaction mixture was stirred for 24 hours at room temperature.

Based on the above results, a proposed reaction mechanism is shown in Scheme 2. The reaction of Cp_2ZrCl_2 with 2 equiv. of EtMgBr gives Cp_2ZrEt_2, which smoothly decomposes at 0 °C to give resonance hybrids Cp_2Zr-ethylene and zirconacyclopropane **(3)**.[3] The Zr–C bond of zirconacyclopropane **(3)** reacts with chlorophosphate to form five-membered zirconacycle **(4)**. Then, elimination of chloride from zirconacycle **(4)** takes place to form zircono-ethylphosphonate.

Table 1 Reaction of a mixture of Cp_2ZrEt_2 and chlorophosphate with electrophiles

Entry	Electrophile	*T*/°C	Time/h	Product	Yield (%)[a]
1	HCl	rt	1	 **2a**	87 (63)
2	I_2	rt	3	 **2b**	85 (60)
3	NBS	rt	3	 **2c**	73 (49)
4		rt	6	 **2d**	77 (56)
5[b]	MeCOCl	50	6	 **2e**	64 (45)

[a] GC yields. Isolated yields are given in parentheses; [b] CuCl (1 equiv.) was added.

 DOI: 10.1039/b107755d

To further explore this reaction, other olefins were used. During the course of our study, we found that styrene also reacted with chlorophosphate in the presence of zirconocene species. When Cp_2ZrBu_2 (Negishi reagent) was treated with 2 equiv. of styrene and chlorophosphate successively, 2-phenylethylphosphonate was observed in 43% yield. In this case, the reaction proceeded *via* the β, β′ carbon–carbon bond cleavage of the zirconacyclopentane.[8]

Further investigations are still in progress in this area.

We are grateful to the National Natural Sciences Foundation of China (20172032) and Tsinghua University for financial support.

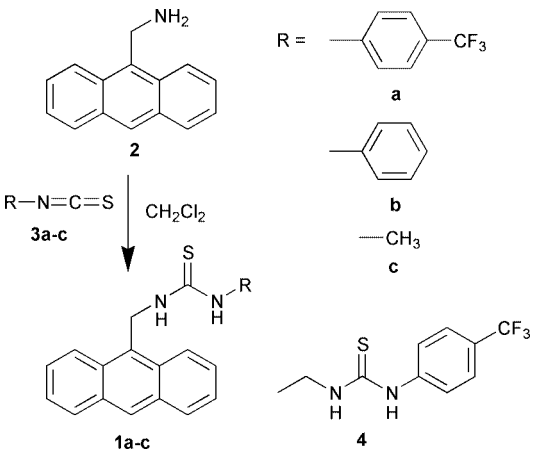
Received (in Cambridge, UK) 23rd August 2001, Accepted 23rd October 2001
First published as an Advance Article on the web 9th November 2001

We demonstrate for the first time that the charge neutral anthracene based fluorescent sensors 1a–c, having an aromatic or aliphatic thiourea moiety as an anion receptor, show *ideal* PET sensor behaviour where the anthracene fluorescence emission is selectively quenched upon titration with AcO^-, $H_2PO_4^-$ and F^- but not by Cl^- and Br^- in DMSO.

There is great interest in the design and synthesis of luminescent based chemosensors for on-line and real time detection of physiologically important ions and molecules,[1] and for environmental monitoring of harmful pollutants.[2] While numerous fluorescent and metal based delayed luminescent sensors for cations and organic molecules have emerged from the fields of supramolecular and coordination chemistry,[3] sensors for selective detection of anions are still relatively rare, despite the fact that several elegant examples of anion receptors have been reported over the years.[4] These, however, often involve the synthesis of complex and challenging organic hosts from scaffolds such as cholic acid,[5] calixarenes and peptides.[6] Luminescent anion sensing has recently been achieved[4] through the use of anion receptors composed, for example, from metal based Lewis acid centres,[7] calix[4]pyrroles,[8] thiouronium[9] and protonated quinoxaline,[10] amine[11] or polyamine moieties,[12] but the use of simple and easily synthesised electroneutral anion receptors for such sensing has been less investigated.[13] Intrigued by this fact, we set out to develop the charge neutral chemosensors **1a–c**, employing the criteria of PET sensing using the *fluorophore–spacer–receptor* model developed by de Silva for the detection of cations.[14] A few research groups have attempted to develop PET anion sensors.[11–13,15] But, to the best of our knowledge no such systems, employing neutral anion receptors, have yet been reported that show *ideal* PET behaviour, *i.e.* (*i*) only the quantum yield (intensity) and lifetime of the fluorescence emission should be modulated upon ion recognition due to (*ii*) changes in the free energy of electron transfer (ΔG_{PET}) between the excited state of the fluorophore and the receptor upon ion recognition, and (*iii*) no changes should be observed in the absorption spectra of the fluorophore.[14]

The three PET chemosensors **1a–c**, were easily made in good yield from readily available starting materials, Scheme 1. The 9-aminomethyl anthracene **2**, synthesised by reducing 9-cyanoanthracene using B_2H_6 in THF, was reacted in dry CH_2Cl_2 at room temperature, under an inert atmosphere with an equimolar amount of 4-(trifluoromethyl)phenyl-, phenyl- and methyl isothiocyanate respectively, **3a–c**, yielding **1a–c** as off-white solids that were purified by crystallisation from CH_2Cl_2. For comparable UV-Vis binding studies, the thiourea receptor **4** was prepared in an analogous way from ethylamine. All products were analysed by conventional methods.† The three different isothiocyanates **3a–c**, were chosen with the aim of being able to modulate or tune the acidity of the thiourea receptor moiety, which would lead to different *receptor–analyte* complex stability and hence different binding constants. Of the three chemosensors, **1a** was expected to show the strongest binding due to this effect, and **1c** the least. We initially investigated the binding of **1a** using $(C_4H_9)_4N(O_2CCH_3)$, since AcO^- is known to form strong directional hydrogen bonding with thiourea, as well as having a functional group of great biological relevance.[16] The ^1H NMR of **1a** in DMSO-d_6, showed two sharp signals at 9.62 ppm and 8.36 ppm for the thiourea hydrogens. These were substantially shifted downfield upon addition of $0.1 \rightarrow 2$ equivalents of $(C_4H_9)_4N(O_2CCH_3)$ ($\Delta\delta$ = 1.92 and 1.66 ppm respectively after 1 eq.) signifying the formation of a 1 : 1 binding through hydrogen bonding with a log β = 3.2.†

The fluorescence emission spectra of **1a** when titrated with AcO^- in DMSO displayed typical PET behaviour. In the absence of AcO^- the fluorescence emission spectra consisted of three sharp bands at 443, 419 and 397 nm, with a shoulder at 473 nm, when excited at 370 nm with Φ_F = 0.1037.‡ Upon addition of the AcO^- ($0 \rightarrow 32$ mM), the intensity of these bands gradually decreased with no other spectral changes being observed (*i.e.* no spectral shifts or formation of new emission bands), Fig. 1a. Using PET nomenclature, the emission can be said to being *ca.* 70% (at 443 nm) '*switched off*', with Φ_F = 0.0070. Concurrently, the absorption spectra of **1a**, consisting of bands at 390, 370, 352 and 336 nm, was hardly affected by the addition of AcO^-.† This confirms the insulating role of the methylene spacer, which minimises any ground state interactions between the fluorophore and the anion receptor. Similar emission and absorption effects were observed for **1b** and **1c**. When the fluorescence titrations of **1a–c** were carried out in CH_3CN, CH_3CO_2Et or THF, the emission was also quenched upon addition of AcO^- but the degree of quenching was somewhat smaller. In EtOH, which is a highly competitive hydrogen bonding solvent, no binding was observed between **1a** and AcO^-. Furthermore, *no* exciplex emission was observed in any of these solvents; in contrast, Teramae *et al.* have recently shown that a pyrene analogue of **1c**, is a ratiometric anion



Scheme 1 The synthesis of **1a–c**. **4** was made in a similar way.

† Electronic supplementary data (ESI) available: ^1H, ^{13}C NMR for **1a–c** and UV-Vis and NMR titration results for **1a** are available as electronic supplementary information (ESI). See http://www.rsc.org/suppdata/cc/b1/b107608f/

 DOI: 10.1039/b107608f

indicator based on the control of intramolecular exciplex emission.[13]

To investigate the selectivity and the sensitivity of the sensor towards biologically important anions, we carried out a series of titrations using $N(C_4H_9)_4^+$ salts of F^-, Cl^-, Br^- and $H_2PO_4^-$ in DMSO. In the case of $H_2PO_4^-$ and F^- the fluorescence emission was quenched by *ca.* 50 (Φ_F = 0.0156) and 90% Φ_F = 0.0011) respectively (at 443 nm), but only minor quenching (<7%) was observed when titrated with Cl^- (Φ_F = 0.108) or Br^- (Φ_F = 0.088), ruling out a quenching by heavy atom effect. We propose that the quenching is likely to be due to the modulations of ΔG_{PET} upon anion sensing. This can be regarded as an enhancement in the rate of electron transfer from the HOMO of the thiourea–anion complex to the anthracene excited state, upon anion recognition *i.e*, the reduction potential of the thiourea is increased causing PET to become competitively more viable, which causes the fluorescence emission to be quenched or *'switched off'*.§ Plotting the fluorescence intensity changes (at 443 nm) as a function of log [anion] further supports this view. Fig. 1b, shows several features commonly seen for PET cation sensors *e.g.* the profiles for AcO^-, $H_2PO_4^-$ and F^- are all sigmoidal, the quenching occurs over two log concentration units, which is consistent with 1 : 1 binding and simple equilibrium. From these changes the binding constant log β for **1a** was measured to be 3.35 (±0.05) for F^-, 2.55 (±0.05) for AcO^- and 2.05 (±0.05) for $H_2PO_4^-$.‡ Similar binding constants were found for **4a** by measuring the changes in its absorption spectra at 286 nm. Importantly, **1a** shows good anion selectivity with AcO^- being recognised over $H_2PO_4^-$, but both represent families of biological important anions. The fact that **1a** shows higher affinity and more efficient quenching for F^- than AcO^- is not surprising, since its high charge density and small size enables it to form strong hydrogen bonding with the thiourea receptor. Measurements using **1b** and **1c** and the same anions showed similar results. For **1b**, the same selectivity trend was observed as for **1a**, with smaller binding constants due to the reduced acidity of the thiourea protons. For **1c** the order of selectivity and the sensitivity was somewhat different with $H_2PO_4^-$ (log β = 2.05 (±0.05)) being selectively detected over AcO^- (log β = 1.75 (±0.05)). These results show that the anion sensor's affinity can be controlled by simple design.[16]

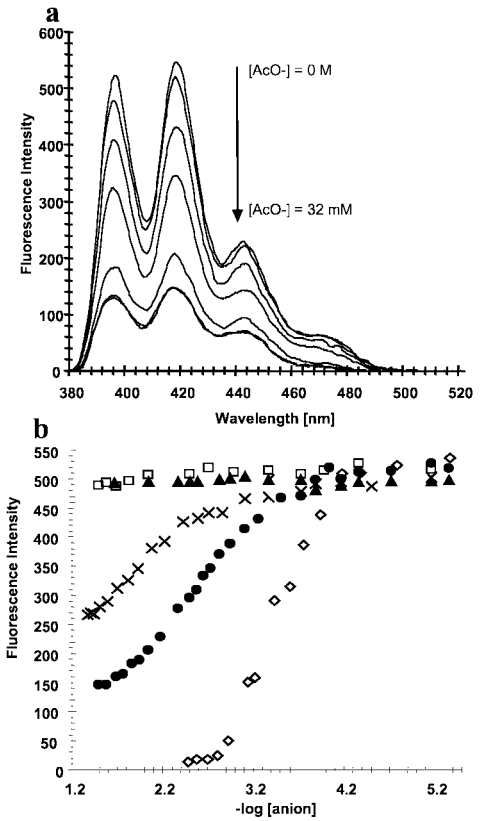


Fig. 1 (a) The changes in the fluorescence spectra of **1a** in DMSO upon addition of acetate. From top: [AcO^-] = 0, 92 μM, 550 μM, 1.8 mM, 8.9 mM, 26 mM, 32 mM. (b) Titration profile for **1a** showing the changes in the fluorescence emission as a function of added anion: ◇ = F^-, ● = AcO^-, × = $H_2PO_4^-$, □ = Cl^-, ▲ = Br^-, when measured at 443 nm. All titrations were repeated two to three times to ensure reproducibility.

In conclusion, the simple fluorescent PET anion chemosensors **1a–c** show *ideal* PET sensing behaviour upon ion recognition, *e.g.* only the fluorescence emission is *'switched off'* in the presence of AcO^-, $H_2PO_4^-$ and F^-. **1a–c** are a very important contribution to the fast growing field of supramolecular anion recognition and sensing.

We thank Enterprise Ireland, Kinerton Ltd, and TCD for financial support, Dr Hazel M. Moncrieff for helpful discussion and Dr John E. O'Brien for NMR.

Notes and references

‡ **1a–c** Φ_F were measured by comparison with anthracene (Φ_F = 0.27 in EtOH); D. F. Eaton, *Pure Appl. Chem.*, 1988, **60**, 1107. log β was determined from the equation:
$\log [(I_{max} - I_F)/(I_F - I_{min})] = \log [anion] - \log \beta$.
§ CV measurements on **4** showed two irreversible oxidative waves. Accurate ΔG_{ET} could not be determined from these measurements. We investigated the PET dependence of **1a** by comparing the Φ_F of **1a** with that of 9-methylanthracene (9MA), which lacks the anion receptor. In the absence of AcO^- the Φ_F of 9MA was found to be 0.284 in DMSO. This suggests that PET is active in **1a** prior to the anion recognition, but becomes even more efficient after anion recognition. In contrast, the addition of 40 mM of AcO^- to 9MA did not affect the Φ_F.

Intermolecular hydroacylation of acrylate esters: a new route to 1,4-dicarbonyls†

Michael C. Willis* and Selma Sapmaz

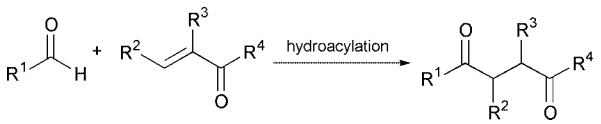
Department of Chemistry, University of Bath, Bath, UK BA2 7AY. E-mail: m.c.willis@bath.ac.uk; Fax: (+44) (0)1225 826231; Tel: (+44) (0)1225 826568

Received (in Cambridge, UK) 31st August 2001, Accepted 15th October 2001
First published as an Advance Article on the web 22nd November 2001

1,4-Dicarbonyl compounds can be prepared using a Rh(I) mediated hydroacylation reaction between (2-aminopicolyl)imines and acrylate esters followed by acid hydrolysis.

The transition metal catalysed hydroacylation reaction in which an aldehyde and an alkene are combined to generate a ketone is a relatively unexplored process. The main limitation of this reaction is the instability of the proposed acyl-metal intermediates and the resulting competitive decarbonylation pathway.[1] Intramolecular variants of the process utilising pent-4-en-1-als as substrates, leading to cyclopentanones as products, have been extensively studied,[2] however reports leading to larger ring sizes[3] or intermolecular examples are scarce.[4] Recently the Jun group have reported the use of a reaction system employing Wilkinson's complex and 2-aminopicoline as catalysts that allows intermolecular hydroacylation to proceed.[5] The success of the Jun system is attributed to the intermediacy of a picolylimine capable of forming a chelate stabilised acylrhodium species.[6] The majority of hydroacylation reactions reported to date utilise unfunctionalised alkenes as substrates thus generating simple ketones as products. We speculated that the use of alkenes substituted directly with either an ester or ketone group would provide direct access to the synthetically challenging 1,4-dicarbonyl array (Scheme 1). These 1,4-difunctionalised motifs are synthetically useful intermediates for the preparation of substituted furans,[7] butyrolactones[8] and succinate derivatives.[9] Such 1,4-dicarbonyl systems are not straightforward to prepare and the approach presented here can be considered as the equivalent of an acyl-anion addition to an enoate.[10] The related hydroformylation reaction has been reported although in these cases, by definition, only a single carbon unit corresponding to the CO molecule is introduced.[11] Using variously substituted and functionalised aldehydes in the corresponding hydroacylation reaction would allow the addition of functionalised carbon chains.[12] In this communication we report our progress towards this goal.

To assess the feasibility of the process we elected to study the reactions of imine **1** as an aldehyde equivalent and thus limit decarbonylation. The reaction of **1** with methyl acrylate under a variety of reaction conditions is summarised in Table 1. Reactions were conducted in a sealed tube using Wilkinson's complex as the catalyst. Upon completion the reaction mixtures were treated directly with 1.0 M HCl to liberate the required 1,4-dicarbonyl adducts. Optimal conditions involved heating a THF solution of the substrates at 135 °C for 6 hours with 10 mol% catalyst (entry 1). Under these conditions the desired product was isolated in 73% yield as a single regioisomer. Lowering the catalyst loading or reaction temperature or decreasing the reaction time resulted in less efficient processes (entries 2–4). The reaction also proceeds if toluene is employed as solvent although a more complex reaction mixture is produced resulting in lower yields (entry 5). Chlorobenzene was also evaluated but resulted in only low conversion to product. The use of 1,4-dioxane allowed a reasonable yield of the desired product to be isolated however solubilty problems were encountered that were not observed with THF.



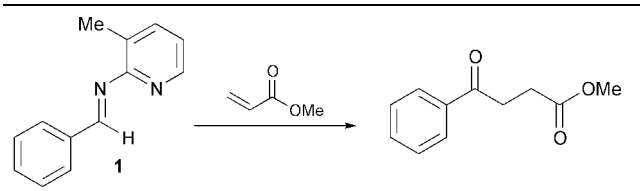
Scheme 1

† Electronic supplementary information (ESI) available: experimental details. See http://www.rsc.org/suppdata/cc/b1/b107852f/

In order to probe the generality of the process a range of substituted enoates were evaluated in the reaction with imine **1** (Table 2). Variation in the ester group is tolerated well, with Me and ^{t}Bu esters both delivering the expected adducts in good yields (entries 1 and 2).[13] Entry 3 demonstrates the tolerance towards amides with *N,N*-dimethylacrylamide generating the corresponding product in 74% yield. The introduction of substituents to the β-position of the alkene significantly reduces the reaction efficiency with methyl crotonate and cinnamate delivering the desired adducts in 24% and 10% yield respectively (entries 4 and 5). Substitution at the α-position has a similar effect on the reaction efficiency with methyl methacrylate yielding 16% of the requisite product (entry 6). A β-substituent could be successfully introduced if it was sufficiently activating, thus the use of *N*-methyl maleimide as the alkene component generated the desired hydroacylation product in 81% yield (entry 7).

The generality with respect to the imine component was next explored; we were particularly interested in assessing the influence of electron withdrawing and donating substituents on the aryl ring. A selection of 2-amino-3-methylpyridylimines bearing a range of substituents were readily prepared and evaluated in the reaction with methyl acrylate (Table 3). Electron withdrawing groups such as -NO_2 and -CN had a beneficial effect on the rate of the reaction with good yields of the desired products being obtained in only 20 and 80 min respectively (entries 2 and 3). Electron donating substituents

Table 1 Reaction of imine **1** with methyl acrylate[a]



Entry	Temp./°C	Solvent	Time/h	Yield (%)
1	135	THF	6	73
2[b]	135	THF	6	47
3	70	THF	7	48
4	135	THF	4	59
5	135	PhMe	6	56

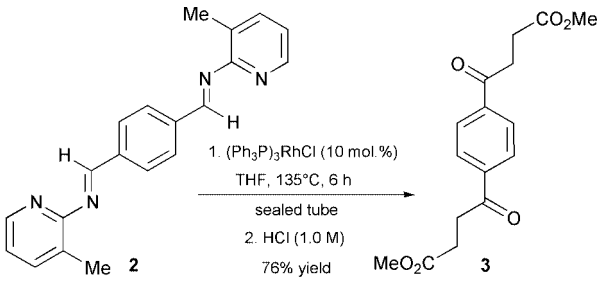
[a] *Conditions*: imine **1** (1.0 eq.), methyl acrylate (2.0 eq), sealed tube, $RhCl(PPh_3)_3$ (10 mol%) followed by HCl (1.0 M). [b] $RhCl(PPh_3)_3$ (5 mol%).

 DOI: 10.1039/b107852f

had a smaller influence on the rate of reaction; a -OMe substituent had minimal effect compared to the parent phenyl system with an 83% yield being achieved after 6 h (entry 4). *para*-Methyl and -bromo groups are also well tolerated delivering the corresponding 1,4-dicarbonyls in 98% and 85% yield respectively (entries 5 and 6). Exchange of a phenyl for the more electron rich naphthyl derived imine again showed little difference with the naphthyl derived adduct being obtained in 86% yield after 6 h reaction (entry 7).

The reason for the rate accelerations observed with the nitro- and cyano-substituted imines is unclear although destabilisation of the chelated intermediate is a possibility. Given these rate accelerations we were interested to see if these more reactive imines would allow α- and β-substituted acrylate esters to be employed as substrates. Unfortunately, although a rate acceleration was observed little difference in yield was obtained, with the nitro-substituted imine delivering products from reaction with methyl crotonate and methyl methacrylate in only 22% and 14% yield respectively.

The use of diimine **2**, prepared in good yield from benzene-1,4-dicarboxaldehyde, offers a potential starting point for two directional synthesis[14] and allowed a double hydroacylation to be attempted. Pleasingly, the required tetracarbonyl product **3** was isolated in 76% yield after 6 hours reaction.[15]



In conclusion, we have demonstrated the general viability of the intermolecular hydroacylation of acrylate esters as a new regioselective route to 1,4-dicarbonyl systems. The imine component of the reaction can tolerate a range of substituents including electron donating and electron withdrawing groups. The enoate component can contain a variety of ester groups as well as amide functionalities with little effect on yield, however, introduction of simple α- or -substituents reduces the efficiency of the reactions. Efforts to expand the substrate tolerance, to identify more efficient catalyst systems and to develop a process that can utilise aldehydes directly are underway in our laboratory and will be reported in due course.

The EPSRC are thanked for financial support of this project. We also thank the EPSRC Mass Spectrometry service at the University of Wales, Swansea, for analyses and Johnson Matthey PLC for the loan of rhodium salts.

15 The preparation of **3** serves as a general procedure: a solution of imine **2** (282 mg, 1.79 mmol) in THF (1 mL) was added to a solution of $RhCl(PPh_3)_3$ (167 mg, 10 mol %) in THF (1 mL) at room temperature and stirred for 1 h. Methyl acrylate (480 μL, 5.37 mmol) in THF (2 mL) was added and the reaction vessel flushed with argon. The reaction tube was sealed and then heated at 135 °C for 6 h. The reaction was cooled to room temperature, diluted with EtOAc (20 mL), poured into aqueous HCl (1 M, 20 mL) and extracted with EtOAc (3 × 20 mL). The organic portions were washed with brine (20 mL), dried ($MgSO_4$) and evaporated *in vacuo*. The residue was purified by flash chromatography (SiO_2, 25% EtOAc–petrol) to give **3** (212 mg, 76%) as pale yellow plates.

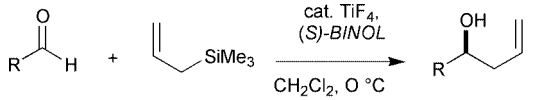
Received (in Cambridge, UK) 5th September 2001, Accepted 1st November 2001
First published as an Advance Article on the web 22nd November 2001

The titanium fluoride–BINOL catalyzed asymmetric allylsilylation of α,α-disubstituted aldehydes provides facile access to highly functionalized, chiral building blocks, which following simple recrystallization affords a key versatile starting material for polyketide synthesis in 96% ee.

Polyketides constitute a large class of naturally occurring structures with diverse, biological activities of importance to human medicine. As a consequence of the common biosynthetic pathways through which these structures are assembled there are often a number of recurring structural patterns in the form of 1,3-dicarbonyls, 1,3-hydroxy carbonyls, and 1,3-diols derived from acetate, propionate, or isobutyrate. Access to fragments that function as building blocks for the synthesis of these structures has resulted in many useful asymmetric synthetic enantioselective and diastereoselective methods.[1] The majority of these address the construction of acetate and propionate derived subunits, while many fewer are available for the preparation of isobutyrate derived subunits. We have recently reported the enantioselective TiF_4–BINOL catalyzed allylsilylation of aldehydes employing allyltrimethylsilane to afford adducts in useful selectivities and yields.[2] In our initial communication, the catalytic, enantioselective allylsilation of $^iPr_3Si$-protected 2,2-dimethyl-3-hydroxypropanal furnished the adduct in 93% yield, albeit in only 84% ee. The importance of such building blocks led us to initiate a program of study aimed at developing methods that would provide for their ready access. Herein we report investigations of this process furnishing fragments possesing the isobutyrate structural motif found in polyketide-derived natural products (eqn. 1). Importantly,



(1)

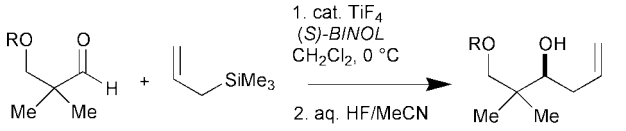
1 **2** **3**

the approach described herein furnishes optically active, crystalline adducts from commercially available reagents, and as such should find use in the ongoing studies towards the development of efficient routes and strategies to polyketide-derived natural products, such as aplasmomycin[3] byrostatins[4] epothilones,[5] mycalamides,[6] and boromycin.[7]

Among the critical advantages offered by the allylation reaction we have developed are: (1) the commercial availability of the ligand ((*R*)- or (*S*)- BINOL), metal (TiF_4), and allyltrimethylsilane; (2) the single step, *in situ*, preparation of the active catalyst from BINOL, TiF_4; (3) the low toxicity of allylsilane as compared to the alternative and often utilized allylstannane reagents; and (4) the volumetric efficiency of the process. In our preliminary laboratory screening of substrate scope for this transformation it was noted that the method was particularly effective for the enantioselective allylation of hindered, aliphatic non-enolizable aldehydes, affording adducts consistently in useful levels of enantiopurity.

The specific use of protected 2,2-dimethyl-3-hydroxypropionaldehyde in the allylation reaction provides access to the recurring structural isobutyrate motif found in polyketide-derived natural products. In an effort to identify the appropriate protecting group strategy that would provide crystalline material in high optical purity, we prepared a number of aldehyde substrates possessing a variety of protecting groups. Preparation of the necessary aldehydes was readily achieved by monoprotection of the 2,2-dimethypropane-1,3-diol, an inexpensive commodity chemical, followed by oxidation with either catalytic TEMPO[8] or catalytic TPAP.[9]

The allylation reaction of these substrates afforded adducts in 55–97% yield and 84–91% ee as shown in eqn. (2) and Table 1.[10,11] It is interesting to note that *O*-silyl, *O*-benzyl, and ester protecting groups all proved to be stable to and compatible with the allylation reaction. Also noteworthy is the ability to utilize both acetate (entry 6) and nitro (entry 5) moieties without complication by potentially competing reactions. Of the various adducts isolated, the 2-naphthoate protected adduct **5g** was isolated as a white crystalline solid in 91% ee and in 97% yield, following desilylation of the adduct. Importantly, after simple recrystallization, product was isolated enriched to 96% ee, as determined by chiral HPLC analysis. Additionally, the same reaction could be carried out with 5 mol% of the titanium catalyst on an 80 mmol scale, with the product isolated in 92% ee and in 72% yield.



(2)

4a-g **2** **5a-g**

In an effort to demonstrate the versatility of these adducts, we have carried out a number of facile, high yielding transformations. Hydrolysis of the naphthoate esters with potassium carbonate in methanol led to diol **6**, which following protection

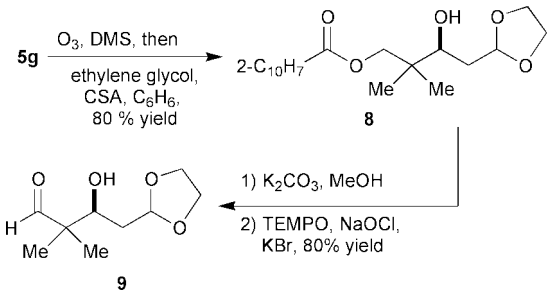
as the corresponding acetonide and ozonolytic cleavage of the olefin afforded chiral aldehyde **7** in 80% overall yield (Scheme 1). Alternatively, ozonolysis could be performed directly on the allyl adduct and the resulting aldehyde protected *in situ* as dioxolane **8** in 80% yield. Following saponification and selective oxidation of the primary hydroxy moiety, aldehyde **9** was obtained in 80% yield (Scheme 2).



Scheme 2 Elaboration of adduct **6g** to aldehyde **10**.

In summary, the TiF_4–BINOL catalyzed allylsilylation of protected aldehydes provides facile access to highly functionalized building blocks in high enantiopurity. These results demonstrate the possibility of employing this reaction for the preparation of significant quantities of chiral starting materials and attests to the tolerance of this catalyst towards a number of potentially reactive functionalities. Importantly, the synthesis study described herein furnishes optically active, crystalline adducts from commercially available reagents, and as such should find applications in the development of increasingly efficient strategies to polyketide-derived natural products.

10 Experimental procedure for naphthalene-2-carboxylic acid (3*S*)-hydroxy-2,2-dimethylhex-5-enyl ester. To a suspension of TiF_4 (0.25 g, 2.0 mmol, 5.0 mol%) in 10 ml CH_3CN was added (*S*)-BINOL (1.15 g, 4.00 mmol, 10.0 mol%) and the mixture stirred 15 min before the solvent was removed under reduced pressure. After 10 min at 1.0 torr, the residue was dissolved in 10 ml CH_2Cl_2 and cooled to 0 °C. To this solution was added allyltrimethylsilane (12.7 ml, 80.0 mmol, 2.00 equiv.) and stirred 1 h to give a dark precipitate to which aldehyde **4g** (10.3 g, 40.0 mmol, 1.00 equiv.) was added neat in two portion to give a dark red-orange solution. This solution was allowed to stir 5 days at 0 °C at which time analysis by ^{1}H NMR showed the reaction to be complete. The reaction mixture was diluted with 2:1 pentane:ether (500 ml), filtered over silica gel and eluted with 2:1 pentane:Et_2O (500 ml). Following rotary evaporation, the resulting residue was treated with 5:95:1.5 HF:MeCN:H_2O (80 ml) for 0.5 h, dissolved in Et_2O (200 ml), washed with 2 M NaOH (2 × 50 ml), brine (100 ml), dried over Na_2SO_4, and concentrated to give a yellow oil (11.65 g, 98% yield). Purification by crystallization from hexanes provided **5g** (8.30 g, 72% yield) as a white solid in 92% ee. (Determined by chiral HPLC analysis Chiradex OD), 98:2 hexanes–iPrOH. $[\alpha]_D^{25}$ (*c* 0.950, $CHCl_3$) = +11.9; mp 46.5 °C; 1H NMR (300 MHz, $CDCl_3$) d 8.61 (s, 1H), 8.06 (dd, *J* = 8.7, 1.6, 1 H), 7.97 (d, *J* = 7.78, 1 H), 7.92 (d, *J* = 8.7, 1 H), 7.60–7.53 (m, 2 H), 5.97-5.83 (m, 1 H), 5.19 (d, *J* = 8.6, 1 H), 5.14 (s, 1 H), 4.48 (d, *J* = 10.9, 1 H), 4.13 (d, *J* = 10.9, 1 H), 3.59 (td, *J* = 8.4, 3.4, 1 H), 2.45–2.39 (m, 1 H), 2.20 (d, *J* = 3.4, 1 H), 2.17–2.12 (m, 1 H), 1.10 (s, 3H), 1.07 (s, 3H); ^{13}C NMR (75 MHz, $CDCl_3$): 167.0, 136.1, 135.6, 132.5, 131.1, 129.4, 128.3, 128.2, 127.8, 127.5, 126.7, 125.2, 118.0, 74.1, 71.2, 38.7, 36.2, 21.8, 19.4; IR (KBr) 3493, 3068, 2971, 2892, 1683, 1475, 1373, 1274, 1230, 1198, 905, 776; EI-MS: 298.1 $(M)^+$; Anal. Calcd. for ($C_{19}H_{22}O_3$) C, 76.48; H, 7.43%; found, C, 76.64; H, 7.26%.
11 At the current level of development the process works optimally with non-enolizable aldehydes. Enolizable aldehydes furnish adducts, albeit in reduced yields and selectivities.

A new 'hybrid' molecular square composed of alternating multiply-bonded dinuclear and mononuclear corners

Jitendra K. Bera,[a] Bradley W. Smucker,[a] Richard A. Walton[b] and Kim R. Dunbar*[a]

[a] *Department of Chemistry, Texas A&M University, P.O. Box 30012, College Station, TX 77842-3012 USA. E-mail: dunbar@mail.chem.tamu.edu*

[b] *Department of Chemistry, Purdue University, 1393 Brown Building, West Lafayette, IN47907-1393, USA*

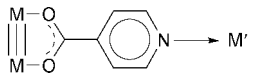
Received (in Columbia, MO, USA) 26th June 2001, Accepted 6th September 2001
First published as an Advance Article on the web 22nd November 2001

The incorporation of both dinuclear (M_2) and mononuclear (M′) units into molecular squares has been achieved by reacting a triply bonded Re_2(II,II) complex that possesses two *cis* isonicotinate donor ligands with Pt(II) molecules that contain substitutionally labile *cis* triflate groups.

The use of dicarboxylate bridging ligands to link quadruply bonded dimetal complexes into open-chain oligomers and polymers was first reported by Chisholm and coworkers over ten years ago.[1] Recently, several other research groups have demonstrated that cyclic architectures with M_2^{n+} units located at the vertices are also accessible from this chemistry.[2] The use of dimetal units in addition to square-planar[3] and octahedral[4] mononuclear building blocks in the design of metallocyclophanes, such as triangles and squares, opens up new prospects for research in this area including the possibility of incorporating mixed-nuclearity precursors into the same molecule. Herein we report the structure of a 'hybrid' molecular square from geometrically designed Re_2(II,II) and Pt(II) starting materials, the first such molecule of its kind to be reported.

In considering the goal of connecting M_2 and M′ units, one approach that occurred to us is to use a ligand such as isonicotinate that can bind to three metal atoms as depicted in Scheme 1. We reasoned that if a suitable dimetal complex with two *cis* isonicotinate ligands could be prepared, then the dangling pyridine groups would be available for further coordination to a square-planar metal center. In this vein, the new compound *cis*-$Re_2Cl_2(\mu\text{-dppm})_2(\mu\text{-}O_2CC_5H_4N)_2$ (**1**) was synthesized from *cis*-$Re_2Cl_2(\mu\text{-dppm})_2(\mu\text{-}O_2CCH_3)_2$[5] [dppm = bis(diphenylphosphino)methane] and isonicotinic acid in ethanol and characterized by NMR spectroscopy, electrochemistry† and X-ray crystallography.‡ As shown in Fig. 1, the *cis* conformation of the parent acetate complex is retained in complex **1**, the result of which is the presence of two orthogonal, uncoordinated pyridine groups of the isonicotinate ligands.

Compound **1** was reacted in a 1:1 ratio with the mononuclear complexes *cis*-$Pt[P(C_2H_5)_3]_2(O_3SCF_3)_2$[6] and $Pt(dbbpy)(O_3SCF_3)_2$[7] (dbbpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine), both of which contain *cis*, labile triflate ligands, to yield complexes **2**§ and **3**,¶ respectively. The ^1H NMR spectra of these products established that the $Re_2Cl_2(\mu\text{-dppm})_2(\mu\text{-}O_2CC_5H_4N)_2$ and PtL_2 units (where L_2 is $[P(C_2H_5)_3]_2$ or dbbpy) are present in a 1:1 ratio. Crystals of $[cis\text{-}Re_2(O_3SCF_3)_2(\mu\text{-dppm})_2(\mu\text{-}O_2CC_5H_4N)_2Pt(dbbpy)]_2[O_3SCF_3]_4$ (**3**),‡ obtained as a CH_2Cl_2–H_2O solvate, revealed that the structure of the cation is a molecular square consisting of alternating $[(dppm)_2Re^{II}_2]$ and $[(dbbpy)Pt^{II}]$ units at the vertices and isonicotinate ligands along the edges (Fig. 2). This is the first example of a 'hybrid' molecular square involving multiply bonded dimetal units in combination with mononuclear units.



Scheme 1

The molecule, which resides on a crystallographic inversion center, is considerably distorted from ideality as clearly illustrated by various metrical parameters within the molecule. For example, the Pt1–Pt1′ diagonal is 11.97 Å whereas the diagonal defined by the midpoints of the two Re_2 units is 13.26 Å. The vertex angles subtended by the Re_2 units are less than the ideal value of 90° [O(1)–Re(2)–O(4) 80.9(7), O(2)–Re(1)–O(3) 79.8(7)°], a situation that leads to a bending of the isonicotinate ligands to accommodate ring closure.

Cyclic voltammetric studies in 0.1 M $^nBu_4NPF_6$–CH_2Cl_2 solutions of the new molecular squares revealed that both compounds exhibit two reversible one-electron oxidations; these are located at $E_{1/2}$ = +0.67 and +0.80 V for **2** (Fig. 3) and at $E_{1/2}$ = +0.54 and +0.67 V for **3**. The parent compound **1** exhibits a single one-electron oxidation at $E_{1/2}$ = +0.45 V (ΔE_p = 60 mV) under the same conditions. The fact that the molecular squares exhibit two closely spaced oxidation processes ($\Delta E_{1/2}$ = 130 mV for both **2** and **3**) is an indication of weak electronic coupling (comproportionation constant[8] K_c = 158) of the Re^{II}_2 units through the Pt^{II} centers.

The results of this study demonstrate the feasibility of preparing novel types of cyclic molecules based on the self-assembly of multiply bonded dimetal units with mononuclear building blocks. Further prospects for incorporating electron-rich metal–metal bonded complexes into cyclic architectures that contain a second type of reactive metal site are attractive ones that are being actively pursued in our laboratories.

Synthesis of dinucleoside pyridylphosphonates involving palladium(0)-catalysed phosphorus–carbon bond formation as a key step

Tommy Johansson[a] and Jacek Stawinski*[ab]

Received (in Cambridge, UK) 28th September 2001, Accepted 30th October 2001
First published as an Advance Article on the web 23rd November 2001

Dinucleoside 3-pyridylphosphonates, as well as their 2- and 4-pyridyl positional isomers, have been synthesised using a palladium(0)-catalysed cross coupling strategy.

A pyridine ring is found in many natural products, *e.g.* in pyridine alkaloids, vitamins (niacin, pyridoxal), nicotinamide adenine dinucleotide phosphate (NADP), and constitutes a functionality often present in drugs (*e.g.* isoniazid—antitubercular activity; sulfapyridine—antibacterial and antiviral properties; pyrilamine—antihistaminic drug).[1]

These prompted us to develop a synthetic method for incorporation of a pyridine moiety in the form of pyridylphosphonate functionality (Chart 1) into natural product derivatives. Since the position of the phosphonyl group on the pyridine ring may be important for biological activity, all three isomeric compounds of type **1**, **2**, and **3** should be accessible for chemical and biological studies.

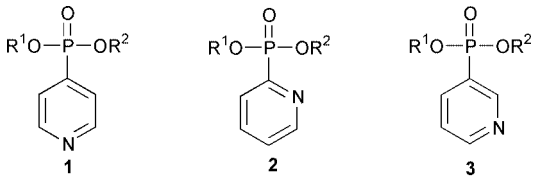

Chart 1

Recently, we have developed efficient and general protocols for the preparation of dinucleoside 2-pyridyl-[2] and 4-pyridylphosphonates[3] but, unfortunately, 3-pyridylphosphonates of type **3** cannot be prepared by these methods.

Introduction of a phosphonyl group into the 3-position of a pyridine ring is rather difficult and the few methods available for this purpose are usually low yielding.[4] Encouraged by the promising results of Hirao *et al.*[5] in the synthesis of diethyl 3-pyridylphosphonate **3**, we have embarked on a more detailed investigation of chemistry and stereochemistry of this palladium(0)-catalysed reaction, as a viable way for preparing dinucleoside pyridylphosphonates **6**–**8**.

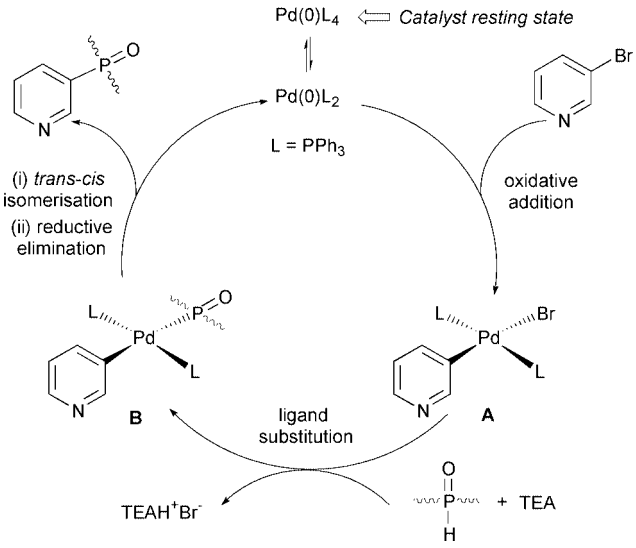
We set out to prepare dinucleoside 3-pyridylphosphonates **6**, for which there was no synthetic method available. This required considerable experimentation to develop the best conditions of solvents and reagents, as well as the nature and quantity of the catalyst. Eventually, the use of equimolar amounts of dinucleoside H-phosphonate **4** and 3-bromopyridine **5a** in the presence of 0.2 equiv. of $Pd(PPh_3)_4$, and 1.2 equiv. of triethylamine (TEA) under reflux in THF, was found to serve most needs.† Using these conditions, a cross coupling of dinucleoside H-phosphonate **4** with 3-bromopyridine **5a** (Scheme 2) in the presence of a base (TEA) catalysed by the added $Pd(PPh_3)_4$ proceeded quantitatively (^{31}P NMR) and afforded the desired 3-pyridylphosphonate derivatives **6** in *ca.* 85% yield.

A palladium(0) catalytic cycle[6] expected for this type of reaction and supported by ^{31}P NMR experiments, is depicted in Scheme 1. It seemed that the most energy demanding step in this cycle was the ligand substitution, *i.e.* the formation of a *trans*-adduct **B** *via* nucleophilic attack of a phosphorus nucleophile on the initial intermediate, *trans*-adduct **A**. Since the only intermediate observed by ^{31}P NMR spectroscopy during the course of the reaction was that of *trans*-adduct **A** [δ_P = 24.2 ppm], the two consecutive steps in which **B** collapsed to the pyridylphosphonate products (see Scheme 1), both had to be fast.‡

To investigate the stereochemical outcome of this palladium(0)-catalysed cross coupling, separate diastereomers of dinucleoside H-phosphonate **4** were subjected to the reaction with 3-bromopyridine **5a** (Scheme 2). We found that the P–C bond formation was completely stereospecific as the R_P diastereomer **4a**, (δ_P = 6.9 ppm) afforded exclusively the diastereomer **6a**, (δ_P = 16.3 ppm), while the S_P diastereomer **4b** (δ_P = 8.6 ppm) produced the other diastereomer of 3-pyridylphosphonate **6b** (δ_P = 17.2 ppm).

To find out if the formation of the P–C bond in this reaction occurred with retention or with inversion of configuration at the phosphorus center in **4**, we decided to synthesise separate diastereomers of dinucleoside 2-pyridylphosphonates **7** and 4-pyridylphosphonates **8** using palladium(0) chemistry and compare them with the same compounds obtained in another way.[2,3]

Dinucleoside 4-pyridylphosphonates **8** were prepared using the protocol developed for 3-pyridylphosphonate **6**, by reacting separate diastereomers of dinucleoside H-phosphonate **4** with



Scheme 1

Scheme 2

4-bromopyridine **5c** in the presence of $Pd(PPh_3)_4$. The reactions were stereospecific and afforded products **8**§ with the same stereochemistry as those formed in the reaction of H-phosphonates **4** with the pyridine–trityl chloride–DBU reagent system.[3] Since the latter provided products **8** most likely with retention of configuration at the phosphorus center,[3] we could tentatively conclude that the palladium(0)-catalysed cross coupling of H-phosphonate **4** with 4-bromopyridine **5c**, and probably also that with 3-bromopyridine **5a**, occurred with the same stereochemistry, *i.e.* with retention of configuration of the phosphorus center of **4**.

Attempted preparation of dinucleoside 2-pyridylphosphonate **7** by a palladium(0)-catalysed coupling of H-phosphonate **4** with 2-bromopyridine **5b**, turned out to be a more difficult task as the protocol developed for the 3-pyridyl isomer **6** afforded the desired product in less than 30% (^{31}P NMR analysis).

Inspired by the recent findings of Hartwig *et al.*[7] that chelating, sterically hindered phosphines are superior (in terms of yields and kinetics) ligands in palladium(0)-catalysed *N*-arylation of amines, we replaced in our catalytic system triphenylphosphine by 1,1′-bis(diphenylphosphino)ferrocene (DPPF). With this modification, the efficiency of 2-pyridylphosphonates **7** formation increased to *ca* 80% (^{31}P NMR analysis) and **7a** and **7b** were isolated in >50% yield.¶‖ By comparing the stereochemistry of 2-pyridylphosphonates **7** formed in this and in a DBU-catalysed reaction,[2] we conclude that both of them provided products with the same stereochemistry at the phosphorus centre. Thus, palladium(0)-catalysed formation of the P–C bond in this instance also most likely occurred with retention of configuration as was found for 3- and 4-pyridylphosphonates **6** and **8**.

It is worth noting that using DPPF in the synthesis of 3-pyridylphosphonates **6** shortened the reaction time from 4 to 2 h.†† Unfortunately, due to separation problems, yields of the isolated products **6** were lower (*ca.* 55%) than those where triphenylphosphine acted as a ligand.

In conclusion, we have developed a new method for the preparation of dinucleoside pyridylphosphonates **6**–**8** based on a palladium(0)-catalysed cross coupling of the corresponding H-phosphonate diesters **4** and halopyridines **5**. The reaction is stereospecific, occurring most likely with retention of configuration and can be considered as a general entry to isomeric pyridylphosphonate derivatives.

We are indebted to Professor P. J. Garegg for his interest in this work. Financial support from the Swedish Natural Science Research Council and the Swedish Foundation for Strategic Research is gratefully acknowledged

Notes and references

† *Typical protocol for the preparation of dinucleoside 3-pyridylphosphonates* **6**. Dry, degassed (argon) THF was used throughout and the reactions were carried out under an atmosphere of argon. A separate diastereomer **4a** or **4b**, (0.529 mmol), $Pd(PPh_3)_4$ (0.20 equiv.), triethylamine (1.2 equiv.) and 3-bromopyridine (1.0–1.2 equiv.) in freshly distilled and degassed THF (10 mL) was refluxed for 4–5 h. After concentration and partition of the reaction mixture between sat. aq. $NaHCO_3$ and CH_2Cl_2, the product was purified by silica gel column chromatography using a stepwise gradient of methanol (0.5–5%) in CH_2Cl_2 containing 0.1% TEA. White solids, purity >98% (^{1}H NMR). **6a** (85% from **4a**, probably R_P diastereomer). HRMS [M + H]$^+$, found 1212.4376. $C_{67}H_{67}N_5O_{15}P$ requires 1212.4371. **6b** (80% from **4b**, probably S_P diastereomer). HRMS [M + H]$^+$, found 1212.4373. $C_{67}H_{67}N_5O_{15}P$ requires 1212.4371. Some diagnostic spectral data (in $CDCl_3$) [compound, δP; δH(H-2 py); δH1′; δC(C-3 py) (J_{CP})]: **6a**, 16.3 ppm; 8.42–8.75 ppm (with pyr-H6, 2H); 6.38 (1H) & 6.26 (1H) ppm; 123.68 ppm (190 Hz). **6b**, 17.2 ppm; 8.86 ppm (1H); 6.39 (1H) & 6.20 (1H) ppm; 123.61 ppm (189 Hz).

‡ The same course of the reaction was observed when H-phosphonate **4** was allowed to react with a separately prepared intermediate **A**[8] in THF under reflux in the presence of TEA.

§ Compounds **8a** (from **4a**, 66% yield) and **8b** (from **4b**, 69% yield) were identical to those obtained in another way.[3] White solids, purity >98% (^{1}H NMR).

¶ The reaction was carried out as described above for 3-pyridylphosphonates **6**, with the exception that $Pd(PPh_3)_4$ was replaced by 0.2 equiv. of $Pd(OAc)_2$ and 0.4 equiv. of DPPF. Compounds **7a** (from **4a**, 54% yield) and **7b** (from **4b**, 51% yield) were identical to those obtained in another way.[2]

‖ The stereochemical course of the reaction was the same as that with $Pd(PPh_3)_4$. In contradistinction to DPPF, conformationally more flexible 1,3-bis(diphenylphosphino)propane (DPPP) was found to be unreactive, which may indicate the importance of rigidity of the ligand in this reaction.

†† With chelating ligands such as DPPF, oxidative addition (Scheme 1) results in the formation of *cis*- rather than *trans*-adducts (of type **A**). This may change geometry and electron distribution in the adduct and facilitate substitution of bromide by a phosphorus nucleophile, which was assumed to be the rate-determining step for the catalytic cycle.

A catalytic system based on Bi(0)–Cu(OTf)$_2$ is efficient for the selective one-pot oxidation of 1,2-disubstituted epoxides to α-diketones under molecular oxygen and DMSO.

The ring opening of epoxides,[1] including stereo-, regio- and enantioselective aspects, has been widely reported for the functionalization of organic compounds. However, the oxidative ring opening of oxiranes has been poorly explored, the oxirane ring being difficult to oxidize selectively. Within epoxide oxidations, the formation of α-hydroxy ketones in the presence of dimethyl sulfoxide and an activating agent has been reported to occur in moderate yields.[2] The oxidative cleavage of the C–C bond of oxiranes can lead to aldehydes or to carboxylic acids, by a Ce(IV)-mediated reaction[3] or by a Bi(III)-catalysed process,[4] respectively. To our knowledge, no report in the literature deals with the direct and catalytic transformation of epoxides to α-diketones.[5]

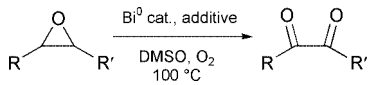
We recently reported the use of Bi(0) under oxidative conditions for the synthesis of carboxylic acids from α-hydroxy acids or terminal aryl epoxides involving the oxidative cleavage of the terminal C–C bond.[6] However, the reaction conditions were not well adapted to disubstituted epoxides.

We describe here a novel and simple methodology based on the use of catalytic amounts of Bi(0) and Cu(OTf)$_2$ (or TfOH), able to oxidize internal epoxides to α-diketones in one step, under relatively mild conditions, using molecular oxygen–DMSO according to Scheme 1.

This reaction involves Bi(III)/Bi(0) as the catalytic system; the possibility of using commercially available Bi(0) powder is interesting, due to its availability, its low cost and its low toxicity.[7]

The results of the oxidation of several 1,2-disubstituted epoxides are presented in Table 1. The reactions are carried out in DMSO at 100 °C and under an oxygen pressure of 1 atm in the presence of 5–10 mol% of Bi(0) powder and 2.5–20 mol% of Cu(Otf)$_2$ or TfOH as the additives. Interestingly, the black Bi(0) powder is dissolved in the organic medium containing the epoxide, affording a light yellow homogeneous solution, provided that the reaction is run under oxygen.

Cyclic, as well as linear 1,2-disubstituted epoxides led to the corresponding 1,2-diketones in good yields. For five and six-membered ring epoxides (entries 1–3, 6), the use of Cu(OTf)$_2$ (2.5–8 mol%) as the additive afforded the best results as compared to the use of other Lewis acids, such as $BiCl_3$, Li(NTf$_2$) or TfOH. Thus, epoxide **1a** afforded 74% isolated yield of cyclohexane-1,2-dione **1b**, whereas the same epoxide led to partial polymerisation in the presence of TfOH or Li(NTf$_2$) as the additives. On the other hand, for larger cycles (n = 12, **5a**) or linear epoxides such as **4a**, with less ring strain, the use of TfOH instead of Cu(OTf)$_2$ resulted in the best yields (entries 4, 5). The main by-products in the oxidation of **4a** and **5a** were the corresponding ketones (5–10% to 29% re-



Scheme 1

Table 1 Bi-catalysed oxidation of epoxides under O_2 (1 atm) in DMSO at 100 °C

Entry	Epoxide	Bi(0) (equiv.)	Additive (equiv.)	Time (h)	Product	Yield
1	 **1a**	0.08	Cu(OTf)$_2$ (0.025)	2	 **1b**	74%
2	 **2a**	0.05	Cu(OTf)$_2$ (0.08)	1.3	 **2b**	77%
3	 **3a**	0.08	Cu(OTf)$_2$ (0.06)	2.3	 **3b**	48%
4	 **4a**	0.10	TfOH (0.2)	2.3	 **4b**	83%
5	 **5a**	0.06	TfOH (0.09)	7.0	 **5b**	70%
6	 **6a**	0.06	Cu(OTf)$_2$ (0.07)	2	 **6b**	52%

 DOI: 10.1039/b106110k

spectively), issued from the epoxide isomerisation in acidic medium.[8] No other by-products were detected.

The oxidation of unsaturated epoxides **2a** and **3a** indicated that olefin functions were not modified by the catalytic system.

The α-diketones in five or six-membered rings were mainly found in their enol form according to ^{1}H-NMR analysis (in $CDCl_3$ at 20 °C). Particularly in the case of entry 3, only the 1,2-dihydroxybenzene form was observed. However, diketones **4b** and **5b** were present with low enolisation (respectively 36 and 30%) under the same analytical conditions.

When a terminal epoxide such as 1-octene oxide was treated under the Bi(0)–$Cu(OTf)_2$ oxidation conditions (as for entry 1), the expected α-keto aldehyde underwent further C–C cleavage leading to a mixture of heptanal and heptanoic acid in 80% overall yield. This result was consistent with our previous observations on the reactivity of terminal epoxides.[6]

The presence of Bi(0) was essential for the preparation of the α-diketone. In the absence of bismuth, **1a** did not lead to **1b** but afforded 2-hydroxycyclohexanone in 55% yield. On the other hand, no diketone was obtained in the absence of O_2 (reactions under N_2) or in the absence of DMSO (reactions in DMF). This result indicates that DMSO would act as the oxygen transfer agent to the epoxide. Accordingly, dimethyl sulfide is evolved in the oxidation process. It was also shown that without any additive, the epoxide was unreactive.

In order to check if Bi(III) species were involved in the catalytic cycle, the reaction of **1a** was carried out in the presence of Bi(III)-mandelate,[9] replacing Bi(0) (conditions of entry 1). The reaction also afforded **1b**, but in low yield (10%). This result was taken to indicate that the reaction could proceed through a Bi(0)/Bi(III) redox couple, in agreement with recent results.[6] We observed that the Bi(0) oxidative dissolution (presumably to Bi(III)) needed molecular oxygen as well as the presence of the epoxide and the additive. Under nitrogen, the black Bi(0) precipitate persisted, and the epoxide oxidation to the α-diketone did not take place.

For the reaction mechanism, still under investigation, we propose the initial oxidative oxirane ring opening to an α-hydroxy ketone intermediate catalysed by the system $Cu(OTf)_2$ [or TfOH]–DMSO. The presence of a strong acid (Lewis or protic one) to activate the oxirane ring seems an important feature of this process. The presence of weakly coordinating triflate species could also have an important role in the reaction. DMSO, in association to the acid, effects the oxidative ring opening.

In a second step, in the presence of Bi(III), presumably issued from Bi(0) oxidative dissolution, a redox reaction affords the α-diketone by oxidation of the ketol. The reduced bismuth species are reoxidized to Bi(III) under molecular oxygen. The use of oxygen at the pressure of 1 atm as the oxidant in this step is an interesting aspect of the process. Recently, another Bi(III)–O_2 system has proven its efficiency in the deprotection of *S,S*-acetals.[10]

In conclusion, a new synthetic transformation is described, involving the oxidative ring opening of epoxides to α-diketones, in a combined Bi(0)–$Cu(OTf)_2$ catalytic system under O_2–DMSO. The process uses commercially available reagents in a one-pot reaction under relatively mild conditions.

Notes and references

General procedure for epoxide oxidation. A mixture of bismuth(0) (0.5 mmol) and the additive (0.5 mmol) in DMSO (15 ml) is heated at 100 °C under O_2 (1 atm). The epoxide (5mmol) in DMSO (5 ml) is then introduced through a serum cap and the mixture is stirred at this temperature until complete consumption of the epoxide (monitored by GC). The reaction mixture is hydrolysed with brine (50 ml) and extracted with diethyl ether (3 × 50 ml). The combined organic layers are dried over $MgSO_4$ and evaporated. The product is purified by column chromatography over silica gel with dichloromethane as the eluent. The products are identified by ^{1}H and ^{13}C NMR and mass spectroscopy, and compared with authentic commercial samples or literature data.

Periodic large mesopore organosilicas have been obtained for the first time using bridged silsesquioxane $(RO)_3SiCH_2CH_2Si(OR)_3$ precursors and triblock copolymers as structure-directing species in acid media.

Recently, beneficial properties of ordered mesoporous materials and hybrid organic–inorganic frameworks have been combined in an interesting class of materials possessing organic fragments fused 'within' the mesoporous framework, denoted periodic mesoporous organosilicas (PMO) through the surfactant-templated condensation of bifunctional organosiloxane presursors $(R'O)_3SiRSi(OR')_3$.[1–5] The development of PMOs offers an opportunity for fine-tuning porous structure, surface and framework characteristics by the judicious choice of the organic groups incorporated, and the synthesis conditions employed, and their properties may open new opportunities in catalysis, separations and advanced materials design. To date, the pore diameters of all reported PMOs are in the range of 2–4 nm,[1–4] however PMOs with larger pores are desirable for a variety of possible applications such as hosts for chemical reactions, uses in separations, immobilisation or encapsulation involving large molecules *etc*. Usually, ordered mesoporous silica phases with large pores are synthesised by using triblock copolymers as templates in strong acid (2 M HCl).[6] The charge density on organosilicate species formed by hydrolysis and oligomerisation of organosiloxanes under strong acid conditions is lower than that on the silicate species formed from tetraethoxysilane (TEOS),[1] and at low surfactant concentrations, no inorganic–organic interaction-induced long-range ordering of block polymers into templates occurs to help organise inorganic polymerising species. Thus the organosiloxane precursors are hydrolysed, and polymerised disordered structures and scattered pore-size distributions are obtained in such experimental conditions. An alternative route towards ordered mesoporous ceramic nanostructures is the utilisation of reformed lyotropic liquid crystal phases as structure-directing media.[7–11] For direct liquid crystal templating, surfactant concentrations are high enough to form long-range ordered assemblies even in the absence of silica–surfactant interactions. Thus, it is not necessary to create strong interactions between surfactant arrays and inorganic species because such interactions may disrupt the already existing long-range ordering of surfactant arrays.[9] Non-ionic block copolymers are very suitable for use in preparing ordered PMO materials by direct liquid crystal templating.[7,9] Feng *et al.* have reported large mesopore silicas using non-ionic Pluronic surfactants as templates in the triblock copolymer–alcohol–water ternary system.[9] In this communication, we report the synthesis of PMO systems with large tunable mesopores and a narrow pore size distribution using pre-existing polymeric liquid crystal phases as templates in the binary triblock copolymer–water system.

In a typical synthesis, colloidal ethanesilica was prepared by mixing an aqueous dilute HCl solution (pH 2) with bis(triethoxysilyl)ethane (BTE). Pluronic P123 ($M_{av} = 5800$), $EO_{20}PO_{70}EO_{20}$ was then added to the mixture, and the ethanol from the hydrolysis of BTE was removed under vacuum. The mass ratio was H_2O/HCl (1.0):P123 (0.8):BTE (3.2). As expected, the use of lyotropic polymer templates for the synthesis of nanocomposites has the advantage that macroscopic, optically transparent monoliths are obtainable, and crack-free monoliths can be obtained in considerable size. They are stable in air and due to their low-k dielectric and transparent properties, may have possible use in optical, electronic or other advanced applications.[5,12] The mesoporous ethanesilica materials were investigated by powder X-ray diffraction (PXRD), as shown in Fig. 1. After hydrothermal treatment and extraction of surfactant,[9] the long-range ordering of the sample is improved. The presence of (100), (110) and (200) peaks in the diffraction patterns is characteristic of well-ordered, 2-D hexagonal mesoporous monolithic materials. The ^{29}Si MAS NMR spectrum (see ESI†) of the hybrid mesoporous materials shows a broad ^{29}Si resonance at −56.5 ppm and a shoulder at −64.2 ppm, corresponding to trifunctional (−56.5 ppm, $RSiO_2(OH)$; −64.2 ppm, $RSiO_3$) silicon.[1–5] There was no evidence of tetrafunctional Q silicons between −90 and −120 ppm, and the absence of SiO_4 species such as $Si(OH)(OSi)_3$ and $Si(OSi)_4$ confirms that no cleavage of the carbon–silicon bond of the BTE starting organosilane compound has occurred during hydrolysis and polymerisation. The presence of T^2 Si atoms was indicative of incomplete condensation of the organosilane precursor, unreacted silanol groups still being present. On the other hand, a high concentration of silanol may be desirable for post-synthesis functionalisation of the mesoporous wall structure.[9] FT-IR spectroscopy† also supported this result, showing the appearance of absorption bands assigned to C–Si streching modes (ν(C–Si), 1273 cm^{-1}), while the broad absorption band at 1000–1200 cm^{-1} (ν(Si–O–Si)) indicates the formation of

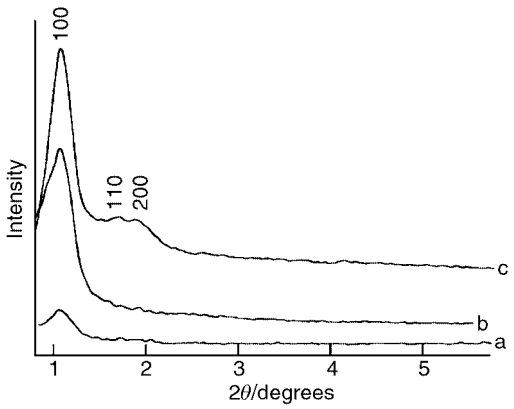

Fig. 1 Powder X-ray diffraction patterns of as-synthesised and surfactant-extracted hexagonal mesophases prepared from a P123/water system (51 wt%). † Electronic supplementary information (ESI) available: TEM image, MAS NMR and FT-IR spectra, and BJH pore size distribution for PMO materials. See http://www.rsc.org/suppdata/cc/b1/b106938c/

 DOI: 10.1039/b106938c

siloxane bonds. Residual silanol groups are evidenced by the ν(Si–OH) streching vibration at 900 cm^{-1}.[13] It is important to note that all silicon atoms are covalently connected to carbon atoms. Powder X-ray diffraction and TEM images of the materials showed that the structural integrity and order of the material is well maintained. In acid media, a slow and moderate condensation of organosilica units probably facilitates the ordering of the organic fragments due to a rigidity of the siloxane network that is lower when it consists of T^2 substructures than when it contains fully condensed T^3 substructures. In silica–block copolymer systems, hydrothermal treatment can lead to an enhancement of mesoscopic ordering and a reduction in shrinkage after removing surfactants. In the present case, after hydrothermal treatment at 100 °C for 24 h and solvent extraction, the materials showed an intensity enhanced diffraction pattern. TEM investigation of PMOs confirmed that they were well organised and have a 2-D *P6mm* hexagonal structure (Fig. 2). In the hexagonal range of the surfactant/water binary system,[14] an increase in surfactant concentration leads to an expansion in the mesopore size. With a ratio of PO/EO > 1, the increase in the hydrophobic volume exceeds the increase in hydrophilic volume, and the pore size can be tuned in the range of 5.8–7.7 nm through changing the concentration of the block copolymers. The N_2 adsorption isotherms at 77 K of the materials show a typical type IV isotherm with a clear H1-type hysteresis loop at high relative pressures and a vertical capillary condensation step at about P/P_0 = 0.75 (Fig. 3), suggesting that the materials have very regular mesoporous channels despite their large pore size. Quantitative analysis shows that the Brunauer–Emmett–Teller (BET) surface area is 957 m^2 g^{-1}, the total pore volume 1.37 cm^3 g^{-1}, and the most probable pore diameter 7.7 nm (BJH model). In conjunction with the unit cell dimension of 9.3 nm estimated from PXRD and TEM, this provides a wall thickness of *ca.* 1.6 nm. The wall thickness is in agreement with results on related systems.[2,15]

Thermogravimetric analysis of surfactant–organosilica mesophases shows a weight loss at 35–80 °C corresponding to the removal of physically adsorbed water and a weight loss at 150–250 °C corresponding to the elimination of surfactant. TGA data for solvent-extracted PMOs show a major weight loss at 200–300 °C corresponding to the decomposition and release of ethane fragments from the hybrid framework. This suggests that the thermal decomposition of surfactants may have a detrimental effect on organic groups in the PMO framework.[15]

In conclusion, a novel large pore size highly ordered PMO material has been synthesised for the first time, and is being investigated for the possible applications in immobilisation and encapsulation of large molecules.

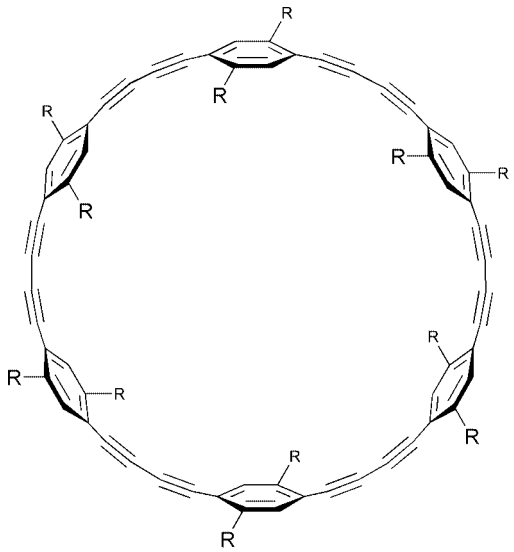
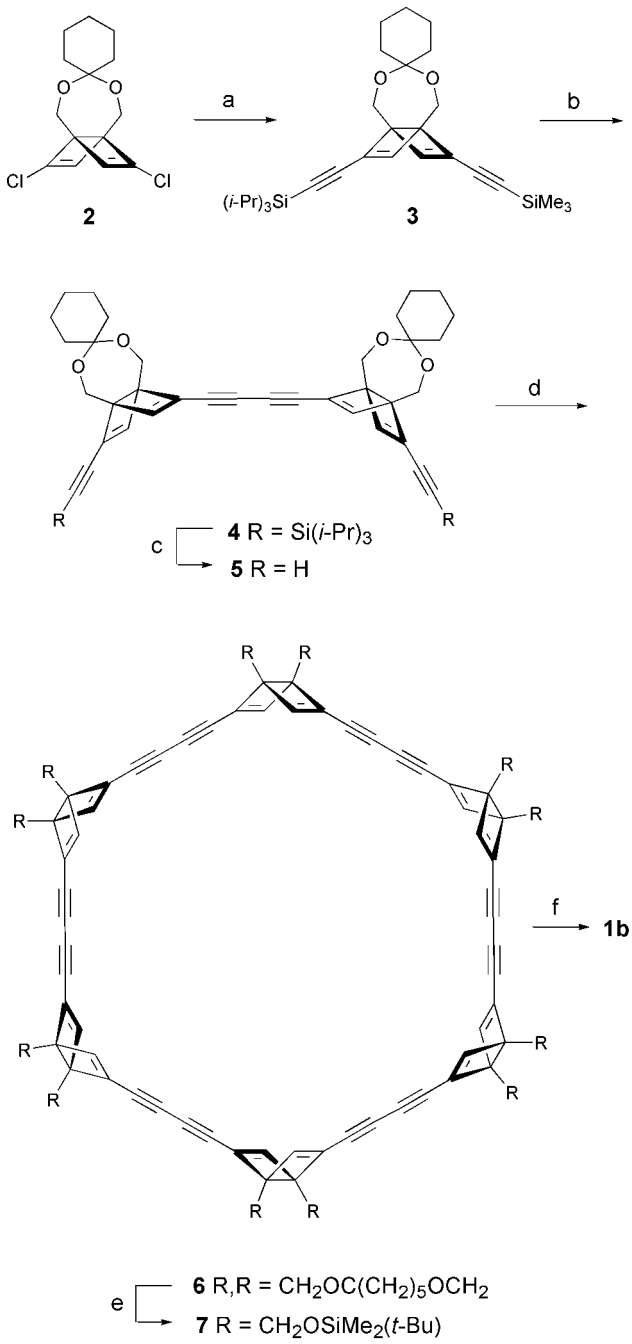
[4$_6$]paracyclophanedodecayne derivative 1 having a novel belt-shaped fully conjugated π-system was photochemically generated from the corresponding hexakis(Dewar benzene) precursor 7 as a highly strained but isolable compound.

Recently much attention has been focused on the design and construction of novel carbon-rich materials with unusual structural, electronic and optical properties.[1] Despite the fascinating structural features, however, π-conjugated carbon-rich macrocycles with a cylindrical structure still remain as a synthetic challenge, although several attempts to prepare related belt-shaped molecules such as cyclacenes,[2] cyclic paraphenylenes[3] and [8.8]paracyclophaneoctayne[4] have been reported. Remarkable examples are cyclic paraphenylacetylenes prepared by Kawase and Oda.[5] The generation of cyclo[*n*]carbons[6] and related polyyne-bridged cyclophanes[7] under mass spectroscopic conditions have also been proposed. In this communication we report the synthesis and characterization of the first [4$_6$]paracyclophanedodecayne derivative **1b**, in which six *p*-phenylene and butadiyne units are alternately connected to form a highly unsaturated cylindrical π-conjugated system. A key feature in the present approach is exploitation of a Dewar benzene as an angular *p*-phenylene synthon.[8] Thus, macrocycle **1b** was photochemically generated from the corresponding hexakis(Dewar benzene) compound **7** as a highly strained but isolable compound.



1a R = H
1b R = $CH_2OSiMe_2(t\text{-Bu})$

Synthesis of the precursor **7**, which also represents a rare example of oligo(Dewar benzene)s,[8,9] was achieved by using Dewar benzene building block **2**[8] as outlined in Scheme 1. Successive Pd-catalyzed couplings of **2** with TMS–acetylene and TIPS–acetylene gave unsymmetrical monomer unit **3**,



Scheme 1 *Reagents and conditions*: (a) (i) Me_3SiCCH, $Pd(PPh_3)_4$, CuI, Et_3N, rt; (ii) $(i\text{-Pr})_3SiCCH$, $Pd(PPh_3)_4$, CuI, Et_3N, rt, 54% (two steps); (b) $Cu(OAc)_2$, CuCl, Py, rt, 85%; (c) Bu4NF, THF, 0 °C; (d) $Cu(OAc)_2$, CuCl, Py, 60 °C, syringe-pump, 15% (two steps); (e) (i) 1 N HCl, THF, rt, (ii) $CF_3SO_3SiMe_2(t\text{-Bu})$, Et3N, rt, 69% (two steps); (f) *hν*, benzene, 12 °C, 100%. Although compounds **4**–**7** are inseparable mixtures of diastereomers, only those with the highest symmetry are illustrated for clarity.

 DOI: 10.1039/b108253c

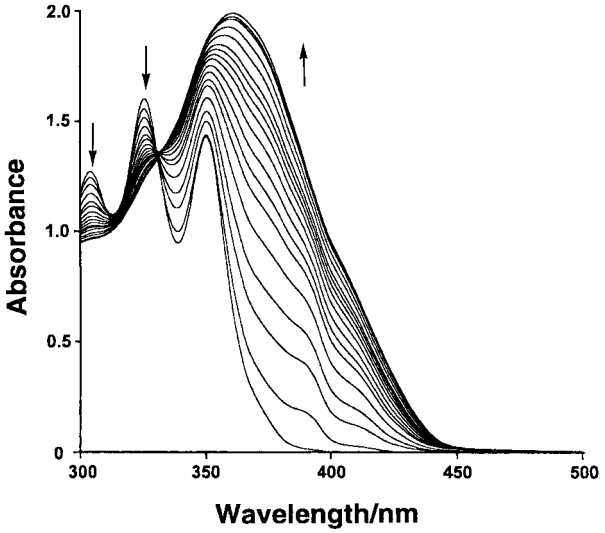


Fig. 1 UV-vis spectral changes observed upon irradiation of **7** in benzene through Pyrex at 30 s intervals.

which was converted to dimer unit **4** by an *in situ* selective deprotection–oxidative coupling sequence.[10] After the removal of the TIPS groups, **5** was subjected to the modified Eglinton coupling[10] under pseudo-high-dilution conditions to afford cyclic hexamer **6** in 15% yield as a mixture of diastereomers after purification by preparative GPC. In this macrocylization, a larger cyclic oligomer, to be assigned as octamer, was also formed as a minor product (5–8% yield). Acid hydrolysis of **6** followed by silylation of the resulting polyol afforded hexakis(Dewar benzene) derivative **7**.

Aromatization of **7** was found to proceed smoothly and cleanly under photochemical conditions to afford **1b**.† Thus, ^{1}H NMR monitoring of the photolysis showed that irradiation of **7** in $CDCl_3$ with a high-pressure mercury lamp through Pyrex at ambient temperature led to the formation of a single product in a nearly quantitative yield. The marked down-field shift observed for the resonance signals due to the olefinic protons (δ 6.80–6.83) and the CH_2OTBS methylene protons (δ 4.00) to δ 7.58 and δ 4.80, respectively, are consistent with the aromatization of the Dewar benzene units. The UV-vis spectral changes recorded during the photolysis of **7** in benzene are shown in Fig. 1; the isosbestic point observed is also indicative of the clean conversion of **7** into **1b**.‡ Macrocycle **1b** was isolated as a rather air-sensitive pale yellow solid which decomposed gradually within several days upon standing in solution or in the solid state under air at room temperature. Although attempts to determine the molecular mass of **1b** by mass spectroscopy with routine ionization methods (EI, FD, FAB) failed, it was successfully determined by ESI-MS as a complex with Na^+. Compound **1b** exhibits simple ^{1}H and ^{13}C NMR spectra in $CDCl_3$ at 25 °C, four singlets in the former and nine lines in the latter, suggesting fast rotation of the *p*-phenylene units on the NMR time scale at this temperature.§ Since to date we have been unable to obtain single crystals of **1b** suitable for X-ray diffraction study, we carried out semiempirical PM3 calculations for model compound **1a** to gain structural information about **1b**. As shown in Fig. 2, the optimized structure of **1a** adopts a cylindrical conformation possessing a well-defined cavity of about 15 Å diameter. The strained nature of **1a** is mainly reflected in the deviation of the acetylene moieties from linearity and the calculated C≡C–C(sp^2) and C≡C–C(sp) bond angles are 170.8° and 171.2°, respectively.

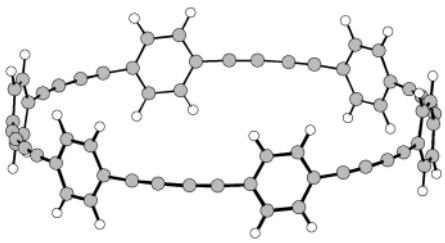

Fig. 2 PM3 optimized structure of **1a**.

In conclusion, we have successfully synthesized and characterized [4$_6$]paracyclophanedodecayne derivative **1b**, possessing the most unsaturated cylindrical π-conjugated system ever isolated. The present results clearly demonstrate the high synthetic potential of our Dewar benzene building block approach for the construction of strained phenylene macrocycles that are difficult to prepare from planar benzene derivatives.

First published as an Advance Article on the web 13th November 2001

β-(3,4-Dimethoxyphenyl)serine methyl ester was obtained in high diastereomeric and enantiomeric excesses under transfer hydrogenation using chiral Ru(η⁶-arene)-*N*-perfluorosulfonyl-1,2-diamine catalysts.

Catalytic transfer hydrogenation using propan-2-ol or formic acid as hydrogen source has become one of the most significant tools for asymmetric reduction of ketones.[1,2] This method is a powerful alternative to asymmetric hydrogenation using molecular hydrogen with chiral Ru(II)-bisphosphane catalysts[3] due to its practical simplicity and the possibility of using easily accessible and less sensitive ligands. Applications include the asymmetric reduction of aromatic[4] or α,β-acetylenic ketones[5] and, more recently, transfer hydrogenation of benzils into chiral hydrobenzoins *via* a dynamic kinetic resolution.[6] Most of these articles deal with Noyori's chiral catalyst Ru(II)-TsDPEN[7] (TsDPEN = *N*-tosyl-1,2-diphenylethylenediamine). However, although very efficient, this catalyst suffers from long reaction time and general low activity.

In an attempt to improve the performance of this catalytic system, we thought to modify the diamine ligand by introducing electron-withdrawing fluorosulfonyl groups, despite some discouraging results reported on the use of triflate substituted ligand **4d**.[4]

In order to evaluate the performance of our catalysts we investigated the transfer hydrogenation of the racemic *threo*-β-hydroxy-α-amino acids **1**[8] for the synthesis of the *threo*-**2** isomer[9] *via* a dynamic kinetic resolution (Scheme 1).

Several ligands (*S,S*)-**4a–e** and (*S,S*)-**5a–e** were prepared starting from homochiral 1,2-diphenylethylenediamine and *trans*-1,2-diaminocyclohexane, respectively. The β-keto-α-amino ester **1** was subjected to transfer hydrogenation in the presence of the reference Ru(II)-TsDPEN catalyst[4] in a 5:2 formic acid–triethylamine azeotrope yielding *threo*-**2** in 94% ee and with high 95:5 *threo/erythro* ratio. Curiously, the catalyst prepared *in situ* by heating TsDPEN ligand **4a** and $[RuCl_2(p\text{-cymene})]_2$ in propan-2-ol in the presence of triethylamine,[4b] led to only 20% conversion compared with 80% for the catalyst prepared without a base (Table 1, entry 1). Changing the arylsulfonyl group in the diamine ligand from toluene-*p*-sulfonyl to a more electron-withdrawing *p*-trifluoromethylben-

[a] Reactions were carried out at 45 °C with S/C (substrate/catalyst) = 40.[b] Conversion and *threo/erythro* ratio were determined by ^{1}H NMR spectroscopy.[c] Enantiomeric purity of *threo*-**2** was determined by HPLC (Daicel Chiralpack AD) of the Z-deprotected compound **3**.[d] S/C = 100.

 DOI: 10.1039/b107822b

zenesulfonyl resulted in a remarkable improvement of activity leading to 100% conversion, but with 90% ee (entry 2).

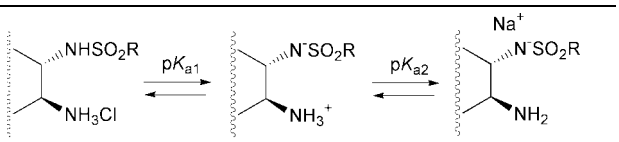
The catalyst prepared from the pentafluorobenzenesulfonamide ligand **4c** and [$RuCl_2$(*p*-cymene)] gave 94% ee of *threo*-**2** (entry 3), but it was less reactive than the catalyst prepared from **4b**. Changing the η^6-arene ligand from *p*-cymene to benzene slightly increased the catalyst activity, while stereoselectivity dropped significantly (entries 3, 4). Using the triflate substituted ligand **4d** in combination with η^6-*p*-cymene, led to total conversion of **1** in 35 h yielding *threo*-**2** in 98% ee (entry 5). The nonaflate-substituted ligand **4e**, despite its higher steric bulkiness with respect to **4d**, gave practically enantiomerically pure *threo*-**2** in only 27 h (entry 6).

The cyclohexyldiamine ligand series **5a–e** led to similar stereoselectivities compared with the diphenylethylenediamine ligands **4a–e**, but necessitated longer reaction times (entries 7–11). The most active catalyst was prepared with the nonaflate substituted ligand **5e** and η^6-*p*-cymene leading to 100% conversion in 40 h with >99% ee (entry 11).

These results show that the stereoselectivity and the catalyst activity are very much influenced by the sulfonamide group and by the η^6-arene of the catalyst. Moreover, the η^6-arene has a profound influence on the diastereoselectivity (*e.g.* entries 3, 4). In an attempt to rationalize our results we determined pK_a values of the diamine ligands[10] (Table 2).

We found that the sulfonyl function does not only affect the acidity of the sulfonamide NH group, but also affects the basicity of NH_2. As expected, the sulfonamide groups display large pK_a variations from 7.4 to 4.5 for ligands **4a–e** and from 8.4 to 3.0 for ligands **5a–e**. The pK_a values of NH_2 range from 11.1 to 8.3 and from 9.4 to 5.7 for **4a–e** and **5a–e**, respectively. Correlation of these pK_a's and the catalysis results revealed that the activity of the catalyst is improved by a decrease of the pK_a of the sulfonamide group and by a decrease of the basicity of the NH_2. For example, the most active catalyst in the cyclohexanediamine series (100% conversion in 40 h with >99% ee) was prepared from the mono nonaflate ligand **5e** which showed the lowest pK_{a1} = 3.0 and pK_{a2} = 5.7 values. The poorest catalyst in this series (50% conversion in 95 h with 88% ee) was prepared from the ligand **5a** showing the highest pK_{a1} = 8.4 and pK_{a2} = 9.4 values. The catalyst prepared from ligands showing intermediate pK_a values (*e.g.* 5.6 and 6.5 for **5d**) proved to have an intermediate reactivity (95% conversion in 72 h with 97% ee). The same correlation is observed in the diphenylethylendiamine series.

Table 2 pK_a values of ligands **4,5-a,b,d,e**[a]



Ligand		**a**	**b**	**d**	**e**
4	pK_{a1}	7.4	—[b]	4.5	4.5
pK_{a2}	11.1	—	8.3	8.5	
5	pK_{a1}	8.4	8.3	5.6	3.0
pK_{a2}	9.4	9.3	6.5	5.7	

[a] pK_a values were determined potentiometrically. [b] The ligand was not soluble under titration conditions.

Although these preliminary results have to be extended to other families of ligands and catalytic systems, pK_a measurements might become a useful tool for ligand design and mechanistic investigations.

In summary, in this work we show that introducing a better electron-withdrawing group on the Noyori's TsDPEN ligand strongly improves the catalyst activity and stereoselectivity in transfer hydrogenation of a β-keto-α-amino acid **1** *via* dynamic kinetic resolution. In particular, the catalyst prepared from the nonaflate ligand **4e** proved to be much more active than the TsDPEN ligand and gave >99% ee. Moreover, the activity and enantioselectivity were found to be influenced by the ligand's pK_a values.

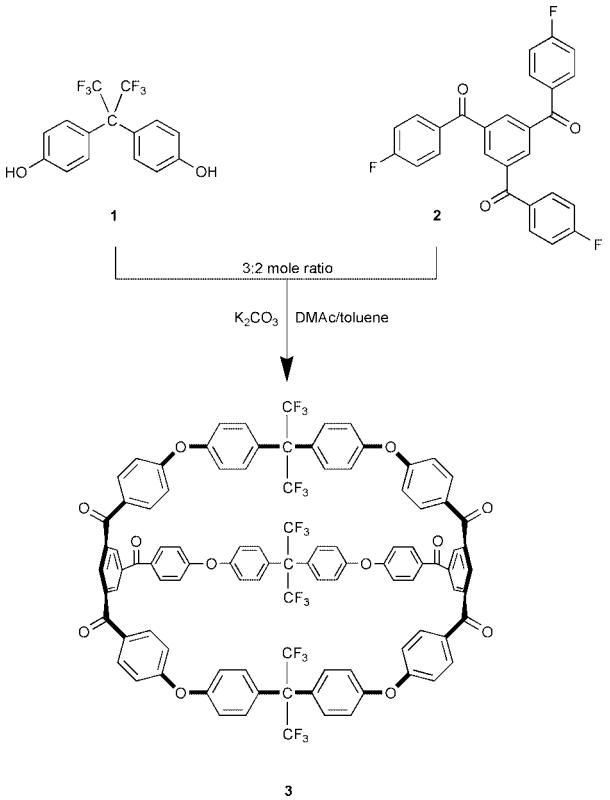
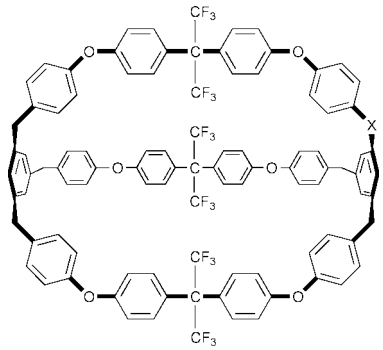
Received (in Cambridge, UK) 7th September 2001, Accepted 23rd October 2001
First published as an Advance Article on the web 13th November 2001

Polycondensation of a trifunctional, ketone-activated fluoroarene with bis- or tris-phenoxides under *pseudo*-high dilution conditions affords a series of very large macropolycyclic aromatic ether ketones; isolation and characterisation of these materials by NMR, MALDI-TOF MS and, for one example (after reduction of the carbonyl groups to methylene linkages) by X-ray crystallography, confirms that polycondensations which would normally lead to highly branched or cross-linked polymers can also give rise to large, closed-network molecules.

The synthetic and structural relationships between linear aromatic polymers and their macrocyclic homologues have been intensively investigated over the past decade,[1] work focusing mainly on the potential of macrocyclic ring-opening polymerisation for reactive fabrication of linear polymers. The reverse reaction—ring closing depolymerisation—has however also been explored for application in the recovery and recycling of high-value condensation polymers.[2] Macrocyclic aromatic oligo-amides are, in addition, of considerable value for the generation of novel supramolecular architectures including catenanes,[3] rotaxanes,[4] and knots.[5] We now describe some preliminary experiments which demonstrate that the ring–chain relationship can be extended to a third dimension. Thus, polycondensations involving trifunctional monomers, which would normally afford highly branched or even fully cross-linked polymers, are here shown also to give, under *pseudo*-high dilution conditions, a series of very large aromatic cage-type molecules.[6]



Scheme 1



Reaction of 4,4′-hexafluoroisopropylidenediphenol (**1**) with 1,3,5-tris(4-fluorobenzoyl)benzene (**2**) was carried out by slow addition of a solution of the two monomers (3 : 2 mole ratio) in dimethylacetamide (DMAc) to potassium carbonate in refluxing DMAc–toluene, with continuous azeotropic removal of water (Scheme 1). A complex mixture of oligomeric and polymeric materials was obtained but the macrobicyclic cage-compound **3** (mp 450 °C) could be isolated straightforwardly from this mixture, albeit in low yield (~5%) , by column chromatography.

Spectroscopic analyses of **3** by MALDI-TOF MS and by ^{1}H and ^{13}C NMR were entirely consistent with the structure shown in Scheme 1, but efforts to obtain single crystals suitable for X-ray analysis were unsuccessful. However, reduction of the carbonyl groups in **3** to methylene linkages using triethylsilane and trifluoroacetic acid (Scheme 1)[7] afforded the fully-reduced cage-compound **4** (42% yield), together with a compound (**5**) in 21% yield in which one ketone group remains unreduced.† Compounds **4** and **5** were readily separated by column chromatography, and **4** eventually yielded crystals suitable for X-ray analysis.‡ Its structure is shown in Fig. 1, from which it is evident that the composition and topology proposed for this compound (and thus by inference for **3**) are correct.

The molecule adopts a semi-collapsed and flattened conformation with no obvious intramolecular interactions other than a weak π-stacking arrangement between a pair of aromatic ether-containing ring systems in the two adjacent arms of the

† Electronic supplementary data (ESI) available: analytical and spectroscopic data for compounds **3**–**5** and **8**. See http://www.rsc.org/suppdata/cc/b1/b108124c/

 DOI: 10.1039/b108124c

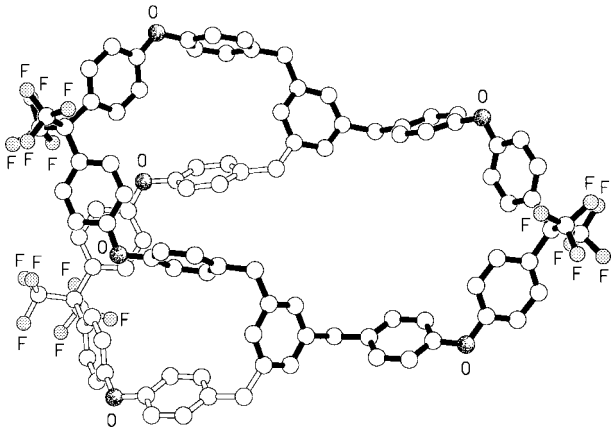


Fig. 1 Molecular structure of the reduced cage-compound **4** (hydrogen atoms are omitted for clarity).

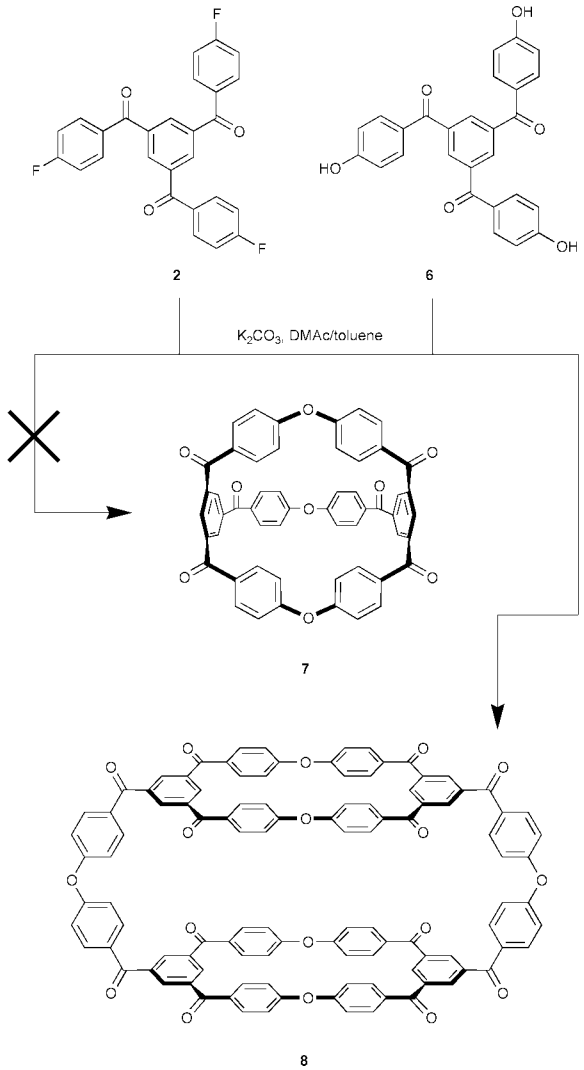
macrocycle. The hexafluoroisopropylidene-linked aromatic residues here display a consistently skewed conformation, but the diarylene-ether units have geometries that range from symmetrically-skewed to near-orthogonal.



Scheme 2

An analogous polycondensation between the trifluoro-compound **2** and tris-phenol **6** (derived from **2** by hydrolysis with potassium hydroxide in DMSO) afforded not the expected cage-compound **7**—a direct analogue of **3**—but its macrotricyclic dimer **8** (Scheme 2). This compound was isolated in pure form by column chromatography (4% yield) and characterised in detail.† It shows a sharp, clearly-defined melting point by DSC at the astonishingly high temperature of 556 °C, reflecting both extreme rigidity of the molecular structure and a quite remarkable thermal stability. The MALDI-TOF spectrum of the original product mixture showed a strong $[M + Na]^+$ peak for compound **8**, but gave no evidence for the monomeric cage **7**. The MALDI-TOF analysis did however indicate the presence of higher polycyclic oligomers of **7**, including the macro-polycyclic trimer and tetramer. Evidence to date, mainly from the ^1H NMR spectra of partially-resolved chromatographic fractions, suggests that the higher-order polycyclic oligomers of **7** comprise increasing numbers of the structural repeat (a six-ring macrocycle with a two-ring linking umit) found in oligomer **8**.

This approach to large, closed-network molecules is clearly not restricted to the aromatic polyetherketone systems described here, but should be generally applicable to *any* type of branching polycondensation, including esterification, amidation and imidation. Such possibilities are currently under investigation, as are the potential applications of these molecules in supramolecular assembly and in cage-opening polymerisation.

We thank Professor F. H. Kohnke of the University of Messina for stimulating discussions.

First published as an Advance Article on the web 13th November 2001

2-Aminobenzyl alcohol is oxidatively cyclised with an array of ketones in dioxane at 80 °C in the presence of a catalytic amount of a ruthenium catalyst and KOH to afford the corresponding quinolines in high yields.

Many synthetic routes are well documented for the formation of quinolines since the quinoline nucleus plays an important role as an intermediate for the design of many pharmacologically active compounds.[1,2] Besides conventional named methods such as Skraup, Döbner-von Miller, Conrad-Limpach, Friedlaender and Pfitzinger syntheses,[1] homogeneous transition metal-catalysed synthetic methods have been attempted because of the wide availability of substrate.[3] We have also reported on the formation of quinolines *via* a ruthenium-catalysed alkyl group transfer from alkylamines to the nitrogen atom of anilines (amine exchange reaction).[4] During the course of our ongoing studies on ruthenium catalysis,[5,6] in connection with this report, we recently found an unusual type of ruthenium-catalysed transfer hydrogenation of ketones by alcohols under the molar ratio of alcohol : ketone = 3 (Scheme 1).[7] It was suggested that the reaction proceeds *via* a sequence involving oxidation of alcohol to aldehyde and cross aldol reaction of aldehyde with ketone to form an α,β-unsaturated ketone which is subsequently hydrogenated to the product by a dihydridoruthenium (RuH_2) generated by the initial oxidation of the starting alcohol. Prompted by these findings and intrigued by the diverse reactivities of ruthenium catalysts, we have directed our attention to the application of this methodology to the synthesis of N-heterocycles. Herein we report a modified Friedlaender quinoline synthesis *via* a ruthenium-catalysed oxidative cyclisation of 2-aminobenzyl alcohol with ketones.[8]

presence of a catalytic amount of a ruthenium catalyst (1 mol% based on **1**) and KOH to afford 2-phenylquinoline (**3**). The reaction was monitored until **1** had disappeared on TLC, which occurred within 1 h. The product yield increased with increase in reaction temperature up to 80 °C (runs 1–3). Tuning the molar ratio of **2** to **1** was critical for the effective formation of **3**. Upon using equimolar amounts of **1** and **2**, the yield of **3** was lower than that when the molar ratio of 2 was used (run 4). This could be due to partial consumption of **2** leading to 1-phenylethanol by transfer hydrogenation of **2** by **1**. Of various ruthenium catalysts employed, $RuCl_2(=CHPh)(PCy_3)_2$ is the choice of preference for the effective formation of **3** (runs 5–11). In all cases, **3** was formed in moderate to high yields with concomitant formation of 1-phenylethanol by transfer hydrogenation of **2** by **1** ranging from 5–12%.† [9]

Given suitable reaction conditions, a series of ketones were screened in order to scrutinise the reaction scope, and several representative results are summarised in Table 2. Alkyl aryl ketones were readily cyclised with **1** irrespective of the examined functional groups on the aromatic ring to afford the corresponding 2-arylquinolines in excellent to good yields. The quinoline yield was not greatly affected by the position of the substituent on the aromatic ring of ketones, whereas the electronic nature of that had some relevance to the product yield. Lower reaction rate and yield were observed with acetophenones having nitro, hydroxy and cyano functional groups on the aromatic ring. With alkyl heteroaryl ketones, the corresponding quinolines were also formed in high yields. In the reaction of dialkylketones, the corresponding quinolines were obtained as a regioisomeric mixture, favoring cyclisation at less-hindered position over α-methylene.[6,7,10] An array of alkyl aryl, cyclic and benzo-fused cyclic ketones having only the methylene reaction site also afforded the corresponding products ranging from 66–97%.

As to the reaction pathway, this seems to proceed *via* an initial oxidative addition of ruthenium to O–H bond of **1** followed by β-hydrogen elimination to give 2-aminobenzaldehyde. The precedents of such an oxidative addition have been well documented in several transfer hydrogenation reactions.[9]

In summary, we have demonstrated that 2-aminobenzyl alcohol can be oxidatively cyclised with an array of ketones in the presence of a ruthenium catalyst to give quinolines in high yields. The present reaction is a novel transition metal-catalysed Friedlaender quinoline synthesis.

The present work was supported by the Basic Research Program of the Korea Science and Engineering Foundation (R01-2000-00044). C.S.C. gratefully acknowledges a MOE-KRF Research Professor Program (2001-050-D00015).

Notes and references

† *General experimental procedure*: a mixture of 2-aminobenzyl alcohol (1 mmol), ketone (2 mmol), $RuCl_2(=CHPh)(PCy_3)_2$ (0.01 mmol) and KOH (1 mmol) in dioxane (3 ml) was placed in a 5 ml screw-capped vial. The system was flushed with argon and allowed to react at 80 °C for 1 h. The reaction mixture was filtered through a short silica gel column (ethyl acetate), washed with brine and dried over Na_2SO_4. Removal of the solvent left a crude mixture, which was separated by column chromatography (silica gel, ethyl acetate–hexane mixture) to give quinolines.

A novel synthesis of substituted bicyclo[2.2.2]octenones and 3,3-sigmatropic shift: a general and stereoselective entry into functionalized *cis*-decalins

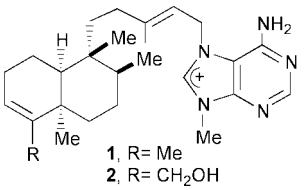
Vishwakarma Singh* and Sridhar Iyer

Department of Chemistry, Indian Institute of Technology Bombay, Mumbai 400 076, India

Received (in Cambridge, UK) 8th October 2001, Accepted 26th October 2001
First published as an Advance Article on the web 14th November 2001

Synthesis of bicyclo[2.2.2]octenones 4a–d, 9 and their Cope rearrangement to substituted *cis*-decalins 3a–d, 12, is described.

Recently, several diterpene alkaloids such as **1**, **2** were isolated from marine sponges of the genus *Agelas*.[1–3] Some members of this family exhibit interesting biological activities such as cytotoxicity, antimicrobial activity and inhibition of Na, K-ATPase.[2a,c,4] Interestingly, these alkaloids contain a *cis*-decalin framework similar to *cis*-cleoradanes.[5] In view of the isolation of these interesting diterpenes and cleoradanes[5] which have a *cis*-decalin skeleton containing contiguous stereocentres, there has been a growing interest in the development of new stereoselective methods for the synthesis of substituted *cis*-decalins.[6–10]

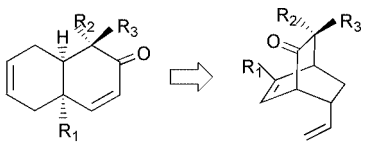


1, R= Me
2, R= CH_2OH

We thought to develop a general and flexible route to *cis*-decalins of type **3** having stereochemically defined substituents, olefinic linkages and a carbonyl group. It was considered that *cis*-decalins such as **3** could be directly obtained *via* a Cope rearrangement of an appropriately designed bicyclo[2.2.2]octenone system of type **4** with an *endo* vinyl moiety and other substituents, in a highly stereocontrolled fashion (Scheme 1). It may be worth mentioning that, while there are no routes to advanced bicyclo[2.2.2]octenones of type **4**, synthesis of even simpler bicyclic precursors involves cycloaddition of ketene equivalents with dienes followed by addition of a vinyl group.[9b,c]

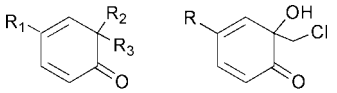
In this communication, we wish to report a new method for the synthesis of bicyclo[2.2.2]octenones of type **4** that directly introduces a vinyl group on to the bicyclic frame and also permits introduction of methyl and other alkyl substituents, and their Cope rearrangement leading to a general, flexible and stereoselective route to highly substituted *cis*-decalins.

Conceptually, the desired bicyclooctenones of type **4** should be available *via* inverse electron demand cycloaddition of cyclohexa-2,4-dienones of type **5** with acyclic 1,3-dienes. Though, there are some methods for preparation of 6,6-disubstituted cyclohexadienones of type **5** *viz*., the alkylation[11a] of



3 **4**

Scheme 1



5 **6**

o-substituted phenols and rearrangement of epoxyfulvene,[11b] these methods are not easily adaptable. We therefore, developed an indirect route to the bicyclic systems of type **4** by *in-situ* generation of cyclohexa-2,4-dienone **6** and butadiene, their cycloaddition, and manipulation of the resulting adduct.

Thus, the addition of sulfolene **8** to a solution of the readily available[12] dimer **7a** in *o*-dichlorobenzene at 140 °C followed by chromatography of the reaction mixture gave the adduct **9a** as a major product. The structure of the adduct was deduced from its spectroscopic and analytical data.† While, the *endo*-stereochemistry of the adduct **9a** was proved through its Cope rearrangement (*vide infra*), orientation of the chloromethyl and hydroxy group was suggested on the basis of general tendency of cyclohexa-2,4-dienones during their cycloaddition and comparison with analogous compounds.[13] Although yield of the above cycloaddition is moderate, the generation of molecular complexity in a single step is noteworthy.

Manipulation of the functional groups of **9a** enabled the stereoselective introduction of alkyl substituents at the carbon bearing hydroxy and chloromethyl groups. Thus, the adduct **9a** was easily converted into epoxyketone **10a** in a quantitative fashion. Treatment of **10a** with zinc in dry dioxane containing ammonium chloride gave the compound **11a** as a result of deoxygenation of the oxirane ring.[14]

Alkylation of **11a** with allyl bromide in the presence of NaH–THF gave a mixture of *syn–anti* (85 : 15) isomers from which the *syn* isomer **4a** was isolated in major amounts. Such type of stereoselectivity in alkylation has been also observed by Stork and Paquette.[15] Alkylation of **11a** with propargyl bromide also gave the propargyl analogue **4c** in a selective fashion, which was converted into the dione **4d** by hydration of the acetylene moiety (Scheme 2). Similarly, more substituted bicyclic precursor **4b** with a methyl group at C-8, and an allyl and a methyl group at C6 was synthesized from the dimer **7b** (Scheme 2). Thus, the present methodology provides a novel and stereoselective route to bicyclic frameworks with an *endo* vinyl moiety, stereochemically defined substituents and a carbonyl group.

Next 3,3-sigmatropic rearrangement of **9a**, and **4a–d** was examined. Thus, a solution of **9a** in *o*-dichlorobenzene was heated at ~ 170 °C which smoothly furnished the bicyclic enone **12** in quantitative yield. Similarly, other bicyclic compounds **4a–d** also underwent 3,3-sigmatropic shifts to give the highly substituted *cis*-decalins **3a–d** (Scheme 3). The structures of all the products were clearly revealed from their spectral data.†

In summary, we have described a new and efficient synthesis of bicyclooctenones of type **4a–d**, **9** with vinyl, methyl and other alkyl substituents and their Cope rearrangement leading to a stereoselective route to substituted *cis*-decalins (**3a–3d**, **12**). This strategy is flexible and adaptable since it permits incorporation of a methyl group at the ring junctions in the

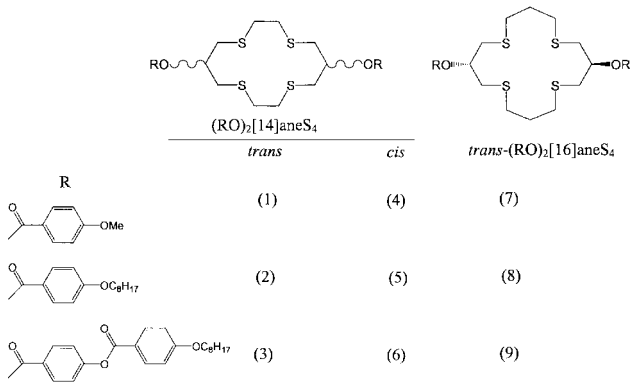
First published as an Advance Article on the web 23rd November 2001

Oligo(benzoate) derivatives of *cis*- and *trans*-$(RO)_2$[14]aneS$_4$, *trans*-$(RO)_2$[16]aneS$_4$, and their corresponding Pd(II) complexes reveal metal-induced mesomorphic behaviour which can be rationalised by conformational locking of the ligand on complexation.

The formation of mesogenic materials from functionalised macrocyclic ligands is the subject of considerable current interest.[1–8] Examples have been reported using N-functionalised aza crowns which afford columnar mesophases,[2–6] although these systems tend to use the aza crown as a central building core for attachment of peripheral groups and the amide nitrogen atoms are generally poor donors to metal ions. Metal ion binding can, however, be facilitated by reduction of the amide linkers of the ligand to tertiary amines. In this way, for example, Lattermann and coworkers have reported[7] the formation of columnar rectangular phases for the octahedral complexes $[M(CO)_3(R_3[9]aneN_3)]$ (R = alkoxybenzyl; M = Cr, Mo, W), while the symmetric functionalisation of polyaza macrocycles to give a range of columnar mesophases has also been reported by the groups of Latterman, Ringsdorf and Goodby.[8]

We were interested in developing functionalised thioether S-donor crowns as potential mesogenic materials. Unlike the N-donor systems, these have to be functionalised on the C-backbone, and although this is not always synthetically straightforward, it affords the polythioether donor core intact and available for metal complexation. A direct comparison can, therefore, also be made between the mesogenic mesomorphic properties of metal-free and metal-complexed materials. Furthermore, the ability of thioether macrocycles to coordinate to a wide variety of metal ions has been demonstrated,[9] and functionalisation of the periphery of the ligand does not appear to alter significantly the complexation properties of the resultant thioether crown.[10] Very little work has been reported on the synthesis of mesomorphic thioether crowns,[1,11,12] and we report herein the synthesis and thermal behaviour of a range of ligands and Pd(II) complexes of oligo(benzoate) ester derivatives.

Compounds **1**–**9** (Scheme 1) were prepared from the corresponding pure *cis* and *trans* dialcohols[13] *via* esterification with the appropriate carboxylic acid, acid chloride or acid anhydride. The reaction of equimolar amounts of $[Pd(MeCN)_4](BF_4)_2$ and each of **1**–**9** in MeCN–CH_2Cl_2 gave yellow solids which afforded yellow crystals upon crystallisation from MeCN–Et_2O. The purity of both the macrocyclic ligand and the corresponding Pd(II) complex was confirmed by ^{1}H and ^{13}C NMR spectroscopy, mass spectrometry (EI, FAB, ES) and by elemental analysis after consecutive recrystallisations. The thermal behaviour of the ligands and their Pd(II) complexes was studied by polarised optical microscopy. None of the ligands showed any mesomorphism, all simply melting directly to the isotropic phase. However, on complexation to Pd(II), the thermal behaviour changed markedly. Thus, while all the complexes of the *cis*-ligands and the two complexes of the *trans*-functionalised ligand with methoxy chains (**1** and **7**) were non-mesomorphic, the remaining complexes were indeed found to be mesomorphic (Table 1), showing monotropic nematic or SmC phases. These phases can be observed clearly by polarised optical microscopy, although decomposition does occur when samples are kept at elevated temperatures for prolonged periods.



Scheme 1

On complexation to Pd(II), the macrocyclic ring becomes conformationally locked and acts as a rigid spacer which couples the terminal mesogenic groups together. Thus, for $[Pd(\mathbf{3})](BF_4)_2$ all four terminal phenyl groups are now part of the same anisotropic unit connected *via* the central complexed crown. The overall anisotropy is now sufficiently high to allow mesomorphism, and a monotropic nematic phase is observed, whereas the metal free ligand simply melts. Furthermore, $[Pd(\mathbf{2})](BF_4)_2$ is also mesomorphic giving a monotropic smectic SmC phase confirming that only two phenyl ester functions are required for mesomorphism. Interestingly, $[Pd(\mathbf{3})](BF_4)_2$ and

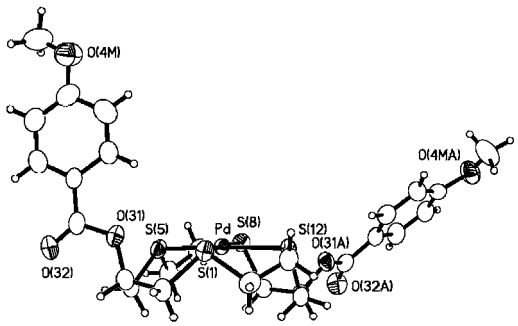

Fig. 2 View of the structure of $[Pd(\mathbf{4})]^{2+}$ with numbering scheme adopted.

$[Pd(\mathbf{9})](BF_4)_2$ are very rare examples of ionic species showing a thermotropic nematic phase.[14]

Further support for the above arguments comes from crystal structure determinations on model anisate derivatives $[Pd(\mathbf{1})](BF_4)_2$, $[Pd(\mathbf{4})](BF_4)_2$ and $[Pd(\mathbf{7})](BF_4)_2$.‡ The structure of $[Pd(\mathbf{1})](BF_4)_2$ shows an S-shaped conformation for the complexed *trans*-ligand (Fig. 1). A zigzag arrangement of cations in the packing diagram is observed as a consequence of the *trans* configuration of the functionalised macrocycle which adopts a [3434] conformation. The Pd(II) cation occupies a crystallographic inversion centre and therefore lies precisely in the S_4 mean plane. No aromatic π–π stacking is observed, although such interactions have been observed for the free ligand **1** where the macrocycle also adopts a [3434] configuration.[1] In contrast, the structure determination of *cis*-$[Pd(\mathbf{4})](BF_4)_2$ reveals a U-shaped cation with the phenyl groups pointing away from the macrocycle which adopts a [3434] conformation (Fig. 2) as for $[Pd(\mathbf{1})]^{2+}$. The Pd(II) ion exhibits a square planar geometry and is displaced out of the S_4 mean plane by 0.0365 Å. The dihedral angle between the mean plane of the phenyl rings and the S_4 mean plane is 82.6(2)° (C1P–C6P) and 41.5(2)° (C1P′–C6P′), with a dihedral angle between the two phenyl rings of 77.5(2)°. This results in the observed twisted U-shaped conformation for the complexed ligand. As in $[Pd(\mathbf{1})]^{2+}$, there are no aromatic π–π interactions between the phenyl groups in $[Pd(\mathbf{4})](BF_4)_2$ (Fig. 4, ESI†), although this is observed for the metal-free ligand which adopts a [223223] conformation.[1]

There is clearly, therefore, a direct conformational and configurational difference between the *cis* and *trans* isomers, which is reflected in mesophase formation. It is of course dangerous to attempt to correlate directly solid-state effects and potential structural features in the mesophase itself, particularly since monotropic behaviour is observed in each case. However, it is tempting to suggest that *trans*-isomers are more favorably disposed towards the formation of nematic mesophases. This is supported further by the results of a structure determination of $[Pd(\mathbf{7})](BF_4)_2$ which shows (Fig. 3) a similar S-shaped configuration to that of *trans*-$[Pd(\mathbf{1})](BF_4)_2$. The central Pd(II) cation occupies a crystallographic inversion centre and therefore lies precisely in the S_4 plane The central Pd(II) cation lies

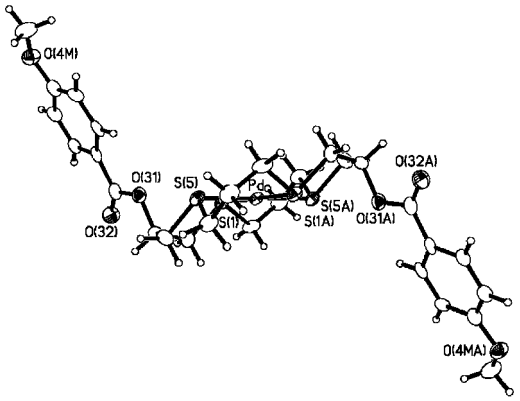

Fig. 3 View of the structure of $[Pd(\mathbf{7})]^{2+}$ with numbering scheme adopted.

in the mean S_4 plane of the macrocycle which adopts a [5353] conformation. Interestingly, however, the packing diagram of $[Pd(\mathbf{7})](BF_4)_2$ shows undulating layers of cations *via* π–π interactions of 3.326 Å with an offset angle of some 64.1° (Fig. 5, ESI†). This confirms that there are clear structural differences between 14- and 16-membered ring systems.

In conclusion, we have demonstrated the ability of a metal ion to induce mesomorphism in non-mesomorphic ligands, defining a sensing function for the ligands. Further, while both *cis* and *trans* isomers of related highly anisotropic macrocycles have been shown previously to be mesomorphic,[1] the conformational locking of the macrocycle resulting from complexation now discriminates between the isomers leading to mesomorphic complexes of *trans*-ligands, and non-mesomorphic complexes of *cis*-ligands.

This work was supported by the EPSRC and by the University of Nottingham.

Received (in Cambridge, UK) 20th September 2001, Accepted 29th October 2001
First published as an Advance Article on the web 14th November 2001

A new cofacial binucleating macropolycycle combining, for the first time, the distinctive coordination properties of [9]aneN$_3$ (1,4,7-triazacyclononane) with those of phenol-based compartmental macrocycles is reported together with binuclear Cd^{II} and Y^{III} complexes, which show segregated and encapsulated complexation, respectively.

The design and synthesis of phenol-based binucleating compartmental macrocycles and the preparation of their homo- and hetero-dinuclear complexes incorporating bridging phenolate donors have important applications in several fields of chemical research.[1] In particular, binuclear complexes with transition metal ions in close proximity can show fascinating magnetic properties[2] and can serve as synthetic analogues of bimetallic biosites.[3] Furthermore, homo- and hetero-dinuclear lanthanide complexes with phenol-based compartmental macrocycles have proved to be useful models in studying the nature and applications of such compounds in lasers,[4] phosphors,[5] tunable photonic devices,[6] and in molecular recognition processes which govern Ln^{III} cation pairing events.[7] Variation of the building blocks[1,8] has afforded compartmental ligands incorporating lateral chains such as 2,2′-bipyridyl,[9] triethylenetetraamine[10] or 1,8-diamino-3,6-dioxaoctane.[11] Interestingly, there are no reports of pre-formed macrocycles being introduced as part of the lateral chains bridging the two phenolic units to give binucleating compartmental or cofacial macropolycycles.

We report herein the synthesis of H_2L and its coordination to Cd^{II} and Y^{III}. H_2L represents a new cofacial binucleating macropolycycle in which, for the first time, the particular coordination properties of [9]aneN$_3$ are combined with those of phenol-based compartmental macrocycles. Thus, direct [2 + 2] Schiff-base condensation of one mol equivalent of 1,4-bis(2-aminoethyl)-1,4,7-triazacyclononane, **3**, with one mol equivalent of 2,6-diformyl-4-methylphenol in MeOH gives, after partial removal of the solvent and addition of light petroleum, the cofacial macropolycycle H_2L in 78% yield as confirmed by ^{1}H, ^{13}C NMR spectroscopy, FAB mass spectrometry and analytical data† (Scheme 1). **3** was synthesised in overall 88% yield by reaction of 1-(*p*-tolylsulfonyl)-1,4,7-triazacyclononane **1** with two equivalents of *N*-tosylaziridine and subsequent detosylation of **2** with concentrated sulfuric acid. The ligand **3** has been reported previously,[12] but only as a by-product of the synthesis of the tris-pendant arm-species 1,4,7-tris(2-aminoethyl)-1,4,7-triazacyclononane. Our synthesis of **3** represents a selective and efficient methodology to the synthesis of asymmetric amine-functionalised [9]aneN$_3$ derivatives.

H_2L is characterised by two large adjacent chambers each with potential N_5O_2 donacity capable of accommodating metal ions with large ionic radii. We sought to determine whether H_2L behaves as a compartmental macrocycle encapsulating and bringing together two metal ions in close proximity, or as a segregated system leaving the metal ions separated within two independent N_5O-donating sites.

Reaction of H_2L with two mol equivalents of both $Cd(NO_3)_2{\cdot}4H_2O$ and Me_4NOH in MeOH–$CHCl_3$ (2 : 1 v/v) under reflux gives yellow plate crystals on partial removal of solvent and diffusion of Et_2O vapour into the remaining solution. The single crystal X-ray structure of $[Cd_2(L)](NO_3)_2{\cdot}$2MeOH confirms‡ the formation of a binuclear complex lying on a two-fold rotation axis with each six coordinate Cd^{II} ion bound to an N_5O donor set within a distorted octahedral environment (Fig. 1). Each Cd^{II} is coordinated to three N-donors of the triaza ring [Cd–N 2.342(3)–2.511(3) Å], to two imine nitrogen atoms [Cd–N(13) 2.293(3) and Cd–N(43) 2.313(3) Å] and to one phenolate oxygen [Cd–O(17) 2.283(2) Å]. The two N_5O-donating chambers of the macropolycycle act, therefore, as isolated donor sets and the phenolate oxygens do not bridge the metal ions. However, the phenolate O-donors are involved in a strong hydrogen-bond with a methanol molecule [H(1M)···O(17) 1.70 Å, O(1M)–H(1M)···O(17) 172°] which is also hydrogen-bonded to the secondary N–H of the triazacyclononane ring [H(7)···O(1M) 2.34 Å, N(7)–H(7)···O(1M) 139°] to form a six-membered ring including the Cd^{II} ion. Significantly, the two aromatic rings of the macropolycycle are stacked with a perpendicular distance of 3.342(4) Å between the mean planes of the rings and a distance of 3.428(4) Å between the centres of the rings (Fig. 1). This face-to-face π–π interaction and additional hydrogen-bonding force the donor atoms of the anionic ligand L^{2-} to assume a peculiar disposition with the phenolate oxygens twisted in opposite directions [twist angle 81.1(3)°] and each pointing towards an individual metal ion. As a result, the phenolate O-donors cannot bridge the Cd^{II}

centres, which are, therefore, segregated each within its own N_5O-donor chamber [Cd···Cd distance 7.017(1) Å].

Reaction of H_2L with $Y(NO_3)_3{\cdot}6H_2O$ in a 1:2 molar ratio under the same conditions as above afforded yellow crystals. The single crystal X-ray structure of $[Y_2(L)(OH)][Y(NO_3)_4(MeOH)_2](NO_3)_2{\cdot}2MeOH$ shows‡ the complex cation lying across a two-fold rotation axis with $[Y(NO_3)_4(MeOH)_2]^-$ and two nitrate counter-anions (Fig. 2). The two Y^{III} centres in the cation lie within the two N_5O donating chambers of L^{2-} and are bridged not only by the phenolate oxygen atoms but also by a hydroxy group. To our knowledge the cation $[Y_2(L)(OH)]^{3+}$ represents one of the few structurally characterised homobinuclear lanthanide complexes with phenol-based compartmental macrocycles.[9,10] Each Y^{III} ion in $[Y_2(L)(OH)]^{3+}$ is eight coordinate and bound to three N-donors from the triazacyclononone framework [Y(1)–N 2.436(9)–2.655(7) Å], two azomethine nitrogen atoms [Y(1)–N(13) 2.418(8) and Y(1)–N(24) 2.472(8) Å], two phenolate oxygens [Y(1)–O(21) 2.391(6) and Y(1)–O(21^{i}) 2.322(6) Å] and a hydroxy O-donor [Y(1)–O(1) 2.277(7) Å]. This coordination mode is similar to that observed for the binuclear Lu^{III} and Dy^{III} complexes with the iminophenolate cryptate obtained by the template Schiff-base condensation of tris(2-aminoethyl)amine and 4-methyl-2,6-diformylphenol, where three phenolate oxygens bridge a pair of adjacent lanthanide ions [Lu···Lu 3.447(1) Å, Dy···Dy 3.4840(4) Å].[13] In the case of the binuclear Pr^{III}, Gd^{III} and La^{III} complexes of phenol-based compartmental macrocycles with 1,8-diamino-3,6-dioxaoctane[11] and 2,2′-bipyridine[9] as lateral chains, the two metal centres are bridged only by the two phenolate oxygen atoms, with nitrate and acetate anions completing the coordination sphere. The Pr···Pr, Gd···Gd and La···La distances are 4.05, 3.97 and 4.135(12) Å, respectively, whereas in $[Y_2(L)(OH)]^{3+}$ the Y···Y distance is significantly shorter at

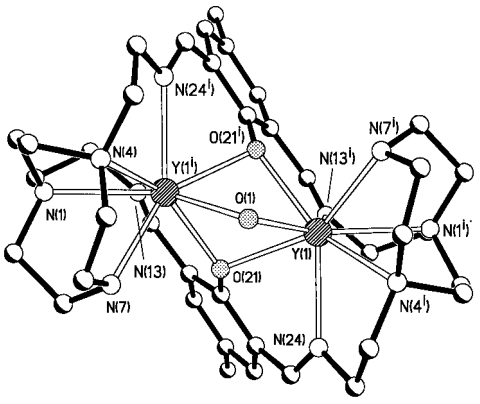

Fig. 2 Structure of $[Y_2(L)(OH)]^{3+}$ with numbering scheme adopted. Hydrogen atoms have been omitted for clarity. Symmetry operation: i = $-x + 1$, y, $-z + 3/2$.

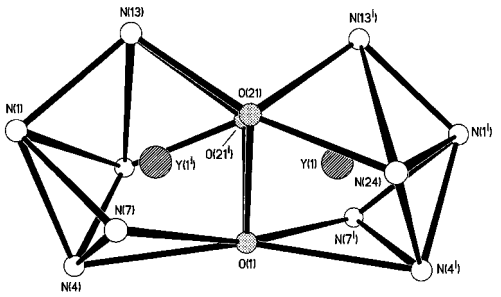

Fig. 3 View of the coordination polyhedra in $[Y_2(L)(OH)]^{3+}$.

3.4295(19) Å, which is considerably shorter than distances reported for binuclear lanthanide complexes.[13] The three bridging oxygen atoms in $[Y_2(L)(OH)]^{3+}$ form an almost equilateral triangle [O(21)···O(21^{i}) 2.747(13) Å and O(21)···O(1) 2.721(12) Å, O(1)–O(21)–O(21^{i}) 59.7(2)° and O(21)–O(1)–O(21^{i}) 60.6(4)°], and the two Y^{III} ions lie 1.716(5) Å out of this O_3 plane. Therefore, the coordination polyhedron at each metal ion can best be described as monocapped distorted dodecahedral (Fig. 3).

The work described herein represents the first example of a phenol-based compartmental system incorporating [9]aneN_3 to afford a large cofacial macropolycycle capable of forming binuclear complexes in which the two metal centres can be segregated or encapsulated. Furthermore, since H_2L can be synthesised directly without using templating metal ions, heterodinuclear complexes may be targeted, and this is currently under investigation.

We thank the EPSRC and University of Nottingham for support.

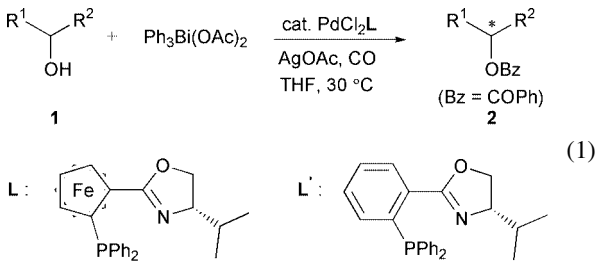
A novel method for kinetic resolution of racemic secondary alcohols *via* their enantioselective benzoylation (up to 48% ee) has been explored using CO, $Ph_3Bi(OAc)_2$, a catalytic amount of chiral Pd(II)-complex and AgOAc.

Kinetic resolution of secondary alcohols through enantioselective acylation is one of the most valuable methods for obtaining optically active alcohols and their derivatives in organic synthesis. In this field, enzymatic methods have widely been used to synthesise several natural products and bio-active compounds.[1] However, structural variations of substrates are limited because of high substrate specificity in enzymatic reactions. Recently, non-enzymatic methods using effective chiral catalysts for asymmetric acylation of alcohols have also been studied intensively.[2]

The carbonylative acylation of alcohols using carbon monoxide (CO) is an alternative tool for the preparation of esters and the various methods catalysed by transition metals have been reported.[3] However, the application of carbonylative acylation to kinetic resolution of racemic alcohols has not yet been reported so far, to the best of our knowledge.[4] We have previously reported transition metal-catalysed carbonylative benzoylation of methanol with phenyl-heteroatom compounds under an atmospheric pressure of carbon monoxide.[5] These findings led us to apply this catalytic system to asymmetric reactions. We have now investigated Pd(II)-complex-catalysed kinetic resolution of secondary alcohols[6] with phenyl-heteroatom compounds using optically active oxazolynylferrocenyl phosphine **L** as a chiral ligand [eqn. (1)].[7] Preliminary results are reported here.



(1)

At first, we examined phenyl-heteroatom compounds such as $PhB(OH)_2$ and $PhSnMe_3$ which have been used as phenylating reagents in some asymmetric reactions by other groups.[8] However, these compounds were not effective for the enantioselective carbonylative acylation. Eventually it was disclosed that organobismuth(V) compound $Ph_3Bi(OAc)_2$ was quite useful for this purpose. Thus, the reaction of secondary alcohols **1** with $Ph_3Bi(OAc)_2$ in the presence of $PdCl_2$**L** catalyst under CO atmosphere proceeded smoothly to give the enantio-enriched benzoyl esters **2** [eqn. (1)].† Typical results are shown in Table 1. Treatment of 1-phenylethanol (**1a**) with $Ph_3Bi(OAc)_2$ (0.6 equiv.) in tetrahydrofuran (THF) under CO (5 atm) in the presence of AgOAc and a catalytic amount of $PdCl_2$**L** afforded 1-phenylethyl benzoate (**2a**) in 34% yield with 19% ee. The unreacted alcohol **1a** was recovered in 52% yield with low enantioselectivity (8% ee). Other solvents such as CH_2Cl_2, Et_2O and CH_3CN and reoxidants such as $CuCl_2$

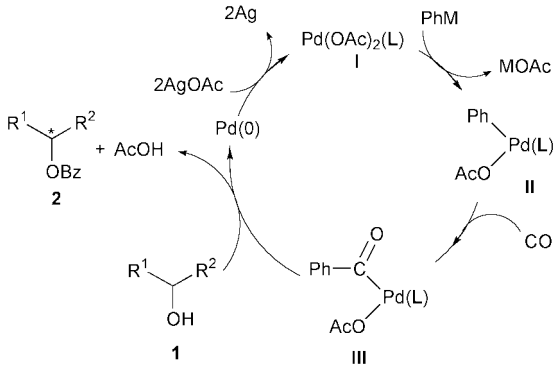
 DOI: 10.1039/b107904b



Scheme 1

$Cu(OAc)_2$ and ammonium cerium(IV) nitrate were not effective. The reaction of **1a** using the bidentate phosphine ligands such as (*R*)-(+)-2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (BINAP) hardly proceeded and only a trace amount of **2a** was obtained. When other benzylic alcohols **1b–d** were used as substrates, the corresponding esters (**2b–d**) were obtained with similar enantioselectivities (19–25% ee). The reaction of cyclic alcohols such as **1e–h** proceeded slower than that of benzylic alcohols and it was necessary to carry out in a slightly higher concentration of **1** to obtain moderate enantioselectivies. In this reaction system, planar chirality of **L** might have some effect on enantioselectivity, and actually the reaction of **1g** using **L′**[9] in place of **L** gave **2g** in 38% yield with 16% ee. The best enantioselectivity was achieved when **1h** was treated with $Ph_3Bi(OAc)_2$ under similar conditions (up to 48% ee of **2h** in 21% yield; s = 3.2[10]).

A plausible reaction pathway is shown in Scheme 1. The reaction of the Pd(II) complex (**I**) with $Ph_3Bi(OAc)_2$ (PhM) affords the phenylpalladium species (**II**) *via* transmetallation followed by migratory insertion of CO to give the benzoylpalladium species (**III**). The attack of **1** to **III** results in the formation of the enantio-enriched **2** together with the Pd(0) species. The Pd(0) species is reoxidized to **I** by AgOAc.

In summary, we have demonstrated the Pd(II)-catalysed kinetic resolution of racemic secondary alcohols using CO and organobismuth(V) compound. Although the enantioselectivity is not yet satisfactory, our catalytic system may provide a novel methodology for kinetic resolution of racemic alcohols. Moreover, only a few example are known to use organobismuth compounds in asymmetric reaction[11] and so the reaction presented here might also be interesting from the viewpoint of organobismuth chemistry. Further work is now in progress aiming to construct a more effective chiral environment for enantioselective carbonylative acylation.

Notes and references

† *General procedure for enantioselective benzoylation of secondary alcohols*: To a solution of $PdCl_2$**L** (32.9 mg) and AgOAc (250.4 mg) in THF were added secondary alcohol **1** (0.50 mmol) and $Ph_3Bi(OAc)_2$ (167.5 mg, 1.50 mmol), and then the mixture was transferred into a 50 mL stainless-steel autoclave. Carbon monoxide (5 atm) was charged and the solution was stirred at 30 °C for 48 h. The resulting mixture was filtered through Florisil and Celite and the filtrate was concentrated under reduced pressure. Purification of the residue by column chromatography gave the benzoyl ester **2** and the unreacted **1**. Enantiomeric excess was determined by GLC or HPLC analysis using suitable chiral columns.

Received (in Cambridge, UK) 14th August 2001, Accepted 17th October 2001
First published as an Advance Article on the web 23rd November 2001

Two 2D coordination polymers $[M(NCS)_2(pzdo)_2]$ (M = Mn, Co; pzdo = pyrazine dioxide) bridged by pzdo ligand are synthesized, which are found to exhibit antiferromagnetic ordering below 8.4 and 11.2 K, respectively.

The construction of molecule-based magnets through a coordination polymer approach is a particular area of contemporary materials research. Judicious choice of bridges is a crucial factor to generate fascinating structures and unusual magnetic properties. Cyano, azido, oxalato and recently emerging dicyanamide ligands have been demonstrated to transmit magnetic interactions efficiently as bridges, and among their coordination polymers, numerous long-range ordering magnetic molecular materials were obtained.[1] Although pyrazine (pyz) and 4,4′-bipyridine have been widely used to build multi-dimensional network, fewer complexes with magnetic ordering have been afforded. In a recent communication the 3D $Mn(N_3)_2(pzdo)$,[2] in which pzdo supports the azide layer in the third direction, has been reported to display a spin-flop state and a higher antiferromagnetic ordering temperature (T_N = 62 K), which is remarkably higher than that for the well separated 2D quadratic azide sheet $[Mn(minc)_2(N_3)_2]_n$[3] (minc = methyl isonicotinate) and is comparable with that of the azide-bridged exclusively 3D compound $[N(CH_3)_4][Mn(N_3)_3]$.[4] By contrast, in a 2D analogous $Mn(N_3)_2(pyz)$ constructed *via* μ-1,1-N_3 and μ-pyz ligands, a lower magnetic ordering temperature (T_N = 2 K) was observed.[5] This signifies that pzdo might have better capability of tuning magnetic coupling than pyz. In order to elucidate the role of the pzdo ligand in mediating magnetic interplay, the 2D coordination polymers $[M(NCS)_2(pzdo)_2]$ (M = Mn **1**, Co **2**) were prepared‡ and their magnetic properties investigated.

X-Ray diffraction analysis§ revealed that **1** and **2** are isomorphous and consist of a 2D quadratic network (Fig. 1). Each metal ion is located at an inversion center and coordinated with four O atoms from bridging pzdo ligands and two terminal NCS^- groups, forming a compressed octahedral environment in which two N atoms lie in axial positions. The NCS^- group is almost linear with an N–C–S angle of 178.8° and bound to metal ion in a bent fashion with C–N–M angles of 161.1–162.1°. The bridging pzdo ligands adopt a *trans* mode similar to 4,4′-bipyridine dioxide in ref. 6(*a*), and extends the structure into a layer with M···M separations being within the range 8.257–8.604 and 8.107–8.461 Å for **1** and **2**, respectively. The 2D grid is similar to that found in $M(NCS)_2(pyz)_2$ (M = Mn, Co, Fe, Ni),[7] in which the pyz connects the metal ions to give a square lattice (intra-sheet M···M distance is *ca.* 7.3 Å).

As demonstrated previously, a striking feature of O,O-bifunctional ligands is their strong capability of forming hydrogen bonds compared with the corresponding N,N-ligands.[6] In both **1** and **2**, the O atom of pzdo not only coordinates with the metal ion, but forms weak hydrogen bonds with hydrogens of pzdo molecules from an adjacent layer [O2···H2a 2.564 Å, C2a–H2a···O2 159.3°; O1···H4b 2.355 Å, C4b–H4b···O1 144.21°: $a = -x+1, -y, -z, b = -x, -y, -z$]. Whereas in the corresponding pyz complexes[7] this feature is pronouncedly absent, its presence here links the 2D sheets into a 3D network with the nearest interlayer M···M separation being 6.940 and 6.892 Å for **1** and **2**, respectively.

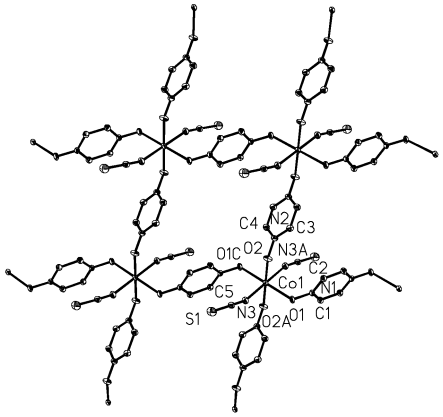

Fig. 1 Two-dimensional grid for **2**. Selected bond distances (Å) and angles (°): Mn(1)–N(3) 2.114(4), Mn(1)–O(1) 2.208(3), Mn(1)–O(2) 2.226(3). For **2**: Co(1)–N(3) 2.045(2), Co(1)–O(1) 2.1116(15), Co(1)–O(2) 2.1315(16).

The variable-temperature magnetic susceptibility χ_M for a collection of small crystals of **1** and **2** was measured in the temperature range 1.8–300 K (Fig. 2). At room temperature, the $\chi_M T$ values of **1** and **2** are 4.34 and 2.73 $cm^3\ mol^{-1}$ K, well consistent with the values of 4.38 and *ca.* 3.0 $cm^3\ mol^{-1}$ K expected for an uncoupled Mn^{2+} ion, and an octahedral high-spin Co^{2+} ion,[8] respectively. The value of χ_M increases as the temperature is lowered, reaching a maximum at *ca.* 12.9 and

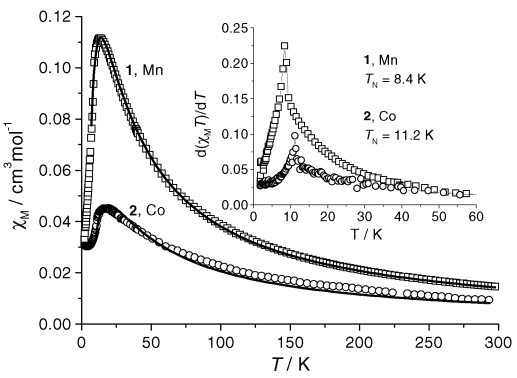

Fig. 2 Temperature dependence of magnetic susceptibility for **1** (□), and **2** (○). Solid lines correspond to calculated curves based on the Lines' model. Inset: $d(\chi_M T)/dT$ *vs.* *T* for **1** and **2**.

† Electronic supplementary information (ESI) available: Fig. S1: two types of coordination mode for pzdo. Fig. S2: perspective view of compound **2** along the [010] direction. See http://www.rsc.org/suppdata/cc/b1/b107334f/

 DOI: 10.1039/b107334f

17.2 K, for **1** and **2**, respectively, indicative of antiferromagnetic interactions between metal ions. The Neel temperatures, T_N, of **1** and **2** were determined from the sharp peak of $d(\chi_M T)/dT$ at 8.4 and 11.2 K, respectively, shown in the inset of Fig. 2.[9] The higher T_N of **2** may be related to the single-ion anisotropy of Co(II) ion. The best fitting of the magnetic data above 7 and 10 K using the Lines' model[10] for a quadratic layer gave the following results: for **1** (Mn), $J = -1.063(3)$ cm^{-1}, $g = 2.033(2)$ with $R = 1.9 \times 10^{-4}$; for **2** (Co), $J = -3.34(3)$ cm^{-1}, $g = 2.35(1)$ with $R = 2.8 \times 10^{-3}$ {$R = \Sigma[(\chi_M)_{obs} - (\chi_M)_{calcd}]^2/\Sigma(\chi_M)_{obs}^2$}. Although $M(NCS)_2(pyz)_2$ (M = Mn, Co) have 2D grids similar to **1** and **2**, no maximum was observed in their χ_M–T plots.[7b]

The field dependence of the magnetization for **1** at different temperatures below T_N (8.4 K) shows a pronounced sigmodial shape, especially at lower temperature (Fig. 3). The behavior is due to a spin-flop transition as observed in ref. 2. The magnetization below T_N increases very slowly with increasing field due to antiferromagnetic ordering, and then increases quickly for a transition from an antiferromagnet to a spin-flop state at a transition field around 30–35 kOe, which is also determined by the maximum of the ac susceptibilty χ' (inset of Fig. 3). The magnetization is only 1.6 $N\beta$ at 70 kOe, far from the saturation value of 5 $N\beta$ for the Mn^{2+} ion, suggesting an antiferromagnetic ordering again. In contrast to **1**, the field dependence of the magnetization for **2** at different temperatures below and around T_N (11.2 K) all show a linear slow increase, as shown in Fig. 4, and no spin flop state was observed. The magnetization under 70 kOe at 1.8 K is only 0.52 $N\beta$, also far from the saturation value of *ca.* 2.5 $N\beta$ expected for a Co^{2+} with $S_{eff} = 1/2$, and $g = 5.0$,[8b] this being further evidence supporting the antiferromagnetic ordering of **2**.

It was well documented that the ordering temperature of a 3D antiferromagnet is slightly lower than $T(\chi_{max})$.[11] Although the hydrogen bonding between layers in **1** and **2** could have a crucial contribution to the magnetic ordering, the antiferromagnets possess obviously 2D characteristics, as the ratio of $T_N/T(\chi_{max})$, 0.646 and 0.649 for **1** and **2**, respectively, is quite low. In summary, compared with corresponding 2D pyz-bridged paramagnetic complexes, the title 2D quadratic networks constructed by pzdo exhibit antiferromagnetic ordering.

‡ *Syntheses*: $Mn(NCS)_2(pzdo)_2$ **1**: this was carried out by mixing an aqueous solution of $MnCl_2 \cdot 4H_2O$ (0.5 mmol, 12.5 ml) with a aqueous solution of NaNCS (2.5 mmol, 12.5 ml). After stirring for 1 h at *ca*. 80 °C an aqueous solution of pzdo (0.50 mmol, 10 ml) was added. The resulting solution was allowed to stand at room temperature after stirring for 0.5 h. After two weeks, a prismatic, purple, X-ray quality single crystal was obtained (yield 60%) (Calc.: C, 30.08; H, 2.02, N, 21.05. Found: C, 30.12; H, 2.16; N, 20.09%).

$Co(NCS)_2(pzdo)_2$ **2**: this was obtained by mixing an aqueous solution of $Co(NCS)_2$ (0.25 mmol, 2.85 ml), with an aqueous solution of pzdo (0.50 mmol, 10 ml). The resulting solution was allowed to stand at room temperature after stirring for 0.5 h. After several days red prismatic crystals appeared (yield, 70%) (Calc.: C, 30.39; H, 2.04; N, 21.26. Found: C, 30.47; H, 2.117; N, 20.45%).

First published as an Advance Article on the web 23rd November 2001

Molecular imprinting can be used to prepare heterogeneous catalysts which mimic their homogeneous counterparts.

Synthetic organic chemistry is now so far advanced that reagent combinations are available to perform a huge spectrum of transformations. Transition metal catalysis features heavily in this arsenal.[1] Homogeneous reactions are often preferred for laboratory scale preparations and the majority of mechanistic elucidations and optimisation studies have been carried out in solution phase. Frequently, however, problems are encountered when taking an optimised laboratory procedure and scaling it up. To take advantage of precedent knowledge, there is a tendency to carry out reactions in homogeneous solution enabling reaction products, yields, rates and safety to be easily predicted. This approach is extremely successful in terms of the synthetic transformation. However, the use of expensive and toxic (*e.g.* palladium) homogeneous catalysts suffers from prohibitive drawbacks. The most important of these, on an industrial scale, is contamination of the final product by trace quantities of the metal. An obvious alternative is the use of heterogeneous catalysis where a polymeric ligand is employed.[2,3] Such catalysts have clear advantages over their homogeneous counterparts. The catalyst is easily separated from the reaction medium, and leaching into the medium (and hence product) is often reduced. Current polymeric ligand/catalyst assemblies are, however, often unsuitable because it is impossible to translate optimised reaction conditions from homogeneous to heterogeneous systems. In homogeneous systems the catalyst/ligand stoichiometry and geometry are uniform across each 'active site' (for a particular intermediate or transition state). Current commercial systems present ligands in non-uniform spatial disposition. This random geometry influences the reaction profile of each active site leading to catalyst inefficiency and unpredictability. The alternative approach has been to attach multidentate ligands to solid supports. These systems, however, have rigid coordination geometry and transfer of the reactions from homogeneous conditions to the solid phase is often not straightforward.

The accepted catalytic cycle for a palladium catalysed cross-coupling reaction is shown in Fig. 1.[4] It is clear that homogeneous reaction protocols have inbuilt flexibility. Ligand stoichiometry and geometry are dynamic throughout the catalytic cycle. A number of features should be noted; (i) Pd(0) complexes favour tetrahedral geometry whereas Pd(II) complexes favour square-planar geometry. (ii) Oxidative addition to Pd(0) complexes bound to four phosphine ligands is slow. (iii) Reductive elimination to yield product takes place from the *cis* complex. It is surprising, perhaps, that these combined factors have not been examined before in the design of efficient polymeric ligand assemblies.

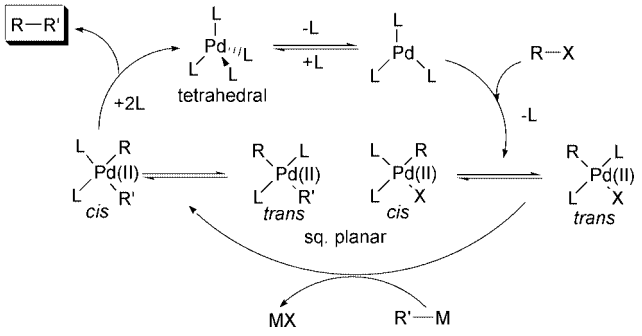

Fig. 1 Catalytic cycles for a cross-coupling reaction.

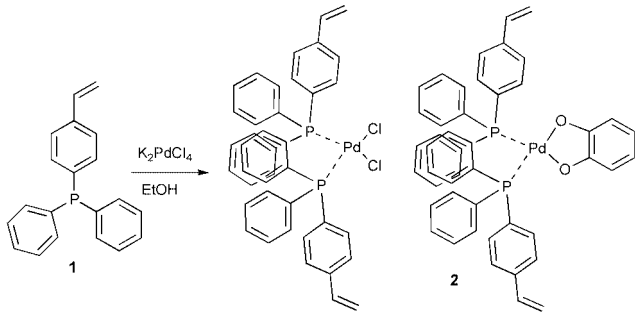
We reasoned that an ideal solid catalyst could be realised by preassembly of the ligand around the metal followed by polymerisation (molecular imprinting[5,6]). In this way the preferred ligand geometry can be tailored depending on the reaction to be catalysed (the rate limiting step can be accelerated). We chose to investigate palladium-catalysed cross- coupling reactions and aimed to assemble (two) phosphine ligands in a '*cis* square-planar' geometry in order to accelerate reductive elimination (often the rate limiting step) and minimise competing pathways leading to sideproducts.

The catalysts were prepared as outlined in Schemes 1–3. We selected a simple, polymerisable phosphine ligand (**1**) for investigation because we expected its synthesis to be relatively straightforward and it is closely related to triphenylphosphine (which is perhaps the most widely used ligand in coupling reactions and whose complexation chemistry is well-documented). Synthesis of **1**[7] was achieved by reaction of the Grignard reagent from 4-chlorostyrene with chlorodiphenylphosphine. This reaction was complicated by polymerisation of starting material and product due to the exothermic nature of both the Grignard reagent formation and its addition to the chlorophosphine. In practice, formation of the Grignard reagent stops below *ca.* 30 °C, and polymerisation becomes a problem above 40 °C. Nevertheless, under carefully controlled conditions a yield of around 60% could be achieved.

2:1 Complexes of the polymerisable phosphine ligand to palladium(II) were synthesised following modifications to the procedures reported for the simple triphenylphosphine complexes.[8] These latter procedures, which use high temperatures, had to be modified to prevent premature polymerisation of the ligand/complex. Consequently, **1** was stirred in warm (40 °C) ethanol. K_2PdCl_4 (in minimum water) was added and the mixture stirred for 3 h. The precipitate which formed was filtered off and purified by careful recrystallisation to give the pure bis-(**1**)–palladium dichloride which was fully characterised. Our strategy relied on the incorporation of the bis-(**1**)–palladium complex into the polymer matrix in its *cis*-form. The dichloride was therefore converted to its catecholate salt **2** by treatment with catechol/KOH in a mixed solvent system. The pure product precipitated from the mixture and was stored in the dark (Scheme 1).

The final polymers were designed to be rigid (preventing relaxation of the imprinted site) so a high proportion of crosslinker was employed in the polymer synthesis. Initial experiments employed methylmethacrylate as monomer (*ca.*

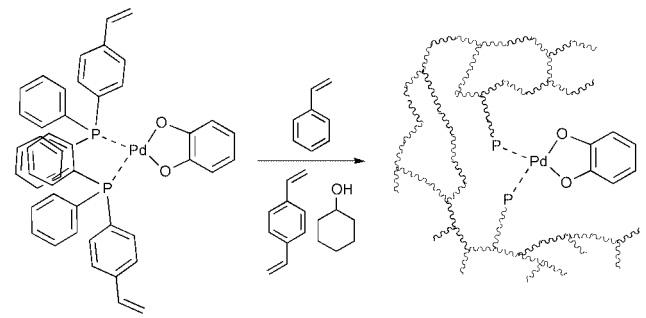
 DOI: 10.1039/b108464j



Scheme 1

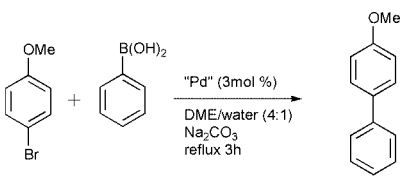
25%), ethylene glycol dimethacrylate as crosslinker (*ca.* 25%) and butanol as porogenic solvent (50%). To this mixture was added palladium complex **2** (initially 0.5% Pd by weight) and the mixture polymerised (AIBN initiation) at ~ 60 °C for 6 h. Polymerisation proceeded smoothly but it was evident that **2** was not homogeneously distributed throughout the polymer (some precipitation and sedimentation of the complex occurred). Use of trichloroethane as solvent enabled a homogeneous solution to be obtained at the polymerisation temperature. However, polymerisation led to a homogeneous 'gel' (rather than a macroporous network polymer). These transparent polymers were not investigated further because we envisaged a macroporous structure being crucial to achieve efficient delivery and removal of reactants/products to and from the catalytic site.

A second series of polymers was prepared employing styrene (25%), divinyl benzene (25%) and butanol (50%). Addition of 0.5% **2** followed by polymerisation led to a macroporous polymer in which the complex was clearly distributed throughout. However, there was still some evidence of poor solubility (precipitation) of the complex when higher Pd loadings were attempted. Switching to cyclohexanol as porogen enabled polymers to be prepared in which the palladium loading could be increased (we chose 5% as maximum). The initial polymer blocks were crushed and washed (to remove porogen and any unbound species) to produce the catalysts as yellow/green powders (Scheme 2).



Scheme 2

The Suzuki reaction[4] between *p*-bromoanisole and phenyl boronic acid was chosen as a model reaction (Scheme 3). The standard reaction conditions were as follows: a mixture of *p*-bromoanisole, phenyl boronic acid (1.2 equivalents), palladium catalyst (3 mol% Pd) and sodium carbonate were stirred in refluxing DME–water (4 : 1) for 3 h. The mixture was allowed to cool and filtered to re-isolate the catalyst. The product was isolated either by precipitation (addition of water) or by extraction (dichloromethane) and column chromatography.



Scheme 3

Under these conditions the catalyst prepared from commercial ligand† led to yields of 46–56%. Re-use of the catalyst led to a slight reduction in the isolated yield (56 → 45%). The catalysts prepared by molecularly imprinting **2** led to consistently higher yields (76–81%). Furthermore, the reaction yield was essentially unaffected by repeated use (catalyst was re-used five times in one series of experiments, giving 80% yield in the fifth experiment) and catalyst loading (0.5 and 5% gave very similar high yields). It is particularly noteworthy that control homogeneous experiments (using $PdCl_2$ and PPh_3) gave yields comparable with the commercial ligand (*i.e.* ~55%, much lower than with the molecularly imprinted polymer). The crude reaction mixture (after filtration) was analysed and found to contain only 1 ppm Pd (0.1 ppm on reuse).

A similar improved performance was observed with 4-nitrobromobenzene and the results were even more impressive with 2-bromoanisole which gave 47% yield (not optimised) with the imprinted catalyst but less than 10% when the commercial ligand was employed under identical conditions. Stille[9] reactions using the same bromides with tributylphenyltin gave only trace quantities of coupled product with the catalyst prepared from commercial ligand. Under identical conditions, both the molecularly imprinted catalyst **2** and homogeneous catalyst gave similarly high yields (65–95%).

In conclusion, we have demonstrated that catalysts prepared by molecular imprinting are clearly far superior to those prepared from traditional polymeric ligands. Their performance is comparable, and often superior, to related homogeneous catalysts. Although it is quite early to draw conclusions it seems likely that the semi-rigid ligand geometry is responsible for the improved performance. Complex **2** is incorporated into the polymer matrix in its square-planar geometry [Pd(II)]. The catalytically active Pd^0 species is therefore slightly strained (tetrahedral). It seems reasonable to suggest that the rate of oxidative addition (the slow step in some cases[10]) is thereby accelerated (having only two phospines per site also serves to increase this rate). Similarly, enforced *cis*-geometry is likely to increase the rate of reductive elimination and minimise side-reactions. The molecularly imprinted catalyst efficiently retains the metal and catalyst efficiency is retained after continual use. This combination of properties makes this new generation of heterogeneous catalysts extremely attractive.

Notes and references

† Commercial polymer bound triphenylphosphine (Aldrich) was treated with K_2PdCl_4 and washed exhaustively to give an orange–yellow solid (12.5% Pd by weight).

A solution-phase route to a tetraethynylated (cyclobutadiene)cyclopentadienylcobalt complex with a *para*-(1,3,2,4)-substitution pattern†

Matthew Laskoski, Jason G. M. Morton, Mark D. Smith and Uwe H. F. Bunz*

Department of Chemistry and Biochemistry, The University of South Carolina, Columbia, South Carolina 29208, USA, E-mail: Bunz@mail.chem.sc.edu

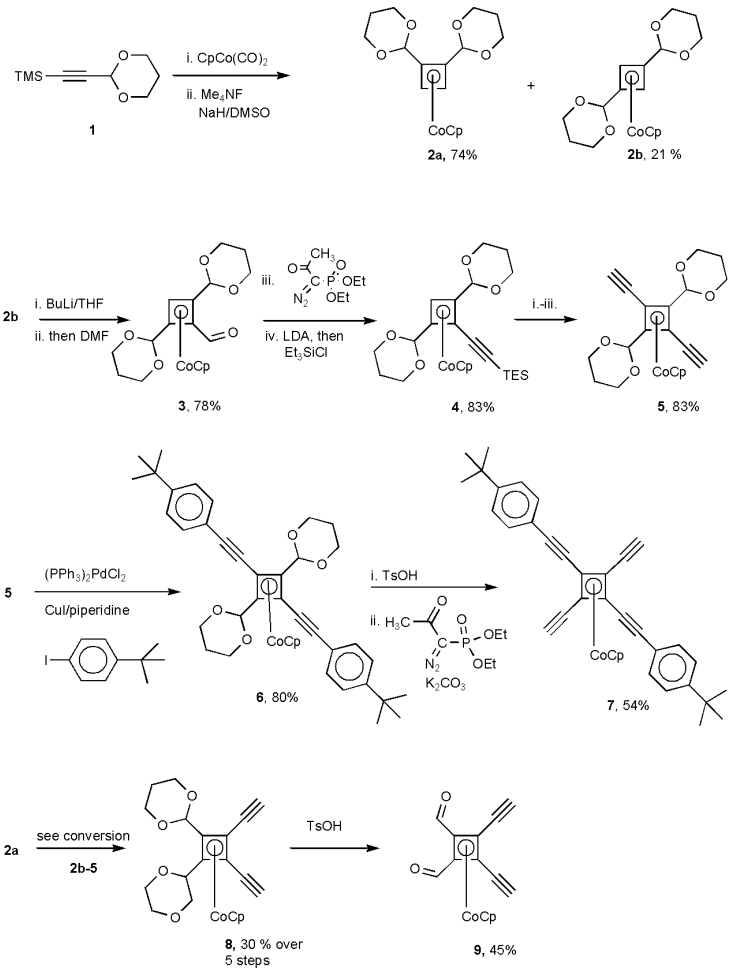
Received (in Cambridge, UK) 1st October 2001, Accepted 22nd October 2001
First published as an Advance Article on the web 23rd November 2001

The synthesis of a tetraethynylated, CpCo-stabilized cyclobutadiene complex *via* a metalation/carbonylation/alkynylation route is reported; this synthetic sequence allows, for the first time, the solution phase synthesis of a tetraethynylcyclobutadiene(cyclopentadienyl)cobalt derivative, and sorts the four alkyne substituents into two *para*-related groups.

We have a long-standing commitment in carbon rich organometallics,[1] concentrating our efforts on synthesis, reactions, and properties of multiply alkynylated cyclobutadiene complexes as building blocks for nano-scale carbon-rich[2] objects. Tetraethynylcyclobutadiene(cyclopentadienyl)cobalt complexes[3–7] are valuable due to their robustness, ease of handling and their potential to form super-polycyclic[3,8] organometallic materials. However, the synthesis of these complexes is tedious, requiring a gas-phase flash vacuum pyrolysis step that bottlenecks the amount of tetraethynyl available.[3] These species invariably display a *ortho,ortho*-substituent pattern of their four substituents, a witness to their genesis by a Bergman-type rearrangement. To expand the chemistry of tetraethynylcyclobutadiene(cyclopentadienyl)cobalt complexes, a solution-phase synthesis with control of their regiochemistry would be advantageous.[9]

Reaction of the ethynylated dioxane **1** with $CpCo(CO)_2$ followed by desilylation furnishes a mixture of the two isomeric acetals **2a** and **2b** in a 3.5 : 1 ratio in a combined yield of 95% (Scheme 1).[9] BuLi cleanly metalates **2b** at the cyclobutadiene ring and leaves the Cp-ring intact. We attribute the facile

† Electronic supplementary information (ESI) available: experimental, including details of preparation and spectroscopic characterization of all new compounds. See http://www.rsc.org/suppdata/cc/b1/b109848a/



Scheme 1

 DOI: 10.1039/b109848a

metalation of the four-ring to the enhanced s-character of the C–H-bonds *and* the *ortho*-metalating power of the two acetal groups, that drive this deprotonation reaction selectively.[10]

Workup of the formed anion with DMF provided the complex **3** in 78% yield after chromatography. Ohira's reagent[11] converts the aldehyde group of **3** into an alkyne that is further protected by lithiation and reaction with triethylchlorosilane to give **4**. Repetition of the metalation/carbonylation/alkynylation process with **4** as substrate furnishes the *para*-diyne **5**, in which the protecting group is lost during the K_2CO_3-promoted Ohira reaction. Pd-catalyzed arylation transforms **5** into **6** (80% yield). In the last steps of the reaction sequence, the acetal groups are cleaved off **6**, and a double Ohira reaction converts the intermediate dialdehyde into the title compound **7** in 54% yield.

As a proof of this concept we explored the chemistry of the major isomer **2a** and have transformed it in an analogous reaction sequence into complex **9**, in which two free alkyne groups and two free aldehyde functionalities reside on the cyclobutadiene complex. This material is surprisingly stable and can be manipulated in air at ambient temperature. The dialdehyde **9** is an attractive building block for further elaboration of linear, cyclic and star-shaped organometallic cyclobutadiene architectures.

The tetrayne **7** is stable and can be handled under ambient laboratory conditions without decomposition. Due to the unusual tetragonal symmetry of the ligand we performed a single crystal X-ray structure determination. Suitable needle-shaped specimen were grown from dichloromethane.‡ Fig. 1 shows the ORTEP of **7**; bond lengths and bond angles are in excellent agreement with literature reported values for alkynylated cyclobutadiene complexes.[1,3,4] The four-membered ring is square with angles in the range of 89–91°, and, typical for cyclobutadiene complexes, the alkyne groups are bent away on average by 10° from the side of the cyclopentadienylcobalt fragment. This feature is observed in other tetraalkynylated cyclobutadiene complexes and is attributed to electronic effects.[4]

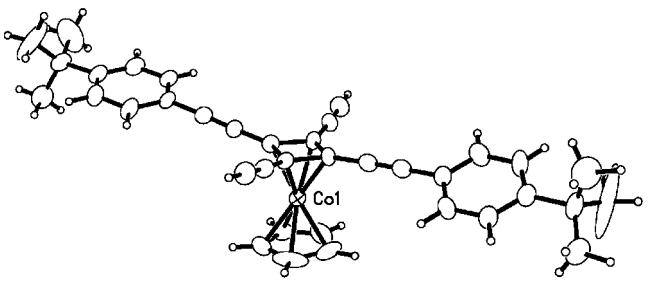


Fig. 1 ORTEP of the tetraethynylated cyclobutadiene complex **7**. Bond lengths and bond angles are in excellent agreement with literature reported values for multiply alkynylated cyclobutadiene complexes.

In conclusion, we have developed a solution-phase route to tetraethynylated, CpCo-stabilized cyclobutadiene complexes. We have executed a stepwise solution-phase synthesis for the hitherto unknown *para*-substituted complex **7**, and could show with the transformation of **2a** into **9** that it will work similarly in the case of the corresponding *ortho*-substituted substrate **2a**. With this methodology, almost complete control over the regiochemistry of the substitution of cyclopentadienylcobalt-stabilized cyclobutadiene complexes is achieved. In future we will report upon the use of these building blocks for novel organometallic oligomers, polymers, cycles and polycycles.

First published as an Advance Article on the web 23rd November 2001

A new type of organic–inorganic semiconductor heterostructure has been successfully fabricated by incorporating a polydiacetylene backbone into layered perovskite compounds by solid-state polymerization.

Much attention has been paid recently to the synthesis and characterization of organic–inorganic layered perovskites because of their exceptional properties and the tunability of their structure.[1–3] Layered perovskites with the general formula $(RNH_3)_2PbBr_4$ (R; C_nH_{2n+1}) naturally form a quantum-well structure consisting of a lead bromide semiconductor sheet sandwiched between organic insulator layers as shown in Fig. 1(a). The layered structure is self-organized through the neutralization of $[PbBr_6]^{4-}$ with organic ammonium in an orientation determined by the hydrogen bonds, and by a van der Waals interaction between adjacent organic ammoniums. Because the insulating organic layers have a wide band gap, excitons are confined in the inorganic $[PbBr_6]^{4-}$ layer; these provide strong photoluminescence with high optical nonlinearity, characteristics with potential applications in optical devices.[4–8] Organic–inorganic perovskites have a wide variety of possible combinations of inorganic and organic parts. Organic materials with specific functionality are combined on a molecular scale with an inorganic matrix with other target properties, creating an organic–inorganic composite with either a combination of the useful properties or one in which new phenomena arise from the interaction between the organic and inorganic components.[9] In this study, we tried to incorporate polydiacetylene systems into the organic–inorganic perovskites. The incorporation of diacetylenic species into the layered perovskites provides the potential for solid-state polymerization through the activation of the materials by an external energy source, as shown in Fig. 1(b). In a one-dimensional conjugated polymer, a Frenkel exciton is produced by optical excitation, whereas Wannier–Mott excitons can be formed under the same conditions in 2D inorganic perovskite quantum wells. The fabrication of such organic-inorganic heterostructures has been long anticipated, ever since Agranovich *et al.* reported the possibility of the existence of a new excitonic state, denoted a hybrid exciton.[10] It is thought that the hybrid exciton can be formed at the interface in organic–inorganic semiconductor heterostructures by the resonant mixing of Frenkel and Wannier exciton states, providing the features of both excitons, and exhibiting a strong nonlinear phenomenon at resonance. However, although hybrid excitons have been investigated theoretically, there are, as yet, no reports on the actual creation of hybrid excitons because of the difficulty in sample preparation. Herein, we report the novel preparation method of organic–inorganic semiconductor heterostructures by topochemical polymerization of polydiacetylenes into layered perovskites.

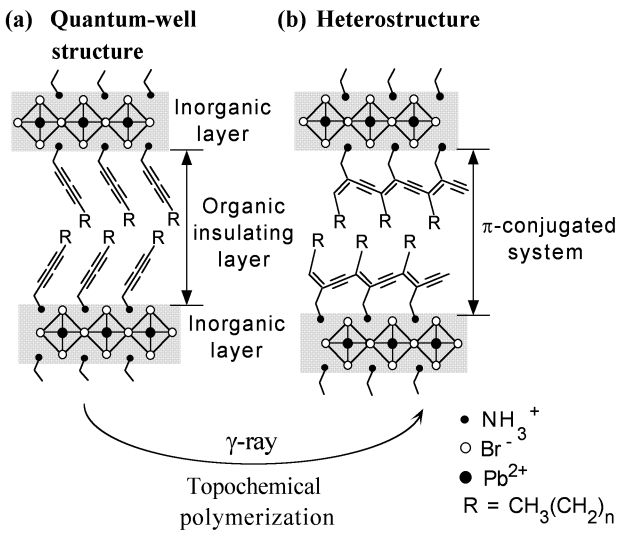

Fig. 1 Model of solid state polymerization performed in layered perovskites $(CH_3(CH_2)_nC{\equiv}CC{\equiv}C(CH_2)NH_3)_2PbBr_4$, DAPbBr(*n*–1), catalyzed by γ-irradiation.

Organic–inorganic perovskites $(CH_3(CH_2)_nC{\equiv}CC{\equiv}C(CH_2)_mNH_3)_2PbBr_4$ [abbreviated DAPbBr(*n*–*m*)], which contain aminodiacetylene organic moieties, were employed as monomer samples. As carefully designed reactant crystal structures are required for topochemical polymerization, we examined the incorporation of various diacetylenic amines into the layered perovskite structure. The diacetylenic amines were synthesized according to the method of Tsibouklis *et al.*[11] DAPbBr(*n*–*m*) were successfully obtained as both powders and thin films by reacting the corresponding alkylammonium bromides $CH_3(CH_2)_nC{\equiv}CC{\equiv}C(CH_2)_mNH_3Br$ with a stoichiometric amount of $PbBr_2$ in *N*,*N*-dimethylformamide (DMF). Powder samples were obtained as precipitates by pouring the reaction solutions into acetone. Films were spin-coated onto SiO_2 from DMF solutions. Solid-state polymerization was carried out using a ^{60}Co γ-source (dose rate 22.3 kGy h^{-1}) at room temperature. Specimens were placed in a glass tube, which was evacuated to 10^{-5} Torr in order to avoid oxidation during γ-irradiation. Polymerizability was monitored by UV–VIS spectra and X-ray diffraction. The DAPbBr(*n*–*m*) films exhibited a clear characteristic X-ray diffraction pattern indicative of a layered perovskite structure consisting of inorganic semiconductor layers of lead bromide and organic insulating layers of diacetylenic ammonium $CH_3(CH_2)_nC{\equiv}CC{\equiv}C(CH_2)_mNH_3^+$. In order to investigate the ability of the diacetylenic ammonium in the perovskites to polymerize, the spin-coated films were irradiated with γ-rays. The polymerization behavior of diacetylenes in DAPbBr(*n*–*m*) was found to be dependent on the alkyl chain length and the position of the diacetylenic unit in the hydrocarbon chains. The results of the

 DOI: 10.1039/b108536k

solid state polymerization of $CH_3(CH_2)_nC{\equiv}CC{\equiv}C(CH_2)_mNH_3^+$ are given in Table 1 together with the *d*-spacing of layered perovskites, as determined by powder X-ray diffraction, for the spin-coated films of both monomer and polymer forms.

In the $m = 1$ compounds, aminodiacetylenes with longer alkyl groups (carbon number $n \geqslant 13$) undergo polymerization under γ-irradiation. Colorless and transparent spin-coated films of DAPbBr(13–1) in monomer form turned red after γ-irradiation. The optical absorption spectra of DAPbBr(13–1) spin-coated film at 19 Mrad irradiation are shown in Fig. 2. The monomer sample exhibited a sharp exciton peak at 378 nm, attributed to the two-dimensional quantum-well structure based on PbBr. After γ-irradiation, a broad peak due to π–π* transitions of polydiacetylene also appeared at around 550 nm, along with the persistent initial exciton peak of perovskite. This implies that a π-conjugated system was successfully incorporated into the quantum-well layered perovskite structure. Exarhos *et al*. and other researchers have reported a method of estimating conjugation length by correlating the observed solid state absorption peak of the π–π* transition.[12,13] By fitting the absorption data obtained for DAPbBr(13–1) to their model, we estimate the conjugation length of polydiacetylene introduced into the perovskite structures to be 22 monomer units. Fig. 3 shows the X-ray diffraction patterns of DAPbBr(13–1) in the monomer and polymerized form. Each spin-coated film produces a series of (00l) diffraction patterns, evidence that the layered structure of alkylammonium cations and lead bromide layers remains intact after topochemical polymerization. The powder X-ray diffraction patterns of the polymerized DAPbBr(13–1) exhibit peaks at 2.60° with $d = 33.4$ Å; however, no peak attributable to the monomer structure was observed. The *d*-spacing increment of 2.7 Å observed after polymerization occurs as a result of conformation changes such as changes in the tilt angle of alkyl groups and the extent of their interdigitation. The polymerizability of DAPbBr(*n*–1) with a shorter alkyl chain was dramatically lower than that with the long alkyl chain (Table 1). DAPbBr(2–1) produced a weak absorbance at shorter wavelengths in addition to an initial exciton peak from the quantum well after γ-irradiation, due to the formation of oligomers rather than a polymer backbone. In the case of DAPbBr(1–1) with short alkylammonium groups, the layered structure was not maintained during the polymeric reaction because of the weak interaction between alkyl chains. The development of polymerization behavior that is dependent on the length of alkyl chains connected to the diacetylene unit is controlled by the presence or absence of favorable orientation for the polymerization via 1,4-addition. Layered structures of DAPbBr(13–1) and DAPbBr(15–1) are well-arranged for polymerization because of the strong self-organization properties of long alkyl chains. In other words, longer alkyl chains favor a molecular arrangement appropriate for topochemical polymerization.

Table 1 Polymerizability of layered perovskites containing aminodiacetylenes DAPbBr(*n*–*m*) catalyzed by γ-irradiation

		After γ-irradiation	
n–*m*	Monomer *d*-Spacing/Å	*d*-Spacing/Å	Polymerizability (conjugation length)
1–1	17.3	Collapse	—
2–1	18.4	16.7	—
13–1	30.7	33.4	○(22 units)
15–1	37.7	38.1	○(27 units)
11–3	31.1	Same as monomer	—

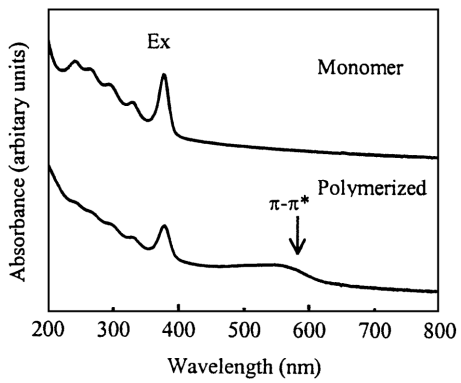

Fig. 2 UV–VIS spectra of spin-coated layered perovskite DAPbBr(13–1) films of monomer and polymerized form (after 19 Mrad γ-irradiation).

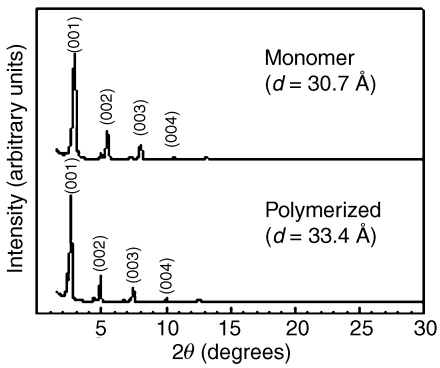

Fig. 3 X-Ray diffraction patterns of DAPbBr(13–1) spin-coated films of monomer and polymerized form.

We compared the polymerizability between DAPbBr(13–1) and DAPbBr(11–3), which have the same total alkyl chain length (*i.e.* $n + m = 14$). Polymerizability is dependent on the spacer length between the butadiyne unit and ammonium groups. DAPbBr(11–3) exhibited no change in the lamellar structure or spectrum after γ-irradiation, indicating that polymerization does not proceed in DAPbBr(11–3). As there are no prominent differences in molecular arrangement between DAPbBr(11–3) and DAPbBr(13–1), the difference in polymerizability is thought to be derived from the packing and flexibility of the diacetylenic ammoniums. Molecules in DAPbBr(13–1) have more freedom to pack in a favorable manner for the reaction, allowing a higher degree of reorganization during the polymerization process.

In summary, we have described a novel method of preparing organic–inorganic semiconductor structures based on layered perovskites. We have successfully incorporated π-conjugated systems using the architecture of diacetylenic ammoniums. We have recently extended this achievement to the production of a hybrid exciton feature, the report on which shall be presented in the near future.

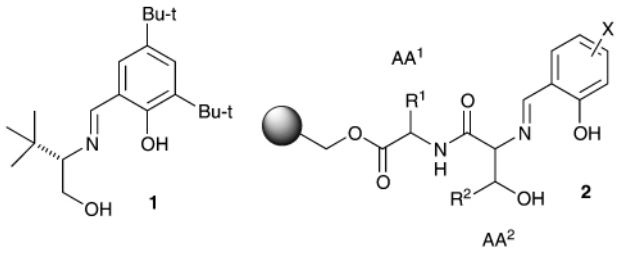
First published as an Advance Article on the web 23rd November 2001

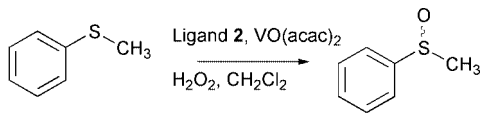
The discovery of a new solid-supported ligand 5 for the catalytic asymmetric oxidation of aryl alkyl sulfides in up to 72% ee using Ti(O^{i}Pr)$_4$ and aqueous H_2O_2 is reported.

The asymmetric synthesis of alkyl aryl sulfoxides has been the subject of much investigation, following the initial reports by Kagan[1] and Modena[2] on the use of a modified Sharpless reagent for the oxidation of alkyl aryl sulfides using alkyl hydroperoxides. More recent work has focussed on the use of H_2O_2 as the oxidant, with the first successful catalytic system discovered by Bolm using the combination of the amino alcohol-derived Schiff base **1** with vanadium.[3,4] An oxidation catalyst that



combines high catalytic efficiency and high enantiomeric excess remains an important goal.[5] The recent development of combinatorial methods for the discovery of new asymmetric catalysts offers a potential solution.[6] The great success that has been achieved by Hoveyda and Snapper in various asymmetric C–C bond forming processes by parallel synthesis of peptide–Schiff base libraries[7] suggested that an optimisation of the Bolm system using these techniques might be possible.

The apparent requirement for a hydroxy group in the ligand (presumably to coordinate to vanadium) suggested structure **2** as an appropriate generic ligand, which would be amenable to solid phase synthesis by standard coupling techniques. We planned on exploring five variables in this modular catalyst design, namely the solid support, amino acid 1, hydroxy amino acid 2, the salicylaldehyde and the choice of metal, with vanadium as the obvious starting point. Our initial library fixed the solid support as Wang, screened a series of L-amino acids (Gly, Ala, Val, Leu, Ile, Phe) as amino acid 1, serine and threonine as amino acid 2, and a series of salicylaldehyde derivatives [3,5-dibromosalicylaldehyde, 2-hydroxynaphthaldehyde, 3,5-di-*tert*-butylsalicylaldehyde (DtBS), 3,5-dichlorosalicylaldehyde, 5-nitrosalicylaldehyde and 3,5-dinitrosalicylaldehyde]. All the ligands were prepared in parallel using standard techniques. The library of 72 ligands was tested in the vanadium-catalysed oxidation of methyl phenyl sulfide **3a** using hydrogen peroxide. We employed two different reaction protocols; in the first, 1 equiv. of VO(acac)$_2$ was simply added to a suspension of the ligand in CH_2Cl_2, followed by addition of H_2O_2 and methyl phenyl sulfide **3a** (Scheme 1); in the second, the ligand was preincubated with a solution of VO(acac)$_2$, and the resin was then filtered and added to the reaction mixture.‡ The latter protocol gave results that were as good as, or better than, the first protocol, so the latter protocol was used in all subsequent experiments.



3a **4a**

Scheme 1 Asymmetric oxidation of methyl phenyl sulfide.

The results from this initial screening indicated that all the ligands were good catalysts for the oxidation, with conversions to the sulfoxide **4** ranging from 56 to 93%, but with the best ee a modest 11% (Wang-Phe-Ser-DtBS). The corresponding threonine derivative (Wang-Phe-Thr-DtBS) gave racemic sulfoxide **4**. As a final check, we also prepared the *allo*-threonine derivative (Wang-Phe-Thr*-DtBS),§ which gave excellent conversion to the sulfoxide, with an improved ee of 17%. Since these results were a substantial improvement on either threonine or serine, we felt that we had identified the optimum amino acid AA^2. We now attempted to optimise this ligand by use of the positional scanning method of Hoveyda and Snapper.[7] A library of 18 salicylaldehyde derivatives was screened, and the results unfortunately confirmed that we had already identified the best component. Finally, we prepared another library (Wang-AA^1-Thr*-DtBS) in which 19 different D- and L-amino acids were used as AA^1, including those with and without functionality. This resulted in the discovery that the use of D-Phe gave a much improved ee of 23%, at a conversion of 89%. Thus, the optimised structure for the asymmetric oxidation of methyl phenyl sulfide **3a** had the structure Wang-D-Phe-Thr*-DtBS **5**. Although this ligand had the advantage that it could be rapidly assembled, and easily removed from the reaction mixture allowing straightforward product isolation, the ee was simply far too low to be useful.

At this stage, we felt it appropriate to explore whether metal ions other than vanadium might be more effective. We therefore screened a series of metals for their ability to catalyse the oxidation of methyl phenyl sulfide by aqueous hydrogen peroxide in the absence of added ligand, and unsurprisingly Mo(VI), W(VI), V(IV) and Ti(IV) all proved effective (with Ti(IV) interestingly being the least effective). When the ligand that had been optimised for the vanadium-catalysed oxidation was tested with these metals, it immediately became clear that the combination of Wang-D-Phe-Thr*-DtBS and Ti(Oi-Pr)$_4$ was a much more effective asymmetric catalyst, giving a reproducible ee of between 62 and 64% (*R*-isomer in excess), with high

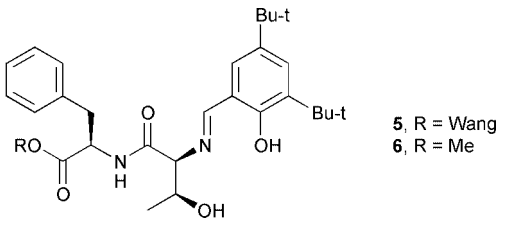
[a] Conversions and ee values were measured using chiral phase HPLC. HPLC conditions are provided in the supplementary material.

conversion. Clearly the low rate of the background reaction is important. Schiff-base titanium complexes are effective for sulfur oxidation,[8–10] and very recently it has been reported that Ti(salen) complexes can be very effective in the same process using hydrogen peroxide as the oxidant.[11]

Since the behaviour of solid-supported ligands and their solution phase counterparts can differ, we converted the optimum ligand into the corresponding methyl ester **6** by treatment with NEt_3 in DMF–MeOH. Use of this solution phase ligand gave an identical 64% ee in the oxidation of methyl phenyl sulfide **3a** to the solid phase analogue (which is therefore a superior catalyst from a practical point of view).

Rather than screening all our previous libraries in the titanium-catalysed oxidation reaction, we tested the corresponding serine, threonine and *O-tert*-butyl threonine derivatives, Wang-D-Phe-Ser-DtBS (27% ee), Wang-D-Phe-Thr-DtBS (23% ee) and Wang-D-Phe-Thr(t-Bu)-DtBS (0% ee) in the titanium-catalysed oxidation of methyl phenyl sulfide **3a**. These results confirm both the importance of the free hydroxyl group and the influence of the stereogenic centre at C-3 of the *allo*-threonine residue.

In order to establish how strongly the titanium was complexed to the solid phase ligand, we incubated a solution of $Ti(Oi\text{-}Pr)_4$ in CH_2Cl_2 with the ligand **5**. The resin was then washed 5 times, and the titanium concentration in each of the washings was measured by ICP-AES. While some residual titanium was detectable in the first washing, in all the four subsequent washings the titanium concentration was below the background level (< 1 ppm). This suggested that leaching of titanium from the resin was minimal, and that as a consequence the catalyst combination of ligand **5** and Ti might be reusable.



Provided the resin was not allowed to dry out, the catalyst could be reused without erosion of conversion or ee (first run, 62% ee, second run, 64% ee), although the ee did degrade with subsequent runs with the same sample of catalyst.

The ee of our catalyst system was comparable with the original results reported by Bolm, so we decided to investigate its scope in the oxidation of a variety of other alkyl aryl sulfides (Scheme 2), and our results are reported in Table 1. The ee values are remarkably consistent, and indicate the utility of the catalyst. Some overoxidation to the sulfone was observed in the case of **3d** (13%) and **3g** (22%), but in all other cases the amount of sulfone was less than 5%.

We thank EPSRC for the award of a research grant (GR/M13633), GlaxoSmithKline and the EPSRC for an Industrial CASE studentship (S. D. G.), and the Commission of the European Union (IHP Network HPRN-CT-2000-00014) for support of a studentship (C. M.).

Notes and references

‡ *General procedure for solid phase asymmetric oxidation of sulfides*. The solid phase ligand (0.015 mmol) was weighed into an Altech tube. Anhydrous CH_2Cl_2 (2.0 ml) was added, followed by the metal salt (0.05 mmol). After 20 min, the resin was filtered, and anhydrous CH_2Cl_2 (2.0 ml) was added to wash the resin. After one min the resin was filtered. A dry reaction tube with a magnetic stirrer was purged and filled with nitrogen three times. Then the resin was added in the reaction tube, followed by distilled CH_2Cl_2 (2.0 ml), the sulfide (1 mmol), and 30% H_2O_2 in water (1.1 mmol) and the mixture was stirred for 5–16 h, depending on the substrate. A sample (1–2 μl) was then removed, and diluted with 10% IPA–heptane, for analysis by HPLC.† To isolate the products, the reaction was worked up by quenching with 10% Na_2SO_3 solution (5 ml). The reaction mixture was extracted with Et_2O (2×10 ml), and the extracts were combined and dried ($MgSO_4$); the solvent was removed under reduced pressure. The crude product was purified by silica flash chromatography (Et_2O–MeOH 95 : 5) to leave the product as a white solid.

§ We found that use of Wang-Tle- Thr*-DtBS also gave an improved ee of 18%, but since resin loading of *tert*-leucine is less straightforward, we used commercially available Fmoc-L-phenylalanine resin for the subsequent libraries.

Octaalkynyltetra[6,7]quinoxalinoporphyrazines: a new class of photosensitisers with potential for photodynamic therapy

Frieder Mitzel,[a] Simon FitzGerald,[b] Andrew Beeby[b] and Rüdiger Faust*[a]

[a] *Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H OAJ. E-mail: r.faust@ucl.ac.uk*
[b] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*

Received (in Cambridge, UK) 24th October 2001, Accepted 30th October 2001
First published as an Advance Article on the web 23rd November 2001

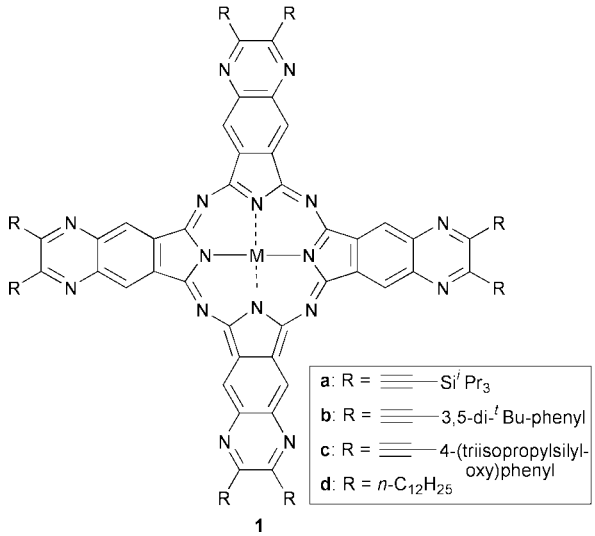
Acetylene-substituted tetra[6,7]quinoxalinoporphyrazines, obtained in two steps from dialkynyl-1,2-diones and 1,2-diamino-4,5-dicyanobenzene, show intense absorptions in the near infrared and have photooxidising properties that make them promising candidates as agents active in photodynamic therapy.

Photodynamic therapy (PDT) is an increasingly valuable method for the treatment of a variety of conditions, among them various forms of cancer, age-related macular degeneration, and, most recently, atherosclerosis.[1–4] At the core of PDT lies the generation of reactive oxygen species by energy transfer from a photosensitiser embedded in the malignant tissue which is irradiated with external light of appropriate wavelength. The reactive oxygen species in turn cause significant cellular damage and thereby ultimately lead to the eradication of the pathogenic tissue. Sensitisers suitable for biomedical applications of this type must meet the minimum requirements of accessibility by light in a biological matrix and of efficient induction of photooxidation. These requirements lead to the definition of a therapeutic window of *ca.* 650–800 nm in the absorption of practical PDT agents. Current applications largely exploit the photosensitising action of functionalised porphyrins such as a mixture of haematoporphyrin derivatives HpD, which is marketed under the tradename Photofrin®.[5] Despite the success of this drug in PDT, efforts are continuing to devise photosensitisers with an improved photochemical profile with respect to that of Photofrin®,[6] whose role in PDT is somewhat limited, among other things, by its low-intensity absorption around 630 nm.

We wish to present here octaalkynyltetra[6,7]quinoxalinoporphyrazines **1a–c** as a new class of photosensitisers which, by virtue of their concise and flexible synthesis and their (photo)chemical properties, are promising candidates as effective PDT agents. As such, **1a–c** represent viable alternatives to some of the phthalo- and naphthalocyanines that are currently being investigated as second generation sensitisers for PDT[6,7] and are a significant advancement over the corresponding octaalkynylphthalocyanines[8,9] and tetrapyrazinoporphyrazines previously reported.[10]

The syntheses of the quinoxalinoporphyrazines **1** are summarised in Scheme 1 and follow a route similar to the one outlined for the related octaalkynyltetrapyrazinoporphyrazines.[10] Key step in the preparation of the new acetylenic chromophores is the condensation of the dialkynyl-1,2-diones **4a–c**[11] with 1,2-diamino-4,5-dicyanobenzene **3** followed by a base-induced cyclotetramerisation of the intermediate quinoxalines to the porphyrazine framework. The alkyl-substituted derivative was prepared for comparison.† The new chromophores are deep blue (**1a**, **1d**) or green (**1b**, **1c**) solids that show good solubility in common organic solvents (CH_2Cl_2, THF).

The electron absorption spectra of compounds **1a–d** in THF are dominated by two transitions, namely the higher-energy *B*-band and the lower-energy *Q*-band, that in case of **1a–c** stretches into the near infrared (Fig. 1). The influence of peripheral substituents on the appearance of the UV–Vis–NIR



1

spectra of the tetra[6,7]quinoxalinoporphyrazines is quite remarkable. Whereas non-acetylenic **1d** shows a *B*-band at 364 nm (ε = 132 000 M^{-1} cm^{-1}) and a *Q*-band at 735 nm (ε = 431 000 M^{-1} cm^{-1}), the corresponding maxima of acetylenic compound **1a** (M = Mg, *B*-band: 388 nm, ε = 288 000 M^{-1} cm^{-1}; *Q*-band at 770 nm, ε = 512 000 M^{-1} cm^{-1}) are significantly batho- and hyperchromically shifted. This indicates that the π-system of the main chromophore of **1a** extends beyond the periphery of the polyazamacrocycle and includes the acetylene substituents. However, an extension of the π-system of **1a** by the appendage of terminal aryl groups to the acetylene units as, for example, in **1b** (*B*-band: 394 nm, ε = 306 000 M^{-1} cm^{-1}; *Q*-band: 770 nm, ε = 517 000 M^{-1} cm^{-1}, THF) does not result in a further bathochromic shift of the *Q*-band. In comparison to octaalkynyltetrapyrazinoporphyrazines[10] and −phthalocyanines,[8,9] whose *Q*-band absorption

 DOI: 10.1039/b109742n

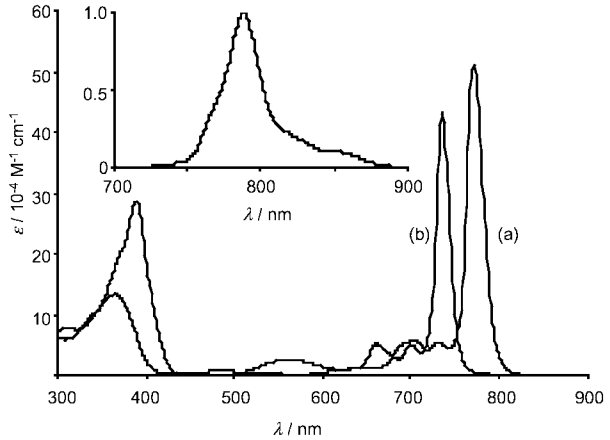

Fig. 1 Electronic absorption spectra of **1a** (a) and **1d** (b) in THF at 298 K. The inset shows the fluorescence spectrum of **1a** in THF at 298K upon irradiation at 388 nm.

maxima centre around 670 nm and 720 nm, respectively, the significantly red-shifted absorption of **1a–c** will allow the use of more deeply penetrating light for the excitation of **1a–c** in biological tissue. In addition, the high molar extinction coefficients associated with their NIR absorptions suggest a more detailed exploration of their suitability for PDT applications. Furthermore, the photostability of the compounds is satisfactory. Their aerated solutions in hexanol show very little degradation upon irradiation with light at a fluence rate of 50 mW cm^{-2} for several hours (*e.g.* 92% of the initial absorption of **1a** (M = Zn) at longest wavelength maximum still present after 4h irradiation). In light of the fluorescence at 790 nm that the alkynyl-substituted compounds **1a–c** exhibit upon irradiation at either their respective *B*- or *Q*-bands (Fig. 1), usage of this class of compounds as fluorescent probes in biological tissue or diagnostic tools in PDT can also be envisioned.

A qualitative evaluation of the photooxidising ability of **1a** (M = Zn) was performed using the singlet oxygen quencher 1,3-diphenylisobenzofuran (DPBF).[12] Hence, an aerated solution of **1a** (M = Zn) and DPBF (120-fold molar excess) in hexan-1-ol was exposed to filtered light (cut-off < 550 nm) of a slide projector lamp while monitoring the 413 nm absorption of DPBF (Fig. 2). No or little photooxidation of DPBF is observed in the absence of either light, **1a** (M = Zn) or oxygen (traces a–c, Fig. 2). However, significant photodegradation of DPBF occured in the presence of **1a** (M = Zn) and oxygen

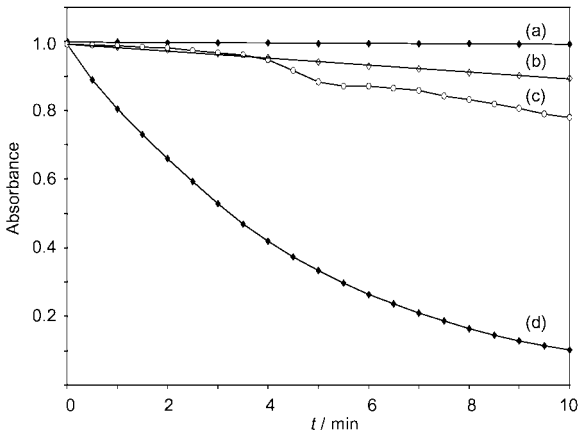

Fig. 2 Photooxidation of 1,3-diphenylisobenzofuran (DPBF) with **1a** (M = Zn) in hexanol at 298 K; c_o(DPBF) = 4.5×10^{-5} mol l^{-1}, c_o (**1a**) = 4.0×10^{-7} mol l^{-1}, light source: slide projector lamp (24 V, 250 W), cut-off filter <550 nm. The absorption at 413 nm was monitored in an aerated solution of **1a** (M = Zn) and DPBF upon irradiation (trace d); trace a, in the absence of light; trace b, in the absence of **1a** (M = Zn); trace c, in the absence of oxygen.

Table 1 Fluorescence lifetimes τ_f, fluorescence quantum yields Φ_f and singlet oxygen quantum yields Φ_Δ for selected tetra[6,7]quinoxalinoporphyrazines[a]

Compound	τ_f/ns	Φ_f[b]	Φ_Δ[c]
1a (M = Mg)	4.3 ± 0.1	0.46	0.19
1a (M = Zn)	2.4 ± 0.1	0.25	0.56
1d (M = Mg)	5.3 ± 0.1	0.59	0.15

[a] All measurements were performed in aerated THF at 298 K. [b] Absolute values (±10%) relative to cresyl violet in MeOH (Φ_f = 0.54) and disulfonated aluminium phthalocyanine in H_2O (Φ_f = 0.40) standards. [c] Obtained by time-resolved phosphorescence measurements using excitation at λ_{ex} = 355 nm. Values are relative to perinaphthenone (Φ_Δ = 0.97) and have an error of ±10%.

(trace d, Fig. 2), clearly demonstrating the photooxidising ability of the zinc quinoxalinoporphyrazine. The corresponding magnesium derivative **1a** (M = Mg) shows a markedly reduced photosensitising effect.

As shown in Table 1, these qualitative findings are further substantiated by the photophysical data obtained for compounds **1a** (M = Mg, Zn) and **1d** (M = Mg). Whereas the magnesium porphyrazinato complexes are strong fluorophores with only limited singlet oxygen producing capacity, the corresponding zinc complex **1a** (M = Zn) is a very efficient singlet oxygen sensitiser with a singlet oxygen quantum yield of Φ_Δ = 0.56. In fact, this value is comparable with that determined for photofrin (Φ_Δ = 0.57 in benzene)[1] and significantly exceeds that determined for silicon naphthalocyanine (Φ_Δ = 0.35 in benzene),[1] an analogue of **1** that has been investigated in the context of PDT applications.

The short and flexible synthesis of alkynyl-substituted quinoxalinoporphyrazines coupled with their high intensity absorption and their emission in the near infrared make them interesting candidates for future PDT applications. While the lipophilicity of the prototypical compounds presented here will require an administration *via*, for example, liposomal formulations, further adaptations of the chromophores to the requirements set by biological environments can be easily achieved by exploiting, for example, the chemistry of the protected phenol functionality in **1c**. Work along these lines is currently under way.

We wish to acknowledge University College London for the provision of a Provost Studentship to F. M. and the EPSRC for a studentship to S. F. We thank Dr A. J. MacRobert for helpful discussions.

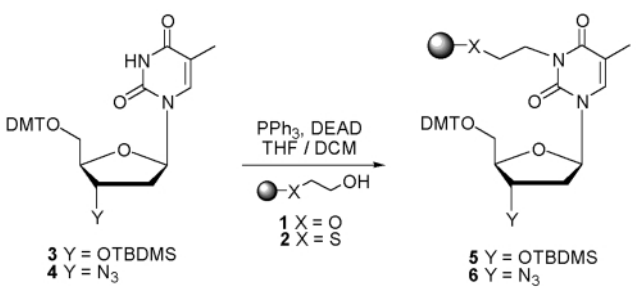
Received (in Cambridge, UK) 8th August 2001, Accepted 19th October 2001
First published as an Advance Article on the web 26th November 2001

Two new thymidine based polymeric supports, in which the nucleosides have been anchored through the thymine moiety to a β-hydroxy thioether functionalized resin *via* a Mitsunobu reaction, have been prepared. A simple and efficient solid-phase synthesis of 5′,3′-bis-derivatized thymidine analogues has so been developed, following methodologies well established in peptide and oligonucleotide chemistry and is here proposed for the preparation of a variety of different nucleoside conjugate products.

Combinatorial chemistry allows the study of the properties of many classes of compounds much faster than a classical serial analysis. The combinatorial approach to the simultaneous polymer-supported synthesis of chemical compounds has allowed the rapid screening of a plethora of different substrates, speeding up lead identification and optimisation, and resulting in fundamental developments in biomedicinal chemistry.[1] Combinatorial syntheses are often carried out as sequential, high fidelity condensation and addition reactions on solid-phase linked scaffolds which are typically polyfunctional molecules.[2] In this frame nucleosides can be regarded as very useful scaffolds to be incorporated into polymeric supports for combinatorial libraries[3] since they contain functional groups which can be differently manipulated and stereogenic centres useful for a defined spatial presentation of the various substituents. In addition, the biomedical potential of nucleoside derivatives is well known. Therefore nucleosides are particularly attractive as platforms for the design of primary screening libraries. Aiming at the synthesis of new functionalized solid supports for combinatorial libraries of chimeric biomolecules incorporating nucleoside moieties (*e.g.* nucleoside analogues, conjugates or other hybrids), we turned our attention to *ad hoc* modified polymeric supports linking suitably protected nucleoside derivatives in which the ribosidic functions are susceptible of further modifications. In order to attach to polymeric supports nucleosides through the base, we have investigated the possibility of immobilizing thymidine derivatives in the solid phase by reacting the imino function of the thymine moiety. For this purpose, the Mitsunobu reaction[4] of aliphatic alcohols with amidic or imidic species may be particularly useful for an efficient *N*-alkylation of pyrimidine nucleoside derivatives; this approach has been also successfully exploited by us in order to glycosylate the N-3 position of uridine derivatives.[5] Starting from our previous experiments, we first tested the solid phase Mitsunobu condensation between sugar protected thymidine **3** and a commercially available hydroxy Tentagel® resin (0.24 meq g^{-1}, **1**, Scheme 1), a polymeric support largely employed in peptide and oligonucleotide synthesis. Such reaction gave satisfactory incorporation yields of the thymidine residue (80% yields by DMT test) but did not result in a practically feasible route, since no mild reaction conditions were found for the final detachment of the intact nucleoside from the solid phase.

Therefore we have devised an alternative synthetic scheme involving the Mitsunobu reaction of β-hydroxyethylthioether Tentagel resin **2**‡ with thymidine derivatives **3** and **4** (Scheme 1) to yield nucleoside derivatized supports **5** and **6**, respectively. Such supports have been designed to allow a simple and efficient release of the nucleosidic material *via* a β-elimination reaction by mild alkaline treatment on the alkylthioethyl function in **5** or **6**, once oxidized to sulfone. We report herein a general synthetic strategy to obtain a variety of thymidine-containing hybrid molecules by exploiting supports **5** and **6** which can form phosphoester or glycosidic linkages using the OH functions, and amide or phosphoramidate bonds exploiting the N_3 group, previously reduced to amine.

Thymidine derivatives **3** and **4** were loaded onto resin **2** in the presence of PPh_3 and DEAD in THF–DCM to produce supports **5** and **6**. The DMT test showed in both cases a typical loading of 0.17 meq g^{-1} (90% yield). To transiently mask the 3′-hydroxy moiety in support **5** (Scheme 1), the *tert*-butyldimethylsilyl (TBDMS) group was employed in view of its well established orthogonality to DMT and its stability under both acidic and mild basic conditions as well as during the steps involved in the glycosidic[6] and phosphotriester[7] linkage formation. The best results in the removal of TBDMS were obtained under treatment with $Et_3N{\cdot}3HF$ (overnight, rt) as verified by coupling the 3′-OH with 2′-deoxycytidine phosphoramidite building block by standard automated phosphoramidite protocol[7] (Scheme 2). The coupling yield was almost quantitative (98%) as checked by DMT cation quantitation on **7** and in no case loss of nucleosidic material was observed. Then the thioether function of the support was oxidized with a mClPBA solution[8] (0.5 M in DCM, 1 h, rt) and, after detritylation of the 5′-OH groups, complete detachment from the support was achieved by treatment with conc. aq. ammonia solution (18 h, 60 °C) giving the desired 3′–3′ phosphodiester linked dinucleotide **8**. The crude detached material was purified by reverse phase HPLC and the identity of isolated **8** was ascertained by ^1H, ^{31}P NMR and MS data.



Scheme 1 Solid support functionalization by the Mitsunobu approach.

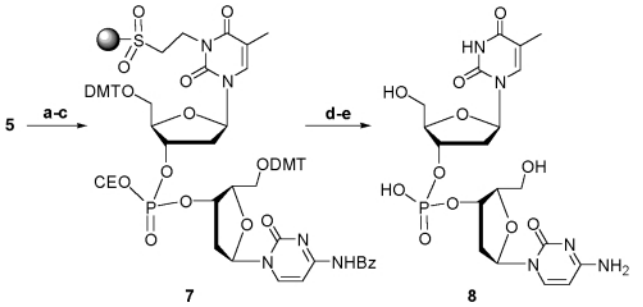
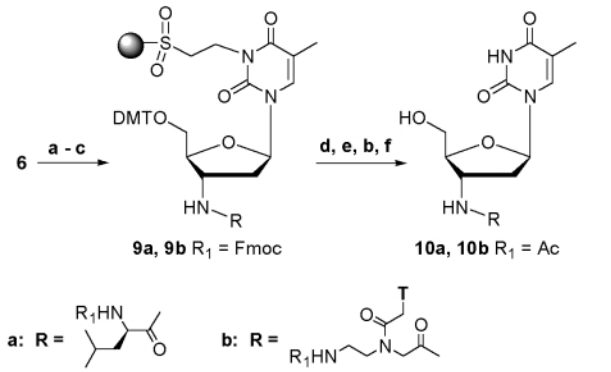
 DOI: 10.1039/b107200p



Scheme 2 **a**: $Et_3N{\cdot}3HF$, THF, overnight, rt; **b**: coupling with dC phosphoramidite building block; 0.1 M tetrazole; I_2–THF–H_2O; **c**: 0.5 M mClPBA in DCM, 1 h, rt; **d**: 1% DCA in DCM; **e**: NH_4OH, 18 h, 60 °C.

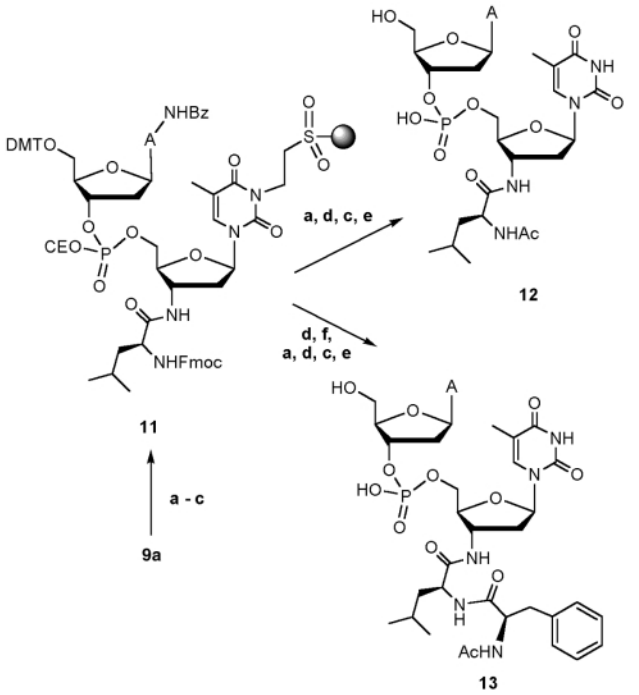


Scheme 3 **a**: FmocNH–amino acid or Fmoc-T(PNA)-OH, DIC, HOBt, nBu$_3$P; **b**: Ac_2O–Py (1 : 1, v/v); **c**: 0.5 M mClPBA in DCM, 1 h, rt; **d**: 1% DCA in DCM; **e**: 20% piperidine in DMF; **f**: NH_4OH, 18 h, 60 °C.

To test the efficiency of support **6** in the synthesis of 3′-amino derivatized thymidine analogues, we first prepared two different thymidine hybrids, **10a** and **10b** (Scheme 3), incorporating at the generated 3′-amino group an aminoacid or a PNA residue, respectively. To this purpose, the 3′-azido function in **6** was reduced to amine and directly coupled in a one pot reaction[9] with Fmoc-Leu-OH (83% yield) or Fmoc-T(PNA)-OH (84% yield) in the presence of DIC–HOBt and PBu_3 in DMF, leading to supports **9a** and **9b**, respectively. After capping with Ac_2O and Fmoc removal on a weighed sample of the supports, the coupling yield was measured by the Kaiser test.[10] Acetylation of the amino functions was followed by thioether oxidation, DMT and Fmoc removal and detachment from supports **9a** and **9b**, which gave **10a** and **10b**, respectively, whose structures have been confirmed by ^{1}H NMR and MS data.

In order to test the compatibility of the synthesized supports with both peptide and oligonucleotide solid phase synthetic strategies, support **9a** was then employed in the synthesis of **11** (Scheme 4), a hybrid dinucleotide having a classical 3′–5′ phosphodiester linkage, by reaction with 2′-deoxyadenosine phosphoramidite building block. Once both DMT and Fmoc protecting groups had been removed by standard methods, acetylation of the support, followed by the above described procedures for the detachment and deprotection, produced **12** (81% yield). On another batch of functionalized support **11**, after amino function deprotection, coupling with Fmoc-Phe-OH was carried out in the presence of DCCI–HOBt in DMF–DCM following a standard Fmoc protocol. DMT and Fmoc removal, followed by acetylation and detachment from the solid support, produced hybrid **13** (73% yield). After HPLC purification, **12** and **13** were characterized by ^{1}H, ^{31}P NMR and MS data.

In conclusion we have reported the synthesis of two new thymidine based solid supports (**5** and **6**) in which the nucleosides are anchored to the solid support through the base, so that both the 5′ and 3′ functions are available for further manipulation. A convenient β-hydroxyethyl-thioether **2** was



Scheme 4 **a**: 1% DCA in DCM; **b**: coupling with dA phosphoramidite building block; 0.1 M tetrazole; I_2–THF–H_2O; **c**: Ac_2O–Py (1 : 1, v/v); **d**: 20% piperidine in DMF; **e**: NH_4OH, 18 h, 60 °C; **f**: Fmoc-Phe-OH, DCCI, HOBt, 6 h, rt.

synthesized and inserted in the solid phase allowing a high yield incorporation of the protected thymidine building blocks by Mitsunobu reaction and, after the desired derivatization at the 3′ and/or 5′ functions, the total release of the nucleosidic material by a classical ammonia treatment. Starting from these supports we have devised a versatile synthetic strategy to obtain a variety of thymidine hybrids following well established peptide and oligonucleotide chemistry. In principle this methodology can be easily exploited to link any other amido or imino-functionalized heterocycle to a solid support.

Further studies are currently in progress to extend the Mitsunobu reaction to anchor other nucleosides on polymeric supports.

We acknowledge MURST, CNR and Regione Campania for grants in support of this investigation and C.I.M.C.F., Università degli Studi di Napoli 'Federico II', for the NMR facilities.

Notes and references

‡ A CPG support with a linker similar to **2** is commercially available from Glen Research with 0.06 meq g^{-1} loading in which the thioether function is already oxidized to sulfone.

Silicon-bridged bis(cyclohexadienyl) iron complexes: the first structurally characterised [1⁴]ferrocenophane†

Tony Hascall, Mark J. Drewitt and Dermot O'Hare*

Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR. E-mail: dermot.ohare@chem.ox.ac.uk

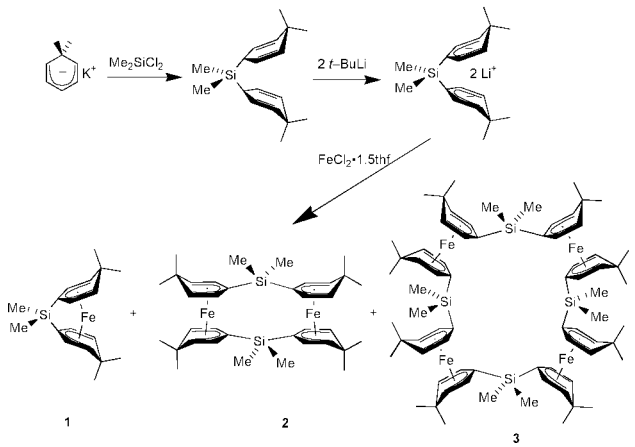
Received (in Cambridge, UK) 4th September 2001, Accepted 9th October 2001
First published as an Advance Article on the web 26th November 2001

Reaction of the Me_2Si bridged bis(6,6-dimethylcyclohexadienyl) dianion with $FeCl_2$·1.5THF gives mono-, di- and tetrametallic complexes; $\{[Me_2Si(DMCh)_2]Fe\}_4$ is the first crystallographically characterised [1⁴]metallocenophane.

[1^n]Metallocenophanes, molecules consisting of n metallocene units joined by single atom bridges,[1] are of interest for several reasons. For example, it is now well established that strained, ring-tilted, [1¹]ferrocenophanes (*ansa*-bridged ferrocenes) undergo thermal, anionic and metal-catalysed ring-opening polymerisation (ROP),[2,3] yielding well-defined, high molecular weight, soluble metal-containing polymers. Oligomeric [1^n]ferrocenophanes are also of considerable interest due to, for example, their novel structural properties and the possibility of metal–metal interactions.[1,4] To date, polymerisation reactions have been limited to metallocenophanes containing cyclopentadienyl rings. We are interested in developing new ligand systems that could offer more flexibility and diverse substitution patterns in order to extend this chemistry.

As part of this research, we have studied metal complexes of the 6,6-dimethylcyclohexadienyl anion (DMCh),[5] which are related to 'open metallocenes'[6] as the ligand can bind to the metal centre though an η⁵-pentadienyl moiety. The dimethylcyclohexadienyl ferrocene analogue, $(DMCh)_2Fe$, has been reported;[5] however, metallocenophanes with bridged cyclohexadienyl ligands are unknown, although recently titanium complexes of the 'constrained geometry' ligand Me_2Si(Bu^{t}N)DMCh have been reported.[7]

A silicon-bridged bis-dimethylcyclohexadienyl ligand was synthesized according to Scheme 1. Thus, addition of 2 equiv. of the potassium salt $K^+(DMCh)^-$ [5,8] to Me_2SiCl_2 gave dimethylbis(dimethylcyclohexadienyl)silane, the NMR spectrum of which (ESI†) is consistent with a C_{2v} symmetric 1,4-diene, indicating reaction has taken place exclusively at the 3-position of the cyclohexadienyl rings. The ligand could be deprotonated with 2 equiv. Bu^{t}Li to yield $Me_2Si(DMChLi)_2$. Reaction of this dianion with $FeCl_2$·1.5THF in THF gives a complex mixture, presumably containing products due to reduction by the DMCh anion[5] as well as insoluble polymeric material. Three products, however, could be isolated: the [1]ferrocenophane analogue, $[Me_2Si(DMCh)_2]Fe$ **1** as well as dimeric and tetrameric species.



Scheme 1

The three products could be separated by virtue of their differing solubilities, and have been characterised by X-ray crystallography‡ in addition to NMR, and microanalysis (ESI†). The monomer **1** is highly soluble in pentane. Its structure (Fig. 1) reveals it to be analogous to a ring-tilted *ansa*-bridged ferrocene. As an indication of the strain in **1**, the value of α, the angle between the average planes defined by the pentadienyl carbons, is 14.5°. For comparison, an angle of 20.8° was observed between the Cp rings in the analogous $[Me_2Si(C_5H_4)_2]Fe$.[9] Thus, on this basis, the replacement of Cp rings with DMCh would appear to have reduced the strain somewhat. Conversely however, the average value of β, the angle between each plane and the bridging atom–bridgehead bond, is slightly greater for $[Me_2Si(DMCh)_2]Fe$ (40.0°) than $[Me_2Si(C_5H_4)_2]Fe$ (37.0°). This deviation from planarity of the sp² bridgehead atom of **1** is also reflected in its ^{13}C NMR resonance, which is found at δ 47.4, an upfield shift relative to unbridged compounds. For comparison, the corresponding value for $(DMCh)_2Fe$ is δ 77.9.[5] It should also be noted that, in general, bis-pentadienyl iron complexes prefer to adopt a *gauche* eclipsed conformation, in which the pentadienyl units are rotated relative to each other by a conformation angle χ of *ca.* 60°.[6] While the structure of $(DMCh)_2Fe$ has not been reported, the related 6-*tert*-butylcyclohexadienylferrocene analogue exhibits such a conformation.[10] In contrast, the silicon bridge of $[Me_2Si(DMCh)_2]Fe$ constrains the DMCh rings to be *syn*-eclipsed ($\chi \approx 0$), thus representing a potential additional source of strain in this molecule.

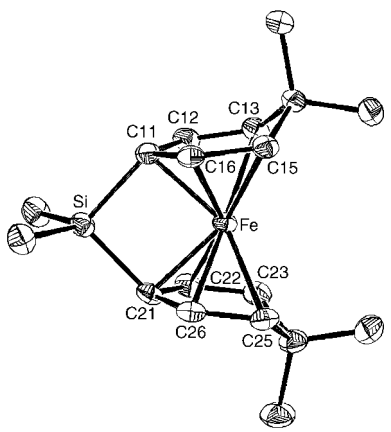


Fig. 1 Molecular structure of $[Me_2Si(DMCh)_2]Fe$ **1**. Selected bond lengths (Å): Fe–C11 2.038(2), Fe–C12 2.052(2), Fe–C13 2.166(2), Fe–C15 2.131(2), Fe–C16 2.038(2), Fe–C21 2.037(2), Fe–C22 2.042(2), Fe–C23 2.149(2), Fe–C25 2.152(2), Fe–C26 2.045(2), Si–C11 1.902(2), Si–C21 1.897(2).

† Electronic supplementary information (ESI) available: experimental details and NMR spectroscopic data. See http://www.rsc.org/suppdata/cc/b1/b107874g/

 DOI: 10.1039/b107874g

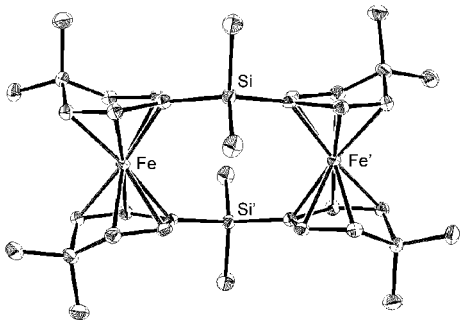

Fig. 2 Molecular structure of $\{[Me_2Si(DMCh)_2]Fe\}_2$ **2**. Labelling scheme for pentadienyl carbons is analogous to that in Fig. 1. Primed atoms are generated by symmetry. Selected bond lengths (Å): Fe–C11 2.094(2), Fe–C12 2.051(2), Fe–C13 2.117(2), Fe–C15 2.133(2), Fe–C16 2.056(2), Fe–C21 2.108(2), Fe–C22 2.056(2), Fe–C23 2.115(2), Fe–C25 2.125(2), Fe–C26 2.057(2), Si–C11 1.876(2), Si–C21′ 1.876(2).

In addition to the monomer **1**, air stable dimeric and tetrameric species are also obtained in low but reproducible yields. The oligomers are much less soluble in hydrocarbon solvents, and can be separated by fractional crystallisation from CH_2Cl_2. The structure of the dimer $\{[Me_2Si(DMCh)_2]Fe\}_2$ **2** (Fig. 2),‡ reveals a molecule on an inversion centre, in which the two halves of the dimer are crystallographically equivalent. The formation of **2** allows significant relief of the strain observed in the *ansa*-bridged species **1**, as demonstrated by an angle α of 5.4°, and an average value of β of 6.5°. The silicon bridged cyclopentadienyl [1²]ferrocenophane, $\{[Me_2Si(C_5H_4)_2]Fe\}_2$, which was reported simultaneously by three groups,[11–13] has a similar ring tilt [α = 4.9(3)°].[12] In both cases, the ring tilt is opposite to that of the monomeric species; the greatest inter-ring separation is observed at the silicon-bridged end of the ring. Furthermore, $\{[Me_2Si(DMCh)_2]Fe\}_2$ is able to adopt the preferred *gauche* eclipsed conformation with an angle χ of 50.7°. Such a conformation is presumably also favoured to reduce steric interactions between the Me_2Si groups; indeed a similar conformation is observed in the structure of $\{[Me_2Si(C_5H_4)_2]Fe\}_2$. The Fe···Fe separation in $\{[Me_2Si(DMCh)_2]Fe\}_2$ is 5.496(1) Å, which is greater than in the cyclopentadienyl analogue (*ca.* 5.17 Å).[11,12]

The third product that can be isolated is the silicon-bridged cyclic tetramer $\{[Me_2Si(DMCh)_2]Fe\}_4$ **3** which is unprecedented in cyclopentadienyl chemistry. The CH_2-bridged parent [1⁴]ferrocenophane has been reported,[14,15] and we have reported the synthesis of a partially methylated analogue,[16] but, to our knowledge, there are no examples of structurally characterized [1⁴]metallocenophanes.§ The structure of $\{[Me_2Si(DMCh)_2]Fe\}_4$ is shown in Fig. 3.‡ It crystallises in the tetragonal space group *P*4/*n* and lies on a crystallographic 4-fold axis. Thus, as with the dimer, the asymmetric unit of $\{[Me_2Si(DMCh)_2]Fe\}_4$ is a single $(DMCh)_2Fe$ unit. The four iron atoms are by necessity coplanar, and the overall shape of the molecule resembles a square. The angle between the planes (α) for each unit is 8.75°, perhaps indicating slightly more strain than in the dimer, while the average β is 5.1°. The Fe···Fe distance between neighbouring iron centres is 6.320(1) Å, a greater separation than in the dimer, while the The Fe···Fe separation across the ring is 8.938(1) Å. Interestingly, while the ^{1}H NMR spectrum of the [1⁴]ferrocenophane $\{[CH_2(C_5H_4)_2]Fe\}_4$ shows only one peak due to the Cp protons,[14,15] the pentadienyl protons of $\{[Me_2Si(DMCh)_2]Fe\}_4$ **3** are observed as eight separate resonances, varying considerably in chemical shift from δ 1.24 to δ 5.35 (C_6D_6). Presumably the upfield-shifted resonances correspond to the protons which are located toward the interior of the cavity, in analogy to the NMR spectra of cyclophanes. The fact that all of the ring protons in $\{[Me_2Si(DMCh)_2]Fe\}_4$ are chemically inequivalent at room temperature suggests the molecule is conformationally rigid, which could perhaps explain why replacement of Cp with DMCh groups has facilitated crystallisation of a [1⁴]metallocenophane analogue.

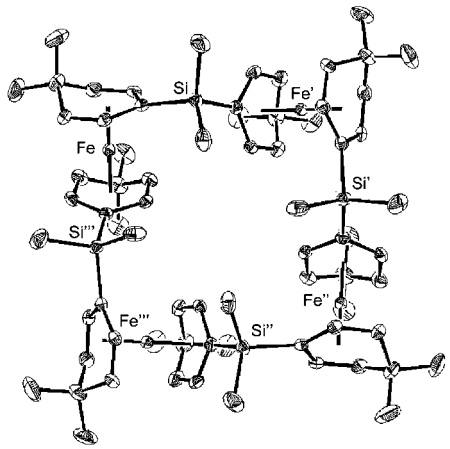

Fig. 3 Molecular structure of $\{[Me_2Si(DMCh)_2]Fe\}_4$ **3**. Labelling scheme for pentadienyl carbons is analogous to that in Fig. 1. Primed atoms are generated by symmetry. Selected bond lengths (Å): Fe–C11 2.090(2), Fe–C12 2.057(2), Fe–C13 2.132(2), Fe–C15 2.131(2), Fe–C16 2.051(2), Fe–C21 2.092(2), Fe–C22 2.057(2), Fe–C23 2.139(2), Fe–C25 2.121(2), Fe–C26 2.056(2), Si–C11 1.870(2), Si–C21′ 1.873(2).

Seven membered rings *via* intramolecular Pauson–Khand reactions†

Leticia Pérez-Serrano, Luis Casarrubios, Gema Domínguez and Javier Pérez-Castells*

Departamento de Química Orgánica y Farmacéutica, Facultad de Ciencias Experimentales y de la Salud, Universidad San Pablo-CEU, Urb. Montepríncipe, Boadilla del Monte 28668-. Madrid, Spain. E-mail: jpercas@ceu.es; Fax: 34913510475; Tel: 34913724788

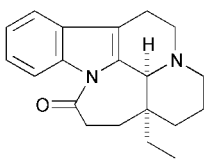
Received (in Cambridge, UK) 10th September 2001, Accepted 29th October 2001
First published as an Advance Article on the web 14th November 2001

Seven membered rings are obtained with good yields by intramolecular Pauson–Khand reactions of some aromatic compounds.

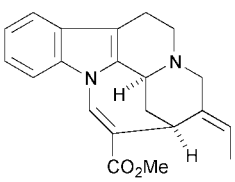
The intramolecular Pauson–Khand reaction is becoming an important tool for the synthesis of natural products.[1] Shortcomings such as low conversions, limited scope and lack of efficient catalytic versions are currently being circumvented by the use of new promotion methods and catalytic conditions. Efforts in this field are directed to achieve efficient catalytic versions of this reaction,[2] and to widen the reaction scope.[3] In the intermolecular version of this reaction, only five and six membered rings annulated to the cyclopentenone ring can be obtained with good conversions. Only very recent examples show the formation, although in very low yields, of some medium sized rings.[4,5] In our ongoing program devoted to extend the use of the intramolecular Pauson–Khand reaction to aromatic substrates, we have introduced benzenes[6] and indoles[7]as part of the enyne skeleton. With these substrates we have obtained polycyclic aromatic systems where the Pauson–Khand reaction formed a five or six membered ring annulated to the cyclopentenone ring. However, many aromatic natural products bear seven membered rings in their structures, examples being the indole alkaloids shown in Fig. 1.

The difficulty in achieving medium sized rings *via* Pauson–Khand reactions seems to be related to the low population of the reactive conformation. The planarity of the aromatic rings may have a decisive influence on the reactivity of enynes connected through them. Furthermore, the new way of promotion of the Pauson–Khand reaction introduced by us, based on the addition of molecular sieves to the reaction medium, is probably based on the adsorption of the substrate favouring the preorganisation of the alkene and alkyne moieties for cyclization.[8] We believed then that it was worth trying to form seven membered rings in these systems and in this paper we show the first results of these attempts.

A group of enynoindoles were obtained starting from methyl 2-indolocarboxylate. The synthesis of these substrates was carried out following our previous work with similar compounds.[7] These compounds were submitted to Pauson–Khand reactions under three different conditions: cooperative trimethylamine *N*-oxide (TMANO)–molecular sieves promotion at room temperature (A), molecular sieves in refluxing toluene (B), and thermal promotion in refluxing toluene (C). The results are summarised in Table 1.



Homoeburnamonine



Apogeissoschizine

† Electronic supplementary data (ESI) available: spectroscopic and analytical characterization of compounds **5–8** and **10**. See http://www.rsc.org/suppdata/cc/b1/b108134a/

The results show the first case described of the formation of a seven membered ring *via* intramolecular Pauson–Khand reaction with good yield. That is the conversion of **2** into **6**.[9] Compound **2** appears to have several structural features that favour the cyclization process. Not only the planarity of the indole nucleus, but also the nitrogen and the buttressing effect of the OTBS group, are probably responsible for this result.[10] Compounds **1** and **3**, with groups different from the OTBS present in **2**, do react although with moderate conversions, whereas compound **4** reacts slightly better. Comparing the three reaction conditions used, the positive effect of the molecular sieves is clear and conditions B (cooperative thermal–molecular sieves promotion) are best.

In all the examples in Table 1 only one stereoisomer was obtained. The stereochemistries of compounds **5–7** were determined by NOE experiments.[11]

In view of this results we prepared a series of aromatic enynes structurally related to compound **2**. The compounds, depicted in Fig. 2, were reacted under conditions A and B. Only compound **9**, the one most closely related to compound **2** , reacted with a good yield (80%) to give **10**, as an only diastereoisomer.

Compounds **11–13** decomposed after few hours of reaction. The cobalt–hexacarbonyl complex was not detected in the reaction of compound **14**, probably due to the basic nitrogen in the imidazole. Compound **15** gave small amounts (*ca.* 10%) of

Table 1 Pauson–Khand reaction of enynoindoles. Formation of seven membered rings

Substrate[b]	Product	Yields (%)[a] A	B	C

a mixture of isomers that may correspond to the expected seven membered ring diastereomeric compounds, or to related bridged compounds similar to those recently described by Lovely.[12] Finally in compound **16** a competitive Nicholas-type reaction took place allowing the recovery of the corresponding phenol.

In summary, herein we describe the first examples of the obtention of seven membered rings *via* intramolecular Pauson–Khand reactions with good yields and total diastereoselectivity. We are actually trying to understand the structural requirements of the substrates that favour this cyclization. A number of aromatic substrates have been tested and reactions observed in a few of them. We are currently trying to increase the scope of this synthesis so that interesting applications to the synthesis of natural products can be devised.

Expansion of structural and functional diversities of DNA using new 5-substituted deoxyuridine derivatives by PCR with superthermophilic KOD Dash DNA polymerase†

Hiroaki Sawai,* Akiko N. Ozaki, Fumie Satoh, Tutomu Ohbayashi, Mohammad M. Masud and Hiroaki Ozaki

Department of Applied Chemistry, Gunma University, Kiryu, Gunma 376-8515, Japan. E-mail: sawai@chem.gunma-u.ac.jp

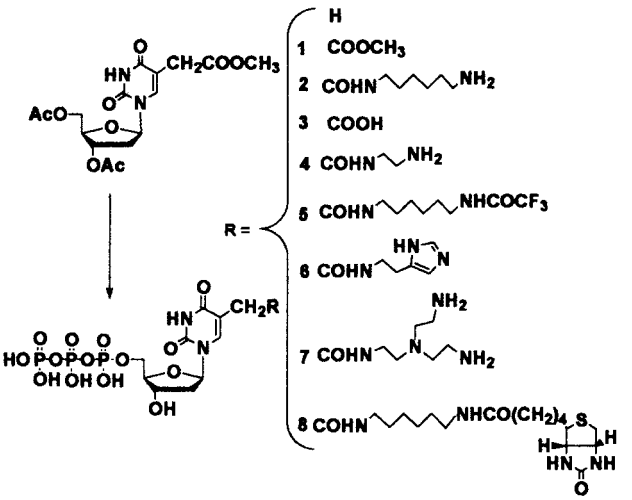
Received (in Cambridge, UK) 30th August 2001, Accepted 26th October 2001
First published as an Advance Article on the web 14th November 2001

KOD Dash DNA polymerase can accept triphosphates of new deoxyuridine derivatives bearing a C5-substituent group *via* an α-methylene linker as a substrate in the polymerase chain reaction (PCR) yielding the corresponding functionalized DNA effectively, while other conventional DNA polymerases cannot tolerate the modification of the substrate.

Modified oligonucleotides with a thymidine analogue bearing a functional group at the C5 position are important tools for biological and biochemical studies.[1–5] If modified DNA can be prepared by PCR from the substrate analogue using DNA polymerase, the resulting modified DNA could be used as a DNA probe by attachment of a reporter group, and as a DNA catalyst or as a DNA aptamer by *in vitro* selection. However, examples of functionalized DNA prepared from modified deoxynucleotides are limited, because DNA polymerases accept a limited range of molecular structures as substrate. Some DNA polymerases can use 5′-triphosphates of modified 2′-deoxyuridines with a C5-side chain carrying a propenyl or propynyl group.[6-13] Reduction of the double or triple bond of the C5 propenyl or alkynyl substituted 2′-deoxyuridines completely inhibits their function as a substrate.[12] These results indicate that an sp or sp^2 hybridized carbon at the α-position of the C5-substituted 2′-deoxyuridine is required as a substrate for DNA polymerases.[6–13] The differences in reactivity of C5-substituted 2′-deoxyuridine triphosphates as substrates may be due to the steric effect of a large side-group, or to the ionic effect of a substituting group. The substrate activity may also depend on the kind of DNA polymerase.

Previously, we reported the synthesis of thymidine analogues bearing an sp^3-hybridized carbon at the C5 α-position with an amino-linker arm, and their introduction into oligodeoxyribonucleotides using a DNA synthesizer.[14,15] Very recently, we found that triphosphates of the thymidine analogues could be accepted by KOD Dash DNA polymerase as a substrate in the primer-extension reaction. The enzyme is a hyperthermophilic DNA polymerase, originally isolated from the extremely thermophilic archaeum, *Pyrococcus kodakaraensis*.[16] Here we present studies of modified DNA synthesis by PCR from the thymidine analogues and their substrate efficiency during PCR using KOD Dash and some other thermostable DNA polymerases. The C5-substituted 2′-deoxyuridine derivatives bearing several functional groups were prepared easily from 5-methoxycarbonylmethyl-2′-deoxyuridine.[14] Hexamethylenediamine, ethylenediamine, tris(2-aminoethyl)amine or histamine was introduced at the C5 position by an ester–amide exchange reaction with 5-methoxycarbonylmethyl-2′-deoxyuridine, and the terminal amino group was blocked by a trifluoroacetyl group.[15] The 5′-triphosphates of the analogues were synthesized by a one-pot method described by Ludwig.[17] The terminal amino-protecting group, CF_3CO, was removed by treatment with concentrated aqueous ammonia quantitatively at low temperature. The resulting terminal amino group was further modified by reaction with a functional molecule such as a biotin-succinimide ester. The nucleotides were confirmed by ESI-Mass spectrum, ^1H and ^{31}P NMR spectra. The amino group is largely in the protonated state at neutral pH, and could contribute to interaction of the anionic-charged backbone of nucleic acids and may function as a general acid catalyst in the DNA catalyst. Hydrolysis of the 5′-triphosphate of 5-methoxycarbonylmethyl-2′-deoxyuridine with sodium hydroxide gave the 5′-triphosphate of 5-carboxylmethyl-2′-deoxyuridine. The carboxylic acid has a negative charge under neutral conditions and could enhance the interaction with a cationic-charged molecule.

We examined the incorporation of the modified thymidine triphosphates in place of TTP during the PCR using four thermostable DNA polymerases, KOD Dash, Taq, Tth, and Vent DNA polymerases. pUC18 plasmid DNA, and DNA **A**, 5′-GGAAACAGCTATGACCATGATTAC-3′ and DNA **B**, 5′-CGACGTTGTAAAACGACGGCCAGT-3′ were used as a template and primers, respectively, for the PCR assay. The PCR with the natural substrate demonstrated formation of the 108 base pair DNA product when using any DNA polymerase, as expected (Fig. 1). The formation of full-length plasmid DNA (2686 bp) was also observed under high enzyme concentration or prolonged reaction time, under which the polymerization could go over the primer yielding the full-length one. Vent DNA polymerase yielded only a small amount of the DNA product because it hydrolyzed the DNA with its strong exonuclease activity. The modified substrates, **1** and **2**, worked as a substrate in the PCR forming the 108mer DNA when using KOD DNA polymerase, although a large quantity of the enzyme was



† Electronic supplementary information (ESI) available: sequencing of the PCR products (108mer DNA) from substrates **1** and **2**. See http://www.rsc.org/suppdata/cc/b1/b107838k/

 DOI: 10.1039/b107838k

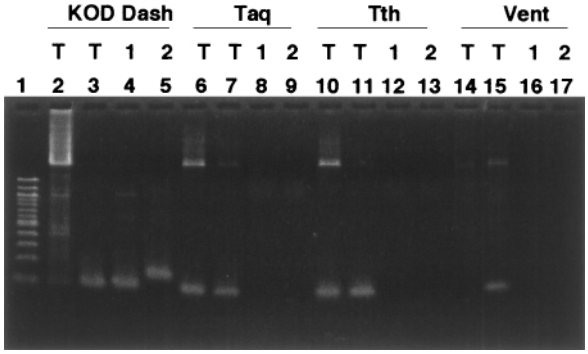


Fig. 1 PCR assays of TTP and its analogs with several DNA polymerases. The mixture (20 μl) for PCR contained 0.5 ng DNA template (pUC18 2686bp), 0.2 μM of each primer, natural dNTPs or modified dNTP mix (0.2 mM of each nucleotide) and 0.5 or 0.05 unit of DNA polymerase in the buffer supplied by the maker for the DNA polymerase reaction. PCR assays were carried out at 94 °C for 1 min, 30 cycles of 94 °C for 30 s–52 °C for 30 sec–74 °C for 1 min, and 74 °C for 5 min for KOD Dash and Vent DNA polymerases; 94 °C for 1 min, 30 cycles of 94 °C for 30 s–52 °C for 30 s–74 °C for 2 min, and 74 °C for 5 min for Taq and Tth DNA polymerases. The reaction mixture was quenched by addition of formamide-dye solution and PCR products were analyzed by 2% agarose gel electrophoresis and visualized by staining with ethidium bromide. 0.5 unit of DNA polymerase was used for the PCR assays except for lanes3, 7, 11 and 15 where 0.05 unit of DNA polymerase was used. Lane 1: Marker DNA (100–1200 bp); lane 2–5: KOD dash DNA polymerase; lane 6–9: Taq DNA polymerase: lane 10–13, Tth DNA polymerase; lane14–17, Vent DNA polymerase. Lanes 2, 3, 6, 7, 10, 11, 14 and 15: TTP + dATP + dCTP + dGTP; lanes 4, 8, 12 and 16: **1** + dATP + dCTP + dGTP; lanes 5, 9, 13 and 17: **2** + dATP + dCTP + dGTP.

required for synthesis of the modified DNA compared with the unmodified one. However, the other widely-used DNA polymerases could not accept these modified substrates and no 108mer modified DNA was obtained. Successful PCR with this template and primers requires the incorporation of 49 modified substrates with a single stretch of four successive thymidine residues. PCR products were obtained on a large scale from the modified substrates, **1** and **2**, and sequenced using a Thermo sequenase radiolabelled terminator-sequencing kit in the usual manner. We confirmed that the sequence of the modified DNAs was the same as that of the template DNA and no mutation took place during the PCR.

Further studies with the modified substrates, **3**–**8**, were carried out using the KOD Dash DNA polymerase to assess the structural feature that can be accepted as a substrate in the PCR. Fig. 2 shows the results of PCR with the modified substrate along with the control reactions with the natural substrate in the presence or absence of the template. The PCR product DNA 108mer was obtained from the modified substrate with a neutral methoxy group (**1**), a terminal protected amine (**5**), or a cationic terminal amine (**2** and **4**). The compound **2** bears a long linker while the compound **4** has a short linker. DNA 108mer with a negative-charged carboxylate at the C5 position of the thymidine residue was also formed from the substrate **3**, although less efficiently under the same condition. However, KOD Dash DNA polymerase could not allow the incorporation of the modified substrate with histamine (**6**) or multi-charged tris(aminoethyl)amine (**7**), probably because of a bulky group with a short linker. The thymidine derivative with biotin at the C5 position *via* a long linker (**8**) was accepted by the enzyme forming the corresponding 108mer DNA. The modified DNA products showed mobility shift on electrophoresis depending on the mass increase and the charge associated with the modified bases.

In conclusion, we found that several new thymidine analogues bearing an sp^3 hybridized carbon at the α-position of the C5-sidearm were good substrates for KOD Dash DNA polymerase yielding the corresponding PCR products. The

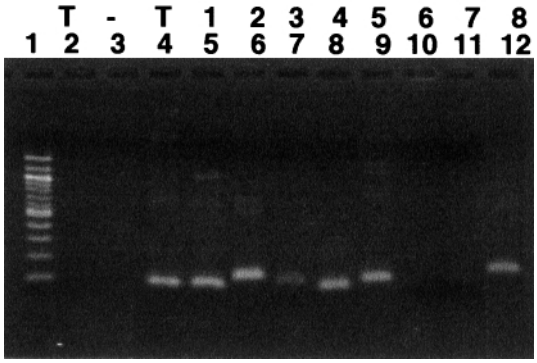

Fig. 2 PCR assays of several TTP analogs using KOD Dash DNA polymerase. PCR assays were carried out in the same way as those in Fig. 1 at 94 °C for 1 min, 30 cycles of 94 °C for 30 s–52 °C for 30 s–74 °C for 1 min, and 74 °C for 5 min for the modified TTP; 94 °C for 1 min, 30 cycles of 94 °C for 30 s–52 °C for 5 s–74 °C for 5 s, and 74 °C for 5 min for the natural TTP. Lane 1: Marker DNA (100–1200 bp); lane 2: negative control without template: TTP + dNTP; lane 3: negative control without TTP: dNTP; lane 4: positive control: TTP + dNTP ; lane 5: **1** + dNTP lane 6: **2** + dNTP: lane 7: **3**+dNTP; lane 8: **4** + dNTP ; lane 9: **5** + NTP; lane 10: **6** + dNTP; lane 11: **7** + dNTP; lane 12: **8** + dNTP (dNTP: dATP + dCTP + dGTP).

thymidine analogues bear various functional groups with a positively charged terminal amino group, negatively charged carboxy group, or neutral ester and amide groups. In contrast to KOD Dash DNA polymerases, conventional DNA polymerases used in this study gave no PCR product from the thymidine analogues. The finding that KOD Dash DNA polymerase tolerates the modification of the substrates could expand the variety of nucleotide analogues that may be used for the synthesis of modified DNA libraries, which will be useful for *in vitro* selection of the functionalized DNA.

First published as an Advance Article on the web 15th November 2001

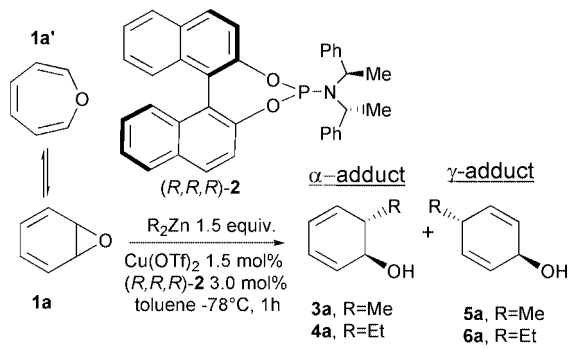
The first catalytic enantioselective trapping of symmetrical and racemic arene oxides with organometallic reagents is reported.

Arene oxide has been subjected to several studies since the demonstration that this class of compounds is formed from aromatic hydrocarbons by the microsomial enzyme fraction from mammalian liver.[1] Much interest, therefore, has been generated concerning the solution chemistry of arene oxide. The nucleophiles utilized in these studies were in most cases heteronucleophiles such as water, alcohols, thiols and amines.[2] There are only few reports dealing with ring-opening reactions of arene oxide carried out with organometallic reagents.[2a,3] Moreover, none of these procedures employing organometallic reagents are catalytic or enantioselective.

We have recently reported a new kinetic resolution of cyclic vinyl oxiranes,[4] a desymmetrization of symmetrical methylidene cycloalkene oxides[5] and a new catalytic regiodivergent kinetic resolution (RKR)[6] based on dialkylzinc reagents and chiral copper complexes of phosporamidite ligands.[7] In the RKR, a single chiral catalyst induces the formation of a distinct regioisomer from each substrate enantiomer with a high ee. The procedure was useful to gain insight into the reaction mechanism of this particular kind of copper-catalyzed allylic alkylation, pointing to reductive elimination as the regio- and stereodetermining step of the addition reaction.

We herein report an unprecedented catalytic and enantioselective desymmetrization of symmetrical arene oxides **1a,b** with hard alkylmetal, and a new, highly enantioselective RKR starting from the racemic arene oxide **8** (Schemes 1, 2 and 3).

Benzene oxide (**1a**) and indan-8,9-oxide (**1b**) were examined as symmetrical arene-oxide substrates (Schemes 1 and 2). Benzene oxide is known to exist in equilibrium with its tautomeric valence structure, the oxepin **1a′**. This compound exists mainly as oxepin at room temperature, even if the oxide component 1a determines the reactions of the system with most agents.[3]



Scheme 1

† Electronic supplementary information (ESI) available: experimental details. See http://www.rsc.org/suppdata/cc/b1/b108541g/

Table 1 Enantioselective trapping-ring-opening of benzene oxide **1a** with R_2Zn[a]

Entry	Substrate	R	Ratio α:γ	Yield (%)[b]	ee (%)[c]
1	**1a**	Me	69:31	85	93
2	**1a**	Et	38:62	88	64

[a] *Conditions*: all reactions were run in accordance with the typical procedure (see ref. 8).[b] Yields are determined on the basis of weight, ^{1}H NMR and GC analysis of the crude reaction mixture.[c] Determined by GC on CSP.

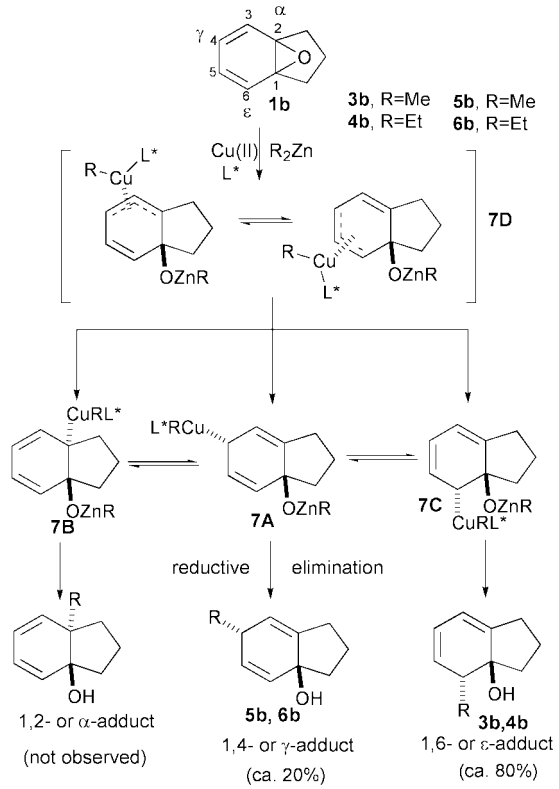
Epoxide **1a** was allowed to react at −78 °C (1 h, 95% conversion) with Me_2Zn (1.5 equiv.) in the presence of a catalytic amount of $Cu(OTf)_2$ (0.015 equiv.) and the chiral ligand (*R,R,R*)-**2** (0.030 equiv.) to give a crude reaction mixture consisting of the not previously synthesized regioisomeric dienols (1*S*,6*S*)-**3a** (α-adduct) and **5a** (γ-adduct) (entry 1, Table 1).[8] The reaction with Et_2Zn gave a slightly different result, with a predominance of the achiral γ-adduct **6a** (entry 2, Table 1).[9] The substituted enantioenriched dihydroaromatic α-adducts (1*S*,6*S*)-**3a** (93% ee) and (1*S*,6*S*)-**4a** (64% ee) were obtained with a complete *anti* stereoselectivity.[10]

Indan 8,9-oxide (**1b**), containing a tetrasubstituted epoxide is known to exist only in the oxide form. The copper-phosphoramidite catalyzed addition of R_2Zn at −78 °C to **1b** (3 h, 95% conversion) gave a *ca*. 80:20 mixture of the corresponding α- and γ-adducts **3b**:**5b** (R = Me) and **4b**:**6b** (R = Et) (Scheme 2).[11]

It is remarkable that the α-adducts **3b** (≥95% ee) and **4b** exclusively derive from an *anti*-stereoselective 1,6-addition pathway (and therefore more appropriately called ε-adducts, Scheme 2). This unexpected regiochemical behavior could be of interest to gain further insight into the interconversion between the regioisomeric (σ-allyl)copper(III) complexes of type **7A–C** that are formed during the oxidative step.[12] Considering the conjugate nature of the starting epoxide, this interconversion between the regioisomeric (σ-allyl)copper(III) complexes of type **7A–C** probably occurs by means of an intermediate delocalized (π-allyl)copper(III) species of type **7D**.[13] In this biased framework the attack at the tertiary carbon terminus atom of **7D** to give **7B** is not favourable for steric reasons, while the attack at the secondary terminus of **7D** to give the (σ-allyl)copper(III) complex **7C** could be highly favoured. The subsequent rate limiting reductive elimination step on **7C** affords the ε-adducts **3b,4b** (1,6-addition products), as observed.

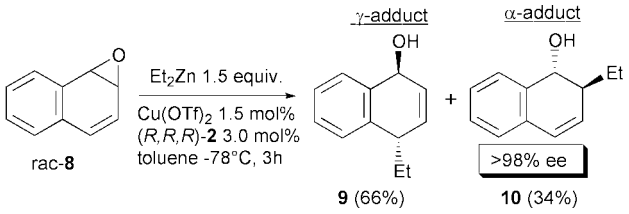
Naphthalene 1,2-oxide (**8**) seems to exist only in the oxide form and it is very prone to spontaneous epoxide ring-opening and aromatization. Despite its extreme chemical reactivity, the addition of Et_2Zn (1.5 equiv.) to racemic **8** in the presence of $Cu(OTf)_2$ (0.015 equiv.) and chiral ligand (*R,R,R*)-**2** (0.030

 DOI: 10.1039/b108541g



Scheme 2

equiv.) proceeded very cleanly to afford a 66:34 mixture of regioisomeric dihydronaphthols **9** (γ-adduct) and **10** (α-adduct), the latter with a remarkable enantioselectivity (>98% ee) (Scheme 3).[11,14] On the other hand, the addition of Et_2Zn to racemic **8** catalyzed by a copper complex with the racemic ligand (*S,S,S*)(*R,R,R*)-**2** afforded with almost complete (>96%) regioselectivity the racemic γ-adduct **9**. A complete examination of these results clearly indicates that also arene oxide *rac*-**8** exhibits a complementary enantiomer-dependent regioselectivity typical of a RKR process, in which the α-adduct **10** is obtained from the less reactive enantiomer (1*S*,2*R*)-**8** of the racemic substrate, while the γ-adduct derives from the more reactive (1*R*,2*S*)-**8**.[6,14]



Scheme 3

In summary, the present work describes an unprecedented catalytic and enantioselective trapping of symmetrical and racemic arene oxides. This method offers a new route to enantioenriched dihydroaromatic alcohols, not easily accessible by means of other synthetic methods. An examination of the regiochemical outcome indicated that a 1,6-addition mode may be operative in a biased system such as indan 8,9-oxide for this particular kind of allylic alkylation.

We gratefully acknowledge funding by the MURST (Rome), the University of Pisa, and Merck (2000 ADP Chemistry Award to P. C.).

7 For an overview of phosphoramidite in catalytic asymmetric conjugate addition, see: B. L. Feringa, *Acc. Chem. Res.*, 2000, **33**, 346.

8 *Typical procedure*: a solution of $Cu(OTf)_2$ (5.8 mg, 0.015 mmol) and **2** (16.2 mg, 0.03 mmol) in anhydrous toluene (2 ml) was stirred at room temperature for 40 min. The colorless solution was cooled to −78 °C and subsequently additioned with a solution of arene oxide (1.0 mmol) in toluene (0.5 ml) and 1.5 mmol of R_2Zn (solution in toluene). The reaction was followed by GC analysis and quenched with saturated aqueous NH_4Cl (see the Supporting Information for further details).

9 The conjugate γ-adducts **5a** and **6a** were obtained only in a mixture with regioisomeric α-adducts **3a** and **4a**. In our hands, it was not possible to isolate in a pure state the achiral γ-adducts **5a** and **6a**, or some simple derivatives of theirs, probably due to a rapid aromatization process.

10 The *anti*-stereochemistry of **3a** was demonstrated by comparison with the product obtained by the addition of MeLi to benzene oxide **1a**, a reaction that is known to proceed with *syn*-stereoselectivity[2a].

11 It is worthy of mention that all the corresponding "blank reactions", performed on epoxides **1a,b** and **8** in the same reaction conditions but in the absence of the chiral ligand (*R,R,R*)-**2**, afforded the corresponding rearranged phenols as the main product (phenol from **1a**, 4-indanol from **1b**, and 1-naphthol from **8**).

12 For very recent experimental evidence supporting the intervention of Cu(III) intermediates, see: A. S. E. Karlström and J.-E. Bäckwall, *Chem. Eur. J.,* 2001, **7**, 1981 and references therein. Even if not indicated in Scheme 2 for the sake of simplicity, the copper(III) complexes **7A–D** are probably cationic species with OTf^- as a possible counterion.

13 The interconversion between the regioisomeric (σ-allyl)copper(III) complexes of type **7A–C** could be reasonably explained also by the intervention of suprafacial 1,3-shifts.

14 All the attempted analyses of the enantiopurity of alcohol **9** both by HPLC- and GC-CSPs gave extensive decomposition of the compound. The absolute configuration of compound (1*R*,2*S*)-**10** was demonstrated by a single crystal X-ray analysis after derivatization of the enantiomer (1*S*,2*R*)-**10** with a chiral auxiliary derived from 4,5-dichlorophthalic acid and (1*S*,2*R*,4*R*)-(−)-2,10-camphorsultam. Details of the procedure will be reported separately in a forthcoming paper.

First published as an Advance Article on the web 26th November 2001

A silicalite membrane has been used to separate a homogeneous catalyst from its mixture with solvent and product of the Heck reaction.

Square-planar complexes of Pd(II) play a central role in many catalyzed C–C bond coupling reactions.[1] Research on the Heck arylation of olefins catalyzed by Pd(II) complexes has developed intensely in recent years[2] mainly due to the use of C,P-[3] and C,N-orthometallated Pd(II) derivatives,[4] which provide very high turnover rates. The main problem remains the recovery of the catalyst, which is required for economic reasons (high cost of noble-metal catalysts), and for obvious process and environmental considerations. One of the ideas put forward to facilitate the separation of solvent and reaction products from the catalysts is catalyst heterogenization, which involves some form of attachment of the catalyst to a solid support. However, although some interesting results have been reported,[2,5] heterogenization is difficult to achieve, and it is often detrimental to catalytic performance.

As an alternative, the use of membranes capable of retaining the homogeneous catalyst has been proposed. Giffels *et al.*[6] used solvent-resistant polymeric membranes to retain homogeneous catalysts (oxazaborolidines). However, in order to have the catalyst rejected by the membrane, molecule enlargement by derivatisation was necessary. De Smet *et al.*,[7] used the same membranes under optimum conditions and were able to retain Ru–BINAP and Rh–EtDUPHOS catalysts without the need for derivatisation. However, optimum membrane use was strongly limited in terms of temperature (below 40 °C), which restricts the range of possible applications, considering not only reaction temperature, but also membrane regeneration treatments. Clearly, it would be highly desirable to retain homogeneous catalysts with a membrane that is both solvent and temperature resistant.

In this work, we have used zeolite membranes to separate homogeneous catalysts from liquid solutions. Zeolites are hydrated aluminosilicates with a framework structure. A variety of zeolites have been synthesized as membranes, with pore sizes in the 0.3 to 0.8 nm range.[8] Silicalite was chosen as the zeolite material for this work, in view of its pores of 0.55 nm, well below the size of usual homogeneous catalysts, but still able to permeate many of the usual solvents and products.

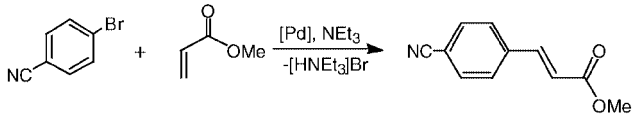
The membranes were grown on the inner side of 11 mm internal diameter porous stainless steel tubular supports. The synthesis procedure was as described in a previous work[9] except for the fact that Ludox AS400 was used as the Si source and the molar proportions in the synthesis gel were 280 H_2O:10 SiO_2:0.22 NaOH:0.5 TPABr, where TPABr represents the template (tetrapropylammonium bromide). After synthesis the template was removed by heating the membrane at 460 °C for 8 h using a 1 °C min^{-1} heating rate. The membranes were characterized by measuring N_2 and SF_6 permeances, as the N_2/SF_6 ideal selectivity (ratio of permeances) is customarily used as an indication of membrane quality. X-Ray diffraction (Rigaku/Max System) revealed that silicalite was the only crystalline material formed on the membrane. Scanning electron microscopy analysis (JEOL JSM 6400) and Si concentration profiling by electron-probe microanalysis (EPMA), indicated that the thickness of the zeolite layer was between 10 and 20 μm, depending on the preparation procedure and the number of synthesis. Table 1 gives the characteristics of the two membranes used in this work. Membrane 1 is a lower quality membrane, as ascertained from its much higher permeance (in spite of a higher zeolite loading), and from the notably lower value of the ideal N_2/SF_6 selectivity. Thus, a considerable number of inter-crystalline defects can be expected on membrane 1. On the other hand, the ideal N_2/SF_6 selectivity of membrane 2 was 26, which for MFI membranes on stainless steel supports, indicates a low concentration of inter-crystalline defects.

Table 1 Some characteristics of the membranes used in this work

Membrane	Zeolite weight gain after synthesis (mg/g of membrane)	N_2 permeance/ mol min^{-1} m^{-2} bar^{-1}	N_2/SF_6 ideal selectivity
1	19	1.37×10^{-6}	10.1
2	11	1.53×10^{-7}	26.2

To carry out separation experiments, the liquid mixture containing the catalyst was loaded at the inner side of the tubular support, *i.e.* in contact with the zeolite layer. The feed pressure was then increased to a value between 2 and 2.3 bar, while keeping the outer side at atmospheric pressure. The system temperature was maintained at −2 °C, to minimize evaporation of the permeated liquid during the experiment (which typically lasted 24–36 h). The initial liquid mixture, the liquid remaining on the feed side of the membrane after permeation (retentate) and the liquid collected at the permeate side were analyzed by V-UV spectrophotometry. The detection limit for the Pd complex with this procedure corresponded to a concentration of 10^{-7} M.

In this work, reaction experiments have not been carried out. Instead, the zeolite membrane was used to separate Pd complexes in mixtures representing possible post-Heck reaction scenarios (Pd complex plus solvent, plus a possible reaction product). From the huge variety of possible Pd catalysts and solvents,[2] we have chosen as an example the Heck reaction of 4-bromobenzonitrile with methyl acrylate [eqn. (1)]:



(1)

Typical conditions are reported in the literature (*e.g.* 0.02% mol catalyst/mol sustrate, dimethylacetamide (DMA) as a solvent, and >99% yield after 1 h at 135 °C).[3d] Our choice of $[Pd(\mu\text{-}Cl)(PPh_3)_2]_2(BF_4)_2$ as a catalyst was based on the well known ability of bis-phosphine derivatives of Pd^{II} to catalyse this

 DOI: 10.1039/b109030p

Table 2 Results of permeation experiments with membrane 2. Concentration of catalyst $\{[Pd(\mu\text{-}Cl)(PPh_3)_2]_2(BF_4)_2\}$ and product (4-cyanomethylcinnamate) in the feed to the membrane separator and on the retentate and permeate liquids after permeation. The solvent was dichloromethane in both experiments

	Feed		Retentate		Permeate	
Experiment	Catalyst conc./M	Product conc./M	Catalyst conc./M	Product conc./M	Catalyst conc./M	Product conc./M
1	3.2×10^{-5}	—	9.5×10^{-5}	—	$< 10^{-7}$	—
2	1.1×10^{-5}	5.9×10^{-3}	7.9×10^{-5}	7.9×10^{-3}	$< 10^{-7}$	3.6×10^{-3}

reaction and on the minimum molecular diameter (calculated using CONQUEST™ software across three different perpendicular planes from its X-ray data in the Cambridge Crystallographic Data Centre)[10] which was 1.22 nm, *i.e.* considerably larger than the zeolite pores. On the other hand, the molecular dimensions of the resulting product (4-cyanomethylcinnamate), calculated between the *meta* H atoms are approximately 0.42 nm, and therefore this molecule is able to transit the zeolite pore network. Similarly, the solvents used (DMA and dichloromethane) have kinetic diameters smaller than the zeolite pores.

The first mixture used (Pd complex, DMA, product) corresponds to usual post-reaction conditions: a solid $[HNEt_3]Br$ phase, and a liquid containing a typical solvent (DMA) and the catalyst (and almost nothing else, given the high yields achieved). The second mixture used (Pd complex, dichloromethane, product) contained dichloromethane instead of DMA. While dichlorometane could also be used as a solvent,[2] it is more frequently employed in the post-reaction workup: after vacuum evaporation of the solvent (*e.g.* DMA), water and dichloromethane are used as extractants to obtain, respectively, an aqueous phase with $[HNEt_3]Br$ and an organic phase containing the product and Pd complex in dichloromethane. This organic phase was the second feed mixture used in this work.

Separation experiments using the first mixture as feed were unsuccessful. Permeation rates were extremely low, and the concentration of Pd complex in the permeate was similar to that in the feed solution. This suggests that the DMA solvent was strongly adsorbed in the zeolite pores, blocking them for the permeation of catalyst and product; that permeation took place mainly through non-selective intercrystalline voids. By contrast, good separation was obtained in experiments where dichloromethane was used as a solvent. Binary solvent/catalyst mixtures were readily separated, even at catalyst concentrations much higher than those usually employed for reaction (experiment 1, Table 2). Although the concentration of $[Pd(\mu\text{-}Cl)(PPh_3)_2]_2(BF_4)_2$ increased three-fold as a consequence of solvent permeation through the membrane, complete catalyst retention was observed, within the limits of detection of the V-UV analyser. A separate experiment was performed using ternary mixtures, with concentrations of catalyst and product at typical end-of-reaction levels. The initial pale-yellow feed solution was separated into a strongly coloured retentate and a transparent permeate. The V-UV analysis (experiment 2, Table 2) confirmed the complete retention of the Pd complex, the concentration of which increased seven-fold in the retentate. The retention of Pd occurred simultaneously with the permeation of both solvent and product. Again, the product concentration in the retentate was higher than in the permeate due to the faster solvent permeation. In spite of the small pressure drop across the membrane (*ca.* 1 bar) high permeation fluxes were obtained (average values of 1.6 kg m^{-2} h^{-1}). Finally, as expected, the results of the separation experiment with the defective membrane 1 (not shown) were unsuccessful, demonstrating that this membrane was unable to retain the catalyst.

In conclusion, given suitable conditions, zeolite membranes can separate homogeneous catalysts from their mixtures with solvents and products. A membrane quality above a certain threshold is required, and also suitable membrane characteristics (pore size, absence of undesired adsorption). We believe that this concept can be applied to a variety of systems, both as a post-reaction separation step and also in a continuous reaction-separation scenario.

An approach to the synthesis of organically templated open-framework metal sulfates by the amine–sulfate route

The first organically templated cadmium sulfates, $[C_4N_2H_{12}][CdCl_2SO_4]\cdot H_2O$ and $[C_4N_2H_{12}]_4[Cd_3Cl_{10}(SO_4)_2(H_2O)]\cdot 3H_2O$, consisting of infinite linear chains and a quasi-2D layer formed by strip-like units respectively, have been synthesized and characterized.

Amongst the variety of open-framework inorganic materials, the metal phosphates constitute one of the largest families.[1] In these materials, the phosphate tetrahedra share corners with the metal–oxygen polyhedra to build networks. Besides the phosphates, open framework 3D metal arsenates,[2] phosphites[3] and germanates[4] have been reported in the literature. Recently, an organically templated zinc selenite with a layered structure has also been reported.[5] One would expect the sulfate tetrahedra to be able to play a role similar to the phosphate tetrahedra, but no open-framework sulfates are known hitherto. We were, therefore, interested in exploring whether open-framework metal sulfates can be synthesized by employing an appropriate strategy. Since the reactions carried out under standard hydrothermal conditions in the presence of amines were not effective, we attempted to synthesize sulfate-based networks by reacting organoammonium sulfates with metal ions. In adopting this approach, we were guided by the significant success achieved in the synthesis of open-framework metal phosphates[6,7] and oxalates[8] by the reaction of metal ions with organoammonium phosphates and oxalates, respectively. In this communication, we report the first success we have had in synthesising two cadmium sulfates, with chain and layer structures, by the reaction of piperazinium sulfate with cadmium chloride. The results suggest that it may indeed be possible to obtain sulfate-based open-framework structures by this route.

Piperazine sulfate, $[H_2N(CH_2)_4NH_2]SO_4\cdot H_2O$ (PIPS), prepared by the reaction of the amine with H_2SO_4,† was characterized by IR spectroscopy and single crystal X-ray diffraction. The structure of PIPS can be described as a 3-D supramolecular network formed by strong N–H···O, O–H···O and C–H···O hydrogen bonds between the diprotonated piperazine, SO_4^{2-} anion and water molecules. Compounds $[C_4N_2H_{12}][CdCl_2SO_4]\cdot H_2O$ **I** and $[C_4N_2H_{12}]_4[Cd_3Cl_{10}(SO_4)_2(H_2O)]\cdot 3H_2O$ **II**, synthesized by the reaction of PIPS with Cd^{2+} ions in butan-2-ol–water under hydrothermal conditions,† were characterized by single-crystal X-ray diffraction,‡ powder X-ray diffraction (PXRD), thermogravimetric analysis (TGA), IR spectroscopy and CHN analysis.

The asymmetric unit of **I** contains 15 non-hydrogen atoms with one crystallographically distinct Cd and S atom each in the asymmetric unit. The Cd atom is six-coordinated by four Cl and two O neighbors, the structure being built up of isolated infinite chains of $[CdCl_2SO_4]^{2-}{}_n$ running along the *b*-axis. In the $[CdCl_2SO_4]^{2-}$chain, $CdCl_4O_2$ octahedra share edges in *trans*-fashion *via* their Cl atoms, and the SO_4 tetrahedra are grafted on to the chain in a symmetrical bridge. The two Cd–μ-Cl–Cd linkages between the adjacent Cd atoms lead to infinite linear chains of *trans*-edge-sharing $CdCl_4O_2$ octahedra. The *trans* orientation of the bridging Cl atom creates a zigzag {–Cd–μ-Cl–Cd–μ-Cl–Cd–} backbone to the linear chain of $CdCl_2O_4$ octahedra. The pairwise canting of the Cd–O bonds gives rise to a helical arrangement responsible for the chirality of the structure. Two of the sulfate oxygens bond to two adjacent Cd sites of the edge-shared $CdCl_4O_2$ in the common symmetrical bridging mode as shown in Fig. 1(a), thus forming a synthetic analogue of the linarite chain.[11] The 1-D chains along the *b*-axis are arranged parallel to one another in the *bc*-plane to form a layer-like arrangement. Such layers are stacked one over the other along the *a*-axis, with the diprotonated amine molecules and the water molecules located in the inter-layer space. The amine and water molecules interact strongly with the inorganic framework through N–H···O and O–H···O hydrogen bonding to stabilize the 3-D structure shown in Fig. 1(b).

The asymmetric unit of **II** contains 33 non-hydrogen atoms with four amine fragments, each corresponding to half-units of piperazine and three water molecules as extra-framework moieties. Two of the four amine fragments and one water molecule are disordered. The structure can be visualized as two parallel chains made up of $CdCl_3O_3$, $CdCl_3O_2$ and SO_4 units, running along the [010] direction. These chains are connected by $CdCl_6$ octahedra, giving rise to an anionic quasi 2-D layer. The structure contains three crystallographically distinct cadmium atoms and one sulfur atom. Cd(1) exists as $CdCl_3O_3$, Cd(2) is penta-coordinated as $CdCl_3O_2$ and Cd(3) is hexa-coordinated as $CdCl_6$. Cd(1) forms two Cd–O–S, and two Cd–Cl bonds besides one Cd–Cl–Cd bond with the neighboring S(1) and Cd(3) atoms. Hexa-coordination is satisfied by bonding to a H_2O molecule. Cd(2) forms a similar connectivity with the

 DOI: 10.1039/b107820h

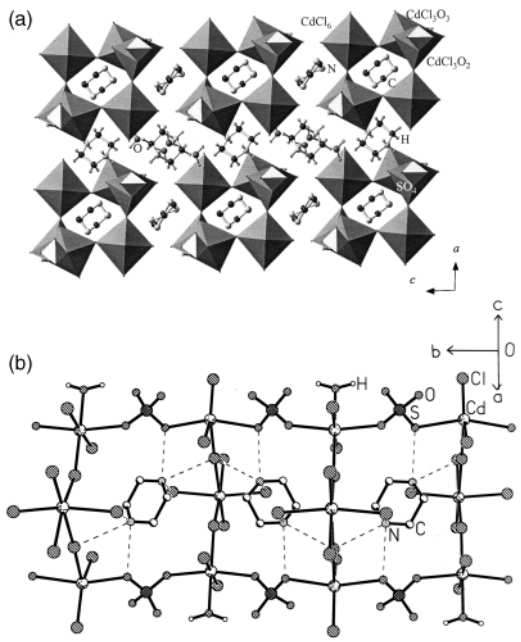

Fig. 2 (a) The quasi 2-D layer of $[C_4N_2H_{12}]_4[Cd_3Cl_{10}(SO_4)_2(H_2O)]\cdot 3H_2O$, **II** with the amine molecules sitting in the middle of the eight-membered aperture. (b) The arrangement of strips in **II** viewed along the *b*-axis.

neighbouring Cd(3) and S(1) but has a distorted trigonal bipyramidal coordination due to absence of a water molecule. Cd(3) on the other hand forms two Cd–Cl–Cd bonds with the two c*is* Cl atoms neighbouring Cd(1) and Cd(2) in addition to four Cd–Cl terminal bonds. The connectivity between $Cd(1)Cl_3O_2(H_2O)$ and $Cd(2)Cl_3O_2$ polyhedra is brought about by the SO_4 tetrahedron *via* corner sharing to form a chain along the *b*-axis. Two such chains are linked by $Cd(3)Cl_6$ octahedron *via* corner sharing between $Cd(1)Cl_3O_2(H_2O)$ and $Cd(2)Cl_3O_2$ polyhedra to form a strip-like quasi 2-D layer. Since the two Cl atoms of the bridging $Cd(3)Cl_6$ octahedra connecting the two chains are in *cis* orientation, the $Cd(3)Cl_6$ octahedra project themselves above and below the plane of the two chains alternately. Such a linkage creates eight-membered apertures within the *strip* in which heavily disordered piperazine moieties reside as shown in Fig. 2(a). These *strips* are held together by N–H···O and C–H···O hydrogen bonds in the *bc*-plane to form a layer-like arrangement. Protonated piperazine and water molecules present between the layers stabilise the 3-D structure [Fig. 2(b)].

To our knowledge the linarite-type chain **I** and the *strip*-like quasi-2D layer **II**, are the first members of the organically templated open-framework metal sulfate family. While there are a few piperazinium templated inorganic hosts, there is only one report of piperazine templated sulfate, comprising a dimer of VO_6 octahedra and SO_4 tetrahedra but this compound does not possess an extended structure.[11] Infinite chains of $[M(T\phi_4)\phi_2]$ stoichiometry in the linarite group minerals[12] are rather rare and generally occur in layered structures such as in iron phosphates[13] and gallium phosphates[14] and in the minerals tsumcorite and bermanite. Such a chain, not known in the metal phosphates, could act as the building block to form higher dimensional structures. It has been shown recently[15,16] that 1-D zinc phosphate ladders and 1-D tancoite type gallium phosphate chains undergo facile transformations to form 3-D open-framework structures. The strip structure of the compound formed in **II**, forming a quasi 2-D layer is unusual and has been found in a open-framework cobalt phosphate.[7]

Notes and references

† *Synthesis*: $[H_2N(CH_2)_4NH_2]SO_4\cdot H_2O$ (PIPS), was prepared by mixing a 1 M aqueous solution of piperazine with 1 M H_2SO_4. (CCDC reference number 170834).

In order to synthesize **I**, 0.1835 g of $CdCl_2\cdot H_2O$ was dissolved in a butan-2-ol-H_2O mixture (2.5 ml/0.49 ml) under constant stirring. To this solution was added 0.5031 g of PIPS and the stirring continued for several hours to obtain a homogeneous mixture. The final mixture with a molar ratio of 1 $CdCl_2\cdot H_2O$: 2.73 PIPS : 30 butan-2-ol : 30 H_2O was transferred into a 7-ml PTFE-lined acid digestion bomb and heated at 423 K for 48 h. **II** was synthesized at a slightly higher temperature (453 K) starting with a reaction mixture of the composition 1 $CdCl_2\cdot H_2O$: 2.75 PIPS : 28.32 butan-2-ol): 36 H_2O. The products contained colorless rod-shaped crystals, suitable for single crystal X-ray diffraction. TGA revealed that both **I** and **II** lose the water molecules in the range 100–150 °C range, with a sharp weight loss around 300° C due to the loss of amine molecules and HCl (calc. 41.25%, obs. 47.58% for **I**; calc. 48.64%, obs. 42.52% for **II**). The dense cadmium sulfate in the case of **I** and chlorosulfate for **II** decompose to CdO at 600 °C. CHN analysis confirmed the amount of organic amine present in both the compounds (Found: C, 12.93; H, 3.79; N, 7.54. Calc.: C, 12.46; H, 3.66; N, 7.26% for **I**. Found: C, 14.72; H, 4.36; N, 8.62%. Calc.: C, 14.68; H, 4.31; N, 8.56% for **II**).

‡ *Crystal data:* $[C_4N_2H_{12}][CdCl_2SO_4]\cdot H_2O$ **I**: M_r = 385.54, monoclinic, space group $P2_1$ (no. 4), a = 9.3500(4), b = 7.4689(3), c = 9.4289(4) Å, β = 116.134(10)°, V = 591.14(4) Å^3, Z = 4, μ = 2.478 mm^{-1}, D_c = 2.166 g cm^{-3}. A total of 2509 reflections were collected in the θ range 2.41–23.24 and merged to give 1582 unique data (R_{int} = 0.021) of which 1539 with $I > 2\sigma(I)$ were considered to be observed. Final R = 0.022, R_w = 0.054 and S = 1.06 were obtained for 144 parameters.

$[C_4N_2H_{12}]_4[Cd_3Cl_{10}(SO_4)_2(H_2O)]\cdot 3H_2O$, **II**: M_r = 1308.54, monoclinic, space group $P2_1/m$ (no.11), a = 12.578(2), b = 13.093(4), c = 13.006(3) Å, β = 94.58(2)°, V = 2135.0(9) Å^3, Z = 4, μ = 2.261 mm^{-1}, D_c = 1.995 g cm^{-3}. A total of 8916 reflections were collected in the θ range 1.57–23.28 and merged to give 3216 unique data (R_{int} = 0.052) of which 2467 with $I > 2\sigma(I)$ were considered to be observed. Final R = 0.058, R_w = 0.095 and S = 1.05 were obtained for 246 parameters.

The structures were solved by direct methods using SHELXS-86[9] and full-matrix-least-squares structure refinement against $|F^2|$ was carried out using SHELXTL-PLUS[10] package of programs. Two amine molecules and one water molecule in **II** being disordered were refined isotropically. CCDC reference numbers 171678 and 171679. A preparative strategy for supramolecular inclusion compounds by combination of dimer formation of isonicotinic acid and coordination bonding

Ryo Sekiya and Shin-ichi Nishikiori*

Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo, 3-8-1 Komaba, Meguro, Tokyo 153-8902, Japan. E-mail: cnskor@mail.ecc.u-tokyo.ac.jp

Received (in Cambridge, UK) 19th September 2001, Accepted 6th November 2001
First published as an Advance Article on the web 16th November 2001

A new inclusion compound host $[Ni(SCN)_2(isoH)_2]$, whose cavity is suitable to include large aromatic guests, has been synthesized by a method of combining the dimer formation of isonicotinic acid by double hydrogen bonds with a 1D Ni thiocyanato complex.

Hydrogen bonding has been widely used in the preparation of supramolecular compounds because of its flexibility and availability.[1] However, there are two drawbacks which need to be considered: its weak bonding force and difficulty in predicting the bonding scheme which is easily affected by the surroundings. These are serious problems in designing hosts for a target guest. A method of solving these problems is to use multiple hydrogen bonds. As such a candidate, a dimer structure of two carboxylic acids connected by two hydrogen bonds might be promising and the key compound reported in this paper is isonicotinic acid (isoH, 4-pyridinecarboxylic acid). In recent studies for building multi-dimensional polymeric metal complexes, nicotinic acid and its derivatives have been sometimes used as building blocks because of their versatile coordination behavior and ability to form hydrogen bonds.[2,3] In the case of isoH, as shown in Fig. 1, double hydrogen bonds connect two isoH molecules to make a long flat building block with two coordination sites. If these building blocks can be arrayed at appropriate intervals then large spaces can be formed between the blocks. To make such a structure, we considered a combination of the isoH dimer and a 1D complex of $[M(SCN)_2]$.[4] In the 1D complex, all equatorial sites of a divalent octahedral metal ion (M) are occupied by SCN^- ambidentate ligands which link adjacent M ions to make an infinite 1D double chain structure, and the axial sites of M are available for bonding isoH dimers. An assembly of the isoH dimers and the 1D complexes generates a 2D network host complex with rectangular grids as shown in Fig. 2. Considering the dimensions of the grid, which has a large height (*ca.* 16.5 Å) and a narrow width (*ca.* 5.5 Å), the host is expected to be suitable for including large aromatic molecules. The narrow width of the grid also has an additional significance since its narrowness prevents formation of an interpenetrating structure for the 2D network complex. It is well known that the formation of an interpenetrating structure of networks with large grids fills up space that could have been available for a guest so that the networks can no longer function as a host.[5]

In our preparative experiments using Ni, Cu and Cd as divalent metal ions,[3,6] a series of targeted inclusion compounds $[Ni(SCN)_2(isoH)_2]\cdot 1/2G$ was obtained, where G is a guest such as anthracene, naphthalene, pyrene, perylene, biphenyl, styrene, anthraquinone, azobenzene, *etc*.† As an example, the crystal structure of an anthracene inclusion compound $[Ni(SCN)_2(isoH)_2]\cdot 1/2C_{14}H_{10}$ (**1**), whose space group is $P\bar{1}$, is shown in Fig. 3.‡ The host of **1** has the same structural framework shown in Fig. 2. There are two types of Ni ions, Ni(1) and Ni(2), which lie on independent inversion centers of the crystal. Both Ni ions have an octahedral coordination structure coordinated by four SCN^- ligands at the equatorial sites and two isoH molecules at the axial sites. Each SCN^- ligand makes a bridge between Ni(1) and Ni(2). A bent bridge structure of the SCN^- ligand forms the doubly bridged chain structure of a 1D $[Ni(SCN)_2]$ complex running along the *b* axis of the crystal (Fig. 3(a)). The 1D $[Ni(SCN)_2]$ complexes are linked by isoH dimer blocks which are formed by double hydrogen bonds as shown in Fig. 2. This linkage is formed between Ni(1) and Ni(2) in independent 1D $[Ni(SCN)_2]$ complexes and runs along the [0 1 2] direction of the crystal. As a result, a 2D network complex extending over the *bc* plane is built up. Fig. 3(a) shows the structure of the 2D network. The distance between two Ni ions in the linkage is 16.239(2) Å, and the span between adjacent Ni ions in the 1D $[Ni(SCN)_2]$ complex is 5.506(1) Å. The whole crystal structure is a layered structure of the 2D network complexes stacked along the *a* axis as shown in Fig. 3(b). This layered structure leads to channel-like cavities parallel to the *a* axis delineated by the rectangular grids of the 2D networks. Anthracene molecules, the centers of which lie at different independent inversion centers of the crystal, are arrayed in the channel-like cavities, in which each anthracene molecule is sandwiched between isoH dimer blocks.

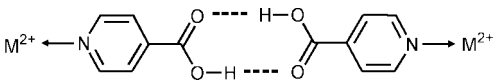

Fig. 1 An isonicotinic acid dimer as a building block.

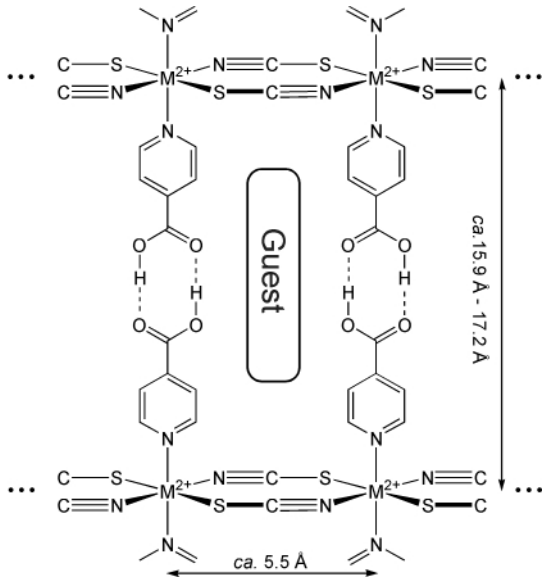

Fig. 2 A 2D network host complex formed by combination of the isonicotinic acid dimers and 1D $[M(SCN)_2]$ complexes.

Our preparative strategy is considered to be applicable to other isoH derivatives. To confirm this, we prepared a pyrene inclusion compound $[Ni(SCN)_2(acrylH)_2]\cdot 1/2C_{16}H_{10}$ (**2**) using 3-(4-pyridinyl)-2-propenoic acid (acrylH) instead of isoH.

 DOI: 10.1039/b108458e

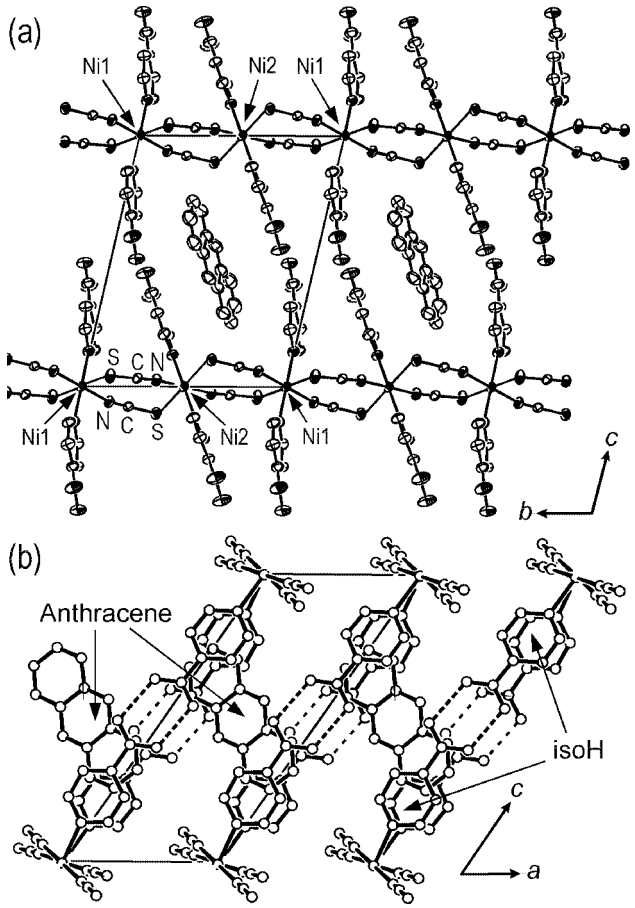

Fig. 3 Crystal structure of $[Ni(SCN)_2(isoH)_2]\cdot 1/2C_{14}H_{10}$ **1**. (a) A view along the *a* axis showing the structure of a 2D network complex extending over the *bc* plane. 1D $[Ni(SCN)_2]$ complexes and –Ni(1)–(isoH dimer)–Ni(2)– linkages run along the *b* axis and the [0 1 2] direction, respectively. (b) A view along the *b* axis. The 2D network complexes are stacked along the *a* axis. The lengths of the double hydrogen bonds indicated by dashed lines are 2.569(4) and 2.639(4) Å.

Fig. 4 shows the crystal structure of **2**.‡ The host structures of **2** and **1** are closely structurally related. The distance between two Ni ions linked by the acrylH dimer is 20.928(1) Å, so that the host of **2** has a potential for including larger aromatics.

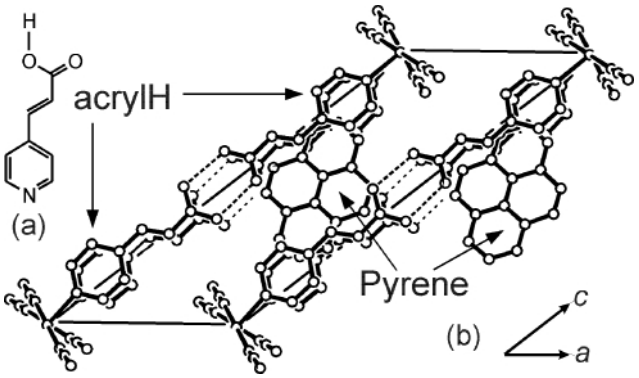

Fig. 4 (a) 3-(4-Pyridinyl)-2-propenoic acid (acrylH). (b) Crystal structure of $[Ni(SCN)_2(acrylH)_2]\cdot 1/2C_{16}H_{10}$ **2** viewed along the *b* axis. The lengths of the double hydrogen bonds indicated by dashed lines are 2.610(4) and 2.636(4) Å.

In conclusion, by means of dimer formation of isoH molecules, a long flat building block that acts as a bidentate ligand has been generated. By assembly of this building block and a 1D $[Ni(SCN)_2]$ complex, a new type of host has been prepared. This preparative strategy is applicable to other isoH derivatives. As an example, a host with an acrylH dimer building block has been prepared. Moreover, another type of structural development, where a molecule with two carboxylic acids is inserted into the isoH dimer building block, is possible. This type of host will be reported elsewhere.

Support of this work by a Grant-in-Aid for Scientific Research(A) Project No. 12354008 from Japan Society for the Promotion of Science is gratefully acknowledged.

† *Preparation*: to 100 mL of acetonitrile suspended with $NiCl_2\cdot 6H_2O$ (1.50 g, 6.3 mmol), KSCN (1.52 g, 15.6 mmol) was added with vigorous stirring. After refluxing the solution for 1 h, precipitated KCl was filtered off and then isoH (1.30 g) and a guest were added to the solution. Crystals of the inclusion compounds were obtained after slow evaporation of the solvent over a period of a few weeks at room temperature.

Reaction of $(NH_4)_2[WS_4]$, $[Ag(MeCN)_4](PF_6)$ and dppm (molar ratio = 1:2:4) in the solid state at 110 °C followed by extraction with CH_2Cl_2 yielded a hexanuclear neutral cluster $[(WS_4)_2Ag_4(dppm)_3]$ 1, while the same materials when mixed directly in CH_2Cl_2 produced a tetranuclear cluster salt $[WS_4Ag_3(dppm)_4](PF_6)$ 2; both compounds showed modest third-order optical nonlinearities.

Over the last three decades, the chemistry of group 6 and 11 mixed-metal sulfide clusters has been attractive due to their potential applications in industrial catalytic systems, biochemical systems, and new materials.[1–9] Many of these clusters are usually synthesized from common solution reactions. However, some others could be prepared by a method denoted 'low heating temperature solid state reaction'.[9a] In this method, $(NH_4)_2[MS_4]$ (M = Mo, W) is allowed to react with copper(I) or sliver(I) salts and other organic ligands at low temperatures (~100 °C). The resulting solid state products are extracted using certain solvents (*e.g.* CH_2Cl_2) to isolate Mo(W)/Cu(Ag)/S clusters. However, this procedure always invoked a question whether the final products are really generated from the solid state reactions. The problem may be tackled by running reactions with the same components both in the solid state and in solution. So far, only a few reactions have been explored to yield positive results.[9b] Herein we report another example of the distinct formation of two W/Ag/S clusters, $[(WS_4)_2Ag_4(dppm)_3]$ (**1**) and $[WS_4Ag_3(dppm)_4](PF_6)$ (**2**), which were isolated from reactions of $(NH_4)_2[WS_4]$ with $[Ag(MeCN)_4](PF_6)$ and dppm in the solid state and in CH_2Cl_2, respectively, along with their crystal structures and third-order NLO properties in solution.

The solid state reaction of $(NH_4)_2[WS_4]$, $[Ag(MeCN)_4](PF_6)$ and dppm in the molar ratio of 1:2:4 was carried out in an open Pyrex tube at 110 °C. During these reactions, an argon stream was introduced in to the tube to remove the NH_3, H_2S and MeCN gases evolved. The reaction mixture gradually became partly molten and its brown yellow color deepened in 1 d. After it was cooled to room temperature, the sintered solid was extracted with CH_2Cl_2 and filtered. Layering Et_2O onto the filtrate led to the formation of the hexanuclear brown yellow cluster **1** in 22% yield.‡ As shown in Fig. 1, the structure of **1** consists of two WS_4Ag_2 cluster fragments and three dppm ligands.§ One dppm links Ag(1) and Ag(2) within a WS_4Ag_2 fragment while the other two interconnect Ag atoms between two WS_4Ag_2 fragments. Such a cluster framework is unprecedented in thiometallates. In the structures of the two WS_4Ag_2 fragments, each WS_4 unit acts as a tridentate ligand, coordinate two Ag atoms while one W=S unit remains intact. The average W–μ_2-S bond length is 0.06 Å longer than the W=S bond, but is 0.07 Å shorter than the W–μ_3-S bond. The two planar WS_2Ag rhombs in each cluster fragment are folded with a dihedral angle of 74–76°. The WS_4Ag_2 core structure is rare. There are only two examples with Cu found in $[WS_4Cu_2(dppm)_3]$[9b] and $[ReS_4(CuNCS)_2]^-$.[10] The Ag atoms of the two WS_4Ag_2 fragments show different coordination geometries. In the fragment containing W(1), each Ag adopts a distorted tetrahedral coordination geometry with two P (dppm), a μ_2-S and a μ_3-S atom. However, the two Ag atoms in the fragment containing W(2) are coordinated by a P (dppm), a μ_2-S and a μ_3-S atom to form an approximately trigonal planar geometry. Because of the different coordination geometries of the Ag atoms, the W(1)–Ag(1) and W(1)–Ag(2) distances in one fragment are slightly longer than those of the W(2)–Ag(3) and W(2)–Ag(4) bonds in the other fragment. The mean W–Ag length (3.0406 Å) of **1** is longer than that observed in $[(WS_4)_2Ag_4(PPh_3)_4]$.[11] The average Ag–S and Ag–P lengths in the fragment containing W(1) are 0.13 and 0.08 Å longer than those of the corresponding bonds in the fragment containing W(2).

On the other hand, upon stirring a mixture of $(NH_4)_2[WS_4]$, $[Ag(MeCN)_4](PF_6)$ and dppm (molar ratio = 1:2:4) in CH_2Cl_2

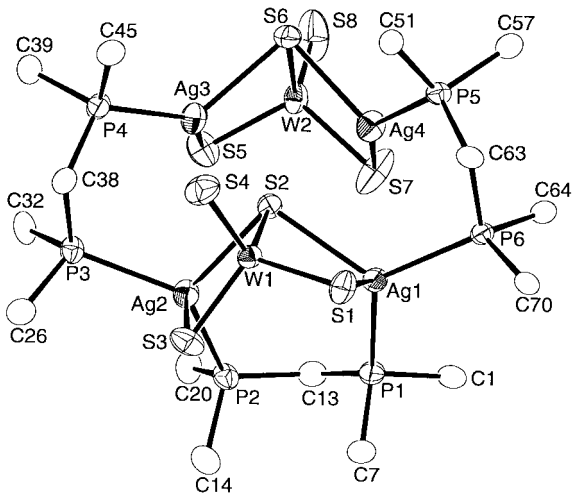

Fig. 1 Molecular structure of the neutral cluster **1**, with labelling scheme and 50% thermal ellipsoids. All phenyl groups are represented by their pivotal C atoms for clarity. Selected bond lengths (Å): W(1)–Ag(1) 3.1500(6), W(1)–Ag(2) 3.1179(5), W(2)–Ag(3) 2.9422(6), W(2)–Ag(4) 2.9523(5), W–S_t(av.) 2.136, W–μ_2-S(av.) 2.197, W–μ_3-S(av.) 2.264, Ag–S(av.) 2.595, Ag–S(av.) 2.438.

 DOI: 10.1039/b107251j

at room temperature for 1 d, there still remained some unreacted $(NH_4)_2[WS_4]$, which was filtered off. Concentration of the filtrate followed by layering with Et_2O on to the solution gave rise to a tetranuclear yellow complex **2** in 52% yield.‡ An X-ray analysis§ revealed that three Ag atoms of the $[WS_4Ag_3(dppm)_4]^+$ cation of **2** are bound to a tetrahedral WS_4 unit at three S–S edges (Fig. 2). The resulting WAg_3 skeleton is approximately T-shaped with an Ag(2)–W–Ag(3) angle of 159.90(2)°. Although such a WS_4Ag_3 core structure has not been observed previously, it is similar to those of analogous Cu clusters such as $[WS_4Cu_3(dppm)_2Br_2]$[9b] and $[WS_4(CuNCS)_3]^{2-}$.[12] In the structure of $[WS_4Ag_3(dppm)_4]^+$, the two of the four S atoms are doubly bridging, and the other two are triply bridging. Two of the four dppm ligands are bidentate while the other two are monodentate. The η^1-coordination of dppm is not especially rare, and is found in some dppm-containing complexes.[9b,13] The average W–Ag (3.0873 Å), Ag–S (2.625 Å) and Ag–P (2.281 Å) bond distances are close to those of the corresponding bonds of **1**.

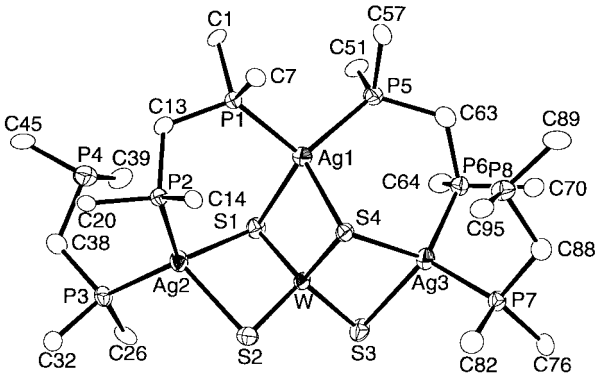

Fig. 2 Structure and labelling of the cluster cation of **2**. Thermal ellipsoids are drawn at the 50% probability level. All phenyl groups are represented by their pivotal C atoms for clarity. Selected bond lengths (Å) and angles (°): W–Ag(av.) 3.0873, W–μ_2-S(av.) 2.188, W–μ_3-S(av.) 2.233, Ag–S(av.) 2.625, Ag–S(av.) 2.281; Ag(2)–W–Ag(3) 159.90(2).

A preliminary study on the third-order NLO properties of **1** and **2** was carried out by a three-dimensional degenerate four-wave mixing (3D DFWM) technique, using a pulsed laser beam (λ = 532 nm) from a frequncy-doubled picosecond pulse mode-locked Nd:YAG laser. The third-order NLO susceptibility $\chi^{(3)}$ was obtained by comparing the measured signals for solutions of **1** and **2** with that for CS_2 as a reference, under the same experimental conditions. The $\chi^{(3)}$ values for **1** (1.0×10^{-3} M) in $CHCl_3$ and **2** (1.0×10^{-3} M) in MeCN, are 2.259×10^{-14} and 5.611×10^{-15} esu, respectively. Although these low concentration solution $\chi^{(3)}$ values are not larger than that reported for $[MoOS_3(CuNCS)_3]^{2-}$,[14] it is expected that higher $\chi^{(3)}$ values could be attained if the clusters could be deposited as thin films *via* CVD techniques. Research into this aspect is currently under way.

Received (in Cambridge, UK) 3rd October 2001, Accepted 30th October 2001
First published as an Advance Article on the web 30th November 2001

A process has been developed for the formation of titania whiskers and nanotubes with the assistance of sonication; titanate whiskers are obtained as a slender sheet with a length of about 1 μm and a width of 60 nm; arrays of titania whiskers with a diameter of 5 nm are prepared from the titanate whiskers; titania nanotubes with a diameter of about 5 nm, and a length of 200–300 nm are also synthesized.

Nanostructured materials have received much attention because of their novel properties which differ from those of bulk materials. Recently, there has been great interest in controlling the shapes of materials and in finding novel properties. One-dimensional (1D) materials are an important category of nanostructured materials and have been widely researched yielding various special structures such as nanotubes, nanorods, nanowires and nanobelts *etc*.[1–5] The materials in nanotube form include carbon, NbS_2, TaS_2, NB, MoS_2, SiO_2, Al_2O_3, MoO_3, WO_3, ZrO_2 and TiO_2. Many other materials can be prepared in the form of rods or wires such as MgO, Fe_2O_3, CaO, MgO, ZnO, GaN and CdSe, of which titania is one of the most extensively researched materials.

Titania, as a semiconductor, shows high photocatalytic activity and is widely used as a catalyst and carrier of catalysts.[6] In addition, titania finds applications in the fields of sensors, new types of solar cells, electrochromic devices, and antifogging and self-cleaning devices.[7–9] The performance of titania in its various applications depends on its crystalline phase state, dimensions and morphology.[10] Many attempts have been made to control the structure of titania. The methods to prepare 1D-structured titania include mainly template synthesis,[11,12] supramolecular assembles,[13] hydrothermal synthesis[14] and inductive synthesis.[15]

In the current paper, both titania whiskers and nanotubes have been synthesized by sonicating titania particles in NaOH aqueous solution followed by washing with deionized water and dilute HNO_3 aqueous solution. This process is more convenient than template methods in which special templates are required which then have to be removed. In addition, the products obtained using template and supramolecular assembly methods have thick walls (40–150 nm) and large diameters (150–600 nm), while the nanotubes obtained in our process have a diameter of 5 nm and a wall thickness of *ca.* 1.3 nm. As is well known, small dimensions are very important for nanostructured materials. Hydrothermal methods can prepare nanotubes with thin walls and small diameters, but take a long time to do so. The current process can prepare titanate whiskers that are an important precursor for other titanates[16] and titania whiskers are obtained from the titanate. Particularly, this process can shape the products as whiskers or nanotubes, or a mixture of whiskers and nanotubes by controlling the operation process. The samples are characterized by X-ray diffraction (XRD) using Co-Kα radiation, transmission electron microscopy (TEM), high-resolution transmission electron microscopy (HRTEM), and energy-dispersive X-ray spectra (EDS).

The precursors for the preparation of titania whiskers and nonotubes are titania particles with an average diameter of about 20 nm, which are prepared by the hydrolysis of titanium butoxide and heat-treatment at 650 °C for 1 h. The X-ray diffraction analysis in Fig. 1(a) shows that the raw titania powder is a mixture of 17% anatase and 83% rutile, estimated according to the formula $X_A = [1 + 1.26\ (I_R/I_A)]^{-1}$.[17]

In a typical synthesis, 150 mg titania powder with diameter 20 nm and 30 mL of 10 M NaOH aqueous solution were placed in a Teflon vessel. The mixture was sonicated by the direct immersion of a 560 W titanium horn for 80 min to prepare titania whiskers. The temperature during sonolysis was about 80 °C. The precipitate was washed with 0.1 M HNO_3 aqueous solution and deionized water. To prepare titania tubes, the mixture was sonicated at 280 W for 60 min. The sonicated solution in the teflon vessel was then placed in an oil-bath and maintained at 110 °C for 4 h. The precipitate was separated by centrifugation and washed with a 0.1 M HNO_3 aqueous solution and deionized water. The product was further dried under vacuum for 12 h.

Fig. 2(a) shows TEM images of the as-prepared whiskers, which are obtained by washing the sonication product with 0.1 M HNO_3 aqueous solution for 2 h and deionized water for 6 h. The as-prepared product has a slender sheet structure with a length of about 1 μm and a width of 60 nm. HRTEM analysis shows that the product has a layered crystal structure. The stoichiometry of the product is estimated to be $H_3Ti_3O_{7.5}$ according to elemental analysis. The IR spectrum shows a stretching vibration of O–H around 3400 cm^{-1} and a bending vibration of H–O–H around 1630 cm^{-1}, which imply the presence of water. The total weight loss from TGA agrees well with the estimated stoichiometry but the weight loss steps are not very well resolved. XRD analysis [Fig. 1(c)] shows broad reflections at 7.64, 5.43, 3.50, 3.02, 2.56, 2.23 and 1.86 Å. The diffraction pattern is close to that of $H_2Ti_3O_7$.[16] The product may be assigned as $H_2Ti_3O_7{\cdot}0.5H_2O$ according to the foregoing results. When the product is further washed with water for 8 h, arrays of whiskers with a diameter of 5 nm are obtained as

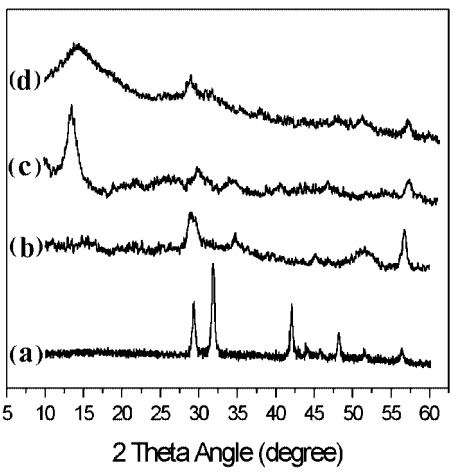

Fig. 1 XRD patterns of as-prepared samples: (a) titania particles, (b) titania whiskers, (c) $H_2Ti_8O_{17}$ whiskers, (d) nanotubes.

 DOI: 10.1039/b108968b

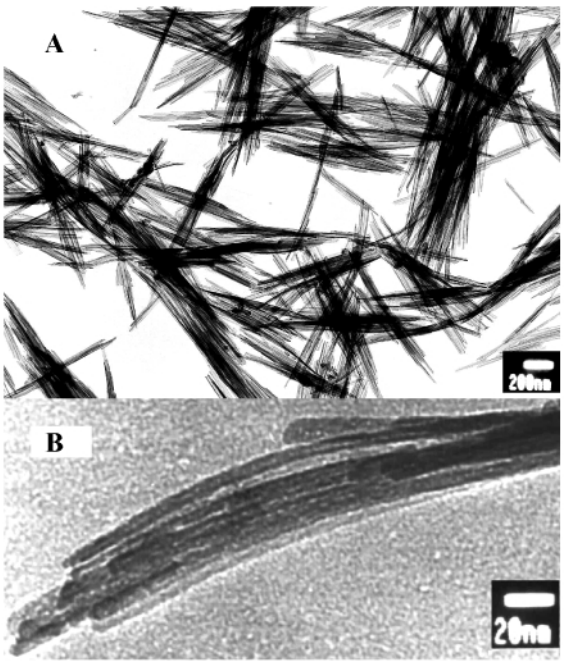

Fig. 2 TEM images of (a) titanate and (b) TiO_2 whiskers.

shown in Fig. 2(b). XRD analysis [Fig. 1(b)] shows that the product is TiO_2 (B) as discovered by Marchand *et al.*[18]

The powders shown in Fig. 3(a) are prepared by sonicating the mixture for 60 min, heat-treating it at 110 °C for 4 h and then washing the product with 0.1 M HNO_3 aqueous solution for 2 h and deionized water for 14 h. The products contain open-ended tubular structures with a diameter of about 5 nm and a length between 200 and 300 nm. XRD analyses show that the phase of the nanotubes is intermediate between $H_2Ti_3O_7{\cdot}0.5H_2O$ and TiO_2 (B). The energy-dispersive X-ray spectra (EDS) indicate that the sample consists of Ti and O in a ratio of 1 : 2 and that Na is absent from the sample.

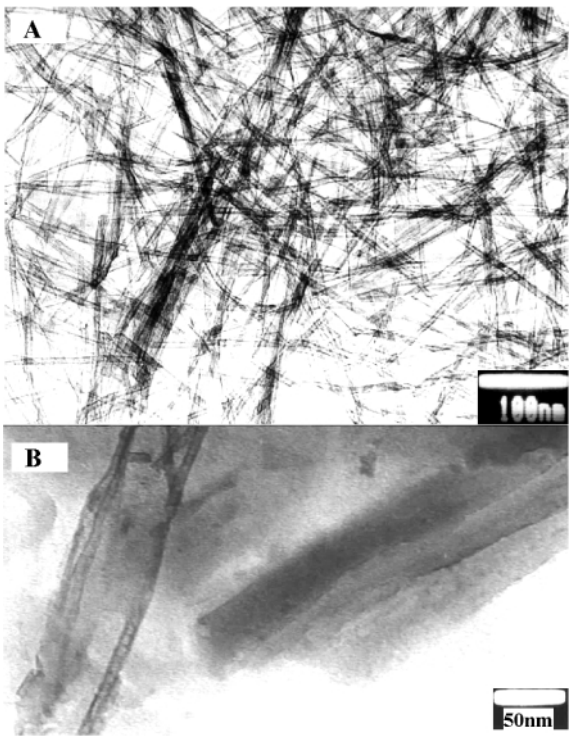

Fig. 3 TEM images of (a) titania nanotubes, (b) powders obtained by heat-treating sonicated products for 4 h at 110 °C followed by washing with water for 5 min.

The processes of formation of titania whiskers and tubes are proposed as follows. When the raw material of titania particles reacts with the NaOH aqueous solution under sonication, some of the Ti–O–Ti bonds are broken and layered titanates are formed, in which titanium–oxygen octahedra form layered lattices and the interlayered regions are occupied by alkali metal ions.[19] When the titanates react with 0.1 M HNO_3 aqueous solution and deionized water, ion exchange and dehydration reactions take place, leading to the formation of the compound $H_2Ti_3O_7{\cdot}0.5H_2O$ as shown in Fig. 1(c).[16] When the products are further dehydrated, titania is formed as proved in Fig. 1(b).[18] The role of sonication is not only to accelerate the reaction between the raw material and the NaOH aqueous solution but also leads to the oriented growth of titanate due to the extreme conditions.[20] It is found that no titanate whiskers can be obtained without sonication.

When the raw material of titania particles is sonicated with the NaOH aqueous solution under conditions of low power, thin small titanate sheets are formed. When the products are heated at 110 °C for 4 h, the small titanate sheets increase in size. The titanate sheets are exfoliated into nanosheets and the nanosheets roll into nanotubes when they are washed with water. The layered structure of the titanate sheets and nanotubes formed at the edge of the sheet are shown in Fig. 3(b). It is assumed that residual electrostatic repulsion due to Ti–O–Na bonds may lead to connection between the ends of the sheets and thus to the formation of a tube structure.[14] The process takes a shorter reaction time and produces longer nanotubes compared to the hydrothermal method for which 20 h are required to prepare titania nanotubes.

Preliminary results show that an effective process has been developed for the preparation of titania whiskers and nanotubes with the assistance of sonication. Further study is being performed to clarify the effect of different experimental parameters on the formation of titania whiskers and nanotubes.

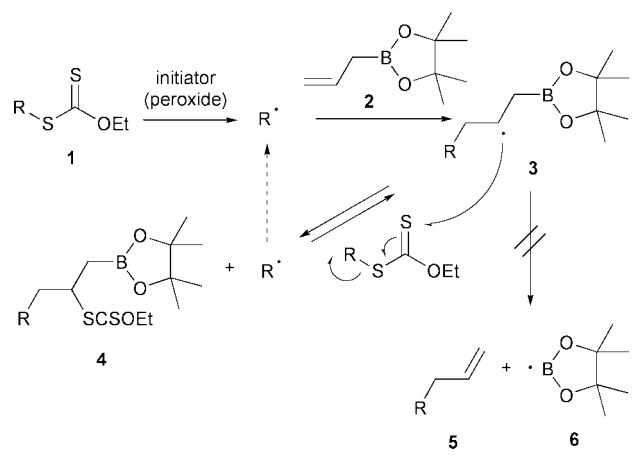
Received (in Cambridge, UK) 23rd October 2001, Accepted 6th November 2001
First published as an Advance Article on the web 30th November 2001

The radical addition of various xanthates to allyl or vinyl boronates occurs smoothly in the presence of a small amount of lauroyl peroxide as initiator to give good yields of usefully functionalised boronates.

The emergence of the poweful palladium induced coupling of boronates with halides, the Suzuki–Miyaura reaction, has caused a renewed interest in the chemistry of boronic acid derivatives.[1] Access to boronates has so far relied heavily on ionic and organometallic processes, with radical reactions playing only a very minor part.[2] The Kharasch addition of halides to vinyl boronates was reported by Matteson some years ago and has been used occasionally since.[3] In one, more recent work, simple radicals generated using stannane chemistry or through the Barton decarboxylation were found to add to vinyl boronates.[4] Ring-closures of radicals α-to the boron atom have also been described.[5] Recent theoretical studies seem to indicate that boronates have a much lower stabilising influence on an adjacent radical, in comparison to boron groups with less donating substituents.[6] In the present communication, we describe a flexible approach to functionalised boronates by application of the xanthate transfer radical addition[7] to both allyl and vinyl boronates.

The radical addition sequence is summarised in Scheme 1 for the case of allyl boronate **2**. Thus, radical **R**·, generated from xanthate **1** by the action of the initiator, undergoes addition to the least hindered end of the terminal olefin to give a new radical **3**, which then engages in a reversible addition–fragmentation process leading to adduct **4** with the concomitant regeneration of radical **R**· to propagate the chain. Addition to the unactivated olefinic bond is possible because **R**· is *not* competitively consumed by reaction with xanthate **1** (this reaction is both reversible and degenerate) and its effective lifetime in the medium is therefore significantly increased. Fragmentation of intermediate adduct radical **3** to give olefin **5** and high energy boryl radical **6** did not seem likely in the light of a recent ESR study of radicals adjacent to boronates.[6]

Indeed, when a small amount of lauroyl peroxide was added portion-wise to a refluxing, concentrated solution of xanthate **1a** (1 M) and a 1.5 to 2-fold excess of allyl boronate **2** in 1,2-dichloroethane, a smooth reaction occured to produce adduct **4a** in high yield (Table 1).† The same transformation could be accomplished with a number of other xanthates containing various functional groups, including ketones, esters, nitriles, and even heterocyclic rings, as shown by the varied examples compiled in the Table 1. The yields have not been optimised but nevertheless are generally quite good.



Scheme 1

The xanthate group in the adduct can be efficiently reduced off either by treatment with a stoichiometric amount of lauroyl peroxide in isopropanol,[8] as illustrated by the conversion of **4e** into **7e**, or by using the more traditional tributyltin hydride as in the reduction of **4a** into **7a** (Scheme 2). The former, tin-free procedure is more convenient for large scale work or for producing samples destined for biological testing. The presence of the xanthate group can alternatively be exploited to create another carbon–carbon bond, for example through a ring closure onto an aromatic ring.[9] For instance, addition over a period of one hour of a stoichiometric quantity of lauroyl peroxide to a refluxing solution of adducts **4a** or **4b** in chlorobenzene resulted in the formation of tetralones **8a** and **8b** in 35 and 42% yield respectively.

Finally, by performing the first radical addition on a vinyl boronate such as **9**, the relative position of the various functions present in the initial xanthate with respect to the boronate group can be easily and conveniently modified. The synthesis of compounds **10a** and **10b** (Scheme 3) provides two examples where the xanthate and the boronate groups are now in a geminal disposition.

Table 1 Synthesis of boronates **4**

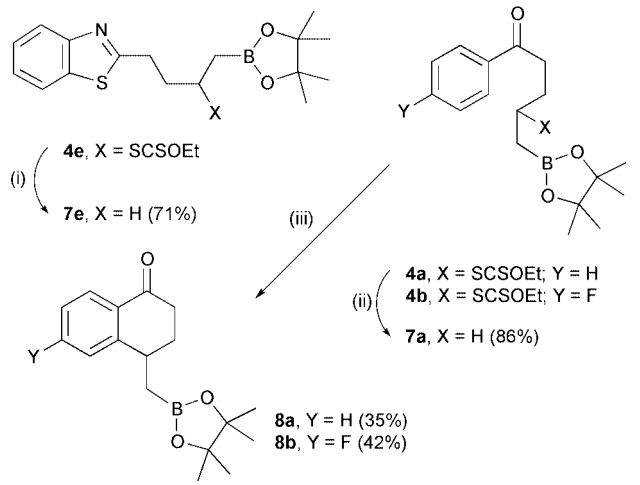
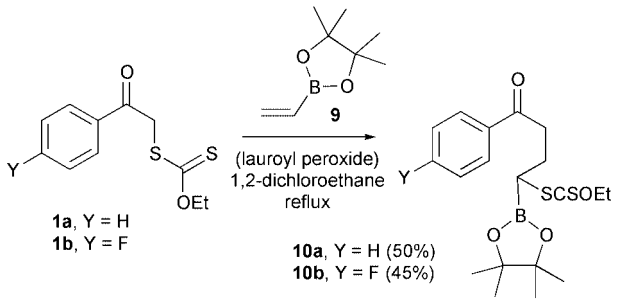


Scheme 2 *Reagents*: (i) lauroyl peroxide (100–110 mol%) propan-2-ol, reflux; (ii) Bu_3SnH, toluene, reflux; (iii) lauroyl peroxide (100–110 mol%), chlorobenzene, reflux.



Scheme 3

The present approach to boronates is simple, yet efficient and flexible. A broad variety of densely functionalised, otherwise inaccessible boronates can be rapidly prepared using cheap and readily available starting materials and reagents.

Notes and references

† *General procedure for the radical addition to allyl and vinyl boronates* **2** *and* **9**. A solution of xanthate **1** (1 mmol) and ally or vinyl boronate **2** or **9** (1.5 mmol) in 1,2-dichloroethane (*ca.* 1 mL) was heated to reflux for 15 min. Lauroyl peroxide (10 mmol%) was then added every 1 h until almost complete consumption of the xanthate. The solvent was removed under reduced pressure and the residue purified by chromatography on silica to give the corresponding adduct **4** or **10**.

Representative spectral and analytical data. (**4a**): ^{1}H NMR (300 MHz, $CDCl_3$): 7.95 (d, J = 6.6 Hz, 2H, H arom), 7.52 (m, 1H, H arom), 7.45 (m, 2H, H arom), 4.62 (m, 2H, OCH_2CH_3), 4.03 (m, 1H, CHS), 3.13 (m, 2H, CH_2CH_2), 2.27–2.10 (m, 2H, CH_2CH_2), 1.39 (t, J = 7.2 Hz, 3H, OCH_2CH_3), 1.37 (d, J = 8.1 Hz, 2H, CH_2B), 1.24 (12H, $4CH_3$). ^{13}C NMR (75 MHz, $CDCl_3$): 214.3, 199.4, 136.9, 133.1, 128.6, 128.2, 83.7, 69.7, 47.5, 36.2, 30.7, 24.9, 13.8. IR (cm^{-1}) ν: 1686 (C=O). Anal. Calc. for $C_{20}H_{29}BO_4S_2$: C, 58.82; H, 7.16. Found: C, 58.85, H, 7.16%.

(**4e**): ^{1}H NMR (300 MHz, $CDCl_3$): 4.67 (q, J = 7.2 Hz, 2H, OCH_2CH_3), 3.99 (m, 1H, CHS), 2.18 (t, J = 7.6 Hz, 2H, $NCCH_2$), 2.12 (m, 2H, $NCCH_2CH_2$), 1.43 (t, J = 7.2 Hz, 3H, OCH_2CH_3), 1.32 (d, J = 7.5 Hz, 2H, CH_2B), 1.25 (bs, 12H, $4CH_3$). ^{13}C NMR (75 MHz, $CDCl_3$): 188.0, 119.4, 83.9, 70.1, 46.4, 32.2, 24.8, 15.1, 13.8. IR (cm^{-1}) ν: 2247. Anal. Calc. for $C_{14}H_{24}BNO_3S_2$: C, 51.07; H, 7.35. Found: C, 51.33, H, 7.47%.

(**10b**): ^{1}H NMR (300 MHz, $CDCl_3$): 7.95-8.10 (m, 2H, H arom), 7.1–7.25 (m, 2H, H arom), 4.55–4.70 (3H, OCH_2CH_3, CHS), 3.18, (t, J = 6.0 Hz, 2H, CH_2CH_2), 2.15–2.37 (m, 2H, CH_2CH_2), 1.4 (t, J = 7.5 Hz, 3H, OCH_2CH_3), 1.28 (bs, 12H, $4CH_3$). ^{13}C NMR (75 MHz, $CDCl_3$): 199.5, 179.3, 136.9, 133.1, 128.6, 128.1, 84.4, 70.13, 37.3, 29.6, 24.9, 14.18. IR (cm^{-1}) ν: 1684, 1598, 1226, 1050. Anal. Calc. for $C_{19}H_{26}BFO_4S_2$: C, 55.34; H, 6.36. Found: C, 55.83, H, 6.07.

(**7e**) A solution of xanthate adduct **4e** (0.23 mmol) in propan-2-ol (1 mL) was heated to reflux for 15 min. Lauroyl peroxide (10 mol%) was then added every 1 h until almost complete consumption of the xanthate (100–110 mol%). The solvent was removed under reduced pressure and the product isolated by chromatography over silica gel with heptane–ethyl acetate (9 : 1). ^{1}H NMR (300 MHz, $CDCl_3$): 7.97 (d, J = 7.2 Hz, 1H, H arom), 7.82 (d, J = 8.1 Hz, 1H, H arom), 7.47 (m, 1H, H arom), 7.33 (m, 1H, H arom), 3.12 (t, J = 7.5 Hz, 2H, CH_2), 1.80 (m, 2H, CH_2), 1.63 (m, 2H, BCH_2), 1.26 (s, 12H, CH_3) 0.90 (m, 2H, CH_2). ^{13}C NMR (75 MHz, $CDCl_3$): 179.0,172.7, 153.0, 125.8, 124.6, 122.4, 121.4, 83.0, 34.1, 31.9, 29.6, 24.8. Anal. Calc. for $C_{17}H_{24}BNO_2S$: C, 64.36; H, 7.63. Found: C, 64.35, H, 8.21%.

Received (in Cambridge, UK) 5th September 2001, Accepted 31st October 2001
First published as an Advance Article on the web 3rd December 2001

A simple and efficient methodology to prepare carbamates has been demonstrated for the first time from symmetrical ureas and organic carbonates in the presence of solid base catalysts.

Carbamates are compounds of growing interest because of their applications in the agrochemicals industry as herbicides, fungicides and pesticides, in the pharmaceuticals industry as drug intermediates and in the polymer industry, in the synthesis of polyurethane. The commercial production of urethane is almost exclusively based on phosgene technology, however, due to worldwide awareness of pollution hazards of phosgene and pollution prevention laws adopted by Governmental agencies it is most essential to substitute it by environmentally benign routes. Efforts have continuously been made for the replacement of the phosgene route with routes such as reductive carbonylation of nitro aromatics and oxidative carbonylation of amines which have shown some promise. However, the former route will suffer from a lack of economical viability in the near future[1] while the latter suffers from hazards in handling of carbon monoxide and oxygen under high pressures. Carbamate synthesis has also been accomplished by several-pot reaction methods such as Hofmann rearrangement from amides,[2] by reaction of chloroformates and amines catalyzed by zinc,[3] and from alcohols to unsubstituted carbamates by treatment with trichloroacetyl isocyanate, followed by hydrolysis on Al_2O_3.[4] Recently, the use of carbon dioxide to replace phosgene has been attracting attention of research workers mainly due to its non-hazardous nature and safety in handling under pressure. Usually powerful organic bases[5] (*e.g.* *N*-cyclohexyl-*N*′,*N*′,*N*″,*N*″-tetramethylguanidine *etc*.) or additives such as crown ethers[6] are required to stabilize carbamate anion generated during amine and CO_2 reaction. This difficulty was partly overcome by using tetraethylammonium hydrogen carbonates (TEAHC),[7] and a combination of potassium carbonate and onium salts[8] as catalysts for the synthesis of carbamates from alkyl halides and amines. However, these methods at present are not attractive for bulk production of carbamates as they utilize only stoichiometric quantities of reagents and generate salts as by-products, which are not easy to dispose.

Recently, two industrially very important methods have been reported for the synthesis of carbamates *viz*., alcoholysis of ureas[9] and carboxylation of amines.[10] We were interested in developing methods for the synthesis of carbamates utilizing solid catalysts, as they are industrially important due to their potential in replacing conventional acid/base catalysts. The use of solid acid/base catalysts for synthesizing organic intermediates and fine chemicals is gaining increasing awareness and is a field of intense research activity.[11] While, working on reactions of alcoholysis of urea (i) and carboxylation of amines (ii) to carbamic acid esters (Scheme 1), we realized that, reactions (i) and (ii) both show poor atom economy and in each case alcohol or amine is produced as a byproduct reducing the functional group efficiency of the reagent. One way of improving the atom economy in reactions (i) and (ii) is to eliminate the use of alcohols and amines. Therefore, we were interested in effecting the conversion of disubstituted ureas and carbonates to carbamates utilizing the total functionality of both the urea and the carbonate. In this communication, we report for the first time, a new methodology for the synthesis of carbamates from substituted ureas and organic carbonates using a highly efficient and simple catalyst system [Scheme 1, eqn. (iii)].† This novel protocol has 100% atom economy while using an environmentally benign reactant source.

Surprisingly, the reaction between aromatic ureas and carbonates has not been studied[12] previously. A non-catalytic reaction between *N*,*N*′-diphenylurea and diphenyl carbonate gave only traces of *N*-phenyl phenyl carbamate after 24 h at 150 °C (see Table 1, entry 1). During the course of our investigations for screening of catalysts it was observed that basic catalysts such as triphenyl phosphine, sodium phenolate *etc*. were more effective than classical acid catalysts such as Lewis acids ($FeCl_3$, $AlCl_3$ *etc*.) and solid acid catalysts such as acidic Al_2O_3 (entry 4). However, heterogeneous basic catalysts *e.g*. Mg–Al hydrotalcite, Li–MgO, $PbZrO_3$, the Na form of zeolite ZSM-5 and amorphous catalyst grade silica gel were found to give excellent results amongst the catalysts examined, which are summarized in Table 1. Most of the catalyst screening and recycling of catalyst studies were carried out aiming for industrially important phenyl *N*-phenyl carbamate (PPC) as the product and for this purpose *N*,*N*′-diphenyl urea (DPU) and diphenyl carbonate (DPC) were chosen as model substrates (entries 2–9). From the catalysts screened, amorphous silica gel was found to be the most suitable catalyst because of its commercial availability, low cost and ease in recycling. Therefore, further studies were carried out using silica gel catalyst. The generalized applicability of the method is also verified and is evident from the range of carbamates synthesized from different ureas and carbonates (Table 1). Aromatic substituted ureas were also found to react smoothly with DPC giving the corresponding carbamates in excellent to high yields (entries 10–14). However, reaction between DPU and dimethyl carbonate (DMC) gave only a poor yield of *N*-phenyl methyl carbamate (entry 15). Interestingly, industrially important *N*-methyl methyl carbamate is produced in excellent yield from dimethyl urea and DMC (entry 16), while dimethyl urea and dibutyl carbonate require highly basic potassium supported silica gel catalyst for excellent yields of carbamate (entry 17). In general it was observed from screening of the substrates that, excellent yields of carbamates are obtained, when an aromatic urea was reacted with an aromatic carbonate and likewise for aliphatic derivatives. Catalyst screening experiments indicated that the basicity of the catalysts plays a vital role in their

activity. Also, from the earlier literature, it is known that basic catalysts are highly efficient for reactions involving carbonates (*e.g.* carbomethoxylation, *trans*-esterification and methylation).[13] The solid-base catalysts tested were all found to give excellent yields of carbamates, however, we believe that for exceptional activity, dual acid/base sites on the solid support are necessary. For catalysts having only basic sites (*e.g.* PPh_3, K_2CO_3, NaOH) only moderate yields of carbamates could be realised.[14] The activity of silica gel catalyst can be attributed to the interactions of organic urea and carbonate with silanol groups on the silica gel surface.[15] The variation in activity of silica gel catalysts procured from two different sources *viz.* W.R.Grace & Co., and Davisil (entries 2 and 3 of Table 1) is thought to be due to the difference in distribution of silanol groups in these two silica gels. Na-ZSM-5 catalysts with Si/Al ratio of 130 essentially behaved like SiO_2 since at these high ratios of Si/Al, Al atoms no longer contribute to a major extent to the framework structure of the zeolite. The activity in these zeolites is likely to be due to basic sites created by oxygen atoms while Al contributes to the Lewis acid sites.[16] Common urea and *N*-methyl urea were also examined for carbamate synthesis from DPC, however, the carbamates formed were unstable and at the end of the reaction ill characterized white solids could only be isolated.

The reusability of catalysts was tested for silica gel and Na-ZSM-5 catalyst and the results are shown in Fig. 1. The results show excellent reusability of both the catalysts for up to five recycles. Calcination for silica gel considerably improves the catalyst activity over simply drying and recycling of the catalyst.

In summary the protocol presented here is environmentally benign, simple and involves inexpensive reagents and can be effectively applied to large-scale synthesis of carbamates in high yield.

Notes and references

† *Experimental procedure:* A symmetrical urea (3.16 mmol), aromatic dicarbonate (155.6 mmol) and W.R.Grace silica gel catalyst (200 mg) were added to a well flushed and dried reaction vessel (50 cm^3) equipped with a stirrer and reflux condenser. The contents were heated under stirring up to 150 °C and kept for 8 h while an inert atmosphere was maintained. After cooling to room temperature, the solid mass was dissolved in acetone, filtered to separate the catalyst and the carbamate isolated in pure form by column chromatography (silica gel, ethyl acetate–chloroform 0.2 : 9.8). All the products were fully characterized by elemental analysis, ^1H NMR, ^{13}C NMR, IR, GC–IR and comparison with authentic samples whenever possible. Recycling of catalyst was carried out by filtration of catalyst from the crude reaction mixture in acetone followed by drying of catalyst and calcination 500 °C for 3 h.

Sequential immobilization of single stranded DNA and complementary PNA molecules in thermally evaporated fatty amine films is demonstrated and evidence for their *in-situ* hybridization is presented.

In a pioneering report, Nielsen and co-workers demonstrated that the entire sugar-phosphate backbone in DNA could be replaced by an *N*-(2-aminoethyl)glycine based polyamide structure and that the DNA bases could be attached to the peptide backbone yielding a class of molecules known as peptide nucleic acids (PNA).[1] Since the discovery of this DNA mimic and subsequent demonstration that PNA molecules obey the Watson–Crick base pairing rules[2] and that they bind with higher affinity to complementary oligonucleotides, PNA has emerged as one of the most suitable candidates for DNA diagnostic[3] and therapeutic applications.[4,5] In this communication, we show for the first time that PNA may be immobilized in thermally evaporated lipid films by simple immersion of the lipid film in the PNA solution and furthermore, that this may be extended to a sequential PNA–DNA immobilization strategy for DNA detection.

Oligonucleotides corresponding to the sequence AGTGATCTAC (**1**) and AGTGATCCAC (**2**) were synthesized as described elsewhere.[6] The PNA oligomer H-GTAGATCACT-$NH(CH_2)_2$-COOH was synthesized manually.[7] **1** is complementary to the PNA sequence while **2** is a single mismatch sequence to the PNA sequence. Pre-formed DNA–PNA solutions were obtained by mixing equimolar quantities of **1** and PNA solution under standard hybridization conditions. 250 Å thick octadecylamine (ODA, Aldrich) films were thermally evaporated onto gold-coated 6 MHz AT-cut quartz crystals, and quartz substrates for quartz crystal microgravimetry (QCM) and UV-melting measurements respectively.[8] The thickness of the films was cross-checked using ellipsometry.

UV-melting experiments on the ODA–DNA/PNA conjugate films were carried out as a test of hybridization. Unlike in the case of hybridization of complementary DNA strands where fluorescent intercalators such as ethidium bromide are routinely used,[6] reports on the use of intercalators for the detection of PNA–DNA hybrids are relatively scarce.[9] Fig. 1A shows plots of the UV-melting data recorded from ODA films in which preformed PNA–DNA duplexes were entrapped (triangles); an ODA film with sequential immobilization of **1** and PNA (squares); an ODA film with **2** and PNA intercalated sequentially (circles) and an ODA film first immersed in PNA followed by **1** (diamonds).[10] The specificity of base-pairing in the DNA–PNA complexes within the ODA matrix is reflected in the lowering of T_m in the case of single base pair mismatch DNA (**2**) with PNA which is much lower (49 °C) than the T_m of complementary DNA (**1**) with PNA (59 °C). Introduction of a single base pair mismatch in the DNA sequence leads to destabilization of the DNA–PNA complex with a lowering of the melting transition temperature. An interesting result of the investigation is the fact that the melting transition of DNA (**1**)–PNA hybrids in the lipid matrix (66 °C, squares) is much higher than the T_m of the ODA film in which preformed DNA–PNA duplexes were incorporated (59 °C, triangles). Another important observation is that the order of immobilization of PNA and DNA in the ODA matrix is not of much consequence (T_m of PNA–DNA hybrids formed by first entrapping PNA and then DNA = 68 °C, diamonds) in the extent of hybridization. The increased stability of the PNA–DNA hybrids formed in the ODA bilayers *vis-à-vis* the duplexes formed in solution and then entrapped within the lipid may be due to the following reason. During sequential immobilisation of DNA followed by PNA (or *vice-versa*), electrostatic attachment of DNA to the ODA monolayer would leave free and exposed the bases on the DNA molecules. Fig. 1B shows a schematic of the expected molecular structure of the ODA–DNA monolayer within the bilayer assemblies after entrapment of PNA. This mode of organization would then enable facile hydrogen bonding of the complementary PNA molecules with the immobilized DNA (Fig. 1B), a process not so easily done in solution. It is also possible that entrapment of pre-formed PNA–DNA complexes would lead to some orientational disorder within the ODA matrix and therefore reduced binding with the lipid. This would be reflected in terms of a lowering of the melting transition temperature as observed in this study. The UV-melting measurements clearly demonstrate that PNA–DNA immobilization and hybridization occurs within the confines of ODA bilayer stacks and furthermore, that it is sensitive to single base mismatches in the DNA sequence.

Fig. 2 presents quartz crystal microgravimetry (QCM) data of the diffusion of the DNA and PNA molecules into the fatty amine films during immersion of the ODA-coated QCM crystals in 1 μM aqueous solutions of **1** followed by PNA (triangles); **2** followed by PNA (squares) and preformed PNA–DNA complexes (circles).[11] In all cases, it is observed that there is extremely rapid diffusion of the DNA and PNA molecules into the lipid matrix. While the diffusion of DNA molecules (both **1** and **2**) into the ODA film is not surprising and may be explained in terms of attractive electrostatic interaction between

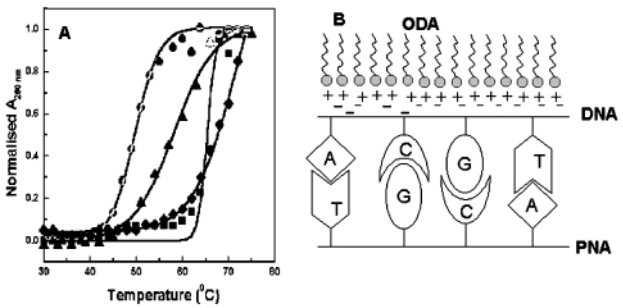

Fig. 1 A) UV melting data for 250 Å thick ODA films on quartz after immersion in 1 μm solutions of **2** followed by PNA (circles); preformed PNA–DNA complexes (triangles); **1** followed by PNA (squares) and PNA followed by **1** (diamonds). The solid lines are sigmoidal fits to the data. B) Schematic showing possible microscopic structure of DNA–ODA composite monolayer binding with complementary PNA.

 DOI: 10.1039/b107727a

the negatively charged DNA phosphate groups and protonated amine groups in the lipid matrix,[12] the significant intake of the extremely weakly charged PNA is clearly due to other interactions. The large PNA uptake is all the more interesting since the presence of DNA molecules **1** and **2** in the ODA matrix should effectively block binding sites with the ODA molecules. It is tempting to attribute the PNA diffusion into the ODA matrix to interactions arising from hybridization of the PNA molecules with the already immobilized DNA. However, a comparison of the QCM curves from the sequential immersion of the ODA films in **1** and **2** followed by immersion in PNA solution (triangles and squares respectively, Fig. 2) reveals that the mass uptake due to PNA alone (the mass increase in the second part of the QCM mass uptake curves) is similar in both cases. This clearly shows that hybridization alone cannot account for the diffusion of PNA into the DNA–ODA films and entropic factors/other interactions drive the diffusion of PNA into the lipid matrix. Indeed, immersion of the ODA films first into PNA solution followed by DNA (data not shown) resulted in significant PNA entrapment further attesting to the above fact. Even though QCM may be used to determine the presence of DNA and PNA molecules in the ODA matrix, it is clearly insufficient in determining whether hybridization had occurred between the entrapped PNA and DNA molecules. Equilibration of the number density of preformed PNA–DNA complexes in the ODA matrix (circles) occurs on time-scales similar to that observed for the single-stranded DNA molecules **1** and **2** as well as PNA. The lower mass uptake in this case (preformed PNA–DNA complexes) may be due to duplex structure preventing complete neutralization of the negative charge on the DNA by the positively charged ODA matrix. Further experiments are required to clarify this point. From the QCM measurements presented in Fig. 2, optimum times of immersion of the ODA films in the different DNA and PNA solutions were determined and used in the preparation of ODA–DNA/PNA composite films for UV melting measurements (Fig. 1A).

To conclude, it has been demonstrated that DNA and PNA molecules may be entrapped in thermally evaporated fatty amine films thus leading to a potentially exciting and novel protocol for the entrapment of oligonucleotides and their analogues. This strategy has been shown to lead to the hybridization of complementary PNA–DNA sequences in the lipid matrix in a sequential immobilization experiment. The specificity of hybridization within the lipid matrix is good and may be easily detected by UV-melting measurements. The possibility of depositing patterned lipid films and entrapping different PNA sequences in the different elements makes this approach promising for gene sequencing by hybridization techniques. A highlight of this approach is that it is both PNA and DNA friendly — no (fairly complicated) thiolation of these molecules needs be done, as is required in other gold film-based immobilization strategies.[3b]

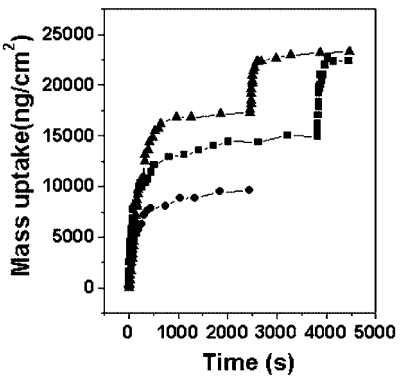

Fig. 2 QCM mass uptake data recorded during immersion of 250 Å thick ODA films in 1 μm solutions of preformed PNA–DNA complexes (circles); sequential immersion in **2** followed by PNA (squares) and **1** followed by PNA (triangles).

7 Merrifield resin derivatized with β-alanine (0.013 meq g^{-1}) employing the standard Boc-protection strategy was used in the synthesis. Cleavage from the solid support using the TFA–TFMSA cleavage procedure yielded the PNA oligomer with a free carboxylic acid at its 'C' terminus. The oligomer was purified by RP-FPLC and its purity rechecked by RP-HPLC and confirmed by MALDI-TOF mass spectroscopy.

8 The films were deposited in an Edwards E306A vacuum coating unit operated at a pressure of better than 1×10^{-7} Torr. The thickness of the deposited films was monitored *in-situ* using an Edwards quartz crystal microbalance (*QCM*).

10 The UV melting experiments were carried out on Perkin Elmer Lambda 15 UV/VIS spectrophotometer fitted with a Julabo water circulator with programmed heating accessory. The quartz substrates bearing the films were cut so as to fit into the cuvette normally used for liquid samples. The DNA–ODA films were heated at a rate of 0.5 °C per minute and the thermal denaturation of the duplex was followed by monitoring changes in the absorbance at 260 nm as a function of temperature. A 250 Å thick ODA film on quartz was taken as the reference.

11 This was achieved by *ex-situ* measurement of the QCM resonance frequency after thorough washing and drying of the crystals using an Edwards FTM5 frequency counter. This frequency counter had a resolution and stability of 1 Hz. The frequency change (Δf) was converted to mass loading (Δm) using the relationship $\Delta m = 12.1\ \Delta f$ (ng cm^{-2}).

The ruthenium cluster moiety $[Ru_6C(CO)_{17}]$ has been attached to ArgoGel polymer beads using supported phosphine ligands and crown ether interactions with ammonium salt functionalities; these show promising results as hydrogenation catalysts for clean chemical conversions.

The immobilisation of catalysts on solid supports represents a major step in the development of cleaner chemical conversions.[1,2] Active materials thus prepared are considerably easier to handle, retrieve and recycle than their homogeneous counterparts. In addition, they may also exhibit improved activities and selectivities over those found for their homogeneous analogues.[3] An approach used frequently in the development of novel heterogeneous catalysts is the chemical linking of the active moiety to the available functional groups of polymer beads. The choice of support plays an important role in the 'tunability' of such heterogenised catalysts to a particular process. For example, some catalytic processes have been performed using rigid polymer backbones[4a] which barely swell in solvents whereas others require more flexibility in the support.[4b] Amphiphilic polystyrene based resins containing polyethylene glycol (PEG) grafts show great potential as supports for metal cluster based catalytic systems. The PEG component provides the vital flexibility needed to minimise steric congestion of the metals as well as the ability to swell in a variety of solvents, thus enabling maximum access to catalytic sites. Metal clusters and their nanoparticle equivalents are known to possess good catalytic properties in a variety of hydrogenation processes and, in general, their activity is well documented and moderately well understood.[5] In this communication we report the functionalisation of ArgoGel (AG) resins by three different methods and subsequent treatment with the $[Ru_6C(CO)_{17}]$ moiety. Initial studies into their catalytic potential are also described.

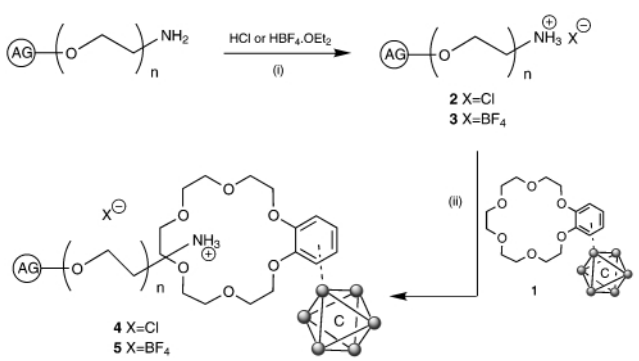
Previous research has shown that the cluster $[Ru_6C(CO)_{17}]$ can be coordinated to benzo-18-crown-6 and the well-known host properties of the crown can be used to connect the cluster moiety $[Ru_6C(CO)_{14}(\eta^6\text{-}C_{16}H_{24}O_6)]$ **1** to an ammonium functionalised chain.[6] This strategy has enabled the site-directed deposition of clusters onto mesoporous silica (MCM-41) containing ammonium bearing tethers.[7] Building on these observations, we treated the ArgoGel amine resin with acid to generate terminal ammonium groups to act as sites onto which **1** could be attached.

Protonation of ArgoGel amine was achieved by treating the beads with an excess of HCl (12 M in water) or $HBF_4{\cdot}OEt_2$ to yield the ammonium bearing beads **2** and **3** (see Scheme 1) respectively in quantitative yield as shown by single bead FTIR, gel-phase ^{1}H HR-MAS NMR and microanalysis (see ESI‡).

† Electronic supplementary information (ESI) available: footnotes to the text. See http://www.rsc.org/suppdata/cc/b1/b106336g/

The colourless beads **2** and **3** were treated with **1** (1.5 equivalents) to give the dark red beads **4** and **5**. The IR spectra of the single bead materials showed sharp resonances at 2079, 1978 and 1833 cm^{-1} (for **4**) and 2044, 2009 and 1805 cm^{-1} (for **5**), indicating the presence of carbonyl groups of the attached ruthenium cluster. The presence of ruthenium was confirmed by X-EDS and ICP-AES analysis. This showed the mass percentage of ruthenium on the beads to be 2.96% (0.049 mmol g^{-1}) for **4** and 1.72% (0.028 mmol g^{-1}) for **5**, which corresponds to a 14% site coverage of **1** on resin **4** and an 8% site coverage of **1** on resin **5**.

A preliminary test of the performance of resin **4** in the catalytic hydrogenation of cyclohexene to cyclohexane resulted in exceptionally high turnovers (TOF = 6520 h^{-1}) and high selectivities for cyclohexane (>99%). The catalytic potential of this material was further investigated in the transfer hydrogenation of ketones (cyclohexanone and benzophenone). It is noteworthy to mention here that these reactions were carried out without the aid of conventionally used external reducing agents or hydrogen sources such as propan-2–ol or formic acid.[8] Remarkably high turnovers were also observed for the hydrogenation of cyclohexanone and benzophenone (3846 and 3191 h^{-1} respectively) and exceedingly high selectivities (>99%) for cyclohexanol and diphenylmethanol respectively (see ESI for reaction conditions§). This indicates good site isolation and accessibility of the ruthenium complexes in the porous organic matrix. The re-use of resin **4** in the above-mentioned hydrogenations did not result in appreciable loss in catalytic activity or selectivity. Further, to rule out the possibility of leaching, in a typical experiment using benzophenone as the substrate, the solid catalyst was filtered off from the reaction mixture after 8 h while hot (373 K) and the reaction was continued with the resulting filtrate for a further 12 h. The kinetics revealed no change in conversion or product selectivity and the resulting filtrate (at the end of the reaction, 20 h) was independently



Scheme 1 Preparation of **4** and **5**: *Reagents and conditions*: i, THF, overnight; ii, CH_2Cl_2, room temp., 48 h, N_2.

 DOI: 10.1039/b106336g

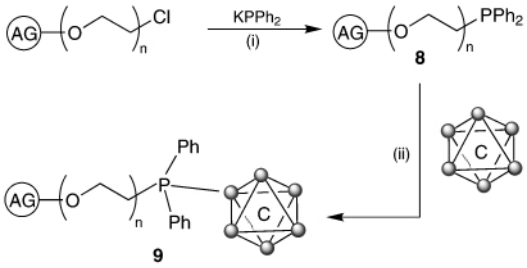
analysed by ICP-AAS for the presence of free ruthenium. Only trace amounts (< 3 ppb) were detected. Moreover, a comparison of the SEM images of the beads before and after catalysis showed no change in the spherical morphology.

The next stage in our bead functionalisation strategy was to increase the loading and strength of binding of the ruthenium cluster to the bead. Conversion of each of the available NH_2 sites on the ArgoGel amine resin to two phosphine groups can effectively double the number of coordination sites available for metal binding and thereby should increase the loading and catalytic activity. In the case of $[Ru_6C(CO)_{17}]$ the stronger bidentate coordination is expected.[9] Diphenylphosphine was treated with paraformaldehyde according to a literature procedure[10] and the phosphido-Mannich intermediate thus formed was added to ArgoGel amine to give the supported phosphine ligand **6** (Scheme 2). The peaks in the ^{31}P NMR spectrum at δ −26 and −27 indicated formation of the supported phosphine ligand. The appearance of two signals was believed to correspond to the bidentate phosphine **6** and some monodentate –$NHCH_2PPh_2$ sites (see ESI¶). Gel-phase ^{1}H HR-MAS NMR spectroscopy showed the presence of phenyl protons at δ 7.48 and 7.82 and a doublet at δ 3.53 (J = 11.5 Hz) which confirmed the presence of the NCH_2PPh_2 species. Microanalysis showed the amounts of N and P to be 0.76 and 2.10%, respectively. This corresponds to 0.54 mmol/g N and 0.68 mmol/g P; a N:P ratio of 1:1.3 showing that not all N–H sites were completely converted. This is in good agreement with the ^{31}P NMR results.

An excess of $[Ru_6C(CO)_{17}]$ was added to a swirled suspension of **6**, resulting in the formation of the dark red beads **7**. NMR, IR and X-EDS all gave evidence that the desired product had formed (see ESI‖). The ^{31}P NMR spectrum showed no peaks at δ −26 and −27 , indicating that all available phosphine sites had coordinated. The new peaks at δ 16 and 24 ppm assigned to different coordination modes of the cluster to the phosphine ligand. ICP-AES analysis showed the beads to be 7.43% by mass ruthenium (0.12 mmol g^{-1}), which corresponds to a site coverage of cluster (assuming bidentate coordination) of 41%.

Since the phosphine bearing beads improved the amount of deposition of ruthenium cluster, an alternative route starting from ArgoGel chloride beads was proposed. In the synthetic procedure, $KPPh_2$ was freshly prepared[11] (from KH and $HPPh_2$) and was added to a suspension of ArgoGel chloride to give the phosphine derivatised beads **8** (Scheme 3). The ^{31}P NMR spectrum showed a peak at δ −21 , indicating the presence of the uncoordinated phosphine functionality (see ESI††). The gel-phase ^{1}H HR-MAS NMR spectra clearly showed the phosphorus bound phenyl groups at δ 7.47 and 7.75 and peaks for the –$OCH_2CH_2PPh_2$ and –CH_2PPh_2 protons at δ 3.64 and 2.48, respectively. Microanalysis showed the mass percentage of phosphorus to be 1.25 (0.40 mmol g^{-1}).



Scheme 3 Preparation of **8** and **9**: *Reagents and conditions*: i, THF, room temp., 30 h, N_2; ii, CH_2Cl_2, room temp, 5 days, N_2.

Treatment of **8** with an excess of $[Ru_6C(CO)_{17}]$ yielded the desired dark red product **9** which was characterised by IR, NMR, microanalysis and X-EDS. ICP-AES showed a larger mass percent of ruthenium on the bead (14.8%, 0.24 mmol g^{-1}) compared with the ArgoGel amine systems, which corresponds to a site coverage of 82%. This was reinforced by X-EDS analysis and the results from microanalysis imply that only one phosphine coordinates per cluster (see ESI‡‡). The ^{31}P NMR spectrum showed no peak at δ −21, indicating that all free phosphine sites had coordinated, giving rise to the new signal at δ 15. The IR spectrum showed the ruthenium carbonyl peaks at the lower wavenumbers of 1965 and 1789 cm^{-1}.

In summary, we have shown the successful derivatisation of two types of commercially available polymer resins which can be used as substrates in heterogeneous catalysis and have demonstrated how the method of functionalisation affects the loading of cluster. Resin **4** exhibits remarkably high activities and selectivities for the hydrogenation of olefins and for the transfer hydrogenation of ketones, without the need for external reducing agents. Further work is in progress to evaluate the catalytic potential of **5**, **7** and **9** as hydrogenation catalysts for a number of diverse organic chemical transformations.

We wish to thank for financial support the EPSRC and ICI (C. M. G. J.), King's College London (K. A. K.) and the Royal Society for a Dorothy Hodgkin Fellowship (Y. D. M). Received (in Cambridge, UK) 25th September 2001, Accepted 6th November 2001
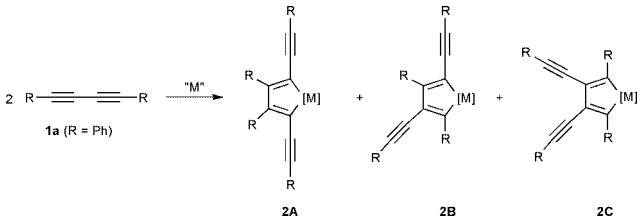
First published as an Advance Article on the web 30th November 2001

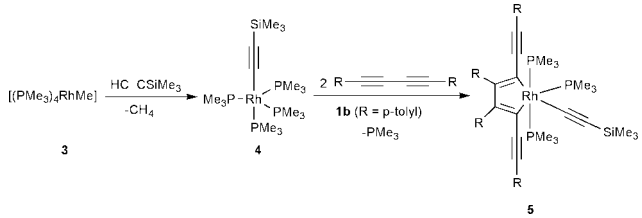
Reaction of 2 equivalents of 1,4-bis(*p*-tolylethynyl)buta-1,3-diyne with [$(PMe_3)_4Rh(–C{\equiv}CSiMe_3)$] gives the unusual, highly luminescent *mer,cis*-[tris(trimethylphosphine)trimethylsilylethynyl-2,5-bis(*p*-tolylethynyl)-3,4-bis(*p*-tolyl)rhodacyclopenta-2,4-diene] 5 in quantitative yield which has been fully characterised by ^1H and $^{31}P\{^1H\}$ NMR, IR, UV–VIS and luminescence spectroscopies, elemental analysis and single crystal X-ray diffraction.

Rigid rod conjugated systems, such as 1,4-bis(phenylethynyl)benzenes,[1–12] 9,10-bis(phenylethynyl)anthracenes[13,14] and 2,5-bis(phenylethynyl)thiophenes,[2] display interesting structural, electronic, non-linear optical and luminescent properties. The same can be expected from structurally similar 2,5-bis(phenylethynyl)metallacyclopentadienyl derivatives **2A** (Scheme 1), which can be prepared by a reductive coupling of



Scheme 1

two diarylbuta-1,3-diyne molecules **1** on a transition metal centre.[15–22] However, in the few reported syntheses of such compounds, various products are formed, including two other isomers of **2** (**B** and **C**), and the yields of the desired isomer **2A** are small: 1.5–4% in the reaction of diphenylbuta-1,3-diyne **1a** with $[Ru_3(CO)_{10}(NCMe)_2]$ in the presence of Me_3NO {[M] = $Ru(NMe_3)(CO)_3$} and 2% in the reaction of **1a** with $[CpCo(PPh_3)_2]$ at 60 °C {[M] = $CoCp(PPh_3)$}, although the reaction of the latter with hexa-2,4-diyne yields 32% of **2A**. The only other analogous monometallic compounds of which we are aware[23] are those containing titanium and zirconium for which isomer **2A** is not observed.[21,22] In the course of our work on rhodium alkynyl complexes,[24–29] we developed a high-yield one-pot synthesis of a luminescent complex **5** *via* the reaction sequence in Scheme 2.



Scheme 2

† Electronic supplementary information (ESI) available: absorption, emission and luminescence spectra for **5**. See http://www.rsc.org/suppdata/cc/b1/b108625a/

Reaction of $[(PMe_3)_4RhMe]$ **3**[30] (20 mg, 4.74×10^{-5} mol) with $HC{\equiv}CSiMe_3$ (6.7 µl, 4.74×10^{-5} mol) in THF (1 ml), gave the alkynyl complex **4** in quantitative yield with loss of methane.[25,26,29] To this, a solution of two equivalents (21.8 mg) of 1,4-bis(*p*-tolyl)buta-1,3-diyne **1b** in THF (2 ml) was added. The reaction was monitored *in situ* by $^{31}P\{^1H\}$ NMR spectroscopy, which showed a partial conversion into a new $(PMe_3)_3Rh^{III}$ complex **5**. After stirring for 2 min, all solvent was removed *in vacuo* and the residue was redissolved in THF (3 ml), thus facilitating the reaction by removing the liberated, volatile PMe_3. This cycle was repeated five times, until the NMR spectra showed the conversion to be complete. Bright yellow product **5** was isolated in 95% yield (40 mg) after recrystallisation from THF–hexane.‡

An X-ray diffraction study of **5**§ revealed a distorted octahedral coordination of the Rh atom (Fig. 1) with a meridonal disposition of the three phosphine ligands. The rhodacyclopentadiene ring is nearly planar: the Rh atom deviates by 0.13 Å from the C(15)C(16)C(17)C(18) plane.

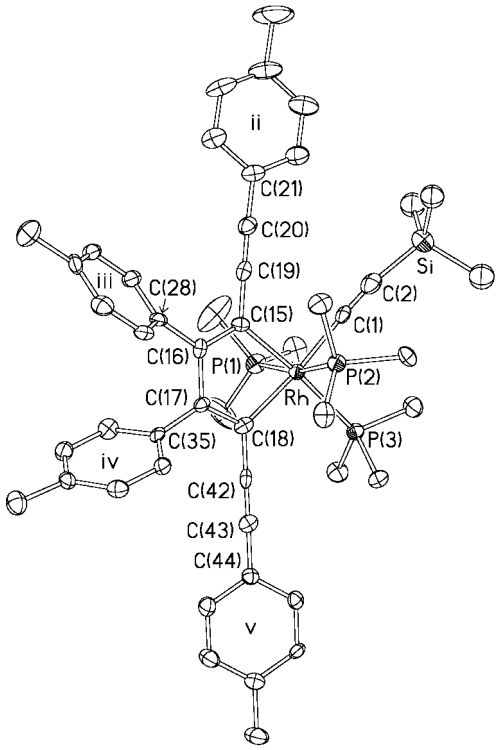


Fig. 1 Molecular structure of **5** showing 50% thermal ellipsoids. The rotational disorder of $P(1)Me_3$ and $SiMe_3$ groups is not shown (H atoms are omitted). Selected bond lengths (Å) and angles (°): Rh–P(1) 2.322(2), Rh–P(2) 2.325(1), Rh–P(3) 2.372(1), Rh–C(1) 2.068(6), Rh–C(15) 2.087(5), Rh–C(18) 2.110(5), C(2)–Si 1.848(7), C(20)–C(21) 1.426(7), C(43)–C(44) 1.432(7); P(1)–Rh-P(2) 168.39(5), C(1)–Rh–C(18) 173.5(2), C(15)–Rh–P(3) 173.9(2), C(1)–Rh–P(2) 85.3(1), P(1)–Rh–P(3) 96.67(5), C(15)–Rh–C(18) 78.8(2).

 DOI: 10.1039/b108625a

Benzene rings *iii* and *iv,* immediately attached to the metallacycle, are inclined to the latter plane by 50 and 66° (due to steric overcrowding), while rings *ii* and *v* are inclined by only 10 and 22°, permitting π-electron conjugation along the 'rod'. Thus, in the metallacycle, the formally double bonds C(15)=C(16) [1.382(6) Å] and C(17)=C(18) [1.389(6) Å] are longer than in cyclopentadiene[31] (1.344 Å) and its derivatives[32] (average 1.341 Å). The C(16)–C(17) bond [1.465(6) Å] is relatively short compared with non-conjugated, *i.e.* non-planar, butadiene moieties[32] (1.478 Å). The C(15)–C(19) and C(18)–C(42) bonds [av. 1.415(7) Å] are short for a C(sp)–C(sp^2) bond[32] (1.431 Å). The alkyne bonds C(19)≡C(20) and C(42)≡C(43) [av. 1.214(7) Å] are longer than the standard value[32] (1.181 Å) as well as the non-conjugated C(1)≡C(2) bond [1.167(7) Å]. Although each of these differences is on the margin of statistical significance, they are all consistent with the model of conjugation. The alkynyl ligand lies close to the rhodacyclopentadiene plane, *trans* to the Rh–C(18) bond, which is longer [2.110(5) Å] than the Rh–C(15) bond [2.087(5) Å] due to the *trans*-influence. The $SiMe_3$ group and the P(1)Me_3 ligand are rotationally disordered, each between two orientations in 1 : 1 and 3 : 1 ratios, respectively.

The $^{31}P\{^1H\}$ NMR spectrum† of **5** displays a doublet of doublets and a doublet of triplets consistent with a meridonal $(PMe_3)_3Rh^{III}$ coordination, where the unique phosphine is *trans* to a Rh–C σ-bond ($^1J_{RhP}$ 82 Hz). The ^1H NMR spectrum indicated four non-equivalents *p*-tolyl groups, three meridonal PMe_3 ligands and a $SiMe_3$ group. Thus, the solution NMR data is entirely consistent with the solid-state structure.

The bright yellow compound **5** displays several intense absorptions in the UV–VIS spectrum with peaks at 480 (ε 36 000), 452 (ε = 43 000), 434 (ε = 31 000), 333 (ε = 36 000) and 312 nm (ε = 55 000 $dm^3\ mol^{-1}\ cm^{-1}$). We noted that NMR samples of **5** in benzene or THF emitted green light when exposed to ordinary fluorescent room lighting. An examination of the luminescence spectra revealed that excitation at 452 nm gave rise to emission bands at 500 and 532 nm (green), whereas excitation at 333 nm showed these two bands as well as stronger emissions at 366 and 384 nm. The absorption spectrum and the emission spectrum resulting from 452 nm excitation are remarkably similar in wavelength and extinction coefficients to those observed previously for 9,10-bis(4-MeSC_6H_4C≡C)anthracene.[13] This is an exciting finding in light of the considerable current interest in luminescent organometallics,[2,33,34] which may have applications as the emissive material in OLEDs. Further photophysical studies on this and related compounds are underway in order to elucidate the nature of the states giving rise to the absorption and emission in **5**.

We have prepared a rare example of a 2,5-bis(arylethynyl)metallacyclopentadiene *via* the regiospecific reductive coupling of two butadiynes at a rhodium centre. The highly luminescent compound is formed in quantitative yield in minutes at room temperature. Solid samples of **5** appear relatively stable to the atmosphere, making this an attractive system for further study and possible applications. The compound offers exciting opportunities for functionalisation at the metal bound alkynyl ligand, the phosphines, and the starting diyne **1**, as well as the possibility of changing the metal centre from Rh to Co or Ir, all of which should allow tuning of the luminescent properties of the system.

J. A. K. H. thanks EPSRC for a Senior Research Fellowship. We thank Mr Simon FitzGerald and Dr Andrew Beeby for assistance with the luminescence specta, Mrs J. Dostal for the elemental analysis, Dr Dmitri S. Yufit for assistance with the structural analysis and Dr Paul J. Low for many helpful discussions and a preprint of ref. 23.

Received (in Cambridge, UK) 6th September 2001, Accepted 31st October 2001
First published as an Advance Article on the web 30th November 2001

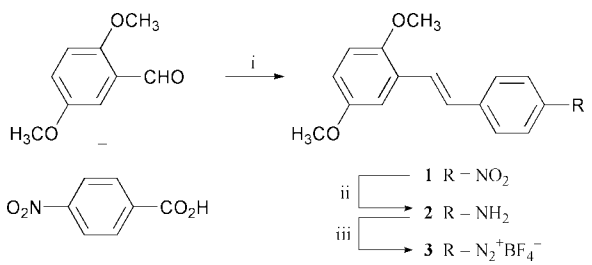
A pH-responsive electrode may be formed by covalent modification of glassy carbon by reduction of a diazonium salt hydroquinone precursor, followed by chemical demethylation.

Early methods for chemically modifying carbon surfaces involved vigorous oxidation processes[1–3] leading to the formation of superficial oxygenated functional groups.[4] These functionalities were then reacted further to effect attachment of the target molecule. The exact nature and number of oxygenated functional groups formed by this method was difficult to control, and corrosion of the carbon surface was often observed.[5] An alternative reductive strategy for electrochemically modifying carbon surfaces has been developed by Pinson *et al.*[6,7] This method makes it possible to graft a wide variety of functionalised aryl groups onto carbon surfaces, which allows the attachment of a broad spectrum of substances and shows great promise for a variety of applications.[8,9]

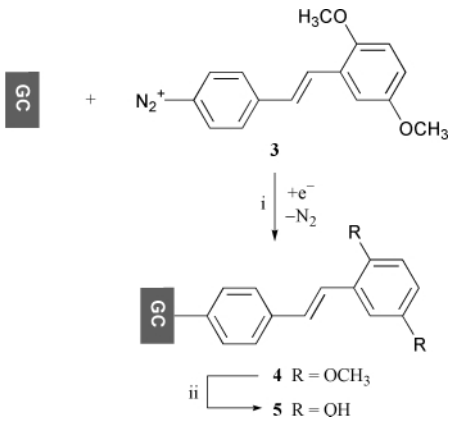
Here, we report the first synthesis of *trans*-2′,5′-dimethoxylstilbene-4-diazonium tetrafluoroborate **3** (Scheme 1), followed by the electrochemical reduction of **3** on the glassy carbon surface to form a monolayer. Chemical demethylation forms a hydroquinone-substituted stilbene-grafted glassy carbon (GC) electrode that is pH-responsive (Scheme 2).

The synthetic route to **3** is shown in Scheme 1. The compounds **1** and **2** were prepared as described previously.[10,11] The diazonium salt **3** was prepared using standard chemistry.†

Fig. 1 shows voltammograms recorded at a GC electrode for a 0.1 M solution of Bu_4NBF_4 in acetonitrile (curve a) and for the first cycle in the presence of 5 mM **3** (Curve b). A broad (500 mV at half height) and irreversible reduction peak located at 500 mV *vs*. Ag/AgCl is observed in a similar manner to those reported previously for other diazonium compounds.[7–9] This corresponds to the one electron reduction of the diazonium functionality. When further cyclic voltammograms are recorded this peak diminishes markedly. Grafting was performed over 20 min on a freshly polished GC electrode at a potential of −0.7 V *vs.* Ag/AgCl to form a complete layer on the GC surface. The broad reduction wave in Fig. 1 is not observed in cyclic voltammograms recorded directly after this potentiostatic grafting process.



Scheme 1 *Reagents and conditions*: i, piperidine, reflux; ii, $FeSO_4$; iii, HBF_4, $NaNO_2$.



Scheme 2 *Reagents and conditions*: i, CH_3CN, −0.7 V *vs.* Ag/AgCl; ii, CH_2Cl_2, BBr_3, then H_2O.

Fig. 2 shows a series of cyclic voltammograms in an aqueous buffer over a range of sweep rates for a grafted GC electrode after demethylation to give the hydroquinone **5**. The anodic and cathodic peak potentials (−26 mV and −156 mV *vs.* Ag/AgCl respectively) are independent of sweep rate. It is noted that redox activity is not observed for the GC-grafted dimethoxy derivative **4**. Furthermore, the anodic and cathodic peak currents are directly proportional to sweep rate, and integration of the peak areas (after background subtraction) yields a constant charge density of 3.1 + 0.1 C m^{-2} (3.0 to 3.3 C m^{-2} for three replicate electrodes). These observations are consistent with a fixed quantity of **5** adhered to the electrode surface and

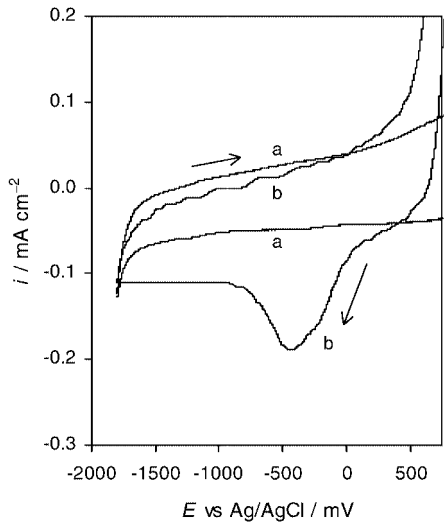


Fig. 1 Cyclic voltammograms in absence (curve a) and presence (curve b) of 5 mM **3** on a freshly polished glassy carbon electrode in a 0.1 M solution of Bu_4NBF_4 in acetonitrile. v = 200 mV s^{-1}.

 DOI: 10.1039/b107921b

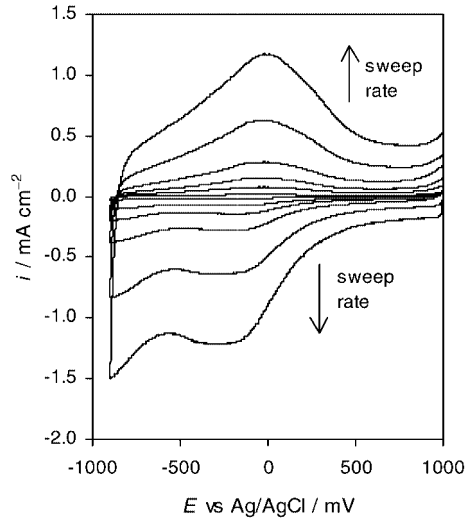

Fig. 2 Cyclic voltammograms for a glassy carbon electrode grafted with **5** in 0.1 M Bu_4NBF_4 in acetonitrile for a series of potential sweep rates: 10, 50, 100, 200, 500 and 1000 mV s^{-1}.

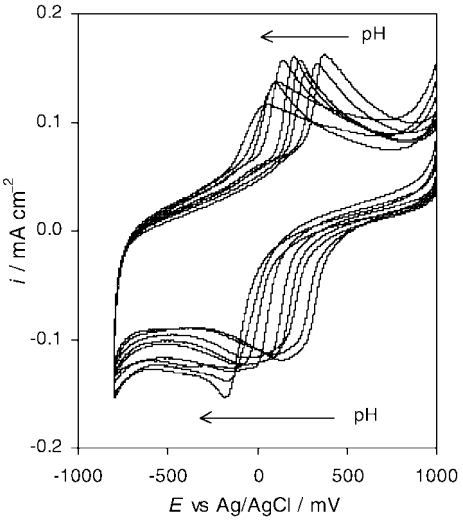

Fig. 3 Cyclic voltammograms for a glassy carbon electrode grafted with **5** in a range of 0.1 M phosphate buffers with pH: 2.65, 4.40, 4.41, 5.25, 6.00, 7.21, 8.16, 9.35 and 10.11. 0.1 M v = 200 mV s^{-1}.

indicate a coverage of 1.6×10^{-9} mol cm^{-2} for the grafted hydroquinone based on a 2 electron redox process. This is consistent with the coverage found by Pinson *et al.* for the formation of a close pack layer of grafted 4-nitrophenyl groups on glassy carbon ($\Gamma = 1.4 \times 10^{-9}$ mol cm^{-2}).[6]

The effects of solution hydrodynamics on a grafted hydroquinone GC rotating disc electrode were examined. Here, the charge associated with the anodic and cathodic peaks does not vary with electrode rotation rate. This is consistent with the redox process being attributable to a firmly tethered surface species rather than a solution species.

Fig. 3 shows cyclic voltammograms for the grafted electrode in a range of aqueous 0.1 M phosphate buffers. Again, the charge associated with the anodic and cathodic peaks does not vary with alteration of solution conditions. There is a progressive cathodic shift in the anodic and cathodic peaks with increase in pH (48.8 and 51.8 mV $decade^{-1}$ respectively). These shifts do not agree well with the expected 58.15 mV $decade^{-1}$ at 20 °C and show poor linearity. However, the open circuit potential of the grafted electrode in these buffers shows good agreement with a slope of 56.18 mV $decade^{-1}$ and good linearity ($r^2 = 0.997$). In comparison, freshly polished bare GC electrodes show only small slopes of *ca.* 10 mV $decade^{-1}$. Consequently, we attribute the pH-sensing utility to the grafted hydroquinone.

In conclusion, we have directly tethered a novel pH-sensing hydroquinone moiety to glassy carbon. The hydroquinone entity is formed after the diazonium grafting reaction from a dimethoxystilbene residue so that the hydroquinone does not impede the coupling process. A Nernstian response for the grafted hydroquinone is found indicating that direct attachment does not alter the hydroquinone couple. Future exploitation of this effect by grafting **3** on other carbon materials such as graphite and carbon could lead to the development of a pH-sensor.

The authors wish to acknowledge the Massey University Research Fund (1998) for financial support of Xinhao Yang.

New cyclodextrin dimer and trimer: formation of biphenyl excimer and their molecular recognition

Ken Sasaki, Masahiko Nagasaka and Yasuhisa Kuroda*

Department of Polymer Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606-8585, Japan. E-mail: ykuroda@ipc.kit.ac.jp

Received (in Cambridge, UK) 5th September 2001, Accepted 1st November 2001
First published as an Advance Article on the web 16th November 2001

New cyclodextrin oligomers bridged with biphenyl moieties are synthesized, among which only the doubly bridged dimer shows excimer formation behaviour in an aqueous solution.

Oligomeric cyclodextrins are one of the most attractive host molecules to provide expanded binding sites showing characteristic specificity. Among possible cyclodextrin oligomers, the dimers have been most extensively investigated.[1] Another interesting aspects of these cyclodextrin oligomers may be potential activities to control the recognition specificity by using conformational change of the relatively large recognition space of the host. The variety of linker moieties connecting the cyclodextrin recognition sites make it possible to create unique specificity and functions compared with rather monotonous recognition abilities of original cyclodextrins. Here we report new types of dimeric and trimeric cyclodextrins bridged with biphenyl moieties which are soluble both in water and various types of organic solvents. The dimer shows unique conformational change which is accompanied by excimer formation between two biphenyl moieties.

The cyclodextrin used in this work is per-*O*-methyl-6A,6D-diamino-β-cyclodextrin (**1**) which is known to be soluble not only in aqueous solution but also in various types of organic solvents.[2] The new doubly bridged cyclodextrin oligomers, **2** and **3**, were obtained from the reaction of **1** with 4,4′-biphenyldicarbonyl chloride in THF in 30% and 9% yields respectively (Scheme 1). The single bridged dimer **4** is also prepared by a similar reaction to the reference compound. One of the great advantages of permethylated cyclodextrin in these syntheses is that the preliminary purification of these products may be performed on a normal silica-gel column which is able to manage relatively large-scale reaction products. The 1H NMR and mass spectra of these compounds show satisfactory agreement with the expected structures.† The electronic spectra of these oligomeric cyclodextrins show quite a normal absorption of the biphenyl moiety at 282 nm in water, of which molar absorption coefficients are roughly proportional to the number of chromophors in the molecule, *i.e.* log ε of **2**, **3** and **4** are 4.70, 4.88 and 4.49 respectively (Fig. 1a). In contrast, an interesting

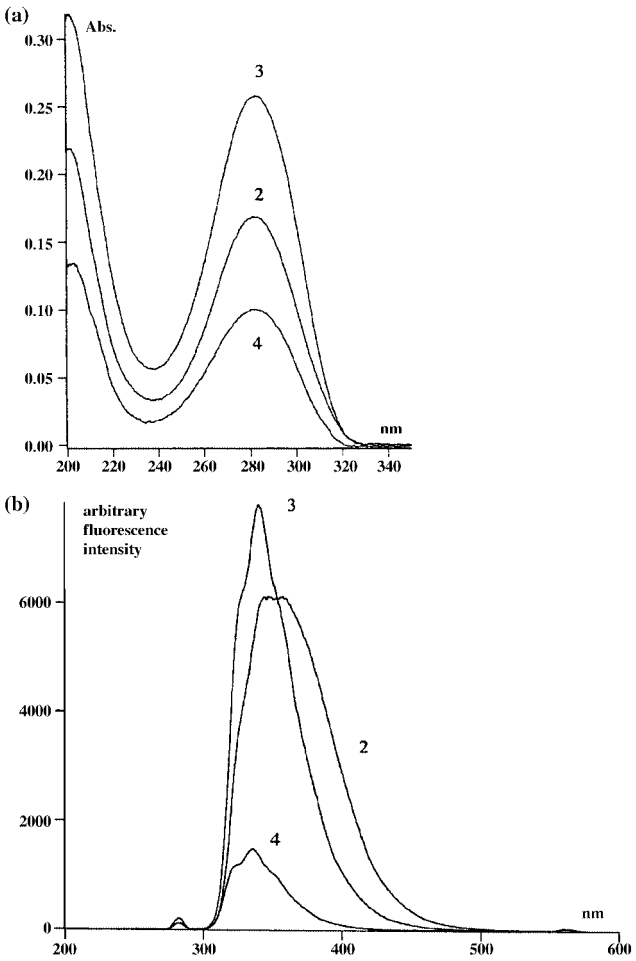

Fig. 1 a) Electronic spectra of cyclodextrin oligomers **2**, **3** and **4** in H_2O. b) Fluorescence spectra of cyclodextrin oligomers **2**, **3** and **4** in H_2O (λ_{ex} = 282nm). [**2**] = [**3**] = [**4**] = 3.4×10^{-6} M.

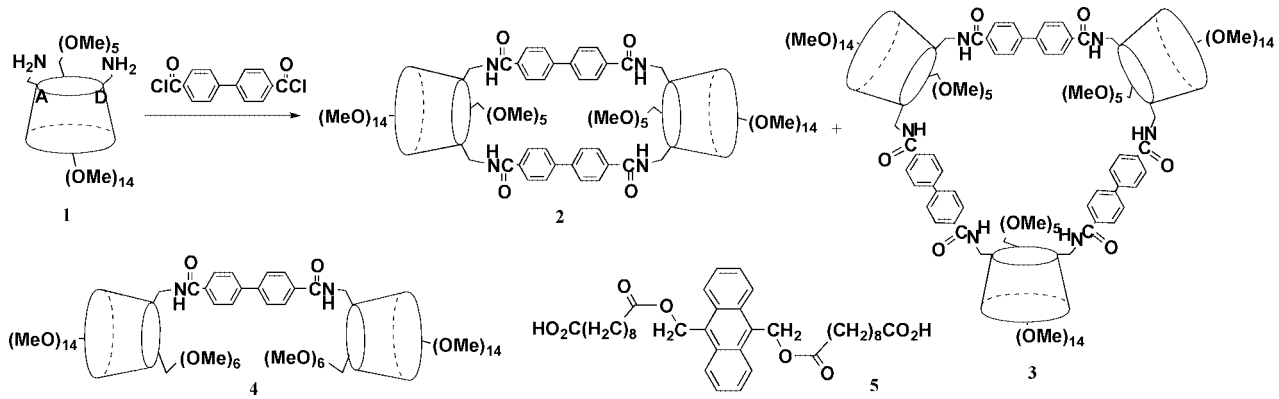
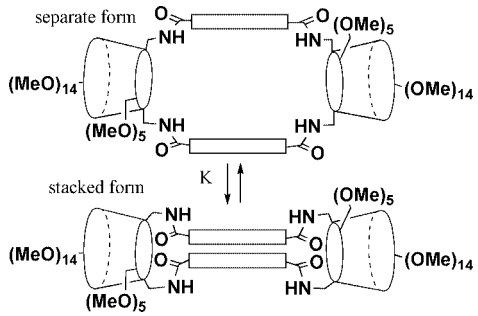


Scheme 1 Cyclodextrin oligomers and substrate.

 DOI: 10.1039/b107987e

difference is observed in the fluorescence spectra of these compounds. As shown in Fig. 1b, the shapes of the fluorescence spectra of **3** and **4** are essentially identical but that of **2** is quite different from others. The red shifted and broadening spectrum of **2** is similar to that of the recently reported biphenyl excimer adsorbed on clay.[3] Since **3** and **4** show no such behaviour, only the closed structure of **2** may assist to associate two biphenyl groups in the parallel mode to generate the excimer emission. It is interesting to understand whether such modified emission of **2** comes from a rigid conformation similar to that of biphenyl molecules strongly adsorbed on clay or from rather simple equilibrium between flexible conformations of **2**. In order to clarify the origin of the driving force of the excimer formation, the fluorescence spectra in different solvents were compared. Interestingly, the fluorescence of **2** in MeOH and $CHCl_3$ becomes the same as that of the monomeric biphenyl group. The observation is quite different from that reported for the 1,3-bis(biphenyl)propane system, where the excimer formation is controlled by the solvent microviscosities.[4] The results indicate that the present cyclodextrin dimer **2** has at least two conformers, the stacked form and the separate form, and the major driving force to control the equilibrium between these two forms is expected to be hydrophobic character (see Scheme 2). This conformational change is also confirmed by measurement of the variable temperature fluorescence spectra in the aqueous solution. The spectra show successive changes from an excimer fluorescence to a monomeric one during temperature change between 273 K and 348 K. The intensities of the spectra at 348 K are *ca*. 1/10 of that at 273 K and the processes are completely reversible. The preliminary analyses of these temperature dependent spectral changes assuming the two-state equilibrium give -8 ± 2 kcal mol^{-1} and -26 ± 5 e.u. for ΔH and ΔS for the present conformational change. The observed entropy change shows rather negative values, which is in contrast to the positive one sometimes observed for the typical hydrophobic processes.[4] The result indicates that the contacting surface of the biphenyl groups may not be wide enough to get large entropy gain during the association process. The thermodynamic parameters also show that *ca.* 50% of **2** in aqueous solution takes the stacked form at room temperature.‡

Finally the molecular recognition of the present new cyclodextrin oligomers is investigated by using the anthracence derivative **5** having two hydrophobic alkyl chains. The association constants for **2**, **3** and **4** determined by spectroscopic titration were 5200 ± 500, 27000 ± 2000 and 8600 ± 500 M^{-1}, respectively. Although the electronic spectra of an anthracene unit at 350–400 nm show slight red shifts with clear isosbestic



Scheme 2

points on addition of these oligomeric cyclodextrins, simple permethylcyclodextrin results in practically no appreciable spectral change of the present anthracene absorption. In spite of the fact that **5** is not necessarily optimised as the best substrate for the present new host molecules, the observed recognition shows interesting behaviour. The largest binding of **3** may suggest that the effects of the statistical enhancement of binding are due to three cyclodextrin units in the molecule and entropic advantage due to two-points fixation of the cyclodextrins at A,D-positions. In contrast, the similar or rather smaller association constants of **2** compared with non-cyclic dimer host **4** may indicates that the entropic advantage is largely cancelled by the extra energy for opening the stacked form of **2** during the association processes.§

Thus the present results show the unique properties of the present new cyclodextrin oligomers and interesting possibilities for controlling the conformations of these cyclodextrin oligomers. Further investigations of the detailed thermodynamic properties of these systems are now under way in our laboratory.

Notes and references

† The products are mixtures of the possible isomers which have different combinations of the positions bridged with the biphenyl moieties (bp), *i.e.* (A-bp-D)$_2$ and (A-bp-A)(D-bp-D) for **2** and (A-bp-D)$_3$ and (A-bp-A)(D-bp-D)(A-bp-D) for **3**. In the present stage the isomers are not separated even by using HPLC. Spectroscopic data of the mixtures, **2**: ^{1}H NMR (500 MHz. $CDCl_3$) δ 7.89–7.51 (16H, m, biphenyl), 5.32–4.98 (14H, m, C1-H), 4.60–2.75 (199H, m, other cyclodextrin H), HRMS(FAB) *m/z* calcd for $C_{150}H_{232}O_{70}N_4$ 3209.4717, found 3209.4680 (Δ = −1.2ppm), **3**: ^{1}H NMR (500 MHz. CDCl3) δ 7.95–7.63 (24H, m, biphenyl), 5.35–5.02 (21H, m, C1-H), 4.50–2.90 (300H, m, other cyclodextrin H), HRMS(FAB) *m/z* calcd for $C_{225}H_{348}O_{105}N_6$ 4816.2142, found 4816.2158 (Δ = +0.3ppm).

‡ The fluorescence of **2** in H_2O at room temperature may contain the excimer fluorescence and the monomeric one which originates from not only the separate form but also the stacked one in a hydrophobic environment.[6]

§ The fluorescence of the anthracene moiety in **5** increases in intensity by 30–50% on addition of the present hosts, indicating some energy transfer from the biphenyl moieties to the guest molecule.

First published as an Advance Article on the web 19th November 2001

A large quantity of metal Zn nanobelts have been synthesized by a simple approach, which involves thermal decomposition of ZnS powder, followed by Zn deposition.

Low dimensional systems represent one of the most important frontiers in advanced materials research.[1–3] Quasi one-dimensional (1D) nanostructured materials, such as nanowires and / or nanotubes, have been successfully synthesized and have received much attention due to their peculiar optical, electrical, thermoelectric properties and potential applications in nanodevices.[4–7] Recently, semiconducting oxide nanobelts, a new group of 1D nanomaterials with a rectangular cross section, have been synthesized, and their morphology is distinctly different from those of nanowires and nanotubes.[8] The nanobelts could be an ideal system for fully understanding dimensionally confined transport phenomena in functional oxides. Through confinement of metals to quasi one-dimension, a variety of changes in their characteristics are induced.[9] Therefore, to fully study the fundamental physical and chemical properties of quasi-1D metal systems, the synthesis of metal nanostructures including nanowires, nanotubes and nanobelts are very important. Up to now, considerable effort has been focused on the synthesis of metal nanowires and nanotubes.[9–14] However, there have been no reports about metal nanobelt synthesis. In this communication, we describe the fabrication of a new quasi-1D metal nanostructure: Zn nanobelts. Successful synthesis of Zn nanobelts will open up the possibility of fully studying physical and chemical properties of quasi-1D metal nanomaterial systems.

A silicon wafer (5 × 10 mm) was used as a substrate for the growth of Zn nanobelts. The substrate was cleaned by a standard treatment in piranha solution (30% H_2O_2–20% H_2SO_4) and rinsed with de-ionized water. Yumoto *et al.* have used pure Zn metal bars as raw materials to fabricate Zn crystals.[15] This method, however, can not produce quasi-one-dimensional Zn crystals such as ribbons or whiskers owing to the fast production of Zn vapor. The produced rate of Zn vapor formed from pure ZnS powder decomposition by thermal evaporation is much slower than the rate of Zn vapor from Zn powder.[16] In order to control the produced rate of Zn vapor, pure ZnS and C powders were used as raw materials in our experiment to synthesize Zn nanobelts. The ZnS was mixed with graphite powder (mass ratio about 1 : 1) and placed in the middle of an alumina boat, and the cleaned Si substrate was placed next to the mixed starting raw powder along the downstream side of flowing argon. The alumina boat, covered with a quartz plate to maintain a higher vapor pressure, was placed in the center of a quartz tube that was inserted in a horizontal tube furnace. Prior to heating, the system was flushed with high purity Ar for 1 h to eliminate O_2, and pumped down to 5×10^{-5} Torr. Then, under a constant flow of high purity Ar gas (100 sccm), the furnace was rapidly heated to 1000 °C (about 5 min) and held at this temperature for 120 min, and subsequently cooled to room temperature. It was observed that white sponge-like products appeared on the surface of the Si substrate.

The synthesized products were characterized using scanning electron microscopy [(SEM) JEOL JSM-6300], X-ray diffraction diffractmetry [(XRD) MXP18AHF], high-magnification TEM [(HRTEM) JEOL-2010] and energy-dispersed X-ray spectrometry (EDS). For HRTEM observation, the products were ultrasonically dispersed in ethanol and a drop of this solution was then placed on a Cu grid coated with a holey carbon film.

SEM observation (Fig. 1a) revealed that the product consisted of a large quantity of wirelike nanostructures. XRD measurement (Fig. 1b) shows that the product is hexagonal structured Zn with lattice constants of a = 0.2655 nm and c = 0.4928 nm, consistent with the standard values for bulk Zn.[17] It should be noted that no diffraction peaks from ZnO or other impurities have been found in our samples. The morphology, structure and composition of the synthesized products have been characterized in detail using SEM, HRTEM, selected area electron diffraction (SAED) and EDS. A low-magnification SEM image (Fig. 2a) of the synthesized products shows that the wirelike nanostructures have typical lengths in the range of several to several tens of micrometers. A representative high-magnification SEM image (Fig. 2b) of a Zn wirelike nanostructure reveals that its geometrical shape is beltlike, distinct from previously reported nanowires and nanotubes, and its thickness is about 20 nm. It can be seen (Fig. 3a and b) that each nanobelt has a uniform width along its entire length, and the typical widths of the nanobelts are in the range 40–200 nm. No nanoparticles were observed at the ends of the nanobelts. The SAED pattern and HRTEM image (Fig. 3c) reveal that the Zn nanobelts are structurally uniform and single crystalline. The SAED pattern (Fig. 3c, inset) recorded perpendicular to the nanobelt long axis could be indexed for the [010] zone axis of

single crystalline Zn and suggests that the nanobelt growth occurs along the <100> direction. In addition, Fig. 3c also shows a lattice-resolved HRTEM image of a Zn nanobelt with a width of *ca.* 100 nm; this image clearly reveals the (001) and (101) atomic planes with separations of 0.4894and 0.2099 nm, respectively. We have also used EDS to address the composition of the nanobelts. EDS analysis (Fig. 4) demonstrates that the nanobelts contain only Zn, and no any other element is found. The Cu peaks are generated by the copper grid.

The question arises as to how the Zn nanobelts are formed. There exist several models to explain the growth for crystalline whiskers including dislocation and vapor–liquid–solid (VLS) mechanisms.[18–21] In the present case, however, none of the above mechanisms seem suitable to account for the growth of the Zn nanobelts. This is because first, no evidence of dislocations was found in our analysis, and second, there were no nanoparticles observed on any ends of the Zn nanobelts. In addition, the only source material used in our experiment is pure ZnS and graphite powder. Therefore, it is likely that the Zn nanobelts follow a growth mechanism similar to the vapor–solid

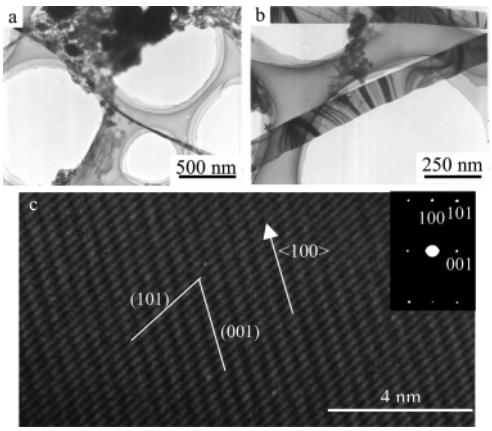

Fig. 3 TEM and HRTEM images of the Zn nanobelts: (a and b) images of several straight and twisted Zn nanobelts. (c) HRTEM image of a Zn nanobelt which shows that the nanobelts are single crystalline and free from dislocation and defects. (Inset) The corresponding electron diffraction pattern recorded with the electron beam perpendicular to the long axis of a belt, showing the growth direction to be <100>.

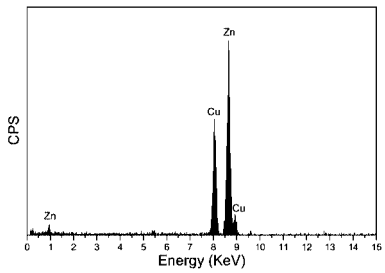

Fig. 4 EDX spectra recorded at the position of the white dot in Fig. 3b.

(VS) mechanism[8–22] First, the unidirectional motion of the Zn atom cloud driven by the carrying gas is a key factor in the preferational 1D growth of the Zn nanobelts. Secondly, the relatively high-saturated vapor pressure of Zn guarantees the concentration of this element necessary for the further growth of the Zn nanobelts. The Zn vapor is generated by the reaction of eqn. (1) at high temperature (1000 °C):

$$\mathrm{ZnS\ (s)} \rightarrow \mathrm{Zn\ (g)} + \mathrm{S\ (g)} \quad (1)$$

$$\mathrm{C\ (s)} + 2\mathrm{S\ (g)} \rightarrow \mathrm{CS_2\ (g)} \quad (2)$$

The Zn vapor is transported to, and deposited on, the surface of Si substrate in the relatively low temperature zone to form nanobelts due to the epitaxial growth of crystals. Meanwhile, the CS_2 vapor [eqn. (2)] is carried away from the furnace by the flowing Ar.

In conclusion, vapor transport has been employed to synthesize single crystalline Zn nanobelts with well-defined morphology distinct from those of metal nanowires and nanotubes. The synthesis of those single crystalline metal nanobelts may open up new possibilities for experimental and theoretical understanding of dimensionally confined transport phenomena of quasi-1D metal nanomaterials.

Light-harvesting metal dendrimers appended with additional organic chromophores: a tetranuclear heterometallic first-generation dendrimer exhibiting unusual absorption features†

Received (in Cambridge, UK) 9th October 2001, Accepted 31st October 2001
First published as an Advance Article on the web 30th November 2001

A new tetranuclear heterometallic complex carrying six pyrenyl chromophores at the periphery has been prepared: this species is an example of a new class of light-harvesting metal dendrimer, in which multinuclear metal dendrimers are surrounded by additional purely organic chromophores.

Dendrimers based on Ru(II) and Os(II) polypyridine complexes have recently attracted a great deal of interest because they can play the role of light-harvesting antenna systems in artificial solar energy conversion schemes.[1–4] Most of the light-harvesting metal-based dendrimers reported so far essentially belong to two general categories: (i) species in which the metal-based chromophores are present in all the positions of the dendrimeric array[1,5] and (ii) species in which a single metal-based chromophore is located at the core of the dendrimer, surrounded by purely organic wedges bearing chromophores at the periphery (Fig. 1).[2,5] In the latter case (ii), the light energy absorbed by the peripheral organic chromophores is transferred to the central metal-based chromophore by energy transfer processes which can be mediated either (a) by the organic dendritic framework by superexchange pathways or (b) by direct coulombic interactions allowed *via* dendritic folding. In the former case (i), both center-to-periphery or periphery-to-center energy transfer processes have been reported, the efficiency of which depends on the energy gradient within the dendritic metal branches. In both cases, strict requirements must be fulfilled for efficient energy transfer, for example the correct energy gradient within the multimetal array [for (i)-type dendrimers] or suitable distance and nature of the dendritic framework [for (ii)-type dendrimers].

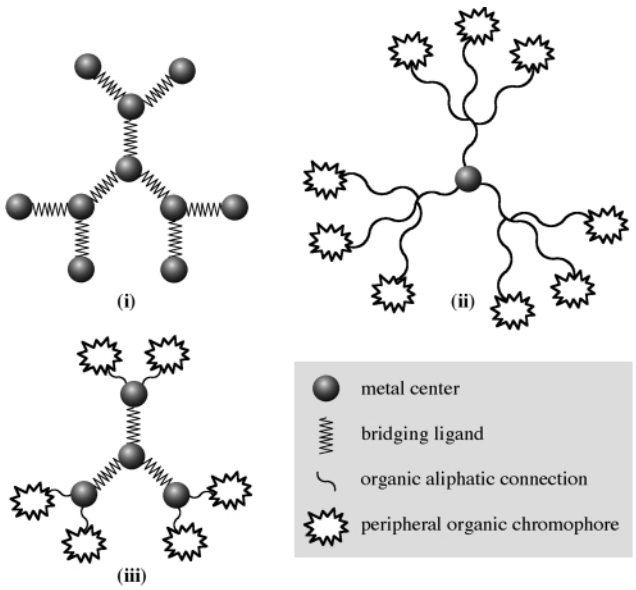

Fig. 1 Representation of metal-based light-harvesting dendrimers.

Here we report the synthesis and the absorption spectra and luminescence properties of a new tetranuclear mixed-metal dendrimeric complex **1** bearing six pyrenyl chromophores at the periphery (Fig. 2). Compound **1** belongs to the first-generation of a large class of luminescent and redox-active metal dendrimers based on the 2,3-dpp bridging ligand [2,3-dpp = 2,3-bis(2′-pyridyl)pyrazine],[1,5,6] and can also be regarded as a new type of light-harvesting dendrimer [(iii) in Fig. 1], coupling some properties of the two types of dendrimers (i) and (ii) discussed above. The four metal-based subunits constitute a (i)-type dendrimer, and the six appended pyrenyl chromophores resemble the peripheral subunits of (ii)-type dendrimers. This new approach allows us to obtain a dendrimer containing three 'layers' of chromophores (from the outer layer to the inner one: six pyrenyl units, three Ru-based chromophores and one Os-based one) in fewer synthetic steps.[6]

The synthesis of **1** is an application of the 'complexes as ligands/complexes as metals' synthetic approach.[7] The procedure is identical to that used for the synthesis of $[Os\{(\mu\text{-}2,3\text{-}dpp)Ru(bpy)_2\}_3]^{8+}$ **2** (bpy = 2,2′-bipyridine).[8] Apparently, the presence of the pyrenyl subunits does not affect the reactivity of the complex-metal species, giving similar yields under analogous reaction conditions.

The absorption spectrum of **1** is shown in Fig. 3, where the spectrum of **2** is also reported for comparison purposes. As expected, at longer wavelengths than 550 nm the spectra of **1** and **2** are almost coincident, with the absorption feature at about 550 nm receiving contributions from spin-allowed metal-to-ligand charge-transfer (MLCT) transitions (namely, Ru→μ-2,3-dpp and Os→μ-2,3-dpp CT) and the long tail which extends towards the IR region assigned to spin-forbidden MLCT transitions involving the Os(II) chromophore.[1,8] In **1**, the intense

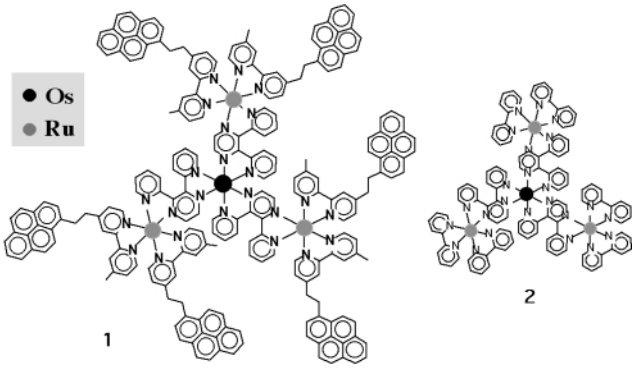

Fig. 2 Structural formula of **1** and of the tetranuclear compound **2**, used as a reference. For simplicity, the charges of the complexes are omitted.

† Electronic supplementary information (ESI) available: synthesis of 4-methyl-4′-[2-(1-pyrenyl)ethyl]-2,2′-bipyridine and synthetic scheme for **1**. See http://www.rsc.org/suppdata/cc/b1/b109068b

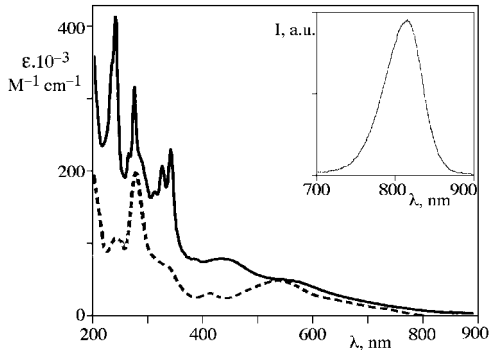

Fig. 3 Absorption spectra in acetonitrile of **1** (——) and **2** (- - - -). In the inset, the luminescence spectrum of **1** is shown.

and structured absorption peaks in the 310–350 nm region and at 239 nm can be mainly assigned to pyrene-centered transitions, 1La and 1Bb, respectively.[9,10] The broad absorption band around 320 nm which is present in **2**, assigned to 2,3-dpp centered (π–π^*) transitions[1,8] is obscured in **1** by the more intense pyrene-centered ^{1}La bands. Finally, the band peaking at 279 nm in **1** receives contributions from both the peripheral pyrenyl chromophores and the four metal subunits of the tetranuclear structure, containing the bpy-centered π–π^* absorption feature, already present in **2**.[6,8]

From the above discussion it appears that **1** significantly absorbs more than **2** in the UV region, confirming our expectations. However, Fig. 3 also shows that **1** absorbs significantly more than **2** in the region 400–550 nm. Indeed the absorption spectrum of **1** exhibits an intense broad band in that region (molar absorption of the band maximum, 8×104 M^{-1} cm^{-1}), which includes the Ru→bpy charge-transfer (CT) band peaking at 420 nm in **2**, but that clearly receives additional contributions from other transitions. To rationalize this behavior it should be considered that the pyrene subunits of **1** are good electron donor groups, in that they can be oxidized at about +1.2 V *vs*. SCE,[11] whereas the polypyridine ligand bpy and expecially the bridged 2,3-dpp are very good electron acceptors (reversible reduction process for 2,3-dpp is around −0.60 V *vs.* SCE).[6,8] The ethylene chains connecting bpy and pyrenyl subunits are flexible enough to allow direct interactions between the pyrenyl subunits with bpy and 2,3-dpp (for 2,3-dpp, CPK models suggest that conformations in which this latter ligand and pyrene can lie in almost parallel planes separated by < 360 pm are possible[12]). Therefore, intramolecular pyrene-to-bpy and/or pyrene-to-μ-2,3-dpp CT transitions (with the latter at lower energy) are possible. The intensity of such transitions can be relatively high: for example, CT transitions in [3,3]paracyclophane–quinhydrones lead to a molar absorbance of between 10^3 and 10^4 M^{-1} cm^{-1} depending on solvent polarity.[13] Significant charge transfer transitions from pyrenyl subunits to polypyridine ligands coordinated to Pt(II) have been recently reported, although in this latter case the pyrene and the polypyridine ligands were directly connected.[14] Similar transitions were also found in the adducts of dibenzyl ether dendrimers with fullerenes.[15] Since the number of such CT transitions in **1** can be high, the relatively intense broad band in the 400–550 nm region is tentatively assigned to these type of transitions (together with contributions from Ru→bpy CT transitions). This somewhat unexpected result is very interesting: the light-harvesting properties of **1** compared to **2** are improved by the presence of the additional peripheral chromophores much more than initially foreseen, due to the coming into play of visible absorption bands which arise from new intercomponent (supramolecular) CT transitions.

The luminescence properties of **1** (deoxygenated acetonitrile at room temperature: λ_{max} = 860 nm; τ = 16 ns; $\Phi = 5 \times 10^{-4}$. The uncorrected luminescence spectrum is shown in the inset of Fig. 3) are practically identical to those of **2** (λ_{max} = 860 nm; τ = 18 ns; $\Phi = 5 \times 10^{-4}$).[8] Therefore, the emission of **1** is assigned to the same excited state responsible for emission of **2**, that is the triplet Os→μ-2,3-dpp CT level.[8] The constancy of the luminescence lifetime and quantum yield on passing from **2** to **1** indicates that the pyrenyl subunits do not affect the luminescence properties of the Os core. Interestingly, the excitation spectrum closely matches the absorption spectrum, demonstrating that the light energy absorbed by the Ru-based chromophores and the peripheral pyrene subunits is quantitatively channelled to the Os core, which plays the role of the energy trap. Taken together, the absorption properties and the energy transfer processes occurring in **1** and the comparison of these data with those of the parent complex **2**, it appears that the presence of suitable peripheral organic chromophores can lead to metal dendrimers which would be better artificial antenna systems compared to the species reported so far.

In conclusion, we have prepared a new type of light-harvesting metal dendrimer, **1**, which couples the structural properties of former studied metal dendrimers. The new compound **1** exhibits better properties compared to the species previously reported, as far as the antenna properties are concerned, owing to the absorption of the additional organic chromophores and also to new absorption features originating from the interaction of the pyrene peripheral subunits with the tetranuclear metal-based core. Work is in progress to study in further detail the photophysical processes and to prepare larger and more complex systems of this type.

We thank MIUR (Project: Fotosintesi artificiale. Processi elementari in sistemi antenna e per separazione di carica), the CNR and the European Community (TMR on Network on nanometer size metal complexes) for financial support. F. L. also thanks the Marie Curie fellowships program.

New insight into the dynamic behaviour of manganese ketene complexes: evidence for the scrambling of a carbene moiety over carbonyl ligands†

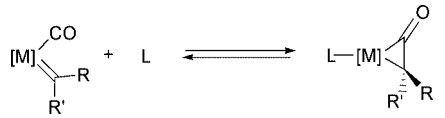
First published as an Advance Article on the web 30th November 2001

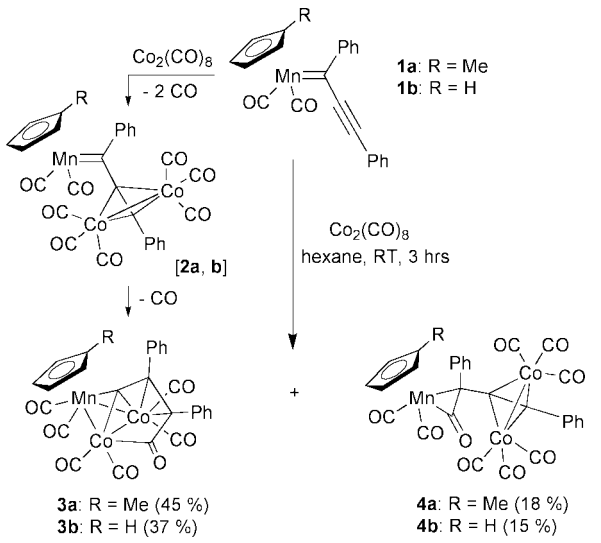
The carbonyl of the ketene ligand in manganese complexes of the type $RCp(CO)_2Mn[\eta^2\text{-}R'(Ph)C{=}C{=}O]$ exchanges rapidly (NMR time-scale) with the CO ligands though a process that involves scrambling of a carbene moiety over the three carbonyl environments.

The formation of a ketene upon CO-insertion into a metal–carbene bond is considered as the key step in several useful synthetic reactions, such as Dötz's benzannulation reaction or the Hegedus β-lactam synthesis.[1] Though the formation of ketene complexes by coupling of CO and carbene ligands on a single metal centre is now well documented,[2,3] it is only recently that the reverse reaction—splitting of a ketene into carbene and CO ligands—has been explicitly observed.[3]



Our current studies on the reactivity of manganese alkynyl–carbene complexes[4] led us to investigate the structures of Mn *ketene* complexes. The present communication provides new insights into the dynamics of the latter species in solution.

The alkynylcarbene complex $RCp(CO)_2Mn{=}C(Ph)C{\equiv}CPh$ (**1**) was reacted with $Co_2(CO)_8$ and, after chromatographic workup, two new species were isolated (Scheme 1). The major product emerged as the cluster $RCpMnCo_2(CO)_6[\mu_3\text{-}\eta^4\text{-}CC(Ph){=}C(Ph)C(O)]$ (**3**), whose structure† exactly parallels that the known $CrCo_2(CO)_9[\mu_3\text{-}\eta^4\text{-}CC(Ph){=}C(OEt)C(O)]$, resulting from thermolysis of the parent group 6 alkynylcarbene complex $(CO)_5Cr[\mu_3\text{-}\eta^3\text{-}{=}C(OEt)C{\equiv}CPh]Co_2(CO)_6$.[5] This strongly suggests that **3** forms *via* the intermediacy of $RCp(CO)_2Mn[\mu_3\text{-}\eta^3\text{-}{=}C(Ph)C{\equiv}CPh]Co_2(CO)_6$ [**2**].



Scheme 1

The structure of the minor product, **4**, was established by X-ray diffraction for R = Me (Fig. 1),§ which revealed it to be a Mn–ketene complex whereby the ketene ligand bears a phenyl substituent and also a phenylalkynyl fragment bonded to a $Co_2(CO)_6$ unit. Without presupposing a mechanism for its formation, which is still to be established,¶ **4** derives from **1** by coordination of the alkyne moiety to a $Co_2(CO)_6$ unit and insertion of a carbonyl into the Mn=C linkage. The ketene adopts the so-called horizontal coordination mode,[6] as expected on electronic grounds.[7] This is evidenced by a value of 68.6° (ideal 90°) for the torsion angle {Cp-centroid}–{Mn}–{middle of C3–C10 vector}–{O3}. Metrical features around the Mn in **4a** are similar to those found in other $RCp(CO)_2Mn$(ketene) complexes.[2c,8]

Unexpectedly, the room temp. ^{13}C NMR spectrum of **4** recorded at 100 MHz showed only one signal in the region where carbonyls—in the broad sense of the term—are usually observed. This signal, observed at δ *ca.* 200, was characteristic only for the CO ligands attached to cobalt, and prompted us to investigate further the structure of **4** in solution. This was conveniently conducted on a ^{13}C-enriched sample of **4b** (R = H), synthesised from $Cp(^{13}CO)_2Mn{=}^{13}C(Ph)C{\equiv}CPh$ and $Co_2(CO)_8$. At 183 K, two additional sets of CO resonances become clearly observable (Fig. 2). The first set, centred at δ 228, is made up of two pairs of signals, C1′ and C2′, and C1″ and C2″, in a 58 : 42 ratio. The second set of signals, centred at δ 249 consists of two singlets, C3′ and C3″, also in a ratio of ~58 : 42. As the temperature is raised, coalescence of C3′ and C3″, C1′ and C2″, and C2′ and C1″ is observed. The C1′ and C2′, and C3′ signals can be attributed to the CO ligands, and to the carbonyl of the ketene ligand, respectively, within one diastereomer of **4b**. The double-primed signals are assigned to the corresponding carbon atoms of the other diastereomer. The fluxional process that permutes C3′ with C3″, C1′ with C2″, and

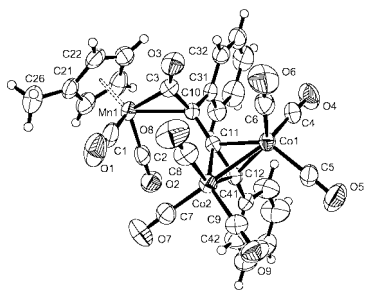


Fig. 1 A perspective view of the complex $MeCp(CO)_2Mn[\mu_3\text{-}\eta^4\text{-}O{=}C{=}C(Ph)C{\equiv}CPh]Co_2(CO)_6$ (**4a**).

 DOI: 10.1039/b109218a

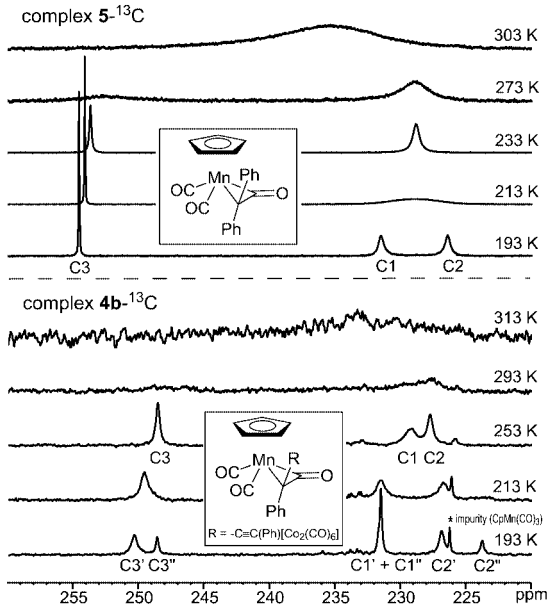

Fig. 2 Selected sections of the ^{13}C NMR spectra (CD_2Cl_2, 100 MHz) of ^{13}C-enriched samples of complexes **4b**-^{13}C (bottom) and **5**-^{13}C (top).

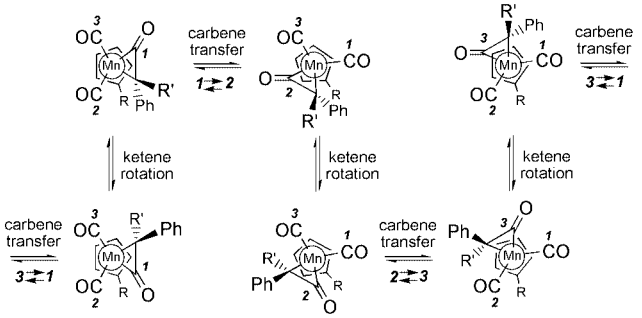
C2′ with C1″ can thus be interpreted in terms of a rapid rotation (NMR time-scale) of the ketene around an axis joining the Mn to the middle of C3–C10 bond. The coalescence behaviour of the C3′/C3″ resonances (and also of the Cp rings within the two diastereomers) led to an energy activation barrier of approximately 10 kcal mol^{-1} for this rotation process. At this stage, it is worth noting that the relative intensity of the C3 signal *vs.* the C1/C2 resonances clearly indicates that ^{13}C has been incorporated into the carbonyl function of the ketene. Above 253 K, the C1, C2 and C3 signals rapidly collapse to give an extremely broad signal located at δ *ca.* 236 ppm at 308 K,‖ suggesting a second type of dynamic exchange now involving the CO ligands attached to Mn *and* the carbonyl of the ketene ligand. This was clearly authenticated by spin saturation transfer experiments between the C1/C2 site and the C3 site.

Suspecting that the above process was more general, we reinvestigated the structure of a ^{13}C-enriched sample of $Cp(^{13}CO)_2Mn(O{=}^{13}C{=}CPh_2)$ (**5**-^{13}C)[8a,9] in solution. Clearly, the variable-temperature ^{13}C NMR spectra show initial coalescence of the CO ligands (C1 and C2) attributable to the rapid ketene rotation, and subsequent coalescence of the CO ligands and the ketene carbonyl (C3) (Fig. 2). The barriers were evaluated as 8.3 kcal mol^{-1} for the ketene rotation, and 12.2 kcal mol^{-1} for the second process. In addition, the J_{CC} value between C3 and the adjacent atom, C10, was found in **5** to be 52 ± 2 Hz at 203 K and 15 ± 2 Hz at 303 K; these data clearly establish the strictly intramolecular nature of the overall exchange process.

Many years ago, Redhouse and Herrmann[8a] did detect a dynamic phenomenon within complex **5** but, with the low-field NMR instrumentation then available, they were unable to observe a limiting low-temperature spectrum. Nor could they detect the ketene carbonyl at δ 254.5 which, unbeknownst to them, was also participating in a fluxional process.

The observation of a dynamic exchange process between the CO ligands and the carbonyl of the ketene in complexes **4** and **5** can be interpreted in terms of rapid transfer (NMR time-scale) of the carbene fragment CPh(R′), where R′ = C≡CPh[$Co_2(CO)_6$] (**4**) or Ph (**5**), over the carbonyl ligands. Scheme 2 intends to illustrate, in a sequential manner, how combinations of ketene rotations and carbene transfers would indeed allow *all three* carbonyls to exchange. Interestingly, we note that for **4b**, when the temperature is raised, the C1 and C2 sites broaden at different rates (see for example Fig. 2, 253 K spectrum). This is likely a consequence of a slight difference in the rate of carbene transfer within each of the diastereomers of **4b** (***1*** ⇆ ***2*** *vs.* ***2*** ⇆ ***3*** in Scheme 2, for instance).



Scheme 2

The carbene transfer could proceed *via* (reversible) cleavage of the ketene into carbene and CO ligands on the Mn centre, as in Grotjahn's Ir system.[3] However, the intramolecular character of the current process would imply the formation of a 20-electron transient species. Alternatively, we suggest that the carbene migration could occur *via* the intermediacy of a 16-electron metallocyclobutan-1,3-dione.

In conclusion, the present observations bring further support to the view of manganese carbonyl ketene complexes as highly fluxional molecules. They are engaged in two independent dynamic processes, which result in the scrambling of the carbene moiety over the three carbonyl ligands.

The final $wR(F^2)$ was 0.0565 (all data). CCDC reference numbers 172720 and 172721. See http://www.rsc.org/suppdata/cc/b1/b109218a/ for crystallographic data in CIF or other electronic format.

¶ Complex **4** can be regarded as the result of the insertion of CO into the Mn=C bond of [**2**]. Yet, when **1a** was reacted with $Co_2(CO)_8$ under CO (4 bars, no significant change in the yield of **4a** was observed. Alternatively, carbene transfer from [**2**] to traces of $MeCpMn(CO)_3$ could also have resulted in the formation of **4a**. Such a mechanism has been demonstrated in a specific case,[8b] but does not apply here since treatment of **1a** by $Co_2(CO)_8$ in the presence of $Cp(CO)_3Mn$ produced exclusively **4a**, with no trace of **4b**. At present, we incline to the view that CO insertion proceeds intramolecularly following the initial replacement of a carbonyl ligand in $Co_2(CO)_8$ by the alkynyl unit in **1**. Thus, formation of [**2**] (and then **3**) may in fact compete with that of **4**.

‖ Attempts to record data at higher temperature (in toluene-d_8) became problematic because of partial decomposition during acquisition.

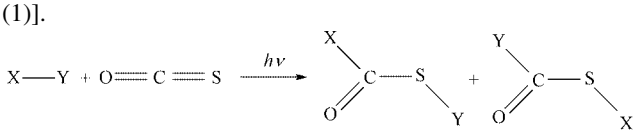
Received (in Purdue, IN, USA) 10th September 2001, Accepted 29th October 2001
First published as an Advance Article on the web 20th November 2001

The novel (bromocarbonyl)sulfenyl bromide, BrC(O)SBr, is formed by the photochemical reaction between Br_2 and OCS isolated together in an Ar matrix at 15 K.

In the interpretation of the IR spectra of argon matrices containing *syn*-(chlorocarbonyl)sulfenyl bromide, ClC(O)SBr,[1] we proposed several pathways to explain the rich photochemistry of this compound. The photodecomposition of the compound follows apparently two distinct reaction channels, one leading to CO and BrSCl, and the other to OCS and BrCl. One of the ensuing pathways we proposed involves the addition of the interhalogen product BrCl to the OCS molecule either to regenerate ClC(O)SBr or to form the constitutional isomer BrC(O)SCl. To test this proposed mechanism, the following general matrix reaction is currently under investigation [eqn. (1)].



with X, Y = halogen, H (1)

In the case of X = Y = Br, the hypothetical product, BrC(O)SBr, is hitherto unknown. Attempts to prepare it by chemical reactions in different conditions, including low temperatures and from different precursors, failed. This route appears then as a useful way of preparing novel species, and especially those that are short-lived under normal conditions.

In the experiments described here, we have explored the photochemically induced matrix reaction between Br_2 and OCS. Different proportions of gaseous Br_2 and OCS were mixed with an excess of Ar by standard manometric techniques. The gas mixtures were deposited on a cooled CsI window using the pulsed deposition technique,[2,3] and irradiated with broad-band UV-visible light. The reaction was followed by analysis of the FTIR spectrum of the matrix. The experimental arrangements are described elsewhere.[1]

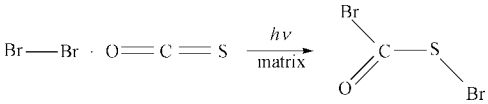
Before irradiation of the matrix, only signals corresponding to the OCS molecule are present in the IR spectrum. These are entirely consistent with results reported previously.[4] Photolysis of the matrix using broad-band UV-visible radiation ($200 \leq \lambda \leq 800$ nm) was observed to produce a decay of the bands associated with the OCS, accompanied by the simultaneous appearance and growth of new absorptions near 2138, 1800, 758, 555, 528, 433, and 418 cm^{-1}. The band near 2138 cm^{-1} is readily identifiable with the formation of free CO,[5] in accordance with the photochemical behavior found previously for OCS under UV light [eqn. (2)]:[4]

(2)

It was suggested in the study of the matrix photochemistry of ClC(O)SBr that the S atoms in the excited ^1D state react with BrCl to form BrSCl. So, too, in the present study, we note the formation of the SBr_2 molecule, identifiable by its IR band near 418 cm^{-1},[6] and formed presumably *via* eqn. (3):

(3)

We can then assign the other four bands that appeared after broad-band UV-visible irradiation of the matrix to the hitherto unknown compound (bromocarbonyl)sulfenyl bromide, BrC(O)SBr, formed in accordance with the general reaction (1), or more specifically in this case with eqn. (4):



(4)

Thus, the strong absorption near 1800 cm^{-1} is most plausibly identified with a ν(C=O) fundamental of such a compound, and the weaker absorption near 434 cm^{-1} shows a closely spaced doublet pattern highly suggestive of a ν(S–Br) fundamental.[1]

The identity of the new molecule has been confirmed (i) by comparison with the results of density functional theory (DFT) calculations, (ii) by the isotopic shifts due to the naturally occurring atomic pair $^{79}Br/^{81}Br$, and (iii) by reference to the properties of related molecules.[1]

The theoretical calculations were performed using the GAUSSIAN 98 program package[7] under the LINDA parallel execution environment. First, the relative stabilities of the two possible conformational isomers of the BrC(O)SBr molecule, *syn* and *anti*, were investigated. The structures of these two planar forms were fully optimized using different theoretical methods (MP2 and B3LYP) with the 6-31+G* basis set. Both models predict the *syn* form to be more stable than the *anti* one, in agreement with all the available experimental and theoretical evidence regarding the conformational properties of the carbonyl sulfenyl compounds.[1,8–11]

The IR spectra for both conformers of BrC(O)SBr were simulated by the different methods. By comparison of the experimental spectrum with those predicted for the two conformers, we are left in no doubt that the matrix reaction produces not the *anti* but only the *syn* form. Table 1 lists the

		95.0		τ

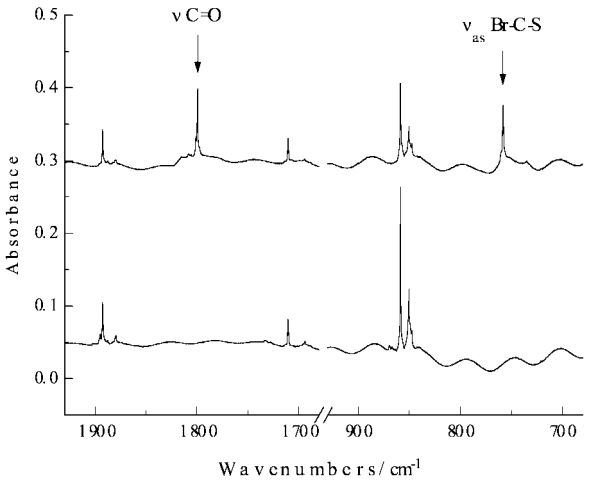

Fig. 1 FTIR spectra of an Ar matrix formed by co-deposition of a gaseous mixture of Br_2, OCS and Ar (10:5:1000) before (bottom) and after (top) photolysis with broad-band UV-visible light ($200 \leq \lambda \leq 800$) for 6 h. The arrows mark bands due to BrC(O)SBr.

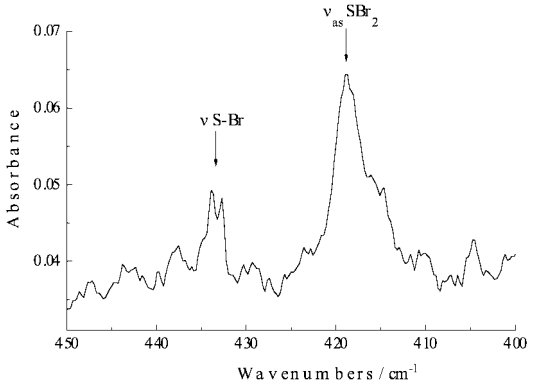

Fig. 2 FTIR spectrum of an Ar matrix formed by co-deposition of a gaseous mixture of Br_2, OCS and Ar (10:5:1000) after photolysis with broad-band UV-visible light ($200 \leq \lambda \leq 800$) for 6 h.

experimental wavenumbers and intensities of the product formed after 6 h of broad-band UV-visible irradiation of the Ar-matrix formed by co-deposition of a gaseous mixture of Br_2, OCS and Ar (10:5:1000), together with the calculated values obtained with the density functional theory method B3LYP/6-31+G*. The assignment of the vibrational modes is also included in the Table.

The excellent agreement between the experimental and simulated spectra thus enables us to confirm the identity of the product. Fig. 1 shows the FTIR spectra of the matrix before and after photolysis in the region where the most intense bands of BrC(O)SBr appeared. The experimental isotopic shift of 1.1 cm^{-1} for the ν(S–Br) band (Fig. 2) is also matched exactly by the predicted one.

Hence the present work confirms that dihalogen molecules react with OCS under matrix conditions [eqn. (1)] as first proposed to account for the matrix photochemistry of ClC(O)SBr, and introduces a novel route to carbonyl sulfenyl compounds.

Chemical Resources Laboratory, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama, 226-8503, Japan. E-mail: tikeda@res.titech.ac.jp

Received (in Cambridge, UK) 16th October 2001, Accepted 9th November 2001
First published as an Advance Article on the web 30th November 2001

Gold nanoparticles covered with a liquid-crystalline compound were successfully prepared, exhibiting characteristic double-melting behaviour.

Liquid crystals are attractive materials, since they show unique properties, such as long-range order, cooperative effects and an anisotropic nature in optical and electronic properties, based on a self-organizing nature in a certain temperature range with fluidity.[1] Furthermore, their phase structures and molecular orientations can be controlled easily and quickly by means of various external stimuli.

These dynamic properties of liquid crystals enable us to apply liquid crystals not only to liquid crystal displays but also to various applications. For example, liquid-crystalline materials containing photocromic moieties are employed in photonic applications,[2] such as optical switching and optical storage based on photochemical phase transitions of liquid crystals.[3] Furthermore, by using the self-organizing nature of liquid crystals, highly ordered structures that are difficult to prepare by other methods are constructed. For example, tetraalkylonium salts $[(C_nH_{2n+1})_2(CH_3)_2HetCl]$ (n = 10, 14, 18; Het = N, P)[4] and their metal complex salts[5] $[(C_{18}H_{37})_2(CH_3)_2N]_2[MCl_4]$ (M = Co, Ni, Cu, Zn, Cd) that exhibit thermotropic liquid-crystalline behaviour, were confirmed to form a layered self-assembly built up from alternating layers of various ions and alkyl segments in a smectic phase.

Recently, metal nanoclusters have attracted a great deal of interest since they show unusual properties compared to the bulk metals.[6] Especially, alkanethiolate-protected metal clusters (MPCs)[7] are promising materials, since they can be handled in a similar manner as general organic compounds due to their high stability to light and air, and solubility in conventional organic solvents. Until now, various types of MPCs have been reported and their potential as functional materials have been studied.[8] On the other hand, since the properties of metal nanocluster aggregates is affected by their morphology, various attempts to control their morphology have been performed by means of physical[9] and chemical[10] processes. Now, a control method with reversible and simple processes is desired.

By providing metal nanoclusters with liquid-crystalline properties, we could introduce the self-assembling ability and the reversible control of morphology of their aggregates by external stimuli, as well as the control of their properties by a simple and solvent-free method. The reversible control of the properties of metal nanocluster aggregates will cultivate their potential as functional nanomaterials. In this communication, as a first step, we report the preparation of gold nanoparticles covered with a liquid-crystalline compound *via* a strong gold–sulfur chemical bond, and its characteristic thermodynamic behaviour. The thiol derivative, 10-[(*trans*-(4-pentylcyclohexyl)phenoxy)] decane-1-thiol (5CP10SH, Fig. 1) was synthesized from *p-trans*-(pentylcyclohexyl)phenol (Kanto Chemical Co., Inc. Tokyo, Japan).† 5CP10SH exhibited monotropic liquid-crystalline behaviour showing a nematic phase (43–34 °C) and a smectic phase (34–21 °C) on cooling. Gold nanoparticles covered with 5CP10SH (5CP10MPC) were prepared in toluene by a two-phase reaction analogous to that reported by Brust *et al*.[7] Tetra-*n*-octylammonium bromide was used as a phase transfer reagent, and tetrachloroaurate(III) ion was reduced to Au(0) with sodium borohydride in the presence of 5CP10SH in toluene (feed mole ratio, $AuCl_4^-$: 5CP10SH = 1 : 1). 5CP10MPC was washed with ethanol and acetone several times and dried *in vacuo*. 5CP10MPC was obtained as a black powder, and could be redispersed readily in nonpolar solvents such as chloroform, benzene and hexane. The reduction of tetrachloroaurate(III) ion to Au(0) was confirmed by the appearance of a surface plasmon absorption band at around 510 nm in a UV–VIS absorption spectrum measured in chloroform.

The purity of the gold nanoparticles were confirmed by ^{1}H NMR and thin-layer chromatography (TLC: silica gel plate, mobile phase: chloroform). Fig. 2 shows the ^{1}H NMR spectra of 5CP10SH (a) and 5CP10MPC (b) in $CDCl_3$.

In Fig. 1(b), a proton signal around 2.6 ppm, which can be assigned to α-protons (CH_2SH), disappeared and the broadening of all proton signals was observed. The disappearance of α-protons indicates the formation of a gold–sulfur bonds, and the broadening of the proton signals demonstrates that all 5CP10SH molecules are covalently linked to the gold surface,[11] *i.e.* there are no parent 5CP10SH molecules remaining in 5CP10MPC; TLC supported this result.

The mean diameter of 5CP10MPC was determined to be *ca.* 3 nm by TEM (JOEL JEM-2010F) measurement. Elemental analysis of 5CP10MPC gave C: 29.6%, H: 4.3%, S: 2.9%, Au: 66.3%. The content of gold was estimated from that of the ash. From the elemental analysis result, the composition ratio of 5CP10MPC was estimated as Au : 5CP10S– = 3.4 : 1. To evaluate the mean composition of the gold nanoparticle, we assumed a model with a 3.0 nm diameter for the gold

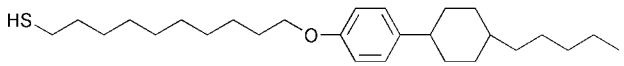

Fig. 1 Chemical structure of 5CP10SH.

 DOI: 10.1039/b108909a

nanosphere. Taking the gold core as a sphere with density ρ_{Au} (58.01 atoms nm^{-3})[12] covered with an outermost layer of hexagonally close-packed gold atoms (13.89 atoms nm^{-2})[12] with a radius of $R_{CORE} - R_{Au}$ (R_{Au} = 0.145 nm), the model predicts that the core contains about 920 Au atoms, of which 320 atoms lie on the surface. Furthermore, from the result of the elemental analysis, there are 270 of 5CP10S– moieties at the surface of the 3.0 nm gold sphere ($Au_{920}(5CP10S–)_{270}$). From this result, 5CP10S– moieties are very closely packed and form a highly ordered monolayer at the surface of 5CP10MPC.

Next, we examined the thermodynamic behaviour of 5CP10MPC by differential scanning calorimetry (DSC; Seiko I&E SSC-5200 and DSC220C). Fig. 3 shows DSC thermograms of bulk 5CP10SH (a) and 5CP10MPC (b). 5CP10MPC exhibited double phase transition behaviour on heating (74 and 114 °C) and cooling (77 and 110 °C) and showed a mesoscopic phase. The thermodynamic behaviour of 5CP10MPC was quite different from that of bulk 5CP10SH. The phase transition temperatures of 5CP10MPC were high and the mesomorphic phase temperature regions were wide compared with those of 5CP10SH. Since this phase transition behaviour occurred reversibly, we judged these exo- and endo-thermic responses as not due to thermal decomposition of 5CP10MPC (for example, cleavage of the S–Au bond), but to a phase transition of the 5CP10S– moieties at the gold nanoparticle surface. As a reference, we performed DSC measurement of a bare gold nanoparticle.‡ The bare gold nanoparticle exhibited no exo- or endo-thermic response within this temperature region. Badia *et al*. reported thermodynamic behaviour of gold nanoparticles covered with various length alkanethiols (C_{12}, C_{14}, C_{16}, C_{18}, C_{20}).[13] All gold nanoparticles exhibited single phase transition behaviour assigned as an order to disorder phase transition of the alkanethiolate monolayer at the gold nanoparticle surfaces. Furthermore, the 5CP10MPC showed fluidity at the mesophase and optically isotropic state as evidenced by polarizing microscopy.

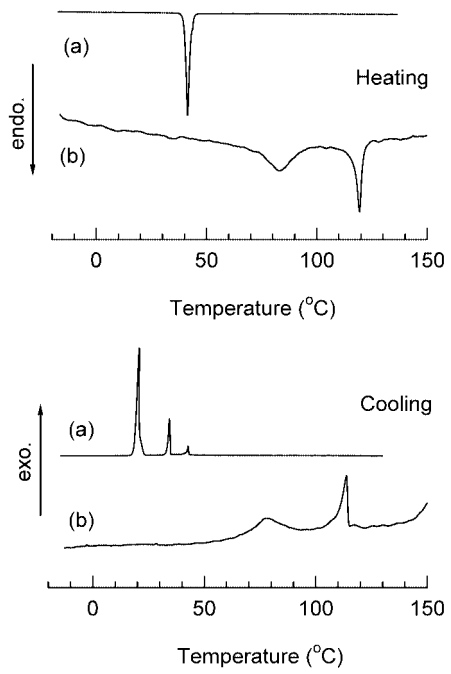

Fig. 3 DSC thermograms of (a) 5CP10SH and (b) 5CP10MPC (scan rate: 5 °C min^{-1}).

The mesomorphic behaviour of the gold nanoparticle indicates the appearance of interaction (cooperative motion) between mesogens at the surface of different gold nanoparticles. By using the mesomorphic behaviour of gold nanoparticles, it might be possible to induce morphological change (interparticle separate, lattice structure *etc*.) of their aggregates. Further detailed studies on the phase transition mechanism of mesogens at the surface of gold nanoparticles and morphological changes of the gold nanoparticle aggregates are in progress.

We thank Professor T. Shiono, Professor H. Kitano and Dr A. Shishido for their useful suggestions and discussions.

ITQ-18 a new delaminated stable zeolite

A. Corma,* V. Fornés and U. Díaz

Instituto de Tecnología Química, UPV-CSIC, Universidad Politécnica de Valencia, Avenida de los Naranjos s/n., 46022 Valencia, Spain. E-mail: acorma@itq.upv.es

Received (in Cambridge, UK) 26th September 2001, Accepted 7th November 2001
First published as an Advance Article on the web 30th November 2001

A new delaminated zeolitic material ITQ-18 has been obtained by expanding and exfoliating a laminar precursor of NU-6 (2); while NU-6 (2) has an N_2 surface area of 35 $m^2\ g^{-1}$ and contains bridging hydroxy groups which are in accessible to pyridine, the ITQ-18 sample prepared has an a external surface area of 588 $m^2\ g^{-1}$ with all bridging hydroxy groups being acidic and accessible to pyridine.

One of the most interesting features of zeolites as catalysts is the control of selectivity due to the regular dimensions of the pores and cavities of the structure that introduces the well known shape selectivity effects. However, there are a large number of potential applications that involve the conversion of molecules with a kinetic diameter much larger than the pore dimensions of current zeolites. Thus, in catalytic reactions such as, for instance, hydrocracking of vacuum gas-oil or waxes, the pores of the zeolite catalysts introduce an undesirable shape selectivity effect that directs towards naphtha and gases instead of to diesel and lubes that would be the preferred product. In the field of fine chemicals, products much bulkier than reactants are formed and, in some cases, they remain occluded in the zeolite, blocking the pores and deactivating the catalyst. In the cases described above one can minimize the diffusion limitations by increasing the ratio of the external to the internal surface of the catalyst. This can be done with zeolites by synthesizing small crystallites[1] in which the number of external active sites accessible to large molecules is increased and the activity for the above mentioned reactions is enhanced.[2] Advances have been made in the last decade to produce zeolite crystals of < 10 nm size[3,4] but, up to now, this has been achieved only in a limited number of structures and, in most cases, the yields of the synthesis is low.

A second option for reacting large molecules would involve the preparation of mesoporous molecular sieves, with pore diameters in the range 3–10 nm, which allow the diffusion of bulky reactants and products in and out of the pores. A certain success has been attained for acid and redox catalysis by working with MS-14 materials of which MCM-41 is an example. However, these materials do not show short–range order and, consequently, from the point of view of the stability and catalytic behaviour, they are closer to amorphous than to zeolitic materials. More specifically, the MCM-41 aluminosilicates prepared for acid catalysis show similar catalytic behaviour to amorphous silica-alumina owing to the weak Brönsted acidities generated.[5]

It would be thus of fundamental and practical interest to synthesize zeolitic materials with strong acid sites, allowing the access of large molecules with fast desorption and diffusion of the products to the gas stream. These types of materials should combine the good thermal and hydrothermal stability of zeolites with active sites of zeolitic nature easily accessible to reactants. With these objectives in mind we have developed a series of zeolitic materials the preparation of which involves the delamination of lamellar precursors of zeolites. By this preparation procedure one can obtain, at the limit, single crystalline sheets of zeolitic nature in where all the catalytic active sites are accessible through the external surface.[6] In this way, two new materials ITQ-2[7] and ITQ-6[8] have so far been obtained from lamellar precursors of MCM-22 and ferrierite structures, respectively. These materials showed external surface areas above 600 $m^2\ g^{-1}$ with strong acid sites of zeolitic nature that were active for catalysing reactions[9] for which the corresponding zeolites were strongly limited by the pore dimensions.

Here we report on a new delaminated material denoted ITQ-18 the structure of which is still unknown but which presents a very large external surfaces area with accessible Brönsted acid sites of zeolitic nature.

It has been reported[10] that the synthesis of Nu-6(2) zeolite occurred by calcination of a lamellar precursor [Nu-6(1)], that could also be pillared.[11] The structure of Nu-6(2) is still unknown but the BET area of this zeolite is 79 $m^2\ g^{-1}$ indicating that either the diameter of the pores is very small or the channels are partially blocked, making this zeolite of no use for practical applications. However, if the structure could be delaminated, then the active sites would be made accessible to reactants making this zeolite useful as a catalyst.

The lamellar precursor Nu-6(1) was synthesized as follows: (a) 1.82 g of 4,4′-bipyridine (Fluka, 98% purity) were dissolved in 10.08 g of ethanol (J.T.Baker) to give solution A; (b) 20.06 g

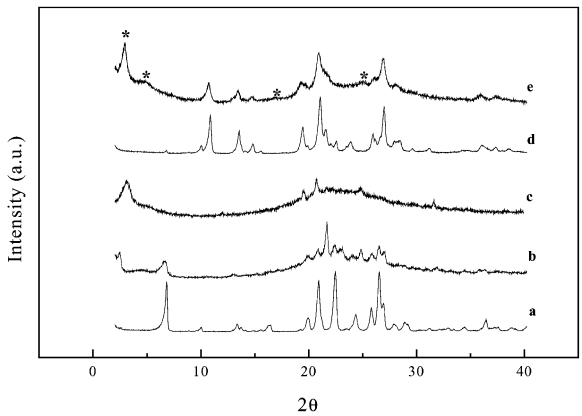

Fig. 1 X-Ray diffraction patterns of (a) as synthesized Nu-6(1), (b) expanded material ($CTMA^+$), (c) expanded material ($DTMA^+$), (d) collapsed material [Nu-6(2)] and (e) ITQ-18.

 DOI: 10.1039/b108777k

Table 1 Textural characteristics

Sample	S_{BET}/m² g⁻¹	S_{MIC}/m² g⁻¹	S_{EXT}/m² g⁻¹	V_{TOT}/cm³ g⁻¹	V_{MIC}/cm³ g⁻¹	V_{BJH}/cm³ g⁻¹
Nu-6(2)	79	44	35	0.1116	0.0220	0.0232
ITQ-18	611	23	588	0.5818	0.0120	0.4147

of sodium silicate (Merck, 8.02% Na_2O, 24.92% SiO_2, 67.05% H_2O) were diluted with 13.38 g of MiliQ deionized water to give solution B; (c) 0.62 g of aluminium sulfate [Merck, 51.34% $Al_2(SO_4)_3$, 48.66% H_2O] and 1.52 g of sulfuric acid (Ridel den Häggen, 98% purity) were dissolved in 22.78 g of MiliQ deionized water to give solution C. Then solution B was stirred into solution A followed by solution C. The mixture was reacted in a stirred stainless steel autoclave for 3 days at 135 °C. The resulting product was filtered off and washed three times with distilled water.

Before drying, the lamellar precursor was expanded using a quaternary alkylammonium hydroxide at pH = 12. The X-ray diffraction pattern of the starting material as well as those of the expanded materials are given in Fig. 1 (a), (b) and (c). It can be seen that cetyltrimethylammonium ($CTMA^+$) was incorporated between the layers giving a new diffraction peak at 2θ = 2.3°corresponding to a basal spacing of the swelled zeolite of *ca*. 4.0 nm [Fig. 1(b)]. Since the basal spacing of the collapsed material [Nu-6(2)] is 0.84 nm [Fig. 1(d)] we could assume that the individual sheets of the zeolite should be *ca*. 0.8–0.9 nm thick and, if this is so, then the interlaminar space of the expanded material should be 3.0 nm which roughly corresponds to two layers of CTMAOH. When this molecule was used as swelling agent, not all layers were expanded as can be deduced from the peak appearing at 2θ = 6.5° in Fig. 1(b). However, when decyltrimethylammonium ($DTMA^+$) cation was exchanged all the peaks associated with the non-expanded material disappeared and the basal spacing of the swollen zeolite was 2.85 nm indicating that the $DTMA^+$ has intercalated all the layers [Fig. 1(c)].

The expanded material was then washed thoroughly with water and a suspension with an excess of water was sonicated (50 W, 40 KHz) for 1 h until delamination of the zeolite occured. Finally, calcination at 853 K gave ITQ-18 the XRD pattern of which is shown in Fig. 1(e).

From the results presented so far, and taking into account the fact that the structure of Nu-6 zeolite is unknown and the expected poor quality of XRD spectra of a delaminated material,[6] it is necessary to confirm the delaminated character of ITQ-18 from other physicochemical properties.

Assuming that ITQ-18 is formed mainly by individual sheets of Nu6 zeolite, this should present a high number of terminal silanol groups. Thus, the ^{29}Si NMR spectrum should show an evident increase of the Q^3/Q^4 ratio corresponding to Si(3SiOH) and Si(4Si) units, respectively. This was indeed observed and also confirmed by IR spectroscopy. Fig. 2, which compares the spectra of ITQ-18 and Nu6(2) in the framework region, shows a large increase of the band at 960 cm^{-1} ascribed to terminal $\equiv SiO^-$ groups, formed upon delamination. It is noted that the ITQ-18 retains the IR bands at 540 and 580 cm^{-1} characteristic of the zeolitic structure, which is consistent with the presence of single sheets in which short range order is retained.

As an important consequence of delamination one should expect a very large increase of external surface area accompanied by a strong decrease in microporosity. Indeed, N_2 isotherms show (see Table 1) that while the external surface area of the zeolite Nu6(2) prepared here is only 35 $m^2\ g^{-1}$, that of the delaminated ITQ-18 material is 588 $m^2\ g^{-1}$, which is about 16 times larger. Meanwhile, the microporosity of ITQ-18 is practically negligible.

Summarizing, we can conclude that all the results from physicochemical characterization are in accord with the assumed structure of ITQ-18 being formed by individual sheets of zeolite.

In order to obtain acid catalysts, the precursor Nu6(1) was synthesized in the form of aluminosilicate with Si/Al ratio of 45.

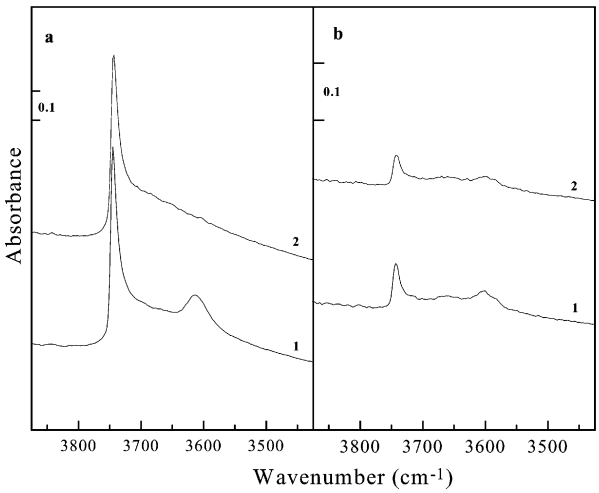

Fig. 3 IR spectra in the OH range for (a) ITQ-18 and (b) Nu-6, before (1) and after (2) pyridine adsorption.

The ^{27}Al MAS NMR spectrum (spectrum not shown) shows the presence of Al^{IV} indicating that, indeed, aluminium was incorporated into the framework of the precursor. After delamination and calcination Al remains in the framework leading to Brönsted acid sites, and the IR spectra in the hydroxy region (Fig. 3) shows a band at 3610 cm^{-1} in both ITQ-18 [Fig.3 (a1)] and, Nu6(2) [Fig.3 (b1)] which corresponds to bridging hydroxy groups that should be acidic. To confirm this assumption pyridine was adsorbed on both materials and it was found that while a negligible amount of the bridging OH groups in Nu6(2) [Fig. 3(b2)] interacted with the probe molecule, confirming the inaccessibility of the micropores of this zeolite, all bridging OH groups in ITQ-18 are accessible to pyridine [Fig. 3(a2)]. In summary, by performing the delamination of a laminar precursor of the Nu-6(2) zeolite, ITQ-18 was obtained which is stable upon calcination, has a very large external surface area, and has an substantial quantity of strong Brönsted acid sites all of which are accessible to pyridine. We should expect ITQ-18 to be active for carrying out acid catalysed reactions.

Financial support by the Spanish MAT2000-1392 is gratefully acknowledged while U. D. thanks the M.E.C. for a doctoral fellowship.

First published as an Advance Article on the web 30th November 2001

Solventothermal reactions of nickel acetate tetrahydrate with 1,2-dicyanobenzene in methanol and ethanol yield novel complexes in which nickel atoms are coordinated by modified phthalocyanine ligands with inner rings bearing methoxy and ethoxy substituents, respectively.

Phthalocyanine compounds and related derivatives have long defined an area of great interest, owing in large part to technological applications deriving from their unique optical, electronic, photochemical, and magnetic properties.[1] Although a large number of metal–phthalocyanine complexes have been synthesized and studied, reports of substituted phthalocyanines that have been fully structurally characterized by X-ray methods have remained relatively scarce.[2–14] To our knowledge, only four examples of structurally characterized phthalocyanine complexes in which the inner ring of the ligand has been modified from the parent phthalocyanine have been reported.[3,6,7,12]

We now report the syntheses and X-ray crystal structures of two new nickel phthalocyanine derivatives in which the ligands have been modified by incorporation of alkoxy groups into the inner ring. The syntheses of these products have been accomplished through adaptation of a standard metal–phthalocyanine synthetic procedure that involves reaction of a metal source with phthalodinitrile (1,2-dicyanobenzene) or a derivative thereof. Specifically, we have carried out reactions of nickel acetate tetrahydrate and 1,2-dicyanobenzene in alcohols under very mild solventothermal conditions, resulting in moderate yields of red-orange block-shaped crystals. The reaction in methanol for 6.5 days at 70 °C affords a 36% yield (based upon starting nickel acetate tetrahydrate) of {14, 28-$(CH_3O)_2$Pc}Ni·CH_3OH **1**.† Reaction in ethanol for four days at 90 °C results in a 27% yield (based upon starting nickel acetate tetrahydrate) of {14, 28-$(CH_3CH_2O)_2$Pc}Ni **2**.† These reactions are represented in Scheme 1. In both cases, byproducts include unmodified PcNi, identified on the basis of its IR spectrum, and other unidentified materials. Compound **1** is sparingly soluble in methanol and soluble in toluene, while **2** is very sparingly soluble in ethanol, and moderately soluble in toluene.

Attempts to increase the yield of **1** or **2** by either running the reaction at a higher temperature or for a longer period of time result instead in the formation of increased amounts of the unmodified phthalocyaninato nickel complex. We have observed that the heating of authentic samples of **1** or **2** under conditions similar to those at which they are synthesized (70 °C for **1** and 90 °C for **2**) for periods of time similar to those employed in their syntheses results in partial decomposition of the modified complexes to the blue unmodified complex. This suggests to us that that the formation of the unmodified complex during the syntheses of **1** and **2** probably occurs *via* decomposition of the modified complexes, rather than by a separate competing reaction pathway. Based upon this result, and upon the separate observation that no reaction is apparent upon heating of unsubstituted (phthalocyaninato)nickel(II) in methanol or ethanol at temperatures equivalent to or in excess of those employed in the synthesis of **1** and **2**, we conclude that modification of the phthalocyanine ligands in these species occurs as they form, rather than *following* the formation of an unsubstituted phthalocyanine. The observation that both **1** and **2** can be isolated and then partially converted to unmodified phthalocyaninato nickel(II) amounts to the first definitive structural characterization of isolable intermediates in the preparative reaction of the unmodified complex in the presence of alcohol solvent. The mechanism(s) of this process have been an important issue in the literature for several decades.[15] Studies aimed at determining the time and temperature required for complete conversion of **1** and **2** to unmodified phthalocyaninato nickel(II) are ongoing.

$$Ni(CH_3COO)_2{\cdot}4H_2O + 1,2\text{-}(CN)_2C_6H_4 \xrightarrow{ROH} 14,\ 28\text{-}(RO)_2PcNi + \text{byproducts}$$

2: R = CH_3CH_2, 90 °C reaction temp.

Scheme 1

Compounds **1** and **2** are isostructural and crystallize as large red–orange triclinic blocks.‡ The salient feature in the molecular structures of both **1** and **2** is the presence of alkoxy groups on the 14 and 28 positions on the phthalocyanine macrocycles. As a result, two sp^3-hybridized carbon atoms are present in the ligands and the planarity seen in unmodified Pc is removed. These compounds are the first characterized examples with this structural motif. Fig. 1 shows the crystallographic numbering system employed for both compounds. Thermal ellipsoid plots of **1** and **2** are shown in Figs. 2 and 3, respectively. Fig. 2 shows a 'top view' of **1**, while Fig. 3 is a 'side view' of **2**, highlighting the saddle shape of the ligand.

The saddle shape seen in both modified Pc ligands is more pronounced in **2**, almost certainly owing to the increased steric

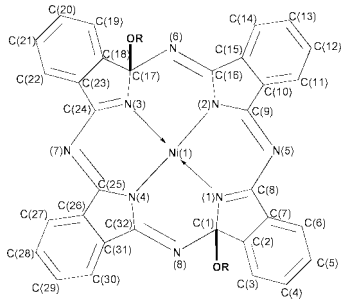

Fig. 1 Line drawing showing the crystallographic numbering system used in **1** and **2** and the positions of the alkoxy groups in both compounds.

† Electronic supplementary information (ESI) available: synthesis and spectroscopic characterization of **1** and **2**. See http://www.rsc.org/suppdata/cc/b1/b109481p/

 DOI: 10.1039/b109481p

bulk of the ethoxy group. We are unsure of the reason **1** and **2** adopt this structure instead of other possibilities that would also serve to accommodate the two alkoxy groups and sp^3-hybridized carbon atoms of the macrocycle. Syntheses of a series of similar compounds and determination of their structures will likely help to answer this question. It is conceivable that other structural motifs may be seen in analogues of **1** and **2**.

The outer rings of the ligands in **1** and **2** show no remarkable features other than the aforementioned overall deviation of the entire ligand from planarity. The bond lengths and angles around the alkoxy-substituted carbon atoms in **1** and **2** are as would be expected for single bonds and sp^3 hybridization of these atoms. All other carbon and nitrogen atoms in **1** and **2**, excepting those in the alkoxy groups, exhibit bond lengths and angles indicative of conjugated double bonds and sp^2 hybridization. The nickel atoms in both **1** and **2** are coordinated in a nearly square planar fashion by four nitrogen atoms. In both cases, two of the Ni–N bonds, on opposite sides of the Ni atom, are longer than the other two Ni–N bonds. In the crystal structure of **1**, one methanol solvate donates a hydrogen bond to a peripheral nitrogen atom in each molecule of the complex, while **2** is free of solvation.

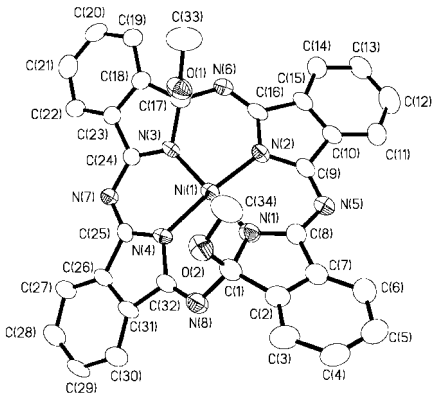

Fig. 2 The crystallographically determined structure, excluding hydrogen atoms and solvated methanol, for **1**. Ellipsoids are drawn at the 50% probability level. Selected bond lengths (Å) and angles (°): Ni(1)–N(1) 1.845(4), Ni(1)–N(2) 1.867(4), Ni(1)–N(3) 1.836(4), Ni(1)–N(4) 1.862(4), C(1)–O(2) 1.418(7), C(1)–C(2) 1.518(8), C(1)–N(8) 1.466(7), C(1)–N(1) 1.472(7), C(17)–O(1) 1.426(7), C(17)–C(18) 1.507(8), C(17)–N(3) 1.479(7), C(17)–N(6) 1.444(7), N(1)–C(8) 1.307(7), N(3)–C(24) 1.309(6); N(1)–Ni(1)–N(2) 89.9(2), N(2)–Ni(1)–N(3) 90.8(2), N(3)–Ni(1)–N(4) 90.5(2), N(4)–Ni(1)–N(1) 90.4(2), C(2)–C(1)–N(8) 112.1(5), C(2)–C(1)–N(1) 103.2(5), N(1)–C(1)–N(8) 112.6(5), N(1)–C(1)–O(2) 111.1(5), C(2)–C(1)–O(2) 114.3(5), N(8)–C(1)–O(2) 103.8(4), N(3)–C(17)–C(18) 103.2(4), N(6)–C(17)–C(18) 112.9(4), N(6)–C(17)–N(3) 114.5(4), O(1)–C(17)–C(18) 114.2(4), O(1)–C(17)–N(3) 102.6(4), O(1)–C(17)–N(6) 109.1(4).

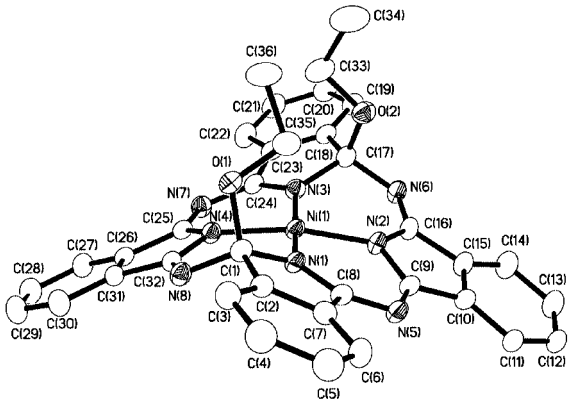

Fig. 3 The crystallographically determined structure, excluding hydrogen atoms, for **2**. Ellipsoids are drawn at the 35% probability level. Selected bond lengths (Å) and angles (°): Ni(1)–N(1) 1.831(4), Ni(1)–N(2) 1.854(4), Ni(1)–N(3) 1.838(4), Ni(1)–N(4) 1.862(4), C(1)–O(1) 1.425(5), C(1)–C(2) 1.517(6), C(1)–N(8) 1.449(6), C(1)–N(1) 1.469(6), C(17)–O(2) 1.414(6), C(17)–C(18) 1.519(6), C(17)–N(3) 1.478(6), C(17)–N(6) 1.452(6), N(1)–C(8) 1.323(6), N(3)–C(24) 1.306(6), N(1)–Ni(1)–N(2) 90.5(2), N(2)–Ni(1)–N(3) 90.8(2), N(3)–Ni(1)–N(4) 90.2(2), N(4)–Ni(1)–N(1) 90.3(2), C(2)–C(1)–N(8) 112.3(4), C(2)–C(1)–N(1) 103.2(4), N(1)–C(1)–N(8) 113.5(4), N(1)–C(1)–O(1) 110.7(4), C(2)–C(1)–O(1) 113.7(4), N(8)–C(1)–O(1) 103.8(3), N(3)–C(17)–C(18) 103.0(4), N(6)–C(17)–C(18) 111.8(4), N(6)–C(17)–N(3) 113.1(4), O(2)–C(17)–C(18) 113.6(4), O(2)–C(17)–N(3) 111.8(4), O(2)–C(17)–N(6) 103.8(4).

It appears that the reaction conditions employed in the synthesis of **1** and **2** are general for primary alcohols, and they lead to the formation of large single crystals that will be amenable to conductivity and optical studies. We believe that this method of synthesis will lead to the discovery of several new phthalocyanine compounds, containing different metals and bearing different alkoxy groups on their ligands.

β,β′-Fused metallocenoporphyrins†

Hong J. H. Wang, Laurent Jaquinod, Daniel J. Nurco, M. Graça H. Vicente and Kevin M. Smith*‡

Department of Chemistry, University of California, Davis, California 95616, USA

Received (in Corvallis, OR, USA) 28th August 2001, Accepted 22nd October 2001
First published as an Advance Article on the web 4th December 2001

The syntheses of a β,β′-fused ruthenocenoporphyrin (9) and a ferrocenoporphyrin dimer (11) are described.

Molecular systems incorporating porphyrins and metallocenes have great potential as catalysts, chemical sensors, and in porphyrin-assisted electron-transfer processes.[1,2] In recent years, molecules containing both porphyrin and ferrocene fragments have emerged as candidates for self-assembled monolayers in light energy conversion systems.[3] In most of these cases, the metallocene fragment is linked to the porphyrin *meso*- or β-positions through various spacers,[2–4] or directly to a central metal ion.[5] Direct linkages through a single C–C bond at the *meso*-positions have been reported[6] and it has also been shown that metalloporphyrins can form η^5-pyrrolyl–π-metal complexes with ruthenocyl moieties.[7] Our goal was to synthesize metallocenoporphyrins fused through the porphyrin β-positions, in order to enhance intramolecular electronic interactions in these systems.

In order to incorporate a five-membered ring (precursor of Cp^-) onto the porphyrin periphery, we investigated novel functionalizations of readily available 2-nitro-tetraarylporphyrins.[8] The remarkable ability of the nitro group to activate tetraarylporphyrins towards [3 + 2] cycloaddition reactions and its propensity to subsequently act as a leaving group was demonstrated by our synthesis of pyrroloporphyrins.[9] We now report two novel β,β′-fused metallocenoporphyrins (**9** and **11**) prepared *via* a key palladium(0)-catalyzed [3 + 2] cycloaddition reaction, previously applied to 1-nitronaphthalene.[10]

Using strict air-free conditions, nickel(II) 2-nitroporphyrins **1** and **2**[11] were treated with 2-[(trimethylsilyl)methyl]-2-propen-1-yl acetate for two days at 90 °C in the presence of an *in situ* prepared palladium(0) catalyst, to form nitrochlorins **3** and **4**, respectively (as shown by the appearance of an intense Q absorption band at 602 nm). Further heating of the reaction mixture at 100 °C for two days gave, upon elimination of nitrous acid, porphyrins **5** and **6** in 80–88% yields. While the cycloaddition reaction took place smoothly also on the copper complexes, the corresponding zinc(II) complexes required harsher reaction conditions and gave low yields (5%) of the β,β′-fused cyclopentenylporphyrins. Acid-catalyzed double bond migration on **5** and **6** afforded, respectively, porphyrins **7** and **8**. Addition of LDA to a solution of **8** in THF caused a color change from red to green which strongly suggested that two of the porphyrin π-electrons are delocalized into the aromatic

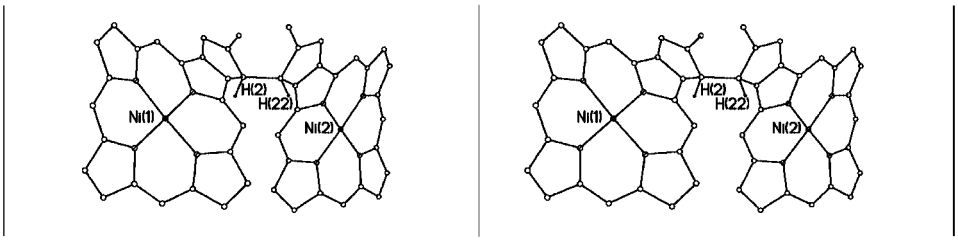

Fig. 2 The molecular structure of **10** in stereoview; 3,5-di-tert-butylphenyl rings and hydrogens, except for those on the bridging carbons, have been omitted for clarity.

system of the newly formed cyclopentadienide anion. Deprotonated **8** reacted with Cp^*RuCl_2 at room temperature for 2–5 days to give air-stable ruthenocenoporphyrin **9** in 25% yield.[12] The formation of **9** was confirmed by LDI–ToF mass spectrometry (m/z = 1408.0) and by ^{1}H NMR spectroscopy (which showed a characteristic singlet at 3.90 ppm corresponding to the fused cyclopentadienide protons).

The molecular structure of **9** was determined by X-ray crystallography (Fig. 1).§ The porphyrin macrocycle was lightly saddled[13] with a MDPMP (macrocyclic atom mean deviation from the porphyrin mean plane) of 0.108 Å. The Ni–N bond lengths averaged 1.965[9] Å, which is longer than in most reported nickel(II) porphyrin crystal structures.[14] The ruthenocenyl rings were aligned in an eclipsed orientation, as is typically observed for this moiety.[14] A porphyrin dimer (**10**) was also isolated (in 15% yield) along with ruthenocenoporphyrin **9** and its structure confirmed by X-ray crystallography (Fig. 2).¶ The use of a ruthenium(III) complex may account for the oxidative dimerization leading to the formation of **10**. Similar dimerizations using $FeCl_3$ as the oxidant have been reported for substituted cyclopentadienides.[15] Both macrocycles in dimer **10** displayed saddle/ruffle hybrid non-planar distortions,[13] had MDPMPs of 0.375 and 0.315 Å, and average Ni–N bond lengths of 1.915[13] and 1.913[6] Å.

Deprotonation of **8** at 0 °C using LDA followed by addition of $FeCl_2$ did not produce the desired bisporphyrinatoferrocene, probably due to the bulkiness of the *meso*-substituents. However under the same conditions, **7** produced the air-stable bisporphyrinatoferrocene **11**[16] in 30% yield. While the UV–visible spectrum of **9** displayed a split Soret band and relatively intense Q bands, that of **11** showed a broad Soret band and no well-defined Q bands. Using variable temperature ^{1}H NMR spectroscopy, two distinct conformational processes could be observed for **11**, arising from hindered adjacent *meso*-phenyls and ferrocene rotations. The β- and cyclopentadienide protons of **11** were found upfield-shifted by 0.5–1 ppm relative to those of **9**. The methyl protons on the fused cyclopentadienide ring of **11** appeared at 1.82 ppm, while the methyl protons on the Cp* ring of ruthenocene **9** gave a singlet at 0.91 ppm. This suggests a partial overlap of the two porphyrin macrocycles with staggered *meso*-phenyl rings.

§ Crystals of **9** were grown from MeOH–THF–H_2O [$C_{90}H_{110}N_4Ni$-Ru·2(THF), FW = 1551.8]. The selected crystal (0.40 × 0.28 × 0.16 mm) was monoclinic, space group $P2_1/m$, with cell dimensions a = 9.3626(5), b = 30.748(2), c = 14.5245(8) Å, β = 99.7930(10)°, V = 4120.5(4) Å^3, and Z = 2. Data were collected with ω-scans on a Bruker SMART 1000 diffractometer with a sealed tube source [λ(Mo-Kα) = 0.71073 Å] at 90(2) K. Diffraction data were collected to 2θ = 63° affording 56880 total reflections. A 2θ cutoff of 55° was applied to give 46122 total, 9601 unique, and 7078 observed ($>2\sigma(I)$) reflections [R_{int} = 0.0898, T_{min} = 0.837, T_{max} = 0.930, ρ_{calc} = 1.251 gcm^{-3}, μ = 0.464 mm^{-1}]. An empirical absorption correction was applied [SADABS 2.0 (Sheldrick, 2000)]. The structure was solved by the Patterson method and refined based on F^2 using all data by full matrix least-squares methods with 492 parameters (Bruker SHELXS-97, SHELXL-97). Hydrogen atom positions were refined with riding models. Final R factors were $R1$ = 0.0773 (observed data) and $wR2$ = 0.192 (all data). CCDC 165704.

¶ Crystals of **10** were grown from MeOH–toluene [$C_{160}H_{190}N_8Ni_2$·2(toluene), FW = 2527.0]. The selected crystal (0.30 × 0.20 × 0.08 mm) was monoclinic, space group $P2_1/c$, with cell dimensions a = 26.7781(15), b = 15.9648(8), c = 36.499(2) Å, β = 101.885(3)°, V = 15269.2(14) Å^3, and Z = 4. Diffraction data were collected and absorption corrected as for **9** (215487 total reflections for 2θ = 63°). A 2θ cutoff of 50° was applied to give 28066 total, 26858 unique, and 13378 observed ($>2\sigma(I)$) reflections [R_{int} = 0.169, T_{min} = 0.916, T_{max} = 0.976, ρ_{calc} = 1.101 gcm^{-3}, μ = 0.299 mm^{-1}]. The structure was solved by direct methods and refined as for **9** with 1685 parameters. Hydrogen atom positions were refined with riding models. Final R factors were $R1$ = 0.0839 (observed data) and $wR2$ = 0.270 (all data). CCDC 165703. See http://www.rsc.org/suppdata/cc/b1/b107732e/ for crystallographic files in .cif or other electronic format.

Tandem ring-closing metathesis reaction with a ruthenium catalyst containing a N-heterocyclic ligand

Tae-Lim Choi and Robert H. Grubbs*

Arnold and Mabel Beckman Laboratories of Chemical Synthesis, Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125, USA. E-mail: rhg@its.caltech.edu

Received (in Cambridge, UK) 12th September 2001, Accepted 29th October 2001
First published as an Advance Article on the web 23rd November 2001

The highly active catalyst 2 was used in tandem RCM to make molecules with various ring systems containing α,β-unsaturated carbonyl compounds.

Tandem cyclization reactions build up molecular complexity rapidly from relatively simple starting substrates.[1] Complicated molecules were synthesized in a single step by carbanion,[2] carbocation,[3] free radical,[4] and Pd coupling reaction[5] whose novelty and efficiency were demonstrated by total syntheses of many natural products. Olefin metathesis has become a useful reaction in organic synthesis,[6] and our group recently demonstrated the viability of tandem ring closing metathesis reactions using catalyst **1**.[7] Unfortunately, catalyst **1** could not incorporate more synthetically valuable functionalized olefins such as α,β-unsaturated carbonyl compounds. However, with the development of the more active catalyst **2**,[8] containing a N-heterocyclic ligand, functionalized olefins could participate in RCM and cross metathesis reactions.[9] Herein, we report tandem RCM reactions by using catalyst **2**, to make synthetically useful α,β-unsaturated lactones and enones.

Various substrates containing different olefin arrays were examined for the tandem cyclization and were found to give moderate to excellent yields (Table 1). Entries 1 through 4 demonstrate the viability of tandem ring-opening/ring-closing

1 2

metathesis. In the case of entries 1 and 2, catalyst **2** reacts with more reactive terminal olefin and the resulting alkylidene opens the 5-membered ring. The sequence of tandem events is completed by ring closing onto the α,β-unsaturated carbonyl olefin (Scheme 1). Fused tricyclic compounds were also synthesized from the highly strained norbonene moiety, but the yields were lower due to competing polymerization (entries 3 and 4).

Another variant of tandem RCM is demonstrated by enyne tandem ring closing metathesis to form fused bicyclic ring systems (entries 5 to 10). In these cases, catalyst **2** also reacts with the terminal olefins preferentially and undergoes rapid intermolecular enyne metathesis to form the first ring, then reacts with the α,β-unsaturated carbonyl olefin to close the final ring (Scheme 2). The fact that 7-membered lactone **A** is never observed, implies that during the first RCM event, the newly formed alkylidene **B** exclusively reacts with acetylenes over acrylates. The more challenging trisubstituted α,β-unsaturated carbonyl olefins were also successfully cyclized (entries 6 and 7). However, an attempt to make a tetrasubstituted α,β-unsaturated carbonyl olefin afforded less than 10% yield of the bicycle with the remainder being monocyclized product. This suggests that disubstituted carbene is formed just as in entry 7, but preferentially reacts with the terminal olefins of the starting molecule over the sterically and electronically demanding α-disubstitued α,β-unsaturated carbonyl olefin. 7,6-Fused bicyclic compounds are available in moderate yield by this method, (entry 8). Lastly, tandem RCM to make 6,5,6- and 6,6,6-fused tricyclic compounds are shown in entries 9 and 10 which demonstrates that this method has potential applications in the synthesis of complex natural products.

The highly active catalyst **2** was used in tandem RCM to make molecules with various ring system. The ability to incorporate α,β-unsaturated carbonyl olefins makes the tandem RCM synthetically more valuable since further manipulations are possible.

The authors would like to thank the NIH for generous support of this research, and Dr M. Scholl, Dr C. W. Lee, Dr S. D. Goldberg, Dr F. D. Toste and A.K. Chatterjee for helpful discussions.

First published as an Advance Article on the web 6th December 2001

Efficient mass transfer enhancements as the result of acoustically oscillated gas bubbles are detected using a microelectrode positioned at variable distances from the gas/liquid interface.

The enhancement in mass transfer as the result of bubble motion is extremely important in many industrial scale electrochemical processes.[1] It is thought to be the result of a number of different mechanisms associated with electrochemical bubble growth, detachment and motion under buoyancy forces away from the solid/liquid interface of an electrode.[2] These mechanisms have been investigated by a number of authors. The work by Whitney and Tobias is particularly noteworthy.[3] These authors studied bubble motion using arrays of microelectrodes produced through photolithographic processing. The individual contribution of single bubbles could be detected from a generator microelectrode. However, in all of these studies the enhancement in mass transfer has involved the motion of bubbles under buoyancy forces alone.

Bubbles are also known to be extremely active acoustically, with the sound of running water (*e.g.* in a small waterfall) largely attributed to bubble entrapment. The subsequent bubble pulsation gives the characteristic 'noise', which is observed.[4] In turn gas bubbles within a liquid interact strongly with incident sound waves. If the sound wave is of the correct frequency and pressure amplitude, then a number of different oscillations of a bubble can be induced. These fall broadly into two classes: a breathing mode (or 'pulsation') where the whole bubble expands and contracts with spherical symmetry about the bubble centre; and a second class which lack spherical symmetry. The shape oscillations called Faraday waves[5] are members of this second class. In the steady state the breathing mode occurs at the frequency of the driving sound field, but in contrast Faraday waves occur at half this frequency. Whilst a breathing mode is always excited, generation of Faraday waves requires the driving field to exceed a threshold amplitude.[6] Both the breathing mode and surface waves move the liquid phase of the media to a greater or lesser extent. Fig. 1 shows a photograph of a gas bubble driven into oscillation by irradiation with sound. The distortions in the surface of the bubble can be clearly seen.

However, the contribution to mass transfer of these modes within the liquid phase has not been reported. Here a microelectrode is used to characterise the mass transfer enhancements produced by an oscillating gas bubble. Microelectrodes were chosen for a number of reasons. These included their ability to operate under steady state conditions, their relatively fast response time and their size.[7,8] In the experiments reported here a microelectrode was positioned close to the gas/liquid interface of an air bubble trapped by buoyancy forces under a solid surface. The liquid phase consists of an aqueous solution[9] of 5 mmol dm^{-3} $[Fe(CN)_6]^{-3}$ in 0.2 mol dm^{-3} $Sr(NO_3)_2$. The microelectrode was positioned close to the gas/liquid interface using an X, Y, Z micrometer and stage. The position of the microelectrode with respect to the gas/liquid interface was verified by monitoring the steady state current recorded in the absence of bubble oscillation. When the electrode (a 25 μm diameter Pt microdisc) was < 125 μm away from the nearest point on the stationary bubble wall, the presence of the gas/liquid interface could be detected as a reduction in the steady state current recorded at the microelectrode.[10–12] This was due to hindered diffusion (negative feedback) as a result of the blocking nature of the gas/liquid interface under the conditions stated. Irradiation of the bubble with sound of the appropriate frequency and amplitude results in oscillation of the bubble surface. This oscillation can be electrochemically detected by the microelectrode positioned close to the gas/liquid interface. The motion of the bubble wall will be detected as an enhancement in mass transfer to the microelectrode as a result of the forced convection of the liquid produced by the oscillation of the bubble wall. Fig. 2 shows the enhancement in mass transfer detected as a function of distance away from the gas/liquid interface. In this case, the bubble was driven into oscillation at a pressure sufficient to generate surface waves on the gas/liquid interface. This was observed in two ways. First, the presence of surface waves on the bubble wall was observed optically as a 'shimmer'. Second, when the microelectrode was positioned close to the bubble wall (*ca.* 5–10 μm) the motion of the bubble wall can be resolved electrochemically. This is shown as an insert on Fig. 2. The insert shows the current and pressure† time traces for a bubble driven to oscillate with surface motion. This clearly shows that the current time trace has a component at $0.5f$ (where f represents the drive frequency, in this case 1.46 kHz). This is characteristic of Faraday waves on the surface of the bubble wall, and is confirmed by the photograph of a bubble under similar conditions shown in Fig. 1. Fig. 2 shows that within the first *ca.* 100 μm, the mass transfer enhancement remains approximately constant. Fig. 2 also shows that the current falls as the distance between the microelectrode and the gas/liquid interface of the bubble increases. However, the perturbation in

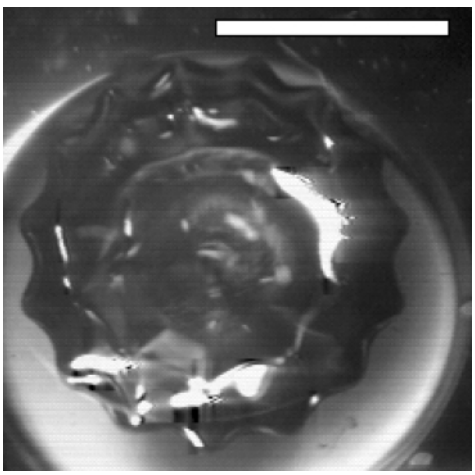

Fig. 1 Photograph taken from below a tethered bubble held by buoyancy forces on the end of a glass rod. The scale bar represents 3 mm. The surface waves can be clearly seen around the perimeter of the gas/liquid interface.

 DOI: 10.1039/b107616g

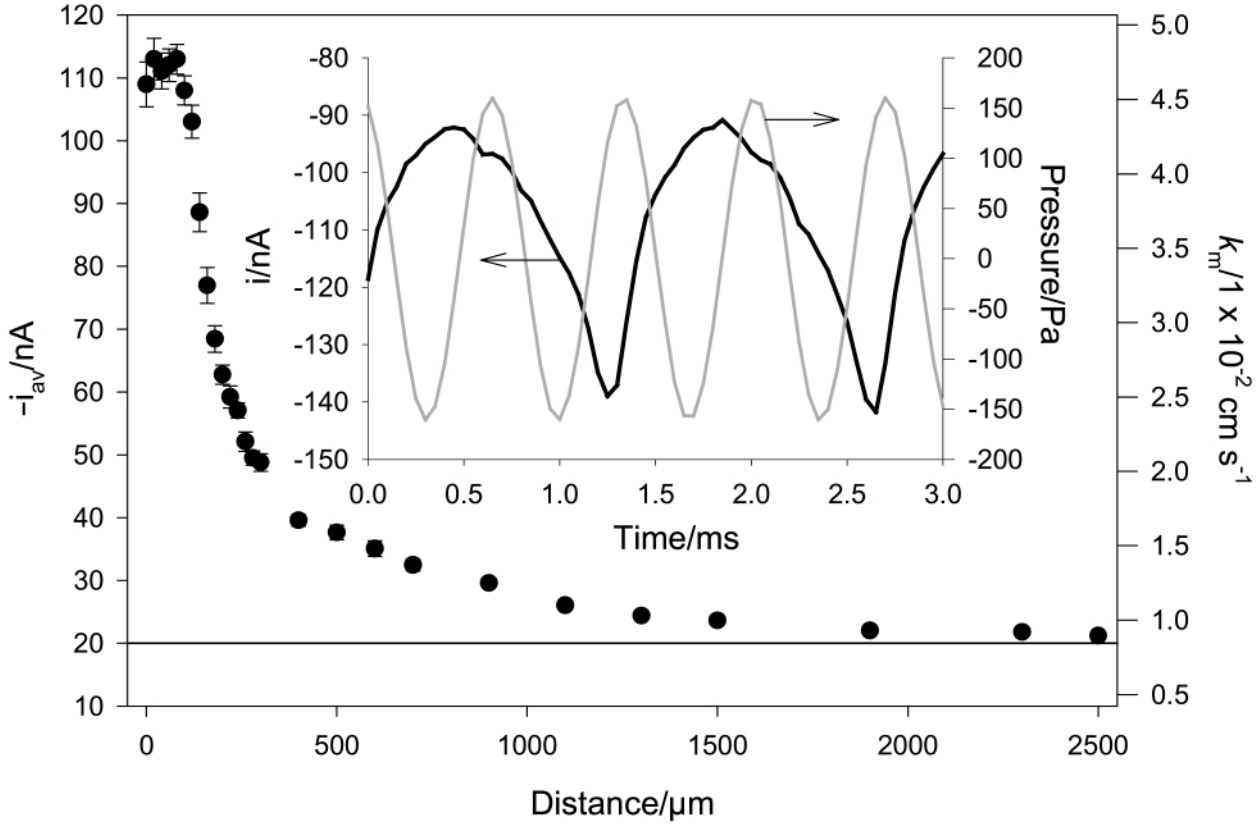

Fig. 2 Plot showing the average current (●) and associated mass transfer coefficient for a single air bubble driven into oscillation by a sound field operating at 1.46 kHz. The solution contained 5 mmol dm^{-3} $[Fe(CN)_6]^{3-}$ in 0.2 mol dm^{-3} $Sr(NO_3)_2$. The error bars show the 95% confidence interval. The insert shows the oscillation in the current (solid line) and pressure† (faint line) as a function of time employing high temporal resolution equipment. The experiment was performed at *ca.* 20–23 °C under aerobic conditions. The solid horizontal line represents the steady state current or mass transfer coefficient for the microelectrode in a stagnant solution.

the mass transfer coefficient can be detected at extended distances away form the gas/liquid interface. A significant enhancement in the time averaged steady state mass transfer to the microelectrode was observed up to distances of *ca.* 2500 μm. This is particularly significant considering that the mass transfer coefficient of the 25 μm diameter platinum microelectrode is already high in stagnant solution (0.008 cm s^{-1}). It is interesting to note that the enhancement in mass transfer as a result of the bubble motion exceeds this value (up to 0.0477 cm s^{-1}) but is brought about by a relatively small pressure amplitude (< 100 Pa). This is a significant point as it clearly demonstrates that enhancing the mass transfer of material to an electrode in this manner would be a significantly more efficient way when compared to the employment of ultrasound to induce cavitation and other high energy phenomena.

Previous studies have shown that ultrasound can enhance mass transfer significantly.[13–15] However, the magnitude of the pressure field required to achieve inertial (transient) cavitation is considerably high. As an example, to generate cavitation in water under standard conditions requires a pressure amplitude in excess of *ca.* 1 atmosphere (101 000 Pa).[4] This is a factor of 1000 higher than the pressures (and in turn a factor of 10^6 in intensity) employed here. Clearly the generation of mass transfer enhancements using acoustically oscillated bubbles, rather than inertial cavitation, would be significantly more efficient. This increase in efficiency is due to the differing mechanisms responsible for the forced convection enhancements observed. The process of inertial cavitation requires that small (*e.g.* of order micron radius) bubbles expand against atmospheric pressure and surface tension forces to a critical radius, before collapsing. However, exciting a large bubble (*e.g.* mm radius) at resonance takes advantage of their exceptionally good acoustic coupling.[4] In turn, the pressure amplitude required to generate surface waves in this case is small, but the enhancement in forced convection is relatively large. As an example, mass transfer coefficients reported from cavitation are on the order[13–15] of 0.1–1 cm s^{-1}. The mass transfer coefficient recorded here is only a factor of 10 less, while the applied pressure is a factor of 1000 less. This is because the excitation of a surface wave does not require a large overall volume change of the bubble, compared to the generation of inertial cavitation.

Notes and references

† Note that the absolute pressure will not be the same as that shown in the insert of Fig. 2 as the presence of the oscillating bubble will alter the measured pressure. The absolute pressure can only be measured when the bubble has been removed from the glass support.

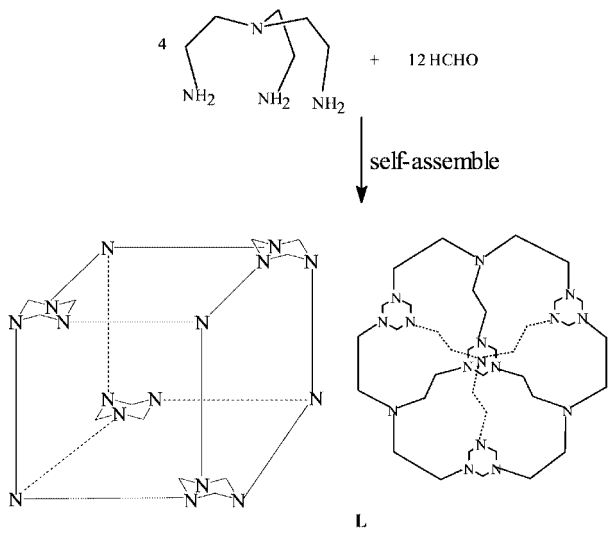
First published as an Advance Article on the web 4th December 2001

A novel highly symmetrical cube-shaped trication $[C_{36}H_{75}N_{16}]^{3+}$ with 16-nitrogen donors is achieved *via* self-assembly in which two water molecules were clathrated within the cavity of the framework.

Highly symmetrical cage-like molecules containing macrocyclic skeleton have always been fascinating targets for synthetic chemists and play an important role in host–guest chemistry.[1] Such frameworks possess cavities capable of entrapping atomic and/or molecular sized guest and have applications of chemistry, biology and materials sciences.[2,3] It has also been postulated that the interior of cage-like molecules can be considered to provide a new phase of matter in which it becomes possible to stabilize reactive intermediates and to observe new forms of stereoisomer.[4] However, for cavities tailored around spherical or globular targets, positioning of binding sites requires the controlled formation of a number of covalent bonds in long, often impractical multi-step syntheses.[5] As an alternative, self-assembly, a special type of synthetic procedure in which several reactions between several reagents occur in one experimental operation to yield the final covalent structure, was used to construct smaller, simpler fragments with enough molecular information to spontaneously reassemble into the desired cavity.[6]

In this paper, we introduce a large spherical cube-shaped host moleculear cation $[H_3L]^{3+}$ (L = $C_{36}H_{72}N_{16}$) (Scheme 1), by way of a self-assembly process in which there appears to be two molecular guests, in the form of two water molecules, within the cavity of the framework. Compound **L** has a T_d-symmetric urotropin-like structure and also somewhat resembles structurally Lehn's sophisticated tricyclic cryptand[7] known as the 'soccer ball molecule' on account of its spherical three-dimensional skeleton. Whereas most of the tricyclic tetraamines such as hexaethylenetetramine[8] and related large tricyclic and cage-like compounds reported by Takemura[9] and Lehn were synthesized by low-yield, long and multi-step methods, compound **L** like that of urotropin forms easily upon mixing of tris(2-ethylamino)amine and formalin† ESI-MS (electrospray ionization mass spectroscopy) in water–methanol solution (in the presence of $HClO_4$) and reveals the presence of a main peak at *m/z* 593, corresponding to the most abundant ion $\{[H_6\mathbf{L}\subset(H_2O)_2][H_2O][ClO_4]_4\}^{2+}$ and confirming the existence of self-assembled cage.



Scheme 1

The most definitive proof for the formation of the T_d-symmetric cage comes from the X-ray crystallographic analysis.‡ One protonated cubed-shaped trication, two guest water molecules as well as three perchlorate anions were found in an asymmetric unit. The cage is slightly deformed from expected T_d symmetry (Fig. 1) with four bridge head nitrogen atoms of tris(2-aminoethyl)amine [N(1), N(11), N(12), and N(13)] and four six-membered $[N(CH_2)]_3$ rings occupying the vertex positions, and the twelve CH_2CH_2 chains along the edges. In addition to its chemical interest, such a host has aesthetic appeal. The edge of the cubic cage is *ca.* 4.3 Å in length (from the head nitrogen atom to the center of the six-membered ring). Among the sixteen nitrogen atoms, three of them, N(2), N(6) and N(13) are protonated with the hydrogen atoms oriented towards the inside of cavity (*endo*), four of them, one from each of the $[N(CH_2)]_3$ six-membered rings, respectively N(7), N(8),

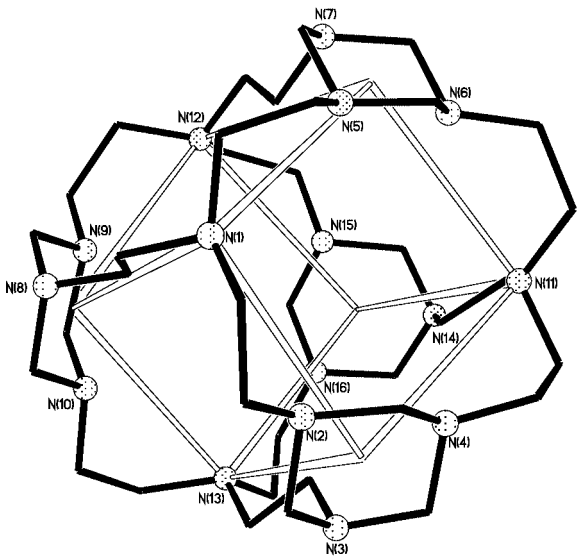


Fig. 1 Molecular structure of the host, showing the T_d-symmetric hexahedral cage. The four bridge head nitrogen atoms of tris(2-aminoethyl)amine and the centers of the six-membered $[N(CH_2)]_3$ rings occupy the vertex positions with the twelve CH_2CH_2 chains forming the edges.

 DOI: 10.1039/b109206p

N(3) and N(14), are *exo* with the lone pairs pointing away from the cavity, whereas the others are oriented towards the inside of the cavity. The twelve *endo* nitrogen bridgeheads delineate the intramolecular cavity. The distances from the center (M) of the cavity to the *endo* nitrogen atoms are in the range of 3.66–3.91 Å, with an average M–N distance of about 3.88 Å. Considering the thickness of each face of the cage, the outer space volume is *ca.* 200 Å^3, while the inner space is just about 50 Å^3. This cavity should be able to form complexes with neutral molecules and anions of appropriate size.

The most interesting structural feature is that there are two water molecules within the cavity of the framework (Fig. 2). The two water molecules lie in the pseudo C_4 axis, which reduces the symmetry of the hexahedral host from T_d to S_4, the O···O separation is *ca.* 2.80 Å with O(1W)–H(1WB)···O(2W) *ca.* 167°, indicating strong H-bonding. An even greater dispersion is observed for the N···O distance range of the twelve *endo* nitrogen atoms from 2.82 to 3.22 Å, with an average N···O separation of about 3.0 Å. These separations are comparable to those found for the N···O hydrogen bonds present in the crystal structure of the NH_4^+ complexes of macrotetrolide antibiotics (2.83–2.93 Å),[10] 18-crown-6 (2.86–2.88 Å),[11] and some H_3O^+ complexes of nitrogen-containing crypts,[12] indicating potential hydrogen bonding between the nitrogen atoms of the host and the included water molecules. Since the host is a protonated ion, and the angles of N(5)–H(5C)···O(1W), N(11)–H(11C)···O(1W) and N(13)–(H13C)···O(2W) are 149°, 175° and 173°, respectively, it is suggested that the host participates in N–H···O hydrogen bonding with the included water molecules. The angles of O(1W)–H(1WA)···N(2), O(2W)–H(2WA)···N(15) and O(2W)–H(2WB)···N(9) are 178°, 167° and 166°, indicating typical O–H···N hydrogen bonding of the water molecules and substantial contact with the host. From the description mentioned above concerning the nature of the hydrogen bonding in the cavity, it is reasonable to speculate that the water molecules may serve as templates; such phenomena involving molecules as templates is not well-established.

Metal template condensation reactions of formaldehyde and amines provide simple, elective, and inexpensive routes to the macrocyclic complexes that have been studied;[13] however, no water molecule or neutral molecule template condensation reactions of formaldehyde and amines have been postulated. In our synthesis of the cryptand, a substantial and aesthetically appealing structure is assembled with modest efficiency from trivial building blocks and eighteen components just using HCHO and tris(2-aminoethyl)amine as starting materials and water molecule as template. This kind of self-assembly is quite interesting for the large cage with high symmetry and falls very nicely into the category of self-assembly and supramolecular chemistry. The hexahedral host reported here is exciting and will be of interest to a wide audience.

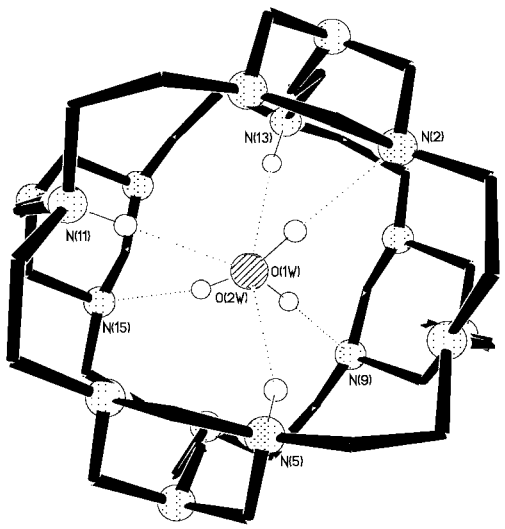

Fig. 2 Perspective view of the host–water complex, showing potential hydrogen bonds. Selected N···O separations (Å). O(1W)···N(2), 2.996(6); O(1W)···N(5), 2.841(6); O(1W)···N(11), 2.994(6); O(2W)···N(9), 2.808(6); O(2W)···N(13), 3.116(6); O(2W)···N(15), 2.958(6).

† *Preparations*. To 100 mL stirred acetonitrile containing perchloric acid (0.5 mL) and sodium acetate (1.2 g, 15 mmol), tris(2-aminoethyl)amine (1.46 g, 10 mmol) in 200 ml dichloromethane and HCHO (2.5 g, 36%, 30 mmol) in 200 ml acetontrile were added drop-wise, respectively. After finishing the addition, the solution was stirred for 4 h and allowed to stand for one week. White solid formed and was removed by filtration, the filtrate was allowed to stand for another week and then the precipitate formed was filtered off and washed with water (3 × 20 mL) and acetone (3 × 30 mL), respectively. Yield 0.35 g (15%) of the compound $[H_3\mathbf{L}\subset(H_2O)_2][ClO_4]_3$. Anal. calcd. for $(C_{36}H_{75}N_{16})(H_2O)_2(ClO_4)_3$: C, 40.6; H, 7.5; N, 21.0; Found: C, 40.4; H, 7.5; N, 20.6%. Pale-yellow crystals suitable for X-ray structure analysis were collected directly.

‡ *Crystal data*. Monoclinic, $P2_1$, molecular formula, $C_{36}H_{75}N_{16}(ClO_4)_3(H_2O)_2$, formula weight, 1066.50, pale-yellow, 0.40 × 0.30 × 0.30 mm, a = 11.483(2), b = 16.512(3), c = 13.051(3) Å, β = 94.82(3)°, V = 2465.8(9) Å^3, Z = 2, T = 293 K, D_c = 1.436 g cm^{-3}. Intensity data were collected on an Enraf-Nonius CCD system. 49970 reflections measured of which 11638 (R_{int} = 0.053) were independent reflection and all were included in the refinement. The structure was solved by direct methods. The oxygen atoms of the perchlorate anions were refined disordered. Non-hydrogen atoms were refined anisotropically, hydrogen atoms attached to the water oxygen atoms and protonated nitrogen atoms were found from difference fourier map, other hydrogen atoms were positioned in their calculated positions. All hydrogen atoms were refined using riding model. Computations were carried on a PC-586 computer using SHELXTL-PC program package. For 705 parameters based on 5921 observed reflections [$I > 2\sigma(I)$] gave the final refined circle R = 0.074, $wR2$ = 0.190 (for all data). CCDC 161379. First published as an Advance Article on the web 4th December 2001

The reaction of molybdenum complexes [MoH_3{E(Ph)[$Ph_2PCH_2CH_2P(Ph)C_6H_4$-*o*]$_2$}] (E = Si or Ge) with carboxylic acids gave carboxylato complexes where the carboxylato ligand coordinates to the metal in a unidentate mode; the formato complex was found to be an effective catalyst for carbon dioxide fixation.

Since the first preparation of the transition-metal silyl derivative, $CpFe(CO)_2SiMe_3$ (Cp = η^5-C_5H_5), by Wilkinson and coworkers in 1956,[1] numerous relevant examples have been reported.[2] We previously reported the unexpected formation of a novel molybdenum–silyl complex, [MoH_3{Si(Ph)-[$Ph_2PCH_2CH_2P(Ph)C_6H_4$-*o*]$_2$}] **1a**, which is obtained by the thermal reaction of [MoH_4(dppe)$_2$] **2**, (dppe = $Ph_2PCH_2CH_2PPh_2$) with $PhSiH_3$ and possesses an unusual quadruply chelated ligand.[3] Recently this methodology has been extended to the reaction of **2** with $PhGeH_3$, which is a higher homologue of $PhSiH_3$, and have obtained the same type of complex **1b** having a Mo–Ge bond.[4] Complexes in which two metal atoms of very different character are held in close proximity seem to offer fascinating opportunities to achieve novel types of reaction. We have studied the reactivity of these complexes and a series of new complexes with this quinquidentate ligand has been synthesized from **1**. For example, **1a** reacted with a dialkyl malonate or gaseous dioxygen to afford an η^1-*O*-enolato type complex or a peroxo type η^2-O_2 complex **3**, respectively.[5,6] Herein we report the synthesis and some reactions of dihydrido(carboxylato)molybdenum complexes.

Treatment of **1** with two equiv. of carboxylic acids such as formic acid, acetic acid or benzoic acid in THF at room temperature readily led to the formation of monocarboxylato molybdenum complexes (**4**, E = Si; **5**, E = Ge) in good yields (70–90%, Scheme 1).† In these reactions, the evolution of hydrogen gas was qualitatively confirmed by GLC analysis. In the ^{1}H NMR spectra of the complexes **4**, hydrido signals appeared at around δ −7.9 as a triplet of triplets corresponding to an A_2K_2X spin system. The ^{31}P{H} NMR spectra of complexes **4** contain two resonances at around δ 87 (br d, J_{PP} 122 Hz) and 58 (br d, J_{PP} 122 Hz) in a 1 : 1 ratio. The presence of only two resonances indicates that the molecule **4** has an effective mirror plane which contains the Mo–Si bond. The IR spectra of complexes **4** showed ν(Mo–H) at 1816–1819 cm^{-1} and two ν(OCO) stretching vibrations (asym and sym) at 1609–1618 cm^{-1} and 1326–1360 cm^{-1}, respectively. The fairly large values of $\Delta\nu$ [$\nu(OCO)_{asym}-\nu(OCO)_{sym}$] ranging from 248 to 272 cm^{-1} suggest that the carboxylato ligands in the complexes coordinate to the metal in a unidentate fashion as shown in Scheme 1.[7] The molybdenum–germyl complexes **5** have very similar IR and NMR spectra to **4**, implying that **4** and **5** are isostructural.

The basic features of the structure of these complexes deduced from the spectra were fully confirmed by single crystal X-ray diffraction on **4b**. A view of the molecule is shown in Fig. 1 with selected bond distances and angles.[8] As expected from the IR and NMR results, this complex contains a quinquidentate P_2SiP_2 ligand and a unidentate acetato ligand occupying the axial site. The structure can be compared with that of the above-mentioned peroxo complex, [MoH{Si(Ph)[Ph_2-$PCH_2CH_2P(Ph)C_6H_4$-*o*]$_2$}(η^2-O_2)] **3**.[5] The Mo–Si distance of

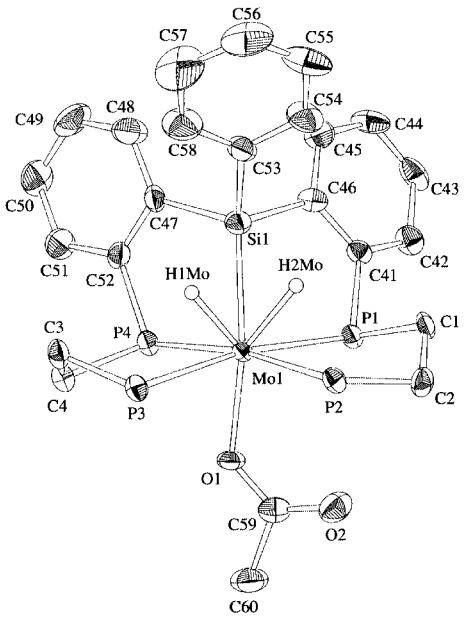

Fig. 1 Thermal ellipsoid plot (30% probability level) for **4b**. Selected bond lengths (Å) and angles (°): Mo1–Si1 2.515(2), Mo1–P1 2.485(2), Mo1–P2 2.507(2), Mo1–P3 2.496(2), Mo1–P4 2.466(2), Si1–C47 1.887(7), Mo1–O1 2.174(5); P1–Mo1–P2 80.31(6), P2–Mo1–P3 96.32(6), Si1–Mo1–O1 143.7(1).

 DOI: 10.1039/b107837m

2.515(2) Å in **4b** is slightly shorter than that of 2.554(5) Å in **3**. On the other hand, the mean Mo–P distance of 2.489 Å in **4b** is a little longer than that found in **3** (2.462 Å).

The parent complex **2** is known to react with carboxylic acids or allyl carboxylates to give cationic and neutral carboxylato complexes, respectively, where the carboxylato ligand coordinates to the metal in a bidentate mode.[9,10] The unusual unidentate coordination of acetate of **4b** may be ascribed to the stability of the P_2SiP_2 coordination.

A toluene solution of complex **1a** was allowed to react under CO_2 pressure (17 atm) at room temperature and **4a** was isolated in 82% yield from the reaction mixture (Scheme 2). Interestingly, **4a** reverted to **1a** quantitatively with accompanying evolution of one mol of CO_2, when warmed in benzene. The reversible insertion reaction of CO_2 into the Mo–H bond under mild conditions is an outstanding feature exhibited by complex **1a** since the parent complex **2** does not react with CO_2 at room temperature although irradiation of a benzene solution of **2** under CO_2 atmosphere yielded a chelated formato-*O,O'* complex.[11] We thought that the high reactivity of **1a** is due to the strong *trans*-influence of the Si fragment since it has been pointed out that the R_3Si group has a strong σ-donor ability and may labilize the ligand in the position *trans* to it.[12] Yet, to date there have been few reports concerning the influence of silyl ligands on the reactivity of transition-metal complexes.[13]

Subsequently, we explored the catalytic activity of **1a** towards carbon dioxide fixation [eqn. (1)]. A toluene solution of

$$HNMe_2 \xrightarrow[PhMe\ \ 110\ °C]{CO_2/H_2,\ \ cat.\ \ \mathbf{1a}\ or\ \mathbf{4a}} HCONMe_2 \qquad (1)$$

complex **1a** was allowed to react under CO_2/H_2 (25/35 atm) pressure in the presence of dimethylamine at 110 °C affording 115 equivalents of *N,N*-dimethylformamide with respect to the complex. In this process, formato complex **4a** was also found to be an efficient catalyst. Presumably, the first step in the catalytic cycle using **1a** may be the formation of **4a**. Neither **2** nor **1b** catalyzed this process suggesting both the Mo–Si linkage and the P_2SiP_2 girdle in **1a** play an important role.

Catalytic carbon dioxide fixation has attracted considerable interest. Most of the reported studies deal with iridium, palladium and ruthenium complexes[14] and reports of catalysis using Group 6 metals are rare.[15] To our knowledge, complex **1a** is the first molybdenum compound which can catalyze the transformation of carbon dioxide into dialkylformamide effectively.

Intramolecular aromatic 1,5-hydrogen transfer in preparation of oxacyclic naphthalic anhydride *via* unusual Pschorr cyclisation

Xuhong Qian,* Jingnan Cui and Rong Zhang

State Key Laboratory of Fine Chemicals, Dalian University of Technology, Dalian 116012, China

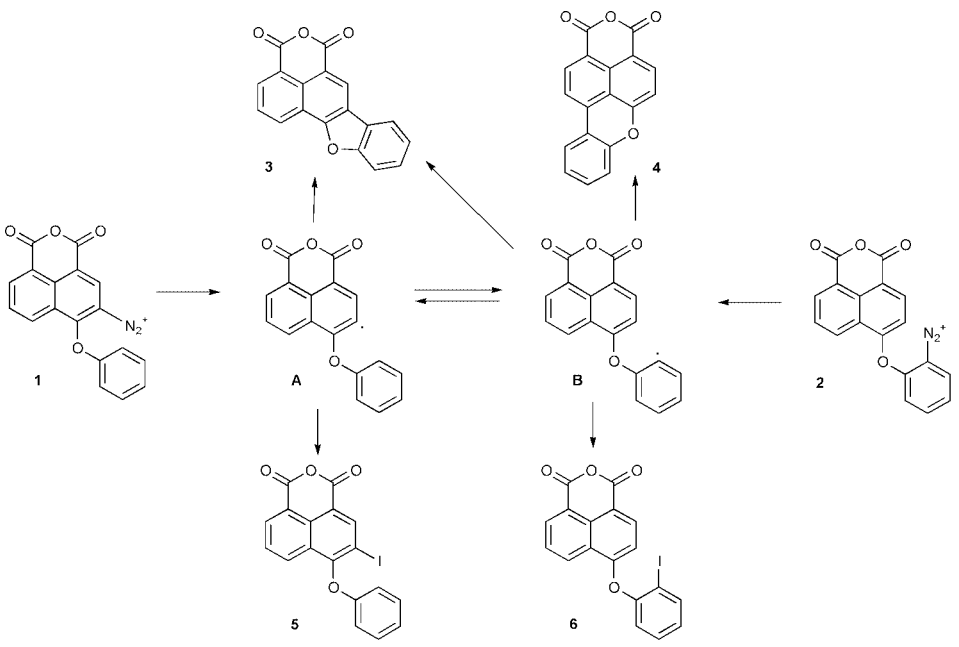
Received (in Cambridge, UK) 20th September 2001, Accepted 1st November 2001
First published as an Advance Article on the web 23rd November 2001

Unusual Pschorr cyclisation *via* naphthyl radical-induced intramolecular aromatic 1,5-hydrogen transfer using the corresponding diazonium salts as starting materials gave five- and six-membered oxacyclic-fused naphthalic anhydride isomers.

Pschorr cyclisation has been widely used in the preparation of polycyclic compounds[1] for over a century.[2] Many applications of this reaction can be found in the pharmaceutical and dye industries. Normally, the reaction was accomplished in a three-step mechanism, namely, the diazotization of an *o*-amino group to a diazonium salt; the dediazoniation of the diazonium salt to a radical intermediate; and the closing of the ring. The rearrangements *via* radical-induced aromatic hydrogen migration to produce isomers are rarely found in Pschorr cyclisation because aromatic compounds are usually poor hydrogen donors. In contrast, radical-induced hydrogen migration is commonly seen when the migrating hydrogen originates from an aliphatic carbon or from a heteroatom.[3,4] After a century of diazonium chemistry, phenyl radical-induced aromatic 1,5-hydrogen migration of the benzophenone derivatives was the only example of such isomerization through Pschorr cyclisation (giving two five-membered ring isomers) and Sandmeyer reaction.[5,6] Despite the lack of reports for similar isomerizations, it has been speculated that aromatic 1,5-hydrogen transfer might be a general phenomenon in aromatic radical transformations. Recently, we found five- and six-membered oxacyclic isomers during preparation of benzoxanthene derivatives used as fluorescent probes. We report herein the naphthyl radical-induced aromatic 1,5-hydrogen transfer in Pschorr cyclisation of the corresponding diazonium salts.

The diazonium salts **1** and **2** were prepared from 4-bromo-1,8-naphthalic anhydride according to the procedure published earlier[7] and all intermediates were characterized by ^{1}H-NMR, MS, IR and elemental analysis.

Pschorr cyclisation of **1** initiated by $CuSO_4$, CuO, or ferrocene produced two isomeric fluorescent compounds **3** and **4** in over 9 : 1 ratio (Table 1, entry 1–3). The most plausible explanation for the 9 : 1 ratio of the isomers is that the initially formed radical **A** rearranged itself to radical **B** by 1,5-hydrogen transfer and that these two radicals in some equilibrium were then converted to the products **3** and **4** (Scheme 1). It has been demonstrated that Pschorr cyclisation and Sandmeyer iododediazoniation of benzophenone derivatives gave cyclized isomers in nearly equal amounts and some iodonized isomers, respectively.[5] However, in our case, the ratio of the cyclized isomers was far from 1 : 1 and the iodonized isomers were hardly found. The iododediazoniation of diazonium salts **1** and **2** gave only iodonized compounds **5** and **6**, respectively (entry 6 and 7). It seems that the 1,5-hydrogen transfer rate between **A** and **B** is slower than that between benzophenone radicals according to the literature.[5] Under similar reaction conditions to entry 1, diazonium salt **2** gave also **3** and **4** in the ratio of 7 : 93 (entry 5). This suggests that radical **B** could be also rearranged into radical **A** and the rate of formation of **B** from **A** is faster than that of **A** from **B.** This indicates that radical **B** is more stable than radical **A**. Even so, the structure of major product and the ratio of isomers still mainly depended on the starting compounds, as the rate of cyclisation to five- and six-membered rings is obviously faster than that of hydrogen transfer. Beyond what we expected, the mode of radical generation had obvious effects on hydrogen transfer, as various initiation methods



Scheme 1

Table 1 Pschorr cyclisation and Sandmeyer iododediazoniation of diazonium salts

Entry	Substrate	Reaction	Products	Ratio[a]	Yield[b] (%)
1	**1**	$CuSO_4$, AcOH, H_2O, reflux	**3**:**4**	90:10	90[c]
2	**1**	Ferrocene, acetone, rt	**3**:**4**	94:6	75[c]
3	**1**	CuO, H_2SO_4, rt	**3**:**4**	92:8	80[c]
4	**1**	$CuSO_4$, AcOH, rt	**3**:**4**	83:17	85[c]
5	**2**	$CuSO_4$, AcOH, H_2O, reflux	**3**:**4**	7:93	86[c]
6	**1**	KI, I_2, H_2O, rt	**5**		73
7	**2**	KI, I_2, H_2O, rt	**6**		88

[a] The ratio was determined by HPLC/MS (Hypersil DDS2 column, H_2O + MeOH + AcOH eluent, retention time: **3**, 32 min, **4**, 29 min).[b] The yield was based on the corresponding amino compounds.[c] The yield was obtained in **3** + **4** mixture.

produced a different ratio of isomers (entries 1–4). It suggests that the rate of 1,5-hydrogen transfer between **A** and **B** is sensitive to the environment and can be enhanced (the ratio of **3** and **4** is 83:17) under the conditions of entry 4. This is different from the case of benzophenone derivatives,[5] where solvent showed no effect on the rate of hydrogen transfer.

Molecular modeling using Pcmodel 6.0 showed some differences in their conformations between these 4-phenoxynaphthalic anhydride radicals and the benzophenone radicals, although they were in an aromatic conjugated system. Two aromatic rings next to ether O atom for radicals **A** and **B** were not in the same plane, while for the benzophenone radicals, the carbonyl and two aromatic rings were in the same plane. These conformational differences can be used to explain their differences in the efficiency of radical-induced 1,5-hydrogen transfer, the ratio of isomers, and the solvent effects.

In conclusion, our investigation not only provided the first example of isomerization *via* naphthyl radical-induced aromatic 1,5-hydrogen transfer in naphthalene derivatives during Pschorr cyclisation, but also implied that radical induced-aromatic hydrogen transfer possibly was more common than previously thought in many other aromatic free radical reactions.

Financial support by National Natural Science Foundation of China and The Ministry of Education of China is greatly appreciated.

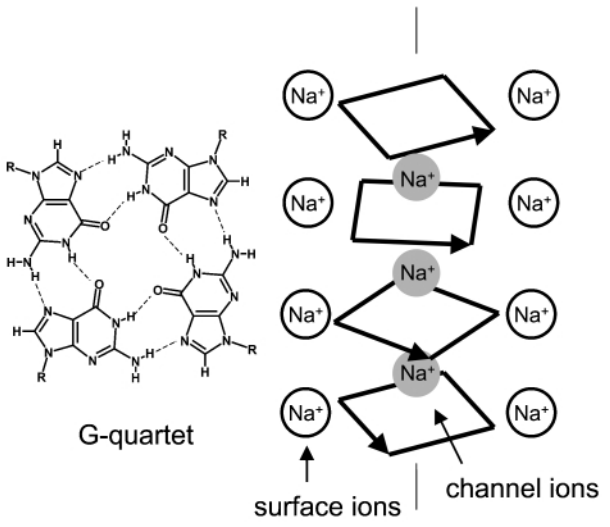
First published as an Advance Article on the web 4th December 2001

We report an unambiguous solid-state ^{23}Na NMR characterization of the surface and channel sodium ions in self-assembled guanosine-5′-monophosphate (5′-GMP) gels.

Guanosine-5′-monophosphate (5′-GMP) is known to form viscous gels in the presence of alkali metal ions in water.[1] Early X-ray fiber diffraction studies[2,3] have established that the 5′-GMP gel structure consists of a tetrameric arrangement of guanine bases (known as the G-quartet) that are stacked on top of one another forming a right-handed helix with 30° rotation and 3.4 Å advance between adjacent G-quartets; see Scheme 1. Although the presence of alkali metal ions is essential for 5′-GMP gel formation, little is known about the location and stoichiometry of metal ions in this class of self-assembled gel systems. Recently, single crystal X-ray studies revealed that the K^+ and Na^+ ions are located between two G-quartets in $d(G_4T_4G_4)$ and $d(TG_4T)$.[4,5] The mode of ion binding in 5′-GMP gels may be similar to that found in the G-rich DNA sequences, but direct detection of alkali metal ions in 5′-GMP gels has not been reported. It should be noted that solution alkali metal NMR has been used to study the self-association of 5′-GMP;[6] however, the traditional alkali metal NMR method cannot yield site-specific information due to rapid ion exchange in solutions.[7] Recent advances in solid-state NMR methodology in dealing with half-integer quadrupolar nuclei have offered new possibilities for alkali metal NMR to be used as a probe to ion binding in biomolecular systems.[8] For example, Rovnyak *et al.*[9] successfully observed solid-state ^{23}Na NMR signals from the Na^+ ions bound to a DNA quadruplex, $[d(TG_4T)]_4$. However, our recent ^{23}Na NMR results for Na-ionophore complexes[10] did not support the spectral assignment for $[d(TG_4T)]_4$. In this study we apply ^{23}Na magic-angle spinning (MAS) and multiple quantum magic-angle spinning (MQMAS)[11] techniques to various types of 5′-GMP gels and report an unambiguous assignment for the surface and channel Na^+ ions bound to G-quadruplex systems.

Fig. 1A shows the ^{23}Na MAS NMR spectrum of a 5′-GMP gel sample prepared by adding 1.7 mL of 4.0 M NaCl (aq.) to a solution of 320 mg hydrated Na_2(5′-GMP) in 3.4 mL water at rt. In this study, this sample will be referred to as the Na gel sample (**1**). As seen in Fig. 1A, three peaks are observed. The sharp peak centered at $\delta = 7$ ppm is attributed to the presence of excessive NaCl salt in the gel sample. This was confirmed by the fact that this peak can be readily removed by gentle washing the gel sample with 2-methylpentane-2,4-diol (MPD) aqueous solution (40% V/V). The broad signal at $\delta = -1$ ppm is assigned to the Na^+ ions bound to the phosphate groups and water molecules (denoted as the surface Na^+ ions in this study). The weak signal centered at $\delta = -19$ ppm is assigned to the Na^+ ions residing inside the G-quartet channel (denoted as the channel Na^+ ions). The assignment for the channel Na^+ ions is supported by our recent observation that the ^{23}Na NMR signal from Na(Nonactin)SCN appears at $\delta = -16$ ppm.[10] In this complex, the Na^+ ion is coordinated by 8 oxygen atoms from the nonactin molecule,[12] in a cubic fashion very similar to that between two G-quartets.

To confirm the above spectral assignment, we prepared two additional 5′-GMP gel samples. The Cs–Na gel sample (**2**) was prepared by adding 1.0 mL of 3.5 M CsCl (aq.) to an aqueous



Scheme 1

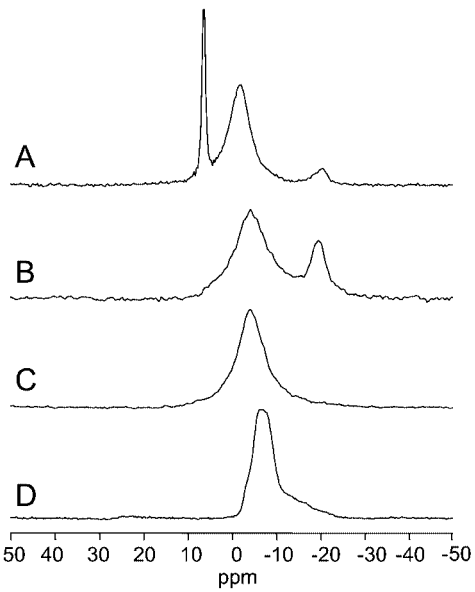


Fig. 1 Solid-state ^{23}Na MAS spectra of 5′-GMP samples. (A) Na gel sample, **1**. (B) Cs–Na gel sample, **2**. (C) K–Na gel sample, **3**. (D) Polycrystalline Na_2(5′-GMP)·$7H_2O$, **4**. All NMR spectra were recorded on a Bruker Avance-500 spectrometer operating at 500.13 and 132.29 MHz for ^{1}H and ^{23}Na nuclei, respectively. The sample spinning frequency was 8000 ± 2 Hz. The RF field strength at the ^{23}Na frequency was approximately 90 kHz.

† Electronic supplementary information (ESI) available: ^{31}P CPMAS spectra of Na gel, Cs–Na gel and Na_2(5′-GMP)·$7H_2O$. See http://www.rsc.org/suppdata/cc/b1/b107353m/

 DOI: 10.1039/b107353m

solution containing 175 mg of Na_2(5′-GMP), followed by recrystallization three times from 40% (V/V) MPD–H_2O. The K–Na gel (**3**) was prepared using KCl (aq.) in a similar procedure as that for **2**. As seen in Fig. 1B, the signal intensity for the surface Na^+ ions is significantly reduced for the Cs–Na gel compared with that for the Na gel sample. This suggests that the Cs^+ ions do not enter the central cavity formed by stacking G-quartets but replace partially the surface Na^+ ions. The observation of a signal at −19 ppm in Fig. 1B indicates that the G-quartet structures are intact in the Cs–Na gel. On the other hand, K^+ ions are preferred over Na^+ ions to occupy at the sites between the G-quartets. Consequently, for the K–Na gel sample, the ^{23}Na NMR signal associated with the channel Na^+ ions disappears completely in Fig. 1C. To make further comparison, we also obtained solid-state ^{23}Na NMR spectra for a polycrystalline sample of Na_2(5′-GMP)·$7H_2O$ (**4**). Because the Na^+ ions in the crystal lattice of **4** are hexacoordinate,[13] the main features of the ^{23}Na MAS spectrum (Fig. 1D) appear between −2 and −10 ppm.

In contrast to the aforementioned low-resolution 1D MAS spectra, the 2D ^{23}Na MQMAS spectra shown in Fig. 2 exhibit significantly improved resolution. For the Na gel sample, the 2D spectrum reveals the presence of two groups of signals originating from the channel Na^+ ions. Careful examination indicates that one of the two spectral regions (labeled as Na2) is severely tilted from the horizontal axis, as illustrated in Fig. 2A. The tilting is a consequence of a distribution of chemical shifts and quadrupole coupling constants, often resulting from the presence of multiple Na^+ sites. From Fig. 2A, the following parameters can be estimated for the Na gel sample: surface Na^+ ions, $C_Q = e^2q_{zz}Q/h \approx 1.6$ MHz, $\eta = (q_{xx} - q_{yy})/q_{zz} \approx 1$, $\delta \approx 3$ ppm; channel Na^+ ions, $C_Q \approx 1.1$ MHz, $\eta \approx 1$, $\delta \approx -18$ ppm. Similarly, the signal for the channel Na^+ ions in the Cs–Na gel sample (Fig. 2B) is also tilted, but does not show resolved signals. This can be explained by a lower ordering of the helices in the Cs–Na gel sample. To further confirm the ordering of helices in gel samples, we obtained ^{31}P CP/MAS NMR spectra (see ESI†). The ^{31}P CP/MAS spectrum of the Na gel exhibits two sharp peaks at 5.0 and 3.8 ppm each with a line width of 200 Hz. On the contrary, the ^{31}P spectrum of the Cs–Na gel shows only a very broad peak at 5.0 ppm of a line width of more than 1000 Hz. The lack of ordering in the Cs–Na gel sample is also reflected from the ^{23}Na MQMAS signal for surface Na^+ ions.

By combining 1D MAS and 2D MQMAS data, we were able to obtain the following parameters for each of the four Na sites in Na_2(5′-GMP)·$7H_2O$: Na1, $C_Q = 1.30$ MHz, $\eta_Q = 0.7$, $\delta = -4.5$ ppm; Na2, $C_Q = 1.85$ MHz, $\eta_Q = 0.5$, $\delta = -2.0$ ppm; Na3, $C_Q = 1.85$ MHz, $\eta_Q = 0.6$, $\delta = -2.0$ ppm; Na4, $C_Q = 2.30$ MHz, $\eta_Q = 0.7$, $\delta = -5.5$ ppm. Based on a simple correlation between C_Q and ion-binding geometry, tentative assignments were made as follows. Na1 can be assigned to the Na site with 4 water molecules and two hydroxy groups from the ribose groups. Na2 and Na3 correspond to the two fully hydrated Na sites. Na4 is due to the site that is coordinated to four water molecules and two N7 nitrogen atoms from the pyrimidine moieties.

Finally, we should point out that the solid-state ^{23}Na NMR spectra for 5′-GMP gels are very similar to those reported for $[d(TG_4T)]_4$.[9] Based on the evidence presented in this study, we conclude that the previous ^{23}Na NMR spectral assignment for $[d(TG_4T)]_4$ was erroneous. In particular, the ^{23}Na NMR signal at 6.8 ppm was incorrectly assigned to channel-bound Na^+ ions. We believe that solid-state ^{23}Na NMR will be a useful technique for detecting Na^+ ions in other metal-directed self-assembly systems as well as in nucleic acids.

Received (in Cambridge, UK) 5th September 2001, Accepted 1st November 2001
First published as an Advance Article on the web 23rd November 2001

A five-stranded β-sheet bearing two histidine residues as part of a metal-binding site has been designed, synthesised and characterised using NMR and electrospray ionization mass spectrometry techniques.

Construction of well-defined structural elements such as isolated helices,[1,2] helical bundles,[3,4] β-turns and hairpins,[5,6] mixed α/β structures[7] and β-sheets[6,8] have employed common design principles such as (a) incorporation of residues with appropriate secondary structural propensities,[1] (b) utilisation of sequence motifs observed in protein three-dimensional structures as structural templates[4,9] or (c) nucleation of specific conformations by sterically constrained non-protein amino acids.[5,10] Indeed, the use of both normal as well as unusual amino acids that nucleate turns with requisite stereochemistry (type I′ and type II′) have been responsible for the successful design of β-hairpins and small sheets that are stable in aqueous[6,8,11] and organic solvents.[5,12] Attempts at the construction of large multistranded sheets as precursors for the rational design of β-sandwiches and β-barrels have been plagued by problems of solubility and difficulty in characterising the designed structures.[13]

We demonstrate in this communication, the construction of a five stranded β-sheet, whose stable, extended backbone can be further utilised as a template onto which a metal-binding site can be grafted.† The designed 34-residue peptide, **B5** [RGIKV^{D}PGETNT^{D}PSVQF**H**TI^{D}PGYKTL**H**E^{D}PARIVLK], has four ^{D}Pro-Xxx segments designed to nucleate type II′/I′ β-turns (Fig. 1). β-branched residues such as Val/Ile/Thr, which are known to promote β-sheet conformation have been appropriately positioned in the strands. A large number of positively charged residues (Arg/Lys) have been included in the designed sequence to enhance solubility and discourage aggregation.

The design of metal binding sites has often stressed the His_xCys_x motif as appropriate ligands for the chelation of transition metals.[14] We have chosen to position two histidine residues (His 17 and His 26) on adjacent (third and fourth) strands of the five-stranded β-sheet towards the construction of a minimal metal-binding motif. Folding of the **B5** peptide sequence into the target structure would bring the two His residues into the required structural juxtaposition for metal-ion chelation. In addition, the Glu8-His17 pair may also serve as a metal binding site. Tridentate coordination involving Glu8, His17 and His26 is impossible if the constraints of the β-sheet are maintained.

The structure of the **B5** peptide was characterized in detail using high-resolution NMR techniques in methanol, as CD studies indicated the peptide to be poorly structured in water. TOCSY and NOESY experiments permitted complete sequence-specific assignments for **B5**. Spectra derived from NOESY experiments revealed various features consistent with β-sheet structure, such as significantly more intense $C_i^{\alpha}HN_{i+1}H$ ($d_{\alpha N}$) NOEs as compared to the corresponding intraresidue $N_iHC_i^{\alpha}H$ ($d_{N\alpha}$) NOEs. The folding of **B5** into β-sheet conformation with the desired strand registry was corroborated by the presence of several key, long-range NH/NH NOEs and medium intensity, cross-strand $C^{\alpha}H$/ $C^{\alpha}H$ NOEs (Fig. 1, 2) between residues E8/H17, N10/Q15, F16/L25, T18/K23 and H26/I31. The observation of sequential d_{NN} NOEs between residues G7/E8, S13/V14, G21/Y22 and A29/R30 served to confirm the position of the turns. H/D exchange experiments

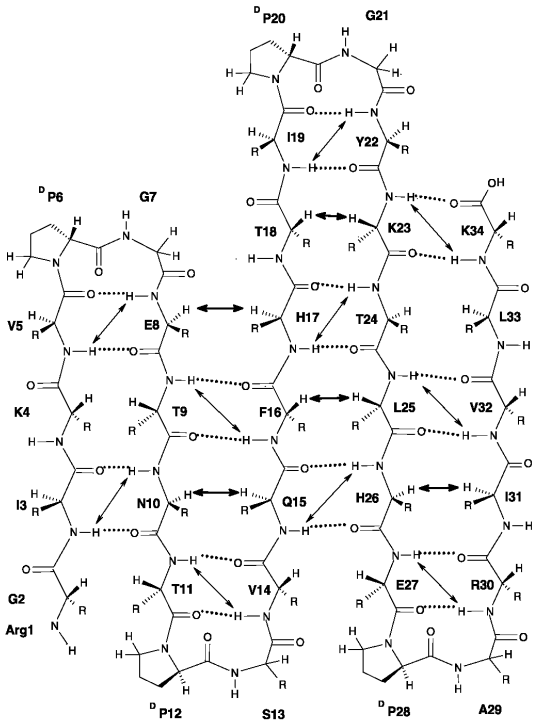

Fig. 1 Schematic representation of the target structure for B5. Important long range NOEs observed are indicated by arrows (darker arrows denote medium NOEs and lighter arrows represent weak NOEs).

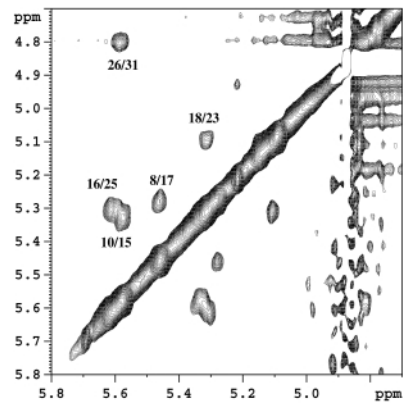

Fig. 2 Partial expansion of the NOESY spectrum of **B5** in CD_3OD at 300 K, indicating long range $C^{\alpha}H$/ $C^{\alpha}H$ NOEs.

 DOI: 10.1039/b107883f

performed on the **B5** peptide in CD_3OD revealed the presence of some slow exchanging amide protons corresponding to residues involved in hydrogen bonding in the β-strands (I3, V5, T9, T11, V14, F16, I19, Y22, T24, R30 and V32).

Structure calculations were performed using DYANA[15] and a total of 228 distance constraints (114 upper and 114 lower), derived from 90 NOEs and H/D experiments. A superposition of ten best structures is shown in Fig. 3a, with a mean RMSD of 1.04 Å for all back bone atoms. Fig. 3b is a ribbon diagram of the mean structure for **B5**, illustrating probable orientations of His17 and His26, the components of the designed metal binding site.

The ability of the peptide to bind a single nickel ion between the two imidazole groups of His17 and His26 was demonstrated by electrospray ionization mass spectrometry (ESIMS) in methanol. Fig. 4 is the ESI mass spectrum of the free peptide and **B5** bound to Ni^{2+}. The mass of the free peptide as revealed by ESIMS is 3785 (Calc. mass = 3785.4). The mass observed for **B5** treated with nickel acetate is 3842, which corresponds to the mass of the peptide + the average mass of Ni^{2+} − 2 [3785.4 + 58.5 − 2; the two most abundant isotopes of nickel are of mass 57.94 (68%) and 59.93 (26.2%)]. The observation of the complex [peptide + Ni^{2+} − 2H] demonstrates simultaneous interaction of the metal ion with two deprotonated imidazole groups. It should be noted that under our conditions of electrospray, coordinated solvent molecules are stripped off the metal ion. Also, attempts to detect sandwich complexes containing a ratio of 2[peptide] : 1 Ni^{2+} were unsuccessful.

Similar results were observed in experiments done with Zn^{2+} ions (data not shown). It is worthy of remark that **B5** has yet another group capable of chelating metal ions, namely Glu8.[16] Indeed, the Glu8/His17 pair could function as a metal ion binding site in a manner analogous to the His17/His26 pair, yielding the observed mass in ESIMS experiments. But **B5** has an overall positive charge of +5 [2 His, 3 Lys, 2 Arg, 1 free amino terminus, 2 Glu and 1 free carboxy terminus], which is reflected in the charge state distribution observed in the ESI mass spectrum of the free peptide (Fig. 4, top); where the +5 charge state is the most abundant. Chelation of a metal ion (M^{2+}) contributes two positive charges to the peptide–metal ion complex, and should have resulted in a shift in the charge envelope of the complex (Fig. 4, bottom). The continued observation of the +5 charge state as the most abundant suggests that two negative charges have been *acquired* by the complex. This is consistent with the loss of two protons by the imidazole groups of His17 and His26 (resulting in two negative charges), rendering the charge of the [His_2-M^{2+}] moiety zero, and maintaining the overall charge of the complex at +5. Involvement of one His and one Glu residue in metal binding would have resulted in the creation of only one new negative charge; in this case the charge state distribution might be expected to be different, with the +6 state being most abundant. CD spectra of peptide–metal complexes closely resembled the parent spectrum, suggesting no major conformational change on metal ion binding, supporting the existence of a preformed template and further indicating the absence of tridentate coordination.

The present design strategy has successfully resulted in the characterisation of a five-stranded β-sheet capable of metal ion coordination. In principle, a metal ion template can be used to assemble individual β-sheet structures to form β-sandwiches and closed β-barrels.

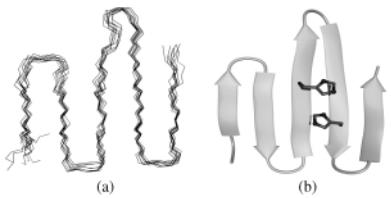

Fig. 3 (a) Superposition of 10 best structures of **B5** obtained from NMR restraints. (b) Ribbon diagram of mean structure illustrating the position of His17 and His26 (side chain positions modeled).

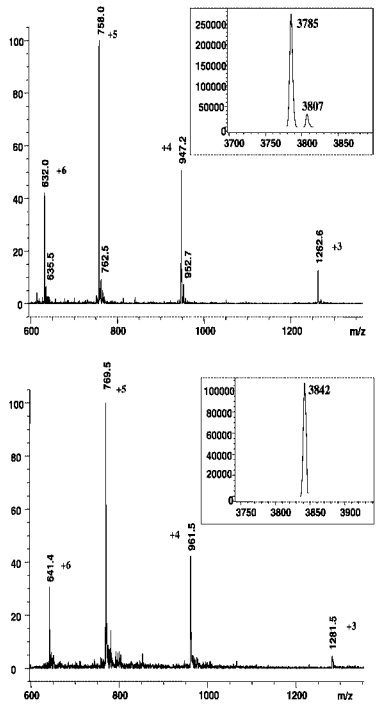

Fig. 4 ESI mass spectra of **B5** (top) and its metallated (Ni^{2+}) form (bottom) illustrating the various charged states observed. Insets show the mass of the two peptide species after deconvolution. Mass spectra were recorded with methanol as the eluting solvent.

Notes and references

† The B5 peptide was synthesised by standard solid-phase methods using Fmoc chemistry and purified by reverse phase HPLC (C18, 10μ) on acetonitrile–water–0.1% TFA gradients. The peptide was characterised by electrospray mass spectrometry and complete NMR analysis on a Bruker 500 MHz spectrometer. Mass spectrometric experiments were carried out on a Hewlett Packard series 1100MSD mass spectrometer.

The large specific interfacial areas and short molecular diffusion distances provided by glass microchips play important roles not only for effective phase-transfer synthetic reaction, but also for avoiding an undesirable side reaction.

Recent microchip technology has opened various application fields in chemistry.[1] In particular, applications in analytical chemistry, called 'Micro Total Analysis Systems (μ-TAS)', have been established as one of the largest research fields.[2] On the other hand, growing interest has also focused on applications in synthetic organic chemistry.[3]

As we have pointed out elsewhere, a liquid microspace such as a microchannel or microwell fabricated on a glass microchip provides interesting characteristics such as short molecular diffusion distance, large specific interfacial area (liquid–liquid or liquid–solid), and small heat capacity, all of which can be expected to promote highly effective chemical reactions in the microchip. By exploiting these characteristics, we have demonstrated general chemical reactions.[4]

The microfabricated device also allows us to exploit characteristics of microfluidics such as formation of laminar multi-phase flow. Laminar flow formed by the same solvents (*e.g.* aq.–aq., or org.–org. two phases) has been exploited for analytical purposes and fabrication purposes such as position-selective etching.[5,6] On the other hand, we have been focusing on the laminar flow formed by different solvents such as aqueous–organic multi phase flow.[7] When the organic and aqueous phases were introduced through the two inlets of the microchannel by syringe pumps, a stable liquid–liquid interface formed as seen in the photographs of Fig. 1. In this case, a large specific interfacial area could be obtained without any stirring. By exploiting the large specific interfacial area provided by organic and aqueous phases, demonstration of a fast and high conversion synthesis involving phase transfer should be possible. In addition, stable two-phase flow also allows us easy separation of two phases inside the microchannel under continuous flow conditions by splitting the reaction channel into two channels at its end. We have already succeeded in phase separation inside the microchannel in analytical applications.[8] Thus we chose the phase transfer reaction as the model synthetic reaction to be demonstrated under two-phase laminar flow.

Recent research related to organic synthesis using a microspace has been reported in the field of microreactors.[9] However, no paper has emphasized the liquid–liquid interface as the novel reaction field although it has a possibility to realize both efficient synthesis and phase separation.

In order to realize our concept in an actual experiment, we carried out a preliminary investigation of a phase transfer diazocoupling reaction as one simple example (Fig. 2). Diazocoupling reactions in microchips have been successfully demonstrated for synthesizing small amounts of azobenzene for the purpose of combinatorial synthesis.[10] In contrast, our system based on continuous multiphase flow is expected to synthesize large amounts of chemicals with high conversion. In our case, rapid phase transfer of starting material and the produced chemical species across the liquid–liquid interface play important roles to realize both the fast chemical reaction and isolation of the produced chemical species.

Here we compare the reaction efficiency of microscale and macroscale reaction conditions. The microscale reaction was performed by introducing ethyl acetate containing 5-methylresorcinol (10^{-3} M) and an aqueous phase containing 4-nitrobenzene diazonium tetrafluoroborate (10^{-4} M) through the two-inlets of the microchip under continuous flow conditions. Volume flow rates of organic and aqueous phases were fixed at 10 μl min^{-1} each. In this case, linear flow rate was estimated to be 1.3 cm s^{-1}. When the organic phase made contact with the aqueous phase, distribution of the resorcinol derivative started in the latter phase, and then, it reacted with the diazonium salt. The resulting main product was electrically neutral and it was re-distributed into the organic phase. In the case of macroscale reactions, 10 ml each of the reagent solutions (organic and aqueous solutions) were poured into a glass vessel (3.5 cm diameter) and stirred. In this case, stirring conditions were varied to evaluate the effect of mixing and specific interfacial area on reaction time and conversion. The experimental conditions are shown in Fig. 3. Letting the reaction mixture stand without stirring gave a long molecular diffusion distance and a small specific interfacial area. The weak stirring

 DOI: 10.1039/b106494k

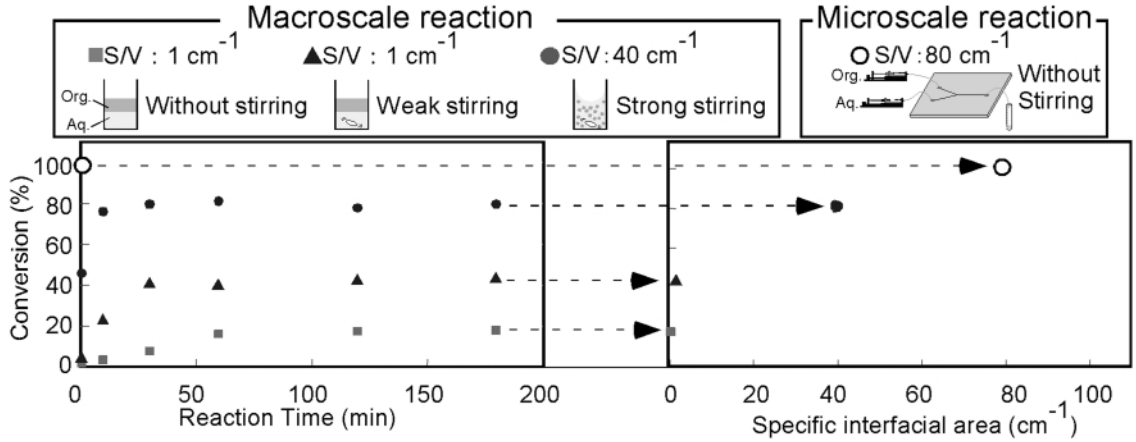

Fig. 3 Reaction conditions and results obtained with phase transfer diazocoupling reaction under microscale and macroscale conditions.

conditions provided effective molecular diffusion conditions, but almost the same specific interfacial area as that without stirring. The strong stirring conditions provided the most effective reaction conditions.

For all the experimental conditions, conversion of the diazonium salt was evaluated by standard reversed phase HPLC using an ODS column. In this case, methanol was used as an eluent at a flow rate of 1 ml min^{-1}. For the microscale reaction, simple introduction of organic and aqueous phases into the microchannel provided a stable liquid–liquid interface, and the specific interfacial area had a larger value than those of the strong stirring and no stirring conditions for the macroscale reaction. In our experimental conditions, the specific interfacial area (surface to volume ratio: S/V) provided by a microchannel 250 μm wide, 100 μm deep and 3 cm in length was calculated to be 80 cm^{-1}.[11]

Fig. 3 also shows reaction profiles and specific interfacial area dependence of conversion for the reaction conditions. For macroscale conditions, increasing the stirring speed gave a fast and high conversion as expected. However, concerning the microscale condition, conversion was higher than for any macroscale conditions studied in this work, although the residence time of starting matrices in the microchannel was only 2.3 seconds. Under macroscale reaction conditions, insoluble precipitate species of a side product were visually observed, the amount of which depended on the mixing conditions (without stirring > weak stirring > strong stirring). In contrast, the microscale reaction conditions gave no precipitate species and the conversion was close to 100%.

For the diazocoupling reaction, an undesirable side reaction of main product and a second diazonium salt to form a bisazo product is known.[12] Thus in our case, the large specific interfacial area and short molecular diffusion distance played important roles in removing the main product from the aqueous phase to the organic phase, which allowed the undesirable side reaction to be avoided. In other words, the microchip condition provided a novel methodology for avoiding a side reaction in a phase transfer synthesis.

Although the amount of starting material of 5-methylresorcinol was in excess compared to that of the diazonium salt, so that the organic phase still included residual material, a conversion of close to 100% was successfully achieved.

This is the first use of the novel synthetic methodology using a microchip, which provides fast and high conversion organic synthesis using the stable liquid–liquid interface formed in the microchannel. The large specific interfacial area and short molecular diffusion distance play important roles not only for effective phase transfer of starting material and produced chemical species, but also for avoiding an undesirable side reaction.

Recent advances in microchip technology have expanded not only for analytical or fabrication purposes but also for proteomics or understanding fundamental fluidic processes. Among them, we have focused on the characteristics provided by a liquid microspace and microfluidics, and demonstrated an attractive application example of microchip technology to synthetic chemistry.

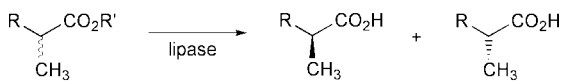
The combination of error prone PCR at high mutation rate and DNA shuffling can be used to invert the direction of enantioselectivity of a lipase-catalyzed hydrolytic kinetic resolution involving a chiral ester.

We have previously demonstrated that the methods of directed evolution[1–3] can be applied successfully in the quest to create enantioselective enzymes for use in organic chemistry.[4,5] The basic strategy involves repeating cycles of gene-mutagenesis and expression coupled with high-throughput screening for enantioselectivity. Specifically, the wild-type lipase from *Pseudomonas aeruginosa*, which catalyzes the hydrolytic kinetic resolution of ester **1** with slight preference for the *S*-acid **2** (selectivity factor $E = 1.1$), was converted into an enzyme-



1 R = n-C_8H_{17}, R' = p-NO_2-C_6H_4 — *S*-**2** — *R*-**2**

variant showing high *S*-preference.[4] The selectivity factor *E*, which reflects the relative reaction rate of the two enantiomers, turned out to be 26. This was accomplished by four cycles of random mutagenesis using error prone polymerase chain reaction (epPCR) at low mutation rate corresponding to an average of one amino acid substitution per enzyme molecule, followed by saturation mutagenesis at sensitive positions (hot spots) in the protein. The wild-type lipase consists of 285 amino acids, a number that needs to be considered when calculating the theoretical protein sequence space.[6] By modifying the so-called combinatorial multiple cassette mutagenesis as originally described by Stemmer,[7] enantioselectivity was recently doubled ($E = 51$).[8] We now show that the *direction* of enantioselectivity can be reversed completely by a combination of high error rate epPCR and DNA shuffling.[3] Previously we observed only a small degree of inversion of enantioselectivity on the basis of epPCR alone.[5] Recently Arnold used epPCR and saturation mutagenesis to convert a D-selective hydantoinase into an L-selective variant (ee = 20%).[9] No other cases of reversal of enantioselectivity by directed evolution have been reported to date.

The original library of enzyme variants produced by applying epPCR at low mutation rate to the wild-type gene of the lipase from *Pseudomona aeruginosa* contained only *S*-selective enzymes.[4,5] We therefore carried out the same experiment at a relatively high mutation rate corresponding to about 2–3 amino acid substitutions per enzyme molecule.[6] Upon screening an enzyme library of 15 000 clones,[10] several *S*-selective variants were identified,[8] but also two *R*-selective enzymes 18F9 and 12G12, characterized by a single mutation (V232I) and four mutations (S112P, S147N, T150A and T226A), respectively. The *E*-values were found to be 2.0 and 1.1, respectively. In addition, enzyme 47E6 (with D113G, I142T, S218L and S268N) was identified, showing no preference for either of the two enantiomers ($E = 1.0$).

Gene 18F9 served as the basis for another cycle of epPCR under otherwise identical conditions. As a result of screening 5000 clones, *R*-selective enzyme-variants 18F9E1 (with M16L, A34T and V232I) and OE7 (with V55A, P86L, D113G and V232I) were discovered, displaying *E*-values of 3.7 and 3.0, respectively. In a similar third cycle of epPCR using gene OE7, enzyme-variant 3B6 (with V55A, P86L, D113G, V232I, S237T and Q275L) was generated, resulting in even higher *R*-selectivity ($E = 7.0$). However, further rounds of epPCR-based mutagenesis failed to produce positive results.

Although DNA shuffling has been shown to be effective in the alteration of such functional properties of enzymes as stability and activity,[3] these efforts did not include the evolution of enantioselectivity.[11] In an initial attempt we shuffled genes 18F9, 12G12 and 47E6, hoping that possible non-productive mutations would be eliminated. However, this turned out not to be the case, because no improvements were detected. Consequently, we increased the size of the gene pool and subjected genes 12G12, 47E6, 18F9, 3B6 and OE7 to DNA shuffling. Although no shift to significantly higher enantioselectivity resulted, three *R*-selective enzyme-variants of comparable enantioselectivity were in fact found, namely 14A5 (with V55A, P86L, D113G, S147N, T150A, V232I, S237T and Q275L), 11C8 (with V55A, P86L, A102V, D113G, V232I and S237T) and 16A7 (with V55A, P86L, S71G, D113G, V232I, S237T and S268C), the *E*-values amounting to 6.7, 6.5 and 7.0, respectively.

Since initial attempts to apply saturation mutagenesis at selected hot spots failed to increase enantioselectivity markedly, we reconsidered DNA shuffling. Hoping to increase diversity, gene 18F9E1, which we had generated earlier but neglected to utilize in further experiments, was shuffled with gene 14A5. Upon inspecting a library of 5000 clones, several *R*-selective variants were found, the best one 1G10 (with M16L, A34T, P86L, D113G, S147N, T150A, V232I and S237T) displaying a selectivity factor of $E = 20$ in the model reaction.

By comparing the mutations present in 18F9E1 and 14A5 with those of the new variant 1G10, it becomes clear that mutations V55A and Q275L have been eliminated by the process of DNA shuffling. Obviously, these two mutations exert a negative effect, which means that in the present case DNA shuffling plays the role of 'correcting' non-productive mutational changes brought about earlier. New mutations were not introduced. Finally, a single round of epPCR on top of this (using gene 1G10 at high mutation rate) resulted in yet another substantial improvement, enantioselectivity in favor of *R*-**2** reaching $E = 30$. In this case the enzyme (15B10) has 11 amino acid substitutions (M16L, A34T, P86L, T87S, V94A, D113G, S147N, T150A, L208H, V232I and S237T). Relative to variant 1G10 three new mutations (T87S, V94A and L208H) have been introduced.

It appears that the evolution of pronounced *R*-selectivity requires greater structural change than in the case of *S*-

 DOI: 10.1039/b109913m

selectivity, which seems to be reflected in the comparatively high number of amino acid exchanges. It is also interesting to note that the amino acid substitutions described herein occur at positions which are quite different from the hot spots that were uncovered in the case of the *S*-selective counterparts.[4,5] Although we do not yet have crystallographic data of any of the *S*- or *R*-selective mutants, the X-ray structural analysis of the wild-type lipase from *Pseudomonas aeruginosa* was recently reported by Dijkstra.[12] Of the 11 mutations that we have identified in the *R*-selective enzyme 15B10, some are near the active site, while others occur at remote positions (Fig. 1). It is likely that the enzyme folds in a slightly different way.[4b]

In summary, we have shown that the appropriate combination of epPCR at high error rate and DNA shuffling can be used to invert the enantioselectivity of an enzyme-catalyzed reaction to a synthetically useful level. Accordingly, the generation of *S*-selective (E = 51) and *R*-selective (E = 30) enzymes is possible on an optional basis. The appropriate evolutionary pressure is exerted in each case by screening for the desired enantiomer (*S* or *R*). Whereas knowledge of the structure of the enzyme or of its mechanism of action is not required, a limited amount of navigation in protein sequence space is necessary. In doing so less than a total of 45000 clones were screened.[10] Work is in progress to illuminate the source of *S*- and *R*-selectivity.

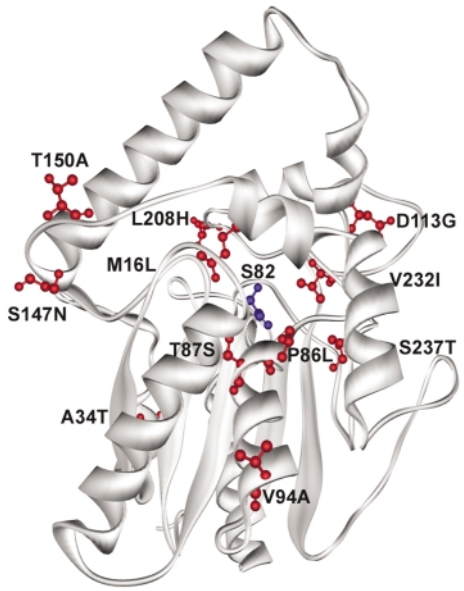


Fig. 1 Structure[12] of the wild-type lipase from *Pseudomonas aeruginosa* showing the active site S82 and the 11 mutations of variant 15B10.

We are also applying DNA shuffling[3] as a tool in the *in vitro* evolution of other enantioselective enzymes for application in synthetic organic chemistry.

Received (in Cambridge, UK) 15th August 2001, Accepted 8th November 2001
First published as an Advance Article on the web 28th November 2001

A cyclic dodecanuclear nickel complex is the first single molecule magnet based on nickel(II) centres; the material is also the highest spin molecule to show resonant quantum tunnelling of magnetisation.

It is eight years since the first report of 'single molecule magnetism',[1] *i.e.* the observation that some complexes with high spin ground states show hysteresis in magnetisation *vs.* field. This phenomenon is of great interest, as it offers the promise of enormous technological advances—the storage of magnetic information in individual molecules—and has allowed studies of fundamental processes such as quantum tunnelling.[2] The latter observation has also led some to propose that single molecule magnets (SMMs) could be used in quantum computing.[3]

The original SMMs were a family of dodecanuclear mixed-valent manganese cages, and since that time other SMMs have been reported. The majority have featured manganese[4] or iron,[5] with one report of a vanadium-based SMM.[6] Here we report the first nickel SMM, and a preliminary account of low temperature studies of its magnetic behaviour.

$[Ni_{12}(chp)_{12}(O_2CMe)_{12}(H_2O)_6(THF)_6]$ **1** (chp = 6-chloro-2-pyridonate)[7] is cyclic, containing twelve Ni(II) centres bridged by pyridonate and acetate ligands (Fig. 1). It has crystallographic S_6 symmetry and all rings within the structure pack parallel to each other, and perpendicular to the crystallographic *c*-axis in the space group $R\bar{3}c$.

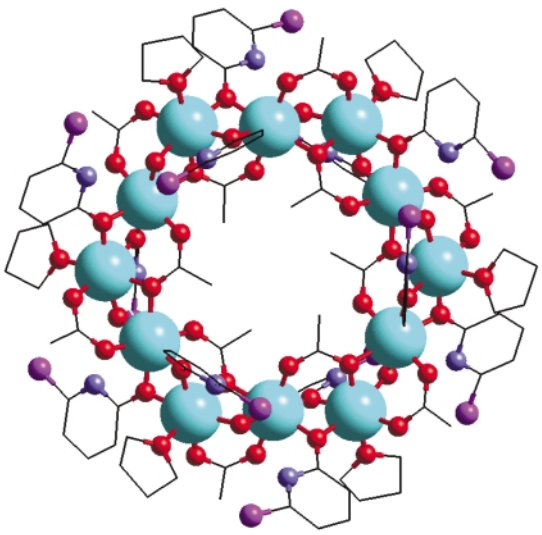

Fig. 1 The structure of **1** (Ni, light blue; O, red; N, blue; Cl, purple; C, black).

Isothermal magnetisation studies on powdered samples‡ at 150 mK saturates at 25.5 μ_B, which confirms a $S = 12$ ground state and gives a *g*-value of 2.13. The curve can be fitted with these parameters and a D/k-value of −0.07 K (D = axial zero-field splitting parameter, k = the Boltzmann constant). When measurements are performed on single crystals with the field parallel to the *c*-axis, hysteresis is seen in magnetisation *vs.* field measurements at sweep rates of 0.035 T s^{-1}, and at temperatures of 0.4 K and lower (Fig. 2: note: M_s, was measured at 1.4 T, *i.e.* a much higher field than shown in Fig. 2). The hysteresis becomes more pronounced as the temperature is lowered and, at 0.2 K and colder, steps become resolved due to resonant quantum tunnelling of magnetisation. These steps, which are most clear at 0.1 and 0.04 K and occur at *ca.* 0, ±0.047 and ±0.094 T (Fig. 2), are due to sudden loss of magnetisation as m_s levels within the $S = 12$ spin ground state manifold come into resonance with m_s levels on the other side of the energy barrier, which allows tunnelling of the magnetisation through this barrier. The levels cross when $\mu_o H_z = nD/g\mu_B$ (where n = an integer). Here the field between two resonances is 0.047 T and $g = 2.13$, therefore we can calculated $D/k = -0.067$ K. The energy barrier for reorientation of magnetisation is given by $E_a = DS^2$, therefore here $E_a/k = 9.6$ K.

Studies of magnetic susceptibility‡ in an alternating field show the frequency (υ) dependent peak in the out-of-phase susceptibility (χ''), characteristic of SMMs (Fig. 3, inset). The maximum moves from *ca.* 0.25 K at 0.001 Hz to *ca.* 0.55 K at the fastest frequency (511 Hz). An Arrhenius treatment of this data gives a second measurement of the energy barrier for reorientation of magnetisation, which is the slope for ln τ *vs.* $1/T$ ($\tau = 1/2\pi\upsilon$), and is found to be between 9 and 10 K, which is in good agreement with resonant tunnelling.

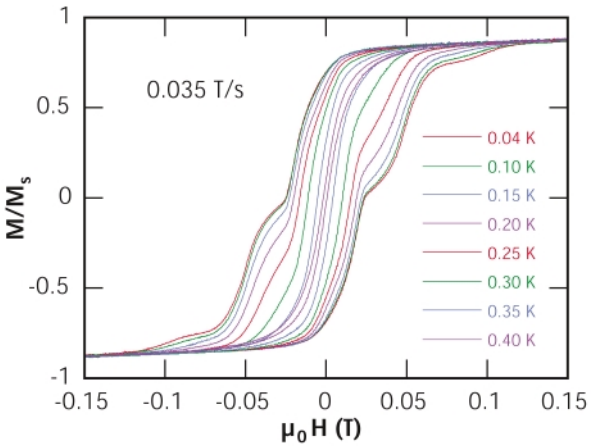

Fig. 2 Magnetisation against field for **1**, showing steps due to tunnelling.

† Electronic supplementary information (ESI) available: saturation magnetisation at 150 mK; $1/\chi'$ *vs.* T. See http://www.rsc.org/suppdata/cc/b1/b108894g/

 DOI: 10.1039/b108894g

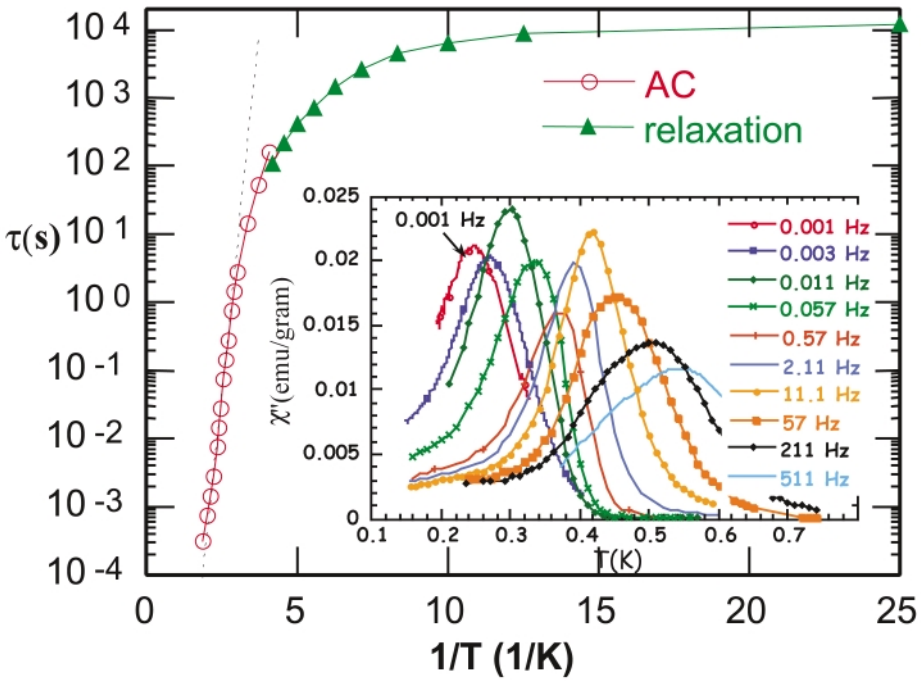

Fig. 3 Main: τ *vs.* $1/T$ measured from ac susceptibility (red circles) or relaxation (green triangles); inset: χ'' of **1** *vs.* T at 10 frequencies.

The exact value for E_a is imprecise, as below 0.2 K saturation is seen similar to that observed in other SMMs. This is because the relaxation rate no longer follows the Arrhenius law as non-thermal pathways become important. Relaxation measurements at below 0.2 K confirm the onset of saturation (Fig. 3).

An unexpected observation is that a plot of $1/\chi'$ *vs.* T from 0.4 to 1.2 K gives a straight line, and extrapolation gives a Weiss constant of +0.25 K, indicating ferromagnetic interactions. At below 1.2 K the cage is predominantly in an $S = 12$ state, therefore *intramolecular* interactions are less important, which implies the positive intercept is due to *intermolecular* exchange. The shortest Ni···Ni contact in **1** between Ni centres in different rings is 10.7 Å, while the distance between ring-centroids is 16.9 Å. This separation and absence of a pathway disfavour an explanation based on super-exchange. Dipolar exchange would give approximately the correct magnitude for this interaction,[10] but would not account for the interaction being ferromagnetic. While intermolecular dipolar exchange has been mentioned in studies of clusters,[9,11] it is neglected in the majority of cases.

Resonant tunnelling of the magnetisation has been observed in molecules where $S = 10$ or lower,[2,5,12] but never in molecules with spin ground states as high as that found for **1**. In other very high spin cages that show slow relaxation of magnetisation, *e.g.* $\{Fe_{19}\}$ cages,[13] intermolecular interactions quench tunnelling effects. The observation of tunnelling in **1** is surprising given both the small anisotropy, approximately one-tenth of that found in $\{Mn_{12}\}$ SMMs,[1] and the evidence of significant coupling between molecules of **1**. These preliminary results require many further experiments for full understanding. Given the apparent value of the intermolecular exchange we may be near a ferromagnetic phase transition. The magnitude of χ'' has an anomalous frequency dependence, which requires further study.

This work was supported by the EPSRC and a TMR network on 'Molecules as Nanomagnets' (HPRN-CT-1999-0012).

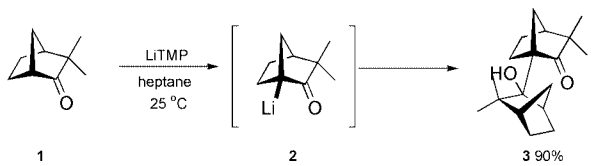
First published as an Advance Article on the web 6th December 2001

The generation and silylation of bridgehead enolates has been accomplished in high enantiomeric excess using a chiral lithium amide base.

The anti-Bredt nature of bridgehead enolates (more accurately described as α-keto carbanions) derived from ketones having small bridges is expected to make their generation difficult or impossible.[1,2] However in certain cases reactive α-keto carbanions have been formed at bridgehead positions, despite the lack of true enolate character. In these situations the intermediate anion appears highly reactive and displays chemistry that is difficult to control. An example is the metallation of (−)-camphenilone **1** with lithium tetramethylpiperidide (LiTMP).[3] Even in the presence of *in situ* trapping agents, such as Me_3SiCl, the presumed intermediate **2** could not be intercepted and only the aldol product **3** was obtained (Scheme 1).†

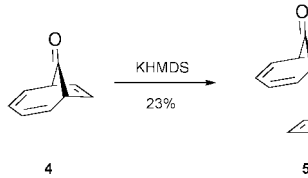


Scheme 1

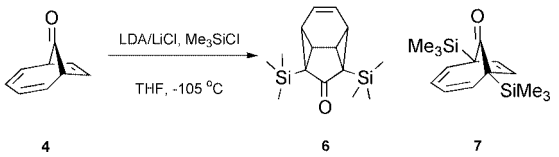
Feldman and coworkers reported that bicyclo[4.2.1]nona-2,4,7-trien-9-one **4** exhibited a similar tendency towards self-addition when treated with potassium hexamethyldisilazide (KHMDS), to give aldol product **5** in 23% yield (Scheme 2).[4]

As part of our programme of research aimed at exploring the applications of chiral lithium amide bases we became interested in the types of bridgehead enolate presumed to be intermediates in the above Schemes. Herein we describe our preliminary investigations in this area, which show that chiral lithium amide bases allow unprecedented enantioselective access to the products of bridgehead substitution in compounds such as **4**.

Initial studies with ketone **4** demonstrated that external quench protocols were ineffective in trapping the carbanion, leading only to the addition product **5**, albeit in an improved yield of 66%. Instead we turned our attention to deprotonation under *in situ* quench conditions with LDA–LiCl in the presence of Me_3SiCl, a method which we have employed in the past with success.[5] Thus addition of ketone **4** to an excess of LDA–LiCl in the presence of Me_3SiCl (method A, see later) at −105 °C led to the formation of an inseperable mixture of *bis* silylated ketones **6** and **7** in a 4 : 1 ratio and in a combined yield of 63% (Scheme 3).



Scheme 2



Scheme 3

The formation of the tetracyclic ketone **6** was unexpected and was confirmed following a single crystal X-ray structure determination.‡ This product is the result of double bridgehead substitution followed by a transannular Diels–Alder reaction, the latter process being precedented for this system.[6] We observed no partially silylated ketones corresponding to **6**, which points to its formation purely *via* **7**. An alternative mechanism involving anion initiated cycloaddition of **4** followed by bis-silylation appears to be ruled out following further experiments described below.

By changing the mode of deprotonation to addition of the base to a mixture of ketone and Me_3SiCl (inverse addition) we hoped to minimise formation of the unwanted bis-silyl compounds **6** and **7**. Selected results using this method (method B) are highlighted in Table 1, along with comparison data using method A. We discovered that upon addition of LDA–LiCl to a solution of ketone **4** and Me_3SiCl at −105 °C, the mono silylated ketone **8** was obtained in 38% yield, accompanied by a mixture of **6** and **7** in 17% yield (entry 2).

Next we attempted the asymmetric deprotonation of **4** by employing chiral base (*R*,*R*)-**9**.[7] By using the inverse addition protocol with (*R*,*R*)-**9** at −105 °C we obtained mono silylated ketone (−)-**8** in 76% yield and with an excellent ee of >96% in addition to bis silylated ketones **6/7** in 23% yield (entry 3).§ Conducting the reaction at −78 °C led to a lower yield and slightly lower enantiomeric excess (entry 4). The absolute configuration of (−)-**8** was determined by single crystal X-ray structure determination (Fig. 1).¶

 DOI: 10.1039/b108986m

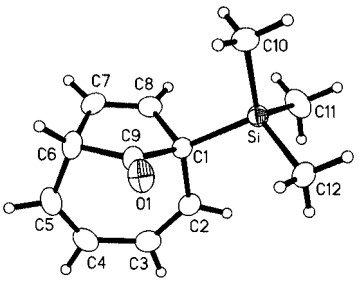

Fig. 1 X-Ray structure of (−)-**8**. Displacement ellipsoids are drawn at the 50% probability level.

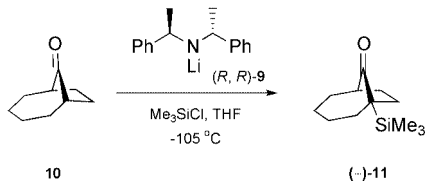
We found no trace of a cyclised isomer of **8** corresponding to **6**, and attempts to induce the internal cycloaddition of **8** by heating led only to decomposition. It therefore appears that disilylation of **4** facilitates the cyclisation to give **6**.

The remarkable and unprecedented asymmetric substitution of ketone **4** prompted us to examine similar bridgehead metallations with the saturated ketone **10**, available from **4** by hydrogenation. Treatment of a mixture of ketone **10** and Me_3SiCl with (*R*,*R*)-**9** gave (−)-**11** in 53% yield and 92% optical purity (Scheme 4). The stereochemical configuration and optical purity were assigned by correlation with our earlier results, following hydrogenation of (−)-**8** to give (−)-**11**.

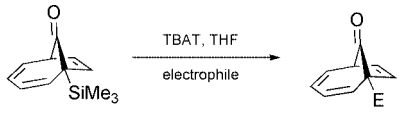
Unfortunately the *in situ* quench approach is incompatible with most electrophiles and we found that inclusion of electrophiles such as methyl iodide, allyl bromide and benzaldehyde gave none of the desired products. However, indirect access to products having alternative types of substituent was found to be possible by fluoride mediated silyl exchange reactions of (−)-**8**, using tetrabutylammonium triphenyldifluorosilicate (TBAT), Table 2.[8]

We expect that substitution occurs without erosion of enantiomeric purity, although this has only been established for entry 5 so far.



Scheme 4

Table 2 TBAT mediated silyl exchange in the presence of electrophiles



(-)-**8**

Entry	Electrophile, E	Yield (%)
1	MeI	42
2	AllylBr	29
3	BnBr	28
4	c-hexylCHO[a]	78
5	PhCHO[b]	72

[a] Obtained with diastereoisomeric ratio (dr) 4:1 [b] Obtained with dr 3:2.

Similarly, treatment of (−)-**11** in the presence of PhCHO with TBAT in refluxing THF gave the aldol product as a mixture of diastereoisomers (3:2) in 93% yield.

The remarkable enantioselective substitution of ketones **4** and **10** described above may pave the way for successful bridgehead metallation of many other types of bridged carbonyl compounds. Efforts to determine the scope of this chemistry are underway.

We are grateful to the University of Nottingham and GlaxoSmithKline for support of D. T. K. under the CASE scheme.

Notes and references

† Our efforts to control the metallation of **1** were unsuccessful leading only to aldol product **3**.

Synthesis of tailored bimodal mesoporous materials with independent control of the dual pore size distribution

Jihong Sun, Zhiping Shan, Thomas Maschmeyer, Jacob A. Moulijn and Marc-Olivier Coppens*

Department of Chemical Technology, Delft University of Technology, Julianalaan 136 2628 BL, Delft, The Netherlands. E-mail: M.O.Coppens@tnw.tudelft.nl

Received (in Cambridge, UK) 1st October 2001, Accepted 6th November 2001
First published as an Advance Article on the web 21st November 2001

A new synthesis method is presented to prepare multi-structured porous materials through a fully chemical route that allows control of the smaller and larger mesopore sizes independently.

A well-defined pore size distribution at various scales is desirable for a variety of applications.[1] Experiments and simulations have shown that a hierarchical combination of independently controlled, well-connected smaller and larger mesopores[2] reduces transport limitations in catalysis, resulting in higher activities and better controlled selectivities.[3]

Since the first reported syntheses of MCM-41, there has been intense research activity in designing and synthesizing structured mesoporous solids with controlled pore sizes.[4] Recently, using a variety of techniques, *physical* templating methods were proposed to create large meso- or macropores.[5] However, scale-up of these approaches may not be easy or cheap, prompting for the development of alternative *chemical* templating methods by which larger mesopores (≥10 nm) could be produced in a controlled way.

Here, we present such a method by means of which particles of a primary mesoporous material, *e.g.* MCM-41, are cross-linked using triblock copolymer assemblies as templating agents to form a material with a secondary bimodal pore distribution. By varying the synthesis conditions in the second step, it is possible to synthesize a broad class of such hierarchically structured silicas (Table 1).

In the first step tetraethylorthosilicate, the template cetyltrimethylammonium bromide (CTAB), water and ammonia were mixed at room temperature in a ratio of 1:0.2:160:1.5. This 'primary product' was filtered off and repeatedly washed with distilled water. After drying and calcination, the structure of the 'primary product' was confirmed by XRD (Fig. 1) and nitrogen adsorption, as MCM-41.[6] Its isotherm (sample 1) is consistent with a narrow pore size distribution around 2.6 nm (Fig. 2), as expected for MCM-41.† In the second step, prior to drying, part of the filtered 'primary product' was immersed in a basic (pH ~ 10) 5 wt% solution of a tri-block copolymer surfactant (*e.g.*, P-123) in a solvent (*e.g.*, ethanol). After aging the gel for 2 d in an autoclave at 100 °C, the 'secondary product' was filtered off, repeatedly washed with distilled water, dried at 120 °C for 3 h and calcined at 500 °C for 6 h in air. The formation of novel structures within the secondary product can be deduced from the N_2 adsorption–desorption isotherms of the calcined samples.

The isotherms of all secondary products (samples 2–8), exhibit two inflections (Fig. 2). The first of these (a flat hysteresis loop at $0.4 < P/P_0 < 0.55$) is shifted to a higher relative pressure compared to that of the primary product, and corresponds to a mean pore size of around 3.0–3.3 nm. Meanwhile, the XRD patterns of the secondary products show that the order of the pores has decreased somewhat, while the (100) peak is slightly shifted to lower angles (corresponding to a *d*-spacing of ~4.2 nm), due to the small primary pore size increase (Fig. 1). This results from solvent penetration in the second step into the hydrophobic core of the liquid crystalline template formed by CTAB.[7] The second inflection (a type IV-A hysteresis loop at $0.8 < P/P_0 < 0.98$) indicates the presence of a significant amount of secondary mesopores, with a synthesis dependent pore size distribution at scales >10 nm (Fig. 2 and

 DOI: 10.1039/b108860b

Table 1). The shape of this hysteresis loop is quite different in its width from the secondary loop of the primary product in the same region and suggests tubular pores instead of interparticle, textural mesoporosity.[8] At the low surfactant concentrations used here, the micelles do not form a liquid crystal phase, but disordered spherical to flexible rod- or worm-like micelles.[9]

During the initial stage of the secondary product synthesis, the primary MCM-41 gel particles are still soft and deformable; surface silanol groups exposed to the micelles form hydrogen bonds with their hydrophilic heads, while silanol groups of adjoining particles condense around the micelles at the higher temperatures in the autoclave. This view is supported by an examination of ^{29}Si magic-angle spinning nuclear magnetic resonance (MAS-NMR) spectra of the secondary materials which show for, *e.g.*, sample 3, three broad peaks at 91 (Q^2), 101 (Q^3) and 109 ppm (Q^4). The ratio of the peak areas is $Q^2:Q^3:Q^4 = 0.03:0.34:1$, whereas for the primary material (sample 1) it is 0.2 : 0.46 : 1. This suggests that the secondary materials are somewhat more condensed as would be expected as a result of covalent cross-linking.[10]

The conditions during the first step are kept constant, resulting in primary gel particles that are reproducibly within the same size range ~20 nm and the pore size distribution of which centers around 3.1 nm. Mainly by using different solvent and/or surfactant compositions during the second synthesis step, the pore size distribution of the secondary material can be controlled without appreciably modifying the pore size distribution of the primary product.

Two experiments show the role P-123 plays during the formation of secondary product. In a "blank" experiment (not using any micelle-forming P-123 in the second synthesis step, sample 2) a secondary product was obtained, the isotherm of which is consistent with a pore size of 16 nm with a 10 nm width, indicating textural mesoporosity. In a second experiment, using non-polar benzene instead of ethanol as solvent with 5 wt% P-123 (sample 4), the peak of the primary product pore size distribution shifts from 3 to 5.4 nm, because benzene is able to considerably swell CTAB aggregates/micelles located inside the primary product pores. The average secondary pore size is the same as that when no P-123 is used (*i.e.* 16 nm with a width of 10 nm). Benzene, being a better organic solvent than ethanol, dissolves P-123 completely without leading to micelle formation,[11] thus resulting in the same secondary pore size as obtained in the absence of copolymer (sample 2). Therefore, only in the presence of P-123 and under conditions where it can form micelles do we observe mesopores larger than 20 nm (*viz.* Table 1) of tubular type. The secondary pore size of sample 1 (>100 nm) is even larger due to textural interparticle meso/macroporosity.

These data are consistent with our postulate that the two pore systems are formed in independent processes. The mechanism for the formation of MCM-41 is well established,[4a,6] but for the generation of the larger mesopores in the secondary product, it is suggested that in ethanol the surfactants form micelles around which the soft particles of the primary product cross-link by condensation of the surface hydroxy groups of adjoining particles. This is schematically shown in Fig. 3. The size of the micelles, and, therefore, of the so-generated larger secondary pores, depends on the synthesis conditions [*e.g.*, surfactant composition (compare samples 6, 7 and 8), solvent polarity (compare samples 4, 3 and 5), and amount of surfactant]. A similar route to fabricate nanotubes has recently been reported.[12]

Transmission electron microscopy (TEM) images are also consistent with a bimodal pore system, showing regions of less ordered, worm-like, small mesopore channels with a diameter of 3 nm, as well as tubular, rounded, large mesopores with a diameter around 40 nm for, *e.g.*, sample 6, consistent with the

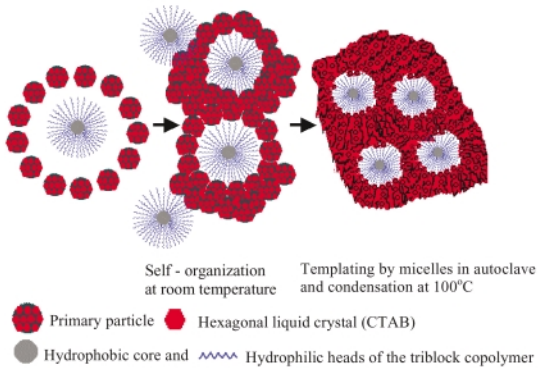

Fig. 3 Schematic representation of bimodal pore formation in the second step.

N_2 adsorption results. It should be noted that the contrast obtainable for amorphous siliceous materials is always inferior to that of ordered materials. Scanning electron microscopy (SEM) images show a smoother morphology for the secondary product compared to the particulate morphology of the primary product.

The method presented here provides a general means to synthesize multi-structured materials with a controlled pore structure over a range of scales. An efficient, hierarchical "road network" can, thus, be designed in a purely chemical way, leading to the desirable structure for a particular application.

We thank Dr P. J. Kooyman for the TEM and P. Boeser for measurement of the adsorption isotherms.

Notes and references

† The typical sharp increase at high pressure is due to inter-particle macroporosity. Also, the XRD pattern is typical for a hexagonally ordered MCM-41, with a *d*-spacing of 3.9 nm for the (100) peak.

Supramolecular encapsulation of hexaaquo metal ions by second sphere coordination

First published as an Advance Article on the web 27th November 2001

Two trianions of 1,3,5-tris(sulfomethyl)benzene each form six hydrogen bonds to the water molecules of octahedral $[M(H_2O)_6]^{3+}$ cations to completely encapsulate the metal complexes *via* second sphere coordination.

In general, second sphere coordination refers to any intermolecular interactions with the ligands directly bound to a metal center, *i.e.* the primary coordination sphere. These interactions are typically weak but can have significant effects on the physical properties of the complex. A number of excellent reviews of second sphere complexes, in general, have recently appeared,[1] as well as more specific examinations of second sphere coordination effects on stability and solubility,[2] transport properties,[3] and even effects on relaxivity of Gd^{3+} ions for MRI applications.[4] Second sphere coordination is also of major importance in biological systems, owing to the ubiquitous nature of transition metal ions and the fact that most of these centers experience at least partial hydration.[5] Several examples exist of second sphere complexes with aquo[6] and ammine[7] coordination compounds, however, the second sphere interactions are only with a fraction of the primary coordination sphere. Herein, we present the complete encapsulation of hexaaquo metal ions *via* twelve hydrogen bonds to a second sphere comprised of two trisulfonated ligands. TGA data show the enhanced stability of the primary hydration sphere. Significantly, this phenomenon appears to be general for trivalent hexaaquo metal cations.

$Fe(NO_3)_3$ was complexed to the sodium salt of the trianion of 1,3,5-tris(sulfomethyl)benzene, Na_3L,[8] in an aqueous solution. Diffusion of methanol into this solution yielded yellow crystals of $\{Fe(H_2O)_6\}[Fe(H_2O)_6(L)_2]\cdot 6MeOH$ **1**, suitable for an X-ray analysis.† The structure is highly symmetrical with an asymmetric unit consisting of one-third of a molecule of L, one methanol molecule, one-sixth of each Fe center and two water molecules, one coordinated to each Fe. The crystal structure shows two types of hexaaquo Fe^{3+} centers in the complex. The first center is completely encapsulated by two molecules of L through twelve hydrogen bonds, six to each molecule of L (Fig. 1a) forming an overall trianionic complex. The methylsulfonate groups on each molecule of L adopt a *cis-cis-cis* orientation (*i.e.* they are all on the same side of the benzene core) and cap one of the triangular faces of the octahedral hexaaquo Fe1 center. All six water molecules of Fe1 are crystallographically equivalent (Fe1–O1 1.996(2) Å). Both H atoms of the coordinated water molecule form hydrogen bonds to two sulfonate oxygen atoms from two different sulfonate groups (O1···O4 2.632(2) Å, O1···O5 2.639(2) Å). Thus, each triangular triaquo face of the Fe complex is staggered with respect to the 1,3,5-substitution pattern of L (Fig. 1b).

The hexaaquo Fe2 center is not encapsulated by L but rather is interspersed between the trianionic second sphere complexes in an efficient charge-compensating manner. It also contains only a single crystallographic type of water molecule (Fe2–O2 1.986(2) Å). Down the *c*-axis, the second sphere complexes alternate in a column with the 'naked' hexaaquo Fe2 centers. Separating these two moieties is a layer of three MeOH molecules. This packing is shown in Fig. 2. There are H-bonds between the coordinated water molecules on Fe2 and O3, the sulfonate oxygen atom not involved in H-bonding to the water molecules of Fe1 (O2···O3 2.644(3) Å). The methanol molecule is also involved in hydrogen bonding to the water molecule coordinated to Fe2 (O6···O2 2.563(3) Å) as well as to one of the sulfonate oxygen atoms already forming a H-bond to the water coordinated to Fe1 (O6···O5 2.769(3) Å). Adjacent columns along the *c*-axis are offset by 7.954(2) Å, corresponding to a third the length of the *c*-axis. Thus, a fourth column added to Fig. 2 would align laterally with the first.

Single crystals were also obtained from separate aqueous complexations of Na_3L with $CrCl_3\cdot 6H_2O$ and $AlCl_3\cdot 6H_2O$, again *via* a methanol diffusion, and these were found to be isostructural with complex **1**.[9] Thermogravimetric analyses (TGA) were performed on all three complexes and similar

 DOI: 10.1039/b110129n

trends were observed in the mass losses.[10] Specifically for **1**, loss of the guest MeOH molecules was rapid, beginning at room temperature to ~110 °C (15.57% calc., 15.88% obs.). This merges with a second mass loss of six water molecules (8.75% calc., 8.95% obs.) up to ~160 °C. Continuing, to ~265 °C, six water molecules (8.75% calc., 8.99% obs.) are lost to fully desolvate the complex. The final mass loss, above 300 °C, corresponds to decomposition of L. The TGA data of all three complexes are shown in Fig. 3 for comparison.

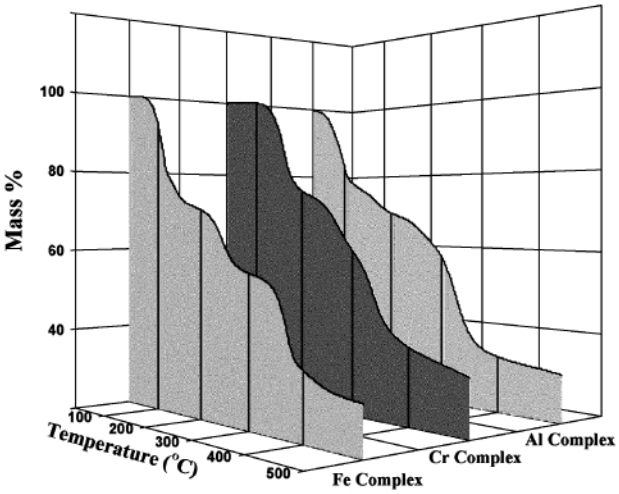

Fig. 3 Thermogravimetric analyses (TGA) of the isostructural $[(M(H_2O)_6)[M(H_2O)_6(L)_2]\cdot 6MeOH$ family of second sphere complexes, where M = Fe^{3+}, Cr^{3+} and Al^{3+}.

Typically, aquo ions in transition metal complexes are lost at temperatures below 150 °C.[11] This correlates very well with the first loss of water observed in **1**, to be assigned to the 'naked' metal cation. The temperature of the second mass loss then shows that the aquo ligands of the encapsulated metal center have been stabilized by >100 °C through the secondary coordination sphere, a very significant value given that only weak interactions are involved.

Notably, isolation of complexes of L with divalent hexaaquo metal cations was not as facile as isolation of their trivalent counterparts. This is not unexpected as, for an analogous encapsulated 2:1 ligand to metal complex, there would only be two-thirds of the positive charge within the capsule to attract the two anionic ligands. As an illustration, a competitive crystallization was performed where equimolar amounts of Na_3L, $Fe(NO_3)_2$ and $Zn(NO_3)_2$ were combined in aqueous solution. Diffusion of methanol into this mixture afforded only yellow crystals of **1**, as confirmed by a partial X-ray data collection. All the Zn^{2+} ions remained in solution.

Sulfonate anions are typically regarded as weakly coordinating ligands.[12] Indeed, most examples of transition metal sulfonate complexes prepared in aqueous media show partial to complete hydration of the metal center.[13,14] While the current results are in keeping with this trend, they also show that, with a sufficient degree of preorganization, sulfonate anions may still have a pronounced effect on the metal center. In addition to showing the stabilization possible with second sphere coordination, in a more general sense, the present study illustrates one of the hallmark principles of supramolecular chemistry,[15] that is, the effects of cooperative binding between multiple weak interactions in a preorganized fashion. Ongoing work concerns elucidating the structural features of the divalent hexaaquo complexes with L as well as hexaammine complexes.

We thank NSERC of Canada and the University of Calgary for financial support of this research.

Received (in Columbia, MO, USA) 14th September 2001, Accepted 30th October 2001
First published as an Advance Article on the web 3rd December 2001

Reaction of the new ligand 1,2-dimethoxy-4,5-bis(2-pyridylethynyl)benzene with different metal centers under similar reaction conditions led to three distinct structure formation processes: molecular ring closure, dimerization, and polymer formation.

In synthetic, covalent organic chemistry the notion of conformers, oligomers and polymers are distinctly separated and irreconcilable. In supramolecular synthesis on the other hand this conception is less stringent. The utilized building blocks and the variety of binding forces that hold supramolecular assemblies together by arranging organic modules in the solid state makes the border of the very notions of conformers, cycles, and polymers more permeable. Here we wish to demonstrate that one organic module 1,2-dimethoxy-4,5-bis(2-pyridylethynyl)benzene **1**[1] can form a supramolecular cycle, a dimer and polymer utilizing different inorganic connectors $Cu(OAc)_2$, $CoCl_2$ and $[Rh(OAc)_2]_2$.

Single crystals suitable for X-ray diffraction† of Cu(**1**)$(OAc)_2{\cdot}CH_3OH$ **2** were obtained by layering a methanol solution (1 mL) of $Cu(OAc)_2{\cdot}H_2O$ (2.0 mg, 0.01 mmol) over a dichloromethane solution (1 mL) of **1** (6.7 mg, 0.02 mmol), with a layer of pure methanol separating them (20% yield). Crystals of $[Co(\mathbf{1})Cl_2]_2$ **3** were prepared similarly, substituting $CoCl_2{\cdot}6H_2O$ for $Cu(OAc)_2{\cdot}H_2O$ and ethanol for methanol (68% yield).‡ Crystals of *catena*-poly{$[Rh(OAc)_2]_2\mathbf{1}{\cdot}CH_2Cl_2$} **4** were prepared similarly to **2** except that $[Rh(OAc)_2]_2$ was substituted for $Cu(OAc)_2{\cdot}H_2O$ (maintaining the ligand to metal ratio) and ethanol was substituted for methanol (40% yield). These three systems each form a distinctly different structure and between them, demonstrate the importance of the free rotation of the pyridyl rings around the carbon–carbon bonds for facilitating the formation of the three structure types.

Compound **2** demonstrates the preference of Cu^{2+} for square planar coordination with copper positioned snugly between the two pyridyl rings. The resulting N–Cu–N (Cu–N 2.01 Å, N–Cu–N 172.98°) bonds close an eleven membered, triangular ring (Fig. 1), which is nearly identical to the structures reported by Bosch and Barnes for 1,2-bis(2-pyridylethynyl)benzene.[2] The square planar coordination of copper is completed by two *trans* oxygens from separate acetate groups.

Compound **3** contains Co^{2+}, which is found in typical tetrahedral coordination.[3] This tetrahedral preference, apparently, cannot be conveniently satisfied through a ring closure that would require a rotation of the pyridyl rings away from the 180° angle found in the copper complex. The result of such a rotation would be an elongated Co–N bond. Instead, the pyridyl rings rotate away from each other by 128° and bind to separate cobalt atoms with bond lengths of 2.03 Å, which is typical for Co–N bonds. The tetrahedral coordination in each case is completed by two chlorine atoms. The overall structure (Fig. 2) consists of two molecules of **1** bridging two cobalt atoms. An inversion center is located in the middle of the dimer.

The polymeric structure of **4** (Fig. 3) results from the linear coordination preference of $[Rh(OAc)_2]_2$. The structure consists

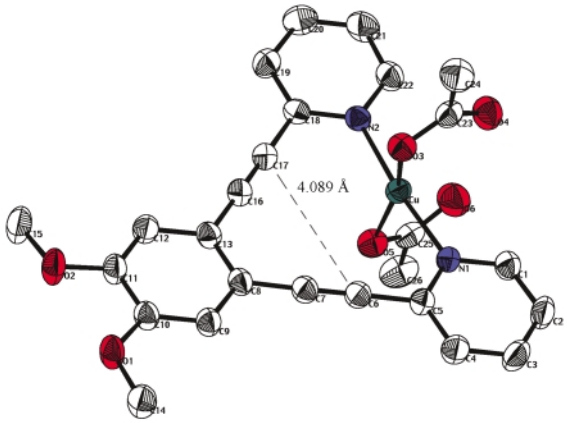

Fig. 1 A single molecule of **2**. The hydrogen atoms and methanol group have been omitted for clarity.

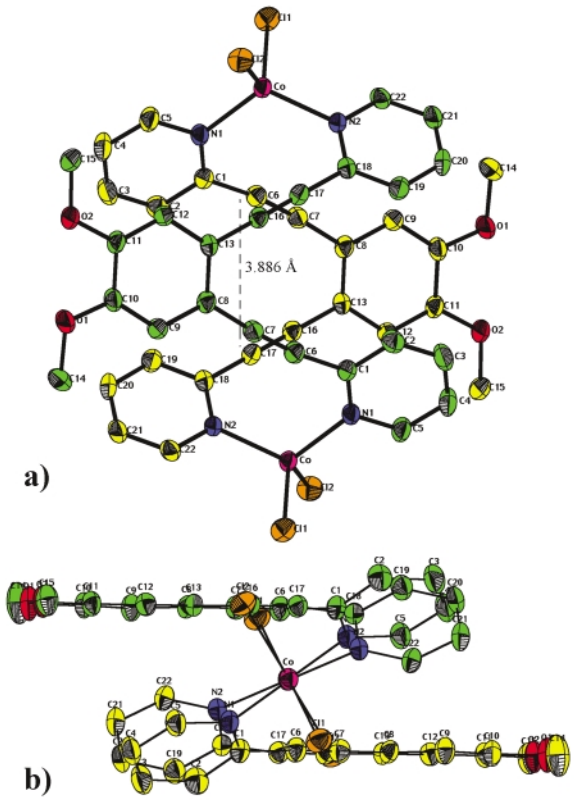

Fig. 2 Hydrogen atoms have been omitted for clarity. (a) a view of **3** from above showing the tetrahedral coordination of cobalt; (b) a view of **3** from the side showing the opposing orientations of **1** and the rotation of the pyridyl rings.

 DOI: 10.1039/b109849g

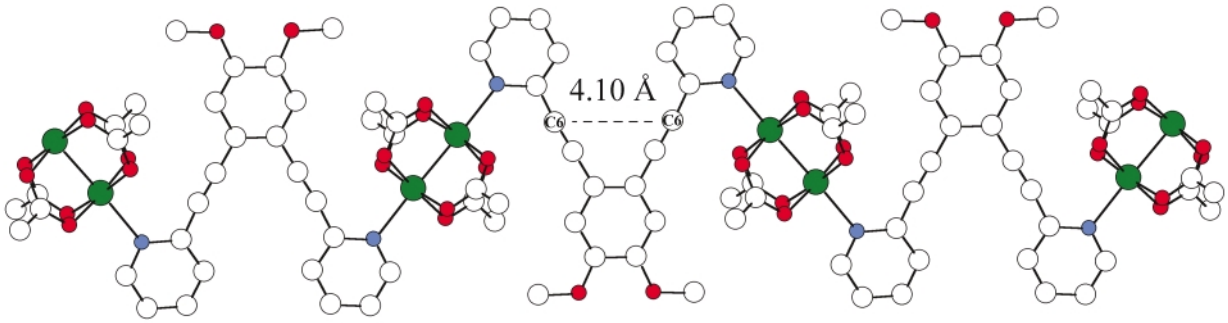

Fig. 3 A view of **4** showing the connectivity of **1** and the rhodium dimer. Hydrogens have been omitted for clarity.

of two acetate-bridged rhodium atoms that connect to the pyridyl rings of two separate molecules of **1** and mimics a conjugated organic polymer. The rhodium is six-coordinate with four equatorial oxygens from the acetate groups, one axial rhodium from the other half of the dimer and one nitrogen belonging to the pyridyl group on the ligand.

Tetrakis(carboxylato)rhodium compounds were first discovered in 1960,[4] but it was not until 1981 that the first polymeric species containing such a rhodium dimer was synthesized.[5] A survey of the CSD indicates that **1** is the largest ligand yet used in such a polymeric species. The polymeric structure is charge balanced, eliminating the need for counter ions competing for binding sites. This leads to higher site symmetry and makes such rhodium dimers attractive building blocks for coordination polymers.[6] Because of its length, the dirhodium moiety cannot fit between the pyridyl rings and achieve ring closure, as in **2**, despite the favorable linear arrangement of the binding sites. Consequently, the pyridyl rings rotate outward by 180° to form a polymer chain with the rhodium dimer bridging adjacent ligands in a zig-zag fashion. This polymer is a supramolecular analogue of the hitherto unknown *ortho*-PPE[7] and as such is a fascinating structure. The Rh–N distance within the polymer is 2.25 Å, typical for Rh–N bonds in such systems.[5,8–10]

One interesting aspect of these structures are the carbon–carbon separations between the alkyne groups on the ligand **1** which, if close enough, could potentially be crosslinked in a Bergman reaction.[11] In **2**, the closed ring conformation results in a C6···C17 separation of 4.089 Å. This is almost the same as the C6···C6 distance of 4.100 Å in **4**, which should represent an unstrained system. By comparison, in **3**, the C6···C17 distance within the same molecule of **1** is 3.886 Å, while the alkyl groups on separate ligands are only 3.548 Å apart (within the range for π–π interactions). This suggests that the copper cation fits between the pyridyl rings without inducing any strain, while in **3**, the dimer formation strains the ligand, bending the pyridyl ligands towards one another, which effects a shorter C6···C17 distance.

These three structures demonstrate the diversity, which can be achieved using **1** that is made possible by the ability of the ligand to distort itself to the preferred coordination environment of the metal center. While one may expect a slight bending of the pyridylethynyl legs either towards or away from each other, these three structures show that rotation of the pyridyl ring around the ethynyl linkage seems more favorable.

Financial support was provided in part by the National Science Foundation through Grants DMR:9873570 and CHE:9814118 and in part by the South Carolina Commission on Higher Education through Grant CHE:R00-U25. The Bruker CCD Single Crystal Diffractometer was purchased using funds provided by the NSF Instrumentation for Materials Research Program through Grant DMR:9975623.

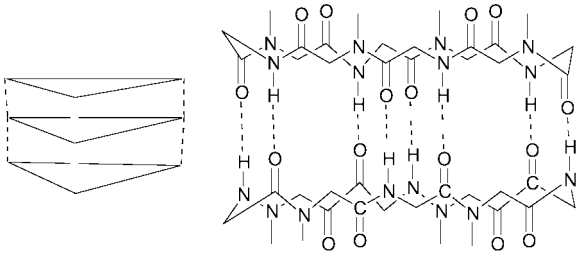
The combination of the *cis*-blocked platinum(II) unit (bu_2-bipy)Pt^{2+} with the unsymmetrical *bis*(pyridine) ligand 4-$NC_5H_4C(=O)NH$-4-C_5H_4N gives the molecular triangle complex $[\{Pt(bu_2bipy)(\mu\text{-}4\text{-}NC_5H_4C(=O)NH\text{-}4\text{-}C_5H_4N)\}_3]^{6+}$, which forms stacked pairs in the solid state through intertriangle NH···OC hydrogen bonds and Pt···OC secondary bonds.

There has been much interest in molecular triangles, assembled through coordination chemistry, some of which stack to form materials, A, with nanometre sized channels.[1] However, the stacking has usually been unpredictable, and so the discovery of stacked triangles in these systems has often been serendipitous.[1,2] On the other hand, cyclic oligopeptides have amide groups oriented perpendicular to the ring and they stack in a predictable way through inter-ring NH···OC hydrogen bonding, to give dimers, B, that model protein β-sheet structures or to give 'protein nanotubes'.[3]

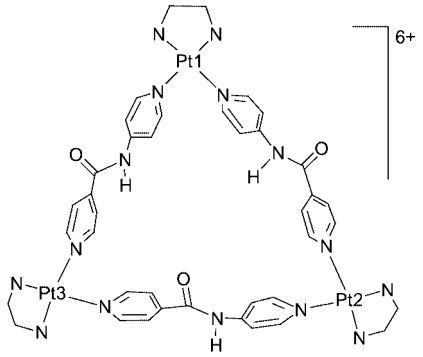


A B

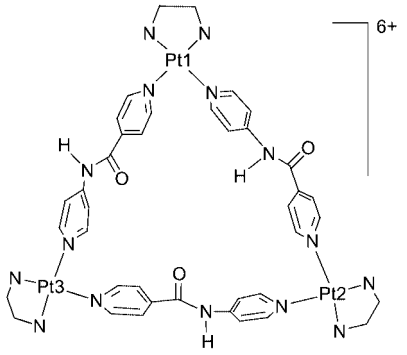
The inorganic molecular triangles have often been prepared using roughly linear, symmetrical bis(pyridine) bridging ligands in combination with a *cis* oriented palladium(II) or platinum(II) unit. Typically, there are no functional groups perpendicular to the triangle to provide orientation through secondary bonding effects,[1,2] and the nature of the stacking, when determined, is often controlled by anion or solvent effects that are difficult to predict. This paper reports a new molecular triangle complex in which a roughly linear bis(pyridine) ligand 4-$NC_5H_4C(=O)NH$-4-C_5H_4N, **1**, is designed to have amide groups between the pyridyl donors[4] that can control the intertriangle stacking.

The reaction of the ligand **1**[4] with $[Pd(bu_2bipy)(thf)_2][BF_4]_2$ or $[Pt(bu_2bipy)(O_3SCF_3)_2]$, bu_2bipy = 4,4′-di-*tert*-butyl-2,2′-bipyridine, occurred by 3 + 3 self-assembly to give the complexes $[M_3(bu_2bipy)_3(\mu\text{-}\mathbf{1})_3]X_6$ (**2a**, M = Pd, X = BF_4; **2b**, M = Pt, X = CF_3SO_3) which were isolated as colorless solids.† These complexes had similar NMR spectra, suggesting similar structures, but the NMR spectra were deceptively simple and did not define the nuclearity of the complexes or the molecular symmetry. The trimeric structure of **2b** was established by an X-ray structure determination (Fig. 1).‡

The cation $[Pt_3(bu_2bipy)_3(\mu\text{-}\mathbf{1})_3]^{6+}$ forms a triangular triplatinum unit with each pair of platinum atoms bridged by a slightly bowed ligand **1**. There are two potential isomers with an unsymmetrical ligand such as **1**, containing NHC_5H_4N (py^a) and $C(O)C_5H_4N$ (py^b) pyridyl donors. The more symmetrical



2b



2b′

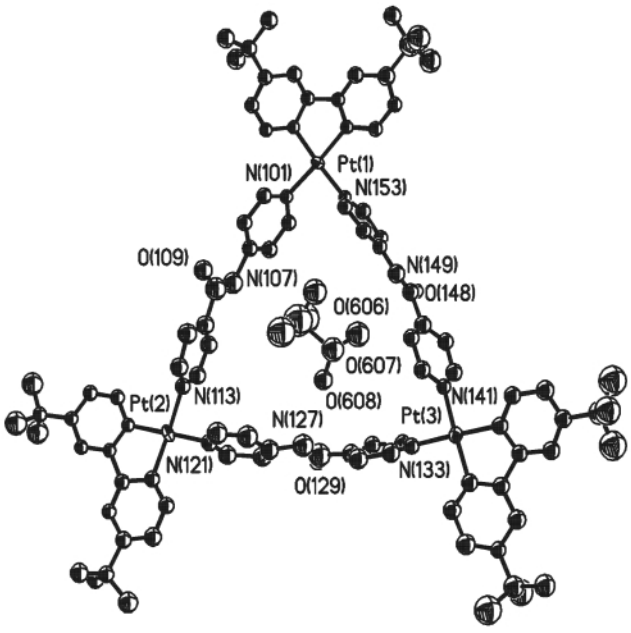


Fig. 1 A view of the cation **2b** with encapsulated triflate anion.

 DOI: 10.1039/b109784a

isomer has symmetry C_{3h}, when each platinum has Pt(py^a)(py^b) coordination, and the less symmetrical isomer has symmetry C_s, when the three platinum atoms have Pt(py^a)$_2$, Pt(py^b)$_2$ and Pt(py^a)(py^b) coordination (assumes free rotation of ligands **1** to give maximum possible symmetry). Complex **2b** has the less symmetrical structure (roughly C_s) with Pt(3), Pt(1) and Pt(2) having Pt(py^a)$_2$, Pt(py^b)$_2$ and Pt(py^a)(py^b) coordination, respectively (Fig. 1). The three Pt atoms form an approximately equilateral triangle with Pt···Pt distances of 13.1 Å, and the three PtN_4 coordination planes are roughly coplanar. However, each pyridyl group of the three bis(pyridyl) ligands is oriented out of the molecular plane so that a large interior cavity is formed. One of the triflate anions is encapsulated in the center of this cavity (Fig. 1). There are relatively short contacts N(127)···O(608) 3.13 and N(149)···O(606) 3.19 Å but the orientation is not appropriate for hydrogen bonding and it is likely that this simply represents a close fit of the triflate ion in the cavity.

The amide groups are oriented roughly perpendicular to the molecular triangle and an interesting supramolecular association occurs between pairs of triangular cations, that are separated by about 5.1 Å and related by a centre of symmetry, as illustrated in Fig. 2. The association occurs primarily through pairwise intertriangle NH···O=C hydrogen bonding between amide groups, with N(107)···O(148A) = N(107A)···O(148) = 2.92 Å. These attractions are supported by two long C=O···Pt contacts with O(129)···Pt(1A) = O(129A)···Pt(1) = 3.36 Å, that probably represent weak electrostatic attractions. The NH groups that are not involved in intertriangle hydrogen bonding take part in hydrogen bonding either with a triflate anion [N(149)···O(206) 2.81 Å] or with a water molecule [N(127)···O(801) 2.90 Å]. The carbonyl groups C(128)O(129) and C(108)O(109) are not involved in hydrogen bonding. The 'dimer of trimer' cations contain two triflate ions in their cavities (Fig. 1) and are surrounded by further disordered triflate ions, as well as by water and acetone solvate molecules. However, there is no further intercation bridging between adjacent 'dimers of trimers'.

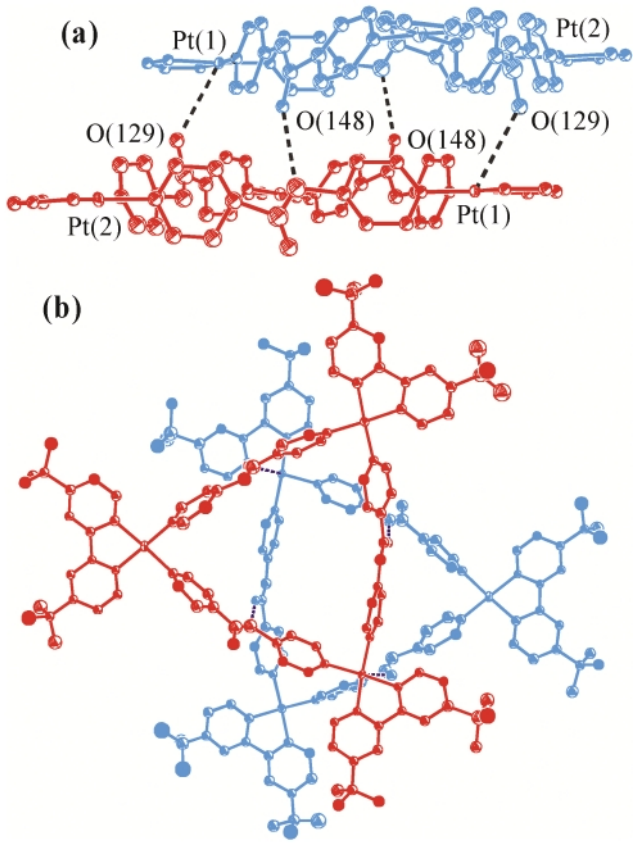

Fig. 2 Side (a) and top (b) views of the dimer of triangles formed *via* hydrogen bonding and weak C=O···Pt interactions between units of **2b**. The triflate anions are omitted for clarity and in (a) only the core atoms of the bu$_2$bipy ligands are shown.

The packing motif is thus different from that of a related triangular hexacation in which all triangles are separated by the same distance and connected by a channel of counter ions and water molecules.[2d] It is possible that the unsymmetrical ring structure found in the structure of **2b** is favored over the more symmetrical one, **2b′**, as a result of the favorable supramolecular association since there is no obvious reason why it would be favored for a simple ring structure. Indeed it should be noted that there is no direct proof that triangles, rather than the more common squares, are present in the solution phase. The complex cation **2b** appears to be the first example of a cyclic coordination compound that forms a dimer architecture similar to that formed by cyclic peptides, and it suggests that the biomimetic approach to organization of molecular triangles and other macrocyclic structures has considerable promise.[3]

Ditopic azathioether macrocycles as hosts for transition metal salts†

Jason B. Love, Joanna M. Vere, Mark W. Glenny, Alexander J. Blake and Martin Schröder*

School of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: m.schroder@nottingham.ac.uk

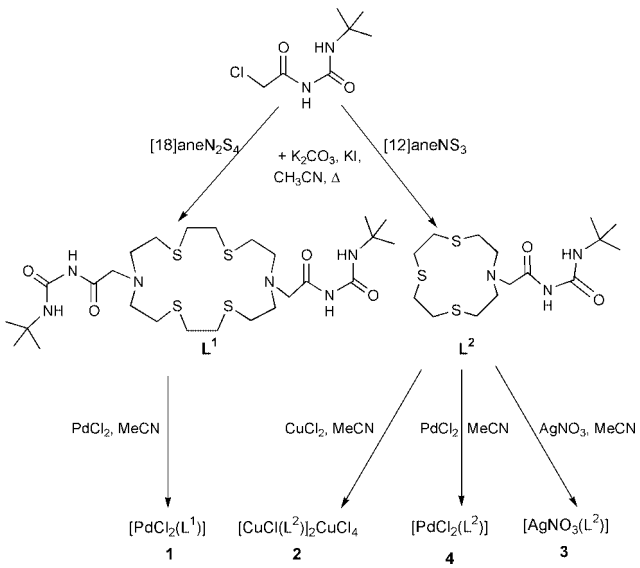
Received (in Cambridge, UK) 17th October 2001, Accepted 14th November 2001
First published as an Advance Article on the web 6th December 2001

The synthesis and complexation of two heteroditopic lariat azathioether macrocycles L^1 and L^2 incorporating acylurea functionalised pendant arms are described; L^1 and L^2 are capable of simultaneously binding both the cationic and anionic moieties of a metal salt as confirmed by the structures of $[PdCl_2(L^1)]$, $[CuCl(L^2)]_2CuCl_4$ and $[Ag(NO_3)(L^2)]$ and by ^1H NMR studies in solution on $[Ag(NO_3)(L^2)]$.

Interest in the design and synthesis of heteroditopic receptors that can simultaneously bind both cationic and anionic moieties of a metal salt stems from the anticipation that such compounds may act as potent ionophores for the selective extraction and transport of base, toxic and/or precious metal salts from process streams.[1–3] A common approach has been to combine cation complexing agents such as crown O-ethers and calixarenes with proven anion receptors,[1–6] facilitating the tandem complexation of Group 1 halides, pseudo-halides and hydrogen phosphates. However, this choice of cation receptor precludes the *simultaneous* complexation of softer transition metal salts. Indeed, general ditopic receptors for transiton metal salts are exceedingly rare,[7,8] Thioether crowns represent powerful ligands for binding transition metal cations, even under low pH conditions where aza ligands are simply protonated and are no longer able to function as cation receptors.[9] We report herein definitive structural evidence for three systems that show simultaneous cation and anion binding.

Reaction of $PdCl_2$ with the new lariat azathiocrown L^1 in boiling MeCN results in the formation of **1** as a yellow powder (Scheme 1).†‡ Binding of Cl^- in solution by NMR methods could not be probed since **1** is soluble only in protic solvents where H-exchange occurs. The structure of **1**§ confirms the Pd(II) centre ligated in a square-planar geometry to the four S-donors resulting in an overall 'chair' conformation of the ligand. A Pd···Cl contact of 3.364(2) Å is observed at both axial sites of the Pd(II) ion and is indicative of weak electrostatic interactions between these centres. However, when viewing the extended molecular structure of **1**, it becomes apparent that the inner urea N atom N(2) is involved in H-bonding to the Cl^- anion of a second, approximately perpendicular molecule [N(2)···Cl(AA) 3.332(5) Å] (Fig. 1). The outer urea N atom N(3) is found to be H-bonding to the acyl oxygen O(1) of the same arm [N(3)···O(1) 2.689(7) Å] so constricting the librational freedom of the anion host. As expected, the symmetry-related equivalent N(2A) is H-bonded to the Cl^- ClD of a third $[PdCl_2(L^1)]$ molecule [N(2A)···ClD 3.331(5) Å] resulting in supramolecular aggregation *via* a zigzag chain. It is therefore apparent that ligand L^1 is capable of binding not only the Pd^{II} cation within the macrocyclic sulfur array, but also the associated Cl^- anions by concerted intermolecular H-bonding and metal–anion electrostatic interactions with the pendant arm.

The reaction between $CuCl_2$ and L^2 in MeOH (Scheme 1) affords dark green **2**.†‡ The molecular structure of **2** (Fig. 2)§ confirms that the asymmetric unit comprises two $[CuCl(L^2)]^+$ cations and a $[CuCl_4]^{2-}$ dianion. In each cation, the Cu(II) centre is coordinated octahedrally with the inner acyl oxygen of the pendant arm occupying an equatorial site.[10] The cations are organized such that the pendant arms assume a 'parallel' arrangement to each other; this position is presumably dictated by the presence of the $[CuCl_4]^{2-}$ anion, which is H-bonded to the inner urea N–H of each arm [N(2)···Cl(6) 3.29(2), N(5)···Cl(5) 3.27(2) Å]. The observed distorted tetrahedral geometry of $[CuCl_4]^{2-}$ is typical for this dianion.[11] As with L^1, the monobrachial azathioether L^2 is therefore able to simultaneously bind cationic and anionic halo-metal fragments; this system formally represents a methodology for the extraction and transport of $CuCl_2$.



Scheme 1 Synthesis and complexation reactions of the heteroditopic ligands L^1 and L^2.

† Electronic supplementary information (ESI) available: full experimental details. See http://www.rsc.org/suppdata/cc/b1/b109486f/

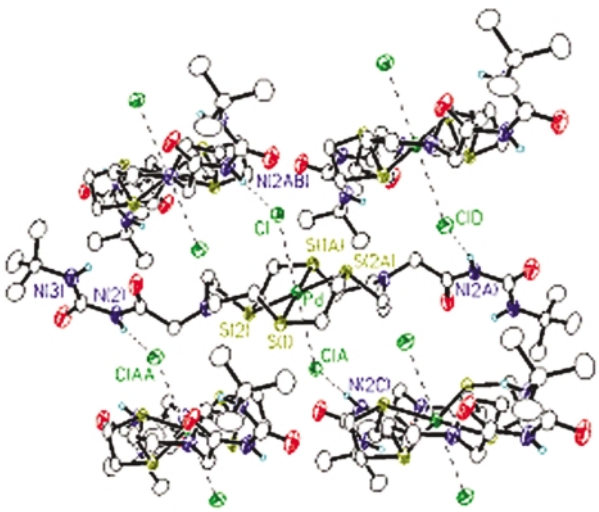


Fig. 1 View of structure of $[PdCl_2(L^1)]$.

 DOI: 10.1039/b109486f

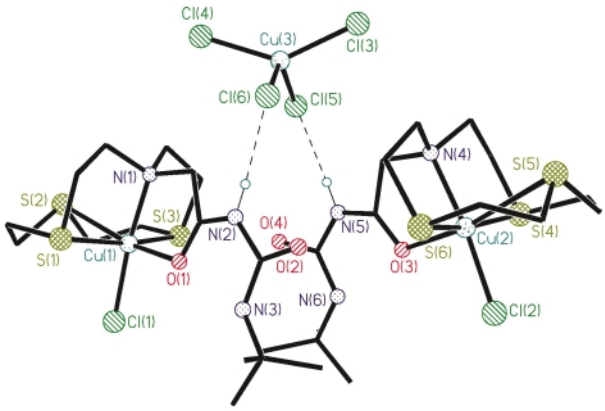

Fig. 2 View of structure of $[CuCl(L^2)]_2CuCl_4$.

Neither **1** or **2** allow for NMR studies on solution complexation. However, the reaction between $AgNO_3$ and L^2 yields $[Ag(NO)_3(L^2)]$, **3**,†‡ which is soluble in CD_3CN. The solid state structure of **3**§ confirms that the Ag(I) cation is complexed by the azathiocrown with the anion receptor arm extending radially (Fig. 3). Inspection of the extended structure reveals a bond between Ag(I) and a S-donor of a second cation [Ag–S(4A) 2.496(2) Å], so completing a five-coordinate, square pyramidal geometry at Ag(I) and affording an overall two-dimensional step-polymeric motif. Although displaying two-fold rotational disorder, the NO_3^- anion is clearly H-bonded to the pendant arm *via* the urea N(15), interacting in varying degrees with O(2), O(2′) and O(1) [N(15)–O(2) 3.27(3), N(15)–O(2′) 2.50(2), N(15)–O(1) 3.43(3) Å].

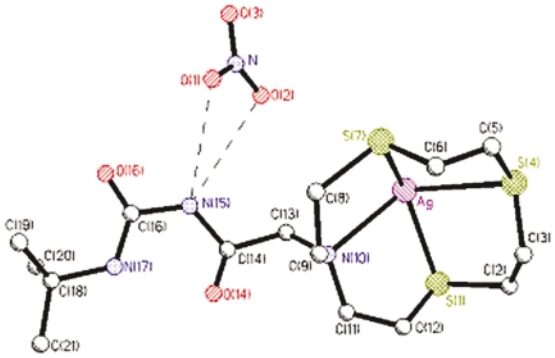

Fig. 3 View of structure of $[Ag(NO_3)(L^2)]$.

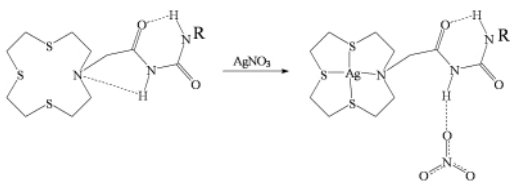
Addition of $AgNO_3$ to a solution of L^2 in MeCN leads initially to an upfield shift for the N(15)–H proton from δ_H 9.01 in L^2 to 8.65 on addition of 0.4 equivalents of $AgNO_3$. This upfield shift reflects the breaking of the internal H-bonding in free L^2 (confirmed by structural studies) on complexation to Ag(I) (Scheme 2). On further addition of $AgNO_3$, this resonance shows the expected downfield shift to δ_H 8.85 for **3** reflecting H-bonding of the acylurea arm to the nitrate anion as confirmed by the crystal structure of **3**. Addition of $[^nBu_4N][NO_3]$ to **3** leads



Scheme 2 Cleavage of internal H-bonding in L^2 on binding to $AgNO_3$.

to further downfield shifts for the N(15)–H resonance (to δ_H 9.39, 9.55 and 9.65 on addition of 1, 2 and 3 equivalents of $^nBu_4NNO_3$, respectively) consistent with anion binding in solution. Significantly, addition of $[^nBu_4N][NO_3]$ to L^2 does not shift the N(15)–H resonance; therefore, anion binding to L^2 can only occur once cation binding within the macrocyclic cavity and concomitant cleavage of the internal H-bonding takes place, thus affording an element of cooperativity to this system. Compound **4** has also been prepared and characterised.†‡

In conclusion, we have confirmed that the combination of thioether macrocycles with functionalised acylurea lariat arms affords heteroditopic receptors that have a wide applicability for the complexation of transition metal salts. These results have important implications for the extraction and transport of transition metal salts, especially at low pH where thioether crowns can still function as avid metal cation receptors.

Host-guest binding of simple cavitands in water

Xuan Gui and John C. Sherman*

Department of Chemistry, 2036 Main Mall, University of British Columbia, Vancouver, BC, Canada V6T 1Z1. E-mail: sherman@chem.ubc.ca

Received (in Columbia, MO, USA) 16th May 2001, Accepted 1st November 2001
First published as an Advance Article on the web 4th December 2001

Simple water soluble cavitands were prepared and the thermodynamics of their binding with neutral guests in water is reported.

Host–guest chemistry has had an interesting history regarding studies in aqueous *versus* organic solvents. In the prehistoric era, BC (before crowns), there was complexation of apolar molecules by cyclodextrins in water; the main driving force for binding was the hydrophobic effect. With the emergence of crowns, cryptands, spherands, and their relatives, the guests became ions, and water was avoided to reduce the competition of hydration of the ions. As chemists became more bold and host designs became more sophisticated, binding of apolar molecules in organic solvents was explored, as pioneered by Cram using the newly created cavitands as hosts.[1] Soon after, Diederich reported his seminal work on the use of cyclophanes to bind apolar guests in solvents ranging from water to CCl_4.[2] Interest has continued in binding of apolar molecules in water,[3] but cavitands have only occasionally been used in such studies. Deshayes has reported the thermodynamics of complexation of neutral molecules in water using a hemicarcerand-like cage host composed of two cavitands.[4] Rebek has fashioned cavitands with deep cavities and has reported complexation studies in aqueous media.[5] Deep cavity cavitands have been used to extract pollutants from wastewater.[6] Positive charges have been incorporated into the upper rim of cavitands[7,8] and binding of polar (mostly anionic) guests has been reported in water.[8] Yet binding of apolar molecules in water by simple cavitands (*i.e.*, with underivatized rims) has received little attention. Here we report the incorporation of water solubilizing groups into the feet of simple cavitands, which allows the exploration of the intrinsic binding affinity of the cavitand moiety in water without the interfering effect of charges or other groups in the rims. The thermodynamic values obtained suggest, as in Diederich's case, that binding is enthalpy driven, which is somewhat at odds with the simple hydrophobic effect.

We recently reported the incorporation of phosphate groups into the feet of cavitands in the synthesis of de novo proteins.[9] Starting from cavitand **1**,[9] the synthesis of water soluble cavitand **2** was accomplished in a similar manner, as shown in Scheme 1.[10] Binding studies using cavitand **2** and a variety of guests were performed using the common methods for systems whose binding constants are in the 10–10^3 range and undergo fast exchange on the ^{1}H NMR timescale: solutions with fixed guest concentrations and varying host concentrations in D_2O (50 mM $(NH_4)_2CO_3$, pD = 9.4) were prepared, ^{1}H NMR spectra were obtained, and the chemical shift of the guest protons was recorded.[11] Job plots of these data gave an indication of 1 : 1 binding stoichiometry, and linear plots of the binding isotherms were generated for verification of stoichiometry.[12] For guests that bound in a 1 : 1 stoichiometry, Benesi–Hildebrand plots were generated to give an initial estimation of binding constants and Δ_{max} ($\delta_{complex} - \delta_{free}$).[12] Non-linear regression of these data gave the final K_a and Δ_{max},[12] which are reported in Table 1. Guests that did not show evidence for binding include methanol, ethanol, *t*-butanol, phenol, THF, pyrrole, and *N*-methylpyridinium iodide. Guests that bind to **2**, but do not yield 1 : 1 binding stoichiometry include dichloromethane and dimethyl carbonate. Enthalpies and entropies for complexation between cavitand **2** and the three best guests were generated *via* van't Hoff plots;[13] the ensuing results are given in Table 2.

The Δ_{max} values can indicate the binding geometry of the complexes. For example, the large Δ_{max} for the acetyl methyl of ethyl acetate suggests that it is bound deeply within the shielding region of the cavitand. Its methylene is clearly further from the cavity. The alkyl methyl group is closer to the cavity than the methylene. At first this may seem impossible, but it is clear that different binding modes are possible. For ethyl acetate, the predominant binding mode is acetyl methyl in the cavity, yet the alkyl methyl can also bind in the cavity, but only a small percent of the time: whereas the obtained association constants represent the sum of the association constants for all

binding modes, the Δ_{max} for a particular proton is the weighted average of the Δ_{max} for this proton in different binding modes.[14]

As has been observed even in the very early binding studies of cavitands in organic solvents, the cavity is complementary to and has an affinity for methyl groups.[15] This is consistent with work on carceplexes and hemicarceplexes, which often show high $\Delta\delta$ for methyl groups.[16] As the present system is in water, additional factors come into play such as removing apolar groups from the hydration sphere.[17] Guests such as phenol, pyrrole, and THF are well solvated by water and do not contain methyl groups; thus they do not bind at all to cavitand **2** in water. Methanol, ethanol, *t*-butanol, and *N*-methyl pyridinium iodide contain methyl groups, but they are too hydrophilic for cavitand **2** to compete with water. Acetonitrile has an electropositive methyl group, but it is also well solvated by water, so it binds weakly. Toluene is far too big to fit completely in the cavity, but it can fit its methyl group in and bury some of its hydrophobic bulk. However, binding of toluene is weak, as much of the apolar molecule must remain in water. The esters are all good binders, as they can readily provide electron deficient methyl groups for the cavity. Note that methyl propionate binds predominantly OMe into the cavity, and ethyl acetate binds predominantly acetyl methyl into the π-electron-rich cavity. In each case the more electron poor methyl dictates the preferred binding mode. Methyl acetate appears to bind with each methyl group equally strongly into the cavity (Δ_{max} = 2.19 and 2.01 ppm; since these are weighted averages of the two binding modes, the methyls likely stick well into the cavity in each mode).

The thermodynamic measurements reveal that binding of neutral guests to simple cavitands in water is enthalpy driven. The common hydrophobic effect, where water is freed up to go into the bulk, is normally entropically favored. Our case is like Diederich's[2] and others'[4,18] where the entropic release of water may indeed be at play, but the overall combination of factors renders complexation entropically unfavored. Somewhat unexpected is that the guest (ethyl acetate) that appears to have the greatest modal preference (it prefers to bind acetyl methyl into the cavity) has the least unfavorable entropy of binding. Clearly the entropic factors, both the costly (*e.g.*, reduction in molecularity and conformational freedom) and the empowering (*e.g.*, freeing up water), are complex.[18] Water is nevertheless required for binding.[17] Just as in Diederich's case, a simple way to view this is that the freeing up of water to bulk is necessary to sufficiently reduce the entropic costs of complexation to see binding. Another way to put this is the obvious general situation in any type of complexation: to observe binding, the solvent must be a very poor competitor for the cavity.

We thank NSERC of Canada for financial support.

13 The temperature range was kept small (283–307 K) to obtain good association constants (to keep the % bound in the 20–80% range) and to legitimize the assumption of temperature independence of enthaply and entropy. For methyl propionate, H_c was used for K_a determinations; for ethyl acetate, H_a was used (see Table 1 and note 14). Temperature was determined from methanol or ethylene glycol thermometers: see J. Sandström, *Dynamic NMR Spectroscopy*, Academic Press, Inc., London, New York, 1982; C. Ammann, P. Meier and A. E. Merbach, *J. Magn. Reson.*, 1982, **46**, 319-312; See also http://bmrl.med.uiuc.edu:8080/~dmorris/nmrt_ref.html. The HOD peak was referenced using a calibration curve against ethyl acetate: see H. E. Gottlieb, V. Kotlyar and A. Nudelman, *J. Org. Chem.*, 1997, **62**, 7512.

14 K. A. Connors, *Chem. Rev.*, 1997, **97**,1325; L. Liu and Q.-X. Guo, *J. Phys. Chem. B*, 1999, **103**, 3461. Generation of K_a from different protons for methyl acetate and toluene give the same values for K_a. But values range for ethyl acetate (170–230 M^{-1}) and for methyl propionate (60–210 M^{-1}). It is not unusual to find artificially lower K_as from protons that are more solvent exposed, as is observed in these cases. See: H. Stamm, W. Lamberty and J. Stafe, *J. Am. Chem. Soc.*, 1980, **102**, 1529; V. Rüdiger and H.-J. Schneider, *Chem. Eur. J.*, 2000, **6**, 3771.

15 D. J. Cram, K. D. Stewart, I. Goldberg and K. N. Trueblood, *J. Am. Chem. Soc.*, 1985, **107**, 2574; J. A. Tucker, C. B. Knobler, K. N. Trueblood and D. J. Cram, *J. Am. Chem. Soc.*, 1989, **111**, 3688.

16 A. Jasat and J. C. Sherman, *Chem. Rev.*, 1999, **99**, 931.

17 Water is indeed needed to see binding, as no binding was observed between the best guest, methyl acetate, and the following guest/solvent combinations: cavitand **1** in CD_3OD, the tetraphosphate ester derived cavitand in $CDCl_3$, the tetraphosphoric acid derived cavitand in CD_3OD.

On the relative magnitudes of *cis* and *trans* influences in metal complexes

Kirsty M. Anderson and A. Guy Orpen

School of Chemistry, University of Bristol, Bristol, UK BS8 1TS. E-mail: guy.orpen@bristol.ac.uk

Received (in Cambridge, UK) 19th September 2001, Accepted 31st October 2001
First published as an Advance Article on the web 4th December 2001

***Cis* and *trans* influences are of similar magnitude in octahedral complexes of Sn^{IV} and Sb^{V} while the *trans* influence is dominant in square planar Pt^{II} (d^8) and d^6-ML_6 cases.**

The concept of *trans* influence, and the related *trans* effect are central to modern molecular inorganic chemistry.[1,2] The *trans* influence, also termed the structural *trans* effect,[3] concerns the ability of a ligand to weaken (and lengthen) the bond *trans* to it in preference to those that are *cis*. Much of the best evidence for this ground-state structural phenomenon and the kinetic *trans* effect is drawn from Pt^{II} chemistry[4] although a substantial literature exists for octahedral transition metal chemistry[5] as recently discussed by Coe and Glenwright.[3] *Trans* influence is also of importance in p-block metal chemistry and some notable examples are cited in refs. 6–9. Theoretical and computational treatments of *trans* influence include the work of Burdett and Albright, Mingos and others.[10,11] While the evidence for *trans* influence in the d-block and especially for d^6 and d^8 metals is well established, the question arises as to its generality. Here we present evidence that at least in p block metal chemistry, *cis* influence can be of similar magnitude to *trans* influence. Further, we offer a qualitative model affording understanding of the relative magnitudes of *cis* and *trans* influences in various electronic circumstances.

Coe and Glenwright[3] pointed out that the mutual effect of ligands is important in determining the extent of *trans* influence and notes that the electron configuration of the metal can also be significant (see pp. 22 and 38 in ref. 3). Indeed in tin(IV) chemistry, Aslanov and coworkers have observed an inverse *trans* influence (see ref. 9 and work cited therein). Here we study the consequences of metal electron configuration by comparing the behaviour of d- and p-block metals with formal valence electron configurations $d^n s^k$ (n = 0, 6, 8, 10; k = 0 and n = 10, k = 0, 2). We approach this problem by seeking appropriate crystal structure data. In a square planar or octahedral complex of the types shown in Scheme 1 we study the effect of a probe ligand L attached to a ML'_n (n = 3 or 5; L′ = L_c = L_t = Cl, CO or NH_3) fragment on the metal–ligand bond lengths *trans* and *cis* to it. Since the *cis* and *trans* ligands are identical, if the *trans* influence is dominant the M–L_t length should change as the M–L bond varies while the M–L_c distance (or its average $<$M–$L_c$$>$) should be relatively invariant. Put in quantitative terms, we can identify three alternative patterns of correlation between M–L_t and $<$M–$L_c$$>$: (i) if the *cis* influence is zero and *trans* influence is completely dominant there should be no correlation (nor would there be if *trans* influence were zero and *cis* influence were not); (ii) if *cis* and *trans* influences are equal then M–L_t should equal $<$M–$L_c$$>$ within experimental uncertainty; (iii) between these extreme cases intermediate degrees of correlation would be expected. In this paper we use three measures of this correlation: the Pearson correlation coefficient (R), the regression line formula and, more crudely, the ratio, S, between the ranges in *trans* and *cis* bond lengths.† We note that R^2 indicates the presence of correlation rather than covariance and so gives no direct information on the relative magnitudes of *cis* and *trans* influence, and S is inevitably not a robust statistic since it depends on extreme values. Therefore the regression line gradient (m in $y = mx + c$, where y = $<$M–$L_c$$>$ and x = M–L_t) is perhaps the more helpful statistic in distinguishing between cases (i), (ii) and (iii). Ideally in case (i) $m \approx 0$, for (ii) $m \approx 1.0$ and for (iii) $0 << m << 1$.

Data were taken from the Cambridge Structural Database[11] for square planar and octahedral metal complexes of the forms: $[Pt^{II}Cl_3L]$, $[W^0(CO)_5L]$, $[Co^{III}(NH_3)_5L]$, $[Te^{IV}Cl_5L]$, $[Bi^{III}Cl_5L]$, $[Sn^{IV}Cl_5L]$, $[Sb^{V}Cl_5L]$ and $[W^{VI}Cl_5L]$ (L = two-electron donor ligand).† The variation of the metal–ligand distances and derived statistics (R^2, m, c, S) are summarised in Table 1. Fig. 1 shows plots of the *trans* length (M–L_t) *vs.* the mean *cis* length ($<$M–$L_c$$>$) for the cases (a) $[Pt^{II}Cl_3L]$, (b) $[W^0(CO)_5L]$, (c) $[Te^{IV}Cl_5L]$, (d) $[Sb^{V}Cl_5L]$ and (e) $[W^{VI}Cl_5L]$.

These plots [Fig. 1(a)–(e)] and the data in Table 1 show varying forms of correlation which depend on the electron configuration of the metal. The d^8 case [Pt^{II}, Fig. 1(a)] has a larger variation in *trans* distance than *cis* (by a factor, S, of 2.4), and shows a corresponding low value of m (0.18). The d^6 cases {$[W^0(CO)_5L]$, Fig. 1(b), and $[Co^{III}(NH_3)_5L]$} are similar to each other (*m ca.* 0.12, S = 2.2–3.1) and to the d^8 case, showing, if anything, slightly more dominance of *trans* influence. The $d^{10}s^2$ cases {$[Te^{IV}Cl_5L]$, Fig. 1(c) $[Bi^{III}Cl_5L]$} show almost perfectly dominant *trans* influence[7] with values of m close to

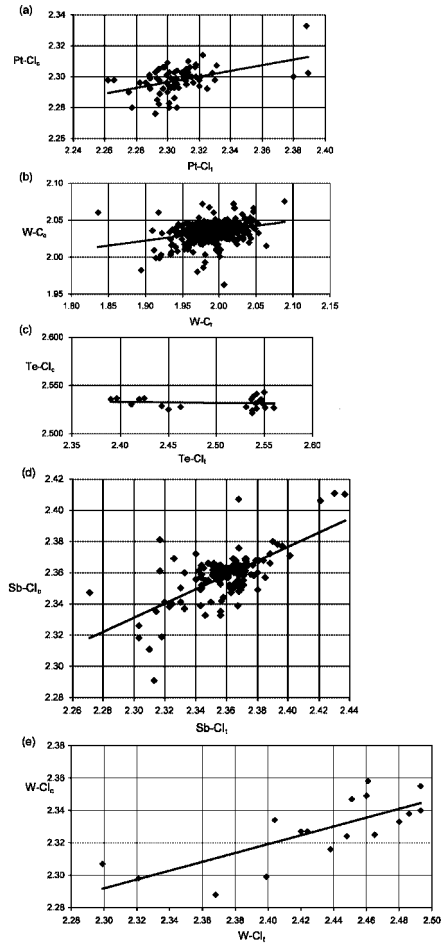

Fig. 1 Scatterplots of M–L_t *vs.* <M–L_c> bond lengths (Å) for (a) [$Pt^{II}Cl_3L$], (b) [$W^0(CO)_5L$], (c) [$Te^{IV}Cl_5L$], (d) [Sb^VCl_5L] and (e) [$W^{VI}Cl_5L$] complexes from the CSD.[11] Regression lines are shown (see Table 1).

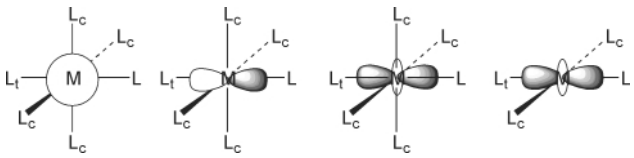
zero and large *S* (*ca.* 7). In marked contrast, the $d^{10}s^0$ cases {[$Sn^{IV}Cl_5L$] and [Sb^VCl_5L], Fig.1 (d)} show higher values of *m* (*ca.* 0.45) and smaller ratio of variation in *trans* and *cis* distances (*S* = 1.2–1.4). Finally the d^0 case {[$W^{VI}Cl_5L$], Fig. 1(e)} shows intermediate behaviour with *m* = 0.27 and *S* = 2.8.

Thus in all cases there is some lengthening of *cis* bond lengths as the *trans* bond is lengthened (except for the $d^{10}s^2$ cases for which the *cis* bond lengths are essentially invariant). In none of these cases is there convincing evidence for *cis* bonds being *strengthened* (and shortened) as *trans* bonds are weakened, as some versions of *trans* influence theory would predict (see discussion in refs. 3 and 10). In their theory of *trans* influence[10] Burdett and Albright indicated that more than one effect may be at work (including competition between ligands for the same metal orbital and polarisation of metal–ligand bond orbitals by low-lying empty orbitals). While this is probably the case, on the basis of our observations we can advance a qualitative orbital model as to relative magnitudes of the *trans* and *cis* influences in d- and p-block metals for differing metal electron configurations. Large *cis* influence [*i.e.* type (ii) behaviour, as seen in the $d^{10}s^0$ cases] implies the importance of a non-directional (s) valence orbital at the metal regardless of which mechanism[10] of *trans* influence is at work. The participation of the s orbital requires that *trans* and *cis* ligands feel equally the (σ bonding) effects of perturbation of the M–L bond. Complete absence of *cis* influence [type (i) behaviour] implies there is no s (or d) orbital involvement with *trans* influence being transmitted through a p orbital which can not overlap with *cis* ligand σ donor orbitals. Intermediate cases may be taken to imply some d (or s) orbital involvement at the metal.

To first order we can then identify three patterns of orbital occupancy and the *cis* and *trans* influence behaviour that



Scheme 2

follows: (a) if the M–L bond contains substantial M s orbital character, *cis* influence is relatively large [see (a) in Scheme 2] as in the $d^{10}s^0$ cases; (b) if the M–L bond has substantial M p orbital character but no s or d character [see Scheme 2(b)] as in the $d^{10}s^2$ cases, *trans* influence is high and *cis* influence is near zero and is shut down by virtue of the s and d orbitals being occupied; (c) if the M–L bond has substantial M d and relatively little M s orbital character [see Scheme 2 (c) and (d)] as in the d^8, d^6 and d^0 cases, then the *cis* influence is small compared to the *trans* influence but not zero, and their relative magnitudes may depend on electron configuration.

This model implicitly omits treatment of π effects which must be significant at least for the carbonyl species. A more complete model would also provide (semi-)quantitative estimates of the relative importance of p *vs.* s or d orbital contributions to the M–L bond or perhaps to the LUMO of the fragment to which L is bound. Development of such a model and its computational testing is in hand.

In summary, the classic *trans*-influence model based on Pt^{II} chemistry is to be used with some caution. While it works well for much of d-block chemistry, in some areas of the periodic table (notably the $d^{10}s^0$ chemistry of Sb^V, Sn^{IV} *etc.*) it does not hold well, and in others (d^0 chemistry) it applies but less powerfully than is often assumed.

We thank Jeremy Harvey for useful discussions and the University of Bristol for financial support (K. M. A.).

Notes and references

† Good quality data {$R < 0.07$ and < 0.05 for $[W^0(CO)_5L]$ species, no errors} were retrieved from the CSD using CCDC software.[12] Ligands L included both neutral and anionic species. Oxidation states and coordination geometries were checked and ambiguous cases eliminated. The mean M–L bond length *cis* to the L ligand (<M–L_c>), the M–L_t and M–L bond lengths were recorded for each appropriate fragment in the structures retrieved. Regression lines were computed with x = M–L_t, y = <M–L_c>. When L = L_c (= L_t), *e.g.* as in $[PtCl_4]^{2-}$, L and L_t were defined by taking the longest bond as M–L. The uncertainties in the individual bond lengths used in this work may be assumed to be on the order of 0.01 Å (see ref. 13).

Parallel kinetic resolution of racemic amines using 3-*N*,*N*-diacylaminoquinazolin-4(3*H*)-ones

Abdullah G. Al-Sehemi, Robert S. Atkinson and Christopher K. Meades

Department of Chemistry, Leicester University, Leicester, UK LE1 7RH

Received (in Cambridge, UK) 11th October 2001, Accepted 9th November 2001
First published as an Advance Article on the web 4th December 2001

The two pseudoenantiotopic *N*-acyl groups of enantiopure 3-[*N*-(3-*m*-acetoxyphenylpropanoyl)-*N*-(3-phenylpropanoyl)amine]-2-isopropylquinazolin-4(3*H*)-one 7 each react with a different enantiomer of 2-methylpiperidine giving rise to efficient parallel kinetic resolution (ee > 95%).

In a normal kinetic resolution (KR) the enantiopure reagent reacts preferentially with one enantiomer of the racemic substrate. Under conditions of stoichiometry (2 eq. amine: 1 eq. reagent) this enantiopreference of the reagent must accommodate the diminishing concentration of the more reactive to the less reactive enantiomer as the reaction proceeds. Although high ees are possible under these conditions using enzymes[1] or chemzymes,[2] more often in practice the substrate is used in excess and only the derivatised enantiomer is isolated.

Vedejs has shown that different enantiomers of a racemic substrate can each be reacted at the same rate with pseudoenantiomeric reagents, designed to allow separation of the two derivatised products (parallel kinetic resolution, PKR).[3] The ees of both these derivatives (88% and 95%) are raised because the concentrations of both unreacted enantiomers decline at the same rate throughout the reaction.

We have shown previously that 3-*N*,*N*-diacylaminoquinazolinones (DAQs) *e.g.* **1** bearing a chiral centre and different *N*-acyl groups are separable into diastereoisomers because the N–N bond is a chiral axis.[4] DAQ[1] **1** (Scheme 1) was obtained by reaction of 3-*N*-benzoylamino-quinazolinone (MAQ[1]) **4** with 2-methylpropanoyl chloride–pyridine and the oily and crystalline diastereoisomers separated by chromatography.[5]

Both these enantiopure diastereoisomers of DAQ **1** react chemospecifically with 2-methylpiperidine to give the *N*-benzoylamide **3**; both also react enantioselectively with this amine even under conditions of stoichiometry (1 eq. DAQ: 2 eq. amine). Since the oily and crystalline diastereoisomers differ in configuration at their N–N axis and produce (*R*)-amide **3** (95% ee) and (*S*)-amide **3** (82% ee), respectively, it is the configuration of the N–N axis which controls the sense of enantioselectivity.

The corresponding DAQ[1] **5** was obtained completely diastereoselectively by reaction of MAQ[1] **4** with acetyl chloride–pyridine.† 2-Methylpiperidine reacts with DAQ[1] **5** at both the benzoyl and acetyl groups (ratio 2.5 : 1); from the high ee of the (*S*)-**3** amide and from the low specific rotation of the unreacted 2-methylpiperidine recovered, it appeared that the two amine enantiomers were each reacting preferentially with different *N*-acyl groups[6] *i.e.* the two *N*-acyl groups in DAQ[1] **5** were playing the rôle of the two pseudoenantiomeric reagents in a PKR (see above).[3]

To maximise the opportunity for PKR to be obtained in these amine acylations, we elected to use enantiopure DAQ[1] **7** which contains the N–N axis as the only chiral element. The isoenergetic transition states (TSs) in which each amine enantiomer reacts with its respective pseudoenantiotopic *N*–acyl group can be represented as in Scheme 2(a) and (b).

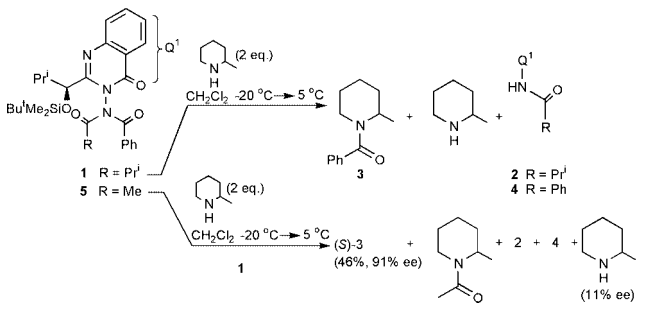
Although the sites occupied by S, M and L (small, medium, large) groups of the amine are arbitrarily assigned, Scheme 2 incorporates the expected *exo*/*endo*⇌*endo*/*exo* conformational equilibrium for the imide moiety of DAQ[1] **7**[4] and our conclusion is that attack of the amine takes place on the face of the *exo*-oriented imide carbonyl group *syn* to the quinazolinone carbonyl group (*exo*:*cis* to Q).[7] Clearly it is important for the success of the PKR that the ratio of these two imide conformations present is 1 : 1 and remains so throughout the reaction.

The synthesis of DAQ[1] **7** as a single enantiomer was accomplished as in Scheme 3.

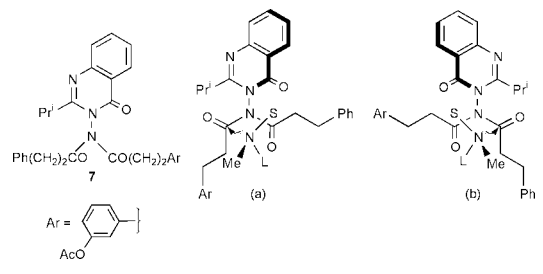
DAQ[2] **6** is chemospecifically attacked by amines at the cinnamoyl carbonyl group.‡ After two kinetic resolutions using (*R*)-2-methylpiperidine (2 eq. DAQ: 1 eq. amine), the recovered DAQ[2] **6** had $[\alpha]_D$ 102 (c = 1, CH_2Cl_2) and showed a single peak on a Chiralcel column under conditions where racemic material showed two peaks. Catalytic hydrogenation gave a sample of DAQ **7** of unknown configuration $[\alpha]_D$ 1 (c = 1.0) but believed to be enantiopure.

Reaction of DAQ[2] **7** (1 eq.) with racemic 2-methylpiperidine (1 eq.) was carried out at 5 °C for 48 h. Separation of the crude amide **8** and MAQ[2] **9** which both contain the phenyl ring from their *m*-acetoxyphenyl ring-containing analogues **10** and **11** (Scheme 4) was accomplished by chromatography.

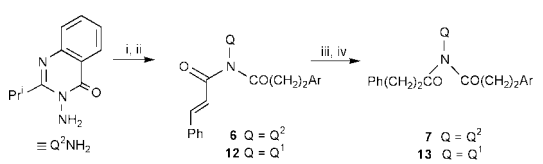
Efficient separation of the amides **8** and **10** from each of their respective MAQ[2]s was then accomplished by trituration with



Scheme 1



Scheme 2



Scheme 3 *Reagents and conditions*: i, PhCH=CHCOCl, pyr. (81%); ii, *m*-acetoxyphenylpropanoylchloride, CH_2Cl_2, pyr. DMF (40%); iii, **6** (2 eq.), (*R*)-2-methylpiperidine (1 eq.), −15 °C, 24 h (KR); repeat; iv, Pd/C, H_2, EtOAc (90%).

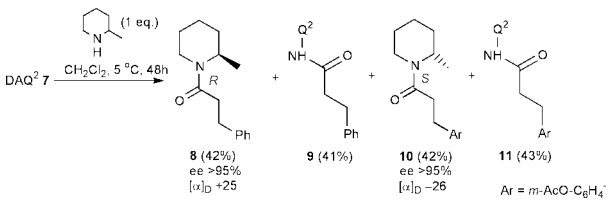
 DOI: 10.1039/b109297a

light petroleum taking advantage of the insolubility of the crystalline MAQ[2]s **9** and **11**. The enantiopurities of amides **8** and **10** recovered by this means were indishinguishable, based on their optical rotations, from authentic samples prepared from enantiopure (*R*)- and (*S*)-2-methylpiperidine respectively and their ees are therefore >95%.

The importance of maintaining strict pseudoenantiotopicity for the two DAQ *N*-acyl groups for PKR was shown using DAQ[1] **13**, prepared by a route analogous to that in Scheme 3 except that the two diastereoisomers of DAQ[1] **12** were separated by chromatography and one of them was hydrogenated to DAQ[1] **13** (Scheme 3).

Reaction of DAQ[1] **13** (1 eq.) with racemic 2-methylpiperidine (1 eq.) proceeded at significantly different rates on the two *N*-acyl groups. After 36 h at 5 °C, the reaction was worked up and after chromatography, amide **10** was obtained in 60% yield§ with a rotation again indistinguishable from a sample prepared by acylation of enantiopure (*S*)-2-methylpiperidine with the appropriate acid chloride. Less than 10% of (impure) amide **8** was isolated in this chromatography.

Not only are the two *N*-acyl groups of DAQ[1] **13** pseudodiastereotopic but the *exo*/*endo*⇌*endo*/*exo* ratio can no longer be assumed to be 1:1 and both these factors lead presumably cooperatively to KR rather than PKR. The dual enantiocomplementarity present in these reactions—the preference for reaction of each of the amine enantiomers with their respective pseudoenantiotopic *N*-acyl group—will carry over to the reactions of enantiopure DAQs in which the *N*-acyl groups are pseudodiastereotopic (as in DAQ[1] **13**) or heterotopic (as in DAQ[1] **5**) and greatly affect the chemoselectivity of attack on the two *N*-acyl groups.¶



Scheme 4

The advantage of reagents such as DAQ **7** for PKR is that their design will be easier than that of pseudoenantiomeric reagents for which identity of reaction rates must be arrived at by empirical means.

We thank the EPSRC and the Ministry of Education (Saudi Arabia) for funding.

Notes and references

† The relative configuration of DAQ[1] **5** corresponds to that of the crystalline diastereoisomer of DAQ[1] **1** from comparison of their X-ray crystal structures (see ref. 6).

‡ From its relatively easy racemisation, DAQ[2] **6** is believed to have an *exo*/*exo* conformation for its imide as for DAQ[1]s **1** and **5** (see ref. 6).

§ Yield based on only 50% of the amine used reacting and on unreacted DAQ[2] **13** (28%) recovered.

¶ Not surprisingly, similar results to those using DAQ[1] **13** are obtained with the analogous DAQ[1] having both *N*-acyl groups as 3-phenylpropanoyl (for which separation of diastereoisomers is not required). The crude amide recovered in this case was of 60% ee; attack on the two diastereotopic *N*-acyl groups in this case delivers enantiomeric products.

Oxo-deficient dioxylene complexes of Mo(VI) containing 3,6-di-*tert*-butylcatechol

Cai-Ming Liu,†[a] Per Restorp,[a] Ebbe Nordlander*[a] and Cortlandt G. Pierpont*[b]

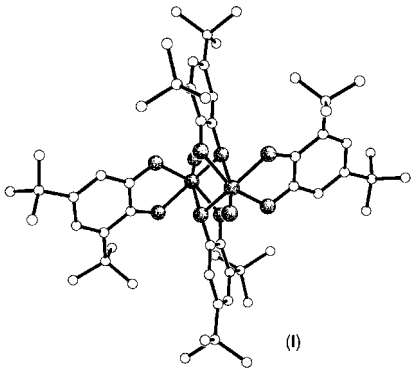
Received (in Purdue, IN, USA) 10th September 2001, Accepted 6th November 2001
First published as an Advance Article on the web 4th December 2001

Strong σ and π donation from the oxygen atoms of 3,6-di-*tert*-butylcatechol contributes to the formation of an oxomolybdenum(VI) complex with an unusually basic oxo ligand.

Metal-catalyzed oxidation reactions that formally involve transfer of an oxygen atom occur as important industrial and biological processes. Molybdenum is the metal at the active site of the oxotransferase enzymes,[1] and it has been used in the commercial production of propylene oxide by the Halcon or Oxirane processes.[2] Both processes are thought to involve oxo transfer from an oxomolybdenum(VI) center, and coligand bonding effects are important in destabilizing strongly bound terminal oxo ligands. The *cis*-dioxomolybdenum(VI) structural unit is one of the earliest and most common features of molybdenum(VI) coordination chemistry. Complexes of Mo(VI) that contain a single oxo, or are without oxo ligands, are unusual and are considered to be oxo deficient. Coligands that are strong **σ** and π donors give oxo-deficient complexes, and ligands of this type appear coordinated to the catalytic molybdenum centers. For the oxotransferase enzymes this is an enedithiolate ligand.[1] The Mo(VI) ions associated with commercial oxidation reactions are thought to contain alkoxo ligands, and transfer of an alkyl hydroperoxide proton to the basic metal oxo ligand initiates oxygen transfer to the olefin substrate.[2]

The coordination chemistry of Mo(VI) with catecholate ligands has shown an interesting dependence upon ligand substituents. The tetrachlorocatecholate (Cl_4cat) ligand reacts with $Mo(CO)_6$ to give dimeric $[Mo^{VI}(Cl_4cat)_3]_2$.[3] Reduction of the dimer in the presence of an oxygen atom donor leads to the $[cis\text{-}Mo^{VI}O_2(Cl_4cat)_2]^{2-}$ dianion. Several other $[cis\text{-}Mo^{VI}O_2(cat)_2]^{2-}$ dianions have been reported with unsubstituted and tethered catecholate ligands.[4] However, the coordination chemistry of molybdenum complexes prepared with catecholate ligands containing electron-releasing *tert*-butyl substituents appears to favor formation of oxo-deficient molybdenum(VI) species. The reaction between 3,5-di-*tert*-butyl-1,2-benzoquinone (3,5-dbbq) and $Mo(CO)_6$ has been observed to form $[Mo(3,5\text{-dbcat})_3]$ as the initial product.[5] Further reaction with trace quantities of dioxygen led to the air-stable $[MoO(3,5\text{-dbcat})_2]_2$ dimer.[6] Structural characterization on the dimer showed that adjacent metal centers were linked by bridging catecholate oxygens (**I**).

Recent work with 3,6-dbbq has shown that *tert*-butyl groups at ring sites adjacent to both oxygen atoms block bridging of the type found for $[MoO(3,5\text{-dbcat})_2]_2$.[7] The reaction between $Mo(CO)_6$ and 3,6-dbbq has been used to form the oxomolybdenum(VI) product $[MoO(3,6\text{-dbcat})_2]$ in dilute solution. Condensation of $[MoO(3,6\text{-dbcat})_2]$ monomers in concentrated solution leads to formation of the chiral tetramer $[Mo(\mu\text{-}O)(3,6\text{-dbcat})_2]_4$‡ shown in Fig. 1. Each Mo center of the square is of the same chirality, ΛΛΛΛ or ΔΔΔΔ, resulting



in right- and left-handed four-membered rings alternating in the crystal structure.§ In this respect, the tetramer stands as a unique example of chiral self-assembly.[4a,8] Along edges, the Mo–O lengths are short (1.8761(4) Å), but of values that are typical for bridging oxo ligands. Corner O–Mo–O bond angles of 93.5(2)° and edge Mo–O–Mo angles of 176.5(2)° show that the Mo_4O_4 core of the tetramer closely resembles a regular square.

Freshly prepared solutions of $[MoO(3,6\text{-dbcat})_2]$ react immediately at room temperature with weak donor ligands (*e.g.* dmso, pyridine *N*-oxide, $OAsPh_3$) to give monomeric $[MoO(3,6\text{-dbcat})_2(L)]$ products. Addition reactions to the tetramer occur more slowly or require elevated temperatures.

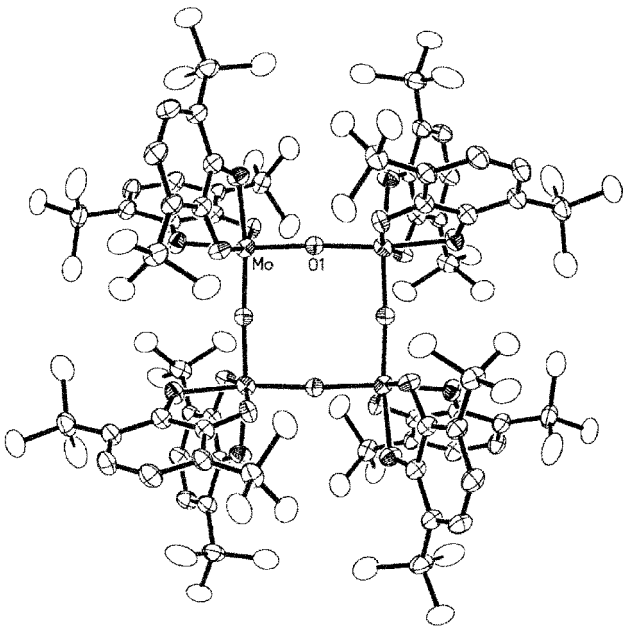


Fig. 1 View of the chiral square ΛΛΛΛ-$[Mo(\mu\text{-}O)(3,6\text{-dbcat})_2]_4$. Selected bond distances (Å) and angles (°) Mo–O^{Oxo} 1.8761(4) Å; Mo–O^{Cat} 1.929(3), 1.993 (3); C–O^{Cat} 1.347(5), 1.344(5); O^{oxo}–Mo–O^{Oxo} 93.5(2); Mo–O^{Oxo}–Mo 176.5(2).

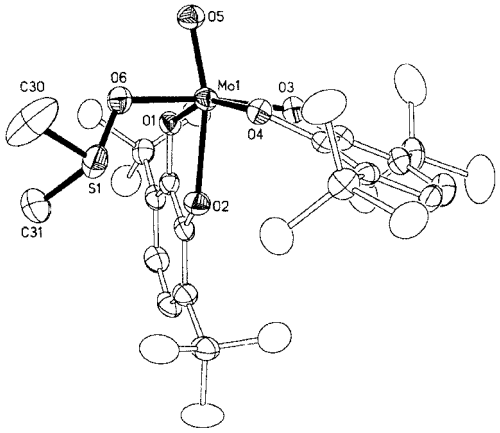

Fig. 2 View of *cis*-MoO(3,6-dbcat)$_2$(dmso). Selected bond distances (Å) and angles (°): Mo–O^{Oxo} 1.690(5); Mo–O^{DMSO} 2.092 (5); O^{Oxo}–Mo–O^{DMSO} 88.1(3).

DMSO has been added to [MoO(3,6-dbcat)$_2$] to give a complex that might potentially be relevant to the chemistry of DMSO reductase.[9] ^{1}H NMR spectra recorded on the product of DMSO addition (in $CDCl_3$) show sharp single resonances for ring and *tert*-butyl protons of the 3,6-dbcat ligands at 6.58 and 1.22 ppm and a resonance for the coordinated dmso ligand at 2.93 ppm.¶ Crystallographic characterization of [MoO(dmso)(3,6-dbcat)$_2$], shown in Fig. 2, has revealed that DMSO addition occurs at a site *cis* to the oxo ligand.§ Consequently, the room-temperature NMR spectrum results from rapid ligand site exchange. Spectra obtained at −98 °C are consistent with the low-symmetry structure found in the solid state. At this temperature four ring proton resonances appear (6.62, 6.59, 6.54 and 6.45 ppm), and *tert*-butyl resonances appear at 0.99, 0.83 ppm, with two overlapped resonances at 1.29 ppm. Proton resonances for the dmso ligand appear at 3.05 and 2.81 ppm showing that rotation about the dmso Mo–O bond is resolved. Room-temperature spectra recorded on solutions of [MoO(dmso)(3,6-dbcat)$_2$] containing additional DMSO show sharp separate resonances for free and complexed dmso molecules indicating that site exchange is either non-dissociative or dissociative by a process that is slow on the NMR time scale. Structural characterization on the pyridine *N*-oxide and triphenylarsine oxide addition products has also provided *cis* addition products pointing to a preference for *cis* coordination by these oxo-donor substrate molecules.[10]

The unusual basicity of the oxo ligand of [MoO(3,6-dbcat)$_2$] results in an apparent dehydration reaction upon treatment with alcohols. In toluene solutions containing isopropyl alcohol, the purple *cis*-diisopropoxide complex, [*cis*-Mo(3,6-dbcat)$_2$-(Pr^{i}O)$_2$],‖ is formed with elimination of water. This reaction normally would be expected to proceed in the reverse direction. Structural characterization of this product has shown that the inner coordination geometry of the Mo (Fig. 3) is similar to that of the tetramer.§ In this case the Mo–O length to the isopropoxide ligands is slightly shorter (1.848(1) Å) than lengths to the bridging oxo ligands. Catecholate substituent effects have been shown to be important in defining charge distribution within complexes containing redox-active metal ions.[11] For the complexes of molybdenum(VI), substituents are responsible for marked differences in the reactivity of co-ordinated oxo coligands.

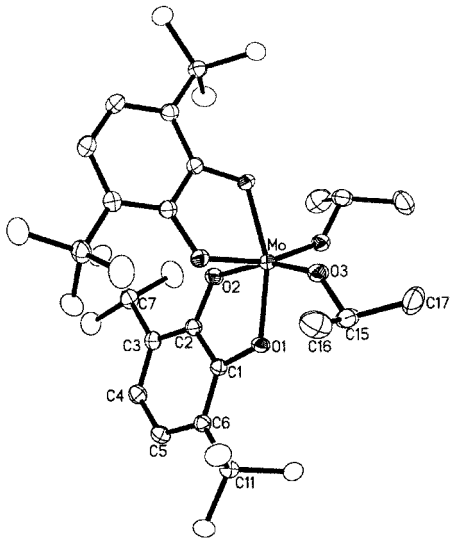

Fig. 3 View of *cis*-Mo(3,6-dbcat)$_2$(OPr^i)$_2$. Selected bond distances (Å): Mo–O^{Cat} 1.955(1), 1.968(1); Mo–O$^{O-Pr^i}$ 1.848(1).

Graduate School of Materials Science, Japan Advanced Institute of Science and Technology, Asahidai, Tatsunokuchi, Ishikawa 923-1292, Japan. E-mail: shira@jaist.ac.jp

Received (in Cambridge, UK) 3rd September 2001, Accepted 8th November 2001
First published as an Advance Article on the web 5th December 2001

Bis(1,5-cyclooctadiene)nickel was found to be an effective catalyst for the addition of the aryl group of arylboron compounds to alkynes in the presence of a proton source, which gives various multisubstituted alkenylarenes or dienylarenes selectively.

Recently much attention has been paid to synthesis of arylalkenes using transition metal catalysts. The reported methods, however, have the following drawbacks. The Heck reaction, one of the most popular reactions leading to arylalkenes, is not so effective for synthesis of multisubstituted arylethenes because multisubstituted ethenes are usually reluctant to participate in the reaction.[1] The addition of a carbon–hydrogen bond of arenes to internal alkynes in the presence of a transition metal catalyst[2] or an acid catalyst,[3] which is an excellent route for multisubstituted arylethenes from the standpoint of atom economy, can be utilized only for rather electron-rich arenes, where the control of the regiochemistry on arenes, in particular monosubstituted benzenes, is difficult. The similar drawbacks hold true also for the transition metal-catalysed oxidative coupling of arenes with alkenes.[4] The nickel-catalysed reaction of arylmagnesium compounds with alkynes gives arylethenes only in low yields, being incompatible with labile functional groups.[5] Furthermore, there has been no convenient way to synthesize aryldienes from alkynes. Herein we report that a nickel complex catalyses the addition of the aryl group of arylboron compounds to alkynes in the presence of a proton source to give hydroarylation products of alkynes, where multisubstituted arylethenes or 1-aryl-1,3-butadienes can be selectively obtained by properly choosing an arylboron compound, a ligand and a proton source.[6]

We first examined the reaction of 2-phenyl-1,3,2-dioxaborinane (**1a**) with 4-octyne (**2a**) in the presence of 5 mol% of bis(1,5-cyclooctadiene)nickel, $Ni(cod)_2$, in dibutyl ether and found that a certain amount of a hydroarylation product of the alkyne, (*E*)-4-phenyl-4-octene (**3a**), was produced (Scheme 1). We considered that the generation of **3a** could occur as shown in Cycle A of Scheme 2. Thus, oxidative addition of the carbon–boron bond of **1a** to the nickel(0) complex followed by insertion of **2a** to the carbon–nickel bond of resulting complex **5** gives alkenylnickel **6**. A small amount of water in the reaction media reacts with complex **6** to afford, through σ-bond metathesis as shown in **7**, Ni–H complex **8**, which undergoes reductive elimination, providing hydroarylation product **3a** and regenerating the nickel(0) complex. Consequently, we expected that addition of a stoichiometric amount of water as a proton source would increase the yield of **3a**, accelerating the σ-bond metathesis. The reaction in the presence of 1 mol amount of water actually proceeded at 80 °C for 5 h to give a 80:20 mixture of **3a** and (4*Z*,6*E*)-4-phenyl-5,6-dipropyl-4,6-decadiene (**4a**) in 98% yield (entry 1 of Table 1).[7] Dimerization–hydroarylation product **4a** should be produced by insertion of another molecule of **4a** into the carbon–nickel bond of **6** to give complex **9**, followed by σ-bond metathesis and reductive elimination (Cycle B in Scheme 2). The reaction was applied to other arylboronates, giving 1:1 adducts as major products (Table 1). The reaction with *p*- or *m*-methoxyphenylboronate proceeded in a similar manner to **1a**, whereas the substitution at an *ortho* position lowered the yield (entries 2–4). An electron-withdrawing substituent decreased the selectivity for **3** over **4** (entry 5). Diphenylethyne also participated in the reaction with **1a** to give a 1:1 adduct exclusively.

Triphenylborane (**11**) as an arylboron compound in combination with triphenylphosphine ligand was also found effective, giving a 264% yield of addition products, where all of the phenyl groups on the boron atom were transferred to alkyne

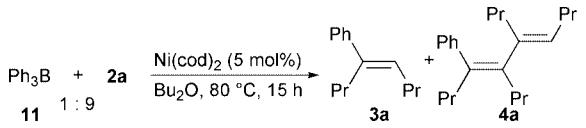
carbons (Scheme 3). Use of 1,1′-bis(diphenylphosphino)ferrocene (DPPF) as a ligand in conjunction with phenol as a proton source increased the selectivity of **3a**.

One of the most striking features in the nickel-catalysed hydroarylation of alkynes is the selective formation of 1:2 adducts between an aryl group and an alkyne, brought about by the introduction of arylboronic acids into the reaction. Thus, treatment of arylboronic acids and alkynes with H_2O in the presence of 10 mol% of $Ni(cod)_2$–PPh_3 (1:4) provided 1:2 adducts **4** selectively (Scheme 4). Various aryl- and heteroarylboronic acids can participate in the reaction to give aryl- and heteroaryldienes as major products (Table 2).[8] Phenylboronic



ligand	proton source	GC yield	**3a**:**4a**
PPh_3 (10 mol%)	H_2O (3.0 equiv)	264%	51:49
DPPF (5 mol%)	PhOH (3.0 equiv)	240%	91:9

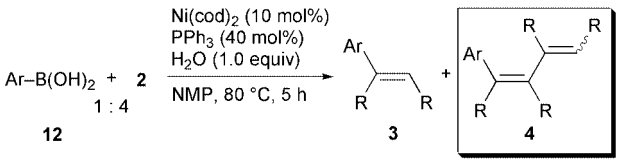

Scheme 4

Table 2 Nickel-catalysed reaction of alkynes with arylboronic acids[a]

Entry	Ar	R	Yield (%)[b]	**3**:**4**
1	Ph	Pr	77	<1:99
2	4-MeO-C_6H_4	Pr	78	8:92
3	2-naphthyl	Pr	73	16:84
4	3-NH_2-C_6H_4	Pr	61	13:87
5	3-thiophenyl	Pr	55	19:81
6[c]	Ph	Ph	72	58:42

[a] The reaction was carried out in NMP (0.34 mL) at 80 °C using an arylboronic acid (0.25 mmol), an alkyne (1.0 mmol), H_2O (0.25 mmol), $Ni(cod)_2$ (2.6 μmol), and PPh_3 (10 μmol). [b] Isolated yield based on arylboronic acid. [c] The reaction was carried out for 24 h.

acid reacted also with diphenylethyne, albeit the selectivity for **4** decreased. To the best of our knowledge, this is the first example of the transition metal-catalysed dimerization–hydroarylation of alkynes.

In conclusion, we have demonstrated that the nickel-catalysed hydroarylation of alkynes provides arylalkenes or aryldienes selectively. Studies on details of the mechanism as well as application of the reaction to other substrates are in progress.

Resolving multiple ^{27}Al sites in $AlVO_4$ by ^{27}Al MAS NMR spectroscopy at 21.15 Tesla

Ulla Gro Nielsen, Jørgen Skibsted and Hans J. Jakobsen*

Instrument Centre for Solid-State NMR Spectroscopy, Department of Chemistry, University of Aarhus, Langelandsgade 140, DK-8000 Aarhus, Denmark. E-mail: ulla@chem.au.dk; jskib@chem.au.dk; hja@chem.au.dk

Received (in Cambridge, UK) 5th October 2001, Accepted 14th November 2001
First published as an Advance Article on the web 4th December 2001

A high-resolution 21.15 Tesla magnet (900 MHz for ^{1}H NMR) along with a home-built CP/MAS NMR probe is employed to succesfully resolve three different ^{27}Al resonances in $AlVO_4$, allowing a precise determination of their quadrupole coupling parameters and isotropic chemical shifts.

The recent technological advancement with the successful construction of a persistent high-resolution superconducting 21.15 T magnet at Oxford Instruments, UK will greatly assist solving one of the most challenging problems encountered in solid-state magic-angle spinning (MAS) NMR studies of half-integer quadrupolar nuclei. This originates from the second-order quadrupolar line-broadening which may give rise to severe overlap of heavily broadened resonances for the central transitions in case of multiple sites. Obviously, this can significantly hamper the characterization and assignment of the resonances for the individual sites. These difficulties may be overcome by performing MAS NMR experiments at the highest possible magnetic field (or at several magnetic field strengths), thereby taking advantage of the inverse proportionality of the second-order quadrupole interaction with the magnetic field and also of the increase in chemical shift dispersion.[1–7] Other techniques aiming at resolving overlapping resonances for half-integer quadrupolar nuclei include the methods of dynamic-angle spinning (DAS),[8,9] double rotation (DOR),[8,10] and multiple-quantum (MQ) MAS[11] NMR spectroscopy. In this communication we demonstrate that the intriguing problem of fully understanding and analyzing ^{27}Al MAS NMR spectra of $AlVO_4$, recorded at several intermediate magnetic field strengths, is most easily achieved from a ^{27}Al MAS NMR spectrum recorded at 21.15 T using a home-built 4 mm 900 MHz CP/MAS NMR probe.[12] This ^{27}Al MAS NMR spectrum represents one of the first solid-state NMR spectra recorded on the 21.15 T Oxford magnet.

^{27}Al MAS NMR spectra of the central transition for $AlVO_4$, a model compound for V_2O_5/Al_2O_3-based heterogeneous catalysts, obtained at the moderate magnetic field strengths of 7.05 and 9.39 T are illustrated in Fig. 1(a) and (b). Both spectra are dominated by a quite narrow peak (resonance position $\delta \approx -10$ ppm) superimposed on a broader resonance constituting two or more overlapping ^{27}Al quadrupolar lineshapes. Clearly a straightforward analysis of these spectra in terms of quadrupole coupling parameters (C_Q, η_Q) and isotropic chemical shifts (δ_{iso}) is not possible except for the narrow resonance ($\delta \approx -10$ ppm). Along with the manifold of spinning sidebands (ssbs) for the satellite transitions (not shown) of this resonance, the ^{27}Al spectrum for the narrow peak, *i.e.* the Al(1) site, can be fully analyzed. At 14.09 T the spectrum in Fig. 1(c) shows that one second-order quadrupolar broadened resonance separates out (in the region 5–30 ppm) from the other resonances, while the narrow peak at $\delta \approx -10$ ppm remains superimposed on a somewhat narrower second (*i.e.* number two) quadrupolar broadened resonance, however, almost fully hidden by maximum overlap with the narrow peak. ^{27}Al MAS NMR spectra recorded at 14.09 T have actually been used to determine precise values for C_Q, η_Q and δ_{iso} by analysis of the manifold of ssbs originating from the satellite transitions for the narrow

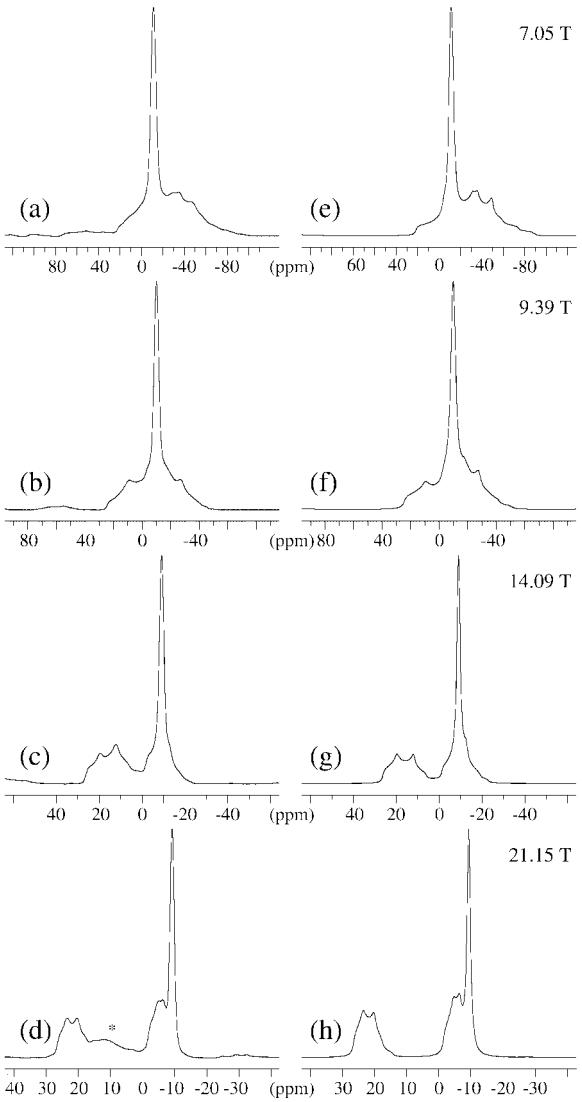

Fig. 1 Experimental ^{27}Al MAS NMR spectra of $AlVO_4$ recorded at (a) 7.05 T (78.1 MHz), (b) 9.39 T (104.2 MHz), (c) 14.09 T (156.3 MHz), and (d) 21.15 T (234.5 MHz) on Varian INOVA-300, -400, -600, and -900 NMR spectrometers, respectively, using home-built 4- and 5-mm CP/MAS NMR probes. The asterisk (*) in spectrum (d) indicate a broad impurity resonance. All experiments employed single-pulse excitation (0.5 μs pulse width, $\gamma B_1/2\pi \approx 55$ kHz), spinning speeds in the range 12–15 kHz, and exact magic-angle setting. Simulated ^{27}Al MAS NMR spectra for $AlVO_4$ are shown on the right-hand side of the experimental spectra, *i.e.* for 7.05 T (e), 9.39 T (f), 14.09 T (g), and 21.15 T (h) using the ^{27}Al NMR parameters (Table 1) determined from the 21.15 and 14.09 T spectra (see text). All spectra are expanded to the same width on a Hz scale.

 DOI: 10.1039/b109042a

peak (Al(1) site) using the STARS program.[13] Furthermore, quite precise values have also been determined from lineshape analysis for the second-order quadrupolar lineshape (Al(3) site) shifted to the region δ 5–30 ppm in the 14.09 T spectrum of Fig. 1(c). We should note that the increased resolution and shift of resonances in Fig. 1(c) are related to the reduced effects of the second-order quadrupolar interaction combined with the increase in chemical shift dispersion. A further and dramatic increase in the spectral resolution is observed when recording the ^{27}Al MAS NMR spectrum at 21.15 T as illustrated in Fig. 1(d). At this magnetic field strength the two ^{27}Al resonances, Al(1) and Al(2), which overlap heavily in the region at $\delta \approx -10$ ppm in the 14.09 T spectrum of Fig. 1(c), become almost completely resolved. Furthermore, for the present sample the spectrum in Fig. 1(d) clearly discloses the presence of a broad ^{27}Al impurity resonance (indicated by an asterisk at $\delta \approx 10$ ppm) from an octahedral ^{27}Al impurity not easily discernible in the lower field spectra. The appearance of this Al impurity (most likely amorphous) came as somewhat of a surprise since no such impurity for the present sample could be detected by powder XRD. Anyway, the 21.15 T spectrum in Fig. 1(d) allows a straightforward lineshape analysis of the two second-order broadened resonances, Al(2) and Al(3), clearly resolved from the narrow Al(1) resonance and the impurity peak, respectively. The resulting C_Q, η_Q and δ_{iso} parameters for these two resonances, along with the Al(1) data derived from a 14.09 T spectrum of the satellite transitions, are considered the optimized parameters for the three Al sites observed for $AlVO_4$ and are summarized in Table 1. The data in Table 1 are used for simulations of the ^{27}Al MAS NMR spectra obtained at the four magnetic field strengths in Fig. 1 and are shown in the right-hand column next to the experimental spectra (Fig. 1(e)–(h)). Excellent agreements are observed between the experimental and simulated spectra for all magnetic field strengths. The minor intensity differences between parts of the experimental and simulated spectra at 7.05, 9.39, and 14.09 T can be ascribed to distortions caused by the broad impurity resonance at $\delta \approx 10$ ppm.

Considering the fact that the crystal structure of $AlVO_4$ is unknown, the present 21.15 T ^{27}Al MAS NMR results (Table 1) for $AlVO_4$ show the presence of two octahedral Al sites (Al(1) and Al(2)) with quite different quadrupole coupling parameters and one penta-coordinated Al site (Al(3)) in the asymmetric unit of its crystal structure.

In conclusion, ^{27}Al MAS NMR at 21.15 T successfully resolves three ^{27}Al sites in $AlVO_4$, allowing a straightforward analysis and characterization of these sites. As an additional benefit, an impurity, unknown to be present beforehand and slightly distorting the spectral intensities at lower magnetic fields, is also resolved at 21.15 T. MQMAS NMR[11] combined with high magnetic fields may be considered an alternative approach to achieve spectral separation of multiple ^{27}Al sites as recently demonstrated in the characterization of USY zeolites.[14] We should note that generally high spinning speeds may be required at 21.15 T because of the increase in chemical shift dispersion. To keep the first-order ssbs outside the ^{27}Al chemical shift range ($\approx$100 ppm) spinning speeds of about 23 kHz is needed, however, such speeds are easily obtained using small rotors. It is also of interest to point out that at the magnetic field of 21.15 T and employing a spinning speed of 50 kHz, recently achieved by Samoson *et al.*,[15] an undistorted ^{27}Al MAS NMR spectrum of the central transition for a single ^{27}Al site with C_Q as large as 26–30 MHz may be obtained (*i.e.* $C_Q(1+\eta_Q/6) \leqslant 30.2$ MHz).[7]

Table 1 ^{27}Al quadrupole coupling parameters (C_Q, η_Q) and isotropic chemical shifts (δ_{iso}) for $AlVO_4$

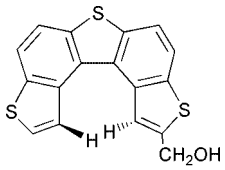
Received (in Cambridge, UK) 10th October 2001, Accepted 8th November 2001
First published as an Advance Article on the web 4th December 2001

Incorporated into chiral phosphatidylcholine (PC) vesicles, [5]thiaheterohelicene with a labile helix that functioned as a probe, developed induced CD absorptions which manifested alterations in Cotton effects and intensities by chirality of PC applied, temperature variations, and coexistence of cholesterol or its 5α-epimer.

Phosphatidylcholine (PC) molecules[1] possess a chiral center at the position of the sn-2 carbon of the glycerol backbone. An ethanol solution of monomeric D-DPPC (*R* configuration) shows a positive Cotton effect around 220 nm, whereas an aqueous solution of aggregated D-DPPC demonstrates the opposite Cotton effect around 225 nm due to the formation of vesicles.[2] Achiral 1,6-diphenylhexa-1,3,5-triene (DPH) embedded in the D-DPPC vesicles, induces chirality to develop weak CD absorptions, due to anisotropic circumstances.[2] This induced CD, however, disappears above 40 °C and the conformation of DPH is not disclosed. This paper describes chiral recognition of single bilayered PC vesicles using 2-hydroxymethylthieno[3,2-*e*:4,5-*e*′]di[1]benzothiophene (5HM) as a probe. Although 5HM has a helical shape arising



P-5HM

from steric repulsion between the terminal hydrogen atoms in the molecule,[3] the helix of 5HM readily undergoes inversion in a solution because of the weakness of the repulsion, causing a rapid racemizarion. However, in chiral environments such as micelles,[4] crystal fields[5] and several species of serum albumin,[6] 5HM develops induced CD because of a shift in the equilibrium between right-handed (P) and left-handed (M) enantiomers, either of which can easily be determined by the sign of the Cotton effect of the CD absorptions. Furthermore, the induced CD of 5HM is fairly intense and appears in the longer wavelength region, characteristic of its widely conjugated aromatic chromophore.

Incorporation of water-insoluble 5HM into the PC vesicles[7] yielded transparent solutions which manifested intense CD absorptions. Fig. 1 shows the CD spectra of 5HM embedded in the D-DPPC (Fig. 1c) and L-DPPC (Fig. 1f) vesicles together with the spectra of an ethanol solution of monomeric D-DPPC (Fig. 1a) and an aqueous solution of aggregated D-DPPC (Fig. 1b). Characteristic bands of 5HM in the vesicles were observed in the range of 250–380 nm. The Cotton effects of these bands were opposite for the L- and D-DPPC vesicles, presumably because of the influence of the reversed twisting of the bilayers on each other. This fact implies that for both vesicles the equilibrium of 5HM was displaced between the P and M enantiomers in the opposite directions to each other. Comparison of Fig. 1c and f with the CD spectra of 5HM in BSA and chiral micelles clearly indicates that racemic 5HM was converted into a P e.e. in the D-DPPC vesicles and into an M e.e. in the L-DPPC vesicles. From the value of the apparent molecular ellipticity, the extent of the P e.e. in the D-DPPC vesicles was estimated to be approximately 6%. Furthermore, an ethanol solution of D-DPPC containing the same concentrations of 5HM demonstrated no induced CD absorptions.

With a rise in temperature, the UV spectra of 5HM in the L-DPPC vesicles displayed obvious hypsochromic shifts at the absorption maximum near 350 nm with the isosbestic points at 286.2 and 302.8 nm (Fig. 2a). This phenomenon can be explained by the assumption that the elevation of temperature brought about an increase in the fluidity of the vesicles along with an increase in the mobility of the 5HM molecules. The plots of the absorbance of that peak against temperature showed the maximum around 40 °C (Fig. 3a), corresponding to the main phase transition temperature (*T*c) of 41.5 °C, as determined by the DSC method.[8] This trend in the temperature dependence of the absorbance was found for other PCs (DMPC, DSPC and DOPC), and this method is thought to be useful for predicting the *T*c of vesicles.[9] On the other hand, the intensities of the induced CD decreased rapidly with a rise in temperature (Fig. 2b). This decrease may be attributed to the increasing fluidity of the vesicles, which reduced the fixation of the mobile helixes (P and M) of the 5HM molecules. In contrast to the case of DPH, it is intriguing that the induced CD of 5HM did not disappear over 40 °C, but merely weakened. The plots of temperature dependence of the CD intensities demonstrated a discontinuous

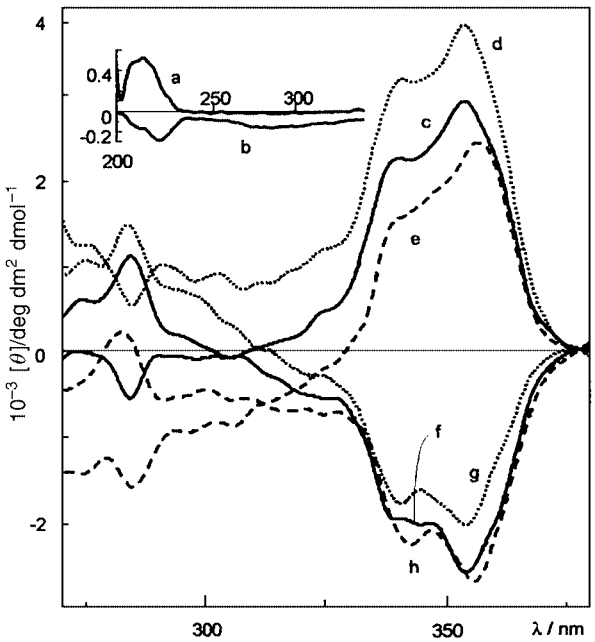


Fig. 1 CD spectra of D-DPPC: (a) in ethanol and (b) in water, CD spectra of 5HM in D-DPPC vesicles: (c) no additives, (d) with Cho and (e) Epi, and CD spectra of 5HM in L-DPPC vesicles: (f) no additives, (g) with Cho and (h) Epi. [D- or L-DPPC] = 5×10^{-4} M, [5HM] = 9×10^{-5} M, [Cho] = [Epi] = 4×10^{-5} M.

 DOI: 10.1039/b109062c

line with two flection points (Fig. 3b). The higher point on the line was at approximately 40 °C which was coincident with the value of the *T*c obtained from the maximum of the absorbance plots. The meaning of the lower point is entirely obscure, but it might be correlated to the pretransition of the bilayered phase. In any event, it is evident that the 5HM in the chiral vesicles provides information on not only chiral recognition, but also on the phase transition of the vesicles.

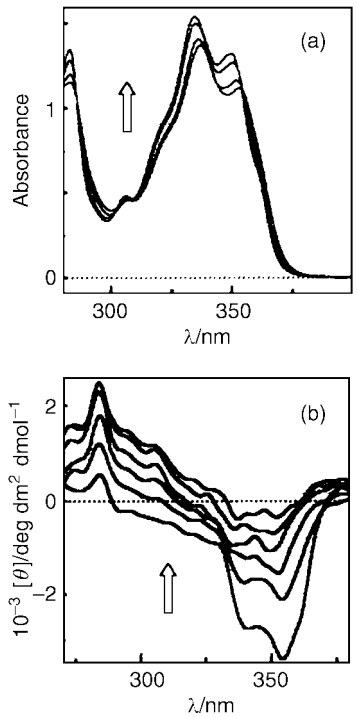

Fig. 2 Temperature dependence of 5HM in L-DPPC vesicles at 5 to 70 °C: (a) UV spectra and (b) CD spectra. [D- or L-DPPC] = 5×10^{-4} M and [5HM] = 9×10^{-5} M.

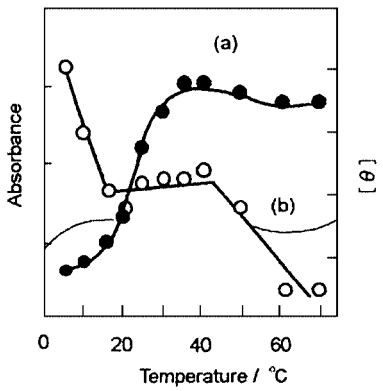

Fig. 3 Plots of temperature dependence of 5HM in L-DPPC vesicles: (a) absorbance at the peak around 350 nm (left axis) and (b) molecular ellipticity ($[\theta]_{284} - [\theta]_{354}$) (right axis).

Next, we examined the effect of the coexistence of cholesterol (Cho) and its epimeric isomer, 5α-epicholesterol (Epi), on the chiral recognition of the DPPC vesicles. Fig. 1c–h exhibits the induced CD spectra of 5HM in the L- and D-DPPC vesicles containing Cho or Epi with 0.44 times concentration of 5HM at 10 °C. In the D-DPPC vesicles, the absorptional intensity around 350 nm increased with the addition of Cho, while the addition of Epi reduced its intensity in comparison to the case with no additives. In marked contrast, the situation was the inverse of the L-DPPC vesicles: Cho reduced the intensity, while Epi slightly enhanced it. These effects suggest that the configuration of the hydroxy groups of Cho and Epi played an important role in the chiral recognition of the DPPC vesicles. Regarding the Cho molecules in the L-PC vesicles, it has been reported that the hydroxy groups exist in the vicinity of the ester carbonyl groups of the PC molecules without hydrogen bonds with the surroundings, and the hydrophobic portions are juxtaposed to the alkyl chains of the PC molecules.[10] Thus, Cho perturbs the orientation of the PC molecules in the gel phase under a temperature of *T*c. These facts may lead to the explanation that the presence of Cho brought about the reduction of the CD intensity in the L-DPPC vesicles because of the decrease in fixation of the 5HM helixes. On the other hand, Epi only slightly affected the increase in the CD intensity. In D-DPPC vesicles, the situations for Cho and Epi seem to be chiroptically opposite to the case in L-DPPC vesicles. These observations imply that the inverse functions of Cho and Epi in the vesicles were revealed by the application of 5HM from the standpoint of chiroptical properties.

Received (in Cambridge, UK) 28th September 2001, Accepted 30th October 2001
First published as an Advance Article on the web 26th November 2001

The CFTA method has proved to be useful for assigning absolute configuration of α-amino esters by ^{19}F NMR.

One of the most convenient and reliable methods for determination of both absolute configuration and enantiomeric excess (ee) of chiral molecules is ^{1}H NMR analyses of the diastereomers formed by reaction of these molecules with chiral derivatizing agents (CDAs).[1] Among various CDAs developed so far, fluorine-containing CDAs have the advantage of allowing ^{19}F NMR to be used as an additional analytical tool.[2] The greater chemical shift differences of ^{19}F signals compared to ^{1}H signals and the simplicity of ^{19}F NMR spectra add greatly to the value of this approach.[3] However, there have been no reliable methods reported for assigning absolute configuration by ^{19}F NMR that are based on a theoretical and predictable explanation of the source of chemical shift differences.[4]

We previously reported the synthesis of α-cyano-α-fluoro-*p*-tolylacetic acid (CFTA). This reagent proved to be an excellent CDA for determination of ee by ^{19}F NMR[5] and for determination of absolute configuration by ^{1}H NMR.[6] As part of our continuing study of the CFTA agent we now report a consistent relationship between the ^{19}F NMR chemical shifts (δ_F) of diastereomeric CFTA amides of α-amino esters and their absolute configurations. Molecular orbital calculations were used to estimate the conformational equilibria of the similar α-cyano-α-fluorophenylacetic acid (CFPA)[3] amides and these equilibria were used to develop a correlation model based on the chemical shift nonequivalence in the ^{1}H NMR of CFTA amides.

We examined a series of CFTA amides of common α-amino esters (**1**–**13**) to obtain the chemical shift differences ($\Delta\delta_F$) between the diastereomers. The ^{19}F NMR spectrum of the CFTA amide of Gly-OMe (**14**) was used as reference (Table 1).[7] The fluorine signals of (*R*,*S*)-isomers (δ_{RS}) always resonated at 2 to 6 ppm higher field compared to those of the corresponding (*S*,*S*) isomers (δ_{SS}), thus giving consistently minus $\Delta\delta_F$ values. For comparison, $\Delta\delta_F$ values for MTPA[8] amides of the same α-amino esters were also examined. These also gave consistently minus $\Delta\delta_F$ signs, although the magnitudes were considerably smaller than those observed for CFTA amides.

The large $\Delta\delta_F$ values and the consistent relationship between the signs and absolute configurations for diastereomeric CFTA amides combine to make the CFTA amide method very reliable for assigning absolute configuration of α-amino esters using ^{19}F NMR.

The $\Delta\delta_F$ values for diastereomeric CFTA amides can be attributed to different biases in the conformational equilibria between the *ap* and the *sp* conformers shown in Fig. 1, as was previously discussed for the CFTA esters.[6] In the former, the F–C_α bond is *anti-periplanar* (*ap*) to the C = O bond, while in the latter, this bond is *syn-periplanar* (*sp*), respectively. The presence of these two conformers in each CFTA amide diastereomer was supported by molecular orbital calculations on the ground state geometry and energies using the quite similar molecules (*R*,*S*)-**15** and (*S*,*S*)-**15**, *i.e.*, two diastereomeric CFPA amides of Val-OMe.[9] The calculations predicted the preference of the *ap* conformer over the *sp* conformer in accord with the conformation deduced from the sense of

Table 1 ^{19}F chemical shifts of diastereomeric CFTA and MTPA amides[a]

[a] Chemical shifts in $CDCl_3$ were determined at 254 MHz for **1**, **3**, **7**, **8**, **12** and at 376 MHz for others. $CFCl_3$ was used as an internal standard.[b] $\delta_{RS\ (or\ SR)} - \delta_{SS\ (or\ RR)}$.[c] Benzyl ester was used.[d] Chemical shift of the racemic CFTA amide.

 DOI: 10.1039/b108842d

chemical shift nonequivalence of the protons in the R and the ester groups between the (*R*,*S*)- and (*S*,*S*)-CFTA diastereomers **1**–**13**.[10]

In the fast equilibrium between *ap* and *sp* conformers for each CFTA amide, the observed δ_F value must be a weighted mean of the chemical shift for each conformer on their populations. Calculation of the δ_F values for (*R*,*S*)-**15** and (*S*,*S*)-**15** predicted that the resonance of the *ap* conformer occurs at higher field than the resonance of the *sp* conformer.[11] The predicted chemical shift differences between *ap* and *sp* conformers (~ 18 ppm) for both diastereomers were considerably greater than that between the diastereomeric two *ap* conformers (~ 1.7 ppm) or the diastereomeric two *sp* conformers (~ 1.5 ppm). From this, we conclude that the observed higher field resonance of the (*R,S*)-CFTA isomer compared to the (*S,S*)-isomer is attributable to a larger population of the *ap* conformer in the (*R,S*)-isomer compared to the population of this conformer in the (*S,S*)-isomer. In addition, these conformational preferences appear to hold for all the diastereomeric amides **1**–**13**.[12] These conformational preferences can be explained by invoking attractive interactions between the eclipsed tolyl and R groups in the (*R*,*S*)-CFTA amide structures. The same interactions would be possible in the *sp* conformer of (*S*,*S*)-amides, but in this case these interactions would increase the population of the *sp* conformer, and hence would shift the ^{19}F signal to lower field.

In order to confirm the presence of attractive interactions, we compared the δ_F values for both (*R*,*S*)- and (*S*,*S*)-diastereomers of **1**–**13** with the δ_F value of racemic **14** (−142.152 ppm), wherein comparable attractive interactions are absent. The signs of the chemical shift differences ($\Delta\delta_F^{Rel}$) of **1**–**13** relative to **14**, *i.e.*, δ_{RS} − (−142.152) for the (*R*,*S*)-isomers and δ_{SS} − (−142.152) for the (*S*,*S*)-isomers, were found to be consistently minus for the (*R*,*S*)-isomers and plus for the (*S*,*S*)-isomers. These results suggest that the *ap* conformer is more populated in the (*R*,*S*)-isomers and less populated in the (*S*,*S*)-isomers, when compared with that of **14**. This strongly supports the presence of attractive interactions proposed above for the amides **1**–**13**.

It should be noted that the regularity observed for the sign of $\Delta\delta_F^{Rel}$ values necessarily provides a simple method for assigning absolute stereochemistry of α-amino esters by using either one of the two CFTA diastereomers. Further investigations to extend the applications and reliability of the CFTA method based on both ^1H and ^{19}F NMR are currently underway.

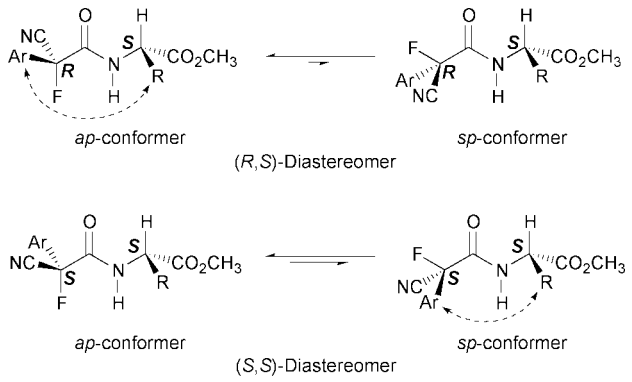

Fig. 1 Conformational equilibria of CFPA (Ar = Ph) and CFTA (Ar = *p*-Tol) amides.

9 The ground state geometry and energies of (*R*,*S*)-**15** and (*S*,*S*)-**15** were calculated by AM1 method using MOPAC 2000 program to give the *ap* and the *sp* conformers shown in Fig. 1 (Ar = Ph, R = *i*-Pr). The structures of these conformers were optimized by *ab initio* calculation (RHF/6-31+G(d), GAUSSIAN 98 program). The energy differences $\Delta E_{sp\text{-}ap}$ by the *ab initio* calculation are as follows. (*R*,*S*)-**15**: 3.60 kcal mol^{-1} ; (*S*,*S*)-**15**: 2.89 kcal mol^{-1}.

10 The ^1H signals due to the R groups in the (*R*,*S*)-isomers consistently appeared at higher field than those due to the corresponding (*S*,*S*)-isomers, while the signals due to the ester group in the (*R*,*S*)-isomers resonated at lower field than those due to the (*S*,*S*)-isomers. Details will be published elsewhere.

11 The ^{19}F chemical shifts of the two conformers in each diastereomeric CFPA amide **15** were calculated using GAUSSIAN 98 program on the structures optimized by RHF/6-31+G(d). δ_F (ppm. $CFCl_3$ as an internal standard): (*R*,*S*)-**15**, *ap* −148.35; *sp* −130.45. (*S*,*S*)-**15**, *ap* −146.70; *sp* −128.97.

12 The larger $\Delta E_{sp\text{-}ap}$ value (3.60 kcal mol^{-1}) in the (*R*,*S*)-**15** obtained by the *ab initio* calculation compared to that (2.89 kcal mol^{-1}) in the (*S*,*S*)-**15** is qualitatively consistent with this consideration. A similar discussion was conducted regarding the ^{19}F chemical shift non-equivalence in the case of diastereomeric CFTA esters (ref. 6). See also: S. K. Latypov, N. F. Galiullina, A. V. Aganov, V. First published as an Advance Article on the web 4th December 2001

A soluble porphyrin dimer linked with bicyclo[2.2.2]octadiene was converted in to insoluble conjugated porphyrin dimer by heating at 200 °C, this provides a new strategy for the process control of conjugated porphyrins.

†The preparation of well defined arrays of porphyrins is a popular area of research, not only for its possible application to the elucidation of natural photosynthesis mechanism, but also for functional molecular devices, *e.g.* molecular scale wires, switches and catalysis for the direct four-electron reduction of oxygen to water.[1] Porphyrins can be directly connected with covalent bonds or assembled with hydrogen bonds or transition metals. Porphyrin dimers or oligomers with no significant π-overlap between the neighboring porphyrins were first studied, and highly conjugated porphyrin dimers or oligomers have attracted much interest in recent years. For example, gable porphyrins developed by Tabushi *et al.*[2] contain clefts for molecular recognition. *Meso–meso* linked porphyrin dimers developed by Osuka *et al.*,[3] where the porphyrins lie approximately orthogonal to each other, exhibit strong electronic communication in their excited states to provide a useful basic structure for molecular photonic wires. On the other hand, the group of Arnold has developed conjugated porphyrin dimers, where porphyrins are linked with conjugated triple bonds.[4] The groups of Crossley and Smith have reported further enhanced conjugated porphyrins, namely, edge-fused porphyrin oligomers.[5] The groups of Osuka and Sugiura have reported conversions of non-conjugated β-*meso* linked porphyrin dimers into conjugated fused porphyrin dimers *via* oxidation.[6] The unusual electronic behavior of such porphyrin arrays due to strong ground state conjugation makes them attractive candidates for real molecular wires. Although conjugated porphyrin oligomers constitute an active area of research, only a few structural types have been explored.[4–6] Here we present a new strategy for preparing a conjugated porphyrin dimer **6** from a non-conjugated porphyrin dimer **5**. This new method is based on the retro-Diels–Alder reaction. In previous papers we reported that soluble porphyrins fused with bicyclo[2.2.2]octadiene were converted into insoluble benzoporphyrins *via* the retro-Diels–Alder reaction by heating at 200 °C.[7] As the thermal process does not require any reagents or purification steps, it is ideal for the preparation of conjugated porphyrins.

Dipyrrole **2** linked by bicyclo[2.2.2]octadiene was prepared from ethyl 4,7-dihydro-4,7-ethano-2*H*-isoindole-2-carboxylate **1** in four steps as already reported.[8] De-ethoxycarbonylation of **2** with KOH in ethylene glycol at 170 °C gave **3**. Bis-porphyrin **5** fused with bicyclo[2.2.2]octadiene was prepared by the 3 + 1 approach.[9] The reaction of 2.0 equivalents of tripyrranedicarbaldehyde **4** with 1.0 equivalent of dipyrrole **3**, followed by oxidation with dichlorodicyano-*p*-benzoquinone (DDQ) and metallation with $Zn(OAc)_2$ gave Zn-**5** in 13% overall yield. The requisite tripyrrane dicarbaldehyde **4** was prepared by the reaction of 3,4-diethylpyrrole with 2.0 equivalents of benzyl 5-acetoxymethyl-4-butyl-3-methyl-1*H*-pyrrole-2-carboxylate in AcOH–EtOH, followed by debenzylation and formylation with methyl orthoformate and CF_3CO_2H.

The retro-Diels–Alder reaction of Zn-**5** was carried out by heating at 200 °C under vacuum (10 mm Hg) for 2 h to give a planar bisporphyrin Zn-**6** in quantitative yield (Scheme 1). As this conversion proceeds very cleanly, pure Zn-**6** (estimated by NMR) was isolated without purification. As mentioned in previous papers,[7] porphyrins fused with bicyclo[2.2.2]octadiene rings are generally soluble in organic solvents, where π–π-stacking is inhibited. Planar porphyrins formed *via* the retro-Diels–Alder reaction are insoluble due to the strong π–π-stacking. This retro-Diels–Alder process provides a powerful strategy for the fabrication of electronic devices from π-extended compounds. Expensive and tedious vacuum deposition techniques for the preparation of electronic devices from insoluble materials are exempted by using soluble precursors.

 DOI: 10.1039/b108391k

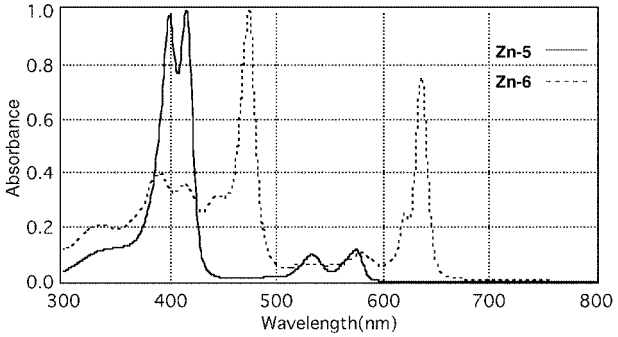

Fig. 1 UV–VIS spectra of bisporphyrins Zn-**5** and Zn-**6**.

As bis-porphyrin **5** is soluble in organic solvents, various metals are also easily introduced into **5** by the reaction with metal salts in organic solvents. Subsequent heating of such metal complexes of **5** gives the metal complexes of **6**, which are difficult to prepare by the reaction of **6** with metal salts. Zn-**5** is soluble in various organic solvents, such as toluene or $CHCl_3$ whereas Zn-**6** is insoluble in toluene or $CHCl_3$.

Absorption spectra of bis-porphyrins Zn-**5** and Zn-**6** were measured in $CHCl_3$ or 5% pyridine–$CHCl_3$, respectively (Fig. 1). The splitting of Soret band (400, 415 nm) was observed in Zn-**5**. The exciton splitting energy in the Soret band is similar to those for the reported gable porphyrins of Tabushi *et al.*.[2] Thus, the dihedral angle and the distance between porphyrins in **5** are estimated to be similar to those of Tabushi's gable porphyrins. As the bicyclo[2.2.2]octane ring is a more rigid spacer than phenylene, porphyrin rings in Zn-**5** are fixed more rigidly than those of other systems. Bis-porphyrin Zn-**5** may be useful as a host for various compounds such as fullerene. In fact, the absorption spectra of Zn-**5** is gradually changed to a broad Soret band at 400 nm by addition of a solution of fullerene, and the splitting of Soret band disappears. Absorption spectra after heating Zn-**5** at 200 °C are shown in Fig. 1. The new absorption spectra can be assigned to be those of Zn-**6**. The red-shift of absorption spectra and the intense Q band are typical for conjugated porphyrin dimers.[5,6] Mass spectra of Zn-**5** and Zn-**6** are identical, since ethylene is eliminated during ionization of Zn-**5**. NMR data support the structure of Zn-**6**.

In conclusion, we have succeeded in the preparation of novel bis-porphyrins **5** and **6**, where the two porphyrin rings are fixed at angles of 120 and 180°, respectively. They provide new models to evaluate intramolecular interaction (singlet or triplet energy transfer or electron transfer) of porphyrin dimers in the excited states or in ground states.[1,4,10]

Asymmetric routes in the reaction of cyclic ketene ortho ester with aldehydes involving the use of chiral Lewis acid

Chan-Mo Yu,* Jae-Young Lee, Kwangwoo Chun, In-Kyung Choi and Suk-Ku Kang

Department of Chemistry and BK-21 School of Molecular Science, Sungkyunkwan University, Suwon 440-746, Korea. E-mail: cmyu@chem.skku.ac.kr

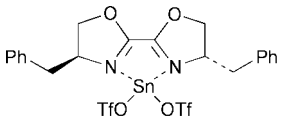
Received (in Cambridge, UK) 16th August 2001, Accepted 6th November 2001
First published as an Advance Article on the web 26th November 2001

Enantio- and diastereoselective synthesis of *threo* 2 and *erythro* 3 was accomplished by the conversion of 1 with aldehydes promoted by chiral borane 10; enantioselctivities range from 45–95% ee, while diastereoselectivities vary from 4.3–49 : 1 with 8 different aldehydes.

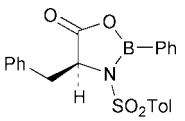
The availability of efficient synthetic methods for achieving absolute stereocontrol *via* a catalytic process in the construction of acyclic systems is of considerable current interest in synthetic chemistry.[1] During the past decades, substantial progress has been made, and as a result, many enantioselective synthetic routes have been extensively explored.[2] Nonetheless, only a few methods exist to establish all stereoisomers selectively, despite their plentiful synthetic potential.[3] Recently we have disclosed novel synthetic methods for the synthesis of both diastereomers **2** and **3** in high levels of stereoselectivity from the ketene ortho ester **1** with an aldehyde mediated by a Lewis acid catalyst (Scheme 1). This highly stereocontrolled transformation for the synthesis of **2** involves the diastereoselective generation of a carbon–carbon bond to form **4** and introduction of ester functionality from hydrolysis of the ortho ester intermediate **4**.[4] A reversal of diastereoselectivity to obtain **3** was realized by an epimerization of intermediate **4** under basic conditions.[5]

The general feature of this transformation is the synthesis of highly functionalized compounds from simple starting materials in high diastereoselectivity. The characteristic feature of this chemical transformation process has encouraged us to carry out further investigation concerning absolute stereoselection to establish all four stereoisomers. This research led to the discovery of efficient enantioselective routes in forming *threo* **2** and *erythro* **3** with high levels of diastereoselectivity and moderate to excellent enantioselectivity. In the course of this study, the absolute configuration of the major component was unambiguously established by comparison with a synthetic sample.

From the mechanistic perspective, major functions for the stereoselectivity are immediately discernable in the catalytic process. Although the exact mechanistic aspects of this transformation have not been rigorously elucidated, the following pathway could be a probable stereochemical route on the basis of product population. We reasoned that if **5** could be a stereochemical model, then it might be possible to control facial selectivity by a chiral catalyst in a predictable fashion. Preliminary investigations for the stereochemical transformation of **1** with aldehyde indicated that the conversion to the corresponding **2** could not be satisfied with a variety of chiral Lewis acids including BINOL–Ti(IV), and bisoxazoline complexes with Cu, Sc, Zn mainly due to a lack of reactivity.[6] However, bisoxazoline–$Sn(OTf)_2$ complex **6**[7] and chiral borane **7**[8] could be a chiral promoter for the enantioselective conversion. Initial attempts to convert **1** to **2** with benzaldehyde in the presence of **6** (20 mol%) at −20 °C in CH_2Cl_2 were met with limited success, providing moderate enantioselectivity with poor diastereoselectivity (47% yield, 76% ee, 2 : 1 dr). A survey of modifications of ligands provided no significant advantages in terms of reactivity and stereoselectivity. On the other hand, reaction of **1** with benzaldehyde in the presence of **7** occurred readily at −78 °C; this chiral Lewis acid was generally superior and chosen for systematic studies.



6



7

Reaction of **1** (R′ = Et) with benzaldehyde in the presence of 20 mol% of **7** for 24 h afforded **2** and **3** in 57% isolated yield in a ratio of 72 : 28 with 77% ee. The lack of diastereoselectivity was attributed to acidic media in the reaction mixture causing epimerization of reaction intermediate **4** for long reaction times. Thus, diastereoselectivity was enhanced by the use of 1 eq. of **7** within 2 h, providing 78% yield in 91 : 9 dr with 83% ee (−78 °C for 2 h in CH_2Cl_2). After surveying numerous modifications of *N*-sulfonylamino acids, the remarkable observation has been made that the use of **10** as a chiral promoter led to the best results in terms of chemical yields and stereoselectivities (PhCHO, 95% yield, **2**:**3** = 97 : 3, 93% ee): (a) chiral Lewis acid **10** was prepared from the reaction of **8** with **9**[9] at 23 °C for 2 h;[10] (Scheme 2) (b) reaction at −78 °C for 30 min in CH_2Cl_2 were the optimal conditions, while with longer reaction times, especially more than 2 h, diminished diastereoselectivity was observed; (c) R^1 = Et in **1** was generally superior to others such as Me and Pr^i in terms of chemical availability and efficacy. It is worthy of note that efficient recovery of the chiral ligand **8** was made after work up procedure.

Under optimal conditions, the reaction was performed by the addition of **1** (R^1 = Et) to a solution of benzaldehyde and **10** in CH_2Cl_2 at −78 °C. After stirring for 30 min, the reaction mixture was quenched with 2 N aqueous HCl followed by work up and silica gel chromatography to afford *threo* **2a** with *erythro* **3a** in a ratio of 97 : 3 as judged by 500 MHz ^{1}H NMR of crude products. With the notion that this protocol might lead to a general and efficient method for the synthesis of multifunctional

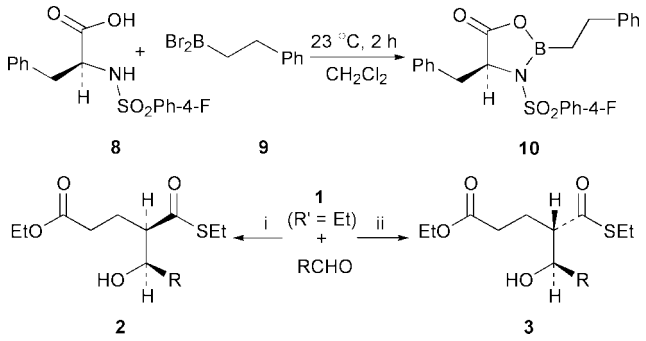

Scheme 2 *Reagents and conditions*: i, **10**, −78 °C, 30 min, CH_2Cl_2; ii, **10**, −78 °C , 2 h, CH_2Cl_2, then DBU, pyridine, −78 °C–23 °C, 24 h.

substances, we set out to determine the scope of reaction with various aldehydes. Indeed, the method is successful with a variety of aldehydes and affords products of high diastereomeric purity with moderate to good enantioselectivies as summarized in Table 1. The ee values were determined by 500 MHz ^{1}H NMR of the corresponding (+)-MTPA ester and/or HPLC or GC analysis using a chiral column as indicated in Table 1.

Table 1 Diastereo- and enantioselective synthesis of **2**[a]

Entry	RCHO	Product	dr (**2**:**3**)[b]	Ee (%)[c]	Yield (%)[d]
1	Ph	**a**	97:3	93	95
2	4-Br-Ph	**b**	95:5	95	88
3	CH_3	**c**	92:8	91	78
4	$PhCH_2$	**d**	95:5	88	77
5	$PhCH_2CH_2$	**e**	94:4	90	83
6	C_6H_{13}	**f**	92:8	84	77
7	PhCH=CH	**g**	81:19	74	79
8	Me_2CH	**h**	88:12	45	61

[a] Reactions were carried out in CH_2Cl_2 at −78 °C for 30 min.[b] Diastereomeric ratio was determined by the analysis of 500 MHz ^{1}H NMR spectra of crude products (all entries) and by GC analysis using HP^{-1} (Hewlett-Packard, cross linked methyl siloxane, 25 m × 0.32 mm × 0.52 μm, entries 3, 4, 6, 8).[c] Ees were determined by preparation of (+)-MTPA ester derivatives, analysis by 500 MHz ^{1}H NMR spectra (entries 1,2,3,4,8) and by HPLC analysis using chiral column (Chiracel OD-H, 3–5% Pr^{i}OH in hexanes, entries 1,2,5,7) and by GC (FID, Chiral Dex-30, G-TA, gamma-cyclodextrin Trifluoroacetyl, 30 m × 0.32 mm, entries 3,6,8).[d] Yields refer to isolated and purified products.

With our research scope of the asymmetric synthesis of *threo* **2**, we turned our attention next to examine possibility of this approach for a reversal of diastereoselectivity.[5] Under optimal conditions, the reaction was performed by addition of **1** to **10** and benzaldehyde in CH_2Cl_2 at −78 °C. After 2 h at −78 °C, freshly distilled pyridine (20 eq.) and DBU (10 eq.) was added during which time a white precipitate was formed. After stirring for 30 min at −78 °C, the cooling bath was removed and the temperature was allowed to rise to 23 °C for 24 h.† After cooling to 0 °C, the reaction mixture was quenched with 2 N aqueous HCl in EtOH followed by work up and silica gel chromatography to afford *erythro* **3a** along with *threo* **2a** in a ratio of 95:5 as judged by 500 MHz NMR of crude products with virtually identical enantiomeric purity compared to that of **2a** in Table 1. In addition, parallel experiments were performed with a variety of aldehydes and the results are summarized in Table 2.

Absolute configuration of **3a** was unambiguously established by a comparison of synthetic samples as illustrated in Fig. 1.‡

In summary, this paper describes methodologies for the enantioselective and diastereoselective synthesis of **2** and **3** in a general and efficient way as a result of the present investigation because of the simplicity of the reaction and the ready availability and efficient recovery of the chiral ligand, and also, absolute configurations of products were unambiguously confirmed by the experiments.

Table 2 Diastereo- and enantioselective synthesis of **3**[a]

Entry	RCHO	Product	dr (**3**:**2**)	Ee (%)	Yield (%)
1	Ph	**a**	95:5	92	88

Notes and references

† It is important to report that the higher temperature especially over 50 °C for the epimerization of intermediate **4** resulted in seriously diminished chemical yields.

‡ Evans aldol product **11** (9:1 dr)[11] was converted to **12** by 3 steps [i, $LiAlH_4$, −78 °C–0 °C, THF; ii, $MeC(OMe)_2Me$, *p*TsOH (5 mol%), CH_2Cl_2; iii, 9-BBN, 0–23 °C THF, then NaOH, H_2O, 40% overall]. Compound **3a** was also transformed to **12** [i, $LiAlH_4$, −78 °C–0 °C, THF; iii, $MeC(OMe)_2Me$, *p*TsOH (5 mol%), CH_2Cl_2, 67% overall]. Both synthetic **12** from **11** and **3a** has not only the same specific rotation sign but also the identical NMR spectra of (+)-MTPA ester derivatives.

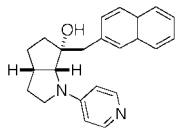
Acylative kinetic resolution of racemic cyclic *cis*-amino alcohol derivatives with a chiral nucleophilic catalyst proceeds enantioselectively (s = 10–21) at ambient temperature to give enantiopure recovered materials, and the % conversion of the acylation can be readily controlled by the amount of acid anhydride.



1

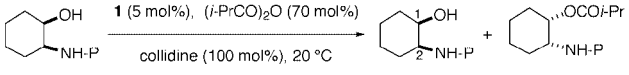
β-Amino alcohol functionality is found in many biologically active compounds and is therefore considered an important pharmacophore.[1] The asymmetric synthesis of β-amino alcohols has been extensively studied.[2] Kinetic resolution[3] is another method of choice, and the enzymatic[4,5] and non-enzymatic[6,7] kinetic resolution of racemic amino alcohol derivatives has been reported. Since the theoretical maximum yield is only 50%, kinetic resolution is worthwhile when it is possible to prepare compounds with extremely high enantiomeric purity, which would otherwise be unattainable by asymmetric synthesis. To obtain enantiopure compounds by the kinetic resolution of racemates, high selectivity factor[3] (s) as well as control of the % conversion of the reaction are indispensable. We report here the preparation of nearly enantiopure (≥99% ee) cyclic *cis*-amino alcohol derivatives *via* acylative kinetic resolution with a chiral nucleophilic catalyst. Practically useful levels of enantioselectivity (s = 10–21) were observed in reactions at ambient temperature and the % conversion was readily controlled by the amount of the acylating agent.

Kinetic resolution *via* enantioselective acylation of racemic alcohols by artificial organic molecules has been a focus of current synthetic attention.[6,8,9] We have shown that chiral nucleophilic catalyst **1** could effectively catalyze the acylative kinetic resolution of racemic diol derivatives.[10] Since acylation of an amino group of amino alcohols readily takes place in the absence of catalyst,[11] the amino group was protected and the effect of the protective group on kinetic resolution was examined (Table 1). *Racemic*-**2** with typical carbamate-protective groups such as Boc and Cbz was resolved with moderate enantioselectivity (s = 4.0–4.5) *via* acylation with **1** (entries 1 and 2). However, **2** with amide-protective groups showed better selectivity (s = 8.7–>13, entries 3–5). Enantiomers of a substrate with a *p*-(dimethylamino)benzoyl group were again[10] found to be most effectively differentiated by **1** (s = >13, entry 5). The effects of the acylating agents on the efficiency of kinetic resolution were re-investigated with the *racemic*-**2** (P=COC_6H_4-*p*-NMe_2) under the conditions similar to those in Table 1. The selected results are as follows: Ac_2O (s = 12), (*i*-$PrCO)_2O$ (s = 17), (*t*-$BuCO)_2O$ (s = 6.2), Bz_2O (s = 6.5), *i*-PrCO-OC_6F_5 (s = 17), (2-MeO-$C_6H_4CO)_2O$ (s = 14), (2,4,6-F_3-$C_6H_2CO)_2O$ (s = 19). Among commercial acid anhydrides, isobutyric anhydride gave the highest selectivity, as previously observed.[10] Although the use of the corresponding pentafluorophenyl ester gave selectivity comparable to that with isobutyric anhydride, it was much less effective in kinetic resolution due to its low reactivity (25% conversion after 2 days). 2,4,6-Trifluorobenzoic anhydride gave the highest selectivity, however, we decided to use isobutyric anhydride for further investigation due to its ready availability.

The results of the kinetic resolution of several cyclic amino alcohol derivatives **2a**–**6** are shown in Table 2. Treatment of *racemic*-**2a** with 60 mol% of isobutyric anhydride in the presence of 5 mol% of **1** at 20 °C led to the recovery of (1*R*, 2*S*)-**2a** in 93% ee at 58% conversion (entry 1). Enantiopure **2a** was obtained with a minimum loss of chemical yield by increasing the amount of acid anhydride to 65 mol% (entry 2). Even with 0.5 mol% of the catalyst (catalyst–substrate = 0.9 mg : 131 mg), the acid anhydride was almost completely consumed within 24 h and enantiopure **2a** was recovered (entry 4). Addition of a stoichiometric amount of collidine does not affect the efficiency

† Electronic supplementary information (ESI) available: experimental details. See http://www.rsc.org/suppdata/cc/b1/b108753c/

Table 1 Effects of protective group P on the kinetic resolution of *racemic*-**2** with **1**



racemic-**2** **2** **3**

Entry	P	Solvent	Reaction time/h	Conversion[a] (%)	Ee of recovered **2** (%)	Ee of **3** (%)	S[b]
1	CO_2t-Bu	$CHCl_3$	24	69	72[c]	33	4.0
2	CO_2CH_2Ph	CH_2Cl_2	5	68[d]	76[c]	—	4.5
3	$COCH_3$	CH_2Cl_2	20	69	96	43	8.7
4	COPh	CH_2Cl_2	20	70	98	42	9.4
5	COC_6H_4-*p*-NMe_2	$CHCl_3$	20	68	>99[c]	47	>13

[a] Conversion was determined by the following equation; conversion (%) = ee (recovered **2**)/ee (recovered **2**) + ee (**3**).[b] S = k (fast-reacting enantiomer)/k (slow-reacting enantiomer), see ref. 3.[c] Absolute congfiguration is (1*R*, 2*S*).[d] Conversion was determined from the ratio of **3** to recovered **2**.

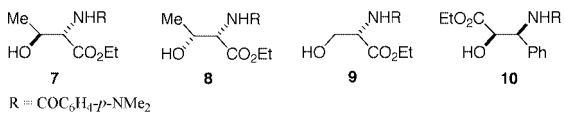
[a] A 0.17 M solution of substrate (0.5 mmol) in $CHCl_3$ was treated with isobutyric anhydride at 20 °C in the presence of a catalytic amount of **1** and 100 mol% of collidine, unless otherwise stated.[b] See footnote *a* in Table 1.[c] Absolute configuration of **2a**, **3**, **4**, and **6** is (1*R*, 2*S*) in each case and that of **5** is (1*S*, 2*R*).[d] Run in 0.05 M solution of substrate.[e] Run in the absence of collidine[f] Run in 0.03 M solution of substrate.[g] Run in CH_2Cl_2.[h] *S* value of the kinetic resolution at −40 °C with 0.01 M solution of substrate.

of the kinetic resolution with 5 mol% of **1** (entries 3 *vs.* 5), while it does affect the efficiency with 0.5 mol% of **1** (entries 4 *vs.* 6). Enantiopure amino alcohol derivatives **3–6** were also recovered at 64–73% conversion by similar treatment of the racemates (*s* = 10–21, entries, 7, 9, 10, and 12). In each case, an alcohol with *S* configuration preferentially underwent acylation. The amide-protective group of (1*S*, 2*R*)-**5** was removed by treatment with 6 M HCl to give (1*S*, 2*R*)-1-aminoindan-2-ol (68% yield), which is the key component of the orally active HIV protease inhibitor indinavir.[12,13] In these acylations with **1**, the % conversion could be simply controlled by the amount of acid anhydride so that enantiopure compounds were readily obtained without careful monitoring of the progress of the reaction. This is in contrast to enzymatic acylative kinetic resolution where excess acylating agent is used.[5,14] Even in the case of non-enzymatic acylative kinetic resolution, acylating agents are not always consumed completely within a reasonable reaction time.[9]

The protocol for kinetic resolution was applied to acyclic amino alcohol derivatives. Acylation of an *anti*-amino alcohol derivative, *racemic*-**7**, under the standard conditions (Table 2, footnote *a*) gave recovered **7** with 93% ee at 70% conversion (*s* = 7.1), while the corresponding *syn*-derivative **8** showed negligible selectivity (*s* = 1.0). Kinetic resolution of **9** with a primary hydroxy group progressed with a selectivity factor of 6.8. Another *syn*-amino alcohol derivative **10** (taxol side-chain) was poorly resolved with **1** (28% ee at 71% conversion, *s* = 1.6). Thus, the relative configuration of the β-hydroxyamine critically affects the enantioselectivity of the kinetic resolution promoted by **1**.



In summary, acylative kinetic resolution of several cyclic *cis*-amino alcohol derivatives with **1** proceeds enantioselectively at ambient temperature to give enantiopure unreacted materials under proper control of the % conversion of the acylation. Complete consumption of acid anhydrides at low catalyst loading indicates that **1** has high catalytic activity. Kinetic and mechanistic investigations are now under way.

Chiral phosphite–phosphoroamidites: a new class of ligand for asymmetric catalytic hydrogenation

Montserrat Diéguez,* Aurora Ruiz and Carmen Claver

Departament de Química Física i Inorgànica, Universitat Rovira i Virgili, Pl. Imperial Tarraco 1, 43005 Tarragona, Spain. E-mail: dieguez@quimica.urv.es; Fax: 34 977559563; Tel: 34 977558046

Received (in Cambridge, UK) 5th October 2001, Accepted 9th November 2001
First published as an Advance Article on the web 6th December 2001

A series of novel phosphite–phosphoroamidite ligands, derived from readily available D-xylose, has been used for the first time in the asymmetric Rh-catalyzed hydrogenation of a series of α,β-unsaturated carboxylic acid derivatives with excellent enantioselectivity (ee up to > 99%).

Many chiral phosphorus compounds have been synthesized as ligands for enantioselective metal-catalyzed hydrogenation.[1] Most of them are homodonor ligands, mainly diphosphines[1,2] and diphosphinites.[3] However, the combination of different functionalities in a ligand has already proved beneficial in enantiodiscrimination.[4] In this context, we have recently reported the successful application of mixed phosphine–phosphite ligands in asymmetric hydrogenation.[5]

In the last few years, a group of less electron-rich phosphorus compounds—phosphite[6] and phosphoroamidite[7] ligands—have also demonstrated their potential utility in asymmetric hydrogenation. Therefore we here report the development of a new class of chiral phosphite–phosphoroamidite ligands (**1–4**), which have the advantages of both types of ligands for asymmetric hydrogenation (Fig. 1). These ligands are derived from natural D-xylose so they also have the advantages of carbohydrates, such as availability at low price and facile modular construction, which makes tedious optical resolution procedures unnecessary and facilitates regio- and stereoselective introduction of different functionalities.[8] To the best of our knowledge this is the first example of phosphite–phosphoroamidite ligands applied to hydrogenation.[9]

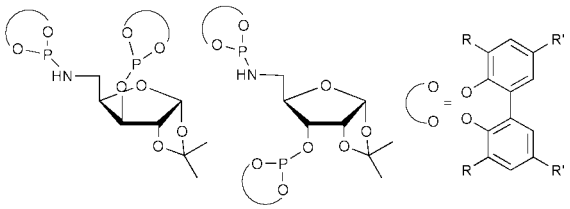

Fig. 1 Phosphite–phosphoroamidite ligands **1–4**.

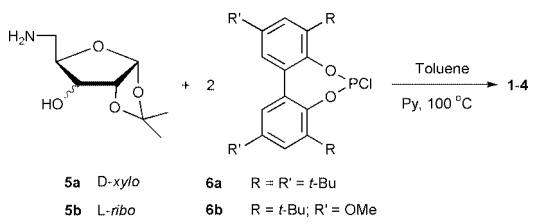
Ligands **1–4**[10] incorporate a chiral furanoside backbone, which determines their underlying structure, and one amino group at the C5 position. The amino furanosides **5**[11] (Scheme 1) serve as basic frameworks to which several phosphoric acid biphenol esters **6**[12] are attached.



Scheme 1 Synthesis of ligands **1–4**.

The modular nature of these sugar ligands allows a facile systematic variation in the configuration of the stereocenter at carbon atom C-3 at the ligand bridge and in the biphenyl substituents, so the optimum configuration for maximum stereoselectivity can be determined. Thus, we investigated how the different groups attached to the *para* positions of the bisphenol moieties affected enantioselectivity using ligands **1** and **2**, which have the same configuration on the carbon atom C-3. We also investigated the influence of the stereogenic carbonatom C-3 by comparing diastereomeric ligands **3** and **4** with ligands **1** and **2**, which have the opposite configuration at C-3 and the same substituents in the biphenyl moieties.

In the first set of experiments, we used the rhodium-catalyzed hydrogenation of **7** to scope the potential of ligands **1–4**. The reaction proceeded smoothly at room temperature. The catalysts were prepared *in situ* by adding the corresponding phosphite–phosphoroamidite ligands to $[Rh(cod)_2]BF_4$ as a catalyst precursor.[13] The results are given in Table 1.

Interestingly, both enantioselectivity and activity notably improved when the hydrogen pressure was raised from 1 bar to 2.5 bar (entry 1 *vs.* 2). However, further increasing the hydrogen pressure had a positive effect on the activity, while the enantioselectivity remained the same (entries 3 and 5). This contrasts with the decrease in enantioselectivity usually observed with bidentate ligands when the hydrogen pressure is raised.[1a,7a,14] This allowed us to perform the reaction at lower catalyst concentration without loss in enantioselectivity and good activity (entry 6).

The addition of one fold excess of ligand did not affect the outcome of the reaction (entry 4). An increase in enantioselectivity (> 99%, entry 7) combined with good activity was found by lowering the reaction temperature. There were no changes in the enantioselectivities over time, which indicates that no decomposition of the catalyst took place.

 DOI: 10.1039/b109043g

The rest of the ligands were compared under 'standard' conditions *i.e.* dichloromethane as a solvent, 5 bar of hydrogen pressure, a ligand-to-rhodium ratio of 1 and at room temperature. Using ligand **2**, with methoxy groups instead of the *tert*-butyl groups in *para* positions of the biphenol moieties, resulted in slightly lower activity and enantioselectivity (entry 3 *vs.* 8). Ligands **3** and **4** whose configuration of carbon atom C-3 is opposite to those of ligands **1** and **2**, respectively, produced a lower reaction rate and enantioselectivity (entry 3 and 8 *vs.* 9 and 10).

The results clearly show that the enantiomeric excesses and activities depend strongly on the absolute configuration of the C3 stereocenter of the carbohydrate backbone and the substituents in the biphenyl moities. Therefore, enantioselectivities and activities were best using ligand **1** with a *S* configuration at C-3 and *tert*-butyl groups in the *ortho*- and *para*-positions of the biphenyl moieties.

We subsequently applied these new highly efficient phosphite–phosphoroamidite ligands **1**–**4** in the Rh-catalyzed hydrogenation of other benchmark dehydroaminoacid derivatives (Table 2). The results followed the same trend as for substrate **7**. The absolute configuration of the hydrogenated products **10** and **12** is opposite that of the hydrogenated product **8**, but they have the same spatial arrangement.[15] The catalyst precursor with ligand **1** produced the highest enantiomeric excess (98%, entries 5 and 10).

It is remarkable that these phosphite–phosphoroamidite ligands showed a much higher degree of enantioselectivity and higher reaction rates than their corresponding diphosphite analogues under similar reaction conditions (entries 1–4 *vs.* 11 and 12).[13,16]

In summary, we have described the first application of phosphite–phosphoroamite ligands in the asymmetric hydrogenation reaction. These ligands can be easily prepared in a few steps from commercial D-(+)-xylose as an inexpensive natural chiral source. Regarding both good activity and the excellent enantioselectivity (up to >99% ee) obtained in simple unoptimised asymmetric hydrogenation of a series of α,β-unsaturated carboxylic acid derivatives, we feel that a promising new class of ligands—the phosphite–phosphoroamidite—has been disclosed for enantioselective Rh-catalyzed asymmetric hydrogenation. Moreover, because of the modular construction of these phosphite–phosphoroamidite ligands,

further structural diversity is easy to achieve, so enantioselectivity and catalyst performance can be maximized for each new substrate as required. Studies of this kind, as well as mechanistic studies, are currently under way.

Palladium catalyzed arylation of malonate accompanying *in situ* dealkoxycarbonylation

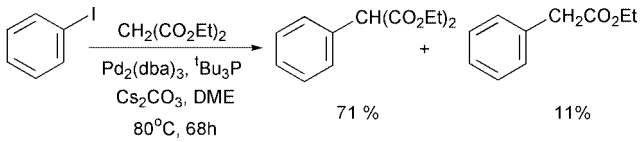
Yoshinori Kondo,* Kiyofumi Inamoto, Masanobu Uchiyama and Takao Sakamoto

Graduate School of Pharmaceutical Sciences, Tohoku University, Aobayama, Aoba-ku, Sendai 980-8578, Japan. E-mail: ykondo@mail.pharm.tohoku.ac.jp

Received (in Cambridge, UK) 18th October 2001, Accepted 7th November 2001
First published as an Advance Article on the web 6th December 2001

One-pot conversion of aryl halides into aryl acetates was achieved by the palladium catalyzed arylation of malonate accompanying *in situ* dealkoxycarbonylation of aryl malonates using Cs_2CO_3 as a base and as a catalyst.

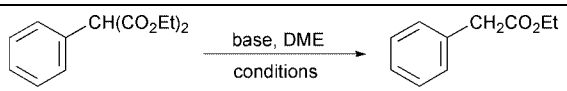
Introduction of an sp^3 carbon side chain into an aromatic ring is one of the important process in organic synthesis and many works have been done using palladium catalyzed reactions.[1] Various approaches have been studied for the synthesis of aryl acetates using coupling reactions[2–4] and very recently significant progress has been made for direct introduction of an acetic acid ester moiety into aromatic rings using palladium catalyzed reactions.[5] On the other hand, introduction of active methylenes into aromatic rings has also been an important subject[6] and Hartwig *et al*. recently succeeded in the arylation of malonate, however a strong base such as NaO^{t}Bu has been used.[7] In connection with our recent studies on chemoselective transformation of functionalized aromatic compounds,[8] we became interested in the introduction of an acetic acid moiety under mild reaction conditions using a weaker base. During the course of our recent studies on the coupling reaction of aryl halides with diethyl malonate, it was found that diethyl phenylmalonate undergoes a dealkoxycarbonylation reaction in the presence of a weak inorganic base. Namely, when we carried out the cross coupling reaction of iodobenzene with diethyl malonate in the presence of $Pd_2(dba)_3$, ^{t}Bu$_3$P using Cs_2CO_3 as a base in dimethoxyethane at 80 °C for 68 h, diethyl phenylmalonate was obtained in 71% yield together with the dealkoxycarbonylated product, ethyl phenylacetate in 11% yield (Scheme 1).



Scheme 1

We focused our interest in this interesting dealkoxycarbonylation and diethyl phenylmalonate was treated with various bases in dimethoxyethane at elevated temperatures. As shown in Table 1, Cs_2CO_3 was found to be the most effective catalyst for the decarbonylative conversion. In order to complete the dealkoxycarbonylation during the cross coupling reaction, the reaction of iodobenzene with diethyl malonate was carried out at an elevated temperature such as 120 °C using 10 equiv. of Cs_2CO_3 for 65 h, and ethyl phenylacetate was obtained in 87% yield exclusively. Similarly, iodoanisole was reacted with the malonate under the same reaction conditions, and 4-methoxyphenyl acetate was obtained in 70% yield. Ethyl 4-iodobenzoate was also successfully reacted with the malonate under the same reaction conditions, and the coupling–dealkoxycarbonylation proceeded smoothly to give the aryl acetate in 61% yield without forming any side reaction products. Aryl bromides were also employed as substrates for this process. The reaction of bromobenzene and 3-bromopyridine gave the corresponding aryl acetates in 78% and 75% yields respectively (Table 2).

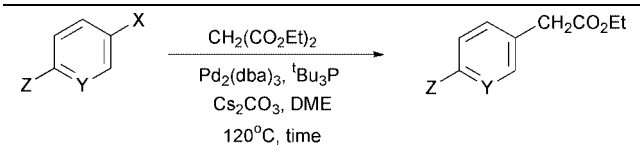
Table 1



Base	Conditions	Yield (%)
Cs_2CO_3	80 °C, 66 h	15 (78)[a]
Cs_2CO_3	120 °C, 70 h	83 (3)[a]
K_2CO_3	120 °C, 67 h	62 (8)[a]
NaH	120 °C, 70 h	0 (99)[a]

[a] Recovery yields in parentheses.

Table 2



X	Y	Z	Time/h	Yield (%)
I	CH	H	65	87
I	CH	OMe	74	70
I	CH	COOEt	76	61
Br	CH	H	70	78
Br	N	H	45	75

A simple and chemoselective introduction of an acetic acid moiety was accomplished by using the present Pd coupling–dealkoxycarbonylation process and further applications of this method for the facile functionalization of biologically active molecules are underway.

Amplification of the reactivity difference between two methylene groups of cyclodextrins *via* a cap

De-Qi Yuan,* Tomonobu Yamada and Kahee Fujita*

Faculty of Pharmaceutical Sciences, Nagasaki University, 1-14 Bunkyo-machi, Nagasaki 852-8521, Japan. E-mail: deqiyuan@net.nagasaki-u.ac.jp; fujita@net.nagasaki-u.ac.jp; Fax: +81-95-846 5736; Tel: +81-95-846 5736

Received (in Cambridge, UK) 17th September 2001, Accepted 14th November 2001
First published as an Advance Article on the web 6th December 2001

A novel concept has been established for making hetero-disubstituted cyclodextrin derivatives. Upon treatment with imidazole, 6^A,6^B-mesitylenedisulfonyl-capped β-cyclodextrin 1 demonstrated a reactivity about 10 times higher at the 6^B position than at the 6^A position, leading to the selective formation of hetero-disubstituted cyclodextrins 3.

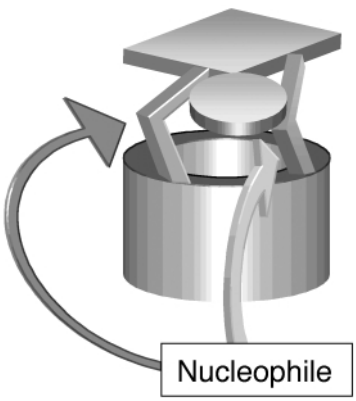
Cyclodextrin derivatives bearing two different sorts of functional groups turn out to be interesting candidates in developing artificial receptors and enzyme-like catalysts.[1] The hetero-bifunctional CDs were not only postulated to effect a three-point recognition of asymmetric species,[2] but also demonstrated to have strong asymmetric induction in catalyzing the chemical transformations such as transamination reactions.[3] However, these hetero-bifunctional CDs are very difficult to access.[4] The routine method includes stepwise substitution of 6^A,6^B-diiodo-β-CD with different nucleophiles.[3] An alternative method included the sulfonylation of mono-substituted CDs.[5] In either case, the reaction is rather a random one and subjected to the competition of over-substitution, giving a mixture of hetero-disubstituted regio-isomers in a comparable ratio together with over-substituted products and starting materials. The separation of desired products is an extremely tedious task, and several reports used the isomeric mixtures in binding and catalysis without separating them from each other.[6]

In principle, as soon as β-CD is modified, the C_7 symmetry is destroyed and all the seven glucose residues become different from each other unless they are all equally modified. That is, a bifunctional β-CD would show different reactivity at its two modified positions. However, this difference is usually trivial as it is observed in the reactions of 6^A,6^B-diiodo-β-CD and can hardly be applied in the selective hetero-bifunctionalization. We reason that any two methylene groups of β-CD, when bridged together by a rigid cap, would have a somewhat fixed conformation since their rotation around the C5–C6 single bond would be greatly confined. If the cap can serve as leaving group in a S_N2 reaction, it may provide a possibility to protect one of the capped methylene residues from the attack of the nucleophile while leaving the other easily accessible to the nucleophile (Scheme 1), that is, to amplify the difference in reactivity between those two modified positions. Herein we describe that the mesitylenedisulfonyl-capped β-CD indeed undergoes a selective ring-opening reaction, and directs imidazole to the 6^B position, offering a promising method to access the hetero-bifunctional CDs.

Mesitylenedisulfonyl chloride was reacted with β-CD in dry pyridine affording the capped CD in *ca.* 20% yield. The capped positions were determined to be 6^A and 6^B by converting the capped CD to bis(phenylthio) species followed by HPLC comparison with authentic samples prepared according to a literature method.[7] The two sulfonated glucosides of **1** are found to be magnetically very different from each other. The geminal protons of one sulfonated methylene group resonate at the magnetic field *ca*. 0.4 ppm higher than those of the other one,[8] implying that the benzene ring is located closer to and thus exercises a stronger shielding effect on one of the two modified methylene residues. This shielded methylene group seems to correspond to glucoside A since the other modified unit demonstrated *ca*. 0.5 ppm upfield shift for its H1, indicating that this H1 is likely to be situated somewhere within the region of ring current effect of the cap, close to the shielded methylene protons.

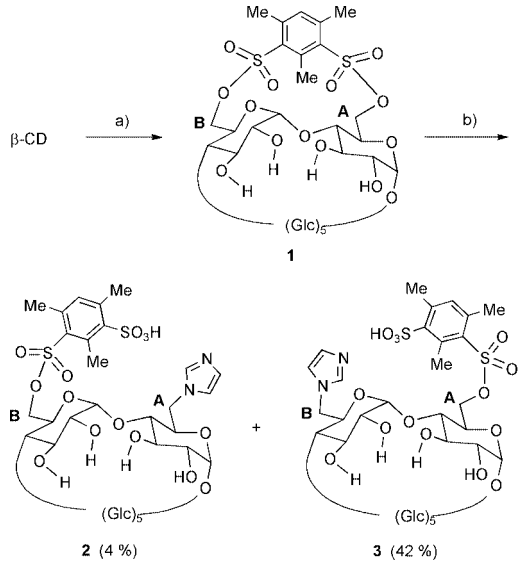
On treatment with imidazole in DMF, **1** undergoes a ring-opening reaction leading to the formation of two hetero-disubstituted CDs which were isolated in 4% and 42% yields, respectively. FAB-MS and NMR spectra show that the two products are regio-isomers containing one imidazolyl group and one mesitylene residue.[9] The result clearly demonstrates that the mesitylene cap does significantly amplify the difference in reactivity between the 6^A and 6^B positions. We also noted that as long as the cap is opened, *i.e.* one sulfonate group is displaced, another sulfonate group becomes much more resistant to the attack of a second molecule of imidazole and therefore remains unaffected till the complete conversion of the starting material (Scheme 2).

In order to find out whether 6^A or 6^B is more accessible to imidazole, we need to clarify the regio-chemistry of the products. NMR spectra afforded important information. In the ^{1}H NMR (in D_2O, CH_3CN as internal standard: δ = 1.98 ppm) spectrum of the minor product, one of the unmodified methylene groups was observed at 2.94 and 3.19 ppm, the sulfonated one at 4.48 ppm, the imidazole-bearing one at 4.36 and 4.21 ppm, and the other methylene groups in the normal range of 3.65–3.85 ppm. It is documented in literature that an imidazole group attached to a methylene carbon of CDs exercises a strong shielding effect on the subunit linked to the anomeric carbon of the 6-imidazolyl glucoside while it does not significantly influence the one on the other side.[10] The upfield shifted unmodified methylene group can be therefore assigned to that of the sugar clockwise to the 6-imidazolyl glucoside (view from the secondary side), *i.e.* the minor product has the structure of compound **2**, and the major product should be compound **3**. In agreement with this assignment, the major



Scheme 1 Illustration for a possible control of reaction selectivity in hetero-bifuctionalization by a suitable cap.

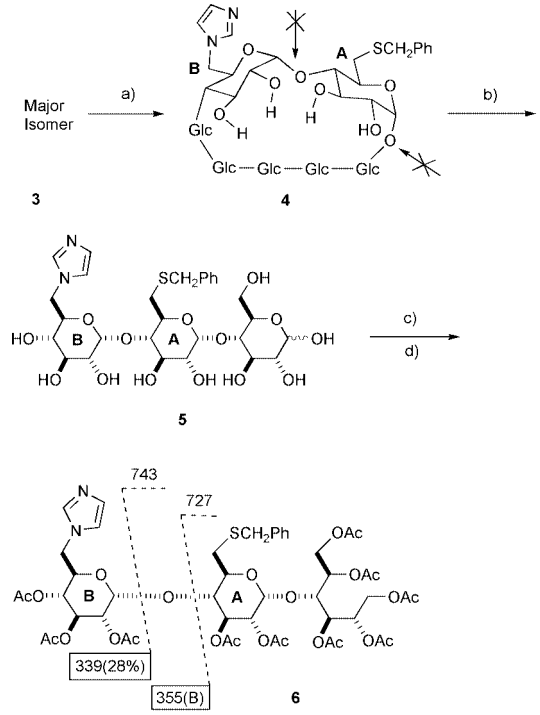
 DOI: 10.1039/b108416j



Scheme 2 Synthesis and selective ring-opening of the mesitylenedisulfonyl-capped β-CD. a) Mesitylenedisulfonyl chloride–dry pyridine, 40 °C, 2.5 h; b) imidazole–DMF, 80 °C, 3 h.

product demonstrated no significant upfield shifts for any unmodified methylene groups, whereas the sulfonated methylene group was observed at 3.93 and 3.83 ppm, about 0.5 ppm upfield shifted to that of the minor product.

The above structural assignment was confirmed by enzyme degradation of **3** followed by MS fragmentation analysis of the degradation product (Scheme 3). The sulfonate group of **3** was replaced by $PhCH_2S$ and the resulting compound **4** was



Scheme 3 Enzymatic transformation of **3** incorporated with MS fragmentation analysis. The data denote the mass units expected from the fragmentation between the two modified sugar residues and the enclosed ones were actually observed in the EI-MS spectrum. a) $PhCH_2SH$–Cs_2CO_3–DMF; b) *Taka amylase A*–10% DMSO-phosphate buffer; c) $NaBH_4$–80% ethanol; d) acetic anhydride.

degradated to maltotriose **5** by *Taka amylase A*,[11] an α-amylase that catalyzes the hydrolysis of the α-1,4-glucoside bond of unmodified α-1,4-glucans but usually leaves that of the modified ones unaffected. The sugar sequence of the maltotriose was analysed by MS after it was subjected to further reduction and per-acetylation. As depicted in Scheme 3, the EI MS of **6** demonstrated strong peaks at *m/z* 355 (base peak) and 339 (28%) which correspond to the fragmentation between the two modified glucoside residues of **6**, whereas the fragments at *m/z* 395 (or 687) and 411 (or 671) expected for the alternative arrangement of Im and $PhCH_2S$ groups were not observed.

In conclusion, the present research postulated to amplify the difference in reactivity between the two modified methylene groups of β-CD by a rigid cap; and proved it practicable by taking mesitylenedisulfonyl capped β-CD as an example, offering a promising approach to access the hetero-bifunctional CDs.

8 *Preparation of capped β-CD* **1**: β-CD (dried overnight *in vacuo* at 100 °C, 3.5 g) was dissolved in dry pyridine (200 ml). The resultant solution was refluxed for a few minutes and the solvent was distilled off until the boiling point of the distillate reached 113 °C. The solution was allowed to cool down to rt and molecular sieves (30 g) were then added in. After the mixture was stirred at rt for a few hours, mesitylenedisulfonyl chloride (1.1 g) was added and the reaction was continued for 2.5 h at 40 °C. Thereafter, the molecular sieves was filtered and the solvent was rota-evaporated. Chromatography of the residue on a reversed-phase Lobar column (RP-18, size C, with a gradient elution from 30% to 65% *aq.* CH_3OH) afforded the capped β-CD **1** (810 mg, 19%). In the ^1H-^{13}C COSY spectrum of **1** (DMSO-d_6, TMS *int.*), one of the sulfonated glucosides was observed at δ 4.58–71.9 and 4.10–71.9 for H6–C6, 3.76–69.8 for H5–C5, 3.22–82.1 for H4–C4, ~3.6–(71.9 to 73.2) for H3–C3, 3.17–71.4 for H2–C2 and 4.40–101.0 ppm for H1–C1 correlation. The other one was observed at δ 4.14–69.9 and 3.84–69.9 for H6–C6, 3.89–69.3 for H5–C5, ~3.25–(81.0 to 81.9) for H4–C4, ~3.65–(71.9 to 73.2) for H3–C3, (3.25 to 3.4)–(71.9 to 72.4) for H2–C2, (4.82 to 4.95)–(101.3 to 102.2) ppm for H1–C1 correlation.

9 *Reaction of* **1** *with imidazole:* Compound **1** (0.5 g, 0.36 mmol) and imidazole (0.5 g, 7.1 mmol) were dissolved in DMF (2 mL) and the solution was stirred at 85 °C for 3 h. The CD species were precipitated with acetone, collected by filtration and applied to chromatography on a reversed-phase Lobar column (RP-18, size C). Elution of the column with 20% *aq.* CH_3OH afforded products **2** and **3** in 4% (elutes faster) and 42% (elutes slower) yields, respectively.

Received (in Cambridge, UK) 19th September 2001, Accepted 14th November 2001
First published as an Advance Article on the web 7th December 2001

Proteins from cisplatin treated bacterial cells were partially separated by 1D polyacrylamide gel electrophoresis and analysed by laser ablation inductively coupled plasma mass spectrometry; using peptide fingerprinting methods central to proteomics, the band containing the highest levels of platinum was found to contain outer membrane protein A, which may be involved in cisplatin uptake.

The highly successful anticancer drug cisplatin was originally observed to prevent the division of *E. coli* cells,[1] and subsequently, it was found that cisplatin forms adducts with DNA, which inhibit protein synthesis and DNA replication.[2] The interaction between DNA and cisplatin has been structurally and kinetically characterised[3] whereas the ways in which cisplatin interacts with other biomolecules are less well understood. Cisplatin binding to proteins in the cell membrane is observed to be favoured over binding to the phospholipids,[4] resulting in alterations to the structure and properties of the membrane, such as permeability.[5] Membrane permeability can affect the toxicity of the compound, with reduced uptake and accelerated efflux mechanisms being involved in some mechanisms of cisplatin resistance in cancer cell lines.[6] A map of cisplatin metabolism in the cell, in which the key proteins involved in the mechanisms of uptake and drug resistance are identified, would be invaluable in order to understand the features that make cisplatin such an effective anticancer drug, and ultimately facilitate the design of improved anticancer therapies.

With current methods, including proteomics, identifying metal–protein complexes from whole cell systems is a mammoth task that depends on detecting subtle differences in, for example, the migration of the metal–protein species during gel electrophoresis. However, it has been shown that it is possible to rapidly detect metal–protein complexes immobilised in gels by laser ablation ICP-MS.[7] In this communication we extend this approach by combining the laser ablation ICP-MS analysis of protein gels with peptide fingerprinting methods, which are routinely applied in proteomics to identify proteins of interest, to enable metal-bound proteins from whole cell extracts to be rapidly identified.

The proteins from *E. coli* cells, which had been incubated with cisplatin, were partially separated by non-reducing gel electrophoresis.[8] The gel lanes were then analysed by laser ablation inductively coupled plasma mass spectrometry (ICP-MS)[9] and the *m/z* of platinum was detected across the gel (see Fig. 1) that were not observed in the control. The distribution of platinum through the gel was not proportional to the distribution of protein, estimated from a densitometry scan of the gel, suggesting platinum has, to some extent, specific protein targets within the cell. The band with the highest ICP-MS response for the *m/z* of platinum relative to the amount of protein present was selected for peptide fingerprinting by electrospray mass spectrometry. The band was excised from the gel, digested with trypsin and the resultant peptides extracted and analysed by electrospray mass spectrometry and MS/MS, typical of proteomics methods.[10] The masses and sequences of these peptides were combined to produce a peptide fingerprint that indicated a single protein was present in the gel fragment and allowed *ca.* 23% of the total protein sequence[11] to be mapped, unambiguously identifying the protein as Outer Membrane Protein A (OmpA).

OmpA is a ubiquitous, porin-like protein[12] that transverses the outer membrane[13] acting as an ion channel with a low permeability to allow the slow penetration of small solutes.[14] These solutes could include cisplatin, as, although the crystal structure implies that the centre of the β-barrel that traverses the membrane would not carry an ion, there are three flexible extracellular loops that may be involved in a conformational change to allow ion uptake.[15] In addition to its porin function, OmpA is involved in the maintenance of cell shape,[16] hence the cisplatin–OmpA interaction could explain the altered membrane permeability and structure of bacterial membranes after incubation with cisplatin.

OmpA has clinical interest as it is involved in bacterial induced toxicity[17,18] and the mechanism of *E. coli* infectivity, in particular the invasion of macrovascular cells enabling the bacteria to cross the blood brain barrier.[19] OmpA is also secreted into the plasma in a complex with two other proteins, peptidoglycan associated protein and murein lipoprotein, by Gram negative bacteria incubated in human serum, and this complex is bound by immunoglobulin G.[18] Thus, further characterisation of the OmpA–cisplatin interaction may provide

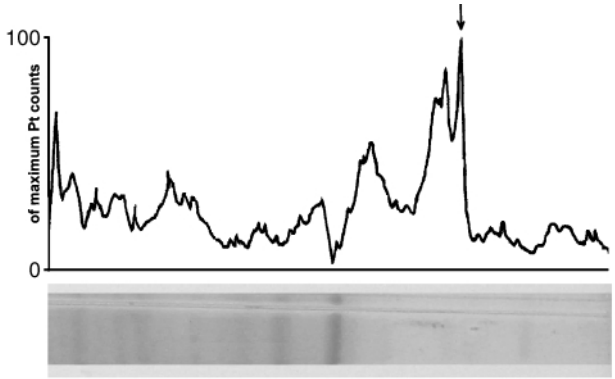

Fig. 1 Non-reducing polyacrylamide gel electrophoresis results for the separation of SDS-denatured proteins from whole bacterial cells after incubation with cisplatin; (top) the ICP-MS trace showing the amount of platinum as a percentage of the maximum reading (6.19×10^4 counts) with distance along the gel and (bottom) a photograph of the gel aligned with the ICP-MS trace. The arrow indicates the region with highest ICP-MS response for the *m/z* for platinum, which was used to identify the gel bands for further analysis.

† Electronic supplementary information (ESI) available: full details of laser ablation ICP-MS and QTOF operating conditions, further experimental details for peptide separation and peptide sequencing maps for OmpA. See http://www.rsc.org/suppdata/cc/b1/b108418f/

 DOI: 10.1039/b108418f

a foundation for drug design against bacterial infections, such as bacterial meningitis.

We are currently conducting further experiments to elucidate the role of OmpA in the uptake and mechanism of cisplatin cytotoxicity. For example, identifying other proteins containing high amounts of platinum immobilised in other areas of the gel to provide a more detailed list of the proteins that are involved in these first stages of the cisplatin interaction with bacterial cells and exploring the effect of incubation time on the cisplatin–protein interactions.

The combination of ICP-MS and protein fingerprinting methods enables proteins tagged with specific elements or isotopes to be rapidly identified. We have also started to use the technique to investigate a new potential ruthenium anticancer drug[20] that shows more specific binding to proteins than cisplatin and these studies will be reported in due course. Furthermore, it may even be possible to extend the technique from cells grown in culture to biopsy material providing a powerful tool for investigating drug metabolism *in vivo*. This combined ICP-MS-protein fingerprinting approach overcomes some of the current limitations of proteomics methods for the investigation of interactions of proteins with small molecules, giving information regarding metal loading of proteins in diseased states as well as identifying drug targets, enabling the rapid characterisation of the molecular basis of disease and therapy.

8 Suspensions of *Eschericia coli* JM109 (Promega, USA) in nutrient broth were incubated for 30 min at 37 °C with and without 10 mM cisplatin. The cells were pelleted by centrifugation and resuspended in distilled water (500 μl) before sonication. The cell debris was pelleted by centrifugation and the proteins in the supernatant fractions were separated by non-reducing SDS gel electrophoresis in a 10% polyacrylamide gel and visualised with coomassie brilliant blue G stain (Sigma). The gels were dried in cellulose membranes and analysed by ICP-MS.
9 The non-reducing SDS gel lanes of the unmodified and cisplatin-incubated *E. coli* cells were placed on a Cetac LSX-200 Laser Ablation System (Cetac Technologies), which was coupled to a Micromass Platform ICP Life-MS (Micromass UK Ltd). The laser and Platform ICP-MS can detect platinum at concentrations below 1 ppb under the conditions specified in the ESI.† The gels were ablated using the laser and the resulting plasma analysed for the platinum isotopes using the Platform ICP.
10 R. Aebersold and D. R. Goodlet, *Chem. Rev.*, 2000, **101**, 269.
11 The protein band containing the highest amount of platinum relative to coomassie blue staining was excised from the gel. This in-gel protein sample was automatically processed and trypsin (Promega, USA) digested using a Micromass MassPREP station as described in the ESI.† The resultant peptides were desalted and separated on a C18 column (see ESI†) and directed into the Z-spray source of a Micromass Q-TOF2 mass spectrometer operated in the positive ion mode. All data were processed automatically by means of ProteinLynx software; protein identification was achieved by analysis with ProteinLynx Global Server version 1.0 by matching both the peptide masses and sequences of the digested proteins.

Sodium sulfate supported synthesis of cationic cyclophanes using microwaves

Perumal Rajakumar* and Venghatraghavan Murali

Department of Organic Chemistry, University of Madras, Guindy Campus, Chennai 600 025, Tamil Nadu, India. E-mail: perumalrajakumar@hotmail.com

Received (in Corvallis, OR, USA) 3rd October 2001, Accepted 1st November 2001
First published as an Advance Article on the web 6th December 2001

A facile microwave-assisted synthesis of a series of cationic cyclophanes, *viz.* benzimidazolophanes 3a–3f, benzotriazolophanes 3g–3j, through efficient double quaternization of the corresponding precyclophanes 1a–1j with appropriate dibromides 2a–2d in solid phase medium, is described.

Cyclophanes with a heterocyclic ring system possesses a favorable binding site for metal ions[1] and hence can have promising properties[2] as molecular hosts. *m*-Terphenyl based benzimidazolophanes[3] and benzotriazolophanes[4] have been reported from our laboratory. The dicationic benzimidazolophanes **3a–3f** and benzotriazolophanes **3g–3j** could be a potential precursor for the synthesis of [2]catenanes.† In view of the emerging importance of the cationic cyclophanes **3a–3j**, attention has been focused on rapid synthesis of such cyclophanes using sodium sulfate as the solid support under microwave irradiation.

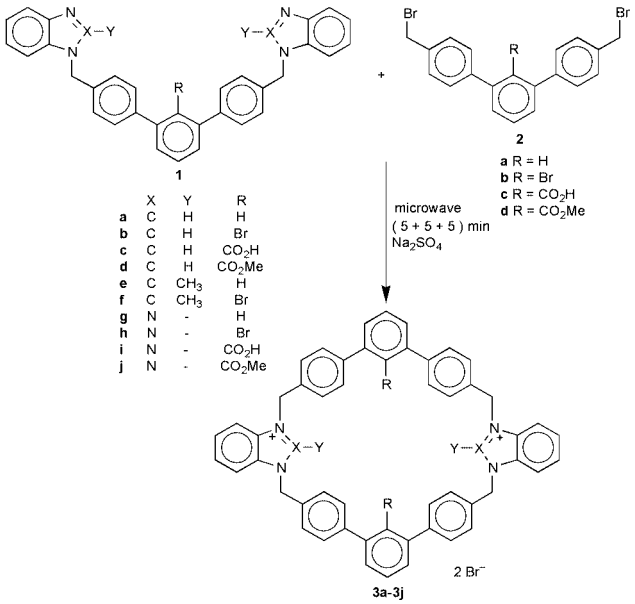
An expeditious solvent-free route to the synthesis of ionic liquids, 1-alkyl-3-methylimidazolium (AMIM) halides, under microwave conditions was reported by Varma *et al.*[5] Recently, solvent free synthesis of metallophthalocyanines under microwave irradiation has been reported by Villemin *et al.*[6] However adopting such solvent free conditions for the synthesis of cyclophanes based on benzimidazole and benzotriazole leads to polymerization. It is well known that for such macrocyclization a high dilution technique is essential. The use of a large excess of conventional volatile solvents like benzene or ethanol for macrocyclization[7] is of ecological and economic concern. Though use of various solid supports like SiO_2, Al_2O_3, Na_2SO_4 for microwave assisted reactions are known,[8] such conditions are seldom used for the synthesis of cyclophanes. Hence we report herewith microwave assisted macrocyclization with solid supports like SiO_2, Al_2O_3 and Na_2SO_4 through a high dilution technique.

For the current investigation we have used a recently introduced (Kenstar, India) modified household microwave oven which has the provision of a wave reflector system for even and uniform heating and a dual wave emission system for rapid heating. The microwave oven was also equipped with a temperature monitoring system with variable Watt power, which helps to control the microwave power to a desirable level.

Cationic cyclophanes **3a–3j** have poor solubility in common organic solvents and hence desorption of the cyclophane from the solid support, like silica or alumina, could not be achieved. Reaction of precyclophanes **1a–1j**[3,4] with the corresponding *m*-terphenyl dibromide **2a–2d**[7] under microwave irradiation condition for 15 min using Na_2SO_4 as solid support afforded the cyclophanes **3a–3j** as shown in Scheme 1.

The cyclophanes thus obtained were characterized by ^1H NMR and ^{13}C NMR as reported earlier from our laboratory.[3,4] The following tabular column shows a comparison of yield and reaction time by the conventional method *viz.* refluxing with CH_3CN for 5 d and microwave assisted synthesis.

From Table 1, it is evident that microwave assisted reactions resulted in a comparable yield of cyclophanes **3a–3j** with that of the conventional method. Benzimidazolophanes were obtained



Scheme 1

in moderate yield but benzotriazolophanes were obtained in relatively lower yields, which is probably due to the decomposing nature of benzotriazole under microwave conditions. However, the method that we report here is definitely superior to the existing conventional method.[3,4] The reaction time is dramatically decreased from 5 d to 15 min. The solid support *viz.* Na_2SO_4 used for high dilution purposes can be easily removed by washing with water. Scaling up of the reaction is feasible, as it needs only less expensive and non-polluting Na_2SO_4.

In order to test the role of thermal catalysation during the course of the reaction, the precyclophane **1a** and the dibromide **2a** were adsorbed on Na_2SO_4 solid support and the reaction mixture was thermolysed under identical conditions. The

Table 1 Comparison of yields of cyclophane by microwave method over conventional method

	Conventional method[3,4]		Microwave method	
Cyclophane **3**	Yield (%)	Reaction time	Yield (%)	Reaction time
a	70	5 d	60	15 min
b	60	5 d	54	14 min
c	50	5 d	40	15 min
d	45	5 d	42	13 min
e	50	5 d	45	14 min
f	55	5 d	40	13 min
g	60	5 d	40	15 min
h	57	5 d	35	13 min
i	40	5 d	30	14 min
j	43	5 d	34	15 min

 DOI: 10.1039/b109003h

microwave oven indicated the temperatures as 50 °C, 60 °C and 70 °C after 5, 10 and 15 min respectively. Hence the reaction mixture was thermolysed from 50 °C to 70 °C during a time interval of 15 min. Starting materials were recovered which clearly indicated the microwave protocol and hence necessitates the use of microwaves for macrocyclization.

In conclusion, a solid phase mediated microwave assisted protocol has been developed for the synthesis of various cationic cyclophanes **3a–3j**. The use of a water-soluble solid support (Na_2SO_4) for microwave-assisted reactions would gain popularity in the area of synthesis of supramolecules.

Notes and references

† *General procedure for the synthesis of cyclophanes* **3a–3j**: The precyclophanes (10 mmol) **1a–1j** and the corresponding dibromides **2a–2d** (10 mmol) were dissolved in DCM, Na_2SO_4 (5 g) was added to the reaction mixture and a slurry was obtained after stirring for 15 min. DCM was then evaporated under vacuo to give a residue. The adsorbed reagents were then placed in a thick corning glass bowl and subjected to microwave irradiation at 400 W for 15 min with a time interval of 5 min. The reaction mixture was then cooled and washed with water (100 mL), then filtered. The residue thus obtained was washed again with chloroform (100 mL) to remove unreacted organic impurities and the residue was dried to afford the cyclophanes **3a–3j**. The organic impurities are found to be mainly the unreacted precyclophanes and the dibromides.

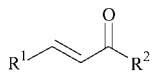
Received (in Cambridge, UK) 18th October 2001, Accepted 9th November 2001
First published as an Advance Article on the web 27th November 2001

Simple aliphatic enones can be converted into the corresponding epoxides in 71–93% ee using *tert*-butylhydroperoxide in the presence of a catalyst derived from dibutylmagnesium and di-*tert*-butyl tartrate.

The asymmetric epoxidation of electron-deficient alkenes, especially enones, is currently the focus of much activity, and advances in this area have been recently reviewed.[1] As this review makes clear, while there are many effective methods for the asymmetric epoxidation of enones bearing aryl-substituents **1** (R^1 and/or R^2 = Ar),[2–6] it appears at present that the only method which is generally applicable to the epoxidation of easily enolisable purely aliphatic enones involves the use of the La–BINOL catalysts developed by Shibasaki.[7] Recent optimisation of this system by the addition of $Ph_3As{=}O$ has resulted in an effective catalytic system using 5 mol% of the La–BINOL complex,[8] with good yields and enantiomeric excesses up to 99%, although 95% ee is a more typical outcome.



1

We reported earlier that simple chalcone derivatives **1** (R^1 and R^2 = Ar) could be converted into the corresponding epoxides with good to excellent ee using a much less expensive catalyst, prepared from diethyl tartrate and dibutylmagnesium.[9] However, this system was not especially effective for the epoxidation of aliphatic enones, resulting in very poor conversions, although with promising ees around 80%. In this communication, we report how we have been able to modify our original procedure so that it is effective for the asymmetric epoxidation of simple aliphatic enones with high ee.‡

As a model system, we investigated the epoxidation of non-3-en-2-one **1b**. Our first breakthrough came when we established that the addition of 4 Å molecular sieves allowed reasonable conversion into the corresponding epoxide **2b** (Scheme 1). As a further modification, we established that it was possible to prepare the presumed catalyst precursor **3**, simply by addition of L-(+)-diethyl tartrate to a solution of dibutylmagnesium in heptane, followed by removal of the solvent and drying. Characterisation of this amorphous material confirmed that it possessed the molecular composition expected for an oligomer of the species **3**, and the IR spectrum revealed the presence of two carbonyl bands (1741 and 1689 cm^{-1}), clearly indicative of at least one ester group coordinating to the magnesium in a way that is very reminiscent of the analogous titanium–tartrate complex characterised by Sharpless.[10] The material was insoluble in all solvents tested, and it was therefore not possible to obtain an NMR spectrum.

This amorphous material proved to be an effective catalyst for the epoxidation of aliphatic enones using *tert*-butyl

hydroperoxide in the presence of 4 Å molecular sieves. The only drawback was that the conversion to epoxide, whilst initially fast, rapidly slowed down, presumably as a result of catalyst inactivation. However, good conversions could be achieved by portionwise addition of further solid catalyst **3** (total of 25 mol%), which was a straightforward solution to the problem. Addition of 25 mol% catalyst initially resulted in very poor conversion. Although in our early experiments we added the catalyst **3** over a period of 3–5 d, it subsequently became clear that the additional catalyst could be added much more quickly, and good conversions could be achieved by addition of a total of 25 mol% catalyst over a period of 24 h. Our results are summarised in Table 1.

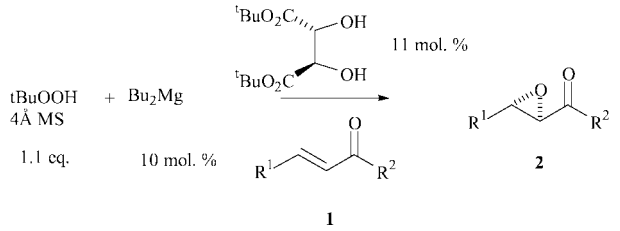
While these results were encouraging, the enantiomeric excesses that we obtained were lower than those obtained by Shibasaki. Although in our initial screening of ligands for the epoxidation of chalcone derivatives we had identified diethyl tartrate as the optimum choice, the most profitable approach to the optimisation of our catalyst now appeared to be a re-appraisal of other related ligands under the new optimised conditions for epoxidation of aliphatic enones. We therefore screened a series of tartrate esters, in which the catalyst was simply prepared *in situ*.

Thus, *tert*-butyl hydroperoxide was dried over 4 Å molecular sieves, Bu_2Mg was then added, followed by addition of the ligand and finally non-3-en-2-one. These conditions were very closely related to our original conditions for the epoxidation of chalcone derivatives, with the use of 4 Å molecular sieves as the only significant alteration to this earlier procedure. Our results are reported in Table 2, and two striking features are evident. Firstly the use of tartrate esters derived from secondary or tertiary alcohols gave much higher conversions with only 10 mol% catalyst, and secondly the observed ee's were now over 90%.

From these results, the optimum ligand appears to be commercially available di-*tert*-butyl tartrate, but the more easily prepared and cheaper dicycloalkyl tartrates all give good results. Use of L-(+)-di-*tert*-butyl tartrate for the epoxidation of a range of other aliphatic enones resulted in equally good results for the long chain aliphatic enones, Scheme 2, although the challenging substrate **1d** still falls short of a usable level of enantiomeric excess. Our results are reported in Table 3.

The higher enantiomeric excesses obtained using the bulkier ester derivatives may be rationalised on simple steric grounds, but the apparently higher catalytic activity of the corresponding magnesium tartrate derivatives of these bulkier tartrate esters is not so immediately explained. The most probable explanation is that the magnesium catalysts formed from the bulkier tartrate esters are simply less prone to hydrolysis, and hence to inactivation.

The magnesium tartrate system appears to offer the prospect of an alternative to the excellent La–BINOL system in which



Scheme 2 Asymmetric epoxidation of aliphatic enones using *in situ* generated catalyst.

although the amount of catalyst required is higher (typically 10 mol% for the Mg system, compared with 1–5 mol.% for the La–BINOL system), the cost of the catalyst precursors is several orders of magnitude less.

We thank EPSRC for the award of a research grant (GR/M13633), Rhodia Chirex for studentship support (SJR), and Professor A. McKillop and Dr S. Bone (formerly Rhodia Chirex) for helpful discussions.

Notes and references

‡ **General procedure for the asymmetric epoxidation of aliphatic enones using di-*tert*-butyl tartrate:** *tert*-butyl hydroperoxide (3.7 M in toluene, 1.1 mmol, 1.1 eq.) was dried over activated powdered 4 Å molecular sieves (200 mg, activated for 4 h at 200 °C) for 2 h. Bu_2Mg (1 M in heptane, 0.1 mmol, 0.1 eq.) was added. After stirring for 30 min, L-(+)-di-*tert*-butyl tartrate (0.11 mmol, 0.11 equiv.) was added. After an additional period of 30 min stirring, the aliphatic enone (1 mmol) was added, and the mixture was stirred for 24 h. The conversion and enantiomeric excess were checked either by chiral phase GC or HPLC. We have observed that best results are obtained with solutions of *tert*-butyl hydroperoxide that have been stored over 4 Å molecular sieves for an extended period.

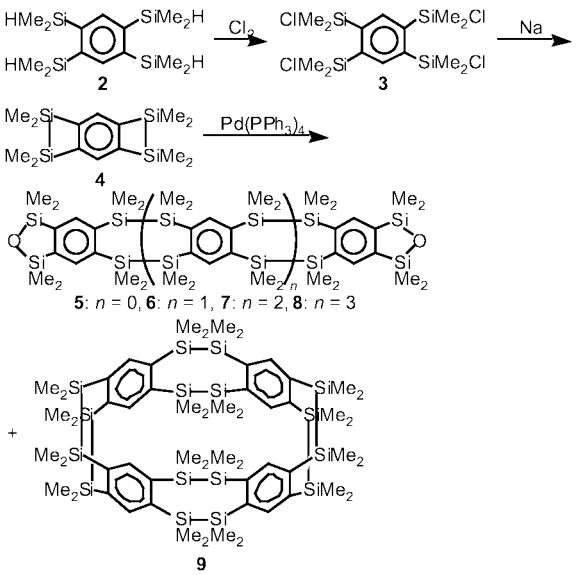
Received (in Cambridge, UK) 29th August 2001, Accepted 6th November 2001
First published as an Advance Article on the web 6th December 2001

The metathesis of the Si–Si bonds of benzo[1,2:4,5]-bis(1,1,2,2-tetramethyl-1,2-disilacyclobut-3-ene) with $Pd(PPh_3)_4$ gave 1,2,9,10,17,18,25,26,27,28,35,36,37,38,39,40-hexadecasila[2_8](1,2,4,5)cyclophane and its open-chain homologs, in which the σ–π conjugation is extended all over the molecule.

The chemistry of cyclophanes with three or more benzene rings has been studied extensively from the viewpoint of conformational analysis and the formation of inclusion compounds.[1] For example, [2_3](1,4)cyclophane (π-prismand)[2–4] and [2_6](1,2,4,5)cyclophane (deltaphane)[3] have been reported to be effective complexing agents with silver ion. The construction of silicon-bridged cyclophanes seems interesting because the silicon bridges would affect the electron states and the structures of cyclophanes.[5,6] Recently we reported the first synthesis of benzo[1,2:4,5]bis(1,1,2,2-tetraisopropyl-1,2-disilacyclobut-3-ene) (**1**)[7] as part of our study on organosilanes with aromatic rings.[8] We report herein that the methyl analog of **1** can serve as a precursor of 1,2,9,10,17,18,25,26,27,28,35,36,37,38,39,40-hexadecasila-[2_8](1,2,4,5)cyclophane (**9**). We also describe the structures and properties of **9** and its open-chain homologs.

Benzo[1,2:4,5]bis(1,1,2,2-tetramethyl-1,2-disilacyclobut-3-ene) (**4**) was prepared according to the same procedure for **1**:[7] the chlorination of **2**[9] and the intramolecular coupling of the



resulting chlorosilane **3** with sodium gave **4**. The intermolecular coupling products such as **5**–**9** were not formed under the conditions used. As the Si–Si bonds of **4** are easily oxidized in the air, **4** was immediately used in the next step without isolation. The metathesis of the Si–Si bonds of **4** with $Pd(PPh_3)_4$[10] gave linear oligomers **5**–**8** and a cyclic oligomer **9** together with a large amount of polymers at room temperature (Fig. 1).† The metathesis of **1** with $Pd(PPh_3)_4$ did not take place at 150 °C because of the steric hindrance of the isopropyl groups.

The structures of the linear oligomers **5**–**8** were determined by spectroscopic data. For example, ^{1}H, ^{13}C and ^{29}Si NMR spectra of the trimer **6** show the presence of three kinds of silicon atoms, three kinds of methyl groups, five kinds of benzene carbons and two kinds of benzene protons. In each oligomer, the terminal Si–Si bonds are oxidized to give Si–O–Si bonds in the air.

The cyclophane **9** was obtained as colorless crystals which is highly insoluble in most organic solvents. The structure of **9** was determined by X-ray crystallography (Fig. 2).‡ This molecule has a rhombic structure consisting of four planar 1,2,4,5-tetrasilylbenzene moieties. The distance between two opposite benzene rings is 7.3 Å. The crystals were obtained by recrystallization from a toluene solution, but no solvent molecule is included in the cavity. The four benzene rings are tilted alternately upward and downward from the cavity. The C(sp^2)–Si–Si–C(sp^2) moieties adopt nearly gauche conformations with the average torsion angle of 54.8°.

The UV spectra of **5**–**7** and **9** are shown in Fig. 3. As the number of repeating units increases, the absorption shifts to the longer wavelength region, and the extinction coefficient becomes far larger than the value expected from the number of repeating units. No significant difference was observed between the linear tetramer **7** and the cyclic tetramer **9**. The bathochromic shift and the increment of extinction coefficients are explained by the σ–π conjugation:[11] π orbitals of a benzene ring are conjugated with four Si–Si σ orbitals, and the four Si–Si σ orbitals are conjugated with the π orbitals of the adjacent benzene rings. Therefore, these compounds are unique systems, in which the σ–π conjugation is extended all over the molecule. Further experiments into the properties of these potentially intriguing compounds are currently under investigation.

Notes and references

† Chlorine was bubbled into a solution of **2** (1.00 g, 3.22 mmol) in carbon tetrachloride (4 ml) at room temperature. When **2** was completely converted into **3**, the solvent was removed under reduced pressure. Compound **3** was obtained almost quantitatively. A solution of **3** in toluene (8 ml) was added dropwise to a refluxing mixture of sodium (1.74 g, 75.7 mmol) and toluene (30 ml), and the reaction mixture was refluxed for 12 h to give **4**. After the solvent was removed under reduced pressure, $Pd(PPh_3)_4$ (0.570 g, 0.493 mmol) and benzene (30 ml) were added to **4**, and the mixture was stirred for 3 h at room temperature. Insoluble materials were removed by filtration and centrifugation. The solvent was evaporated, and the residue was separated by HPLC (ODS, methanol–THF (6 : 4)) to give **5** (8.5 mg, 0.8% from **2**), **6** (6.2 mg, 0.6%), **7** (5.3 mg, 0.5%), **8** (2.5 mg, 0.2%) and **9** (0.9 mg, 0.1%).

First published as an Advance Article on the web 6th December 2001

Use of tributylphosphate, an organophosphate, as the phosphorus source in place of phosphoric acid, has enabled the synthesis of several new open-framework zinc(II) and cobalt(II) phosphates, under solvothermal conditions.

Amongst the many inorganic open-framework structures known to-date, the metal phosphates constitute a large family.[1,2] The synthesis of these compounds is generally carried out under hydrothermal conditions by taking a metal salt and phosphoric acid in the presence of an organic amine, which may act as a template or structure-directing agent. Other strategies include the use of amine phosphates.[3] We have examined whether the use of an organic phosphorus source in place of H_3PO_4 would provide a new way to synthesize these fascinating compounds. This is of interest because the formation of open-framework structures is kinetically controlled and can be highly sensitive to the reaction conditions. In addition, the use of an organic source of phosphorus enables one to employ non-aqueous media for the synthesis. We have carried out several reactions of metal ions with tributylphosphate, both in alcohol and aqueous media, and obtained several open-framework cobalt, zinc and iron phosphates possessing different architectures. In this communication we report this new route for the synthesis of open-framework phosphates.

In a typical synthesis, zinc(II) chloride was dissolved in a butan-2-ol–water mixture. Tributylphosphate was added to the solution followed by an organic amine under constant stirring. The homogenized gel was sealed in a Parr autoclave and heated at 180 °C for 60 h. With different amines (*N*-(2-aminoethyl)-1,3-propanediamine in **I**, 4-(aminomethyl)piperidine in **II** and piperazine in **III**) the reactions yielded three-dimensional phosphates of the following compositions: $[C_5N_3H_{18}]$-$[Zn_3(HPO_4)_3(PO_4)]$ **I**, $[C_4N_2H_{14}]_4[Zn_5(PO_4)_4]_4{\cdot}5H_2O$, **II** and $[C_4N_2H_{12}][Zn_2(PO_4)(H_2PO_4)_2]$ **III**. While **I** and **II**, which possess channels are new, **III** has been reported in the literature.[3]

The structure of **I** is based on a three-dimensional network involving ZnO_4, PO_4 and HPO_4 tetrahedra with all the zinc atoms being linked to P atoms *via* oxygen. There are no Zn–O–Zn linkages present in the structure, hence no three-ring features are observed. The structure of **I** is built up of a stack of parallel layers linked by the corner-shared (CS) 4-ring chains embedded in the interlayer space (Fig. 1a). The layer in turn is made up of zigzag ladders consisting of 8-ring apertures as shown in Fig. 1b. The oxygens of the phosphate of the CS chains link on either side to the zinc tetrahedra of the layers. Such linkages between layers and CS chains result in 16-ring apertures along the *c*-axis, into which the terminal hydroxy groups project.

The framework of **II** is built up from layers and 4-ring ladders. The layers are made up of three types of chains (**A**, **B** and **C**) as can be visualized in Fig. 1c. The phosphate tetrahedra on the chains of type **A** and **B** add on to another set of ZnO_4 tetrahedra to form the 'tubule' like feature, whereas the phosphate tetrahedra common to these chains and the oxygens of the newly added ZnO_4 tetrahedra connect to the oxygens of the 4-ring ladder to form the three-dimensional architecture with 12- and 6-ring channels along the *a*-axis (Fig. 1d). The protonated amine molecule (4-(aminomethyl)piperidine decomposes to give 1,4-diaminobutane) sits in the cavities and interacts with the framework *via* hydrogen bonding.

For the synthesis of cobalt(II) phosphates, a known amount of $CoCl_2{\cdot}6H_2O$ was dissolved in butan-2-ol and tributyl phosphate added to the solution under stirring. The amine (piperazine in **IV**, **V** and diethylentriamine in **VI**) was added after a few minutes and the mixture stirred until it became homogeneous. The gels were sealed in Parr autoclaves at 180 °C for 60 h. By

Also shown by dotted lines is the ZnO_4 tetrahedron connecting to the oxygen atoms of the phosphate groups of chains (type **A** and **B**) to form the tubule. (d) Ball and stick view of 6- and 12-ring cavities of **II** along the *a*-axis.

 DOI: 10.1039/b107898b

such reactions, we obtained three new open-framework cobalt phosphates $[C_4N_2H_{11}][Co_2(PO_4)(H_2PO_4)_2]$ **IV**, $[C_4N_2H_{12}][Co_2(PO_4)_2]$ **V** and $[C_6N_4H_{22}][Co_7(PO_4)_6]$ **VI**. Of these, **IV** and **VI** possess three-dimensional frameworks and **V** has a layered architecture. Although these cobalt phosphate are new, their zinc phosphate analogues are known in the literature.[3–5] We have also synthesized a known mixed valence iron phosphate[6] by this route.

Framework **IV** is isostructural with the zinc phosphate **III** and has a three-dimensional structure built up of infinite CS chains containing 4-rings running perpendicular to each other and connected at various junctions.[3] Four such junctions form a 16-membered clover-shaped aperture, with the pendant hydroxyl groups from the phosphorus projecting in the cavities. The protonated piperazinium cations occupy the 4-ring windows (Fig. 2a). Framework **V** has a layered topology made up of 3- and 4-membered rings formed by vertex linkage between CoO_4 and PO_4 tetrahedral units. The anionic layer is built up of two kinds of chains, **D** and **E**, made from 3- and 4-rings (Fig. 2b). The presence of a 3-ring chain results in a step-like feature in the layer due to the strain involved in accommodating it and also gives rise to an infinite one-dimensional Co–O–Co chain.

Compound **VI** possesses a three-dimensional architecture and is made of CoO_6, CoO_4 and PO_4 polyhedra, which connect to give rise to a Co_7O_6 cluster. The cobalt octahedron is surrounded by six cobalt tetrahedra to form the Co_7 cluster. Such clusters are linked *via* six PO_4 tetrahedra to other clusters to form the structure. The clusters are arranged in such a manner that each cluster is displaced by half the length of the *c*-axis from its neighbour, forming a honeycomb layer. The next layer of clusters is identical to the first but is displaced along the *a*-axis by half the unit cell so that the honeycomb channels are capped. This type of three-dimensional AB type stacking results in the formation of 8-membered channels at an angle to the *c*-axis (Fig. 2c).

The various structures obtained by using tributylphosphate as the phosphorylating agent confirm that we have found a new route for the formation of open-framework phosphates. The use of the phosphate ester enables us to carry out the reactions under non-aqueous conditions and to isolate new framework structures. It may be noted that pure open-framework Co(II) phosphates have been considered difficult to prepare. The use of the phosphate ester influences the release of phosphate ions in the solution, thereby affecting the course of the reaction and the products formed. The method can be readily extended to phosphonates, carboxylates and other systems.

We thank Unilever plc for their generous support of this work.

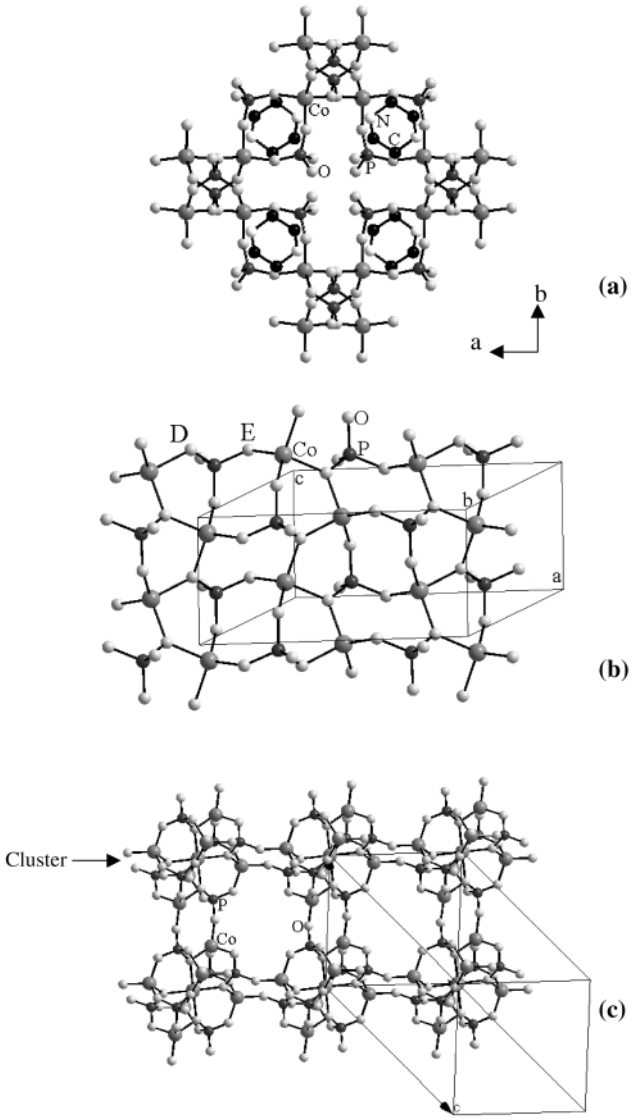

Fig. 2 (a) Structure of **IV** showing clover-shaped 16-ring channels. Also seen are the piperazinium molecules in the 4-ring windows. (b) Structure of **V** showing a single layer. Note the presence of two types of chains **D** and **E** and the infinite Co–O–Co chains. (d) Structure of **VI** showing the 8-membered channels at an angle to the *c*-axis formed by the linkage of Co_7O_6 clusters.

Received (in Cambridge, UK) 15th August 2001, Accepted 13th November 2001
First published as an Advance Article on the web 6th December 2001

The report shows that highly doped anatase-like binary mixed oxides constitute a route to improve the performance of nanosized titania photocatalysts under sunlight excitation.

Photocatalytic destruction of organic pollutants in the presence of TiO_2 appears to be a viable decontamination process of widespread application, no matter the state (gas or liquid) or chemical nature of the process target.[1] However, its technological application seems limited for several reasons, among which the most restrictive one is the need to use an ultraviolet (UV) excitation source. The efficient use of sunlight may then appear as an appealing challenge for developing the future generation of photocatalytic materials working with non-polluting energy sources.

In order to explore the photocatalytic behavior of highly doped anatase-like binary mixed oxide systems, we have tried to synthesize substitutional mixed oxides including typical acceptors (like Cr, Ni), donors (like V or Mn), cations with both properties (like Fe) or with intrinsic photocatalytic properties (like Ce, Mo or W), up to a total of 9 different metals. For a random distribution of substitutional acceptor/donor of charge dopants, a gaussian-like density of states appears at the lower/upper part of the conduction/valence band.[2] The corresponding density of states is directly proportional to the dopant concentration, thus giving a clear tool to manage visible light absorption. Nevertheless, a high doping concentration may have detrimental effects because the photocatalytic rate constant typically decreases with a growing level of dopant.[3]

A microemulsion preparation method was used as it facilitates, as much as possible, the homogeneity of chemical composition at a nanoscale level as well as the production of particles with a narrow size distribution.[4] Ti(IV) isopropoxide was added to an inverse emulsion containing an aqueous solution (0.5 M) of precursors salts dispersed in *n*-heptane using Triton X-100 (Aldrich) as surfactant and hexanol as co-surfactant. The resulting mixture was stirred for 24 h, centrifuged, decanted, rinsed with methanol and calcined at 723 K for 2 h.

In Table 1, we report the materials synthesized; in the best cases, up to *ca.* 25 at.% is successfully introduced in the titania structure. Fe, Mn, Ni and Ce-containing mixed oxides have small (maximum) dopant concentrations, expected at least in the first case. The microemulsion method is able to obtain mixed oxides with surface area in the 35–145 $m^2\ g^{-1}$ interval with (primary) particle size ranging from 5 to 13 nm. X-Ray diffraction (data not shown) and Raman spectroscopy (see below) of the systems give evidence that all samples have an anatase-type structure, except the Ti–Cr case, where XRD allows us to roughly estimate a 55:45 anatase:rutile mixture. The absence of well-developed, bulk-like dopant-atom single oxide phases was confirmed using both techniques.

Photocatalytic activities of the highly doped Ti–M mixed oxides in the gas phase toluene mineralization are presented in Table 2. The photocatalytic reactor was made of two concentric Pyrex tubes. The catalyst (100 mg) was coated onto the central section (150 mm) of the inner tube (16 mm o.d.). The reacting mixture (100 ml min^{-1}) was prepared by injecting toluene (*ca.* 1000 ppmv) into a wet oxygen flow before entering the photoreactor. After flowing the mixture for 1 h in the dark (control test), four fluorescent day-light lamps (6W, Sylvania F6W/D, irradiation range 360–750 nm, UV content of 3%) were switched on. Gas composition outlet was analyzed using an on-line gas chromatograph equipped with a capillary column and an electron ionization detector. Toluene photo-oxidation was chosen to test activity as it is a large component of environmental aromatic hydrocarbons and is thought to be an important constituent of anthropogenic emissions in urban atmospheres. In addition, its photo-oxidation is a demanding reaction. Included in Table 2 is the activity of some single oxides prepared by microemulsion and the commercial (anatase + rutile) P25 (Degussa) material. Samples with Fe, Mn, Ni and Ce are not active and were not included in the table.

Among the catalysts tested, those containing W appear to have the highest activity although with a moderate selectivity to benzaldehyde, somewhat paralleling the selectivity of the pure WO_3 oxide. The Ti–W, Ti–Mo and Ti–Nb series present activity while Ti–V and Ti–Cr series do not display detectable photocatalytic activity. It is important to note that these samples

always display lower activity than the home-made titania reference if UV rather than visible light is used. It should be also mentioned that the WO_3 oxide is active although its small surface area leads to a very low reaction rate per gram.

UV-visible spectra suggest that V and Cr containing samples do not present a simple band gap as occurs with titania (Fig. 1). In the visible region of the spectrum, V displays d–d charge localized transitions (for V^{5+}/V^{4+} in the 400–600/600–800 nm region)[5] while Cr has several (O to Cr) charge transfer bands.[6] The electronic modifications induced in the anatase-like oxides with respect to titania evidence the main reason for the failure of the Ti–V and Ti–Cr catalysts. On the other hand, it can be noted that, in agreement with a previous report,[7] the decrease of the V content of the mixed oxide yields active materials when the dopant-atom is below 6 at.% (data not shown).

Samples containing maximum quantities of Nb, Mo and W display (Fig. 1) UV-visible spectra typical of semiconductor materials with estimated band gap absorption onset at 395, 465 and 420 nm, which can be compared with the *ca.* 380 nm characteristic of our nanosized titania specimen. These active samples, as well as the home-made titania reference, have particle sizes in the 5 to 9 nm range, where only moderate size dependency of activity is expected.[8] Comparison with titania references (Table 2) suggests that our samples present up to a four-fold increase with respect to nanosized titania samples, having an activity enhancement with the level of doping for W and a less concentration-dependent behavior for Mo and Nb.

Raman analysis of these three series may allow us to rationalize these results. The spectra of pre-reaction (calcined) materials with varying Ti–M atomic ratios are shown in Fig. 2.

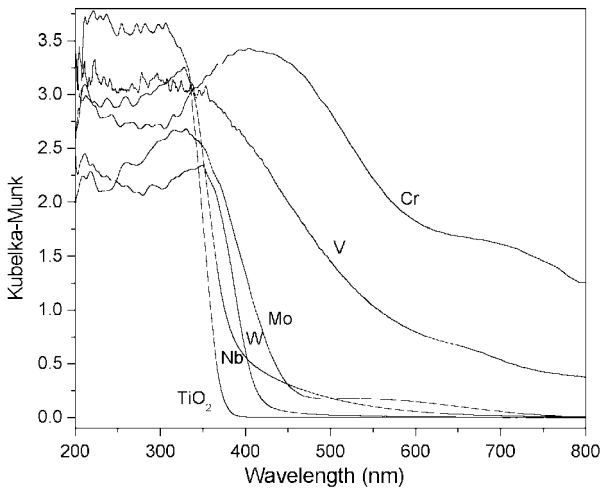

Fig. 1 UV-visible reflectance spectra of Ti–M samples with the highest dopant-atom content.

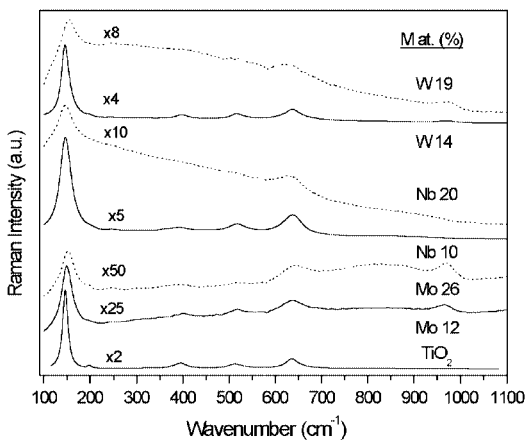

Fig. 2 Raman spectra of Ti–W, Ti–Mo and Ti–Nb specimens.

The analysis of Raman bands suggests that all active materials having a 20–25 at.% level of doping have a surface partially covered by hetero-atom moieties; bands at 975 cm^{-1} for W[9] and 971 cm^{-1} for Mo[10] correspond to W=O and Mo=O bond stretchings, while the 636 cm^{-1} frequency band has a contribution from a Nb–O–Nb deformation.[11] A broad band appears on the Mo spectra in the 690–935 cm^{-1} range.[10,11] All the mentioned bands are characteristic of surface MO_x entities supported on titania, without having any evidence of bulk single oxide formation,[9–11] in agreement with XRD. However, W and Nb materials with lower (*ca.* 10–15 at.%) dopant-atom quantities hardly display discernible Raman bands associated with (single) hetero-atom moieties, while the Mo specimen shows less distorted (frequency/intensity) anatase bands and a decreased intensity for bands ascribed to surface Mo species (Fig. 2), both facts in agreement with the presence of a decreasing amount of Mo species on the titania surface.[10]

The comparison of characterization results with catalytic behavior under solar-type (Table 2) and UV lights suggests that highly doped materials with anatase structure can have significant activity in VOCs elimination under visible light excitation. However, the percentage of hetero-atom present in the catalyst seems to have little relevance for Mo and Nb systems and a significant importance in the case of W. For W, the presence of dopant-atom ad-species on the surface may have catalytic consequences; however, a catalyst produced by deposition of a 4 wt.% WO_x on the anatase synthesized by a two-step microemulsion method displays null activity enhancement over the parent, home-made TiO_2 reference.

It therefore appears that, apart from the impurity derived change in the absorption threshold energy, dependence on the dopant-atom nature seems to have a strong correlation with the main d-electron configuration, as has been already observed by others using UV light.[12–15] In the case of solar light, our study indicates that the heavier elements of group VI are the best dopants for yielding efficient photocatalytic degradation of toluene using highly doped titania samples. This behavior contrasts with that observed for low dopant level samples under UV excitation, which present activity for group V and VI dopant-atoms.[1]

The authors thank the 'Ayuntamiento de Coslada' for partial support of this work.

Remarkable organophosphorus cage compounds from the reaction of cobaltocene and the triphosphole $P_3C_2Bu^t_2CH(SiMe_3)_2$: crystal and molecular structures of $[Co(\eta^5\text{-}C_5H_5)(\eta^4\text{-}C_4H_4CHCHP_6C_4Bu^t_4)]$ and $P_6C_4Bu^t_4CH(SiMe_3)$

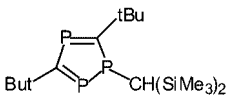
Received (in Cambridge, UK) 7th September 2001, Accepted 16th November 2001
First published as an Advance Article on the web 6th December 2001

The novel cage compounds $[Co(\eta^5\text{-}C_5H_5)(\eta^4\text{-}C_4H_4CHCHP_6C_4Bu^t_4)]$ and $P_6C_4Bu^t_4CH(SiMe_3)$ are formed from the reaction between cobaltocene and the triphosphole $P_3C_2Bu^t_2CH(SiMe_3)_2$.

Organophosphorus cage compounds are of considerable current interest and synthetic routes usually involve cyclooligomerisation of phospha-alkynes (sometimes metal mediated) or coupling of polyphospholyl anions.[1–4] Recently we described a series of cages containing an additional heteroatom $P_6C_4Bu^t_4E$ **1** (E = S, Se, Te and GeI_2). The chalcogen containing compounds were obtained by an unprecedented reaction involving the facile specific insertion reaction into a P–P bond of the hexaphospha-prismane, $P_6C_4Bu^t_4$.[5,6]

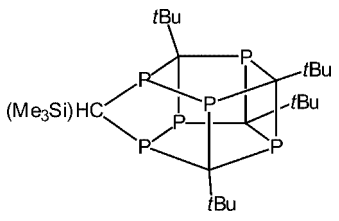
We and others,[7] in unpublished work, have noted that in alkylation reactions of the $P_3C_2Bu^t_2$ anion with $BrCH(SiMe_3)_2$ which afforded the first known 1,2,4-triphosphole, $P_3C_2Bu^t_2CH(SiMe_3)_2$ **2**[8] on occasions also gave two isomeric



2

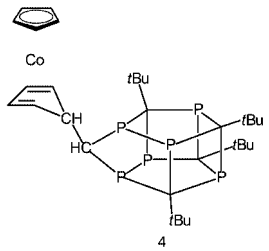
organophosphorus cage compounds, $P_6C_4Bu^t_4CHSiMe_3$, albeit in low yield. Since a light-induced radical coupling reaction (with partial elimination of the $CH(SiMe_3)$ side-chain), might be responsible, we have studied the reaction between **2** and the stable organometallic radical cobaltocene.

Thus, treatment of $[Co(\eta^5\text{-}C_5H_5)_2]$ with the triphosphole $P_3C_2Bu^t_2CH(SiMe_3)_2$ **2** in refluxing toluene for 4 h, afforded an approximately equimolar mixture of two novel organophosphorus cage compounds; (i) the colourless $P_6C_4Bu^t_4CH(SiMe_3)$ **3** (6.4%) and (ii) the remarkable red 18e diamagnetic cobalt(I)



3

complex $[Co(\eta^5\text{-}C_5H_5)(\eta^4\text{-}C_4H_4CHCHP_6C_4Bu^t_4)]$ **4** (5.8%). Both compounds exhibited parent ions in their mass spectra‡ and were fully structurally characterised by single crystal X-ray diffraction methods.§ (Figs. 1 and 2). The organosilanes which are lost from the triphosphole side-chain during the reaction,



4

(most likely a $CH(SiMe_3)_3/Si_2Me_6$ mixture), were not isolated.

Compound **3** exhibits the expected $^{31}P\{^1H\}$ NMR spectrum,‡ consisting of six distinct resonances whose chemical shifts are all typical for saturated phosphorus atoms in cage structures. Of special structural significance are the signals at 197.5 and 178.8 ppm, which both show only small further P–P couplings, and can be easily assigned to the two cage phosphorus atoms which are bonded solely to carbon, whereas the other four resonances, each involving large doublet patterns, ($^1J_{P(1)P(2)}$ 238.1 and $^1J_{P(4)P(5)}$ 226.5 Hz) arise from the two sets of phosphorus atoms directly bonded to each other.

The molecular structure of **3**, (Fig. 1), represents an addition to the $P_6C_4Bu^t_4E$ family of cages, being derived from the hexaphosphapentaprismane $P_6C_4Bu^t_4$ by a $CHSiMe_3$ bridge linking the two five-membered $P_3C_2Bu^t_2$ rings. The C–C, C–P and P–P bond lengths in **3** all lie in the expected single bond range.

The cobalt complex **4**, which is also a $P_6C_4Bu^t_4E$ cage family member, shows a similar pattern of lines in its $^{31}P\{^1H\}$ NMR spectrum to **3**. It clearly results from the conversion of one of the

original η^5-ligated C_5H_5 rings of cobaltocene into an η^4-bonded C_4H_4CH–fragment of a substituted cyclopentadiene ring, linked to the newly generated $P_6C_4Bu^t{}_4CH$-cage fragment. The overall geometry of the organophosphorus cage in **4**, (Fig. 2), is little different from that observed in **3**, and the bent (C_4H_4CH)–ring fragment and the very similar C(6)–C(7)–C(8)–C(9) bond distances (averaging 1.412(8) Å) suggest electron delocalisation within the η^4-cyclopentadiene–cobalt moeity.

We thank the British Council for financial support (to N. S. and J. F. N.) for part of this work.

Electrooxidation of tetrathiafulvalene (TTF) carried out in the presence of $(Bu_4N)_2TTF(CO_2H)_2(CO_2)_2$ as supporting electrolyte affords wholly TTF organic materials in which TTF cations are associated with $TTF(CO_2H)_2(CO_2^-)_2$ as counteranions.

The electronic properties of radical cation salts of the TTF series strongly depend on the way in which donor π-orbitals overlap in the solid state.[1] This is the consequence of the crystal packing which is itself the result of several intermolecular interactions involving both donors and anions such as hydrogen bonds or van der Waals dispersion forces. In this context, the design of organic anions which can be easily chemically tuned is becoming a main trend.[2] We recently focused on anions derived from carboxylic acids which display a variety of shapes and symmetries and are also likely to build polymeric anionic networks by hydrogen bonds.[3]

We now report the synthesis and characterizations of TTF salts based on the $TTF(CO_2H)_2(CO_2^-)_2$ dianion. The synthesis of a π-donor TTF bearing an anionic group has been previously investigated in order to further form upon electrooxidation the corresponding neutral zwitterionic π-radical.[4] In contrast, our approach consists here of using the tetrabutylammonium salt $2Bu_4N^+,TTF(CO_2H)_2(CO_2^-)_2$ (**1**)† (synthesized from $TTF(CO_2H)_4$[5] and $(Bu_4N)OH$ as starting materials) as supporting electrolyte in the electrooxidation of a donor (TTF itself for example) more easily oxidisable than the TTF core of the anion.

From cyclic voltammetry (Fig. 1), it appears that, as expected from the electron withdrawing character of carboxylic acid groups, the first oxidation potential of $TTF(CO_2H)_4$ (0.57 V *vs.* Ag/AgCl) is clearly greater compared to that of TTF (0.38 V *vs.* Ag/AgCl). The transformation of two $-CO_2H$ groups in two $-CO_2^-$ carboxylate groups, leading to salt (**1**), induces a lowering of the first oxidation potential of 0.09 V (0.48 V *vs.* Ag/AgCl) which nevertheless remains greater than that of TTF.

This result outlines, *a priori*, that only the oxidation of TTF must occur in electrocrystallization experiments when $(Bu_4N)_2TTF(CO_2H)_2(CO_2)_2$ is used as supporting electrolyte, $TTF(CO_2H)_2(CO_2^-)_2$ acting only as a counterion. The electrocrystallization experiments were carried out typically as follows: 20 mL of solution of (**1**) (0.02 mol.L^{-1} in a 90 : 10 CH_2Cl_2–EtOH mixture) were charged in a H-shaped cell, 15 mg of TTF were introduced in the anodic arm and a constant current (I = 2 μA) was applied for twenty days. This led to black single crystals that were formulated as $(TTF)_2[TTF(CO_2H)_2(CO_2)_2]$ (**2**) thanks to their X-ray crystal structure.

Compound (**2**) crystallizes in the centrosymmetrical triclinic space group. The asymmetric unit consists of one $TTF^{\cdot+}$ radical cation and half $TTF(CO_2H)_2(CO_2^-)_2$ anion. This anion is centrosymmetric and fully planar and its nature is unambiguously deduced from the analysis of the bond lengths which appear very close at hand from those encountered in starting salt (**1**); furthermore, a symmetrical intramolecular hydrogen bond situation, also previously described in hydrogenomaleate anion,[6] is observed for both salts (Fig. 2). This shows that TTF cores of $TTF(CO_2H)_2(CO_2^-)_2$ anions remain neutral. As a consequence, all unsubstituted TTF molecules are at the +I oxidation state, which is in good accordance with the observed bond lenghts (*e.g.* an increase of the central C···C bond together with a lowering of the S···C bonds, compared to neutral unsubstituted TTF molecules[7]).

In the crystal structure, TTF units of the anions and $TTF^{\cdot+}$ radical cations are piled up in stacks with the alternance $TTF^{\cdot+}/TTF^{\cdot+}/TTF(CO_2H)_2(CO_2^-)_2$. These stacks, shifted one from each other, form β-type like sheets, giving rise to six relative situations between molecules (numbers 1–6 in Fig. 3). In the stacks, a bond over cycle overlap occurs between the TTF core of the anion and a $TTF^{\cdot+}$ radical cation (interaction 1). However, no S···S distance lower than the sum of van der Waals radii of two sulfur atoms is observed. On the contrary, the strong interaction 4 between two $TTF^{\cdot+}$ species, where a bond over bond overlap situation and four short S···S distances (d = 3.388(5) Å and d = 3.405(5) Å) are present, leads to well defined $(TTF^{\cdot+})_2$ dimers. With regard to adjacent interactions, a

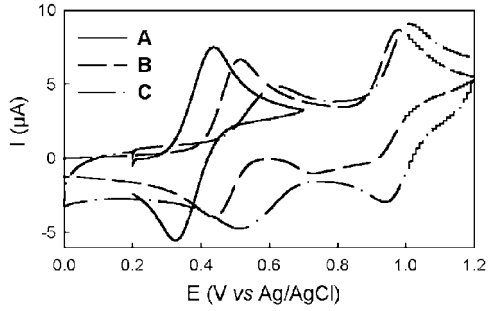

Fig. 1 Cyclic voltammograms of TTF (**A**), $(Bu_4N)_2TTF(CO_2H)_2(CO_2)_2$ (the second wave is not reversible) (**B**) and $TTF(CO_2H)_4$ (**C**) (solvent: acetonitrile; supporting electrolyte: Bu_4NPF_6; v = 0.5 V s^{-1}; reference: Ag/AgCl).

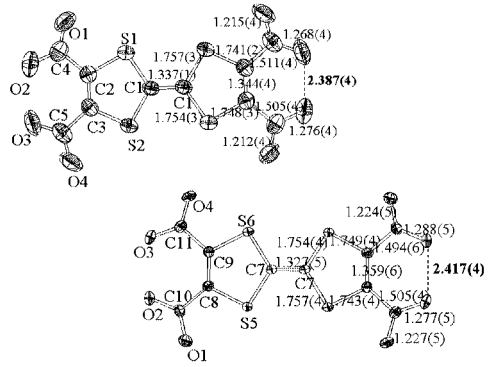

Fig. 2 Ortep views with the numbering scheme and bond lengths (in Å) of $TTF(CO_2H)_2(CO_2^-)_2$ anion in (**1**) (top) and (**2**) (bottom)**.** Bold values are related to O···H···O hydrogen bond lengths; hydrogen atoms have not been located. Ellipsoids are drawn at 50% probability.

 DOI: 10.1039/b108888b

few S···S contacts are also encountered, implying in particular two $TTF^{\cdot+}$ cations (d = 3.537(4) Å and d = 3.560(6) Å for situation 6; d = 3.586(5) Å and d = 3.661(5) Å for situations 2 and 3, respectively).

Of particular interest also are the interactions between neighbouring sheets in the plane denoted A in Fig. 3, where C–H···O interactions are involved (Fig. 4). Such bonds implying hydrogen atoms, either from TTF core in salts based on EDT–$TTFCONH_2$[8] or from ethylene groups of BEDT–TTF molecules,[2b,9] play an important role in the packing of organic conducting salts and consequently in the electronic collective properties.

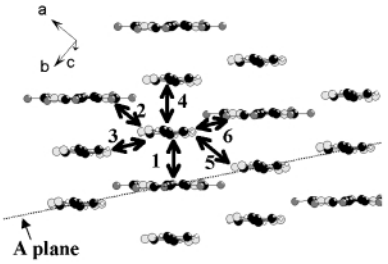

Fig. 3 β-Type like sheet in $(TTF)_2[TTF(CO_2H)_2(CO_2)_2]$ (**2**), including both $TTF^{\cdot+}$ radical cations and $TTF(CO_2H)_2(CO_2^-)_2$ anions.

The original structural feature is that, in a way, the anionic sheets do not exist, allowing a connection of the β-type sheets formed by the TTF units *via* rather strong C–H···O type hydrogen bonds (H(4)···O(4) 2.260(3) Å; H(1)···O(2) 2.356(3) Å).[10] A hydrogen bond network, also including intra-sheet C–H···O interactions (H(1)···O(1); H(3)···O(4)), thus appears (Fig. 4) with cyclic motifs as the one showed in Fig. 4, denoted $R_2^4(8)$ in Etter's notation.[11]

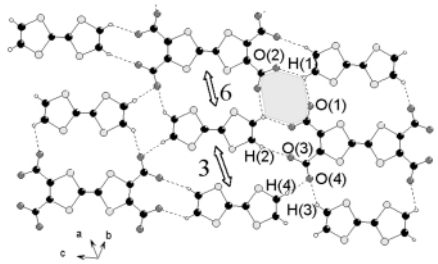

Fig. 4 C–H···O hydrogen bonds network in a A type plane of (**2**). Bond distances (in Å) : H(4)···O(4) 2.260(3); H(1)···O(2) 2.356(3); H(2)···O(3) 2.508(3); H(1)···O(1) 2.544(3); H(3)···O(4) 2.599(3).

As expected from structural considerations discussed above, (**2**) exhibits a $(TTF^{\cdot+})_2$ dimer absorption band[12] at λ = 750 nm (Fig. 5), and a semiconducting behaviour (E_a = 0.10 eV) with

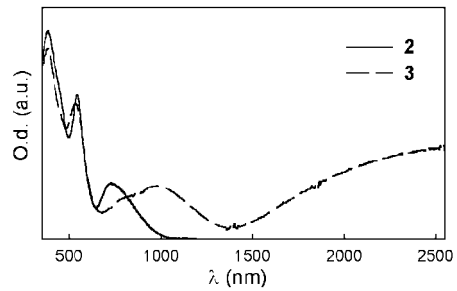

Fig. 5 Optical spectra of $(TTF)_2[TTF(CO_2H)_2(CO_2)_2]$ (**2**) and $(TTF)_3[TTF(CO_2H)_2(CO_2)_2]$ (**3**).

a weak room temperature conductivity ($\sigma = 10^{-5}$ S cm^{-1}). A mixed valence situation would *a priori* lead to a better conductivity. In fact, this situation is encountered in another compound (**3**), a dark brown powder obtained as a minor product in some of the electrocrystallization experiments: (**3**) presents a broad mixed valence absorption band[12] around 2500 nm (Fig. 5). Moreover, from EDX microanalysis,[13] (**3**) can be tentatively formulated as $(TTF)_3[TTF(CO_2H)_2(CO_2)_2]$, *i.e.* the association of two $TTF^{\cdot+}$ cations and one neutral TTF molecule with one $TTF(CO_2H)_2(CO_2^-)_2$ anion. Efforts are under way to obtain single crystals of (**3**).

In conclusion, we have succeeded in the synthesis of wholly TTF salts. This unprecedented concept where TTF-derived anions are incorporated in the donor slabs due to the inter-affinity of the TTF cores, suppressing the classical anion layers, can be extended to various mono, di and polycarboxylic acids derived from TTF. Studies on these promising full organic materials are in progress.

Received (in Cambridge, UK) 26th October 2001, Accepted 15th November 2001
First published as an Advance Article on the web 6th December 2001

Zinc sulfide nanoparitcles synthesized in AOT reverse micelles can be recovered by compressed CO_2; more dispersed and uniform nanoparticles can be obtained.

Surfactants can form reverse micelles in non-polar solvents under suitable conditions. Water is readily solubilized in the polar core, forming a so-called water pool. The use of micellar water droplets as a novel environment for nanoparticle synthesis has attracted much attention due to its potential advantages compared with the traditional nanoparticle synthesis methods.[1–5] Since the reaction is restricted in the water core, the diameter of the obtained product particles can be controlled by the size of the water core which is related to the water-to-surfactant ratio (w). Recovery of the particles from the reverse micelles is one of the main steps in this method, and some techniques have been used to recover the particles, such as super-rate centrifugation and filtration. In these methods surfactant is usually precipitated together with the nanoparticles. It is often an exhaustive procedure to remove the surfactant completely and the obtained product particles are always embeded in the surfactant.[6] Ideally the synthesized nanoparticles should be precipitated while the surfactant should remain in the solution.

It is known that a compressed gas can dissolve in an organic solvent and change its properties.[7] The properties of the solvent can be tuned continuously by the pressure of the gas because the solubility of the gas is a function of the pressure. Generally, the properties of a reverse micellar solution vary with the property of the solvent. Thus, the product nanoparticles in reverse micelles may be recovered by dissolving a gas into the solution at suitable conditions. In this work, we used compressed CO_2 to recover the ZnS nanoparticles synthesized in reverse micelles. To our knowledge, similar work has not been reported in the literature, although compressed CO_2 has been used in extraction and fractionation, fine particle generation and recrystallization.[8–11]

In this work isooctane was used as the solvent in which the surfactant AOT can form reverse micelles.† The micellar solution was expanded after CO_2 is dissolved. The volume expansion coefficient $\alpha = (V-V_0)/V_0$ (V_0 and V are the volumes of the solution before and after adding CO_2) and cloud point pressure (P_c) at which AOT begins to precipitate were required for our experiments. These parameters were determined in this work by using the apparatus reported previously.[12]

Na_2S and $ZnSO_4$ can be solubilized in the water pool of the reverse micelles. The synthesis of ZnS nanoparticles in the reverse micelles was similar to that reported by other authors.[13]‡ ZnS particles were formed rapidly in the reverse micelles due to the high rate of the droplet-exchange process.[14]

The existence and concentration of ZnS nanoparticles in the reverse micelles at different CO_2 pressures can be studied by UV spectroscopy.[13]§ The temperature-controlled high-pressure sample cell used was the same as that used previously.[15] As examples, Fig. 1 shows the UV spectra of reverse micellar solutions (w = 15) containing ZnS and Na_2SO_4 at 308.15 K and different CO_2 pressures. For each experiment, the UV cell contained 0.28 mg ZnS and 0.039 g AOT, and the cell was full of solution after expansion with CO_2. Thus, the concentration of ZnS and AOT in the solution are 0.16 mg mL^{-1} and 50 mmol L^{-1} if precipitation does not occur. The absorbances at 271 nm and 220 nm are attributed to ZnS nanoparticles and AOT, respectively.[13] The absorbance of ZnS decreases with increasing pressure, which indicates precipitation of ZnS particles. Our experiments using CO_2-free solutions showed that the absorbance at 271 nm increased linearly with the concentration of ZnS in the concentration range 0–0.5 mg mL^{-1}. Thus, the precipitation percentage of ZnS can be calculated from the absorbance. Fig. 2 shows the dependence of the precipitation percentage of ZnS (P_{ZnS}%) with CO_2 pressure under different conditions. Fig. 2 illustrates that more ZnS particles are precipitated at higher pressures, and less ZnS particles are precipitated at lower w. About 93% ZnS particles can be precipitated at 5.50 MPa for w 15. However, the precipitation of AOT is not considerable at this pressure, as can be seen from Fig. 1. This was further confirmed by an experiment using an optical high-pressure autoclave,[12] which indicated that the

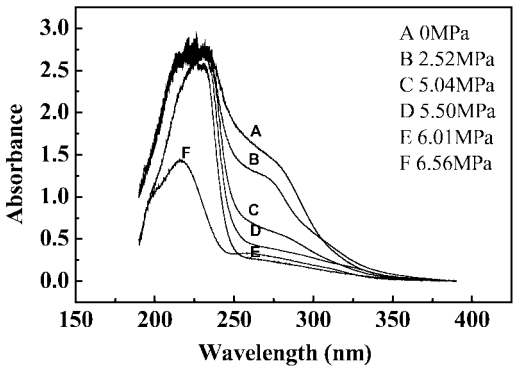

Fig. 1 UV spectra of ZnS in reverse micelles (w = 15, [AOT] = 50 mmol L^{-1}) at 308.15 K and different pressures.

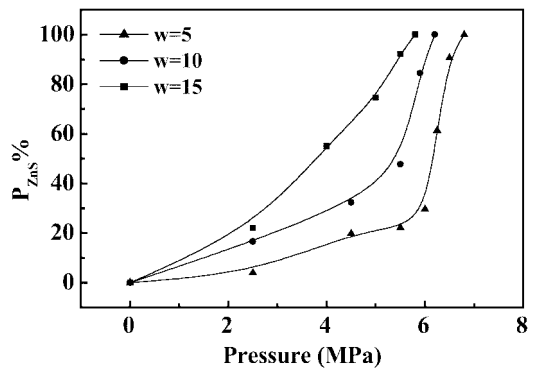

Fig. 2 Precipitation percentage of ZnS (P_{ZnS}%) from reverse micelles ([AOT] = 50 mmol L^{-1}) at 308.15 K.

 DOI: 10.1039/b109802k

cloud point pressure at which AOT begins to precipitate was 5.61 MPa.

On the basis of the investigation above, we could select suitable conditions to prepare and recover ZnS nanoparticles using a larger stainless steel cell of volume 32.60 mL containing a stirrer.¶ To obtain the largest recovery of ZnS without precipitation of AOT, we selected w = 15, and recovered the ZnS from the reverse micelles at 5.50 MPa. The particle size of ZnS was determined by transmission electron microscopy (TEM),‖ and photographs are shown in Fig. 3(a) and (b). The mean particle sizes are of the order of 3–8 nm (stiring rate = 100 rpm) and 1–3 nm (stiring rate = 400 rpm), respectively. The considerable effect of stirring rate on the particle size is due to the enhanced degree of molecular mobility at higher stirring rates. In order to study the effects of operating conditions *i.e.* the value of w, concentration of the surfactant, pressure and temperature on the particle size and size distribution, the particles were also prepared and recovered under other conditions; all the photographs show that small and dispersed particles can be obtained by this method.

Fig. 3 TEM photographs of ZnS particles obtained from reverse micelles ([AOT] = 50 mmol L^{-1}, w = 15, [Na_2S] = [$ZnSO_4$] = 8.14 mmol L^{-1}) at 308.15 K and 5.50 MPa; (a) with a stirring rate of 100 rpm, magnification 100 K (1 mm = 10 nm) and (b) with a stirring rate of 400 rpm, magnification 200 K (1 mm = 5 nm).

This work is supported by the National Natural Science Foundation of China (20133030), Ministry of Science and Technology of China (G20000781), and UK/China R & D Project. We are very grateful to Professor Martyn Poliakoff and Mr Adam O'Neil for their valuable suggestions and advice.

Notes and references

† *Materials*: CO_2 (>99.995% purity) was provided by Beijing Analytical Instrument Factory. The surfactant AOT was obtained from Sigma with a purity of 99%. The isooctane, Na_2S, $ZnSO_4$ and $BaCl_2$ supplied by Beijing Chemical Plant were all A. R. grade. Double distilled water was used.

‡ *Typical experimental procedure* for synthesis of ZnS particles in reverse micelles: two micellar solutions containing, respectively, Na_2S and $ZnSO_4$ at the same molar concentration were mixed at constant temperature. The concentration of AOT, w (molar ratio of water to AOT), and the volume of the two solutions were also the same.

§ *Typical experimental procedure* for UV spectra: a spectrophotometer (Model TU-1201, Beijing General Instrument Company) was used to monitor the precipitation of ZnS particles in the reverse micelles at different CO_2 pressures. The path length and the inner volume of the cell are 1.32 cm and 1.74 cm^3, respectively. In a typical experiment, a predetermined amount of micellar solution containing ZnS was loaded into the sample cell. CO_2 was charged until the desired pressure was reached and the system was stabilized at this pressure. The UV spectrum was recorded after equilibrium was reached.

¶ *Typical experimental procedure* for recovery of ZnS particles from reverse micelles: ZnS particles synthesized in the reverse micellar solution were precipitated by CO_2 and deposited at the bottom of the cell. Then CO_2 and the solution were released. IR and a $BaCl_2$ titration experiment indicated that Na_2SO_4 precipitated together with ZnS. Thus, the precipitated sample was washed with water to remove the Na_2SO_4 and then dried in vacuum at 308.15 K for 4 h.

‖ The maximum resolution of the Hitachi H-600A electron microscope was 0.5 nm. A drop of a dispersed solution of particles in ethanol was placed onto a carbon-coated copper grid. After evaporation of the solvent under vacuum electron micrographs were recorded.

Salt effect in the synthesis of mesoporous silica templated by non-ionic block copolymers

Chengzhong Yu,[a] Bozhi Tian,[a] Jie Fan,[a] Galen D. Stucky*[b] and Dongyuan Zhao*[a]

Received (in Purdue, IN, USA) 24th August 2001, Accepted 12th October 2001
First published as an Advance Article on the web 6th December 2001

The use of inorganic salts during the synthesis of mesoporous materials with block copolymers can dramatically widen the syntheses domain (in temperature, surfactant concentration, *etc.*) and broaden the range of surfactants that can be utilized to produce highly ordered mesostructures.

Mesoporous materials with controlled morphology have potential uses in catalysis, separation, chromatography and large molecular release systems.[1] Recently, highly ordered mesoporous silica SBA-15[2] synthesized by commercial amphiphilic block copolymer surfactants has attracted much attention.[3–5] It is noteworthy that in all the reported synthesis methods for SBA-15 the temperature is optimally controlled at 35–40 °C in order to obtain high ordering of the mesostructures. Moreover, compared to the large number of available block copolymers, only a fraction of these surfactants has been utilized to produce highly ordered mesostructures.

Inorganic salts have been used to control the morphology and porosity of SBA materials.[6] In non-ionic surfactant templating systems, the effect of ionic strength has also been studied.[7,8] Generally, specific interactions are emphasized in these reports, which lead to better order either in mesostructure or morphology.

In this communication we report the synthesis of highly ordered mesoporous silica materials through the use of inorganic salts at low temperatures. The salt effect described here dramatically increases the range of the synthesis parameters that can be used to obtain highly ordered mesostructures as well as the number of block copolymer surfactants that can be used.

Two block copolymers, P123 and B20-5000,[9] are used as the structure-directing agents. The syntheses were carried out according to previous reports,[2,10] except that different amounts of inorganic salts were used at controlled temperatures. In a typical synthesis, 2.0 g of P123 and 8.8 g of potassium chloride were dissolved in 60 mL of 2.0 M HCl at 15 °C. To this solution, 4.2 g tetraethyl orthosilicate (TEOS) were added under vigorous stirring. The final reactant molar composition was 0.02 P123 : 6 KCl : 6 HCl : 166 H_2O : 1 TEOS. After stirring at the same temperature for 1 day, the mixture was transferred into an autoclave and heated at 100 °C for another 24 h. The solid products were collected by filtration and dried at room temperature in air. The resulting powders were calcined at 550 °C for 4 h to remove the templates.

Powder X-ray diffraction (XRD) patterns of as-synthesized and calcined SBA-15 synthesized with P123 and 2 M KCl at 15 °C are shown in Fig. 1(a). Both patterns show well-resolved XRD peaks, which can be assigned to the (100), (110) and (200) reflections of the 2-D hexagonal space group (*p6mm*). The cell parameters are 11.9 and 9.1 nm for as-synthesized and calcined SBA-15 synthesized with salt at 15 °C, respectively. The nitrogen sorption isotherm of the calcined sample is type IV with type H_1 hysteresis loops typical of mesoporous materials with 1-D cylindrical channels (Fig. 2). SBA-15 synthesized at 15 °C has a pore size of 5.9 nm (calculated from both the adsorption and desorption branch by BdB model[11]), a BET surface area of 610 $m^2\ g^{-1}$ and a pore volume of 0.83 $cm^3\ g^{-1}$. These data are similar to those from previous reports.[2,6] The relatively smaller cell parameter and pore size can be attributed to the salt effect (see discussion below). Transmission electron microscopy (TEM) studies have further corroborated the highly ordered hexagonal structures (data not shown).

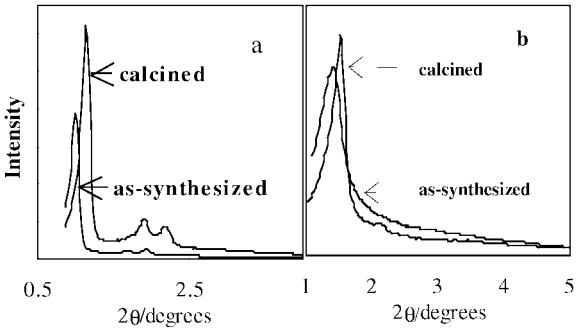

Fig. 1 XRD patterns of as-synthesized and calcined mesoporous silica prepared using (a) P123 at 15 °C with 2.0 M KCl and (b) B20-5000 at 40 °C with 1.0 M KCl. X-Ray data were collected with a Cu-Kα radiation source using a Scintag X_2 diffractometer.

This is the first report that highly ordered mesoporous SBA material can be synthesized at low temperature. By using the same reactants at 15 °C but without salt, no precipitation can be obtained. This is believed to be related to the specific nature of PEO and PPO segments in water. Both PEO and PPO are more

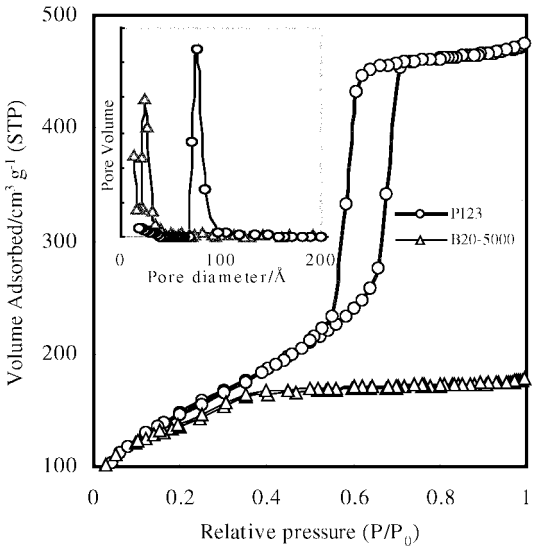

Fig. 2 Nitrogen adsorption–desorption isotherm plots and pore size distribution curve (inset) of calcined mesoporous silica synthesized by P123 and B20-5000 with inorganic salts. N_2 adsorption measurements were performed at 77 K using a Micromeritics ASAP2000 analyzer.

 DOI: 10.1039/b107640j

soluble in water at low temperatures, thus the hydrophilicity/hydrophobicity volume ratio is greater than at high temperature.[12] The formation of the ordered mesostructure precipitate is dependent on the the free energy of formation of the solid mesostructured phase and the free energy of the interface interactions of the silica species and solvent as well as the free energy of organization of the block copolymer as it associates with the species in solution. For the latter contribution, it is interesting to note that at 17 °C the critical micelle concentration (CMC) of P123 is 4.5 wt%,[13] while in a typical synthesis condition of SBA-15 the concentration of P123 in starting reactants is ~3.0 wt%. The decreasing ability to obtain composite phase separation at low temperature parallels the CMC dependence on temperature, making it a useful approximation to the collective free energies of interaction of all the inorganic, solvent, and organic species in solution. Increasing temperature is a convenient method to decrease the CMC by increasing the hydrophobicity of PEO blocks and reducing the hydrophilicity of PPO blocks. On the other hand, the addition of inorganic salts has the same effect as an increase in temperature.[14] For example, the CMC and critical micelle temperature (CMT) of Pluronic P65[15] and F127[16] show a marked decrease in the presence of added sodium chloride. This salt effect also lowers the thermodynamic radius of micelles,[14] and this is in accordance with the decrease in cell parameter and pore size decreasing observed in our experiments. The successful synthesis of highly ordered SBA-15 at low temperature confirms that using inorganic salts is an alternative to increasing temperatures.

The synthesis temperature of highly ordered SBA-15 can be lowered to 10 °C when the concentration of KCl is 2.5 M. On the other hand, at relatively higher temperatures such as 38 °C, the concentration of P123 in starting reactants can be lowered to 1 wt% with 1 M KCl. Other inorganic salts such as NaCl, Na_2SO_4 and K_2SO_4 can also be used to synthesize highly ordered SBA-15 at low temperatures.

It might be argued that during the synthesis of SBA-15 materials, using relatively high temperature is much more convenient than using high concentration of inorganic salts. However this is not necessarily the case, as evident in the uses of the salt effect in the synthesis with another block copolymer B20-5000. It is reported that only disordered mesoporous silica can be obtained with this block copolymer, even at high temperature.[17] By using 1 M KCl at 40 °C, a well-ordered cubic silica structure can be synthesized with a molar reactant composition of 0.01 B20-5000 : 3 KCl : 1.5 HCl : 167 H_2O : 1 TEOS. XRD patterns of as-synthesized material show the first peak at 2θ = 1.36; after calcination at least two peaks are observed (2θ = 1.51, 2.09, Fig. 1(b)). Combined with TEM results, these peaks can be indexed to the (110), (200) reflections of an I type cubic structure. The cell parameters are 9.2 and 8.3 nm for as-synthesized and calcined sample, respectively. TEM images (Fig. 3) also confirm this cubic structure, the cell parameter of calcined sample measured from TEM is 8.0 nm, in good accordance with XRD results. The nitrogen sorption isotherm of the calcined sample is type IV with a slight hysteresis (Fig. 2). The calcined cubic silica structure synthesized by B20-5000 at 40 °C with 1.0 M KCl has a small pore size of 2.4 nm (calculated by the BJH model), a BET surface area of 485 $m^2\ g^{-1}$ and a pore volume of 0.28 $cm^3\ g^{-1}$. We have synthesized large cubic silica mesostructures SBA-16[10] and FDU-1[18] and, in view of the large headgroup ratio of B20-5000, we propose that this cubic structure is similar to that of SBA-16.[10]

In general, the use of inorganic salts in the synthesis of mesoporous materials can give highly ordered structures under very mild conditions. The salt effect provides an alternative and sometimes a required methodology for the synthesis of highly ordered mesoporous materials with certain surfactants that have high CMC values, or in syntheses for which a high temperature is not favored. Using this method, other highly ordered mesoporous materials have been obtained using B40-2500, F98, F108 and F127 as templates. Detailed work will be reported in the future.

From new tricyclic bisaminal derivatives to *trans-N,N′*-disubstituted cyclams

Raphaël Tripier, Jean-Marie Lagrange, Enrique Espinosa, Franck Denat and Roger Guilard*

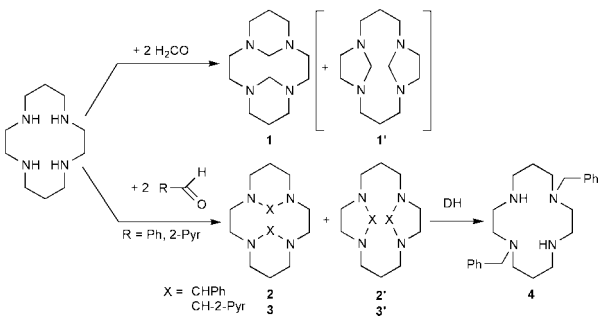
First published as an Advance Article on the web 7th December 2001

The reactivity of cyclam towards different aldehydes is discussed and the new tricyclic bisaminal derivatives thus obtained are characterized by X-ray crystallography; a new synthesis of *trans*-dibenzylcyclam is also reported.

The design and the synthesis of tetraazacycloalkane derivatives have been the subject of growing interest during the past years owing to the ability of such macrocycles to coordinate various metal cations.[1] Among them, cyclam (1,4,8,11-tetraazacyclotetradecane) has been extensively studied. The presence of four secondary amine functions allows unlimited derivatisation of the macrocycle. However, the selective *N*-functionalisation of cyclic polyamines is not obvious and still represents a challenge.[2] For example, the reaction of cyclam with two equivalents of an alkyl or aryl halide yields a mixture of mono-, di-, tri- and even tetrasubstituted macrocycles. Moreover, in the cyclam series, three *N,N′*-disubstituted isomers exist, depending on the relative positions of the pendant arms, *i.e.* two different *cis*-disubstituted derivatives and the [1,8] isomer also called *trans*-disubstituted cyclam. The *trans*-disubstituted cyclams are of special interest since they can lead to hexacoordinated complexes when the substituents are coordinating arms. *trans-N,N′*-diprotected cyclams are also convenient precursors for the synthesis of three-dimensional systems such as cyclam based cryptands.[3] In order to overcome the tedious work-up necessary to isolate the aimed isomer, we have used the *trans* 'autoprotected' cyclam 1,4,8,11-tetraazacyclotetradecane-5,12-dione for the synthesis of several macropolycycles.[4] However, the substituents which can be introduced on the two remaining amine functions are limited to those surviving the conditions required for the reduction of the amide groups. We have recently reported powerful syntheses of *trans*-disubstituted cyclams involving a tricyclic intermediate obtained by refluxing cyclam with a 30% NaOH solution in dichloromethane.[5,6] This bisaminal cyclam can also be obtained by action of aqueous formaldehyde on cyclam.[7,8]

In this paper, we describe the reactivity of cyclam with various aldehydes. The formaldehyde reacts readily at room temperature and yields the most stable macrotricycle **1** containing two six-membered rings (Scheme 1). Surprisingly, no reaction is observed using benzaldehyde instead of formaldehyde under the same conditions. However, refluxing cyclam



Scheme 1

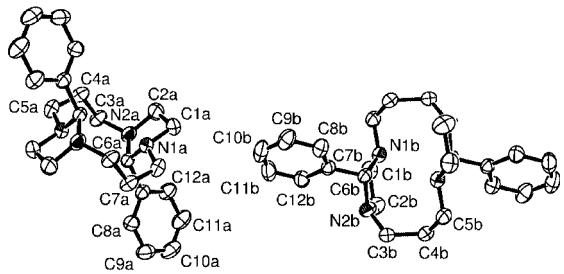


Fig. 1 ORTEP[14] view of **2′**. Ellipsoids are at the 50% probability level. Two half molecules belong to the asymmetric unit.

with three equivalents of benzaldehyde in THF over one week, gives the unexpected bisaminal derivative **2′** containing two five-membered rings as the major product while **2** is the minor derivative.† The two isomers **2** and **2′** are obtained in a 1 : 2 ratio as determined from the ^{1}H NMR spectrum. In these conditions, 2-pyridinecarboxaldehyde (R = 2-Pyr) gives mainly the compound **3**. From these results, it clearly appears that the formation and the structure of the bisaminal compounds are strongly dependent on the nature of the aldehyde as well as on the reaction conditions. We have studied the influence of temperature on the reactivity of cyclam towards 2-pyridinecarboxaldehyde. Ethanol has been chosen as a solvent and the reaction time has been fixed at 24 h. The relative amount of **3** increases with temperature from 50% at 0 °C up to 90% in refluxing ethanol, showing that the macrotricycle containing two six-membered rings is logically the thermodynamic product, while the kinetic product is the isomer containing two five-membered rings **3′**. Consequently, with formaldehyde, which is the most reactive aldehyde among the three tested ones, the compound **1′** should be observable at low temperature. Indeed, cooling down the reaction of cyclam with formaldehyde to −20 °C gives the isomer **1′** in 30% yield, as evidenced by NMR. Compound **1′** readily isomerises into **1** when increasing the temperature. A comparable behaviour of the product of the reaction of glyoxal with triethylenediamine has been observed.[9]

The macrotricycles 15,16-diphenyl-1,5,8,12-tetraazatricyclo[10,2,1,1^{5,8}]hexadecane **2′** and 15,16-dipyridin-2-yl-1,4,8,11-tetraazatricyclo[9,3,1,1^{4,8}]hexadecane **3** have been fully characterized by spectroscopic methods, including 2D NMR experiments, and satisfactory elemental analyses have been obtained. The structures of **2′** and **3** have been established unequivocally by single-crystal X-ray analyses (Figs. 1 and 2).‡ These compounds crystallise with two half molecules belonging to their respective asymmetric unit. In both structures, the two aminal bridges naturally adopt a *trans* conformation. The structure of **3**, in which the two hexahydropyrimidine six-membered rings are in a chair conformation, can be compared to those of **1** or protonated forms of **1** which have been previously reported.[5,7,10] In the solid state, **3** adopts a eq,ax-eq,ax-[2323] conformation like **1**.[8] For steric reasons, the pyridine moieties are in axial positions while the hydrogen atom on each of the two aminal units is equatorial to the six-membered ring.

1	H	2.90[b]	5.45[b]	68.4
1′		n.d.[c]	n.d[c]	88.8
2	Ph	—	6.23	71.9
2′		—	5.23	83.3
3	2-Pyr	—	6.29	72.5
3′		—	5.12	84.4

[a] $CDCl_3$ solvent. [b] Ref. 8. [c] Not determined.

However, the equatorial aminal hydrogen atom is sterically compressed with the lone pair of one nitrogen atom belonging to the other six-membered ring, as discussed previously for compound **1**.[8] The distance between these two atoms in **3** is similar to that reported for **1** (2.26 Å). Consequently, the chemical shift of the equatorial hydrogen atom at rt in $CDCl_3$ is remarkably high (δ = 6.29 ppm) (Table 1). The two phenyl groups in **2′** are also in axial positions and the hydrogen atoms are equatorial to the five-membered rings. The distance between the equatorial hydrogen atom and the closest nitrogen atom is higher than in **3** (2.37 Å) and the equatorial aminal protons in **2′** resonate as a singlet at higher field (δ = 5.23 ppm). It is noteworthy that unlike the protons, the aminal carbon atoms are more deshielded in **2′** and **3′** than in **2** and **3**. To our knowledge, the structure of **2′** gives the first crystallographic evidence of the formation of a cyclam derivative containing two imidazolidine five-membered rings.

Bisaminal derivatives of cyclam are known as convenient precursors for the synthesis of disubstituted cyclams. Indeed, quaternization of two non-adjacent nitrogen atoms of the 1,4,8,11-tetraazatricyclo[9,3,1,1^{4,8}]hexadecane **1** with a suitable alkylating reagent, followed by cleavage of the two aminal bridges with a 3 M NaOH aqueous solution, yields the aimed *trans*-difunctionalised cyclam.[5,6] In particular, Kaden has shown that reductive cleavage of the bisaminal **1** with Raney-Ni in liquid NH_3 yields a mixture of *trans* and *cis* dimethylcyclam.[11] We have studied the reduction of the new bisaminal cyclams with $NaBH_4$. For instance, the treatment of the crude mixture of the isomers **2** and **2′** with a large excess of $NaBH_4$ in refluxing EtOH, gives the *trans*-dibenzylcyclam **4** in 38% yield. Thus, the 1,8-dibenzylcyclam is obtained in a reasonable overall yield (31%). This *trans* diprotected cyclam might be used as a precursor for various *trans* difunctionalised cyclams, since many functional groups can survive the mild conditions required for the removal of the benzyl moieties. This approach represents an alternative route to the known methods.[2]

The results reported herein show how the cyclic structure of cyclam might confer to this tetraamine a peculiar behaviour towards different aldehydes. For the first time, cyclam bisaminal type compounds containing *a priori* unfavourable five-membered imidazolidine rings have been obtained. In order to further study the effects governing the formation of the bisaminal derivatives, and also to extend the scope of this reaction to the preparation of new ligands, the reactivity of other aldehydes towards cyclam is now under investigation.

Formation of different framework structured dimeric dianions formed from the reduction of 2,4,6-tricyano-1,3,5-triazine and 1,3,5-tricyanobenzene†

Rico E. Del Sesto, Atta M. Arif and Joel S. Miller*

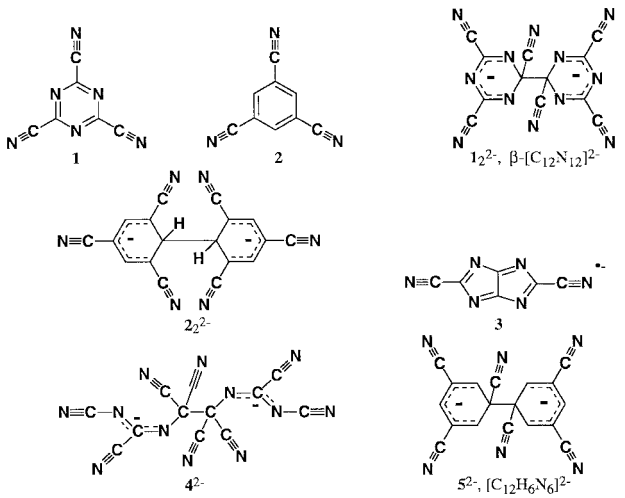
Department of Chemistry, University of Utah, 315 S. 1400 E. RM 2124, Salt Lake City, Utah, 84112-0850, USA. E-mail: jsmiller@chemistry.utah.edu

Received (in Corvallis, OR, USA) 11th September 2001, Accepted 15th October 2001
First published as an Advance Article on the web 28th November 2001

Reduction of 2,4,6-tricyano-1,3,5-triazine (1) and 1,3,5-tricyanobenzene (2) leads to dianionic dimers with long, ~ 1.57 Å, central C–C bonds. In contrast to 1, which dimerizes at the nitrile substituted carbon, 2 has a different motif as it dimerizes at the hydrogen substituted carbon.

Polynitrile substituted organic molecules are strong electron acceptors that have enabled the development of molecule-based conductors[1] and magnets.[2] For the latter, reduced radical-anionic nitriles can coordinate to metal centers to build covalently bonded extended structures in 1-, 2-, and 3-D.[2] New, reduced polynitrile acceptors may lead to new structure types and new properties. The 2,4,6-tricyano-1,3,5-triazine (**1**) and 1,3,5-tricyanobenzene (**2**) polynitriles have not received much attention. Their D_{3h} symmetry presents the opportunity for building extended 2- and 3-D network structures. Furthermore, upon reduction the radical anion may lead to new magnetic materials, including interesting ferrimagnetic and spin-frustrated systems if all three nitriles (or triazine nitrogens) coordinate to a spin-bearing metal center.

A previous attempt to form $\mathbf{1}^{\cdot-}$ by reduction with sodium and potassium led to the speculation that $\mathbf{3}^{\cdot-}$ was formed through rearrangement of the radical anion $\mathbf{1}^{\cdot-}$[5] based upon the ^{14}N splitting in the EPR spectra suggesting a set of 4 equivalent nitrogens and a second set of two equivalent nitrogens, which is consistent with $\mathbf{3}^{\cdot-}$ and not $\mathbf{1}^{\cdot-}$. Expecting that $\mathbf{3}^{\cdot-}$ was unlikely based upon mechanistic considerations, we sought $\mathbf{1}^{\cdot-}$ or its ensuing species *via* electron transfer reactions under milder reduction conditions.



The electrochemistry of **1** shows a cathodic peak at −0.39 V, which shows no reversibility at scan rates from 5–2000 mV s^{-1}. Additionally, an irreversible anodic oxidation is seen at +0.70 V, but appears only after the first pass through the reduction.

† Dedicated to Michael Hanack on the occasion of the 70th birthday.

Unable to isolate any species *via* electrochemical methods, **1** was reacted with the strong electron donor $Cr^o(1,3,5\text{-}C_6H_3Me_3)_2$, $Cr(Mes)_2$, [$E^\circ_{1/2}$ = −0.92 V vs. SCE],[4] which led to the formation of $[Cr(Mes)_2]_2\mathbf{1}_2$‡ composition, whose structure§ consists of the σ-dimer of $\mathbf{1}^{\cdot-}$, β-$[C_{12}N_{12}]^{2-}$, $\mathbf{1}_2^{2-}$ (Fig. 1). This is an isomer of {(1,1,2,2-tetracyano-1,2-ethanediyl)bis[imino-(cyanomethylene)]}bis[cyanamide] ion(2−) $\mathbf{4}^{2-}$, α-$[C_{12}N_{12}]^{2-}$, a linear form of $[C_{12}N_{12}]^{2-}$ previously reported.[5] The central C39–C40 bond of $\mathbf{1}_2^{2-}$ is 1.57 Å. Albeit slightly longer than a typical C–C σ bond it is in excellent agreement with 1.58 Å observed for the central C–C bond in α-$[C_{12}N_{12}]^{2-}$.[5] Examples of bond lengths within the ring are 1.463 Å for C39–N2, 1.467 Å for C39–N3, 1.285 Å for C37–N3, 1.348 Å for C37–N1, 1.350 Å for C38–N1, and 1.289 Å for C38–N2. The longer bond lengths to C39/C40 and shorter bonds to N3/N5 indicate that the anionic charge is localized on the outer half of the ring. However, the rings maintain their planarity, and the ring bond angles around central C′s (C39 and C40) range from 106 to 118.5° indicating that they still maintain some sp^2 character. The two rings are twisted 67° about the C39–C40 bond, as defined by the C45–C39–C40–C46 torsion angle.

The $\upsilon_{C\equiv N}$ absorptions in **1**° are at 2302w, 2276m, 2255s cm^{-1}, but occur only as a very weak peak at ~2245 cm^{-1} in $\mathbf{1}_2^{2-}$. The ring C=N aromatic stretch occurs at ~1520 cm^{-1} for **1**° that increases to ~1590 cm^{-1} upon reduction and dimerization. The minimal change in the $\upsilon_{C\equiv N}$ frequency and 70 cm^{-1} shift in the $\upsilon_{C=N}$ also indicate that the anionic charge is localized within the ring.

EPR studies of $\{[Cr(mes)_2]^+\}_2[\mathbf{1}]_2^{2-}$ show only an absorption at g = 1.990, characteristic of bis(aryl)chromium(I) cations, *e.g.* g = 1.9859 for $[Cr^I(C_6H_6)_2]^{\cdot+}$.[6] The temperature dependence of the magnetic susceptibility, χ, shows typical Curie-Weiss behavior, $\chi \propto (T - \theta)^{-1}$, with an effective

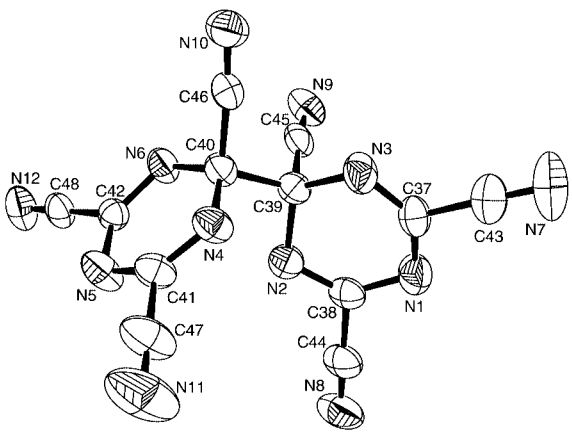


Fig. 1 ORTEP drawing (50%) of, $\mathbf{1}_2^{2-}$ in $\{[Cr(mes)_2]^+\}_2\mathbf{1}_2^{2-}$. Bond lengths are 1.463(3) Å for C39–N2, 1.467(3) Å for C39–N3, 1.285(3) Å for C37–N3, 1.348(3) Å for C37–N1, 1.350(3) Å for C38–N1, and 1.289(3) Å for C38–N2.

 DOI: 10.1039/b108297n

moment of 2.40 μ_B between 20 and 300 K, and a θ value of −8 K. This is consistent with two independent S = 1/2 spins arising from the two Cr^I centers per formula unit, with a *g*-value of 1.990, which would have the expected room temperature effective moment of 2.43 μ_B.

The previously reported electrochemical reduction of 1,3,5-triazine results in this same dimerization[7] producing the C–C σ-dimer, $[C_6H_6N_6]^{2-}$, which could be isolated after proton abstraction from an aqueous solution, and characterized by NMR.

Similar irreversible electrochemical behavior was reported for **2**,[8] which exhibits an irreversible reduction at −1.35 V *vs.* SCE in MeCN, and an anodic irreversible oxidation at −0.03 V.[8] It was speculated that **2** was reduced to the dianion, $\mathbf{2}^{2-}$, which then reacts with a second **2**° to form $\mathbf{5}^{2-}$, which would be isostructural with the previously discussed $\mathbf{1}_2{}^{2-}$.

However, reduction of **2** with $Co^{II}Cp^*_2$¶ (Cp* = pentamethylcyclopentadienide), [$E^\circ_{1/2}$ = −1.47 V],[4] led to the isolation of $[Co^{III}Cp^*_2]\mathbf{2}$, whose crystal structure‖ reveals the formation of the σ-dimer of $\mathbf{2}^{\cdot-}$ involving the *unsubstituted* ring carbons, $[C_{18}H_6N_6]^{2-}$, $\mathbf{2}_2{}^{2-}$ (Fig. 2), with the central C50–C50′ distance at 1.56 Å, comparable to $\mathbf{1}_2{}^{2-}$. The C50 carbons are sp^3 hybridized with all bond angles averaging 109.4°. Bond lengths within the benzene rings are C50–C51 1.509 Å, C51–C52 1.362 Å, C52–C53 1.424 Å, C53–C54 1.405 Å, C54–C55 1.364 Å, and C55–C50 1.523 Å.

Dimerization of $\mathbf{1}^{\cdot-}$ occurs at the substituted ring-C rather than at the ring-N, most likely due to formation of the more energetically stable C–C bond (*ca.* 200 kJ mol^{-1}) with respect to an N–N bond.[9] However, $\mathbf{2}^{\cdot-}$ dimerizes at the unsubstituted ring carbon, analogous to the radical cation of tris(dimethylamino)benzene, which also forms dimers at the unsubstituted carbon.[10] Studies of the reaction of the $\mathbf{2}^{\cdot-}$, *via* photoinduced electron transfer (*in situ* production of $\mathbf{2}^{\cdot-}$), with benzyl[11] and alkyl[12] neutral radicals yielded major products of the benzyl/alkyl substituted **1** at the unsubstituted carbon as well. In both cases, the reactivity of $\mathbf{2}^{\cdot-}$ at the unsubstituted carbon was attributed to the spin density being highest at those carbons, hence dimerization of the radical anion at these carbons as well. This behavior is similar to that of the 1,3,5-tripyrrolidinobenzene, which also dimerizes upon reduction at the unsubstituted carbon.[13]

The $\{[Co^{III}Cp^*_2]^+\}_2\mathbf{2}_2{}^{2-}$ is EPR silent at room temperature, and is diamagnetic at 20 and 300 K consistent with S = 0 Co^{III} and S = 0 dimerized organic radicals.

Analogous to the $\mathbf{1}_2{}^{2-}$ and $\mathbf{2}_2{}^{2-}$, similar types of σ-dimers have been reported for TCNE[14] and TCNQ[15] radical anions. In both cases, the σ-bond can undergo hemolytic cleavage by thermolysis yielding the original individual radical anions.[14–16]

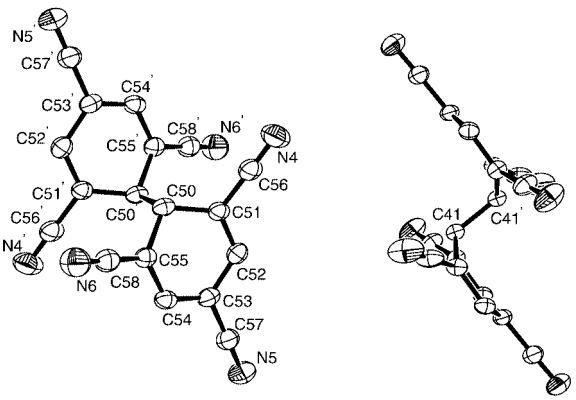

Fig. 2 ORTEP drawing (50%) of $\mathbf{2}_2{}^{2-}$ in $\{[Co^{III}Cp^*_2]^+\}_2\mathbf{2}_2{}^{2-}$. Bond lengths within the benzene rings are C50–C51 1.509(4), C51–C52 1.362(4), C52–C53 1.424(4), C53–C54 1.405(4), C54–C55 1.364(3), and C55–C50 1.523(3) Å.

The isolated electron transfer complexes suggest that the formation of a stable radical anion of $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$ is not favorable, as they undergo dimerization to produce the closed-shell dianions, $\mathbf{1}_2{}^{2-}$ and $\mathbf{2}_2{}^{2-}$, respectively. Although $\mathbf{1}^{\cdot-}$ was not isolated, these results suggest that some type of molecular rearrangement or reaction, possibly through an intermediate similar to the isolated $\mathbf{1}_2{}^{2-}$, is responsible for the unexpected EPR signal seen in the reduction of **1** by Carrington and coworkers.[3]

A novel and economical route to (±)-horsfiline using an aryl iodoazide tandem radical cyclisation strategy

Dimitrios Lizos, Régis Tripoli and John A. Murphy*

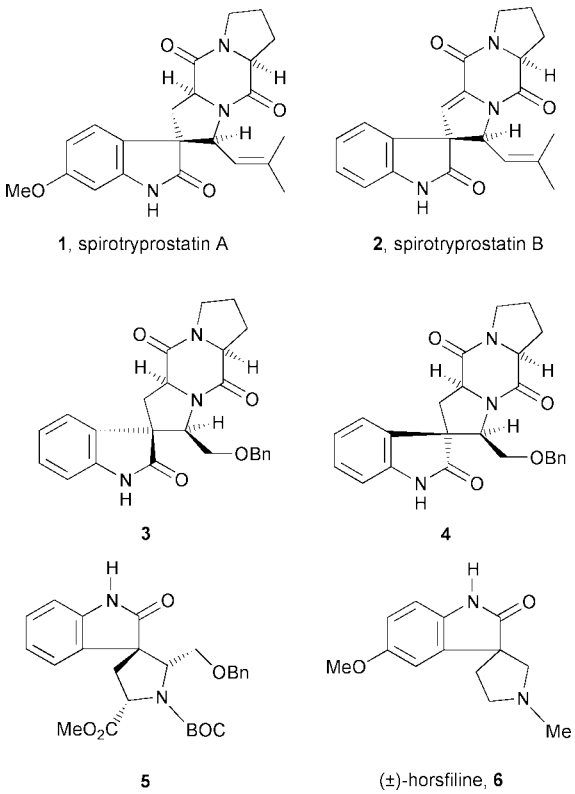
Department of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, UK G1 1XL. E-mail: john.murphy@strath.ac.uk; Fax: +44 141 548 4822; Tel: +44 141 548 2389

Received (in Cambridge, UK) 24th September 2001, Accepted 23rd October 2001
First published as an Advance Article on the web 29th November 2001

(±)-Horsfiline has been synthesised using a tandem radical cyclisation as the key step.

The spiropyrrolidinyloxindole nucleus is found in a number of natural products of diverse origin. However, despite their attraction as synthetic targets, the biological profile of these compounds was not exciting—until recently. The recent discovery of more members of this family such as spirotryprostatin A (**1**) and spirotryprostatin B (**2**) caused an increased interest, because they showed *mild* activity as cell-cycle inhibitors,[1] since cell-cycle inhibition frequently equates with *in vitro* anti-cancer activity. However, the crucial discovery was in 1999, when Danishefsky *et al.* showed[2] that unnatural analogues (**3**–**5**), synthesised in the laboratory, were truly potent inhibitors of at least one human breast cancer cell line [more than four orders of magnitude more powerful than spirotryprostatin A itself].

With this as background, we set ourselves the task of finding a new and flexible approach to the synthesis of the spiropyrrolidinyloxindole nucleus, and now present our route, which features a tandem radical cyclisation approach as the key step, in the synthesis of one member of the natural spiropyrrolidinyloxindoles, horsfiline (**6**). Horsfiline[3] has been synthesised by a number of research groups[4–9] using diverse methodologies; the synthesis of Jones and Wilkinson[4] deserves particular mention here since it also used a radical cyclisation approach, although very different from our own. Specifically, our approach features the aryl iodoazide[10] tandem radical cyclisation strategy, which we have recently used to prepare the complex alkaloid, (±)-aspidospermidine.[11]



1, spirotryprostatin A **2**, spirotryprostatin B

3 **4**

5 (±)-horsfiline, **6**

Scheme 1

The starting materials for our synthesis are the commercially available and economical compounds, itaconic acid and *p*-anisidine. Double deprotonation of *t*Boc-protected *p*-anisidine **7** (prepared in 91% yield from *p*-anisidine) with *t*-BuLi and reaction with 1,2-diiodoethane afforded the iodide **8** (86%).[12] Deprotection of the *t*-Boc group (89%) and reductive amination with benzaldehyde yielded the required *N*-benzyl derivative **10** (95%). Meanwhile, selective esterification of itaconic acid[13] (82%) and then conversion to the acid chloride **11**, was followed by coupling to the amine **10**, affording amide **12** in 94% yield from the mono-acid. The plan was now to convert this compound to the corresponding azide **18**. Direct reduction of **12** with DIBAL-H yielded alcohol **13**; however, this appeared to be contaminated by, and was inseparable from, the methyl derivative **14** that would result from conjugate addition of DIBAL-H at the α,β-unsaturated amide group. This complication was avoided by protecting the alkene in **12** by conjugate addition of thiophenol. The resulting sulfide **16** (96%) was then reduced to afford the alcohol **17** (55%). [Unexpectedly, this reaction also produced a small amount of amine **15**.] Oxidation of the sulfide and thermal elimination of the resulting sulfoxide yielded the desired alcohol **13** (72%), which was smoothly converted to the azide **18** (68%) with diphenylphosphoryl azide.[14] Cyclisation with tris(trimethylsilyl)silane (TTMSS) followed by *in situ* methylation afforded[15] the tricycle **20** (60% over 2 steps). Finally, this was debenzylated[7,9] to afford horsfiline **6** (87%).

This simple approach to horsfiline illustrates that the aryl iodoazide tandem radical cyclisation strategy[11] is a powerful methodology for accessing the important spiropyrrolidinyloxindole nucleus.

We thank the EPSRC Mass Spectrometry Service Centre, Swansea, for mass spectra, the University of Strathclyde for University studentships (D. L. and R. T.) and the Royal Society for a Leverhulme Senior Research Fellowship (JAM).

$(silox)_3RePMe_3$ (silox = $^tBu_3SiO$) is carbonylated to the double insertion product $(silox)(Me_3P)\{cis\text{-}(CO)_2\}Re\{trans\text{-}(CO_2Si^tBu_3)_2\}$

Adam S. Veige, Peter T. Wolczanski* and Emil B. Lobkovsky

Cornell University, Baker Laboratory, Department of Chemistry & Chemical Biology, Ithaca, New York, USA 14853. E-mail: ptw2@cornell.edu

Received (in Purdue, IN, USA) 30th August 2001, Accepted 6th November 2001
First published as an Advance Article on the web 6th December 2001

A rare example of the migratory insertion of a O-bound ligand, OSi^tBu_3, to a carbonyl occurred in the carbonylation of $(silox)_3RePMe_3$ to afford the double insertion product $(silox)(Me_3P)\{cis\text{-}(CO)_2\}Re\{trans\text{-}(CO_2Si^tBu_3)_2\}$.

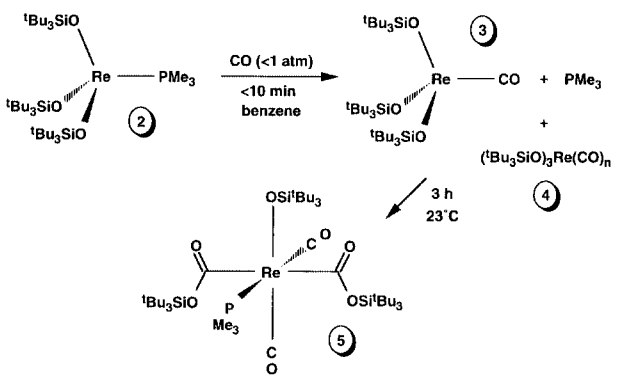
Investigations of low coordinate, low valent monomeric and dimeric early transtion metal complexes have been aided by the use of the bulky ancillary siloxide ligand, $^tBu_3SiO$ (silox).[1,2] During nearly 20 years of study, in only one case has silox directly participated in the observed chemistry, shuttling from one tungsten to the other in the conversion of $[(silox)_2W(CO)]_2$ to $(silox)_3WW(silox)(CO)_2$.[3] During the course of carbonylating a rhenium siloxide derivative, evidence of two formal CO insertions into Re–OSi^tBu_3 bonds was obtained. The insertion of CO into any metal–heteroatom bond is unusual, and the modest number of L_nMCO_2R isolated,[4–10] observed,[11] or inferred[12,13] from carbonylation reactions are mostly late transition metal compounds;[4–11] double insertions have not been discovered.

Reduction of $(silox)_3ReCl_2$ **1**[14] by Na/Hg in neat PMe_3 afforded $(silox)_3RePMe_3$ **2** in 57% yield upon crystallization from hexanes [eqn. (1)]. Green **2** is diamagnetic, as expected for

$$(silox)_3ReCl_2 \xrightarrow[-2\ NaCl]{Na/Hg,\ PMe_3} (silox)_3RePMe_3 \qquad (1)$$
1 **2**

a C_{3v} (e^4, $^1A_1$) molecule, and exhibited resonances at δ 1.22 and 1.38 (J_{PH} 10.4 Hz) in its ^1H NMR spectrum corresponding to the silox and PMe_3 protons, respectively.†

As shown in Scheme 1, within 10 min carbonylation of $(silox)_3RePMe_3$ **2** generated free PMe_3 and a mixture of silox–carbonyl complexes, $(silox)_3Re(CO)_x$. One strong IR absorption at 1851 cm^{-1} was observed accompanied by several weaker absorptions at 2018, 1932, 1881 and 1807 cm^{-1}; all shift to 1805 cm^{-1}, and 1960, 1891, 1836 and 1770 cm^{-1} when ^{13}CO was employed. Crystallization from hexanes afforded dark green $(silox)_3ReCO$ **3**, [ν(CO) 1851 cm^{-1}, $^{13}C\{^1H\}$ NMR, δ 195.37] in 79% yield. An X-ray crystal structure determination of **3** confirmed its C_{3v}, monocarbonyl structure (Fig. 1), but the data quality only permitted isotropic refinement.‡ Normal



Scheme 1

distances [d(ReO) = 1.852(14) Å (av.), d(SiO) = 1.676(10) Å (av.), d(ReC) = 1.842(17) Å, d(CO) = 1.21(2) Å] are observed, but the angles [$\angle$(O–Re–O) = 117.2(15)° (av.), $\angle$(O–Re–C) = 99.7(29)° (av.)] reflect a distortion toward trigonal monopyramidal (tmp) coordination from tetrahedral. While intersilox repulsions are the probable cause, there is also a subtle electronic advantage to the tmp geometry derived from π-bonding. The remaining IR bands in the original mixture are considered to belong to the carbonyls of $(silox)_3Re(CO)_n$ **4** (n > 1). It is probable that **3** and free CO are in equilibrium with **4**, since a single broad resonance is observed for the silox ligand in the ^1H NMR spectrum of the mixture, and $(silox)_3Re^{13}CO$ (**3**-^{13}C) rapidly exchanges with CO.

Continued monitoring of the solution containing $(silox)_3RePMe_3$ **2** and CO revealed the growth of a new compound **5** at the expense of $(silox)_3ReCO$ **3** and $(silox)_3Re(CO)_n$ **4**. A 2:1 ratio (δ 1.29: δ 1.41) of siloxides was determined by ^1H NMR spectroscopy, and a new PMe_3 resonance was observed at δ 1.22 (J_{PH} 9.2 Hz). Interestingly, the IR spectrum of **5** revealed three CO absorptions at 2024, 1935 and 1631 cm^{-1}. Clearly a type of acyl was present in **5**, and the higher terminal CO frequencies indicated significant competition for π-electron density on Re. The $^{13}C\{^1H\}$ NMR spectrum of **5** corroborated the inequivalent siloxides, and revealed three additional resonances at δ 183.85 (J_{PC} 4.6 Hz), 188.45 (J_{PC} 100.7 Hz) and 198.80 (J_{PC} 8.3 Hz). The large J_{PC} and low frequency CO absorption forced consideration of a phosphaacyl, –$COPMe_3$, but a search of the Cambridge Crystallographic Database revealed no analogous compounds, and it seemed unlikely that carbonyls on a *tris*-silox rhenium(III) fragment would be sufficiently electrophilic to incur formation of a zwitterionic phosphaacyl complex. In addition, the $^{31}P\{^1H\}$ NMR spectrum of **5** revealed a δ −5.58 resonance consistent with a Re–PMe_3 bond.

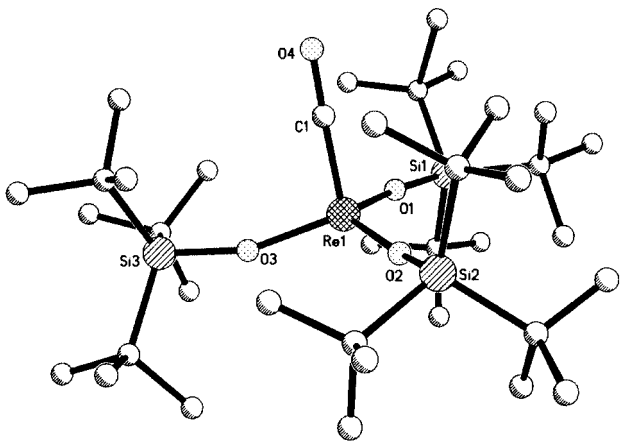


Fig. 1 Molecular view of $(silox)_3ReCO$ **3**. Since the J_{PC} 100 Hz could be assigned to a large *trans*-P–Re–^{13}CO coupling, a CO insertion to form a siloxy–acyl ligand, $CO_2Si^tBu_3$, was considered. An X-ray structural study of (silox)(Me_3P){*cis*-$(CO)_2$}Re{*trans*-$(CO_2Si^tBu_3)_2$} **5** corroborated this possibility, and proved fully consistent with the spectral data.†‡ As Fig. 2 reveals, **5** possesses *trans*-siloxyacyl ligands and *cis*-CO ligands, one *trans* to a PMe_3 and one *trans* to the remaining siloxide. The environment is pseudo-octahedral, with ∠(O3–Re–CO) = 94.6(3), 171.5(3)°, ∠(OC–Re–CO) = 93.7(3)°, ∠(P–Re–CO) = 84.8(2), 176.8(2)°, and ∠(P–Re–O3 = 86.9(2)°. The silacarboxylates are tipped away from the bulky siloxide [∠(O3–Re–C3) = 104.0(2)°, ∠(O3–Re–C16) = 107.9(2), ∠(C3–Re–C1) = 76.0(2)°, ∠(C16–Re–C1) = 74.8(3)°] and PMe3 [∠(P–Re–C3) = 101.2(2)°, ∠(P–Re–C16) = 95.7(2)°, ∠(C3–Re–C2) = 81.1(3)°, ∠(C16–Re–C2) = 81.2(2)°] ligands. From the perspective of covalent radii, the rhenium–silacarboxylate distances are somewhat long [d(Re–C_{ac}) = 2.077(6), 2.078(5) Å], belying the acyl CO stretch that suggests significant π-back-bonding into this unique ligand.

The remaining distances are rather normal, although the d(Re–O) of 2.032(5) Å is long when compared to systems that favor O(pπ)→M(dπ) interactions.[1–3,14] Clearly the d^4 rhenium mitigates the usual strong π-donor tendencies of the siloxide. Taking the Re–O_3 bond as the z axis, and Re–P in the xz plane, it is likely that d_{xy} and d_{xz} are filled, leaving d_{yz} as the lone receptor orbital for π-donation from the siloxide. Sterics must also play a role in limiting the interaction, as the bulk of the silox is clearly tipped away [∠(Re–O3–Si3) = 157.4(3)°] from the PMe_3 and into the space above the acyl oxygens and a carbonyl. Back-bonding into the silacarboxylates and CO by the filled d_{xy}, and into the two carbonyls by d_{xz}, provides the competition for electron density that renders the CO stretches relatively high. When exposed to ^{13}CO, the CO opposite the PMe_3 ligand was identified as the most labile.

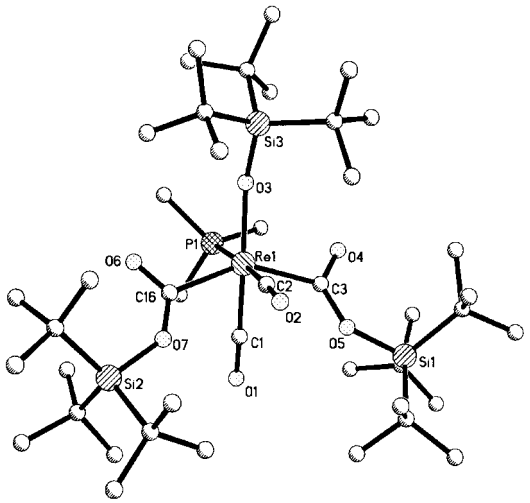

Fig. 2 Molecular view of (silox)(Me_3P){*cis*-$(CO)_2$}Re{*trans*-$(CO_2Si^tBu_3)_2$} **5**. Selected (see text) interatomic distances (Å) and angles (°): Re–C1 1.934(11), Re–C2 1.965(10), Re–P 2.486(3), Si1–O5 1.698(4), Si2–O7 1.691(4), Si3–O3 1.637(5), C1–O1 1.150(9), C2–O2 1.141(8), C3–O4 1.215(7), C3–O5 1.339(9), C16–O6 1.214(8), C16–O7 1.314(8); C3–Re–C16 144.5(3), Re–C3–O4 108.8(5), Re–C16–O6 111.2(4), Re–C3–O5 125.4(4), Re–C16–O7 123.7(4), C3–O5–Si1 134.1(3), C16–O7–Si2 137.3(4).

Presumably the weakening of D(M–OR) in moving to the late metals enables CO insertion to be favorable, because there is no kinetic reasoning that suggests it is intrinsically slow. Consistent with the thermodynamic reasoning is the observation of H(silox) loss from (silox)$_3$RePMe$_3$ **2** upon hydrogenation. The mechanism of CO insertion, whether internal[4–7] or external[9,11] [*i.e.* L_n(silox)Re + CO → {L_nReCO}$^+$[OSi^tBu_3]$^-$ → L_nRe-$CO_2Si^tBu_3$], is currently unknown, but it is likely that the unfavorable sterics of a (silox)$_3$Re$(CO)_x(PMe_3)_y$ ($x + y$ = 2–4) carbonyl derivative would favor insertion to relieve strain about the Re core.

First published as an Advance Article on the web 6th December 2001

The longest wave absorption band of the tetramethylthiotetrathiafulvalene cation radical, which is usually interpreted as a π-dimer band, is shown to be the intrinsic cation radical absorption, all studied cation radicals in solution at room temperature exist as paramagnetic monomers and only tetrathiafulvelene and tetramethyltetrathiafulvalene cation radicals undergo π-dimerization at low temperatures.

Currently, the alleged ability of stoichiometric cation-radical salts derived from tetrathio substituted tetrathiafulvalene (TTF) to form π-dimers at room temperature is widely viewed as a proof of the presence of significant intramolecular interactions between the oxidized TTF moieties within a number of supramolecular structures.[1–3] Although NIR absorption bands of a number of tetrachalcogeno TTF cation radicals were ascribed to intrinsic absorptions,[4] the band at *ca*. 850 nm observed in solutions of tetramethylthiotetrathiafulvalene (TMT-TTF) cation radicals is interpreted as the 'π-dimer signature' and, moreover, it has even been claimed that in solution, cation radicals exist only in dimerized diamagnetic form.[5] Here we present the results of our studies unequivocally demonstrating that the above interpretation, based exclusively on analogies is doubtful and that the cation radicals derived from TTF, tetramethyl TTF (TMTTF), TMT-TTF and bis(ethyleneditio) TTF (ET) exist in monomeric paramagnetic form, at least at room temperature.

Formation of π-dimers from ion radicals can easily be monitored by appearance of a new long-wave absorption band (red-shifted from the longest-wave absorption band of the ion-radical) and deviation of the EPR signal intensity from the Curie Law with eventual disappearance of the EPR signal. For TTF derivatives, appearance of a long-wave band in the absorption spectrum of 3,9(10)-dimethyldibenzo $TTF^{\cdot+}$ upon increasing the concentration or decreasing the temperature in acetonitrile, was interpreted as formation of π-dimers.[6] However, no dimerization has been observed for the cation radicals of TTF itself and dibenzo TTF in acetonitrile when cooled to the point when crystallization occurred. The complete change in absorption spectra for $TTF^{\cdot+}$ in ethanol was observed only at 225 K (10^{-3} M solution)[7] and 77 K (10^{-5} M solution)[8] and, although no EPR studies have been made in this case, the interpretation was confirmed by comparison with the solid state spectra. At room temperature, no dimers in 10^{-3} M solutions of $TTF^{\cdot+}$ were present.[8] The above examples of two derivatives differing only by the presence of two methyl groups, dibenzo $TTF^{\cdot+}$ (which does not undergo dimerization) and 3,9(10)-dimethyldibenzo $TTF^{\cdot+}$ (which dimerizes at temperatures close to the room temperature) show that the ability of cation radicals to form π-dimers can depend on quite minor structural changes and, probably, reflects the propensity of a cation radical to form dimers in the solid state.

Unfortunately in the case of $TMT\text{-}TTF^{\cdot+}$, an obviously erroneous absorption spectrum has been reported in the paper describing its first synthesis: 461 nm was given as a longest wave absorption maximum.[9] This paper and the misleading analogy with $TTF^{+\cdot}$, became a source of numerous misinterpretations,[1–3,5,10] whereas the later paper with the correct data[11] (850 nm) remained unnoticed.

The non-stoichiometric salts of TTF are usually less soluble than the stoichiometric ones and often precipitate upon chemical or electrochemical oxidation of the TTF derivatives, a fact that makes the isolation of the pure stoichiometric salts difficult. Recently, we developed an efficient and convenient synthetic procedure for preparation of TTF derived cation radicals involving oxidation by iodobenzene diacetate and a strong acid.[12] This enabled us to reinvestigate the spectroscopic solution behavior of TTF derived cation radicals.

Let us first consider the electronic absorption spectra. UV/Vis/NIR spectra recorded at room temperature for solutions of cation radicals in acetonitrile, methylene chloride and ethanol at various concentrations (10^{-3}–10^{-5} M) in the range of 250–2000 nm are in accord with the published data.[4a,6,7,8,11] Interestingly, the spectra are practically concentration and counter-anion independent (Cl, BF_4, tosylate and CF_3SO_3 anions have been checked so far) and only small shifts of absorption maxima (about 2–5 nm) have been observed in acetonitrile, methylene chloride and ethanol, whereas the general shape of absorption bands remains virtually the same. All spectra are also temperature independent within the experimental error. Considerable bathochromic shifts of the longest-wave absorption bands are observed in the series $TTF^{\cdot+}$, $TMTTF^{\cdot+}$, $TMT\text{-}TTF^{\cdot+}$, $ET^{\cdot+}$ (Table 1). This phenomenon is predictable: an energy change diagram showed that even a single alkylthio substituent attached to the TTF moiety interacts

Table 1 Calculated (TD B3LYP/6-31G**//HF/6-31G**) and experimental longest wave absorption maxima for the cation radicals of TTF, TMTTF, TMT-TTF and ET

Cation radical	Calculated λ_{max}/nm (oscillator strength)	Calculated λ_{max} (nm) (oscillator strength)[a]	Experimental λ_{max}/nm (ε)[b]
$TTF^{\cdot+}$	509 (0.070)	556 (0.05)	580 (4,200)
$(TTF_2)^{2+}$	753 (0.280)	—	714 (EtOH)[7]
$TMTTF^{\cdot+}$	567 (0.123)	—	652 (7,400)
$MeSTTF^{\cdot+}$	729 (0.083)	—	785[13]
$TMT\text{-}TTF^{\cdot+}$	711 (0.043)	—	843 (9,700)
$ET^{\cdot+}$	956 (0.185)	867 (0.28)	954 (10,500)

[a] From ref. 4*a*, calculated by the LNDO/S PERTCI method using the experimental geometry (TTF) and HF/6-31G** geometry (ET). [b] In acetonitrile, room temperature.

 DOI: 10.1039/b104934h

mostly with the HOMO^{-1} and not with the HOMO[14] (in the LCBO-MO approximation) and, since the long wave absorption band of TTF cation radical is mainly a HOMO–SOMO transition, *a strong bathochromic shift* for the alkylthio substituted TTF cation radicals is anticipated. This simplified consideration is fully confirmed by higher-level calculations.[15] Geometries of the cation radicals have been optimized on the Hartree–Fock level using the 6-31G** basis set, which has been shown to reproduce the experimental geometry of ET$^{\cdot+}$ within 0.02 Å error.[16] We found that the geometries of other derivatives are reproduced at this level within the same error, whereas the DFT method gave poor results. Noteworthy, geometry optimization of $(TTF_2)^{2+}$ gave the energy minimum at the distance of 3.5 Å between the planes of the slightly distorted TTF molecules, *i.e.*, close to the experimental in solid state, whereas optimization failed for $(TMT\text{-}TTF_2)^{2+}$. The absorption spectra (Table 1) have been calculated using time-dependent density functional theory (TDDFT), which has been demonstrated to afford accurate predictions for neutral molecules and radicals‡ (see ref. 17 and refs. therein). The low energy absorption of methylthio TTF$^{+\cdot}$ (MeSTTF$^{+\cdot}$) is predicted at 729 nm in a reasonable agreement with the experimental value of 785 nm for the dihydrothieno-fused analog.[13] Noteworthy, this band was also ascribed to the π-dimer solely on the grounds of concentration dependence that might stem from any other kind of intermolecular interaction rather than from π-dimerization, as soon as no temperature/concentration anomalies of the EPR signal and appearance of the new π-dimer absorption bands were reported.

Concentrated solutions ($>10^{-3}$ M) of the cation radicals exhibit features of aggregation (intensities of additional absorption bands are *counteranion and concentration dependent*). Spectroscopic features of such solutions will be discussed elsewhere.

Although the theoretical considerations and UV/VIS/NIR spectroscopy results discussed above mean that the probability of cation radical dimerization at room temperature is very small, the direct proof can only be provided by EPR measurements at different temperatures. Our experiments show that all studied cation radicals exhibit strong EPR signals (1 spin per molecule within *ca*. 30% of the experimental error) at room temperature in concentrated (*ca*. 5×10^{-4}) solutions in acetonitrile and ethanol. The *g*-factors of 2.0080, 2.0078 and 2.0075 were found for the cation radicals of TTF, TMT-TTF and ET, correspondingly, in ethanol at 300 K.§ The coupling constant of ^{33}S (0.380 mT, 4S) determined for TMT-TTF$^{\cdot+}$ is close to the value (0.370)[18] found for ET$^{\cdot+}$.

The temperature dependence of the EPR signals was studied for the TTF and TMT-TTF cation radicals in ethanol. The intensity of the EPR signal from TTF$^{\cdot+}$ obeyed the Curie Law up to 265 K and disappearance of the signal at 220 K together with the reported changes in absorption[7] can be safely interpreted as proof for the formation of π-dimers (Fig. 1). Essentially the same trend was observed in methylene chloride and acetonitrile, although the lower solubility in the former and relatively high melting point of the latter make these solvents less suitable.

Owing to a sharper dependence of TMT-TTF$^{\cdot+}$ solubility on temperature, this salt crystallized out of the solution (10^{-4} M) already at *ca*. 280 K, however, above this temperature the Curie Law was obeyed. In more dilute solution (10^{-5} M), crystallization occurred at *ca*. 230 K and at 190 K the signal was still present (Fig. 1). Crystallization of TMT-TTF$^{\cdot+}$ during measurements is also confirmed by the strong temperature hysteresis that was practically absent in the case of TTF$^{\cdot+}$. No other signals in the region of $g \sim 2$ and $g \sim 4$ were detected.

In conclusion, we find that all studied cation radicals in solution at room temperature exist as paramagnetic monomers. The assertion is based on electronic absorption spectra, which are concentration independent in a wide range of concentrations and the presence of a strong EPR signal. The EPR measurements at different temperatures confirm formation of π-dimers for TTF$^{\cdot+}$ below 265 K. No dimerization for TMT-TTF$^{\cdot+}$ was observed up to crystallization at 280 K and 230 K, depending on the concentration. In this case, the paramagnetic monomers were present even at 190 K. Although π-dimerization could be favored in linked analogs,[1–3,5] the reported spectral features fully correspond to those expected for the free cation radicals.

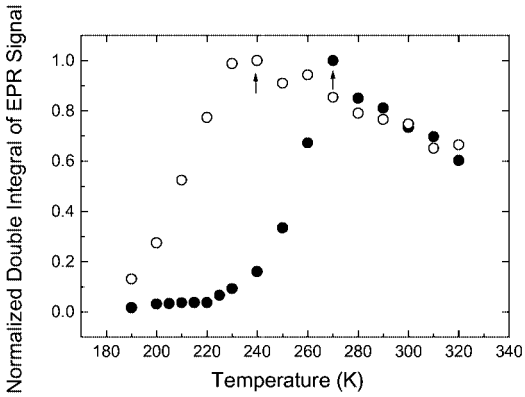

Fig. 1 Temperature dependence of normalized double integral intensity of the EPR signal for TTF$^{\cdot+}$ (closed circles) and TMT-TTF$^{\cdot+}$ (open circles) in ethanol. Arrows point out the beginning of the Curie Law region.

The three closely-related compounds $[Ti(N^iPr)Cl_2(NHMe_2)_2]$ 1, $[Ti(NC_6H_5)Cl_2(NHMe_2)_2]$ 2 and $[Ti(NC_6F_5)Cl_2(NHMe_2)_2]$ 3 all crystallize in the space group *C*2/*c* with the titanium atoms lying on two-fold axes at (0, *y*, 1/4); in compounds 1 and 2 the molecules are linked in one-dimensional infinite chains by intermolecular Ti–Cl···H–N hydrogen bonds along the direction of the crystallographic *c* axis, whereas in 3 offset face-to-face interactions between the C_6F_5 rings break down the hydrogen bonded chains.

The importance of non-covalent interactions between hydrogen-substituted arene rings in supramolecular chemistry is now well-recognised.[1] Arene–perfluoroarene interactions represent a special case and are, for instance, responsible for the 24 °C melting point of the 1:1 benzene–perfluorobenzene complex (while those of neat benzene and perfluorobenzene are 5.5 and 4 °C, respectively).[2] Such mixed arene–perfluoroarene interactions have recently attracted renewed attention in a range of supramolecular contexts.[3] More recently, reports of the possible importance of supramolecular interactions between pairs of perfluoroarene rings in organic and inorganic/organometallic contexts have appeared.[4] Hunter and Sanders were the first to propose a simple model for the interpretation of intermolecular π-interactions between aromatic molecules.[5] Also recently, Dance and coworkers[6] reported density funtional calculations on the gas-phase dimers $(C_6H_6)_2$ and $(C_6F_6)_2$ and concluded that (i) intermolecular interactions between perfluorinated aromatic rings are slightly *more attractive* than those of the hydro analogues (due mainly to an increased van der Waals component); (ii) calculated intermolecular potentials for offset face-to-face (*off*) interactions between pairs of C_6F_6 rings are twice as favourable as edge-to-face or vertex-to-face interactions; and that (iii) there are no major differences between the supramolecular embraces adopted by poly-phenyl and poly-fluorophenyl systems. Despite these recent, promising indicators of such supramolecular interactions, no clear-cut, 'head-to-head' study has been reported showing the relative importance of fluoroarene–fluoroarene interactions in comparison with possible arene–arene or other (*e.g.* hydrogen bonded) supramolecular motifs. Here we report the molecular and supramolecular structures of a series of closely related compounds that further demonstrate the importance of fluoroarene–fluoroarene interactions in crystal engineering.

As part of our research programme in transition metal imido chemistry[7] we found that the reaction of a very wide range of primary amines RNH_2 (R = alkyl or aryl) with $[TiCl_2(NMe_2)_2]$ in benzene leads to the highly air- and moisture-sensitive imido-bis(dimethylamino) titanium complexes $[Ti(NR)Cl_2(NHMe_2)_2]$ in good to excellent yields.[8] In this communication we focus on the molecular and supramolecular structures of three of these compounds, namely where R = ^{i}Pr **1**, C_6H_5 **2** or C_6F_5 **3**.†‡ The solid state molecular structures are fully consistent with the solution ^{1}H and ^{13}C-{^{1}H} NMR and solid state IR (Nujol mull) spectra given as ESI.†

The molecular structures of $[Ti(NR)Cl_2(NHMe_2)_2]$ (R = ^{i}Pr **1**, C_6H_5 **2** or C_6F_5 **3**) are presented in Fig. 1.‡ All adopt approximately trigonal bipyramidal geometries (equatorial NR and Cl groups) with linear or near-linear Ti=N–R linkages; the intramolecular distances and angles in **1**–**3** are unexceptional in comparison with other titanium imido complexes.[9] Hydrogens were placed in calculated positions (N–H 0.87 Å, C–H 1.00 Å). The structures are approximately isomorphous, with all three compounds crystallizing in the space group *C*2/*c* and the Ti atoms lying on crystallograhpic two-fold axes (passing through the Ti=N bond) at (0, *y*, 1/4) or a symmetry-equivalent position. While the molecular structures of **1**, **2** and **3** are very similar, their supramolecular structures differ significantly.

Molecules of $[Ti(NiPr)Cl_2(NHMe_2)_2]$ **1** form hydrogen bonded chains in the solid state as shown in Fig. 2(a). Hydrogen bonds form between the N–H groups of $NHMe_2$ ligands and Ti–Cl group hydrogen bond acceptors on neighbouring titanium complexes, and propagate in the direction of the crystallographic *c* axis. The Ti–Cl···H–N contacts of 2.51 Å may within error be considered 'short' according to Brammer and Orpen's classification[10] based on a detailed analysis of crystallographic data.[9] Moving on to the phenylimido system $[Ti(NC_6H_5)Cl_2(NHMe_2)_2]$ **2** [Fig. 2(b)] we encouter the same hydrogen-bonded supramolecular arrangement with experimentally comparable Ti–Cl···H–N contacts of 2.46 Å and Cl···H–N angles (158° in **2** *vs.* 160° in **1**). There are single C–H_{arene}···C pairwise contacts (C–H···C = 3.17 Å) between rings of one hydrogen-bonded chain of **2** and the neighbouring one. However, these are considered to be secondary consequences of the favoured Ti–Cl···H–N hydrogen bonded arrangement established for **1** (where no arene–arene interactions are possible). The *a* [16.913(1) *vs.* 16.260(1) Å] and *c* [12.044(1) *vs.* 11.935(1)] unit cell lengths for **1** and **2** are fairly similar while the *b* unit cell dimensions of 9.101(1) and 10.303(1) Å,

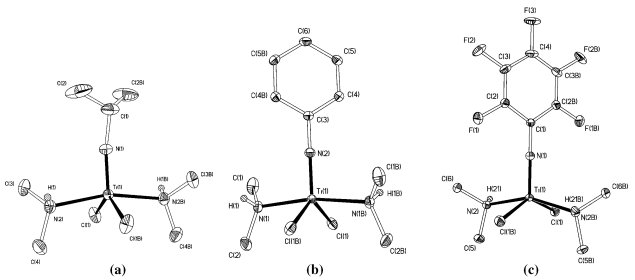

Fig. 1 Structures of $[Ti(NR)Cl_2(NHMe_2)_2]$ [(a) R = ^{i}Pr **1**; (b) R = C_6H_5 **2** and (c) R = C_6F_5 **3**]. C-bound H atoms omitted; displacement ellipoids drawn at the 25% probablility level; H atoms drawn as spheres of arbitrary radius.

† Electronic supplementary information (ESI) available: characterisation and crystal data for compounds **1**–**3**. See http://www.rsc.org/suppdata/cc/b1/b109251k/

 DOI: 10.1039/b109251k

respectively, show the greatest difference (being the direction in which the larger imido substitutent, ^{i}Pr *vs.* C_6H_5, is oriented).

Turning now to the perfluorophenylimido complex $[Ti(NC_6F_5)Cl_2(NHMe_2)_2]$ **3** [Fig. 3(a)] we see immediately that the unit cell has considerably distorted to disrupt the hydrogen bonded chain and arrange the neighbouring perfluorophenyl rings in a close, offset face-to-face (*off*) arrangement. The Ti–Cl···H–N distances of 2.93 Å (associated C···H–N angles = 136°) may now be classified[10] as 'long', and are approximately equal to the sum of the van der Waals radii for H (1.2 Å) and Cl (1.75 Å).[11] The solid state (Nujol mull) IR spectra of **1**, **2** and **3** feature $NHMe_2$ ligand ν(N–H) stretches of 3228, 3220 and 3275 cm^{-1}, respectively, consistent with the variations in Cl···H–N interactions determined by X-ray diffraction. While the unit cell *a* length [15.696(3) Å] in **3** is comparable to those in **1** and **2** (unsurpringly since it is perpendicular to the direction of propagation of the (formerly) hydrogen-bonded chain), there is a substantial expansion in the *b* direction [unit cell length = 15.569(1) Å] and a concomitant large contraction in the *c* unit cell length [6.7371(9) Å]. The separation between neighbouring titanium centres is *c*/2 = 3.365 Å which is just slightly larger than the interplanar separation of 3.23 Å between neighbouring C_6F_5 rings.

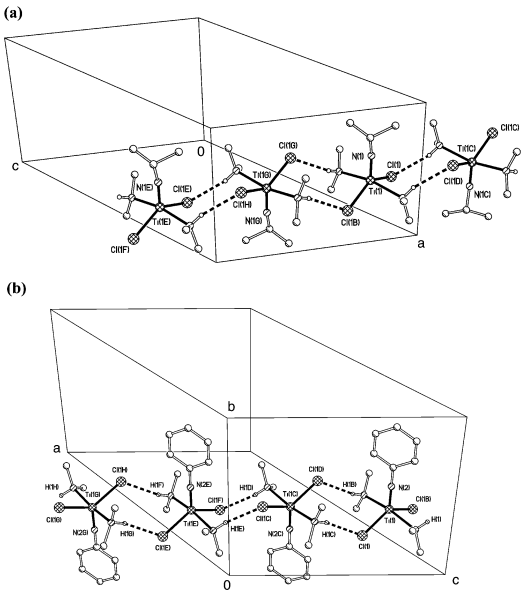

Fig. 2 Portion of the hydrogen-bonded chains of $[Ti(NR)Cl_2(NHMe_2)_2]$ [(a) R = ^{i}Pr **1**; (b) R = C_6H_5 **2**] with carbon-bound H atoms omitted and other atoms drawn as spheres of arbitrary radius.

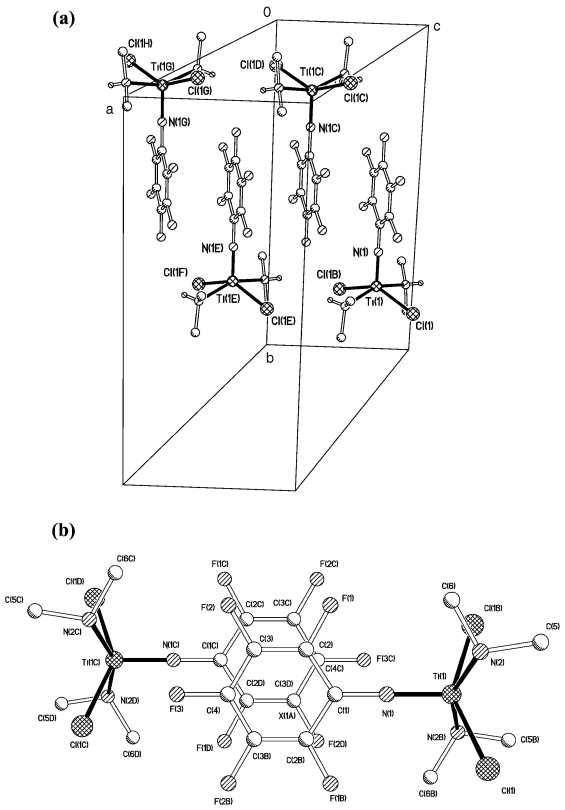

Fig. 3 (a) Portion of the π-stacked chains of $[Ti(NC_6F_5)Cl_2(NHMe_2)_2]$ **3** with carbon-bound H atoms omitted. Intermolecular Ti–Cl···H–N distances = 2.93 Å and Cl···H–N angle = 136°. (b) Relationship between the C_6F_5 groups bonded to N(1) and N(1C). Projected strictly onto the {C(1),C(2),C(3),C(4),C(2B),C(3B)} least-squares plane. Separation between C_6F_5 planes = 3.23 Å.

Fig. 3(b) shows in projection the *off* arrangement of two adjacent C_6F_5 rings. Each of the rings shown is involved in four close contacts to the neighbouring ring, namely two with C···C 3.264(3) Å and two with F···C 3.256(4) Å. In the π-stacked motif in crystals of **3** this gives each ring eight contacts in total (four with each of its two neigbours). The C···C and C···F contacts can be favourably compared to Dance and coworkers' calculated values of 3.19 and 3.14 Å, respectively, for gas-phase *off*-$(C_6F_6)_2$ (being the most stable supramolecular arrangement for this dimer).[6]

In summary, the crystal structures of the three compounds **1**–**3**, when taken together, provide further evidence for the comparatively strong driving force of supramolecular $C_6F_5\cdots C_6F_5$ π-stacking interactions in the solid state. Such interactions appear to be at least as strong as other, well-documented examples such as M–Cl···H–N–M hydrogen bonding.[10] We are continuing to investigate the supramolecular and crystal engineering roles of these types of interactions between C_6F_5 rings for both imido and non-imido systems.

This work was supported by the EPSRC, DSM Research and Millenium Pharmaceuticals Ltd. We thank Professor Ian Dance for disclosing some additional computational results.

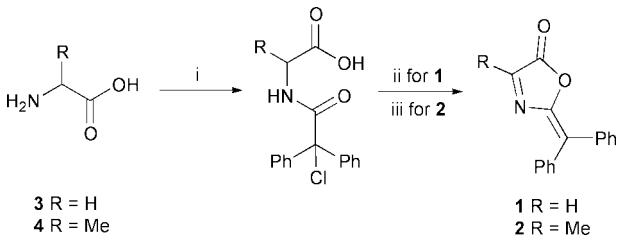
First published as an Advance Article on the web 6th December 2001

Monophenyl and diphenyl pseudoxazolone derivatives of glycine and alanine were prepared and found to be time-dependent inhibitors of hepatitis A virus (HAV) 3C and human rhinovirus (HRV) 3C proteinases with IC_{50} values in the micromolar range.

Cysteine proteinases have attracted much attention as therapeutic targets because of their implication in many diseases such as osteoporosis, Alzheimer's, and arthritis.[1] As part of our ongoing effort on the inhibition of hepatitis A virus (HAV) and human rhinovirus (HRV) 3C cysteine proteinases, we have explored pseudoxazolones as a new motif for inhibition of these enzymes.

HAV causes an acute infection of the liver whereas HRV is the major causative agent for the common cold in humans.[2] Like other picornaviruses, the HAV and HRV genome consists of a small positive strand RNA, which upon translation produces a single polyprotein precursor. This polyprotein undergoes multiple proteolytic cleavages by the 2A and/or 3C proteinases to produce the structural and nonstructural viral components.[3] In HAV, these cleavages are mediated solely by the 3C enzyme, a cysteine proteinase present in all picornaviruses.[4] Crystal structures of HAV 3C[5] and HRV 3C[6] have revealed that these enzymes are distinct from the papain cysteine proteinases and have folds that closely resemble the chymotrypsin serine proteinases.

Several potent inhibitors of HAV 3C and HRV 3C proteinases have been reported by our group[7] and by others.[8] The ability of pseudoxazolones to react with thiols at the imine[9] position suggests that these compounds can be used to inhibit thiol containing enzymes (Fig. 1). We first explored the diphenyl pseudoxazolone analogue of glycine **1** and alanine **2**. These compounds are readily prepared using a modified literature procedure.[10] Condensation of glycine **3** or alanine **4** with 2-chloro-2,2-diphenylacetyl chloride (Scheme 1) gives the corresponding halo adducts, which upon reaction with acetic anhydride–pyridine or DCC undergo cyclization followed by elimination of HCl to afford the desired compounds **1** and **2**. Testing of these compounds against HAV 3C C24S mutant§ indicates that **1** is a time dependent inhibitor with an IC_{50} of 33 μM (Table 1). However, the alanine derivative **2** was found to be less active with an IC_{50} >100 μM, possibly because the methyl group in **2** offers some steric interaction to the nucleophilic thiol of the enzyme. Our next approach was to prepare the monophenyl pseudoxazolone analogues of glycine **5a**,**b** and alanine **6a**,**b**. These compounds can be synthesised as depicted in Scheme 2.[10b,c] Although these pseudoxazolones have previously been reported as a mixture of *E* and *Z* isomers, we were able to separate each isomer by flash column chromatography for full characterisation. The *E* and *Z* configurations were assigned based on the proton (^{1}H) chemical shift of the olefinic hydrogen. The *E* isomer has its olefinic proton



Scheme 1 *Reagents and conditions*: (i) 2-chloro-2,2-diphenylacetyl chloride, propylene oxide, ethyl acetate, Δ (ii) DCC, propylene oxide, CH_3CN, 80% over 2 steps. (iii) Ac_2O, pyridine, 68% over 2 steps.

Table 1 Inhibition data for HAV 3C and HRV 3C proteinases

Compound	HAV 3C IC_{50} (μM)[a]	HRV 3C IC_{50} (μM)[b]
1	33	38
2	>100	>100
5a	6	16
5b	4	17
6a	26	43
6b	>100	>100

[a] *Fluorometric assay conditions*: 0.1 μM HAV 3C, 10 μM Dabcyl-GLRTQSFS-Edans, 2 mM EDTA, 0.1 mg/mL BSA, 100 mM KH_2PO_4–K_2HPO_4, 1% DMF, pH 7.5, 5 min pre-incubation of the enzyme with inhibitor. [b] *Continuous UV assay conditions*: 0.4 μM HRV 3C, 250 μM EALFQ-pNA, 50 mM HEPES, 150 mM NaCl, 1 mM EDTA, 1% DMF, pH 7.5, 5 min pre-incubation of the enzyme with inhibitor.

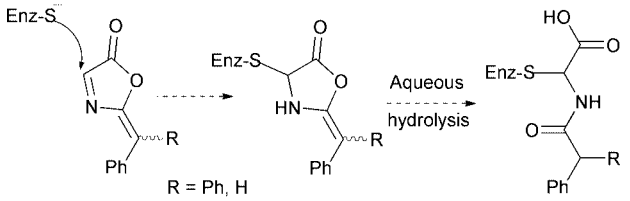


Fig. 1 Possible mode of inactivation by cysteine proteinase.

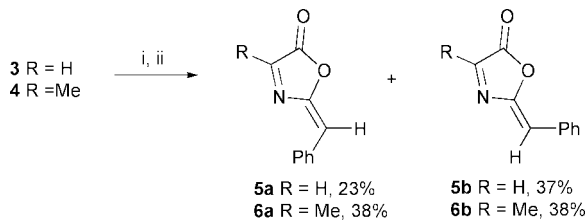

Scheme 2 *Reagents and conditions*: (i) DL-2-chloro-2-phenylacetyl chloride, NaOH, H_2O, 0–5 °C; (ii) Ac_2O, pyridine, the yields reported are over two steps.

 DOI: 10.1039/b109095j

aligned with the oxazolone ring oxygen and is more deshielded (Fig. 2) compared to the *Z* isomer which is aligned with the imine nitrogen. These observations were further supported by two X-ray crystal structures of **5b** and **6a**¶ (Fig. 3). Although interconversion of the *E* and *Z* double bond is possible, this was not observed for the monophenyl pseudoxazolones. Assay of **5a** and **5b** against HAV 3C proteinase gives time dependent inhibition with IC_{50} of 6 μM and 4 μM, respectively. However, compounds **6a** and **6b** display different levels of inhibition. The *E* isomer **6a** is a time dependent inhibitor with an IC_{50} of 26 μM. However, the *Z* isomer **6b** displays weaker inhibition, with an IC_{50} > 100 μM, indicating that the enzyme has a selectivity for the *E* over the *Z* isomer when there is substitution at the imine carbon. Other derivatives with different substitution at the imine position (data not shown) display the same type of behaviour. This is possibly due to some unfavourable electronic interaction of the phenyl group of **6b** in the active site of the enzyme.

Assays of these pseudoxazolones against HRV 3C proteinase (Table 1) also show the same pattern of inhibition as that observed for the HAV 3C enzyme. Although the inhibition levels are weaker for the HRV 3C proteinase, it should be noted that the amount of enzyme used in the HRV assay (0.4 μM) is more than that for HAV (0.1 μM) because of the limitations of the UV assay used for the former.

In summary, we have shown that pseudoxazolones are potent inhibitors of HAV and HRV 3C enzymes with micromolar IC_{50} values in the range. Although the monophenyl pseudoxazolones of glycine **5a** and **5b** show comparable inhibition, this is not the case with the alanine derivatives, indicating that the enzymes have selectivity for the *E* **6a** over the *Z* isomer **6b**. X-Ray crystal structures of **5b** and **6a** have helped to assign the geometrical configuration of the monophenyl pseudoxazolone analogues. The inhibition data and mass spectrometry suggest that the enzyme forms a covalent bond with the inhibitors. Further mechanistic studies involving ^{13}C labelled analogues and pseudoxazolones with other substitution patterns are in progress. The use of pseudoxazolones for inhibition of other cysteine proteinases is also being explored.

We thank Drs Bruce Malcolm (Schering Plough), Ernst Bergmann and Craig Garen (Biochemistry Department, University of Alberta) for enzyme preparation and helpful suggestions. We are grateful to Dr Robert McDonald for crystallographic analyses. These investigations were supported by the Natural Sciences and Engineering Research Council of Canada (scholarship to N. I. M.; summer studentship to L. S.) and the Alberta Heritage Foundation for Medical Research (scholarship to Y. K. R.).

Notes and references

§ Enzyme inhibition studies for HAV 3C employed a recombinant C24S mutant in which a non-catalytic external cysteine (Cys24) was replaced by serine and which displays catalytic properties indistinguishable from the wild type enzyme. For an ideal peptide substrate mimicking the 2B/2C junction of the large precursor polyprotein with glutamine preferred at the P_1 residue: the k_{cat} of this enzyme is about 1.8 s^{-1} with a K_m of 2.1 mM at pH 7.5.[4] HRV 3C assays used the 3C proteinase from serotype 14.[7a]

A stable, high relaxivity, diaqua gadolinium complex that suppresses anion and protein binding†

Dimitri Messeri,[a] Mark P. Lowe,[a] David Parker*[a] and Mauro Botta[b]

Received (in Cambridge, UK) 12th September 2001, Accepted 14th November 2001
First published as an Advance Article on the web 6th December 2001

The high relaxivity of $[GdaDO3A]^{3-}$ (r_{1p} = 12.3 mM^{-1} s^{-1}, 20 MHz, 298 K, τ_m = 30 ns) in water is maintained in serum solution because the binding of protein and endogeneous anions, *e.g.* HCO_3^-/CO_3^{2-} is suppressed by electrostatic repulsion.

All of the gadolinium complexes used currently as contrast agents in magnetic resonance imaging are mono-aqua species.[1,2] Complexes which possess two bound water molecules have not been used despite the large increase in relaxivity expected from the enhanced paramagnetic contribution, (r_{1p} in eqn. (1), where c is complex concentration, q is the number of

$$r_{1p} = \frac{cq}{55.6}\left[\frac{1}{T_{1m} + \tau_m}\right] \quad (1)$$

inner sphere waters, τ_m is the water exchange lifetime and T_{1m} is the longitudinal water proton relaxation time). The failure to develop such q = 2 systems has arisen for several different reasons. They may possess insufficient kinetic or thermodynamic stability with respect to acid or cation mediated dissociation to allow their safe use *in vivo*.[1–3] In other cases the complexes tend to bind endogeneous anions in serum—such as phosphate, carbonate or lactate—displacing one or both of the inner sphere waters in the ternary complexes and lowering the relaxivity.[4] Occasionally the water exchange lifetime, τ_m is rather long, limiting the relaxivity. Finally, in the presence of a protein such as serum albumin, aided by the interaction of, for example, side chain carboxylates in Glu or Asp residues, the inner sphere waters again may be displaced.[5] Thus although several promising q = 2 gadolinium complexes have been defined,[6] none has been shown to overcome simultaneously each of these constraints.

The complex [GdDO3MA] has been shown to possess sufficiently high stability[7] to allow its safe use *in vivo*. Using this as a starting point, we have examined the behaviour of the derivatives $[GdgDO3A]^{3-}$ **2** and $[GdaDO3A]^{3-}$ **3**, based on the hypothesis that their anionic side chains would inhibit the encounter with negatively charge species. For purposes of comparison, we have contrasted their behaviour to the related series of tetra-substituted complexes **4a**–**c**, derived from the archetypal lanthanide ligand, DOTA (DOTA = 1,4,7,10-tetraazacyclododecane tetraacetate).

The ligands and their Eu and Gd complexes were prepared as stereoisomeric mixtures by reported methods[8] and gave satisfactory ^1H NMR and high resolution ESMS data. The number of bound water molecules in aqueous solution at pH 7 was measured for the series of Eu complexes (Table 1), and revealed that $[EuaDO3A]^{3-}$ possessed two bound waters, whereas in $[EugDO3A]^{3-}$ the Eu ion only bound one. The form of their europium emission spectra also differed significantly in the hypersensitive ΔJ = 2 and 4 manifolds and in the observation of only two distinct transitions in the ΔJ = 1 region for $[EugDO3A]^{3-}$, and three for $[EuaDO3A]^{3-}$. The total emission spectrum of the latter closely resembled that of [EuDO3A]. Emission spectra were also examined in the presence of a simulated extracellular ionic background (30 mM $NaHCO_3$, 100 mM NaCl, 0.9 mM KH_2PO_4, 2.3 mM/0.13 mM potassium lactate/citrate), and in the presence of each anion separately—over the pH range 3.5–10.5. Spectra obtained† revealed that carbonate was bound preferentially in each case. However, the onset of this effect shifted from around pH 7.5 for [Eu-

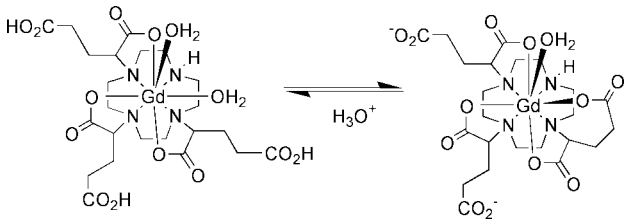
aDO3A]$^{3-}$ to *ca.* pH 8 for [EugDO3A]$^{3-}$. Taken together, these luminescence studies suggested that intramolecular (seven-ring) carboxylate ligation occurred for [EugDO3A]$^{3-}$, displacing one of the bound waters and slightly suppressing competitive carbonate binding at higher pH (Scheme 1). Different behaviour was exhibited by [EuaDO3A]$^{3-}$, which remained a diaqua species at ambient pH; presumably eight-ring chelate formation is too strained.



Scheme 1

Relaxivity measurements were made for each complex as a function of pH and magnetic field (NMRD profile). Data are collated in Table 1, together with measurements of water-exchange lifetimes, τ_m, using VT-^{17}O NMR methods[1,2] and estimates of rotational correlation times, τ_r, derived from iterative fitting of NMRD profiles. Most striking is the high relaxivity and the short water exchange lifetime of [GdaDO3A]$^{3-}$, in comparison to both [GdgDO3A]$^{3-}$ (q = 1, long τ_m) and [GdDO3A] (q = 1.8 but rather long τ_m and shorter τ_r). The comparative NMRD profiles (298 K) highlight these differences (Fig. 1). The fast water exchange rate (τ_m = 30 ns, 298 K) for [GdaDO3A]$^{3-}$ is intriguing; it may be a consequence of the structuring effect of the pendant carboxylate groups on the nature of the second sphere of hydration.

The pH dependence of relaxivity for [GdaDO3A]$^{3-}$ was examined at 65.3 MHz in serum and in a simulated extracellular anionic background. At high pH, carbonate ions chelate to the lanthanide centre displacing both water molecules. Limiting maximal relaxivity values were reached at pH 7.3 and 7.0 in the anionic (r_{1p} = 10.1 mM^{-1} s^{-1}, 293 K) and serum (12.3 mM^{-1} s^{-1}) backgrounds respectively, consistent with the pH-dependence of Eu emission intensity discussed above. Polyanionic lanthanide complexes are susceptible to proton and cation-mediated dissociation pathways.[3b,10,11]

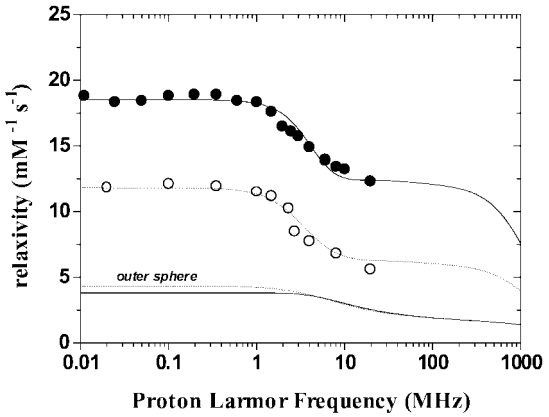


Fig. 1 NMRD profiles for [GdaDO3A]$^{3-}$ (●) and [GdgDO3a]$^{3-}$ (○) (298 K). Best fitting parameters included Δ^2 = 2.75 (3.14) × 10^{-19} s^{-1}, and τ_r = 130 (130) ps.

A useful empirical method assessing kinetic and equilibrium lability has been reported recently. Relaxivity measurements (pH 7 phosphate buffer) are taken as a function of time (0 →125 h) in the presence of endogeneous cations (*e.g.* Zn^{2+}) that may promote dissociation of the free Gd^{3+} ion, which is then trapped as its insoluble phosphate,[12] reducing the observed relaxivity. In this empirical 'screen', [GdaDO3A]$^{3-}$ was ten times more kinetically inert than [GdDTPA]$^{2-}$ (Magnevist) which has been used clinically since 1988.

In summary, [GdaDO3A]$^{2-}$ is the first q = 2 complex that has been shown to be suitable as the basis of an MRI contrast agent. The fast water exchange rate, and minimisation of anion/protein binding suggests it may be a particularly attractive candidate as the basis for higher MW conjugates as needed in MR angiography studies, for example.[1,2]

This work was supported by the EPSRC and Guerbet s.a. (Paris) and was carried out under the EC COST Action D-18, 'Lanthanide Chemistry for Diagnosis and Therapy'.

NMR observation of a new lignin structure, a spiro-dienone†

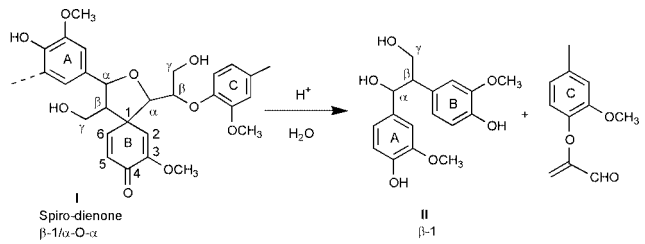
Liming Zhang* and Göran Gellerstedt

Department of Pulp and Paper Chemistry and Technology KTH, Royal Institute of Technology, SE-100 44 Stockholm, Sweden

Received (in Cambridge, UK) 13th September 2001, Accepted 14th November 2001
First published as an Advance Article on the web 6th December 2001

A spiro-dienone structure (β-1/α-O-α) has been observed as one of the important structures present in spruce and aspen lignins, with abundance as high as 3% in spruce lignin.

Lignin macromolecules consist of phenylpropanoid units that are linked to each other by various types of ether and carbon–carbon bonds. Opinions on the occurrence and frequency of the β-1 linkage in lignin have been quite divergent among wood chemists. The abundance of the β-1 structure has been estimated to range from 1% to 15% in spruce lignin,[1–3] depending on the analytical method applied. The β-1 structure has been observed to be one of the major type of lignin inter-unit linkages by studies using mild hydrolysis[4,5] and thioacidolysis.[6] On the other hand, efforts to detect the β-1 structure in milled wood lignin (MWL) by using ^{1}H NMR,[1] 2D HMQC NMR[7,8] or ozonation[2] have not been very successful, suggesting that this structure might only be a minor constituent in milled wood lignin.



Scheme 1

To explain the discrepancies in the applied analytical methods, it has been suggested that a precursor of the β-1 structure, a dienone structure (**I** in Scheme 1) might be present in native lignin.[9] On acid hydrolysis, the dienone structure would be converted to the β-1 structure (**II** in Scheme 1).

There have been several reports in the literature showing supporting evidence for the presence of such a precursor in lignin. We have observed previously that mild acid hydrolysis of spruce wood meal, pre-methylated with diazomethane, resulted in the release of lignin β-1 dimers predominantly carrying a free phenolic hydroxy group on ring B.[6] This observation suggested that the ring B originally was present in the form of a dienone structure. More evidence supporting the existence of the dienone structures in lignin includes the recent isolation of the sesquineolignan woorenol,[10] the synthesis of spirocyclohexadienone structure by radical coupling of lignin-like model compounds[11] and the isolation of an isochroman structure among the lignin degradation products after a DFRC treatment[12] as well as some 3D NMR evidence.[13] In the present communication, we present direct observations of the spiro-dienone structures of type **I** in spruce and aspen MWLs by NMR techniques.

Two spruce MWL samples and one aspen MWL were prepared. One of the spruce lignin samples (MWL1) was prepared from freshly cut spruce wood by milling with steel-balls for 3 days.[14] The other spruce lignin sample (MWL2) was prepared from an aged spruce wood log by milling with porcelain balls for 14 days.[15] The spiro-dienone structure was

† Electronic supplementary information (ESI) available: ^{13}C, QUAT, HMBC and HSQC NMR spectra. See http://www.rsc.org/suppdata/cc/b1/b108285j/

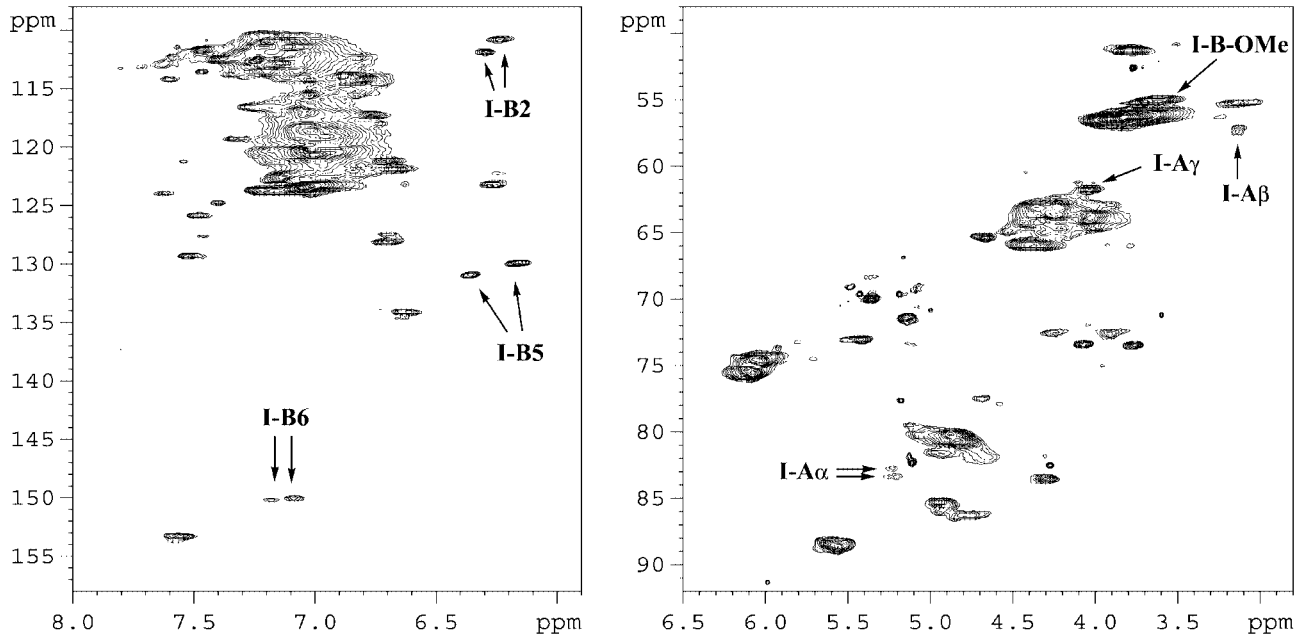


Fig. 1 Signals for the spiro-dienone structure (β-1/α-O-α) were observed and assigned in the HSQC spectrum of an acetylated spruce milled wood lignin (MWL1 acetate in acetone-d_6).

 DOI: 10.1039/b108285j

observed in both spruce and aspen lignins using NMR analyses. In the quantitative ^{13}C NMR spectrum, the signal at 180.7 ppm was assigned to the carbonyl group at position B4. According to the quantitative ^{13}C NMR analyses, the abundance of the dienone structure was estimated to be more than 3% in MWL1, 1.5% in MWL2 and about 1.8% in the aspen lignin.

In the HSQC spectra (Fig. 1) of the two acetylated spruce lignin samples, signals for Aα, Aβ, Aγ, B2, B5, B6 and B-OCH_3 were assigned. The quaternary carbon B1 was observed at 55.5 ppm by a QUAT spectrum. The connections between Aα, Aβ and Aγ and those between B5 and B6 were observed by HSQC-TOCSY experiments. The long-range connections between H-B5/C-B1, H-B5/C-B3, H-B2/C-B4, H-B2/C-B6 and H-B6/C-B4 were established by HMBC experiment.

According to the HSQC spectrum (Fig. 1), there are two isomeric forms of the spiro-dienone structure (**I**) in MWL1. In MWL2, on the other hand, only one of the isomers could be observed. Furthermore, the MWL1 sample contained only a tiny amount of the β-1 structure (**II**) whereas MWL2 had a high content of the β-1 structure (**II**) in the *erythro* conformation. The signal for the α-CH of the *threo* form of the β-1 structure (**II**) appears at 76.6/6.02 ppm, whereas the same signal for the *erythro* β-1 structure (**II**) appears at 75.8/6.13 ppm, very close to the predominant signal for the α-CH of the β-O-4 structures (75.4/6.11 ppm). Possibly, one of the spiro-dienone isomers was less stable and was converted to the *erythro* β-1 structure (**II**) either during storage of the wood or during the extended period of milling. In aspen milled wood lignin, the content of **I** was also found to be higher than the β-1 structure (**II**) according to the intensity of their respective NMR signals. Therefore, the spiro-dienone structure **I** can actually be the predominant form of the β-1 structures present in both soft- and hardwood native lignins.

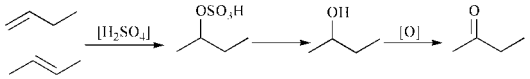
***In situ* mixing of ruthenium trichloride with one equivalent of 1,10-phenanthroline yields a highly active catalyst for synthesis of butanone from buta-1,3-diene.**

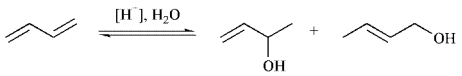
Butanone is an industrial solvent, nowadays produced on a Mton scale per year.[1] It is presently prepared from butenes in a three-step process according to eqn. (1).[2] The use of large



(1)

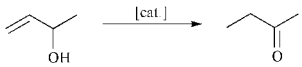
quantities of concentrated sulfuric acid, which need to be reconcentrated after the second step, make this process in principle less desirable from an environmental and an economical point of view. Therefore, new synthetic strategies have been developed in recent years.

Butadiene is readily obtained from naphtha cracker C_4-streams and its two double bonds make it susceptible towards electrophilic addition. Routes to butanal using butadiene *via* addition of amines[3] or alcohols,[4] followed by isomerisation of the allylic double bond and hydrolysis, have been patented. Acid-catalysed hydration of butadiene gives rise to two regioisomeric alcohols [eqn. (2)], but-3-en-2-ol and but-2-en-1-ol, in



(2)

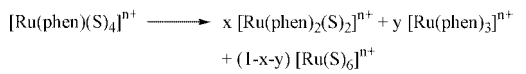
an equilibrium that lies heavily on the left-hand side. The former alcohol can be isomerised to butanone [eqn. (3)].[5] In a one-pot



(3)

synthesis, the thermodynamically favourable formation of butanone avoids an extensive (and thus costly) butadiene recycle. Unfortunately, almost all catalysts capable of allylic alcohol isomerisation are strongly poisoned by butadiene.

In the early 1990s, the synthesis of butanone from butadiene catalysed by a mixture of $[Ru(acac)_3]$ (Hacac = pentane-2,4-dione), 1,10-phenanthroline (phen) and a Brønsted acid in water was published.[6] However, the reported cumulative turn over number (TON) of 1200 in 32 h is not sufficiently high to be economically interesting. The limited TON is due to catalyst deactivation *via* two pathways: ligand redistribution and metal reduction, which result in inactive $[Ru(phen)_2(S)_2]^{2+}$ (S = solvent) and $[Ru(phen)_3]^{2+}$ species [eqn. (4)].[6,7] Yet, despite



(4)

considerable effort,[8] until now no catalyst was found to be more active.

Strongly coordinating anions like chlorides were originally thought[6] to hamper catalysis by blocking vital coordination sites. In fact, $[RuCl_3{\cdot}xH_2O]$ in combination with two equivalents of 2,2′-bipyridine (bpy) gave only low activity. However, during the course of our studies,[7] it was found that the presence of chloride ions in some cases had a promoting effect. Here, we report the reinvestigation of $RuCl_3$ as catalyst precursor in the synthesis of butanone from butadiene.

The results of *in situ* experiments for the direct conversion of butadiene to butanone are shown in Table 1.† The blank experiments shown in entries 1 and 2 confirm the need for both ruthenium and phenanthroline. Especially the amount of ligand is crucial. Whereas $RuCl_3$ with two equivalents of phen (entry 5) gives only moderate activity that is comparable to previous results (entry 3), $RuCl_3$ with one equivalent phen is by far superior as is shown in entry 4. This result demonstrates clearly that with a chloride-containing precursor high activity can be obtained, contrary to earlier ideas. Mixed with one equivalent of bipyridine, $RuCl_3$ is only as active as $Ru(acac)_3$ with one phen (entry 6).

Not only are initial rates higher, the $RuCl_3$–phen system surpasses the $Ru(acac)_3$–phen system if TONs are considered as well. After a mere two hours, 1400 turnovers can be attained. Importantly, the $RuCl_3$–phen system is exceedingly selective. The most important side products in this reaction are the Diels–Alder dimer of butadiene (vinyl cyclohexene) and butenes together with methyl vinyl ketone, but their formation can be reduced to less than 1% with a suitably low initial butadiene loading of the autoclave. Thus, high TONs can be reached with a minimum amount of side products. This is demonstrated by an experiment in which the amount of butadiene is fed into the autoclave in two consecutive portions. A cumulative TON of 2750 in less than 10 h was obtained. It is to be foreseen that an even higher TON can be reached, since no serious catalyst deactivation occurred over the two runs.

The unexpected high activity of the $RuCl_3$–phen system may be explained by the role the chloride anion plays in preventing the ligand redistribution reaction shown in eqn. (4). Its strong coordination may prevent extensive formation of inactive bis- and tris-phenanthroline complexes, thereby increasing the

 DOI: 10.1039/b108328g

concentration of catalytically active mono-phenanthroline ruthenium complexes. To verify this hypothesis, several samples taken during the reaction were analysed with mass spectrometry (MS). In the early stages of the reaction, Ru(III)- and Ru(II)-complexes with one phenanthroline, such as $[Ru(phen)Cl_2]^+$ and $[Ru(phen)(S)Cl]^+$ are dominant. This is the first time that ruthenium complexes containing only one phenanthroline ligand could be identified in this reaction.[6] Two other species are present in minor amounts: $[Ru(phen)_2Cl_2]^+$ and its Ru(II) analogue. Most noteworthy is the complete absence of complexes with three phenanthroline ligands. During the reaction, mono-phenanthroline complexes are converted to complexes with two phenanthroline ligands, but *not* with three. At the end of the 10 h reaction, complexes with only one phenanthroline ligand can still be detected. These results from MS prove that chloride ions indeed coordinate strongly to the ruthenium centre and prevent the formation of $[Ru(phen)_3]^{n+}$. In the $Ru(acac)_3$–phen system, between 20 and 40% of the ruthenium was present as $[Ru(phen)_3]^{2+}$.[6]

The present $RuCl_3$–phen system is much more sensitive to the ligand to metal ratio than the $Ru(acac)_3$–phen system. When two equivalents of phenanthroline are added to $RuCl_3$, the strong chloride coordination becomes a problem. $[Ru(phen)_2Cl_2]^+$ is formed instantly and chloride dissociation is slow.[9] With $Ru(acac)_3$, initial dissociation of acac is rate limiting and the influence of phenanthroline concentration is therefore much smaller.

The greater basicity and flexibility of bipyridine compared to phenanthroline render its coordination more reversible and this in turn makes ligand redistribution more prominent. Hence, the lower activity of $RuCl_3$ with one equivalent bpy can be explained by the increased formation of $[Ru(bpy)_2Cl_2]^+$, which is confirmed with MS on a spent catalyst.

Complete removal of chloride ions by silver(I) salts, replacing them with the non-coordinating anions toluene-*p*-sulfonate or trifluoromethane sulfonate, makes the catalyst much less stable. After an induction period, the reaction starts with a comparable rate ($k = 0.64\ h^{-1}$; Table 1, entry 7), but a TON of only 340 is reached after 10 h. These results underline the role of the chloride ion. Removal of chlorides increases ligand redistribution considerably, thereby reducing catalyst lifetime and overall product yield. On the other hand, increasing the chloride concentration by addition of NaCl or using HCl instead of toluene-*p*-sulfonic acid (Table 1, entry 8), decreases reaction rate and TON only slightly. This evidently shows that the hitherto found low activity of $RuCl_3$–phen systems was due to the amount of ligand and not to the presence of coordinating chloride anions.

In conclusion, an improved catalyst system has been found for direct synthesis of butanone from butadiene. $RuCl_3$ *in situ* combined with one equivalent of phenanthroline catalyses this conversion with an initial TOF of 960 h^{-1} and a cumulative TON of at least 2750 after 10 h. This superior result compared to previously reported systems emphasises the need for catalysts that prevent ligand redistribution. The possible use of relatively cheap $RuCl_3$ and HCl brings an industrial process for the direct synthesis of butanone from butadiene within reach. Future studies are aimed at further minimising ligand redistribution, optimisation of the reaction conditions as well as addressing the intriguing question on the valency of Ru in the active complex under butadiene hydration conditions and better understanding of deactivation reactions.

This research was supported by the Technology Foundation STW, applied science division of NWO and the technology programme of the Ministry of Economic Affairs. The authors are indebted to Mr W. W. Jager (SRTCA, The Netherlands) for his skilful technical assistance and to Dr W. J. L. Genuit (SRTCA, The Netherlands) for recording the mass spectra. Dr J. G. de Vries (DSM, The Netherlands) and Mr W. G. Reman (SRTCA, The Netherlands) are thanked for stimulating discussions.

Notes and references

† In a typical experiment, a high-pressure autoclave was filled with 0.09 mmol $[RuCl_3{\cdot}xH_2O]$, the appropriate amount of ligand and 3.5 mmol acid (for the acid-catalysed hydration of butadiene as shown in eqn. (2)). After addition of the diglyme–water (70:30) solvent mixture, the autoclave was closed and purged three times with dinitrogen. Next, buta-1,3-diene was added (10 ml) and the autoclave was heated to 145 °C. After 10 h, the autoclave was cooled to room temperature and the contents were analysed with GLC.

Nitration of aromatic compounds using a zeolite catalyst and a combination of dinitrogen tetroxide and air in a sealed system leads to high yields and *para*-selectivities in a clean, solvent-free process.

Electrophilic aromatic substitution reactions are of considerable importance in the production of fine chemicals. However, many traditional processes suffer serious disadvantages, including low selectivity for the desired product and the requirement for large quantities of mineral or Lewis acids as activators. Such acids cause corrosion and generate large volumes of spent reagents. Major efforts are therefore being made to develop processes with lower environmental impact.

Inorganic solids offer significant benefits by providing effective catalysis and, in some cases, enhanced selectivity.[1] For example, in our own research we have utilised zeolites to enhance the *para*-selectivity in chlorination,[2] bromination,[3] acylation[4] and methanesulfonylation[5] reactions of simple aromatic substrates. In addition, such solids are easily recycled.

Aromatic nitration is particularly important since nitro compounds are versatile feedstocks for a range of industrial products, including pharmaceuticals, agrochemicals, dyestuffs, and explosives. Traditional nitration with a mixture of nitric and sulfuric acids[6] is notoriously unselective for nitration of substituted compounds, and disposal of the spent liquors presents a serious environmental concern.[7] Consequently, several alternative methods for aromatic nitrations have been developed.[8–15]

At present, the best combination of high yield, high *para*-selectivity and low solvent use is nitric acid, zeolite HBEA (Hβ) and acetic anhydride (for moderately active aromatics)[12] or trifluoroacetic anhydride (for deactivated aromatics).[13] Even these systems, however, produce carboxylic acid as by-product.

An alternative approach to clean nitration, pioneered by Suzuki *et al.*, involves dinitrogen tetroxide and ozone,[16] or dinitrogen tetroxide with oxygen and a catalyst.[17] The use of oxygen rather than ozone was appealing and we demonstrated that use of zeolite Hß as catalyst provided improved *para*-selectivity and easier catalyst recovery.[18] However, the method still employed a large excess of dinitrogen tetroxide, a halogenated solvent, cooling and a reaction time of two days. Therefore, we continue to study the reaction in order to find ways of overcoming the remaining disadvantages. A recent publication from Suzuki *et al.* reveals that his group is also trying to perfect this zeolite-catalysed approach,[19] and we now therefore disclose our own further findings.

Our initial objective was to improve our previous procedure[18] by avoiding the need for cooling, decreasing the excess of dinitrogen tetroxide used and eliminating the solvent. These features were dictated by the volatility of dinitrogen tetroxide (bp 21 °C). Simply using an autoclave pressurised to 200 psi with oxygen allowed a reaction with the desirable features to proceed quickly and in high yield. Furthermore, when oxygen was replaced by air the reaction was still efficient. With air it required about 12 h to go to completion, still quicker than under the previous conditions.[18] By contrast, when the pressurising gas was nitrogen, virtually no nitration occurred, demonstrating the involvement of oxygen in the reaction.

It was not known whether the by-product was water, nitric acid or a mixture of the two. Eqn. (1) (n = 0–6) covers the various possible stoichiometries.

$$24\ \mathrm{ArH} + (12 + 2n)\ \mathrm{N_2O_4} + (6 + n)\ \mathrm{O_2} = 24\ \mathrm{ArNO_2} + 4n\ \mathrm{HNO_3} + (12 - 2n)\ \mathrm{H_2O} \quad (1)$$

A series of reactions involving different proportions of chlorobenzene to dinitrogen tetroxide was allowed to react to completion (2 days). The results suggested that 3 mol of ArH react with 2 mol of N_2O_4 to give 3 mol of nitro product and 1 mol of HNO_3 (eqn. (2), *i.e.* n = 2 in eqn. (1)).

$$3\ \mathrm{ArH} + 2\ \mathrm{N_2O_4} + \mathrm{O_2} = 3\ \mathrm{ArNO_2} + \mathrm{HNO_3} + \mathrm{H_2O} \quad (2)$$

Various zeolites, with different pore structures, counter-cations and Si:Al ratios, were examined under the new conditions. All zeolites tested catalysed the reaction and provided a modest increase in *para*-selectivity compared to reaction in the absence of catalyst. Zeolite Hß was somewhat faster and gave greater *para*-selectivity than the others, but the differences were not major.

Zeolite Hß was tested with a range of other substrates (Table 1). All substrates tested gave good yields of nitration products, with modest increases in the amounts of *para*-isomer in comparison with traditional methods. The relative reactivities did not appear to be consistent with a normal electrophilic aromatic substitution mechanism.

In an attempt to obtain further information about the system, we investigated the simple adsorption of N_2O_4 on zeolite Hß as a function of temperature. The amount adsorbed dropped steadily as the temperature was increased, but there was still some adsorption even at 80 °C and the amount adsorbed at 20 °C was in the region of 1.53 mmol N_2O_4 per gram of zeolite. By employing excess zeolite we were able to conduct a reaction in ordinary glassware at 20 °C and near-atmospheric pressure, which enabled direct observation of the reaction mixture. Adsorption of N_2O_4 alone onto the zeolite imparted a pale brown hue to the solid. However, when benzene was allowed into the system, the colour of the adsorbed material immediately became much darker. Following admission of oxygen the reaction proceeded slowly to give nitrated product.

We speculate that the dark colour is indicative of an adsorbed intermediate formed by interaction of the substrate with N_2O_4,

Table 1 Nitration of various substrates with N_2O_4, zeolite Hβ and air[a]

Substrate	Yield[b] (%)	*p/o* ratio
Toluene	76	0.9
Benzene	97	—
Fluorobenzene	95	10.1
Chlorobenzene	97	5.6
Bromobenzene	90	4.2

[a] Reactions were carried out with zeolite (3.0 g), substrate (33.0 mmol), and N_2O_4 (1.4 ml, *ca.* 23 mmol), under 200 psi air pressure at room temperature.[b] Calculated by quantitative GC.

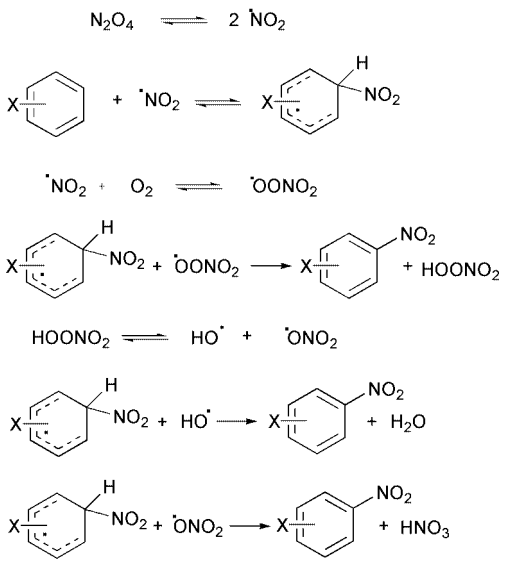
 DOI: 10.1039/b108952h

and that its conversion into product requires another reactive species to be formed more slowly between oxygen and the excess N_2O_4. The relative reactivities of different substrates and the small differences observed between the catalytic activities of proton and sodium forms of the same zeolites do not seem to be in line with an acid-catalysed electrophilic substitution reaction under these conditions. We therefore suspect that the reaction is radical in nature. Scheme 1 gives a tentative mechanism that is consistent with the stoichiometry. A similar overall result would be produced if NO_2 radicals were to abstract the first hydrogen atoms and the HNO_2 produced were then to react with oxygen to give $HOONO_2$. However, in that event nitration would be expected in the absence of oxygen.

In previous reports of nitrations of aromatic compounds using dinitrogen tetroxide and zeolites in the absence of solvent, the reactions have been conducted at elevated temperatures in the gas phase.[20,21] It was assumed that the stoichiometry was as shown in eqn. (3) (*c.f.* eqn. (1) with $n = 0$). If that were correct, it is likely that some of the product was formed by the action of nitric acid on the substrate at the elevated temperatures. Therefore, the reactions were likely to be complex and conclusions about the mechanisms based on the overall results need to be treated with caution.

$$4\ ArH + 2\ N_2O_4 + O_2 = 4\ ArNO_2 + 2\ H_2O \qquad (3)$$

In the recent work of the Suzuki group, superior selectivities for production of *para*-isomers were achieved at low conversion using H-ZSM-5 as the zeolite and the substrate as its own solvent in the liquid phase.[19] In the present work we have shown how it is possible to carry out the reaction to give high yields, with modest *para*-selectivities, without solvent, with only the stoichiometric quantity of dinitrogen tetroxide, using air instead of oxygen, and under mild conditions (ambient temperature and a modest pressure). Under these conditions the reaction is rather slow, but simply raising the temperature to 30–40 °C in the sealed system can reduce the required reaction period dramatically. Therefore, only two remaining obstacles prevent this reaction from fulfilling all the desired criteria. One is the relatively low *para*-selectivity (though already better than for traditional methods). The other is the production of a modest amount of nitric acid as by-product, which can deactivate the zeolite by adsorption or reaction, limits the efficiency of usage of the dinitrogen tetroxide feed and could lead to plant corrosion. We continue to search for ways to overcome these remaining disadvantages.



Scheme 1 A speculative mechanism for the reaction. Any or all of the steps involving reaction of the substrate–NO_2 adduct with another radical could proceed by either of two mechanisms: (i) direct hydrogen atom abstraction; or (ii) electron abstraction to give a Wheland intermediate and an anion, followed by proton abstraction from the Wheland intermediate by the anion. Whether the zeolite would play an active part in catalysing any of the processes or merely assist through stabilisation of intermediates by adsorption is an open question.

The reaction of chlorobenzene illustrates the general procedure for the nitration process. The zeolite (3 g) was placed in a 450 ml autoclave, followed by chlorobenzene (3.71 g, 33 mmol). Liquid dinitrogen tetroxide (*ca.* 1.4 ml, *ca.* 23 mmol) was added quickly to the mixture, the autoclave was sealed and pressurised to 200 psi with air, and the mixture was stirred at room temperature for 14 h. The autoclave was then opened and the product was extracted with dichloromethane (200 ml). The extract was washed with water (50 ml), dried ($MgSO_4$) and concentrated under reduced pressure to give the product, which was analysed by GC (hexadecane was added as internal standard).

We thank Zeolyst International for gifts of zeolites and S. A. thanks the Government of Qatar for a studentship.
