A novel reusable Lewis acid catalyst has been prepared by the heterogenization of a Lewis acid/tetrapropylammonium adduct; anchoring of tin chloride on quaternary ammonium chloride functionalized MCM-41 yielded a catalyst with higher activity compared to the corresponding silica analogue in terms of turnover rates and product yield in the Prins condensation of isobutene and formaldehyde to isoprenol.

The heterogenization of common Lewis acid catalysts is a subject of immense importance in view of achieving clean technology, based on the fact that heterogeneous catalysts are, in principle, best suited for industrial applications, as ideally they can be recycled and reused easily.[1] A direct immobilization of such catalysts on an inorganic support is not often advantageous due to the possible leaching of the supported species during the reaction and also in many cases the activity is considerably less than for the unsupported Lewis acid.[2] To enhance the activity it may be preferable to anchor the metal catalyst to the support through a chemical chain rather than directly bond it to the support surface.

MCM-41 materials which are characterized by highly ordered pore systems with tunable pore sizes, large specific surface area and pore volume, and high density of surface silanols, provide excellent opportunities in inclusion chemistry and catalysis. A large number of functionalized entities including both organic and inorganic ligands has been introduced in the channels to generate novel catalyst materials.[3] Here we report the preparation of a novel Lewis acid catalyst comprising $SnCl_4$ as the active component anchored on a tetraalkylammonium chloride functionalised MCM-41 material. A comparison is made with the corresponding silica gel analogue in the model reaction of isobutene–formaldehyde condensation to 3-methylbut-3-en-1-ol (isoprenol), which is an important synthesis block for industrially valuable terpenes.[4] Lewis acid catalysts such as $SnCl_4$ and $ZnCl_2$ have been employed in the synthesis of isoprenol from isobutene and formaldehyde under mild conditions, however, the yield was low due to the formation of many side products (Scheme 1).[5]

So called ionic liquids or molten salts which can be prepared by the reaction of a tetraalkylammonium halide ($NR_4^+X^-$) and a Lewis acid (MX) are reported to be effective catalysts in Friedel–Crafts reactions and the utility of such catalysts directly

immobilized on inorganic supports has been recently demonstrated by Holderich and coworkers among others.[6] Similarly, we adopted the nucleophilic addition of tetraalkylammonium chloride to tin chloride to obtain penta-coordinated tin anionic species, $[NR_4^+][SnCl_5^-]$.[7] These types of complexes were immobilized on silica gel and MCM-41 supports by a three-step procedure (Scheme 2). Pure silica MCM-41 (pore diameter = 3.7 nm, surface area = 1100 $m^2\ g^{-1}$) was synthesized following a modified procedure involving pH adjustment and salt addition during crystallization to improve the wetting stability.[8] Silica gel (pore diameter r = 6 nm, surface area = 500 $m^2\ g^{-1}$) was purchased from Aldrich. To a suspension of 10 g of dehydrated silica/MCM-41 support in 50 g anhydrous toluene was added 6 g of a toluene solution of trimethoxysilylpropyl chloride. The suspension was refluxed for 6–7 h in an oil bath followed by filtering and washing with excess toluene to remove the excess of reagent. 5 g of chloropropylated silica and 7 g of tripropylamine were further suspended in 30 g of anhydrous toluene and refluxed for 24 h. After the reaction the material was filtered off, washed fully with excess toluene and dried *in vacuo*. Elemental analysis revealed a loading of 0.98 and 2.5 mmol of chloropropyl groups per gram of silica gel and MCM-41 supports, respectively. The amount of chloride ions present on the silica gel and MCM-41 support after the reaction with tripropylamine as determined by titration with standard $AgNO_3$ solution and potassium chromate indicator were found to be 0.50 and 1.20 mmol g^{-1} of support, respectively.

1.04 g of a solution of anhydrous $SnCl_4$ in 10 ml dichloromethane was added dropwise to a suspension of the functionalized silica in 40 ml dichloromethane followed by stirring overnight at ambient temperature. After reaction, the material was exhaustively washed with dichloromethane and dried *in vacuo*. The starting silica gel and MCM-41 before use were dehydrated *in vacuo* at 450 °C. All operations including preparation of the unsupported $SnCl_4$–TPACl complex and its direct reaction with unfunctionalized silica were conducted inside the glove box under dry nitrogen atmosphere in order to prevent any hydrolysis of Sn compounds.

The tin chloride loadings of silica and MCM-41 hybrid catalysts as determined by energy dispersive X-ray analysis (EDAX-JEM-35, JEOL Co., link system AN-1000, Si–Li

detector, sensitivity > 0.1 wt%) were found to be 0.46 and 1.11 mmol g^{-1}, respectively. The MCM-41 structure remained intact after the catalyst anchoring. The retention of organic groups on the functionalized support after anchoring the $SnCl_4$ was proved by IR spectroscopy. The formation of a complex between tin chloride and tetrapropylammonium chloride in dichloromethane solution was confirmed by ^{119}Sn NMR (external standard). A shift in the NMR signal from −665.0 to −725.2 ppm after the reaction with tetrapropylammonium chloride reflects a change in the coordination number at tin.[7] The tin/chlorine atomic ratio in the anchored catalysts determined by elemental analysis (EDAX): 0.195 for SIL–TPA$^+SnCl_5^-$ and 0.204 for MCM–TPA$^+SnCl_5^-$, was in accordance with such complex formation. The solid state ^{119}Sn MAS NMR study of the $SnCl_4$–tetraalkylammonium adduct anchored on MCM-41 is now in progress in order to obtain more precise definition of the environment around the Sn.

The results of the Prins condensation of isobutene and formaldehyde to isoprenol over different catalysts are summarized in Table 1.†‡ It is clear that complexation of tin chloride with tetrapropylammonium chloride improves the selectivity towards the unsaturated alcohol. Tin chloride alone under anhydrous conditions displayed high activity but the selectivity to MBOH was poor. The tin chloride catalysts immobilized on organic quaternary ammonium functionalized silica/MCM-41 showed highest selectivity towards the unsaturated alcohol, MBOH (88–95%). More interestingly, the MCM-41 based catalyst is far more active than its silica counterpart and outperforms the latter both in terms of isoprenol yield and catalyst turnover. An X-ray fluorescence spectroscopic analysis of the filtrate after the reaction (X-ray spectrometer Phillips PW-1410; sensitivity > 0.5 ppm Sn) revealed that the new catalysts are resistant to leaching under the reaction conditions. Furthermore, when a subsequent reaction was performed with the filtrate after separating the catalyst by adding fresh formaldehyde and isobutene, no formaldehyde conversion was observed. Recycling of the catalyst leads to no appreciable loss in activity. Increasing the reaction time to 3.5 h, increased the MBOH yield to a maximum of 90%. The performance of an $SnCl_4$/silica catalyst, prepared by treating a chloroform solution of tin chloride and silica, in the selective synthesis of MBOH is poor compared to immobilized complexes. Also, a direct immobilization of the complex on silica (Silica/TPA–$SnCl_4$) was not advantageous in terms of MBOH yield.

The present MCM-41 based Lewis acid catalyst system satisfactorily meets the ultimate aims of heterogenization of metal complexes. In short, we have demonstrated the preparation and application of a novel stable, reusable, heterogeneous Lewis acid catalyst, which shows almost the same turnover rate (TON = 2.63×10^{-3} s^{-1}) as that obtained in solution with the homogeneous catalyst (TON = 2.68×10^{-3} s^{-1}). We believe that the accessibility of the active sites for the reactants will be highest in the present case as it is anchored to the support through a organic chain rather than being directly bonded to the support surface. In addition, the regular and well ordered hexagonal array of pores present in the MCM-41 support provides nanosized micro-reactors for the reaction. The better catalytic activity obtained with the MCM-41 supported catalyst compared to the silica supported counterpart indicates a favorable reaction environment inside the well ordered pores of the former where the active sites are grafted through an organic spacer. Another important feature of this catalyst is the higher concentration of active sites per gram of the support compared to the silica support.

T. M. J. is grateful to the Blechner foundation for a post-doctoral fellowship.

Notes and references

† Tetrapropylammonium chloride (4 mmol) was dissolved in 40 g of dry dichloromethane and 1.04 g (4 mmol) of anhydrous tin chloride was added slowly with constant stirring. The mixture was stirred overnight at ambient temperature and the solution was concentrated *in vacuo* to obtain a white crystalline material which was recrystallised from dichloromethane–hexane and stored under moisture free conditions. Analysis: found (calc.) Sn 24.78 (24.61), Cl 36.40 (36.74)%.

‡ The Silica/TPA–$SnCl_4$ catalyst was prepared by adding a chloroform solution of the complex prepared as mentioned above to 4 g of pre-dried silica support suspended in chloroform with constant stirring. The excess solvent was removed after overnight stirring and the material was extracted with chloroform for 12 h in a Soxhlet apparatus. The material was finally dried and kept under moisture free conditions before use.

First published as an Advance Article on the web 15th May 2001

The layered gallium fluorophosphate $Ga_3F_2(OH)_4(H_2PO_4)(HPO_4)_3$ $[H_3N(CH_2)_6NH_3]_2{\cdot}3.5H_2O$ (1) crystallises at room temperature from the supernatant liquid taken during the hydrothermal synthesis of the large-pore material ULM-5; the phase has a topology not previously seen among the Group 13 phosphates.

For almost 20 years a great deal of research has focussed on the synthesis of open-framework phosphates. The work was instigated by Wilson *et al.* who first described aluminium phosphates with zeolite-like structures for potential use in applications such as gas separation, ion-exchange and catalysis.[1] Phosphates of metals from almost every group of the Periodic Table have now been synthesised, usually using the hydrothermal technique ($T \approx 200$ °C).[2] In certain cases these new materials have found use as selective catalysts for organic transformations, further fuelling interest in their properties.[3,4] As well as 3D zeolite-like frameworks, the phosphates exhibit structures of lower dimensionalities, ranging from layered (2D) through chain (1D) to molecular (0D). Understandably, recent research in the area has focussed on determining the reaction mechanism of the formation of phosphates, with the goal of the rational synthesis of a new framework material of pre-designed architecture by application of appropriate synthetic conditions. For example, Taulelle *et al.* have shown by *in situ* NMR the existence of oligomers in the solution[5] whereas Rao *et al.* have, in the past few months, proposed an aufbau principle for the building up of 3D zinc phosphates from lower dimensional structures.[6]

The gallium fluorophosphates represent a large family of open-framework materials that we have been studying.[7] During *in situ* X-ray diffraction studies on their hydrothermal synthesis a number of crystalline transient phases have been observed which appear prior to the crystallisation of the expected product.[8,9] The structural characterisation of these intermediates has been hampered by the fact they are metastable and have never been stabilised under ambient conditions. We have recently begun a study of the isolation of metastable phases from the same reaction mixtures used to the prepare open-framework 3D phases, with the aim of a deeper understanding of the solution chemistry involved in the reactions and of producing possible structural models for the intermediate phases.[10–12]

The novel, layered gallium fluorophosphate **1** was isolated as single crystals from the supernatant liquid remaining after one hour under hydrothermal conditions of the reactant mixture that forms the large-pore gallium fluorophosphate ULM-5.† Structure solution was successfully performed by single-crystal X-ray diffraction and this reveals an unusual topology not previously seen in phosphate chemistry.‡ The phosphate layers have empirical formula $[Ga_3P_4O_{20}F_2H_9]^{4-}$ and are intercalated with charge balancing 1,6-hexanediammonium cations, as well as occluded water molecules [Fig. 1(a)]. Fig. 1(b) shows a view of the structure perpendicular to a single layer, and illustrates how the solid is constructed from corner-sharing $\{H_xPO_4\}$ tetrahedra, and $\{GaO_3(OH)_2F\}$ and $\{GaO_4F_2\}$ octahedra. The $\{GaO_4F_2\}$ units share axial fluorines with two $\{GaO_3(OH)_2F\}$ units to produce a trimer, which is bridged on both sides by four $\{H_xPO_4\}$ tetrahedra. There are three types of $\{H_xPO_4\}$ tetrahedra: the first is shared between three gallium atoms and has a unique terminal P–O bond of 1.575(5) Å corresponding to a P–OH moiety; the second is shared between two gallium atoms and presents two terminal P–O bonds [1.543(5) Å and 1.584(5) Å] while the third is also shared between two gallium atoms but has one longer (1.60 Å) and one shorter P–O bond type (1.49 Å), corresponding to P–OH and P=O moieties.

The secondary building unit (SBU) of the structure can be thought of as a $Ga_3F_2(OH)_2(H_xPO_4)_4$ heptamer, as shown in Fig. 2(a). These are bound by P–O–Ga linkages to produce the porous layer containing ten-ring windows. The lamellar structure of **1** is novel, but parts of the structure bear a striking resemblance to a chain gallium fluorophosphate we have recently isolated at room temperature.[10] The latter phase is constructed from infinite chains of $\{GaO_4F_2\}$ octahedra and

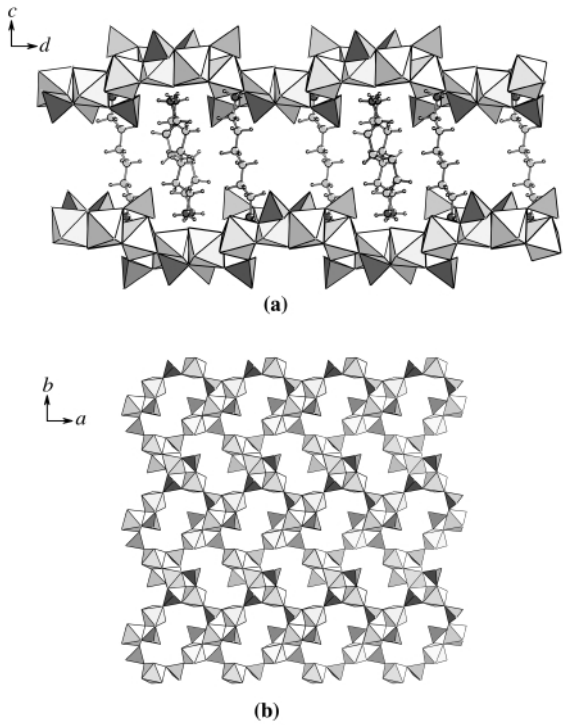

Fig. 1 Polyhedral view of the title compound (a) parallel to the layers, along *a*, showing intercalated 1,6-hexanediammonium cations, and (b) perpendicular to the layers, along *c* (occluded species not shown for clarity). Dark grey polyhedra are phosphorus-centred and pale grey gallium-centred, dark grey circles are N, pale grey circles C, and smaller pale grey circles H.

 DOI: 10.1039/b102753k

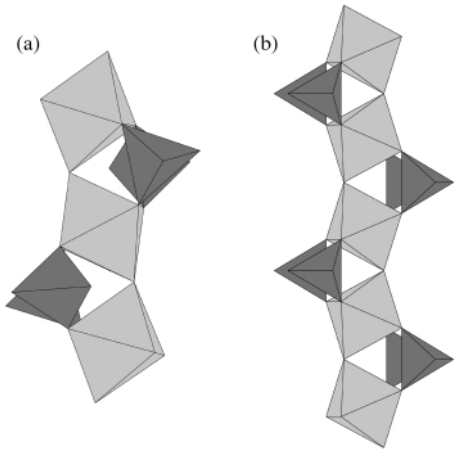

Fig. 2 (a) Polyhedral view of the secondary building unit of the title compound (b) part of the infinite chain of the 1D material Ga(H-PO_4)$_2$F·$H_3N(CH_2)_3NH_3$·$2H_2O$ with the tancoïte-type.[10]

{HPO_4} tetrahedra whose mode of linking is exactly the same as the SBU in the new phase, as illustrated in Fig. 2(b).

We have now isolated phosphates with 1D,[10] 2D (this work) and 3D[12] structures at room temperature, and thus for our system there is no evidence for a particular stability of low-dimensional structures at low temperature. All of these phases have structures not previously seen for the gallium fluorophosphates when hydrothermal synthesis is used and therefore room temperature crystallisation provides a route to novel, open-framework phases. What is particularly noteworthy about the new compound, and the other phases we have now isolated at room temperature, is the existence of gallium in solely octahedral sites, whereas the phases produced under hydrothermal conditions may contain gallium in four-, five- and six-coordinate sites. NMR studies on a related system also showed the transformation of six-coordinate metal centres to a lower coordination number site when hydrothermal conditions are reached.[5] In order to test the generality of this crystallisation model, we are currently surveying phases produced from other gallium fluorophosphate systems under mild conditions.

Notes and references

† The title compound crystallised from the supernatant liquid taken during the synthesis of the gallium fluorophosphate ULM-5.[13] The reaction mixture, 2 GaOOH : 1 P_2O_5 : 1.3 $NH_2(CH_2)_6NH_2$: 1 HF : 80 H_2O (initial pH = 2.5), was sealed in a Teflon-lined, 23 mL autoclave and placed in a furnace preheated at 180 °C for 1 h. After cooling to room temperature, the solid product was recovered by suction filtration and identified by powder X-ray diffraction as a new crystalline phase GaP_2O_7-$(OH_{1-x}F_x)(C_6H_{18}N_2)$·$nH_2O$.[14] The filtrate was retained and allow to stand at room temperature in a closed Teflon vessel. After several months, colourless, rod-shaped crystals of **1** were recovered.

‡ *Crystal data*: for $Ga_3F_2(OH)_4(H_2PO_4)(HPO_4)_3[H_3N(CH_2)_6NH_3]_2$·$3.5H_2O$: M = 999.6, colourless crystals, 0.36 × 0.14 × 0.04 mm, monoclinic, space group $P2_1/c$, a = 10.201(2), b = 14.417(4), c = 23.195(6) Å, β = 95.91(3)°, V = 3393.0(2) Å^3, Z = 4, D_c = 1.957 g cm^{-3}, μ = 2.659 mm^{-1}, index ranges $-12 \leqslant h \leqslant 12$, $-18 \leqslant k \leqslant 10$, $-28 \leqslant l \leqslant 27$, total data 20 065, independent data with $I_o > 2\sigma(I_o)$ 6931. Intensity data were collected at room temperature with a Siemens SMART three-circle diffractometer equipped with a CCD bidimensional detector [λ(Mo-Kα) = 0.71073 Å]. Data reduction was performed with the SAINT software and absorption corrections were applied using the SADABS program.[15] The structure was solved by direct methods and refined by full-matrix, least squares based on F^2 using the SHELXTL software package.[16] All non-hydrogen atoms were refined anisotropically except water molecules. All water molecules were unambiguously located although two of them (Ow3, Ow4) present a disorder with half occupancy of two sites. Hydrogens from the organic molecules were placed in calculated positions and treated as riding (N–H = 0.89 and C–H = 0.97 Å). Number of variables = 395; final $R(F)$ = 0.0562, wR (F^2) = 0.1319, GOF 1.026, minimum and maximum peak in difference electron density map −0.987 and 0.962 e Å^{-3}.

Highly diastereoselective additions of methoxyallene and acetylenes to chiral α-keto amides†

So Won Youn, Yong Hae Kim,* Jeong-Wook Hwang and Youngkyu Do*

Center for Molecular Design & Synthesis, School of Molecular Science, Department of Chemistry, Korea Advanced Institute of Science and Technology, Taejon, 305-701, Korea. E-mail: kimyh@mail.kaist.ac.kr

Received (in Cambridge, UK) 9th January 2001, Accepted 24th April 2001
First published as an Advance Article on the web 15th May 2001

α-Keto amides bearing (*S*)-indoline chiral auxiliaries reacted with lithiated methoxyallene or lithium acetylides to produce the corresponding dihydrofuranones 7 through formation of the tertiary α-hydroxy allenes, or tertiary α-hydroxy acetylenes, respectively, at −78 °C with high diastereoselectivities (up to > 99% de).

A number of diastereoselective nucleophilic additions of organometallic reagents to α-keto amides[1] bearing appropriate chiral auxiliaries have been reported as useful methods for the synthesis of optically active tertiary α-hydroxy acid derivatives, which are valuable for the asymmetric syntheses of medicinal agents and natural products.[2] Creating a tertiary alcohol center in which the stereochemistry can be controlled by a defined chiral environment in the addition of organometallic reagents to ketones still represents a significant challenge.[3]

Lithiated methoxyallene[4–6] is a promising nucleophile because the products produced by its addition to carbonyl compounds[7–8] can be converted into a variety of interesting compounds such as enones[9] or dihydrofuran derivatives.[10] In particular chiral propargylic alcohols[11] are useful intermediates in the synthesis of natural products.[2,12] Although a number of stereoselective additions of acetylides to aldehydes[11a–c] have been reported, asymmetric addition of acetylides to ketones to produce chiral tertiary alcohols is little known.[11d,e] A highly enantioselective addition of cyclopropanylacetylide to aryltrifluoromethyl ketone as a special substrate has been reported as the first example.[11d,e] However, a general method to prepare chiral tertiary α-hydroxy acetylenes has not yet been reported.

Recently, we reported that chiral α-keto amides derived from (*S*)-indoline-2-carboxylic acid resulted in high stereoselectivity in stereocontrolled additions of organometallics[1b] and allylation.[1c] On the supposition that these chiral α-keto amides might be good chiral auxiliaries, we examined the diastereoselective additions of lithiated methoxyallene **2** and lithium acetylides **3** to various chiral α-keto amides **1**.

The lithiated methoxyallene **2** was generated by treatment of methoxyallene (2.5 eq.) with *n*-BuLi (2.0 eq.) in THF at −78 °C for 30 min.[7b] Lithium acetylide **3** was prepared by addition of *n*-BuLi (1.5 eq.) to a solution of acetylene (1.7 eq.) in THF at 0 °C, followed by cooling to −78 °C after 30 min.[11a] Lithiated methoxyallene or lithium acetylide was reacted with α-keto amides at −78 °C in THF. Since the allene adducts **4** are generally labile[7b,c] so giving low yields (Table 1), the crude product **4** was reacted to obtain **6** without purification. Two equivalents of **2** were added to **1** at −78 °C in THF. The reaction mixture was stirred for 10 min at −78 °C and then quenched with distilled water. Extraction with CH_2Cl_2, drying over $MgSO_4$, and concentration gave crude product **4**, which was treated with a solution of *t*-BuOK (0.5 eq.) in DMSO at 50 °C. The reaction mixture was stirred for 1 h and then quenched with H_2O. Extraction with Et_2O, drying over $MgSO_4$, and concentration gave the crude residue, which was purified by column chromatography on SiO_2 to give dihydrofuran derivatives **6** which were treated with 5% HCl and extracted with diethyl ether and EtOAc at pH 11. The combined organic layers were dried over $MgSO_4$ and concentrated to give dihydrofuranones **7**. The results obtained are summarized in Table 2.

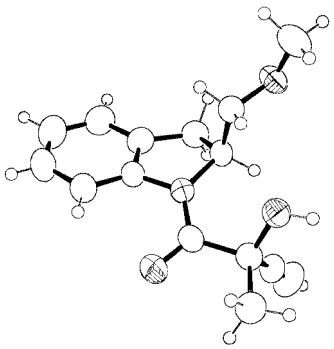

Fig. 1 X-Ray structure of **5g**.

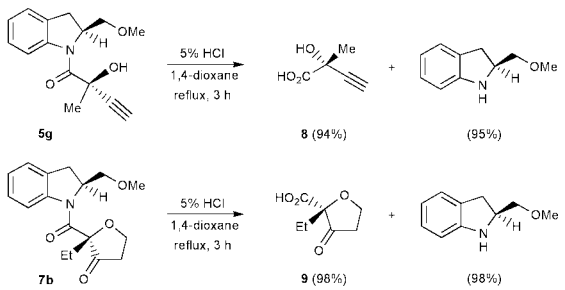
The purified products **4**, **5** and **6** were identified by ^{1}H, ^{13}C NMR,[7b–d] IR and MS. The ratios of diastereomers were determined by HPLC using a chiral OD column. The absolute configuration of **5g** was determined by comparison of the specific rotation of **8** ($[\alpha]_D^{25}$ −40.2°, *c* = 1.7, acetone) with the literature value[13] ($[\alpha]_D^{24}$ −41.0°, c = 10, acetone) and its structure determined by X-ray analysis (Fig. 1).[14] The ratios of diastereomers were unaltered during the process. Compound **8** has been found in plant growth regulators[2e] and highly enantiomeric excess synthesis of **8** has not been reported previously.

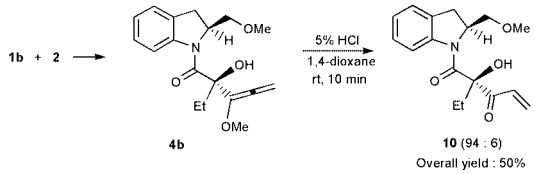
Enol ethers of 2,5-dihydrofuran derivatives **6** were readily hydrolyzed by HCl solution (H_2O:1,4-dioxane = 10:1) to provide the corresponding 3(2*H*)-dihydrofuranones **7** in good yields (75–80%), which are interesting intermediates as analogues of muscarone.[15b] Their structural element appears in other biologically active compounds[15] and their transformation to certain deoxy sugar derivatives can be performed. The indoline α-keto amides have a great advantage in terms of cleavage of the amide bond to give chiral products and recover the indoline chiral auxiliary.[1b,c,16] The cleavage of the amide bond of indoline amides is much easier than that of alkyl amides such as proline amides. For instance, the chiral products **5g** or **7b** were readily hydrolyzed with 5% HCl in 1,4-dioxane under reflux for 3 h to give the corresponding 2-hydroxy-2-methylbut-3-ynoic acid **8** or 2-ethyl-3(2*H*)-dihydrofuranone-2-carboxylic acid **9** in 94–98% yields, respectively, as shown in Scheme 1. The chiral auxiliary was recovered in 95–98% yield without loss of optical purity. Earlier work[11d,e] on asymmetric addition of acetylide to a ketone (not a chiral auxiliary) gave one chiral tertiary alcohol from a specific ketone leading to one compound. Our method, however, provides a general methodology to produce chiral tertiary α-hydroxy carboxylic acid acetylenes.



Scheme 1

Conversion of the hydroxyalkylated allenes into the α,β-unsaturated ketones under acidic conditions is also a useful reaction.[9] It is noteworthy that treatment of **4b** with 5% HCl provided enone **10** within 10 min at 25 °C as shown in Scheme 2. The ratio of diastereomers was also unaltered during hydrolysis. The enone moiety may be an interesting precursor for Michael-type additions or cycloadditions.[17]

In summary, it has been demonstrated that the reaction of α-keto amides derived from (*S*)-indoline-2-carboxylic acid with lithiated methoxyallene or lithium acetylide can provide useful



Scheme 2

intermediates, chiral tertiary α-hydroxy acid derivatives with high diastereoselectivities.

Aqueous solutions of unipositive cadmium; reactions of $(Cd^{I})_2^{2+}$(aq)†

Olga A. Babich* and Edwin S. Gould*

Department of Chemistry, Kent State University, Kent, Ohio 44242, USA. E-mail: obabich@kent.edu

Received (in Irvine, CA, USA) 5th March 2001, Accepted 23rd April 2001
First published as an Advance Article on the web 15th May 2001

Aqueous solutions 10^{-3} mol dm^{-3} in $(Cd^{I})_2$, prepared by treating O_2-free solutions of $Cd(ClO_4)_2$ or $Cd(O_3SCF_3)_2$ with Cd powder at 65 °C, can be handled by conventional methods; the comproportionation constant (Cd^{2+} + Cd ⇌ Cd_2^{2+}) is estimated as 0.018 (24 °C, I = 1.14 M) and the formal oxidation potential as −0.45 V; this atypical state readily reduces I_3^-, $IrCl_6^{2-}$, pyridine complexes of $(NH_3)_5Ru^{III}$, and superoxo derivatives of $(NH_3)_5Co^{III}$.

The atypical oxidation state cadmium(I) has been prepared and identified in the dimeric cation, $(Cd^{I})_2^{2+}$, in aluminium chloride melts by Corbett *et al.*,[2–4] and has been further studied in the crystalline state.[5] Moreover, a highly reactive species, thought to be Cd^{+}(aq), has been generated *via* pulse radiolysis of aqueous Cd^{2+} solutions by several workers.[6–8]

However, we find no reports describing aqueous solutions of unipositive cadmium manipulable by conventional methods. By avoiding halide and other nucleophilic ligands which favor disproportionation of Cd(I), we have generated 10^{-4}–10^{-3} molar solutions of this state, have estimated its redox potential, and have examined several of its reactions.

All preparations and reactions involving Cd(I) were carried out under argon. Typically, cadmium carbonate (0.97 g, G. F. Smith 99.995%)[9] was dissolved in a 5% molar excess of concentrated $HClO_4$ or triflic acid (HTf), diluted to 15 ml, heated to 60–65 °C, treated with 1.90 g of Cd powder (Aldrich 325 mesh) with stirring for 5–10 min, then cooled to 24 °C. Stirring was maintained for 20–30 min. After centrifugation, the Cd(I) content in the supernatant was estimated by reaction with KI_3 (352 nm). At equilibrium (24 °C), 1.7–1.8% of the Cd(II) taken is converted to Cd(I). After separation from Cd metal, it decays slowly ($t_{½}$ = 25 h at 24 °C).

Attempted analogous preparations of Zn^{I} (from Zn metal and $ZnTf_2$) and Mg^{I} (from Mg metal and $MgTf_2$) yielded no soluble reductant.

Concentrations of the reducing ion are very nearly proportional to $[Cd^{II}]$ taken (Fig. 1), thus being consistent with the formulation Cd_2^{2+}, rather than monomeric Cd^{+}. The comproportionation constant [eqn. (1)] corresponds to a $\Delta E°$ value of

$$Cd^{2+} + Cd \rightleftharpoons Cd_2^{2+};\ K = 0.0177 \pm 0.0003\ (24\ °C,\ I = 1.14\ M) \quad (1)$$

−0.10 V, which, in combination with the standard potential for Cd(II,0) (−0.403 V),[10] yields potentials −0.45 V for Cd(II,I) and −0.35 V for Cd(I,0). Dimeric Cd(I) is then a reductant thermodynamically comparable to U(III) ($E°$ −0.52 V).

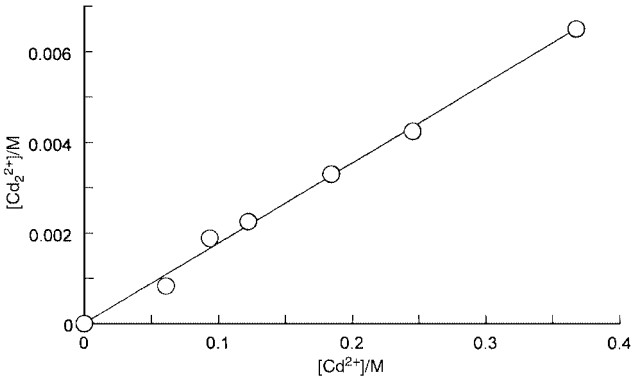

Fig. 1 Variation of concentrations of unipositive cadmium $(Cd_2)^{2+}$ with Cd(II) taken. Reactions with Cd metal powder were initiated at 65 °C and were equilibrated at 24 °C. The slope of the regression line, 0.0177 ± 0.0003, is taken as the equilibrium quotient for the comproportionation reaction: Cd^{2+} + Cd ⇌ Cd_2^{2+}, corresponding to a $\Delta E°$ value −0.10 V.

The sensitivity of Cd(I) to both strong acids and bases limits the number of redox reactions that can be studied. Rate constants for four such reactions are summarized in Table 1. Conversions are first order in both redox partners. Solutions of Cd_2^{2+} do not react perceptibly with $PtCl_6^{2-}$, vitamin B_{12a} (aquacob(III)alamin), quinoxaline, or the *N*-methylphenazonium cation, and its reaction with Cr(VI) in 2-ethyl-2-hydroxybutanoate buffer (pH 3.6) is inconveniently slow.

Reactions with the le$^-$ oxidants, $IrCl_6^{2-}$, Ru(III) and the $[(NH_3)_5Co^{III}]_2$–superoxo cation almost certainly involve an odd-electron species related to monomeric Cd(I). Formation of this from the dimer in a preequilibrium homolysis (Cd_2^{2+} ⇌ 2 Cd^{+}) would be reflected in a half-order dependence on [reductant], contrary to our kinetic picture. Generation of this transient must then require an act of electron transfer to the oxidant. Since it is likely that this transfer precedes breakage of the Cd–Cd bond, we have designated this intermediate as Cd_2^{3+}. We have further chosen this as a reasonable candidate for the necessary follow-up step, although generation and reaction of monomeric Cd^{+} itself cannot be excluded. Kinetic curves obtained with each of these le$^-$ reagents show no irregularity indicative of accumulation or loss of this odd-electron species on the time scale of the principal reaction, pointing to a two-step process, eqns. (2) and (3).

$$Cd_2^{2+} + Ir^{IV} \rightarrow Cd_2^{3+} + Ir^{III}\ \text{(slow, rate-determining)} \quad (2)$$

† Electron Transfer, part 146. For part 145, see ref. 1.

Table 1 Reductions with aqueous cadmium(I), 24 °C[a]

Oxidant	Product	I/M	λ/nm	k/dm^3 mol^{-1} s^{-1}
I_3^{-}[b]	I^-	0.075	352	$(1.00 \pm 0.04) \times 10^5$
$[(4\text{-AcPy})(NH_3)_5Ru]^{3+}$	$[(4\text{-AcPy})(NH_3)_5Ru]^{2+}$	0.030	520	68 ± 3
$[(NH_3)_5Co(O_2)Co(NH_3)_5]^{5+}$	$[(NH_3)_5Co(O_2)Co(NH_3)_5]^{4+}$ [c,d]	0.060	295	$(3.8 \pm 0.1) \times 10^2$
$IrCl_6^{2-}$[c]	$IrCl_6^{3-}$	0.28	489	$(1.41 \pm 0.04) \times 10^3$

[a] $[Cd_2^{2+}] = 2.5 \times 10^{-6}$–$2.6 \times 10^{-4}$ M; $[Cd^{2+}] = 1.5 \times 10^{-4}$–$1.5 \times 10^{-2}$ M; [oxidant] = 5.5×10^{-6}–4.2×10^{-4} M. [b] Solution buffered with 0.025 M *N*-(2-acetamido)-2-aminoethanesulfonic acid (ACES); pH 6.8. [c] Reaction with Cd_2^{2+} in excess. [d] Reduction of $(Co^{III})_2$–superoxo to $(Co^{III})_2$–peroxo cation; pH 5.6.

 DOI: 10.1039/b102041m

$$Cd_2^{3+} + Ir^{IV} \rightarrow 2\ Cd^{2+} + Ir^{III}\ \text{(rapid, kinetically silent)} \quad (3)$$

The relative rates for the two steps imply a much more negative le$^-$ potential for the intermediate Cd_2^{3+} than for Cd_2^{2+}, with the two necessarily totaling 2(−0.45) V. A lower limit for the formal potential of the initiation step (2) can be estimated by applying the simplified Marcus relationship [eqn. (4)][11] to the oxidation by $IrCl_6^{2-}$, for which the outer-sphere rate constant,

$$\log k_{Cd,Ir} = 1/2(\log k_{Cd} + \log k_{Ir} + \Delta E°/0.059) \quad (4)$$

$k_{Cd,Ir}$, is ⩽1400 $M^{-1}\ s^{-1}$ (Table 1). The self-exchange rate, k_{Ir}, for Ir(IV,III) and its standard potential have been documented[12] as $10^{5.4}\ M^{-1}\ s^{-1}$ and 0.87 V, and the self-exchange rate, k_{Cd}, for $(Cd_2)^{3+/2+}$ may be assumed to lie above $10^{-12}\ M^{-1}\ s^{-1}$, the minimum rate recorded for single electron self-exchanges involving simpler aquated metal ions.[11] We then calculate that $\Delta E°$ for the initiation step, eqn. (2), falls below 0.76 V, with $E°$ for $(Cd_2)^{3+/2+}$ thus more positive than +0.11 V, and the formal potential for $(Cd_2)^{3+} \rightarrow 2Cd^{2+}$ therefore more negative than −1.01 V (*vs.* NHE). The wide gap in potentials separating the initial loss of an electron from a main group two-electron metal reducing center and the oxidation of the resulting odd-electron intermediate appears to be a general feature of reagents of this type. The gap in this case (> 1.12 V) lies between that estimated[13] for In(I,II,III) (0.4 V) and that for Tl(I,II,III) (1.92 V).[14]

We are grateful to the National Science Foundation for support of this work, to Dr J. D. Corbett for valuable discussions, to Dr V. Manivannan for preparation of the ruthenium(III) oxidant, and to Mrs Arla McPherson for technical assistance.

Calcium oxide and strontium oxide as environmentally benign and highly efficient heterogeneous catalysts for the Tishchenko reaction of furfural

Tsunetake Seki, Kazumasa Akutsu and Hideshi Hattori*

Center for Advanced Research of Energy Technology, Hokkaido University, Kita-13, Nishi-8, Kita-ku, Sapporo 060-8628, Japan. E-mail: hattori@carbon.caret.hokudai.ac.jp

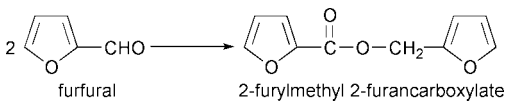
Received (in Cambridge, UK) 13th March 2001, Accepted 24th April 2001
First published as an Advance Article on the web 15th May 2001

CaO and SrO exhibit high activities for the challenging Tishchenko reaction of furfural.

The Tishchenko reaction is dimerization of aldehydes to yield the corresponding esters by the action of aluminium alkoxides.[1–5] For about a century, a number of catalysts for the Tishchenko reaction of various types of aldehydes have been developed to obtain the product esters in high yields. While many aldehydes have been converted to the Tishchenko dimers in good yields, few studies have been successfully carried out on the Tishchenko reaction of furfural. This reaction has been reported to be difficult when carried out using traditional aluminium alkoxides, boric acid or tetracarbonylferrate(−II) as catalysts.[2,6,7] Recently, some homogeneous catalysts such as $(C_5Me_5)_2LaCH(SiMe_3)_2$ and $La[N(SiMe_3)_2]_3$ have been reported to be effective for the Tishchenko reaction of furfural, though these catalysts require a long reaction time to give the product ester in a synthetically satisfactory level of yield.[8,9] In addition, removal of those homogeneous catalysts from the resulting solution causes loss of catalyst and reduction of the product yields. Moreover, in view of environmental concerns, avoidance of use of toxic transition metal catalysts in industrial processes is encouraged. Herein, we report environmentally benign, highly effective heterogeneous catalysts for the Tishchenko reaction of furfural. The general reaction equation is shown in Scheme 1.

Alkaline earth oxides, MgO, CaO, SrO and BaO, were prepared from $Mg(OH)_2$, $Ca(OH)_2$, $SrCO_3$ and $BaCO_3$, respectively, by thermal decomposition at elevated temperatures *in vacuo*. Lanthanum oxide was prepared from $La(OH)_3$ by the same procedure as the alkaline earth oxides, the $La(OH)_3$ being obtained from an aqueous solution of $La(NO_3)_3$ upon hydrolysis with aqueous ammonia, followed by washing with distilled water and drying at 373 K. ZrO_2 and ZnO were prepared from $Zr(OH)_4$ and $Zn(OH)_2$, respectively, by thermal decomposition at elevated temperatures *in vacuo*. γ-Alumina used as a catalyst and as a KOH/alumina-supported catalyst was supplied from the Catalysis Society of Japan (JRC-ALO4). Hydrotalcite (Mg/Al = 2) was synthesized as reported.[10] Alumina-supported KF (KF/alumina) was purchased from Fluka, and its KF content was determined as 8.2 mmol g^{-1} by XRF. Alumina-supported KOH catalyst (KOH/alumina) was prepared by impregnation of γ-alumina (JRC-ALO4) with an aqueous solution of KOH, followed by drying at 373 K in air; the KOH content was 1.2 mmol g^{-1}. The pretreatment temperatures and surface areas of the catalysts examined are listed in Table 1.

Furfural was purchased from Aldrich, and was purified by distillation under a reduced pressure.



Scheme 1 Tishchenko reaction of furfural.

The reaction was carried out in an H-shaped glass batch reactor. The two branches of the reactor were separated by a breakable seal. A sample of the catalyst precursor was placed in one branch, outgassed at an elevated temperature for 2 h, and sealed. The reactant was stored in the other branch until it was introduced through the breakable seal by distillation into the branch containing the catalyst thermostated at liquid nitrogen temperature. Reaction was initiated by melting the reactant at a reaction temperature followed by stirring. The product was identified by ^{1}H NMR and GC–MS analysis. GC analyses to determine yields of the product ester were carried out using a column of DB-1 (total length: 60 m; diameter: 0.25 mm).

Table 1 shows the activities of solid base catalysts for the Tishchenko reaction of furfural when the reaction was carried out with 100 mg of catalyst using 10 mmol of furfural as reactant. Among the solid base catalysts examined, only CaO and SrO gave the product ester in high yields. When the reaction was carried out at 353 K for 6 h in the presence of 100 mg of SrO, the product ester was obtained in almost quantitative yield. To our knowledge, there have been no reports of catalysts giving the Tishchenko dimer in > 77% yield.[8] Even at a lower reaction temperature of 323 K, the product ester was obtained in a yield of 70% over SrO. In addition to the high activities, the catalytic selectivities of CaO and SrO to 2-furylmethyl 2-furancarboxylate were almost 100%. This clearly emphasizes that CaO and SrO are highly efficient for the Tishchenko reaction of furfural. Although MgO and BaO were reported to

Table 1 Activities of solid base catalysts for the Tishchenko reaction of furfural[a]

Catalyst	Pretreatment temperature/K	Surface area/ m^2 g^{-1}	Yield[b] (%)
MgO	873	267	< 1
CaO	873	48	61
CaO	873	48	78[c]
SrO	1273	12	83
SrO	1273	12	95[c]
SrO	1273	12	70[d]
BaO	1273	2	0
La_2O_3	873	33	0
ZrO_2	873	42	0
ZnO	873	2	0
γ-Alumina	773	173	0
Hydrotalcite (Mg/Al = 2)	673	118	0
Fluka-KF/alumina	673	40	0
1.2 mmol g^{-1}-KOH/alumina	873	160	0

[a] Catalyst weight, 100 mg; furfural, 10 mmol; reaction temp., 353 K; reaction time, 4 h. [b] Yield was determined by the GC analysis of the resulting solution and was calculated by the equation: yield (%) = {[2 × (mol% of 2-furylmethyl 2-furancarboxylate)]/[(mol% of furfural) + 2 × (mol% of 2-furylmethyl 2-furancarboxylate)]} × 100. [c] Reaction time, 6 h. [d] Reaction temp., 323 K; reaction time, 12 h.

 DOI: 10.1039/b102389f

be active for the Tishchenko reaction of other aldehydes such as benzaldehyde and pivalaldehyde,[11,12] they were inactive for the present reaction. Based on a previous study,[11] it is conjectured that both basic (O^{2-}) and acidic (metal cation) sites on alkaline earth oxides participate in the Tishchenko reaction of furfural. The strength of basic sites lies in the order MgO < CaO < SrO < BaO, while that of acidic sites is in the opposite order. Thus, it appears that CaO and SrO having moderate acidic and basic sites in comparison with MgO and BaO are appropriate for the dimerization of furfural.

Other solid base catalysts such as La_2O_3, ZrO_2, ZnO, γ-alumina, hydrotalcite, KF/alumina and KOH/alumina were all inactive for the Tishchenko reaction of furfural. Although KF/alumina has been reported to show high activities for the Tishchenko reaction of benzaldehyde and pivalaldehyde,[12,13] it was not active at all for the Tishchenko reaction of furfural.

SERRS detection of PNA and DNA labelled with a specifically designed benzotriazole azo dye†

Duncan Graham,* Rachel Brown and W. Ewen Smith

Received (in Cambridge, UK) 8th March 2001, Accepted 27th April 2001
First published as an Advance Article on the web 15th May 2001

PNA and DNA have been detected for the first time with a specifically designed non-fluorescent SERRS active label; this is also the first use of SERRS to detect PNA.

In the post human genome project era a significant effort will centre on the detection of known nucleic acid sequences and variations within those sequences. Currently most methods of achieving this detection rely on the use of specific molecular biological assays and a physical detection technique which selectively identifies a label in a sensitive and discriminatory manner. Fluorescence and radio labelling are the most widely used physical techniques.[1,2] Recently we have reported the detection of labelled oligonucleotides using surface enhanced resonance Raman scattering, SERRS.[3–5] The main benefits of using SERRS rather than fluorescence are the ability to discriminate between labels in a mixture, without separation, at femtomole levels or below and the more extensive, simpler labelling chemistry which can be employed.[4]

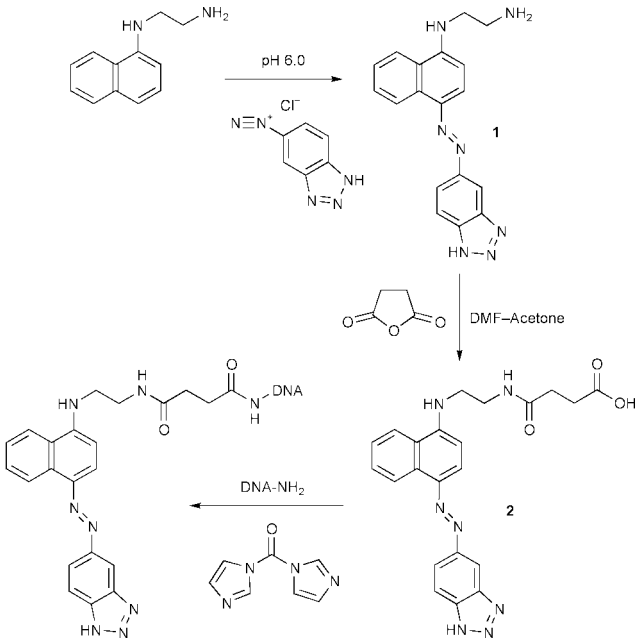
To obtain SERRS a dye requires to be adsorbed onto a roughened surface of certain metals of which the most widely used are silver and gold. The dye is required to obtain molecular resonance enhancement and the surface attachment provides enhancement by interaction with the plasmons on the metal surface. The combined enhancement processes provide a Raman signal of equivalent sensitivity to that of fluorescence. The sharp vibrational signals provide much better selectivity and since many dyes which are not fluorophores are effective, the chemistry can be much simpler and more extensive. A very effective metal surface used in this laboratory is that of citrate reduced silver colloid.[6] Aggregating agents such as sodium chloride or acid provide the most effective roughened surface and tune the surface plasmon to match the frequency of the excitation used.[7] In all previous SERRS studies involving DNA we have used commercially available fluorophores as the labels, as fluorescence is quenched in SERRS thus allowing the enhanced light scattering to be observed. Surface adsorption has been by electrostatic attraction of positively charged ammonium groups on the label to negatively charged citrate groups on the surface of the metal colloid used in our studies. In this approach the adsorption is not robust and can be affected by the presence of other agents such as metal chelators and no use is made of the extensive additional chemistry available for use with SERRS methodologies.

Previously we reported the synthesis of benzotriazole monoazo dyes specifically designed to provide SERRS by complexing directly to the silver surface, through the benzotriazole moiety which displaced the citrate surface layer.[8] In this communication we report the synthesis of a derivative of one of the previous dyes which is capable of undergoing solid phase addition to both DNA and PNA to make the oligomers SERRS active. The benefits of using these labels are that they are easy to produce, they give distinctive SERRS signals which are different from the previously used fluorophores, and they bind *via* complexation to the silver surface in a way which produces virtually irreversible binding.

The route followed for synthesis of the dye is shown in Scheme 1. *N*-(1-Naphthyl)ethylenediamine was chosen due to the presence of the primary aliphatic amine. Once an azo linkage has been produced the electron density on the aromatic amine is pulled into the ring system[9] dramatically reducing the reactivity of the amine as a nucleophile. Thus the aliphatic amine provides a reactive functionality to further derivatise the dye once synthesised. Dye synthesis was achieved by a diazonium coupling using 5-aminobenzotriazole to produce the orange dye, *N*-[4-(5′-azobenzotriazolyl)naphthalen-1-yl]ethylenediamine [**1**]. This dye was further functionalised to produce *N*-[2-(4′-(5″-azobenzotriazolyl)naphthalen-1-yl)aminoethyl]-succinamic acid [**2**]. The acidic dye was then capable of addition to amino linked DNA and PNA *via* amide formation on the solid phase.

A DNA oligomer was synthesised by routine solid phase phosphoramidite chemistry[10] and a monomethoxytrityl protected amino link added to the 5′-terminus.[11] Removal of the monomethoxytrityl group and addition of the activated dye produced the 5′-dye labelled DNA on the solid phase. The dye was activated by addition of carbonyl diimidazole to form the active ester. Cleavage and deprotection produced the crude labelled oligonucleotide which was purified by ion exchange HPLC. The coupling efficiency was estimated as > 83% by integration of the peaks from the HPLC.

PNA has a N-terminus which can be used to react in the same way as the amino link in DNA, however two Fmoc protected amino-3,6-dioxaoctanoic acid (AEEA-OH) spacers[12] were



Scheme 1 Synthesis of the benzotriazole label and addition to amino linked DNA.

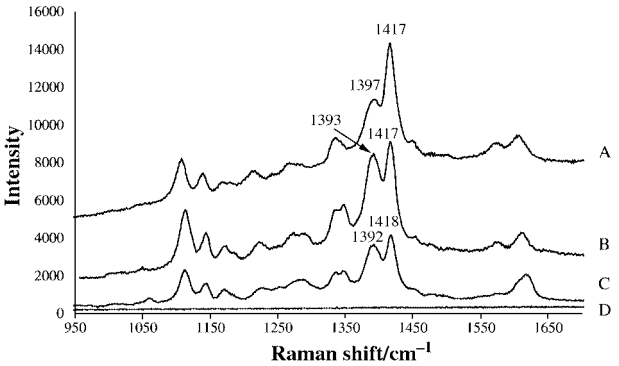

Fig. 1 The SERRS spectra obtained for free dye (A), dye labelled DNA (B), dye labelled PNA (C) and aggregated colloid with no dye (D). The spectra were obtained under different conditions and are scaled to allow comparison.

added to distance the dye from the PNA sequence. An 8mer was synthesised using Fmoc/Bhoc chemistry[12] and the two spacers added to the N-terminus. Removal of the Fmoc protecting group from the terminal spacer allowed addition of the benzotriazole carboxylic acid dye in the same way as for the DNA. Use of the dye as a monomer in the PNA synthesis cycle resulted in a mixture of products and poor coupling due to the unprotected triazole system, hence the use of the carbonyl diimidazole. Deprotection yielded the crude oligomer as a purple solid due to protonation of the azo linkage. Purification by reverse phase HPLC gave the pure dye labelled PNA with an estimated coupling efficiency of ~55% for the dye. The low coupling could be from a number of sources, such as cross-reaction of the unprotected triazole group. However, as only one monomer was being added this yield was acceptable.

The oligomers were then investigated for their ability to produce SERRS using citrate reduced silver colloid. A Renishaw microprobe system was used with 1 mW of 514.5 nm excitation at the sample. The optimum conditions for obtaining SERRS of both benzotriazole labelled oligomers vary. For the DNA oligomer the highest signal intensity was obtained when the phosphate backbone was neutralised by the addition of spermine prior to addition to the silver colloid. Use of an excess of spermine also provides aggregation of the colloid to produce the desired SERRS signals.[4] The spectrum is shown in Fig. 1B. The spectrum is consistent with that of the uncoupled dye (Fig. 1A) and displays the stretches at ~1393 cm^{-1} and 1417 cm^{-1} that are indicative of an azo tautomer.

A citrate assay was used to monitor the release of citrate from the surface after the addition of the benzotriazole dye, to the colloid. This proved that citrate was released from the surface after addition of the benzotriazole dye, but if spermine was added alone to induce aggregation then citrate was not released. This indicates that the benzotriazole is indeed complexing directly with the metal and not by a charge–charge interaction which appears to occur during spermine aggregation. Additionally, SERRS signals can be obtained from the dye labelled oligonucleotide without the use of spermine by using alternative aggregating agents such as phosphate buffer or nitric acid. This is in direct contrast to the oligonucleotides labelled with the fluorophores which in previous studies only produced intense SERRS with spermine. Thus we can conclude that the benzotriazole dye acts as a surface complexing agent and displaces citrate to provide attachment of modified oligonucleotides to a silver surface.

The conditions for obtaining SERRS of the PNA oligomer differ in that the oligomer is dissolved in 0.l% TFA and has a neutral backbone. Thus there is no need for the use of spermine as a charge neutralising agent. Also the TFA acts as an aggregating agent, again negating the need for the addition of spermine as an aggregating agent. The addition of the labelled PNA oligomer to a colloidal suspension produced a strong and distinct SERRS spectrum identical to that obtained for the labelled DNA (Figure 1C). In order to investigate the SERRS of the PNA labelled oligomer, a set of standard aggregating agents was tested with the labelled 8mer and the resulting SERRS recorded (Table 1). The values show that the intensity of the signals for the labelled PNA can be improved by the addition of an aggregating agent. However, if the solution is made basic by the addition of triethylamine then the intensity of the signals decreases, indicating that the PNA provides optimal signal to noise ratios in acidic conditions which are compatible with the conditions used for the standard synthesis of PNA. Spermine still appears to enhance the intensity of the spectrum, as it is an efficient aggregating agent.

Table 1 The intensity of the major peak in the PNA spectrum with different aggregating agents. All spectra were recorded in one scan of ten seconds and at 2×10^{-11} mole equivalents

Species studied	Intensity of peak at 1418 cm^{-1}
Colloid + TFA	No peaks
Colloid + BtDYE PNA + triethylamine	866
Colloid + BtDYE PNA	1074
Colloid + BtDYE PNA + spermine	1269
Colloid + BtDYE PNA + NaCl	2341
Colloid + BtDYE PNA + TFA	4148
Colloid + triethylamine	No peaks

In conclusion, we have synthesised benzotriazole azo dye labelled oligomers specifically designed to give SERRS. This dye is not an effective fluorophore and gives an indication of the additional labelling chemistry available for use with SERRS. The dye has been added to both DNA and PNA and SERRS obtained from both species. This type of label has additional benefits since the covalently attached benzotriazole group gives strong bonding, particularly to silver and copper surfaces, and provides a new and effective DNA–metal bonding chemistry. This is the first time that SERRS has been obtained from PNA and it is clear that it is easier to obtain SERRS from PNA than DNA.‡§

Excited state intramolecular proton transfer (ESIPT) in 2-phenylphenol: an example of proton transfer to a carbon of an aromatic ring

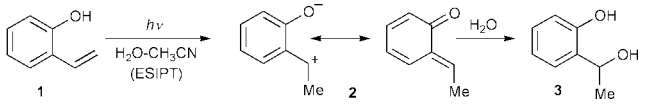
Matthew Lukeman and Peter Wan*

Department of Chemistry, Box 3065, University of Victoria, Victoria, British Columbia, Canada V8W 3V6. E-mail: pwan@uvic.ca

Received (in Corvallis, OR, USA) 19th January 2001, Accepted 13th April 2001
First published as an Advance Article on the web 15th May 2001

The title compound undergoes excited state intramolecular proton transfer (ESIPT) from the phenol moiety to the 2′-carbon position of the phenyl ring (not containing the phenol hydroxy group), to generate the corresponding keto isomer (a quinone methide).

Many aromatic organic molecules possessing both acidic and basic functionalities experience simultaneous enhancement of the acidity and basicity of these groups upon electronic excitation. Often this enhancement is sufficient for direct protonation of the basic site by the acidic group through the overall process of excited state intramolecular proton transfer (ESIPT).[1a–c] The basic group is usually an aromatic heterocyclic nitrogen atom or a carbonyl oxygen atom, and the reaction is usually aided by a ground state hydrogen bond with the proton donor.[1a–c] ESIPT is a topic of continued interest for many groups world-wide, as represented by some selected recent papers in this area.[1d–f] All reported examples of ESIPT to oxygen and nitrogen heteroatoms (from OH or NH acids) are reversible, and such 'energy-wasting' reactions have been exploited for use as photostabilizers although other applications have been envisaged due to their inherent photochromic nature.[2] The first example of ESIPT to carbon (from phenol) was reported by Yates and co-workers[3] while studying the photohydration reactions of *o*-hydroxystyrene (**1**) and *o*-hydroxyphenylacetylene [eqn. (1)]. Photolysis of **1** in aqueous

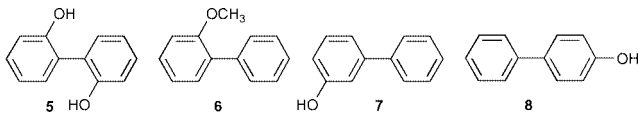


(1)

MeCN gave the hydration product **3** *via* *o*-quinone methide **2**. The primary photochemical step (from S_1) is ESIPT from the phenol to the β-carbon of the alkene moiety. Reverse proton transfer in **2** (from C–H to phenolate oxygen) is highly unfavourable and, instead, the intermediate is trapped completely by water to give **3**.[3,4]

To our knowledge, there are no explicit examples of ESIPT to a carbon atom that is part of an aromatic ring. However, Webb and coworkers[5] have suggested that the geminate recombination process in the ESPT reaction of 1-naphthol could result in protonation at the C-5 and C-8 ring carbons positions, *via* solvent-mediated ESIPT. In addition, reports of the photoprotonation (by aqueous acid) of the ring carbons of a variety of aromatic rings is well-known.[6] What is unknown is whether an explicit ESIPT to an aromatic ring carbon could operate in appropriately designed systems. Such systems would be unique as examples of a new type of ESIPT process. We present results for the photochemical deuterium exchange in 2-phenylphenol (**4**) that is entirely consistent with an explicit ESIPT from the phenol moiety to the ring carbon (position 2′) of the benzene ring not bearing the hydroxy group.

Exhaustive photolysis of **4** in 1 : 1 (v/v) D_2O–MeCN solution (Rayonet RPR-100 photochemical reactor; 254 nm lamps; 10^{-3} M; < 15 °C; argon-purged solutions; 1 h) yielded (after a H_2O-wash) **4** that is deuterated exclusively on the ring not bearing the hydroxy group. ^{1}H NMR (360 MHz) analysis of the sample showed that 70% of the 2′-(*ortho*) positions and 30% of the 4′-(*para*) positions were deuterated (not excluding dideuteration of the 2′-position since there are two such positions). These observations are consistent with an excited state where there is substantial charge transfer from the phenol ring to the benzene ring and would not be unusual based on photochemistry of some hydroxy-substituted biphenyls and biaryls already reported by our group.[6c,7] Similar results were observed for the photolysis of **5**† whereas photolysis of **6**–**8** gave no observable exchange.



For **4** and **5**, no exchange was observed in solutions that were not photolyzed. Clearly the hydroxy group is necessary for reactivity. The lack of reactivity for **7** and **8** suggest that the exchange observed for **4** and **5** may be due to an explicit ESIPT between the phenol OH and the 2′-position of the other benzene ring.

To investigate the possibility of an ESIPT mechanism for exchange, subsequent photolysis of **4** were carried out in MeCN solutions containing varying concentrations of D_2O and the extent of exchange analyzed by NMR. The results are plotted in Fig. 1. Under the conditions employed for these experiments, exchange at the *para* position was too low to be reliably measured (typically < 10% across the D_2O concentrations used). The plot shows that *ortho* exchange (which is significantly more efficient than exchange at the *para* position) is independent of D_2O concentration above 0.2 M D_2O. At lower concentrations, there is a rapid rise in the efficiency for exchange at the *ortho* position (see inset), reaching a plateau level at about 0.2 M D_2O. These observations strongly suggest that exchange at the *ortho* and *para* positions take place *via* different mechanisms. The rapid rise in yield of *ortho* exchange with increasing D_2O content at low concentrations essentially corresponds with the extent of exchange of the hydroxy proton of **4**; that is, once all of **4** has been deuterated at the hydroxy group (to give **4**-*OD*), the efficiency of photochemical deuteration at the *ortho* position is solvent independent. This is further corroborated by independent photolysis of a crushed crystalline sample of **4**-*OD*, which gave exclusive exchange (about 10%) at the *ortho* position, with no observable exchange at the *para* position. These results are consistent with a mechanism of *ortho* exchange involving ESIPT (Scheme 1). In this mechanism, photolysis of **4**-*OD* results in ESIPT to the 2′-carbon position, to generate the *o*-quinone methide intermediate **9**. Reverse transfer of a proton or water-assisted tautomerization gives **4**-*2′D* (after H_2O wash). A related ESIPT has been reported for compound **10** (and related systems) although in this case, the basic site is a nitrogen of an aromatic heterocyclic ring.[8] What we have shown in this work is that the *ortho* carbon atoms (on a simple

 DOI: 10.1039/b100817j

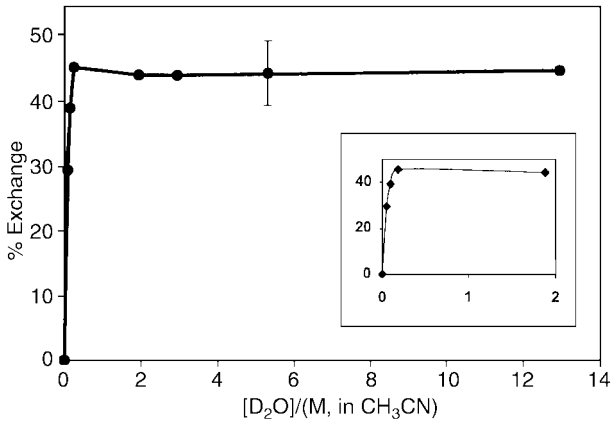


Fig. 1 Plot of % exchange at the *ortho* (2′) position observed for **4** *vs*. D_2O concentration (in MeCN). (Inset: expanded plot at low D_2O concentration).

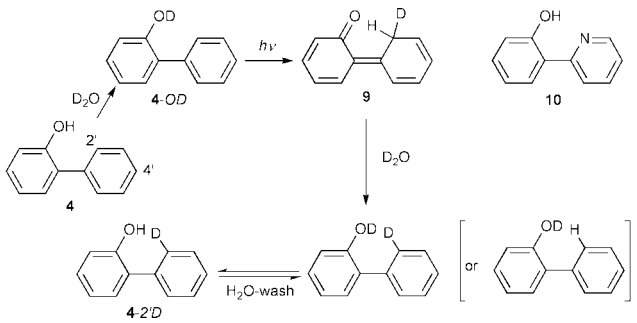

Scheme 1

benzene ring) are sufficiently basic to accept the acidic proton in these systems.‡

The *para* (4′) carbon is too far away from the acidic hydroxy (phenol) proton to be directly protonated intramolecularly. Indeed, its exchange yield is much lower. These results imply that a different mechanism is operative for deuterium incorporation at the *para* position. This is further corroborated by the following experiments. Photolysis of **4** in 1:1 MeOD–MeCN resulted in deuterium incorporation exclusively at the *ortho* position and suggests that only the ESIPT mechanism operates in MeOH–MeCN. Fluorescence emission spectra of **4** in a number of solvents gave additional insights into the mechanism of exchange at the *para* position (Fig. 2). These spectra show that **4** does not undergo excited state dissociation of the phenolic proton in neat MeCN or MeOH whereas 1:1 H_2O–MeCN is sufficiently polar to allow the dissociation, and hence formation of the excited state phenolate ion at 415 nm. That water is generally required for adiabatic deprotonation of phenols is well-known and has been specifically studied for **4** in H_2O–MeOH solutions.[9] These results are consistent with a mechanism of deuterium incorporation at the *para* position involving protonation (at the 4′-carbon) of the excited or ground state phenolate ion, formed *via* deprotonation from S_1 that requires water. This is apparently not an efficient process as the carbon protonation step must compete with fluorescence of the excited state phenolate as well as reprotonation at the oxygen site. This mechanism of deuterium incorporation probably also contributes to the overall exchange observed at the *ortho* position in aqueous solution (the extent of which is unknown at present) although the evidence suggests that ESIPT is the only mode of reaction responsible for exchange in neat organic solvents and in the solid state.

In summary, the results observed are consistent with a new type of ESIPT in which the acidic proton from a phenol is

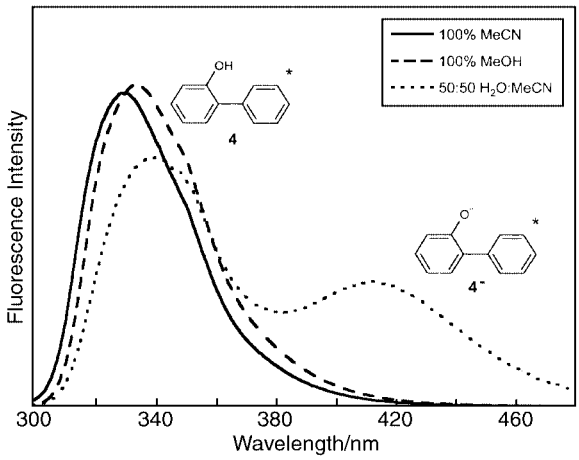

Fig. 2 Fluorescence emission spectra observed for **4** in 1:1 H_2O–MeCN, neat MeCN and neat MeOH (λ_{ex} = 285 nm; τ (neat H_2O) = 0.53 ns;[9] (1:1 H_2O–MeOH) = 1.25 ns;[9] estimated Φ_f (neat MeCN) ≈ 0.1).

directly transferred to a carbon atom of a benzene ring. The transfer is effectively reversible resulting in deuterium incorporation when carried out in D_2O. The dynamics and generality of this new type of ESIPT await further exploration.

Notes and references

† In this case, deuteration occurs on both rings since the system is symmetrically substituted.

‡ One would expect the ESIPT efficiency to be substantially lower when nitrogen is replaced by carbon. We have estimated the quantum yield for deuterium incorporation at the *ortho* (2)′-position in 1:1 D_2O–MeCN to be ≈ 0.02.

Using ethylene glycol derivatives of aluminium isopropoxide and ethyl orthosilicate precursors in the sol–gel process, discrete aluminosilicate nanoparticles were produced that had a strong Brönsted acidity, high surface area and high thermal stability; these properties were ascribed to a high dispersion of the aluminium atoms in the silica matrix.

Acid catalysts have been the subject of considerable fundamental research, since they represent a very relevant family of solid acids that are widely utilized in the chemical and petrochemical industries.[1] In regard to catalysis, pure SiO_2 is of limited use, owing to the absence of active sites in its matrix. The substitution of Si in the SiO_2 matrix by Al, creates a negative charge on the SiO_2 framework with an associated H^+ being bound to a nearby oxygen atom to maintain charge neutrality. This results in the formation of Brönsted acid protons as Al–OH–Si bridges. One factor affecting the Brönsted acidity is the dependency on the bond angle in Si–O–Al,[2,3] while another important factor may be said to result from 'the degree of dispersion of the Al ions'. Taking account of the latter factor, in the multi-component sol–gel processes for the general preparation of aluminosilicates, it is important to control the rate of hydrolysis of the precursors. As the hydrolysis rates of the respective precursors are considerably different in the preparation of aluminosilicates gels composed of different mixtures of the elements will be formed (Al_2O_3 in the SiO_2 matrix), instead of a homogeneous hybrid material. This difficulty can be largely overcome by controlling the hydrolysis rates through the formation of more stable aluminium complexes. Zarur and Ying[4] have recently reported that an ultra-high component dispersion plays a pivotal role in the preparation of catalysts with high reactivity and thermal stability that are needed for a variety of applications. Since solid acidic catalysts are used in various catalytic reactions, it is very important to develop them to have a reproducible and strong surface acidity. In the present work, we aimed to prepare an aluminosilicate acid catalyst containing well-dispersed Al ions, and to then clarify its acidic characteristics.

Discrete nanoparticles of aluminium silicate (denoted $Al_2O_3{\cdot}SiO_2$) having well dispersed Al atoms, were prepared by mixing 0.23 mol of ethyl orthosilicate (TEOS) with aluminium isopropoxide (0.02 mol) to prepare a sample with an Si : Al ratio of 11.5. Ethylene glycol was added to this suspension, and a resultant phase-separated mixture was formed which changed to a white suspension after stirring for 1 h at 35 °C. This suspension was mixed with an aqueous NaOH solution (0.13 mol, 300 cm^3) using a spray gun to form a mist to enable the hydrolysis reaction to proceed slowly and homogeneously. The suspension was kept at 50 °C for 2 d, and then finally aged for a further 2 d at 120 °C. The sample obtained was washed well and dried in air at 35 °C and then finally calcined in an oxygen stream for 10 h at 600 °C. An acidic ZSM-5 zeolite (HZSM-5, Si : Al = 11.9) provided by the Tosoh company, and a silica–alumina sample containing 5 wt% of Al_2O_3 (denoted as SA-5) prepared by a conventional sol–gel method[6] were used as reference samples. The prepared $Al_2O_3{\cdot}SiO_2$ sample had a specific surface area of 711 $m^2\ g^{-1}$, which was larger than that of the SA-5 sample (216 $m^2\ g^{-1}$).

All ^{27}Al and ^1H MAS NMR measurements were carried out in a field of 7 T using a Varian UNITY INOVA 300 spectrometer with a 7-mm diameter zirconia rotor, filled with dry air. Before the ^1H NMR measurements, all samples were evacuated at 450 °C to eliminate any physisorbed water. Tetramethylsilane (TMS) was used as the external reference for the ^1H signals, and all the spectra were calibrated to this reference. ^{27}Al NMR spectra were measured by using a $\pi/20$ pulse and a recycle delay time of 1 s. For Al NMR measurements, all samples were evacuated at 27 °C. The ^{27}Al signals and their chemical shifts were referenced in ppm with respect to an external $Al(H_2O)_6^{3+}$ standard in a 1 M aqueous $Al(NO_3)_3$ solution.

The ^{27}Al MAS NMR spectra for the three samples are shown in Fig. 1. These are potentially very helpful for probing the quantity, coordination and location of aluminium atoms in aluminosilicates, even though the quadrupolar nature of the nucleus does not allow observation of the structurally significant fine structure of the bands. The $Al_2O_3{\cdot}SiO_2$ sample showed an ^{27}Al band centred at 54.6 ppm, in the region corresponding to tetrahedrally coordinated aluminium (Al^{IV}). It is notable that there is virtually no component at 0 ppm, characteristic of an aluminium ion in octahedral coordination (Al^{VI}).[5–7] The spectra of the HZSM-5 and SA-5 samples give a pattern similar to that of $Al_2O_3{\cdot}SiO_2$, with the intensity of the 54.6 ppm band largest for HZSM-5, and smallest for SA-5 among the samples used. The HZSM-5 and SA-5 samples also had a distinctive band at 0 ppm, indicating the presence of six-coordinate aluminium ions. It cannot be emphasized too strongly that this band was not observed in our $Al_2O_3{\cdot}SiO_2$ sample. These NMR results demonstrate that the Al oxide moiety was successfully incorporated into the silica framework by the present preparation method using ethylene glycol.

The resulting spectra from the ^1H MAS NMR measurements are shown in Fig. 2. The ^1H MAS NMR spectrum for HZSM-5 was composed from the sum of the contributions of the following types of OH groups: (i) SiOH at *ca.* 1.8 ppm; and (ii) SiO(H)Al at 4.2 and 6.3 ppm (the latter as a weak shoulder).[8]

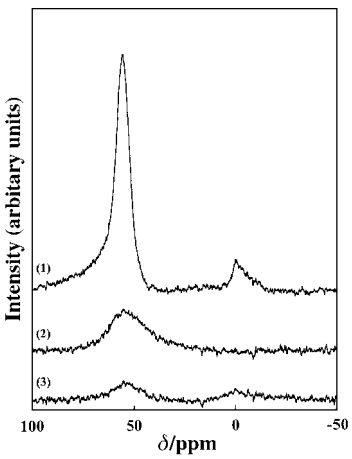

Fig. 1 ^{27}Al MAS NMR spectra for samples evacuated at 27 °C: (1) HZSM-5, (2) $Al_2O_3{\cdot}SiO_2$, (3) SA-5 samples.

 DOI: 10.1039/b100641j

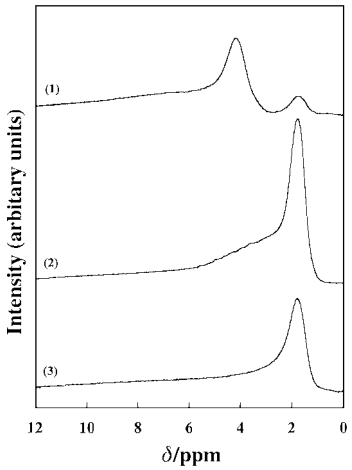

Fig. 2 ^{1}H MAS-NMR spectra for samples evacuated at 450 °C: (1) HZSM-5, (2) $Al_2O_3{\cdot}SiO_2$, (3) SA-5 samples.

Similar to HZSM-5, a distinctive broad feature with a maximum centred around 3.8 ppm was found for the $Al_2O_3{\cdot}SiO_2$ sample, together with the emergence of an intense signal around 1.8 ppm. In contrast to these samples, the broad band was scarcely discernible for the SA-5 sample, and the band at 1.8 ppm was dominant. For the SA-5 sample, a broad band around 2.7 ppm, assigned to an AlOH species, was detected when a deconvolution technique was applied to the observed spectrum.[5,8] As a result, for the $Al_2O_3{\cdot}SiO_2$ sample, the existence of a higher number of strongly acidic Brönsted-acid sites compared to the SA-5 sample is evident, although not so strong in acid strength and in as large a quantity as those observed for the HZSM-5 sample.

It is well known that the adsorption of CO on zeolites gives rise to carbonyl stretching vibration (ν_{CO}) bands at higher wavenumber relative to the free molecule (2143 cm^{-1}), depending on the strength of interaction.[9,10] These bands are expected to be observable through the interaction of CO with Brönsted acid sites, even at room temperature. The procedure used to record the IR spectra *in situ* and the details of the sample cell used have been reported in previous papers.[5,8]

The adsorption of CO on the 450 °C-treated HZSM-5 sample at 22 °C resulted in the development of a distinct ν_{CO} band with a maximum around 2170 cm^{-1}, and its band-maximum shifted to a lower wavenumber of 2168 cm^{-1}, with a distinct shoulder toward the lower wavenumber end (Fig. 3) at a pressure of 26.6 kPa. The spectrum measured at higher pressure was deconvoluted into two components at 2170 and 2165 cm^{-1}. Another feature is the appearance of a band at 2228 cm^{-1}. It should be noted that a similar spectral pattern, except for the 2228 cm^{-1} band, was obtained for the $Al_2O_3{\cdot}SiO_2$ sample, where a strong band was found at 2170 cm^{-1}. As for the SA-5 sample, the two bands discussed for the other samples were scarcely observed, although a strong band could be seen at 2228 cm^{-1}. In addition, the FTIR spectra in the OH vibrational stretch region showed prominent band features with two components for the HZSM-5 sample, one at 3745 cm^{-1}, and the other, a broad band, at around 3620 cm^{-1}. The appearance of the band at 2170 cm^{-1} was accompanied by a shift in the OH band observed at 3620 cm^{-1}, *i.e.* an interaction with the Brönsted acid site, and the 2165 cm^{-1} band was related to an interaction with the silanol group, related to the band at 3745 cm^{-1}.[5,11] For the $Al_2O_3{\cdot}SiO_2$ sample, the IR spectrum showed a discernible shoulder at 3620 cm^{-1} at the foot of a strong band at 3745 cm^{-1}, showing a similar trend to the HZSM-5 system in this regard. On the other hand, the SA-5 sample exhibited a faint shoulder around 3620 cm^{-1}, and a strong band was observed around 3745 cm^{-1}. The strong band around 3745 cm^{-1} scarcely changed even after CO adsorption on the SA-5 sample, coinciding with the absence of a band at around 2170 cm^{-1}. Taking into account the IR and the NMR data, there is no doubt about the existence of the Brönsted acid site in the $Al_2O_3{\cdot}SiO_2$ sample; the $Al_2O_3{\cdot}SiO_2$ sample possesses a larger number of Brönsted acid sites, and a more homogeneous site distribution compared to sample SA-5.

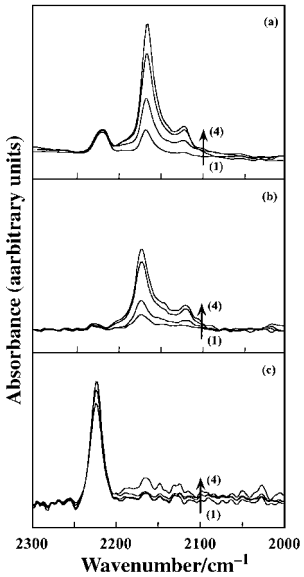

Fig. 3 FTIR spectra of CO adsorbed on the samples: (a) HZSM-5, (b) $Al_2O_3{\cdot}SiO_2$, (c) SA-5. The samples were first evacuated at 450 °C and then equilibrated with increasing pressures of CO gas at 27 °C: (1) 6.65, (2) 13.3, (3) 20.0 and (4) 26.6 kPa.

The distinctive band at 2228 cm^{-1} arising from the adsorbed CO species as observed in the spectra of the HZSM-5 and SA-5 samples is due to the interaction of CO with strong Lewis acid sites through a σ-donor bond.[9,10] It is of note that this band does not appear for the $Al_2O_3{\cdot}SiO_2$ sample, clearly indicating the lack of a Lewis acid centre. This result corresponds well with the NMR data, which shows a lack of octahedral aluminium sites. These data are indicative of the stability of the lattice of the $Al_2O_3{\cdot}SiO_2$ sample.

In conclusion, we have shown that the preparation of an $Al_2O_3{\cdot}SiO_2$ sample utilizing ethylene glycol as a solvent, leads to a sample having a strong Brönsted acid character. The appearance of this strong acidic property is attributable to a high dispersion of aluminium atoms at the atomic level in the SiO_2 lattice, which is more complete than that observed for a sample prepared by the general sol–gel method. Utilizing the present method, we can prepare various hybrid materials that consist of elements which are well dispersed at the atomic level, and expect such highly component-dispersed materials to exhibit many applications in catalysis, adsorption technology and other areas of importance.

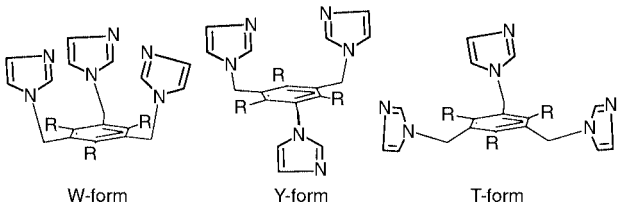
First published as an Advance Article on the web 15th May 2001

The structural characterization of a 3D nanoporous complex $\{[Cu_6(tib)_8(OH)_4](OH)_8\cdot 22H_2O\cdot 4MeOH\}_n$ 1 [tib = 1,3,5-tris-(imidazol-1-ylmethyl)benzene] assembled from the tripodal ligand tib and $Cu(MeCO_2)_2$ shows that π–π interactions resulting from the novel T-shaped conformation of the ligand are the key trigger for the construction of the backbone of a framework with channels of size 12.00 × 18.91 and 10.30 × 13.66 Å.

Employing multidentate organic ligands and metal ions to construct organic–inorganic hybrid materials[1] *via* coordinative metal–ligand bonds has become a major strategy.[1,2] Frameworks with specific topologies such as honeycomb grids and interpenetrating nets have been obtained by assembly of suitable metal ions with rationally designed rigid tripodal ligands such as 1,3,5-trisbenzonitrile (tcb),[3] 1,3,5-tris(4-ethynylbenzonitrile)benzene (teb)[4] and 2,4,6-tris(4-pyridyl)-1,3,5-triazine (tpt).[5–7] For example, tcb gives an extended honeycomb framework[3] by assembly with AgO_3SCF_3, while in the case of tpt, a (12,6) interpenetrating net[6] was obtained by reaction of the ligand with $Ni(NO_3)_2$. Recently, Robson and coworkers[7] reported another honeycomb-like framework[7] obtained by assembly of $Cu(MeCO_2)_2$ with the rigid tripodal ligand tpt.

In order to investigate the relationship between the topology of the assembly and the conformation of the ligand, two flexible tripodal ligands, 1,3,5-tris(imidazol-1-ylmethyl)-2,4,6-trimethylbenzene (titmb)[8,9] and 1,3,5-tris(imidazol-1-ylmethyl)benzene (tib)[10] were employed. Our previous work showed that titmb has two conformations, namely, *cis,cis,cis*-conformation (W-form) and *cis,trans,trans*-conformation (Y-form). An extended honeycomb framework with large cavities[8] was formed with titmb in W-form, whilst a 2D sheet-like framework[9] containing the ligand in both W- and Y-form was obtained from $Cu(dien)^{2+}$ ions and titmb. Most recently, a study also showed that a discrete M_3L_2 cage-like complex was assembled from tib in W-form with zinc(II) acetate.[10]



We report herein, to our knowledge, the first example of a 3D nanoporous complex $\{[Cu_6(tib)_8(OH)_4](OH)_8\cdot 22H_2O\cdot 4MeOH\}_n$ assembled from the tripodal ligand tib, in which π–π interactions play important roles in the construction of the backbone of the framework. In addition all the tib ligands are in a novel, unprecedented T-form conformation.

Standing of a blue MeOH–H_2O solution of tib and $Cu(MeCO_2)_2\cdot 2H_2O$ (L : M = 3 : 2) overnight resulted in the formation of blue sheet-like crystals with the formulation $\{[Cu_6(tib)_8(OH)_4](OH)_8\cdot 22H_2O\cdot 4MeOH\}_n$ **1**‡ and the structure was characterized by crystallographic analysis.§ Complex **1** shows no feature for carboxyl antisymmetric (ν_{asym} 1560 cm^{-1}) or symmetric (ν_{sym}, 1416 cm^{-1}) vibrations in the IR spectrum, indicating the absence of acetate anion, in agreement with the elemental analyses and crystallographic results.

There are two types of coordination environments for the copper ions (Fig. 1). Cu1 is coordinated by four N atoms from four tib ligands and one O atom from one OH anion giving a distorted N_4O square-pyramidal geometry, in which the four N atoms form the equatorial plane. By contrast Cu2 is coordinated only by four N atoms from four tib, leading to a distorted N_4 square-planar geometry.

It is interesting that in this complex, all tib ligands are in the T-form, as (Fig. 1). One imidazolyl ring lies outside the phenyl plane, but the centers of the other two imidazolyl rings are in the plane of the phenyl group and situated in a linear manner, to form a capital 'T'. Each tib is ligated to three copper atoms *via* the nitrogen atoms of the three imidazolyl groups. Two adjacent tib ligands adopt a top-to-bottom orientation and are joined together by atoms Cu1 and Cu1a to generate a rhombic Cu_2L_2

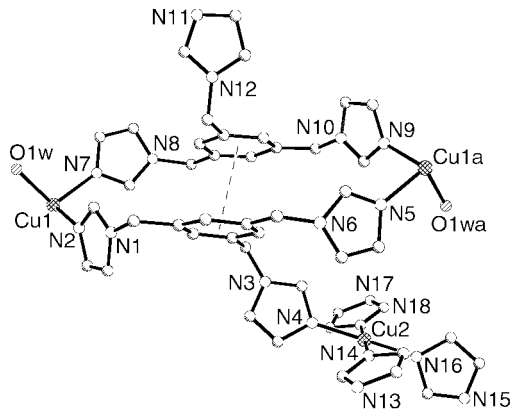


Fig. 1 Coordinative environment of copper atoms in **1** (π–π interactions indicated by dashed lines). Selected atomic distances (Å) and bond angles (°): Cu1–N 1.981(6)–2.006(6), Cu1–O 2.357(8); N–Cu1–N 88.3(2)–91.8(2)/161.1(3)–179.6(3), N–Cu1–O 89.1(3)–101.3(3); Cu2–N 1.991(6), N–Cu2–N 88.2(2)–91.8(2)/180. Cu1–Cu1a 13.76. All hydrogen atoms and solvate molecules are omitted for clarity.

† Electronic supplementary information (ESI) available: part of packing diagram selected to show Cu··O interactions and O··O hydrogen interactions (Fig. 1S). See http://www.rsc.org/suppdata/cc/b1/b100325i/

 DOI: 10.1039/b100325i

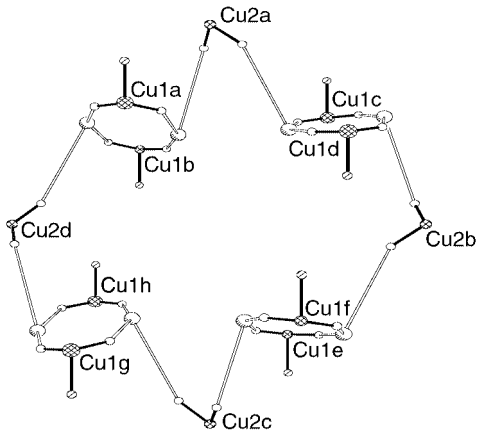

Fig. 2 Schematic drawing of a $Cu_{12}L_8$ macrocyclic ring in the *xz* plane. The large cross-hatched ellipsoids and small hatched ellipsoids represent Cu and O atoms respectively, while the large and small ellipsoids represent phenyl rings and coordinated N atoms, respectively. Heavy lines represent the Cu–N bonds while open lines connect the phenyl rings with coordinated N atoms. All hydrogen atoms and solvate molecules are omitted for clarity.

unit (as shown in Fig. 1), in which strong π–π interactions formed between the two tib ligands, with the two parallel phenyl rings separated by 3.55 Å, and a Cu1···Cu1a distance of 13.76 Å.

Four independent Cu_2L_2 units are joined together by four other Cu atoms, forming an $Cu_{12}L_8$ macrocyclic repeating unit which is composed of $Cu_{12}C_{144}N_{48}$ (as shown in Fig. 2); the total volume of the unit, 23.19 × 18.91 × 13.66 Å, is the same as the cell unit. Repeating the $Cu_{12}L_8$ units in space, a 3D nanoporous framework is then formed (Figs. 3 and 4), in which there are two types of channels with different sizes. Along the *y* axis, a channel with hole dimensions of 12.00 × 18.91 Å, which are defined by the Cu–Cu seperation, is shown in Figs. 2 and 3. However, when viewed along the *z* axis, four Cu_2L_2 units with each two sharing a Cu atom are connected by two other Cu atoms, forming a rectangular Cu_8L_8 unit ($Cu_8C_{144}N_{48}$) opening with dimensions of 10.30 × 13.66 Å (Fig. 4). There are $22H_2O$ and 4MeOH molecules in a complete $Cu_{12}L_8$ repeating unit, all within the channels. Indeed, all the modeled water molecules in this structure are in close contact to either Cu^{2+} ions (*e.g.* Cu1–Ow4 3.097(12) Å, Cu2–Ow2 2.642(10) Å) or the hydrogen atoms of methanol and water molecules (Fig. 1S, see ESI†). The free pore volume of a unit is estimated, using the PLATON program[11] (squeeze), to be 847 Å^3 (15.0% of the total).

The result described here shows that π···π interactions, resulting from the novel T-shaped conformation of the ligand, are the key trigger for the construction of the backbone of the framework. This is the first example determined by X-ray structure analysis showing a 3D nanoporous structure constructed by Cu(II) ions and a flexible tripodal ligand. This work also shows that the topology of assembly is obviously affected by the ligand conformation. The novel T-form of tib is favourable in the formation of π···π interactions between two nearest adjacent ligands. This nanoporous complex may have the ability to selectively enclathrate moderately sized guests. Encapsulation reactions of guest molecules are now under study.

Synthesis and structure of $[Sn_9(Ndmp)_7(HNdmp)_2O_2]$, containing a bidentate double-cubane oxo fragment (H_2Ndmp = 2-amino-4,6-dimethoxypyrimidine

Neil Feeder, Eilís A. Harron, Marta E. G. Mosquera, Anthony D. Woods and Dominic S. Wright*

Chemistry Department, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: dsw1000@cus.cam.ac.uk

Received (in Cambridge, UK) 7th February 2001, Accepted 19th April 2001
First published as an Advance Article on the web 15th May 2001

The reaction of $Sn(NMe_2)_2$ with H_2Ndmp (H_2Ndmp = 2-amino-4,6-dimethoxypyrimidine) and H_2O (*ca.* 4:4:1 equivalents, respectively) gives the cage complex $[Sn_9(Ndmp)_7(HNdmp)_2O_2]$ 1, containing an oxo double-cubane fragment $[Sn_7(Ndmp)_6O_2]$ coordinated to a neutral $(HNdmpSn)_2(\mu\text{-}Ndmp)$ unit; 1 is the largest imido Sn(II) complex so far characterised.

The reactions of $Sn(NMe_2)_2$ with aliphatic primary amines (RNH_2) provide an efficient low-temperature route to imido Sn(II) cubanes of the type $[SnNR]_4$.[1] However, we showed recently that the analogous reactions of 2-amino-pyridines and 2-amino-pyrimidines produce mixed-oxidation state complexes of formulae $[Sn_7(NR)_8]$, in which two cubane units are fused *via* a central Sn(IV) atom into double-cubane structures.[2] By illustrating that larger oligomers can be obtained, depending on the nature of the organic substituents present, this discovery provides a new direction in the chemistry of imido Sn(II) compounds (which has previously been dominated by the simple imido cubanes[3–5]). Previous studies by Veith and Lange illustrated that the imido–oxo cubane $[Sn_4(NBu^t)_3O]$,[6] in which formal replacement of Bu^tN group in the cubane $[Sn(NBu^t)]_4$ by isoelectronic O^{2-} has occurred, can be used as an 'ether-like' ligand in the donor–acceptor adduct $[Sn_4(NBu^t)_3O{\cdot}AlMe_3]$.[7] Our interest in this ligand stems from the very high development of negative charge on the O centre, making it a highly effective, sterically demanding donor for high oxidation state metal ions.[8] We show here that the double-cubane framework $[Sn_7(NR)_8]$ provides access to a bidentate homologue of this ligand system, $[Sn_7(NR)_6O_2]$, present within the structure of the cage $[Sn_9(Ndmp)_7(HNdmp)_2O_2]$ (H_2Ndmp = 2-amino-4,6-dimethoxypyrimidine).

Complex **1** was originally obtained fortuitously from the 1:1 reaction of H_2Ndmp with $Sn(NMe_2)_2$ in toluene, in low (15%) yield. Subsequently, it was shown that the 1:1 reaction of rigorously dried H_2Ndmp with $Sn(NMe_2)_2$ gives the expected double-cubane $[Sn_7(Ndmp)_8]$.[2b] These observations suggest that the initial formation of **1** was due to water of crystallisation present in the H_2Ndmp. Complex **1** can be isolated using a variety of stoichiometric ratios of $H_2Ndmp:Sn(NMe_2)_2:H_2O$ (*ca.* 4:4:1, respectively[8]), the cleanest reaction being obtained using the apparently correct mixture of H_2Ndmp (9 equiv.) and H_2O (2 equiv.) with $Sn(NMe_2)_2$ (10 equiv.) (Scheme 1).† Like the formation of the double-cubanes $[Sn_7(NR)_8]$, the production of **1** formally involves disproportionation into Sn(0) and Sn(IV). However, there was no obvious indication of the presence of Sn metal here, so that the exact course of the reaction remains unclear at this stage. Although the ^{119}Sn NMR spectrum of **1** in DMSO at room temperature shows the presence of Sn(II) (a broad resonance at δ −284.8, width *ca.* 210 Hz) and Sn(IV) (at δ +75.4), the low solubility of the complex in other organic solvents (once isolated) precluded variable-temperature studies which may have resolved the two Sn(II) environments.

$$9\ H_2Ndmp + 10\ Sn(NMe_2)_2 \xrightarrow[-Sn(0)]{2H_2O} \underset{1}{[Sn_9(Ndmp)_7(HNdmp)_2O_2]} + 20\ Me_2NH$$

Scheme 1

The low-temperature crystallographic study of **1**‡ shows that it is the cage compound $[Sn_9(Ndmp)_7(HNdmp)_2O_2]$, consisting of a neutral $[Sn_7(Ndmp)_6O_2]$ oxo double-cubane fragment coordinated *via* both O centres to the Sn(II) centres of a $[\{Sn(HNdmp)\}_2(\mu\text{-}Ndmp)]$ fragment (Fig. 1). In addition, there

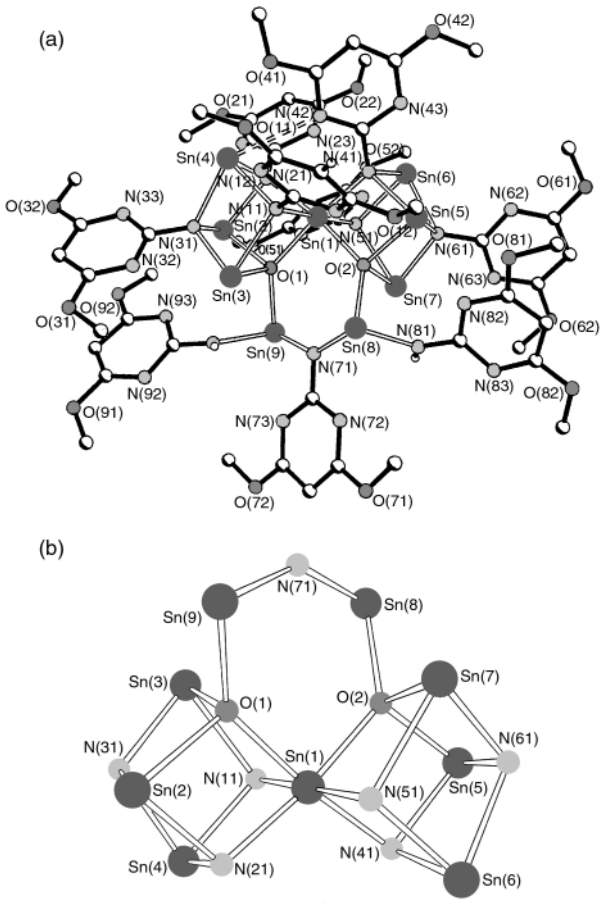

Fig. 1 (a) Molecular structure of **1**. H-atoms and the lattice-solvation by toluene molecules have been omitted for clarity. Selected bond lengths (Å) and angles (°): Sn(1)–O(1) 2.129(5), Sn(1)–O(2) 2.139(4), Sn(1)–N range 2.103(4)–2.139(6), Sn(2,3,5,7)–N range 2.162(6)–2.378(6), Sn(2,3,5,7)–O range 2.238(4)–2.268(4); O(1)–Sn(1)–O(2) 90.2(2), N–Sn(1)–O/N within cubanes range 81.6(2)–82.6(2) [between adjacent 97.3(2)–105.7(2), opposite 171.7(2)–179.3(2)], Sn–O(1,2)–Sn within cubanes 99.9(2)–103.1(2), Sn–N–Sn within cubanes range 96.5(2)–105.2(2), N–Sn–N within cubanes range 76.8(2)–81.8(2), O–Sn–N within cubanes 72.9(2)–76.8(2); Sn(8)–O(2) 2.186(4), Sn(8)–N(81) 2.227(6), Sn(8)–N(71) 2.142(6), Sn(9)–O(1) 2.185(5), Sn(9)–N(91) 2.141(6), Sn(9)–N(71) 2.131(6); Sn(1,2)–O(1,2)–Sn(8,9) mean 133.9, O(1,2)–Sn(8,9)–N(71) mean 88.3, Sn(8)–N(71)–Sn(9) 142.4(3), Sn(2,3,5,7)–O(1,2)–Sn(8,9) range 105.8(2)–110.6(2); (b) The $Sn_9N_7O_2$ 'handbag' core of **1**.

 DOI: 10.1039/b101247i

are three toluene molecules in the lattice. The coordination of the Sn(II) centres by the oxo double-cubane in **1** is similar to the behaviour of $[Sn_4(NBu^t)_3O]$ in its complexes with Al,[7] Li and Fe,[8] and of the $[(Me_3Si)(NBu^t)_2Sn_2O]$ fragment to $SnCl_2$ in $[(Me_3Si)(NBu^t)_2Sn_2O{\cdot}SnCl_2]$.[9] However, apart from $[Sn_4(NBu^t)_3O]$ no other oxo–imido Sn(II) complexes of this type have been structurally characterised. In addition, the structure of **1** (containing a total of nine Sn centres) is the largest Sn imido cage to be structurally characterised.

The Sn–O bond lengths to the central Sn(IV) atom [Sn(1)–O mean 2.13 Å] in **1** are similar to the Sn(IV)–N bonds [Sn(1)–N range 2.103(4)–2.139(6) Å] and to the Sn(II)–O bonds in $[Sn_4(NBu^t)_3O]$ and its metal complexes (*ca.* 2.10–2.17 Å).[9] The Sn(II)–O bonds in **1** are considerably longer than anticipated [Sn(2,3,5,7)–O range 2.238(4)–2.268(4) Å], and are within the range of values observed for the Sn(II)–N bonds [Sn(2,3,5,7)–N 2.162(6)–2.378(6) Å] in **1**. Thus, despite the substitution of two of the imido groups for O centres, the range of bond lengths and angles found in the $[Sn_7(Ndmp)_6O_2]$ oxo double-cubane unit of **1** is broadly similar to that observed in the structurally characterised double-cubanes $[Sn_7(NR)_8]$.[2] The internal Sn–O–Sn angles found in the $[Sn_7(Ndmp)_6O_2]$ unit of **1** [Sn–O(1,2)–Sn range 99.9(2)–103.1(2)°] are similar to those observed $[Sn_4(NBu^t)_3O]$ and its complexes *ca.* 102°].[7,8]

The most obvious difference between the $[Sn_7(NR)_8]$ double-cubanes and the oxo double-cubane core of **1** is found in the geometry of the central Sn(IV) atom. Coordination of the O centres to the [{Sn(HNdmp)}$_2$(μ-Ndmp)] fragment results in the compression of the O(1)–Sn(1)–O(2) angle [90.2(2)°] and in an associated expansion of the N(21)–Sn(1)–N(41) angle [105.7(2)°] [opposite to the Sn(IV)O_2 fragment]. This leads to a departure from the rigid C_2-symmetric geometry found in $[Sn_7(NR)_8]$ (with N–Sn–N angles between the $[Sn_4(NR)_4]$ cubane subunits of *ca.* 99°)[2] to a more irregular octahedral geometry for the central Sn(IV) atom in **1**. The association of the $[Sn_7(Ndmp)_6O_2]$ and [{Sn(HNdmp)}$_2$(μ-Ndmp)] units [O(1,2)–Sn(8,9) mean 2.186 Å] produces an envelope-shaped, six-membered SnO_2Sn_2N ring, in which the plane of the Sn(IV)O_2 unit is inclined to the plane of the Sn(9)N(71)Sn(8) fragment by 31.5°. Structurally characterised Sn(II) complexes containing two-coordinate imido groups are very rare[10–12] and the presence of a 'captured' [{Sn(HNdmp)}$_2$(μ-Ndmp)] unit in **1** is unprecedented in this area. The Sn–(μ-N) bond lengths in this unit [Sn(8)–N(71) 2.142(6), Sn(9)–N(71) 2.131(6) Å] are longer than the Sn–N bonds between the Sn(II) centres and two-coordinate imido-N centres in the closest analogue to **1**, the *nido*-cubane $[\{SnN(C_6H_3OMe\text{-}2\text{-}Me\text{-}6)\}_2Sn(NMe_2)_2]$ [2.106(2) and 2.120(2) Å] (consisting of a 'trapped' $[SnN(C_6H_3OMe\text{-}2\text{-}Me\text{-}6)]_2$ dimer unit coordinated by a $Sn(NMe_2)_2$ monomer).[12] The expansion of the Sn–(μ-N)–Sn angle in the [{Sn(HNdmp)}$_2$(μ-Ndmp)] fragment [142.4(3)°] above that in the $[SnN(C_6H_3OMe\text{-}2\text{-}Me\text{-}6)]_2$ dimer units of the latter [102.4(1)°] is presumably a consequence of the greater ring size in **1**.

In summary, we have illustrated that the double oxo cubane arrangment can be accessed by hydrolysis. This is the next homologue of the monodentate $[Sn_4(NR)_3O]$ ligand, and its synthesis provides a key first step in the expansion of the coordination chemistry of this class of ligands. However, still to be achieved is the synthesis of $[Sn_7(NR)_6O_2]$ in the absence of coordinated Sn(II) fragments, and the investigation of these species as bidentate ligands to a range of metals. The application of **1** as a source of $[Sn_7(Ndmp)_6O_2]$ is under investigation.

Notes and references

† *Synthesis* of **1**: a mixture of 2-amino-4,6-dimethoxypyrimidine (0.70 g, 4.5 mmol) and H_2O (18 μdm^{-3}, 1.0 mmol) in toluene (10 ml) was added to a solution of $Sn(NMe_2)_2$[13] (1.04 g, 5.0 mmol) in toluene (20 ml) at −78 °C, and the reaction mixture stirred for 30 min. The mixture was allowed to warm to room temperature and stirred (12 h). A faint white precipitate was then filtered off. The solvent was reduced to *ca.* 10 ml and the light yellow powder formed was dissolved by the addition of further toluene (15 ml). Storage at room temperature gave **1** as a light yellow powder. Crystals can be grown by prolonged storage of dilute solutions at room temperature. Elemental analysis and ^{1}H NMR shows that *ca.* two of the three toluene molecules present in the lattice are removed by placing crystalline or powdered samples of **1** under vacuum (10^{-1} atm, 15 min) during isolation. Yield of powder 0.49 g (40%, based on H_2Ndmp consumed and one toluene in lattice); 215 °C melting with decomp. to brown semi-solid. IR (Nujol, NaCl), ν_{max}/cm^{-1} 3396s (N–H str.), 3303s (N–H str.), other bands at 1491m, 1459vs, 1420m, 1246w, 1214s, 1188s, 1160s, 1119s d, 1065s, 1003w, 935w, 795s. ^{1}H NMR (d_6-DMSO, +25 °C, 400.129 MHz), δ 6.55 (s, 9H, aryl rings), 5.31 (s, 2H, N–H), 3.72 (s, 27H, MeO) [toluene at 7.10 (m, Ph), 2.27 (s, Me), *ca.* one per molecule of **1**]. ^{119}Sn NMR (141.21 MHz, d_6-DMSO, +25 °C, rel. sat. $SnCl_2/D_2O$), δ 75.4 (s), −284.8 (br s). Found (typical of several analyses on different reactions) C 28.8, H 2.9, N 15.5; calc. for **1**·C_6H_5Me, C 28.5, H 2.9, N 14.7%.

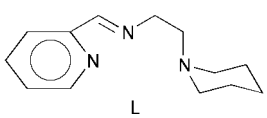
Received (in Cambridge, UK) 15th January 2001, Accepted 5th April 2001
First published as an Advance Article on the web 15th May 2001

A novel one-dimensional copper(II) compound $[Cu(L)(\mu_{1,3}\text{-}N_3)(ClO_4)]_n$ [L = tridentate Schiff base, formed by condensation of pyridine-2-aldehyde and 1-(2-aminoethyl)-piperidine] has been synthesized and structurally characterized; it exhibits ferromagnetic interaction *via* end-to-end azido ($\mu_{1,3}$-N_3) linkages, as rationalised by DFT calculation.

The investigation of magnetic properties of molecule-based magnetic materials (1D, 2D and 3D) has become a fascinating subject in the fields of condensed matter physics, material chemistry as well as inorganic chemistry.[1] Considerable efforts have been directed in preparing and characterizing molecular systems which can exhibit ferromagnetic properties.[2] Bridging ligands play a central role since they transmit the electronic information between the paramagnetic centres; among these the azido ligand has been proved to be efficient. The versatility of the azido ligand lies in its diverse bridging modes that lead to binuclear,[3a] tetranuclear,[3b] cubane-like,[3c] 1D,[3d] 2D[3e] and 3D[3f] compounds. In general, the coordination modes observed for the bridging azido group are end-to-end (μ-1,3) with antiferromagnetic interaction[4] and end-on (μ-1,1) with ferromagnetic interaction.[3a] However, in copper(II) systems where the azido ligand adopts the end-on mode, antiferromagnetic interaction is observed when the bridging M–N–M angle is $> 108°$.[3d] Ribas and coworkers showed, on the basis of theoretical calculations, that there is also a possibility of ferromagnetic interaction between paramagnetic centres when the azido ligand binds in μ-1,3 fashion.[5] Only one compound based on nickel(II) and displaying the end-to-end azido bridging mode exhibiting a ferromagnetic interaction is reported in the literature.[6] To the best of our knowledge, such a magnetic behaviour in 1D copper(II) systems has not been reported to date. Here we report the synthesis and crystal structure of a new one-dimensional (1D) compound, $[Cu(L)(\mu_{1,3}\text{-}N_3)(ClO_4)]_n$ **1**† and the first observation of ferromagnetic interaction through end-to-end azido bridges in copper(II) systems.



The IR spectrum of **1** shows two very strong bands assigned to the asymmetric stretching vibrations of N_3 [$\nu_{as}(N_3)$] centred at 2073 and 2050 cm^{-1} and the stretching vibrations of C=N bond of Schiff base [ν(C=N)] at 1603 cm^{-1}.

The structure determination‡ reveals that the copper atoms are bridged by azido units in an end-to-end fashion with the occurrence of a 1D polymeric infinite chain along the *a*-axis. A ZORTEP view of the asymmetric unit with the symmetry related fragment is shown in Fig. 1. In the chain each copper atom occupies a pseudo octahedral environment with a CuN_5O chromophore. The three nitrogen atoms (N1, N2 and N3) from the tridentate Schiff base ligand and N4 from the bridging azido ligand form the equatorial plane around Cu1 atom. One nitrogen atom (N6*) from another bridging azido ligand and oxygen atom (O4) of the perchlorate anion are in *trans* axial position around Cu1. The equatorial Cu–N bond distances are in the range [1.936(7)–2.080(6) Å]. The deviation of Cu1 from the mean plane formed by the four equatorial nitrogen atoms is *ca.* 0.076(3) Å while the maximum deviation of any equatorial atom (N2) from the mean plane is 0.032(3) Å. The equatorial least squares planes of the two copper atoms are not parallel and form a dihedral angle of 29.4(7)°. For two adjacent copper(II) atoms within the chain (Cu1 and Cu1*), one nitrogen (N4) of the bridging azido is linked to the equatorial base of Cu1 whereas the other nitrogen (N6) of the same azido is linked in an axial fashion to Cu1*. The torsion angle Cu1–N4–N5–N6–Cu1* is 91.6(8)° while the shortest Cu···Cu separation is 5.773(2) Å within the one-dimensional chain and 8.117(3) Å between two adjacent chains.

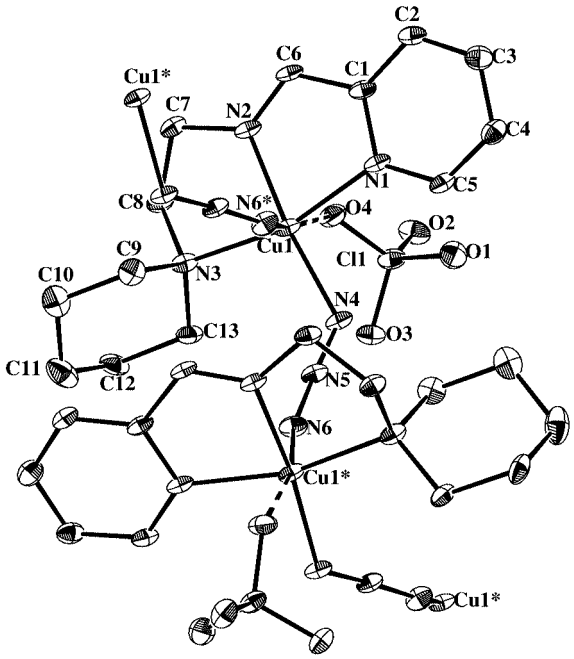


Fig. 1 ZORTEP plot with labelled scheme of $[Cu(L)(\mu_{1,3}\text{-}N_3)(ClO_4)]_n$ **1** (thermal ellipsoids are drawn at 50% probablity). Selected bond lengths (Å) and angles (°): Cu1–N1 2.046(6), Cu1–N2 1.948(6), Cu1–N3 2.080(6), Cu1–N4 1.936(7), Cu1–N6* 2.486(7), Cu1–O4 2.691(7), N4–Cu1-–N6*, 88.0(3), N1–Cu1–N4 94.6(3), N1–Cu1–N3 163.2(2), N1–Cu1–N2 80.1(2), Cu1–N4–N5 125.6(5), N4–N5–N6 177.1(8).

Magnetic studies were performed using a SQUID magnetometer on a crystalline sample in the temperature range 300–2 K in an applied field of 1 kOe. The $\chi_M T = f(T)$ plot (Fig. 2) indicates the occurrence of a ferromagnetic interaction between the Cu(II)

 DOI: 10.1039/b100529o

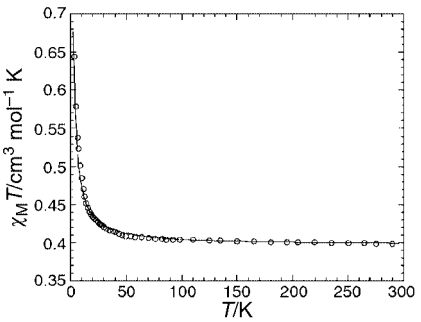

Fig. 2 $\chi_M T$ *vs.* T plot for **1**. The solid line corresponds to the best fit.

ions *via* the end-to-end azido bridge. A fit of the experimental data [where the susceptibility was corrected for TIP (55×10^{-6} cm^3 mol^{-1} per Cu)] was performed using a high-temperature series expansion of the susceptibility;[1a,7] this led to the following parameters: $J = +1.36$ cm^{-1} and $g = 2.06$ with an agreement factor R (defined as $\Sigma[(\chi_M T)_{calc} - (\chi_M T)_{obs}]^2/\Sigma[(\chi_M T)_{obs}]^2$) equal to 10^{-4}. No interchain interaction was included in the fit procedure.

It has already been shown that the different orientations of the equatorial planes (*i.e.* the relative orientations of the $x^2 - y^2$ singly occupied orbitals) of two adjacent Cu atoms are at the origin of the nature and the strength of the magnetic interaction.[8] In order to rationalize the origin of the ferromagnetic interaction, we carried out two types of calculations using the DFT method.[9,12] § The calculation of the exchange parameter within a binuclear unit of the infinite chain leads to a positive J value of +1.6 cm^{-1} indicating that a weak ferromagnetic exchange interaction should be present as observed experimentally. The second calculation was carried out on a mononuclear fragment in order to visualize the magnetic orbital and to try to give a qualitative interpretation of the observed ferromagnetic interaction.[13] It has been found that the magnetic orbital has a contribution from the azido π orbital for the azido nitrogen atom located in the equatorial plane of copper Fig. 3(a)] while a very weak contribution from the σ-like orbital of the azido bridge is found for the nitrogen occupying the axial position as schematized in Fig 3(b). The origin of the ferromagnetic exchange interaction can thus be rationalized as due to the quasi-orthogonality of the magnetic orbitals of the two mononuclear fragments. It is worth noting that the presence of a contribution from the σ orbital of the azido bridge is due to the fact that for a Cu–$\mu_{1,3}$-N3–Cu torsion angle of 91.6(8)° (close to 90°) the Cu–N6–N5 angle [135.7(5)°] is rather large [Fig. 3(b)]. A zero delocalisation should theoretically be observed for a Cu–N6–N5 angle of 90° while it should be maximal for 180°. On the other hand, the fact that the Cu–N4–N5 angle [125.6(5)°] is closer to 90 than to 180° results in a rather large delocalisation of the metal electron density towards the π orbital of the azido bridge. The very weak coupling parameter is mainly due to the unusual axial–equatorial bridging mode of the azido ligand. The consequence is a good π-type delocalisation of the Cu1 electron density towards the bridging azido ligand nitrogen atoms N(4) and N(6), while the apical position of N(6) and the long Cu–N(6) distance results in a rather poor σ-type delocalisation from Cu1*. The overlap density which is mainly localized on N(6) is thus very small leading to a weak exchange coupling parameter.

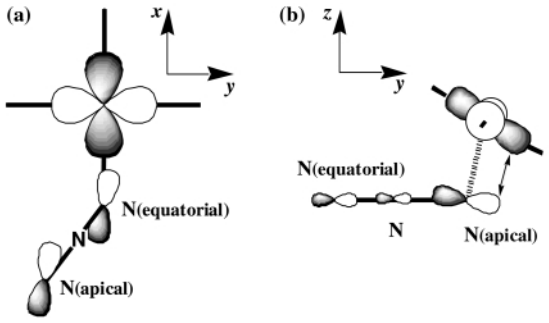

Fig. 3 The magnetic orbital of the copper fragment interacting with (a) the azido nitrogen in the equatorial plane and (b) the azido nitrogen in apical position.

We wish to thank Council of Scientific and Industrial Research, New Delhi for financial support (granted to N. R. C).

† **CAUTION**: perchlorate as well as azide salts should be used in small quantities and handled with care since explosion may occur.

A methanolic solution (5 cm^3) of 1-(2-aminoethyl)piperidine (1 mmol, 0.128 g) was added to a methanolic solution (20 cm^3) of pyridine-2-aldehyde (1 mmol, 0.106 g). The reaction mixture was refluxed for 1 h and evaporated on a water bath until the volume reduced to *ca.* 5 ml to obtain a viscous liquid which was added to the methanolic solution (10 cm^3) of $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol, 0.370 g). The resulting reaction mixture was refluxed for 15 min. To it NaN_3 (1 mmol, 0.065 g) dissolved in methanol (5 cm^3) was added and the resulting deep green solution was stirred for 1 h. This was then filtered and the filtrate kept in the open atmosphere. After a few days deep green shiny single crystals suitable for X-ray diffraction were obtained. (Yield 80%). Anal. Found (calc.): C, 36.89 (36.96); H, 4.50 (4.50); N, 19.89 (19.90); Cu, 15.00 (15.05)%.

First published as an Advance Article on the web 15th May 2001

$[Se_2Cr_3(CO)_{10}]^{2-}$, the first selenium-capped trichromium carbonyl cluster, has been prepared and its reaction with $Mo(CO)_6$ studied.

Although numerous carbonylchromium complexes have been reported, they have little tendency to form clusters with Cr–Cr bonds.[1] Up to now, only three homometallic chromium carbonyl clusters with a Cr_3 ring have been structurally characterized.[2–6] The rare Cr–Cr bonds in these clusters are made possible with the stabilizing ligands such as μ_3-S,[4,6] μ_3-PR,[5] and diphosphene,[6] and importantly, with the aid of the existence of the bridging carbonyls in each case.[4–6] Nevertheless, no fully characterized carbonylchromium cluster with Cr–Cr bonds stabilized with heavier main group elements has been known.[7,8] We have prepared the first example of the selenium-capping trichromium carbonyl cluster complex $[Et_4N]_2[Se_2Cr_3(CO)_{10}]$ **1**, in which three Cr–Cr bonds are present and all the carbonyls are terminally coordinated.

Numerous attempts to gain entry to the Se–Cr–CO system using SeO_2 with $Cr(CO)_6$ in basic KOH–MeOH solutions were not successful. However, it was found that use of the highly concentrated NaOH–MeOH solutions followed by cation metathesis with $[Et_4N]Br$ resulted in **1**. Note that the isolation of **1** succeeds only in the NaOH–MeOH solutions but not in the KOH–MeOH solutions due to alkali metal cation effects on the stabilization of the cluster anion. The Mo-substituted dichromium cluster complex $[Et_4N]_2[Se_2Cr_2Mo(CO)_{10}]$ **2** was obtained by treatment of the parent compound **1** with $[Mo(CO)_6]$ in acetone.† The anionic clusters of **1** and **2** represent rare examples of carbonylchromium clusters which possess three and one chromium–chromium bonds, respectively.

The anion of cluster **1** exhibits a trigonal bipyramidal structure with the Cr_3 ring capped above and below by μ_3-Se atoms, in which the Se atom donates four electrons to the Cr_3 ring making it a 48e$^-$ species, in accord with three chromium atoms with three Cr–Cr bonds. The anion possesses two mirror planes: one passing through the Cr_3 ring and the other one lying in the $Cr(1)Se_2$ plane (Fig. 1).‡ The Cr–Cr distances of 2.849(2) and 2.926(3) Å are somewhat longer than predicted from the covalent radius of Cr (1.28 Å).[9] However, they are comparable to Cr–Cr bonds found for $[SCr_3(CO)_{12}\{Cr(CO)_5\}]^{2-}$ (average 2.850 Å),[4] $[(Bu^tP)Cr_3(CO)_{10}(Bu^tPPBu^t)]$ (2.814–2.851 Å),[5] $[SCr_3(CO)_{12}]^{2-}$ (average 2.828 Å),[6] and $[Cr_6Se_8(PEt_3)_6]$ (average 2.81 Å),[10] and are slightly shorter than that in $[\{TeCr(CO)_5\}_2Cr_2(CO)_8]^{2-}$ (3.052 Å).[11] The fairly long Cr–Cr bonds reflect their weakness and may account for the rarity of carbonylchromium clusters. Unlike the previously reported carbonyltrichromium clusters,[4–6] the anion of **1** possesses only terminal carbonyls, with two Cr atoms coordinated with three carbonyls and the unique Cr(1) attached to four carbonyls. Of interest is that the four Cr(1)–C distances [1.832(9)–1.917(9) Å] are somewhat greater than those for Cr(2) [1.816(9)–1.855(7) Å], indicative of weaker Cr–C bonding for the Cr(1) atom with four coordinated carbonyls. The same effect is also observed in the larger Se–Cr(1) distance [2.575(2) Å] compared with the Se–Cr(2) distance [2.387(1) Å].

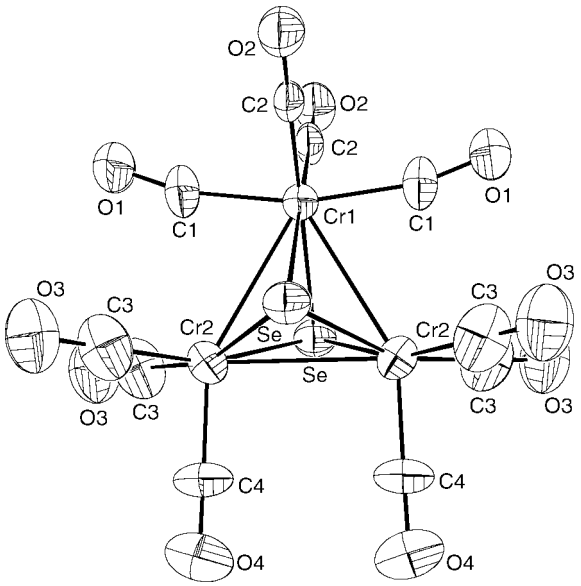

Fig. 1 Crystal structure of the dianion of **1** showing 30% thermal ellipsoids and the atom labelling scheme. Important bond lengths (Å) and angles (°): Se–Cr(1) 2.575(2), Se–Cr(2) 2.387(1), Cr(1)–Cr(2) 2.849(2), Cr(2)–Cr(2a) 2.926(3), Cr(1)–C(1) 1.917(9), Cr(1)–C(2) 1.832(9), Cr(2)–C(3) 1.855(7), Cr(2)–C(4) 1.816(9); Cr(2)–Cr(1)–Cr(2a) 61.81(7), Cr(1)–Cr(2)–Cr(2a) 59.09(3).

Employing a similar methodology to the Se–Mo–CO system failed, and we therefore treated **1** with $[Mo(CO)_6]$ in acetone to see if any carbonylchromium fragment can be replaced by an incoming molybdenum moiety. This was found to be so; the $Cr(CO)_4$ fragment in **1** can be exchanged by $Mo(CO)_4$ to form the mixed-group 6 metal complex **2**, $[Et_4N]_2[Se_2Cr_2Mo(CO)_{10}]$. X-Ray analysis shows that the anion of **2** is structurally similar to that of **1**, with the Cr(1) atom replaced by the Mo(1) atom (Fig. 2).‡ The formulation of **2** was further substantiated by ICP metal analysis. While the Cr–Cr bond of 2.947(2) Å is still long and similar to the Cr–Mo distances (average 2.9512 Å), the average Se–Cr length (2.4157 Å) is significantly shorter than that of the Se–Mo distances (2.6744 Å).

In summary, the first synthesis of a trichromiumcarbonyl cluster anion by the stabilization of the μ_3-Se atoms has been achieved. The ease of replacing one Cr moiety of **1** with the Mo fragment suggests the possibility in making other mixed-metal carbonylchromium clusters which may help elucidate the bonding characteristics of the Cr–Cr and Cr–M bonds. Further investigation is under way.

A research grant (NSC 89-2113-M-003-031 to M. Shieh) from National Science Council of Taiwan is gratefully appreciated.

Important bond lengths (Å) and angles (°): Se(1)–Cr(1A) 2.4123(9), Se(1)–Cr(1) 2.4190(9), Se(1)–Mo(1) 2.6745(7), Se(1A)–Mo(1) 2.6743(7), Mo(1)–Cr(1) 2.9511(9), Mo(1)–Cr(1A) 2.9513(9), Cr(1)–Cr(1A) 2.947(2), Cr(1)–C(3) 1.845(6), Cr(1)–C(4) 1.850(5), Cr(1)–C(5) 1.815(7); Cr(1)–Mo(1)–Cr(1A) 59.92(3), Cr(1A)–Cr(1)–Mo(1) 60.04(2).

Notes and references

† *Synthetic procedure:* All experiemnts were performed under N_2 atomsphere. A mixed solution of MeOH (30 mL) and hexanes (7.5 mL) was added to a mixture of SeO_2 (0.21 g, 1.89 mmol) and $[Cr(CO)_6]$ (0.8 g, 3.64 mmol), and NaOH (3.0 g, 82.5 mmol). The mixed solution was heated to reflux in an oil-bath at 70 °C for 12 h to give a dark-red solution which was filtered and concentrated, and a MeOH solution of $[Et_4N]Br$ (3.0 g, 14.3 mmol) was added dropwise, precipitating the solid. The solid was washed several times with MeOH and CH_2Cl_2. The residue was recrystallized from diethyl ether–MeCN several times to give purplish-red **1** (0.42 g, 0.49 mmol) (52% based on Se). IR (ν_{CO}, MeCN): 1990w, 1914s, 1869m cm^{-1}. Anal. Found for **1**: C, 36.55; H, 4.67; N, 3.31%. Calc.: C, 36.55; H, 4.72; N, 3.28. Compound **1** is soluble in MeCN and acetone, but insoluble in other organic solvents. Crystals suitable for X-ray analysis were grown from CH_2Cl_2–MeCN solution.

Acetone (25 mL) was added to a mixture of **1** (0.23 g, 0.269 mmol) and $[Mo(CO)_6]$ (0.10 g, 0.379 mmol). The mixed solution was stirred at room temperature for 11 days and the color changed from dark-red to brown. The resultant solution was filtered and solvent was removed under vacuum. The residue was washed with CH_2Cl_2, extracted with MeCN, and then recrystallized with CH_2Cl_2–MeCN several times to give purplish-red **2** (0.16 g, 0.178 mmol) (66% based on **1**). IR (ν_{CO}, MeCN): 2068w, 2002m, 1916vs, 1868s, 1827m cm^{-1}. Anal. Found for **2**: C, 35.22; H, 4.56; N, 3.14; Cr, 11.20; Mo, 9.09. Calc.: C, 34.76; H, 4.49; N, 3.12; Cr, 11.57; Mo, 10.68%. Complex **2** is soluble in MeCN and acetone. Crystals suitable for X-ray analysis were grown from diethyl ether–MeCN solution.

‡ *Crystal structure data*: for **1**: $C_{26}H_{40}Cr_3N_2O_{10}Se_2$: M = 854.51, orthorhombic, space group *Cmcm*, Z = 4, a = 8.607(3), b = 24.591(8), c = 15.941(4) Å, V = 3374.0(18) $Å^3$, D_c = 1.682 g cm^{-3}, λ(Mo-Kα = 0.70930 Å, μ = 3.16 mm^{-1}. A total of 1656 unique reflections were collected on a Nonius (CAD-4) diffractometer at 298 K in the 2θ range 2.0–50° using θ–2θ scans, and an absorption correction by azimuthal (ψ) scans was applied. The structure was solved by direct methods and refined both with NRCC-SDP-VAX and SHELXL-97 packages. Both refinements gave the similar results; however, the latter gave the lower R values and smaller esds on distances and angles. Therefore, the results of the SHELXL-97 refinement were used here. The $[Et_4N]^+$ cations are disordered and the H atoms were placed in calculated positions and refined with a riding model. All the other non-hydrogen atoms were refined with anisotropic temperature factors. Full-matrix least squares on F^2 converged to R = 0.1123 (all data), 0.0406 [$I > 2\sigma(I)$]; wR = 0.1142 (all data), 0.1037 [$I > 2\sigma(I)$].

For **2**: $C_{26}H_{40}Cr_2MoN_2O_{10}Se_2$: M = 898.46, orthorhombic, space group *Pnna*, Z = 4, a = 24.8153(3), b = 16.0695(3), c = 8.6204(2) Å, V = 3437.55(11) $Å^3$, D_c = 1.736 g cm^{-3}, λ(Mo-Kα) = 0.71073 Å; CCD SMART diffractometer, and SADABS absorption correction (T_{min} = 0.569, T_{max} = 0.634). A total of 22975 reflections were measured, and 3957 unique reflections ($2\theta < 55°$, R_{int} = 0.0406) were used in the refinement. All the non-hydrogen atoms were refined with anisotropic temperature factors. Full-matrix least squares refinement on F^2 converged to R = 0.0774 (all data), 0.0495 [$I > 2\sigma(I)$]; wR = 0.1697 (all data), 0.1442 [$I > 2\sigma(I)$]. All calculations were performed using SHELXTL packages.

Received (in Cambridge, UK) 7th March 2001, Accepted 23rd April 2001
First published as an Advance Article on the web 15th May 2001

Super-microporous aluminosilicate catalysts possessing pores in the range 14–20 Å may be prepared *via* primary amine templating alone or in combination with post-synthesis Al-grafting.

The design and synthesis of materials that have a well defined pore structure similar to that of zeolites, but with larger pores, has been a main research goal in solid acid catalysis over the past decade.[1] Recent advances, which include the synthesis of the M41S family of mesoporous solids,[2] have to some extent achieved this goal. Many other varieties of mesoporous materials with pores of size typically above 25 Å have been prepared.[3] Until recently, much less attention has been paid to the synthesis of materials with pores in the super-microporous (10–20 Å) range. Solid acid materials in this pore size range are important since they bridge the gap between microporous zeolites and mesoporous materials. Bagshaw and Hayman[4] used ω-hydroxy-bolaform surfactants to template the formation of super-microporous silicas. Zhao *et al*.[5] reported the preparation of MCM-41 materials with tailored pore openings in the super-microporous range. Sun *et al*.[6] used adamantanamine while Serranno *et al*.[7] employed cetyltrimethylammonium or dodecyltrimethylammonium ions for the formation of microporous materials. Here we report the primary amine templated synthesis of super-microporous aluminosilicate materials whose pore size can be further tailored *via* post-synthesis grafting of Al. Post-synthesis grafting of extra Al also serves to remarkably improve the acidity and catalytic activity of the materials.

We have previously reported on the preparation of *mesoporous* aluminosilicates (Al-MMS, Al-HMS)[8–10] using the primary amine templating route.[11] Our previous work has shown that the pore size of Al-MMS (Al-HMS) materials is to some extent dependent on the alkyl chain length of the primary amine template with longer amines resulting in larger pores.[12,13] The pore size was also found to be dependent on the Si/Al ratio, *i.e.* the pore size was reduced at low Si/Al ratios.[8–10,12,13] This meant that pore sizes at the lower end of the mesopore range (*ca*. 20 Å) were only obtainable for highly aluminous samples and that pores in the super-microporous range (10–20 Å) could not be achieved even at Si/Al ratios as low as 7.[8–10,12,13] Previous work has also shown that materials prepared at gel Si/Al ratios in the range 80–1 always have higher than expected Si/Al ratios implying relatively low levels of Al incorporation into the solid products.[8–10,12,13] We have now found that it is possible to circumvent the limitation on the lowest pore size obtainable by improving the incorporation of Al. This is achieved by modifying our previous synthesis procedure[10] so as to ensure optimum dissolution of the Al source. Furthermore performing post-synthesis grafting of extra Al can reduce the pore size of the resulting materials further.

The synthesis procedure used[10] was modified as follows: desired quantities of aluminium isopropoxide ($Al(i\text{-}C_3H_7O)_3$) were dispersed in 35 ml of isopropyl alcohol with vigorous mechanical stirring at 70 °C for 15 min in order to dissolve the highest possible amount of the aluminium source. The resulting solution was cooled to room temperature and then added under magnetic stirring to a solution of 0.2 mol tetraethyl orthosilicate (TEOS) in 80 ml of absolute ethanol. The resulting mixture was then heated at 70 °C under vigorous stirring for 4 h to obtain the polymerised Si–O–Al species. After cooling to room temperature (under stirring) the inorganic precursor was added to a clear solution of 0.05 mol dodecylamine (DDA) in a mixture of 80 ml of deionised water and 120 ml of absolute ethanol under slow stirring. The stirring was maintained for 5 min after which the resulting mixture was allowed to age at room temperature for 20 h. The solid product was obtained by filtration, washed with two portions of 100 ml of ethanol, air-dried overnight at room temperature and finally calcined in air at 650 °C for 4 h. This procedure was used to prepare aluminosilicate materials with Si/Al molar ratios of 40 : 1, 20 : 1 and 10 : 1, designated Al-MMSX where X is the synthesis gel Si/Al ratio. Al-grafting was performed on the Al-MMSX samples as follows: 1.28 g of a solution of chlorhydrol ($[Al_2Cl(OH)_5{\cdot}2H_2O]$, 6.4 mol l^{-1} with respect to aluminium) was dissolved in 50 ml of distilled water and stirred at 80 °C for 1 h. 1.0 g of Al-MMSX was added to the solution and the resulting suspension stirred for a further hour at 80 °C. After cooling to room temperature, the solid was filtered off and washed with distilled water until free of Cl^- ions, dried in the oven at 100 °C and finally calcined at 500 °C for 4 h. The resulting Al-grafted materials were designated AlAl-MMSX.

The elemental compositions, *d* spacing and textural properties of the present Al-MMS materials are shown in Table 1 and 2. The bulk Si/Al ratios of the samples indicate that Si and Al are incorporated into the solid framework in proportions closely related to the synthesis gel composition. A significant observation is that Al-MMS40 and Al-MMS10 are Al rich, *i.e.* a greater proportion of Al in the synthesis gel is incorporated into the solid product compared to Si. This is a departure from our previous studies where we always obtained silica rich materials.[8–10,12,13] The modified synthesis procedure used here, in which the dissolution of the Al source is optimised, therefore allows for greater Al incorporation into the solid product. The *d* spacings of the present Al-MMS samples (see Table 2) are in all cases lower (by *ca*. 5%) than those we have previously

Table 1 Elemental composition, acid content and catalytic activity of super-microporous Al-MMS samples

Sample	Si/Al	Acid content/ mmol g^{-1}	Cumene conversion (%)[a] 50 min	150 min
Al-MMS40	39.0	0.36	35	28
AlAl-MMS40	22.8	0.57	53	47
Al-MMS20	22.0	0.56	47	41
AlAl-MMS20	14.9	0.75	59	54
Al-MMS10	9.0	0.73	59	51
AlAl-MMS10	7.4	0.82	67	60

[a] The conversion of cumene was performed in a tubular stainless steel, continuous flow, fixed-bed microreactor system with helium as carrier gas at 300 °C as previously described in ref. 10.

Table 2 Textural properties of super-microporous Al-MMS samples; values in parenthesis are micropore surface area and volume

Sample	Basal (d_{100}) spacing/Å	Surface area/ $m^2\ g^{-1}$	Pore volume/ $cm^3\ g^{-1}$	Pore size/ Å
Al-MMS40	32.4	1023 (488)	0.45 (0.18)	20.5
AlAl-MMS40	32.0	643 (406)	0.33 (0.17)	17.7
Al-MMS20	31.1	864 (497)	0.38 (0.19)	18.4
AlAl-MMS20	30.2	562 (403)	0.28 (0.17)	16.3
Al-MMS10	30.5	684 (520)	0.31 (0.20)	17.7
AlAl-MMS10	29.8	358 (286)	0.24 (0.18)	14.5

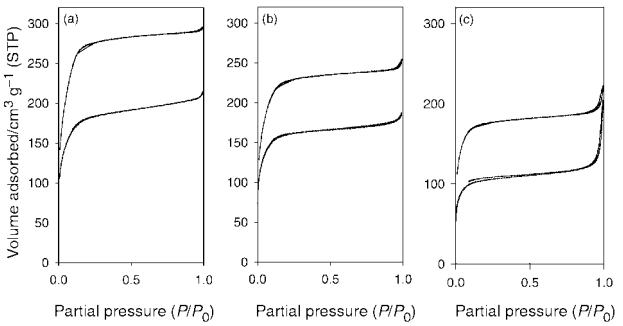

Fig. 1 Nitrogen sorption isotherms of super-microporous primary amine templated aluminosilicates, prepared at gel Si/Al ratios of (a) 40, (b) 20, (c) 10, before (top) and after (bottom) post-synthesis grafting of Al.

observed.[10] It is worth noting that the *d* spacings observed here are generally lower than those normally obtained for M41S type mesoporous materials.[1–3] Powder XRD patterns (not shown), for the present Al-MMS samples are similar to those of comparable mesoporous materials,[10–14] *i.e.* comprising of a single (100) peak at low 2θ values. This is an indication that the present samples are as well ordered as any other primary amine templated mesoporous aluminosilicates.

The clearest indication that the greater Al incorporation attained here results in materials with super-microporous rather than mesoporous character is given by the textural parameters in Table 2. The surface area, pore volume and pore size obtained for the present samples are generally lower than those previously observed for mesoporous Al-MMS (Al-HMS) materials.[10–14] We have previously reported surface areas of 1200, 1195 and 967 $m^2\ g^{-1}$, and pore volumes of 0.65, 0.52 and 0.49 $cm^3\ g^{-1}$ for mesoporous Al-MMS materials prepared (with dodecylamine as template) at gel Si/Al ratios of 40, 20 and 10, respectively.[10] The pore volumes of the present samples are therefore at least 30% lower than those of analogues mesoporous materials.[10] A particular feature of the present Al-MMS samples is that they exhibit a high proportion of micropore surface area and volume as shown in Table 2. The pore size of the materials (obtained using BJH analysis) is, as shown in Table 2, clearly in the super-microporous range. This is illustrated by the N_2 sorption isotherms shown in Fig. 1. The isotherms exhibit high adsorption at low ($P/P_o < 0.2$) partial pressures which is characteristic of super-microporous materials. The isotherms do not exhibit the mesopore filling step (at $P/P_o > 0.2$) normally observed for mesoporous materials.

We have found that performing post-synthesis grafting of Al can increase the microporous character of the Al-MMS samples. The effect of Al-grafting on pore size and porosity is illustrated in Fig. 1; the super-micropore filling step is shifted to lower partial pressures (lower pore size) after grafting. As shown in Table 2, the pore size of AlAl-MMS samples is lower than that of Al-MMS materials by 2–3 Å. This reduction in pore size is accompanied by a decrease in surface area and pore volume, which in turn leads to an increase in the *proportion* of micropore surface area and volume. Indeed sample AlAl-MMS10 is virtually microporous, with a pore size of 14.5 Å and the proportion of micropore surface area and volume is above 75%. It is likely that the Al is grafted into the pore walls thus reducing the pore size. This does not, however, effect the basal spacing (see Table 2). We note that structural ordering (as indicated by powder XRD) is largely unaffected by the grafting process. In addition to tailoring the pore size, Al-grafting also increases the acid content and catalytic activity as shown in Table 1. (The acid content was determined by exposing the samples to cyclohexylamine for 16 h following which they were heated at 100 °C for 4 h to remove physisorbed amine. The samples were then subjected to thermogravimetric analysis and the weight loss between 240 and 420 °C was used to calculate the acid content assuming that each acid site interacts with one base molecule.[9]) The increase in acid content is greatest for AlAl-MMS40 (*ca.* 60%) and lowest for AlAl-MMS10 (*ca.* 12%). The increase in acidity is reflected by the higher cumene cracking[10] activity for the AlAl-MMS samples. Interestingly, the sample (Al-MMS10) with the highest cation exchange capacity (CEC = 42 meq./100 g) takes up less 'extra Al' than Al-MMS40 with a CEC of 12 meq./100 g. (CECs were measured using the Kjeldahl method after NH_4^+ exchange.) This implies that the take up of extra Al is not entirely an ion exchange process. Rather it appears that grafting also occurs on silanol groups as previously described.[15,16] The take up of extra Al is therefore consistent with our previous observation that the concentration of silanols in Al-MMS type materials decreases with Al content.[10] Indeed under similar grafting conditions the pure silica material incorporates at least twice as much Al as the Al-MMS samples.

Primary amine templating of mesostructured aluminosilicates is known to provide solid acid catalysts whose activity is generally higher than that of materials prepared *via* quaternary ammonium ion templating.[10,12,17] Recently, it has also been shown that the wormhole-like structure of primary amine templated aluminosilicates has three-dimensional connectivity.[18] Such connectivity is an important factor with respect to catalytic activity. This report therefore represents the first synthesis of super-microporous aluminosilicates with three-dimensional connectivity. These super-microporous materials combine all the advantages of primary amine templated aluminosilicates, and also offer the potential for size and shape selective catalysis of large substrates, which is not possible for mesoporous materials.

E. B. G. would like to thank CONICIT for the Venezuelan financial support. C.O.T. and O.R.S. scholarships are also acknowledged. R. M. is grateful to the EPSRC for an Advanced Fellowship.

Ethers reacted with acid chlorides in the presence of a catalytic amount of $MCl_{5/6}$ (M = Mo, W, Nb or Ta) to give esters in 75–98% yield; a stoichiometric reaction of dioctyl ether with $MoCl_5$ afforded 1-chlorooctane in 93% yield and addition of benzoyl chloride to the resulting mixture gave octyl benzoate in 49% yield.

C–O bond cleavage is a versatile reaction in organic synthesis; in particular, the catalytic cleavage of the C–O bond of ethers is very attractive.[1] There are several examples of catalytic C–O bond cleavage of ethers in the presence of acid chlorides and Lewis acids such as $ZnCl_2$,[2] $FeCl_3$,[3] $SnBr_2$,[4] $CoCl_2$,[5] $AlCl_3$,[6] YCl_3,[7] $LnCl_3$,[8] Al[9] and Zn.[10] As for group 6 metal compounds, low-valent molybdenum compounds such as $Mo(CO)_6$[11] and $ArMo(CO)_3$[12] have been used as catalysts for acylative cleavage of ethers. It is generally believed that these catalytic reactions proceed *via* a cationic mechanism in which the acid chloride reacts with the catalyst first to generate a RCO^+ ion. Addition of an ether gives an oxonium salt ($RCO_2{}^+R'_2$) followed by cleavage of the C–O bond to give an ester. Here, we report a novel catalytic system for acylative cleavage of ethers [eqn. (1)] using group 5 or 6 metal halides and propose a novel catalytic reaction mechanism.

$$R^1OR^2 + R^3COCl \xrightarrow{\text{cat. } MCl_{5/6}} R^3CO_2R^1 \quad (1)$$

M = Mo, W, Nb or Ta

A representative procedure for the catalytic C–O bond cleavage is as follows: All reactions were carried out under nitrogen and metal chlorides were handled under nitrogen. Solvents were dried and distilled. To a mixture of molybdenum(v)chloride (0.1 mmol, 27 mg) and dichloroethane (DCE) (5 ml) was added dibutyl ether (1 mmol, 130 mg) and benzoyl chloride (1 mmol, 141 mg). The reaction mixture was stirred at 80 °C for 3 h. GC analysis of the resulting mixture after hydrolysis showed the formation of butyl benzoate in 95% yield. Purification by column chromatography on silica gel afforded butyl benzoate in 75% isolated yield. The results are summarized in Table 1.

The C–O bond of dibutyl ether was cleaved in the presence of 10 mol% of $MoCl_5$ and *n*-caproyl chlorides at 80 °C for 24 h and the caproic acid *n*-butyl ester was obtained in 96% yield (Run 2). The lower reactivity of aliphatic acid chlorides than that of aromatic acid chlorides has been reported in the case of graphite.[13] In the reaction reported here, there is no significant reactivity difference between the aromatic acid chloride and the aliphatic acid chloride. Dioctyl ether also reacted with benzoyl chloride and *n*-caproyl chloride to give octyl benzoate and *n*-caproyl acid *n*-octyl ester, respectively, in high yield (Runs 3 and 4). It is interesting to note that some unsymmetric ethers showed selective cleavage of the C–O bond. For example, methyl *tert*-butyl ether reacted with benzoyl chloride to give methyl benzoate in 99% yield (Run 5) *i.e.* the Bu^t–O bond in methyl *tert*-butyl ether was selectively cleaved. Allyl propyl ether was also selectively cleaved under the same conditions. The allyl–O bond was cleaved to give caproyl acid propyl ester (Run 6). In contrast, for allyl trimethylsilyl ether, selective cleavage of the Si–O bond was observed (Run 7) and the allyl–O bond was not cleaved. Other group 5 and 6 metal chlorides were also quite active for acylative cleavage of ethers. Dibutyl ether reacted with benzoyl chloride in the presence of 10 mol% of WCl_6 for 24 h to give butyl benzoate in 96% yield (Run 8). When $NbCl_5$ and $TaCl_5$ were used as catalysts, catalytic C–O bond cleavage was also successful and butyl benzoate was obtained in 98 and 96% yield, respectively (Runs 9 and 10).

In order to investigate the reaction mechanism, a stoichiometric reaction of dioctyl ether with molybdenum(v) chloride was carried out at 80 °C. After 3 h, 1-chlorooctane was obtained in 93% yield [eqn. (2)]. To the resulting mixture, benzoyl chloride was added and octyl benzoate was obtained in 49% yield [eqn. (3)].

$$C_8H_{17}OC_8H_{17} + MoCl_5 \xrightarrow[80\ ^\circ C,\ 3\ h]{DCE,} \underset{93\%}{C_8H_{17}Cl} + \underset{\text{reaction mixture}}{[C_8H_{17}OMoCl_n]} \quad (2)$$

$$\underset{\text{reaction mixture}}{[C_8H_{17}OMoCl_n]} \xrightarrow[80\ ^\circ C,\ 3\ h]{PhCOCl} \underset{49\%}{PhCO_2C_8H_{17}} \quad (3)$$

Table 1 Acylative cleavage of ethers with acid chlorides in the presence of $MCl_{5/6}$[a]

Run	Ether	RCOCl	$MCl_{5/6}$	Time/h	Product	Yield[b] (%)
1	Bu_2O	PhCOCl	$MoCl_5$	3	$PhCO_2Bu$	95(75)
2	Bu_2O	$C_5H_{11}COCl$	$MoCl_5$	24	$C_5H_{11}CO_2Bu$	96(78)
3	$C_8H_{17}OC_8H_{17}$	PhCOCl	$MoCl_5$	1	$PhCO_2C_8H_{17}$	88(78)
4	$C_8H_{17}OC_8H_{17}$	$C_5H_{11}COCl$	$MoCl_5$	3	$C_5H_{11}CO_2C_8H_{17}$	94(82)
5	$CH_3OC(CH_3)_3$	PhCOCl	$MoCl_5$	1[c]	$PhCO_2CH_3$	99(76)
6		$C_5H_{11}COCl$	$MoCl_5$	1	$C_5H_{11}CO_2C_3H_7$	98(81)
7		$C_5H_{11}COCl$	$MoCl_5$	3	$C_5H_{11}CO_2CH_2CH{=}CH_2$	75(58)
8	Bu_2O	PhCOCl	WCl_6	3	$PhCO_2Bu$	96
9	Bu_2O	PhCOCl	$NbCl_5$	24	$PhCO_2Bu$	98

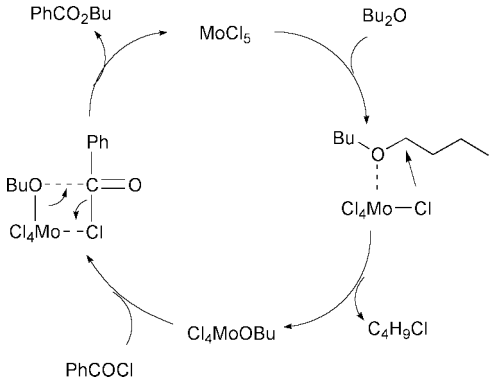
 DOI: 10.1039/b100852h

The results obtained here showed that the ether reacted with $MoCl_5$ first, to form 1-chlorooctane and the $[C_8H_{17}OMoCl_n]$ complex, although this complex was not characterized.† Benzoyl chloride then reacted with the molybdenum complex to give octyl benzoate. A proposed mechanism is shown in Scheme 1. The mechanism proposed here is quite different from the cationic mechanism which has been generally proposed for the catalytic acylative cleavage of the C–O bond of ethers. For example, Alper and Huang[11] and Tsonis[12] used group 6 metal carbonyl or substituted group 6 metal carbonyl complexes to catalyze the acylative cleavage of ethers. In both studies a mechanism was proposed whereby acid chloride reacts with the metal carbonyl to form a RCO^+ ion, followed by the reaction with an ether to produce an oxonium salt which is then cleaved to give the ester.



Scheme 1 Proposed reaction mechanism for catalytic acylative cleavage of ethers using $MoCl_5$.

The C–O bond of ethers can be cleaved only by $MoCl_5$ in our system which is similar to stoichiometric C–O bond cleavage of ethers with Lewis acids. The role of the acid chlorides in the reactions reported here does not lead to formation of the oxonium salt but rather provides Cl^- to Cl_4MoOR to regenerate $MoCl_5$ and esters.

First published as an Advance Article on the web 15th May 2001

The polymer $[Ni_2(C_4N_2H_3S)_4]_n$ with excellent electrical conductivity and ferromagnetic interaction between the nickel(II) centers has been prepared by the hydrothermal reaction of $Ni(O_2CMe)_2$ with pyrimidine-2-thiol in DMF–H_2O; X-ray diffraction shows that the polymer possesses a lamellar structure formed from the conjunction system of pyrimidine rings and Ni(II) centers.

The increasing interest in inorganic–organic hybrid framework assemblies has resulted in a great deal of research effort focused on the development of new functional materials ranging from zeolite-like coordination polymers[1] to multilayered perovskites,[2] which possess various potential applications, such as in electrical conductivity[3] and magnetism.[4,5] For instance, Shimizu *et al.* reported a layered 'inorgano–organic' solid where the inorganic component is composed of sulfonate-bridged silver(I) centers and the organic moiety is a phenyl group.[6a] Monfort *et al.* reported a metamagnetic two-dimensional molecular material prepared from nickel(II) and azide bridging ligand.[6b] In this field, studies have mainly been focused on inorganic–organic hybrid materials containing N-donor ligands, and relatively few efforts have been made to investigate transition metal organosulfur coordination polymers[7,8] although the coordination chemistry of organosulfur compounds has been intensively studied for more than twenty years.[9]

As a result of the tendency of thiolates to bridge metal centers to yield insoluble or sparingly soluble polymers, it is difficult to control the reactions of thiolates with metal ions and obtain single crystals of polymeric metal thiolates suitable for X-diffraction analysis. Our recent researches revealed the reaction of N-donor-containing thiols such as pyridine-2-thiol with silver ions led to soluble complex species, which can be converted into silver–thiolate or silver–thione polymers under appropriate conditions.[10] Considering that pyrimidine-2-thiol can adopt a variety of coordination modes in its coordination chemistry[11] it was deduced that coordination polymers with novel structures may be isolated through the reaction of M(II) transition metal ions with pyrimidine-2-thiol. We have succeeded in the isolation of coordination polymers by the hydrothermal reaction of bivalent transition metal ions and pyrimidine-2-thiol. Here, we demonstrate the formation of a nickel(II)–pyrimidine-2-thiolate polymer $[Ni_2(C_4H_3N_2S)_4]_n$ **1** ($C_4H_3N_2S$ = pyrimidine-2-thiolate), with lamellar structure. In contrast to other Ni(II) compounds and coordination polymers with lamellar structure,[6c] the interesting features of **1** are its paramagnetic and semiconducting properties.

At 90 °C, the hydrothermal reaction of $Ni(O_2CMe)_2$ with pyrimidine-2-thiol in DMF–H_2O (v:v = 1:2) for 48 h and crystallization by slow cooling of the reaction solution to room temperature led to the growth of a large amount of dark-brown, sheet-like crystals of **1**. The crystalline product **1** is very stable even at *ca.* 200 °C in air. Elemental analysis showed the formula of the product was $[Ni(C_4H_3N_2S)_2]$. X-Ray diffraction analysis conformed that **1** is a lamellar polymer built from the $[Ni_2(C_4H_3N_2S)_4]$ dimeric unit† as shown in Fig. 1. This unit develops along the *ab* plane into a honeycomb structure in which the shortest distance between metal centers is 3.774 Å. Therefore, the solid state polymer can be viewed as a two-dimensional lamellar structure composed of $[Ni_2(C_4H_3N_2S)_4]$ dimeric units, wherein the nickel(II) centers are linked by sulfur atoms of thiolate and the pyrimidine ring in the pyrimidine-2-thiolate ligands to form inorganic and organic layers, as shown in Figs. 2 and 3. Each pyrimidine-2-thiolate in **1** acts as a μ_3-bridge to link three nickel atoms through S and N atoms. There are two types of coordination modes for pyrimidine-2-thiolate: one in which pyrimidyl groups of pyrimidine-2-thiolate ligands protrude into the interlayer region [Scheme 1(a)]; and the other in which they act as bridges lying on the layer plane to link Ni(II) centers [Scheme 1(b)]. The interlayer distance is 8.119 Å. Each nickel atom is six-coordinated by three S atoms and three N atoms from three different pyrimidine-2-thiolate ligands in distorted octahedral fashion. The Ni–N bond lengths range between 2.055 and 2.142 Å, while the Ni–S bond lengths range from 2.438 to 2.593 Å. The average S–Ni–N, N–Ni–N and S–Ni–S angles are 85.14,

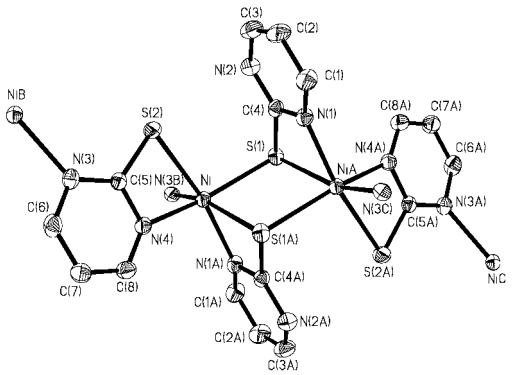

Fig. 1 Structure of the basic unit $[Ni_2(C_4H_3N_2S)_4]$. Selected bond lengths (Å) and angles (°): Ni–N(1A) 2.055(3), Ni–N(4) 2.074(3), Ni–N(3B) 2.142(3), Ni–S(1) 2.4378(10), Ni–S(2) 2.4522(10), Ni–S(1A) 2.5929(10); N(1A)–Ni–N(4) 98.09(12), N(1A)–Ni–N(3B) 93.72(11), N(4)–Ni–N(3B) 101.89(12), N(1A)–Ni–S(1) 91.61(9), N(4)–Ni–S(1) 159.62(8), N(3B)–Ni–S(1) 95.28(8), N(1A)–Ni–S(2) 166.20(9), N(4)–Ni–S(2) 68.52(8), N(3B)–Ni–S(2) 92.46(8), S(1)–Ni–S(2) 100.10(3), N(1A)–Ni–S(1A) 66.76(9), N(4)–Ni–S(1A) 84.59(8), N(3B)–Ni–S(1A) 160.25(8), S(1)–Ni–S(1A) 82.84(4), S(2)–Ni–S(1A) 107.24(3), Ni–S(1)–Ni(A) 97.16(4).

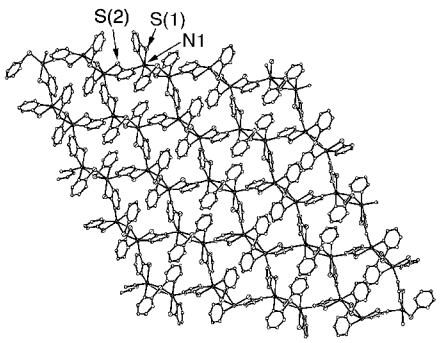

Fig. 2 View of the lamellar structure in **1**.

 DOI: 10.1039/b101422f

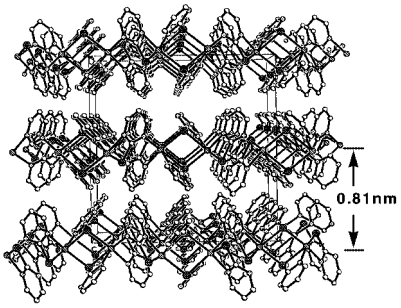

Fig. 3 Structure of **1** showing the interlayer network.

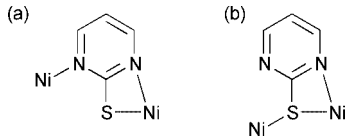

Scheme 1 Coordination modes of pyrimidine-2-thiolate in **1**.

97.90(1) and 96.72°, respectively. All nickel atoms of each layer are nearly coplanar with deviations being within 0.18 Å.

The cryomagnetic behavior of **1** has been studied. $\chi_M T$ and χ_M *vs.* T plots of the temperature-dependent magnetic susceptibility data for **1** are shown in Fig. 4. At room temperature, $\chi_M T$ is 2.60 cm^3 K mol^{-1} per dimer at 299.1 K and increases slightly to a maximum value of 2.78 cm^3 K mol^{-1} at 60 K. It decreases from 60 K and reaches 1.44 cm^3 K mol^{-1} at 7.9 K. The magnetic moments from 300 to 5 °C are slightly smaller than calculated values using the free-ion approximation for Ni(II) with high spin configuration. Least-square fitting using eqn. (1)‡ of all experimental data leads to J, J' and g values of 19.5 cm^{-1}, −7.3 cm^{-1} and 2.103 with the agreement factor $R = 2.0 \times 10^{-4}$. Fitting to this model demonstrates the existence of ferromagnetic interactions between the two nickel(II) centers of the dimer unit and antiferromagnetic interactions both between adjacent dimer units and between adjacent layers. The magnetic behavior for **1** is quite different from a nickel(II)–azide two-dimensional polymer, in which each nickel(II) center are high spin and normally show ferromagnetic interactions.[6b]

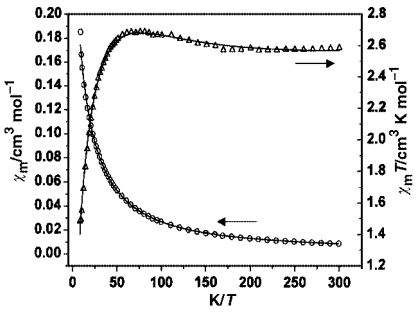

Fig. 4 Temperature–dependent magnetic susceptibility of **1**, (○)χ_m, (△)$\chi_m T$ and (−) the best fit obtained.

According to the literature,[12] the evidence for interaction between metal cations in extended solid structures is provided not only by characteristic uniform structural features but also by their physical properties such as electrical conductivity. The semiconductivity of **1** was therefore studied. Determination of the conductivity of **1** (powder sample from ground crystals) indicates an electrical conductivity of 5.00×10^{-3} S cm^{-1} at 28 °C which increases with temperature (Fig. 5), indicating that **1** is a semiconductor. By examining its structure, the semiconducting property of **1** can be attributed to its characteristic structural feature of the interconnected array of nickel(II) with pyrimidine; the semiconducting property provides evidence for nickel and pyridine ring interactions.

We gratefully acknowledge financial support from the NSF of China and Fujian Provice and Key project from CAS.

First published as an Advance Article on the web 15th May 2001

Chiral octahedral cobalt complexes, K[Co(edta)]·2H_2O and K[Co(trdta)]·2H_2O, induce enantioselective addition of diisopropylzinc to pyrimidine-5-carbaldehyde, affording the pyrimidyl alkanol with high (85–94%) enantiomeric excesses.

Enantioselective reactions are one of the most important areas in organic chemistry.[1] Chiral transition metal complexes play an important role in asymmetric reactions with most chiral metal complexes being prepared using chiral organic ligands. On the other hand, metal complexes such as the octahedral cobalt complex with achiral ethylenediamine (en) ligands, *i.e.* $[Co(en)_3]^{3+}$ shows chirality due to the topology of coordination of the achiral ligand.[2] A 'chiral-at-metal'[3a] complex with achiral ligands has been used in diastereoselective synthesis,[3b] and a 'chiral-at-metal' complex with chiral ligands has been used in enantioselective synthesis.[4] However, the application of 'chiral-at-metal' complexes with achiral ligands towards enantioselective synthesis has been a difficult problem. It is noteworthy that, as early as 1929, Shibata and Tsuchida[5] reported an enantiomer selective asymmetric oxidation of racemic 3,4-dihydroxyphenylalanine using a chiral cobalt complex $[Co(en)_2NH_3Cl]Br_2$. However, highly enantioselective syntheses using chiral metal complexes (due to the topology of achiral ligands) is a challenge.

One of us (H. O.) previously reported the preparation of chiral octahedral cobalt complexes with ethylenediaminetetraacetate (edta) and trimethylenediaminetetraacetate (trdta), *i.e.* K[Co(edta)]·2H_2O **1**[6a] and K[Co(trdta)]·2H_2O **2**.[6b]

In the course of our continuing study on asymmetric autocatalysis,[7,8] we found that the sense of the enantioselectivity of the addition of diisopropylzinc (*i*-Pr_2Zn) to pyrimidine-5-carbaldehydes is affected by chiral materials[9] such as chiral quartz[9a] and sodium chlorate.[9b]

We report here a highly enantioselective addition of *i*-Pr_2Zn to 2-(*tert*-butylethynyl)pyrimidine-5-carbaldehyde **3** in the presence of chiral metal complex **1** or **2** (Fig. 1). The absolute configurations of the formed pyrimidyl alkanol with high (85–94%) ee's were controlled by the chirality of the octahedral cobalt complexes **1** and **2**.

Experiments were conducted as illustrated in Scheme 1. To a suspension of finely powdered chiral crystals (0.025 mmol) of cobalt complex **1** or **2**, aldehyde **3**[10] (1.05 mmol) and *i*-Pr_2Zn (2.15 mmol)[11] were added portionwise. In the presence of $(+)_{546}$-K[Co(edta)]·2H_2O **1**, (*S*)-alkanol **4** with 91% ee was obtained in 91% yield (Table 1, entry 1). On the other hand, in the presence of $(-)_{546}$-K[Co(edta)]·2H_2O **1**, (*R*)-alkanol **4** with 94% ee was obtained (entry 3). Thus, the absolute configuration of chiral complex **1** determines the absolute configuration of the newly formed pyrimidyl alkanol **4**.

In a typical experiment (Table 1, entry 3), to a toluene suspension (0.1 ml) of $(-)_{546}$-K[Co(edta)]·2H_2O **1** (10.6 mg, 0.025 mmol) and aldehyde **3** (9.4 mg, 0.05 mmol), a toluene solution (1.0 M) of *i*-Pr_2Zn (0.15 mmol) was added over a period of 15 min at 0 °C. After the mixture was stirred for 14 h at 0 °C, toluene (4.8 ml), *i*-Pr_2Zn (0.4 mmol, 1.0 M toluene solution), and a toluene solution (1.5 ml) of aldehyde **3** (37.6 mg, 0.2 mmol) were added successively, and the reaction mixture was stirred for 3.5 h. Then, toluene (14.4 ml), *i*-Pr_2Zn

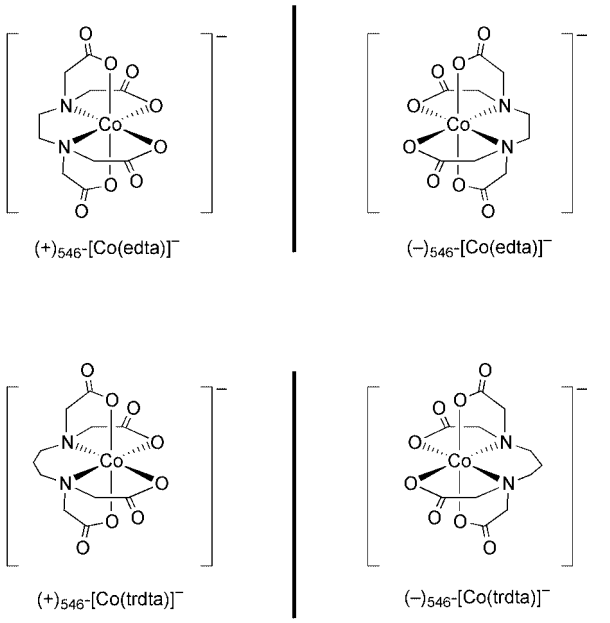

Fig. 1 Chiral structures of ethylenediaminetetraacetatocobaltate(III) and trimethylenediaminetetraacetatocobaltate(III).

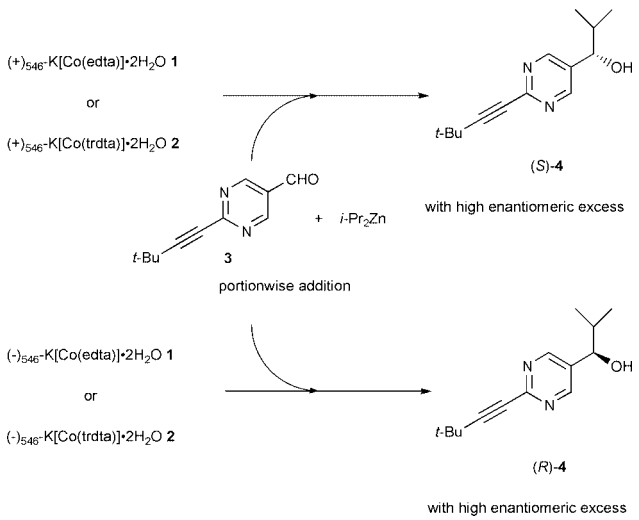

Scheme 1 Highly enantioselective asymmetric autocatalysis in the presense of chiral octahedral cobalt complex **1** and **2**. edta: $(^-O_2CH_2C)_2N(CH_2)_2N(CH_2CO_2^-)_2$; trdta: $(^-O_2CH_2C)_2N(CH_2)_3N(CH_2CO_2^-)_2$.

 DOI: 10.1039/b102143p

(1.6 mmol, 1.0 M toluene solution) and a toluene (4 ml) solution of aldehyde **3** (150.6 mg, 0.8 mmol) were added successively, and the mixture was stirred at 0 °C for an additional 3 h. The reaction was quenched by hydrochloric acid (1 M, 5 ml), and satd. aq. sodium hydrogen carbonate (15 ml) was added. The mixture was filtered using Celite, and the filtrate was extracted with ethyl acetate. The combined organic layers were dried over anhydrous sodium sulfate and evaporated. Purification of the residue by silica gel thin layer chromatography (developing solvent, hexane–ethyl acetate = 2 : 1 v/v) gave (*R*)-pyrimidyl alkanol **4** (244 mg) with 94% ee in an isolated yield of 99%.

Since the cobalt complex **1** is practically insoluble in toluene, enantioselective addition seems to occur at the interface between the crystal of metal complex **1** and the solvent. When $(+)_{546}$-K[Co(trdta)]·2H_2O **2** was used instead of $(+)_{546}$-K[Co(edta)]·2H_2O **1**, the formation of (*S*)-**4** with 85% ee was induced (entry 5), and the reaction using $(-)_{546}$-K[Co(trdta)]·2H_2O (**2**) gave (*R*)-**4** with 88% ee (entry 6).

In summary, enantioselective addition of *i*-Pr_2Zn to pyrimidinecarbaldehyde **4** in the presence of $(+)_{546}$-K[Co(edta)]·2H_2O **1** or $(+)_{546}$-K[Co(trdta)]·2H_2O **2** gave (*S*)-**4** with high ee's, respectively, and the reaction in the presence of $(-)_{546}$-K[Co(edta)]·2H_2O (**1**) or $(-)_{546}$-K[Co(trdta)]·2H_2O **2** afforded (*R*)-**4** with high ee's, respectively. We have clearly demonstrated that the chirality at the cobalt is responsible for the enantioselective addition of *i*-Pr_2Zn.

Table 1 Enantioselective addition of diisopropylzinc to aldehyde **3** in the presence of chiral octahedral cobalt complexes **1** and **2**

		Alkanol **4**[a]		
Entry	Cobalt complex	Yield (%)	Ee (%)	Config.
1	$(+)_{546}$-K[Co(edta)]·2H_2O **1**	91	91	*S*
2		98	89	*S*
3	$(-)_{546}$-K[Co(edta)]·2H_2O **1**	99	94	*R*
4		92	90	*R*
5	$(+)_{546}$-K[Co(trdta)]·2H_2O **2**	90	85	*S*
6	$(-)_{546}$-K[Co(trdta)]·2H_2O **2**	90	88	*R*

[a] Ee was determined by HPLC analysis using a chiral stationary phase (Chiralcel OD).

A multidentate phosphinoalkoxide ligand as a building block in mixed polylithium aggregates

Alexander Feustel and Gerhard Müller*

Fachbereich Chemie, Universität Konstanz, Universitätsstr. 10, 78464 Konstanz, Germany.
E-mail: gerhard.mueller@chemie.uni-konstanz.de

Received (in Cambridge, UK) 19th December 2000, Accepted 26th April 2001
First published as an Advance Article on the web 15th May 2001

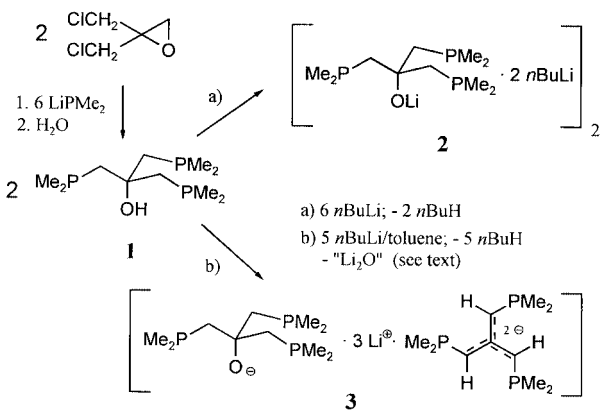
The tris(dimethylphosphinomethyl)-substituted lithium alkoxide [$LiOC(CH_2PMe_2)_3$] acts as a building block in mixed polylithium aggregates, effectively capping triangular Li_3 polyhedral faces; it further reacts with lithium organyls to yield the Y-conjugated, symmetrically tris(dimethylphosphino)-substituted trimethylenemethane dianion.

Chelating phosphinoalkoxides[1] have been used extensively as ligands to transition metals where much of the pertinent interest stems from the fact that many such complexes are effective catalyst precursors in a variety of industrially useful processes.[2,3] In contrast to this, only a few main group metal complexes of phosphinoalkoxides have been described.[3b–d,f,4] The same applies to lanthanide complexes.[5] We are interested in multidentate phosphinoalkoxides which we expect to effectively complex more lithium cations than required for charge neutrality (lithium trap) thereby resulting in mixed multinuclear lithium aggregates which also incorporate additional anions.

The tris(phosphinomethyl)-substituted alcohol **1** was found to be particularly useful in this respect. It was prepared from 1-chloro-2,3-epoxy-2-chloromethylpropane by reaction with 3 equivalents of $LiPMe_2$ (Scheme 1)[6] following the synthesis of the corresponding perphenyl compound.[3c] Compound **1** reacts with excess *n*BuLi (2.5 M solution in hexane)[3c] at −78 °C without additional solvent to form the lithium alkoxide which crystallizes with two equivalents of *n*BuLi as a hexalithium dimer† with crystallographic inversion symmetry (compound **2**; Scheme 1).‡ In the mixed *n*-butyllithium/lithium alkoxide aggregate **2** the six lithium atoms are arranged at the corners of a slightly distorted octahedron (Fig. 1). Two opposite triangular Li_3 faces of the octahedron are capped each by the μ_3-oxygen atoms of one alkoxide ligand. In addition, each of the lithium atoms of these Li_3 faces is coordinated by one of the phosphino groups of the same ligand. Thereby three lithium atoms are held closely together by one of the deprotonated monoanionic ligands **1** in a very compact and effective way. Particular indications of this are the short Li–O bonds and the Li–P bond distances (see Fig. 1).[7] Charge neutrality in dimeric **2** is achieved by four additional *n*-butyl anions which bridge four of the remaining triangular faces of the octahedron. As is often the case for hexameric octahedral compounds with a 1 : 1 stoichiometry of cation to anion, the two unbridged faces of the octahedron are on opposite sides of the polyhedron. It should be noted that solid *n*BuLi itself is an octahedral hexamer.[8] To our knowledge, in addition to [*n*BuLi· Li*O*t*Bu*]$_4$[9] only one other mixed organolithium/lithium alkoxide aggregate has been structurally characterized to date.[10]

Formation and structural details of **2** strongly suggest that [$LiOC(CH_2PMe_2)_3$], formed initially by deprotonation of **1**, has further lithium binding capacity trapping two additional lithium cations. The fragment $[Li_3OC(CH_2PMe_2)_3]^{2+}$ itself seems to be an ideal building block for mixed oligomeric lithium aggregates, in which the lithium atoms are at the vertices of trigonal polyhedral faces.

Proof for this comes from a second, unexpected reaction of **1** with *n*BuLi. In contrast to the synthesis of **2**, which was performed in the absence of solvent (other than the hexane contained in the 2.5 M solution of *n*BuLi), **1** reacts with excess *n*BuLi in toluene alone at room temperature to form the Y-conjugated, symmetrically tris(dimethylphosphino)-substituted trimethylenemethane dianion which, to our knowledge, has not been described before.[11] It crystallizes with the beforementioned fragment $[Li_3OC(CH_2PMe_2)_3]^{2+}$ as counter ion (compound **3**; Scheme 1).† At the center of the molecular structure of **3** (Fig. 2)‡ is an equilateral triangle of lithium atoms which is capped on one side by the deprotonated alcohol **1** in much the same way as in the structure of **2**. The other side of the



Scheme 1

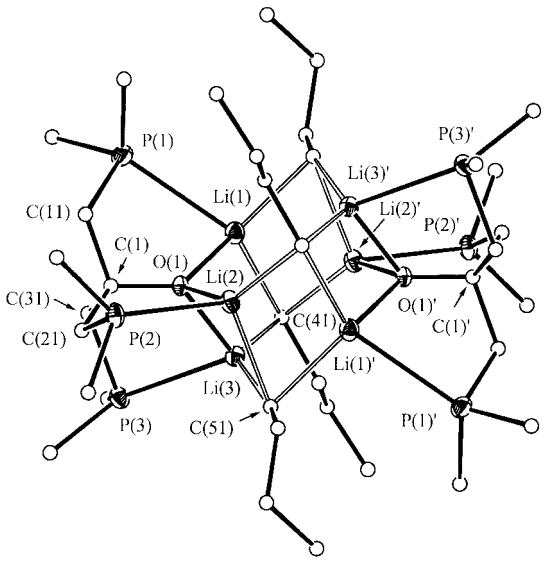


Fig. 1 Molecular structure of **2** in the crystal (ORTEP-III; displacement ellipsoids at the 30% probablility level. Primed atoms are related to those without a prime by a center of inversion). Distances (Å): Li(1)–O(1) 1.904(4), Li(2)–O(1) 1.897(4), Li(3)–O(1) 1.916(4), Li(1)–P(1) 2.755(4), Li(2)–P(2) 2.613(4), Li(3)–P(3) 2.736(4).

 DOI: 10.1039/b010115j

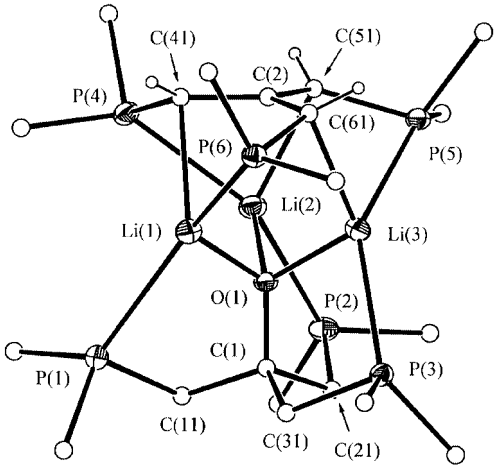

Fig. 2 Molecular structure of **3** in the crystal (ORTEP-III; displacement ellipsoids at the 30% level. For clarity, C atoms are drawn as spheres with arbitray radii; H atoms omitted except those at the methylene C atoms). Distances (Å): Li(1)–O(1) 1.888(4), Li(2)–O(1) 1.877(3), Li(3)–O(1) 1.885(4), Li(1)–P(1) 2.665(4), Li(2)–P(2) 2.696(4), Li(3)–P(3) 2.638(4), Li(1)–P(6) 2.550(3), Li(2)–P(4) 2.592(4), Li(3)–P(5) 2.562(4).

Li_3 triangle is coordinated by the tris(phosphino)-substituted trimethylenemethane dianion. Thereby each lithium atom is coordinated to one of the phosphino groups and a methylene carbanionoid carbon atom of an adjacent arm of the dianion. Each of the lithium atoms are four-coordinate, being bonded to one oxygen, two phosphorus, and one carbon atom. It should be noted that in the only other dilithium trimethylenemethane derivative structurally characterized so far,[12] the lithium atoms are disposed on opposite sides of the trimethylenemethane dianion while in **3** the fragment $[Li_3OC(CH_2PMe_2)_3]^{2+}$ forces the lithium atoms to be located on only one side, in accord with our assumption that $[Li_3OC(CH_2PMe_2)_3]^{2+}$ should be an ideal building block for trigonal polyhedral lithium faces. Both the structural data (Fig. 2) as well as the ^{31}P and particularly the ^{7}Li NMR spectra indicate that the Li atoms in **3** are more tightly bound to the trimethylene dianion rather than to the alkoxide. This follows clearly from the shorter Li–P bonds and the additional Li–C bonds to the dianion while the NMR data indicate that at room temperature the alkoxide is freely rotating around the central C–O axis with respect to the Li_3 triangle (with the dianion being held firmly in place).†

The unexpected formation of the tris(dimethylphosphino)-substituted trimethylenemethane dianion in **3** upon reaction of **1** with excess *n*BuLi involves the formal loss of Li_2O. At present we do not know whether Li_2O is actually formed in the reaction sequence, or whether the O^{2-} anion is part of a larger mixed aggregate.[13] We believe that expulsion of O^{2-} occurs after multiple deprotonation of **1** not only at oxygen but also at one or more of the methylene carbon atoms. The formation of the trimethylenemethane dianion from **1** is then believed to be driven by the reduction of negative charge on the anion by loss of O^{2-} and by the formation of a Y-conjugated π-system.[14]

Notes and references

† *Syntheses*: **2**: to 0.3 g (1.2 mmol) of **1** 2.0 ml (5.0 mmol) of a 2.5 M solution of *n*BuLi in hexane was added at −78 °C. The reaction mixture was warmed to room temperature whereupon a clear solution formed from which immediately small colorless crystals of **2** precipitated. After 30 min the crystals rapidly decomposed to an amorphous solid. The recording of NMR spectra is hampered by the necessity to avoid solvents in the synthesis of **2** (see synthesis of **3**).

3: Toluene (0.75 ml) was added to 110 mg (1.7 mmol) of neat *n*BuLi. Subsequently 140 mg (0.55 mmol) of **1** was added dropwise at room temperature, throughly mixed, and left standing for 2 d. The yield of **3** in solution is *ca.* 70% (^{31}P NMR). Colorless needles formed which proved suitable for X-ray diffraction. Mp 165 °C (decomp.); Anal. $C_{20}H_{45}Li_3OP_6$; calc: C, 47.27; H, 8.92; found: C, 47.02; H, 8.34%. ^{31}P {^{1}H} NMR (162 MHz, toluene-d_8, 25 °C, ext. 85% H_3PO_4): alkoxide: δ −59.5 [br s]; dianion: −64.2 [q (1 : 1 : 1 : 1), $^{1}J_{PLi}$ 58 Hz]; ^{31}P{^{1}H} NMR (toluene-d_8, −80 °C): alkoxide: δ −63.3 [m]; dianion: −64.2 [qd, $^{1}J_{PLi}$ 58, $^{2}J_{PP}$ 19 Hz], $T_C \approx -45$ °C; ^{7}Li {^{1}H} NMR (155 MHz, toluene-d_8, 25 °C, ext. 1 M LiBr in THF-d_8): δ 0.35 [dq, $^{1}J_{LiP}$ 14 Hz, with 3 alkoxide P, $^{1}J_{LiP}$ 58 Hz, with 1 dianion P]; ^{7}Li{^{1}H} NMR (toluene-d_8, −80 °C): δ 0.35 [dd, $^{1}J_{LiP}$ 42 Hz, with 1 alkoxide P, $^{1}J_{LiP}$ 58 Hz, with 1 dianion P], $T_C \approx -20$ °C.

‡ *Crystallography*: single crystals of **2**, grown as described above, were transferred immediately to the diffractometer (Enraf-Nonius CAD4) and examined at −78 °C under strict exclusion of air and moisture in a frozen oil drop (Mo-Kα radiation, λ = 0.71069 Å). *Crystal data* for **2**: $C_{36}H_{84}Li_6O_2P_6$, M = 776.49, monoclinic, space group $C2/c$, a = 21.440(2), b = 17.254(1), c = 14.121(1) Å, β = 103.000(9)°, V = 5089.8(8) Å^3, Z = 4, D_c = 1.013 g cm^{-3}, μ(Mo-Kα) = 2.4 cm^{-1}. 4498 unique reflexions (*hkl* range: ±25, +20, +16) up to $((\sin\theta)/\lambda)_{max.}$ = 0.595 Å^{-1}, *R*/*wR*/*S* = 0.047/0.132/1.04 for 236 refined parameters and all data (non-H atoms anisotropic, H atoms fixed). $\Delta\rho_{fin}$(max./min.) = 0.41/−0.37 e Å^{-3} (SHELXS-97, SHELXL-97).

Single crystals of **3**, grown as described above, were examined at −78 °C in a frozen oil drop. *Crystal data* for **3**: $C_{20}H_{45}Li_3OP_6$, M = 508.20, triclinic, space group $P\bar{1}$, a = 9.087(2), b = 11.851(2), c = 15.175(3) Å, α = 81.323(7), β = 89.812(7), γ = 73.27(2)°, V = 1545.7(5) Å^3, Z = 2, D_c = 1.092 g cm^{-3}, μ(Mo-Kα) = 3.6 cm^{-1}. 5713 unique reflexions (*hkl* range: −10, ±14, ±18) up to $((\sin\theta)/\lambda)_{max.}$ = 0.604 Å^{-1}, *R*/*wR*/*S* = 0.040/0.120/1.04 for 295 refined parameters and all data (non-H atoms anisotropic, methylene H atoms refined freely with isotropic displacement parameters, all others fixed). $\Delta\rho_{fin}$(max./min.) = 0.64/−0.47 e Å^{-3}.

The best structural model of ADH so far: a pyrazolylbis(thioimidazolyl)borate zinc ethanol complex

Jan Seebacher, Mouhai Shu and Heinrich Vahrenkamp*

Institut für Anorganische und Analytische Chemie der Universität Freiburg, Albertstr. 21, D-79104 Freiburg, Germany.

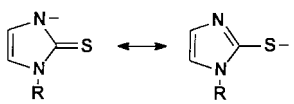
Received (in Cambridge, UK) 8th January 2001, Accepted 17th April 2001
First published as an Advance Article on the web 15th May 2001

The new *N,S,S* ligand $[HB(tim^{o\text{-}An})_2(pz^{Ph,Me})]^-$ (L^1) was combined with zinc perchlorate and ethanol to form the complex $[L^1{\cdot}Zn(ethanol)]ClO_4$ which is the first zinc complex in which the *N,S,S* ligation of zinc and the attachment of ethanol occurring in the active center of horse liver alcoholdehydrogenase (ADH) have been reproduced; the structural details of the $ZnNS_2O$ coordination in the complex and in DMSO-inhibited ADH are in reasonably good agreement.

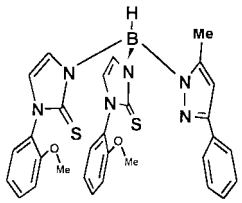
Both the function and the coordination environment of zinc in horse liver alcoholdehydrogenase, ADH,[1,2] are unusual. Zinc supports, but does not participate in, a redox reaction, *i.e.* the hydride transfer interconverting alcohol and aldehyde; and in the resting enzyme zinc is in an uncharged state, being bound to one histidine and two cysteinate residues. It can be assumed that the latter is the prerequisite for the former, making it possible that in the enzymatic environment the alcohol is bound to zinc as an alkoxide and that its ß-hydrogens are labilized for removal as H^- by NAD^+.

These unusual properties have made it impossible until now to build coordination compounds of zinc which correctly model the coordination environment of the metal[3–5] or which show a reasonable catalytic activity for hydride transfer to NAD^+/NADH systems.[6–8] Most of the *N,S,S* ligands which were designed and used for this purpose have too strong a tendency to form oligonuclear thiolate-bridged zinc complexes, and the fixation of the very labile Zn–OR function in mononuclear zinc alkoxides has required the use of coligands which suppress the desired catalytic activity of zinc. The closest approximations to structural models[9–11] were achieved by Parkin *et al.*[4] and ourselves.[5] Parkin's group prepared tetrahedral L·Zn–X complexes of a new *N,S,S* ligand L. We prepared tetrahedral $(RS)_2Zn(N,O)$ complexes using pyridine-derived alcohols or aldehydes as *N,O* ligands. A realistic functional modelling, *i.e.* by using NAD^+ derivatives as hydride acceptors, has been tried in only a few cases and with little success.[8,12,13]

The work described in this communication was triggered by a report by Reglinski *et al.*,[14] which describes the simple synthesis of tris(thioimidazolyl)borate ligands. In these ligands the thioimidazolyl sulfur donors can be considered 'tame' thiolate donors according to the following resonance formulation:



In agreement with this there is no sulfur bridging in metal complexes of thioimidazolylborate ligands and such ligands are quite reliable tetrahedral enforcers.[4,7,14–16] Furthermore, their synthesis allows the incorporation of pyrazolyl functions as mixed pyrazolylthioimidazolylborates with *N,S,S* or *N,N,S* donor sets.[4,15,16] Having realized this, it was a matter of varying the substituents on the pyrazole and thioimidazole groups of a pyrazolylbis(thioimidazolyl)borate[16] (*i.e.* a *N,S,S* ligand) in order to generate an appropriate electronic and geometrical environment for a ligated zinc ion to accommodate an alcoholic substrate in an ADH model complex.



Ligand L^1 was found to fulfil these conditions. Its constituent 1-(*o*-anisyl)-2-thioimidazole† is accessible from 2-methoxyaniline and KSCN by the established procedure.[17] The reaction between two equivalents of the thioimidazole and one equivalent each of 3-phenyl-5-methylpyrazole and KBH_4 in boiling toluene leads to very good yields of $K[L^1]$.† The reaction between $K[L^1]$ and $Zn(ClO_4)_2{\bullet}6H_2O$ in non-dehydrated ethanol produces the raw complex **1** in nearly quantitative yield.‡ Crystals of **1** for the structure determination were obtained by slow evaporation from ethanol.†

$$[HB(tim^{o\text{-}An})_2(pz^{Ph,Me})Zn(C_2H_5OH)]\,ClO_4{\bullet}C_2H_5OH$$

1

Complex **1** fulfils the conditions to be a close structural model of ADH. It bears a tridentate *N,S,S* ligand and an ethanol molecule comprising a $ZnNOS_2$ coordination pattern as in the enzyme and its pentafluorobenzyl alcohol-inhibited derivative.[2] The structure determination§ (see Fig. 1) has shown the complex to be tetrahedral to a good approximation. The alcohol ligand is embedded between the three aromatic substituents of

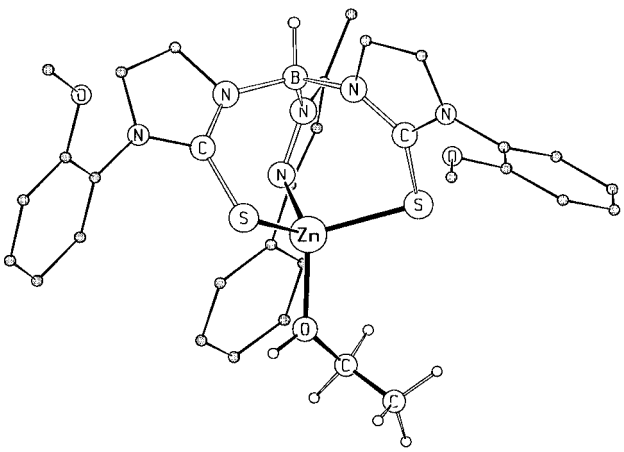


Fig. 1 Molecular structure of the cation of **1**. The OH hydrogen atom, which was not localized crystallographically, was placed on a reasonable position along the hydrogen bond to the attached second ethanol molecule.

 DOI: 10.1039/b100281n

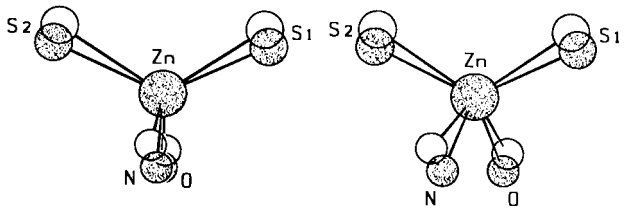

Fig. 2 Superpositions of the $ZnNOS_2$ cores of **1** (open circles) and DMSO-inhibited ADH[2] (filled circles). Left: ZnS_2 in the plane of the drawing, right: rotated by 20° about a vertical axis.

Table 1 Comparison of the $ZnNOS_2$ units in **1** and in DMSO-inhibited ADH[2]

	1	ADH•DMSO
Zn–N/Å	2.012(3)	2.02
Zn–O/Å	1.970(3)	2.13
Zn–S/Å	2.282(1), 2.314(1)	2.19, 2.25
N–Zn–O/°	116.8(1)	94.2
N–Zn–S/°	100.2(1), 111.7(1)	107.4, 113.1
O–Zn–S/°	105.4(1), 109.8(1)	102.5, 103.3
S–Zn–S/°	113.2(1)	129.4

L[1]. It is attached to a second ethanol molecule by a hydrogen bond, sharing this property with Parkin's tris(thioimidazolyl)borate–zinc–CH_3OH•CH_3OH complex.[7] It seems that the electronic 'saturation' of the zinc ion by the soft sulfur donors and the hydrophobicity of the aromatic environment provide the driving force for the preferred attachment of the less polar alcohol ligand, rather than the water or hydroxide ligands which are present in the reaction solution and which become bound to zinc in similar preparations of zinc complexes with tridentate *N,N,N* or *N,N,O* environments.[18]

The bond lengths and bond angles of **1** are very similar to those in Parkin's S_3Zn–CH_3OH complex.[7] Moreover they agree satisfactorily with those in the ADH structure of highest resolution (1.8 Å), *i.e.* that of the DMSO-inhibited enzyme.[2] Fig. 2 and Table 1 give the details for the $ZnNOS_2$ units. Both units can be described as close to tetrahedral, as can be seen in Fig. 2 by the perpendicular arrangements of the SZnS and NZnO planes. Almost all differences in bond lengths and bond angles are within an acceptable range. The major distortions lie in the enzyme's very small N–Zn–O and very large S–Zn–S angles and in the difference between the Zn–O('substrate') bond lengths.

In summary, a new thioimidazolylborate based *N,S,S* ligand has been prepared and used to obtain a zinc complex which binds ethanol on its fourth coordination site. This corresponds to the first step in the catalytic cycle of horse liver alcoholdehydrogenase (ADH), the incorporation of ethanol within the active center which contains *N,S,S* ligated zinc. The resulting complex **1** is the first model complex that reproduces both the *N,S,S* ligation and the alcohol binding.

This work was supported by the Deutsche Forschungsgemeinschaft.

Notes and references

† The new compounds were characterized by elemental analyses. Complex **1** shows the OH absorption in the IR spectrum as a broad band centered at 3150 cm^{-1} which is typical for O–H···O hydrogen bonding. ^1H NMR ($CDCl_3$): δ 1.18 (t, *J* 7.0 Hz, 6H, ethyl-CH_3), 2.50 (s, 3H, pz-CH_3), 3.61 (q, *J* 7.0 Hz, 2H, ethyl-CH_2), 3.62 (q, *J* 7.0 Hz, 2H, ethyl-CH_2), 3.82 (s, 6H, OCH_3), 6.40 (s, 1H, pz-CH), 6.94 (d, *J* 2.1 Hz, 2H, tim-CH), 7.02 (d, *J* 2.1 Hz, 2H, tim-CH), 7.0–7.6 (m, 13H, aromatic).

The first luminescent tetranuclear copper(I) μ_4-phosphinidene complex†

Vivian Wing-Wah Yam,* Eddie Chung-Chin Cheng and Nianyong Zhu

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, China. E-mail: wwyam@hku.hk

Received (in Cambridge, UK) 8th February 2001, Accepted 25th April 2001
First published as an Advance Article on the web 15th May 2001

The first luminescent tetranuclear copper(I) phosphinidene complex $[Cu_4(\mu\text{-dppm})_4(\mu_4\text{-PPh})](BF_4)_2$ has been synthesized and isolated; the red-light emitting properties and air-stability of the complex in the solid state may render great potential for this new class of compounds in the future development of semiconducting luminescence materials and applications in LED technology.

The recent growth in interest in the chemistry of transition metal–pnictogenide complexes has been prompted in part by the potential of utilizing such compounds as precursors of binary pnictogenides in the development of electronic and optical materials.[1] With different particle size, the luminescence and optical properties of the transition metal–pnictogenides may vary dramatically due to the quantum size effect.[2] Therefore one of the important aspects in this field is to prepare particles or synthesize model complexes with a controllable and uniform size. In view of this, together with our recent efforts on the syntheses and isolations of a number of polynuclear coinage metal chalcogenide complexes with a d^{10} electronic configuration,[3] we believe that an exploration into the related phosphinidene complexes might give rise to new classes of soluble molecular materials of uniform size, with easily tunable luminescence properties *via* the participation of different ancillary ligands. To the best of our knowledge, phosphinidene complexes of d^{10} transition metals are extremely rare.[4,5] Herein, is described the first report on the isolation, characterization and X-ray crystal structure of a novel red-light emitting tetranuclear copper(I)–phosphinidene complex, $[Cu_4(\mu\text{-dppm})_4(\mu_4\text{-PPh})](BF_4)_2$ **1** [dppm = bis(diphenylphosphino)-methane], which is stable to air in the solid state and highly soluble in common organic solvents. Its photophysical properties have also been investigated.

Reaction of $[Cu_2(\mu\text{-dppm})_2(MeCN)_2](BF_4)_2$[6] with $PhPH_2$ and $Na(acac)\cdot H_2O$ (acac = acetylacetonate) in THF under nitrogen gave an orange precipitate. Recrystallization from dichloromethane–diethyl ether afforded **1** as air-stable orange-red crystals in 80% yield. The formulation of **1** was confirmed by elemental analyses, positive FAB-MS, ^1H and ^{31}P NMR spectroscopy.‡ The solid state structure was established by X-ray crystallography.§

Fig. 1 shows the perspective drawing of the complex cation of **1**. The four copper atoms are almost coplanar and form a rectangular array, with the four bridging dppm ligands arranged in a saddle-like configuration. The Cu–Cu distances range from 2.8225(9) to 3.4451(1) Å, and show no significant $Cu^I\cdots Cu^I$ interactions. The phosphinidenic phosphorus sits at the apex of the distorted square-pyramid and quadruply bridges the four copper atoms, with projection of *ca.* 0.70 Å above the idealized Cu_4 plane. The plane of the phenyl ring on the phosphinidene is perpendicular to the Cu_4 plane and has an orientation that bisects the two longer Cu–Cu edges, Cu1–Cu4 and Cu2–Cu3, so as to minimize the steric hindrance experienced by the phenyl rings on the phosphinidene and the two dppm ligands that were folded upwards. This is also in accordance with the observed elongation of the Cu–Cu long edges and the shortening of the short edges when compared to the isoelectronic but less sterically demanding chalcogenide counterparts, $[Cu_4(\mu\text{-dppm})_4(\mu_4\text{-S})](PF_6)_2$ [3.128(1), 2.869(1) Å] and $[Cu_4(\mu\text{-dppm})_4(\mu_4\text{-Se})](PF_6)_2$ [3.271(4), 2.908(4) Å].[3c,d] The Cu–P(phosphinidene) bond distances of 2.2811(1)–2.3230(1) Å are comparable to other Cu^I–μ_4-PR systems, such as $[Cu_{24}\{P(Me_2(Pr^iMe_2C)Si)\}_{12}]$ [2.226(3) Å] and $[Cu_{18}(PPh)_4(PPh_2)_{10}(PHPh_2)_3]$ [2.272(2)–2.449(2) Å].[4] All the Cu–P(dppm) bond distances are typical of those reported in other copper(I)–dppm systems.[7] It is of note that all Cu–P(dppm) bonds on the same side as the phosphinidene moiety are longer than those on the other side. This is simply a consequence of the steric requirements for the accommodation of the phosphinidene and the dppm ligands on the same side of the Cu_4 rectangle.

The ^1H NMR spectrum of **1** in CD_2Cl_2 at ambient temperature shows four broad methylene proton signals with equivalent integrals, indicative of the absence of a flipping motion for dppm and the rotation of the phosphinidene group. This is different from the situation in $[M_4(\mu\text{-dppm})_4(\mu_4\text{-E})]^{2+}$ (M = Cu, Ag; E = S, Se, Te), where flipping motions of the dppm ligands occurs and only one methylene signal has been observed.[3c–e] The $^{31}P\{^1H\}$ NMR spectrum shows the unresolved phosphinidene P signal at δ −94.97, a much more downfield environment compared to the structurally related AuI–phosphinidene complexes, $[2,4,6\text{-}Bu^t_3C_6H_2P(AuPPh_3)_4](BF_4)_2$ (δ −47.69) and $[2\text{-}MeC_6H_4P(AuPPh_3)_4](BF_4)_2$ (δ −54.6).[5]

The electronic absorption spectrum of **1** in CH_2Cl_2 shows a low-energy absorption band at *ca.* 466 nm (Fig. 2). The electronic absorption spectral data are summarized in Table 1. With reference to previous spectroscopic work on the related metal chalcogenido systems,[3] the low energy absorption band at 466 nm, which is absent in the copper(I) precursor complex, is likely to be originated from the [P(phosphinidene) → Cu]

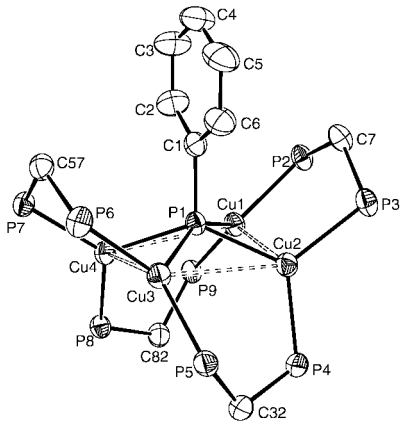

Fig. 1 Perspective view of $[Cu_4(\mu\text{-dppm})_4(\mu_4\text{-PPh})]^{2+}$ with atomic numbering scheme. The phenyl rings of the dppm ligand are omitted for clarity. Thermal ellipsoids are drawn at the 30% probability level.

ligand-to-metal charge-transfer (LMCT) transition. An assignment of such low-energy bands to intraligand IL (phosphinidene) transitions is unlikely as the related gold(I) phosphinidene complex, $[2\text{-}MeC_6H_4P(AuPPh_3)_4](BF_4)_2$,[5b] is reported to be colourless, indicating the absence of low-energy absorption in this region. The high-energy band at 268 nm is attributed to the intra-ligand transition of dppm.

Excitation of **1** in the solid state and in fluid solutions at $\lambda \approx$ 500 nm results in intense long-lived red luminescence (Table 1). Excitation bands at *ca*. 339 and 469 nm were observed upon monitoring the emission at 816 nm (Fig. 2). The close resemblance of the excitation spectrum to the electronic absorption spectrum is suggestive of an emission origin derived from the [P(phosphinidene) → Cu] LMCT transition. The observed lifetime in the microsecond range indicates the spin-forbidden nature of the emission, that is tentatively assigned to be originated predominantly from the triplet state derived from the [P(phosphinidene) → Cu] LMCT transition that mixed with a metal-centred (d–s/d–p) Cu^I state. Such an assignment is based on the fact that the phosphinidene group, being isoelectronic with and similar to the unsubstituted chalcogenides, is a good σ-donor. The red-shift in the emission energies upon lowering the temperature is supportive of such an assignment as it can readily be rationalized by the shrinking of the Cu_4 skeleton, which lowers the energy of the sσ acceptor orbitals derived from the overlap of the 4s orbitals of copper. Assignment based on similar grounds has been reported on the related systems with d^8–d^8 metal–metal interactions.[8]

The present work demonstrates a facile, high-yield synthesis towards soluble luminescent copper(I) phosphinidene complexes. This may, in one way or the other, open up new avenues to the chemistry of polynuclear copper(I) complexes by utilizing the $[Cu_4(dppm)_4]PR$ unit as the building block for higher nuclearity copper(I) complexes and clusters, through various functionalizations on the organic R group. Examples of polynuclear gold(I) aggregates made by using this approach have been illustrated by Schmidbaur *et al.*[9] The present system may also serve as a potential precursor to advanced luminescent materials for applications in the electro-luminescent technology; the emission colour of which could be readily fine-tuned by employing various R groups that have different electron-donating/withdrawing ability.[10]

The first ^{1}H-NMR investigation of the reversible interaction of two small minor groove binding molecules with a synthetic tetraplex DNA structure is reported.

Nucleic acids reversibly interact with a broad range of small organic molecules, such as intercalators or minor groove binders, which represent one of the most important lines of drug development and of current chemotherapy against cancer, viral, and some parasitic diseases. Even though these compounds are known to bind to double stranded DNA, several investigations involving the interaction of small ligands with unusual structures of nucleic acids have been reported,[1–3] including multistranded tetraplex forms.[1,4–7] A multitude of proteins have been shown to interact with these structures which, particularly, are implicated in the molecular biology of telomeres.[8–10] A high level of telomerase activity has been associated with cancer cells and may be essential for their immortality. G-quartet DNA[11] inhibits telomerase activity and, therefore, compounds that bind to this arrangement can negatively interfere with telomerase activity. This is the strongest argument in favour of the potential role of G-tetraplexes as a potential target for anticancer drug design. In this frame, we wish to report here the preliminary results from a NMR investigation of the reversible interaction of the minor groove binding agent distamycin A (Dist-A) and the related drug netropsin (Net) with the synthetic tetraplex [d(TGGGGT)]$_4$.

A wide array of G-tetraplex topologies, groove widths, loop conformations, and alternative DNA base associations have been observed to date.[4–7] The structure of the four stranded hexamer [d(TGGGGT)]$_4$ used for the present study has been already characterized by NMR and X-ray crystallography.[12] This tetraplex possesses a four-fold symmetry with all strands parallel to each other, which afford four grooves of identical medium width, and all nucleosides in an anti conformation. The 1D NMR proton spectra (T = 300 K; 500 MHz), recorded at several points during the titration of the tetraplex with Dist-A, are shown in Fig. 1. The first addition of 0.5 mol equiv. of Dist-A to the oligonucleotide caused several notable variations in the spectrum. Particularly, a general change in chemical shift of DNA proton resonances was observed, whereas a new set of broad signals appeared between 6 and 7 ppm which were assigned to the drug protons. An increase of Dist-A concentration up to 2 mol equiv. caused drug resonances to gradually grow in intensity and a progressive drift of DNA signals. Anyhow, during the early stage of the titration, the four strands were magnetically equivalent upon interaction with the drug. Surprisingly, at nearly 2:1 ligand–tetraplex stoichiometry, a further addition of drug caused a complication in the spectrum due to the presence in solution of different species in slow exchange on the chemical shift time scale. In fact, a new set of proton signals could be observed, whose intensities rose with increasing amounts of drug with a concomitant falling off of the original signals, which completely disappeared at a ratio of 4:1 drug–DNA. At this point, in spite of a general broadening of all signals, a single, well-defined species, was plainly observable in solution and any further addition of ligand did not lead to substantial changes. The final NMR spectrum showed that the binding of the ligand to the tetraplex caused the loss of the original four-fold symmetry of the free tetraplex. Particularly, 8 imino proton, 4 methyl and 12 aromatic proton resonances were clearly discernible, thus pointing to a two-fold symmetry for the 4:1 complex.

In order to clarify the binding mode of Dist-A, several NOESY spectra at 300 K (500 MHz) of the final complex were acquired at different mixing times (250, 180, 100, and 50 ms). The whole of the data provided by these experiments allowed us a preliminary conclusion that the tetraplex retained the original

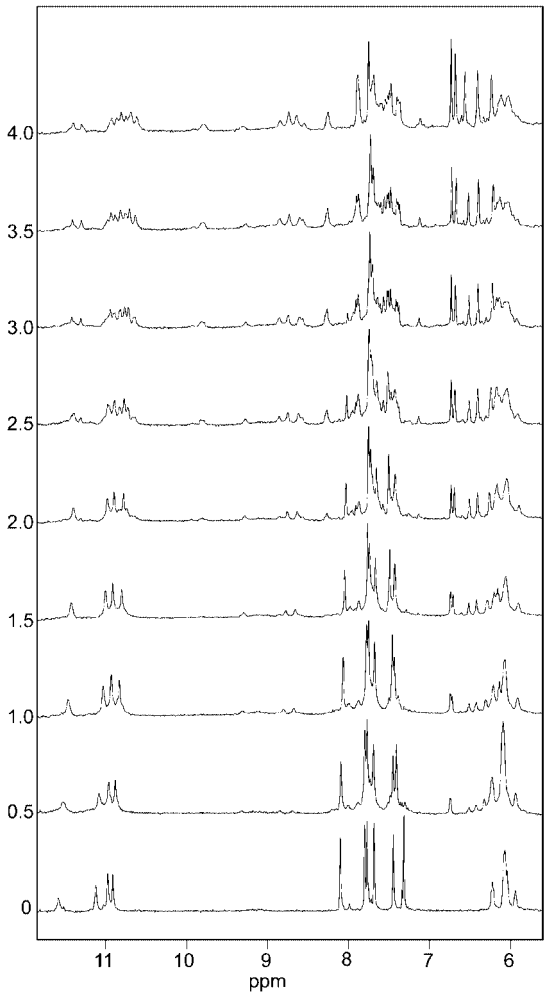

Fig. 1 Titration with Dist-A of 1.4 mM solution of [d(TGGGGT)]$_4$ containing 2 mM phosphate buffer, 0.2 mM EDTA and 70 mM KCl, pH 7.3, in 9:1 H_2O–D_2O at 300 K (500 MHz). ^{1}H NMR spectra were recorded using pulsed-field gradient WATERGATE[15] for H_2O suppression. A time domain deconvolution was used to further reduce the H_2O signal. The drug–DNA mole ratios are shown along the side of the spectra.

† Electronic supplementary information (ESI) available: 2D NOESY and ^{1}H NMR spectra for netropsin/tetraplex and distamycin/tetraplex complexes. See http://www.rsc.org/suppdata/cc/b1/b100460n/

 DOI: 10.1039/b100460n

conformation upon binding of the drug, since all intranucleotide and internucleotide connectivities of the free tetraplex were still visible. However, the evaluation of possible perturbation at the binding sites, such as small changes of the glycosidic bond angle, would require a comprehensive analysis of the NOE buildup rate and a quantitative analysis of internucleotide base to sugar NOE intensities, which have not been carried out at the present. Furthermore, the presence of ligand–ligand contacts between formyl hydrogen (FH) at 7.68 ppm and amidinium protons at 9.75 ppm and among NH1 amide proton at 8.25 ppm, C20 hydrogen at 1.49 ppm and the afore cited hydrogen at 9.75 ppm, indicated that the drug molecules simultaneously bound to the tetraplex two by two, with each term of the dimeric pairs with an antiparallel orientation and in close contact to its partner (as observed with duplex DNA).[13] An alternative explanation, exchange between two orientations of one molecule, so that the ligand–ligand NOEs arise from a combination of transferred NOE and exchange effects, could be ruled out since the NOE contacts were still visible in the NOESY spectra acquired at short mixing time (*i.e.* 50 ms), where spin diffusion phenomenon is dramatically reduced.

NOESY spectra also showed DNA–ligand contacts between imino proton at 11.28 and C20 hydrogen at 1.49 ppm and imino proton at 11.38 and both NH1 amide proton at 8.25 ppm and amidinium protons at 9.75 ppm. Other cross peaks in correspondence with DNA and ligand resonances were present in the NOESY spectra but line broadening and signal overlapping prevented us from unequivocally ascertaining which of them were actually due to ligand–DNA contacts.

It is noteworthy that, throughout the whole titration, a single set of signals was present for Dist-A protons, which only grew in intensity and did not show any significant change in chemical shift values with increasing drug concentration. This observation suggests that, (i), even at low ligand–DNA stoichiometries (*e.g.* 0.5 : 1), simultaneous binding of two Dist-A side by side, in a highly cooperative mode, is dominant; (ii), both in the 2 : 1 and in the 4 : 1 complexes, the bound pair of Dist-A, reorientates itself in a fast process on the NMR time scale, similar to that observed for the binding of Dist-A to duplex DNA structures.[14]

In conclusion, the above preliminary results can be interpreted as follows. Below 2 : 1 ligand–tetraplex stoichiometry, Dist-A, in a dimeric form, binds each groove of the tetraplex to form short-lived complexes on the NMR time scale. Therefore, only one set of signals for the four strands is observed. The fast exchange behavior of the lower complex (2 : 1 Dist-A–tetraplex) could be changed only to an intermediate regime by decreasing the temperature of the system. As the temperature was reduced from 300 to 280 K, there was only a general broadening of the resonances, with peaks belonging to Dist-A broadening more than the other peaks, probably due to the slower reorientation of the Dist-A dimer. At higher drug–DNA ratios, a second Dist-A dimer tightly and specifically binds the tetraplex, to give a 4 : 1 complex, in slow exchange with the 2 : 1 complex, as indicated by the presence of separate proton resonances for the two species. This behavior can be explained assuming that binding of the second drug pair is more favorable than binding of the first one. Finally, the dyad symmetry of the 4 : 1 complex is consistent with a model comprising two Dist-A dimers simultaneously spanning, in fast reorientation, two opposite grooves of the tetraplex, as illustrated in Fig. 2. Notably, a fully saturated complex with all grooves occupied by drug molecules was not observed. Binding of dimer Dist-A may, most likely, expand the binding groove (as observed with duplex DNA),[13] and simultaneously reduce the size of the two adjacent grooves, thus preventing a further interaction with other Dist-A molecules.

Addition of Net to the oligonucleotide (data not shown) caused gradual changes in the chemical shift and a broadening of DNA proton resonances. At a ligand–DNA ratio of 4 : 1 the titration was virtually completed. The four strands were found to be magnetically equivalent throughout the titration, since no splitting of resonances was observed at any stage. This behavior

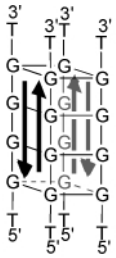

Fig. 2 Pictorial illustration of the proposed binding mode of Dist-A (arrows) to parallel-stranded tetraplex $[d(TGGGGT)]_4$.

could be explained assuming that the ligand is in fast exchange on the NMR time scale with its binding sites on the tetraplex. This fast exchange behavior could not be changed to a slow or intermediate regime by altering the temperature of the system. NOESY experiments at 300 K (500 MHz) performed at different mixing times did not show any long-range ligand–ligand interactions, whereas only a single ligand–DNA contact between H3 proton at 6.43 ppm and aromatic DNA proton at 7.72 could be unambiguously identified. These data can be tentatively explained assuming that electrostatic repulsion between the ends of the doubly charged Net molecules prevents their side-by-side arrangements into the grooves. Thus, in contrast to Dist-A, netropsin complexes the tetraplex with one drug molecule bound per groove. As for Dist-A, a comprehensive analysis of NOESY spectra showed that the structure of the tetraplex remained similar to the original conformation upon binding of netropsin, as indicated by the presence of all the intranucleotide and internucleotide connectivities of the free tetraplex.

The present communication represents the first ^{1}H-NMR investigation of the reversible interaction of groove binding agents with a tetraplex structure of DNA. Detailed structural analysis of the above 4 : 1 distamycin A–DNA complex as well as studies involving other DNA sequences and/or ligands are currently in progress.

Immobilization of cytochrome c at Au electrodes by association of a pyridine terminated SAM and the heme of cytochrome

Hiromichi Yamamoto, Haiying Liu and David H. Waldeck*

Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania 15260, USA. E-mail: dave@pitt.edu

Received (in Cambridge, UK) 23rd February 2001, Accepted 23rd April 2001
First published as an Advance Article on the web 9th May 2001

Electrochemical methods are used to demonstrate that cytochrome c can be immobilized on electrodes that are coated with self-assembled monolayers of 4-pyridinyl–CO_2–$(CH_2)_n$–S ($n > 6$) through interaction between the pyridine terminal unit and the heme of the cytochrome.

One avenue toward better sensors and enzyme electrodes is the use of a long tether, whose terminal functionality can selectively bind a biomolecule. Here this strategy is explored with the redox protein cytochrome c. Electron transfer reactions with cytochrome c have been extensively studied, both to clarify its function in biological systems and to provide a canonical example of a redox active protein.[1] Cytochrome c has been immobilized on CO_2H terminated self-assembled monolayers (SAMs) through electrostatic interactions between the carboxylate and the exterior of the protein[2] and by covalent linkage.[3] This work investigates the ligation between the terminal unit of a 4-pyridinyl–CO_2–$(CH_2)_n$–S ($PyCO_2$–C_n, n = 2, 6, 11, 16) SAM and the heme of horse-heart cytochrome c. The data show that immobilization of cytochrome is achieved by the pyridine functionality when the alkane tethers are long enough, n = 6, 11, 16. In addition, the immobilization causes a large negative shift of the formal potential $E^{\circ\prime}$ that does not occur for other immobilization strategies. The data also show that the electron transfer rate for the oxidation is enhanced over that for the reduction; *i.e.* an asymmetry in the rates becomes evident. These data suggest that the pyridine interacts with the iron in the cytrochrome's heme.

The experiments used a three-electrode (Pt auxiliary, Ag/AgCl reference) electrochemical cell with a working electrode that was a Au ball (*ca.* 1 mm diameter) to which the disulfide was self-assembled (see ESI† for details on the construction of the electrode and its characterization). Capacitance measurements were used to assess the quality of the SAM. For the immobilization studies the SAM coated electrodes were incubated in a cytochrome c solution and measurements were made in 25 mM phosphate buffer solution at pH 7. Details on the preparation of the SAM materials are given in the ESI†. For the studies with OH terminated layers and $PyCO_2$–C_2, in which the cyt c is not immobilized, the purified cytochrome c was 30–50 μM in the buffer solution (see ESI† for further details).

Fig. 1 shows cyclic voltammograms for some of the systems that were studied. Fig. 1(a) and (b) show voltammograms for SAMs that have pyridinal functionalities. The solid line curves show the electrode's response after it has been removed from the incubation solution, rinsed, and placed in contact with a buffer/electrolyte solution that does not contain cytochrome c. The data in Fig. 1(a) shows no faradaic response for the buffer solution because cytochrome c does not adsorb onto the surface of $PyCO_2$–C_2, but does show a response when the electrode contacts a solution containing cytochrome c (dashed line). Fig. 1(b) shows that some cytochrome adsorbs on the $PyCO_2$–C_{11} SAM and displays a negative shift in the apparent formal potential. A corresponding experiment using a SAM in which the pyridine nitrogen is blocked with a methyl group shows no faradaic current. Hence the adsorption of cytochrome c requires that the nitrogen atom of the pyridine be accessible to the protein and the alkane chain be long enough. Fig. 1(c) shows voltammograms for HO-terminated films,[4] in contact with cytochrome c solution (dashed line). The solid line voltammogram is the same system with 0.8% pyridine (by volume) added to the solution. Two redox waves (apparent $E^{\circ\prime}$ of −17 and −325 mV) are found upon pyridine addition. The redox wave at −17 mV is assigned to the redox reaction of unmodified cytochrome c and the wave at −325 mV is assigned to the redox reaction of cytochrome c in which pyridine is coordinated to the heme. In this system, a positive potential sweep oxidizes the iron, and complexation with the pyridine occurs (or is strengthened). As the voltage is swept back negative the pyridine is not removed until the iron is reduced at the more negative reduction potential of the pyridine-coordinated moiety. To summarize, these data show that $PyCO_2$–C_{11} SAMs immobilize cytochrome c and cause an $E^{\circ\prime}$ shift that is consistent with an interaction between pyridine and the heme.

Voltammograms were collected as a function of the voltage scan rate for each of the electrodes. For the HO–C_6 and $PyCO_2$–C_2 SAMs with cytochrome in solution, the peak current depended on the square root of the scan rate, indicating that the cytochrome is not immobilized on the electrode surface. For the HO_2C–C_{10} and the $PyCO_2$–C_n (n = 6, 11, 16) SAMs, the peak current was linear with the voltage scan rate, indicating that the

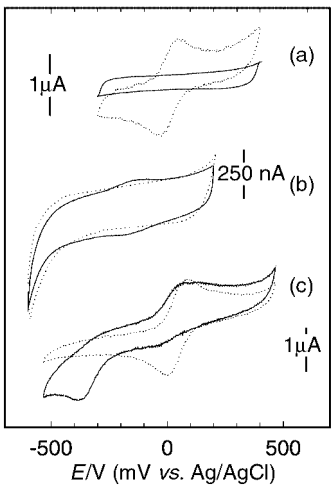

Fig. 1 Cyclic voltammograms are shown for gold electrodes that are coated with (a) 4-pyridinyl–CO_2–$(CH_2)_2$–S, (b) 4-pyridinyl–CO_2–$(CH_2)_{11}$–S, and (c) HO–$(CH_2)_6$–S SAMs. In (a), the solid line shows a voltammogram for an electrode that was incubated in 50 μM cytochrome solution for 30 min and placed in contact with a 25 mM buffer solution, and the dashed line shows the same electrode in contact with a 50 μM cytochrome c buffer solution. In (b) the solid line corresponds to the Py terminated layer after it was incubated in the cytochrome solution and the dashed line corresponds to the background curve. (c) Shows a voltammogram for cytochrome in a buffer solution (dashed line) and a voltammogram for a cytochrome solution containing 0.8% pyridine (solid line).

cytochrome is immobilized on the surface, as demonstrated by the data in Fig 1. The apparent formal potential, $E^{\circ\prime}$, for the cytochrome immobilized on pyridine are significantly shifted negative of the other systems (see Table 1). For the HO_2C–C_n SAMs, the adsorption is attributed to electrostatic and hydrogen bonding interactions between the lysine groups ($-NH_3^+$) on the cytochrome c periphery and the carboxylic acid group of the SAM.[2] The negative shift of $E^{\circ\prime}$ suggests a different adsorption state for cytochrome on the pyridinyl layers than on the carboxylic acid layers and a significant interaction of the pyridine with the heme. The nitrogen in the pyridinyl moiety of the SAM and the long alkyl chain are both needed for significant adsorption to occur.

Available literature results support the interpretation that the pyridine terminated SAMs coordinate to the heme. Recent Raman and NMR studies show that Met80, which is axially bound to the iron in the heme of cytochrome c, can be displaced by an imidazole or pyridine.[5] The apparent $E^{\circ\prime}$ values in the pyridine containing solution were found to be −17 and −325 mV, which is consistent with the reported result for yeast iso-1-cytochrome c that complexes with imidazole.[6] Thus, the large negative shift of the $E^{\circ\prime}$ (342 mV) by pyridine in solution is caused by the axial ligand exchange from Met80 to pyridine on the heme's iron. The 10–20 mV shift in the $E^{\circ\prime}$ of the unsubstituted cytochrome is consistent with the change in solution dielectric constant caused by 1% pyridine.[7] These observations strongly suggest that the large shift of 150 to 160 mV in the $PyCO_2$–C_n coated electrodes results from association of the pyridine with the heme. Although the potential shift observed on the SAM is about half of the shift found for the free pyridine, such a result is consistent with a reduced ability for optimal coordination when the pyridine is tethered to the SAM. Although a change in the local dielectric constant[7] or local field effects[8] may contribute to the potential shift, they are expected to be smaller than the shift observed here and show a chain length dependence.

The dependence of the voltammogram's peak position on the voltage scan rate can be used to quantify the electron transfer rate constant. For the $PyCO_2$–C_6, $PyCO_2$–C_{11}, and $PyCO_2$–C_{16} SAMs the oxidation waves do not shift with increasing scan rate; *i.e.* the rate remains too fast for the instrument to resolve. In contrast, the reduction peaks shift (see Table 1) and show a dependence on the alkane chain length of the SAM, reflecting the impact of the tunneling barrier thickness[9] on the electron transfer rate. This asymmetry in the transfer rate is consistent with stabilization of the heme by the pyridine. Such an interaction would enhance the oxidation rate and inhibit the reduction rate for which a dependence of the peak position on the voltage scan rate is evident. The increase in the reduction peak's potential shift with scan rate as the alkane chain length increases reflects a slowing of the electron transfer rate because of an increased tunneling barrier width. A more quantitative analysis of the electron transfer kinetics is underway and will be reported elsewhere.

This study shows that cytochrome c can be immobilized on $PyCO_2$–C_nS SAMs with alkane chains of $n > 6$, and the adsorption occurs through association of the pyridine with the cytochrome's heme. This latter conclusion is supported by the large potential shifts, an induced asymmetry in the reduction and oxidation rates, and other literature results. Fig. 2 depicts the mode of binding that is envisioned for this system. In contrast to electrostatic binding with surface functionalities, the pyridine associates directly with the redox center, which should create a better defined geometry between the protein and the electrode. This approach will allow the electron transfer kinetics to be explored without the limitations imposed by an inhomogeneous distribution of protein orientations with respect to the electrode. On a practical level, this strategy of ligating to metal redox centers or binding to a biomolecule's active site promises improved selectivity for the electrochemical detection of biomolecules.

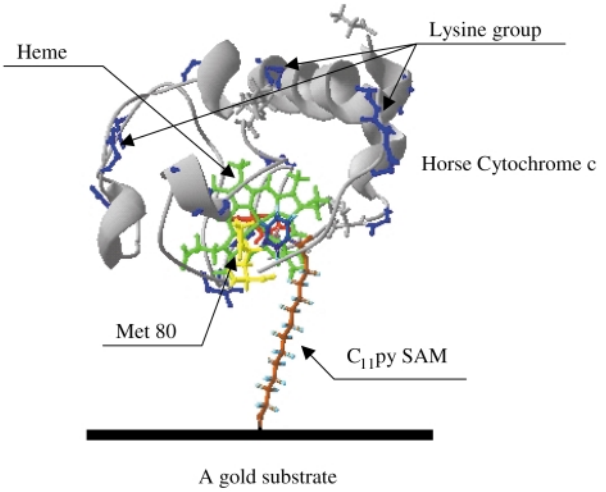

Fig. 2 Illustration of the association of a pyridine tether to the heme of cytochrome c. Also shown are the lysine groups that are present on the protein surface.

We are grateful to Professor J. Shin, A. R. Lajmi, and A. M. Napper for helpful advice. We acknowledge the Department of Energy for partial support of this work. We thank Hach Corporation for loan of the VoltaLab PGZ407 during part of this study.

Conformational isomerism leads to supramolecular isomerism and nanoscale inclusion in 2D extended framework solids based on *C*-methylcalix[4]resorcinarene

Leonard R. MacGillivray,*[a] Jennifer L. Reid[b] and John A. Ripmeester[b]

Received (in Columbia, MO, USA) 14th February 2001, Accepted 25th March 2001
First published as an Advance Article on the web 9th May 2001

Co-crystallization of *C*-methylcalix[4]resorcinarene 1 with 4,4′-bipyridine 2 in the presence of *m*-xylene results in the formation of a 2D brick framework, 3c·2(*m*-xylene), that possesses nanoscale cavities that host four aromatics as guests in which 1 adopts a 'T-shaped' conformation.

With the recognition that strategies for the deliberate design[1] of molecular crystalline solids[2] can lead to new materials with predictable properties realized (*e*.g. inclusion),[3–6] increased efforts have been placed upon understanding and controlling those factors that govern the assembly of molecules and/or ions in the solid state. For the design of extended solids with cavities that accommodate molecules as guests,[7] relatively strong, directional forces (*e.g*. hydrogen bonds) have attracted much attention in this regard owing to the structure-directing abilities of such interactions to be predicted with a reasonable degree of accuracy. Despite successes in exploiting such forces, however, it is, perhaps, surprising to note that nanoscale processes of molecular inclusion,[8] where, for example, multiple copies of a guest occupy a closed cavity in a solid, remain rare. Indeed, the successful engineering of cavities able to accommodate multiple guests can, in principle, provide a route to solids with guests that undergo reaction in the solid state[9] and bear relevance to problems of separations of large molecules.[10]

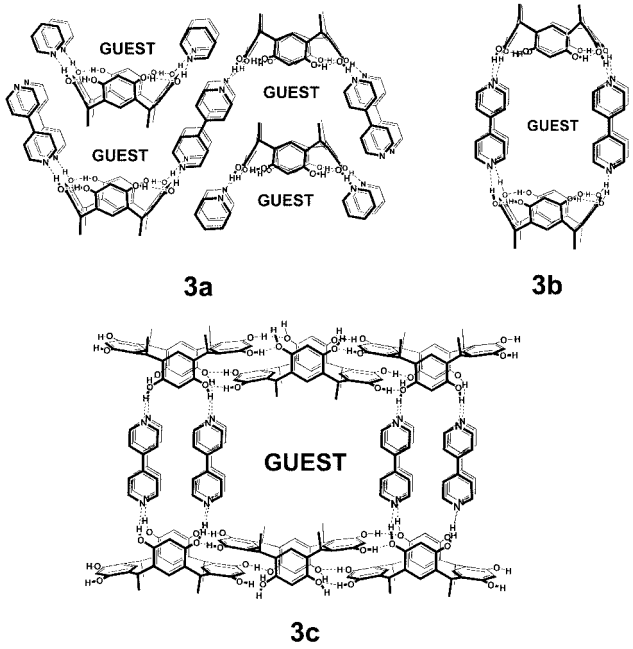
With this in mind, using a template-based method to molecular self-assembly we report the ability of the components of two supramolecular isomers **3** of composition **1**·2(**2**) (where **1** = *C*-methylcalix[4]resorcinarene, **2** = 4,4′-bipyridine),[11] that define a hydrogen-bonded, wave-like network **3a**[12] and carcer-and-like capsule **3b**,[13] to undergo a structural reorganization in the presence of a suitable aromatic guest to form a two-dimensional (2D) isomer **3c** of the parent components (Scheme 1). The network **3c**·2(*m*-xylene) defines a 2D symmetrical brick framework[14–16] that exhibits closed multi-molecular cavities of nanoscale dimensions, that, owing to the ability of **1** to adopt a 'T-shaped' conformation,[17] accommodate four identical aromatics as guests. Whereas supramolecular isomerism involving ligand conformational isomerism has been observed in inclusion compounds based on coordination polymers,[18] **3c**·2(*m*-xylene) represents, to our knowledge, a novel example of an organic inclusion compound that exhibits supramolecular isomerism involving conformational isomerism by a molecular receptor.†

When **1** (0.020 g) was co-crystallized with 2 equiv. of **2** (0.011 g) from a boiling aliquot of EtOH in the presence of 10 equiv. of *m*-xylene according to eqn. (1), single crystals of

$$\mathbf{1} + 2(\mathbf{2}) + 10(m\text{-xylene}) + \text{EtOH (excess)} \rightarrow \mathbf{3c}\cdot 2(m\text{-xylene}) \quad (1)$$

3c·2(*m*-xylene) suitable for X-ray analysis grew within a period of approximately 4 days. The formulation of **3c**·2(*m*-xylene) was determined by single-crystal X-ray diffraction‡ and ^{1}H NMR spectroscopy.

A space-filling view of the X-ray crystal structure of **3c** is shown in Fig. 1. As in the case of the wave-like framework **3a**·guest (guest = ferrocene, toluene, MeCN)[11,12] and carcer-and-like capsule **3b**·guest (guest = nitrobenzene),[13] four molecules of **2**, each of which serves as a bifunctional hydrogen



Scheme 1

 DOI: 10.1039/b102856c

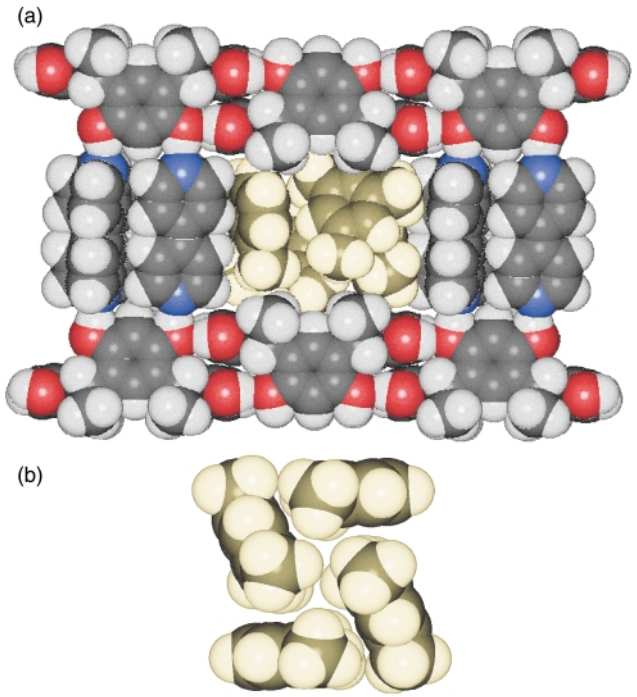

Fig. 2 Space-filling view of the guests of **3c**: (a) a view showing the guests within the brick framework, and (b) a view showing the edge-to-face π–π interactions of the guests. Color scheme: grey–yellow = guest atoms (Note: two *m*-xylene guests lie disordered, each across three sites).

bond acceptor, have assembled with **1** such that the bipyridines participate in four O–H···N hydrogen bonds with two opposite resorcinol units of the macrocycle [O···N separations (Å): O(1)···N(1) 2.770(4), O(2)···N(3) 2.727(4), O(5)···N(4) 2.774(4), O(6)···N(2) 2.725(4)]. Unlike **3a** and **3b**, however, the pyridine units of **3c** interact with **1** such that they participate in edge-to-face, rather than face-to-face, π–π interactions[24] along the upper rim of **1** and the cavity of **1** is closed. The remaining resorcinol units, which are co-planar and lie approximately perpendicular to the resorcinol moieties involved in the O–H···N forces, form four intermolecular O–H···O hydrogen bonds with two neighbouring molecules of **1**, making **1**, in the form of a 'T-shaped' building block,[17] an eight-fold hydrogen bond donor [O···O separations (Å): O(1)···O(4) 2.749(4), O(2)···O(7) 2.754(4), O(3)···O(5) 2.768(4), O(6)···O(8) 2.735(3)]. As a consequence of the assembly process, a 2D layered symmetrical brick framework **3c**, with large, closed rectangular cavities (cavity dimensions *ca*. 14 × 11 × 6 Å) of idealized D_{2h} symmetry, has formed.§

A view depicting the guests of **3c**·2(*m*-xylene) is shown in Fig. 2. Four molecules of *m*-xylene, which lie around a crystallographic center of inversion, are located within each cavity [Fig. 2(*a*)] such that the aromatics assemble by way of edge-to-face π–π interactions [Fig. 2(*b*)].[24] In this arrangement, two guests, which are related by symmetry, are positioned within the cavity such that the aromatic rings of the guests interact with **2** by way of edge-to-face π–π interactions,[23] while the remaining guests, each of which lies equally disordered across three sites, fill the host, in contrast to the ordered guests, such that the aromatics lie approximately parallel to the face of the cavity. Thus, the cavities of **3c**·2(*m*-xylene) have formed by way of template effects involving multiple guests in which the size, shape and electronic properties of an individual guest, presumably, do not favour an assembly process that leads to **3a** or **3b**.[15] Here, the conformational flexibility of **1** has provided access to a cavity, in the form of **3c**, that accommodates four molecules of *m*-xylene in which the O–H···N interactions between **1** and **2** are maintained[11–13] and **1** self-assembles by way of O–H···O forces.[17]

We have revealed the ability of **1**, in a 'T-shaped' conformation,[17] to assemble with **2** in the presence of a suitable guest to form a 2D symmetrical brick framework **3c** that possesses cavities of nanoscale dimensions which host four identical aromatics as guests. With such observations realized, we are currently investigating whether **3c** may be used as a host for multiple guests able to undergo reaction in the solid state.[9] We are also exploring whether molecules may be selected, *a priori*,[15] to induce formation of additional supramolecular isomers, able to accommodate single or multiple guests, based on **3**.¶ These observations should also bear relevance to materials in which derivatives of **1** and **2** are employed for the assembly process.

We are grateful for funding from the Natural Sciences and Engineering Research Council of Canada (graduate scholarship, J. L. R.).

Notes and references

† Molecular receptors typically adopt a number of conformations which make such molecules attractive building blocks for assembly processes leading to supramolecular isomerism by extended frameworks.[19] For an earlier account of **3c** see ref. 20.

‡ *Crystal data* for **3**·2(*m*-xylene): triclinic, space group $P\bar{1}$, a = 12.908(1), b = 13.791(1), c = 16.649(1) Å, α = 93.770(1), β = 102.761(1), γ = 91.189(2)°, U = 2882.3(3) Å^3, D_c = 1.27 g cm^{-3}, Mo-Kα radiation (λ = 0.71070 Å) for Z = 2. Least squares refinement based on 4226 reflections with $I_{net} > 2.0\sigma(I_{net})$ (out of 7512 unique reflections) led to a final value of R = 0.059. Aromatic and hydroxy hydrogen atoms were placed by modelling the moieties as rigid groups with idealised geometry, maximising the sum of the electron density at the calculated hydrogen positions. Structure solution was accomplished using SHELXS-86[21] and refinement was conducted using SHELXL93[22] locally implemented on a pentium-based IBM-compatible computer. Structure refinements and production of the figures were accomplished with the aid of RES2INS.[23]

Photochemical generation of acetonitrile oxide *via* the C–N bond cleavage of 3-methyl-2-(4-nitrophenyl)-2*H*-azirine

Hiroshi Inui and Shigeru Murata*

Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo, Meguro, Tokyo 153-8902, Japan. E-mail: cmura@mail.ecc.u-tokyo.ac.jp

Received (in Cambridge, UK) 13th March 2001, Accepted 24th April 2001
First published as an Advance Article on the web 15th May 2001

Acetonitrile oxide (2) is produced by the irradiation of the title azirine 1 in the presence of O_2 in fluid solutions and in low-temperature matrices through the capture of the biradical 7 with O_2, which is generated by the photochemical C–N bond cleavage of the azirine ring.

The photochemistry of 2*H*-azirines has aroused wide interest from the mechanistic and synthetic points of view. It has been established that the photolysis of 2*H*-azirines causes the C–C bond cleavage to yield 1,3-dipolar nitrile ylides, the [3 + 2] cycloaddition reactions of which provide a useful method for constructing a variety of five-membered heterocyclic systems.[1] However, in the course of our studies of the reactivities of photolytically-generated intermediates having an electron-withdrawing group,[2] we found that the photodecomposition of the title azirine **1** proceeded by a mechanism drastically different from that reported for 2*H*-azirines so far. In this paper, we report the photochemistry of the azirine **1** in fluid solutions and in low-temperature matrices, where the first example of the selective C–N bond cleavage in the 2*H*-azirine photochemistry, as well as of the photochemical generation of acetonitrile oxide (**2**) through trapping of the intermediate with O_2, is demonstrated.

The new azirine, 3-methyl-2-(4-nitrophenyl)-2*H*-azirine (**1**),[3] was obtained by the reaction of 1-(4-nitrophenyl)propan-2-one trimethylhydrazonium iodide with sodium hydride in dimethyl sulfoxide,[1b,c] and purified by silica gel column chromatography with hexane–chloroform (1 : 1). When a degassed solution of **1** containing 5% (v/v) acrylonitrile in acetonitrile was irradiated with the Pyrex-filtered light of a high-pressure mercury lamp, **1** was recovered nearly quantitatively. In the ^{1}H NMR spectrum of the photoreaction mixture, no signals assigned to the pyrroline, which could be formed by the cycloaddition of the expected nitrile ylide **3** with acrylonitrile, were observed. On the other hand, under conditions identical to those described above, except for the saturation of the solution with O_2, irradiation of **1** afforded 4-nitrobenzaldehyde (**4**, 46%) and 4-nitrobenzoic acid (14%), together with the adduct identified as the isoxazoline **5** (45%). The formation of **5** could be interpreted in terms of the capture of acetonitrile oxide (**2**) generated in the course of the photoreaction of **1** with acrylonitrile. The structure of **5** was confirmed by comparison of spectroscopic data with those of an authentic sample, which was obtained by a chemical generation of **2** by the base-induced reaction of phenylisocyanate with nitroethane in the presence of acrylonitrile.[4,5]

There are no precedents of the photochemical generation of **2** in solution, though it has been reported that photolysis of ozone matrix-isolated in Ar containing acetonitrile at 15 K gave **2** together with hydroxyacetonitrile.[6] We propose that **2** is produced by a fragmentation of the dioxazoline **6**, which is generated by the capture of the biradical **7** with O_2 (Scheme 1). The formation of 4-nitrobenzaldehyde (**4**) in amounts equimolar with the isoxazoline **5** is also explained by this scheme, assuming that the cycloaddition reaction of **2** with acrylonitrile proceeds quantitatively. Thus, the generation of **2**, as well as the failure to obtain the product derived from the nitrile ylide **3**, strongly suggests that the photolysis of **1** causes not the C–C bond but the C–N bond cleavage to produce the biradical **7** as a reactive intermediate.

To gain further evidence of the C–N bond cleavage in the irradiation of **1**, we examined the photochemistry of **1** in an Ar matrix at 10 K. Irradiation (> 300 nm) of **1** matrix-isolated in Ar resulted in a slow decrease in intensities of the IR peaks due to **1** (1537, 1351, and 858 cm^{-1}). Simultaneously, IR peaks appeared at 2046, 1597, and 1340 cm^{-1}, indicating the formation of product having a cumulenic double bond (designated as **A**). In the UV-vis spectrum, upon photolysis of **1** a broad band with a maximum at 341 nm appeared with isosbestic points at 266 and 317 nm. To identify the structure of **A**, we carried out the calculations of vibrational frequencies for the nitrile ylide **3**, which would be a possible candidate for **A**, with the DFT method (B3LYP/6-31G(d)).[7,8] Unfortunately, as shown in Table 1, the vibrational frequencies calculated for **3** are not consistent with those observed for **A** in the following two points: (i) a large deviation of the wavenumber predicted for the C=N$^+$=C$^-$ stretching of **3** from that of the observed cumulenic double bond, and (ii) a lack of the peak predicted to have a relatively large intensity at 1027 cm^{-1} for **3**. However, we have found that the vibrational frequencies calculated for the ketene imine **8** are in excellent agreement with those observed for **A** (Table 1). Therefore, we conclude that the photoproduct of **1** in an Ar matrix at 10 K is not the nitrile ylide **3**, but the

[a] Measured in Ar at 10 K; s = strong; m = medium; w = weak. [b] Calculated frequencies are scaled by the use of a linear scaling function; See ref. 7. Relative intensities are designated in parentheses. Frequencies with relative intensities greater than 5% were given in the table.

ketene imine **8**. The direct observation of **8** provides a strong piece of evidence in support of the C–N bond cleavage in the photolysis of **1**, because the formation of **8** is rationalized in terms of the Curtius-like rearrangement of the methyl group in the biradical **7** having a vinyl nitrene character.[9]

When **1** was photolyzed (> 300 nm, 10 K) in the Ar matrix doped with a large amount of O_2 (20%), we could observe no IR peaks assigned to **8**. Instead, the irradiation afforded 4-nitrobenzaldehyde (**4**), the structure of which was readily confirmed by comparison of the IR spectrum with that of the authentic sample matrix-isolated in Ar at 10 K, together with a species having IR bands at 2334 and 1315 cm^{-1} (designated as **B**) as primary photoproducts. The species **B** could be identified as acetonitrile oxide (**2**) on the basis of the agreement of the vibrational frequencies with those reported for **2**.[6,10] Isotopic labeling supports this identification of **B**. With use of $^{18}O_2$ (97% doubly labeled), the intense band at 2334 cm^{-1} was slightly shifted (1 cm^{-1}), while a large isotopic shift of 28 cm^{-1} was observed in the band at 1315 cm^{-1}, which is assigned to the N–O stretch. These values are in fair agreement with those reported for the isotopic shifts of the bands assigned to **2**.[6,11] Consequently, the generation of **2** in the photolysis of **1** in the presence of O_2, which is presumed on the basis of the characterization of reaction products in solutions, is unambiguously confirmed by the direct observation using a low-temperature matrix-isolation technique.

It is generally accepted that the photochemical C–C bond cleavage of 2*H*-azirines to produce nitrile ylides proceeds from the excited singlet state having an n–π* character.[1] However, the theoretical calculation using the INDO/S method[12] predicted that the lowest excited singlet state of **1**, S_1, could be roughly described as a local π–π* excitation of its 4-nitrophenyl group. Moreover, it is reasonable to think that a large spin-orbit interaction in the nitro group can accelerate the intersystem-crossing from the S_1 state to the excited triplet state, T_1. Thus, we propose that the selective C–N bond cleavage observed in the photolysis of **1** results from the participation of its T_1 state. This assumption is supported by the DFT calculations on the triplet biradicals which are expected to be formed by the bond cleavage. It was found that the biradical **7** formed by the C–N bond cleavage was more stable by 7.6 kcal mol^{-1} than the triplet biradical formed by the C–C bond cleavage. The triplet biradical **7** can be readily captured by O_2 to afford **6**, while in the absence of O_2, the biradical undergoes the Curtius-like rearrangement to yield **8** from its singlet state which would be accessible from the triplet state.

In conclusion, it is established that on the irradiation of the azirine **1**, the C–N bond is selectively cleaved, in contrast to the C–C bond cleavage of the normal 2*H*-azirines reported so far. On the basis of the calculations, we propose that the selective C–N bond cleavage is due to the participation of the excited triplet state of **1** in the bond cleavage. Moreover, we have demonstrated that acetonitrile oxide (**2**) is produced through the capture of **7** with O_2 followed by the fragmentation, which would provide a convenient method of photochemical generation of **2**.

This work was supported in part by grants from the Ministry of Education, Science, Sports and Culture of Japan (No. 12020214) and from the Core Research for Evolutional Science and Technology (CREST).

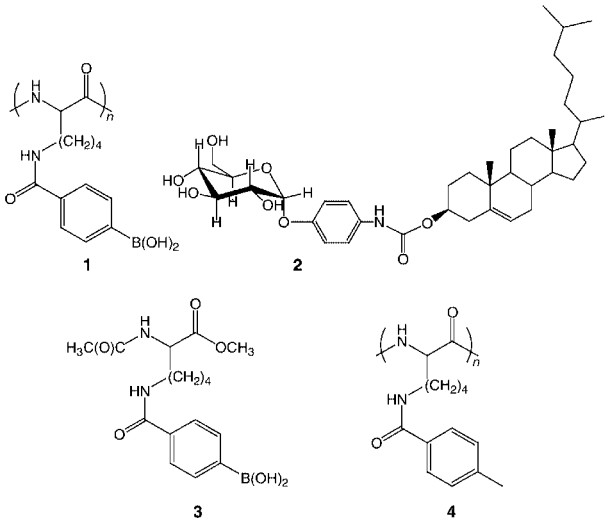
First published as an Advance Article on the web 15th May 2001

The combination of boronic acid-appended poly(L-lysine) 1 and sugar-based gelator 2 yields a novel organo-polymer gel, consisting of vesicles held together by polymer molecules.

The assembly of certain low-molecular weight compounds (gelators) into complex, three-dimensional networks in which organic solvent molecules are confined, leads to the formation of organic gels.[1] Polymer gels, on the other hand, have three-dimensional structures created by cross-linked covalent bonds.[2] Hence, they are generally more robust than organic gels, however, they lack the characteristic, excellent thermo-reversibility inherent to organogels.[3] Recently, several groups have been able to improve the robustness of hydrogen-bond-based,[3,4] as well as cholesterol-based[5] gels by polymerization of the gelator molecules. Feringa *et. al.*[6] have shown that increased thermostabilization of methacrylate-containing cyclohexane-based gels can be achieved by *in situ* polymerization. In our group, the introduction of multi-point hydrogen bonding sites into cholesterol-based gelators, and the utilization of metal–ligand interactions in sugar-based gelators have resulted in a remarkable stabilization of these gel systems.[7] Moreover, polymerization of a bis(diacetylene)-containing gelator also improves gel stabilization.[3] Thus, combination of polymers with low-molecular weight gelators is a new and interesting concept which can lead to more robust gel systems.

In this paper we show how the gelating capability of cholesterol–saccharide conjugate gelator **2** is facilitated by the addition of boronic acid-appended poly(L-lysine)[8] **1** (Scheme1),



Scheme 1

† Electronic supplementary information (ESI) available: experimental details and synthesis of compounds **3** and **4**. See http://www.rsc.org/suppdata/cc/b1/b102436c/

in a DMSO–H_2O mixture. Moreover, the formation of the gel is shown to be pH-reversible due to the intrinsic properties of the boronic acid–sugar interaction governing the gelation process. Furthermore, transmission electron microscopy (TEM) images[9] of the gel revealed a remarkably novel superstructure consisting of a network of polymer-coated vesicles, held together by boronic acid-appended poly(L-lysine) molecules. This contrasts with most other gels that show structures consisting of fibrous networks. On the basis of TEM and dynamic light scattering (DLS) measurements, a mechanism for gel formation is proposed.

Compounds **1** and **2** were synthesized according to literature procedures[7b,8] and utilized to perform the gel test.[10] To a solution of **2** in DMSO (90 μL) was added a solution of **1** in water (20 μL) at pH 11.5 to favor the boronic acid–sugar interaction.[11] After heating, the system was allowed to cool in order to grow the organogel. This procedure was repeated at several concentrations of **2**, maintaining the concentration of **1** constant (1.8 mmol dm^{-3}), which yielded a maximum T_{gel} of 58 ± 3 °C at a concentration ratio of polymer to gelator of approximately 1:6 (Fig. 1). In good agreement with these results, a maximum T_{gel} of 62 ± 3 °C was observed, at a polymer to gelator ratio of approximately 1:5 by varying the concentration of **1** while maintaining the concentration of **2** constant (10.6 mmol dm^{-3}). Compound **2** has previously been shown to form gels with many solvents.[7b] However, since it did not form a gel in DMSO–H_2O (9:2 v/v) in the absence of **1**, the addition of the latter expands the gelation capabilities of **2** to more polar solvents. To investigate the role of both the poly(L-lysine) chain and the boronic acid moiety in the gelation process, reference compounds **3** and **4** were used respectively (Scheme 1).† Gelation tests carried out with **3** or **4** (1.8 mmol dm^{-3}) and

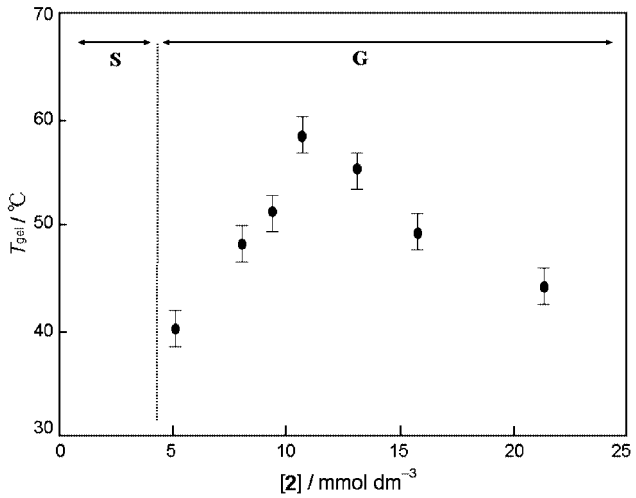


Fig. 1 Concentration dependence of the T_{gel} of **1** (1.8 monomer unit mmol dm^{-3}) upon addition of **2** in DMSO–H_2O (9:2 v/v). S: solution, G: gel.

 DOI: 10.1039/b102436c

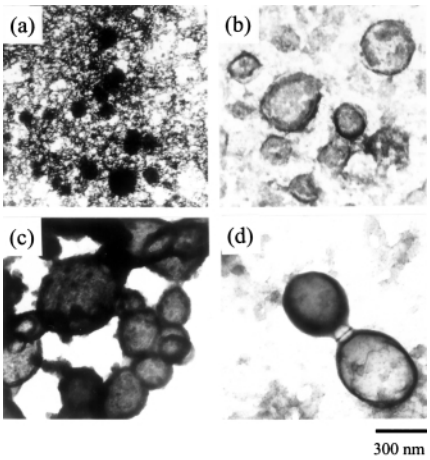

Fig. 2 TEM images of a 10.6 mmol dm^{-3} solution of **2** (a); a solution of **1** (1.8 mmol dm^{-3}) and **2** (2.6 mmol dm^{-3}) (b); a gel of **1** (1.8 mmol dm^{-3}) and **2** (10.6 mmol dm^{-3}) at T_{gel} = 58 ± 3 °C (c); and a gel of **1** (1.8 mmol dm^{-3}) and **2** (15.9 mmol dm^{-3}) at T_{gel} = 44 ± 3 °C (d).

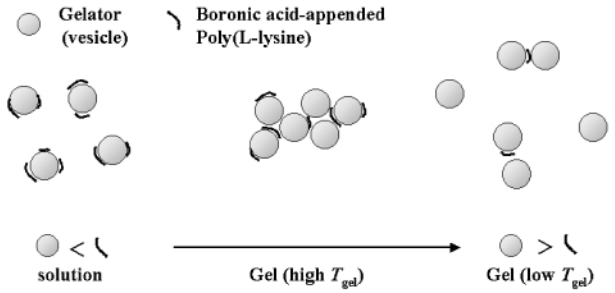

Scheme 2

gelator **2** (0–21 mmol dm^{-3}) did not result in gel formation, indicating that both the poly(L-lysine) chain, and the boronic acid moiety are a prerequisite for gelation to occur. Under alkaline conditions, the boronic acid moiety of **1** can interact with the glucopyranosyl moiety of **2**, forming covalent bonds with the 4,6-diol of the saccharide,[12] thus creating a connection between the polymer (**1**) and the gelator (**2**). Under acidic conditions (pH 5), on the other hand, the addition of **1** to a solution of **2** did not cause gel formation. The gelation behavior of this particular system is obviously pH dependent, since it relies on the boronic acid–saccharide interaction for gel formation.

To shed light on the mechanism of gel formation, TEM was employed (Fig. 2). In sample (a), containing only compound **2** (10.6 mmol dm^{-3}), monodisperse colloidal particles with diameters of approximately 50–100 nm, can be observed.[13] In sample (b), representative of gelator **2** (2.6 mmol dm^{-3}) plus polymer **1** (1.8 mmol dm^{-3}) in the solution state, slightly larger (200–400 nm in diameter), monodisperse vesicles are present. However, in sample (c), representative of the gel state with a high T_{gel} (**1**: 1.8 mmol dm^{-3}, **2**: 10.6 mmol dm^{-3}), no individual structures are present, but only a network of vesicles can be observed. In sample (d), representative of the gel state with a low T_{gel} (**1**: 1.8 mmol dm^{-3}, **2**: 15.9 mmol dm^{-3}), similar features as in sample (b) can be observed. To obtain a more accurate evaluation of the dimensions of the vesicles observed by TEM, DLS measurements were carried out.[14] The average diameters of the features observed in samples (a)–(d) are 121, 302, 2140, and 495 nm, respectively. The high average diameter observed for sample (c) could correspond to either very large vesicles present in solution, or to aggregates of smaller vesicles. In light of the TEM results (see Fig. 2c), the latter is more viable.

From the results presented, a mechanism for gel formation can be proposed (Scheme 2). In the presence of a large excess of **1** with respect to **2**, the gelator can form vesicles which are completely coated by the polymer, giving rise to individual vesicles (Fig. 2b). As a consequence, gel formation is not observed at high concentrations of **1** with respect to **2**. When the concentration of gelator is increased and the ratio of polymer to gelator is approximately 1:6, the number of vesicles increases and the amount of **1** is not sufficient to completely coat all the vesicles (Scheme 2). Therefore, aggregation of the gelator vesicles occurs, giving rise to an extended network of vesicles held together by polymer molecules and thus, the formation of the gel is observed (Fig. 2c). When the concentration of gelator **2** is increased even further, the amount of polymer **1** present in the system is not sufficient anymore for the formation of an extended network of vesicles (Scheme 2). Under these conditions, only dimers can still be observed in the TEM images and T_{gel} decreases.

In contrast to most gel structures that have been reported so far, consisting of fibrous networks running through the gels,[1,15] an assembly of vesicles of gelator **2** held together by polymer **1** is at the basis of this particular gel. Remarkably, the building blocks of this novel gel structure are polymer-coated gelator vesicles, which assemble into a superstructure, the gel, whilst maintaining the identity of vesicles. The gel cannot be defined as a polymer gel since the polymer chain length is far too short (100–200 nm, if fully stretched) to allow cross-linking of polymer chains by vesicles. One can thus regard the gelation as being induced by the 'cross-linking' of vesicles by polymers, but not by the 'cross-linking' of polymers by vesicles. Studies are currently underway to further elucidate the more detailed mechanism of gel formation proposed in this paper and to investigate the possibilities of utilizing poly(L-lysine)-based polymers for the formation of robust gels useful in aqueous systems.

Hydrolytic kinetic resolution of mono- and bisepoxides as a key step in the synthesis of insect pheromones†

Sharon Chow and William Kitching*

Department of Chemistry, The University of Queensland, Brisbane, 4072, Australia.

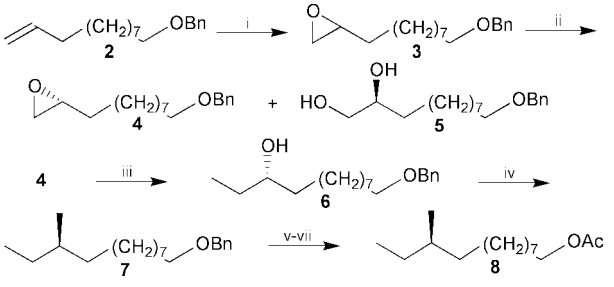
Received (in Cambridge, UK) 7th March 2001, Accepted 23rd April 2001
First published as an Advance Article on the web 16th May 2001

The synthetic utility of the readily separated epoxides, diols, epoxydiols and tetrols of high enantiomeric excesses, obtained by hydrolytic kinetic resolution (HKR) of functionalised mono- and bisepoxides with (salen)Co(OAc) complexes, is demonstrated by their efficient transformations to important insect pheromones.

Many insect pheromones incorporate a medium to long alkyl chain with some oxygen functionality, often alkyl branching, with a specific or strongly dominating chirality and double bond configuration.[1] These structural features, and the regio- and stereo-regularities associated with nucleophilic opening of terminal epoxides and displacement of sulfonate ester groups, suggest that ready availability of epoxides and 1,2-diols of high enantiomeric excesses (ee's), would expedite acquisition of such pheromones. Most hydrolytic kinetic resolutions (HKR)[2] of terminal epoxides relate to simple epoxides not bearing other functionality.[3] We now demonstrate that structurally more diverse epoxides respond well to the procedures developed by Jacobsen,[2] which utilise (salen)Co(OAc) complexes, such as, (acetato)(aqua)((*R*,*R*)(−)-*N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-cyclohexanediamino)cobalt(III) (**1**).[4]

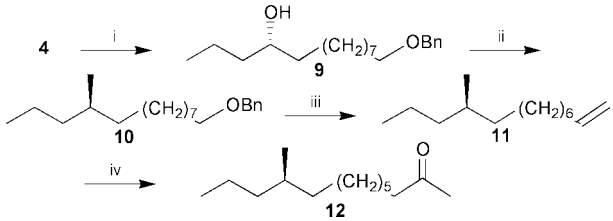
Our exploratory work was directed towards (*R*)-(−)-10-methyldodecyl acetate **8** and (*R*)-(−)-10-methyltridecan-2-one **12**. The acetate is a pheromone from the smaller tea tortrix moth (*Adoxophyes* species), with the (*R*)-enantiomer slightly more bioactive than the (*S*).[4] (*R*)-(−)-10-Methyltridecan-2-one is the sex pheromone of the southern corn rootworm (*Diabrotica undecimpunctata*).[4] The procedure (Scheme 1) commenced with the benzyl ether of undecen-10-ol, **2**, which was epoxidised to furnish the HKR substrate **3**. This was stirred with 0.5 mole% of (*R*,*R*)-**1** and 0.55 mole eq. H_2O at rt (*ca*. 22 °C) for 20–24 h.[2,4] Chromatography on silica yielded (*R*)-epoxide **4** and (*S*)-diol **5**, with excellent recovery (48 and 46% respectively). Manipulation of the epoxide afforded (*R*)-acetate **8** with $[\alpha]_D^{23}$ −5.40° (*c* 0.97, $CHCl_3$). (Reported for **8**, acquired by longer routes: $[\alpha]_D$ −5.84° ($CHCl_3$)[5] and −5.93° ($CHCl_3$).[6]) Reconstitution of diol **5** afforded the (*S*)-epoxide, which was transformed to the (*S*)-(+)-pheromone, with $[\alpha]_D^{23}$ +5.29° (*c* 1.02, $CHCl_3$).



Scheme 1 *Reagents and conditions*: i, *m*-CPBA (78%); ii, 0.5% eq. (*R*,*R*)-**1**, 0.55 eq. H_2O (48% for **4**, 46% for **5**); iii, Me_2CuLi (99%); iv, MsCl, Et_3N then Me_2CuLi (60%); v, O_3, Me_2S (42%); vi, K_2CO_3, MeOH (67%); vii, Ac_2O, Py (100%).

† Electronic supplementary information (ESI) available: references describing previous syntheses of insect pheromones, an illustrative procedure for HKR of a bisepoxide and a comparison between asymmetric dihydroxylation (of an alkene) and HKR (of the corresponding epoxide). See http://www.rsc.org/suppdata/cc/b1/b102181h/

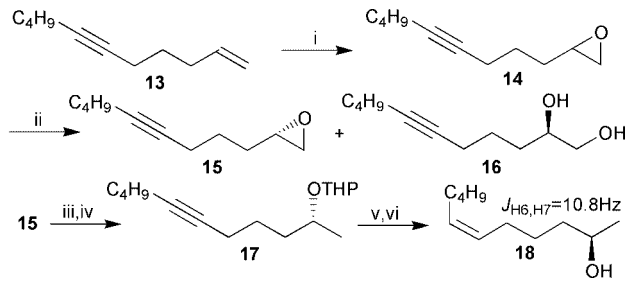
The methyl ketone **12** was obtained by processing epoxide **4** as summarised in Scheme 2. After epoxide opening and mesylate displacement, [2,3]-Wittig rearrangement of **10** afforded terminal alkene **11**, which under Wacker conditions, provided the desired compound **12** ($[\alpha]_D^{23}$ −1.63° (*c* 0.70, $CHCl_3$); reported value, $[\alpha]_D^{24}$ −1.71° ($CHCl_3$)[7]). The less active (*S*)-(+)-ketone could be obtained from the corresponding (*S*)-epoxide, by reconstituting from diol **5**.



Scheme 2 *Reagents and conditions*: i, EtMgBr, CuI (62%); ii, MsCl, Et_3N then Me_2CuLi (40%); iii, ^{n}BuLi, −78 °C (43%); iv, $PdCl_2$, CuCl, DMF–H_2O, O_2 (90%).

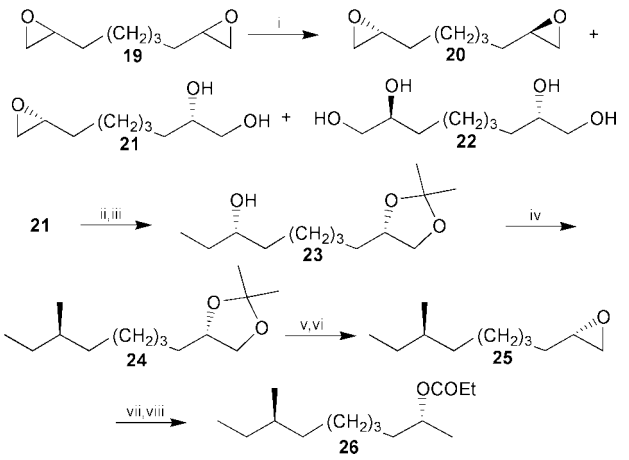
An important component from ant-lions (*Euroleon nostras* and *Grocus bore*) is (*R*)-(−)-(*Z*)undec-6-en-2-ol (nostrenol) **18**,[8] and its synthesis (Scheme 3) begins with chemoselective epoxidation of enyne **13**. HKR of epoxide **14** furnished (*S*)-epoxide **15** of 95% ee (Mosher ester analysis of the alcohol resulting from hydride opening). Ti-mediated stereospecific *Z*-reduction[9] of protected alcohol **17** led to (*R*)-(−)-pheromone **18**, $[\alpha]_D^{23}$ −5.48° (*c* 0.70, $CHCl_3$) (reported value, $[\alpha]_D$ −6.08° (neat).[8]) As before, reconstitution of diol **16** to the (*R*)-epoxide could afford (*S*)-(+)-(*Z*)undec-6-en-2-ol.

Whereas asymmetric dihydroxylation of dienes affords tetrols,[10] successful HKR of bisepoxides would afford three easily separable components, with the predominating epoxydiol facilitating bi-directional and selective functionalisation. The conversions of nona-1,8-diene to (1*R*,7*R*)-1,7-dimethylnonyl propanoate **26** (Scheme 4), the female produced sex pheromone of the western corn rootworm (*Diabrotica virgifera virgifera*),[4]

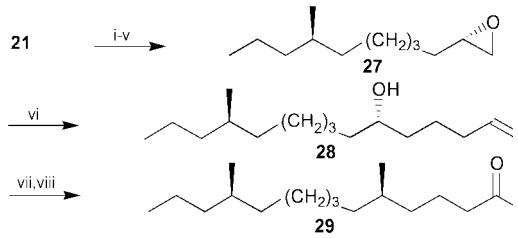


Scheme 3 *Reagents and conditions*: i, *m*-CPBA, CH_2Cl_2; ii, 0.5% eq. (*S*,*S*)-**1**, 0.55 eq. H_2O (43% for **16**); iii, $NaBH_4$, EtOH (73% over 2 steps); iv, DHP, H^+ (84%); v, $Ti(O^iPr)_4$, ^{i}PrMgBr, Et_2O then H_2O; vi, MeOH, H^+ (54% over 2 steps).

 DOI: 10.1039/b102181h



Scheme 4 *Reagents and conditions*: i, 1.0% eq. (*R*,*R*)-**1**, 0.8 eq. H_2O, (24% for **20**, 46% for **21**, 15% for **22**); ii, DMP, H^+ (78%); iii, Me_2CuLi (98%); iv, MsCl, Et_3N then Me_2CuLi (70%); v, MeOH, H^+ (76%); vi, MsCl, Et_3N then K_2CO_3, MeOH (27%); vii, $NaBH_4$, EtOH (92%); viii, $(EtCO)_2O$, Py (79%).

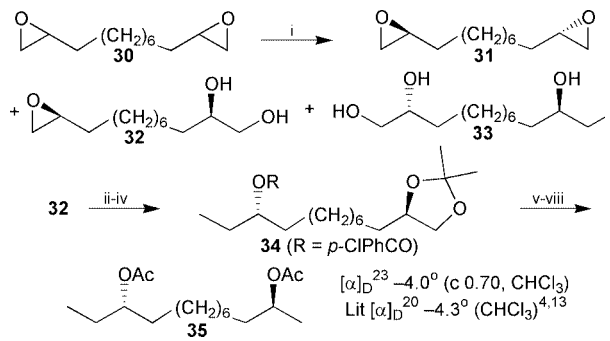


Scheme 5 *Reagents and conditions*: i, DMP, H^+ (82%); ii, EtMgBr, CuI (91%); iii, MsCl, Et_3N then Me_2CuLi (41%); iv, MeOH, H^+ (99%); v, MsCl, Et_3N then K_2CO_3, MeOH (48%); vi, $H_2C{=}CH(CH_2)_2MgBr$, CuI (34%); vii, MsCl, Et_3N then Me_2CuLi (53%); viii, $PdCl_2$, CuCl, DMF–H_2O, O_2 (74%).

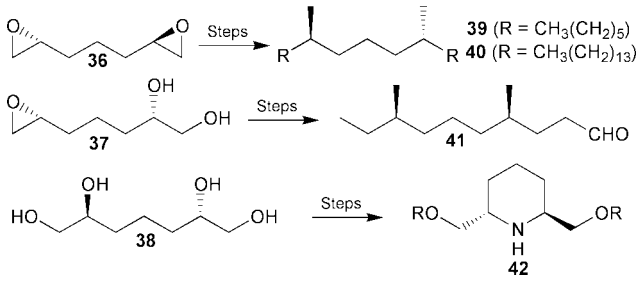
and to (6*R*,12*R*)-6,12-dimethylpentadecan-2-one **29**, the female produced pheromone of the banded cucumber beetle (*Diabrotica balteata*)[4] illustrate this. Thus, racemic bisepoxide **19** was exposed to (*R*,*R*)-**1** and 0.8 eq. H_2O to provide (2*R*,8*R*)-bisepoxide **20** (24%), epoxydiol **21** (46%) and tetrol **22** (15%). Manipulation of epoxydiol **21** afforded (1*R*,7*R*)-pheromone **26**, with $[\alpha]_D^{23}$ −7.17° (*c* 0.70, $CHCl_3$) (reported value, $[\alpha]_D$ −7.57° ($CHCl_3$)[11]).

The same epoxydiol, **21**, provided the bioactive (6*R*,12*R*)-6,12-dimethylpentadecan-2-one,[4] **29**, by the procedure summarised in Scheme 5. (For **29**, $[\alpha]_D^{23}$ −0.43° (*c* 0.40, $CHCl_3$); reported value, $[\alpha]_D^{22}$ −0.5° ($CHCl_3$).[12])

HKR of the bisepoxide of dodeca-1,11-diene, **30**, proceeded satisfactorily to afford epoxydiol **32** that has been processed to (2*S*,11*S*)-2,11-diacetoxytridecane **35**, a sex pheromone component of the female pea midge, *Contarinia pisi*, a serious pest of commercial peas.[4,13] (Scheme 6). Similarly, reductive opening



Scheme 6 *Reagents and conditions*: i, 1.0% eq. (*S*,*S*)-**1**, 0.6 eq. H_2O (23% for **31**, 26% for **32**, 12% for **33**); ii, DMP, H^+ (65%); iii, CH_3MgBr, CuI (91%); iv, Ph_3P, *p*-chlorobenzoic acid, DEAD, THF (80%); v, MeOH, H^+ (83%); vi, MsCl, Et_3N then K_2CO_3, MeOH (44%); vii, $LiAlH_4$, Et_2O (79%); viii, Ac_2O, Py (68%).



Scheme 7

($NaBH_4$, EtOH, 84%) of the (*R*,*R*)-bisepoxide of tridecan-1,12-diene led to (2*S*,12*S*)-2,12-diacetoxytridecane ($[\alpha]_D^{23}$ +1.77° (*c* 1.21, $CHCl_3$); reported value, $[\alpha]_{578}$ +2.04° ($CHCl_3$)[13]), also from the pea-midge.

The bisepoxide of hepta-1,6-diene with 1.4 mole% (*R*,*R*)-**1** and 1.0 mole eq. H_2O (Scheme 7) afforded bisepoxide **36**, free of its *meso* isomer (NMR), and epoxydiol **37** was stereoisomerically pure. Routes to (4*R*,8*R*)-4,8-dimethyldecanal (Tribolure) **41**, an important pheromone component of several *Tribolure* species including the red flour and confused flour beetles,[4] and C_2 symmetric dimethylalkanes, **39** and **40**, pheromone components of female spring hemlock looper (*Lambdina athasaria*) and female stable flies (*Stomoxys calcitrans*) respectively,[4] have been developed. Tetrol **38** has been converted to C_2 symmetric piperidines **42**.[14]

The above examples considerably widen the scope of the HKR approach. High ee's have resulted, and solvent addition with the longer chain bisepoxides may be beneficial.[3] A full discussion of these and related results will be reported at a later date.

We thank Professor Dr W. Francke for a listing of optical rotations of some compounds described in ref. 13.

A kinetically controlled molecular switch based on bistable [2]rotaxane†

Jae Wook Lee, Kyungpil Kim and Kimoon Kim*

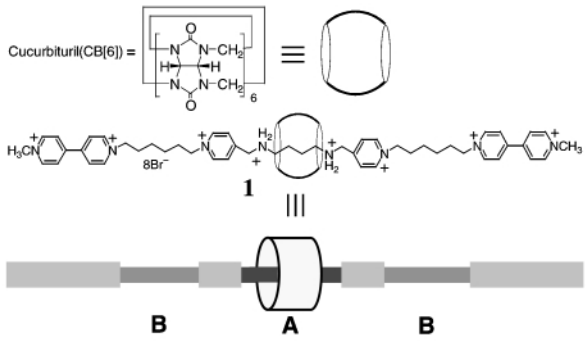
Received (in Cambridge, UK) 17th April 2001, Accepted 30th April 2001
First published as an Advance Article on the web 16th May 2001

A bistable [2]rotaxane that behaves as a kinetically controlled molecular switch is synthesized; switching from one state to the other is driven by pH change but the reverse process requires pH change plus thermal activation.

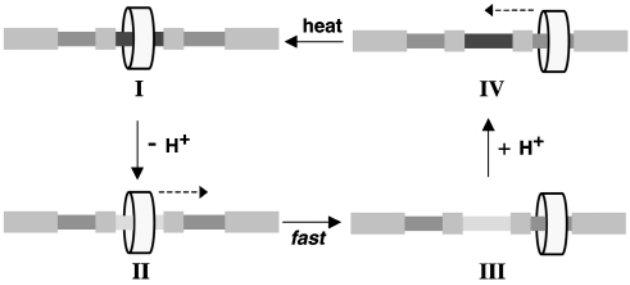
The construction of nanometer-scale devices such as molecular machines and switches from molecular components ('bottom-up' approach) is of much interest in modern science and technology.[1] Mechanically interlocked molecules such as rotaxanes and catenanes have great potential as such molecular devices because the relative positions of their components can be induced to change by external chemical, electrochemical or photochemical stimuli.[2,3] In appropriately designed systems, such mechanical movements occur between two different well-defined states so that they behave as molecular switches that are potentially useful in molecular-scale information storage and processing as well as sensors. In most cases, the molecular switches operate under thermodynamic control. In other words, since such a system is in thermodynamic equilibrium when it responds to a stimulus, it reverts to its initial state upon removal of the stimulus, which means that the new state cannot be 'locked in'.[4] Here we present a novel bistable [2]rotaxane behaving as a kinetically controlled molecular switch—the new state induced by an external stimulus can be 'locked in' after removal of the stimulus.

Cucurbituril (CB[6]),[5] a macrocyclic cage compound forms host–guest complexes with protonated diaminoalkanes (log$K$ = 5.19 at 40 °C for diaminobutane at pH = 1), the stabilities of which, however, depend on pH. Taking advantage of this fact, we[6] and others[7–9] have constructed interlocked species such as rotaxanes, polyrotaxanes, molecular necklaces and molecular switches using CB[6] as a molecular bead. Recently, CB[6] was found to form a stable inclusion complex with 1,6-di(pyridinium)hexane (log$K$ = 4.40 at 25 °C);[10] this complex formation is little affected by the pH of the solution. Taking these inclusion properties of CB[6] into account, we have designed and synthesized a bistable [2]rotaxane (**1**) consisting of CB[6] as a bead, one protonated diaminobutane unit as a station (**A**), two pyridinium groups as linkers, two hexamethylene units as further stations (**B**), and two terminal viologen groups (Scheme 1). [2]Rotaxane **1** is synthesized from the corresponding 'string' and CB[6] by 'slippage'.[11]† The ^{1}H-NMR spectrum of **1** is consistent with the desired [2]rotaxane structure. The signals for the internal CH_2 protons of the protonated diaminobutane unit, which are now located inside CB[6], are up-field-shifted relative to those in the free 'string'. On the other hand, there is no chemical-shift change in the hexamethylene units. These observations are consistent with the structure (state **I**, Scheme 2) in which the CB[6] bead in **1** resides exclusively at station **A**.

Deprotonation of the protonated diaminobutane unit in **1** promotes the movement of CB[6] from station **A** to station **B**.



Scheme 1 Bistable [2]rotaxane **1**.



Scheme 2 Switching cycle of bistable [2]rotaxane **1**.

Diisopropylethylamine (DIEA) was found to be an ideal base to drive the switching process because it is strong enough to deprotonate the NH_2^+ while behaving concurrently as an unreactive nucleophile towards the viologen units. Reprotonation can be performed by addition of a suitable acid such as DCl. The pH-controlled switching processes of **1** have been monitored by ^{1}H NMR spectroscopy (Fig. 1).

In a typical experiment, DIEA (2.1 eq.) is added to a solution of **1** (state **I**) in D_2O. The ^{1}H NMR spectrum shows that, upon base addition, deprotonation of the NH_2^+ in station **A** occurs and CB[6] moves from station **A** to station **B**, while leaving the viologen unit intact but the chemical shifts of viologen and pyridinium units are influenced by the CB[6] movement (Fig. 1b). Resonances for $-NH_2^+CH_2(\bullet)CH_2(\blacklozenge)CH_2CH_2NH_2^+-$ protons disappear and new signals, which can be assigned to $-NHCH_2(\bullet)CH_2(\blacklozenge)CH_2CH_2NH-$ protons without CB[6], become visible as a result of the relocation of CB[6]. At the same time, signals for the hexamethylene units (station **B**) split into *two* sets: one set shows dramatic chemical-shift changes (upfield shifts) whereas the other set shows no change.[12] This observation suggests that the CB[6] bead locates at one of the two **B** stations (state **III**, Scheme 2).

Upon addition of DCl (2.2 eq.), the $-NH_2^+CH_2(\bullet)CH_2(\blacklozenge)$ proton signals shift downfield due to protonation of the amine groups, while the signals for the hexamethylene unit remain unchanged, suggesting that the CB[6] bead *does not* shuttle back quickly to station **A** (state **IV**) (Fig. 1c). In fact, the reverse process is very slow at rt: the CB[6] bead shuttles back ~50%

† Electronic supplementary information (ESI) available: synthetic procedure and characterization data of **1** and colour versions of Schemes 1 and 2. See http://www.rsc.org/suppdata/cc/b1/b103380h/

 DOI: 10.1039/b103380h

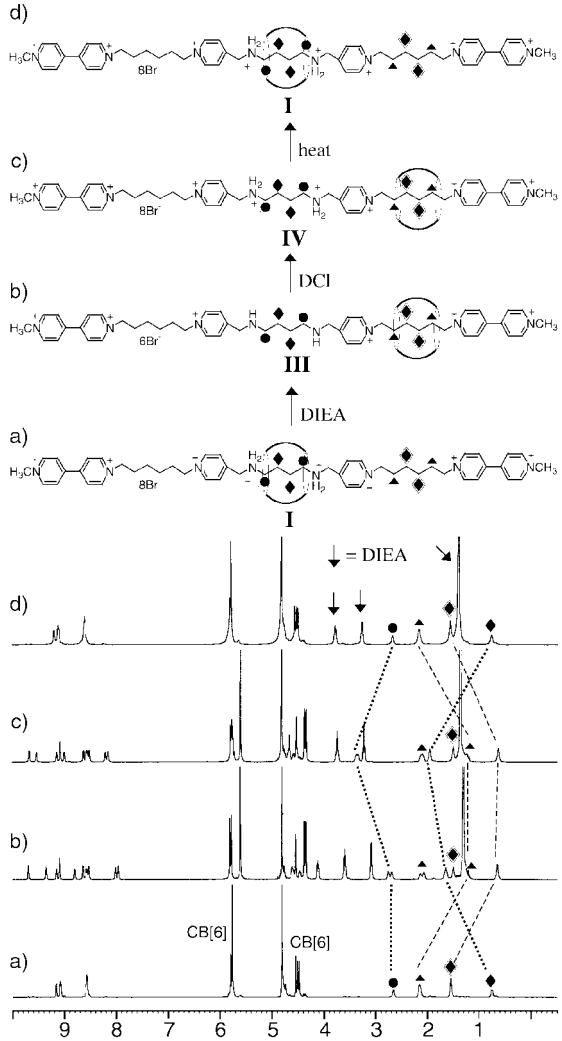


Fig. 1 Comparison of the ^{1}H-NMR spectra (in D_2O at 25 °C) of **1**. (a) **1** (state **I**), (b) after treatment of DIEA (state **III**), (c) after treatment of DCl (state **IV**), and (d) after heating at 80 °C (state **I**); the spectrum was taken after cooling at 25 °C.

to station **A** after two weeks at rt. The extremely slow reverse process at rt indicates that it has a high activation barrier. Indeed, when the same sample is warmed up to 80 °C, the CB[6] bead shuttles back quickly and completely to station **A** (Fig. 1d). The rate of the reverse process is measured to be 7.4×10^{-5} s^{-1} at 60 °C and the activation barrier ($\Delta G^{\ddagger}$) 26 kcal mol^{-1}. Therefore, this novel bistable [2]rotaxane behaves as a kinetically controlled molecular switch in which the kinetically stable new state is maintained at rt after removal of an applied stimulus. The complete cycle of the molecular switch is given in Scheme 2.

In summary, we present a kinetically controlled molecular switch based on [2]rotaxane. The switching of the molecular bead from one site to the other site is driven by pH change, but the reverse process requires pH change plus thermal activation. This novel switching system may thus provide useful insights in designing 'safeguarded' molecular switches.

Ambient temperature reversible addition–fragmentation chain transfer polymerisation†

John F. Quinn,[a] Ezio Rizzardo*[b] and Thomas P. Davis*[a]

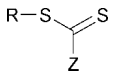
Received (in Cambridge, UK) 26th February 2001, Accepted 24th April 2001
First published as an Advance Article on the web 16th May 2001

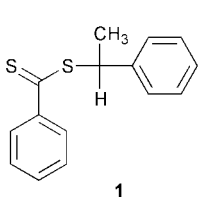
Reversible addition fragmentation chain transfer was performed at ambient temperature for the first time.

Reversible Addition Fragmentation Chain Transfer Polymerisation (the RAFT process) is a powerful technique for synthesising well-defined polymer architectures with low polydispersity.[1–3] The technique employs a transfer agent of the general formula:

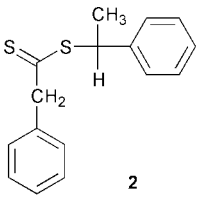


which reacts with growing polymer chains *via* Scheme 1 shown below. Reaction then proceeds with growing polymer chains reacting alternately with the two sulfur atoms in the polymeric RAFT agent. In this system, R must be a good leaving group that is able to re-initiate polymerisation and the Z group strongly influences the stability of the intermediate disulfur macroradical species.[4,5]

In order to synthesise certain novel materials, it is desirable to develop a RAFT agent that can be used at rt and with initiation techniques such as UV or gamma radiation. However, preliminary studies by the authors have shown that at low temperatures (~25 °C), the presence of a common RAFT agent (1-phenylethyl dithiobenzoate, **1**) strongly retards the polymerisation of

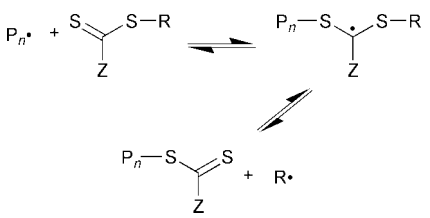


1



2

alkyl acrylates. This is consistent with previous work from the CSIRO group, which has shown that variation of the Z group from phenyl to methyl reduces retardation in the polymerization of *n*-butyl acrylate at 80 °C.[4] This retardation may be due to either a low rate of fragmentation of the intermediate (lessening the number of propagating radicals), or failure of the phenylethyl group to re-initiate polymerization at these low temperatures. To counter the first problem, a simple variation was made to the Z group of the RAFT agent, in order to give a less stable macroradical intermediate, thereby increasing the rate of fragmentation. In this study, by changing the Z group from a phenyl to a benzyl group, the radical in the RAFT intermediate is changed from being in a disulfur benzylic position to a less stable disulfur alkyl position. This should increase the rate of fragmentation and result in faster establishment of the RAFT equilibrium. Therefore, using such a RAFT agent it could be anticipated to observe living behaviour in the polymerization of alkyl acrylates at lower temperatures, rather than the demonstrated retardation caused by 1-phenylethyl dithiobenzoate. The RAFT agent synthesised for this study was 1-phenylethyl phenyldithioacetate (**2**).‡



Scheme 1

Methyl acrylate was polymerised in septa capped ampoules in a water bath at rt using AIBN as the initiator and 1-phenylethyl phenyldithioacetate (1-PEPDTA) as the RAFT agent. Given that AIBN has a much longer half-life at 25 °C than it does at 60 °C, a higher than normal concentration was used (36.1×10^{-3} molL^{-1}). A significant exotherm was observed in the control experiments (methyl acrylate, AIBN only), with the resultant runaway reaction causing the monomer to boil and the septa to break in the first ten minutes of the reaction. Conversely, the polymerization of methyl acrylate with added 1-PEPDTA proceeded without autoacceleration *via* pseudo first order kinetics, as shown in Fig. 1.§

Further, use of 1-PEPDTA in polymerisation of methyl acrylate at 25 °C gives low polydispersity poly(methyl acrylate) (M_n = 241,417, PDI = 1.19) that shows living behaviour (*i.e.* the molecular weight increases linearly with conversion). This is demonstrated in Fig. 2.

It should be noted that the molecular weights obtained experimentally adhere closely to those predicted from theory (Fig. 2, unbroken line). The exception to this is the final data point, where the theoretical molecular weight is considerably lower than the experimental one. An explanation for this deviation is the use of Mark Houwink Sakurada coefficients for

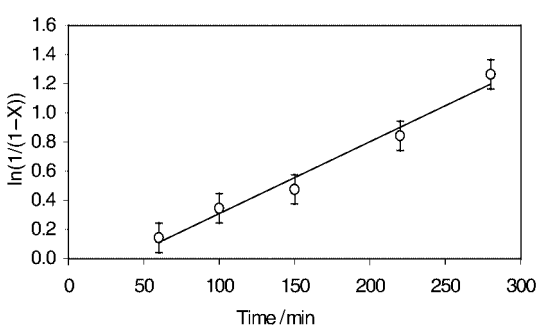


Fig. 1 Pseudo first order rate plot for the bulk polymerisation of methyl acrylate mediated with 1-PEPDTA at 25 °C. Error determined from duplicates.

† Electronic supplementary information (ESI) available: data used for the graphs in Figs. 1 and 2. See http://www.rsc.org/suppdata/cc/b1/b101794m/

 DOI: 10.1039/b101794m

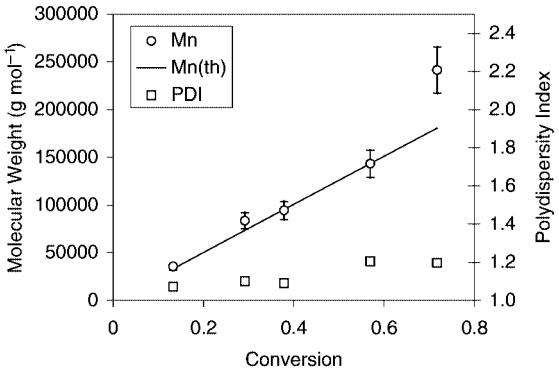

Fig. 2 Evolution of molecular weight and polydispersity index with conversion for 1-PEPDTA mediated polymerisation of methyl acrylate at 25 °C.

polystyrene in the molecular weight determination of the polymer. When analysing a polyacrylate, this would be expected to give an error anywhere between 10 and 100% (with larger error at higher molecular weight), and therefore may account for the observed discrepancy between the actual and theoretical values.

These results demonstrate that by adjusting the structure of the Z group in the RAFT agent living polymerization at rt is possible. The structural adjustment is required to decrease the stability of the intermediate radical, therefore causing the equilibrium (Scheme 1) to shift to increase the concentration of propagating polymer chains. In this study this was achieved by changing the RAFT agent from 1-phenylethyl dithiobenzoate, which gives rise to a disulfur benzylic radical intermediate, to 1-phenylethyl phenyldithioacetate, which yields a less stable disulfur alkyl radical intermediate.

The authors wish to acknowledge the support of the Co-operative Research Centre for Polymers and Dr J. P. A. Heuts and A/Professor R. P. Chaplin for helpful discussions.

Notes and references

‡ *Synthesis*: 1-Phenylethyl phenyldithioacetate was synthesised using the following method. Benzyl chloride (20 g) was added dropwise to a mixture of magnesium turnings (3.75 g) in dry diethyl ether (100 ml). Following the vigorous initial reaction, the solution was refluxed for 3 h to ensure complete reaction. The mixture was then chilled and carbon disulfide (12.0 g) was added dropwise over 30 min, and then the mixture stirred at 0 °C for the following 2 h. The mixture was then poured onto ice-water (300 ml) and the aqueous portion collected following three washes with diethyl ether. A final layer of diethyl ether was added, and the mixture acidified using 30% aqueous HCl. Phenyldithioacetic acid (~7 g) was collected *via* rotary evaporation of the ether. The acid was then reacted with styrene (9.0 g), with a small amount of acid catalyst (toluene-*p*-sulfonic acid) in CCl_4 (10 g). The product was then precipitated in cold methanol and recrystallised from methanol as fine yellow crystals (3.2 g). ^{1}H NMR: δ = 1.7 d 3H, δ = 4.2 s 2H, δ = 5.1 q 1H, δ = 7.3 m 10H. ^{13}C NMR ($CDCl_3$): 20.5, 49.9, 57.9, 127.2, 127.6, 127.7, 128.5, 128.6, 129.1, 136.9, 141.0 and 233.6. IR: Aromatic C–H stretch, 3062, 3028 cm^{-1}; Aliphatic C–H stretch, 2966, 2925 cm^{-1}; Overtone indicative of monosubstituted aromatic 2000–1650 cm^{-1}; Aromatic ring stretch, 1601, 1494, 1453 cm^{-1}; Thiocarbonyl C=S stretch, 1219, 1125, 1028 cm^{-1}; Out of plane aromatic C–H bend 764, 697 cm^{-1}; Weak sulfide C–S stretch, 646, 591 cm^{-1}. Melting point = 35 °C.

§ *Polymerization*: A solution of methyl acrylate with an initial 1-PEPDTA concentration of 3.9×10^{-3} mol L^{-1} and an AIBN concentration of 36.1×10^{-3} mol L^{-1} was prepared. The stock solution was divided into five individual ampoules and deoxygenated by purging with nitrogen for approximately 15 min. The ampoules were then placed in a constant temperature water bath at 25 °C, and an ampoule was removed after 60, 100, 150, 220 and 280 min. The reactions were stopped by cooling the solutions in an ice bath followed by the addition of hydroquinone. The polymer was isolated by evaporating off the residual methyl acrylate, initially in a fume cupboard to remove the bulk of the liquid, and then in a vacuum oven at 25 °C. Final conversions were measured by gravimetry, and the molecular weight distribution measured using gel permeation chromatography. Each experiment was performed in duplicate. Blank solutions, containing only methyl acrylate and AIBN were also prepared and polymerised using the same methods.

Enhanced chemical reversibility of redox processes in cyanine dye rotaxanes

Jonathan E. H. Buston,[a] Frank Marken[b] and Harry L. Anderson*[a]

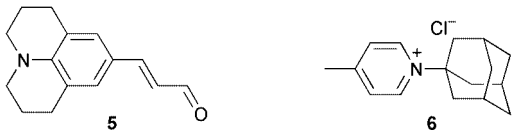
Received (in Cambridge, UK) 6th March 2001, Accepted 1st May 2001
First published as an Advance Article on the web 16th May 2001

When a cyanine dye is encapsulated inside the cavity of α-cyclodextrin, by rotaxane formation, its one-electron oxidation and reduction become reversible, due to a thousand-fold increase in the kinetic chemical stability of the oxidised and reduced forms of the chromophore.

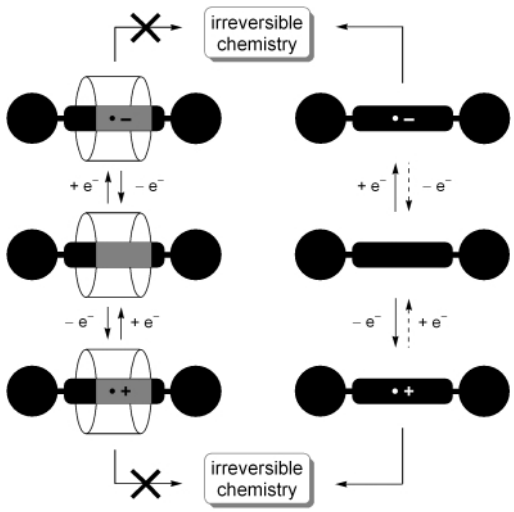
Encapsulation of redox-active guests inside dendrimers and molecular cages often affects the kinetics and thermodynamics of electron transfer, just as the proteins which wrap round biological redox centres control electron transfer in Nature.[1] Conversely, changes in oxidation state can have a dramatic effect on the strength of host–guest interactions.[2] Stoddart and coworkers have used this phenomenon to create rotaxanes[3] which work as molecular machines;[4] oxidation or reduction of the dumbbell component changes the preferred location of the macrocycle, resulting in translational motion. Here we report a redox-active rotaxane which demonstrates a different effect: the macrocycle acts as a protective sheath, preventing the oxidised and reduced forms of the dumbbell from undergoing further chemistry, making both redox processes reversible, whereas in the absence of the threaded macrocycle, the oxidised and reduced forms of the dumbbell are rapidly destroyed by subsequent irreversible reactions (Scheme 1). Electrochemical devices generally require repeated redox cycling without side reactions, so this encapsulation effect may be widely beneficial.

The rotaxanes studied here consist of a cyanine dye dumbbell threaded through α-cyclodextrin. The two rotaxane isomers **1a** and **1b**, and the analogous free dye **2**, were prepared from julolidine aldehyde **3**[5] and diphenylpyridinium **4**[6] as summarised in Scheme 2. This reaction gives a 28% yield of a 3:2 mixture of **1a** and **1b**. Although this yield is modest, it represents a ten-fold improvement compared with our previous synthesis of cyanine dye rotaxanes[7] from aldehyde **5** and adamantylpyridinium **6**. We have also prepared rotaxanes from



the combinations **3** + **6** and **4** + **5**, but **3** + **4** gives the highest yield. The longer julolidine aldehyde **3** probably forms a stronger complex with α-cyclodextrin, with the carbonyl group protruding further through the macrocycle. The diphenylpyridinium **4** also reacts with this aldehyde at a lower temperature than **6**, which leads to a higher yield of dye, as these dyes gradually degrade under the reaction conditions. The two stereoisomers **1a** and **1b** were separated by chromatography and structurally characterised using 2D NMR techniques. The pattern of NOEs shows that the predominant isomer **1a** has the narrower 6-rim of the cyclodextrin towards the julolidine end of the dye, whereas **1b** has the opposite orientation. These NOE results show that the cyclodextrin is located round the reactive polymethine region of the π-system, in both isomers.

The highly conjugated structure of cyanine dyes results in small HOMO–LUMO gaps, making them easy to oxidise and reduce. The one-electron oxidation and reduction potentials ($E_{1/2}^{Ox}$ and $E_{1/2}^{Red}$) and peak absorption wavelengths (λ_{max}) of rotaxanes **1a** and **1b** and free dye **2**, in DMSO, are compared in Table 1.† The different environment around the chromophore in the rotaxanes slightly shifts the absorption, but there is remarkably little variation in the redox potentials. The inclusion of a redox-active guest inside a cyclodextrin often hinders its electrochemical oxidation or reduction,[1] but this effect is not observed in rotaxanes **1a** and **1b**. However, encapsulation has an amazing effect on the electrochemical reversibility of both redox processes, as seen from the cyclic voltammograms of **1b** and **2**, both at a scan rate of 0.2 V s^{-1}, in Fig. 1. The oxidation and reduction of the free dye **2** are chemically irreversible, as shown by the missing peaks in the reverse sweep and by the appearance of a product signal associated with the reduction process at 0.20 V *vs.* Ag. The cyclic voltammogram of the rotaxane **1b** shows that the oxidation and the reduction are now both fully reversible; both processes are well-defined, diffusion controlled, and remain reversible even when the scan rate is reduced to 0.02 V s^{-1}. Identical behaviour is observed for the other rotaxane isomer **1a**. We have tried increasing the scan rate with the free dye **2** in an attempt to achieve reversible



Scheme 1 Rotaxane-encapsulation stabilises the oxidised and reduced forms of the dumbbell, making its electrochemistry reversible.

Table 1 Redox potentials (*vs.* Ag) and λ_{max} for **1a**, **1b** and **2** in DMSO†

behaviour, and both responses (oxidation and reduction) do indeed become reversible when the scan rate exceeds 20 V s^{-1}. This demonstrates that the shielding effect of the cyclodextrin macrocycle reduces the rate of follow-on reactions of the radical dication and neutral radical forms of the dye by at least three orders of magnitude. The separation between the forward and reverse current peaks (ΔE_p) for both redox processes in both rotaxanes is 78 mV, which is larger than expected for a simple reversible electron transfer process ($\Delta E_p \approx 56$ mV at 298 K). However the peak-to-peak separation does not increase with increasing scan rate, so that there is no evidence that the cyclodextrin retards electron transfer from the electrode surface to the cyanine. These electrochemical measurements were carried out in DMSO (with 0.1 M Bu_4NPF_6) because it is the best solvent for all three compounds. Similar behaviour is also observed in water and in acetonitrile. The rotaxanes **1a** and **1b** are highly soluble in water and give well defined reversible oxidation and reduction signals in this solvent (with 0.1 M KCl electrolyte) whereas the free dye **2** is sparingly soluble in water and exhibits similar irreversible redox processes to those observed in DMSO, complicated by accumulation of material on the electrode surface. In acetonitrile (0.1 M Bu_4NPF_6) the free dye **2** is much more soluble, but its redox processes are still irreversible at 0.2 V s^{-1} scan rate; the rotaxanes are less soluble and tend to adsorb onto the electrode, but both their redox processes remain fully chemically reversible. The electrochemistry of cyanine dyes has been extensively studied because of its relevance to the use of these dyes as photographic silver halide sensitisers.[8] The irreversible oxidation and reduction of **2** is typical for dyes of this type, and fast scan potentiodynamic and AC techniques have been developed to overcome this problem. The irreversiblility of these redox processes is generally attributed to dimerisation of the electrochemically generated radicals, and in a few cases dimeric products have been isolated and characterised.[9]

Previously we have shown that rotaxane formation can enhance the photostability of cyanine dyes. This effect is also observed with these rotaxanes and both compounds fade slower than the free dye **2** when irradiated with visible light in air-saturated aqueous solution (relative rates of fading for **1a**, **1b** and **2** are 0.031 : 0.044 : 1.00 respectively). It is possible that the photo-bleaching of **2** involves photo-induced electron transfer, leading to a direct link between the enhanced photostability and enhanced redox reversibility of these rotaxanes. The mechanisms of these reactions remain to be elucidated but it is significant that rotaxane encapsulation protects the chromophore in both its excited state and in its oxidised and reduced forms. The kinetic stabilisation of the radical dication and neutral radical forms of the dye inside the cyclodextrin cavity is analogous to the stabilisation of radical intermediates by enzymes.[10]

F. M. thanks the Royal Society for a University Research Fellowship and New College, Oxford, for a Stipendiary Lectureship. This work was supported by the EPSRC.

Notes and references

† The redox potential measurements in Table 1 and Fig. 1 were carried out in DMSO (0.1 M Bu_4NPF_6) by cyclic voltammetry using a conventional three-electrode system with a 0.5 mm diameter Pt disc working electrode, a Pt wire counter electrode and a Ag wire pseudo-reference electrode, under argon at 20 °C. The concentration of **1a**, **1b** and **2** was *ca*. 1 mM. The scan rate was 0.20 V s^{-1} in all cases except for the measurements on **2** in Table 1, where a 20 V s^{-1} scan rate was used to achieve reversibility. $E_{1/2}$ values were estimated from the midpoint of the forward and reverse current peak for each redox process, and were calibrated with internal ferrocene ($E_{1/2}^{Ox}$ = 0.78 *vs*. Ag).

s-Block metal inverse crowns: synthetic and structural synergism in mixed alkali metal–magnesium (or zinc) amide chemistry

Robert E. Mulvey

Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, UK G1 1XL. E-mail: r.e.mulvey@strath.ac.uk

Received (in Cambridge, UK) 16th February 2001, Accepted 20th March 2001
First published as an Advance Article on the web 20th April 2001

This article focuses on the special chemistry that can take place when certain lithium (or other heavier alkali metal) amides are combined with certain magnesium (or zinc) bisamides. Some of the reaction mixtures studied follow a straightforward path leading to simple heterobimetallic compositions with predictable structures, whereas others take an unexpected turn to behave as powerful oxygen scavengers or as regioselective bases to yield novel products with unpredictable host–guest macrocyclic structures. We refer to these new compounds as 'inverse crown ethers' or 'inverse crowns' because their arrangement of Lewis acidic and Lewis basic sites is opposite to that encountered in conventional crown ether complexes. This developing phenomenon appears to be a direct result of pairing together the two distinct metal types in the same complex, as the chemistry cannot be replicated by complexes containing one or the other metal type on its own.

Introduction

Diagonal neighbours in the periodic table, lithium and magnesium in the form of organolithium (pioneered by Schlenk) and organomagnesium halide (pioneered by Barbier and Grignard) reagents respectively, have both served the synthetic community for nearly one hundred years. Thumb through the pages of any current journal specialising in synthesis and you will almost certainly find several examples of these centenarians at work, performing some or other organic transformation. They are organometallic reagents *par excellence*. Accordingly, the literature on them is vast and ever increasing. Interested readers should consult the following sources[1,2] as a starting point for information. The present article does not deal with organolithium or organomagnesium compounds *per se*, but rather with organolithium–magnesium (and related organosodium–magnesium and organopotassium–magnesium) compounds, *i.e.* heterometallic mutations containing two different s-block metals. In theory, mixing the metal components in this way could promote beneficial synergic effects, and lead to mixed-metal compounds having their own unique chemical profiles distinct from those of the homometallic compounds from which they are derived. This synergism could be manifested in altered reactivities and selectivities as a function of altered activated complexes and intermediates. It could also deliver new chemistry and new structures, not known or not possible for the conventional homometallic compounds. In practice, though as yet only a select few studies have addressed the application of mixed lithium–magnesium compounds in chemistry, several promising observations have already been recorded. Notably, Oshima and coworkers have demonstrated that magnesium-ate complexes '$LiMgR_3$' are more effective than their Grignard counterparts (RMgX) in halogen–magnesium exchange reactions with organic halides for the preparation of aryl- and alkenyl-magnesium reagents, which are subsequently trapped by an assortment of electrophiles.[3] Also, following a systematic study of alkylation reactions of pyridine, Richey and Farkas concluded that 'solutions prepared by mixing solutions of dialkylmagnesium and alkyllithium compounds exhibit behaviour different from that of either organometallic compound alone'.[4] Turning from organic synthesis to coordination chemistry, Karsch and Reisky make the point that the key to the formation of the first magnesium compound with six Mg–P bonds lies in its 'ate formulation $[Li(12\text{-crown-}4)_2]^+[Mg\{(PMe_2)_2C(SiMe_3)\}_3]^-$, *i.e.* a mixed lithium–magnesium system albeit in the form of a solvent (crown ether)—separated ion pair.[5] Combining the two metals together has similarly proved advantageous in areas of polymer chemistry: Hsieh and Wang report that dialkylmagnesium, by itself, is not an active initiator for diene and styrene polymerization, but it participates in polymerization when complexed either with the alkyllithium initiator or with the propagating polymer–lithium molecules;[6] Antkowiak and Hall have patented the use of mixed lithium–magnesium amides based on hexamethyleneimine as anionic initiators for diene polymer and copolymer elastomers.[7] It is pertinent to note that in not one of these molecular/macromolecular applications is the structure of the active lithium–magnesium species known with any certainty. This general lack of knowledge coupled with the potential advantages alluded to earlier have prompted us to follow a programme of research designed to shed light on the fundamental structural consequences of mixing lithium (or another alkali metal) with magnesium (or zinc) in an organoelement environment. Mindful of the need to focus on synthetically useful compounds, we have directed our attention towards amide derivatives. Long-standing favourites of the synthetic chemist and thus commercially available, lithium amide reagents are specialists in the art of selective proton abstraction; recent studies have suggested that magnesium amides may also be useful and exhibit different reactivities/selectivities in this regard.[8] The extensive library of structural data available on these homometallic systems provides a further incentive for concentrating on amide derivatives because if any form of structural synergism were to result from pairing lithium and magnesium in a particular amide environment, then it should be easily recognised. It transpires that

Robert Emmet Mulvey was born in Glasgow in 1959 and educated at Saint Gregory's secondary school. Both of his degrees (B.Sc.-Hons in 1981 and Ph.D. in 1984) were obtained at the University of Strathclyde, the latter achieved under the supervision of the late Dr Ron Snaith. Following two years as a postdoctoral research assistant with Professor Ken Wade at the University of Durham, he returned to Strathclyde in 1986 to take up a Royal Society Research Fellowship. Remaining at Strathclyde in the intervening years, he has held a Personal Professorship there since 1995. Currently the Head of Inorganic Chemistry in the department he was elected to the Fellowship of the Royal Society of Edinburgh (FRSE) in 2001. Past winner of the Meldola Medal and Prize, he is an author of more than 100 research publications in the area of main group metal chemistry.

unique structural arrangements and, linked to this, unique chemistry, can indeed be generated by this heterobimetallic approach, as exemplified by the so-called 'inverse crown ether' complexes and related mixed-metal macrocycles which form the basis of this article. To put the novelty of this new class of compound into context, a brief survey of the contrasting structural types adopted by more mainstream mixed lithium–magnesium compounds is now presented.

'Ordinary' mixed lithium–magnesium compounds

Access to compounds of this type is usually achieved simply by mixing together the component homometallic compounds in the absence or presence of a Lewis base cosolvent [eqn. (1)]. In

$$x\ \mathrm{LiR} + y\ \mathrm{MgR_2} \longrightarrow \begin{cases} (\mathrm{Li}_x\mathrm{Mg}_y\mathrm{R}_z) \\ (\mathrm{Li}_x\mathrm{Mg}_y\mathrm{R}_z{\bullet}\mathrm{L}_n) \quad +n\,\mathrm{L} \end{cases} \qquad (1)$$

homoleptic cases (*i.e.* with only one type of anionic ligand) the product of such mixing need not necessarily be formulated as '$LiMgR_3$', since products with stoichiometries discordant from that employed in the reaction can sometimes prevail. Especially common in this regard is 'Li_2MgR_4'. This phenomenon is a direct consequence of the fact that structural factors dictate the composition (in particular, the Li : Mg ratio) of the mixed-metal product. To elaborate, the building up of their molecular architectures can be formally regarded as a two-stage process, each stage of which involves a distinct type of bonding which may be designated as *anchoring* or *ancillary*.

The foundation/framework of the structure is provided by *anchoring* bonds as they comprise the stronger, more covalent, predominately σ-based Mg–R interactions. Depending mainly on the steric requirements of the surrounding 'R' ligands, this framework is generally either tetrahedral or trigonal planar in disposition. *Ancillary* bonding can be defined as those more ionic interactions, which enable the lithium ions to affix to this framework to give contacted ion pairs. To maximise the number of such electrostatic contacts the lithium atoms will affix μ_2 rather than terminally. Tetrahedral MgR_4 units have six edges, so three diagonally opposed pairs of edges to accommodate pairs of lithium ions, while triangular MgR_3 units have three edges, one of which can accommodate a single lithium ion (Fig. 1): in this way are formed the common Li_2MgR_4 and

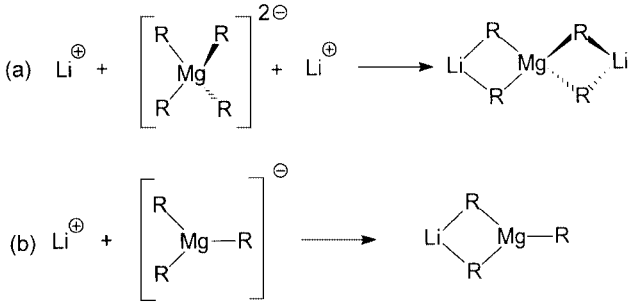

Fig. 1 Building up 2 : 1 and 1 : 1, Li : Mg stoichiometries through tetrahedral (a) and trigonal planar (b) 'anchoring' frameworks, respectively.

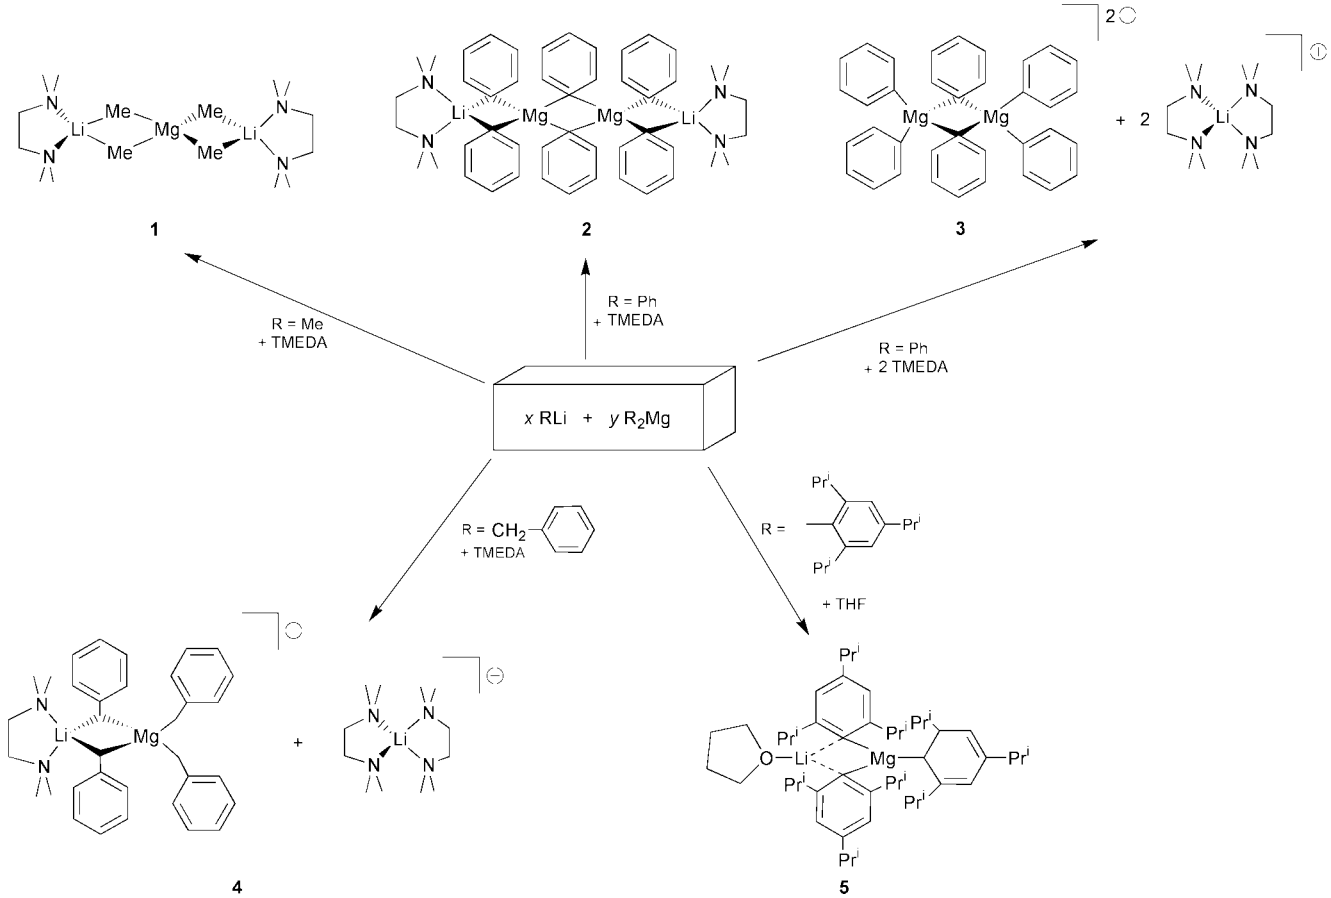
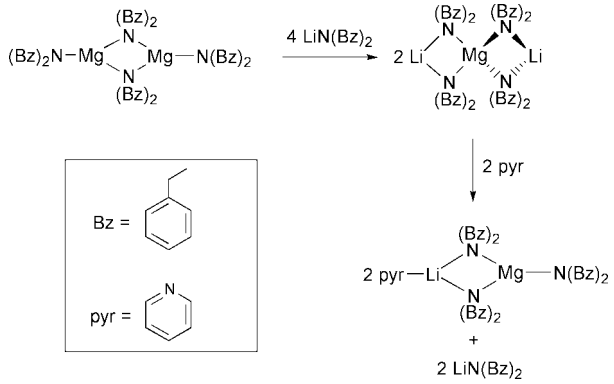
$LiMgR_3$ stoichiometries respectively, and charge neutrality is attained. Both of these scenarios can be found within the series of lithium organoC-magnesate structures **1**–**5**[9–12] shown in Scheme 1. An additional point is raised by the structure of **2**:[10] planar 'R' ligands (shown flat here, but in reality would be tilted out of the plane) can rotate to avoid interlocking with each other so creating a sterically relaxed opportunity for two or more Mg atoms to participate in the framework unit (in solvent-free homometallic $[(MgPh_2)_\infty]$[13] this process occurs *ad infinitum* to give a polymeric arrangement). An alternative way to describe the anchoring/ancillary demarcation is to consider that anions will preferentially bind first to magnesium, on account of its



Scheme 1

greater Lewis acidity, until coordinative saturation is reached giving $(MgR_4)^{2-}$ or $(MgR_3)^-$ complex ions. These magnesium-fixed anions can therefore not usually satisfy the coordinative needs of approaching lithium cations within the limitations of a contacted ion pair arrangement and so solvent molecules are required to fill the remaining coordination sites. In certain cases, for example in structure **3**, solvent molecules can completely detach the lithium ions from the primary framework to generate solvent-separated ion pairs.

These basic structural types are not confined to alkyl and aryl ligands, as they also extend to amido systems. A clear example of the delicate balance between the tetrahedral and the trigonal planar frameworks is illustrated in a family of dibenzylamido $[^-N(CH_2Ph)_2]$ systems (Scheme 2).[14,15] Sterically, the optimum number of dibenzylamido ligands to fit around a magnesium atom would appear to be three since homometallic $[\{Mg[N(CH_2Ph)_2]_2\}_2]$ has a trigonal planar magnesium geometry within its dimeric solid-state constitution. However, introducing dibenzylamidolithium into this system induces coordination expansion about magnesium to create an alternative tetrahedral $(MgR_4)^{2-}$ framework made up of four dibenzylamido ligands R, set within a (Li_2MgR_4) formulation. This coordination expansion can be rationalised predominantly in terms of steric and valency effects: with the terminal coordination site on monovalent lithium vacant there is additional space for the benzyl arms of the bridging amido ligands to occupy. In the exclusively-magnesium structure this site is blocked by the presence of a terminally attached dibenzylamido ligand. When pyridine is added to the heterometallic structure a new dative Li–N bond is formed filling the terminal coordination site and forcing the bridging amido ligands closer towards the magnesium atom. This extra steric strain placed on magnesium reduces its ability to tolerate four (tetrahedral) coordination, thus prompting the displacement of one amide ligand (and its Li^+ partner) to leave a more sterically relaxed three-coordinate (trigonal planar) environment. Electronic effects must also be taken into consideration. Pyridine, a good σ donor, will also stabilise the lithium atom electronically. Other monodentate donor solvents such as THF will do likewise in other bulky amide systems, *e.g.* in $[(THF)\cdot LiMg\{N(c\text{-}C_6H_{11})_2\}_3]$.[16] The same basic motif can be found in mixed-anion systems, typified by the alkyl–amido complex $[(py)\cdot LiMg(HMDS)_2(Bu)]$[16] [HMDS = $^-N(SiMe_3)_2$]. Therefore the stabilising role of the solvent ligand in raising the coordination number of the lithium atom to three is an important factor in the conversion of lithium-rich Li_2MgR_4 structures into $LiMgR_3$ alternatives.



Scheme 2

Pyridine or THF will also stabilise the tris(amide) derived from the sterically demanding hexamethyldisilazane [HMDS(H)]. Interestingly, however, the 1:1, Li:Mg motif remains intact even in the absence of any such solvent molecules.[17] As depicted in Fig. 2, the loss of solvent (N or O donor atom)—lithium dative bonding is balanced by the gain of $H_3C\cdots Li$ interactions (mean length, 2.307 Å) made possible by the bending of the $SiMe_3$ substituents towards the semi-naked lithium atom. Pseudo-agostic interactions of this type are becoming increasingly familiar in structures where alkali metals have low (formal) coordination numbers; here the affinity of the Li atom for the methyl substituent is heightened by the marked polarisation within the $Si^{\delta+}$–$CH_3^{\delta-}$ units, *i.e.* the carbon atoms of the methyl groups carry a substantial negative charge. It is therefore not surprising that, from a standpoint of length, these $H_3C\cdots Li$ interactions can be likened to the electron-deficient C–Li bonds, which formally involve anions, of simple alkyllithiums such as $[(Bu^tLi)_4]$[18] and $[(EtLi)_4]$[19] (mean lengths, 2.246 and 2.25 Å, respectively).

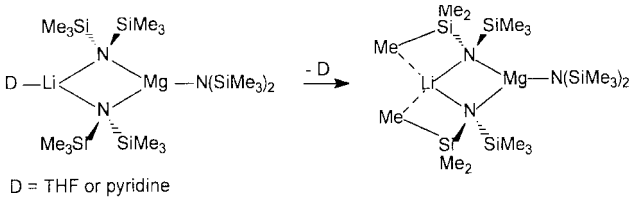


Fig. 2 Additional stabilisation of the Li atom can be achieved through a dative D–Li bond or, in the absence of a donor solvent, through $H_3C\cdots Li$ agostic interactions.

Chelational stabilisation of lithium atoms is possible when the 'R' substituents within bridging amide ligands contain an additional heteroatom, two or three atoms removed from the amido nitrogen atom. The first mixed lithium–magnesium amide $[Li_2Mg\{N(CH_2CH_2NMe_2)CH_2Ph\}_4]$, reported in 1993,[20] exhibits this feature in having five-membered (NCCNLi) chelate rings the tertiary amine nitrogen atoms of which serve to increase the coordination number of the lithium atoms from two to four.

'Extraordinary' mixed alkali metal–magnesium compounds

(i) Inverse crown ether complexes

During our attempts to reprepare the aforementioned solvent-free tris(amide) $[LiMg\{N(SiMe_3)_2\}_3]$ **6** a surprising development came to light. It was found repeatedly that the reaction solutions preferentially crystallised an oxygen-contaminated variant of formula $[Li_2Mg_2\{N(SiMe_3)_2\}_4(O_2)_x(O)_y]$ **7**, despite the fact that an inert-atmosphere protocol was employed throughout the synthetic procedure (or so we had assumed).[17] Reacting the mixtures [eqn. (2)] for 1 h then cooling the

$$BuLi + Bu_2Mg + 3\ HN(SiMe_3)_2 \xrightarrow{\text{trace of } O_2/H_2O} z\ [Li_2Mg_2\{N(SiMe_3)_2\}_4(O_2)_x(O)_y] + z'\ BuH + \text{other products} \quad (2)$$

solutions afforded **7** in typically poor, but reproducible yields of 1–5%: none of the intended (oxygen-free) product **6** precipitated from solution, which perhaps reflects its previously noted high solubility (in arene or hydrocarbon solvents). Since the initial report of **7** we have managed to increase its yield five-fold (best to date, 24%). This improvement came as a direct result of deliberately exposing the reaction mixture to the atmosphere (!) whilst stirring it for four days. Clearly, as small quantities of **7** can be produced even when standard precautions are taken to avoid moisture/oxygen contamination, the mixed lithium–magnesium HMDS system must be an extremely efficient oxygen scavenger. However, the source of the oxygen contamination, whether it be dioxygen or moisture or a combination of both, is yet to be unambiguously established.

The molecular structure of **7** (Fig. 3) reveals a discrete eight-membered ring made up of alternating nitrogen and metal atoms, with the latter atoms themselves alternately lithium and magnesium. Peroxide or oxide ions occupy the core of the ring to render the molecule neutral overall. The peroxide and oxide-

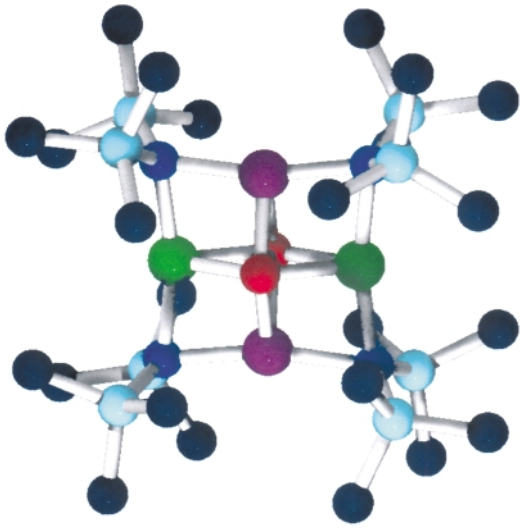

Fig. 3 Molecular structure of $[Li_2Mg_2\{N(SiMe_3)_2\}_4(O_2)_x(O)_y]$ showing peroxide core. Colour code for figures:[39] alkali metal, purple; Mg, green; Zn, yellow; N, dark blue; Si, light blue; C, black; O, red.

based molecules can be differentiated in arene solution by ^{1}H NMR spectroscopic studies. In the conventional host–guest chemistry of crown ether complexes,[21] electron-poor metal cation guests are stabilised by coordination to a series of Lewis basic oxygen centres fixed within a macrocyclic ligand host. Contrast that situation through a representative [12]crown-4 complex with the generalised structure of **7** (Fig. 4) and one can

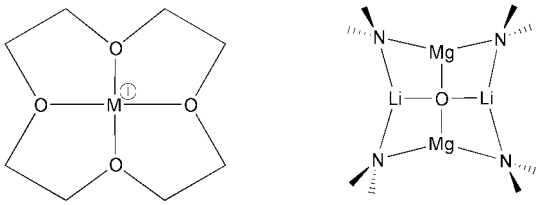

Fig. 4 A representative [12]crown-4 complex *vs*. the generalised structure of **7**.

see at a glance that while both macrocycles offer four built-in binding sites for the entertainment of the core guest the relative positions of metal and oxygen atoms have been interchanged. This topological comparison prompted us to coin the name 'inverse crown ether' complex to describe **7** and its isostructural analogues, even though no ether functionality is actually involved (a referee suggested an alternative name, metal amide chemistry, or 'MAC', crowns: but while this is perhaps more distinctive and certainly more apt given that they were discovered in Scotland, this description could be confused with metallo-crowns which are a known class of compound. In our view, the 'inverse' prefix is also essential to convey the difference with conventional crowns). The idea of a 'crown' made up of metal atoms would certainly sit easily with those people interested in royalty! At this juncture it is germane to mention that a similar description, 'anti-crowns', was introduced a few years prior to our work by Hawthorne and Zheng with regard to a series of [12]mercuracarborand-4 complexes in recognition of their charged-reversed relationship to normal [12]crown-4.[22] Contrary to the situation in the inverse crown systems, oxide or peroxide anions do not feature in anti-crown chemistry presumably because the softer acid Hg atoms prefer to bind softer bases such as Cl^-, Br^-, I^- or *closo*-$B_{10}H_{10}^{2-}$.

On further investigation it soon became apparent that the basic structural motif of **7** was not a unique, one-off oddity, but rather the progenitor of a family of such structures. The synthesis and crystallographic characterisation of **8**[23] (Fig. 5) established that inverse crown ethers could be made using other amide ligands, in this case derived from 2,2,6,6-tetramethyl-

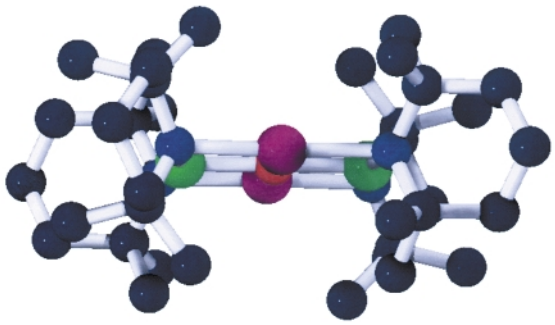

Fig. 5 Molecular structure of $[Li_2Mg_2(TMP)_4(O)]$ viewing the eight-membered ring from the side.

piperidine [TMPH = $HN(Me)_2CCH_2CH_2CH_2C(Me)_2$]. Significantly this cyclic amide ligand is even more sterically demanding about its ligating N head than HMDS, which prompts the thought that extreme steric hindrance may be a prerequisite for the formation of an inverse crown ether. Pre-attached to the metal centres, these bulky ligands may on exposure to the oxygen contaminant, suppress altogether or at least kinetically inhibit the formation of metal oxide salts which would seem more likely products from lattice energy considerations.

More important extensions to the family followed on turning our attention from lithium to the heavier alkali metals. Applying the same synthetic approach but this time using butylsodium or butylpotassium in place of the lithium congener [eqn. (3)],

$$BuM + Bu_2Mg + 3\ HN(SiMe_3)_2 \xrightarrow{\text{trace of } O_2/H_2O} z\ [M_2Mg_2\{N(SiMe_3)_2\}_4(O_2)_x(O)_y] + z'\ BuH + \text{other products} \quad (3)$$

M = Na, K

produced the first sodium–magnesium $[Na_2Mg_2\{N(SiMe_3)_2\}_4(O_2)_x(O)_y]$[23] **9** (Fig. 6) and potassium–magnesium

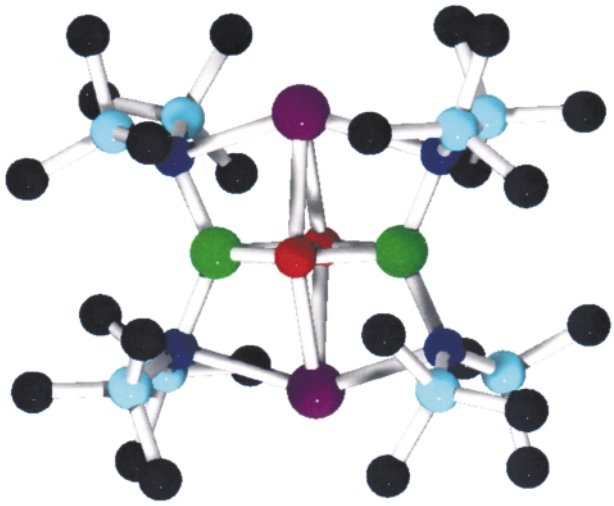

Fig. 6 Molecular structure of $[Na_2Mg_2\{N(SiMe_3)_2\}_4(O_2)_x(O)_y]$.

$[\{K_2Mg_2[N(SiMe_3)_2]_4(O_2)\}_\infty]$[24] **10** (Fig. 7) inverse crown ethers, respectively. Sodium can sometimes mimic the coordinative behaviour of its smaller Group 1 nearest neighbour so the existence of the former category of crown is not that surprising. On the other hand potassium organic derivatives normally exhibit marked structural differences to their lithium counterparts on account of the significantly larger size and softer, more polarisable nature of the K^+ cation; hence the fact that a potassium-based inverse crown ether is readily preparable bears testimony to the stability of these new macrocyclic systems. However there is one major distinction between **10** and **7** for while both have broadly similar molecular structures, in

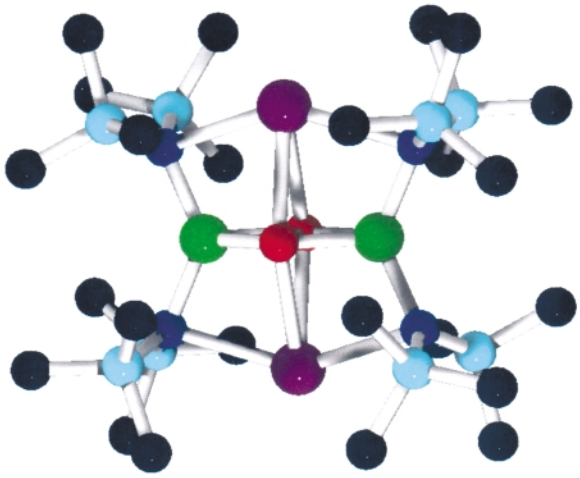

Fig. 7 Double asymmetric unit of $[\{K_2Mg_2[N(SiMe_3)_2]_4(O_2)\}_\infty]$.

the latter it is discrete but in the former it joins up through intermolecular $(Me_2Si)H_3C\cdots K$ interactions to give a linear polymeric arrangement (Fig. 8). Therefore **10** could be

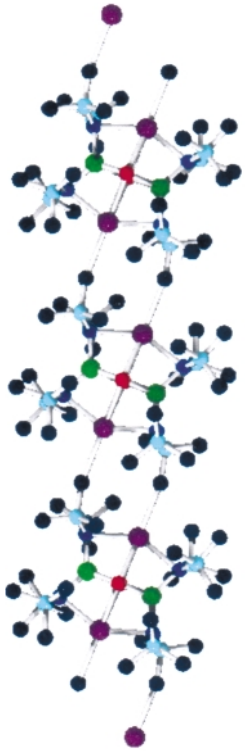

Fig. 8 Extended structure of $[\{K_2Mg_2[N(SiMe_3)_2]_4(O_2)\}_\infty]$.

described as the first supramolecular inverse crown ether structure, but this description exaggerates the distinction because such extended structures are quite common in the wider context of organopotassium chemistry.[25] Certain trends can be discerned from this Li/Na/K series of structures. Most obviously, the pairs of Mg atoms within the dicationic octagonal rings are always displaced towards the centre of the ring as a result of strong Mg–O bonding. The magnitude of this displacement grows in concert with the increasing size of the alkali metal partner in the ring as gauged by the endocyclic N–Mg–N bond angles (mean values 193.3, 218.4 and 227.8° for the Li, Na and K structures respectively). Similarly, the small Li atom in **7** and **8** is pulled towards the centre of the ring through strong Li–O bonding, resulting in endocyclic N–Li–N bond angles greater than 180°. In contrast the Na and K atoms occupy peripheral ring sites with endocyclic N–Na–N and N–K–N bond angles significantly less than 180°, reflecting longer, weaker Na–O/K–O bonding.

Extension to zinc. Having established that it is possible to vary the Group 1 metal in the inverse crown ether octagons, the next logical step was to consider possible replacement of the Group 2 metal, magnesium. The health problems associated with beryllium deterred us from experimenting with the lightest member of Group 2, so instead we turned our attention towards the next nearest neighbour, calcium. Though a significant size differential exists between Mg and Ca (*e.g.* 0.28 Å for ionic radii), that between Li and K is substantially greater (corresponding value, 0.60 Å). This favourable steric comparison, coupled with the knowledge that $[\{Ca[N(SiMe_3)_2]_2\}_2]$[26] is isostructural to the Mg congener, suggested to us that a calcium-based inverse crown would be an easily accessible target. In practice this has not been borne out. Thus far it has proved problematical to obtain any solids from mixtures of $LiN(SiMe_3)_2$ and $Ca[N(SiMe_3)_2]_2$ as they generally remain in solution (in oxygenated arene media) even at subzero temperatures. However on one occasion we did manage to isolate and crystallographically characterise a solid product which transpired to be the calcium analogue of **6**, the tris(amide) $[LiCa\{N(SiMe_3)_2\}_3]$ **11**.[27] This solvent-free system (a THF-solvate was earlier reported by Davies[28]) adopts the same basic motif as **6** but with an additional feature, a double ration of intramolecular agostic interactions $H_3C\cdots Li$ and $H_3C\cdots Ca$, *i.e.* involving both types of metal atom separately. It is still an open question whether or not this extra coordinative stabilisation has a bearing on the failure (hitherto) to observe an inverse crown ether molecule within the mixed lithium–calcium system, but it most certainly contributes to its excellent solubility in organic solvents.

More success in this regard came upon switching our attention to the Group 12 metal zinc. This proved to be a perfect mimic for magnesium in all but one respect: attempts to prepare in donor-free media a lithium–zinc inverse crown ether complex analogous to **7** did not yield any products save unreacted starting material, namely $LiN(SiMe_3)_2$ and $Zn[N(SiMe_3)_2]_2$. This is consistent with the generalisation that reactivity (specifically here, Lewis acidity) diminishes on moving from magnesium to zinc. No such problems were encountered on replacing the lithium amide by its more reactive sodium or potassium congener. Thus the first inverse crown ether complexes of zinc, namely $[Na_2Zn_2\{N(SiMe_3)_2\}_4(O)]$ **12** and $[\{K_2Zn_2[N(SiMe_3)_2]_4(O_2)_x(O)_y\}_\infty]$ **13** were readily prepared by the method outlined in eqn. (4).[29] To obtain the former the

$$\begin{array}{l} ZnCl_2 + 2\ LiN(SiMe_3)_2 \longrightarrow Zn[N(SiMe_3)_2]_2 + 2\ LiCl \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \downarrow \text{MN(SiMe}_3)_2,\ \text{trace of } O_2/H_2O \\ \text{other products} + [M_2Zn_2\{N(SiMe_3)_2\}_4(O_2)_x(O)_y] \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \text{M = Na, K} \end{array} \qquad (4)$$

solution had to be heated to reflux, whereas to obtain the latter only gentle heating was necessary. This series of reactions therefore follows the classical reactivity trend associated with the alkali metal series (Li < Na < K). Future work will ascertain whether this trend holds for the complete homologous series, *i.e.* will formation of the (thus far hypothetical) Rb and Cs analogues be even more facile than that of K? The structures of **12** and **13** (Figs. 9 and 10, respectively) are isomorphous with each other and with their magnesium-based analogues **9** and **10**. Intermolecular $(Me_2Si)H_3C\cdots K$ contacts give a linear polymeric arrangement in the case of **13**, in the same way as that in **10**. Corresponding bond lengths and bond angles between **12** and **9** and between **13** and **10** show little variation, though the

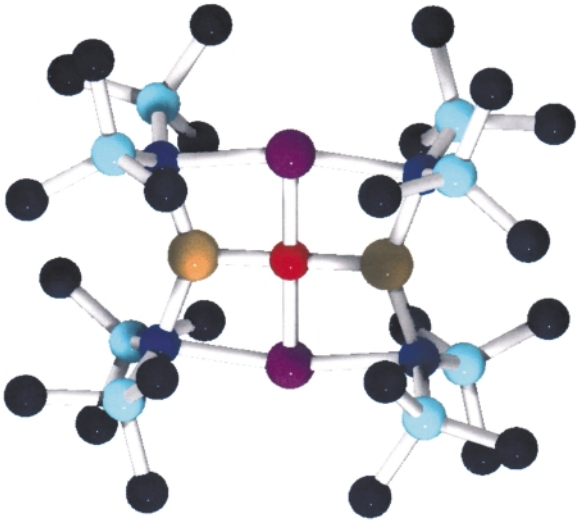

Fig. 9 Molecular structure of $[Na_2Zn_2\{N(SiMe_3)_2\}_4(O)]$.

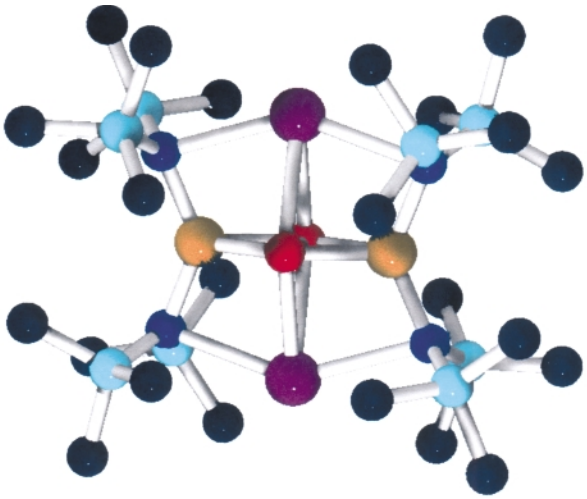

Fig. 10 Double asymmetric unit of $[\{K_2Zn_2[N(SiMe_3)_2]_4(O_2)\}_\infty]$.

Zn–N bonds are systematically 0.07–0.08 Å shorter than the Mg–N bonds.

(ii) Inverse crown complexes

Pioneered by Pederson and first reported in 1967,[30] crown ether compounds and their many offshoots now make up a colossal field within supramolecular chemistry:[31] ring structures in this category come in countless different shapes and sizes, accumulated through the work of over thirty years of intensive research. This knowledge prompted us to pose the question, 'could we extend a stage further the analogy with conventional crown ether chemistry by also synthesising inverse analogues of different ring shapes and ring sizes?' We were pleased to discover that the answer is in the affirmative albeit at this stage to an extremely modest degree. Thus in this section two such types containing twelve or twenty-four ring atoms are discussed. Note that in labelling these larger ring systems 'inverse crown' complexes, as opposed to 'inverse crown ether' complexes, we simply want to draw the distinction that the former type do not contain any oxygen (atoms or anions) at all, though in common with the latter type their Lewis acidic (metal cation)–Lewis basic (heteroatom anion) positions are reversed relative to those in conventional crown ether complexes.

The breakthrough in our quest to prepare a larger inverse crown ring system came unexpectedly when the reaction that previously produced oxo-centred $[Li_2Mg_2(TMP)_4(O)]$ **8**, was repeated but with butylsodium in place of butyllithium as the alkali-metallating source [eqn. (5)]. Remember that in the corresponding HMDS-based system substituting sodium, or

$$BuNa + Bu_2Mg + 3\ HN(Me)_2CCH_2CH_2CH_2C(Me)_2 + arene \rightarrow {}^{1}/_{x}\ [Na_4Mg_2\{N(Me)_2CCH_2CH_2CH_2C(Me)\}_6(arene{-}2H)] + {}^{1}/_{y}\ BuH + other\ products \quad (5)$$

arene = C_6H_5Me, C_6H_6

even potassium, for lithium, does not alter the general nature of the product as all three metals give an inverse crown ether complex. However this time the move to the next heaviest alkali metal induces a dramatic chemical and structural transformation through the formation of the tetrasodium–dimagnesium amide-arenediide $[Na_4Mg_2(TMP)_6\{C_6H_3(CH_3)\}]$ **14**, which is oxygen free.[32] We subsequently prepared a benzene-derived analogue $[Na_4Mg_2(TMP)_6(C_6H_4)]$ **15**, to prove that this novel reaction chemistry is applicable to other arene solvents (toluene was the solvent used in the preparation of **14**). Structural preferences dictate the unusual 4Na : 2Mg stoichiometry of these products, not that used in the original reaction mixtures (*i.e.* 1Na : 1Mg). Yet, perplexingly, attempts to reprepare **14** and **15** using the 'correct' 4Na : 2Mg reaction stoichiometry are hampered by solubility problems. The structures of **14** (Fig. 11) and **15** (not

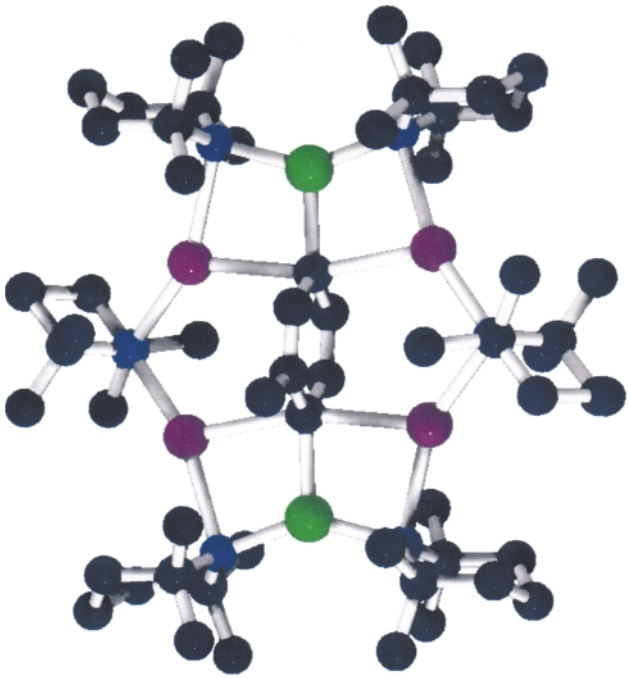

Fig. 11 Molecular structure of $[Na_4Mg_2(TMP)_6(C_6H_3CH_3)]$.

shown) are essentially equivalent. Metal atoms and nitrogen atoms alternate within their $Na_4Mg_2N_6$ ring, which is severely puckered. The encapsulated arene molecules lie approximately orthogonal to the mean plane of this ring, locked into position by a combination of Mg–C σ bonds ('anchoring' bonds—see earlier) and Na–C π bonds ('ancillary' bonds). Of particular interest are the metallation sites of the toluene- and benzene-based dianions (2,5- and 1,4-positions, respectively) which are coincident with the placements of the Mg atoms within the dicationic $Na_4Mg_2N_6$ ring. This signifies that a special type of chemistry beyond the scope of mainstream organometallic reagents is operating here. To elaborate, while toluene can be easily monometallated to generate the resonance-stabilised benzyl carbanion, its dimetallation presents a much more challenging task. Reagents such as butyllithium/TMEDA can pull off more than one hydrogen atom, but only in a random unpredictable way which leads to a complex assortment of incompletely characterised polylithiated species.[33] Contrast this

with the controlled, regioselective dimetallation (dimagnesiation) of toluene facilitating the construction of pure **14**. However, there is another more important distinction: in the case of **14** the CH_3 substituent, which carries the most acidic hydrogen atom (by several pK_a units), remains fully intact (solution ^{1}H NMR studies support the crystal structure determination in this respect), as instead deprotonation occurs exclusively at ring sites. Treating toluene with an appropriate mainstream organometallic base normally leads (ultimately) to benzyl ($PhCH_2^-$) products,[34] since resonance stabilisation reaches a maximum when a hydrogen atom is removed from the CH_3 substituent. Hence it can be reasoned that a special ring template effect is responsible for directing the abnormal metallation chemistry inherent in the synthesis of **14** and for locking the toluene-based dianion in place to prevent any possible tautomerism from taking place which might have generated a thermodynamically more desirable benzyl isomer. The revelation that the weaker carbon acid benzene undergoes an identical double deprotonation during the formation of **15** is also highly significant. This would appear to be direct proof that a powerful synergic effect (the existence of which was speculated upon in the Introduction) is at work here because neither $Mg(TMP)_2$ on its own, nor NaTMP on its own, can metallate benzene (let alone regioselectively dimetallate it!) under the mild conditions used to make **15**. Almost certainly, a single type of structure, the immediate precursor to **14** and **15**, executes both the template effect and the mixed sodium–magnesium synergic effect.

The precise nature of this intermediate structure has not yet been established, but as a working model we tentatively suggest the (hypothetical) $[Na_4Mg_2(TMP)_8]$ molecule depicted in Scheme 3. Made up of authentic features seen in other structures such as mixed-metal Mg–N–Na bridges and tris-amido Mg coordination, this model appears ideally tailored for trapping an arene molecule and bringing about its twofold deprotonation by utilising the terminal amide ligands on the magnesium atoms, the diagonally opposed positions of which are fixed within the constraints of the twelve-membered ring. The byproduct of this process would therefore be the starting amine 2,2,6,6-tetramethylpiperidine. While we are currently investigating the reaction of NaTMP and $Mg(TMP)_2$ in the absence of an arene solvent, it is conceivable that $[Na_4Mg_2(TMP)_8]$ may only have a transient existence (or may not exist at all without arene ligand stabilisation) and thus may not be isolable or easily detected.

The unpredictable nature of this area of heterometallic chemistry was demonstrated again, even more emphatically, when the reaction shown in eqn. (5) was repeated using butylpotassium in place of butylsodium. By analogy with the sodium and potassium inverse crown ether complexes **9** and **10**, it would be logical to expect that the potassium products would adopt the same basic structural motif as that found in **14** and **15**. This time, however, the introduction of the heavier alkali metal effects a spectacular ring expansion in the form of the unprecedented hexapotassium–hexamagnesium twenty-four membered macrocyclic amides $[K_6Mg_6(TMP)_{12}(C_6H_4CH_3)_6]$ **16** and $[K_6Mg_6(TMP)_{12}(C_6H_5)_6]$ **17**.[35] Fig. 12 shows the

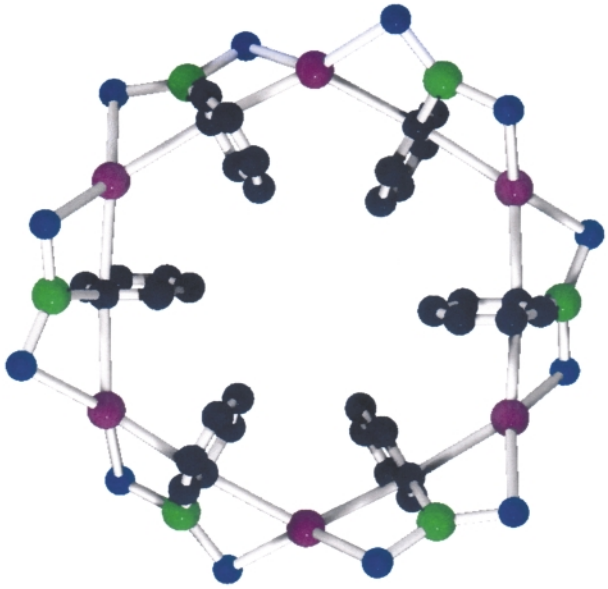

Fig. 12 Molecular structure of $[K_6Mg_6(TMP)_{12}(C_6H_5)_6]$.

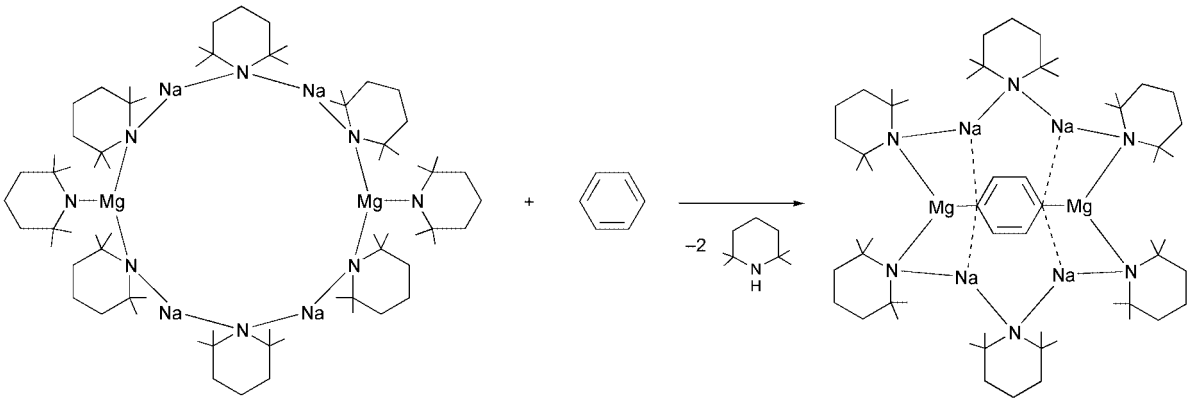
structure of **17**, which is representative of both. Here the $[(KNMgN)_6]^{6+}$ ring system acts as a polymetallic host to six singly deprotonated arene anions. Mirroring the situation in **14**, the toluene-derived ligands in **16** have intact Me substituents and hydrogen atoms missing from ring sites, the positions of which are coincident with the placings of the magnesium atoms within the host ring. Thus a ring template effect appears to be operating in this system as well, though in this case the elusive templating molecule must be larger and have more breadth than its sodium counterpart (see Scheme 3) given that only one end of the arene molecule experiences deprotonation, implying that the other end lies distant from a magnesium atom. Following the pattern laid down in the smaller sodium ring systems, the encapsulation of the arene anions is achieved through a combination of anchoring Mg–C σ bonds and ancillary alkali metal–C π bonds but the hapticity of the phenyl rings changes from μ-$\eta^1:\eta^1:\eta^1:\eta^1$ to μ-$\eta^3:\eta^2$ in line with the larger size and coordinative capacity of the potassium atom. The interaction of alkali metal cations with π-systems is becoming an increasingly significant feature in chemistry with implications for biology as discussed in a recent review.[36] It will be interesting to ascertain the structural consequences of introducing rubidium or caesium as the alkali metal in this system: will the transition to a larger ring arrangement (here from one of twelve to one of twenty-four ring atoms) continue or more likely given their propensity for adopting polymeric arrangements, will cyclisation cease and



Scheme 3

cede to an infinite chain structure? Studies are in hand to find the answer to this question.

Outlook

Inverse crown ether and inverse crown complexes represent an important new class of s-block compound. The fundamental chemistry controlling their formation is intriguing and complex, and could not have been predicted from previous knowledge of s-block structural chemistry, even through a mountain of such data has been accumulated in recent years. There are clearly still some gaps in our understanding of these existing inverse crown ether complexes and their inverse crown relatives which ongoing research will hopefully soon resolve. Next it will be essential to establish the chemical profiles of this aesthetically attractive collection of ring compounds. For example, will the Mg–C σ bonded systems behave like typical Grignard reagents or will they have a unique chemical character of their own? We are particularly keen to ascertain how far we can extend this new class of compound. Bearing in mind that they are formally composite materials of four distinct component parts (M^+, M^{2+}, R_2N^-, and anion$^-$ or dianion^{2-}), the potential for permutation appears vast. There may even be scope for extending this chemistry beyond the s-block to, for example, the transition metal series in view of the availability therein of M^{2+} cations and the fact that $[LiMn\{N(SiMe_3)_2\}_3]$[37] is essentially isostructural to $[LiMg\{N(SiMe_3)_2\}_3]$. We look forward to continuing this fundamental development work with one eye focussed on how we might usefully apply it in areas such as anion complexation and template synthesis. Artificial organic host molecules for anions are receiving considerable attention at present. Main group metal cations, especially Mg^{2+} and Ca^{2+}, are found in abundance in natural protein receptors where they play decisive roles in binding anionic substrates, in structure enforcement, or in allosteric switching. Yet their use in artificial receptors is not currently well developed. An expanded series of inverse crown type compounds might therefore serve a useful purpose as a database of model structures for learning more about the ways in which metal-based molecules selectively bind anions.[38]

Acknowledgements

I must give special thanks to René Rowlings (for synthetic studies) and Alan Kennedy (for X-ray crystallographic studies) for making the bulk of the discoveries featured in this article. Along the way they have been aided and abetted at Strathclyde by Lorna Barr, Allison Drummond, Glenn Forbes, Jonathan MacLellan, Charlie O'Hara and Phil Rodger, at Newcastle by Bill Clegg and Steve Liddle, and at Melbourne, Australia by Colin Raston and Brett Roberts. I am also indebted to my fellow Strathclyders, David Armstrong and Kenny Henderson for their invaluable advice and significant input to the project, and to Alastair Florence for producing the cover illustration. I must also thank the referees of the manuscript for their helpful, constructive comments. The generous financial support of the EPSRC is also gratefully acknowledged.

Concise total syntheses of epothilone A and C based on alkyne metathesis

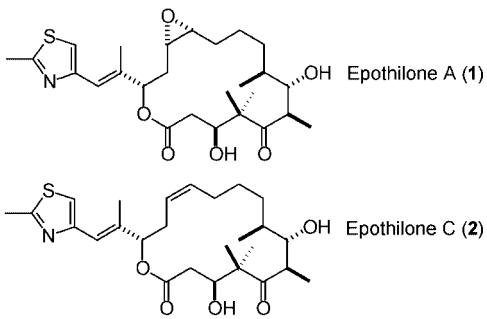
Alois Fürstner,* Christian Mathes and Karol Grela

Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, D-45470 Mülheim/Ruhr, Germany. E-mail: fuerstner@mpi-muelheim.mpg.de; Fax: ++49 208 306 2994; Tel: ++49 208 306 2342

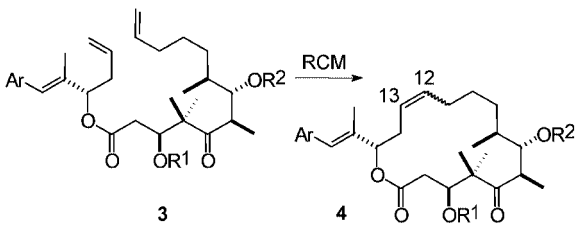
Received (in Cambridge, UK) 20th February 2001, Accepted 8th May 2001
First published as an Advance Article on the web 25th May 2001

A ring closing alkyne metathesis reaction catalyzed by the molybdenum complex 26 followed by a Lindlar reduction of the resulting cycloalkyne product opens an efficient and stereoselective entry into epothilone A and C.

The discovery that epothilone A (**1**)[1] and congeners share a common mechanism of action with paclitaxel (Taxol®) in triggering programmed cell death (apoptosis) and exert high activity even against paclitaxel-resistant human cancer cell lines *in vitro* has spurred considerable drug development programs worldwide.[2] As a consequence, these compounds became the focal point of many preparative studies aiming at their total synthesis as well as at a synthesis-driven mapping of the structure–activity relationship of these promising natural products.[2,3]



In this context it is remarkable that the first three successful approaches towards **1** were all based on ring closing alkene metathesis (RCM) for the formation of the 16-membered ring. Product **4** thus formed can be selectively epoxidized at the $\Delta^{12,13}$-bond and hence constitutes an excellent precursor for epothilone A.[4–6]



Although these studies were early highlights showing the enormous potential of RCM for advanced organic synthesis,[7] they *invariably suffered from the fact that there was little—if any—selectivity in favor of the required (Z)-alkene* **4** (Table 1). As this serious problem arose only towards the very end of rather laborious sequences and since the isomeric alkenes could not be readily separated at this stage, it is hardly surprising that subsequent total syntheses of **1** were largely based on strategies other than RCM that ensure better control over all structural elements of this target.[8]

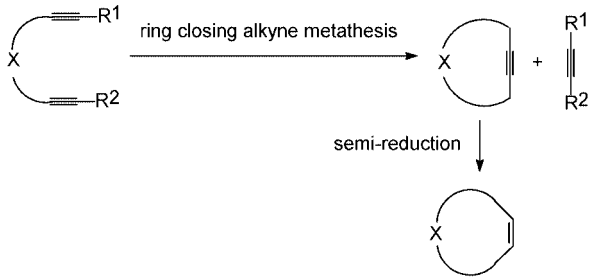
Recently, our group was able to show that the ring closing metathesis of *diynes* constitutes a promising alternative that retains all the advantages of metathetic conversions† but allows for the first time the gearing of the stereochemical issue to the cyclization event.[9] If combined with a Lindlar-type reduction, this method opens a *stereoselective entry into (Z)-alkenes* (Scheme 1). We felt that epothilone A constitutes an ideal testing ground for the scope of this emerging new methodology (Scheme 2).[9–11] Described below is the successful reduction of this plan to practice.

Table 1 RCM approaches towards epothilone A and C: formation of (*E*,*Z*)-mixtures (Ar = 2-methyl-4-thiazolyl)

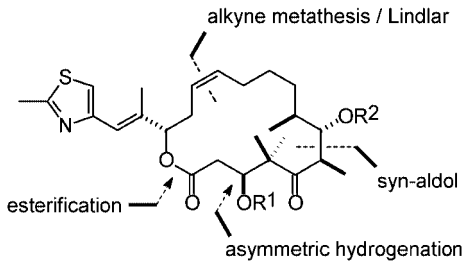
Catalyst[a]	R^1	R^2	Yield	*Z*:*E*	Ref.
[Ru]	TBS	TBS	86%	1.7:1	4*b*
	TBS	TBS	94%	1:1	6*a*
	TBS	H	85%	1.2:1	5*b*
	H	H	65%	1:2	4*b*
[Mo]	TBS	TBS	86%	1:2	4*b*

[a] [Mo] = Mo(=NAr)(=CHCMe$_2$Ph)[OCMe(CF$_3$)$_2$]$_2$; [Ru] = (PCy$_3$)$_2$(Cl)$_2$-Ru=CHPh.

Earlier studies had revealed that the selectivity gained in the formation of the three contiguous stereocenters at C-6, C-7 and C-8 by an aldol reaction strongly depends on the remote functionalization of the enolate partner.[2,3] The best results were reported by Schinzer *et al*. who employed ethyl ketone **11** bearing a conformationally rigid and chelating 1,3-dioxane unit as control element for this purpose.[6] We took recourse to this



Scheme 1 Stereoselective synthesis of (*Z*)-alkenes by ring closing alkyne metathesis/Lindlar reduction.

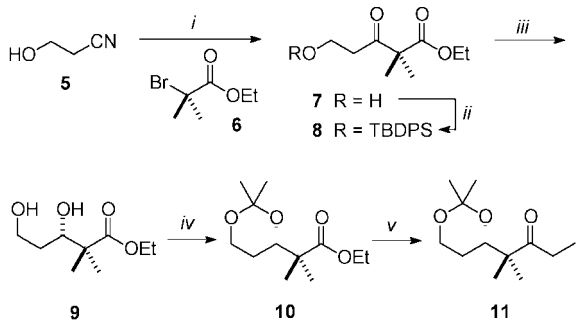


Scheme 2 Retrosynthetic analysis of epothilone C (**2**).

DOI: 10.1039/b101669p

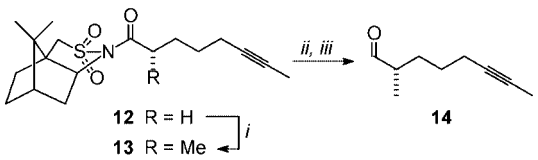
elegant solution, seeking, however, an improved and shorter entry into the required key building block **11**.

Our synthesis starts from commercially available 3-hydroxypropionitrile **5** which reacts with the zinc enolate derived from bromo ester **6** to afford ketoester **7** in 71% yield on a multigram scale (Scheme 3). This Reformatsky-type reaction is best carried out with the assistance of ultrasound.[12] Silylation of **7** with *tert*-butyldiphenylsilyl chloride under standard conditions followed by an asymmetric hydrogenation of **8** catalyzed by [((*S*)-binap)$RuCl_2$](NEt_3) in the presence of Dowex (H-form) to ensure acidic conditions delivers the unprotected diol **9** in high enantiomeric purity (ee = 94%).[13]‡ All attempts to perform the reduction directly with the unprotected substrate **7** resulted in rather poor conversion. Acetalization of **9** followed by reaction of the resulting product **10** with EtMgBr in toluene in the presence of NEt_3 affords compound **11** in excellent overall yield. The presence of the base during the addition of the Grignard reagent to the ester is essential, as it enolizes the ketone primarily formed and thereby avoids the formation of the corresponding tertiary alcohol by addition of a second equivalent of EtMgBr.[14]



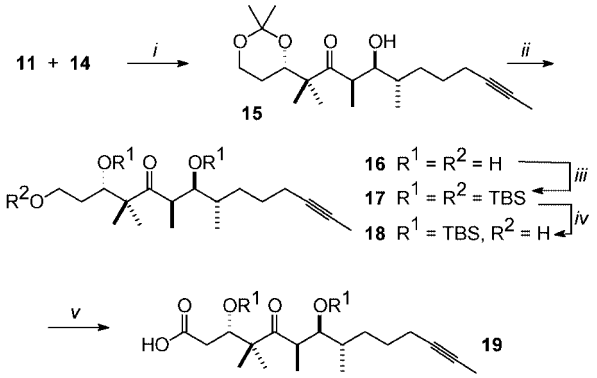
Scheme 3 *Reagents and conditions*: i, Zn, ultrasound, THF; then aq. HCl, 71%; ii, TBDPSCl, imidazole, DMF, 90%; iii, [((*S*)-binap)$RuCl_2$](NEt_3) (6 mol%), H_2 (65 bar), Dowex, EtOH, 80 °C, 71%; iv, 2,2-dimethoxypropane, acetone, camphorsulfonic acid cat., 92%; v, EtMgBr, NEt_3, toluene, 70 °C, 68%.

Having secured an improved access to this key building block, the subsequent aldol reaction was carried out in close analogy to that described by Schinzer *et al.*[6] The required aldehyde component **14** is readily formed as shown in Scheme 4, exploiting the excellent facial guidance exerted by Oppolzer's bornane sultam in the alkylation of substrate **12** (d.r. = 96:4).[15] Reaction of the lithium enolate derived from **11** with compound **14** affords aldol **15** in 70% yield (Scheme 5). The selectivity for the desired *anti*-Cram product was 7:1 (HPLC), which is easily separated from the minor isomer by flash chromatography. Further elaboration of this compound involving deprotection of the acetal, per-silylation of the resulting triol **16**, and regioselective cleavage of the primary TBS-ether in **17** is performed in analogy to literature routes.[5,6] Oxidation of the resulting alcohol **18** with PDC in DMF smoothly affords the desired carboxylic acid **19** ready for esterification with a suitable thiazol fragment.

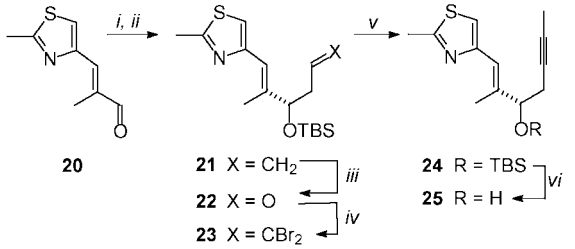


Scheme 4 *Reagents and conditions*: i, n-BuLi, THF–HMPA, MeI, −78 → −60 °C, 94%; ii, $LiAlH_4$, THF, 85%; iii, Pr_4NRuO_4 cat., NMO, CH_2Cl_2, MS 4 Å, 90%.

The preparation of the latter (Scheme 6) starts with an allylation of aldehyde **20** with (+)-Ipc_2B(allyl) as described earlier,[5] followed by silylation of the crude material with TBSCl and imidazole, thus delivering the homoallyl alcohol derivative **21** in 89% yield over both steps in excellent enantiomeric excess



Scheme 5 *Reagents and conditions*: i, LDA, THF, −78 °C, 70%; ii, PPTS, MeOH, 85%; iii, TBSOTf, 2,6-lutidine, 92%; iv, camphorsulfonic acid cat., CH_2Cl_2–MeOH (1:1), 78%; v, PDC, DMF, 83%.

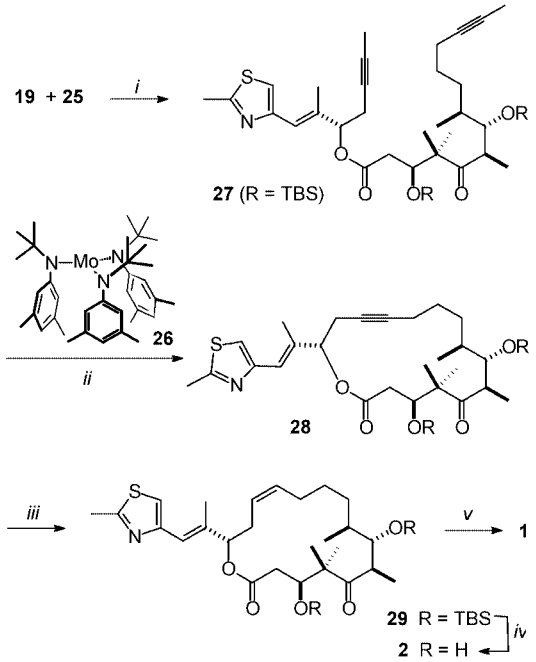


Scheme 6 *Reagents and conditions*: i, (+)-Ipc_2B(allyl); ii, TBSCl, imidazole, DMF, 89% (over both steps); iii, (1) OsO_4 cat., NMO; (2) $Pb(OAc)_4$, 86%; iv, CBr_4, PPh_3, CH_2Cl_2, 68%; v, *n*-BuLi, MeI, THF, 65%; vi, TBAF·$3H_2O$, THF, 74%.

(ee > 97%). Oxidative cleavage of its terminal double bond affords the somewhat unstable aldehyde **22** which is immediately used for a subsequent Corey-Fuchs reaction.[16] Specifically, treatment of **22** with CBr_4 and PPh_3 gives the expected 1,1-dibromo derivative **23**,[2c] which is converted into alkyne **24** by means of *n*-BuLi in THF and trapping of the acetylide anion thus formed with MeI. Desilylation under standard conditions followed by esterification of the resulting alcohol **25** with compound **19** sets the stage for the crucial macrocyclization step. It should also be noted that all attempts to form product **25** from aldehyde **20** by direct asymmetric propargylation were unrewarding in terms of yield and optical purity.

We were pleased to see that diyne **27** is in fact smoothly converted into the 16-membered cycloalkyne **28** in 80% isolated yield on exposure to catalytic amounts of the molybdenum amido complex **26**[17] in toluene–CH_2Cl_2 at 80 °C (Scheme 7). This outcome is particularly noteworthy as it compares well to the results obtained in the conventional RCM approaches (Table 1) in terms of yield and reaction rate. Furthermore, it clearly attests to the mildness and preparative relevance of the method since (i) neither the basic N-atom nor the sulfur group of the thiazole ring interfere with the catalyst, (ii) the labile aldol substructure, the rather electrophilic ketone, as well as the ester- and silyl ether groups are fully preserved, (iii) no racemization of the chiral center α to the carbonyl is encountered, and (iv) the rigorous chemoselectivity of the catalyst is confirmed, which reacts smoothly with alkynes but leaves pre-existing alkene moieties unaffected.§ Therefore, this particular example in concert with the previous applications from our laboratory[9–11] substantiates the notion that alkyne metathesis in general holds great promise for target oriented synthesis.

Lindlar reduction of cycloalkyne **28** followed by cleavage of the silyl ether groups in the resulting (*Z*)-alkene **29** by means of aq. HF in Et_2O–MeCN as the reaction medium delivers epothilone C **2** in 79% yield. Because the selective epoxidation of **29** has already been described by various groups,[2–6] this approach also constitutes a formal total synthesis of epothilone A **1**.



Scheme 7 *Reagents and conditions*: i, DCC, DMAP, CH_2Cl_2, 81%; ii, **26** (10 mol%), toluene–CH_2Cl_2, 80 °C, 8 h, 80%; iii, Lindlar catalyst, quinoline, H_2 (1 atm), CH_2Cl_2, quant.; iv, aq. HF, Et_2O–MeCN, 79%; v, dimethyldioxirane, 70% (ref. 4).

Generous financial support by the Deutsche Forschungsgemeinschaft (Leibniz award to A. F.) and the Fonds der Chemischen Industrie is gratefully acknowledged. K. G. thanks the Alexander-von-Humboldt Foundation for a fellowship.

Notes and references

† For a discussion of the strategic advantages of metathesis in general over more conventional transformations see ref. 18.

‡ The need to perform this reduction under slightly acidic conditions determines the choice of the protecting group for the primary alcohol; the TBDPS group turned out to be optimal, whereas the TBS ether was found to be too unstable.

§ Other available catalysts for alkyne metathesis are (i) $Mo(CO)_6$–*p*-chlorophenol and (ii) alkylidyne complexes such as $(t\text{-}BuO)_3W{\equiv}CCMe_3$. System (i), however, requires very harsh conditions (≥130 °C), whereas the tungsten alkylidyne is sensitive towards basic nitrogen atoms or sulfur(II) groups in the diyne substrate. Therefore they are not appropriate for the cyclization of **27** to **28**. For a more detailed discussion see ref. 11*a*.

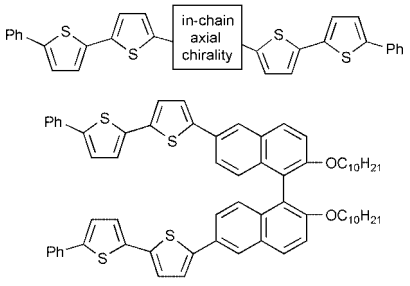
Received (in Columbia, MO, USA) 14th August 2000, Accepted 10th April 2001
First published as an Advance Article on the web 22nd May 2001

A chiral oligothiophene, possessing in-chain chirality, was prepared and its racemate was characterized by single crystal X-ray crystallography; the in-chain chiral 1,1′-binaphthyl moiety interrupts the π-conjugation and affects the solid state properties of the oligothiophene.

Oligothiophenes are attracting attention as functional materials for (opto)electronic devices.[1,2] Soluble oligothiophenes are especially valuable in applications where reproducible high chemical purity is essential and recently developed solution printing techniques can be utilized, *e.g.* in 'plastic electronics' based upon field effect transistors.[2] The well-defined oligomers are also studied as models for the parent polymers.[3] The crystal structures of a number of oligothiophenes have been reported.[2,4]

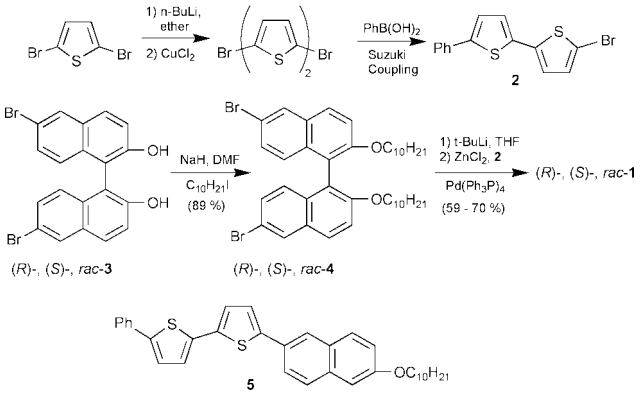
The introduction of chirality into the oligo- or polythiophenes is expected to provide an additional engineering tool for these materials, arising not only from intrinsic chirooptical and chiroelectronic properties but also from diastereomeric interactions in the solid state.[5,6] Polythiophenes with various chiral pendant groups and in-chain 1,1′-binaphthyls have been reported.[7,8]

We report on the synthesis and single crystal X-ray structure determination of 6,6′-bis(5-phenyl-2,2′-bithiophen-5′-yl)-2,2′-bis(decyloxy)-1,1′-binaphthyl (**1**), a chiral oligothiophene, possessing in chain chirality.



(*R*)-, (*S*)-, and *rac*-**1**

The convergent synthesis of (*R*)-, (*S*)-, and *rac*-**1** is based upon the connection of two achiral modules **2** to the chiral module **4**, which is available in the (*R*)-, (*S*)-, and racemic-forms. 5′-Bromo-5-phenyl-2,2′-bithiophene (**2**) is obtained in two steps: (1) 2,5-dibromothiophene is treated with 1 equiv. of n-BuLi in diethyl ether, followed by oxidation with $CuCl_2$ to give 5,5′-dibromo-2,2′-bithiophene,[9] (2) Suzuki coupling of phenylboronic acid in the presence of an excess of 5,5′-dibromo-2,2′-bithiophene gives **2** in 68% yield.[10,11] 6,6′-Dibromo-2,2′-bis(decyloxy)-1,1′-binaphthyls (**4**) are prepared according to the previously published procedures for analogous bis(dodecyloxy) derivatives by etherification of 6,6′-dibromo-1,1′-binaphthyl-2,2′-diols (**3**) with iododecane in the presence of NaH in DMF.[12] The modules **2** and **4** are linked *via* Negishi coupling providing (*R*)-, (*S*)-, and *rac*-**1** in 59–70% yields (Scheme 1).[13,14] Analogous synthetic procedures were used to obtain the model bithiophene **5**.



Scheme 1 Synthesis of (*R*)-, (*S*)-, and *rac*-**1**, and the structure of the reference compound **5**.

Orange, block-shaped crystals of *rac*-**1** suitable for X-ray diffraction experiments were grown by slow evaporation of the solvent from a hexane–chloroform solution.[15] The structure displayed by **1** is that of a twisted binaphthyl with the alkoxy chain of one naphthyl unit packing against the naphthyl–thiophene–thiophene–phenyl π-system of the other half of the molecule (Fig. 1). Each of the π-systems is nearly planar, exhibiting small interplanar twist angles.[16] Possible 2-fold symmetry about an axis perpendicular to the C(1)–C(25) binaphthyl linkage is broken by the differing conformations displayed by the alkoxy chains. The difference is a single torsion angle. The conformation about the C(2A)–C(3A) bond is *trans* [C(1A)–C(2A)–C(3A)–C(4A) = −176.2(4)°], whereas the C(2B)–C(3B) conformer is *gauche* [C(1B)–C(2B)–C(3B)–C(4B) = −68.8(5)°]. The remainders of both chains are in all-*trans* conformations. Because of the difference in conformation, the plane containing C(2B–10B) lies parallel to the adjacent π-system, while the C(2A–10A) plane is essentially perpendicular to the adjacent π-system. Both chains lie in close contact with

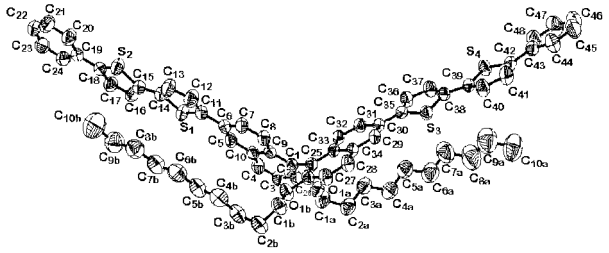


Fig. 1 The conformation for the crystal structure for *rac*-**1**. Ellipsoids are shown at 50% probability.

† Electronic supplementary information (ESI) available: synthesis and characterization data for **1**, **2**, **4**, and **5**; crystal packing plots for *rac*-**1**. See http://www.rsc.org/suppdata/cc/b0/b007355p/

 DOI: 10.1039/b007355p

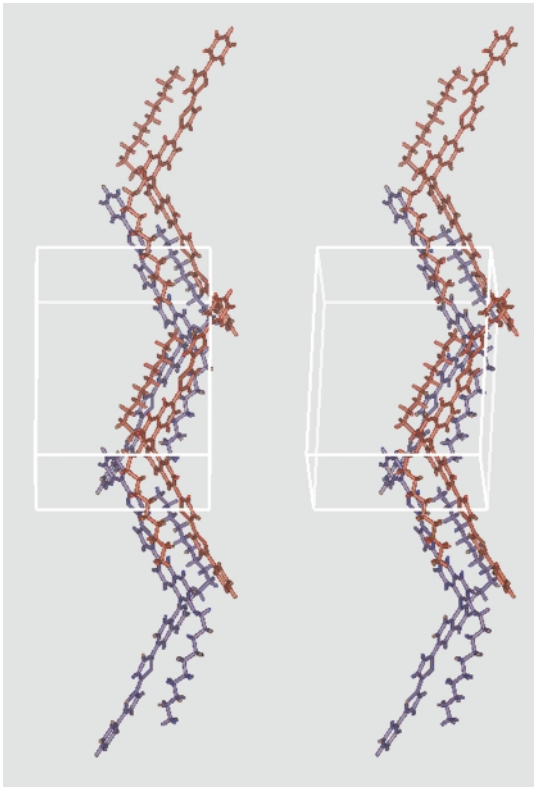

Fig. 2 Crystal packing for *rac*-**1**: stereoview (approximately *bc*-plane) of the tetramer fragment of the zig-zag chain extending along the *c*-axis. The enantiomers are color-coded.

each π-system, with alkyl hydrogens pointing towards the π-systems. We suggest that this interaction influences the conformation of the binaphthyl core. The binaphthyl twist displayed [C(9)–C(1)–C(25)–C(33) = 107.3(3)°] is larger than that observed in binaphthyl (101.4°)[17] and most other 2,2-disubstituted binaphthyls, *e.g.* 2,2′-dihydroxy-1,1′-binaphthyl (92.5°)[18] and 2,2′-bis(bromomethyl)-1,1′-binaphthyl (86.8°).[19]

For the discussion of the crystal packing in *rac*-**1**, the two π-conjugated moieties of **1** may be viewed as a molecular hinge. The phenyl–bithiophene–naphthyl moieties from the mirror image enantiomers form a quasi-one-dimensional zig-zag chain extending along the *c* axis (Fig. 2). Such a chain of molecular hinges is facilitated by the alternating enantiomers. Along the *a* axis, the chains pack side-by-side to form quasi-two-dimensional zig-zag layers, which pack on top of each other in a 'lock-and-key pattern'. The homochiral π–π interactions are negligible as the phenyl–bithiophene–naphthyl moieties form alternating stacks with the alkyl chains.

With bithiophene **5** as a reference, UV-vis spectra of **1** reveal that the nonplanar chiral binaphthyl moiety highly attenuates the π-conjugation.[8] The broad π–π* transitions (λ_{max} = 393 nm) for **1** and **5** are essentially superposable, except for the molar absorptivities, which in **1** are approximately twice those in **5** (log ε_{max} = 4.9 and 4.6). The fingerprint regions of the IR spectra of solid (*R*)- and (*S*)-**1** show small differences compared to the IR spectrum of *rac*-**1**. Also, the melting point of *rac*-**1** is about 40–50 °C higher than those for the (*R*)- and (*S*)-enantiomers, suggesting the presence of a racemic compound.[20] Moreover, the melting point of bithiophene **5** is even higher, about 95 °C above *rac*-**1**. The solubility in chloroform (g mL^{-1}) increases in the following order: (*S*)-**1** (2×10^{-1}) > *rac*-**1** (8×10^{-4}) > **5** (2×10^{-5}), *i.e.* the opposite order to the melting points. These significant differences in solubilites are of importance for the solution processability of oligothiophenes.

In summary, the introduction of chirality into the oligothiophene chain leads to significant differences in solid state properties between stereoisomers and should be an important factor in their solution processability. Further studies on crystal packing and materials properties of chiral molecular hinges in the neutral and doped states are in progress.

This research was supported by the National Science Foundation (CHE-9806954 to A. R. and CHE-9812146 to J. J. S.). We thank Drs Lianhe Yu, Nai Xing Wang, and Jun Li for preparation of synthetic intermediates and conductivity measurements. We thank Dr R. Cerny of the Nebraska Center for Mass Spectrometry for the mass spectral determinations.

First published as an Advance Article on the web 22nd May 2001

Charge-assisted π-stacking interactions result in the formation of large porous arrays formed from the inclusion of metal tris(phenanthroline) cations into *p*-sulfonatocalix[4]arene anions.

A great deal of work in crystal engineering[1–3] has focussed on the manipulation, control or prediction of solid state structure of organic[2,4,5] and organometallic or coordination compounds[6–9] through hydrogen bonding interactions.[10] Lower in energy than many hydrogen bonds, but now reasonably well understood, are π-stacking interactions of the edge-to-face and face-to-face types.[11–13] As early as 1989 Gavezzotti and Desiraju were able to classify the structures of a number of aromatic hydrocarbons based on the ratio of carbon to hydrogen and its effect on their mutual π-stacking interactions.[14] More recently a number of studies have shown that limited π-stacked motifs may be predicted and perhaps conserved over a number of related structures. This is particularly true in cases where there is a significant donor–acceptor or ionic component to the stacking interaction.[15,16] What is most intriguing about π-stacking interactions from a crystal engineering point of view is that such supramolecular 'bonds' represent the interaction of two relatively large surfaces (*cf.* the point-like nature of hydrogen bonds). Thus a well-controlled π-stacked system has the potential to command a very great deal of space within a crystal lattice. In this paper we report the initial successful results of our attempts to engineer extended π-stacked arrays based on charge assisted interactions between *p*-sulfonatocalix[4]arene anions (**1**)[17,18] and metal 1,10-phenanthroline cations.

The molecular cavity in the *p*-sulfonatocalix[4]arene tetra- and pentaanions ($\mathbf{1}^{4-}$ or $\mathbf{1}^{5-}$) is both electron rich and flexible (it is able to alternate between approximate C_{4v} and C_{2v} symmetry while retaining a 'cone' conformation).[17–20] The cleft-shaped C_{2v} conformation is particularly suited to the inclusion of planar aromatic guest species and we reasoned that reaction of Na_5·**1** with transition metal tris(1,10-phenanthroline) dications is likely to result in the formation of a π-stacked motif based on $[M(phen)_3]^{2+} \cap \mathbf{1}^{n-}$ (n = 4–5). This motif should be conserved over a wide variety of structures containing different M and other co-species, particularly solvent molecules (anion **1** is commonly highly hydrated in the solid state[21]). It was found that first row transition metal tris(phen) complexes were extremely readily prepared mechanochemically.[22,23] Simple grinding together of the appropriate stoichiometric ratio of metal salt (halide, nitrate) and phen gave rapid colour changes indicative of the formation of the desired tris(chelate) complexes. Co-complexes with $\mathbf{1}^{n-}$ were similarly prepared by grinding of the resulting mixture with the calixarene. The mixtures were extracted into aqueous solution in order to prepare single crystals suitable for X-ray crystallographic analysis. Thus grinding of $Ni(NO_3)_2 \cdot 6H_2O$ with 1,10-phenanthroline resulted in the formation of a reddish solid over a period of *ca.* two minutes. Subsequent grinding with hydrated Na_5·**1** gave rise to a red-pink, water-insoluble mixture. Similarly, dissolution of the mechanochemically generated $[Ni(phen)_3](NO_3)_2$ in water followed by addition of aqueous Na_5·**1** gave a pink precipitate. This solid was recrystallised from water–acetone (4:1) to give a remarkable crystalline solid of formula $[Ni(phen)_3]_2[\mathbf{1}^{4-}] \cdot n H_2O$ (**2**) (n = *ca.* 28). Under slightly different conditions (small excess of phen) the related $[Na(H_2O)_4(phen)][Ni(phen)_3]_4[\mathbf{1}^{4-}][\mathbf{1}^{5-}] \cdot n H_2O$ (**3**) (n = *ca.* 22) was formed. Complexes **2** and **3** were characterised by X-ray crystallography.† Reaction with a variety of metal phen complexes such as $[Fe(phen)_3]^{2+}$ also gave related products which will be reported separately.

The structure of complex **2** comprises two independent, infinite chains of offset face-to-face π-stacked $[Ni(phen)_3]^{2+}$ cations propagating in the crystal *a* and *b* directions. The strand running along *b* exhibits interplanar separations of 3.356 and 3.546 Å. The former is comparable to the distance of *ca.* 3.35 Å found in graphite and shorter than the 3.48 Å separation for the direct face-to-face overlap observed for $[Cr(C_6H_6)_2] \cdot C_6F_6$.[15] Interplanar separations in the second strand (along *a*) are also short at 3.454 and 3.466 Å and of similar offset to one another, although markedly different to the *b* strand. In the strand running along *b* the independent $[Ni(phen)_3]^{2+}$ cations are included within the cavities of the *p*-sulfonatocalix[4]arene(4−) anion cavities (Fig. 1) with an edge-to-face arrangement, closest $C_{phen} \cdots$calixarene aryl ring centroid distances 3.600 and 3.739 Å. This interaction is facilitated by the C_2 symmetric 'pinched cone' conformation adopted by the calixarene, also noted for water inclusion.[20] The *a* strand also exhibits a herringbone type π-stacking intermediate between the edge-on and face-on modes, with the outside of the calixarenes (*cf.* the 'sandwich herringbone' structure of pyrene[14]). The calixarenes themselves engage in mutual intermolecular face-to-face (sulfonate head to phenolic tail) π-stacking with an interplanar separation of 3.292 Å. This gives the characteristic *p*-sulfonatocalix[4]arene clay-like bilayer packing.[3,21] The overall result is a trapezoidal grid-like arrangement of π-stacked strands leaving void spaces corresponding to large water-filled channels running along the *b* direction, Fig. 2. The intra-channel water is partially ordered, with most oxygen positions located and being modelled as 50% occupancy. This effectively corresponds to the formation of an extremely large hydrophilic portion of the usual bilayer structure and arises from the

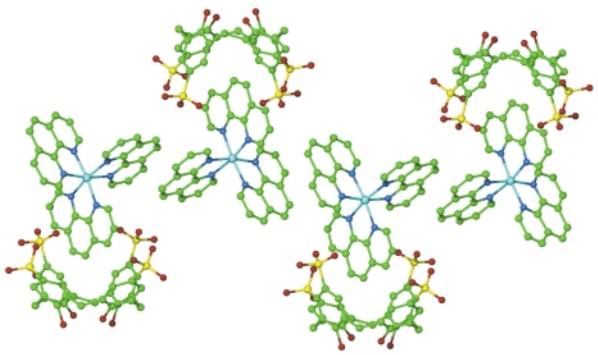

Fig. 1 Infinite π-stacked chain in **2** showing the inclusion of $[Ni(phen)_3]^{2+}$ cations within the cavity of a *p*-sulfonatocalix[4]arene(4−) anion, in a C_{2v} symmetric conformation.

 DOI: 10.1039/b103411c

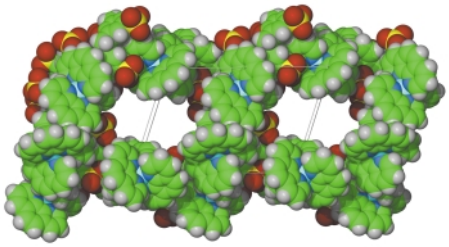

Fig. 2 Crystal packing in **2**. Only one of the two independent $[Ni(phen)_3]^{2+}$ cations is included within the *p*-sulfonatocalix[4]arene(4−) anion (crystal *b* direction). The calixarenes engage in mutual face-to-face π-stacking, while the second chain of $[Ni(phen)_3]^{2+}$ cations runs along the crystallographic *a* axis. The result is large water-filled channels of approximate van der Waals dimensions 7.5 × 10.5 Å.

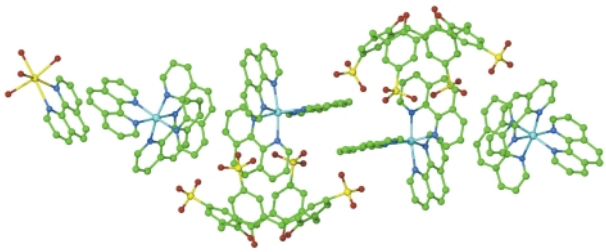

Fig. 3 The $[Na(phen)(H_2O)_4][Ni(phen)_3]_4$[*p*-sulfonatocalix[4]arene-(4−)][*p*-sulfonatocalix[4]arene(5−)] stacked chains in **3**. The two independent $[Ni(phen)_3]^{2+}$ cations both form part of the same chain.

inclusion of the second $[Ni(phen)_3]^{2+}$ cation necessary for charge balance.

The crucial aspect from a crystal engineering perspective is the prediction and conservation of the $[Ni(phen)_3]^{2+}\cap$*p*-sulfonatocalix[4]arene(*n*−) motif with its large, accessible π-surface, resulting in π-stacked chain formation. In this system addition of a small excess of the basic phen is sufficient to deprotonate some of the calixarene anions further to give $[Na(H_2O)_4(phen)][Ni(phen)_3]_4[\mathbf{1}^{4-}][\mathbf{1}^{5-}]\cdot nH_2O$ (**3**). Compound **3** displays an entirely novel packing mode for the much studied *p*-sulfonatocalix[4]arene which is not based on a clay-like bilayer, nor the recently reported spherical or tubular types.[24] Each calixarene is almost entirely surrounded by $[Ni(phen)_3]^{2+}$ cations in order to maximise π-stacking interactions. The core of the structure is again the $[Ni(phen)_3]^{2+}\cap$*p*-sulfonatocalix[4]arene(*n*−) motif and again an infinite 'sandwich herringbone'[14] type π-stacked chain is observed, although it is very different to that found in **2**. In this case the included $[Ni(phen)_3]^{2+}$ cation stacks with a symmetry equivalent of itself on one side and the second independent $[Ni(phen)_3]^{2+}$ unit on the other (interplanar distances *ca*. 3.50 and 3.59 Å). Thus the two independent $[Ni(phen)_3]^{2+}$ cations form part of the same chain, which zig-zags across the unit cell body diagonal. The $[Na(phen)(H_2O)_4]^+$ cation forms the pivot of the chain at which point the face-to-face π-stacking of the $[Ni(phen)_3]^{2+}$ cations gives way to a herringbone type edge-to-face interaction. Thus the full chain exhibits an ···ABCCBABCCB··· arrangement in which A = $[Na(phen)(H_2O)_4]^+$, B = $[Ni(phen)_3]^{2+}$ and C = $[Ni(phen)_3]^{2+}\cap$*p*-sulfonatocalix[4]arene(*n*−), Fig. 3. The water molecules of the $[Na(phen)(H_2O)_4]^+$ cation hydrogen bond to calixarene sulfonato functionalities and one solvent water molecule. The result is again large water filled channels running in the crystallographic *b* direction that are bounded by the interlocking, zig-zag π-stacked chains, Fig. 4. The included water is predominantly ordered with half the oxygen sites being full occupancy and the other half being split across more than one position.

This study has shown that there is a strong solid-state preference for maximising π-stacking interactions and π-surface contact to such an extent that the $[Ni(phen)_3]^{2+}\cap$*p*-sulfonatocalix[4]arene(*n*−) motif is conserved over two very different structures. A further $[Fe(phen)_3]^{2+}$ analogue has also been isolated and will be reported separately. In each case channel structures are a direct and predictable consequence of the very bulky nature of the crystal synthons. Such new porous materials may prove highly interesting in separation/adsorption applications since the intra-channel interactions are very different and distinct from the forces holding the channel framework together.

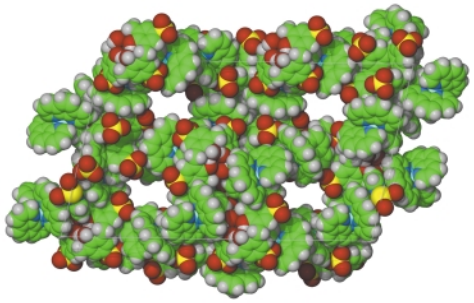

Fig. 4 Water-filled channels in **3**. Approximate channel van der Waals dimensions 4 × 7 Å.

An unprecedented two-fold interpenetrated heterometallic $4^6 6^4$ network constructed by five-connected copper metal nodes

Long Pan, Nancy Ching, Xiaoying Huang and Jing Li*

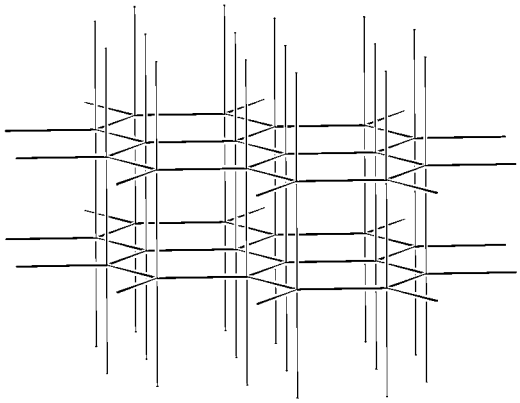
Department of Chemistry, Rutgers University, Camden, NJ 08102, USA. E-mail: jingli@crab.rutgers.edu

Received (in Columbia, MO, USA) 3rd March 2001, Accepted 2nd May 2001
First published as an Advance Article on the web 25th May 2001

Hydrothermal reactions making use of dichromate metal anion as a *secondary ligand* yielded a novel three dimensional, bimetallic copper(II)–chromium(VI) network with an unprecedented $4^6 6^4$ topology consisting of Cu(II) ions as five-connected nodes; two such networks, completely identical, interlock to generate a two-fold interpenetrated structure.

Self-assembled inorganic/organic frameworks that mimic prototypical structures have received intense attention in the field of coordination chemistry. Synthetic approaches making use of carefully selected, suitable metal centers as nodes and *exo*-bidentate or multifunctional ligands as connectors have produced numerous fascinating archetypal structures, including diamond (6^6-α),[1] α-Po ($4^{12}6^3$),[2] α-$ThSi_2$ (10^3-b),[3] $SrSi_2$ (10^3-a),[4] PtS (4^28^4),[5] SiO_2 (6^48^2-b),[6] and NbO (6^48^2-a),[7] which have experimentally confirmed the topologies predicted by theory. In certain cases, coordinated systems have generated interesting structures that do not appear to be adopted by simple inorganic compounds, as in the case of the 'dense' net (7^59).[8] These inorganic/organic frameworks often contain large open spaces that may be subject to interpenetration. The interlocking networks may or may not be identical. To date, the highest degree of catenation that has been reported is eleven-fold.[9] All of these extraordinary structures are of fundamental importance in structural design and in the understanding of structure–property correlations. Considering the existing coordination systems, one notes that while numerous monometallic structures have been prepared, there has been little progress concerning the synthesis of heterometallic frameworks. With the premise that metal anion functional groups such as CrO_4^{2-}, MoO_4^{2-}, $Cr_2O_7^{2-}$ and $Mo_2O_7^{2-}$ can form effective M–O–Cr or M–O–Mo bonds,[10] where M is typically a late transition metal, we have successfully applied a synthetic strategy to make use of these metal–anion functional groups as *secondary ligands* in the assembly of heterometallic networks. In this communication, we report a two-fold interpenetrated bimetallic network containing Cu^{2+} metal centers and bridging $Cr_2O_7^{2-}$ metal anions. The structure can be classified as a 4^66^4 topological type built upon pure five-connected nodes,[11] as defined by Wells (Scheme 1).[12] To the best of our knowledge, this structure represents the first example of coordination polymers possessing such a topology.

$Cu(4,4'\text{-bpy})_{1.5}Cr_2O_7{\cdot}H_2O$ **1** was prepared in single-crystal form by the hydrothermal reaction of $Cu(NO_3)_2{\cdot}3H_2O$, 4,4′-bpy, $K_2Cr_2O_7$ and deionized water in the ratio of 1 : 1 : 0.5 : 5555 at 150 °C for 3 days.† A dark-red single crystal suitable for single-crystal X-ray diffraction was isolated.‡ The coordination environment of Cu in **1** is shown in Fig. 1. Each copper metal has a distorted octahedral coordination. The apical positions are occupied by one coordinated water (O8) and one dichromate oxygen ($O6^i$), while the equatorial positions are occupied by three nitrogen atoms (N1, N2 and N3) from different 4,4′-bpy ligands with roughly identical Cu–N bond lengths (2.009–2.033 Å). The remaining equatorial position is occupied by another oxygen (O1) from the second dichromate group. The Cu–O bond distances for the apical oxygen atoms (Cu–$O6^i$ = 2.330 and Cu–O8 = 2.511 Å) are significantly longer than the equatorial Cu–O bond length of 1.972 Å, liable to Jahn–Teller distortion of Cu(II) (d^9). The coordination environments around Cu–O–Cr and the $Cr_2O_7^{2-}$ group are consistent with those reported in a comparable dichromate compound.[13] Each Cu center in the framework acts as a five-connected node by connecting the three pyridine nitrogen atoms from the 4,4′-bpy at the equatorial positions to form a 2D Cu–bpy (6,3) network and by further bonding to the oxygen atoms of the $Cr_2O_7^{2-}$ metal anions to give rise to a unique network with an unprecedented 4^66^4 topology (Fig. 2). The coordination of the Cu(II) in this structure is quite different from those in the two well known Cu–bpy compounds, the six-connected Cu(II) in $Cu(4,4'\text{-bpy})SiF_6$,[14] and the three-connected Cu(I) in $Cu(4,4'\text{-bpy})NO_3{\cdot}1.5H_2O$.[15] As shown in Fig. 2, the single 4^66^4 network of **1** contains large one-dimensional open channels parallel to the *a*-axis. The cross-section of the channel window is *ca.* 11.2 × 22.0 Å. Note that the $Cr_2O_7^{2-}$ anions protrude into the channel, causing a slight distortion of the N2–Cu–N3 bond angle of 170.22(19)°. This results in a narrow 'neck' at the middle of each channel with a shortest O···O distance of *ca.* 4.4



Scheme 1 4^66^4 net.

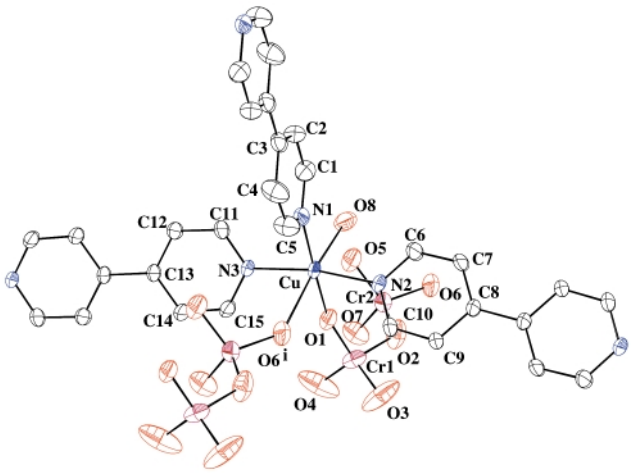


Fig. 1 The coordination environment of Cu in **1** (ORTEP drawing with ellipsoids at 50% probability).

 DOI: 10.1039/b102155a

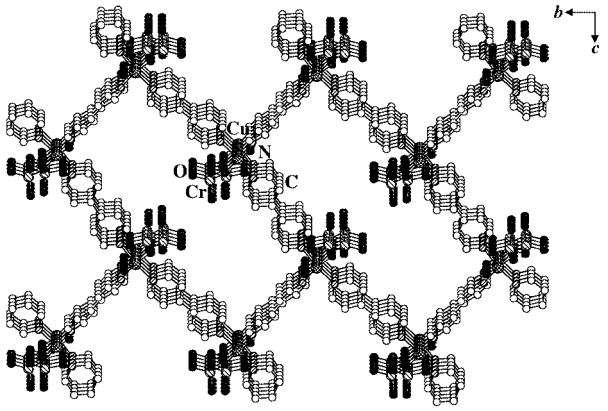

Fig. 2 A view along the crystallographic *a*-axis showing a single $4^6 6^4$ 3D network of **1**. The cross-shaded circles represent Cu atoms; large singly shaded circles are Cr atoms; and small singly shaded, open and solid circles are N, C, and O atoms, respectively.

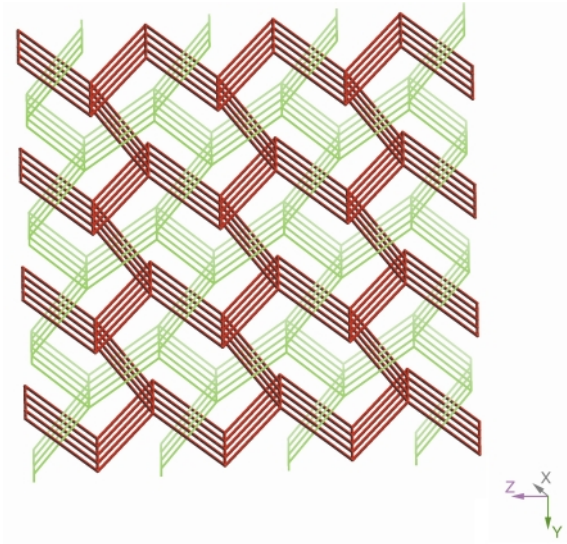

Fig. 3 A view along the *a*-axis showing two identical $4^6 6^4$ nets built upon five-connected copper nodes. These two 3D nets interlock to generate a two-fold interpenetrated structure of **1**.

Å. The two shortest Cu–Cr distances in **1** are 3.543(14) and 5.1629(18) Å, respectively. A two-fold interpenetrating framework is generated by accommodating two identical $4^6 6^4$ networks into the structure (Fig. 3). As clearly illustrated in Fig. 3, pure five-connected copper atoms constitute the nodes of this structure. Note that this $4^6 6^4$ net is topologically analogous to the inorganic network B_2 in AlB_2 (see Scheme 1).[16]

In conclusion, we have shown that the inorganic metal anion $Cr_2O_7^{2-}$ can act as an effective secondary ligand in constructing a bimetallic structure with an unprecedented $4^6 6^4$ topology built upon five-connected Cu^{2+} metal centers. The structure has the same topology as that of the inorganic network B_2 in AlB_2. The design and synthesis of novel bimetallic structures using other metal–anion secondary ligands and metal centers other than Cu(II) are currently under investigation.

We gratefully acknowledge financial support from the National Science Foundation (Grant DMR-9553066).

Notes and references

† *Preparation* of $Cu(4,4'\text{-bpy})_{1.5}Cr_2O_7{\cdot}H_2O$ **1**: hydrothermal reaction of $Cu(NO_3)_2{\cdot}3H_2O$ (0.0242 g, 0.1 mmol), 4,4′-bpy (0.0156 g, 0.1 mmol), $K_2Cr_2O_7$ (0.0143 g, 0.05 mmol) and 10 mL deionized water in the ratio of 1:1:0.5:5555 for 3 days at 150 °C followed by slow cooling to room temperature over an 8 hour period produced block-like dark-red crystals of **1** in about 30% yield and an unidentified brown powder. Reactions which attempted to form a single phase were not successful. When the ratio of $K_2Cr_2O_7$:$Cu(NO_3)_2{\cdot}3H_2O$ was reduced from 0.5:1 to 0.25–0.125:1, only an orange solution resulted. Column-like pink crystals were collected after evaporation of this solution. The structure of these crystal was determined to be $[H_2\text{-}4,4'\text{-bpy}]Cr_2O_7$.[17]

‡ *Crystal data* for **1**: $Cu(4,4'\text{-bpy})_{1.5}Cr_2O_7{\cdot}H_2O$, MW = 531.83, monoclinic, space group $P2_1/c$ (No. 15), a = 8.176(2), b = 14.718(3), c = 15.952(3) Å, Z = 4, V = 1880.4 Å^3, D_c = 1.879 g cm^{-3}, crystal size 0.15 × 0.15 × 0.10 mm, μ(Mo-Kα) = 2.306 mm^{-1}. The intensity data were collected with an Enraf-Nonius CAD4 diffractometer using graphite-monochromated Mo-Kα radiation (λ = 0.71073 Å). 3687 unique reflections of which 2240 with $I > 2\sigma(I)$; $R_1[I > 2\sigma(I)]$ = 0.0538, wR_2 (all data) = 0.0883, GOF = 1.182. The structure was solved by direct methods (SHELXS-86) and refined by full-matrix least-squares methods (SHELXL-97). All non-hydrogen atoms were refined anisotropically. CCDC 159168. Received (in Cambridge, UK) 7th March 2001, Accepted 1st May 2001
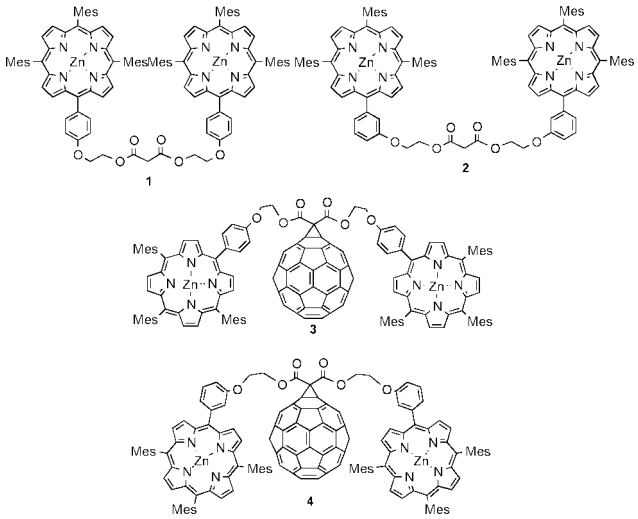
First published as an Advance Article on the web 22nd May 2001

Complexation of ZnP-C_{60}-ZnP triads with diazabicyclooctane (DABCO) leads to rigid assemblies that display considerably prolonged charge-separated states.

Control over the separation, specific alignment and composition in donor–acceptor assemblies at a molecular level is a formidable task, especially in artificial reaction centres. Meaningful incentives can be lent from the organisation-principle in the bacterial photosynthetic reaction centre:[1] the different light- and redox-active components are embedded *via* noncovalent interactions into a protein matrix. In principal, biomimetic methodologies, such as hydrogen-bonding, donor–acceptor complexation, electrostatic interactions and π–π stacking, guarantee the control over modulating the composition and, simultaneously, achieving well-defined and rigid architectures, with high directionality and selectivity.[2]

In the present communication we wish to present a simplistic but powerful means to regulate donor–acceptor separations and orientations. Successively, rigid, confined model ensembles are self-assembled, starting from a flexible **ZnP-C_{60}-ZnP** system and DABCO.[3,4] The newly formed tetrads undergo, upon photoexcitation, efficient energy and electron transfer in toluene and *o*-dichlorobenzene solutions, respectively.

We selected for the current investigation the strongly fluorescing zinc tetraphenyl porphyrin (**ZnP**) chromophore as a photo-sensitive marker to monitor the extent of excited state interaction with the adjacent fullerene core. The porphyrinic precursors **1** and **2** were synthesised using a statistical approach,



starting with pyrrole and the corresponding benzaldehydes and subsequent reaction with malonyl chloride. In the final step, attachment to C_{60} was achieved *via* modified Bingel-conditions.[4a]

New compounds **1**–**4** were completely characterised (see ESI†). The two different substitutional patterns of the phenyl-linkages (*i.e. para vs. meta*) were chosen to control possible orientations between the fullerene and porphyrin chromophores.

At first the porphyrin's emission in **3** and **4** was recorded in a variety of solvents and compared to that of a **ZnP-ZnP** reference (**1**). Most importantly, the *para*- and *meta*-linked **ZnP-C_{60}-ZnP** systems both gave rise to a fairly strong emission quenching of the ZnP chromophore with fluorescence quantum yields (Φ) on the order of 0.001 (see Table 1). Although the solvent polarity differs quite substantially the emission intensity changed only marginally. For reference the emission quantum yield (Φ) of **3** in toluene and also in *o*-dichlorobenzene is about 0.04.

The anisotropy of the fullerene surface, as it prevails in the well-ordered but alternating assembly of electron rich hexagons with electron deficient pentagons, generally gives rise to marked 'through-space' interactions.[5] Thus, when structurally possible, fullerene-based ensembles adopt conformations in which the fullerene and the donor moieties come in close proximity, from which we hypothesise that the rapid deactivation of the ^{1}*ZnP state in **3** and **4** implies a rate-determining transition to form the electron transfer mediating 'intramolecular exciplex'.

In general a more efficient quenching (~ two-fold) was noted for the *meta*- (**4**) relative to the more electron-rich *para*-linked derivatives (**3**). A possible interpretation for this evidently solvent-independent outcome relates to the different substitution pattern given on the phenyl ring and the subsequent impact that stems from an electronic interaction with the fullerene core.‡ The *meta*-isomer is clearly more susceptible to interactions between the fullerene core and the porphyrin moiety. In line with this purely structural assumption is the observation that a weakly emitting transition around 800 nm was found only for the *meta*-linked **ZnP-C_{60}-ZnP** (**4**) in toluene. This NIR emission originates from a charge transfer state, despite its quantitative cancellation in stronger polar solvents, such as THF, *o*-dichlorobenzene and benzonitrile.

Time-resolved transient absorption spectroscopy was conducted to probe the fate of the photoexcited ZnP chromophore and to inspect the identity of the resulting products. In

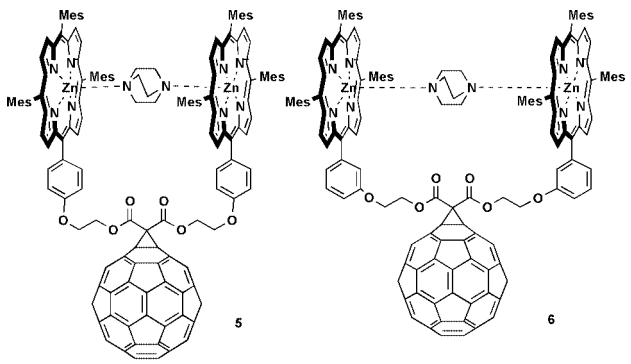
particular, the instantaneously formed ZnP singlet–singlet absorption, which is in reference **1** subject to a slow intersystem crossing (2.5 ns) to the triplet excited state, decays rather rapidly (~100 ps) following the completion of the short laser pulse in **3** and **4** (18 ps; 532 nm). Furthermore, this fast deactivation is coupled with a synchronously occurring grow-in of a new transient absorption, which in all solvents revealed a set of VIS and NIR maxima at ~650 and 1030 nm, respectively.[5] These features resemble the spectral fingerprints of the one-electron oxidised ZnP and the one-electron reduced fullerene, respectively. From this we conclude that the resulting $ZnP^{\bullet+}$–$C_{60}^{\bullet-}$ radical pair is formed *via* a photoinduced electron transfer from the ZnP singlet excited state to the electron accepting fullerene. The charge-separated state, formed with moderate quantum yields, decayed on a time scale of a few hundred nanoseconds to regenerate the ground state.

Addition of DABCO to a toluene and *o*-dichlorobenzene solution of triads **3** and **4** led to a strong reactivation of the ZnP emission (Fig. 1 and Table 2). Taking the emission reactivation into account the ZnP in both tetrads disclose nearly the same fluorescence quantum yields. Parallel picosecond experiments, which indicate prolonged ^{1}*ZnP singlet lifetimes (~185 ps) in **5** and **6** compared with **3** (106 ps) and **4** (75 ps), further



corroborated the emission studies. Both effects can be rationalised in terms that complexation of DABCO to the vacant sites of the two ZnP (*i.e.* dz^2-orbitals)[3] increases the donor–acceptor separation considerably (*i.e.* triad *vs.* tetrad). The bridging motif with the monomeric compounds **5** and **6** was confirmed by molecular modelling using semi-empirical methods. The formation of coordination oligomers can be largely excluded since no dependence of the spectroscopic properties on the DABCO concentration was observed for 1.3×10^{-5} M solutions of **3** and **4**. The amplification of the emission between the triads and corresponding tetrads is less prominent in toluene (ε = 2.38) than in *o*-dichlorobenzene (ε = 9.93). To follow up on this issue, the pathway of ZnP deactivation was examined by revisiting the pico- and nanosecond experiments. In *o*-dichlorobenzene, the typical radical ion fingerprints, formed concurrently with the ^{1}*ZnP decay, unmistakably attest to an electron transfer mechanism.

On the contrary, the absorption features noted upon excitation of a toluene solution are fundamentally different. In fact, new broad absorption maxima at 360 and 720 nm are an exact match of the fullerene triplet features.[5] The above experiments, considered in concert, infer that a rapid intramolecular energy transfer, from the ^{1}*ZnP (2.06 eV) to the energetically lower lying ^{1}*C_{60} (1.79 eV),[5] prevails in toluene with a quantum yield of 0.57. This is then followed by an efficient *intersystem crossing* to generate the triplet excited state (1.50 eV)[5] with a unimolecular rate constant of 7.1×10^8 s^{-1}. The energy transfer pathway in **5** and **6** is in sharp contrast to the excited state behaviour seen for **3** and **4**, disclosing even in toluene the spectral characteristics of the $ZnP^{\bullet+}$-$C_{60}^{\bullet-}$ radical pair.

The forward electron transfer is, however, not the only parameter affected by the increased donor–acceptor separation (*i.e.* triad *vs.* tetrad): in addition, markedly higher quantum yields (Φ) and longer lifetimes (τ) of the $ZnP^{\bullet+}$–$C_{60}^{\bullet-}$ radical pair were noted. Interestingly, the back electron transfer dynamics in **5** and **6** gives rise to approximately the same rate constant of 1.3×10^6 and 1.4×10^6 s^{-1}, respectively, reflecting the nearly equal donor–acceptor separations in these rigid systems.

In conclusion, we have shown by spectroscopic and photochemical means that a simple complexation of DABCO to a series of flexible **ZnP-C_{60}-ZnP** triads, and thereby affording the corresponding tetrads, is a powerful tool to control the design and photophysical properties of rigidly, confined donor–acceptor systems.§

Notes and references

‡ Further support for this difference can be deduced from the ground state absorption spectra, which in the case of the *meta*-substituted isomer reveals a marked red-shift of the *Soret*- and *Q*-band transitions (*e.g.*, in toluene 550 → 552 nm; 588 → 590 nm).

Some mechanistic observations on the borohydride mediated reductive cyclisation of tosylhydrazones

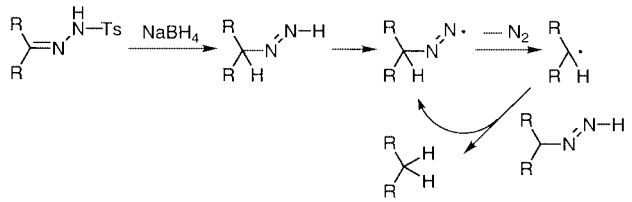
Luis D. Miranda[a] and Samir Z. Zard*[ab]

[a] *Institut de Chimie des Substances Naturelles, CNRS, 91198 Gif-Sur-Yvette, France. E-mail: zard@icns.cnrs-gif.fr*
[b] *Laboratoire de Synthèse Organique associé au CNRS Ecole Polytechnique, 91128 Palaiseau, France*

Received (in Cambridge, UK) 30th January 2001, Accepted 27th March 2001
First published as an Advance Article on the web 22nd May 2001

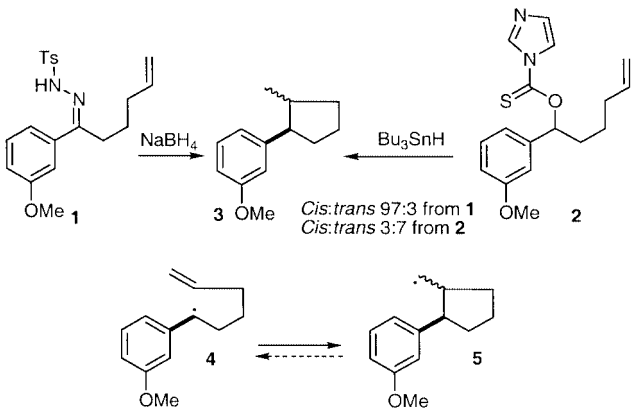
The previously described, highly stereoselective ring-closure of δ-unsaturated tosylhydrazones upon reduction with borohydride may not be a radical process but rather an ene-type concerted transformation of the intermediate mono-substituted diimide.

Reduction with borohydride of tosylhydrazones derived from ketones may lead to the formation of radical species through loss of molecular nitrogen as shown in Scheme 1.[1] Various other related and important transformations such as the reduction of diazonium salts,[2] the Wolff–Kishner reaction,[3] the Wharton rearrangement,[4] sometimes proceed through a similar radical pathway.



Scheme 1

In a pioneering study in this area, Taber and colleagues[5] described a remarkably diastereoselective cyclisation reaction starting with hydrazone **1** (Scheme 2). This transformation was presumed to involve ring closure of a benzyl type radical **4**, and the unusually high diastereoselectivity (97:3) was ascribed to the non-reversibility of the cyclisation step under these specific conditions. The corresponding tributylstannane mediated ring-closure starting from the imidazole thiocarbamate derivative **2** is much less stereoselective, leading to a 3:7 ratio of the same diastereoisomers **3**, and the possible reversibility of the ring-forming step was invoked as the cause of the erosion in selectivity. While reversible 5-*exo* cyclisations involving benzylic and other stabilised carbon centred radicals are known,[6] it seemed to us that the ring-opening, reverse step, must be too slow in this case to compete with hydrogen atom abstraction from the stannane by the primary radical **5**. In the present study, we adduce evidence indicating that the radical cyclisation is indeed irreversible under the stannane reduction conditions and that the cyclopentane formation in the case of the hydrazone precursor may in fact not be a radical process at all.

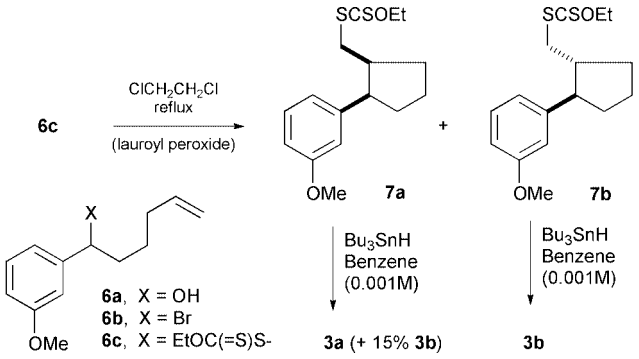


Scheme 2

Our approach hinges on the separate generation of the cyclised radical **5** and showing that this species does *not* undergo ring opening under dilute tributylstannane reduction conditions. This was accomplished by exploiting the properties of the xanthate transfer reaction.[7] In this case, the cyclised product is itself a xanthate and therefore allows the regeneration of the cyclised radical. The requisite starting xanthate **6c** was readily obtained in 66% overall yield by reacting crude bromide **6b**, itself derived from alcohol **6a**, with commercially available potassium *O*-ethyl xanthate. Heating this xanthate with a small amount of lauroyl peroxide in 1,2-dichloroethane (0.1 M) resulted in the smooth formation of cyclopentylmethyl xanthates **7a** and **7b** in a 3:7 ratio and in 78% combined yield (Scheme 3). It is interesting to note that the ratio of the *cis* and *trans* isomers did not change when the reaction was conducted at 1 M concentration. This is a first indication that the cyclisation is not so readily reversible under these conditions.

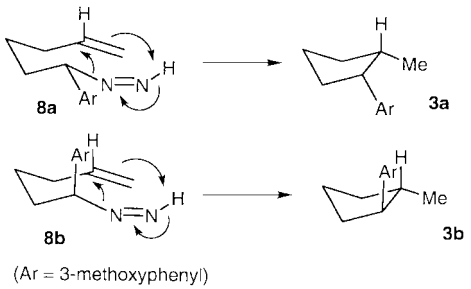
The two isomers could be separated using preparative thin-layer chromatography, albeit with some difficulty. Reductive dexanthylation of the pure *trans* isomer **7b** using tributylstannane in benzene at 0.001 M concentration gave the corresponding pure *trans* methyl cyclopentanes **3b** in 70% yield. Perhaps more importantly, exposure of an almost pure sample (95:5 *cis*:*trans*) of the thermodynamically less stable *cis* isomer **7a** to the same conditions gave methylcyclopentanes **3a** and **3b** in 85:15 ratio, *i.e. with only a very slight modification of the initial relative stereochemistry*. Clearly, under such highly dilute conditions, a roughly 3:7 mixture of the two diastereoisomers should have been obtained in both cases if the equilibrium between radicals **4** and **5** was fast in comparison to hydrogen atom abstraction from the stannane.

The above findings constitute strong evidence against the operation of a radical mechanism in the transformation of the tosylhydrazone depicted in Scheme 2. The high diastereoselectivity cannot be explained by a kinetically controlled,



Scheme 3

 DOI: 10.1039/b101053k



Scheme 4

irreversible radical ring closure. The radical cyclisation in such systems is inherently poorly diastereoselective: a similar 1 : 2.5 *cis* : *trans* ratio was recently reported by Studer,[8] who generated the analogous 1-phenylhex-5-enyl radical by heating the TEMPO derived precursor at 130 °C. Cyclisations involving non-stabilised secondary radicals also take place with a modest preference for the *trans* isomer.[9] The very high *cis*-selectivity observed by Taber and his colleagues in the present case is probably the result of an intramolecular, ene-type pericyclic process, as shown in Scheme 4. Placing the aryl group in the less hindered pseudo-equatorial position leads to the *cis* isomer. Such a concerted mechanism parallels that proposed for reductions with diimide itself,[10] the rigid, highly organised transition state being more consonant with the observed high *cis* selectivity. Thus, depending on the structure, the experimental conditions, and the eventual presence of initiators, monoalkyldimides (monoalkyldiazenes) may react by an ionic, a radical, or a concerted pericyclic-type mechanism. Whatever the exact mechanism operating in the present case, the observations of Taber and co-workers[3,5] will certainly have important consequences for organic synthesis.

A versatile synthesis of planar chiral ligands

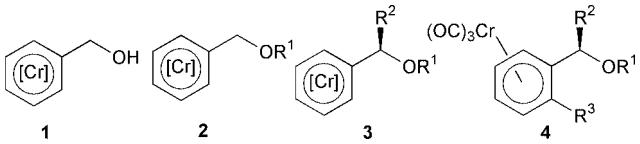
Susan E. Gibson (née Thomas)* and Hasim Ibrahim

Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS. E-mail: susan.gibson@kcl.ac.uk

Received (in Cambridge, UK) 4th April 2001, Accepted 25th April 2001
First published as an Advance Article on the web 22nd May 2001

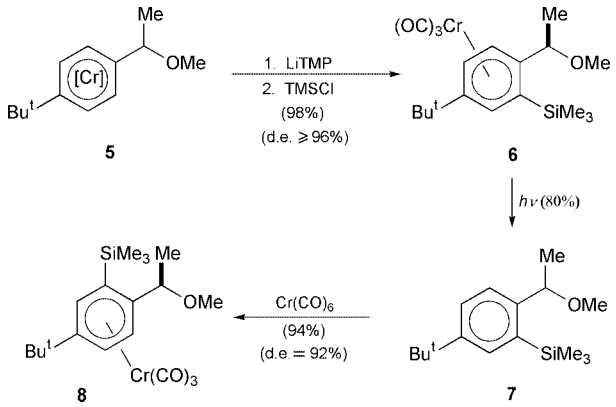
Introduction of a *p*-Bu^t substituent onto tricarbonylchromium(0) complexes of benzyl ethers facilitates clean and selective *ortho* functionalisation; this reactivity is the basis of a key step in a short and versatile synthesis of enantiomerically pure planar chiral complexes.

The potential of non-racemic chiral (arene)tricarbonylchromium(0) complexes as ligands in asymmetric catalysis has been recognised.[1] As a result, an increase in activity in this area in the last three years has led to the successful application of planar chiral (arene)tricarbonylchromium(0) complexes as catalyst ligands in a diverse range of transformations including rhodium-catalysed hydrogenation of ketones,[2] palladium-catalysed aminations of aryl bromides,[3] palladium-catalysed hydrovinylations of styrene,[4] rhodium-catalysed hydroborations of styrene,[5] palladium-catalysed allylic alkylations,[6] iridium-catalysed hydroaminations[7] and Lewis acid-catalysed Diels–Alder reactions.[8] It is acknowledged, however, that although a variety of different synthetic strategies exists for the preparation of planar chiral (arene)tricarbonylchromium(0) complexes, there is still a need for more general approaches that allow the efficient preparation of a greater number of complexes.[1] We recently demonstrated that tricarbonylchromium(0) complexes of benzyl ethers, **2**, which are readily available from (benzyl alcohol)tricarbonylchromium(0) **1** could be asymmetrically functionalised to give complexes **3** in high yield and ee using chiral base methodology.[9] In view of the current interest in planar chirality and the flexibility and efficiency of our route to **3**, we wanted to convert the central chirality of **3** into complexes with planar chirality, represented by **4**. We report herein how we achieved this goal and in doing so provided the foundations of a novel and versatile route to non-racemic planar chiral (arene)tricarbonylchromium(0) complexes.



1 **2** **3** **4**

In contrast to the highly selective deprotonation–electrophilic quench chemistry to tricarbonylchromium(0) complexes of derivatives of α-methylbenzylamine,[10–12] deprotonation and subsequent electrophilic quenching of tricarbonylchromium(0) complexes of benzyl ethers is known to be unselective using the bases Bu^{n}Li,[10] Bu^{s}Li[11] and Bu^{t}Li,[11,12] giving rise to mixtures containing *inter alia* products of ring deprotonation and benzylic deprotonation. Our attempts to deprotonate **3a** (R^1 = R^2 = Me) with LiTMP and quench with chlorotrimethylsilane under a wide range of conditions also gave messy mixtures containing *ortho, meta* and *para* silylated products derived from uncontrolled ring deprotonation. Our attention then turned to the novel complex **5**,† synthesised initially in racemic form by thermolysis of the corresponding benzyl ether with hexacarbonylchromium(0) (97%). It was anticipated that the *p*-Bu^t substituent on **5** would direct deprotonation–electrophilic quench to the desired *ortho* positions of the ether. On reaction with LiTMP followed by a chlorotrimethylsilane quench, we were delighted to isolate the *ortho* silylated product **6** in 98% yield (Scheme 1). The ^{1}H NMR spectrum of **6** indicated that



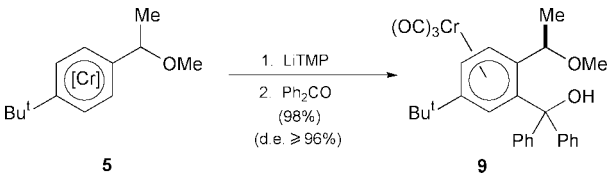
5 **6** **8** **7**

Scheme 1

only one diastereomer had been generated. To confirm that this was the case, the tricarbonylchromium(0) unit was removed from **6** to give **7** which was subsequently heated with hexacarbonylchromium(0) to give a 24:1 mixture of diastereomers **8** and **6**. Re-examination of the ^{1}H NMR spectrum of **6** established the absense of diastereomer **8** and hence the diastereoselectivity for the conversion of **5** to **6** is ≥96%.

In view of the highly selective introduction of a trimethylsilyl group into complex **5**, we decided to investigate the introduction of substituents which would provide useful donor atoms to metals. Deprotonation of **5** with LiTMP followed by addition of benzophenone gave the *ortho*-substituted product **9** in 98% yield (Scheme 2). The relative stereochemistries of the trimethylsilyl isomers **6** and **8** and the hydroxy complex **9** were initially assigned using the model developed for tricarbonylchromium(0) complexes of α-methylbenzylamine derivatives.[10–12] An X-ray crystallographic analysis of **9**[13] revealed that these assignments were correct and that co-ordination of the base to the ether oxygen plays a crucial role in the observed diastereoselectivity. Introduction of a sulfur-containing group was demonstrated on the ethyl ether complex **10**. Reaction of **10** with LiTMP followed by diphenyl disulfide gave complex **11** in 57% yield and ≥96% de (Scheme 3).

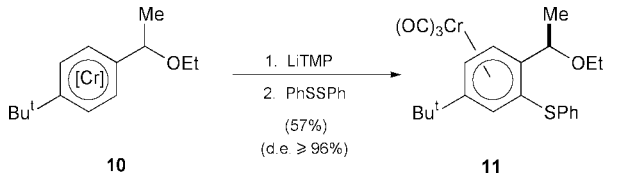
Having demonstrated that *ortho* substituents could be introduced into the *p*-Bu^t substituted complexes **5** and **10** in good yield and with high diastereoselectivity, we turned our attention to synthesising complexes of type **4** in enantiomerically pure form. Complex (4-*tert*-butylbenzyl alcohol)tricarbonylchromium(0), **12** [synthesised in 97% yield from the commercially available alcohol and hexacarbonylchromium(0)] was reacted with acidic methanol to give complex **13** in 97% yield (Scheme 4). (It is of note that the *p*-Bu^t substituent not



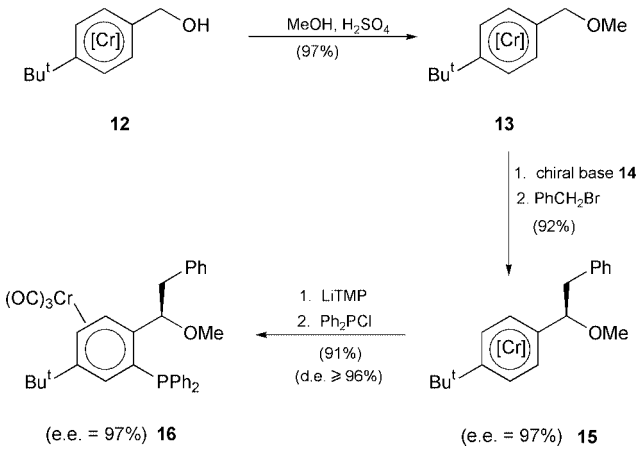
5 **9**

Scheme 2

 DOI: 10.1039/b103058m

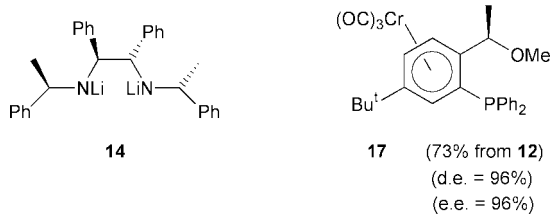


Scheme 3



Scheme 4

only gives rise to the excellent selectivity described herein, but it also confers a high degree of stability and crystallinity on its (arene)tricarbonylchromium(0) complexes.) Subsequent treatment of **13** with chiral base **14** followed by benzyl bromide gave complex **15** in 92% yield and 97% ee (as determined by chiral



HPLC analysis). The absolute stereochemistry of **15** was assigned as *R* based on results obtained in our previous studies using chiral base **14** and benzyl ether complexes lacking the *p*-Bu^t substitutent.[9] Finally deprotonation of **15** with LiTMP followed by addition of Ph_2PCl gave complex **16** in 91% yield, ⩾96% de and 97% ee. A similar three-step sequence created complex **17** in 96% ee and ⩾96% de in 73% overall yield from complex **12**.

In conclusion, we have demonstrated that the introduction of a *p*-Bu^t substituent onto tricarbonylchromium(0) complexes of benzyl ethers enables them to be cleanly and selectively functionalised at the *ortho*-position for the first time. This new mode of reactivity has enabled us to convert readily-available (4-*tert*-butylbenzyl alcohol)tricarbonylchromium(0), **12**, into enantiomerically pure planar chiral complexes **16** and **17** in three steps. As each step involves the introduction of a new substituent, this sequence constitutes a very versatile synthesis of planar chiral complexes, many of which have potential as ligands in asymmetric synthesis.

The authors thank King's College London for a studentship (H. I.).

Reactions of linear triplatinum complexes, *linear*-[Pt_3(μ-dpmp)$_2$(RNC)$_2$](PF$_6$)$_2$ (1), with excess tetracyanoethylene (tcne) afford the novel nitrene-bridged asymmetrical A-frame triplatinum complexes, [Pt_3(μ-dpmp)$_2$(μ-$C_{12}N_8$)(RNC)$_2$](PF$_6$)$_2$ (2a: R = 2,6-xylyl; 2b: R = 2,4,6-mesityl, dpmp = bis(diphenylphosphinomethyl)phenylphosphine), in which two tcne molecules are coupled to form a (heptacyanocyclopent-1-enyl)nitrene moiety.

Studies on organic reactions promoted by multinuclear metal centres are directly implicated in the development of industrial heterogeneous catalysts and could lead to metal–surface mimetic chemistry.[1] Multimetallic systems have the potential to organize different types of reaction processes in synergetic fashion into new homogeneous reactions which are not established by mononuclear metal centres. Recently, we have reported the linearly ordered, side-by-side triplatinum complex, *linear*-[Pt_3(μ-dpmp)$_2$(RNC)$_2$](PF$_6$)$_2$ **1a** (R = xylyl (Xyl)), which reacted with H^+, NO^+, electron-deficient alkynes and *p*-nitrophenyl isocyanide, affording asymmetrical and double A-frame triplatinum clusters through their oxidative insertion into the Pt–Pt single bonds.[2,3] Here, we have examined reactions of **1** (R = Xyl, mesityl (Mes)) with a strongly electron-deficient olefin, tetracyanoethylene (tcne), and have successfully isolated and characterized the novel, nitrene-bridged triplatinum complexes, [Pt_3(μ-dpmp)$_2$(μ-$C_{12}N_8$)(RNC)$_2$](PF$_6$)$_2$, in which two tcne molecules are coupled to form a (heptacyanocyclopent-1-enyl)nitrene moiety.

Complex **1a** readily reacts with excess of tetracyanoethylene (tcne) to afford pale green crystals formulated as [Pt_3(μ-dpmp)$_2$(μ-$C_{12}N_8$)(XylNC)$_2$](PF$_6$)$_2$ **2a** in high yield.‡ Similar reaction of **1b** also gave [Pt_3(μ-dpmp)$_2$(μ-$C_{12}N_8$)(MesNC)$_2$](PF$_6$)$_2$ **2b** in 38% yield. The IR and ^{1}H NMR spectra of **2** indicated the presence of two terminal isocyanide ligands, and the ^{31}P{^{1}H} NMR spectra exhibited three multiplets with ^{195}Pt satellite peaks in a 1 : 1 : 1 ratio. The detailed structure of **2a** was determined by X-ray crystallographic analysis and an ORTEP plot for the complex cation is illustrated in Fig. 1.§ The complex cation involves an asymmetrical triplatinum core supported by two dpmp ligands. The Pt(1)–Pt(2) distance of 2.6446(8) Å corresponds to a Pt–Pt single bond, and the Pt(2)–Pt(3) separation of 3.2150(8) Å is indicative of the absence of a Pt–Pt bond. The two tcne molecules are coupled to form a (heptacyanocyclopent-1-enyl)nitrene moiety which is inserted into one of the Pt–Pt bonds of **1a** (Scheme 1). Structurally characterized nitrene-bridged platinum and palladium complexes are extremely rare[4] in spite of their importance as metal–surface nitrene intermediates in the metal-catalyzed reduction of NO and nitro compounds and, to our knowledge, this is the first example of a trinuclear platinum complex with a nitrene-bridging ligand. The N(11) atom rather asymmetrically bridges Pt(2) and Pt(3) and adopts a planar sp^2 geometry with the sum of the bond angles being 359.9°. The Pt_2N plane is almost co-planar with the [C(11)C(12)] olefin unit and the relatively short N(11)–C(11) bond length indicates that the electron density on the N atom is delocalized through a p_π–p_π interaction between the nitrene and olefin units as shown in Scheme 1. The C(11)–C(12) bond length is longer than that of a usual C–C double bond. A similar tendency was observed in [Ir_2(CO)$_2$(μ-dppm)$_2$(μ-NPh)][5] and [Rh_2(CO)$_2$(dppm)$_2$(μ-N(*p*-$NO_2C_6H_4$))][6] (dppm = bis(diphenylphosphino)methane). The heptacyanocyclopent-1-enyl moiety adopts an envelop conformation with the C(14) atom in the apex site and the C(13), C(14) and C(15) atoms having sp^3 tetrahedral configuration. The present type of tcne cyclic dimerization is very rare; the only related compound reported is *N*-(heptacyanocyclopent-1-enyl)triphenylphosphoranimine which was formed by reaction of tcne with triphenylphosphine.[7]

The cyclic dimerization of tcne did not proceed by the dppm-bridged diplatinum complex, [Pt_2(μ-dppm)$_2$(XylNC)$_2$](PF$_6$)$_2$,[8] although it proceeded rapidly with the triplatinum complex **1a**; the reaction was monitored by electronic absorption spectral change with an isosbestic point at 345 nm. The reaction with excess of tcne (> 10 equiv.) proceeded with a first order dependency on the starting complex **1a** with the pseudo-first order rate constant of 4.0×10^{-3} s^{-1}. Whereas no stable intermediate was observed, the tcne adduct **A** might be formed at the initial step by analogy with the reaction of **1a** with electron-deficient alkynes (Scheme 1).[3] The strong *trans* influence of the Pt–Pt bond may cause the zwitterionic Pt–C bond breaking (**B**), together with the nucleophilic attack of the

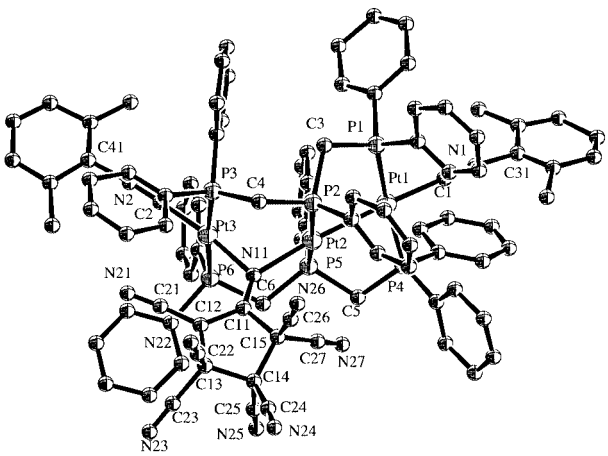

Fig. 1 ORTEP diagram for the complex cation of **2a**. ‡ To 20 mL of dichloromethane solution containing 71 mg of *linear*-[Pt_3(μ-dpmp)$_2$(XylNC)$_2$](PF_6)$_2$ was added 37 mg of tcne (0.29 mmol). The reaction solution was stirred at room temperature for 1 h, and the color of the solution immediately changed from orange to pale green. The solvent was removed under reduced pressure and the residue was washed with benzene and diethyl ether; it was then extracted with 20 mL of dichloromethane. The solution was concentrated to *ca.* 10 mL and was kept in a refrigerator after the addition of a small amount of Et_2O to afford block-shaped pale green crystals of [Pt_3(μ-dpmp)$_2$(μ-$C_{12}N_8$)(XylNC)$_2$](PF_6)$_2$ **2a** in 86% yield. Anal. Calc. for $C_{94}H_{76}N_{10}P_8F_{12}Pt_3$: C, 46.91; H, 3.18; N, 5.82. Found: C, 46.67; H, 3.30; N, 5.54%. IR (Nujol/cm^{-1}): 2189, 2168 (XylN≡C), 1571 (C=C), 840 (PF_6). UV–Vis (CH_2Cl_2): λ_{max}/nm (log ε) 404 (3.22). ^{1}H NMR (C_2Cl_2): δ 1.34, 1.98 (s, *o*-Me, 6H), 2.9–5.5 (m, CH_2, 8H), 6.1–8.8 (m, Ar, 56H). ^{31}P{^{1}H} NMR (CD_2Cl_2): δ −5.7 (m, 1P, $^1J_{PtP}$ 2450 Hz), 0.2 (m, 1P, $^1J_{PtP}$ 2906 Hz), 6.1 (m, 1P, $^1J_{PtP}$ 2556 Hz). Recrystallization of **2a** from a acetone–diethyl ether mixed solvent yielded block-shaped crystals of **2a**·$(CH_3)_2CO$ which were suitable for X-ray crystallography.

A similar procedure using *linear*-[Pt_3(μ-dpmp)$_2$(MesNC)$_2$](PF_6)$_2$ **1b** (62 mg) afforded pale green crystals of [Pt_3(μ-dpmp)$_2$(μ-$C_{12}N_8$)(MesNC)$_2$](PF_6)$_2$·CH_2Cl_2 (**2b**·CH_2Cl_2) in 38% yield. Anal. Calc. for $C_{97}H_{82}N_{10}P_8F_{12}Cl_2Pt_3$: C, 46.24; H, 3.28; N, 5.56. Found: C, 46.48; H, 3.08; N, 5.70%. Complex **1b** was prepared by the reaction of **1a** with MesNC and was characterized by X-ray crystallography, which will be reported elsewhere. IR (Nujol/cm^{-1}): 2186, 2169 (MesN≡C), 1573 (C=C), 838 (PF_6). UV–Vis (in CH_2Cl_2): λ_{max}/nm (log ε) 391 (3.37). ^{1}H NMR (CD_2Cl_2): δ 1.28, 1.90 (s, *o*-Me, 6H), 2.06, 2.20 (s, *p*-Me, 3H), 3.4–5.2 (m, CH_2, 8H), 6.2–8.6 (m, Ar, 54H). ^{31}P{^{1}H} NMR (in CD_2Cl_2): δ −7.3 (m, 1P, $^1J_{PtP}$ 2514 Hz), −1.6 (m, 1P, $^1J_{PtP}$ 2926 Hz), 4.2 (m, 1P, $^1J_{PtP}$ 2571 Hz).

§ *Crystal data* for **2a**·$(CH_3)_2CO$: $C_{97}H_{82}N_{10}OP_8F_{12}Pt_3$, M = 2464.82, T = −118 °C, monoclinic, space group $P2_1/c$, a = 13.872(4), b = 53.155(12), c = 15.130(4) Å, β = 97.90(2)°, V = 11 050(4) Å^3, Z = 4. A pale yellow, block-shaped crystal was fixed on the top of a glass fiber with Paraton N oil. 14381 reflections ($4 < 2\theta < 45°$) were measured on a Rigaku AFC7R diffractometer with graphite monochromated Mo-Kα radiation. The structure was solved by Patterson methods using the program DIRDIF94 and was refined with SHELXL-93 to R_1 = 0.068 for 10081 independent reflections with $I > 2\sigma(I)$ and wR_2 = 0.227 for all data.

First published as an Advance Article on the web 22nd May

Complete elimination of Mn^{3+} dissolution from a $LiMn_2O_4$ spinel compound at 60 °C has been achieved by enclosing each particle with a $LiMn_{2-x}Co_xO_4$ solid-solution thin film having a high Co concentration at the surface.

$LiMn_2O_4$ cathode materials have received much attention due to their environmental friendliness and low cost compared to $LiCoO_2$ and $LiNiO_2$. However, their practical applications as Li-ion cells are hindered by structural instability from acidic HF attack on the spinel particles, as a result of the reaction of the $LiPF_6$ salt with residual water in the cell at elevated temperatures.[1–4] This leads to a disproportionation reaction ($2Mn^{3+} \rightarrow Mn^{4+} + Mn^{2+}$) at the particle surface, resulting in the formation of a defective spinel. The reaction moves progressively inward with increasing exposure to the electrolyte, especially at elevated temperatures. This reduces the intercalation capacity, and therefore should be prevented to ensure long-cycle life for elevated-temperature performance. To reduce such inherent structural degradation, a marginal increase in the overall Mn valence to above +3.5 has been reported.[5–9] However, such methods do not significantly improve the structural stability since a fraction of Mn^{3+} ions still exist in the spinel structure. The most effective way to block Mn dissolution is to completely encapsulate the spinel particles with oxides that are resistant to acidic HF. There have been several attempts to minimize Mn dissolution, but none have blocked the dissolution completely. Such studies even showed a deterioration in cathode-cycle performance compared to unmodified samples or decreased capacity fading during cycling at 55 °C.[10–12]

Here, we report a low-temperature coating method using Co_3O_4, and its effect on the cycling performance at 60 °C in Li/$LiMn_2O_4$ cells. This new approach completely blocks Mn dissolution from the $LiMn_2O_4$ particles.

$LiMn_2O_4$ powder 'bare sample' was prepared by firing a stoichiometric mixture of MnO_2 (EMD) and $LiOH{\cdot}H_2O$ at 750 °C for 20 h. The powder, with an average particle size of 13 μm after sieving, was used for coating and for the electrochemical experiments. To coat each particle with the solution of Co_3O_4, cobalt(III) acetate was first dissolved in methanol, then slowly mixed until it reached the appropriate viscosity. The solution was then mixed with the $LiMn_2O_4$ powder in a mole ratio of 10:1 (Mn:Co). The coated powder was dried at 150 °C for 1 h, and then fired at 400 °C for 8 h in a dry-air atmosphere. The electrochemical cycling experiments were carried out at 60 °C with coin-type cells (size 2016) containing a $LiMn_2O_4$ spinel electrode, a Li metal anode, a microporous polyethylene separator, and an electrolyte consisting of a 1 M $LiPF_6$ solution in a 1:1 EC–DMC mixture (by volume). To fabricate the cathode, the spinel powder was blended with Super-P carbon black (to assist in current collection) and with a polyvinylidene fluoride (PVDF) binder in a mass ratio of 92:4:4.

X-Ray diffraction (XRD) patterns of the bare- and coated-$LiMn_2O_4$ powders were indexed to cubic spinel (*Fd*3*m*). The Co_3O_4-coated sample shows no indication of Co_3O_4 or other phases, except for increased peak broadening compared to the bare sample (Fig. 1). This broadening may be due to the formation of a disordered spinel phase throughout the particle, with decreasing Co concentration inward. Raman spectroscopy of the coated sample clearly showed the presence of a Co_3O_4 phase (peak at 693 cm^{-1}), and electron-probe microanalysis

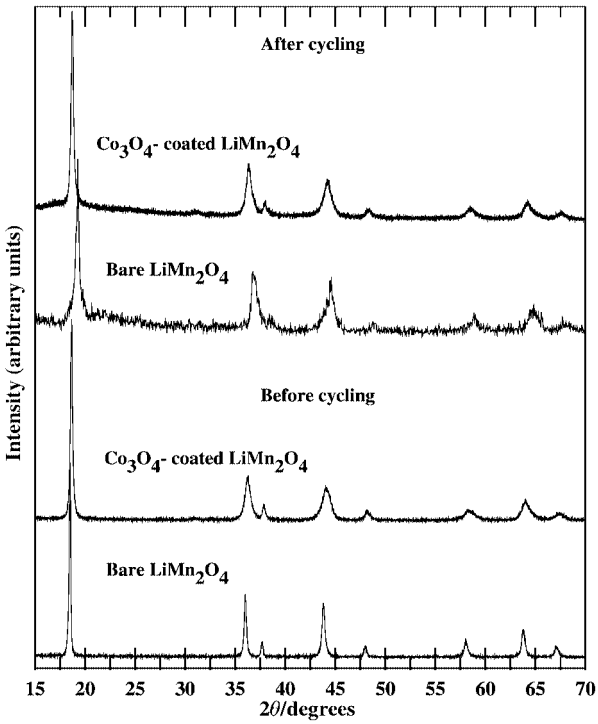

Fig. 1 XRD patterns of bare and Co_3O_4-coated $LiMn_2O_4$ powders before and after cycling.

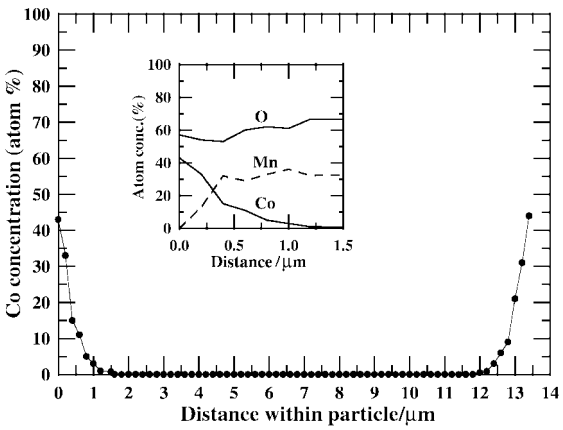

Fig. 2 EPMA of Co concentration across a particle cross-section; the inset corresponds to elemental analysis of the particle within 1.5 μm.

 DOI: 10.1039/b101677f

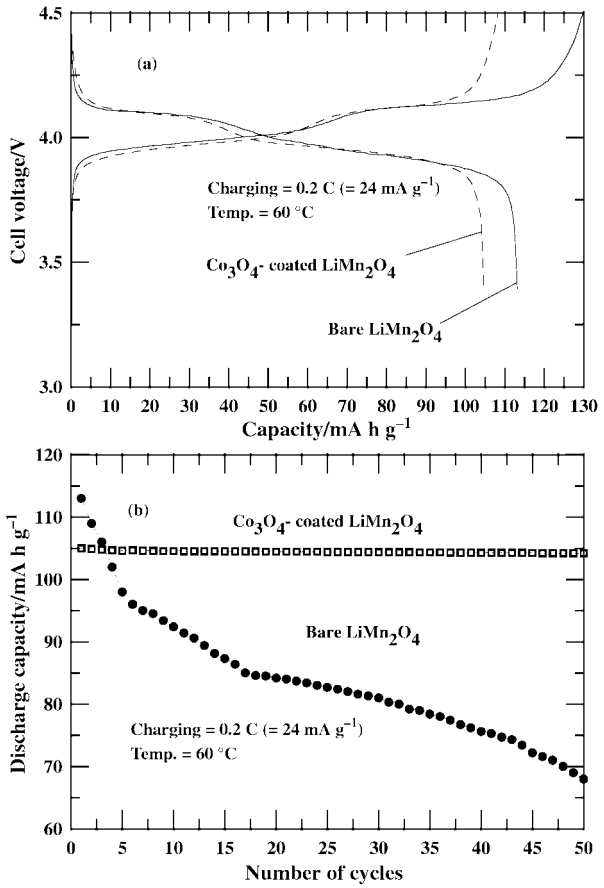

Fig. 3 Plots of (a) voltage profile of bare and Co_3O_4-coated $LiMn_2O_4$ at a charging rate of 0.2 C between 4.5 and 3.4 V, and (b) cycle-life performance of bare and Co_3O_4-coated $LiMn_2O_4$ at a charging rate of 0.2 C between 4.5 and 3.4 V. The coin-type half cells were cycled at 60 °C with a Li-metal anode

(EPMA) of the Co atoms across the particle shows a 43% Co concentration at the surface, as shown in Fig. 2, which is consistent with the Raman data. In addition, Co atoms were mainly distributed within *ca*. 1 μm from the surface, and their concentration sharply decreased further inside the particle. Results indicate the formation of a solid-solution $Li_zMn_{2-x}Co_xO_4$ thin-film phase near the surface by interdiffusion between $LiMn_2O_4$ and Co_3O_4. However, some portion of the unreacted Co_3O_4 resides on the solid solution. It is expected that the coating of each particle with $Li_zMn_{2-x}Co_xO_4$ and Co_3O_4 thin-film coatings, which are resistant to HF attack, can prevent Mn dissolution into the electrolyte.

All spinel compounds with a defective cubic structure have lattice constants smaller than the well-ordered $LiMn_2O_4$ phase, because of the higher concentration of the relatively large Mn^{3+} ion (ionic radii of Mn^{3+} and of Mn^{4+} are, respectively, 0.65 and 0.53 Å).[13] Therefore, from the XRD pattern, all the spinels within the $LiMn_2O_4$–$Li_4Mn_5O_{12}$–λ-MnO_2 tie-line-triangle in the Li–Mn–O phase diagram will have diffraction peaks that lie to higher 2θ values than those of $LiMn_2O_4$. This feature can be seen in the XRD patterns of the spinel electrodes after cycling at 60 °C and after equilibration at 3.4 V for 50 h (Fig. 1). They show a shift in the spinel peaks to higher 2θ values (a = 8.122 ± 0.003 Å), accompanied by peak broadening (the lattice constant of the bare sample before cycling is 8.234 ± 0.005 Å). This shows that the starting $LiMn_2O_4$ spinel becomes defective during cycling at 60 °C. However, the coated sample does not show any peak shift (a = 8.178 ± 0.005 Å) or peak broadening after cycling.

The cycling behavior of bare- and coated-$LiMn_2O_4$ materials was tested in coin-type half-cells using Li metal as the anode between 4.5 and 3.3 V at a rate of 0.2 C (= 24 mA g^{-1}) at 60 °C. Fig. 3 shows the initial voltage profiles of the samples. The discharge capacity of the coated sample was 105 mA h g^{-1}, while that of the bare sample was 113 mA h g^{-1}. The decreased irreversible capacity upon coating, 3 mA h g^{-1} *vs.* 17 mA h g^{-1} in the bare sample, is significant. Furthermore, there is negligible capacity loss in the coated sample over 50 cycles, while that of the bare sample shows a 41% loss. It is believed that surface encapsulation by both Co_3O_4 and $Li_zMn_{2-x}Co_xO_4$ prevents Mn dissolution from HF attack at 60 °C.

The enumeration of structures for γ-alumina based on a defective spinel structure

Graeme W. Watson[a] and David J. Willock*[b]

Received (in Cambridge, UK) 27th February 2001, Accepted 20th April 2001
First published as an Advance Article on the web 22nd May 2001

Atomistic potential calculations of the relative energies of γ-alumina structures as a function of tetrahedral Al distribution give an exhaustive list of configurations which is used to estimate thermodynamic probabilities, subsequent relaxations allow the influence of configurational entropy on structure to be assessed.

γ-Alumina finds widespread use as a stable, highly porous medium for the support of active catalysts such as particulate transition metals. The material is formed on dehydration of the hydroxide boehmite and is the stable form of alumina from this route between 750 and 1025 K.[1] The structure is generally regarded as amorphous although it is known that the oxygen anions form an fcc lattice with Al ions occupying both octahedral and tetrahedral sites. The cubic structure resembles a defective spinel in which both tetrahedral and octahedral cation positions are occupied. In the proper spinel structure, $MgAl_2O_4$, Al^{3+} ions appear in half the octahedral holes and Mg^{2+} in 1/8 of the tetrahedral holes. Various experiments have attempted to apportion the Al cations in γ-alumina between the two possible sites. In 1991 X-ray and neutron diffraction were combined to give lattice parameters for the cubic cell.[2] The line widths of specific reflections were used to suggest that the Al tetrahedral sub-lattice is extremely disordered and that the distribution of Al between tetrahedral and octahedral sites was roughly 50 : 50, although the assignment of the occupancy ratio was difficult as no reflections from the octahedral sub-lattice alone are present in the diffraction pattern. More recently, ^{27}Al MAS NMR has been used to show that 70 ± 2% of Al ions occupy octahedral sites.[3] This is close to the proportion that would be expected for a spinel structure in which all octahedral Al are in place and the tetrahedral sites are partially occupied to give 75% of cations in an octahedral environment. Here, we show that this simplified model of the structure allows the calculation of the lattice energy for all possible arrangements of tetrahedral Al in the simplest stoichiometric unit cell using atomistic potentials. Furthermore the structures of the most thermodynamically stable lattices can be geometry optimised to allow thermally averaged structural data such as the lattice constants to be estimated.

Aluminas in general are based around close packed arrangements of O^{2-} anions with Al^{3+} occupying octahedral and/or tetrahedral holes. α-Alumina has the corundum structure with a hexagonal close packed arrangement of anions and exclusively octahedral cations. The α-polymorph has been widely studied using both atomistic potential and periodic quantum chemical approaches. The θ-alumina structure is based on a face centred cubic packing of anions similar to the γ-phase[4] and contains both octahedral and tetrahedral aluminium ions. Based on these two ordered structures new potentials for octahedral and tetrahedral aluminium were fitted using the GULP program[5] starting from the shell model potentials derived for α-alumina by Lewis and Catlow.[6] The full procedure used in fitting and the resulting parameter set will appear at a later date. We note here that the new potentials are able to reproduce the experimental lattice constants of the two phases used in fitting to within 0.15 Å.

A unit cell of overall stiochiometry Al_2O_3 in the spinel form requires a supercell of at least three basic spinel cells ($Al_{64}O_{96}$) which we produce by extension of the *c*-vector. Recently Allan *et al.*[7] have used a sampling technique to consider the configurational entropy for the mixed oxide MnO/MgO and find convergence with supercells containing only 32 atoms; accordingly, we expect this cell to be sufficiently large to avoid artifacts due to cell size affects. In this cell we have 24 possible tetrahedral Al sites to be filled by 16 atoms. The total number of possible distinguishable structures is simply $^{24}C_{16}$ = 735 471. Using an EV5 DEC alpha workstation a single lattice energy calculation for this supercell using GULP takes approximately 1.2 CPU seconds and so the complete set of structures can be assessed in a little over ten days. The amount of data generated would, however, require a considerable amount of computer storage and so to make these calculations feasible we have developed an automated driving program. All that is stored after each of the initial runs is the binary code and the lattice energy. The binary code is formulated so that each tetrahedral site in the structure is assigned a binary digit that is set to 1 for occupancy by Al and 0 for a vacant site. In the current study a 24-bit number uniquely identifies a configuration and is saved as an integer. The program generates all possible configurations simply by counting through all 24-bit integers and generating an input file for those which have 16 bits set to 1. As they are identified the lattice energy is calculated and both input and output files are replaced by the next configuration.

Our procedure gives an exhaustive list of tetrahedral Al occupancies and the corresponding lattice energies for the structure fixed at the standard spinel geometry. The resulting configurations were grouped according to calculated lattice energy and the number of configurations *vs.* lattice energy is shown in Fig. 1. Here we have calculated the lattice energy per mole of Al_2O_3 formula units: the lowest energy configuration was found to be unique together with the number of configuration peaks at around 200 kJ mol^{-1} higher energy where some 55 000 structures have similar energies. Since we store the code for each structure we can easily regenerate a configuration of interest. For example, we find that the lowest energy structures have a uniform distribution of tetrahedral Al atoms whereas the

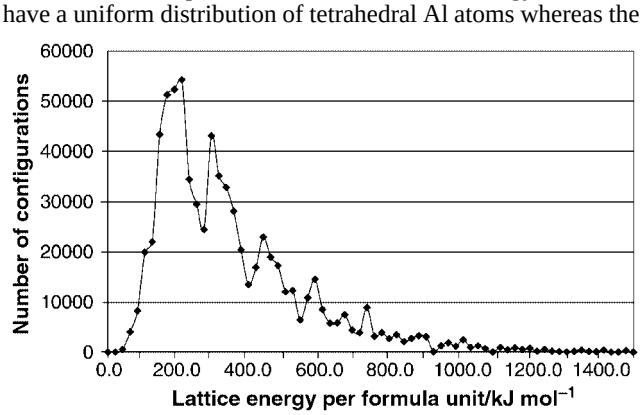

Fig. 1 The number of configurations as a function of calculated lattice energy. Structures are grouped in intervals of 21.1 kJ mol^{-1}.

 DOI: 10.1039/b101877a

highest energy structures have the occupied tetrahedral sites clustered together and one third of the unit cell contains no tetrahedral Al atoms. This calculation also gives us direct access to the partition function for the tetrahedral site distributions allowing the calculation of thermodynamic probabilities. For example, the probability, $P(\Delta E_i)$, of a given lattice energy is:

$$P(\Delta E_i) = \frac{n_i \exp\left(-\frac{\Delta E_i}{RT}\right)}{\Sigma_j n_j \exp\left(-\frac{\Delta E_j}{RT}\right)} \quad (1)$$

where n_i is the number of structures with energy ΔE_i greater than the lowest energy structure. Since γ-alumina is formed from boehmite at elevated temperatures we chose T = 900 K. Even at this high temperature the few low energy structures dominate despite the entropic factor in favour of higher energy states.

In these initial calculations no geometry optimisation was allowed so that all possible structures could be considered. It is well known that structural relaxation can be important in obtaining accurate relative energies using atomistic simulation. In this case the occupation of an Mg^{2+} tetrahedral site by a smaller Al^{3+} cation will cause lattice strain. Despite this we expect the ordering of the structural energies to be a good indication of which are the important structures to consider. Accordingly we carried out relaxations on the most probable of the lattices generated. The list of structures was ordered according to lattice energy and the program adapted to reconstruct them from the list and carry out lattice relaxations using GULP. To determine how far down the list to proceed the thermodynamic probability of each structure was calculated from eqn. (1) (with n_i = 1) using the recorded static lattice energy. Sub-sets of structures were generated by successively decreasing the acceptance probability limit. Geometry optimisations were performed using the same automated procedure as described previously but now the GULP input file was written to perform relaxations at constant pressure, *i.e.* a full relaxation of all atomic co-ordinates and lattice vectors.

Fig. 2 shows the probability distribution of lattice energies at 900 K after relaxations for three sub-sets containing increasing numbers of structures in roughly 50 000 steps. The distribution shows significant differences for the change from 78 137 to 129 205 structures but the addition of a further 50 000 structures results in only minor alterations suggesting that most of the additional structures do not optimise to thermodynamically accessible configurations. There are now two degenerate lowest energy structures. These are found in the smallest list and remain the minima for the longer lists indicating that the initial ordering by structural energy has allowed the minimum energy structure to be identified rapidly. After relaxation the number of

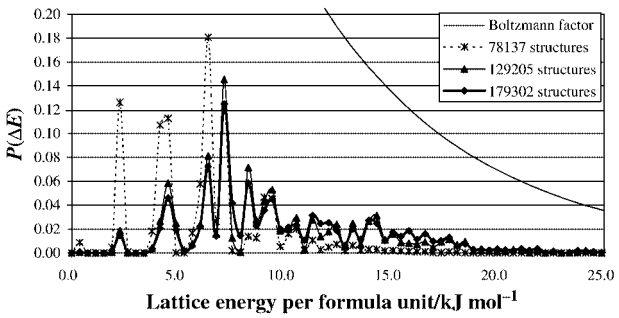

Fig. 2 Probability *vs.* lattice energy from eqn. (1) at 900 K with structural relaxation taken into account for three sub-sets containing 78 137 (crosses, dotted), 129 205 (triangles, thin solid) and 179 302 (diamonds, thick solid) structures. Boltzmann factor shown as a feint line. Structures grouped in 0.38 kJ mol^{-1} intervals.

Table 1 Comparison of calculated and experimental lattice vectors

	Number	*a*/Å	*b*/Å	*c*/Å
Expt. $MgAl_2O$[8]		8.080	8.080	8.080
Expt. γ-alumina[2]		7.911	7.911	7.911
Min. energy structure	1	8.277	8.245	8.203
Thermal average[a]	78 137	8.251	8.251	8.269
	129 205	8.254	8.254	8.271
	179 302	8.254	8.254	8.278

[a] Thermal averages use eqn. (1) with T = 900 K.

structures within a few kJ mol^{-1} of the minimum is much greater than for the simple structural energy calculations and so the entropic effect of tetrahedral ion configurations is much greater. The probability of the lowest energy structures is extremely small and the probability distribution shows a great many structures with configurations up to 20 kJ mol^{-1} above the minimum being significant. The highest peak in $P(\Delta E_i)$ occurs at 7.2 kJ mol^{-1} and represents some 12 200 structural alternatives.

After relaxation the lattice parameters were also recorded for each configuration to allow the lattice vectors, *a*, *b* and *c*, to be calculated as thermodynamic averages of the relaxed structures. Based on the sub-sets of relaxed structures from Fig. 2 we find the lattice parameters given in Table 1 where we also compare the averaged data to experimental results and to one of the minimum energy structures. The other degenerate minimum energy form is identical to that in Table 1 with *a* and *b* interchanged. These minima structures show a distortion away from cubic symmetry. On averaging this is reduced to a small tetragonal distortion of the basic unit cell. The convergence of the cell dimensions with sub-set size is further confirmation that all thermodynamically significant configurations have been taken into account.

Early investigations of γ-alumina reported tetragonal distortions of the unit cell.[9] It appears from these calculations that the observed symmetry comes about from the interplay of many possible configurations of cations. Closer inspection of the listed data shows that the individual microstates occur in pairs with equivalent distortions in the *a* and *b* directions, in the averaging process these are removed to give the experimentally observed cubic structure. In the real crystallites this tendency toward distortion will lead to lattice strain which may contribute to the longer scale defect structure of the material.

This research was funded, in part, through an EPSRC IMI project, a collaboration between chemists, materials scientists and chemical engineers from academia and industry, involving Cardiff, Birmingham, Cambridge and Glasgow Universities with financial support from Synetix, Johnson Matthey, BP-Amoco, Cambridge Reactor Design and Molecular Simulations Inc.

Simple paper chromatography using brine as an eluent affords the two enantiomers of metallo-supramolecular triple-helicates. The technique may be scaled up for preparative resolution by using cellulose columns in conventional column chromatography.

We have recently described a facile route for assembly of metallo-supramolecular architectures from inexpensive commercial reagents.[1–3] One of the architectural motifs that we have prepared through this technology is a class of metallo-supramolecular helicates[1] that have a cylindrical architecture of similar dimensions to protein binding units that target the major groove of DNA.[2] Excitingly these synthetic tetracationic units also recognise the major groove of DNA and induce remarkable structural effects, wrapping up double-stranded DNA in an intramolecular fashion.[2] Such structural effects are unprecedented with synthetic DNA binders. Being helical, these supramolecular cylinders exist in two enantiomeric forms and we have been keen to resolve these as we anticipated that the DNA-binding of the two enantiomers might be quite different. There has been considerable recent interest in the resolution of metal complexes, much of which centres around resolution of DNA-binding metal polypyridyl complexes. The main techniques traditionally employed involve the use of chiral anions either to achieve diastereoselective crystallisation or as a component of a chiral chromatographic mobile phase.[4,5] Similar methods have also been applied to some polypyridyl and benzimidazole based metallo-helicates.[4,6]

We have attempted diastereoselective crystallisations of our supramolecular cylinders with a range of chiral anions without success. Chromatographic techniques have proved a little more successful, with some resolution being achieved on SP Sephadex C25 with aqueous disodium (−)-*O*,*O*′-dibenzoyl-(L)-tartrate solution as the mobile phase.[7] The deep purple colour of the bis iron(II) cylinder (arising from an MLCT transition) makes it very easy to follow by eye under chromatographic conditions. Although some resolution is apparent, passing these supramolecular cylinders down Sephadex columns did not lead to the formation of two discrete bands even after multiple cycles. Instead a broad, streaked band was obtained, the front and back of which contained enantio-excesses of the two respective helical isomers. Changing to other chiral anions (*e.g.* sodium *d*-antimonyltartrate, (*S*)-(+)-1,1′-binaphthyl-2,2′-diyl hydrogenphosphate) or to the other enantiomer of the chiral dibenzoyl tartrate anion did not seem to offer further improvement. Frustrated with these conventional chromatographic techniques, we considered whether DNA itself might be used to separate the two enantiomers. To use DNA as a stationary separation phase, we impregnated chromatographic paper with DNA following a previously outlined procedure,[8] and then added a racemic mixture of the di-iron cylinders. Washing the paper with ethanol afforded a solution containing an enantio-excess of one of the isomers (as evidenced by a strong CD spectrum). Solutions containing an excess of the other enantiomer could be obtained by extended washing of the residue with ethanol. Alternatively the DNA-impregnated paper could be used for chromatography using 0.16 M aqueous sodium acetate solution (pH 6.90) as eluent. This led to a spot remaining fixed to the baseline and a spot moving up the plate (associated with some streaking). Washing these two spots off the paper with ethanol gave solutions with opposite CD spectra. However, the solutions obtained from the DNA-impregnated paper technique showed an instability towards hydrolysis (as evidenced by the loss of the MLCT absorption signal over a period of hours), not observed with pure solutions of the compound, indicating that the procedure had introduced some reactive impurities.

Since paper itself is chiral (being essentially a cellulose derived product) we decided to examine whether the chiral fibres in paper might themselves be capable of affording separation. The compound was spotted onto Whatman 3MM CHR chromatography paper, and paper chromatography conducted with brine (aqueous 20 mM NaCl solution) as the eluent. To our surprise and delight the purple product split beautifully into two distinct spots as shown in Fig. 1. Washing the spots from the paper (with saturated aqueous sodium chloride followed by addition of ethanol) afforded solutions with opposite CD spectra (Fig. 2). The UV-Vis absorption and mass spectra of the solutions are identical, confirming that the chromatography is affording two enantiomers and not two otherwise alternate species. The solutions obtained by this method show no evidence of hydrolytic instability. This separation technique has been scaled up to allow preparative separation simply by using commercially available cellulose particles (~20 micron; Aldrich) as the stationary phase in a column and this allows ready resolution of the di-iron and di-nickel triple helical complexes.[9]

A survey of the chiral separation literature (Chirbase) seeking examples of metal complexes being separated on paper or cellulose, revealed that Dwyer and Sargeson[10] had used a

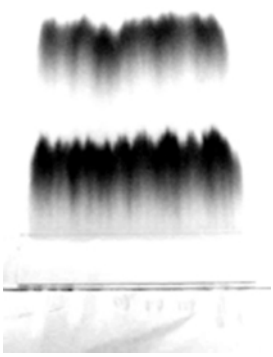

Fig. 1 Photograph of a paper chromatograph of the di-iron triple helical complex on Whatman 3MM CHR paper using 20 mM aqueous NaCl solution as the eluent.

 DOI: 10.1039/b101970h

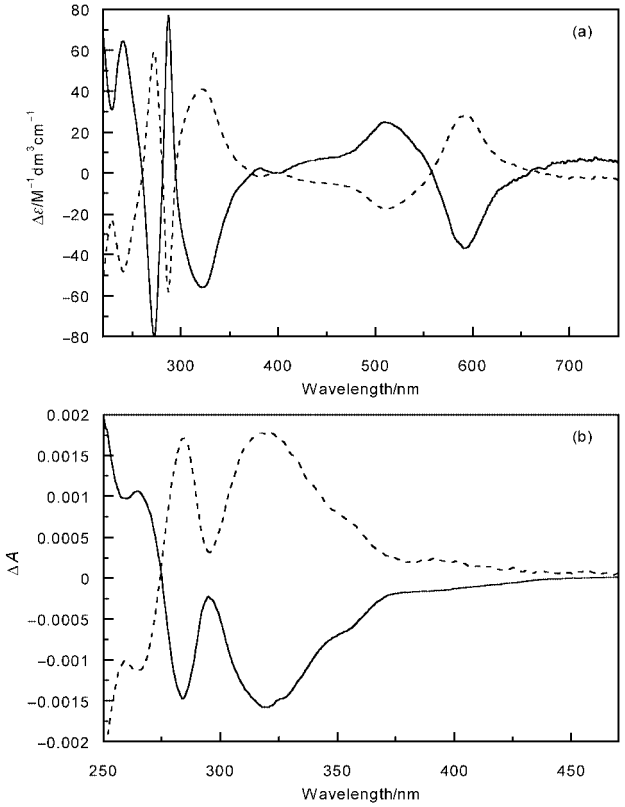

Fig. 2 CD spectra of the two bands eluted from the column for (a) the iron(II) complex ($\Delta\varepsilon$ determined using ε_{545} = 14000; The retention of one compound is significantly greater than the other and so the concentration of the eluted sample is lower for the retained enantiomer) and (b) the nickel(II) complex.

similar technique in 1963 to separate *diastereo*-isomers of cobalt(III) complexes with propane-1,2-diamine ligands but the technique does not subsequently appear to have been widely applied to the separation of enantiomeric metal complexes, although resolution of ruthenium polypyridyls on HPLC columns containing silica modified with cellulose derivatives has recently been described.[11]

We have shown that simple paper chromatography is a powerful method of separating the two enantiomers of our metallo-supramolecular helical cylinders, and that this can be extended to preparative scale resolution using cellulose columns. We are currently investigating the application of this technique to other metal complexes and other metallo-supramolecular architectures, and also investigating the DNA-binding of our resolved cylinders.

Ti–Pt intermetallic compound catalysts more active than Pt for hydrogen dissociation and ethylene hydrogenation

Takayuki Komatsu,* Daigo Satoh and Ayumu Onda

Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152-8550, Japan. E-mail: komatsu@chem.titech.ac.jp

Received (in Cambridge, UK) 14th March 2001, Accepted 30th April 2001
First published as an Advance Article on the web 25th May 2001

The intermetallic compound, $TiPt_3$, showed much higher catalytic activity than pure Pt catalyst for H_2–D_2 equilibration and ethylene hydrogenation, whereas Ti_3Pt only catalyzed the former reaction with a similar activity to $TiPt_3$.

Intermetallic compounds (IMCs) have unique crystal structures different from those of the component metals. However, the catalytic properties of IMCs have been scarcely studied except for those of so-called hydrogen storage alloys.[1] We have already reported unique catalytic selectivities of some IMCs, such as Co–Ge,[2] Pt–Ge[3,4] and Ni–Sn[5,6] compounds, in hydrogenation and dehydrogenation reactions. For example, Pt_3Ge gives butenes with high selectivity in the hydrogenation of buta-1,3-diene.[3] However, the activity of the above IMCs is always much lower than that of the pure metals, Co, Pt and Ni, because of their very low activity for the dissociation of hydrogen. For example, H_2–D_2 equilibration proceeds on Pt at 298 K, whereas a higher temperature of 523 K is necessary for Pt_3Ge to obtain a similar reaction rate.[3] The low activity of IMC catalysts probably results from their surface structure, that is, the active transition metal atoms are separated by the other element, *e.g.* Ge and Sn, which are almost inert towards the hydrogen dissociation reaction. However, IMCs between two transition metal elements might be expected to be active catalysts for reactions with hydrogen. In this study, we examined the catalytic activity of Ti–Pt IMCs for H_2–D_2 equilibration and the hydrogenation of ethylene and found that they had much higher activity than pure Pt catalyst.

IMC catalysts were prepared by arc melting a mixture of titanium (Soekawa Chemical, 99.9%) and platinum (Tanaka Kikinzoku, 99.95%) under an argon atmosphere. The resultant ingots were crushed in air and filtered into particles with diameters below 25 μm. Powders of pure Ti (Nilaco, 99.98%) and pure Pt (Nilaco, 99.98%) were also filtered into particles with similar diameters. The crystal structure of the IMCs was identified by powder X-ray diffraction (Rigaku, RINT 2400). Single-phase crystals of $TiPt_3$ and Ti_3Pt IMCs were obtained from mixtures with Ti/Pt atomic ratios of 1:3 and 3:1, respectively. The crystallinity of the TiPt IMC obtained from the mixture with Ti:Pt = 1 was not as good as those of $TiPt_3$ and Ti_3Pt. Therefore, we only examined the catalytic properties of $TiPt_3$ and Ti_3Pt as IMC catalysts. H_2–D_2 equilibration was carried out with a glass flow and circulation system connected with a quadrupole mass spectrometer (Spectra International, MICROVISION). Before each reaction, the catalyst was pretreated 'reduced' with flowing hydrogen at a specific temperature for 1 h and evacuated at 298 K for 10 min. A mixture of H_2 (6.6 kPa) and D_2 (6.6 kPa) was then circulated through the catalyst at the reaction temperature of 195 K and the formation of HD was monitored by mass spectrometry. Hydrogenation of ethylene was carried out with the same reaction apparatus. After the same pretreatment of the catalysts, a mixture of ethylene (2.7 kPa) and H_2 (13 kPa) was circulated through the catalyst at the reaction temperature of 251 K. The total pressure was monitored to measure the extent of reaction.

To measure the catalytic activity for the dissociation of hydrogen, the H_2–D_2 equilibration was carried out on $TiPt_3$, Ti_3Pt, Pt and Ti. Fig. 1 shows the fraction of HD in hydrogen as a function of reaction time. On Pt powder catalyst reduced at 573 K, the fraction of HD gradually increased with reaction time. When Pt was reduced at 873 K, the rate of HD formation drastically decreased owing to the agglomeration of the fine powder. It is clear that the surface of the Pt powder is reduced at 573 K and that metallic Pt catalyzed the dissociation of hydrogen at 195 K. On the other hand, Ti powder reduced at 573–1173 K did not catalyze hydrogen dissociation, probably because Ti is not reduced even at 1173 K.

For $TiPt_3$ reduced at 873 K, the rate of HD formation was much higher than that on Pt. SEM images showed that the Pt powder reduced at 573 K consisted of particles with diameters of *ca.* 3–5 μm partially agglomerating to form lumps of 10–25 μm diameter. On the other hand, the reduced $TiPt_3$ consisted of particles with diameters of 10–25 μm. From these observations, the specific surface area of $TiPt_3$ must be lower than that of Pt. Therefore, it is concluded that $TiPt_3$ has higher activity towards hydrogen dissociation than pure Pt. The higher activity of IMC catalysts than their component metals has not previously been reported in the H_2–D_2 equilibration.[2,3,5] The reduction temperature affected the activity of $TiPt_3$ *i.e.* a lower reaction rate was observed when $TiPt_3$ was reduced at 573 or 1173 K. At 573 K, Ti atoms on the surface of $TiPt_3$ would not be reduced completely. XPS measurements would clarify the oxidation state of surface Ti atoms. At 1173 K, $TiPt_3$ particles agglomerated to form large lumps, resulting in lower activity.

The other IMC, Ti_3Pt, reduced at 873 K, also exhibited a higher rate of HD formation than Pt. Its activity was similar to that of $TiPt_3$ reduced at 873 K. It is clear that Ti_3Pt also has a higher activity than Pt towards the dissociation of hydrogen. For Pt–Ge[3] and Ni–Sn[5] IMCs, the activity for the H_2–D_2 equilibration decreases with a decrease in content of Pt and Ni *i.e.* PtGe

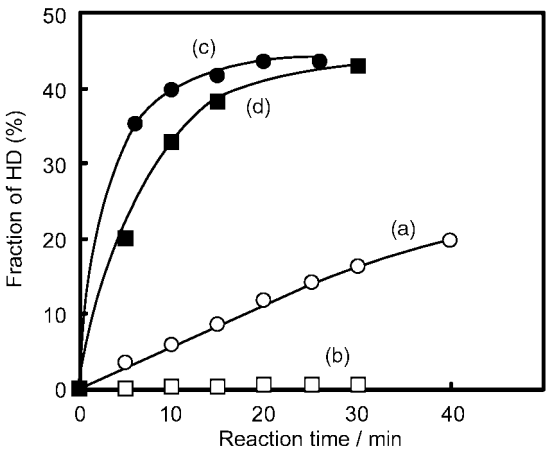

Fig. 1 H_2–D_2 equilibration at 195 K on Pt (a), Ti (b), $TiPt_3$ (c) and Ti_3Pt (d) reduced at 573 K (Pt), 873 K ($TiPt_3$ and Ti_3Pt) and 1173 K (Ti).

 DOI: 10.1039/b102415a

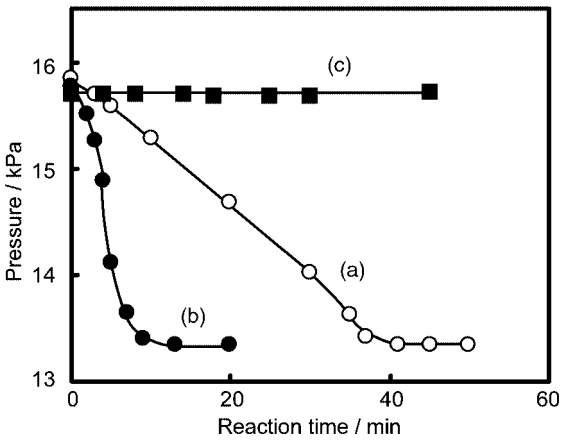

Fig. 2 Hydrogenation of ethylene at 251 K on Pt (a), $TiPt_3$ (b) and Ti_3Pt (c) reduced at 573 K (Pt) and 873 K ($TiPt_3$ and Ti_3Pt).

and Ni_3Sn_4 have much lower activity than Pt_3Ge and Ni_3Sn, respectively. Ge and Sn would retard the activity by reducing the number of adjacent Pt or Ni atoms. The comparable activity of Ti_3Pt to that of $TiPt_3$, which has a nine times larger Pt:Ti atomic ratio, suggests that a pair of Ti and Pt atoms constitutes an active site for the hydrogen dissociation. Reduction of Ti_3Pt at 573 and 1173 K resulted in low activity probably because of the same reasons as for $TiPt_3$.

On the basis of the above it is expected that $TiPt_3$ and Ti_3Pt would have higher activity than Pt for the hydrogenation of ethylene. Fig. 2 shows the change in total pressure with reaction time during the hydrogenation of ethylene at 251 K. On Pt reduced at 573 K, the pressure decreased with reaction time, indicating the consumption of hydrogen to form ethane and reached a steady state after 40 min of reaction. The decrease in pressure (*ca*. 2.5 kPa) suggests the complete conversion of ethylene into ethane. This was confirmed by gas-phase analysis with a gas chromatograph. On $TiPt_3$ reduced at 873 K, the pressure decreased more rapidly than that on Pt and gas-phase analysis revealed that the hydrogenation was complete in 10 min. This indicates that $TiPt_3$ has higher activity than Pt also for the hydrogenation of ethylene, as expected from its higher activity for the dissociation of hydrogen. On the other hand, Ti_3Pt reduced at 873 K did not catalyze the hydrogenation of ethylene at all, though it showed similar activity to $TiPt_3$ for the dissociation of hydrogen. In this case, Ti–Pt pair sites are not able to activate both ethylene and hydrogen.

The higher activity of Ti–Pt IMC catalysts than Pt suggests the possibility of other IMCs consisting of two transition metal elements of being highly active catalysts for hydrogenation and dehydrogenation reactions.

We gratefully thank Professor Takeyama for helping us to prepare the intermetallic compounds.

The title compound was synthesized by hydrothermal methods and characterized by single-crystal X-ray diffraction, which reveals an open-framework structure containing dumbbell-shaped windows with hydrophilic and hydrophobic characteristics.

Crystalline porous materials such as aluminosilicates (zeolites), aluminophsphates, pillared clays, and other layers are widely used in catalyst and separation applications.[1,2] Recently, coordination polymers and organic networks sustained by coordinated covalent bonds and directional noncovalent interactions have become a rapidly expanding field. However, a major challenge in the highly porous coordination materials is their fragility. Unlike zeolites, which are held together with rugged covalent bonds, their solid molecules are glued with relatively weak intermolecular forces. To date the number of coordination networks with new structural aspects is increasing,[3–16] but to our knowledge thermally stable network structures sustained by π–π interactions are still rare or lacking.

Using polyfunctional squarates as molecular building blocks, we and other groups have prepared compounds that exist as supramolecular networks in the solid state.[13–15] We have recently focused our attention on introducing noncovalent interactions for constructing new classes of zeolite analogues possessing hydrophilic and hydrophobic void characteristics. In this present work, we report a supramolecular complex, $[\{Co_2(C_{12}H_8N_2)_4(\mu\text{-}C_4O_4)(OH_2)_2\}C_4O_4]\cdot 8H_2O$ **1**, that adopts a neutral open-framework structure with one-dimensional channels containing disordered water molecules.

Hydrothermal reaction of Co_3O_4, squaric acid, and 1,10-phenanthroline (phen) in molar ratios at 1:3:2 at 200 °C for 96 h in water produced crystals of **1**.‡ The X-ray structure analysis of **1** reveals an extended structure composed of the building-block units (Fig. 1).§ The discrete dinuclear cations, two octahedrally coordinated cobalt(II) centers bridged by a squarate ligand, are alternately connected squarate anions *via* hydrogen bonds to form infinite chains, $[\cdots C_4O_4\cdots\{Co(OH_2)_2\text{–}C_4O_4\text{–}Co(OH_2)_2\}\cdots]_n$, incorporating phen ligands (Fig. 2 arrows). The interatomic O···O distances between the ligated waters and the oxygen atoms of squarates are in the range 2.63–2.65 Å indicative of strong hydrogen bonds. The strength of the interionic hydrogen bonds of *ca*. 40–190 kJ mol^{-1} makes for the construction of more robust framework structures.[17] The infinite chains are further held together by the natural tendency of π overlap in phen molecules yielding a planar sheet [Fig. 2(a)]. A significant feature is that the planar sheets are stacked in three dimensions to give 'sinuous' channels with a dimension (phen to phen distances) of nearly 12 × 7 Å, in which free water molecules fill the dumbbell-shaped voids [Fig. 2(b)]. Thermogravimetric analysis (TGA) reveals that the guest water molecules are liberated below 100 °C, a weight loss of 8.73% consistent with the loss of eight water molecules in the

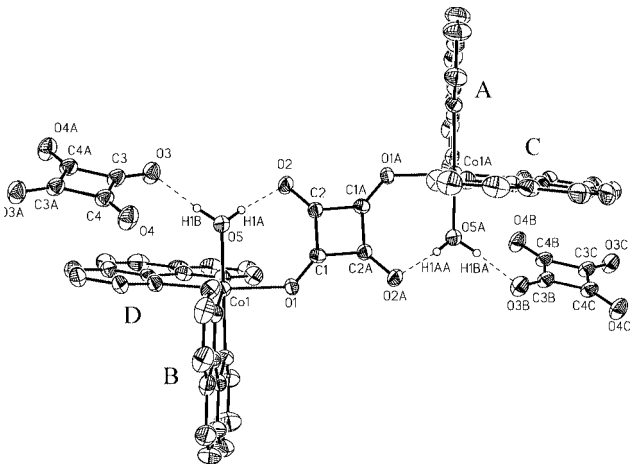

Fig. 1 ORTEP drawing of the building block units relating to the discrete μ-squarate-bridged cobalt(II) cations and squarate anions in **1** with thermal ellipsoids at 50% probability. A and B phen molecules induce the pair of in-planar-sheet π–π interactions while C and D induce the pair of out-of-planar-sheet π–π interactions. Selected bond distances (Å): Co(1)–O(5) 2.076(3), Co(1)–O(1) 2.118(2), C(1)–O(1) 1.256(4), C(2)–O(2) 1.252(4), C(3)–O(3) 1.261(4), C(4)–O(4) 1.257(4), O(5)–O(2) 2.649(3), O(5)–O(3) 2.634(3).

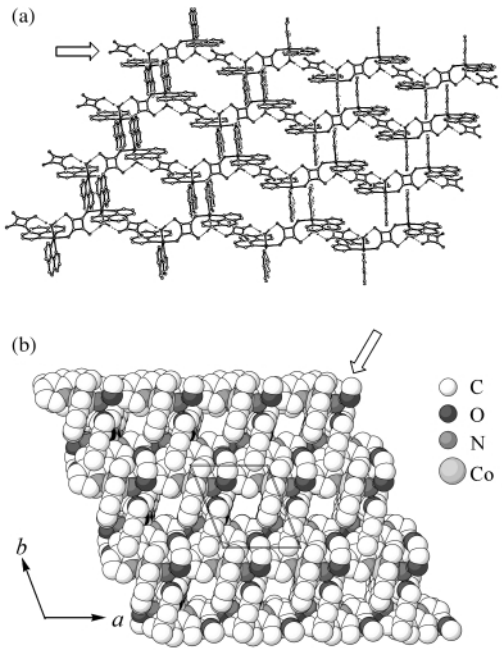

Fig. 2 (a) Ball-and-stick representation of the sheetlike network in **1**, showing the dumbbell-shaped windows (12 × 7 Å) with hydrophilic and hydrophobic characteristics; (b) perspective view of the open-framework structure containing one-dimensional channels along the crystallographic *c* axis. The arrows show the infinite hydrogen-bonding chains. Lattice water molecules are omitted for clarity.

† Electronic supplementary information (ESI) available: TGA curve for **1** and X-ray powder diffraction patterns. See http://www.rsc.org/suppdata/cc/b1/b100921o/

 DOI: 10.1039/b100921o

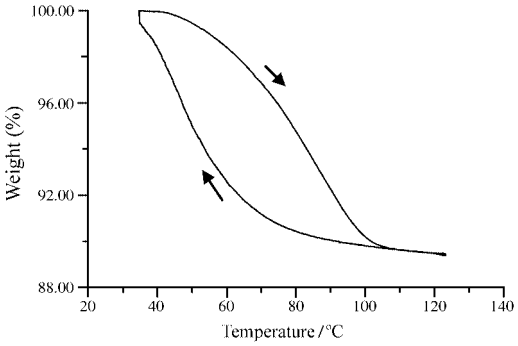

Fig. 3 TGA profile of a reversible N_2 adsorption–desorption cycle on **1**. The sample was initially heated at 120 °C for 0.5 h, cooled to 40 °C, maintained at 40 °C for 0.5 h, and then heated again to 120 °C.

channels. No weight loss was observed the temperature range 100–200 °C. The powder X-ray diffraction pattern of a sample heated to 200 °C for 2 h shows that the positions of the most intense lines remain unchanged relative to the simulated pattern based upon the single-crystal data. In order to examine the porous functionality of **1**, an N_2 adsorption–desorption study was conducted. Fig. 3 reveals a reversible N_2 adsorption–desorption cycle, which was confirmed by TGA with purified N_2 as the purging gas (2 atm). Besides demonstrating that the channel structure is retained throughout this process, this study also indicates that the cooperative π–π interactions are robust enough to sustain such an open space in crystals. Moreover, the most intriguing feature of the dumbbell-shaped windows is the presence of hydrophilic (the pendant C=O groups of squarates protrude into windows) and hydrophobic (phen groups) void characteristics that have a natural affinity for organic molecules. Further experiments to explore whether this nanoporous material can be filled by organic guests are in progress.[18]

The reaction of $Pr(NO_3)_3{\cdot}6H_2O$ with 4,4′-bipyridine *N,N′*-dioxide (L) and $K_3[M(CN)_6]$ [M = Fe^{III}, Co^{III}] gives isomorphous heteropolynuclear complexes with formula $[\{(H_2O)_5LPr–NC–M(CN)_5\}(\mu\text{-}L)]{\cdot}0.5L{\cdot}4H_2O$, which exhibit a novel supramolecular architecture created by the interplay of coordinative, hydrogen bonding and π–π stacking interactions.

The design of supramolecular polymetallic architectures with novel topologies of the spin carriers is of current interest in the field of molecular magnetism. A successful strategy leading to heteropolymetallic systems with extended structures consists in self-assembly processes involving anionic building-blocks (templates), which contain a paramagnetic ion, and assembling complex cations with potentially free coordination sites. Terminal cyano groups act as efficient bridging ligands, promoting strong ferro- or antiferro-magnetic interactions between adjacent metal ions.[1] The homoleptic cyanometalates, $[M(CN)_6]^{3-}$ (M = Cr^{III}, Fe^{III}),[2] and, recently, $[Mo^{III}(CN)_7]^{4-}$ and $[W(CN)_8]^{3-}$,[3,4] are among the most employed building-blocks and generate an extremely rich coordination chemistry.

In the past decade, a plethora of cyano-bridged bimetallic systems with interesting architectures and spectacular magnetic and photomagnetic properties have been characterized.[1–4] Most of these systems contain either two different 3d metal ions, or a 3d and a 4d/5d transition metal ion. In contrast, the lanthanide cations have been rarely used as nodes for the construction of cyano-bridged heteropolymetallic coordination networks. The following families of cyano-bridged lanthanide–transition metal complexes, exhibiting extended structures, have been obtained by using homoleptic cyanometalates as templates: (a) $LnM^{III}(CN)_6{\cdot}nH_2O$ (M^{III} = Cr^{III}, Fe^{III}, Co^{III}, Ru^{III}, Ir^{III});[5] (b) $KLnM^{II}(CN)_6{\cdot}nH_2O$ (M^{II} = Fe^{II}, Ru^{II});[6] (c) $Ln_2[M^{II}(CN)_4]_3{\cdot}nH_2O{\cdot}m$DMF ($M^{II}$ = Ni^{II}, Pd^{II}, Pt^{II});[7] (d) one-dimensional chain complexes with the general formula $[LnL_2(H_2O)_m\text{-}Fe^{III}(CN)_6]{\cdot}nH_2O$ (Ln = Gd, L = betaine, m = 3, n = 0;[8] Ln = Sm, L = dimethylacetamide, m = 4, n = 5[9]).

Very recently, Champness and coworkers have characterized interesting 2- and 3-D coordination framework polymers of Er^{III} and Sm^{III}, which have been obtained by using 4,4′-bipyridine *N,N′*-dioxide as a bridging ligand.[10] Surprisingly, in comparison with other divergent ligands (*e.g.* 4,4′-bipyridine), the potentialities of 4,4′-bipyridine *N,N′*-dioxide in the construction of coordination networks and crystal engineering have been little exploited.[11,12]

Aiming to combine the bridging ability of the cyano groups with that of 4,4′-bipyridine *N,N′*-dioxide (L), we have obtained two isomorphous heterometallic compounds, $[\{(H_2O)_5Pr–NC–M(CN)_5\}(\mu\text{-}L)L]{\cdot}0.5L{\cdot}4H_2O$ (M = Fe^{III}, **1**; Co^{III}, **2**), with a novel supramolecular architecture.

The two complexes were obtained by mixing aqueous solutions of $Pr(NO_3)_3$ and $K_3[M(CN)_6]$ (M = Fe, Co) with an ethanolic solution of 4,4′-bipyridine *N,N′*-dioxide.† FTIR spectra show characteristic bands of bridging and terminal cyano groups: 2144, 2065 cm^{-1} (**1**); 2142, 2076 cm^{-1} (**2**).

The crystal structures of **1** and **2** have been solved.‡ Since the cobalt derivative **2**§ is isomorphous with **1**, only the structure of the iron derivative **1** is described here. The supramolecular order at the nanometric scale of $[\{(H_2O)_5LPr–NC–Fe(CN)_5\}(\mu\text{-}L)]{\cdot}0.5L{\cdot}4H_2O$ is created by an interesting interplay of coordinative, hydrogen bonding and π–π stacking interactions. The structure can be described as being formed by $\{(H_2O)_5LPr–NC–Fe(CN)_5\}$ neutral binuclear entities, which are bridged by 4,4′-bipyridine *N,N′*-dioxide, resulting in infinite zigzag chains (Fig. 1). Within the binuclear moieties, the $[Fe(CN)_6]^{3-}$ anion acts as a monodentate ligand, that is, with one CN^- group coordinated to the praseodymium atom [Pr–N 2.636(2) Å]. The Fe–CN–Pr linkage is slightly angular [C–N–Pr 162.87(16)°], with a Fe···Pr distance of 5.664 Å. Three 4,4′-bipyridine *N,N′*-dioxide molecules are directly bonded to one Pr^{III} atom. Two form bridges between the praseodymium atoms, while the third acts as a terminal ligand. The Pr^{III} ion exhibits a coordination number of nine: eight oxygen atoms, arising from five aqua and three L ligands, and one nitrogen atom from the cyano bridge. The Pr–O distances vary between 2.406(1) and 2.518(1) Å. The praseodymium atoms are alternately 'bridged' through intra-chain hydrogen bonds involving uncoordinated 4,4′-bipyridine *N,N′*-dioxide molecules and the aqua ligands (Fig. 1). The distance between the triply 'bridged' praseodymium atoms (13.439 Å) is slightly shorter than that between the simply bridged atoms (13.937 Å).

The terminal organic ligands further extend the structure *via* π–π stacking interactions with identical terminal L ligands from adjacent zigzag chains, resulting in brick wall-like sheets (Fig. 2). The distances associated with the ligand-to-ligand π–π interactions are in the range 3.47–3.51 Å. The perfect face-to-face π-stacked alignment of the peripheral pyridyl *N*-oxide moieties of the terminal ligands is clearly favored by dipole–dipole interactions.[13] The uncoordinated 4,4′-bipyridine *N,N′*-dioxide molecules play a special role in increasing the dimensionality of the supramolecular architecture. Each uncoordinated molecule is simultaneously hydrogen bonded to four aqua ligands, two of these being coordinated to two adjacent praseodymium atoms in a chain, while the other two aqua ligands arise from another chain belonging to a neighboring brick wall sheet (Fig. 3).

The cryomagnetic properties of **1** have been investigated between 2 and 300 K. The value of $\chi_M T$ at room temperature (2.15 $cm^3\ mol^{-1}$ K) roughly corresponds to the expected value for an uncoupled low-spin Fe^{III}(S = ½)–Pr^{III}(J = 4) system.

 DOI: 10.1039/b101070k

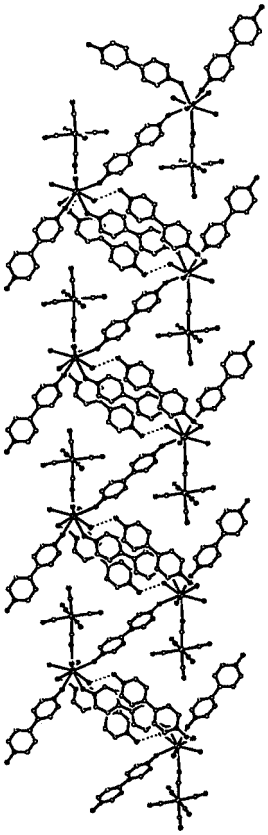

Fig. 1 Perspective view of a zigzag chain, also showing the uncoordinated 4,4′-bipyridine *N,N′*-dioxide molecules, which are hydrogen bonded to the aqua ligands coordinated to two praseodymium atoms. Along a chain, the praseodymium atoms are alternately simply and triply bridged (one genuine bridge and two $OH_2\cdots$4,4′-bipyridine *N,N′*-dioxide$\cdots H_2O$ 'bridges').

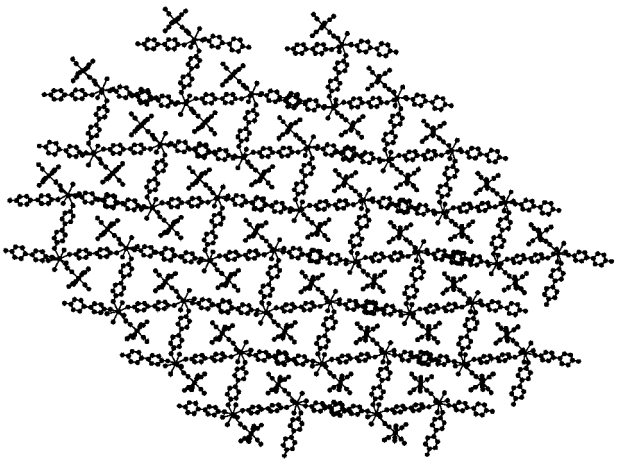

Fig. 2 Packing diagram of compound **1** showing the brick wall-like backbone resulting from π–π stacking interactions between the terminal ligands belonging to different chains. The uncoordinated 4,4′-bipyridine *N,N′*-dioxide molecules, as well as the crystallization water molecules, have been omitted.

The high temperature limit of $\chi_M T$ is calculated using the equation $(\chi_M T)_{HT} = (Ng_{Fe}^2\beta^2/3k)[S_{Fe}(S_{Fe} + 1)] + (Ng_{Pr}^2\beta^2/3k)[J_{Pr}(J_{Pr} + 1)]$, which gives $(\chi_M T)_{HT} = 1.98$ cm^3 mol^{-1} K. The difference between the experimental and calculated values is due to the intervention of the first-order orbital momentum associated with low-spin Fe^{III}. Upon lowering the temperature, $\chi_M T$ decreases continuously reaching 0.40 cm^3 mol^{-1} K at 2 K.

Since both Pr^{III} and low-spin Fe^{III} ions show a temperature dependence for $\chi_M T$,[14] this system is not appropriate for the accurate investigation of the 3d–4f magnetic interaction. However, these complexes open new perspectives to the magnetochemistry of 3d–4f cyano-bridged systems. Further work on similar compounds, especially on those containing Cr^{III} and Gd^{III} ions, both without orbital contributions to the magnetic susceptibility, is in progress and will be presented in subsequent papers.

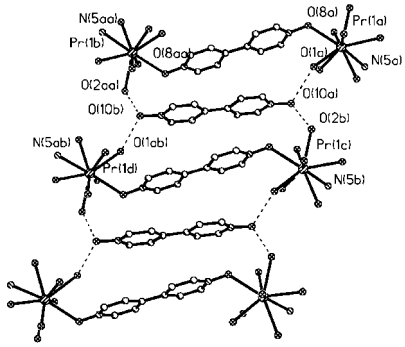

Fig. 3 Hydrogen bond interaction between the uncoordinated 4,4′-bipyridine *N,N′*-dioxide molecule and four aqua ligands arising from two different chains: O(10a)$\cdots$O(1a) 2.832 Å, O(10a)$\cdots$O(2b) 2.739 Å.

Aldol-type carbon bond formation of ethereal oxonium ylide†

Yuichi Sawada, Takashi Mori and Akira Oku*

Department of Chemistry and Materials Technology, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606-8585, Japan. E-mail: oku@ipc.kit.ac.jp

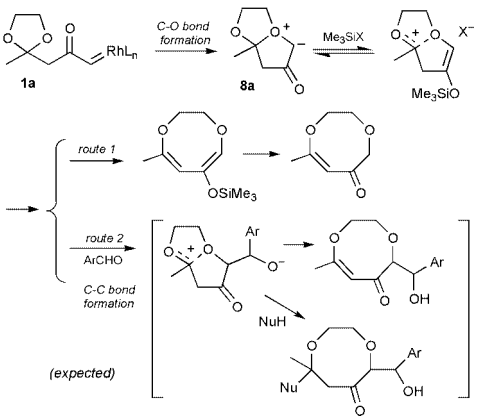
Received (in Cambridge, UK) 8th March 2001, Accepted 2nd May 2001
First published as an Advance Article on the web 25th May 2001

The Rh(2)-catalyzed reaction of 2-(3-diazo-1,1-dimethyl-2-oxopropyl)-2-methyldioxolane (1b) with arylaldehyde in the presence of $(Me)_3SiCl$ and $Ti(i\text{-}PrO)_4$ gave 2-aryl-(hydroxy)methyl-8,8-dimethyl-7-methylene-3,6-dioxocane-1-one (6) and 2-aryl(hydroxy)methyl-4-(2-chloroethoxy)-4,5,5-trimethyl-3-oxacyclopentanone (7); these are the first examples of C–C bond formation of ethereal oxonium ylide *via* enol silyl ether intermediates.

In general, when the ambiphilic character of onium ylides is properly controlled by imparting a relatively long lifetime, consecutive C–C bond formation on the carbanion can be realized as already exemplified widely by phosphonium and sulfonium ylides.[1,2]

However, similar bond formations have not been reported for ethereal oxonium ylides. This is probably because their extremely short lifetime[3] kinetically retards electrophilic attack by ordinary carbon electrophiles. Despite this defect, the [1,*n*]-ambiphilicity of intramolecularly formed bicyclic O-ylide, *e.g.* **8**, will enable the ylide to react with carbon electrophiles under appropriate conditions such as, for example, transforming the ylide to a more stable intermediate which retains the nucleophilic character of the ylide and also the use of a Lewis acid.

As the study model of this reaction, we chose the transition metal-catalyzed reaction of diazo ketones bearing a cyclic acetal ring to be carried out in the presence of a silyl reagent.[4] This is because we recently found evidence that bicyclic oxonium ylide, generated from a diazoketone-substituted cyclic acetal, was transiently transformed by the action of chlorotrimethylsilane (Me_3SiCl) to the corresponding enol silyl ether as evidenced by the chlorosilane-catalyzed ring-expansion reaction (Scheme 1, *route 1*).[5] On this basis, we expected that the intermediate enol ether would react with a carbon electrophile, particularly in the presence of an appropriate acid catalyst, to give a C–C bonded adduct (*route 2*). Considering chlorosilane as the acid-catalyst,[6] we designed a one-pot reaction of diazocarbonyl-substituted cyclic acetals with aldehydes in hope of realizing the aldol-type C–C bond formation in conjunction with a ring-enlargement reaction. In this paper we would like to report the first example of the C–C bond formation of ethereal oxonium ylide.



Scheme 1

As the model compounds to be studied, dioxolane-substituted diazoketones **1a** and **1b** were prepared.[4b] First of all, as a standard reaction, Rh(2)-catalyzed reaction of **1a** was performed in the presence of benzaldehyde (3 eq.) but in the absence of chlorosilane reagents. Products obtained were the [1,2]-rearrangement product **2a** and ring-expansion product **3** (Table 1, entry 1), but none of the expected aldol-type products, *e.g.* **6** and **7**. Introducing an electron-withdrawing group to the *para*-position of arylaldehyde was also unsuccessful (entry 2). Thus, the direct reaction of oxonium ylide with aldehyde is much slower than the [1,2]-rearrangement giving **2a** and β-elimination giving **3**. To suppress the rearrangement, Me_3SiCl[7] was added to trap the ylide intermediate and, in fact, remarkably promoted the ring-expansion to give **3** (entry 3).[8] This indicates that Me_3SiCl promotes the β-elimination (ring-expansion) of ylide **8a** whereas it suppresses the [1,2]-rearrangement,[9] when the ylide has enolizable hydrogens at the 4-position of 1-oxonium-6-oxabicylo[3.3.0]octan-3-one (**8a**).

Based on this finding a similar reaction with **1b**, which bears two methyl substituents on the side chain, was examined in expectation of suppressing the enone formation. When benzaldehyde or anisaldehyde was used as the electrophile, the expected C–C bond formation between the ylide and aldehyde did not take place but, instead, ring-expansion product **4** and ring-switching product **5** were obtained (entries 4 and 5). However, with *p*-nitrobenzaldehyde, the expected C–C-bonded products **6d** and **7d** were obtained (entry 6) (Scheme 2). Both were unequivocally formed by the aldol-type reaction between the aldehyde and oxonium ylide **8b** or its enol silyl ethers **10b** and **11b** (Scheme 3). The reaction was highly stereoselective because **6d** and **7d** were formed as a single diastereoisomer.[10] At low temperature (entry 7), although product yields were not improved, ring-expansion product **6d** was suppressed to some

Table 1 Rh(2)-catalyzed reaction of **1** with aldehyde and Me_3SiCl

Entry	Substrate	*Ar*CHO	Lewis acid (mol%)	Products (%)

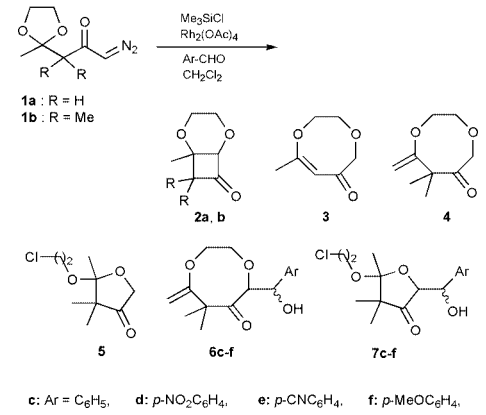
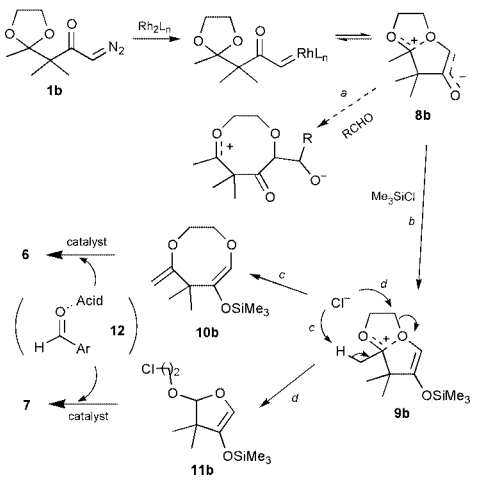


Scheme 2



Scheme 3

extent, indicating that the ring-expansion from the bicyclo[3.3.0] system to an eight-membered ring requires a higher activation energy than the S_N2 attack by Cl^- ion (Scheme 3). Similarly, with *p*-cyanobenzaldehyde C–C-bonded products **6e** and **7e** were again obtained (entry 8).

Not only benzaldehydes bearing withdrawing groups but also unsubstituted benzaldehyde and even anisaldehyde afforded similar C–C bonded products provided that an appropriate Lewis acid was used in addition to $Rh_2(OAc)_4$ and Me_3SiCl (entries 9–11). Among several Lewis acids examined, Ti(*i*-OPr)$_4$ was the most appropriate for this reaction. Stereoselectivity of the C–C bond formation in the presence of Lewis acid, however, was not so high as was observed with electron-deficient aldehydes without Lewis acid (*vide supra*). Thus, two isomers were formed for **6f** in which the isomer ratio was *anti*/*syn* = 2.5, whereas for **7f** it was 2.0.

Kanemasa and coworkers recently reported that, in the presence of trimethylsilyl triflate or $ZnCl_2$–Me_3SiCl, ethyl diazoacetate reacts with aldehyde to give a β-keto ester.[11] In the Rh-catalyzed reaction of **1b**, however, a similar diketone was not obtained indicating that **1b** cannot react directly with aldehyde but only *via* oxonium ylide **8b** (Scheme 3).

In Scheme 3, route *a* shows direct nucleophilic attack of ylide **8b** on aldehyde, but that this did not occur is evidenced by the negative results obtained in the absence of Me_3SiCl (Table 1, entries 1 and 2). Route *b* shows an indirect route to the C–C bond formation from **8b** *via* enol silyl ethers **10b** and **11b**. First, oxonium ion intermediate **9b** may be formed from **8b**. Subsequently, conjugate base Cl^- attacks **9b** on either the bridgehead methyl group for abstracting proton (route *c*) or the methylene group of the acetal ring in an S_N2 manner (route *d*), cleaving C–O bonds, to give **10b** or **11b**, respectively. Hydrogen chloride, generated from the proton abstraction process, acts as an acid-catalyst to activate aldehydes and enol silyl ethers as well to undergo the aldol-type C–C bond-forming reaction.[12] This was verified by the finding that addition of Et_3N to the reaction with nitrobenzaldehyde suppressed the formation of **6d** and **7d**. Another possible route to **6** or **7** by the reaction of **4** or **5** with aldehyde was ruled out by the negative result of independent treatment of **4** or **5** with nitrobenzaldehyde in the presence of Me_3SiCl.

In conclusion, the formation of **6** and **7** can be attributed to the aldol-type reaction between aldehyde and enol silyl ethers **10b** and **11b**, both derived from ylide **8b**, in that not only Lewis acids but also Me_3SiCl act as the catalyst. To expand the scope of C–C-bond formation of ethereal oxonium ylides, further study will be needed.

This study was supported by a Grant-in-Aid for Scientific Research on Priority Areas (B) 'Dynamic Control of Stereochemistry', No. 10208203.

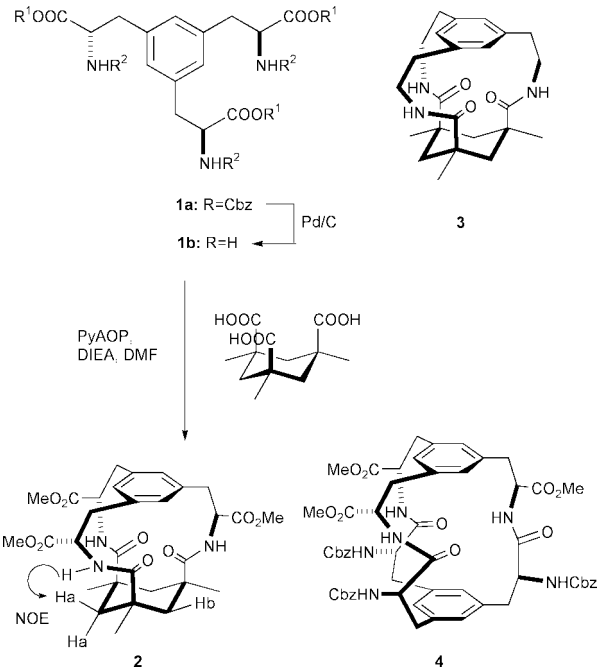
The synthesis of the optically active C_3-symmetric cage-like trisamide 2 was easily accomplished by the reaction of 1b with Kemp's triacid; structure elucidation revealed the presence of an array of H-bonds closing the structure as a capsule.

We have for some time been interested in constructing new C_3-symmetric molecules based on amino acid **1**.[1] The tripodal structure of this compound in combination with Kemp's triacid[2] with its unusual triaxial alignment of the carboxylic acid groups,[3] would make possible the synthesis of the cage-like structure **2**. A similar compound **3** was indeed suggested by Kemp and Petrakis in their paper from 1981,[2] but to the best of our knowledge, it has never been synthesised. In this communication, we describe the synthesis of **2**, as shown in Scheme 1.

The protected trisphenylalanine derivative **1a** was synthesised in three steps from commercially available trimesic acid as described previously.[4] Removal of the benzyloxycarbonyl protecting groups by hydrogenation over Pd/C, gave a quantitative yield of **1b**. Slow addition, *via* syringe pump, of a mixture of Kemp's triacid, PyAOP‡ and Hünig's base to **1b** provided **2** in 8–11% yield§ (Scheme 1). This rather low yield was to be expected, as judged from other similar reactions.[5]

Several attempts to improve the yield of the reaction were made by employing different coupling reagents. Replacing PyAOP with the combination EDC–HOBt had no positive effect on the yield and remaining HOBt was difficult to remove from the product during purification. EDC alone failed to provide any product, while HATU gave essentially the same yield as PyAOP. Further, using the PyAOP-procedure as above but increasing the rate of the addition of the coupling reagent or using smaller amounts of the solvent resulted in the formation of more polymeric material, which made purification difficult. Nor did slow addition of the coupling reagent and extending the reaction time (48–72 h), with or without heat, improve the situation; only polymeric material and decomposition of the coupling reagent was indicated by NMR-analysis.



Scheme 1

The free trisamine **1b** could possibly also combine with its corresponding trisacid under amide bond formation. As one of several combinations, one would expect a C_3-symmetric cage-like compound **4** to be formed in which the general structure of **1** served both as the 'top' and the 'bottom' of the cage. Unfortunately, **4** could not be identified in such experiments. Mass spectroscopy revealed only the formation of material with higher molecular weights in the range of oligomers. This outcome was not totally unexpected since the formation of **4** would require a considerable entropy drop of the system. On the other hand, we believe that in the reaction employing Kemp's acid, the preorganisation of its triaxial carboxylic acid groups[3] in the acidic state and also as triester,[2,3c,6] facilitated the formation of the cage.

Since all attempts to grow crystals of **2** useful for X-ray structure determination have hitherto failed, its structure was studied by molecular mechanics computation, NMR- and mass spectroscopy. According to molecular mechanics calculations (MM3),[7] starting from a large number of input structures based on molecular models, the structure of **2** having the cyclohexane ring in the chair conformation had the lowest energy found (Fig. 1). H-bonds between the amide protons of one arm and the carbonyl oxygens of the adjacent arms were clearly seen and the C_3-symmetric character of **2** was indeed reproduced.

It was also evident from the ^{1}H NMR spectrum that **2** was C_3-symmetric, since only one set of signals appeared. As expected, the shift of the various protons had changed as compared to those of **1b**. Thus, the α-proton signal was shifted down-field, from 3.97 ppm in **1b** to 5.25 ppm in **2**, and the multiplicity changed from a double doublet in **1b** to a triple doublet in **2**. This was attributed to the coupling to both the amide protons and the β-protons. In **1b**, no coupling between the α-proton and NH was observed and the signal of the α-proton was a double doublet as a result of its coupling only to the β-protons. For **2**, the N**H**–Hα coupling was clearly seen in the COSY spectrum.† Also the β-proton resonances showed changes in shift and appearance. From being a double doublet at 2.87 ppm, with a coupling constant of 7.2 Hz in **1b**, the corresponding signal in **2** was split into a double doublet at 3.48 ppm and a double doublet

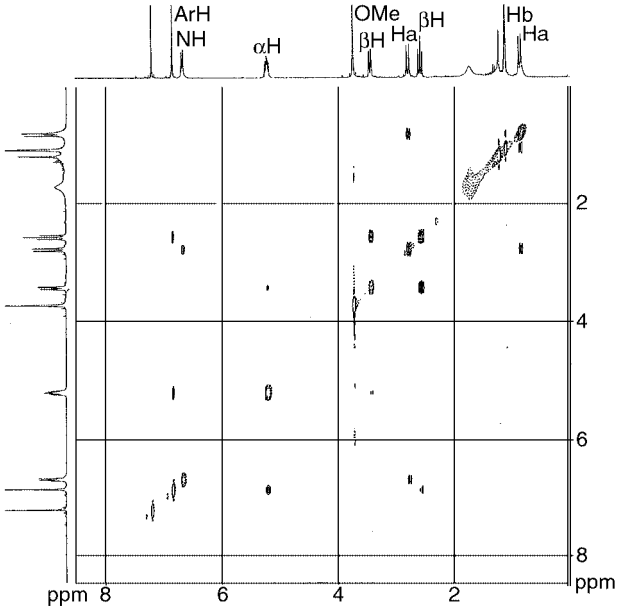

Fig. 2 NOESY spectrum of **2** in $CDCl_3$.

at 2.62 ppm ($J_{\alpha,\beta}$ = 6.9 Hz). One of these protons (at 3.48 ppm) presented a weak NOESY correlation to the α-proton, (Fig. 2). This observation supported the H-bonding in the MM3-model. As seen in Fig. 1, the α- and gauche β-protons are positioned 2.36 Å apart. These protons are located near the extension of the aromatic plane, *i.e.* in the down-field shift region, as can be seen in Fig. 1. The effect was confirmed by ^{1}H NMR. The anti relation between the two β-protons was expressed by the large geminal coupling constant ($J_{\beta-\beta}{}^1$ = 15.7 Hz). The signal originating from the methylene protons in Kemp's acid itself appeared at 2.54 ppm, while the corresponding proton resonance in **2** appeared as two different doublets, one at 2.83 ppm and the other at 0.89 ppm, with a large geminal coupling constant of 15.7 Hz. NOESY experiments revealed that the equatorially positioned protons (the signal at 2.83 ppm) presented a NOE enhancement effect to N**H**CO (Fig. 2). No such effect was observed for the axial protons (0.89 ppm). This observation also supports the H-bonding shown in the MM3-model. As seen in Fig. 1, the NH–Ha distance is only 2.0 Å. The array of NH···O=C hydrogen bonds closes the cage, thus hindering guest molecules to enter. Moreover, the space available inside the cage is probably too small to accommodate a guest particle. This was estimated by MM3[7] energy minimization of an imaginary inclusion complexes between a hydrogen or helium atom and the cage, which resulted in *ca.* 8 kcal mol^{-1} higher energy of both complexes as compared to the empty cage.

The protruding carboxylate groups of **2** may be used as attachment points for various structures *via* ester- or amide bonds. Compound **2** would then serve as a core of dendritic structures. Synthetic work in this direction as well as molecular recognition studies are in progress.

§ Compounds **1b** and **2** were characterised by ^{1}H and ^{13}C NMR spectroscopy (400 MHz, 298 K) and by mass spectroscopy (FAB). NOESY experiment was used to make individual ^{1}H NMR assignment. Polarimetric measurements were performed at 20 °C.

Preparation of **1b**. Compound **1a**[4] (1.0 g, 1.27 mmol) was dissolved in MeOH (50 mL), Pd/C (50 mg) was added and the mixture was hydrogenated at 1 atm overnight. After removal of the catalyst by filtration through Celite, **1b** was obtained as an amorphous white powder (0.48 g, 99%). mp 207.0–208.8 °C. ν_{max}(KBr)/cm^{-1} 3409.9(NH), 2962.5, 1743.5(CO), 1674.1. ^{1}H NMR (300 MHz, CD_3OD) δ 6.81 (s, 3H), 3.97 (dd, J = 8.5 Hz, 3H), 3.51 (s, 9H), 2.87 (dd, J = 7.2 Hz, 6H). ^{13}C NMR (75 MHz, CD_3OD) δ 171.5, 137.9, 131.9, 55.9, 54.3, 37.8. $[\alpha]_D$ +16.3° (*c* 0.55, MeOH). HRMS (FAB + H$^+$) calculated for $C_{18}H_{27}N_3O_6$ 381.1900. Found 382.1967 [M$^+$ + H].

Preparation of **2**. A solution of Kemp's triacid (0.033 g, 0.13 mmol), PyAOP (0.20 g, 0.38 mmol) and DIEA (65 μL, 0.38 mmol) in DMF (10 mL) was added, *via* a syringe pump, to a solution of **1b** (0.050 g, 0.13 mmol) and DIEA (65 μL, 0.38 mmol) in DMF (90 mL), over 10 h. The reaction mixture was stirred for an additional 12 h at rt. The solvent was then removed under reduced pressure and the residue was dissolved in diethyl ether (20 mL). The organic phase was washed with 1 M HCl (10 × 10 mL) in order to remove remaining PyAOP. The volume of the organic phase was reduced and the crude product was chromatographed (CH_2Cl_2–MeOH 30:1, R_f = 0.5) to give **2** as a semi-solid (7 mg, 8%). ν_{max}(KBr)/cm^{-1} 3379.1(NHCO), 2954.7, 1895.2, 1743.5(CO), 1643.2, 1535.2. ^{1}H NMR (400 MHz, $CDCl_3$) δ 6.91 (s, 3H), 6.73 (d, J = 10.2 Hz, 3H), 5.27 (ddd, $J_{H\alpha-Hb}$ = 6.9 Hz, $J_{H\alpha-NH}$ = 10.2 Hz, 3H), 3.78 (s, 9H), 3.48 (dd, J = 6.9 Hz, 3H), 2.83 (d, J = 15.8 Hz, 3H), 2.62 (dd, J = 7.3 Hz, 3H), 1.15 (s, 9H), 0.89 (d, J = 15.6 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 176.0, 172.2, 135.3, 129.6, 52.4, 52.2, 43.6, 40.9, 37.2, 35.9. $[\alpha]_D$ −3.4° (*c* 0.35, MeOH). Stereoselective construction of *trans*-1,2-benzooxadecaline frameworks by three-component cascade reactions of an α-phenethyl-β-borylallylsilane with aldehydes†

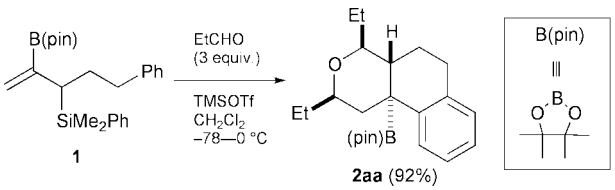
Michinori Suginome,* Yutaka Ohmori and Yoshihiko Ito*

Department of Synthetic Chemistry and Biological Chemistry, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606-8501, Japan. E-mail: suginome@sbchem.kyoto-u.ac.jp

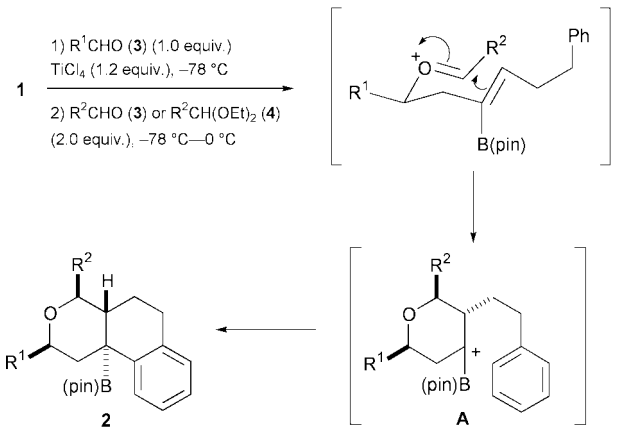
Received (in Cambridge, UK) 20th March 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 25th May 2001

Reactions of α-phenethyl-β-borylallylsilane with aldehydes afforded tricyclic *trans*-1,2-benzooxadecaline frameworks stereoselectively in the presence of Lewis acids *via* sequential incorporation of two different aldehydes followed by cationic cascade cyclization, ending up with intramolecular Friedel–Crafts reaction.

Synthetic reactions in which multiple chemical bonds are created sequentially in a single reaction vessel are highly attractive in terms of efficiency in organic synthesis.[1] In particular, such reactions involving sequential coupling of multiple components have gained increasing attention to achieve high structural diversity which is one of the most important issues in recent synthetic organic chemistry. In our recent report that focused on the alkenylborane synthesis *via* β-borylallylsilanes, we briefly mentioned that reaction of α-phenethyl-β-borylallylsilane **1** with aldehyde afforded tricyclic **2aa** as a sole diastereomer in the presence of TMSOTf [eqn. (1)].[2,3] The reaction may proceed sequentially through allylation of the aldehyde with **1** and acetal formation with the second equiv. of the aldehyde, followed by Prins-type oxonium ion–alkene cyclization, ending up with intramolecular Friedel–Crafts reaction.[4] The remarkable increase in molecular complexity with the high stereoselection prompted us into further investigation. Herein, we report that selective formation of the *trans*-1,2-benzooxadecalines with a wide range of substituents was realized by a sequential reaction of two different aldehydes with **1**. Moreover, formation of related tricyclic frameworks on the basis of the same reaction protocol is also described.



Aiming at the selective, sequential reaction of **1** with aldehydes, we initially tried a stepwise addition of two aldehydes into a solution of **1** in the presence of TMSOTf. Thus, after propionaldehyde (**3a**, 1 equiv.) was completely consumed in the reaction mixture, acetaldehyde (**3b**, 2 equiv.) was subsequently added. Work-up of the reaction mixture, however, gave tricyclic benzooxadecaline derivative **2aa** as a major product, in which two molar equiv. of **3a** were incorporated. Selective synthesis of tricyclic benzooxadecalines, in which two different aldehydes were incorporated in a stepwise manner, was achieved by means of $TiCl_4$ instead of TMSOTf (Scheme 1).[2] In the presence of $TiCl_4$ (1.2 equiv.), aldehyde **3a** (1.0 equiv.) was reacted at −78 °C, to the consumption. Subsequent addition of **3b** (2.0 equiv.) to the reaction mixture at −78 °C, followed by warming the mixture to 0 °C, resulted in the exclusive formation of **2ab** in good yield, which had ethyl and methyl groups selectively at the right positions (Table 1; entry 1). With the optimized reaction conditions, some aliphatic and aromatic aldehydes and acetals as the second electrophile were employed in combination with the first aliphatic aldehydes for the present three component cascade cyclization. When propionaldehyde diethylacetal (**4a**) and isobutyraldehyde (**3c**) were employed as the second electrophiles, the corresponding products were obtained in good yields (entries 2 and 3). However, reaction of pivalaldehyde (**3d**) under the same reaction conditions gave **2ad** only in moderate yield, although the selectivity for the formation of **2ad** was perfect (entry 4). It was found that the yield was much improved by the additional use of TMSOTf in the second step with **3d** (entry 5).‡ A similar but more pronounced effect of the additional use of TMSOTf was found in the reaction of benzaldehyde (**3e**), which hardly



Scheme 1 Three-component cascade reaction of **1** with electrophiles.

10	**3c** (*i*-Pr)	**3a**	A	**2ca** (33)

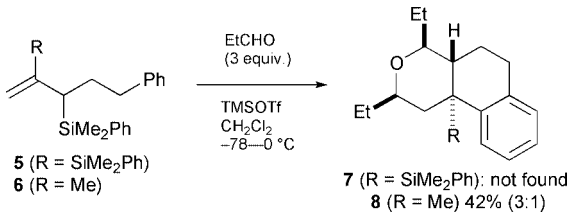
[a] Aldehydes were used as the second electrophiles unless otherwise noted. [b] Condition A: (1) R^1CHO (1 equiv.), $TiCl_4$ (1.2 equiv.), −78 °C, (2) R^2CHO or $R^2CH(OEt)_2$ (2 equiv.), −78–0 °C. For condition B, TMSOTf (2 equiv.) was added with the second electrophiles. [c] Isolated yield. [d] The corresponding diethyl acetals were used as the second electrophiles.

† Electronic supplementary information (ESI) available: experimental details and spectral data. See http://www.rsc.org/suppdata/cc/b1/b102613p/

 DOI: 10.1039/b102613p

gave the desired product in the absence of TMSOTf (entries 6 and 7). Although use of (*E*)-2-hexenal as the second electrophile resulted in the formation of a complex mixture of undesired products, the corresponding acetal (**4f**) afforded the tricyclic product **2af** having alkenyl group as R^2 (entry 8). We also examined the variation of the first electrophile. Reaction using **3b** in combination with **3a** gave **2ba** with high selectivity (entry 9). Although we found that use of more sterically demanding **3c** as the first electrophile resulted in much lower yields, only **2ca** without any other tricyclic products were found in the reaction mixture (entry 10). Presumably, **3c** as well as **1** may be consumed completely in the first step by any side reaction, resulting in the highly selective formation of **2ca**.

To evaluate the role of the boryl group in the cyclization, we examined the reactions of the related allylsilanes bearing silyl (**5**) and methyl (**6**) groups at the β-positions.§ Under the same reaction conditions as for the preparation of **2aa** from the β-

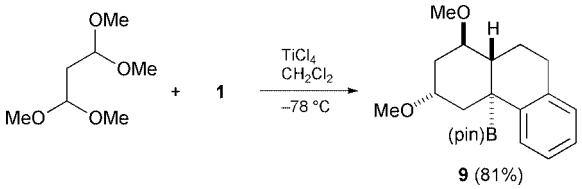


5 (R = $SiMe_2Ph$)
6 (R = Me)

7 (R = $SiMe_2Ph$): not found
8 (R = Me) 42% (3:1)

boryl counterpart **1**, 3 molar equiv. of **3a** were reacted with **5** and **6** in the presence of TMSOTf [eqn. (2)]. While the former (**5**) gave only a complex mixture of products, the methyl derivative afforded tricyclic product **8** along with its diastereomer in a ratio of 3:1 in a total yield of 42%. This result suggests that the sequential reaction with aldehydes giving the tricyclic skeleton is efficiently controlled by the boryl group with respect to yield and stereoselectivity. Presumably, the electronic nature of the β-substituent has the predominant effect on the formation and cyclization of the cationic intermediates, *e.g.*, **A** in Scheme 1.

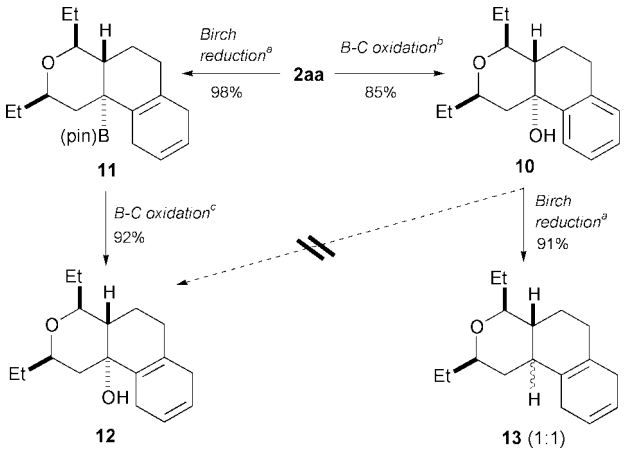
A related cascade cyclization using 1,1,3,3-tetramethoxypropane with **1** in the presence of $TiCl_4$ afforded boryl-substituted *trans*-1,2-benzodecaline derivative **9** in good yield



9 (81%)

[eqn. (3)]. Interestingly, the relative stereochemistry of the two methoxy groups was *trans*, indicating the second carbon–oxygen bond activation leading to cyclization may involve chelation of the two methoxy groups onto the titanium metal.

The tricyclic organoboron compounds served as useful synthetic precursors for the corresponding tertiary alcohols bearing the hydroxy groups at the bridgehead carbon atoms (Scheme 2). Thus, treatment of **2aa** with trimethylamine oxide at 160 °C gave the bridgehead alcohol **10** in 85% yield. Further synthetic elaboration was demonstrated by sequential treatment of **2aa** with Li–NH_3 and H_2O_2, which gave the dienyl alcohol **12** *via* isolation of **11**. An attempt at an alternative pathway to **12** *via* Birch reduction of **10** resulted in the reduction of the tertiary, benzylic hydroxy group to give **13** in high yield as a 1:1 mixture of diastereomers, indicating that the boryl group served as a masked hydroxy group in the transformation into **11**.



Scheme 2 *Reagents and conditions*: a) Li, liq. NH_3, *t*-BuOH, −33 °C; b) $Me_3NO{\bullet}2H_2O$, diglyme, 160 °C; c) H_2O_2, NaOH aq., THF, 50 °C.

In summary, we report a cascade cyclization giving *trans*-1,2-benzodecaline skeletons *via* sequential reaction of α-phenethyl-β-borylallylsilane **1** with aldehydes. The stereochemical aspects and high structural diversity may deserve further investigation of the present stereoselective cyclization. Furthermore, the boryl group incorporation at the bridgehead tertiary carbon atom as a hydroxy equivalent may open up new possibilities for the synthesis of polycyclic bridgehead alcohols *via* cationic cyclization.

Notes and references

‡ A general procedure (A) for the three component cascade reaction of **1** with electrophiles. To a mixture of **1** (50 mg, 0.12 mmol) and **3** (0.12 mmol) in CH_2Cl_2 (0.12 mL) was added a CH_2Cl_2 solution of $TiCl_4$ (2.0 M, 74 × 10^{-3} mL, 0.15 mmol) at −78 °C, and the mixture was stirred at −78 °C for 2 h. To this was added **3** or **4** (0.25 mmol) at −78 °C, and the mixture was stirred at 0 °C for 3 h. Aqueous $NaHCO_3$ (sat.) was added to the mixture. Extraction with AcOEt followed by silica gel column chromatography afforded **2**. For procedure B, the addition of the second electrophile (**3** or **4**) was followed by the addition of TMSOTf (45 × 10^{-3} mL, 0.25 mmol) at −78 °C.

§ The requisite β-silylallylsilane **5** and β-methylallylsilane **6** were prepared by palladium-catalyzed bis-silylation of 5-phenylpenta-1,2-diene[5] and Suzuki-Miyaura cross-coupling of **1** with iodomethane,[6] respectively.

First published as an Advance Article on the web 25th May 2001

Increasing the time allowed for hydrothermal crystallisation during high temperature (150 °C) synthesis of MCM-41 appears to result in some ordering (nanocrystallites) within the pore walls which is accompanied by increase in pore wall thickness, pore size, silica condensation and the formation of elongated or rod-like particles.

The synthesis of organised inorganic materials is currently the subject of a great deal of research effort in materials science. Since the discovery of the M41S family of mesoporous silicas, prepared *via* a mechanism in which supramolecular assemblies of surfactant micelles act as templates for the organisation of inorganic silicate precursors,[1,2] the use of surfactant species to direct the organisation of mesoporous silica has been achieved over a wide range of synthesis conditions.[3] Recent advances indicate that mesoporous silica materials with a wide range of properties may be prepared by careful control of the synthesis conditions.[4–7] However, despite their excellent structural ordering and well defined pore size distribution, mesoporous silicas possess a largely amorphous inorganic framework; their pore walls are amorphous and in many ways exhibit properties similar to those of amorphous silica. The preparation of mesoporous silicas with semi-crystalline or crystalline walls, similar to those of zeolites, is desirable with respect to their stability and use as heterogeneous catalysts or ion exchangers.[8] Although the preparation of surfactant-templated mesoporous oxides (*e.g.* titania, zirconia) with semi-crystalline walls has been recently achieved,[9,10] there are no reports on mesoporous silica with any degree of pore wall ordering. This report describes some pore wall ordering observed in mesoporous silica materials which suggests the presence of nanocrystallites within the pore walls. The pore wall ordering, observed during the course of our work on high temperature (> 150 °C) synthesis of MCM-41, may provide some insights into the preparation of MCM-41 materials with crystallographically ordered pore walls. Materials with pore wall ordering (nanocrystallites) were obtained by extending the crystallisation time in an otherwise normal MCM-41 synthesis procedure under basic conditions. The emergence of pore wall order (*i.e.* nanocrystallites within the pore walls) was accompanied by an increase in the unit cell parameter and the formation of thick and highly condensed silica pore walls along with morphological transformation from the usual spherical shaped particles to elongated or rod-like particles. The apparent pore wall ordering was observed using transmission electron microscopy (TEM) and selected area electron diffraction (SAED).

The nanocrystallite containing MCM-41 materials were prepared using a normal procedure which was modified by increasing the time allowed for hydrothermal crystallisation from 48 to 96 h as follows; tetramethylammonium hydroxide (TMAOH) and cetyltrimethyammonium bromide (CTAB) were dissolved in distilled water by stirring at 35 °C to give a clear solution. The silica source, fumed silica (Sigma), was then added to the template solution under stirring for 1 h. After further stirring for 1 h to allow the silica to be fully dispersed, the resulting synthesis gel of molar composition SiO_2 : 0.25 CTAB : 0.2 TMAOH : 40 H_2O was left to age for 20 h at room temperature following which the gel was transferred to a Teflon-lined autoclave and heated at 150 °C for 96 h. The solid product was obtained by filtration, washed with distilled water, dried in air at room temperature and calcined in air at 550 °C for 8 h to obtain the final material designated as MCM-41(96).[11,12] We note that careful control of the crystallisation temperature was essential for obtaining nanocrystallite-containing MCM-41. In particular temperatures significantly lower than 150 °C resulted in materials with lower unit cell parameters, thinner pore walls and no evidence of pore ordering or nanocrystallites.

Fig. 1 shows typical TEM micrographs obtained for MCM-41(96). The particle morphology is consistent with the elongated or rod-like particles previously observed for this type of material.[12] We have previously reported that the morphology of materials (such as MCM-41(96)), which are prepared for extended crystallisation periods, differs from the normal spherical shaped particle morphology observed for MCM-41, and that they are mainly made up of elongated rod-like spheres.[12] Similar rod-like MCM-41 particles have also been previously obtained *via* a two-step synthesis procedure involving post-synthesis restructuring.[13] Fig. 2 shows representative TEMs with the corresponding SAED patterns. First we note that from the TEMs in Fig. 2, it is possible to observe the pore channels which run along the particle axis. Secondly, the SAEDs are unusual for MCM-41 in that they show several diffuse diffraction rings which is an indication that the MCM-41(96) particles exhibit some local ordering. A likely explana-

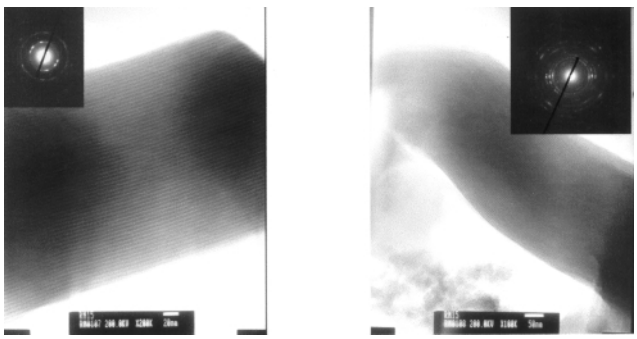

Fig. 2 Representative TEM micrographs and corresponding SAED patterns for MCM-41(96).

 DOI: 10.1039/b101812o

tion for the diffraction rings is that the pore walls of MCM-41(96) possess some crystalline character, perhaps in the form of nanocrystallites which occur within the pore walls.[9] We have previously shown that the pore wall thickness of materials similar to the MCM-41(96) sample reported here is much higher than that of conventional MCM-41.[11] The pore walls of such materials are up to twice as thick as those of conventional MCM-41 (crystallised at 150 °C for 48 rather than 96 h).[11] Indeed the pore walls of MCM-41(96) type materials are amongst the thickest we have encountered for any MCM-41 material. It is therefore possible that nanocrystallites can nucleate within the thick pore walls of MCM-41(96) thus resulting in semi-crystalline pore walls and the pore ordering observed in Fig. 2. Mesoporous metal oxides possessing thick pore walls and semi-crystalline frameworks have previously been reported.[9] The presence of thick pore walls was considered as being important in the nucleation and growth of nanocrystallites within the mesoporous metal oxide frameworks.[9]

The typical surface area and pore volume of MCM-41(96) materials was in the range 650–700 $m^2\ g^{-1}$ and 0.70–0.8 $cm^3\ g^{-1}$, respectively. These values are rather lower than those of conventional MCM-41 presumably due to the thicker pore walls. The thick pore walls also, in part, account for the large unit cell size observed (typically 70 Å). The pore size is however not compromised by the thick pore walls and is indeed much larger than that in conventional MCM-41.[11,12] The powder X-ray diffraction (XRD) pattern for a typical MCM-41(96) sample is shown in Fig. 3. The XRD pattern is typical of a relatively well ordered material and shows an intense basal (100) diffraction peak and some higher order peaks. The 100 peak is shifted to lower 2θ values (compared to conventional MCM-41) indicating an expansion in the lattice parameter. We note that although we did not observe any clearly defined high angle peaks in the powder XRD patterns of MCM-41(96), the amorphous silica 'halo' peak usually present in MCM-41 materials was virtually absent. Typical N_2 sorption isotherms (not shown) for MCM-41(96) materials exhibit a well developed step in the relative pressure (P/P_o) range 0.45–0.6 characteristic of capillary condensation (filling) into uniform mesopores.[11,12,14] The isotherms also exhibit some (triangle shaped) hysteresis which is characteristic of MCM-41 materials with pores larger than 40 Å.[14] It is worth noting that the thick walls of MCM-41(96) are accompanied by greater silica condensation. ^{29}Si MAS NMR spectra of as-synthesised (surfactant containing) MCM-41(96) indicated that the pore walls are primarily made up of fully condensed Q^4 silica units with a small contribution from incompletely cross-linked Q^3 units.[11,12] Q^4/Q^3 ratios in the range 4.0 to 5.0 and typically *ca.* 4.5 were obtained for MCM-41(96) materials compared to a ratio of 1.4 for conventional MCM-41. As expected the Q^4/Q^3 ratio was even higher for the calcined MCM-41(96) samples that were used for TEM analysis. It is worth noting that the thick, highly condensed pore walls and the implied presence of nanocrystallites is consistent with the improved thermal and hydrothermal stability previously observed for MCM-41(96) materials.[11]

We have considered other possible explanations for the origin of the diffraction rings observed in Fig. 2. A possible explanation is that the diffraction rings arise from multi-particles or particle aggregates. Although we do not rule out this possibility, we were however unable to obtain diffuse diffraction rings from multi-particles of several other MCM-41 materials that were prepared under different conditions; the diffraction rings were a feature of MCM-41(96) materials. It appears therefore, that mesoporous MCM-41 silica with semi-crystalline pore walls may be prepared by increasing the time allowed for hydrothermal crystallisation, in an otherwise normal MCM-41 synthesis procedure under basic conditions. In the present case it is likely that extending the crystallisation time allows for more extensive diffusion of additional silicate units and surfactant species into the growing surfactant/silica mesophase. Additional silicate units increase the wall thickness and extent of silica condensation while additional surfactant species increase the volume and density of the surfactant (micellar) phase thus increasing the pore size. The increased silicate accretion may favour the nucleation and growth of nanocrystallites. The findings reported here suggest that crystallisation temperature and time are likely to be important factors in attempts to prepare mesoporous silicas with semi-crystalline or crystalline pore walls.

The author is grateful to the EPSRC for an Advanced Fellowship and the Royal Society for an equipment grant.

A concise route to (−)-morphine

Hiroshi Nagata, Norio Miyazawa and Kunio Ogasawara*

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980-8578, Japan.

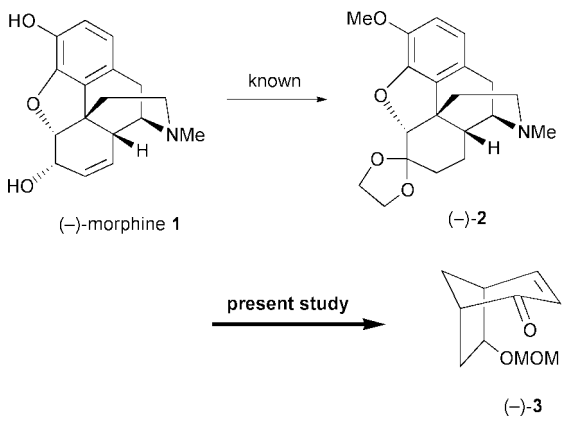
Received (in Cambridge, UK) 20th February 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 25th May 2001

A concise enantio- and diastereocontrolled route to (−)-morphine has been developed starting from a bicyclo[3.2.1]octenone chiral building block through an acid-catalyzed tandem retro-aldol-oxonium ion-mediated hydrophenanthrene formation reaction as the key step.

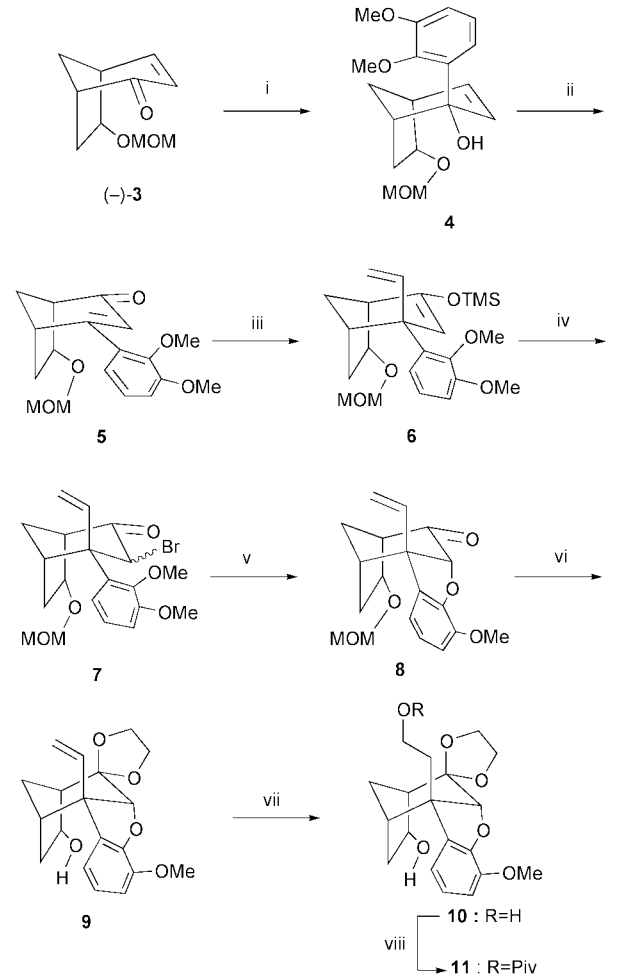
The total synthesis of (−)-morphine **1**, the main alkaloid of the opium poppy, has been a challenging target for organic chemists for many decades.[1,2] Although a number of successful syntheses have been developed to date since the first accomplishment by Gates[3] in 1952, only a few could produce the alkaloid in an enantio- and diastereocontrolled manner. We report here a concise diastereocontrolled synthesis of the key intermediate[4] dihydrocodeinone ethylene ketal (−)-**2** of (−)-morphine **1** and the related opium alkaloids starting from the bicyclo[3.2.1]octenone chiral building block[5] (−)-**3** by employing a tandem retro-aldol cleavage and oxonium ion-mediated cyclization[6] as the key step (Scheme 1).

Enantiopure enone **3**, $[\alpha]_D^{26}$ −438.6 (*c* 1.6, $CHCl_3$)], was reacted with 3-lithioveratrole generated *in situ* by reaction of veratrole with butyllithium,[7] to give diastereoselectively tertiary alcohol† **4**, mp 82–84 °C, $[\alpha]_D^{26}$ −151.6 (*c* 1.5, $CHCl_3$)], which on oxidation with pyridinium chlorochromate (PCC) afforded β-aryl-enone **5**, $[\alpha]_D^{26}$ +173.5 (*c* 3.0, $CHCl_3$)], in 81% yield. Construction of the dihydrobenzofuran moiety of the target molecule was carried out at this point by employing the procedure developed by Mulzer and coworkers[4] in their synthesis of **1**. Thus, reaction of **5** with vinylmagnesium chloride in THF containing HMPA in the presence of copper(I) bromide and trimethylsilyl chloride furnished silyl enol ether **6** in 75% yield by concurrent diastereoselective 1,4-addition and *O*-silylation. Exposure of **6** to *N*-bromosuccinimide (NBS) gave α-bromoketone **7** in excellent yield as an inseparable mixture of two epimers (5:1). When the mixture was refluxed in DMF,[4e] intramolecular etherification took place to give rise to dihydrobenzofuran **8**, mp 80–82 °C, $[\alpha]_D^{23}$ −109.7 (*c* 0.5, $CHCl_3$)], in 81% yield as a single diastereomer. Since terminal hydroxylation of the vinyl functionality of **8** under hydroboration–oxidation conditions[8] brought about formation of a mixture by concomitant reduction of the carbonyl functionality in the molecule, the ketone was first protected under mild conditions[9] using 1,2-bis(trimethylsiloxy)ethane in the presence of trimethylsilyl triflate. Under these conditions, **8** furnished hydroxyketal **9** in 71% yield with concurrent removal of the MOM-protecting group. Primary hydroxylation carried out at this stage under standard hydroboration–oxidation conditions[8] afforded diol **10** whose primary hydroxy functionality was selectively acylated with pivaloyl chloride to give hydroxypivalate **11**, the substrate of the key acid-catalyzed hydrophenanthrene formation reaction, in 72% yield. Overall yield of **11** from (−)-**3** was 22% in eight steps (Scheme 2).

Conversion of **11** into the key hydrophenanthrene intermediate **16** could be accomplished in one step just by refluxing with ethylene glycol in benzene with removal of generating water. Thus, **11**, on reflux with ethylene glycol in benzene using a Dean–Stark apparatus in the presence of a catalytic amount of toluene-*p*-sulfonic acid,[2c] furnished the hydrophenanthrene **16**,

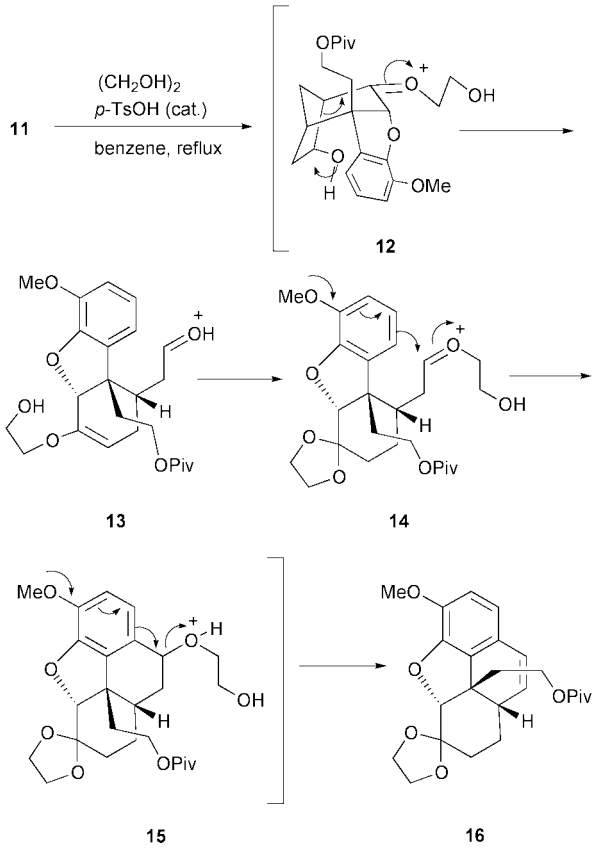


Scheme 1

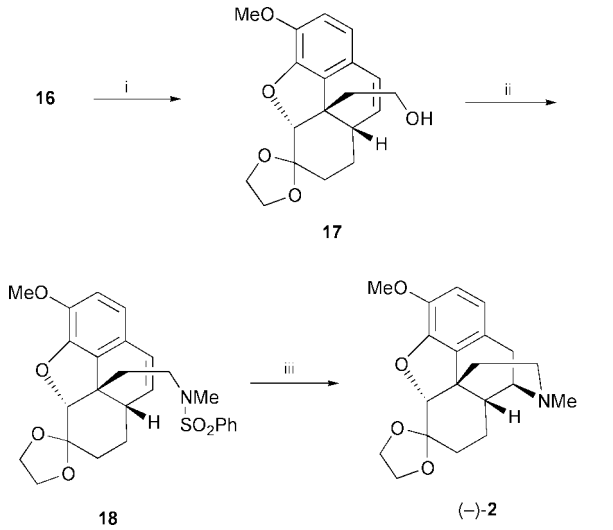


Scheme 2 *Reagents and conditions*: i) 3-Li-veratrole, THF, −78 °C. ii) PCC, CH_2Cl_2 (81% in 2 steps). iii) vinyl-MgCl, CuBr-Me_2S, TMS-Cl, HMPA, THF (75%). iv) NBS, CH_2Cl_2, rt (99%). v) DMF, reflux, 30 min (82%). vi) $(CH_2OTMS)_2$, TfOTMS(cat.), CH_2Cl_2 (71%). vii) BH_3-Me_2S then 30% H_2O_2, NaOH (72%). viii) Piv-Cl, pyridine (87%).

 DOI: 10.1039/b101668g



Scheme 3



Scheme 4 *Reagents and conditions*: i) $LiAlH_4$, THF, rt (100%). ii) $PhSO_2NHMe$, 1,1′-(azodicarbonyl)dipiperidine, Bu_3P, THF (78%). iii) Li, NH_3, *t*-BuOH, THF (70%).

$[\alpha]_D^{25}$ +20.6 (*c* 0.7, $CHCl_3$), in 50% yield as a single product after 15 h. The reaction may be explained by initial formation of oxonium ion **12** which underwent retro-aldol cleavage leading to another oxonium ion **14** *via* protonated aldehyde **13** after reaction with an ethylene glycol in the reaction medium.[2c] The reaction proceeded further under the conditions to bring about cyclization to give hydrophenanthrene **16** through a transient **15**. Although we did not examine this point extensively, the addition of ethylene glycol seemed to be essential to accelerate this cyclization reaction[2c] (Scheme 3).

Transformation of **16** into the penultimate intermediate **18** of the target molecule (−)-**2** could be carried out in a straightforward manner. The pivaloyl group from **16** was first removed by reduction and the resulting primary alcohol **17**, mp 92–94 °C, $[\alpha]_D^{28}$ +31.4 (*c* 0.7, $CHCl_3$), was then transformed into the tertiary sulfonamide **18** by employing the modified Mitsunobu reaction.[4,10] Thus, the reaction of **17** with *N*-methylbenzenesulfonamide in the presence of 1,1′-(azodicarbonyl)dipiperidine[10] and tributylphosphine gave **18**, mp 113–115 °C, $[\alpha]_D^{26}$ −28.5 (*c* 0.1, $CHCl_3$)]{ref. [4d]: mp 115–117 °C, $[\alpha]_D^{20}$ −24.1 (*c* 1.0, $CHCl_3$)}, in 78% yield, whose spectroscopic data were identical with those reported.[4d] Since this compound has been transformed into (−)-morphine **1** and the related opium alkaloids *via* the key intermediate **(**−)-2,[4] the present synthesis constitutes a formal synthesis at this point. Actually, our product (−)-**18** furnished the key morphinan (−)-**2**, mp 170–172 °C, $[\alpha]_D^{27}$ −167.1 (*c* 0.1, $CHCl_3$)]{ref.[4d]: mp 173–175 °C, $[\alpha]_D^{20}$ −173.3 (*c* 1.0, $CHCl_3$)}, in 70% yield on treatment with lithium in liquid ammonia containing *tert*-butanol.[4d,11] Overall yield of (−)-**2** from **11** was 27% in four steps, thus, 6% in twelve steps from the chiral building block (−)-**3** (Scheme 4).

The present methodology for the synthesis of the key intermediate of (−)-morphine may be utilized widely not only for the construction of the alkaloids having a *cis*-fused tetrahydrophenanthrene framework but also for the synthesis of the *trans*-fused congeners as the bicyclo[3.2.1]octenone chiral building block allows diastereocontrolled construction of the pivotal stereogenic center owing to its inherent convex-face selectivity.

A rapid, inexpensive method for producing water-soluble enzyme-coated micro-crystals which exhibit dramatically enhanced catalytic activity and stability in non-aqueous media and can be re-dissolved easily in aqueous solution is described.

Enzymes can frequently show poor activity in organic media when compared to their respective activities in aqueous solution.[1] It has been well documented that lyophilisation (a frequent choice of enzyme preparation for storage and use in organic media) causes pronounced structural perturbation for most proteins, including one of the enzymes in this study, subtilisin Carlsberg (SC).[2,3] To overcome these problems, many strategies aimed at optimising enzyme activity, such as a range of immobilisation methods and manipulation of the micro-environment have been studied. Amongst others, the mode of enzyme preparation,[4–6] co-lyophilisation with lyoprotectants[7] and salts,[8,9] imprinting with substrates and substrate analogues,[10] additives[11] and cross-linked protein crystals[12] have been explored. Here we demonstrate how enzyme preparations of high activity can be rapidly and economically produced using a novel process[13] resulting in the formation of protein-coated micro-crystals (PCMCs).

The procedure for the preparation of PCMCs is summarised in Fig. 1. An aqueous protein solution is mixed with a concentrated solution of an excipient, such as a salt (*e.g.* K_2SO_4), a sugar or an amino acid. A primary requirement is that the excipient (the crystal-forming component) should show high solubility in water and negligible solubility in the precipitating water-miscible organic solvent. This combined aqueous mixture is then added dropwise with rapid mixing to a water miscible solvent (*e.g.* 1-PrOH), whereupon the protein and excipient instantly co-precipitate. The structure of the co-precipitate (SC loading in SC–K_2SO_4 = 8 wt%) typically consists of micron-sized crystals with protein molecules located at their surface. A major advantage is that during the process the organic solvent dehydrates the enzymes by a mechanism that minimises denaturation and appears to leave the majority of enzyme molecules in an active conformation. In addition a fine-particle (0.1–5 μm) suspension is formed so that the protein-coated crystals are homogeneously dispersed in the organic solvent. We have found that routine transferral of this suspension either by pipette or an automated liquid-handling system is very straightforward. This therefore means that enzyme-coated micro-crystals are ideally suited for use in biocatalyst screening programmes. For use in organic solvents, the enzyme-coated micro-crystals can be dried *in situ* to form a fine powder, or the precipitating solvent can be decanted off and replaced by a different solvent. Alternatively for aqueous applications, the enzyme-coated micro-crystals can be rapidly re-dissolved into aqueous solution.†

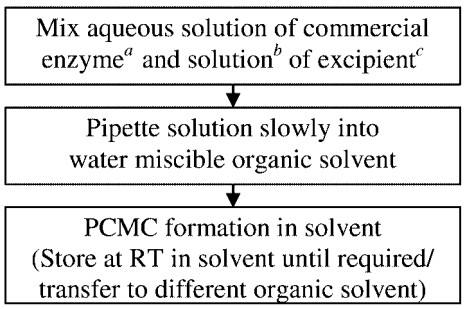

Fig. 1 Procedure for preparation of protein-coated micro-crystals.[a] At pH optimum, both pure and impure preparations can be used. [b] At or near saturation. [c] Component of crystal immobilisation matrix consists of either a salt, an amino acid or a sugar.

Table 1 shows a comparison of the catalytic activity of SC either as a lyophilised powder or after formation of the SC-coated K_2SO_4 micro-crystals (SC-K_2SO_4)‡ in different solvents. The transesterification reaction of *N*-AcTyrOEt using 1-PrOH was monitored in acetonitrile (AcCN–1% H_2O v/v). Significantly, the catalytic rate for all PCMC preparations was over three orders of magnitude higher than that typically found using a lyophilised preparation.[5] Among the solvents tested (Table 1), propan-1-ol and ethanol were found to be the most effective, whereas with SC polar aprotic solvents gave lower activity, but nevertheless markedly increased the activity compared to lyophilised preparations. We found that the water content of the organic solvent used for precipitation is quite flexible (0–20% H_2O v/v). Only at water contents greater than 20% is the activity significantly reduced.

Transmission electron microscopy (TEM) showed that co-precipitates formed in organic solvent were crystalline, resulting in rectangular crystals as shown in Fig. 2 for SC–K_2SO_4 produced in 1-PrOH. Tapping-mode atomic force microscopy (TM-AFM) imaging (data not shown) shows that the protein molecules are located in a fairly uniform layer on the surface of the crystal, where they are easily accessible to the substrate. Interestingly K_2SO_4 crystals formed in the absence of protein are larger. This too indicates that enzyme molecules, located at

the crystal surface, limit crystal growth by acting like a 'poison'.

There are two ways the PCMCs can be stored, as a dry powder or *in situ* as a suspension in 1-PrOH. Historically, drying to a powder has been the preferred route for storage of enzyme and protein powders, but we find a loss of (up to 40%) catalytic activity as a result of air-drying, which can be regained by coating in surfactant (PPG 2025 or Span 80). Alternatively, when stored directly in the precipitating solvent, remarkably a suspension of PCMC-subtilisin can be stored for 14 months at RT with negligible loss in activity (see Table 1).

In order to assess the generality of this novel method we extended our study to lipases employing the kinetic resolution of (±)-1-phenylethanol as a model reaction. We chose as a starting point a lipase screening kit consisting of a set of 10 lipases which are available in lyophilised form and are of varying purity. Initially we screened the lipases in the set for high enantioselectivity E[14] (E > 200) in a model reaction: the conversion of (*R*,*S*)-phenylethanol to (*R*)-phenyl ethyl acetate using vinyl acetate as acyl donor. The activities of these lipases either *as received* or after precipitation to form the enzyme-coated micro-crystals are shown in Fig. 3. Remarkably, the catalytic activity is enhanced significantly for most of the enzyme-coated lipases§ when compared to the *as received* preparations. For PCMC-*Pseudomonas* sp. lipase and PCMC-using lipase B from *Candida antarctica* (CALB) the reaction is complete in 0.5 and 2 h, respectively. PCMC-*Pseudomonas* sp. lipase was found to be 200-fold more active than the *as received* preparation. Coated micro-crystals of CALB and lipase from *M. miehei* showed a 5 and 15-fold increase in catalytic activity, respectively. No change in the enantiomeric ratio (E > 200 in all cases) was observed. A 60-fold increase in the activity of K_2SO_4–CALA (E = 1) was observed. However, one enzyme system K_2SO_4–*Alcaligenes sp.* showed no improvement.

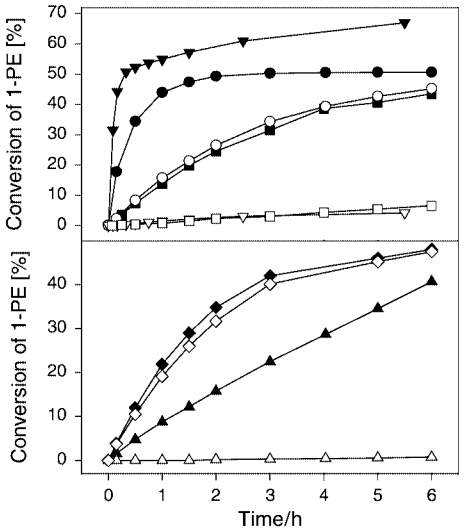

Fig. 3 Comparison in catalytic activity of lipase-coated micro-crystals and the *as received* preparations for the kinetic resolution of (±)-1-phenyl-ethanol (1-PE). PCMCs were made using K_2SO_4 as support and 1-PrOH–1% H_2O as precipitating solvent. (▼) PCMC-*Pseudomonas* sp. lipase; (▽) lipase from *Pseudomonas* sp.; (●) PCMC-CALB; (○) CALB; (■) PCMC-*Mucor miehei* lipase; (□) lipase from *Mucor miehei* lipase; (◆) PCMC-*Alcaligenes* sp. lipase; (◇) *Alcaligenes* sp. lipase; (▲) PCMC-CALA; (△) CALA. Reaction conditions: dry *tert*-butyl methyl ether (2.5 ml), lipase** (2.5 mg, except for CALA: 5 mg), 1-PE (0.1 M), vinyl acetate (0.3 M), T = 30 °C and shaken at 200 rpm. Samples were analysed by HPLC.††

The preparation of enzyme-coated micro-crystals for routine biocatalysis in organic media is fast, cheap, and requires only standard laboratory equipment. Suspensions of highly active PCMCs show significantly improved ease of handling/dispensing and storage in liquids compared to their lyophilised counterparts. This suggests that the methodology may find widespread application as a generic method for the production of biocatalysts with predictable morphology and handling capacity in automated screening applications.

We would like to thank Dr David McComb and Mr Jim Gallagher for the use of EM facilities at the University of Glasgow. The work was supported by the BBSRC, a David Phillips Research Fellowship (MCP) and funding for MK. We would also like to thank Mr Andreas Elmecker for image processing.

Notes and references

† Specific activity of subtilisin Carlsberg, *Candida antarctica* lipase B and *Mucor miehei* lipase is fully retained upon re-dissolution into aqueous solution. Other enzymes used were not investigated in this regard.

‡ Subtilisin Carlsberg, Type VIII (Sigma, UK) (4 mg) was dissolved in 100 μl of Tris buffer (10 mM, pH 7.8). To this, 300 μl of a saturated solution of excipient was added. This combined solution was then added drop-wise to a shaking vial (150 rpm) containing 6 ml of the organic solvent.

§ PCMC-lipases: *Candida antarctica* lipases L-2, and L-5, *Pseudomonas* sp. lipase L-6, *Mucor miehei* lipase L-9, *Alcaligenes* sp. lipase L-10 (Roche Diagnostics, Germany). Procedure as for SC except: 2.5 mg of L-2, L-6, L-9, L-10; 5 mg of L-5 dissolved in 62 μl of phosphate buffer (50 mM, pH 7.0) and 188 μl of a saturated solution of K_2SO_4 was then added. Addition to 3.75 ml of 1-PrOH–1% H_2O as described above. The PCMCs were washed with dry *tert*-butyl methyl ether to remove 1-PrOH.

***In-situ* planar chirality was induced in an achiral ligand by intramolecular π-stacking interactions upon complexation with silver(I) and crystallisation, to give a single-stranded helix with a nanoscale pitch which assembled into a three-dimensional network.**

The utilisation of chirality in coordination-polymer chemistry is best exemplified by helicity. However, the factors controlling the formation of coordination helices are still not well understood despite the considerable attention this area has received.[1] When achiral ligands are employed to form helices they usually give racemates[2] although there are a few exceptions where spontaneous resolution upon crystallisation (conglomerate crystallisation) occurs.[1b,3] When chiral ligands are employed they can be used as either enantiopure ligands or racemic mixtures. Enantiopure ligands often lead to the stereoselective synthesis of helices[4] whereas racemic mixtures of ligands are less predictable.[5] Typically, helical architectures have been constructed using simple heterocycles[1a,c,2b,6] or flexible oligopyridines.[2c,4a,7] The use of thioether-heterocyclic ligands in this context has been less well studied.[1b] Recently we observed[8] that an acyclic thioether-oligopyridine ligand, 2,6-bis(2′-pyridylmethylsulfanylmethyl)pyridine, upon interaction with Ag(I) folded, through strong intraligand π-stacking interactions, in such a way as to exhibit planar chirality. Our strategy was to develop this flexible ligand for polymer formation by retaining most of its features but replacing the central pyridine ring with a 2,3-substituted pyrazine linker. In terms of investigating helix self-assembly, this achiral ligand system has properties in common with chiral ligands derived from racemic mixtures for it may develop planar chirality *in situ* through complexation and conformational folding upon crystallisation. Recently, planar-chiral elements have been incorporated into cyclophanes and used to influence the self-assembly of supramolecular arrays.[9]

The new ditopic ligand **L** (Fig. 1) was prepared in moderate yield (67%) by the base coupling of 2,3-bis(chloromethyl)pyrazine[10] and 6-methyl-2-(sulfanylmethyl)pyridine.[11]† Reaction of **L** with $AgClO_4$ in a 1:2 molar ratio in MeCN gave a pale-yellow solution which was partially reduced in volume and then treated with diethyl ether to give a white precipitate in 85% yield. Microanalysis of the complex was consistent with a 1:2 ligand:metal ratio.‡ The complex was moderately soluble in MeCN but not appreciably soluble in other common organic solvents. Electrospray mass spectrometry under normal operating conditions in MeCN showed only one peak at *m/z* 489.0 with an appropriate isotopic pattern for the 1:1 $[Ag(\mathbf{L})]^+$ ion. ^{1}H and ^{13}C NMR spectra were consistent with a symmetrical structure for the complex. Variable temperature ^{1}H NMR spectra measured in CD_3CN showed no significant changes other than broadening of peaks down to the temperature limit of the solvent. The symmetrical nature of the ^{1}H NMR spectra implied that the solution species was either symmetric and static, or more likely, asymmetric and undergoing dynamic processes. X-Ray crystal structure analysis§ of the complex revealed a one-dimensional single-stranded helix consisting of repeating $[Ag_2(\mathbf{L})](ClO_4)_2$ units (Fig. 2). The complex underwent conglomerate crystallisation and the crystal chosen for X-ray analysis belonged to the enantiomorphic space group $P6_522$. As is necessary for this space group only the *M* enantiomer of the helix is observed in the crystal. Since **L** was achiral when reacted with Ag(I), the bulk sample should contain equal amounts of both types of enantiomorphic crystals. The helix runs along the 6_5 screw axis with an exceptionally long pitch of 52.48(2) Å, equal to the length of the *c* axis (Fig. 3).[3a,4a] The pitch is long despite the compact nature of the 'three-layer' π-stacked ligand. The intraligand π-stacking distances determined from atom···atom contacts between rings range from

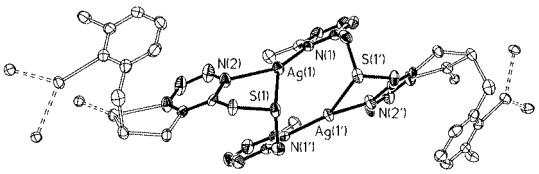

Fig. 2 Fragment of the helix showing the folding of the ligand. The coordination geometry and π stacking about the silver ions are highlighted in black, and dashed bonds indicate the continuation of the polymer (50% probability ellipsoids). Selected bond lengths (Å) and angles (°): Ag(1)–N(1) 2.234(5), Ag(1)–N(2) 2.374(5), Ag(1)–S(1) 2.588(2); N(1)–Ag(1)–N(2) 134.6(2), N(1)–Ag(1)–S(1) 144.9(1), N(2)–Ag(1)–S(1) 77.1(1).

 DOI: 10.1039/b101875m

3.30–4.41 Å, with symmetry-related pyridine rings tilted at 22.2° to the central pyrazine ring. The 'three-layer' stack causes the two sets of ligand donors, $N_{pyridine}SN_{pyrazine}$, to be arranged in opposite directions which is ideal for the linking of metal centres in polymer formation. The 'three-layer' π-stacking also confers planar chirality on the ligands, with the same *P*,*M*,*P* enantiomer being observed throughout the helix (Fig. 1).[12] CPK models indicate that it is not possible to build the diastereomerically-related *P* helix with this *P*,*M*,*P* enantiomer of the ligand but that the enantiomerically-related *P* helix can be built with the *M*,*P*,*M* enantiomer. Each Ag(I) atom adopts a distorted trigonal planar arrangement, which links symmetry-related ligands by $N_{pyrazine}$,S chelation from one ligand and $N'_{pyridine}$ donation from the other. Thus each ligand binds to four Ag(I) ions. In the repeating units the distance between the Ag(I) ions is 3.116(1) Å, which lies within the range (2.86–3.22 Å) for similar systems.[8,13] The trigonal planes in the repeating unit are tilted at 68.2° with respect to each other. In addition, the trigonal planes across the pyrazine are tilted by a further 16.3°. The combined tilting of these planes across the 'three-layered' π-stacked ligands generates the shallow helical twist and hence is responsible for the long pitch of the helix. Previously, we found that the related ligand bis(2-pyridylmethyl)sulfide formed a dimeric side-by-side complex with silver(I).[8] That discrete complex was almost identical to the section of the helix highlighted in black in Fig. 2 and indicates that this dimeric arrangement is particularly favourable for ligands of this type in the presence of silver(I).

The helices are close packed (Fig. 3) in such a way that each pyridine ring is involved in an intermolecular π-stacking interaction with a pyridine ring on an adjacent helix (atom···atom contacts between rings range from 3.63 to 3.74 Å). Between any two adjacent helices there are two such interactions per turn of helix. These interactions help to generate a tightly packed three-dimensional network with no solvent accessible volume (Fig. 3). This is further evidenced by the relatively short Ag···Ag distance [8.210(2) Å] between adjacent helices. These intermolecular interactions are probably responsible for the packing together of homochiral helices on crystallisation and the resulting conglomerate crystallisation.

We have shown that an achiral ligand predisposed to intramolecular π-stacking can generate *in-situ* planar chirality on coordination to silver(I) and the formation of a coordination polymer. In addition, this property results in the formation of a single-stranded helix and the packing of homochiral helices. This work points to a complementary approach to that of using racemic mixtures of ligands as a means of investigating the effect of chirality in molecular recognition processes in coordination-polymer chemistry. Currently we are actively pursuing the use of *in-situ* chirality in the formation of supramolecular architectures.

We thank Professor Ward T. Robinson and Dr Jan Wikaira (University of Canterbury) for X-ray data collection, Associate Professor Bill Henderson (University of Waikato) for electrospray MS data and the University of Otago for financial support.

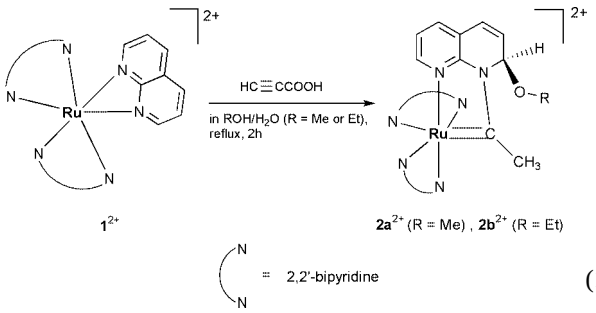
First published as an Advance Article on the web 25th May 2001

The reaction of $[Ru(bpy)_2(napy\text{-}\kappa^2N,N')](PF_6)_2$ [1]$(PF_6)_2$ (napy = 1,8-naphthyridine) with propiolic acid yielded a Ru–carbene complex with a five-membered metallacycle involving a 1,8-naphthylidine framework.

Reactions of transition metal complexes with terminal alkynes have been utilized to prepare vinylidene complexes,[1] which are characterized by the electrophilicity of the α carbon. In fact, vinylidene–metal complexes are converted to alkoxy–alkyl carbene complexes by reaction with alcohols.[2] We have reported that the non-bonded nitrogen of napy-κ*N* of $[Ru(bpy)_2(napy\text{-}\kappa N)(CO)]^{2+}$ attacks the carbonyl carbon to form a five-membered metallacycle upon one-electron reduction of the napy moiety (napy = 1,8-naphthyridine).[3] Moreover, $[Ru(bpy)_2(napy\text{-}\kappa^2N,N')]^{2+}$ exists in equilibrium with $[Ru(bpy)_2(napy\text{-}\kappa N)(solvent)]^{2+}$ in polar solutions.[4] Thus $[Ru(bpy)_2(napy\text{-}\kappa^2N,N')]^{2+}$ readily forms a 1:1 adduct with various substrates upon opening of the chelate ring. The reaction of $[Ru(bpy)_2(napy\text{-}\kappa^2N,N')](PF_6)_2$ [1]$(PF_6)_2$ with propiolic acid in alcohol was conducted to elucidate whether the non-bonded nitrogen of napy or alcohol attacks the α carbon of the vinylidene moiety. Here we report the isolation of a Ru–carbene complex with a metallacycle **2a**$^{2+}$ (eqn. 1), and the reversible conversion between **2a**$^{2+}$ and the vinyl complex **3**$^{+}$ upon acid–base treatment.



(1)

A CH_3OH/H_2O (3:2 v/v) solution containing [**1**]$(PF_6)_2$ (60 mg, 72 μmol) and HCCC(O)OH (7 mg, 100 μmol) was refluxed for 2 h, and [**2a**]$(PF_6)_2$ was obtained from the solution (eqn. 1). Recrystallization of the crude product from CH_3CN/CH_3OH (4:1 v/v) gave single crystals of [**2a**]$(PF_6)_2 \cdot CH_3CN$ in 64% yield.† The similar reaction between [**1**]$(SbF_6)_2$ and HCCC(O)OH in C_2H_5OH/H_2O (4:1 v/v) under similar reaction conditions afforded [**2b**]$(SbF_6)_2$ in 56% yield (eqn. 1).†

The molecular structure of **2a**$^{2+}$ determined by X-ray diffraction analysis is shown in Fig. 1.[5] The ruthenium atom of **2a**$^{2+}$ has octahedral geometry with four nitrogen atoms of two bpy ligands, one nitrogen from napy and one carbon of the CCH_3 group. The characteristic features of **2a**$^{2+}$ are the C–N bond formation between the CCH_3 group and one nitrogen of napy, and the attachment of the CH_3O group to the 2-position of the napy moiety. The resultant five-membered metallacycle consisting of Ru, N(1), C(11), N(2), and C(2) atoms in an almost planar structure, and the sum of the bond angles around the five-membered ring is almost 360°. Despite the attachment of CH_3O to the 2-positon of the napy moiety, the resultant ligand still maintains the planar structure in **2a**$^{2+}$. As a result, the napy moiety and the five-membered metallacycle are co-planar. The Ru–N(4) (2.156(9) Å) bond *trans* to Ru–C(2) is substantially longer than the other Ru–N bonds of **2a**$^{2+}$ (2.03(1)–2.08(1) Å), suggesting a strong *trans* effect of the carbene ligand. The Ru–C(2) bond distance (1.93(1) Å) is in the expected range of hexa-coordinated ruthenium carbene bonds (1.941–1.98 Å),[6] and the bond length is longer than those expected for penta-coordinated ruthenium carbene complexes (1.810–1.861 Å).[7] The ^{13}C NMR spectrum of **2a**$^{2+}$ also showed the α-carbon signal of the Ru–CCH_3 group at δ 293 as a singlet, similar to most Ru carbene complexes.[2,6a–c,7e,f]

The complex [**2a**]$(PF_6)_2$ was stable in $CH_3OH/(CH_3)_2CO$ and $H_2O/(CH_3)_2CO$. On the other hand, the methyl signals of the CH_3O and the Ru–CCH_3 groups of **2a**$^{2+}$ (δ 2.95 and 2.85, respectively) gradually weakened with time in the ^1H NMR spectrum in $(CD_3)CO/CD_3OD$ (1:1 v/v). The Ru–CCH_3 signal vanished in 30 min at ambient tenperature, and the CH_3O one disappeared after 12 h at 65 °C. At the same time, the methyl signal of free methanol appeared at δ 3.33. Moreover, **2a**$^{2+}$ was

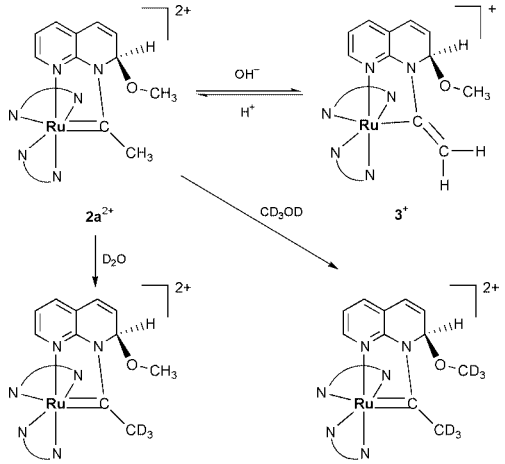

Scheme 1

converted to **2b**$^{2+}$ in $C_2H_5OH/(CH_3)_2CO$ for 1 week at room temperature. Thus, the Ru–CCH_3 and CH_3O groups of **2a**$^{2+}$ underwent H/D exchange and substitution, respectively, by CD_3OD (Scheme 1). The rate of the H/D exchange was faster than substitution by CD_3OD, and the H/D exchange reaction was greatly enhanced in D_2O, since the Ru–CCH_3 signal (δ 2.78) disappeared after 5 min in the ^{1}H NMR spectrum of **2a**$^{2+}$ in $(CD_3)_2CO/D_2O$ (10 : 1 v/v). On the other hand, treatment of [**2a**]$(PF_6)_2$ with an equiv. amount of aqueous NaOH in CD_2Cl_2 caused the appearance of new signals at δ 4.96 and 2.99, and δ 92.5 in the ^{1}H NMR and ^{13}C NMR spectra, respectively, and the proton and carbon signals of the Ru–CCH_3 group of **2a**$^{2+}$ completely disappeared. The addition of 1 equiv. of HPF_6 to the solution regenerated the ^{1}H NMR and ^{13}C NMR spectra of **2a**$^{2+}$. Such complete recovery of **2a**$^{2+}$ in the cycle of the acid–base treatments without producing CH_3OH is indicative of the reversible conversion between the carbene complex **2a**$^{2+}$ and the vinyl complex **3**$^+$ without opening the five-membered metallacycle (Scheme 1).

The carbene complex **2a**$^{2+}$ is probably formed *via* a Ru–vinylidene intermediate formed by the reaction of **1**$^{2+}$ with HCCC(O)OH, though it is not clear whether the decarboxylation takes place before or after the formation of the Ru–vinylidene framework. Although vinylidene complexes react with alcohols to produce a variety of alkoxy–alkyl carbene complexes, the α-carbon of the carbene moiety of **2a**$^{2+}$ linked exclusively with the non-bonded nitrogen of napy in MeOH. Such novel N–C bond formation must be assisted by the attachment of the CH_3O^- group at the 2-position of the napy ligand, since intra-molecular attack of the non-bonded nitrogen of napy to the carbonyl carbon of $[Ru(bpy)_2(napy\text{-}\kappa N)(CO)]^{2+}$ is initiated by the ligand localized one-electron reduction.

Ruthenium(II)-catalyzed [2 + 2 + 2] cycloaddition of 1,6-diynes with electron-deficient nitriles†

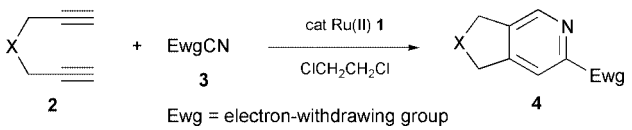
Yoshihiko Yamamoto, Satoshi Okuda and Kenji Itoh*

Department of Molecular Design and Engineering, Graduate School of Engineering, Nagoya University, Chikusa, Nagoya 464-8603, Japan. E-mail: Itohk@apchem.nagoya-u.ac.jp

Received (in Cambridge, UK) 20th March 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 25th May 2001

Ru(II)-catalyzed cycloaddition of 1,6-diynes with electron-deficient nitriles gave the desired bicyclic pyridines in moderate to high yields.

Transition-metal-catalyzed [2 + 2 + 2] cyclocotrimerization of two alkyne molecules and a nitrile has been recognized as a straightforward protocol providing substituted pyridines.[1,2] Although the selective cyclocotrimerization of two different alkynes and a nitrile was achieved using stoichiometric cobalt[1] or zirconium reagents,[3] the catalytic controls of both the chemo- and regiochemistries have remained as a crucial problem. In this context, the intermolecular coupling between an α,ω-diyne and a nitrile was first pioneered by Vollhardt *et al*. in their work on the catalytic reactions of $CpCo(CO)_2$,[4,5] and subsequently this strategy has been successfully applied for the synthesis of Vitamin B_6.[6] Electron-deficient nitriles, however, have been reported to be hardly involved in such a useful pyridine annulation. Ethyl cyanoformate and pentafluorobenzonitrile gave the desired pyridines only in poor yields, lower than 10%. In sharp contrast, we found that a ruthenium(II) complex, Cp*Ru(cod)Cl (Cp* = pentamethylcyclopentadienyl **1**), effectively catalyses the cycloaddition of 1,6-diynes and nitriles activated by an electron-withdrawing group (Scheme 1), although the same Ru(II) complex failed to promote the reaction with simple nitriles such as acetonitrile or benzonitrile.[7]



Scheme 1

Typically, to a solution of dimethyl dipropargylmalonate (**2a**)‡ in 1,2-dichloroethane was added a solution of the catalyst **1** and ethyl cyanoformate (**3a**) (0.02 and 1.5 equiv. to **2a**, respectively) in 1,2-dichloroethane at rt. The solution was stirred for 30 min at 60 °C to give the desired pyridine **4a** in 83% yield (Table 1, entry 1). The side reaction of **2a** leading to arene byproducts was completely suppressed. In the same manner, benzoyl cyanide (**3b**) gave the corresponding pyridine **4b** as a sole product in high yield (entry 2). On the other hand, acetyl cyanide (**3c**) and tosyl cyanide (**3d**) required higher catalyst loading (10 mol%) and temperature (80 °C). The former selectively gave the desired pyridine **4c** in 90% yield (entry 3), although the concomitant formation of the dimer **5a** was observed in the reaction of **3d** (entry 4). In addition to acyl and sulfonyl cyanides, polyhaloalkylcyanides could be used for the

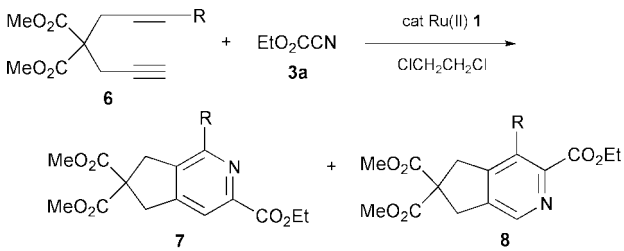
[a] All reactions were carried out with a nitrile (1.5 equiv.) in 1,2-dichloroethane under Ar. [b] Isolated yields.

present ruthenium-catalyzed pyridine annulation. In the presence of 10 mol% **1**, trichloroacetonitrile (**3g**) and pentafluorobenzonitrile (**3f**) were reacted with **2a** at 60 °C to afford pyridines **4e** and **4f** in 44 and 67% yields, respectively (entries 5 and 6). By employing *N*,*N*-dipropargyl tosylamide (**2b**) and dipropargyl ether (**2c**) as diyne components, 3-pyrroline- and 2,5-dihydrofuran-fused pyridines **4g** and **4h** were obtained in 75 and 49% yields, respectively (entries 7 and 8).

In order to establish the regiochemistry of the Ru(II)-catalyzed pyridine annulation, unsymmetrical 1,6-diynes **6a–c** were subjected to cycloaddition with **3a**, leading to 2,3,4,6-substituted isomers **7** and/or 2,3,4,5-substituted isomers **8** (Scheme 2). As a result, one of these isomers was predominantly obtained, depending on the nature of the alkyne substituents. In the presence of 5 mol% **1**, a octa-1,6-diyne **6a** (R = Me) reacted with **3a** at 60 °C for 2 h to afford a 88 : 12 mixture of **7a** and **8a** in 78% yield. The presence of an alkyl-substituent at the terminal position of the diyne decreased the reactivity. Similarly, the cycloaddition between a phenyl-substituted diyne **6b** (R = Ph) and **3a** was carried out using the 20 mol% catalyst at 60 °C. In this case, **7b** was isolated as a sole pyridine isomer in 50% yield. In contrast, the reaction of an ester **6c** and **3a** proceeded at rt and, unexpectedly, a 2,3-dialkoxycarbonyl isomer **8c** was obtained as a major product along with a minor isomer **7c** in 78% total yield. Therefore, the electron-



R = Me: 5 mol%, 60 °C, 2 h; 78% (**7a** : **8a** = 88 : 12)
R = Ph: 20 mol%, 60 °C, 6 h; 50% (**7b** : **8b** = 100 : 0)
R = CO_2Me: 5 mol%, r.t., 1 h; 78% (**7c** : **8c** = 13 : 87)

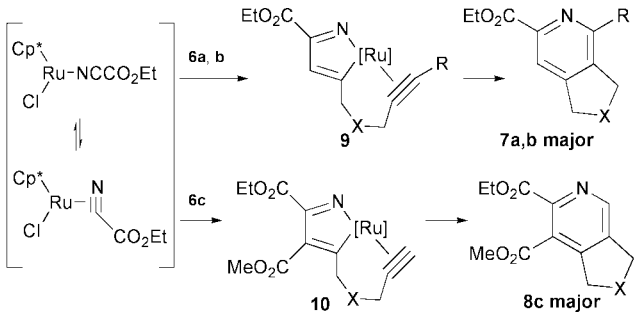

Scheme 3

withdrawing ester group in **6c** reversed both the reactivity and the regioselectivity.

The origin of the observed regiochemistry and the difference in reactivity can be reasonably explained by the following mechanism (Scheme 3). The substituent on a nitrile component plays a critical role in the present protocol: electron-deficient nitriles having a carbonyl, sulfonyl, or polyhaloalkyl substituent gave rise to the desired pyridine product, although acetonitrile and benzonitrile gave little of the corresponding cycloadduct. This is probably because the electron-withdrawing group lowers the antibonding orbital level of the C–N triple bond to facilitate the oxidative cyclization involving the nitrile. In this situation, the catalytic cycle starts from the oxidative cyclization of a nitrile **3** and one alkyne terminus of a diyne **6** on the ruthenium center to form an azaruthenacyclopentadiene intermediate **9** or **10**. The regiochemistry of the product is determined in this stage. In the case of the alkyl- or aryl-substituted diynes **6a** and **6b**, the sterically less hindered terminal alkyne moiety can be favorably involved in the oxidative cyclization to form the intermediate **9**. The subsequent intramolecular alkyne insertion and reductive elimination steps afford the final pyridine product **7** as a major isomer. On the other hand, the diyne monoester **6c** forms predominantly the intermediate **10** because the oxidative cyclization occurs at the electron-deficient alkyne terminus due to its effective accommodation of the d-electron from the ruthenium center. As a result of the efficient formation of **10**, the cycloaddition of **6c** proceeded smoothly even at rt and gave **8c** as a major product.

Templated SAMs for metal ion recognition

Barbara Colonna and Luis Echegoyen*

Department of Chemistry and Center for Supramolecular Science, University of Miami, Coral Gables, Florida 33124, USA. E-mail: echegoyen@miami.edu

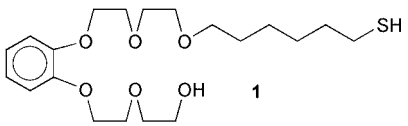
Received (in Columbia, MO, USA) 29th January 2001, Accepted 17th April 2001
First published as an Advance Article on the web 25th May 2001

Self assembled monolayers of a polyether derivative selectively detect potassium cations when templated in their presence.

Self-assembled monolayers (SAMs) that incorporate receptor molecules can act as molecular recognition interfaces and thus as selective sensors for specific analytes.[1–3] Binding sites can also be formed within the SAMs during their preparation, if they are grown in the presence of appropriate analytes that template the aggregation processes.[4] This process could also be described as molecular imprinting, although this term is usually reserved for polymer systems, where binding of functionalized monomers by a template molecule is followed by polymerization and template removal.[4–6] Well-defined cavities with selective binding properties are thus formed in the polymeric backbone which are able to recognize analytes that are similar or identical to the template.

The first preliminary report involving imprinted SAMs was published by Sagiv[7] in 1979, but the concept went largely unexplored for a long time until recently, when the strategy was employed to generate binding sites for organic substrates at the surface of modified electrodes.[8–11] It seems as if more examples are appearing more frequently, probably due to the simplicity of the approach which largely relies on the principle of self-assembly and requires minimal synthetic effort. Perhaps surprisingly and to the best of our knowledge, no examples of SAM formation involving metal ions as templates have been reported to date. In this communication, we report the preparation and the electrochemical investigation of potassium-templated SAMs on gold which selectively detect K^+ but not Na^+.

Receptor **1** was designed to bind metal cations in the polyether loop, which was purposely fused to the aromatic ring



1

for rigidity, but allowed to retain enough flexibility for intra- as well as inter-molecular templating upon self-assembly on the gold surface. The thiol group provides the anchoring point to the gold substrate. The polymethylene spacer separating the polyether recognition site and the anchoring group should facilitate the formation of the monolayers by van der Waals forces. The compound was synthesized in three steps. Reaction of catechol with 2-chloroethoxyethanol afforded a diol **2**, which was monoalkylated with a small excess of 1,6-dibromohexane. Finally, the resulting bromide **3** was converted into **1** by treatment with thiourea followed by basic hydrolysis.†

SAMs **A** and **B** were prepared by immersing glass-sealed gold bead electrodes for 24 h in an EtOH solution of **1** (1 mM) (**A**) or an EtOH–H_2O (1 : 1) solution of **1** (1 mM) and KCl (0.1 M) (**B**). The electrodes were then rinsed with H_2O, EtOH and CH_2Cl_2 and dried under a stream of Ar. Impedance measurements were performed using an aqueous solution of Et_4NCl (0.1 M) and $[Ru(NH_3)_6]Cl_3$ (1 mM), a SAM modified gold bead as the working electrode, a coiled platinum counter electrode and a Ag/AgCl reference electrode. Experiments were conducted at the formal redox potential of the $[Ru(NH_3)_6]^{3+/2+}$ couple with a frequency ranging from 100 kHz to 0.1 Hz. The spectra were analyzed by the 'EquivalentCircuit'[12] software package. Binding of cations to the receptor moiety of a non-electroactive SAM can be monitored by impedance spectroscopy using the positively charged redox couple $[Ru(NH_3)_6]^{3+/2+}$ as a probe.[13] An increase in the charge transfer resistance (R_{ct}) is observed upon complexation of the metal cations,[13,17] and is due to electrostatic repulsion between the cation and the positively charged ruthenium redox couple. These changes were used to monitor the recognition of alkali metal cations by monolayers of **1**.

The charge transfer resistances (R_{ct}) of the SAMs **A** and **B** were measured in the presence of increasing concentrations of KCl. For **A** [Fig. 1(a)], R_{ct} is 1.35 kΩ cm^2 immediately after preparing the SAM and in the absence of KCl. Upon KCl additions, R_{ct} increases slightly until it reaches a limiting value of 2.14 kΩ cm^2 at a salt concentration of 100 mM. Thus, the effect of salt addition is reasonably small. For **B** [Fig. 1(b)], R_{ct} is 2.20 kΩ cm^2 in the absence of KCl but upon addition of this salt the resistance increases dramatically and reaches a value of

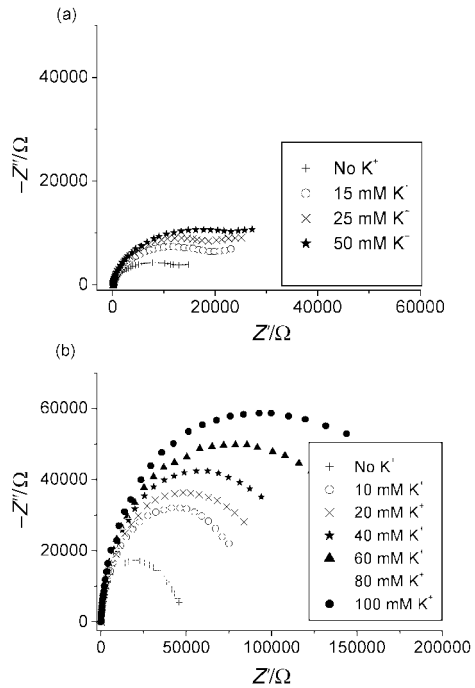


Fig. 1 (a) Nyquist electrochemical impedance spectroscopy plot of the monolayer of **1** grown in the absence of KCl (**A**), and exposed to different K^+ concentrations. Experiments were conducted in H_2O, using Et_4NCl (0.1 M) as supporting electrolyte and $[Ru(NH_3)_6]Cl_3$ (1 mM) as redox probe at E = −0.165 V and the frequency range 100 kHz–0.1 Hz. (b) Nyquist electrochemical impedance spectroscopy plot of the monolayer of **1** grown in the presence of 0.1 M KCl (**B**), and exposed to different K^+ concentrations. Experiments were conducted in H_2O, using Et_4NCl (0.1 M) as supporting electrolyte and $[Ru(NH_3)_6]Cl_3$ (1 mM) as redox probe at E = −0.165 V in the frequency range 100 kHz–0.1 Hz.

 DOI: 10.1039/b102144n

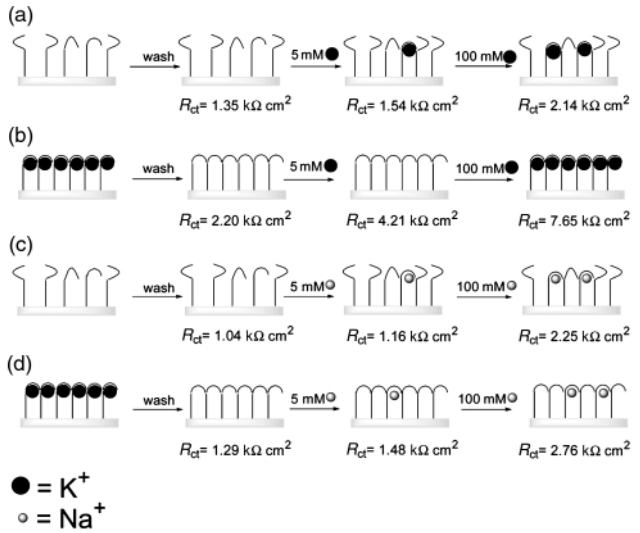

Fig. 2 Cartoon representation of the binding of metal cations by SAM of **1** grown: (a) in the absence of KCl (**A**), K^+ titration; (b) in the presence of 0.1 M KCl (**B**), K^+ titration; (c) in the absence of KCl (**A**), Na^+ titration; (d) in the presence of 0.1 M KCl (**B**), Na^+ titration.

7.65 kΩ cm^2 at a salt concentration of 100 mM. The area coverage for monolayers **A** ($\phi_A = 1.96 \times 10^{-9}$ mol cm^{-2}) and **B** ($\phi_B = 2.43 \times 10^{-9}$ mol cm^{-2}) were determined by reductive desorption in a 0.5 M KOH solution,[18] and are in accordance with the relative R_{ct} values of **A** and **B**. The association constants (K) for potassium binding by **A** and **B** were determined by fitting the experimental R_{ct} values and concentrations of KCl using a Langmuir isotherm.[13] The value of K was found to be 124 ± 20 M^{-1} for **A** and 353 ± 30 M^{-1} for **B**). The difference between these two values demonstrates that the templated monolayer **B** has a higher binding affinity for potassium cations than **A**. In the case of **B**, the self-assembly of **1** on gold is assisted by the cations which induce the formation of optimal binding domains [Fig. 2(b)]. The resulting pre-organized recognition sites favor cation recognition at the interface. The template effect is also reflected in the response to changes in cation concentration. The addition of 5 mM KCl produces a small change in the R_{ct} of **A** but a large increase in the R_{ct} of **B** [Fig. 2(a) and (b)].

The ability of **A** and **B** to recognize sodium cations was also tested. In both instances, however, small changes in the R_{ct} values were observed [Fig. 2(c) and (d)] upon addition of NaCl, suggesting that recognition of Na^+ ions by the monolayer of **1** is very modest. Interestingly, the R_{ct} of the templated monolayer **B** is only 2.76 kΩ cm^2 in the presence of 100 mM NaCl. This monolayer has instead a R_{ct} of 7.65 kΩ cm^2 in the presence of 100 mM KCl. The different behavior indicates that **B** has a pronounced selectivity for potassium cations.

Summarizing, we have demonstrated for the first time that binding sites for potassium cations can be imprinted into SAMs when the monolayer is assembled on gold in the presence of this metal cation. The resulting modified gold electrodes detect potassium cations in water with good selectivity over sodium cations. This approach to chemical sensors is simple and efficient and can be easily extended to the realization of SAMs for the recognition of analytes other than potassium cations.

† *Experimental conditions*: Preparation of 2-(2-{2-[2-(2-hydroxyethoxy)-ethoxy]phenoxy}ethoxy)ethanol **2**: a mixture of catechol (5.5 g, 50 mmol) and K_2CO_3 (35 g, 250 mmol) in anhydrous MeCN, was heated for 30 min under a stream of Ar. 2-Chloroethoxyethanol (14.9 g, 120 mmol) was added and reflux was maintained for 40 h. The suspension was then filtered and the solids washed with CH_2Cl_2 (150 mL). The combined organic phases were evaporated under reduced pressure and the residue was re-dissolved in CH_2Cl_2 (150 mL) and washed with water (3 × 50 mL). Purification by column chromatography [SiO_2, CH_2Cl_2–EtOAc (1:1) to EtOAc–EtOH (9:1)] afforded **2** in 44% yield.

Preparation of 2-[2-(2-{2-[2-(6-bromohexyloxy)ethoxy]ethoxy}phenoxy)ethoxy]ethanol **3**: a mixture of **2** (0.9 g, 3.15 mmol) and NaH (60% in mineral oil) (0.36 g, 9 mmol) in anhydrous THF (200 mL) was stirred at room temperature under a stream of Ar. After 30 min 1,6-dibromohexane (4.76 g, 19.5 mmol) was added and the mixture was left stirring for 16 h. After addition of MeOH the solvent was evaporated under reduced pressure. The residue was dissolved in CH_2Cl_2 (200 mL) and washed with H_2O (3 × 100 mL). Purification by column chromatography [SiO_2, hexane–EtOAc (1:1)] afforded **3** in 76% yield.

Preparation of 2-[2-(2-{2-[2-(6-mercaptohexyloxy)ethoxy]ethoxy}-phenoxy)ethoxy]ethanol **1**: a solution of 2 (1.2 g, 2.7 mmol) and thiourea (0.813 g, 10.7 mmol) in EtOH (80 mL) was left refluxing under a stream of Ar for 16 h. The solvent was evaporated under reduced pressure and the residue suspended in an aqueous solution of KOH (60 mL, 0.84 g, 15 mmol), and stirred for 2 h. The reaction mixture was acidified with HCl and CH_2Cl_2 (150 mL) was added. Washing with H_2O (3 × 100 mL) and purification by column chromatography afforded **1** in 33% yield. $\delta_H(CDCl_3)$ 1.28–1.39 (5H, m), 1.54–1.63 (4H, m), 2.48 (2H, t, *J* 7.3 Hz), 3.45 (2H, t, *J* 6.7 Hz), 3.59 (2H, t, *J* 5.2 Hz), 3.64–3.76 (6H, m), 4.12–4.20 (4H, m), 6.88–6.90 (4H, m); *m/z* (FAB+): 402 (M^+,70%), 403 (M^+ + 1, 100%).

Short syntheses of enantiopure calystegine B_2, B_3, and B_4

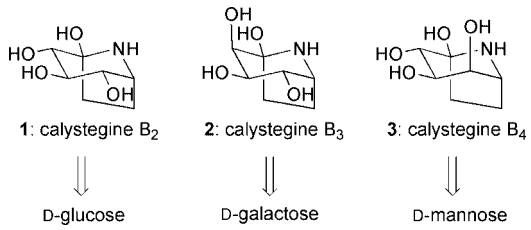
Philip R. Skaanderup and Robert Madsen*

Department of Chemistry, Building 201, Technical University of Denmark, DK-2800 Lyngby, Denmark. E-mail: rm@kemi.dtu.dk

Received (in Corvallis, OR, USA) 12th March 2001, Accepted 26th April 2001
First published as an Advance Article on the web 31st May 2001

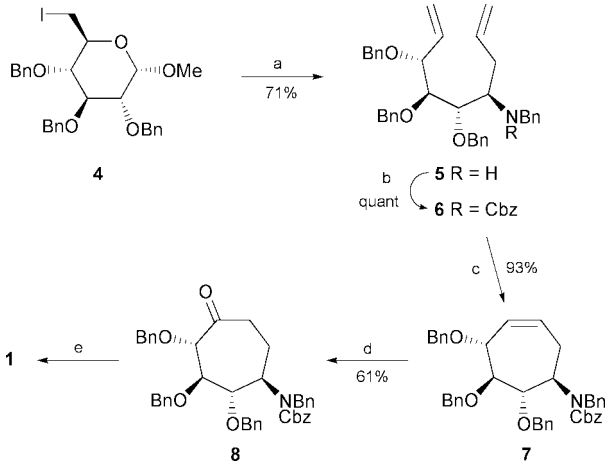
Calystegine B_2, B_3, and B_4 have been prepared in 5 steps from the benzyl protected methyl 6-iodoglycopyranosides of glucose, galactose and mannose, respectively, by using a zinc-mediated domino reaction followed by ring-closing olefin metathesis as the key steps.

Many polyhydroxylated alkaloids are important glycosidase inhibitors due to their structural resemblance to sugars.[1] A special class of these alkaloids is the calystegines which consist of a polyhydroxy-nortropane ring system.[2] Up to date, 14 different calystegines have been isolated from various plant species. Their structures have been elucidated mainly by NMR spectroscopy and they have been divided into four different classes: A, B, C and N. The absolute configuration, however, is known only for calystegine B_2 (**1**) and the configuration of all the remaining calystegines is presumed to be analogous to that of **1** based on biosynthetic considerations.[2] So far, only calystegine A_3 and B_2 have been prepared by chemical synthesis.[3]

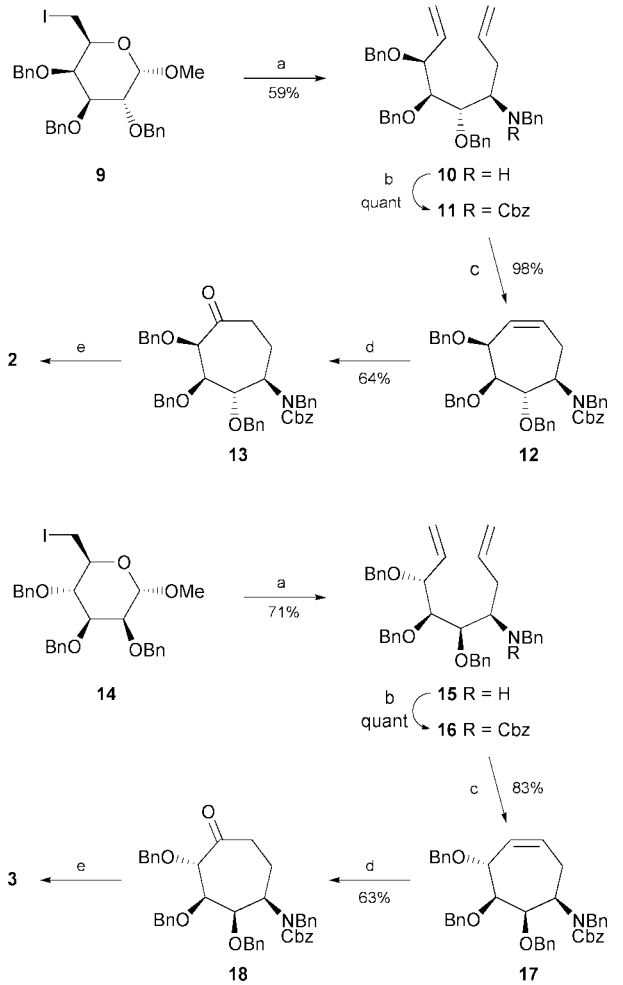


We have recently introduced a zinc-mediated domino reaction followed by ring-closing olefin metathesis for synthesis of polyhydroxylated carbocycles from sugars.[4,5] The domino reaction allows for the stereocontrolled introduction of an amino group and is then well suited for preparing the seven-membered carbocycle in the calystegines. Herein, we exploit these reactions for short syntheses of calystegine B_2, B_3 (**2**) and B_4 (**3**) starting from glucose, galactose and mannose, respectively.[6] Calystegine B_2 and B_4 are potent inhibitors of β-glucosidase and trehalase.[7]

The starting material for all three syntheses is the corresponding benzyl protected methyl 6-deoxy-6-iodo-α-D-glycopyranoside (Scheme 1). Sonicating a mixture of glucopyranoside **4** and excess zinc dust in dry THF caused a reductive fragmentation to generate the 5,6-unsaturated aldehyde[8] which was trapped *in situ* as the corresponding benzyl imine. Slow addition of allyl bromide to the mixture led to allylation of the imine to give a 5:1 mixture of amino dienes. The major diastereomer **5**[3a] was isolated in 71% yield and the stereochemistry verified after completing the synthesis of **1**. Cbz-protection of the amino group gave **6**† which was metathesised into cycloheptene **7** with the saturated *N*-heterocyclic carbene catalyst $(PCy_3)(C_3H_4N_2mes_2)Cl_2Ru{=}CHPh$.[4,9,10] The double bond in **7** is slightly polarized and can be hydroborated[11] followed by oxidation[12] in



Scheme 1 *Reagents and conditions*: (a) Zn, $BnNH_2$, $CH_2{=}CHCH_2Br$, THF, sonication, 40 °C; (b) CbzCl, $KHCO_3$, EtOAc, H_2O; (c) 2% $(PCy_3)(C_3H_4N_2mes_2)Cl_2Ru{=}CHPh$, CH_2Cl_2, rt; (d) BH_3·THF, THF, −50 → 0 °C, then NaOH, H_2O_2, 0 °C, then Dess-Martin periodinane, CH_2Cl_2, rt; (e) H_2, Pd/C.



Scheme 2 *Reagents and conditions*: (a) Zn, $BnNH_2$, $CH_2{=}CHCH_2Br$, THF, sonication, 40 °C; (b) CbzCl, $KHCO_3$, EtOAc, H_2O; (c) 2% $(PCy_3)(C_3H_4N_2mes_2)Cl_2Ru{=}CHPh$, CH_2Cl_2, rt; (d) BH_3·THF, THF, −50→ 0 °C, then NaOH, H_2O_2, 0 °C, then Dess-Martin periodinane, CH_2Cl_2, rt; (e) H_2, Pd/C.

 DOI: 10.1039/b102353p

a one pot procedure to give a 3:1 mixture of ketones. Major ketone isomer **8** was isolated in 61% yield and hydrogenated to give calystegine B_2 ($[\alpha]_D^{20}$ +23.8 (*c* 0.31, H_2O)). NMR data and optical rotation were in accordance with those reported for the natural product.[13]

The same sequence was then applied to the synthesis of calystegine B_3 and B_4 (Scheme 2). Subjecting galactose-derived iodoglycoside **9** to the domino reaction gave a 2:1 mixture of amino dienes. Major diastereomer **10**‡ was isolated in 59% yield and then converted into cycloheptene **12**. Hydroboration and oxidation gave a 3:1 mixture of ketones and the major isomer **13** was isolated in 64% yield. Hydrogenation then furnished calystegine B_3 ($[\alpha]_D^{20}$ +75.6 (*c* 0.55, H_2O)) with NMR data and optical rotation in accordance with the data for the natural compound.[13] Subjecting mannose-derived iodoglycoside **14** to the domino reaction gave a 8:1 mixture of amino dienes and the major diastereomer **15**§ was isolated in 71% yield. The stereochemical outcome in these allylations is noteworthy. In all three cases the major product is the (*R*)-benzylamine which is the correct stereochemistry for the calystegines. The major product **15** from mannose is consistent with predictions from the Felkin-Anh model while the major isomers from glucose and galactose are not. This, however, does correspond with our previous experience on zinc-mediated alkylations of glucose and mannose substrates.[4a] Finally, amine **15** was converted into cycloheptene **17** which was hydroborated and oxidised to give a 3:1 ratio of ketones. The major isomer **18** was isolated in 63% yield and deprotected to give calystegine B_4 ($[\alpha]_D^{20}$ −46.4 (*c* 0.18, H_2O)). NMR data and optical rotation were similar to those reported for the natural product.[7]

In conclusion, a general strategy for preparation of the calystegines has been devised. Calystegine B_3 and B_4 have been prepared for the first time and their absolute configuration confirmed. These syntheses should hold great promise for making the calystegines and their analogues more readily available for biological investigations.

We thank the Danish Natural Science Research Council for financial support.

First published as an Advance Article on the web 31st May 2001

Hydrogen–deuterium exchange between methane and an acid zeolite is a model reaction (refs. 1–6) for which experimental rate constants and activation energies can be compared with theoretical values, obtained with Eyring's transition state theory (ref. 7).

Obtaining rate constants for zeolite catalysed reactions, is neither experimentally nor theoretically straightforward. Experimentally, the apparent reaction rates are influenced by the adsorption behaviour of the molecules.[8,9] Intrinsic reaction parameters can only be obtained by fitting the reaction rate data to a model. Another problem is the uncertainty about the exact number of acid sites in a zeolite, due to the existence of extra-framework Al and lattice defects. The accuracy of theoretically calculated rate constants depends strongly on the model used to represent the zeolite. Usually a fully relaxed cluster,[3,4] which can only model the local environment of the acid site, is employed. Thus adsorption, and structural, long range effects cannot be accounted for in model cluster calculations.

The aim of the present paper is to check the validity of calculated rate constants. Therefore we compared them with reliable experimental values.[6] The kinetics of hydrogen–deuterium exchange between methane and deuterated acid FAU- and MFI-type zeolites have been determined in a circulation batch reactor with on-line mass spectrometric product analysis, in the temperature range 450–550 °C. The apparent activation energy was in the range 122–150 kJ mol^{-1} and a kinetic isotope effect ($k_{OH/CD}/k_{OD/CH}$, see Fig. 1) of *ca.* 1.7 was found for MFI catalysts. This was explained by suggesting that the O–D/O–H bond dissociation is the rate determining step or that the mechanism is not concerted.

Rate constants can be calculated when all the steps involved in the reaction are characterised. The reactants, transition states, and products are localised with cluster type calculations as used successfully before.[10] During the geometry optimisation we look for a local minimum for reactants, and products and for a first-order saddle point for transition states. The cluster we used consists of three T-atoms (one Al and two Si) and was allowed to relax completely during the optimisations. The DFT calculations used the B3LYP functional[11] and a 6-31G* basis set. They were done with Gaussian98.[12]

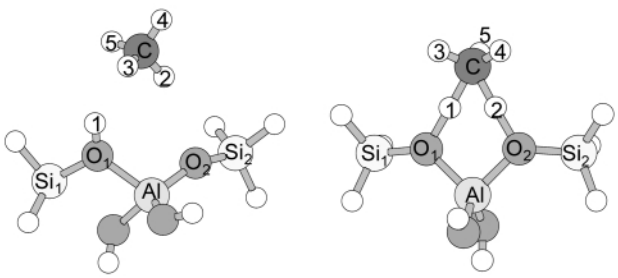

Fig. 1 Geometry of (a) CH_4 adsorbed on acid site of zeolite, (b) transition state, with the labelling of the atoms as in Table 1. For $k_{OH/CD}$: 1 = H, 2–5 = D and for $k_{OD/CH}$: 1 = D, 2–5 = H.

We found a symmetrical transition state with the exchanging hydrogens in the middle between the methane carbon and the cluster oxygen, as can be seen in Fig. 1. The interatomic distances are given in Table 1 along with the values obtained in previous studies using another level of calculations.[1,3,4]

The reaction rate constants are evaluated by using the canonical transition state theory of Eyring, Evans and Polanyi.[7] The general expression for the reaction rate constant k_r is:

$$k_r = \frac{k_B T}{h} \cdot \frac{Q^{\ddagger}}{\prod_i Q_i} \cdot e^{-\frac{E_{bar}}{k_B T}} \quad (1)$$

where k_B and h are respectively Boltzman's and Planck's constants, T is the temperature. E_{bar} is the activation barrier of the reaction. It is the energy difference between energies of reactants and transition-state and contains the zero point energy corrections. Q_i and $Q^{\ddagger}$ represent the partition function of reactants and transition-state (the index i running over all reactants). For the evaluation of eqn. (1) we use molecular partition functions.[7] With the assumption that rotational (r), vibrational (v) and electronic (e) movements are independent of each other, the molecular partition function Q is given by $Q=Q_tQ_rQ_vQ_e$, Q_t being the translational partition function.

For the H–D exchange reaction of methane, the reaction rate constant per acid proton becomes:

$$k_r = (N_A V)\left(\frac{k_B T}{h}\right) \cdot \frac{\left(Q_v^{\ddagger} Q_r Q_t\right)_{TS}}{\left(Q_v Q_r Q_t\right)_{CH_4}\left(Q_v Q_r Q_t\right)_{HZ}} \cdot e^{-\frac{E_{bar}}{k_B T}} \quad (2)$$

N_A is Avogadro's number and V is the volume of one mol under the considered P and T. It appears because of the use of concentrations in the rate laws.

Numerical values for the rigid rotor, harmonic oscillator partition functions are obtained after a frequency calculation by Gaussian98.[12,13] Eqn. (2) was used to calculate the rate constants for a temperature ranging from 300 to 800 K. An Arrhenius-plot gives an apparent activation energy of 157.0 kJ mol^{-1}, in close agreement with the experimental value.[6]

A comparison between the experimentally measured values of the exchange rate and the theoretically calculated ones can be found in Fig. 2. The rate constant depends on both the zeolite structure type and the Al content of the zeolite. Since our cluster contains two Si and one Al the Si/Al ratio is two. The calculated reaction rate constant $k_{OH/CD}$ of 1.97×10^{-7} s^{-1} agrees well with the experimentally obtained values at low Si/Al ratio.[6]

On deuteration, the reaction rate will decrease. In Table 1 rate constants for reaction of non-deuterated/deuterated zeolite (indicated with subscript OH or OD, respectively) with non-deuterated/deuterated methane (indicated subscript with CH or CD, respectively) are given. Deuteration of one of the exchanging atoms has a larger impact than deuteration of the non-exchanging atoms of methane: $k_{OH/CH}/k_{OD/CH} \approx k_{OH/CD}/$

[a] At 750 K. [b] At 673 K.

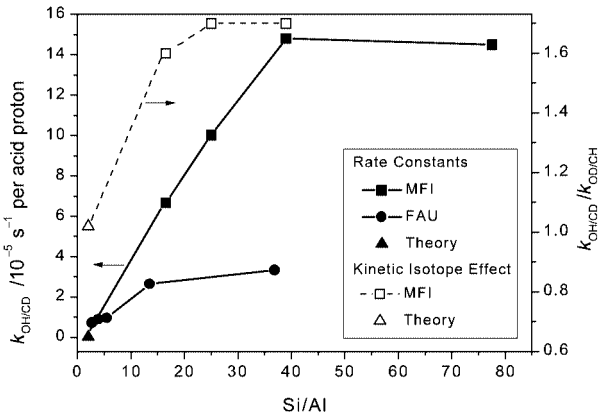

Fig. 2 Solid line and symbols: rate constants, $k_{OH/CD}$, at 700 K in function of Al-content. Dashed line and open symbols: kinetic isotope effect, $k_{OH/CD}$/$k_{OD/CH}$, at 700 K. Experimental values are taken from ref. 6.

$k_{OD/CD} \approx 1.7$ whereas $k_{OH/CD}/k_{OD/CH} = 1.02$. This is a consequence of the symmetrical transition state.

The experimental values for the kinetic isotope effect, $k_{OH/CD}/k_{OD/CH}$, are larger than the theoretical values (see Fig. 2). Unfortunately there are not enough experimental data to extrapolate to lower Si/Al ratios to validate the theoretical prediction.

It is promising to see that present day quantum chemical techniques allow the evaluation of rate constants of a simple zeolite catalysed reaction as they are yielding a lower limit for high alumina zeolites. Feasible differences between theory and experiment can be explained in several ways: (1) the cluster is only an approximation to a real zeolite lattice and does not include structural and long range effects; (2) different Si/Al ratio compared to real zeolites; (3) uncertainty on the obtained frequencies. We will use our method of calculation of rate constants for more complex reactions, *e.g.* acid zeolite catalysed methylation of toluene to form xylene[14] to check its validity.

The first full-sandwich potassacarborane and a novel 'carbons-adjacent' $R_2C_2B_{10}H_{11}^-$ monoanion

Guofu Zi, Hung-Wing Li and Zuowei Xie*

Received (in Cambridge, UK) 7th March 2001, Accepted 2nd May 2001
First published as an Advance Article on the web 31st May 2001

By taking advantage of a cage carbon-linked *o*-carborane, the full-sandwich potassacarborane and a novel carborane monoanion have been prepared and structurally characterized for the first time, in which the cage carbon atom adjacency of the precursor is maintained.

It has been well documented that *o*-$R_2C_2B_{10}H_{10}$ (R = H, alkyl, aryl) can be readily reduced by alkali metals to form the [*nido*-$R_2C_2B_{10}H_{10}]^{2-}$ dianion in which the cage carbon atoms are in *meta* positions.[1] The cage C–C bond is completely broken during this two-electron reductive process.[1] The structures of its alkali metal salts have recently been reported.[2] These salts are very useful versatile synthons for the production of numerous metallacarboranes of s-, p-, d-, and f-block elements.[1] Protonation of [*nido*-$R_2C_2B_{10}H_{10}]^{2-}$ affords two isomers, the kinetic one **A** and the thermodynamic product **B**, as shown in Scheme 1.[3] Isomer **B** is more stable than **A** by 6.7 kcal mol^{-1} according to the computational results.[4] We have found that the two cage carbon atoms remain adjacent in *ortho* positions during the two-electron reductive process if they are linked by a short bridge, which leads to the isolation and structural characterization of the first full-sandwich potassacarborane and the novel isomer of the $[R_2C_2B_{10}H_{11}]^-$ monoanion. These new findings are reported in this communication.

Treatment of μ-1,2-[*o*-$C_6H_4(CH_2)_2$]-1,2-$C_2B_{10}H_{10}$[5] with excess finely cut potassium metal in THF at room temperature gives, after recrystallization from a THF/CH_3CN solution of 18-crown-6, the first full-sandwich potassacarborane [*closo-exo*-{μ-1,2-[*o*-$C_6H_4(CH_2)_2$]-1,2-$C_2B_{10}H_{10}$}$_2K_3$(18-crown-6)$_2$][(18-crown-6)K$(CH_3CN)_2$] (**1**) as yellow crystals in 74% yield.† **1** is extremely air- and moisture-sensitive but remains stable for months at room temperature under an inert atmosphere. Protonation of **1** generates a novel carborane monoanion [{μ-1,2-[*o*-$C_6H_4(CH_2)_2$]-1,2-$C_2B_{10}H_{11}$}K(18-crown-6)]$_n$ (**2**) as colorless crystals.† These transformations are summarized in Scheme 2. Both **1** and **2** have been fully characterized by various spectroscopic, elemental and X-ray analyses.

The ^{1}H NMR spectra show that methylene protons on the carborane cage in both **1** and **2** are non-equivalent in solution, and support the ratios of 1.5 18-crown-6 and one acetonitrile molecule per carboranyl ligand for **1**, and one 18-crown-6 molecule per ligand for **2**, respectively. The ^{13}C NMR spectra are consistent with the results derived from their ^{1}H NMR spectra. The ^{11}B NMR spectra exhibit 2:2:1:2:1:1:1 and 1:4:3:1:1 splitting patterns for **1** and **2**, respectively. Their solid-state IR spectra display both a characteristic doublet centered around 2450 cm^{-1} and a shoulder at about 2360 cm^{-1} attributable to a K–H–B stretching mode.[6]

An X-ray analysis‡ reveals that **1** is a centrosymmetric molecule consisting of well-separated, alternating layers of discrete cations [(18-crown-6)K$(CH_3CN)_2]^+$ and complex anions [*closo-exo*-{μ-1,2-[*o*-$C_6H_4(CH_2)_2$]-1,2-$C_2B_{10}H_{10}$}$_2K_3$(18-crown-6)$_2]^-$. In the anion, the K2 atom sits at an inversion center and bonds to two *nido*-carboranyl ligands in a η^6 fashion to form a fully sandwiched metallacarborane, shown in Fig. 1. It is interesting to note that the cage carbon atom adjacency of the precursor is maintained in the product due to the presence of the short bridge between the two cage carbon atoms. The six atoms of the hexagonal C_2B_4 bonding face are coplanar compared with the staggered arrangement of the two carbon atoms of the hexagonal face in the 'carbons-apart' dianionic species [*nido*-$R_2C_2B_{10}H_{10}]^{2-}$.[3] The average K2–cage atom distance of 3.064(4) Å is close to the corresponding value of 3.174(2) Å observed in [*closo-exo*-{$(C_6H_5CH_2)_2C_2B_{10}H_{10}$}$K_2(THF)_2(O_2C_4H_8)_{0.5}]_n$.[2]

In contrast to **1**, **2** adopts a polymeric structure in which the carboranyl and potassium ions serve as alternating bridging groups to give a zigzag carborane–K–carborane–K chain that is maintained in one-dimension throughout the lattice (Fig. 2). The

 DOI: 10.1039/b102131c

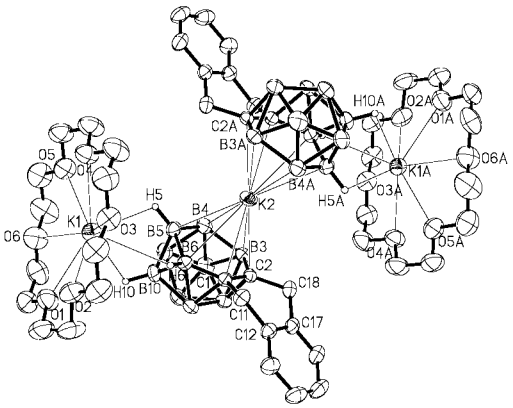

Fig. 1 ORTEP illustration of [*closo-exo*-{μ-1,2-[*o*-$C_6H_4(CH_2)_2$]-1,2-$C_2B_{10}H_{10}$}$_2$$K_3$(18-crown-6)$_2$]$^-$ in **1** with thermal ellipsoids drawn at the 35% probability level.

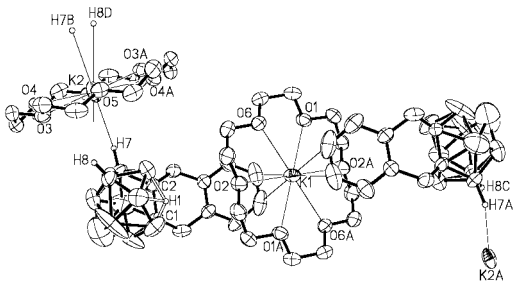

Fig. 2 ORTEP illustrations of **2** showing a portion of the infinite polymeric chain (thermal ellipsoids drawn at the 35% probability level).

most significant part of this structure is the arrangement of the cage atoms: 5-coordinate carbon and boron (C1, C2 and B11), 6-coordinate boron (B3–B5, B7, B8, B10 and B12), and 7-coordinate boron (B9 and B6), shown in Fig. 3. There are two pentagonal belts, one (B6B7B8B9B10) is capped by two boron atoms (B11 and B12) and the other (C1C2B3B4B5) is partially capped by one μ_3-H atom. This is a brand new isomer of the $[R_2C_2B_{10}H_{11}]^-$ monoanion which has never been observed before. Since **2** is prepared in a hot acetone solution, it is reasonable to suggest that **2** is the thermodynamic ('stable') product, which is also supported by ^{11}B NMR data. It is very obvious that the presence of a short bridge plays a significant role in the generation of the novel carborane monoanion in **2**.

In summary, the 'carbons-adjacent' carborane dianion and monoanion of the C_2B_{10} system can be readily produced by introducing a short bridge between two cage carbon atoms of an *o*-carborane. This study implies that these anions may exhibit a different chemistry from the corresponding 'carbons-apart' species.

Tailored palladium containing silica spheres

Lubomira Tosheva and Johan Sterte*

Division of Chemical Technology, Luleå University of Technology, S-971 87 Luleå, Sweden. E-mail: jost@km.luth.se

Received (in Cambridge, UK) 2nd March 2001, Accepted 4th May 2001
First published as an Advance Article on the web 31st May 2001

Palladium containing silica spheres are tailored by a multi-step procedure consisting of: (i) preparation of ion exchange resin–silica composites, (ii) Pd ion exchange, and (iii) calcination.

Controlled preparation of porous materials is of great technological interest for areas such as heterogeneous catalysis and molecular sieving.[1,2] Advanced porous structures *e.g.* metallic macrostructures, have attracted special attention due to their unique properties. By colloidal crystal templating porous gold flakes have been produced with the size of the pores corresponding to the size of the latex micospheres used as templates.[3] A number of macroporous, free-standing metal films have been prepared employing colloidal silica crystals as pore-size determining templates.[4] Silica sol has been used as a nanoglue to synthesise composite aerogels containing different guest components *e.g.* Pt and Au.[5] Recently, we reported a method for the preparation of silica-based macrostructures using anion exchange resins as templates.[6,7] This method involves treatment of resin beads with silica solutions followed by calcination. The resin bead templates determine the final shape of the macrostructures whereas the combustion of the resin provides the materials with high and controlled porosity. Here, we report the synthesis of palladium containing silica spheres prepared by resin templating. The procedure is based on the fact that the resin–silica composites obtained after the ion exchange of silica species retain a high anion exchange capacity facilitating introduction of negatively charged ions such as $PdCl_4^{2-}$ in a second step. Upon calcination the resin bead templates are removed and the palladium is obtained in an oxide form.

Macroporous strongly basic Dowex MSA-1 resin beads (mesh size 20–50, chloride form) were used as received from Sigma. In a typical synthesis batch, 30 g of resin were mixed with 150 g of sodium water glass solution (21.4 wt% SiO_2, 6.7 wt% Na_2O, Akzo Nobel) in a polyethylene reactor. The synthesis mixture was treated in an oil bath preheated to 100 °C under reflux until the initially floating resin particles sank, after 4 h. The resin–silica composites obtained were separated by decanting, rinsed repeatedly with distilled water and dried at 105 °C. Palladium was subsequently introduced into the composites by ion exchange using a solution of 0.01 M palladium chloride ($PdCl_2$, Aldrich) dissolved in 1 M hydrochloric acid. Composites and palladium solutions were mixed in different weight ratios (*e.g.* 1 g composite mixed with 5, 10 or 20 g of Pd solution and the corresponding samples were designated as Pd5, Pd10 and Pd20) in a beaker and placed on a shaker overnight. After this procedure the initially brownish color of the Pd solutions turned colorless. The Pd–resin–silica composites were decanted, rinsed repeatedly with distilled water and dried at 105 °C. Finally, the composites were calcined at 600 °C for 5 h after heating to this temperature at a rate of 1 °C min^{-1}.

Visually the Pd materials obtained after the removal of the ion exchanger consisted of solid and hard brownish spheres. The color intensity was increased with an increase in the palladium solution to composite weight ratio used. A SEM image representative for those spheres is shown in Fig. 1(a). The shape of the particles was identical to the shape of the initial ion exchange resin beads but the spheres shrunk upon calcination. A similar result was obtained for the silica spheres obtained after calcining the resin–silica composites and correspondingly the shrinkage observed was not related to the insertion of palladium into the composites. The Pd spheres were built up by fine particles with a size of < 100 nm which is comparable to the pore size of macroporous resins.[8] The primary particles of the Pd silica spheres were similar to those of calcined resin–silica composites and no conclusions about the palladium dispersion can be drawn by the SEM investigation.

Pd silica spheres were ground into a powder and X-ray diffraction patterns were recorded in order to identify the form of palladium obtained after the calcination. During the grinding no white material was observed suggesting that the palladium was distributed within the spheres. Fig. 1(b) shows the XRD pattern of the Pd20 sample. Two phases may be seen in this pattern: an amorphous one, emanating from the amorphous silica phase, and a crystalline one, corresponding to the presence of palladium oxide in the spheres.[9] The XRD patterns of the Pd10 and Pd5 samples were similar to that shown in Fig. 1(b) but with lower peak intensities related to the decreased Pd loading. No additional peaks due to the presence of other

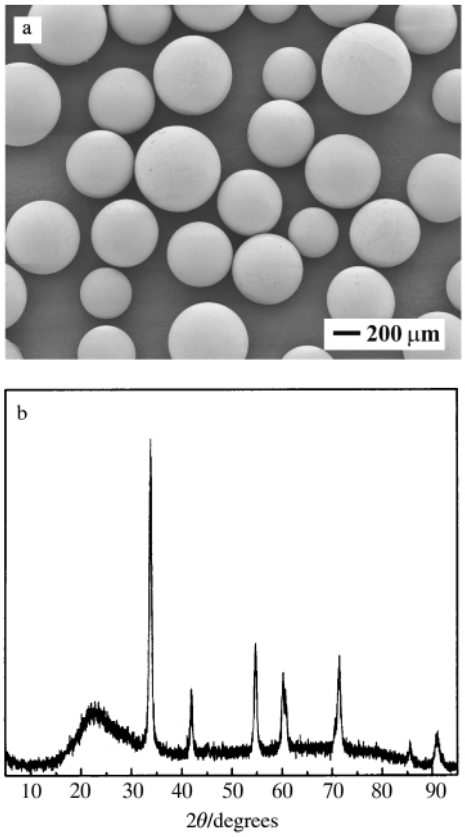

Fig. 1 A representative SEM image of the Pd containing silica spheres (a) and XRD pattern of the Pd20 sample (b). SEM was performed on a Philips XL scanning electron microscope equipped with a LaB_6 emission source. XRD patterns were collected at room temperature with a Cu-Kα X-ray source using a Siemens D5000 instrument.

Table 1 BET surface areas, total pore volumes, yield, Pd loading and Pd uptake for the spheres prepared

Spheres	BET surface/ area/$m^2\ g^{-1}$	Total pore volume[a]/$cm^3\ g^{-1}$	Yield (wt%)	Pd loading/(wt%)	Pd uptake[b](%)
Silica	93	0.26	38.39	—	—
Pd5	840	0.64	38.84	1.37	99.8
Pd10	1043	0.75	38.05	2.80	99.3
Pd20	1203	0.88	38.08	5.59	97.9

[a] Calculated by converting the volume adsorbed at a relative pressure of 0.995 to the volume of the liquid adsorbate. [b] Calculated from the Pd concentration in the initial Pd solution and in the solution after the ion exchange as determined by atomic absorption spectrometry.

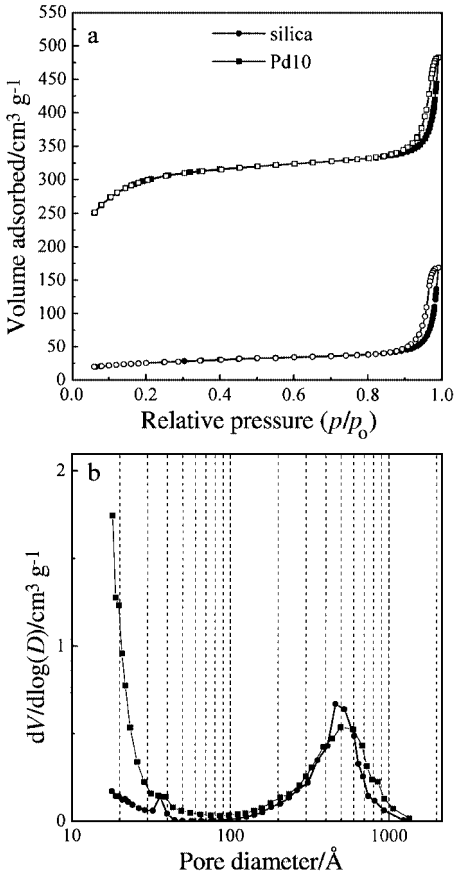

Fig. 2. Nitrogen adsorption isotherms at 77 K for calcined silica and Pd10 spheres; solid symbols, adsorption; open symbols, desorption (a) and the corresponding pore size distributions (b). The pore size distributions were calculated from the desorption branch of the nitrogen isotherm by the BJH method. The data was collected with a Micromeritics 2010 Gas Adsorption Analyser after the materials were degassed at 300 °C for 12 h.

palladium phases were detected in the XRD patterns of the Pd containing spheres prepared.

Fig. 2(a) shows nitrogen adsorption isotherms for calcined silica and Pd10 spheres. The isotherm for the calcined silica spheres was of type IV which is typical for mesoporous materials.[10] Langmuir type isotherms typical of microporous materials, with identical, nearly horizontal, adsorption and desorption branches, were obtained for the Pd containing spheres. Some mesopores were also present in these spheres as seen from the distinct hysteresis loop at high relative pressures. From the pore-size distributions presented in Fig. 2(b) is seen that the amount of mesopores (imposed by the removal of the ion exchange resin) is approximately the same for the two samples, whereas the amount of micropores is increased for the Pd containing spheres. The surface area values, calculated with the BET equation as well as the total pore volumes are listed in Table 1. Judging from these values and the pore-size distributions one can conclude that: (i) the insertion of palladium into the resin–silica composites leads to substantially larger BET surface areas of the calcined samples; (ii) the increase in the surface area is related to the amount of palladium present within the spheres; and (iii) the increase in the surface areas may be related to an increase in the micropore volume of the calcined materials. These results are surprising and further investigations are needed in order to explain the rather dramatic changes observed.

Finally, the yield, the amount of solid material obtained per gram of composite, was determined from the weight difference between dried composites at 150 °C and calcined spheres (Table 1). From the yield and from the similar hardness of the silica and the Pd silica spheres one may conclude that there was no substantial silica leakage from the resin–silica composites during the Pd ion exchange. Based on the yields, the Pd loading was calculated and listed in Table 1. Considering the Pd uptake data (also included in Table 1) one may conclude that the ion exchange of Pd into the resin–silica composites was almost complete.

The results presented show that hard and solid silica spheres containing a controllable amount of palladium can be prepared using macroporous ion exchange resins as templates. Owing to the high surface areas and large pore volumes, these materials are interesting for catalytic applications. Currently our efforts are directed to further characterise the palladium in the silica spheres and results will be presented in a subsequent publication. The procedure may also be used for the preparation of silica spheres containing other active catalytic phases.

We thank the Swedish Research Council for Engineering Sciences (TFR) for partial financial support of this work.

Controlling the formation of discrete complexes or a 1-D directional coordination network by the binding ability of anions†

Abdelaziz Jouaiti, Valérie Jullien, Mir Wais Hosseini* Jean-Marc Planeix and André De Cian

Laboratoire de Chimie de Coordination Organique, Université Louis Pasteur, F-67000 Strasbourg, France. E-mail: hosseini@chimie.u-strasbg.fr

Received (in Cambridge, UK) 5th March 2001, Accepted 8th May 2001
First published as an Advance Article on the web 31st May 2001

Based on the coordination ability of ClO_4^-, BF_4^- and Cl^- anions, a switch from discrete octahedral Co(II) complexes to a directional 1-D network was demonstrated using organic tectons based on a pyridine unit as a monodentate coordination site and a terpyridine moiety as a tridentate coordination pole; whereas with non-coordinating anions discrete mononuclear complexes were obtained, for Cl^- anion a 1-D coordination network was obtained in the presence of $CoCl_2$ under self-assembly conditions; the X-ray study on a single crystal revealed the centrosymmetric packing of the 1-D networks.

The self-assembly process based on the use of metals and organic ligands is a powerful strategy allowing generation of polynuclear assemblies displaying a variety of finite architectures.[1] The same strategy is also currently used to prepare coordination networks which are infinite assemblies possessing translational symmetry.[2]

Let us focus on 1-D coordination networks obtained by a single translation of an assembling core defined by the coordination of the metal to the organic tecton. Although many examples of 1-D networks using metals with linear coordination geometrics and bis-monodentate tectons have been prepared, for metals adopting other coordination geometries such as square planar, tetrahedral or octahedral only a rather small number of investigations have been reported. The majority of coordination networks reported so far are based on 4,4′-bipyridine,[3] however, few examples based on bis-bidentate[4,5] or tetrakis-monodentate[6,7] ligands have been also reported. Finally, only a few structurally characterised networks based on bis-tridentate tectons have been published.[8–10]

For coordination networks based on metal cations and anionic organic tectons bearing the same but opposite charges, the charge compensation criteria is fulfilled. In this case, the design of the network may be based on the match between the coordination features of the metal and the organic tecton. However, when charge neutrality is not achieved by the two partners, the presence of a third component is required thus leading to a three-component system. For a combination of neutral tectons and metal cations, based on the binding ability of the anion, two possibilities may be considered. Non-coordinating anions would mainly play a charge compensating role without interfering directly with the metal centres, whereas coordinating anions form direct bonds with the metal cation. In the latter case, one may take advantage of this requirement to control the coordination sphere around the metal cation. For example, for metal centres adopting O_h geometry, the use of bulky and coordinating anions such as Cl^- would lead to the occupation of the two axial positions thus leaving the square planar base for construction of coordination networks.[11]

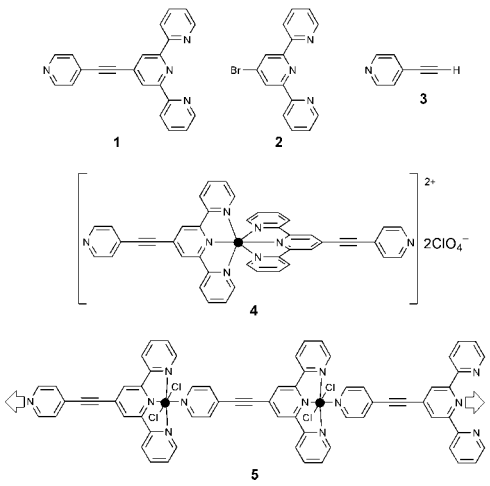
Here we report the design and synthesis of a tecton **1** and, depending on the coordinative nature of the anion (Cl^-, ClO_4^-), the formation of either a discrete complex **4** or a 1-D directional network **5** using Co(II) complexes.

Ligand **1** (Scheme 1) is based on a combination of a pyridine (py) and terpyridine (terpy) units. The junction between the mono- and tri-dentate units was achieved using an ethynyl spacer. The latter was chosen because it should minimise possible steric effects affecting the packing of 1-D networks in the solid state and should allow electronic communication between the py and terpy sites.[12] An example of a py directly connected to a terpy has been reported by Constable *et al.*[13]

For Co(II) cations adopting O_h geometry, in the case of non-coordinating anions such as ClO_4^-, all six available coordination positions may be occupied by two terpy moieties belonging to two molecules of **1** acting as ligands thus leading to a discrete complex **4** (Scheme 1). However, in the presence of coordinating anions such as Cl^-, the two anions would occupy the two axial positions leaving four coordination sites located at the square planar plane of the octahedron. Then **1** may act as a tecton by connecting the metal centres into a 1-D network such as **5**. Indeed, the four available coordination positions may be occupied by a terpy moiety belonging to one tecton **1** and by the py unit belonging to another tecton **1**, leading by a single translation of an assembling core defined as [py–$CoCl_2$–terpy], to a 1-D network. Moreover, owing to the unsymmetrical nature of **1**, a directional 1-D network should be obtained. The latter point is of interest for directional physical properties if one could avoid centrosymmetric packing of directional 1-D networks.

The starting material for the synthesis of **1** was **2**[14] which was prepared according to published procedures.[14] The synthesis of **1** was achieved by coupling **2** with **3**[15] in the presence of $Pd(OAc)_2$ and Ph_3P in Et_3N under reflux for 48 h. Pure ligand **1** was obtained as a white powder in 98% yield after chromatography (Al_2O_3, hexane–diethyl ether 6:4).

Upon slow diffusion at room temp. of a MeOH solution containing $Co(ClO_4)_2{\cdot}6H_2O$ (4 mg) into a $CHCl_3$ solution of **1** (5 mg), orange crystals were obtained after *ca.* 4 h. An X-ray study‡ on a single-crystal showed the presence of **4** with the following relevant features: the crystal (monoclinic) was



Scheme 1

† Dedicated to François Mathey on the occasion of his 60th birthday.

 DOI: 10.1039/b102042k

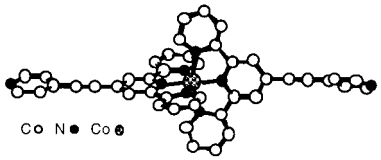


Fig. 1 X-Ray crystal structure of the mononuclear Co complex **4**. ClO_4^- anions, H atoms and solvent molecules are omitted for clarity. For distances and angles see text.

composed of **1**, Co^{2+}, $2ClO_4^-$ and $2CHCl_3$. For the cationic complex **4** comprised of one cation and two ligands **1**, the metal adopts a distorted O_h geometry with all six coordination positions occupied by 6 N atoms belonging to two terpy units. Whereas the two N–Co distance are 1.88 and 1.92 Å in the case of both central py units, the other N–Co distances are between 2.00 and 2.14 Å. For nitrogen atoms in *cis* disposition the N–Co–N angle varies from 78.5 to 103.0°, whereas for those in *trans* configuration, the N–Co–N angle varies from 156.9 to 178.4° (Fig. 1). No specific interactions between **4** and ClO_4^- anions are observed. Interestingly, the same observations were made for an analogous ligand (in which the terpy unit was connected by the same ethynyl spacer to the py moiety at the position 3) upon treatment with $Co(BF_4)_2{\cdot}6H_2O$ (synthesis and X-ray data not reported here).

Upon slow diffusion at room temp. of a MeOH solution containing $CoCl_2{\cdot}6H_2O$ (6 mg) in to a CH_2Cl_2 solution of **1** (6 mg,), purple crystals were obtained after *ca*. 24 h. An X-ray study‡ revealed the presence of the 1-D network **5**. The crystal (monoclinic) was composed of **1**, Co^{2+}, $2Cl^-$ and 1 CH_2Cl_2. As expected for the coordinating Cl^- anion, a directional 1-D neutral network based on the interconnection of $CoCl_2$ units by **1** is observed. The assembling core is a distorted octahedral Co(II) complex for which the coordination sphere is composed of two Cl^- and four N atoms. The two Cl^- anions occupy the two axial positions with a Co–Cl distance of *ca* 2.463 Å and Cl–Co–Cl angle of 179.5°. The square base of the octahedron is composed of one py belonging to **1** and one terpy unit belonging to next tecton **1** with Co–N distances of 2.131 Å for the py unit and 2.048 Å for the central py of the terpy moiety. The other two Co-N distances are *ca*. 2.162 Å. Whereas the Cl–Co–N angle varies from 88.6 to 91.3°, the N–Co–N angle varies between *ca*. 76.7 and 103.3°. The N–Co–N angle between the py and the central py unit of the terpy moiety is 180.0°. The py and the terpy units are not coplanar but are tilted by *ca* 112 ° (Fig. 2).

Owing to the unsymmetrical nature of **1**, the 1-D network is directional by nature. In principle, a directional 1-D network may either be packed in centrosymmetric or non-centrosymmetric modes in the crystalline phase. In the example reported here, the directional networks are positioned in a parallel fashion but oriented in opposite directions, thus leading to an overall non-directional system (Fig. 2). This centrosymmetric packing may be due to cancellation of dipolar moments.

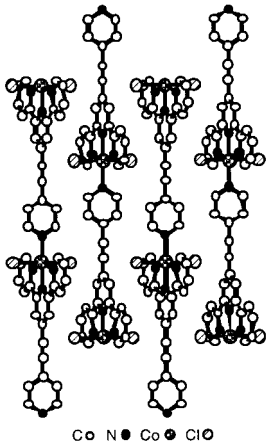

Fig. 2 A portion of the X-Ray crystal structure of the directional 1-D network **5** showing the packing of consecutive networks in 'head-to-tail' fashion. H atoms and solvent molecules are omitted for clarity. For distances and angles see text.

In conclusion, using a neutral tecton such as **1** and Co(II), depending on the its coordination ability, the role of the auxiliary anions in directing either the formation of discrete complexes or a 1-D network was demonstrated. Indeed, unsymmetrical ligand **1** based on two different coordination poles and non-coordinating anions such as ClO_4^- lead to the formation of a discrete Co(II) octahedral complex **4**, whereas, for a coordinating anion such as Cl^-, the self-assembly of $CoCl_2$ and **1** leads to the formation of a neutral and directional 1-D network **5** in the solid state. The directional 1-D networks are packed parallel to each other with opposite orientation. Since the discrete complex **4** possesses two non-coordinating pyridine units, it may act as an exo-ligand and thus may be used as a metallatecton[16] for generating heteronuclear coordination networks. This aspect is under current investigation.

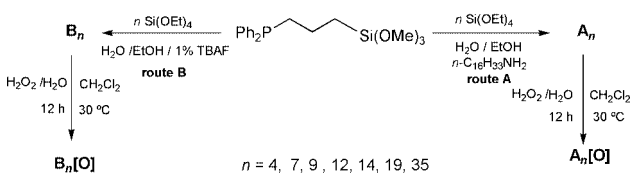
Direct complexation of europium nitrate into HMS materials containing phosphine oxide groups covalently linked to a silica matrix is accomplished and is shown to work much better than into the corresponding materials prepared in the absence of surfactant.

The study of luminescent materials has been the subject of extensive research in the past decade.[1–3] Of particular interest are rare-earth-ion-based systems which can give rise to a variety of optical applications such as fiber amplifiers and solid-state lasers.[4,5] The sol–gel approach is an attractive means of synthesising these materials since it allows both the control of the devices and a great diversity of chemical composition.[6] Numerous studies have been carried out on nanocomposite hybrid materials prepared by incorporating Eu^{3+} or Tb^{3+} complexes into sol–gel matrices.[7–9] With a view to avoiding the inhomogeneous dispersion of rare-earth complexes within the silica matrix, we have recently studied the hydrolytic polycondensation of isolated europium complexes with phosphine oxides bearing one hydrolysable $Si(OR)_3$ group.[10] We have shown that the Eu^{3+} are well encapsulated within the resulting nanostructured hybrid materials which present highly luminescent properties. We now report a very simple and original route to Eu^{3+} containing hybrid materials. This method consists of the direct incorporation of europium salts into a hybrid organic–inorganic material containing phosphine oxide groups covalently linked to the silica matrix and able to complex Eu^{3+}.[11] This rare-earth ion was selected as a representative rare-earth ion because of its unique fluorescence properties.[12] We show that ordered HMS materials containing phosphine oxide groups prepared by using the direct synthetic approach[13] are much more convenient for the complexation of Eu^{3+} than the corresponding materials prepared in the absence of surfactant. The luminescence behaviour of the materials was considered.

The hybrid materials $\mathbf{A}_n$ (Scheme 1) were obtained by co-hydrolysis and polycondensation of a mixture of $Ph_2P(CH_2)_3Si(OMe)_3$[14] and of n equiv. of $Si(OEt)_4$ (n = 4, 7, 9, 12, 14, 19 and 35) in the presence of *n*-hexadecylamine as template (route A). The corresponding materials $\mathbf{B}_n$ (route B) were prepared in the absence of template but in the presence of 1% TBAF as catalyst [n in index for materials $\mathbf{A}_n$ and $\mathbf{B}_n$ corresponds to the number n of equiv. of $Si(OEt)_4$]. The xerogels were prepared according to published procedures.[15] Treatment of the materials $\mathbf{A}_n$ and $\mathbf{B}_n$ with a large excess of an aqueous H_2O_2 solution for 12 h at 30 °C afforded the solids $\mathbf{A}_n$**[O]** and $\mathbf{B}_n$**[O]**, respectively (Scheme 1).[16] After washing and drying, the solid-state ^{31}P NMR spectroscopy of the resulting white solids revealed the complete formation of P=O centres. Some relevant physical properties of these materials are given in Table 1. The BET surface areas of both materials were determined by the N_2 adsorption–desorption isotherm measurements. The materials $\mathbf{A}_n$**[O]** (n = 4–35) exhibit type IV isotherms, characteristic for mesoporous materials while the materials $\mathbf{B}_n$**[O]** display type II isotherms, indicative of macroporosity. The XRD patterns of the materials $\mathbf{A}_n$**[O]** exhibit an intense diffraction peak corresponding to the d_{100} spacing (Table 1). and in some cases (for $n \geqslant 19$) a much less intense peak corresponding to d_{110} and d_{200} spacings indicating a hexagonal mesostructure. In contrast, the XRD patterns of the solids $\mathbf{B}_n$**[O]** display no peak. Both types of solids were subsequently treated with an excess of an ethanol solution of $Eu(NO_3)_3{\cdot}6H_2O$ (2 equiv. of Eu^{3+} per P=O) heated under reflux for 14 h. The resulting solids **EuA**$_n$**[O]** and **EuB**$_n$**[O]** were copiously washed with acetonitrile to eliminate the non-complexed salt until no traces of $Eu(NO_3)_3$ were detected in the filtrate. After drying, the extent of the complexation reaction within both types of materials was first determined by solid-state ^{31}P NMR spectroscopy. For $n \leqslant 14$, the ^{31}P NMR spectra of the materials exhibit two signals (Table 2), one was attributed to the free P=O groups (33.1–37.4 ppm) and the other which was shifted upfield (−107.1 to −112.0 ppm), to P=O groups coordinated to Eu^{3+}. The percentage of complexed P=O sites was calculated by integration of the signals and the results are reported in Table 2 and in Fig. 1. When $n > 14$, the solid state ^{31}P NMR spectra of both materials display only one signal attributed to the starting phosphine oxide. Elemental analyses for Eu, P, N (and in some cases Si) were carried out, and the percentages of complexed Eu^{3+} were then calculated considering that one Eu^{3+} coordinates three P=O groups (Table 2).[17] This method of calculation afforded percentages of complexed Eu^{3+} in good agreement with the percentages calculated by ^{31}P NMR spectroscopy. This strongly suggests that the uptake of one Eu^{3+} requires three P=O groups within the materials.

Thus, direct incorporation of $Eu(NO_3)_3{\cdot}6H_2O$ within both types of materials is possible for $7 \leqslant n \leqslant 14$. The uptake of Eu^{3+} depends highly on the type of the materials (prepared in the presence or in the absence of surfactant) and on the dilution of the organic moiety into silica (Fig. 1), the higher percentage of



Scheme 1 $\mathbf{A}_n$**[O]** and $\mathbf{B}_n$**[O]** corresponds to materials $Ph_2PO(CH_2)_3SiO_{1,5}/nSiO_2$ prepared in the presence and in the absence of surfactant, respectively.

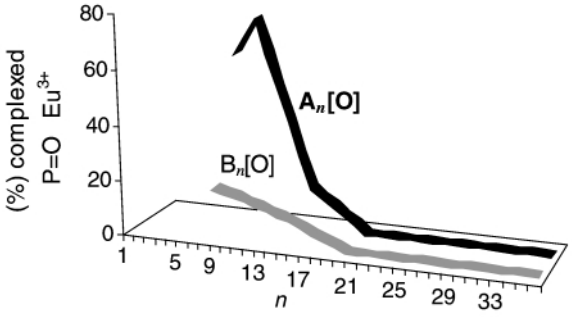

Fig. 1 Percentage of complexed P=O–Eu^{3+} groups (calculated from solid-state ^{31}P NMR spectroscopy) within **A$_n$[O]** and **B$_n$[O]** materials as a function of the 'dilution' n.

complexation (about 80%) being obtained for the material **A$_9$[O]**. Furthermore, it is remarkable to observe (Fig. 1) that, for a given 'dilution' of phosphine oxide moieties into silica, in particular for n = 7 and 9, the amount of incorporated Eu^{3+} is always low for the materials prepared in the absence of surfactant. This great difference between the properties of materials **A$_n$[O]** and **B$_n$[O]** towards the complexation of Eu^{3+}, shows that the ordered mesoporous hybrid materials **A$_9$[O]** and **A$_7$[O]** in which the P=O are located within the pores[18] are suitable for the complexation of Eu^{3+}, while the materials **B$_n$[O]** (n = 7 and 9) in which the distribution of P=O groups is uncontrolled, are not. This suggests that the complexation of Eu^{3+} requires not only three P=O groups in close proximity to each other but in a favourable geometry. It is worth noting that the complexation of Eu^{3+} is optimum but incomplete (80%) for **A$_9$[O]**. For n < 9, the P=O groups are certainly in close proximity to each other but nevertheless they do not allow an optimum complexation of Eu^{3+} probably for steric reasons. That illustrates how restrained is the complexation of Eu^{3+} within the materials. For the dilutions n > 14, there is neither complexation for the ordered materials **A$_n$[O]** nor for **B$_n$[O]**. The distances between the P=O groups are then likely much too large to allow the complexation.

The emission spectra of both types of materials were measured at 2 K under laser excitation at 325 nm. Fig. 2 displays the emission spectra of materials **EuA$_9$[O]** and **EuB$_7$[O]** as examples. The line emission of materials incorporating Eu^{3+} ions were assigned to the transition from the $^5D_0$ level to the ^7F_i levels (i = 0, 1, 2, 3, 4).[19] The strongest transition, $^5D_0 \rightarrow {}^7F_2$ occurs at 618 nm and is the characteristic 'europium red'

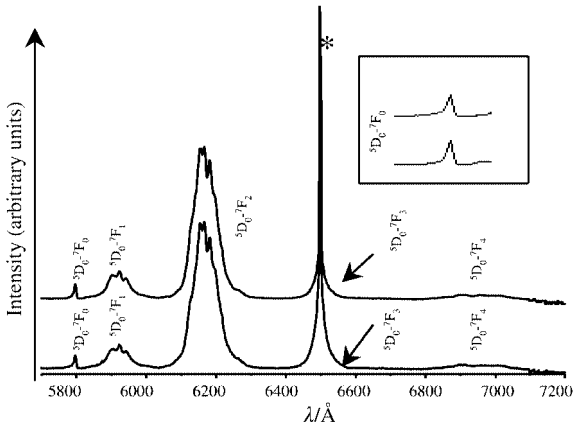

Fig. 2 Emission spectra of **EuA$_9$[O]** (upper) and **EuB$_7$[O]** (lower) recorded under laser excitation at 325 nm at 2 K. * Corresponds to 2nd order-scattered laser beam. The insert shows the $^5D_0 \rightarrow {}^7F_0$ emission.

luminescence. We observed a decrease of the red colour as the percentage of Eu^{3+} decreases. It is of note that the emission spectra are very similar for both types of materials. Of special interest is the $^5D_0 \rightarrow {}^7F_0$ emission which exhibits in both cases only one line indicating a unique chemical environment around the Eu^{3+} ions.[19] Thus, when the complexation of Eu^{3+} is possible within the materials **A$_n$[O]** or **B$_n$[O]**, the local environment around Eu^{3+} is the same whatever the route for the preparation of hybrid materials (route A or B).

In summary, we describe for the first time, a very simple method for the complexation of Eu^{3+} within hybrid materials. We show that the ordered HMS materials containing phosphine oxide groups within the pores are mostly convenient for the complexation of Eu^{3+} which requires three P=O centres.

Received (in Cambridge, UK) 9th March 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 31st May 2001

The first examples of zinc compounds with bridging fluorine and hydrogen atoms [{HC(CMeNAr)$_2$}Zn(μ-X)]$_2$ (Ar = 2,6-Me$_2$C$_6$H$_3$, X = F, 8; X = H, 9) have been synthesised and structurally characterised.

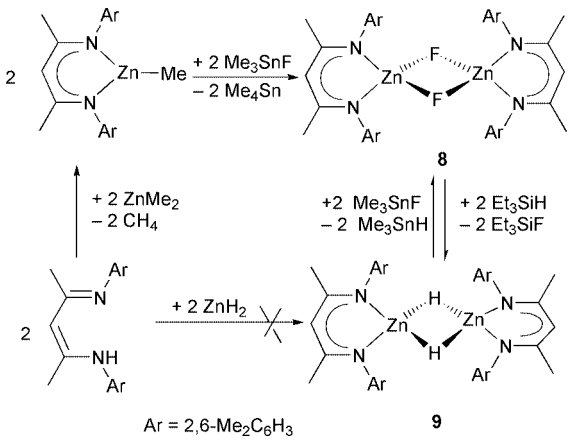
Recent reports have shown increasing interest in the utilisation of zinc hydride complexes as reducing reagents[1] and as precursors for various transformations.[2] Generally, zinc hydride complexes are synthesised from ZnH_2.[3] However, the impurity, thermal mobility and the inertness of ZnH_2 compared to its group 13 analogues often resulted in impure products.[4,5] In addition, hydrogen is believed to play a bridging role between two zinc atoms in many zinc hydride complexes as presumed in ZnH_2, resulting in polymeric or oligomeric species that are difficult to crystallise and characterise.[5] Therefore, zinc hydride complexes are less well known and have been less thoroughly investigated than the group 13 analogues and other zinc reagents. Before this work started, only three zinc hydride complexes had been structurally characterised, namely [Me$_2$N(CH$_2$)$_2$N(Me)ZnH]$_2$ **1**,[6] [{η^3-HB(3-RC$_3$N$_2$H$_2$)$_3$}ZnH] (R = Bu^t) **2**[2] and [(Me$_3$PN)ZnH]$_4$·4THF **3**.[7] In these three compounds, all hydrogen atoms are terminally arranged. The bridging role of hydrogen atoms in zinc hydride complexes remains crystallographically unveiled. Kläui *et al.*[8] had successfully synthesised [{η^3-HB(3-R-5-MeC$_3$N$_2$H$_2$)$_3$}ZnH] (R = *p*-Tol) **4** from the metathesis reaction of Et$_3$SiH with the first structurally characterised zinc fluoride compound [{η^3-HB(3-R-5-MeC$_3$N$_2$H$_2$)$_3$}ZnF] (R = *p*-Tol) **5**.[8] However, Kläui's fluorination method is not applicable for most of the other zinc precursors due to their moisture sensitivity.

Recently, we trapped 'molecular' ZnF_2 and MeZnF by using organotitanium fluorides as matrices to yield [(Cp*TiF$_3$)$_8$(ZnF$_2$)$_3$] **6** and [(Cp*TiF$_3$)$_4$(MeZnF)$_2$] **7**, respectively.[9] Compound **7** is an intermediate for the formation of **6**, the methyl groups in **7** can be easily exchanged by Me$_3$SnF to afford **6**. This implies that zinc fluorides can be made by fluorination of the corresponding alkyl derivatives with Me$_3$SnF[10] if suitable supporting ligands are chosen. Herein, we describe the preparation and structural characterisation of [{HC(CMeNAr)$_2$}Zn(μ-X)]$_2$ (Ar = 2,6-Me$_2$C$_6$H$_3$, X = F, **8**; X = H, **9**).

The reaction of [{HC(CMeNAr)$_2$}ZnR] (R = Me, Et)[11] with 1 equiv. of Me$_3$SnF in toluene at 100 °C for 8 h resulted in the disappearance of solid Me$_3$SnF. After removal of all volatiles *in vacuo*, the residue was recrystallised from hot toluene affording **8** as colourless crystals suitable for X-ray single crystal determination in high yield (80%). EI-MS shows the molecular ion peak of the dimeric **8**, in agreement with the structure established by X-ray analysis. Having observed several cases of the same bridging fashion of fluorine and hydrogen,[12] we inferred that the corresponding hydride should similarly contain bridging hydrogen atoms with a composition of [{HC(CMeNAr)$_2$}Zn(μ-H)]$_2$ **9**. The electron deficient three-centre–two-electron intermolecular Zn–H–Zn bonds are more favoured in **9** due to the bulky substituents at N of the diketiminato ligand that prevent the condensation through N atoms as seen in **1** and **3**. Consequently, we treated **8** with an excess amount of Et$_3$SiH (5–10 equiv.) in benzene under refluxing conditions for 16 h. After the removal of all volatiles, the residue was recrystallised from hot benzene resulting in colourless crystals of **9** in high yield (75%). The dimeric nature of the compounds is indicated by EI-MS and confirmed by X-ray crystallography. Unlike **1** and **2,** compound **9** cannot be obtained from the reaction of ZnH_2 with [ArN=C(Me)CH=C(Me)NHAr]. However, upon treatment of **9** with Me$_3$SnF in benzene under reflux for 6 h, compound **9** can be readily converted back to **8** (Scheme 1). Satisfactory microanalyses of **8** and **9** have been obtained.† The ^{1}H NMR spectrum reveals a singlet for the bridging hydrogens of **9** (δ 4.59), while the ^{19}F NMR of compound **1** shows a singlet for μ-F at δ −61.6.

The structures of **8** and **9** have been determined by X-ray single crystal analysis and are shown in Figs. 1 and 2, respectively.‡ Both molecular structures are dimeric with an inversion centre in the centroid of the four-membered Zn$_2$X$_2$ (X = F, H) ring. The two zinc atoms in **8** and **9** are bridged by fluorine and hydrogen atoms, respectively, forming the three-centre–four electron Zn–F–Zn and the three-centre–two-electron Zn–H–Zn bonds.

The average Zn–N bond length in **8** (1.955 Å) is quite close to that in **9** (1.967 Å), but the six-membered ring in **9** formed by Zn and the ligand backbone is essentially planar (mean deviation 0.0149 Å). There is a C_2 axis passing through C(2), Zn(1), Zn(1A) and C(2A) atoms in **9**. However, in compound **8**, the ligand backbone is slightly folded. The (μ-F)–Zn bond lengths in **8** [F(1)–Zn(1) 2.0034(11), F(1)–Zn(1A) 1.9473(12), av. 1.975 Å] are close to the sum of the covalent radii, and *ca.* 0.126 Å longer than the terminal F–Zn bond length found in **5** [1.849(4) Å]; they are also comparable to those in **6** and **7**. The (μ-H)–Zn bond lengths (1.766 Å) from the refinement of X-ray diffraction data are slightly shorter than those in the ionic MeZnBH$_4$ (av. 1.82 Å).[13] The distances are longer than the terminal H–Zn bond lengths found in **1** (1.62 Å) and **3** (1.50 Å), respectively.



Scheme 1

 DOI: 10.1039/b102275j

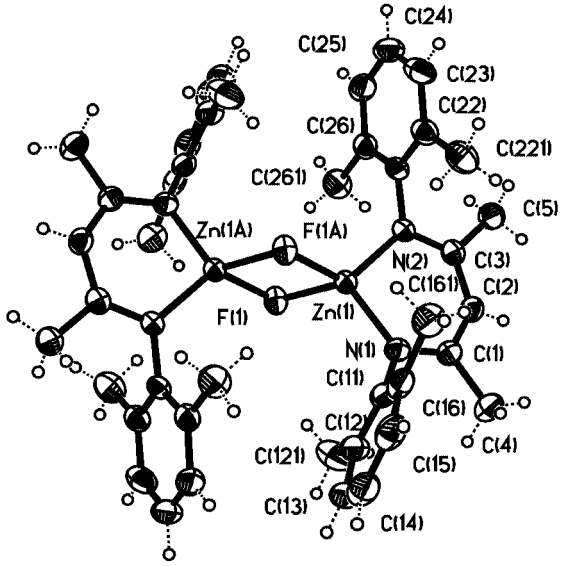


Fig. 1 The molecular structure of **8** in the crystal (with 50% probability elllipsoids). Selected bond lengths (Å) and angles (°): Zn(1)–N(2) 1.951(2), Zn(1)–N(1) 1.9588(14), Zn(1)–F(1) 2.0034(11), Zn(1)–Zn(1A) 2.9754(6), F(1)–Zn(1A) 1.9473(12), F(1A)–Zn(1)–F(1) 82.28(5), Zn(1A)–F(1)–Zn(1) 97.72(5).

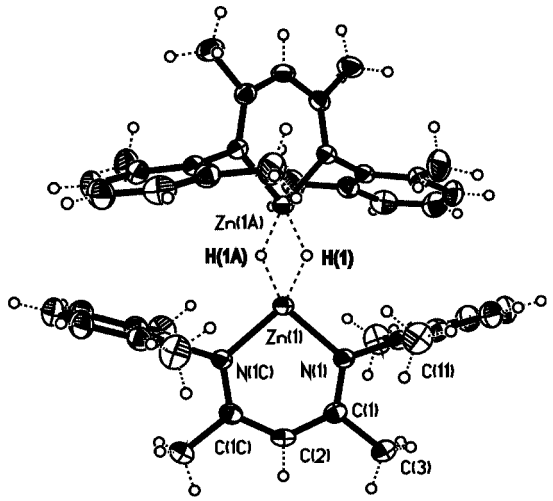

Fig. 2 The molecular structure of **9** in the crystal (with 50% probability ellipsoids). Lattice solvents are omitted. Selected bond lengths or distances (Å) and angles (°): Zn(1)–H(1) 1.766, Zn(1)–N(1) 1.9672(17), Zn(1)–N(1A) 1.9673(17), Zn(1)–Zn(1A) 2.4513(9), Zn(1)–H(1)–Zn(1A) 87.9, H(1)–Zn(1)–H(1A) 92.1.

The shorter (μ-H)–Zn distance compared to the (μ-F)–Zn bond length correlates well with a smaller Zn(1)–H(1)–Zn(1A) angle (87.9°) and a wider Zn(1)–F(1)–Zn(1A) angle (97.72°). Consequently, a wider H(1)–Zn(1)–H(1A) angle (92.1°) results compared to the F(1)–Zn(1)–F(1A) angle (82.28°), which leads to a significantly shorter Zn–Zn distance [2.4513(9) Å] in **9** (by 0.522 Å) than that in **8** [2.9754(6) Å]. This short Zn–Zn distance is in the range of the sum of the covalent radii (2.50 Å), but a Zn–Zn interaction is unlikely.

In summary, we have developed an efficient route to zinc fluorides that are key precursors for the corresponding hydrides. We have also established the first examples of zinc compounds with bridging fluorine and bridging hydrogen atoms. Further studies with **2** are in progress.

Both B3LYP and CCSD(T) computational results suggest that fluorine substitution can dramatically stabilize FGe≡N, with respect to Ge=NF, both from a kinetic and from a thermodynamic viewpoint.

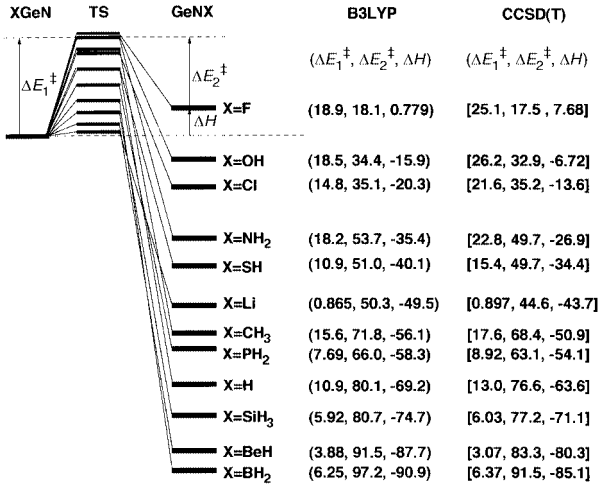
The chemistry of unsaturated organometallic compounds with multiple bonds between a group 14 atom and a heteroatom has assumed increasing importance during the last two decades, as shown by the large number of reviews[1] dealing with both experimental and theoretical aspects. In organogermanium chemistry, several very interesting new compounds with pπ–pπ bonds between the heteroatoms have been reported: Ge=C,[2] Ge=O,[3] Ge=S,[4] Ge=Ge[5] and Ge=N.[6] Of these species, the germaimines, compounds with a Ge=N double bond, have been studied extensively both experimentally[7] and theoretically.[8] Although there have been a great number of reports concerning the chemical and physical properties of these stable species, stable compounds with a Ge≡N triple bond (*i.e.* germanitriles) are still unknown. Naturally, the steric protection of the linear grouping of atoms in the triple bond system is much less possible than for a double bond system so that prospective syntheses are very problematical. Indeed, it has already been proposed that compounds of triply bonded germanium are the next frontier.[9,10]

These novel germanitriles raise a number of intriguing questions regarding their structures, energies, physical properties, and stabilities. Experimental difficulties have so far frustrated attempts to answer these questions. Nevertheless, this information can be obtained by the application of reliable computational methods. Thus, in this work we use carefully calibrated density functional theory (DFT) and high level *ab initio* computations to predict systems where XGe≡N is more stable than the isomeric Ge=NX, and where relatively large barriers separate the two isomers, hoping to stimulate experimental testing of these theoretical predictions.

To the best of our knowledge, no quantum chemical calculations for such compounds have yet been carried out, let alone a systematic theoretical study of substituent effects on the stabilities of germanitrile species. In view of the interest in isolating compounds containing a Ge≡N triple bond, we consider the possibility of stabilizing this moiety with various substituents. At present, we report a theoretical study concerning the effect of various substituents X (X = H, Li, BeH, BH_2, CH_3, SiH_3, NH_2, PH_2, OH, SH, F and Cl) on the relative stability of XGe≡N and Ge=NX isomers, as well as on the transition states connecting them.

Three regions on the potential energy surfaces are considered in this work: XGe≡N (germanitriles), the transition states, and Ge=NX (germaimines); see eqn. (1) in Table 1. The geometries and energetics of the stationary points on the potential energy surface of eqn. (1) have been calculated using non-localized DFT in conjunction with the 6-311++G(d,p) basis set, which is denoted as B3LYP/6-311++G(d,p).[11] All the stationary points have been positively identified as equilibrium structures (number of imaginary frequencies N_{imag} = 0) or transition states (N_{imag} = 1). Single-point energies were also calculated at CCSD(T)(frozen)/6-311++G(3df,3pd)//B3LYP/6-311++G(d,p) (hereafter designated CCSD(T)), to improve the treatment of electron correlation. Unless otherwise noted, relative energies given in the text are those determined at CCSD(T) and include vibrational zero-point energy (ΔZPE) corrections determined at B3LYP/6-311++G(d,p).[12]

The results of our theoretical study of unimolecular reaction [eqn. (1)] are summarized in the schematic reaction profiles in Scheme 1. Selected geometrical parameters of XGe≡N, Ge=NX, and the transition state for the reaction are collected in Table 1. Several intriguing results from Scheme 1 and Table 1 are as follows.



Scheme 1

First, as one can see in Scheme 1, the calculated energy difference between XGe≡N and Ge=NX, Δ*H*, is strongly dependent on the substituent X. Namely, for most substituents (*i.e.* X = H, Li, BeH, BH_2, CH_3, SiH_3, NH_2, PH_2, OH, SH and Cl), germaimines, Ge=NX, are more stable than the isomeric germanitriles, XGe≡N, by −6.7 to −85 kcal mol^{-1} at the B3LYP and CCSD(T) levels of theory. Additionally, it is apparent in Scheme 1 that electronegative substituents can reduce the energy difference between XGe≡N and GeN=X. Furthermore, Δ*H* is positive only for X = F. That is to say, FGe≡N is more stable than the corresponding Ge=NF by 7.7 kcal mol^{-1} at the same level of theory. It is therefore predicted that the more electronegative the substituent, the more stable the germanitrile (XGe≡N).

Secondly, it is found that the energy difference (Δ*H*) between XGeN and GeNX increases as the X element moves from left to right across both the first-row (from B to F) and second-row (from Si to Cl) in the periodic table. For instance, Δ*H* increases in the order (in kcal mol^{-1}) : BH_2 (−85) < CH_3 (−51) < NH_2 (−27) < OH (−6.7) < F (+7.7) and SiH_3 (−71) < PH_2 (−54) < SH (−34) < Cl (−14). In addition, there is a reduction in Δ*H* energies between the first- and second-row X substituents. That is, CH_3 > SiH_3, NH_2 > PH_2, OH > SH, and F > Cl. The

reason for these trends can easily be understood in terms of the X–Ge *vs*. X–N bond energies. Generally speaking, elements which are more electronegative than Ge increase the XGe≡N *vs*. XN=Ge energy differences (relative to X = H), while more electronegative elements decrease them. For example, ΔH is positive for X = F, where a very strong F–Ge bond and a very weak F–N bond[13] can overturn the large (*ca*. 64 kcal mol^{-1}) intrinsic preference of HN=Ge over HGe≡N.

Thirdly, as we can see in Scheme 1, electronegative substitution not only reduces the energy gap (ΔH) between XGe≡N and Ge=NX, but it also raises the barrier ($\Delta E_1^{\ddagger}$) to the XGe≡N → Ge=NX isomerization, thus increasing the kinetic stability of the germanitrile molecules. For instance, our CCSD(T) calculations suggest that the barrier for the isomerization of XGe≡N to Ge=NX decreases in the order (in kcal mol^{-1}): X = OH (26) > X = F (25) > X = NH_2 (23) > X = Cl (22) > X = CH_3 (18) > X = SH (15) > X = H (13) > X = PH_2 (8.9) > X = BH_2 (6.4) ≈ X = SiH_3 (6.0) > X = BeH (3.1) > X = Li (0.90). Likewise, the barrier height ($\Delta E_2^{\ddagger}$) for the reverse reaction (from Ge=NX to XGe≡N) is also dependent on the electronegativity of substituents X. That is to say, the more electronegative the substituent, the smaller the activation barrier from Ge=NX to XGe≡N. For example, our CCSD(T) results indicate that the trend in activation energy ($\Delta E_2^{\ddagger}$; in kcal mol^{-1}) mirrors the trend in electronegativity of the substituent: X = F (18) < X = OH (33) < X = Cl (35) < X = Li (45) < X = NH_2 (50) ≈ X = SH (50) < X = PH_2 (63) < X = CH_3 (68) < X = H (77) ≈ X = SiH_3 (77) < X = BeH (83) < X = BH_2 (91). Taken together, our theoretical findings suggest that fluorine is a particularly appealing possibility because of the strength of the Ge–F bond.

In summary, from our survey of the unimolecular isomerization of XGe≡N → Ge=NX reactions, the present computational results predict that germanitrile XGe≡N itself lies at the minimum of the potential energy surface, and can be strongly stabilized in both a kinetic and thermodynamic sense with a proper choice of substituents. In particular, based on the DFT and CCSD(T) results, we confidently predict that FGe≡N should be stable with respect to the products of unimolecular isomerization and should be the most likely of the species to be detected experimentally.

We encourage experimentalists to carry out further experiments to confirm our predictions.

We are grateful to the National Center for High-Performance Computing of Taiwan for generous amounts of computing time. We also thank the National Science Council of Taiwan for their financial support.

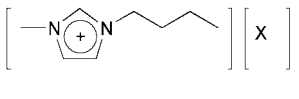
First published as an Advance Article on the web 31st May 2001

Ionic liquids act as powerful media (or additives) in scandium triflate catalysed Diels–Alder reactions not only for facilitating of catalyst recovery but also for accelerating reaction rate and improving selectivity.

Scandium triflate catalysed C–C bond formation reactions, pioneered by Kobayashi, have recently been received considerable attention due to their broad synthetic utility.[1] However, there are limitations to performing these catalytic reactions on a large scale due to their low turnover numbers (TONs are usually < 10–20). To explore the possibility of repetitive use of catalyst, several polymer- or dendrimer-bound scandium catalysts have very recently been employed.[2] However, most supported scandium catalysts require complicated synthetic manipulations and, moreover, their catalytic activity still remains far from satisfactory. Recently, a new approach has been adopted for catalyst separation and recycling in a few types of catalytic reaction involving the use of room-temperature ionic liquids,[3] *i.e.* a salt mixture with a melting point below ambient. Air- and moisture-stable room-temperature ionic liquids consisting of 1,3-dialkylimidazolium cations and their counter anions, in particular, have attracted growing interest in the last few years. In these solvents, catalysts having polar or ionic character can be immobilised without additional structural modification and thus the ionic solutions containing the catalyst can be easily separated from reagents and products.

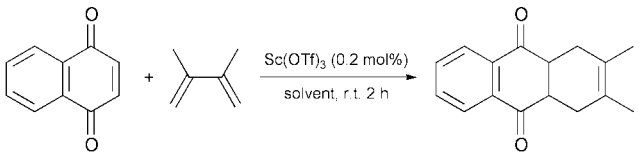
Herein, we report that ionic liquids [bmim][X] **1a–c** ([bmim]$^+$ = 1-butyl-3-methylimidazolium cation; **1a**: X = PF_6; **1b**: X = SbF_6; **1c**: X = OTf)[4] act as powerful media (or additives) in scandium triflate catalysed Diels–Alder reactions[5] not only for facilitating of catalyst recovery but also for accelerating reaction rate and improving selectivity.



[bmim][X] **1a-c**
a: X = PF_6
b: X = SbF_6
c: X = OTf

In a preliminary study, 1,4-naphthoquinone dissolved in [bmim][PF_6] **1a** was treated with 3.0 equiv. of 1,3-dimethylbutadiene in the presence of 10 mol% of $Sc(OTf)_3$, the amount used usually in conventional organic solvents.[6] Surprisingly, under such conditions, the reaction proceeded in seconds with sudden generation of heat and color change of the reaction mixture to dark brown. This observation may suggest that the reaction using 10 mol% of catalyst was too fast to control. Therefore, we reduced the amount of catalyst gradually to 0.2 mol%, for which the reaction was completed smoothly within 2 h at room temperature whereas the same reaction in CD_2Cl_2 is extremely sluggish (compare Table 1, entries 5 and 1). Even use of only 0.1 mol% of $Sc(OTf)_3$ catalyst in ionic liquid **1a** was sufficient to complete the reaction. It was found that the catalytic activity was not much affected by the counter ions of ionic liquids **1a–c** employed in this work (Table 1, entries 5–7). Moreover, very interestingly, the use of only 1 equiv. of the ionic liquid **1a** as an additive in CH_2Cl_2 solvent gave a satisfactory rate acceleration effect (entry 4, Table 1). A kinetic study clearly illustrates the remarkable difference in reaction rate in ionic liquid **1a** and in CH_2Cl_2 (Fig. 1).

Table 1 $Sc(OTf)_3$ catalyzed Diels–Alder reactions[a]



Entry	Solvent	Yield(%)[b]
1	CD_2Cl_2	22
2	**1a** (0.1 equiv.) + CD_2Cl_2	46
3	**1a** (0.5 equiv.) + CD_2Cl_2	85
4	**1a** (1 equiv.) + CD_2Cl_2	> 99
5	**1a**	> 99
6	**1b**	> 99
7	**1c**	> 99

[a] *Reaction conditions*: 3 mmol of 2,3-dimethylbuta-1,3-diene, 1 mmol of 1,4-naphthoquinone, 0.2 mol% of $Sc(OTf)_3$, 1 mL of solvent, 20 °C, 2 h. [b] Estimated by ^{1}H NMR spectroscopy.

We next examined Diels–Alder reactions of other substrates in the presence of 0.2 mol% of $Sc(OTf)_3$ at 20 °C. As shown in Table 2, in all cases the reactions proceeded with increased reaction rate and were complete within 4 h. Similar rate acceleration effects have been observed in Diels–Alder reactions using water or $LiClO_4$ in diethyl ether as reaction medium.[7] It should be also noted here that the rate acceleration effect of ionic liquids have been observed by us in other catalytic reactions, *e.g.*, (salen)Mn catalysed asymmetric epox-

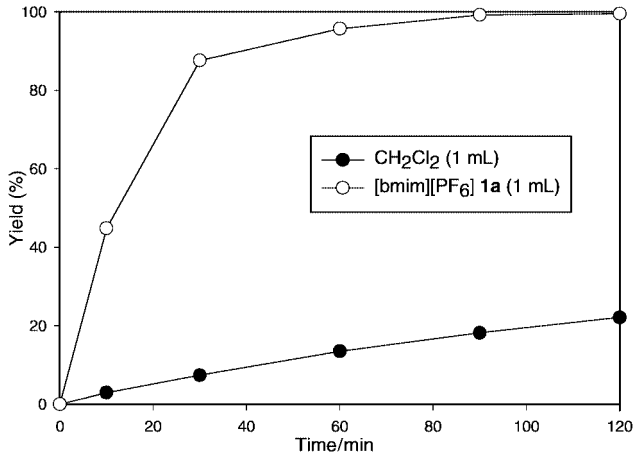


Fig. 1 Kinetic studies in the reaction of 1,4-naphthoquinone (1 mmol) with 2,3-dimethylbuta-1,3-diene (3 mmol) in the presence of 0.2 mol% of $Sc(OTf)_3$ at 20 °C.

 DOI: 10.1039/b101140p

Table 2 $Sc(OTf)_3$ catalyzed Diels–Alder reactions in ionic liquid **1a**[a]

Entry	Dienophile	Diene	Product	*Endo*:*exo*[b]	Yield (%)[c]
1				> 99:1 (94:6)	94
2				—	88
3				> 99:1 (95:5)	96
4				—	80
5				> 99:1	84
6				> 99:1	71

[a] *Reaction conditions*: 3 mmol of diene, 1 mmol of dienophile, 0.2 mol% of $Sc(OTf)_3$, 1 mL of **1a**, 20 °C, 4 h. [b] *Endo*/*exo* selectivities were estimated by ^{1}H NMR spectroscopy; *endo*/*exo* selectivity obtained in CH_2Cl_2 shown in parentheses; see ref. 6. [c] Isolated yield.

idation of olefins,[8] $Sc(OTf)_3$ catalysed Friedel–Crafts alkylation of arenes,[9] and $Sc(OTf)_3$ catalysed Friedel–Crafts alkenylation of arenes.[10] Another exciting point of the use of ionic liquids is the improvement of the *endo*/*exo* selectivity in the studied reactions. In ionic liquid **1a**, reaction proceeded with *endo* selectively (*endo*:*exo* = > 99:1, Table 2, entries 1, 3, 5 and 6). This compares to 94:6 (entry 1) in CH_2Cl_2.[6]

Finally, upon completion of the reaction, the ionic liquid phase containing **1c** and $Sc(OTf)_3$ was almost quantitatively recovered by simple extraction of product with Et_2O. The recovered ionic liquid phase containing the catalyst was reused several times without any loss of activity even after the eleventh use (Table 3).

In conclusion, we have demonstrated that ionic liquids act as powerful media (or additives) not only for facilitating catalyst recycling but also for accelerating reaction rate and selectivity enhancement in scandium triflate catalysed Diels–Alder reactions. Therefore, this novel immobilisation methodology involving the use of ionic liquids can be expected to have great

potential ability to solve the intrinsic problems (decrease of catalytic activity and selectivity, and complicated structural modification of catalysts) of the conventional immobilisation methodology of homogeneous catalysts. Further applications of this methodology to other catalytic reactions are under investigations in our laboratory.

This research was supported by a grant from the Ministry of Science and Technology in Korea.

Received (in Cambridge, UK) 2nd March 2001, Accepted 10th May 2001
First published as an Advance Article on the web 31st May 2001

Trinuclear, μ_3-oxo mixed metal acetato complexes, $[CoMn_2(\mu_3\text{-}O)(MeCO_2)_6(py)_3]$ (py = pyridine) encapsulated in zeolite HY, exhibit high catalytic efficiency in the selective aerial oxidation of *para*-xylene to terephthalic acid; interestingly, the formation of 4-carboxybenzaldehyde, the worrisome impurity in the conventional process, is suppressed significantly over these solid catalysts.

Terephthalic acid, one of the largest volume commodity chemicals, is commercially manufactured by dioxygen oxidation of *para*-xylene using cobalt and manganese salts, at 473–500 K, in acetic acid ($MeCO_2H$) solvent and bromide ion as promoter.[1,2] High yields and selectivity for terephthalic acid are obtained. Replacement of the homogeneous catalyst with a solid catalyst is a desirable alternative which will eliminate toxic metal ions from the waste effluents in the process. One such method of preparing solid, heterogeneous catalysts is encapsulation of active metal complexes inside the pores of zeolites or zeolitic materials.[3–5] We had reported earlier the presence of reactive μ_3-oxo Co/Mn mixed cluster complexes in homogeneous reaction medium.[6] In this communication we report, for the first time, the encapsulation of these complexes, $[CoMn_2(\mu_3\text{-}O)(MeCO_2)_6(py)_3]^n$ (n = +1 or 0) inside the cages of zeolite HY [hereafter referred to as $CoMn_2$(O)-Y]. The hydrothermal stability and catalytic activity of these solid cluster catalysts in the *heterogeneous* dioxygen oxidation of *para*-xylene are also reported. It is found that these heterogeneous catalysts were highly active and selective for the oxidation of *para*-xylene to terephthalic acid. A comparative study indicates that the zeolite-Y-encapsulated *heteronuclear*, cluster complex, $CoMn_2$(O)-Y is more efficient than the corresponding *homonuclear* cobalt and manganese cluster complexes, $[Co_3(\mu_3\text{-}O)(MeCO_2)_6(py)_3]$ and $[Mn_3(\mu_3\text{-}O)(MeCO_2)_6(py)_3]$, respectively, in HY [hereafter referred to as Co_3(O)-Y and Mn_3(O)-Y, respectively].

Co(II), Mn(II) and mixed Co(II)/Mn(II) exchanged HY zeolites were prepared by the ion exchange method, wherein zeolite HY was contacted with aqueous solutions of $Co(MeCO_2)_2{\cdot}4H_2O$ and $Mn(MeCO_2)_2{\cdot}4H_2O$ in requisite proportions at 338 K with stirring for 4 h. The ion-exchanged zeolites (Co-Y, Mn-Y, Co,Mn-Y) were washed with distilled water several times and dried at 373 K. In a typical preparation of the encapsulated metal cluster complex, the corresponding ion exchanged zeolite Y sample (1.5 g) was suspended in 15 ml glacial $MeCO_2H$. To this slurry was added pyridine (3 ml), NaBr (0.5 g), aq. H_2O_2 (50%, 10 ml) and distilled water (5 ml). The mixture was stirred, while bubbling air through the solution, for 2 h at 298 K. The solid product [Co_3(O)-Y, pink; Mn_3(O)-Y, pale brown; $CoMn_2$(O)-Y, purple] was filtered off, washed with glacial $MeCO_2H$ and dried under vacuum. 'Neat' cluster complexes of the composition $[Co_3(\mu_3\text{-}O)(MeCO_2)_6(py)_3]ClO_4$ [referred to as Co_3(O)], $[Mn_3(\mu_3\text{-}O)(MeCO_2)_6(py)_3]ClO_4$ [referred to as Mn_3(O)] and $[CoMn_2(\mu_3\text{-}O)(MeCO_2)_6(py)_3]$ [referred to as $CoMn_2$(O)] were prepared, for comparative studies, by known procedures.[7–9] The formation and purity of the complexes was confirmed by elemental analysis, FT-IR, UV–VIS and EPR spectroscopies.

The FT-IR spectra of the encapsulated complexes showed characteristic bands corresponding to acetate groups at *ca.* 2924, 1624, 1458, 1340, 1221, 680 and 623 cm^{-1}. The FT-IR bands due to pyridine were observed at around 1545, 1489 and 790 cm^{-1}. A shift in the position of the bands due to encapsulation was observed. Representative FT-IR spectra of encapsulated clusters, Mn_3(O)-Y and $CoMn_2$(O)-Y, are shown in Fig. 1. The 'neat' cluster complexes in $MeCO_2H$–H_2O–NaBr medium showed a characteristic band of ligand origin and a charge transfer band (O $\rightarrow$ Mn/Co) in the UV–VIS spectra, the positions of which were sensitive to the metal ions [Co_3(O): 250, 355 nm; Mn_3(O): 254, 320 nm and $CoMn_2$(O): 254, 345 nm). The encapsulated clusters in zeolite-Y exhibited a marked shift in the band positions (Fig. 2). The diffuse reflectance UV-VIS spectra (Fig. 2) are dominated by the band of ligand origin; the weak charge transfer band could be seen only in Co_3(O)-Y.

EPR spectra provided evidence for the formation and stability of cluster complexes in zeolite-Y. Mn_3(O) and Co_3(O) complexes showed a broad EPR signal at g = 2.008 (peak-to peak line width = 500 G) and 2.259 (peak-to-peak linewidth of 1050 G), respectively. The intensity of these signals decreased with temperature to 77 K corresponding to an antiferromagnetic behaviour of the complexes. For Co_3(O), the signal arises from the low lying excited states while Co_2Mn(O) was EPR silent. Mn_3(O) in frozen solutions of 38 ml HOAc–5.6 ml H_2O–86.5 mg NaBr [Fig. 3(a)] at 82 K, showed an EPR signal with partially resolved Mn hyperfine features. These hyperfine features could not be seen in the solid complexes due to intermolecular interactions. Encapsulated Mn_3(O) clusters showed EPR signals (g = 2.012) similar to that of frozen solutions [see Fig. 3(a) and (b)] and indicate the formation and isolation of cluster molecules in zeolite-Y. $CoMn_2$(O)-Y exhibited signals at g = 2.026. Co_3(O)-Y showed a broad signal

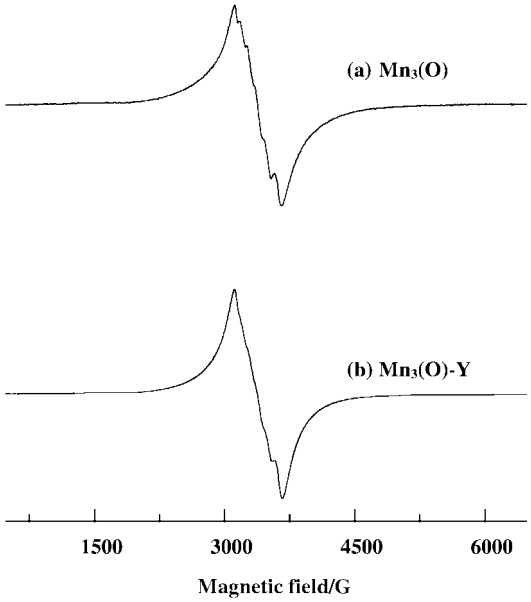

Fig. 3 X-band EPR spectra of $Mn_3(O)$ in 38 ml HOAc–5.6 ml H_2O–86.5 mg NaBr at 82 K (a) and $Mn_3(O)$-Y (b) at 298 K.

at g = 2.220 at 298 K which disappeared on lowering the temperature below 120 K.

The encapsulated cluster catalysts are highly active in the dioxygen oxidation of *para*-xylene at 550 psig (air) and 473 K (Table 1). The oxidation products (identified by GC and GC-MS) are *para*-tolyl alcohol (A), *para*-tolualdehyde (B), *para*-toluic acid (C), 4-carboxybenzaldeyde (D) and terephthalic acid (E). Small amounts of benzoic acid (F) were also observed. Among the 'neat' complexes, the mixed metal cluster complex, $CoMn_2(O)$ exhibited high catalytic activity similar to that of the conventional catalyst system[6] [$3Co(MeCO_2)_2$ + $1Mn(MeCO_2)_2$] with 100% *para*-xylene conversion and > 97% selectivity for terephthalic acid. The solid, heterogenized catalyst, $CoMn_2(O)$-Y, at 100% conversion of *para*-xylene, was even more selective (99.4% selectivity for terephthalic acid; only 0.01% of 4-carboxybenzaldehyde, a worrisome impurity in the conventional process which imparts colour to the terephthalic acid product and whose concentration must be reduced at great cost by post-oxidation processes) than the 'neat' cluster and conventional homogeneous catalysts. A longer reaction time (4 h) was required for complete conversion of *para*-xylene (Table 1). The 'neat' and conventional catalysts required only 2 h. This is probably due to diffusional limitations in the zeolite catalysts. The solid catalysts were separated by simple filtration from the terephthalic acid by converting the latter into a water-soluble sodium salt. The separated catalyst has similar activity (on recycling) and spectroscopic characteristics as that of the fresh catalyst indicating the preservation of its structural integrity and reusability. The EPR spectra of the catalysts, at 82 K, before and after the reaction were almost the same confirming the stability of these complexes under the reaction conditions. Leaching of metal ions (Co and Mn) into solution at the end of the oxidation reaction [550 psig (air), 473 K and 4 h] was investigated by AAS and EPR spectroscopies. While AAS did not reveal any leaching of metal ions, EPR spectral measurements revealed trace amounts of Mn ions (*ca*. 0.5% of the metal in the zeolite; about 50 ppm of Mn in solution) leached into the reaction solution which is too low to account for the catalytic activity. Catalytic runs with this trace amount of metal ions in solution exhibited low *para*-xylene conversions (25 wt%) with *para*-tolyl alcohol (A) and *para*-tolyl aldehyde (B) as products; terepthalic acid was not detected.

Our studies also revealed that mixed metal *heteronuclear* catalysts [$CoMn_2(O)$] are more active than the *homonuclear* catalysts [$Mn_3(O)$ and $Co_3(O)$]. To our knowledge this is the first example of a solid catalyst for the oxidation of *para*-xylene to terephthalic acid with catalytic efficiencies comparable, if not superior to that of state-of-art homogeneous catalysts.

Table 1 Catalytic activity of μ_3-oxo metal cluster complexes in selective oxidation of *para*-xylene[a]

Catalyst	Time/ h	Conv. (wt%)	Product distribution (wt%)[c] A	B	C	D	E	F
$Co_3(O)$	2	73.1	0.7	32.4	20.4	28.9	16.6	1.0

Received (in Cambridge, UK) 28th February 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 31st May 2001

The self-assembly reaction of the monomeric nest-shaped cluster $[NEt_4]_2[MoOS_3Cu_3I_3]$ 1 or twin nest-shaped cluster $[NEt_4]_4[Mo_2O_2S_6Cu_6I_6]$ 2 with the bridging ligand 4,4′-bipyridine (4,4′-bipy) gave a 2D polymeric cluster $\{[NEt_4][Mo_2O_2S_6Cu_6I_3(4,4'\text{-bipy})_5]\cdot MeOH\cdot H_2O\}_n$ 3, which exhibits a significant improvement of optical limiting effect in its nonlinear optical properties relative to 1 or 2.

Thiometallic clusters continue to attract great interest not only because of their unusual catalytic activities in biological and industrial processes[1] but also their intriguing optical and electrical properties.[2] Among these physical properties, there is an interest in their optical limiting effect for potential application in protecting optical sensors from laser beams of high intensity. The design and synthesis of new materials with large optical limiting capability represents an active field in modern chemistry, physics, and material science.[3] Results from previous studies suggest that structural, geometrical and constitutional alternations of these clusters can give rise to variations in nonlinear optical properties (NLO).[4] Thus, the relative contributions of different NLO mechanisms change with the types of clusters, which is expected to explore a switching for NLO properties of inorganic clusters. In particular, polymeric aggregation of thiometallic clusters could result in enhancement of the optical limiting effect (OL).[5] However, it is suspected that the polymeric structures in the solid state could dissociate in solution due to the weak bridging interaction of labile anions. We herein report a significant improvement in OL effect by converting a monomeric thiometallic cluster to an inorganic–organic polymeric hybrid material, which shows a low tendency to dissociate in solution using 4,4′-bipyridine (4,4′-bipy), a versatile linker, for the synthesis of open chain polymers and supramolecular cyclophanes.

It was reported that when $[NEt_4]_2[MoOS_3Cu_3I_3]$ **1** was treated with an excess of NEt_4I in CH_2Cl_2, dimerisation occurred affording a twin nest-shaped cluster $[NEt_4]_4[Mo_2O_2S_6Cu_6I_6]$ **2**.[6] The iodide anion in clusters **1** and **2** can be substituted by pyridine (py) to give a neutral cluster $[MoOS_3Cu_3I(py)_5]$.[6,7] Based on this finding, reaction of **1** or **2** with an excess of 4,4′-bipy in DMF–MeCN resulted in the formation of an air-stable, two-dimensional (2D) polymeric cluster with two different nest-shaped cluster subunits, $\{[NEt_4][Mo_2O_2S_6Cu_6I_3(4,4'\text{-bipy})_5]\cdot MeOH\cdot H_2O\}_n$ **3**.‡ Polymeric cluster **3** shows good stability in the solid state as well as in solution.

A single-crystal X-ray diffraction study of **3** reveals an infinite 2D coordination network that crystallizes in a triclinic system with space group *P*1.§ The polymeric cluster has no center of symmetry. This feature has an important influence on the optical properties of cluster compounds. The structure of **3** consists of an open 2D anionic network with distorted hexagonal chair cavities, $[NEt_4]^+$ counter ions and lattice solvent molecules. As shown in Fig. 1, some of the iodine atoms in clusters **1** and **2** were substituted by 4,4′-bipy ligands, with the remaining iodine atoms terminally coordinating to copper atoms. Apart from one non-bridged 4,4′-bipy ligand, the other 4,4′-bipy ligands form nearly linear bridges between Cu atoms of neighboring nest-shaped $[MoOS_3Cu_3]$ cores. Interestingly, the configuration of polymeric anions can be viewed as two zigzag chains, which are propagated by cell translations along the *a* and *b* axes (Fig. 2). The edges of one chain formed by $[Cu_2(\mu\text{-}S)(\mu\text{-}4,4'\text{-bipy})]_2$ double bridges and a $[Cu_2(\mu\text{-}4,4'\text{-}$

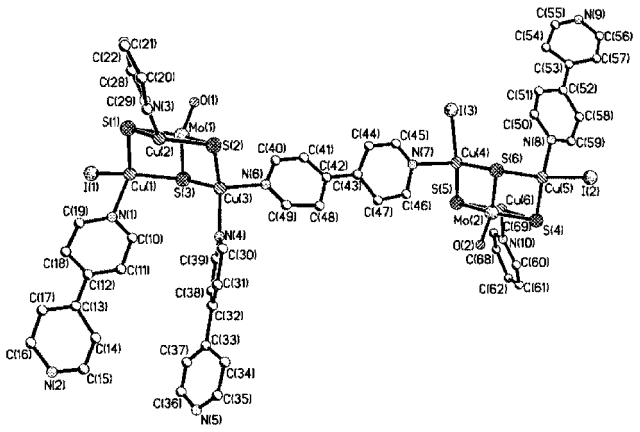

Fig. 1 Structure of the anion in **3** with the atom-numbering scheme. Hydrogen atoms are omitted for clarity.

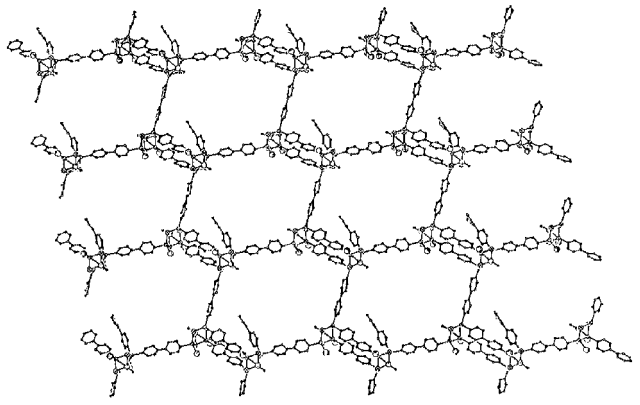

Fig. 2 Perspective view along the *c* axis of the 2D network in $[Mo_2O_2S_6Cu_6I_3(4,4'\text{-bipy})_5]^-{}_\infty$, showing the cavities.

† Electronic supplementary information (ESI) available: preparation, crystal structure details and nonlinear optical measurements for **3**. See http://www.rsc.org/suppdata/cc/b1/b101929p/

 DOI: 10.1039/b101929p

bipy)] single bridge are alternately perpendicular to each other by turning points of 4,4′-bipy shared copper atoms, while another chain is extended *via* [Cu(μ-S)Cu] moieties. Two zigzag chains share the same $[Cu_2(\mu\text{-}S)(\mu\text{-}4,4'\text{-bipy})]_2$ double bridges, the intersections of which are nest-shaped $[MoOS_3Cu_3]$ cluster cores. Another important structural feature of the cluster anion is the cross extending of two zigzag chains that creates very large chair-shaped inner cavities (*ca*. 21.67 × 21.74 Å). These dimensions are much larger than those in other reported 2D network complexes with 4,4′-bipy bridges.[8] The average distance between adjacent Mo atoms is 14.84 Å in the inner cavity. The coordination at the Mo centers remains nearly tetrahedral: the angles range from 107.77(19) to 113.5(6)°. The angles around Cu atoms range from 95.9(6) to 122.0(5)°, suggesting that the coordination geometry of the Cu atoms is highly distorted tetrahedral. This, together with the observation of 4,4′-bipy with non-planar pyridine rings bridging many Cu centers with elongation of the Mo–Cu bond lengths relative to **1** and **2**, is necessary for building up a 2D network polymeric cluster **3** with very large cavities. To our best knowledge, polymer **3** features the first example of a heterometallic cluster polymer with thiometalates and 4,4′-bipy bridges.

The NLO properties of polymeric cluster **3** were investigated. The nonlinear refractive negative n_2-values of nest-shaped Mo/Cu/S clusters indicate strong self-defocusing performances.[6,7,9] Our motivation to study clusters of this structural mode originates from the fact that the combination of the self-defocusing and nonlinear absorption makes the cluster a competent candidate for optical limiting application.[10] Furthermore, an obvious improvement of optical limiting capability is found when the monomeric nest-shaped clusters are assembled to lead to twin nest-shaped clusters, probably due to skeletal extension of the metal nuclei.[4] Accordingly, it is speculated that the clusters **1** and **2** in polymeric forms such as **3** may also possess large optical limiting effects.

With reference to the similar measurement conditions for clusters **1** and **2**, *z*-scan theory was employed to obtain the NLO parameters for **3**.[11] The peak fluence for a *z* scan is *ca*. 1 J cm^{-2} for a *z* scan over 1 ns. The α_2 and n_2 values extracted from 7 ns experimental data are 2.6×10^{-5} m W^{-1} M^{-1} and -4.2×10^{-12} m^2 W^{-1} M^{-1}, respectively. The nonlinear absorptivity is comparable to those of $[W_2S_8Ag_4(AsPh_3)_4]$[12] and $[MoS_4Cu_6I_4(py)_4]_n$,[5] but, is obviously superior to those of **1**[9] and **2**.[6] The nonlinear refractive self-defocusing behavior is also stronger in **3** than in **1**[9] and **2**.[6] Of note is the optical limiting results for **3** at a relatively low concentration of 1.2×10^{-4} mol L^{-1} in DMF solution (Fig. 3). The transmittance is normalized to its linear transmittance at low incident fluence. The thresholds (fluence at which transmittance drops to half its linear value) of the sample are 0.4 and 0.7 J cm^{-2}, respectively, when irradiated by 0.5 and 10 Hz repetition-rate laser pulses. These values are much lower than those of 10 and 2 J cm^{-2} for **1**[9] and **2**,[6] respectively, indicating that the optical limiting performance for polymeric cluster **3** was efficiently improved compared with that of the monomer and twin nest-shaped clusters **1** and **2**. Also, polymeric cluster **3** shows good photostability during the optical determinations. Important evidence for this is that the sample still retained good optical limiting behaviour while the fluence of the 10 Hz laser pulses is passed through the solution sample.[13] Further support arises from the fact that the sample remained effective three months after its preparation.

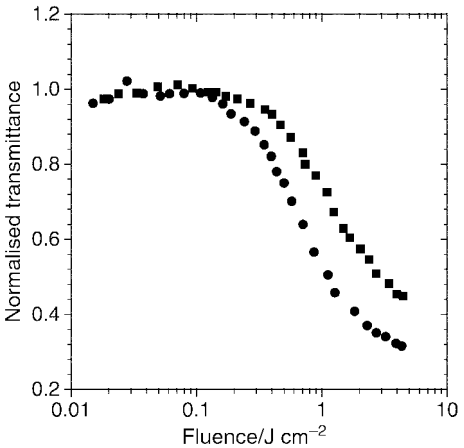

Fig. 3 Optical limiting response of **3** obtained for 7 ns, 532 nm laser pulses with various pulse intervals: 0.5 Hz (●) and 10 Hz (■). The solution was loaded in a 1 mm cell with a linear transmittance of 72%.

Reactions of coordinated geminal dichromium reagents with aldehydes: stereoselective formation of (*Z*)-2-chloroalk-2-en-1-ols†‡

Kazuhiko Takai,* Ryo Kokumai and Takahumi Nobunaka

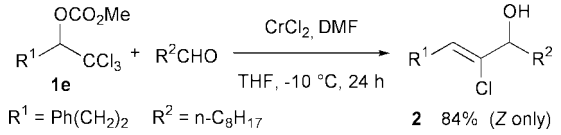
First published as an Advance Article on the web 31st May 2001

Treatment of a carbonate ester of 2,2,2-trichloroethanol derivative with $CrCl_2$–DMF in THF gives a β-carbonate-coordinated geminal dichromium species, which adds to an aldehyde and eliminates an acyloxychromium group to afford a (*Z*)-2-chloroalk-2-en-1-ol stereoselectively.

Intramolecular coordination of a hetero atom to a metal center often fixes the molecular conformation,[1] and thus carbon–carbon bond formation proceeds in a stereoselective manner. We disclose here that the effect is observed in geminal dichromium species, and that a stereoselective coupling between a geminal trichloroalkane having an adjacent acyloxy group and an aldehyde leading to a (*Z*)-2-chloroalk-2-en-1-ol proceeds with chromium(II) chloride. Chromium(II) reduces geminal dihaloalkanes, such as 1,1-diiodoalkanes,[2a] iodoform,[2b] $Me_3SiCHBr_2$,[2c] and $Bu_3SnCHBr_2$,[2d] to give geminal dichromium species, which add to aldehydes to afford Wittig-type olefins with high *E*-selectivity. However, such Wittig-type olefinations do not proceed in the trichloroalkane **1e**, and a new double bond is formed between the carbons bearing halogen and the acyloxy group [eqn. (1)].



In 1986, Steckhan reported the reduction of 1-phenyl-2,2,2-trichloroethanol with $CrCl_2$ in aqueous DMF to obtain (*Z*)-2-chlorostyrene in 44% yield, along with 2,2-dichlorostyrene in 10% yield.[3] Although the yield of 2-chlorostyrene was moderate, the observed *Z*-selectivity was quite high. The stereoselectivity was explained by 1) fixation of the conformation by intramolecular coordination of the β-hydroxy group to chromium(III) of the monochromium species **3**, and 2) selective reduction of a chlorine atom at the less hindered side leading to geminal dichromium species **4** (Scheme 1). Because the reduction was performed in the presence of proton sources, *i.e.*, aqueous conditions and the hydroxy group of the starting trichloride, the procedure could not be applied for carbon–carbon formation. Thus, we first examined the effects of solvents using a hydroxy-protected 2,2,2-trichloroethanol **1a** [Table 1, R^1 = $Ph(CH_2)_2$, R = Ac].

Table 1 Reactions of 2,2,2-trichloroalkanol derivatives and nonanal with chromium(II)[a]

		Yield (%)[b]				Recov. (%)	
Run	R	**2**	**5**	**6**	**7**	Aldehyde	**1**
1	Ac (**a**)	62	29	< 5	< 5	15	7
2		30[c]	2	35	16	33	0
3		27[d]	52	0	0	56	32
4	COPh (**b**)	61	23	7	2	15	13
5	$CO(C_5H_4N)$ (**c**)[e]	< 5	0	89	0	94	0
6	Ms (**d**)	0	0	96	0	91	0
7	CO_2Me (**e**)	77	8	19	6	8	13
8	Me_3Si (**f**)	60	0	< 5	< 5	< 5	44

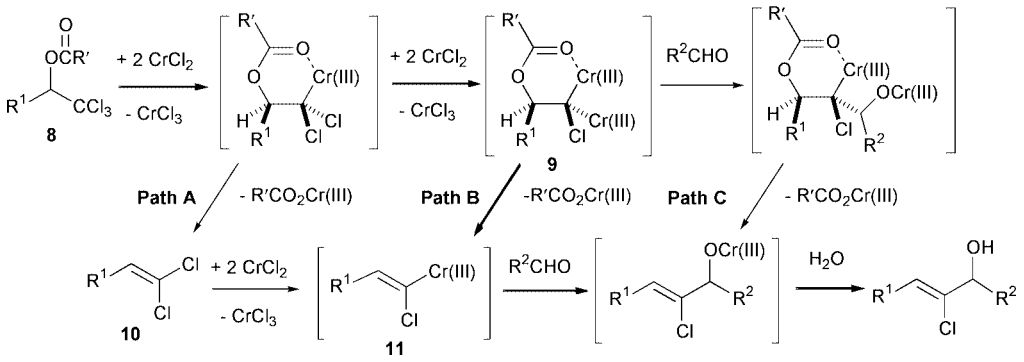
[a] R^1 = $Ph(CH_2)_2$, R^2 = n-C_8H_{17}; Reaction was conducted on a 1.0 mmol scale. Two mmol of trichloride **1**, 8 mmol of $CrCl_2$, 8 mmol of DMF were used per mmole of nonanal. [b] Isolated yields. [c] The reaction was conducted in DMF solvent. [d] The reaction was conducted without addition of DMF. [e] $CO(C_5H_4N)$ = pyridine-2-carbonyl.

Treatment of **1a** in the presence of nonanal with $CrCl_2$ in DMF at 0 °C for 24 h gave the desired coupling product **2** in 30% yield along with **6** and **7** in 35% and 16% yields, respectively (Table 1 run 2).[4] A *Z*-isomer was obtained exclusively as expected.[5] Although the yield could not be improved in THF solvent (run 3), pre-treatment of 1 equiv. of $CrCl_2$ with DMF before addition of the trichloride **1a** and nonanal accelerated the reaction, and the yield was improved to 62% (run 1).[2a] Benzoate **1b** gave almost the same yield with **2**. However, reactions with the pyridine-2-carbonyloxy compound **1c** and mesylate **1d** produced the 1,1-dichloroalkene **6** as a main product, and most of the aldehyde was recovered. Among the protecting groups examined, a carbonate gave the best result (run 7).

There are three possible reaction pathways which have different timings of the elimination steps of acyloxychromium (Scheme 2). In Path A, acyloxychromium is smoothly eliminated when one of the chlorine atoms is reduced, and 1,1-dichloroalkene **10** is produced as an intermediate. Then, the chlorine atom at the less hindered *trans* position of **10** is selectively reduced to give **11**, which adds to an aldehyde. In Path B, acyloxychromium is eliminated after the second reduction to the geminal dichromium species **9**.[2,6] The elimination gives the alkenylchromium **11** directly, and addition to an aldehyde proceeds. The third Path C also includes the acyloxy-coordinated geminal dichromium species **9**, and addition to an aldehyde at a non-coordinated chromium of **9** occurs before elimination of acyloxychromium.

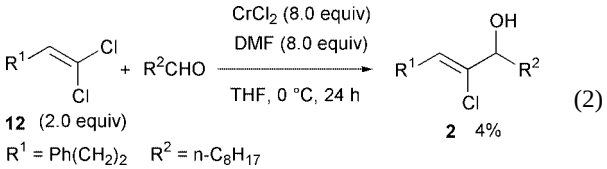
The hydroxy-protecting groups with oxygen act as leaving groups in the reaction sequence.[7] Trichlorides **1c** and **1d**, which

 DOI: 10.1039/b102387j



Scheme 2 Possible reaction pathways for the coupling reaction.

have good leaving groups, afforded **6** as a major product, and only a small amount of the 1,1-dichloroalkene **6** was produced when the adduct **2** was obtained in high yield. In addition, treatment of a mixture of 1,1-dichloroalkene **12** and nonanal with $CrCl_2$–DMF in THF at 0 °C for 24 h produced the adduct **2** in only 4% yield, and most of **12** (75%) was recovered unchanged [eqn. (2)].[8] These results suggest that this addition



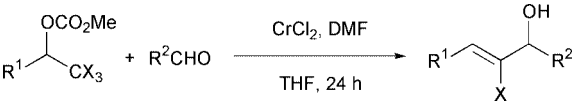
(2)

reaction does not proceed through the 1,1-dichloroalkene **10** (Path A) but through the geminal dichromium species **9**.

During the reactions of **1a**, **1b** and **1e** with nonanal, the Wittig-type olefination[2a] leading to 1-phenyl-4-chlorotridec-4-en-3-ol derivatives was not observed. This suggests that the coupling reaction does not proceed *via* Path C either, leaving Path B as the only possible reaction pathway.

The results of the coupling reactions between carbonates of 2,2,2-trichloroethanols and aldehydes are shown in Table 2.[9]

Table 2 (*Z*)-Selective coupling of 2,2,2-trihaloalkyl carbonates and aldehydes with chromium(II)[a]



Run	R^1	R^2	X	Temp/°C	Yield (%)[b]
1	$Ph(CH_2)_2$	n-C_8H_{17}	Cl	−10	84
2				0	77
3				25	52[c]
4			Br	−10	X = Br 16[d] X = Cl 31[d]
5		c-C_6H_{11}	Cl	−10	69
6		Ph	Cl	−10	71
7		(*E*)-PrCH=CH	Cl	−10	46
8	c-C_6H_{11}	n-C_8H_{17}	Cl	−10	68
9	Ph	n-C_8H_{17}	Cl	−10	63

[a] Reaction was conducted on a 1.0 mmol scale. Two mmol of trihalides, 8 mmol of $CrCl_2$, and 8 mmol of DMF were used per mmole of an aldehyde. [b] Isolated yields. Isomer ratios were determined by isolation, GLPC, and/or NMR. [c] 0.8 mmol of $CrCl_2$, 9 mmol of manganese, and 9 mmol of Me_3SiCl were employed per mmole of nonanal. [d] *Z*-Isomers were obtained exclusively.

2-Chloroalk-2-en-1-ols having a *Z*-configuration were produced selectively in all cases. To reduce the amount of chromium salt used in the reaction, we attempted a catalytic reaction using manganese as a reductant of chromium(III).[10] The reaction proceeded at 25 °C, however, the yield decreased to 52% (run 3). When 2,2,2-tribromoethanol derivative was used as the trihalide, the corresponding bromo and chloro compounds were obtained (run 4).[2b,11,12]

Can a fluorous biphase solvent system improve a polymer immobilized heterogeneous hydrogenation catalyst?

Shannon L. Vinson and Michel R. Gagné*

Department of Chemistry, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599-3290, USA. E-mail: mgagne@unc.edu

Received (in Corvallis, OR, USA) 29th January 2001, Accepted 23rd April 2001
First published as an Advance Article on the web 31st May 2001

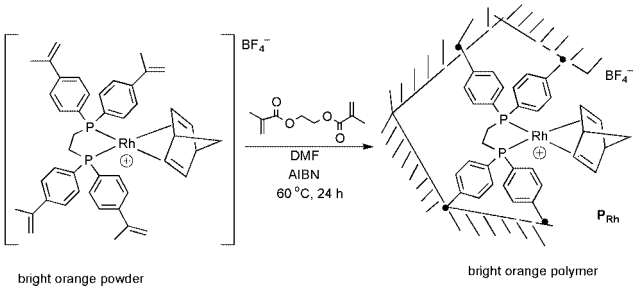
When diphosphine rhodium(I) hydrogenation catalysts are incorporated into organic polymers that contain a permanent pore structure, they can be utilized in fluorous biphase solvent systems, where reaction rates increase with the fluorous content of the solvent.

The application of a fluorous biphase system (FBS) to separate products from a catalyst was both an intellectual and technical achievement in catalysis research.[1] At its heart, the FBS relies on the reversible temperature dependent miscibility of perfluorinated and nonfluorinated liquids,[2] and the solvent preferences of organic products, substrates, and catalysts that contain ligands with perfluorinated substituents. This reversible temperature dependent miscibility provides the means to separate a catalyst from its product, and as such it has been applied in a number of catalyzed reactions.[2] These methods are characterized by high turnover numbers and relatively low catalyst leaching. Moreover, fluorous solvents show gas solubilities modestly higher than typical organic solvents,[2b] a property that could lead to higher reaction rates, in for example, olefin hydrogenation and hydroformylation.

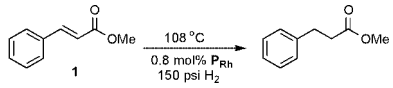
We recently reported an olefin hydrogenation catalyst that was copolymerized into the matrix of a highly cross-linked macroporous (permanent pore structure) polymer.[3] The advantage of this solid support is that it does not require polymer swelling for access to its internal volume, and should thus be compatible with any solvent system. These heterogenized catalysts have already demonstrated easy separation and efficient recyclability in polar, nonpolar, and protic organic solvents, however, they can be less active than their solution-based analogues.[4,5] The combination of higher gas solubility coupled with the ease of adapting an existing heterogeneous catalyst for use in fluorous solvents[6] (*i.e.* no synthetic modifications) suggested that the combination be examined.

For testing purposes, a cationic diphosphine hydrogenation catalyst (2 mol%) was copolymerized into an ethylene dimethacrylate-based polymer (98%) as shown in Scheme 1. These materials contain ~100 μmol Rh g^{-1} dry polymer and ~400 m^2 g^{-1} surface areas (N_2 BET).[3,7]

To compare the activity and longevity of $\mathbf{P_{Rh}}$ in a FBS and a typical organic solvent, we carried out a series of catalyst recycling experiments under conditions where substrate conversion was incomplete, enabling run-to-run and solvent-to-solvent comparisons. Longer reaction times always provided 100% conversion to product. We examined a relatively simple hydrogenation substrate, methyl-*trans*-cinnamate **1** (Scheme 2), toluene for our organic phase, and the benchmark 1:1 perfluoromethylcyclohexane (PFMC)–toluene for our FBS.[8] In the PFMC–toluene mixture the polymer floats at the interface, while it sinks in toluene. Once monophasic (~103 °C when [**1**] = 0.2 M),[9] the polymer in the FBS floats to the surface until cooling and phase separation.[10].



Scheme 1



Scheme 2

The plot in Fig. 1 charts the evolution of $\mathbf{P_{Rh}}$ activity in the hydrogenation of **1** in FBS and toluene. Each reactor was run side by side, and percentage conversions were determined after 1 h by GC after careful venting. Once an aliquot was obtained for analysis, the vessels were re-introduced into the glove box and the product/substrate removed from the catalysts. For the FBS, the organic phase was removed with a pipette and the fluorous layer washed 3 times with additional toluene (this results in some PFMC loss, *vide infra*). In the toluene case, the solution was decanted and the polymer similarly washed with toluene. Additional substrate/toluene was added under the inert atmospheric conditions, and in the fluorous case additional PFMC was added every 2–3 runs to a total volume of 2 mL.

It is evident from the graph that the FBS yields a slightly more active catalyst than in toluene alone, and although the rate is reproducibly higher in the FBS, the absolute rate difference may not be significant as batch to batch variability exists (±20%).[11] Over the 15 runs, the catalysts completed ~1400 and ~800 turnovers in the FBS and toluene, respectively. Combining the filtrate solutions for the 15 runs and analyzing for Rh

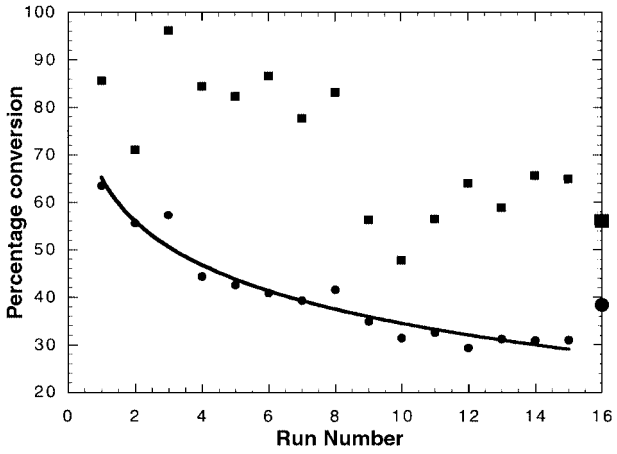


Fig. 1 Catalyst recycling for the hydrogenation of **1**. FBS (■)—1:1 $CF_3C_6F_{11}$–toluene, 0.79 mol% $\mathbf{P_{Rh}}$; toluene (●)—0.76 mol% $\mathbf{P_{Rh}}$. 108 °C,150 psi H_2, 1 h. For run # 16, both samples were run under identical FBS conditions.

 DOI: 10.1039/b101203g

(ICP), indicated that only minor catalyst leaching (~1%) occurred in both systems.

To determine if the toluene catalyst's activity was inherently lower, or if it had slightly less Rh than the FBS,[11] a 16th run was carried out in the 1:1 PFMC–toluene biphase. A 10% increase in conversion (Fig. 1) indicates that under the reaction conditions, the FBS does increase the absolute product output and thus the rate difference cannot be solely ascribed to a difference in the polymer's Rh content. Although we don't know unequivocally the reason(s) for loss of activity in the two solvents, we suspect that it comes from catalyst deactivation during the recycling process, as both systems routinely reach 10,000 turnovers in side-by-side experiments, although complete conversion was always achieved 2–3× more quickly in the FBS.[12]

It is also apparent from Fig. 1 that the run-to-run throughput of the catalyst in the FBS is not as reproducible as in toluene. Based on the mechanics of this recycle experiment, we suspected that the variability might be due to changes in the PFMC–toluene ratio. In practice, PFMC losses occurred during product extraction and washing (3×) of each run as it is slightly soluble in toluene, and the aliquots were removed at or near the reaction temperature leading to some evaporative loss (bp ~77 °C). Since the reactivity spikes coincided with the addition of fluorous solvent (every 2–3 runs, to 4 mL), we hypothesized that higher fluorous–organic solvent ratios might be responsible for the enhanced reactivity.

This hypothesis was tested by a series of control experiments varying the ratio of PFMC–toluene (1:3, 2:2, 3:1 and 4:0; 4 mL total volume). To eliminate batch-to-batch variability effects we measured the effect of fluorous composition in a series of recycle experiments where the same catalyst was used for each solvent ratio. Moreover, the experiments were conducted from least to most reactive to ensure that catalyst decomposition would not be misinterpreted as a decrease in activity.

The plot in Fig. 2 clearly shows that the 1 h conversion increases with increasing fluorous content, suggesting that the 'noise' in Fig. 1 is actually due to small changes in the volume fraction of PFMC in the FBS. This trend is unusual as homogeneous catalysts typically become *less reactive* as the fluorous content of the solvent increases.[13] Several possibilities are *a priori* possible: (1) changes in H_2 diffusion rates under mass transport limited conditions. The possibility that H_2 diffusion from gas to solution is slower than catalysis, and sensitive to fluorous content has been eliminated by showing that under similar homogeneous conditions, a doubling and tripling of the soluble catalyst, [(dppe)Rh(nbd)$^+$ B(Ar$_f$)$_4^-$] leads to a doubling and tripling of product turnover.[14] Thus, H_2 diffusion through the meniscus occurs faster than does catalysis.[15] (2) Increasing substrate concentration in the polymer phase with increasing fluorous content (a fluorophobic effect). For example, model experiments show that 80 mg of blank EDMA polymer will lower the [decane] in PFMC from 75 to 50 mM. To compensate for the decrease, the [decane] in the polymer phase must be ~600 mM. A similar effect leading to higher local substrate concentration in the catalyst containing polymer phase could lead to the observed rate accelerations. Experiments to assess the probability that these or other effects are responsible for this unusual rate acceleration are underway.

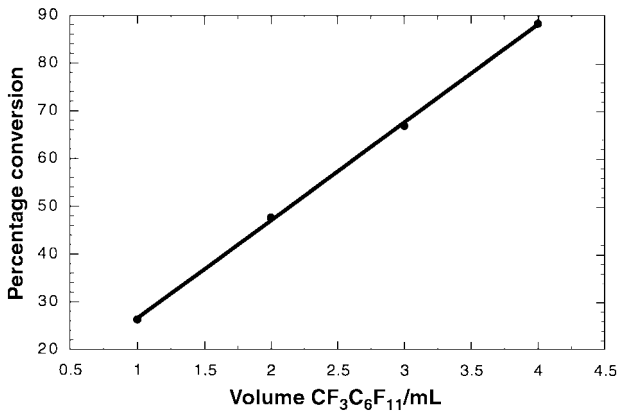

Fig. 2 Hydrogenation of **1** at different $CF_3C_6F_{11}$–toluene ratios (4 mL total volume, 0.76 mol% $\mathbf{P_{Rh}}$, 106 °C, 150 psi H_2, 1 h).

Although the polymer catalyst $\mathbf{P_{Rh}}$ does not suffer from the problem of catalyst/product separation of typical solution catalysts, the FBS does engender some useful and interesting properties to these immobilized catalysts. Chief among these is an increase in activity that directly correlates with the fluorous content of the solvent. The ease of utilizing a catalyst designed for use in organic solvents to operate in fluorous solvents is also noteworthy.

Soc. Jpn.*, 1999, **72**, 1911.

5 The polymer's interior pores are essentially unstirred therefore access to the catalyst sites is controlled by passive diffusion processes.

6 For an alternative approach using fluorous soluble polymeric ligands, see: W. Chen, L. Xu and J. Xiao, *Chem. Commun.*, 2000, **10**, 830; D. E. Bergbreiter, J. G. Franchina and B. L. Case, *Org. Lett.*, 2000, **2**, 393

7 B. P. Santora, M. R. Gagné, K. G. Moloy and N. S. Radu, *Macromolecules*, 2001, **34**, 658.

8 In a typical run ~80 mg of polymer (~100 μmol Rh g^{-1}) and 150 mg of **1** were used along with 4.0 mL of toluene or 2.0 mL toluene and 2.0 mL PFMC. The Fischer–Porter vessel was emmersed into a pre-equilibrated oil bath, and when monophasic, the vessel was charged and vented 3× with 150 psi H_2 and charged to the final pressure.

9 The consolute temperate rises above 108 °C when concentrations of **1** are greater than 1 M.

10 The polymer sinks in the 25% v/v fluorous solution, while it floats to the surface for the 50, 75 and 100% PFMC experiments.

11 Analysis of different physical sections of the polymer monolith by AA indicates that Rh is *not* evenly distributed in the matrix (±20%). Crushing and mixing macroscopically homogenizes the Rh, however, this makes the reported recycling experiments more cumbersome, and was avoided.

12 In a typical high turnover experiment ~5 mg of polymer (0.01 mol%) and 800 mg of **1** were subjected to the same conditions listed in ref. 8. To minimize evaporative loss of solvent, aliquots to measure reaction progress were taken approximately every 24 h. After 40 h the toluene typically completes ~2300 turnovers, while the FBS completes ~9000; both systems do eventually show complete conversion.

13 D. Rutherford, J. J. J. Julliette, C. Rocaboy, I. T. Horváth and J. A. Gladysz, *Catal. Today*, 1998, **42**, 381; B. Richter, A. L. Spek, G. van Koten and B. Deelman, *J. Am. Chem. Soc.*, 2000, **122**, 3945.

14 These experiments were carried out with 25, 50 and 66% fluorous content (0.5, 1.0 and 1.5 mol% catalyst). Differences in activity as a function of fluorous content varied less than 10%, with absolute rates being similar to polymer rates.

15 At this time we cannot rule out the possibility that H_2 diffusion *from solution to polymer* is sensitive to fluorous content.

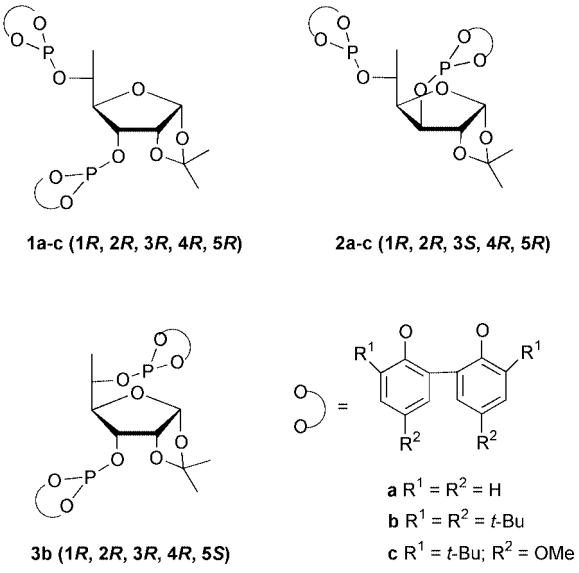
Received (in Cambridge, UK) 16th February 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 31st May 2001

A series of diphosphite ligands, derived from readily available D-(+)-glucose, have been used for the first time in the palladium-catalysed allylic alkylation reaction with high enantioselectivity (ee up to 95%) and activity in standard conditions.

One of the main objectives in modern synthetic organic chemistry is the catalytic enantioselective formation of C–C bonds.[1] In this respect, Pd-catalysed allylic alkylation is a powerful and highly versatile procedure. In recent years, the asymmetric version of this reaction has been reported with various C_2- and C_1-symmetric bidentate chiral ligands providing excellent enantiomeric excesses.[2] However, one drawback of using these ligands is that they are often synthesised from expensive chiral sources and in tedious synthetic steps. Therefore it is important to develop new chiral ligands derived from readily available simple starting materials and to show their applicability in C–C bond formation. In this context, carbohydrates, which have been widely used in organic synthesis as inexpensive starting materials or as chiral auxiliaries,[3] have only recently shown their huge potential as a source of highly effective chiral ligands.[4]

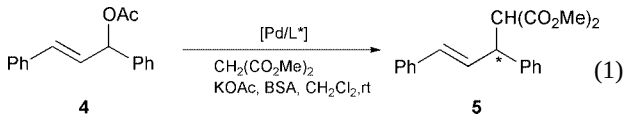
In this context, we have recently described the synthesis of a new class of furanoside diphosphite ligands (Scheme 1), prepared in a few steps from readily available D-(+)-glucose, and their successful use in the rhodium catalysed asymmetric hydroformylation of vinyl arenes (ee values up to 91%).[5]

The advantage of these ligands is that their modular nature allows a facile systematic variation in the configuration of the stereocenters (C-3, C-5) at the ligand bridge and in the biphenyl substituents, allowing the optimum configuration for maximum stereoselectivity to be determined. In this paper we report on the use of this new class of sugar diphosphite ligands in enantioselective Pd-catalysed allylic alkylation. We also examined the effect of the configuration of the stereogenic centers C-3 and C-5 since this was expected to be important for the catalytic reaction because of the proximity of these centers to the metal. The influence of the substituents on the biphenyl moieties was also studied. Although the combination of mixed phosphite–oxazoline,[6] phosphite–thioether[7] functionalities and phosphite–phosphine[8] ligands has already been successfully used in Pd-catalysed allylic alkylation, to the best of our knowledge this is the first example of diphosphite ligands being applied to this type of reaction.



Scheme 1

For initial evaluation of the new ligands we chose the palladium(0)-catalysed addition of dimethyl malonate to *rac*-1,3-diphenyl-3-acetoxyprop-1-ene (**4**) [eqn. (1)] because this



4 **5** (1)

reaction has been carried out with a wide variety of ligands carrying different donor groups, enabling direct comparison of the efficacy of different ligand systems. In addition, many successful ligands developed for this reaction have been found to have broader applicability in other related reactions.[2]

Asymmetric allylic substitution of **4** was carried out with the palladium complex generated *in situ* by mixing the corresponding chiral ligand and $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$, under basic Trost conditions.[9] Results are given in Table 1.

6 7 8

Scheme 2

The reaction at room temperature using ligand **1a** with two unsubstituted biphenol moieties provided (*R*)-**5** with an ee value of only 2% (entry 1). The presence of bulky *tert*-butyl groups in the *ortho*-positions of the biphenyl moiety (ligands **1b** and **1c**) had a positive effect on the enantioselectivity (ee values up to 64%, entries 2 and 3). Furthermore, the presence of *tert*-butyl groups also had an extremely positive effect on the activity (entry 1 *vs.* entries 2 and 3).

The use of ligands **2a**–**c**, in which the configuration of carbon atom C-3 is opposite to those of ligands **1a**–**c** (Scheme 1), produced improved enantioselectivities and activities (entries 1–3 *vs.* entries 4–6). Thus, ligand **2b** showed not only higher asymmetric induction (84%) but also very high catalytic activity (5 minutes for total conversion of substrate, entry 5). Such remarkably high activity, which can be explained by the large π-acceptor ability of the diphospite ligands, contrasts with the low activity reported for other homo-donor ligands.[2,4k,12] The enantioselectivity was increased to 95% (*S*)-**5** when ligand **2c**, with methoxy groups instead of *tert*-butyl groups in the *para* positions of the biphenyl moieties, was used (entry 5 *vs*. entry 6).

The use of ligand **3b**, which resulted from changing the configuration of C-5 from (*R*) to (*S*) in ligands **1**, leads to lower activity and slightly lower enantioselectivity than the catalytic system Pd/**1** (entry 2 *vs.* entry 7). Moreover, comparison of entries 2, 5 and 7 clearly shows that the enantiomeric excesses are strongly dependent on the absolute configuration of the carbon C-3 stereocenter of the carbohydrate backbone. The best enantioselectivities were obtained using ligands **2b** and **2c** with (*S*) configuration at C-3. The presence of methoxy groups in the biphenyl moieties significantly improved the enantioselectivity (ee up to 95%).

Note that these diphosphite ligands showed higher enantioselectivity and reaction rates than their corresponding diphosphines **6** and **7**[13] (entries 8 and 9) and the *xylo*-furanoside diphosphine **8**[11] analogue (entry 10) under the same reaction conditions (Scheme 2). The similar enantioselectivities obtained with ligands **6** and **7** confirms that the configuration of C-5 has no relevant influence on the enantiodiscrimination as observed for the diphosphite ligands.

In summary, we have described the first application of diphosphite ligands in asymmetric allylic alkylation reactions. These ligands can be prepared in a few steps from commercial D-(+)-glucose as an inexpensive natural chiral source. The combination of high enantioselectivities (ee up to 95%) and high activities in simple unoptimized reactions and the low cost of the ligands makes these catalyst systems very attractive for further research. These results also open up a new class of ligands for enantioselective Pd-catalysed allylic alkylation, which will be of great practical interest. For example, phosphites are less sensitive to oxidation than phosphines. Moreover, because of the modular construction of diphosphites, structural diversity is easy to achieve, so enantioselectivity can be maximised for each new substrate as required. Studies of this kind, as well as mechanistic studies, are currently under way.

We thank the Spanish Ministerio de Educación y Cultura and the Generalitat de Catalunya (CIRIT) for their financial support (PB97-0407-C05-01 and 04).

Optical thermometer based on the stability of a phosphorescent 6-bromo-2-naphthol/α-cyclodextrin$_2$ ternary complex

R. Elizabeth Brewster, Matthew J. Kidd and Merlyn D. Schuh*

Department of Chemistry, POB 1719, Davidson College, Davidson, NC 28036, USA. E-mail: meschuh@davidson.edu

Received (in Columbia, MO, USA) 6th March 2001, Accepted 24th April 2001
First published as an Advance Article on the web 31st May 2001

The phosphorescence lifetime of a water-soluble ternary complex of 6-bromo-2-naphthol and α-cyclodextrin has been found to decrease by more than two orders of magnitude over a 58 °C temperature range, which makes this molecular system well suited for use as the first optical thermometer based solely on phosphorescence lifetimes.

A ternary molecular complex consisting of two molecules of α-cyclodextrin (CD) and one molecule of 6-bromo-2-naphthol (BN) emits readily detectable BN phosphorescence in aqueous solutions containing molecular oxygen, an efficient triplet-state quencher.[1] It is believed that the triplet-state BN molecule is protected from quenching by being encapsulated in the hydrophobic core of the CD molecules, which are assumed to make contact with each other concentrically along the rim of the larger opening of the toroidal CD molecule. The phosphorescence lifetime of the BN/CD$_2$ complex is reported herein to have a very high temperature sensitivity and to be useful as the first reported aqueous optical molecular thermometer based only on phosphorescence lifetimes.

There has been increasing interest in the use of molecular luminescence to make remote temperature measurements by passing the luminescence signal from the sensor material through an optical fiber[2] or by incorporating the luminescent probe molecule directly into the site at which the temperature is to be measured.[3] Most of these optical thermometers make use of fluorescence and have been designed around temperature-dependent excited state lifetimes,[2–10] shifts in fluorescence or absorption spectra,[11–14] changes in fluorescence intensity,[3,10,15] or black-body radiation spectra.[16]

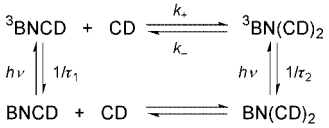
One of the highest sensitivities for an optical thermometer was reported for the delayed fluorescence of acridine yellow dissolved in a rigid saccharide glass.[10] In this sensor material the sensitivity is ultimately determined by the triplet-state lifetime. Over the reported temperature range, the lifetime of delayed fluorescence and the ratio (intensity of delayed fluorescence)/(intensity of phosphorescence), I_{df}/I_p, changed only about four-fold, and the average percentage relative sensitivities to temperature of the delayed fluorescence lifetime and the I_{df}/I_p ratio were reported to be 2.0% and 4.5%, respectively.[10]

The following is a brief description of our instrumentation and experimental procedure. Excitation pulses (FWHM of 6–7 ns and typical energy of 1–10 mJ) at 280 nm or 345 nm were produced as the frequency-doubled output of a Quanta Ray Nd/YAG-pumped dye laser. Phosphorescence was focused into a 0.25 m Jarrell Ash spectrometer and detected at 525 nm, the wavelength for maximum phosphorescence intensity. The spectrometer was operated with a spectral resolution of approximately 40 nm. The photomultiplier was gated off electronically for 2 μs to coincide with the occurrence of the large scattered light signal. For each lifetime measurement, 500–1000 oscilloscope traces were averaged so that a drop of phosphorescence intensity of up to three orders of magnitude could be analyzed. Sample temperature was maintained within ±0.1 °C by using a circulating constant-temperature bath. All solutions contained CD and BN concentrations of 0.01 M and 9.4×10^{-5} M, respectively.

Phosphorescence signals were fitted by non-linear least squares regression and generally were found to be single exponential for at least the first two to three orders of magnitude decay in signal. The only exception was at the highest temperature, 59.7 °C, where the phosphorescence intensity was reduced sufficiently to prevent reliable curve-fitting beyond the initial drop of 1.5 orders of magnitude. The residuals for single-exponential fits were random, and correlation coefficients were usually greater than 0.998. The standard deviation for all measured phosphorescence lifetimes, τ, was less than 0.5%. Within experimental uncertainty, τ values were the same when either 280 nm or 345 nm was used as the excitation wavelength.

The value of $1/\tau$ increases dramatically from 800 s^{-1} to 133 000 s^{-1} over the temperature range 1.6–59.7 °C, and the good fit of the Arrhenius equation to the data is seen in Fig. 1. The slight leveling of the plot at the lowest temperature is not unexpected in view of the approach of the reciprocal phosphorescence lifetime to a limiting value, which for 1-bromonaphthalene in glass is 71 s^{-1} at 77 K.[17] Nevertheless, if all data are included, the Arrhenius activation energy, E_a, of 69 ± 2 kJ mol^{-1} for Fig. 1 is 2.4 times larger than the activation energy of 28.3 kJ mol^{-1} for the delayed fluorescence lifetime of acridine yellow.[10] For a plot of $1/\tau$ *vs.* temperature (K) the relative sensitivity is defined as the slope divided by the value of $1/\tau$ and is expressed as E_a/RT^2. The percentage relative sensitivity ranges from 11% at 1.6 °C to 7.5% at 59.7 °C. The large sensitivity reported herein is, to our knowledge, the largest value reported for an optical thermometer, and the small standard deviations associated with the values of τ reveal that temperature differences smaller than 0.1 °C can be measured.

Since BN phosphorescence is detectable only from the ternary complex in aerated solutions, the following mechanism, which has been used for similar phosphorescent complexes,[18,19] is reasonable.



Use of the steady state approximation in solving the associated rate equations shows that the phosphorescence should decay with a single exponential lifetime, τ, expressed in eqn. (1).

$$(1/\tau - 1/\tau_2)^{-1} = \frac{k_+[\mathrm{CD}]}{k_-/\tau_1} + \frac{1}{k_-} \quad (1)$$

Values of τ were measured for [CD] in the range 0.008–010 M at 24 °C and 50 °C. The value of τ_2 is independent of [^{3}BN(CD)$_2$] and was varied until a plot of the left-hand side of eqn. (1) *vs.* [CD] was linear and had the largest correlation coefficient. The value of k_- was determined from the intercept. The percentage increase was found to be larger for k_- than for $1/\tau_2$ as the temperature was increased from 24 °C to 50 °C and showed the cause for the large value of E_a to be dissociation of the ternary complex.[20] Excellent support for this conclusion

 DOI: 10.1039/b102156g

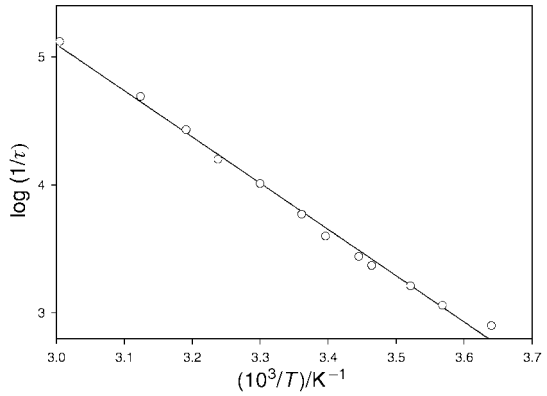


Fig. 1 Arrhenius plot of the reciprocal phosphorescence lifetime, $1/\tau$ for the $BN(CD)_2$ complex.

comes from recent theoretical and experimental studies of the ternary complex of triplet state naphthalene with two α-cyclodextrin molecules.[21] The optimized, low-energy theoretical structure of the complex shows that naphthalene is longitudinally encapsulated between the CD molecules, the secondary cyclodextrin hydroxylic rims face each other, and hydrogen bonds between the hydroxylic groups stabilize the complex. Triplet–triplet absorption was used experimentally to measure an activation energy of 66.5 kJ mol^{-1} associated with oxygen quenching of encapsulated triplet state naphthalene. The similarity of the activation energies reported herein and in reference 21 shows that the shortening of τ with increasing temperature depends little on the structural difference between BN and naphthalene. Since quenching by oxygen occurs upon complete or partial dissociation of the complex, the activation energy arises primarily from the breaking of several hydrogen bonds between the cyclodextrin rings.

BN does not have good long-term stability by itself in aqueous solution, and a sample kept in the dark for seven months developed a light brownish tint. However, CD acts as a good stabilizer, and a sample of the $BN(CD)_2$ complex stored for seven months in the dark developed no tint, and no change in the UV/visible spectrum was detected. Although prolonged use of a solution containing BN and CD at room temperature produced no change in phosphorescence signal, prolonged use at 60 °C caused the phosphorescence intensity to decrease by a few percent.

In summary, the first optical thermometer based only on phosphorescence lifetimes is reported, which has the following important advantages. 1) It has perhaps the highest sensitivity reported for an optical thermometer. 2) Adequate phosphorescence can be produced by using a range of excitation wavelengths, notably between 280–345 nm. The laser-induced phosphorescence intensities of the $BN(CD)_2$ complex and 6-bromo-2-naphthyl sulfate (BNS) in deaerated solution are similar.[22] Since similar phosphorescence intensity of BNS is produced by both laser and broad bandpass-filtered, 7 J flashlamp excitation, it should also be possible to produce adequate phosphorescence from the $BN(CD)_2$ complex using a simple, relatively inexpensive flashlamp excitation source. 3) The instrumentation required to produce and detect long-lived phosphorescence is relatively low in cost. 4) The water solubility of the molecular complex should make it useful as a direct probe of temperature in physiological samples and solutions. 5) Over most of the operational temperature range, the phosphorescence lifetime changes in accordance with the Arrhenius equation which permits a direct correlation to be drawn between τ and temperature without additional calibration. The limitations of the $BN(CD)_2$ optical thermometer are its relatively limited operational temperature range and its slow degradation at prolonged high temperatures. However, the small amounts of BN and CD required as samples in a functional thermometer are inexpensive and can be replaced as necessary.

Imine chloroboration: reaction of boron trichloride with a bulky diazadiene gives not a diazaborolium salt, but a 2,4,5 trichloro-1,3,2-diazaborolidine†

Reaction of *N,N′*-bis(2,6-diisopropylphenyl)-1,4-diazadiene with BCl_3 in hexane gave the crystalline product of double chloroboration, *N,N′*-bis(2,6-diisopropylphenyl)2,4,5-trichloro-1,3,2-diazaborolidine, which was characterised by single crystal X-ray diffraction, microanalysis and multinuclear NMR spectroscopy.

Hydroboration has become one of the principal vehicles of functional group interconversion. Additions of B–H across all manner of unsaturated bonds, including C=O and C=N, are extremely well documented.[1] Haloboranes, conversely, are best known as Lewis acids and ether cleavage agents, where the mode of reactivity is insertion into a single bond,[2] as opposed to addition across a multiple bond. Addition of a haloborane reagent across a multiple bond, 'haloboration', is less widely studied; though isolated reports of such reactivity began in the mid-20th century, covering alkynes, aldehydes and isocyanates,[3] only recently through the work of Suzuki and coworkers has the synthetic utility of the reaction type been systematically probed, concentrating on the bromoboration of alkynes.[4] Chloroboration of alkenes has also been recently identified as the mechanism for the living cationic polymerisation of isobutene.[5] During the attempted synthesis of a very bulky diazaborolium salt, it was discovered that the compound produced was the product of a double B–Cl addition across two aldimine C=N bonds, the first case, to our knowledge, of imine haloboration. In our attempts to explore novel metal boryl chemistry, it became necessary to prepare extremely bulky diazaborolium salts. These species have been known for some time to be available *via* the addition of boron halides to diazadiene ligands.[6] Interest in the area has recently been revived,[7] spurred by the isolation of stable carbenes by Arduengo *et al.*[8] However, during all of these syntheses, which were in most cases directed at further reduction of the putative diazaborolium halides to produce 6π pseudoaromatic diazaborole compounds, no diffraction data were collected on the diazaborolium compounds.

Reaction† of $(2,6\text{-}Pr^i_2C_6H_3NCH)_2$ with BCl_3 in hexane produced an orange powder, **1a**. This was isolated by filtration and from the filtrate, diffraction quality crystals of **1b** were grown. Both the orange powder **1a** and the crystals **1b** showed the same microanalysis, corresponding to the 1 : 1 product, and had identical NMR spectra in $CDCl_3$. The spectra appeared consistent with the expected diazaborolium formulation $[(2,6\text{-}Pr^i_2C_6H_3NCH)_2BCl_2]^+Cl^-$, save for the fact that the 'diazaborolium' ring CH protons resonated at 6.9 ppm, slightly upfield of where they are normally found (8–9 ppm)[6,7] in the ^1H NMR spectrum, and the ^{11}B NMR signal was slightly shifted from its expected position, and much broader than expected for a pseudo-tetrahedral boron site. More puzzling was the observance of two distinct isopropyl methine resonances. This was indicative not only of extremely slowed aryl ring rotation, but also of a lack of an approximate plane of symmetry in the molecule in any conformation.

The reason for the spectral anomalies became clear upon solution of the X-ray diffraction data:‡ The crystalline compound is not an ionic salt **1a**, but the neutral diazaborolidine molecule **1b** (see Fig. 1 and Scheme 1), the result of a double chloroboration of the diazadiene. Only a single chloride remains

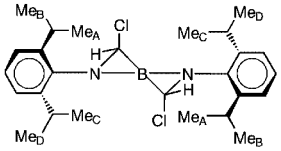

Scheme 2

bound to boron, completing the trigonal-planar geometry around that atom. The other two chlorides have added to the carbons of the diazadiene fragment, in an *anti* configuration, generating two chiral centres. Structurally **1b** bears close similarities with previously reported diazaborolidines of which there are two characterised by single-crystal X-ray diffraction [$(MeNCH_2)_2BMe$ and $(EtNCH_2)_2BMe$],[9] and one by gas-phase electron diffraction [$(MeNCH_2)_2BCl$].[10] All exhibit a puckered ring with slight pyramidalization at nitrogen, and one methylene group lying above, and one below, the mean ring plane. However, in **1b**, each nitrogen is rigorously planar, due to the bulky aromatic substituent. These aryl rings are slightly skewed from orthogonality (+14.4 and −14.3°) with the diazaborolidine ring by repulsions from the chlorides. This generates a C_2-symmetric environment about the boron (Scheme 2).

The IR spectrum of **1a** showed an absorption in the region 1580–1590 cm^{-1} indicative of a boron-coordinated imine,[6,7] whereas that of the crystals **1b** contained no such band. Furthermore, **1a** and **1b** were established to be different materials by powder X-ray diffraction. This identified **1a** as the expected diazaborolium salt, even though NMR spectroscopy in $CDCl_3$ showed it to be identical to **1b**. This leads to the conclusion that conversion of the initially formed diazaborolium salt to **1b** is completed in that solvent. The alternative possibility that in $CDCl_3$ the chlorides in **1b** dissociate from the carbons is excluded by the observation of distinct signals for the isopropyl methine resonances, directly ascribable to the reduction in symmetry generated by the addition of the chlorides above and below the diazaborolium ring plane (Scheme 1). Similar behaviour was observed in CD_3CN.

The fact that **1b** is indistinguishable by elemental analysis from the diazaborolium formulation, and the previous lack of diffraction data, offered the possibility that this unexpected reactivity had been missed in previous literature, but careful re-examination of published data showed that the diazaborolium formulation was amply supported by conductivity, IR and ^1H and ^{11}B NMR data.[6,7] The chloroboration reaction is therefore exclusive to **1**. Since previously reported examples include close analogues of **1**, including one case[7] which is identical save for the substitution of methyl groups in the aryl 2- and 6-positions for the isopropyl groups in **1**, the key to the reactivity appears to lie in the increased bulk. It may be that the boron atom cannot sustain four-coordination in the presence of the two diisopropylphenyl groups. In hexane solvent, the nucleophilicity of chloride, once ejected from the coordination sphere of the boron atom, would be high. Allying this to the fact that boron halides in their role as Lewis acids are often employed in order to encourage attack by nucleophiles at *ipso* carbon atoms, including such roles for imine additions[11] leads to a tentative mechanism such as that shown in Scheme 1. That the reaction proceeds to completion in the more polar solvents deuterochloroform and deuteroacetonitrile, more facilitative of ionization, further supports a description of the reactivity as a double 1,3-nucleophilic rearrangement.

A structural factor of particular note is the pronounced shortening in the diazaborolidine ring C–N bonds, which at a mean distance of 1.415(3) Å lie closer to the distances found in the pseudo-aromatic diazaboroles (mean of known values to date: 1.404 Å)[7,9] than to the more normal single bond values found in other known diazaborolidines (mean 1.459 Å).[9,10] The C–Cl distances in **1b** are conversely rather long at 1.84 Å, but are comparable to those in $(CHCl_2)_3N$ obtained by chlorination of triformamide;[12] the C–N and C–Cl distances in that case were 1.418(2) and 1.800(1) Å, respectively. It is a very rare situation because chloroamides are normally assumed to adopt an ionic

Scheme 3

form, *i.e.* the equilibrium shown in Scheme 3 lies to the left.[13] The analogy between this long-known behaviour and the newly discovered diazaborolium/diazaborolidine dichotomy is a strong one. In both cases, the molecular form would appear to retain a significant contribution from the ionic form in the ground-state equilibrium structure, as evidenced by the short C–N and long C–Cl bonds and rigorously planar nitrogen.[12] This type of behaviour has previously been termed single-bond–no-bond resonance.[14] No such behaviour is apparent in the much more common quaternary ammonium α-chloro-organonitrogen species.[14]

An important distinction between the two cases discussed[12,13] above is that there is only one chloride on each carbon in **1**; as an isolable synthon for a mono-α-chloro secondary amine, **1** is unique. We intend to pursue this analogy in parallel with the reduction chemistry of the current system to access highly hindered diazaboroles. It is also apposite to reflect that the use of extreme steric bulk does not always merely pacify chemical reactivity, but in certain circumstances can engender new and unexpected directions of that reactivity.

We thank the EPSRC and Creators Ltd for a Total Technology studentship, the Nuffield Foundation for an Undergraduate Research Bursary, and the Royal Society for an equipment grant.

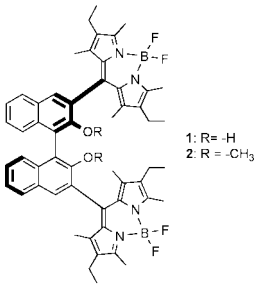
First published as an Advance Article on the web 22nd May 2001

The optically active binaphthalene boron–dipyrromethene (BDP) conjugate 1 shows chiral discrimination towards the enantiomers of 1-phenylethylamine by distinguishable quenching rates of the BDP fluorescence.

The chiral discrimination between enantiomers during molecular recognition processes[1] is of great importance in many fields of pharmaceutical chemistry, bio- and food technology.[2] For instance, the knowledge of the stereochemical structure of a potential drug is essential for rational and successful drug design as potency, selectivity and bioavailability can differ markedly for enantiomers of a chiral compound.[3] Solution-based sensor systems can be an important aid in these development processes,[4] since they allow the study of the processes of drug–receptor interactions. A functionalization with chromogenic[5] or fluorescent[6] reporter molecules facilitates the application of spectrophotometric and fluorometric analytical techniques that offer many advantages for highly sensitive chiral recognition. The use of steady-state and time-resolved fluorometry especially can improve rapid and quantitative analysis and is well-suited for high-throughput screening.[7] In our approach towards efficient enantioselective fluorescent sensor molecules, we relied on the versatile[8,9] and, when equipped with an appropriate receptor, efficiently chemically switchable[9] boron–dipyrromethene (BDP) fluorophore and designed the enantiomerically pure BDP conjugate **1**. 1,1′-bi-2-naphthol, known to selectively recognize optically active amines or amino acids,[5d,10] was chosen by us as the chiral receptor unit. In this communication, we report on the ability of **1** to differentiate between (*R*)- and (*S*)-1-phenylethylamine by specific modulation of its fluorescence signal at wavelengths > 500 nm.

The optically active *R*-enantiomers of **1** and the reference



compound **2** were obtained from enantiomerically pure 1,1′-binaphthalene carbaldehydes[11a,b] and 2,4-dimethyl-3-ethylpyrrole by literature procedures.[11c,d]

In agreement with earlier studies on a phenol-appended BDP dye,[9a] deprotonation of the hydroxy groups of **1** leads to a strong decrease of the fluorescence (Φ_f^1 = 0.62), most probably involving a photoinduced electron transfer-like quenching mechanism. Fig. 1 shows this 'switching OFF' of the BDP emission at 542 nm for a microtitration of **1** with diisopropylethylamine in acetonitrile.† Whereas the emission band position does not change during the titration, the BDP $S_1 \leftarrow S_0$ absorption band shifts slightly to the blue (from 523 to 521 nm). For **2**, where the hydroxy groups are exchanged with methoxy groups, no spectral shifts occurred in either, absorption (526 nm) or emission (542 nm, Φ_f^2 = 0.80), and only at comparatively high amine concentrations (*ca.* $> 10^{-2}$ M) was a slight reduction in fluorescence observed. To get better insight into the nature of the quenching process(es) involved, time-resolved fluorescence titrations were carried out. In the case of purely static quenching, *i.e.* when a non-fluorescent ground-state complex is formed, the fluorescence lifetime remains constant (τ_f = const.) and only the amplitude is gradually decreased during the titration ($a \neq$ const.). When dynamic quenching occurs, the number of emitting molecules is not changed (a = const.) but the lifetime is reduced ($\tau_f \neq$ const.) with increasing quencher concentration as a result of an increase in collisional frequency of an excited fluorophore with a quencher. Time-resolved quenching experiments with diisopropylethylamine revealed single exponential decays for both dyes. However, whereas for **2** the amplitude of the 6.17 ns component does not change, in the case of **1** an increase in base concentration leads to a concomitant decrease of the amplitude of the 5.15 ns decay species. At high amine concentrations, a slight but gradual decrease of the fluorescence lifetime is found for **1** and **2**, with an unchanged amplitude in the case of **2**. These results, along with the spectrophotometric changes, suggest that the reaction of diisopropylethylamine with **1** leads to the formation of an entirely non-fluorescent, deprotonated species of **1**, *i.e.* static quenching occurs, the respective K_S being determined to 1.1×10^4 M^{-1}.‡ Moreover, at high concentrations, base-induced dynamic quenching seems to be responsible for a reduction in fluorescence decay time for both, the sensor molecule as well as the reference compound. Reprotonation by TFA restored the initial fluorescence intensity.

These findings, along with our recent investigations on the transfer of chiral information from the optically active 1,1′-binaphthalene skeleton to the appended BDP-chromophores,[12] encouraged us to test the ability of **1** for chiral discrimination of optically active bases, (*R*)-(+)- and (*S*)-(–)-1-phenylethylamine (*R*-/*S*-PEA). In analogy to the results reported in the preceding

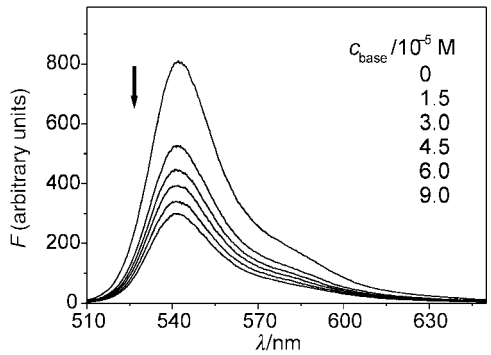


Fig. 1 Decrease in BDP fluorescence upon addition of diisopropylethylamine to a 5×10^{-6} M solution of **1** in acetonitrile; excitation at 490 nm.

 DOI: 10.1039/b102376b

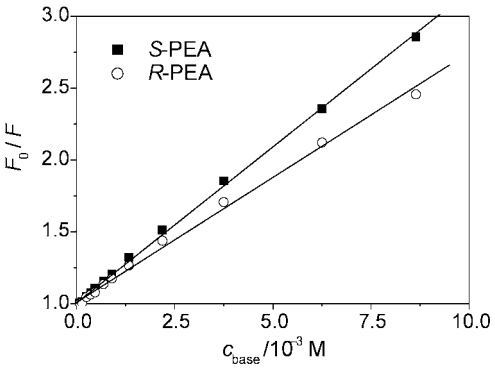

Fig. 2 Plots for the quenching of **1** with *S*-PEA and *R*-PEA in acetonitrile ($c_1 = 5 \times 10^{-6}$ M, excitation/emission at 490/540 nm, $r = 0.999/0.998$ for *S*-PEA/*R*-PEA).

paragraph, an interaction between a chiral quencher and the 1,1′-binaphthalene receptor unit should be detectable by specific changes of the BDP fluorescence signal. Upon addition of *R*- and *S*-PEA respectively, a decrease of the intensity of the fluorescence band was observed (Fig. 2), the emission maximum remaining virtually unchanged. The hypsochromic shifts in absorption (to 518 and 519 nm for *R*-PEA/**1** and *S*-PEA/**1**) are twice as large as those measured for the achiral bases. In addition, the molar absorptivities increase, the presence of *R*-PEA resulting in a stronger effect. The fluorescence lifetimes of **1** are unaffected by *R*- and *S*-PEA, and only at amine concentrations $>10^{-2}$ M does the excess of base lead to bimolecular, diffusion-controlled quenching. Analogous studies of **2** revealed that the fluorescence signal shows no comparable response upon addition of PEA, except for the dynamic quenching. This indicates that the hydroxy groups are essential for an interaction between the chiral analytes and the binaphthalene BDP conjugate, entailing specific modulations of the spectroscopic signal. Enantiomer-specific changes in the absorption spectra of 1,1′-binaphthol–amine associates have been reported before[13] and have been attributed to the formation of differently structured diastereomeric complexes,[13,14] most probably involving (more or less) strongly hydrogen-bound ground-state complexes (R–OH$\cdots$NR$_3$) or ion pairs of RO$^-\cdots$HNR$_3^+$-type. In the case of **1**, such differences in binding of *R*- and *S*-PEA can also result in a structural reorientation of the BDP chromophores. A better verification of the nature of the sensor molecule–analyte interaction/complex formation was not possible with the methods employed here, because several BDP-localized transitions which are centered in the region of the binaphthyl absorption hampered a closer inspection of the spectroscopic changes taking place directly at the binding/reaction site.[13]

In order to examine the efficiency of the quenching process for *R*- and *S*-PEA, the experimental data were analysed according to the equation for static quenching.‡ Fig. 2 shows the corresponding plots for the quenching of **1** with *R*- and *S*-PEA. The different slopes clearly indicate the suitability of **1** as a chirally discriminating sensor for optically active amines. The steeper slope for quenching with *S*-PEA, based on a higher $K_S = 226$ M^{-1} for *S*-PEA–**1** as compared to $K_S = 161$ M^{-1} for *R*-PEA–**1**, suggests that association of the *S*-enantiomer and **1** is more efficient. The ratio of $K_S(R–S)/K_S(R–R) = 1.40$ is comparatively high for amine complexes of a simple binaphthol receptor unit in acetonitrile[10*f*,*g*,13] and clearly stresses the potential of **1** as an enantioselective sensor molecule.

In conclusion, we have shown that the combination of the chiral recognition features of a substituted 1,1′-binaphthalene unit with the favourable spectroscopic properties of the BDP chromophore presents a promising approach towards 'ON'–'OFF' signaling of chiral analytes, advantageous both in spectral region and time domain.

Notes and references

† For the equipment used and general experimental procedures including fluorescence quantum yield determination, see ref. 9*b*. All quantum yields and lifetime data were obtained at 295 K, the uncertainties of the quenching constants are $< \pm 4\%$ ($n = 4$).

‡ If fluorescence quenching is caused by static as well as dynamic interactions of sensor and analyte molecules, the single quenching constants can in principle be separated by considering time-resolved emission data (for details, see J. R. Lakowicz, *Principles of Fluorescence Spectroscopy*, Plenum, New York, 1983, p. 260). In the case of **1**, dynamic quenching was only observed at very high concentrations of the corresponding bases. The quenching of the BDP fluorescence was nearly complete at much lower base concentrations due to static interactions, *i.e.* deprotonation (for diisopropylethylamine) or association (for the chiral amines) reactions. Therefore, the static quenching constants K_S reported here could readily be determined according to $F_0/F = 1 + K_S c_Q$, where F_0 is the fluorescence yield in the absence of quencher Q, F is the respective parameter in the presence of Q, c_Q is the concentration of the quencher and K_S is the association constant, in a concentration range where no reduction in fluorescence lifetime was observed. In all of these cases, plots of F_0/F *vs.* c_Q were strictly linear with correlation coefficients $r > 0.99$.

Unique acid catalysis of heteropoly compounds (heteropolyoxometalates) in the solid state

Makoto Misono

Department of Environmental Chemical Engineering, Kogakuin University, 1-24-2 Nishi-Shinjuku, Shinjuku-ku, Tokyo 163 8677, Japan. E-mail: misono@cc.kogakuin.ac.jp

Received (in Cambridge, UK) 20th March 2001, Accepted 11th May 2001
First published as an Advance Article on the web

Fundamental and superior characteristics of heteropoly compounds (heteropolyoxometalates) in the solid state that make them suitable for catalyst design at the atomic/molecular levels are described, together with important principles required for the understanding and design of solid heteropoly catalysts. First, the molecular nature of heteropolyanions (metal oxide clusters), which can be preserved in the solid state, enables control of the acid and redox properties over a wide range. Second, the presence of hierarchical structures (primary, secondary and tertiary structures) can lead to three catalysis modes—surface-type, pseudoliquid (or bulk-type I) and bulk-type II. Precise control of pore size is possible through the understanding of the microstructure, which results in unique shape selectivity observed for various reactions. Heteropoly compounds are green catalysts functioning in a variety of reaction fields and efficient bifunctional catalysts when combined with other components. The elucidation of catalytic processes is also possible at the atomic/molecular level due to their molecular nature. The positions and dynamic nature of protons as well as organic reaction intermediates in the pseudoliquid phase can be clarified by spectroscopic techniques. Various reactions promoted by solid heteropoly catalysts are collected from recent publications to illustrate the usefulness of the above ideas and of heteropoly catalysts themselves.

1 Catalyst design at the atomic/molecular level

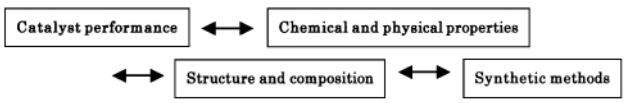
1.1 Importance and feasibility

Efficient catalysts are key materials in chemical technologies which supply useful substances to society and assist maintaining the environment as healthy as possible: in short, catalysts represent a key technology for a sustainable society. Although recent progress has been remarkable for homogeneous and biochemical catalysts, in particular the latter, heterogeneous (solid) catalysts are still of substantial importance in catalytic technology, and have several advantages. Therefore development of these is centred to solving global and local problems.

It is much more difficult to design heterogeneous catalysts than to interpret reactions over model solid catalysts. Hence, the development of practical (or commercial) catalysts still mostly relies on trial-and-error approaches, assisted by phenomenological knowledge on existing commercial catalysts and sophisticated knowledge on simple model catalysts. The design of practical catalysts at the atomic or molecular level has long been pursued,[1,2] since precisely designed multifunctional catalysts are obviously desirable. However, catalyst design at this level is still a distant goal in many instances.

1.2 Our approach

We have endeavored in the last two decades to establish the methodology of catalyst design by studying crystalline mixed oxides. In addition to their crystallinity, our criteria to choose catalyst materials are; (i) wide variation of composition whilst retaining the basic crystal structure and (ii) catalytic performance near the level required for practical application. Such materials include heteropoly compounds, perovskite-type mixed oxides and zeolites whose structures can be well defined at least for the solid bulk phases. Differences between the surface and solid bulk phase appear to be much smaller for these metal oxides than for metallic catalysts. This is particularly true for heteropoly compounds if the preparation and characterization of catalysts are carefully carried out. Here, the term 'heteropoly compounds' (abbreviated as HPAs) will be used for heteropolyoxometalates which include heteropolyacids and their derivatives. Heteropolyacids are hydrogen forms of heteropolyanions produced by the condensation of more than two kinds of oxoanions. Typical heteropolyanions are shown in Fig. 1. Using heteropoly compounds we attempted to establish the following relationships at the atomic/molecular levels as shown in Scheme 1.



Scheme 1

This article reports important progress to establish the basis for catalysts design since the publication of special issue of *Chemical Reviews* on polyoxometalates in 1998.[3] It will attempt to show that heteropoly compounds have various attractive and important characteristics in terms of catalysis and are promising materials for catalyst design at the atomic/molecular level.

Makoto Misono received his Bachelor, Master, and Doctor's degree in Engineering from the University of Tokyo and started his academic career in 1966 at the University of Tokyo, where he became a full professor in 1983. He spent two years in the USA for his postdoctorate (1967–1969; at the University of California, Santa Barbara, and Mellon Institute, Pittsburgh). He has been studying heterogeneous catalysis mainly of mixed oxides for 40 years and gave a plenary lecture at the 10th International Congress on Catalysis, Budapest, in 1992 on the subject of molecular catalyst design of solid heteropoly compounds. Since his retirement from the University of Tokyo with the Emeritus professorship in 1999, he has been a professor at Kogakuin University, a private technical university located in the center of Tokyo. He is a former president of Catalysis Society and a vice president of Chemical Society of Japan. He was elected a member of Science Council of Japan in 2000. He is now more involved in various activities related to the environment and chemistry such as green/sustainable chemistry and clean fuel-exhaust of automobiles.

Catalysts based on heteropoly compounds are hereafter denoted heteropoly (or HPA) catalysts. Earlier books and review articles may be referred to regarding the basic chemistry[4] and general catalysis[5] of HPAs. HPA catalysts have already been applied to several large-scale commercial processes.[6]

2 Basic concepts unique for solid HPA catalysts

In my view, the following concepts are essential to understand and design HPA catalysts, in addition to the knowledge generally required to understand heterogeneous catalysis of the ordinary mixed oxides.

2.1 Primary, secondary and tertiary structures

At an early stage of our study it was recognized that the hierarchical structure of solid HPAs was important for the understanding of the heterogeneous HPA catalysis, and we denoted the substructures as primary, secondary and tertiary.[7] This may appear a very simple idea, but enormously helped the progress of our research. Fig. 2 shows a simplified illustration of such hierarchical structures. The primary structure is the structure of heteropolyanion itself *i.e.* the metal oxide cluster molecule and details the molecular nature of solid HPA catalyst. Fig. 2 shows the most ubiquitous form which has the Keggin structure. The secondary structure is the three-dimensional (usually regular) arrangement consisting of polyanions, counter cations and additional molecules. The secondary structure is flexible to different extents depending on the counter cation and the structure of the polyanion, and is the basis of bulk-type catalysis of solid HPA catalysts (see below). The tertiary structure represents the manner in which the secondary structure assembles into solid particles and relates to properties such as particle size, surface area, and pore structure,[8] and plays an important role in heterogeneous catalysis. Without understanding this hierarchical structure, one can neither understand solid HPA catalysts properly nor take advantage of their molecular nature, and the idea of bulk-type catalysis described below would not have evolved.

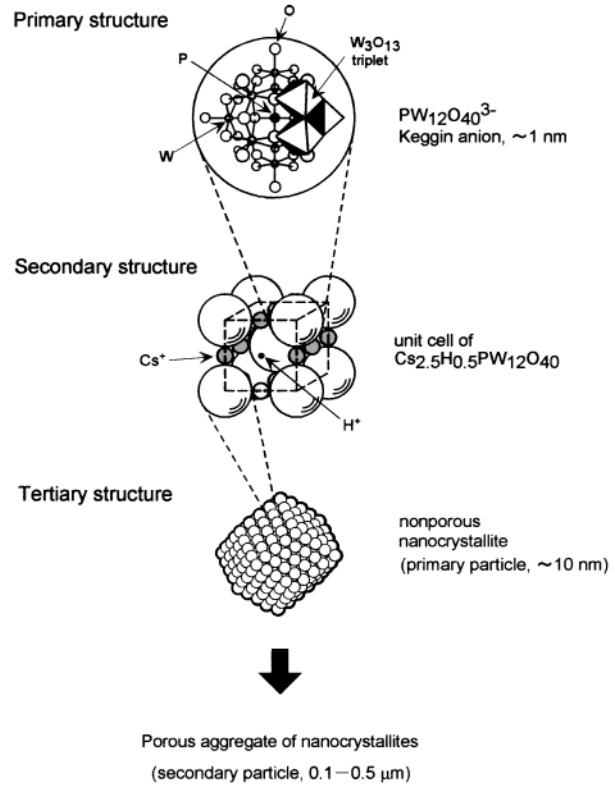

Fig. 2 Primary, secondary and tertiary structures; hierarchical structure of heteropoly compounds (HPAs) in the solid state.

2.2 Three types of catalysis

We have demonstrated that there are three totally different modes of catalysis for solid HPAs (Fig. 3). Surface-type catalysis (a) is ordinary heterogeneous catalysis which takes place on the solid surface (two-dimensional reaction field on outer surface and pore wall). Modes (b) and (c) represent bulk-type catalysis where the reaction fields are three-dimensional in contrast to the surface-type catalysis. When the diffusion of reactant molecules in the solid (diffusion in the lattice rather than pores) is faster than the reaction, the solid bulk forms a pseudo-liquid phase in which catalytic reaction can proceed [Fig. 3(b)]. In this instance, reactant molecules in the gas or liquid phase penetrate in between the polyanions (primary structure), sometimes expanding the distance between the polyanions, and react inside the bulk solid. The products come out to the surface and are released to the gas or liquid phase. Pseudoliquid catalysis, proposed in 1979, was not favourably accepted initially, since it appeared very unusual for heterogeneous mixed oxide catalysts. Now, however, such catalysis is more firmly established.[5a–c] In the pseudoliquid phase such catalysts appear as solids but behave like liquids (solvent). As the active sites in the solid bulk *e.g.* protons, take part in catalysis, very high catalytic activities are often observed in the bulk phase. Phase transitions accompanied by an abrupt change in catalytic performance are also observed.[5a]

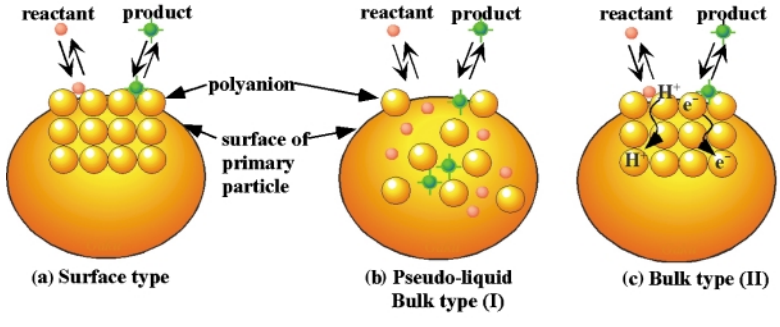

Fig. 3 Three types of catalysis for solid heteropoly compounds: (a) surface type; (b) pseudoliquid: bulk type (I), (c) bulk type (II).

The second bulk-type catalysis [bulk-type (II), Fig. 3(c)] is found for oxidation catalysis at high temperature when the diffusion of redox carriers (protons and electrons in this case) is rapid in the solid bulk, and the whole bulk participates in the reduction–oxidation cycle.[9] It should be noted that, as the contribution towards catalysis of the solid bulk varies with the relative rate of diffusion to that of reaction, intermediate cases between surface and bulk catalysis arise. Solid HPAs containing cations of low ionic radii to charge ratio (H^+, Na^+, Cu^{2+}, *etc.*) readily absorb small polar molecules and tend to exhibit pseudoliquid behaviour and are soluble in water. Cs and NH_4 salts (scarcely soluble in water, due to low solvation energy) usually show only surface-type catalysis.

The importance of this idea may be clearly understood by the following examples. Fig. 4(a) plots the relative activity and number of strong acid sites *vs.* the extent of neutralization (or the Na content) for acidic Na salts of $H_3PW_{12}O_{40}$.[10] Hereafter, $H_3PW_{12}O_{40}$, one of the most widely used HPA catalysts is abbreviated as HPW unless stated otherwise. The reactions are of bulk type (I) and the acidity is related to the number of protons in the entire bulk. It is evident in Fig. 4(a) that the rates of bulk-type reactions and the bulk acidity decrease monotonically with the Na content, thus showing good parallelism between catalytic activity and acidity. This also demonstrates that the acid catalysts can be designed by control of their acidity in this manner. In contrast, no monotonical change is found for several reactions catalyzed by acidic Cs salts, $Cs_xH_{3-x}PW_{12}O_{40}$ (denoted CsX), as shown in Fig. 4(b).[5a,b,11] These reactions are of surface type, as revealed by plots of the rates *vs.* the *surface acidity* (number of protons on the surface). The surface area sharply rises from 1–2 $m^2\ g^{-1}$ for Cs1 and Cs2 to *ca.* 150 $m^2\ g^{-1}$ for Cs3. The mechanism of the increase in surface area is interpreted in a later section of the article. As is obvious in Fig. 4(c), a good correlation is obtained.[12] Another important point to be noted is that the specific activity of CsX [catalytic activity per surface proton, the slope in Fig. 4(c)] is much higher than known solid acids such as zeolites and silica–alumina. This fact demonstrates the high performance of HPA catalysts.

Bulk-type catalysis (II) is also an essential concept required to understand and design HPA catalysts.[13] This has been found to be relevant for oxidation reactions at high temperatures. If the rates of *bulk-type oxidation* (*e.g.* oxidative dehydrogenation) are plotted against the surface redox property, very poor correlations are found, but the rates exhibit good correlations with *bulk* redox property. In contrast, the rate of *surface-type* oxidation correlates very well with the *surface redox property*. This is very similar to the acid catalysis shown in Fig. 4. Without knowing this fact, the development of practical oxidation catalysts would be very difficult.

2.3 Merits of HPA catalysts

The advantages of hetreopoly compounds for heterogeneous catalysts are summarized in Table 1.[5] There are several large-scale industrial processes utilizing HPA catalysts as oxidation and acid catalysts both in the solid state and in solution.[5a,b,6] Most are environmentally friendly, so that HPA catalysts are regarded as promising green (or sustainable) catalysts.[14,15]

Table 1 Merits of solid heteropoly catalysts for catalyst design at the atomic/molecular level

1	Systematic variation of acid and redox properties are possible for catalyst design.
2	Molecular nature of solid heteropoly compounds originating from heteropolyanion molecules enables precise design of catalysts and molecular description of catalytic processes
3	A variety of reaction fields are available for catalytic systems.
4	The unique basicity of polyanions

3 Novel aspects of pseudoliquid catalysis

3.1 Variety of reaction fields

Pseudoliquid behavior [bulk-type (I) catalysis] has also been found for liquid–solid heterogeneous systems. For example, the relative catalytic activities of HPW and Cs2.5 dramatically change with the polarity of reacting molecules;[5b] HPW > Cs2.5 for pinacol rearrangement (pseudoliquid catalysis) and HPW < < Cs2.5 for alkylation of aromatics (surface-type catalysis). HPW shows high activities for the reactions in the solid bulk (pseudoliquid), since protons inside the solid can be utilized, while Cs2.5 having a large quantity of protons on the surface (see below) is active for surface-type reactions. Bulk type (II) catalysis has not yet been observed probably because the reaction temperatures are low. The various reaction fields containing a liquid phase are illustrated in Fig. 5.

The catalysis of solid HPAs in the liquid phase has been well documented.[16] For example, three reactions differing in polarity of reactants were compared using several alkali- and alkaline-earth salts of HPW. It was shown that the decomposition of cyclohexyl acetate is catalyzed on the solid surface (surface-type), and that pinacol rearrangement proceeds in the pseudo-liquid phase. On the other hand, esterification of benzoic acid and butan-1-ol is mainly catalyzed by HPA dissolved in solution, although most of HPA remains in the solid state. The order of catalytic activity, therefore, is very different between the reactions. This again demonstrates the importance of distinguishing surface- and bulk-type catalysis for the catalyst

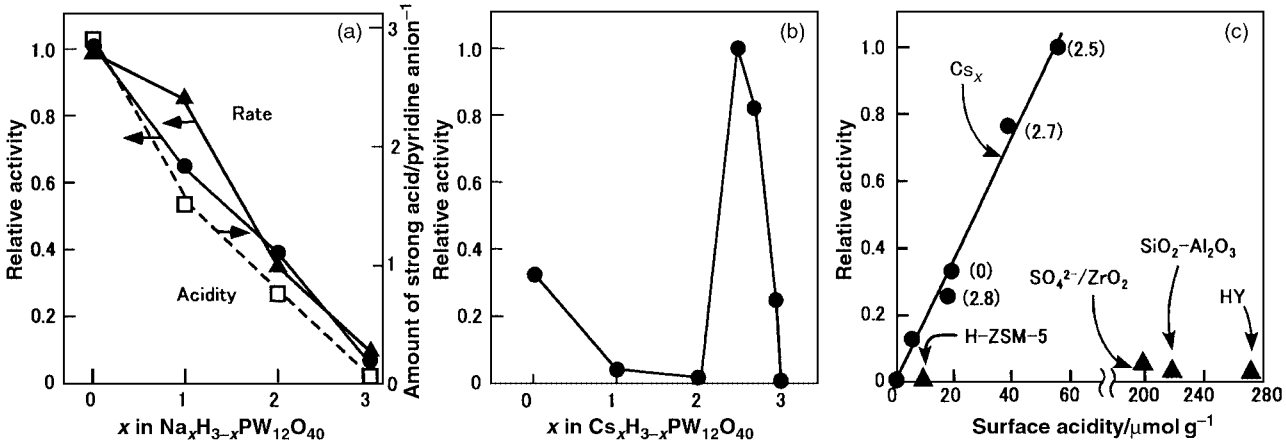

Fig. 4 Importance of differentiating surface- and bulk-type catalysis. (a) Bulk-type (I) (pseudoliquid) catalysis and bulk acidity of Na salts of $H_3PW_{12}O_{40}$ (HPW): (▲) conversion of methanol, (●) dehydration of propan-2-ol, and (□) bulk acidity measured by strongly held pyridine. (b) Rates of alkylation of 1,3,5-trimethylbenzene by cyclohexene catalyzed by Cs salts of HPW (surface-type catalysis). (c) Rates of alkylation over Cs salts [data from Fig. 4(b)] are plotted *vs.* the surface acidity, together with the same plots for several other solid acids.

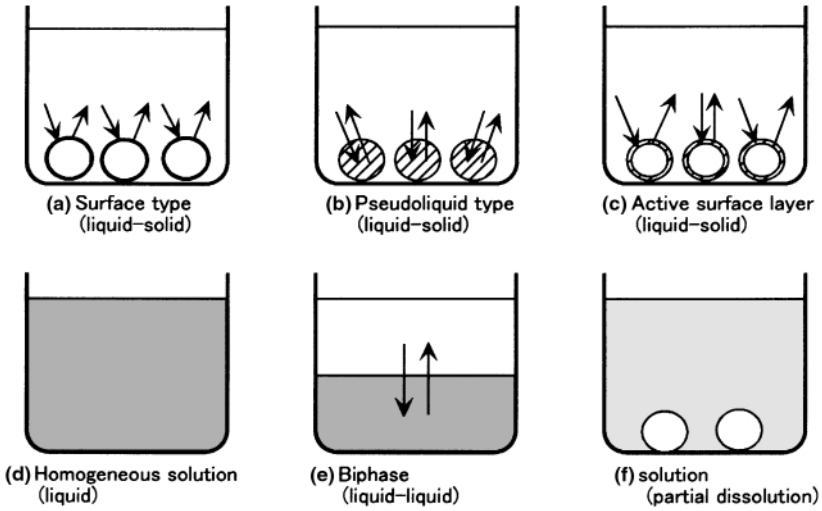

Fig. 5 Various reaction fields of HPA catalysis in reaction systems containing a liquid phase.

design of HPAs. Fig. 5(a) and (d) correspond to the ordinary heterogeneous catalysis (liquid–solid) and homogeneous (solution) catalysis, respectively. Phase-transfer catalysis for liquid–liquid biphase systems [Fig. 5(e)] is well known and there are at least two large-scale commercial processes using HPA catalysts.[6,14] Catalysis by solid HPAs for solid state reactions[17] and in a new phase formed on the surface layer[14] [Fig. 5(c)] are new. In the latter, protons introduced on the surface layer of Cs3 create a new active phase similar to a 'pseudoliquid' (Fig. 6).

Among other recent interesting observations is the unique relationship between the shape of the primary structure, the resulting secondary structures, and the remarkable influence on the catalytic activity.[18] The thermodynamically favored synthesis of methyl *tert*-butyl ether (MTBE) from isobutylene and methanol proceeds at low temperature (323 K) on Dawson-type hetropolyacids ($H_6P_2W_{18}O_{62}$ and $H_6P_2Mo_{18}O_{62}$) rapidly and selectively. In contrast, the reaction is very slow over Keggin-type heteropolyacids, in spite of the higher acid strength and comparable acid content. We found that Dawson-type heteropolyacids are amorphous under the reaction conditions due to the ellipsidal shape of the polyanion, whereas Keggin-type polyanions having spherical shape are crystalline (bcc structure). Owing to this difference the former forms active pseudoliquids, while the latter are much less active (Table 2). As for MTBE synthesis catalyzed by $H_4SiW_{12}O_{40}$, Bielanski's group has made an extensive study and proposed a hypothesis that the reaction takes place on the surface to which methanol and protons are supplied from the pseudoliquid phase.[19]

3.2 Protons, water and organic molecules in pseudoliquids

To understand and design pseudoliquid catalysts at the molecular level, information about the acidic protons, such as their location, mobility and donating ability (acid strength), is indispensable. Information about the interactions between acidic protons and small basic molecules such as water and alcohols provides useful knowledge about pseudoliquid catalysis, since water is often contained in the working state and plays an important role. Furthermore, the states and dynamics of protons in the solid are interesting subjects of solid-state chemistry. In our early studies we observed protons in HPW using MAS NMR, then directly detected (by a combination of NMR and IR) the reaction intermediates of ethanol dehydration in the pseudoliquid phase, and disclosed the dynamic behavior of methanol.[5b,6]

While IR is usually a powerful tool to study solid catalysts the IR spectra of OH bands of heteropolyacids are ambiguous. For highly hydrated HPW, the OH stretching and bending modes of water and protonated water are detectable, but for more dehydrated states they do not show any clear IR bands in contrast to silica or zeolite catalysts.

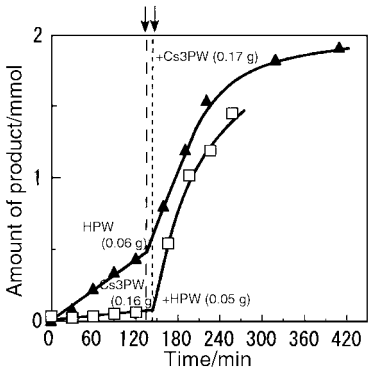

Fig. 6 Catalysis in a novel phase formed on the surface layer of a solid HPA for a liquid–solid reaction system. Hydrolysis of bistrimethylol propane monoformal in water at 348 K. The reaction rate rises sharply when the second component is added after a certain reaction time (indicated by arrows). The rates after the addition are much higher than the sum of the rates of each component, indicating the formation of an active layer on the surface of Cs3.

Table 2 Unique relationships between shape of polyanion (primary structure), secondary structure and catalytic activity

Primary structure[a] (shape)	Secondary structure at the working state	Catalytic activity for MTBE synthesis at 323 K
Dawson (ellipse) $H_6P_2W_{18}O_{62}$ $H_6P_2Mo_{18}O_{62}$	Amorphous	Very high
Keggin (spherical) $H_3PW_{12}O_{40}$ $H_4SiW_{12}O_{40}$	Crystalline (bcc)	Very low

[a] See Fig. 1.

Recently, reliable IR spectra of HPW·$n$$H_2O$ with different degrees of hydration have been reported independently by us[20b] and Zecchina's group.[21] Fig. 7 shows our results where the water contents are quantified (reliable at least for n = 0 and 6). Very broad bands ranging from 3500 to 1200 cm^{-1} are evident. For n = 6 (hexahydrate) for which the structure has been established,[5] an extremely broad band is observed which we assigned to $H_5O_2^+$ ($H_2O\cdots H^+\cdots OH_2$) present in the hexahydrate. A broad band having a peak at about 3200 cm^{-1} was observed for dehydrated sample (n = 0–0.5), which was

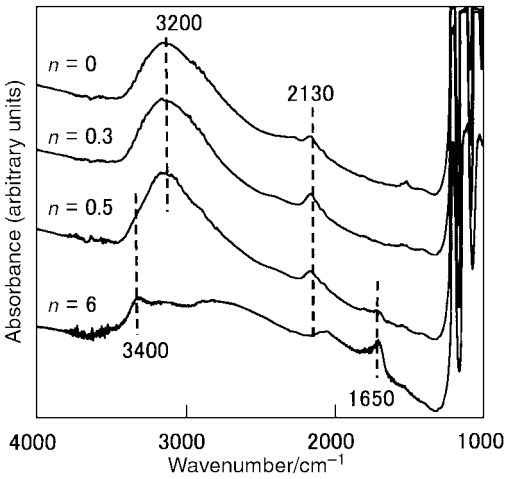

Fig. 7 IR spectra of $H_3PW_{12}O_{40}{\cdot}nH_2O$ with a variety of hydration states ($0 < n < 6$).

assigned to isolated acidic protons bonded to peripheral oxygens of the polyanion. These bands seem to exist in the IR spectra reported in earlier studies, but their presence and significance have not been well recognized.

Zecchina's group reported high quality IR spectra and provided valuable discussion of the IR bands.[21] The extremely broad band observed for the hexahydrate is reasonably interpreted by the nearly flat potential of a proton in a hydrogen bond. However, they possibly underestimated the water content of some samples (see below) and therefore their assignment of the IR bands is probably partially incorrect. The evacuation of hydrated HPW at 300–340 K leads to the hexahydrate which is fairly stable.[5a–c] Usually a higher temperature (as high as *ca.* 350 K) is necessary for further dehydration. Therefore, the sample of Zecchina's group which was obtained upon evacuation at room temperature for 3 min has probably $n > 6$, whereas the sample obtained by evacuation for 150 min is most likely the hexahydrate.

The states and dynamics of protons and water in HPW have been clarified by an extensive study using solid-state ^1H, ^{31}P and ^{17}O MAS NMR.[22] For example, the P NMR spectra of $HPW{\cdot}nH_2O$ (n = 0–6) which was prepared from the hexahydrate by evacuation at 373–423 K are shown in Fig. 8. H NMR spectra measured at 298 and 173 K showed a very broad peak for $n = 6$ due to the dipole–dipole interaction in $H_5O_2^+$, and a sharp peak for the other samples. The following important conclusions can be deduced from the NMR data.

(a) Acidic protons are present in three forms; (i) proton attached to polyanions, (ii) H_3O^+ (hydronium ion monomer) or H_2O strongly interacting with acidic protons, and (iii) $H_5O_2^+$ (hydronium ion dimer). H_3O^+ and $H_5O_2^+$ weakly interact with polyanions by hydrogen bonding. Acidic protons in the anhydrous sample attach to the polyanion leading to a significant chemical shift in the ^{31}P NMR spectrum. The probable bonding states are schematically illustrated in Fig. 9.

On the basis of IR studies, Zecchina's group concluded that for intermediate hydration states ($0 < n < 3$), the acidic proton does not form H_3O^+ but rather O–H···OH_2 .[21] However, the close resemblance in the chemical shifts of the P NMR spectra (*e.g.* $n = 2.1$ measured at 173 K, Fig. 8) and of CsX[8,25] suggests the formation of H_3O^+; acidic protons interact very weakly with polyanions. The remainder of the acidic protons remain directly bonded to the polyanions. It should also be noted that the acid strength of HPW is greater than that of zeolites (see below, Table 3).

(b) The broad peak observed at 298 K (n = 0 .5–4) splits into several peaks at 173 K (Fig. 8, $n = 0.5$, 2.1 and 4.0). This means that the rate of proton migration (exchange) is slow at 173 K and at 298 K is of the order of 200 Hz which is much faster than the rate of ordinary catalytic reactions. This study also indicated

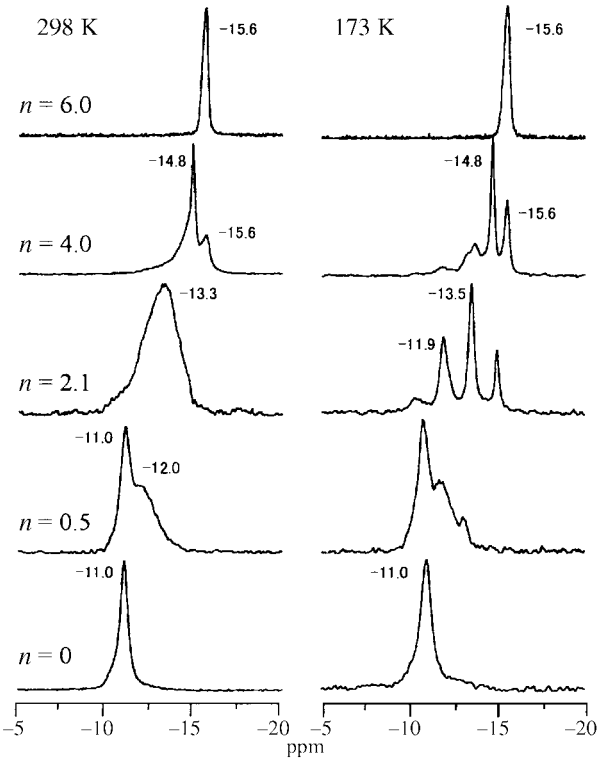

Fig. 8 ^{31}P NMR spectra of $H_3PW_{12}O_{40}{\cdot}nH_2O$ with a variety of hydration states ($0 < n < 6$) measured at 298 and 173 K.

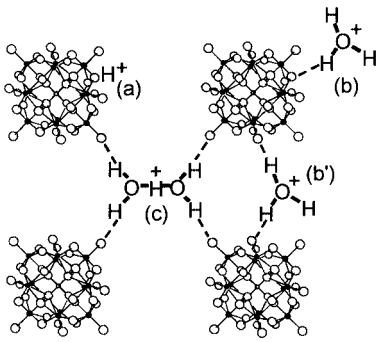

Fig. 9 Models proposed for the states of acidic protons and water in solid $H_3PW_{12}O_{40}{\cdot}nH_2O$ ($0 < n < 6$); two possible positions are shown for H_3O^+.

Table 3 Acid strengths of various solid acids

Solid acid	Initial heat of NH_3 sorption/kJ mol^{-1}	Approximate peak temperature of NH_3 desorption/K
$H_3PW_{12}O_{40}$	195	850
$Cs_{0.5}H_{2.5}PW_{12}O_{40}$	170	830
SO_4/ZrO_2	165 (190)[a]	1000 (as N_2)
HZSM-5 (Si/Al = 13)	150	670
SiO_2-Al_2O_3	145	600

[a] Value in parentheses refers to the very initial value.

that water in the lattice enhances the mobility of protons. The high mobility of protons may facilitate protonation in acid catalysis.

(c) The relative intensities of the split peaks follow a binominal distribution, indicating a uniform (random) distribution of protons and water in the solid.

(d) In the anhydrous state ($n = 0$), there is one type of acidic proton species attached to the polyanion at least on the NMR time scale. This is consistent with our IR data. We observed an apparently single broad band for the dehydrated sample (n = 0).

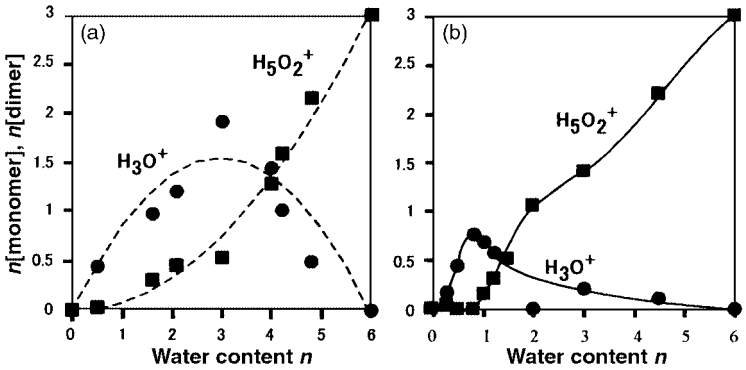

Fig. 10 Amounts of H_3O^+ (monomer) and $H_5O_2^+$ (dimer) per polyanion in $H_3PW_{12}O_{40}{\cdot}nH_2O$ ($0 < n < 6$). (a) Samples prepared by evacuation of the hexahydrate at 373–423 K. Dashed lines were calculated by assuming that water molecules are randomly removed from the hexahydrate. (b) Samples prepared by rehydration of anhydrous $H_3PW_{12}O_{40}$ at room temperature.

(e) The concentrations of the three proton species in $HPW{\cdot}nH_2O$ (n = 0–6) change with the extent of dehydration as shown in Fig. 10(a). The trends are in agreement with those calculated by assuming random removal of water.

In contrast, $HPW{\cdot}nH_2O$ prepared by the addition of water to an anhydrous sample at room temperature is quite different [Fig. 10(b)]. The main reason for the difference may be the lower temperature of preparation for which the diffusion of water is slow. Rehydration leads mainly to $H_5O_2^+$ instead of H_3O^+ at $n > 2$. Careful preparations are always necessary to obtain HPA samples having uniform composition. In particular, special caution must be taken to avoid rehydration, since anhydrous HPAs are very sensitive to moisture (even from water adsorbed on walls of apparatus).

3.3 Acidity

The acid strength of HPAs vary in a wide range depending on the polyanion structure and its constitutuent elements (both hetero and addenda atoms), as well as on the extent of hydration and reduction. Most results indicate that HPW after dehydration, the strongest HPA known so far, is a much stronger solid acid than zeolites including ZSM-5, and is close to that of superacids.[5,23] Indeed some believe HPW to be a superacid[24] while others claim that its acidity is comparable with zeolites.[21] The counter cation is also an important factor. Table 3 summarizes the acid strength as monitored by ammonia sorption (adsorption and absorption) and desorption for several solid acids,[23,25] and Fig. 11 shows the results of calorimetric measurements of NH_3 sorption on Cs2.5 and HPW at 423 K. Caution in interpretation of the results may be necessary for HPW which tends to exhibit pseudoliquid behaviour. Ammonia is absorbed into the bulk and forms ammonium salts, so that the lattice energy of the salts should be considered in calculating the heat of sorption.

Quantum chemical studies with higher levels of approximation on a full Keggin unit have recently been attempted. The stronger acidity of HPW than $H_3PMo_{12}O_{40}$ (HPMo) is indicated by density functional theory (DFT).[26] In early calculations, the position of protonation was inferred to be at bridging oxygen atoms.[27] Recently the same conclusion was deduced by a DFT calculation applied to a full Keggin unit including geometrical optimization.[28] Our ^{17}O MAS NMR and IR data are in agreement with this conclusion.[20b,22]

There are at least five different mechanisms for the evolution of acidity of solid HPA salts[5a] and hence the acidic properties are complicated unless the structures are carefully scrutinized. NMR studies revealed that protons of a novel nature are formed by the reduction of Ag and Pd salts of HPW.[29] Protons are reversibly formed by the reduction of $Ag_3PW_{12}O_{40}$ and are much more catalytically active than the protons in HPW for several reactions in the presence of H_2. ^1H NMR spectroscopy showed that protons in the former are more mobile than those of the latter. The influence of the mobility of protons on catalytic performance is an interesting topic. Similar behaviour is observed for Ag zeolites and can be formulated by reactions (1)–(3).[29c]

4 Recent topics in surface-catalysis of Cs and NH_4 salts of HPW

4.1 Microstructure

The microstructure, or the tertiary structure (particle size, surface area, pore distribution, *etc.*) of insoluble acidic Cs and NH_4 salts of HPW is of great interest since Cs2.5 showed extremely high catalytic activities for various reactions in the liquid phase as a strong solid acid.[5a–c] The activity is often more than ten times greater than that of zeolites and more than three times that of the parent HPW. Activity much higher than that of HPW was also reported for Cs2.4 prepared in a slightly different manner.[30] Furthermore, the size of the micropores of Cs2.5 is nearly uniform, can be controlled at the sub nm level and leads to remarkable shape selective catalysis.[23,31] Acidic NH_4 salts are also active and for benzoylation $(NH_4)_4HPW_{12}O_{40}$ was more acive than Cs2.5.[32] Ag and Tl salts seem to have similar microstructures.[33]

The main reason for the high activity of Cs2.5 is its high surface acidity *i.e.* the large number of strongly acidic protons on the surface.[5a–c] The number of surface sites is about half of the total number of protons contained in the solid owing to its high surface area (*ca.* 150 $m^2\ g^{-1}$). Cs2.5 is a strong acid being only slightly weaker than the parent HPW (Table 3). Other

reasons for the high activity are moderate hydrophobicity of the surface, a bimodal pore distribution and acid–base bifunctionality (see below). All of these factors are interesting and important for heterogeneous catalysis.

Extensive and detailed studies using ^{31}P NMR, XRD, electron diffraction, AFM and SEM, adsorption of N_2, Ar, *etc*, as well as quantitative chemical analysis, have recently been carried out to clarify the microstructures of the acidic Cs and NH_4 salts.[25] Those measurements were applied comprehensively to the preparation processes *i.e.* solutions, precipitates and resulting solids obtained after drying and heat treatment, and provided a consistent view about the microstructures of Cs2.5 and other CsX salts. Their formation processes thus deduced are schematically illustrated in Fig. 12.

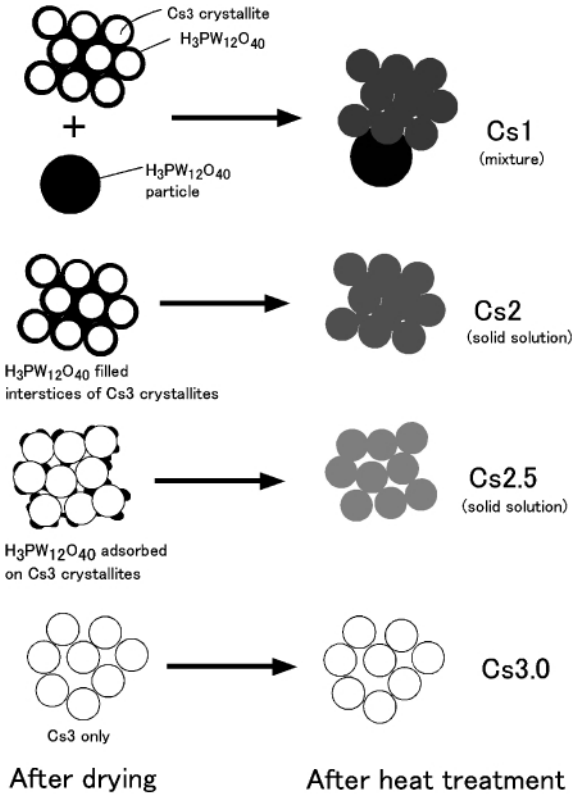

Fig. 12 Schematic illustration of the formation processes of acidic Cs salts: Left; after drying, right; after heat treatment.

Upon titration of an aqueous solution of HPW with a Cs_2CO_3 aqueous solution at 298 K, very fine precipitates of Cs3 (nanoparticles of *ca*. 10 nm in diameter) are formed, to which HPW is partly adsorbed with the remaining HPW present in the solution. As the titration proceeds, the amount of HPW in solution decreases, forming Cs3 precipitates. At the stoichiometry of Cs2 (Cs_2CO_3 added: HPW = 1 : 1), the precipitates are fine particles (also *ca*. 10 nm in diameter) of Cs3, the surface of which are covered by nearly a monolayer of HPW. Their surface area is very low (1 $m^2\,g^{-1}$), since the fine particles stick together densely after drying. This model is supported by the fact that the particle size estimated from XRD linewidths is *ca*. 10 nm, while that estimated from the BET surface area is 500 –1000 nm.

When Cs_2CO_3 is added beyond a stoichiometry of X = 2, the surface area increases sharply, since most of HPW precipitates as Cs3 and the amount of HPW remaining in solution or adsorbed on precipitates diminishes rapidly. Hence, micropores start to develop which would have been absent if the remaining HPW had densely connected the nanoparticles. ^{31}P NMR (which can differentiate between polyanions containing 0, 1, 2 or 3 protons) demonstrated that thermal treatment at 373–473 K leads to a nearly uniform solid solution of $Cs_3PW_{12}O_{40}$ (Cs3) and $H_3PW_{12}O_{40}$ (HPW) *via* diffusion of protons and Cs^+ ions, the lattice constant changing accordingly. This process has been unambiguously confirmed by the formation of the identical solid solutions when Cs3, impregnated by various amounts of HPW, is treated at 473 K, as shown by the P NMR spectroscopy (Fig. 13).

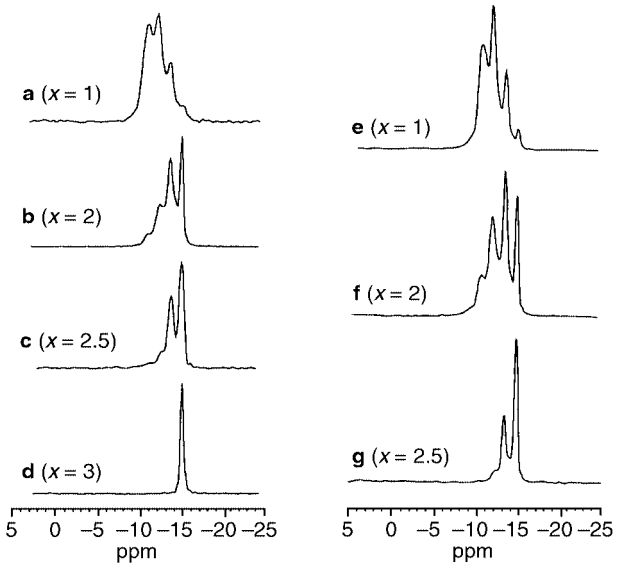

Fig. 13 Comparison of the ^{31}P NMR spectra of $Cs_xH_{3-x}PW_{12}O_{40}$ (CsX) [(a)–(d)] with Cs salts having the same compositions (CsX, X = 1, 2, 2.5) prepared by impregnation of $Cs_3PW_{12}O_{40}$ (Cs3) by HPW [(e)–(g)]. All samples were thermally treated at 473 K.

Cs2.5 has a bimodal pore size distribution; micropores ranging from 0.5 to 1.0 nm (peak at 0.65 nm and mostly > 0.75 nm) and mesopores (peak at 4–5 nm).[30,34] It is deduced that the micropores arise from spaces between nanocrystallites (10–20 nm) in loose and random aggregates and mesopores arise from spaces between the nanocrystallites and between aggregates of size *ca*. 100–500 nm (see Fig. 2). The micropores account for about 70% of the total surface area of Cs2.5 [see below, Fig. 15(d)]. Misfits in the connection of nanocrystallites have recently been suggested as the origin of small micropores (see below).[35] Another possible origin of micropores are polyanion vacancies as proposed for $Cs_4PMo_{11}VO_{40}$.[36] However, no firm and detailed conclusion has been obtained for the origin of the micropores which have a rather sharp size distribution.

A surprising finding of the microstructure is the epitaxial assembly of Cs and NH_4 salts, which was discovered unexpectedly [Fig. 14 and Fig. 15].[37,38] When the Cs salts are

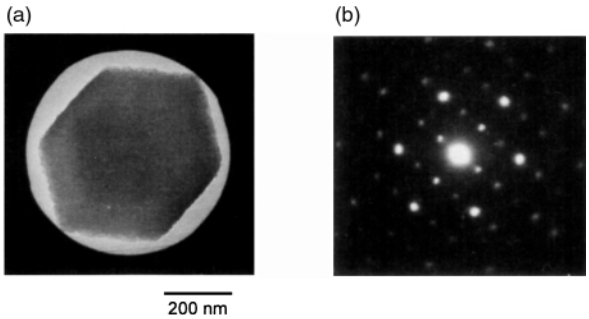

Fig. 14 Electron diffraction pattern of $(NH_4)_3PW_{12}O_{40}$ prepared by titration at 368 K using NH_4HCO_3: (a) the area in which the diffraction pattern was taken and (b) diffraction pattern.

prepared at a temperature as high as 370 K, the initially formed nanocrystallites (*ca*. 10 nm) assemble together with the identical orientation of crystal planes, leaving micropores between the nanoparticles [Fig. 15(b)], in contrast to Cs2.5

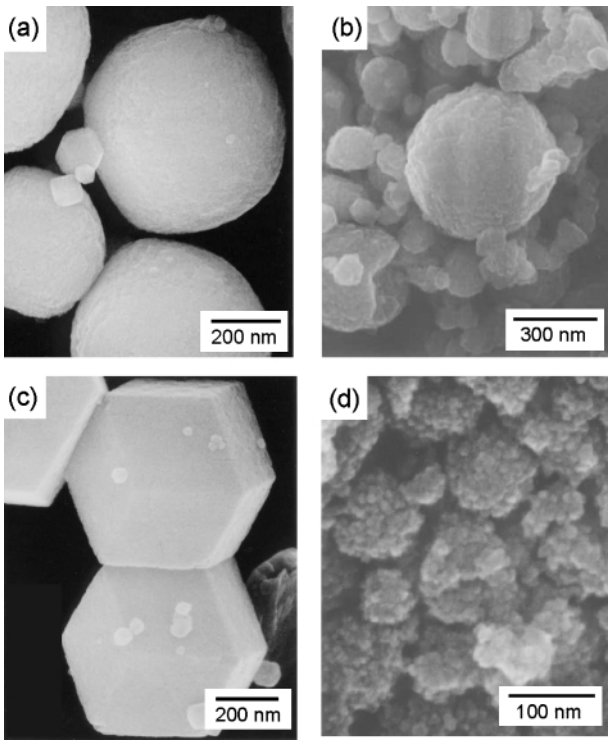

Fig. 15 SEM images of (a) $(NH_4)_3PW_{12}O_{40}$ prepared by titration at 273 K, (b) $Cs_3PW_{12}O_{40}$ (Cs3) prepared by titration at 368 K, (c) $(NH_4)_3PW_{12}O_{40}$ prepared by titration at 368 K and (d) $Cs_3PW_{12}O_{40}$ (Cs3) prepared by titration at 298 K. Cs2.5 is similar to Cs3 in appearance.

prepared at room temperature [Fig. 15(d)]. This is most remarkable when a stoichiometric NH_4 salt is prepared by means of homogeneous precipitation using urea decomposition.[34] The initially formed particles are spherical and slightly oriented aggregates [resembling the NH_4 salt formed by titration at low temperature shown in Fig. 15(a)], that are comprised of nanocrystallites of size *ca*. 10 nm with micropores (*ca*. 0.6 nm) in the spaces between the nanocrystallites, and mesopores (2–10 nm) between the loosely bound nanocrystallites and/or between the aggregates (100–1000 nm). The particles then gradually turn into large 'crystalline' microporous aggregates (400–1000 nm) having regular dodecahedral shape and few mesopores [similar to but larger than the particles shown in Fig. 15(c)]. The particle size estimated by XRD linewidth measurements (> 260 nm) is much greater than the size calculated from the surface area (10–20 nm), indicating that epitaxial connections occur between nanocrystallites. AFM and SEM images confirm that aggregates consist of fine particles of size *ca.* 10 nm. Electron diffraction (ED) shows regular discrete spots indicating crystallinity (Fig. 14). All of these observations indicate that the dodecahedral particles are 'crystalline' aggregates of nanoparticles and are porous. A monodispersed particle size (*ca*. 1000 nm) can be obtained by controlling the precipitation procedure (Fig. 16).[39] Spherical aggregates shown in Fig. 15(a) and (b) also give discrete ED patterns.

4.2 Shape selectivity

Remarkable shape selectivity has been reported for several acid-catalyzed reactions over Cs salts using molecules having different sizes. While Cs2.5 is active for most reactions, Cs2.1 and Cs2.2 only catalyzed reactions of small molecules.[5a,b,23] Shape selective catalysis has also recently been found for oxidation and hydrogenation reactions. Okuhara and coworkers confirmed that Cs2.1 has only micropores of size *ca.* 0.45 nm (in contrast to Cs2.5 for which both micropores of > 0.75 nm and mesopores of *ca*. 5 nm are present), and demonstrated shape selective catalysis, on the basis of the comparison of the catalytic activities of Pt-Cs2.1, Pt-Cs2.5 and Pt-SiO_2, for (i) oxidation of methane, carbon monoxide and benzene, and (ii) hydrogenation of ethylene and cyclohexene.[40] Shape selectivity in the products was found for the reaction of *n*-butane.[41] The large-pore Pt-Cs2.5 was very selective for the isomerization to isobutylene (94%), while cracked products (C_1–C_3) markedly increased with a decrease in the size of micropore (only 48% isobutene formed for Pt-Cs2.1) attributed to slow diffusion of the branched alkane in small micropores. Okuhara and coworkers proposed that small spaces formed by misfits in the connection of nanocrystallites are the origin of the small micropores of Cs2.1 (0.45 nm),[34] as illustrated in Fig. 17.

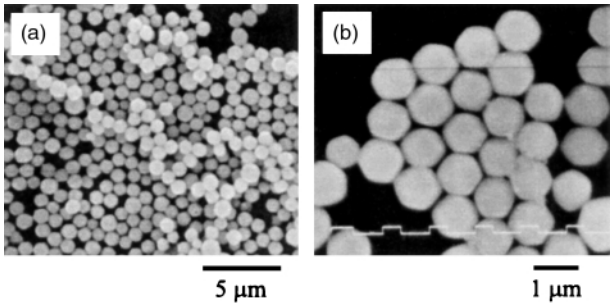

Fig. 16 SEM images of monodispersed $(NH_4)_3PW_{12}O_{40}$ prepared by titration at 368 K.

4.3 Surface acidity of $Cs_xH_{3-x}PW_{12}O_{40}$, CsX

The unusual change with X of the catalytic activity of CsX is reasonably interpreted by the surface acidity [Fig. 4(c)]. Here, the surface acidity is estimated by multiplying the number of polyanions on the surface (calculated from the surface area and the size of polyanion) and the number of protons per polyanion on the surface (from the proton content of the solid, or the chemical formula). Recently, the surface acidity, or the number of protons, on the surface of CsX (X = 2–3), has directly been measured by an IR study of CO adsorption at 110 K (Fig. 18).[20a] CO adsorbed on Cs2.5, for example, exhibits three bands; a band at 2165 cm^{-1} attributable to CO adsorbed on acidic proton sites, at 2154 cm^{-1} to CO on Cs^+ ion, and at 2139 cm^{-1} to physisorbed CO [Fig. 18(d)]. For comparison, the IR spectra of Cs3 is also shown, where both the 2165 cm^{-1} band and a broad band in the OH stretching region are absent [Fig. 18(b)].

As expected, the intensity of the first band (2165 cm^{-1}, CO on proton site) changed in parallel with the catalytic activity as shown in Fig. 19.[20a] In this way, the surface acidity estimated previously as described above has been confirmed by the direct measurement of the surface proton sites. None of the IR bands of adsorbed CO were detected for CsX (X = 0–2). Even if the very low surface areas of these Cs salts (X = 0–2) are taken into account, the IR bands would have been detected at least for HPW (4–5 $m^2\ g^{-1}$). The reason for the absence of the IR bands for HPW is not clear.

4.4 Hydrophobicity: water-tolerant solid acid catalysts

It has been shown in an earlier study that the surface of organic salts of HPW exhibit hydrophobicity.[42] Recently, the hydrophobicity was semi-quantitativley evaluated for Cs2.5 and Cs3 by comparison of water and benzene adsorption.[43] The hydrophobicity thus evaluated is in the order of HZSM-5 (high silica) > silica ≈ Cs3 > Cs2.5 ≈ HZSM-5 (low silica) > silica–alumina > alumina (ZSM-5 and silica were pretreated at 673 K, silica–alumina and alumina at 573 K, and Cs2.5 and C3 at 473 K). This indicates that Cs2.5 is moderately hydrophobic similarly to low-silica HZSM-5. As expected from this fact, it was demonstrated that Cs2.5 was very active as a water-tolerant solid acid catalyst.[44,45] The relative activity of water-tolerant solid acids varies with the nature of the reaction. Cs2.5 is usually much more active for the hydrolysis of esters than other inorganic solid acids, but less active than acidic organic resins.

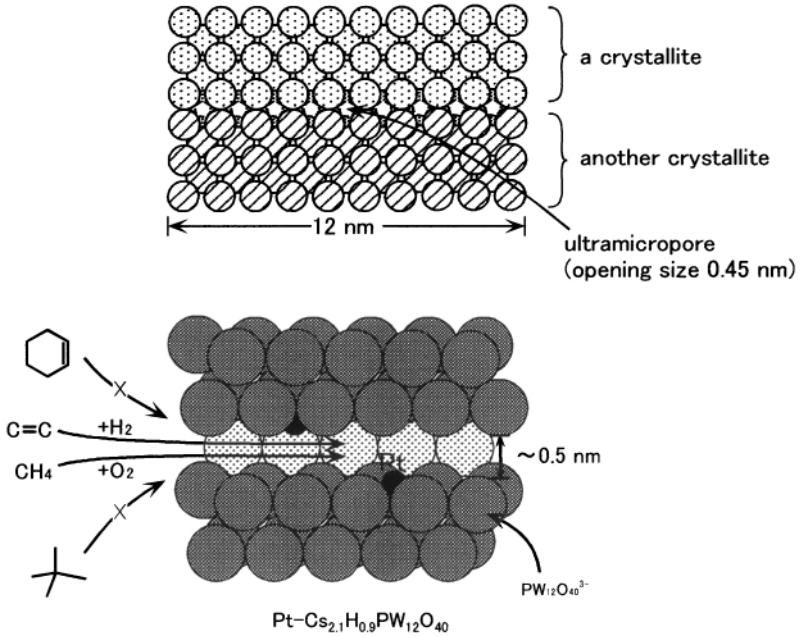

Fig. 17 A model of small micropores formed by misfits of two naoncrystallites of Pt–$Cs_{2.1}H_{0.9}PW_{12}O_{40}$.

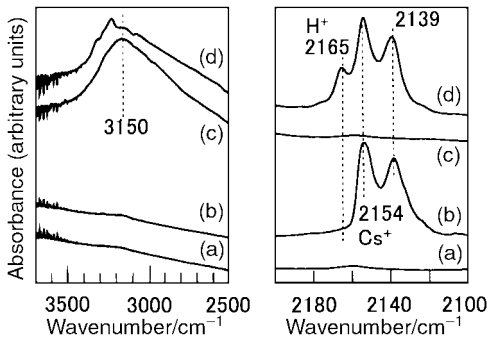

Fig. 18 IR spectra of CO adsorbed on HPAs measured at 100 K. (a) Before and (b) after adsorption of CO on $Cs_3PW_{12}O_{40}$ (Cs3); (c) before and (d) after adsorption of CO on $Cs_{2.5}H_{0.5}PW_{12}O_{40}$.

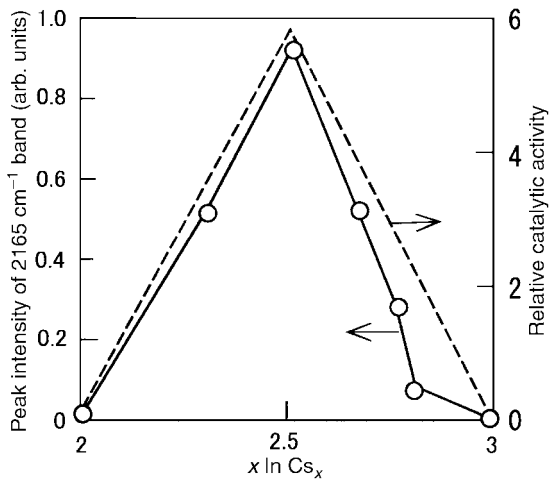

Fig. 19 Changes of the peak intensity of the 2165 cm^{-1} band (CO adsorbed on proton sites) and the catalytic activity of $Cs_xH_{3-x}PW_{12}O_{40}$ (CsX) as a function of X for the rate of alkylation of 1,3,5-trimethylbenzene by cyclohexene at 353 K.

However, for the reaction of a nitrile and an alcohol in an excess of water, Cs2.5 was the most active as shown in Table 4.[45]

5 Efficient catalysts developed based on HPA

Table 5 lists recent examples of catalytic reactions using solid HPA. Earlier examples may be found in ref. 5(*b*).

Table 4 Comparison of catalytic activities of various solid acids for the reaction of acrylnitrile and *N*-adamantanol to form *N*-adamantylacrylamide (NAA) in the presence of an excess of water.[a] Results in the absence of water shown in parentheses

Catalyst	Yield[b](%)	Selectivity[c](%)	TON[d]
$Cs_{2.5}H_{0.5}PW_{12}O_{40}$	84 (97)	92 (93)	36 (42)
HY zeolite	8 (79)	82 (89)	2 (0.2)
Amberlyst 15	68 (100)	82 (81)	1 (1)

Nafion-SiO_2	40 (97)	94 (93)	22 (61)

[a] *Reaction conditions*; catalyst: 0.2 g, acrylnitrile: 60 mmol, 1-adamantanol: 1.3 mmol, 373 K, 6 h. [b] % Yield; 100 × (NAA formed)/(*N*-adamantanol added). [c] % Selectivity; 100 × (NAA formed)/(NAA formed + acrylamide formed). [d] TON (turnover number); mol NAA formed/mol acid sites in catalyst.

5.1 Bifunctional catalysts

HPAs show acidity as well as unique basicity; these properties as well as their oxidizing ability can be controlled over a wide range which is of use in catalyst design. The co-existence of these properties can be utilized to prepare bifunctional and multifunctional catalysts. It has been shown that the oxidation of methacrolein to methacrylic acid proceeds in two steps; the first step is acid-catalyzed esterification to form an intermediate and the second step the oxidation of the intermediate which is rate-determining. Hence this reaction can be catalyzed in a synergistic manner utilizing acidity and oxidizing ability.[7] It is interesting to note that these two properties compete in the case of oxidation of isobutyric acid to methacrylic acid, with acidity accelerating side-reactions (Scheme 2).

The much higher activity of Cs2.5 than conventional solid acids can not be explained by acidic properties alone [Fig. 3(c)], so that acid–base bifunctional catalysis was suggested for Cs2.5.[5b]

Efficient catalytic reactions can be realized by the combination of HPA catalysts with noble metals. One-stage oxidation of ethylene to acetic acid has been commercialized (10000 ton yr^{-1}) by combining a Keggin-type HPA catalyst and Pd.[46] Here, the addition of Se or Te to Pd is essential to suppress the complete oxidation to CO_2. The overall reaction [eqn. (6)] is suggested to proceed in two steps [eqn. (4) and (5)], a Wacker-type mechanism (*via* acetaldehyde) being excluded. Control of acidity and tertiary structure was important for catalyst

Table 5 Acid-catalyzed reactions with solid heteropoly compounds[a]

Reaction	Catalyst	Reference
$RCO_2H + R'OH \rightarrow RCO_2R'$	$H_3PW_{12}O_{40}$, $H_4SiW_{12}O_{40}$/MCM-41	59

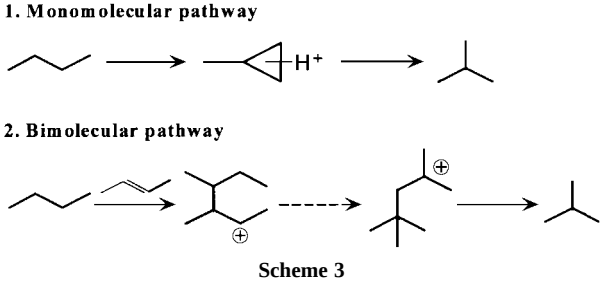
development. (The photo on the cover is the plant used for this process developed by Showa Danko, Co., Ltd.)

$C_2H_4 + H_2O \rightarrow EtOH$ (acid catalysis) (4)

$EtOH + O_2 \rightarrow MeCO_2H + H_2O$ (oxidation) (5)

$C_2H_4 + O_2 \rightarrow MeCO_2H$ [overall reaction] (6)

The combination of Pd or Pt with Cs2.5 creates active and selective catalysts for the isomerization of *n*-alkanes (C_4–C_7).[47] Deactivation and cracking which are significantly observed over Cs2.5 alone are dramatically diminished by the addition of noble metals in the presence of H_2. Without acidity, the activity is very low. Interestingly, acidity completely prevents the hydrogenolysis of alkanes catalyzed by noble metals. A mechanism essentially based on a classical bifunctional catalysis has been proposed; acid catalyzed isomerization + dehydrogenation–hydrogenation. Recently, a mechanistic study using ^{13}C labeled *n*-butane[48] has revealed that the selective isomerization to isobutane over Pt dispersed on Cs2.5 mostly takes place by a monomolecular mechanism, while the reaction proceeds less selectively *via* a bimolecular mechanism in the case of Cs2.5 alone (Scheme 3). At higher reaction temperatures, the



Scheme 3

contribution of the bimolecular mechanism increases also for Pt-Cs2.5. Kozhevnikov and coworkers reported that HPW combined with Pd produces only soft coke in the oligomerization of propene and the removal of coke by combustion takes place at a much lower temperature than in the case of HPW alone which forms both soft and hard cokes.[49]

5.2 Supported HPA catalysts

Hydrogen forms (or free acids) of HPAs usually have low surface areas. On the other hand, very active Cs2.5 having a large surface area tends to become a milky suspension during liquid-phase reactions, which makes it difficult to separate the catalyst after the reaction is finished. To solve these problems, many attempts have been made to disperse and fix HPA catalysts on various supports, where the stability of the HPA and firm fixation are the key issues. Support materials such as silica, carbon, and organic resins have been applied with varying levels of success, with new supporting materials and methods being actively pursued. Although the structure and composition of supported HPAs are sometimes uncertain, high catalytic activities are often observed and separation made easier.

Izumi *et al*, prepared HPW and Cs2.5 included in a silica matrix by an *in situ* sol–gel method. Recently, shape selectivity was observed for alkylation of phenol by formaldehyde owing to the micropores of a silica matrix.[50] Supported HPAs prepared by this method have been applied as photocatalysts.[51] Soled *et al*. reported an *in situ* preparation of Cs2.5 inside silica particles.[52] Cs-containing silica is added to an aqueous solution of HPA. As the HPA solution diffuses into pores of silica, a Cs salt starts to precipitate at a certain level of concentration, resulting in an egg-yolk type impregnation. Large-pore zeolites like MCM-41[53] and layered clays[54] have been applied as supports of HPA. HPAs loaded in layered double hydroxide were active for epoxidation and showed shape selectivity.[54] *In situ* synthesis of HPAs in the supercage of Y-zeolite is an interesting method for the preparation of supported HPA catalysts.[55] For metal oxide supports, interactions between the surface and the HPA often degrade the polyanion structure. On basic solids such as MgO and Al_2O_3, the Keggin structure readily decomposes, as expected from instability of HPAs in aqueous solution at high pH. Even on the surface of silica, which has only weak interactions with HPAs, these tend to decompose to smaller clusters. In most cases the decomposition is significant at a low loading level whereas the starting polyanion structure is predominant when the loading level is high. Supporting on or imbedding in organic polymers has also been attempted. Recent examples include polyazamethines,[56*a*] polyaniline,[56*b*] and polyphenylene oxide.[56*c*] As expected from

the moderate stabilities of organic ammonium and oxonium salts, the HPA structures appear to remain mostly intact. In addition, chemical interactions between the polymer and HPA sometimes modify the catalytic performance in a desirable manner.

6 Future

Notable progress has been achieved recently in heterogeneous acid catalytic reactions of HPAs. Full utilization of the pseudo-liquid phase and further development of bifunctional and shape-selective catalysis will be interesting targets for the future. Specifically organized secondary and tertiary structures that are synthesized by using novel cations and polyanions may open up new areas of catalysis. If the structure, composition and stability of polyanions are properly controlled on supports, solid HPA catalysts will find much wider practical applications. The development of regeneration methods for deactivated HPA catalysts is another important subject for practical applications. As for catalysis in solution, unconventional reaction fields such as multi-phase catalysis are promising. From the viewpoint of fundamental study of HPA catalysis, the basicity of the surface of the heteropolyanion (or unique complexation character) together with its role in catalysis is of interest and understanding of the catalytic reaction at the molecular/atomic level is expected to be accomplished in the near future.

More progress is anticipated for oxidation catalysis of HPAs although oxidation catalysis lies outside the scope of the present article. The design of primary structures (structure and composition) has been successful for oxidation in solution and may be extended to heterogeneous catalysis, if HPAs are stabilized or reaction systems chosen carefully. Examples include diiron and dimanganese substsituted Keggin anions as shown in Fig. 1(c)[57] which efficiently catalyze selective oxidation of alkanes, although enhancement of reaction rate is still desirable. A variety of polyanion structures and compositions (new and known) as well as recent progress in novel synthetic methods promises the development of efficient catalysts based on HPAs. For example, an exotic HPA synthesized by Newmann and Dahan is efficient in selective oxidation.[58] Owing to various advantages, HPAs are hoped to play important roles as green catalysts in chemical syntheses in a sustainable manner.

Acknowledgements

Rhodium bis-phosphine catalysts on mesoporous silica supports: new highly efficient catalysts for the hydrogenation of alkenes†‡

Cathleen M. Crudden,* Daryl Allen, Michael D. Mikoluk and Jian Sun

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick, P.O. Box 45222, Canada, E3B 6E2. E-mail: Cruddenc@unb.ca

First published as an Advance Article on the web 7th June 2001

A bidentate rhodium phosphine complex anchored onto a mesoporous molecular sieve was shown to be an active catalyst for the hydrogenation of alkenes, with the activity dependent on the method of grafting, and in general, exceeding that of related homogeneous catalysts.

Remarkable developments in homogeneous catalysis have taken place over the past two decades.[1] Unfortunately, the recovery of the precious metals and expensive ligands from the reaction medium is often not feasible. For this reason, there have been many approaches to 'heterogenizing' homogeneous catalysts by attaching well defined molecular species to polymeric supports.[2] Despite the development of some very effective supported systems,[3] a general strategy for mimicking solution phase behaviour is yet to be developed. Reactions on supports are generally slower and less predictable than their solution counterparts, commonly requiring excesses of reagents, higher temperatures and longer reaction times.[4]

The discovery of mesoporous molecular sieves has provided new possibilities in catalysis.[5] These mesoporous materials have unique structures characterized by high surface areas, large pores, and high long-range order; properties that make them ideal catalyst supports. MCM-41-type silicates have been used as supports for a variety of metals and metal complexes.[6] Recently, Shyu *et al.* described a supported analogue of Wilkinson's catalyst, prepared by treating MCM-41 with $(EtO)_3Si$-$(CH_2)_3$-PPh_2 and then $RhCl(PPh_3)_3$.[7] Our approach to the preparation of a Rh complex supported on a mesoporous molecular sieve involves the use of a bidentate phosphine in order to minimize leaching, and a cationic complex to prevent dimerization through chloride bridges[8] (Fig. 1). The catalysts thus obtained are highly active for the hydrogenation of olefins, even more than the corresponding homogeneous complexes. The magnitude of the activity and the nature of the grafted species is strongly dependent on the method of grafting. To the best of our knowledge, this is the first report of a bidentate rhodium phosphine complex grafted onto a mesoporous molecular sieve.

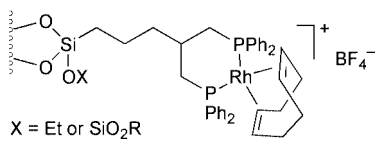

Fig. 1 Supported Rh catalyst.

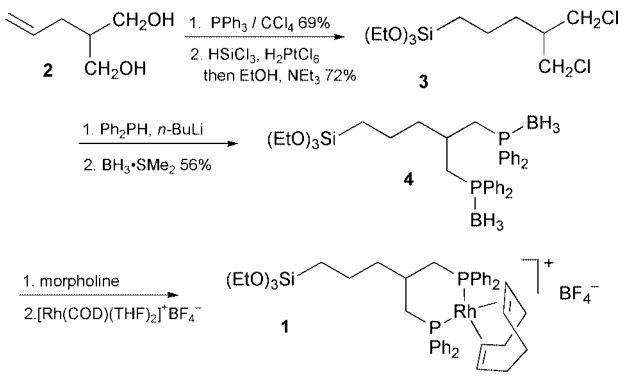
Catalyst **1** is prepared as shown in Scheme 1.[9] Alkylation of diethyl malonate with allyl bromide (89% yield) and reduction of the ester groups with $LiAlH_4$ (69% yield) provides diol **2**. Treatment of **2** with PPh_3 in CCl_4 followed by hydrosilylation of the pendant olefin using H_2PtCl_6 yields **3**. The phosphine substituents were introduced using Ph_2PLi, and protected prior to isolation. Compound **4** was purified by flash chromatography and then deprotected with morpholine. Treatment with $[Rh(COD)(THF)_2]^+BF_4^-$§ generated the homogeneous Rh complex **1**. This was spectroscopically characterized and then grafted onto the surface of a molecular sieve (SBA-15-type)[5] at 25, 110 and 165 °C (method A). Grafting was also carried out in the presence of an inert spacer, $EtSi(OEt)_3$ (method B).[10] The resulting catalysts were characterized by MAS NMR, TEM, and nitrogen adsorption.



Scheme 1 Synthesis of Rh catalyst **1**.

^{31}P MAS NMR analysis of these materials revealed that as the grafting temperature was increased, the resonance at 14 ppm which corresponded to the homogeneous complex **1** (Fig. 2A) decreased while a new peak at 35 ppm, attributable to a P(V) species, appeared.[11] When the complex was grafted in refluxing mesitylene, the resulting material (**1-mps-165A**) was composed entirely of the P(V) species (Fig. 2B). Grafting in the presence of an inert spacer (method B) proved to be optimal (Fig. 2B).

The various Rh complexes were examined for their ability to catalyze the hydrogenation of isosafrole (**5**), Table 1.¶ With the exception of **1-mps-25A**, all the mesoporous catalysts tested are *more active than the corresponding homogeneous catalysts* (entries 1, 2).

Catalyst **1-mps-25B**, prepared in the presence of $EtSi(OEt)_3$, has the highest activity (3300 turnovers h^{-1}, entry 6). These results are consistent with the results of Shyu,[7] who found that their MCM-41-modified catalyst was *ca.* 3× more active than Wilkinson's catalyst. Since **1-mps-25B** also had the lowest loading on support, the increased activity may be due to site isolation.[12] The least active catalyst of those examined, **1-mps-25A**, also has the highest Rh loading of 2.0%, consistent with this postulate. Studies are currently underway to measure the proximity of the Rh complexes on support.[12] Simple mixing of $[Rh(COD)_2]^+BF_4^-$ with the mesoporous support in the absence of any phosphine also led to an active hydrogenation catalyst (entry 7). The presence of an intermediate heteropoly acid species to aid in adsorption was not found to be necessary in this case.[13]

Retention of Rh on the surface was also a function of the grafting method. Supported systems with lower loadings of Rh were found to be more prone to leaching as determined by ICP-

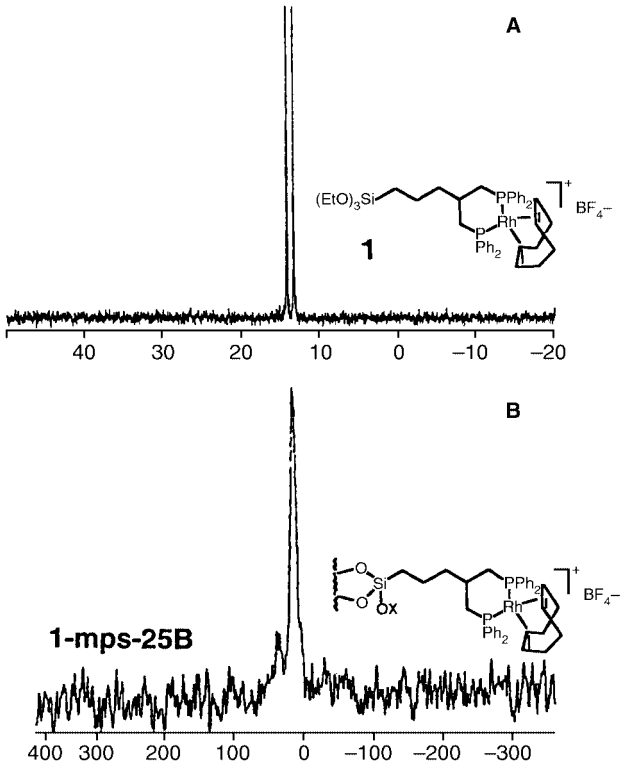

Fig. 2 ^{31}P NMR of homogeneous (**A**) supported (**B**) Rh complexes.

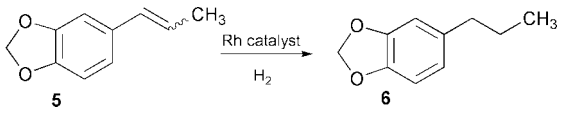

Table 1 Hydrogenation of **5**[a]

Entry	Catalyst[b]	Loading on support[c]	Turnover Frequency[d]
1	**Rh$^+$/DPPP**	n.a.	350
2	**1**	n.a.	750
3	**1-mps-110A**	1.4%	> 1600
4	**1-mps-25A**	2.0%	200
5	**1-mps-165A**	1.4%	1030
6	**1-mps-25B**	0.34%	3300
7	**Rh$^+$/mps**	3.3%	2300

[a] All reactions were carried out at rt, 750 psi of H_2, $[substrate]_{init}$ = 0.06 M in dry, deoxygenated, distilled THF. Reaction times were between 30 and 90 min. Solutions were prepared in a glove box under argon. [b] mps = mesoporous silicate. [c] Wt%, determined by ICP MS analysis. [d] Turnovers per hour.

MS analysis of the reaction mixture after filtration through a nylon filter. Catalyst **1-mps-25B** (0.3% Rh by weight) lost a significant amount of Rh after the first use (21–36%) and less (*ca.* 5%) in subsequent runs. Catalyst **1-mps-110A** (1.4% Rh by weight) was much more robust, and lost only 2–3% Rh during the first run.

In conclusion, we have demonstrated that rhodium complexes heterogenized on mesoporous molecular sieves are highly active catalysts for the hydrogenation of olefins. With one exception (**1-mps-25A**), the supported complexes are all more active than the corresponding homogeneous catalysts.

Dr Robert Young and Merck & Company are thanked for their generous support of this research, along with the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Canada Foundation for Innovation (CFI). Michael Lumsden of Dalhousie University is thanked for the MAS NMR data. Professor Stephen Bergens is thanked for helpful discussions and an anonymous reviewer is thanked for very valuable suggestions.

Notes and references

§ Prepared by treatment of $[Rh(COD)Cl]_2$ in THF with $AgBF_4$ and filtration of the resulting solution through Celite-545 (not acid washed).
¶ Isosafrole was purified by column chromatography, distillation, deoxygenated with three freeze, pump, thaw cycles, and purified immediately prior to use by passage through a short plug of dry alumina. The catalyst was found to be extremely sensitive to trace amounts of oxygen and deactivates with time, even when stored in a glove box.

Received (in Cambridge, UK) 17th April 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 7th June 2001

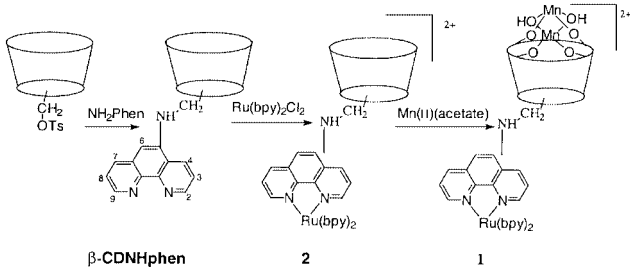
The synthesis and structure of a novel donor–acceptor complex comprised of a photosensitising ruthenium polypyridyl moiety covalently linked to a β-cyclodextrin unit bearing a hydroxy-bridged manganese(III) dimer 1 is described; the dimanganese complex undergoes a photoinduced electron transfer and may represent an attractive model system for elucidating aspects of photosystem II.

The current interest in novel donor–acceptor systems capable of photoinduced charge separation is driven by applications such as biomimetic chemistry, charge storage devices and nanoelectronic components. Recently, a number of elegant systems have been developed,[1] employing flash-quench methods and sacrificial quenchers to mimic part of the photoinitiated processes leading to oxidation of water in photosystem II.[2] We aimed on the other hand to develop a system incorporating a dimanganese site, in which the excited state energy of the sensitiser was sufficient to drive the electron transfer without the need for sacrificial reagents.

In the approach outlined here we have developed a $Ru(bpy)_2$ sensitiser linked *via* a β-cyclodextrin bridge to a hydroxo bridged Mn(III) dimer (Scheme 1). This is the first report in which the donor and acceptor moieties are external to cyclodextrin which acts as the mediating bridge in the D–A system.

By employing the highly rigid CD bridge, the inter-site separation and relative orientation of the reactants is thought to be consistent with those estimated for photosytem II. Moreover, this system mimics an important feature of PSII in that up to 10 water molecules are included in the cyclodextrin. In the photosystem, water oxidation is thought to be thermodynamically promoted by association of water with the Mn sites.

Our synthetic strategy is outlined in Scheme 1. The chelating β-cyclodextrin phenanthroline ligand, was prepared by refluxing 5-amino-1,10-phenanthroline, NH_2phen,[3] with 6^A-deoxy-6^A-*O*-*p*-toluenesulfonyl-β-cyclodextrin[4] in NMP for 5 h, the product was purified *via* recrystallization and purity confirmed by ^{1}H NMR (ESI†). This ligand was then coordinated to $Ru(bpy)_2$, by reaction with *cis*-$Ru(bpy)_2Cl_2$. The progress of the reaction was monitored by cation exchange HPLC and **2** was purified by column chromatography, on neutral alumina with acetonitrile–methanol (1 : 2 v/v), and isolated as a dichloride salt prior to coordination of the dimanganese centre.



Scheme 1

The ability of β-CD to coordinate metals such as Zn(II), Cu(II), Co(II) and Mn(III) has been known for some time, the metals are proposed to bind as hydroxo bridged dimers to the CD *via* the secondary hydroxyls, O-2 and O-3 of adjacent pyranose rings.[5–7] Mn was shown previously to coordinate effectively to β-CD *via* oxidative addition, on stirring of $Mn(OAc)_2$ and β-CD in an ethanol–DMF mixture containing 0.2 mol dm^{-3} NaOH under an inert atmosphere. Following this procedure, as outlined by Nair and Dismukes,[6] **2** was employed in place of β-CD and the formation of a high yield (*ca.* 60%), of the dimanganese bound complex was observed. The reaction was followed by TLC as **1** was found to be unstable in the aqueous solution employed for HPLC. This complex is soluble but unstable in water decomposing to **2** within minutes. It is stable over weeks in DMF and DMSO. At pH > 9.5 the complex was observed to be stable in water for up to 30 min.

Purity and structural confirmation for ligands and complexes were obtained through cation exchange HPLC, one- and two-dimensional ^{1}H NMR (ESI†), elemental analysis (ESI†) and magnetic susceptibility studies.

The ^{1}H NMR spectrum of **2** reveals well-resolved signals between 6 and 10 ppm, integrating for the 23 protons associated with the $Ru(bpy)_2(NH_2phen)$ unit and a complex pattern of signals associated with the β-CD are observed between 3 and 5 ppm. The paramagnetic dimanganese centre causes significant broadening of the ^{1}H NMR spectrum for **1**. However bands associated with the $Ru(bpy)_2$ unit remained sharp because of their distance from the paramagnetic Mn(III) centres.

Coordination of the bridged Mn(III) sites to the cyclodextrin moiety is accompanied by the appearance or enhancement of prominent features in the FTIR spectrum between 1700 and 1200 cm^{-1} (ESI†). Such bands, ascribed to alterations in included water on coordination of the metal sites, and to the OH bridging groups are analogous to those described previously in the simple Mn_2CD complex and for other OH bridged metallocyclodextrins,[8,9] Their presence is consistent with coordination of the manganese site to the secondary 2- and 3-hydroxy sites on the β-CD.[9–11]

The effective magnetic moment of complex **1** was found to be 3.46 μ_B per Mn at 296 K which is lower than the anticipated value of 4.9 μ_B for the spin-only value for the high-spin d^4 electronic configuration of Mn(III), calculated on the basis that no magnetic interactions are occurring between the metal ions.[12] This value is however, consistent with that reported for Mn_2CD by Nair and Dismukes[6] for a weakly antiferromagnetically coupled OH bridged dimanganese(III) moiety, the (III) oxidation state of which was confirmed to be EPR silent.[13]

Exhaustive experiments were performed on **1** and **2** using positive and negative ion ES and FAB MS techniques. No identifiable molecular ions were observable for either complex, however, the results obtained from ES and FAB positive ion

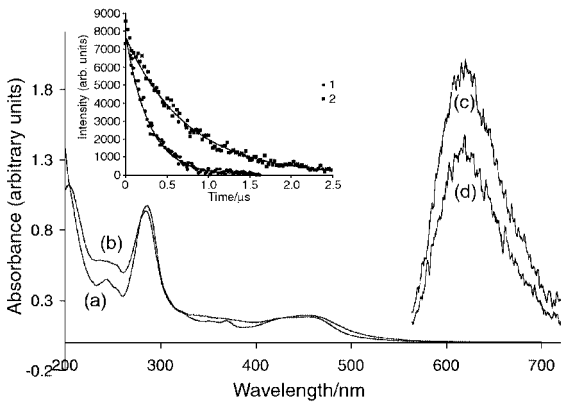

Fig. 1 Absorption of (a) **2** and (b) **1** and normalised emission spectra of (c) **1** and (d) **2** at room temperature in DMF, inset, emission decays of **1** and **2** at room temp. in DMF monitored at 620 nm and excited at 355 nm.

experiments showed the presence of many CD containing ions and also species such as $[Ru(bpy)_2(NHphen\beta\text{-}CD)Cl]^+$ (*m/z* 890) and $[Ru(bpy)_2(NHphen)]^+$ (*m/z* 608) were identified for both **1** and **2**. Although many of the spectra were far too weak to identify ions associated with the $Mn_2(OH)_2$ bridging system in **1** they do support the general structure of the ruthenium coordinated cyclodextrin species. The absorption and emission spectra of **1** and **2** are shown in Fig. 1, the main features in the visible region for both complexes are associated with Ru(II) to bpy charge transfer transitions, 450 nm for **1** ($\log \varepsilon = 4.15$) and 453 ($\log \varepsilon = 4.52$) for **2**. The strong similarity between the UV–VIS spectra of **1** and **2** is anticipated on the basis that the simple Mn_2CD shows a very weak transition at 480 nm, ($\log \varepsilon = 0.9$), which would be expected to have little impact on the strong CT transitions in the visible region. Significantly, no new features are present which would indicate ground state interactions across the molecule or that the manganese oxidation state is altered by comparison with Mn_2CD.

The formal potentials for the $Ru^{2+/3+}$ redox reaction are essentially indistinguishable in **1** and **2** (at 1.06 and 1.09 V *vs.* SCE respectively). Consistent with the spectroscopic data, this conformity suggests that there is little ground state interaction between the Ru and Mn sites. The Mn sites of **1** can be oxidised and reduced within an accessible potential window, with reduction appearing as a single electron step at −1.08 V and oxidation occurring as a single electron step at 1.41 V *vs.* Ag/AgCl. The electrochemical behaviour of Mn is scan rate dependent, under slower scan rate conditions, both $Mn^{2+/3+}$ and $Mn^{3+/4+}$ couples are irreversible. This is thought to be due to decomposition of the complex on formation of Mn(II) and Mn(IV). At faster scan rates (>1000 V s^{-1}) these redox processes become chemically reversible. Thus, while the oxidised state is not indefinitely stable thermodynamically, its lifetime is at least 40 μs.

This observation is important for photoinduced electron transfer and indicates that the Mn(IV) state will be stable if the time constant for back electron transfer is less than a few microseconds.

1 and **2** both emit at cryogenic and room temp. Although emission intensities and lifetimes at 77 K are comparable for **1** and **2**, at room temp. the luminescence of **1** is significantly reduced by binding of the manganese centre, as shown in Fig. 1. This behaviour is reflected by the luminescence quantum yield, where ϕ_{em} of **2**, 0.012, is reduced by 50% to 0.006 for **1** and also in the emission lifetime data (Fig. 1, inset), where the lifetime of **2** is reduced from 820 to 220 ns on coordination of the Mn_2 site. Calculation of the radiative and non-radiative rate constants for **1** and **2** reveals that the primary source of this decrease is a reduction in k_{nr} for **1**.

Assuming electron transfer is the source of quenching in **1,** we have used eqn. (1), where $\tau_{complex}$ is the emission lifetime of

$$k_{et} = (1/\tau_{complex}) - (1/\tau_{model}) \quad (1)$$

1 and τ_{model} the emission lifetime of a suitable structurally analogous model complex, in this case complex **2**, to estimate the electron transfer rate k_{et}, as 2×10^6 s^{-1}. Consistent with the rather large distance and weak electronic coupling that would be anticipated between the donor and acceptor sites, this electron transfer rate constant is low. This result is entirely consistent with the ground-state spectroscopic and electrochemical data presented earlier. It is important to consider whether a photoinduced electron transfer is likely to involve oxidation or reduction of the Ru^{3+}* centre. An insight into this process can be obtained by combining the ground state spectroscopic and electrochemical data.[14] This analysis reveals that the driving force for manganese oxidation is *ca.* −1.94 eV while the manganese reduction is thermodynamically uphill by *ca.* 0.04 eV. Therefore, it appears that the PET will involve electron transfer from the Mn(III) centre to Ru^{3+}* leading to the formation of Ru^{2+}. We are currently undertaking flash photolysis studies on **1** in order to confirm the photoinduced process is electron transfer and to investigate the issue of subsequent ground state electron transfer reactions.

In conclusion, we present here the synthesis of a novel β-CD bridged D–A complex in which a hydroxy-bridged dinuclear Mn site appears to behave as a donor in an excited state electron transfer. Beyond creating a novel supermolecule with potential biomimetic properties, this work represents a new approach to developing donor–acceptor systems in which interactions can be modulated by simple alterations in the synthetic procedure. For example, a number of alternative metals may be coordinated to the CD in an analogous manner to the manganese described here. Furthermore, the synthetic strategy employed here preserves access to CD cavity by guests such as phenols, quinones and even ferrocene. These guests are likely to allow us direct control over the strength of electronic coupling between donor and acceptor without having to synthetically functionalize the materials.

We thank Dr Mary McNamara, DIT, for useful discussions and Mr M. Burke, DCU for NMR. T. E. K. and R. J. F. acknowledge Johnson Matthey for a generous loan of ruthenium trichloride under the Loans Scheme. The DIT scholarship programme and Higher Education Authority are gratefully acknowledged for supporting this work.

Carbene transposition involving double dehydrogenation of an sp^3 carbon†

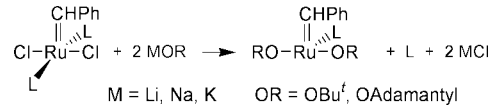
Joseph N. Coalter III, John C. Huffman and Kenneth G. Caulton*

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405-7102, USA. E-mail: caulton@indiana.edu

Received (in Cambridge, UK) 14th March 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 7th June 2001

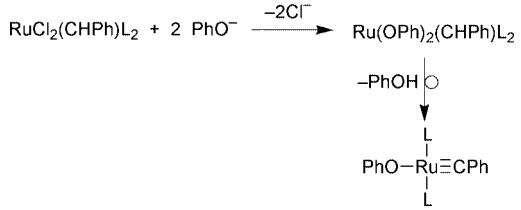
***Two* benzylic hydrogens of 2,6-$Me_2C_6H_3O^-$ coordinated to $RuCl(PCy_3)_2(CHPh)^+$ are transferred to the benzylidene ligand, liberating toluene to form a new carbene which is covalently linked to the aryloxide ligand.**

Replacement of the chloride ligand in the olefin metathesis catalyst $RuCl_2(CHR)LL'$ (L, L′ = tertiary phosphines or other neutral donors) by other pseudohalides has been actively studied, but no clear trends or dramatic improvements in reactivity have yet to emerge.[1] Two groups[2,3] have recently reported replacement of both chlorides by alkoxides on the benzylidene complex, with the result [eqn. (1)] that some



(1)

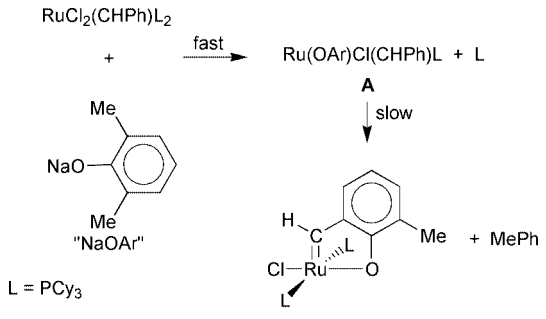
combination of steric and electronic (*e.g.* π-donor) effects causes loss of one PCy_3 to give a four-coordinate species with an apparent 14-valence electron count. This species is attractive because it has an empty orbital *cis* to the carbene ligand, a feature lacking in isolable $RuCl_2(CHR)L_2$. Fluoroalkoxide analogs have also been synthesized,[2] but phenoxides behave very differently[3] [eqn. (2)], proceeding further to a benzylidyne



(2)

product by liberation of phenol. We now report the wholly distinct consequence of increasing the steric bulk of the phenoxide

Reaction of $RuCl_2(CHPh)(PCy_3)_2$ with $NaOC_6H_3Me_2$-2,6·THF (NaOAr·THF: 1 equiv) in THF proceeds rapidly to a benzylidene complex with only one coordinated phosphine and *one* coordinated aryloxide (a second equivalent of NaOAr·THF does not replace a second Cl^-) [**A**, eqn. (3)]. This product is

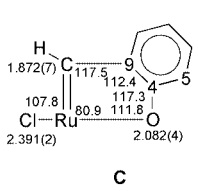


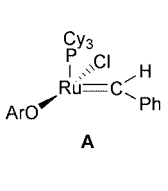
(3)

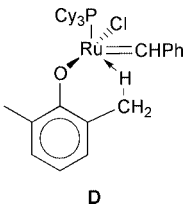
† Electronic supplementary information (ESI) available: synthetic and spectroscopic data. Crystallographic data and selected bond lengths and angle for **B**. See http://www.rsc.org/suppdata/cc/b1/b102422c/

proven to have only one phosphine by the carbene proton doublet structure (16.8 ppm), as well as by the observation of free phosphine (by ^{31}P NMR). This product then evolves more slowly by transfer of two hydrogens from one *ortho*-methyl group of the aryloxide to the benzylidene carbon [**B**, eqn. (3)]. After purification on an alumina column, the product **B** clearly shows the following ^1H NMR signals: *one* aryl methyl signal, of intensity three, only *three* aryl ring chemical shifts, each of unit intensity, and a Ru=C*H*R singlet at 16.4 ppm (unit intensity). Curiously, this carbene proton signal of **B** shows no resolved multiplet structure, although unresolved broadening is evident. The formation of toluene is also observed, as is the *disappearance* of free PCy_3, in the conversion of **A** to **B**. The $^{13}C\{^1H\}$ NMR supports this assignment, showing six aromatic signals, one Ar*C*H_3 signal (16.1 ppm), diastereotopic *C*H_2 ring carbons for the PCy_3 ligands, and a broad signal at 277.7 ppm for Ru=*C*.

A crystal structure determination of **B** (Fig. 1)‡ confirms this remarkable transformation. The coordination geometry at Ru is the traditional square-pyramidal, but one anionic ligand is now covalently linked to the carbene ligand. As shown in **C**







(distances in Å, angles in degrees), this unusual carbene/aryloxide ligand forms a planar five-membered chelate ring without substantial angular distortion at the carbene carbon. The

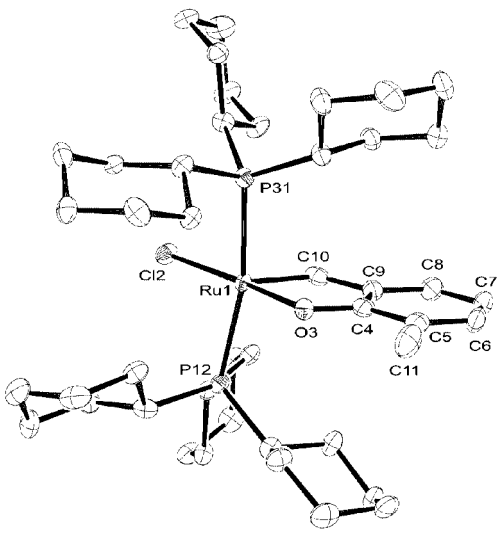


Fig. 1 ORTEP drawing of the nonhydrogen atoms of **B**. Selected distances (Å): Ru–C(10) 1.872(7), Ru–O(3) 2.082(4), Ru–Cl(2) 2.3910(17), Ru–P(12) 2.3947(19), Ru–P(31) 2.4005(19).

 DOI: 10.1039/b102422c

five-membered ring interior angles sum to 539.9° (540° if planar), and the angles that suffer the greatest compression are that at aryloxide oxygen (111.8° is small for M–O–Aryl) and at Ru (compare C=Ru–O of 80.9° to C=Ru–Cl of 107.8°). There are no agostic interactions between the cyclohexyl hydrogens and the open coordination site *trans* to the carbene (shortest Ru–C 3.3 Å).

The accumulated empirical evidence[1] shows that the magnitude of the $^3J_{PH}$ value is dependent on the dihedral angle P–Ru=C–H, and thus the orientation of the carbene plane with respect to the P–Ru line can be estimated. In intermediate **A**, $^3J_{PH}$ is large enough to be readily resolved (6 Hz), consistent with calculation and experiment, which give a dihedral angle of *ca.* 0°. In **B**, where no $^3J_{PH}$ is resolved, the carbene hydrogen has a dihedral angle of 90°, consistent with earlier reports that $^3J_{PH}$ in this conformation is near zero.[1]

Numerous recent developments in olefin metathesis chemistry have been directed to appending a good leaving group to reduce the L : Ru ratio in the molecule to 1 : 1, or to attach the molecule to a polymer to facilitate separation of catalyst from product.[4] What the present report offers is the potential for more permanent (*i.e.* anion-tethered) attachment of the *initial* carbene to the molecule, which contrasts to attachment *via* a pendant neutral donor (olefin[5] or ether[6]).

The *mechanism* of the double hydrogen transfer that converts a methyl to a carbene in eqn. (3) is not yet established. However, the precedent[7] that 14-electron Ru^{II} recruits agostic interactions from sterically accessible C–H hydrogens makes **D** a likely starting point on this transformation. The driving *force* for this reaction appears to be steric in origin, since only *one* ArO^- replaces chloride in the initial step of eqn. (3) and since the sterically expelled phosphine recoordinates when the bulky aryloxide and the benzylidene ligands are combined compactly into a single ligand incorporating both RO^- and carbene functionalities. Toluene elimination also provides an entropic assist worth *ca.* 8 kcal mol^{-1} at 300 K.[8] The different behavior shown by tertiary alkoxides or phenoxide and by 2,6-dimethylphenoxide is certainly due to the reactivity of benzylic hydrogens.

This work was supported by the donors of the Petroleum Research Fund, administered by the American Chemical Society.

Light harvesting and energy transfer in a ruthenium–coumarin-2 copolymer†

Xavier Schultze, Jason Serin, Alex Adronov and Jean M. J. Fréchet*

University of California, Berkeley, CA 94720-1460, USA. E-mail: frechet@cchem.berkeley.edu; Fax: +1(510) 643-3079; Tel: +1(510) 643-3077

Received (in Cambridge, UK) 26th April 2001, Accepted 15th May 2001
First published as an Advance Article on the web 7th June 2001

Copolymers containing Ru(bpy)$_3$ and coumarin-2 chromophores prepared using both grafting and copolymerization approaches exhibit Förster-type energy-transfer efficiencies ranging from 70% to above 98%.

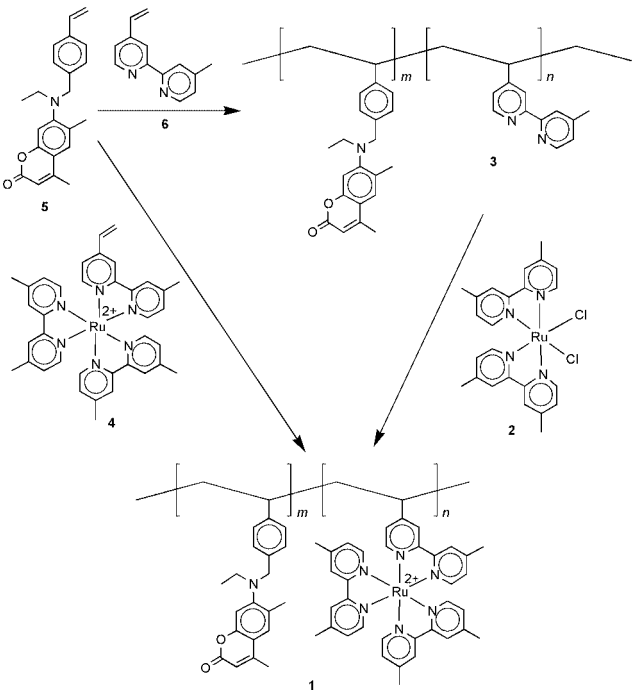
Molecular assemblies capable of harvesting light and transforming the absorbed energy have attracted great interest in recent years because of their applicability in such domains as light emitting diodes, fluorescent labeling of biological molecules, and photonic devices.[1] We have recently described several dendritic systems containing light-harvesting dyes at the periphery that efficiently absorb and channel light to a different dye at the focal point by a Förster-type mechanism.[2] Although these systems exhibit extremely high energy-transfer efficiencies, the demanding multi-step synthesis required for their preparation may limit their use to speciality applications. To circumvent this limitation, we have explored analogous light-harvesting linear polymers in which the donor–acceptor ratios were optimized by mimicking the dendrimer models and found that their antenna properties,[3] although less impressive than those of the corresponding dendrimers, are nevertheless very good.

Ruthenium-containing macromolecules are attracting widespread interest due to their photochemical and electrochemical properties.[4,5] We now report our results concerning the synthesis and characterization of a linear Ru(bpy)$_3$–coumarin-2 copolymer (**1**) that exhibits the energy transfer efficiency generally observed with light harvesting dendrimers,[5] without requiring the multi-step synthesis involved in the design of these molecules. Two strategies were used (Scheme 1): (i) grafting the ruthenium complex **2** on a bipyridine–coumarin-2 functionalized copolymer (**3**), and (ii) copolymerization of a ruthenium functionalized monomer (**4**) with a coumarin-2 functionalized monomer (**5**). The first route enabled us to obtain a copolymer that exhibits an energy transfer efficiency of 70% between the coumarin-2 and the Ru(bpy)$_3$ units. More interestingly, the copolymerization route afforded a better performing copolymer that displays quantitative energy transfer efficiency.

The styrene functionalized coumarin-2 monomer (**5**) was synthesized by coupling coumarin-2 with vinyl benzyl chloride as described elsewhere.[3] The 4-vinyl-4′-methylbipyridine monomer (**6**) was obtained using a modified literature procedure.[6] Copolymerization of these two monomers using a 3 to 1 feed ratio (mol fraction of **5** = 0.75) was carried out at 90 °C with AIBN as the initiator in a minimum amount of dichlorobenzene. The polymer was precipitated twice into Et_2O to remove the unreacted monomers. Molecular weights ranging from 5000 to 15 000 Daltons were obtained along with a polydispersity of 1.6, typical of AIBN initiated polymerizations. Elemental analysis of copolymer **3** showed that the resulting polymer was composed of *ca.* 25% of the bipyridine monomer and 75% of the coumarin-2 monomer, as expected from the feed ratio.

To perform grafting of the ruthenium complex, we used the method reported by Fraser and co-workers.[7] Two equiv. of dichloride **2** were refluxed in MeOH in the presence of an excess of $AgPF_6$ for 12 h and the solution was then added to a suspension of copolymer **3** in dimethoxyethane. After 48 h at reflux, the reaction mixture was filtered, concentrated, redissolved in dichloromethane and extensively washed with water to remove any unreacted ruthenium complex. A dark red polymer was obtained after precipitation in Et_2O.

The UV spectra of the polymer before and after the grafting reaction with ruthenium complex **2** are given in Fig. 1. The starting polymer displays two strong absorption bands at 290 and 350 nm, which are characteristic of the coumarin-2 and the bipyridine units. After reaction with the ruthenium complex a new absorption band was observed at 465 nm, which indicates successful grafting of the ruthenium bis(bipyridine) onto the



Scheme 1

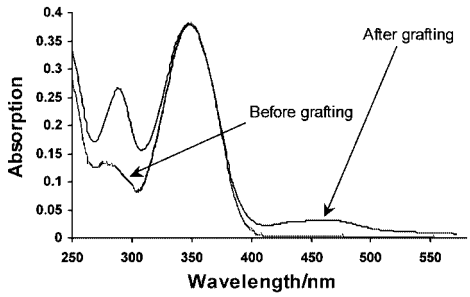


Fig. 1 Normalized UV-Vis spectra of copolymer **3** before and after grafting.

† Electronic supplementary information (ESI) available: experimental details. See http://www.rsc.org/suppdata/cc/b1/b103792g/

 DOI: 10.1039/b103792g

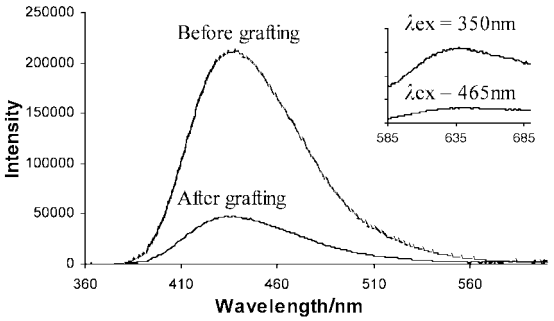

Fig. 2 Fluorescence spectrum of copolymer **3**, in the region of coumarin-2 emission, before and after grafting. Inset shows the spectrum of the same copolymer in the region where the $Ru(bpy)_3$ acceptor complex emits.

polymer. The absorption band at 290 nm is further increased due to the two additional bipyridine ligands introduced by the reaction. Fluorescence resonance energy transfer studies were carried out to determine the efficiency of energy transfer from the coumarin-2 chromophore to the ruthenium complex. The efficiency was calculated by comparing the coumarin-2 emission in the starting polymer **3** (a donor model compound) to the emission of this dye in the polymer obtained after grafting of ruthenium (Fig. 2). Based on the quenching of this emission, an energy transfer efficiency of 70% was determined for the grafted copolymer. Additionally, a 5-fold increase of the ruthenium emission was observed upon excitation of the coumarin-2 units (λ_{ex} = 350 nm) over excitation of the ruthenium complex directly (λ_{ex} = 465 nm), this type of amplification is the direct result of energy transfer (Fig. 2, inset).

Although the grafting route enabled us to obtain a polymer displaying good energy transfer characteristics, the functionalization of the polymer, estimated from the relative UV-Vis absorbance of the coumarin-2 and $Ru(bpy)_3$ units, was not quantitative (*ca.* 30%) and some insoluble material was also formed, decreasing the polymer yield. Therefore the copolymerization of monomers **4** and **5** was studied. The ruthenium-containing monomer **4** was prepared using a modified literature procedure.[8] Polymerization of the monomers was then performed at 90 °C with AIBN in DMF (mol fraction of **5** = 0.75). The resulting polymer was purified by precipitation in Et_2O and extensive washing with MeOH. The UV-visible spectrum of the polymer showed that incorporation of the ruthenium monomer **4** was as expected from the feed ratio, *ca.* 25%, with the remainder of the polymer repeat units consisting of the coumarin-containing monomer **5,** therefore the copolymerization route is much more effective for the introduction of the $Ru(bpy)_3$ complex than the grafting reaction.

The absorption spectrum of the copolymer (Fig. 3) is similar to that of the material obtained by the grafting route except that it displays stronger bipyridine and ruthenium metal to ligand charge transfer bands at 290 and 465 nm. Excitation of this polymer at 350 nm results in an emission spectrum (Fig. 4) that is totally quenched at 440 nm (the coumarin emission), indicating that quantitative energy transfer between the coumarin-2 and the $Ru(bpy)_3$ units occurs in this copolymer. Furthermore, the intensity of the ruthenium emission at 630 nm is increased by a factor of 2.7 when the polymer is illuminated at 350 nm *vs.* 465 nm. This increase is lower than that observed for the grafted copolymer, again indicating that, as a result of incomplete grafting, a higher concentration of donors relative to acceptors was present in that case.

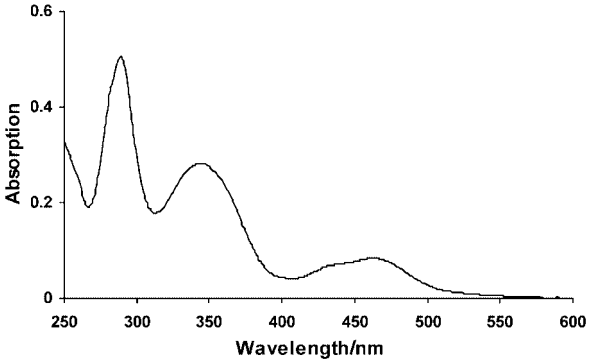

Fig. 3 UV spectrum of polymer **1**, obtained by the copolymerization route.

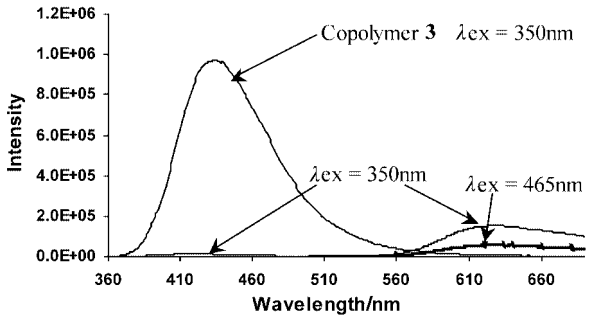

Fig. 4 Fluorescence spectrum of polymer **1**, obtained by the copolymerization route.

In conclusion, readily accessible linear copolymers containing coumarin-2 and $Ru(bpy)_3$ units can provide quantitative energy transfer from the coumarin-2 units to the ruthenium centers. This finding opens interesting perspectives in the field of solar energy conversion.[9] The application of such a system to photovoltaic devices is currently under investigation.

Design of histidine-Zn^{2+} binding sites within a β-hairpin peptide: enhancement of β-sheet stability through metal complexation

Geoffrey Platt,[a] Chun-Wa Chung[b] and Mark S. Searle*[a]

[a] *School of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: Mark.Searle@nottingham.ac.uk*

[b] *Glaxo-SmithKline, Medicines Research Centre, Stevenage, Hertfordshire, UK*

Received (in Cambridge, UK) 18th January 2001, Accepted 9th May 2001
First published as an Advance Article on the web 8th June 2001

We describe the design and characterisation of two simple 'metalloproteins' based on Zn^{2+} co-ordination sites involving histidine residues close to the N- and C-termini of two β-hairpin peptides (His_2-β, KHYTVSINGKKITVHI and His_3-β, HKHYTV-SINGKKITVHI); we show by NMR and circular dichroism spectroscopy that Zn^{2+} complexation co-operatively enhances the stability of these partially pre-organised β-sheet peptides.

Metals play a pivotal structural and catalytic role in numerous protein and enzyme scaffolds.[1] Metal complexation stabilises some of the smallest structural motifs known (zinc finger domains),[2] while changes in metal co-ordination shell and ligand lability are central to catalytic turnover in enzymatic processes.[3–5] Previously, metal binding sites have been designed into proteins and short peptides, through the incorporation of both natural and non-natural amino acids, to study the effects on protein stability and peptide secondary structure.[6–9] While effects on structural enhancement of α-helical peptides have been described,[7] the extension of these principles to the templating of β-sheet structures[10] for subsequent use as novel molecular architectures for molecular recognition or catalysis, has been rather limited. Previously, the His_3-Zn^{2+} co-ordination site within carbonic anhydrase, which employs residues within β-sheet and β-turn,[11] has been used successfully to design a zinc binding site on one face of an octapeptide incorporating a type II (Pro-^{D}Ser) turn.[9] Here, we investigate by NMR and CD spectroscopy the effect of zinc co-ordination on the stability of β-sheet secondary structure in a partially pre-organised β-hairpin peptide. We show that engineering a metal binding site between the termini of two β-strands, resulting in both His_2-Zn^{2+} and His_3-Zn^{2+} co-ordination shells, co-operatively enhances β-sheet secondary structure in a β-hairpin system.

In previous studies, we have described the folding of a model 16-residue β-hairpin system (KKYTVSINGKKITVSI) that is ~50% populated in aqueous solution.[12] We have replaced a Lys-Ser cross-strand pair in the β-hairpin sequence (underlined) with a His-His pair to facilitate cross-strand metal binding initially through a His_2-Zn^{2+} co-ordination site (peptide **His_2**-β; residues Lys2 to Ile17 in Fig. 1(a)). In a second peptide, we have extended the N-terminal sequence by an additional overhanging His residue to generate a potential His_3-Zn^{2+} co-ordination site (peptide **His_3**-β). We envisaged that the greater conformational flexibility of the terminal His (which is not part of the β-sheet), should greatly facilitate Zn^{2+} co-ordination, with the final tetrahedral site occupied by either the C-terminal carboxylate group or a solvent molecule [Fig. 1(b)] in an analogous fashion to the carbonic anhydrase catalytic site.

NMR analysis of Hα chemical shift deviations from random coil values[13] provides a useful handle on the extent of folding prior to metal complexation, showing that the two β-hairpins (**His_2**-β and **His_3**-β) are similarly populated in aqueous solution at pH 7.0 and that the additional N-terminal His residue has little effect on β-hairpin folding. A number of cross-strand Hα↔Hα NOEs, in particular between Ser 7↔Lys12 and Thr5↔Thr14, together with long range NH↔NH (Val6↔Ile13) and NH↔Hα NOEs (Ser7↔Ile13) establish that the peptides fold with the proposed strand alignment shown in Fig. 1(a), with stabilising interactions between side chains consistent with this fold (for example Tyr4↔Val15). The similarity of the Hα shifts for His3 and His16 precludes the observation of an Hα↔Hα NOE between these residues, but Hα chemical shift perturbations are consistent with cross-strand interactions close to the N- and C-termini. Calculation of His pK_a values from pH titration analysis of His Hε chemical shifts, shows them to fall in the range 5.73 to 6.36 suggesting that metal complexation will be optimum around pH 7 where all imidazole rings are unprotonated. The pH-dependent stability profile determined from changes in CD ellipticity and Hα chemical shifts shows that the population of folded hairpin decreases below pH 5.5, consistent primarily with the formation of a $HisH^+$-$HisH^+$ pair between opposing β-strands that has a significant destabilising effect on β-hairpin structure. The difference in Hα chemical shift deviations from random coil values at pH 3.5 and 7.2 are shown in Fig. 2 for **His_2**-β. Interestingly, all shifts are perturbed at low pH suggesting that an electrostatic repulsion between $HisH^+$ residues (His3 and His16) close to the N- and C-termini, as well as protonation of the C-terminal carboxylate group, has a co-operative destabilising effect on the hairpin that is sensed by all residues, including those in the distant NG turn sequence. Similar effects are observed for both peptides **His_2**-β and **His_3**-β. Thus, the data indicate that at pH 7 the two peptides are already populating a partially pre-organised β-hairpin conformation.[12]

The uncomplexed peptide shows a very weak band at 216 nm in the CD spectrum due to β-sheet and β-turn conformation in equilibrium with random coil, the latter resulting in a strong negative ellipticity at 200 nm (Fig. 3).[14] CD data are also shown

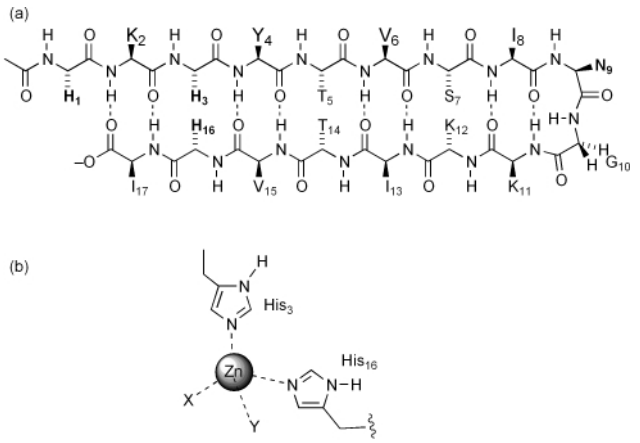

Fig. 1 (a) Schematic representation of peptide **His_3**-β (1–17) showing the peptide main chain alignment; residues are identified using the single letter amino acid code. **His_2**-β (2–17) lacks the N-terminal His (Lys2-*N*-acetylated), the same numbering scheme is used for each peptide; (b) proposed zinc co-ordination site; for **His_3**-β X = His1, Y = H_2O or the C-terminal carboxylate group of Ile17, for **His_2**-β X = H_2O, Y = H_2O or CO_2^-.

 DOI: 10.1039/b100702p

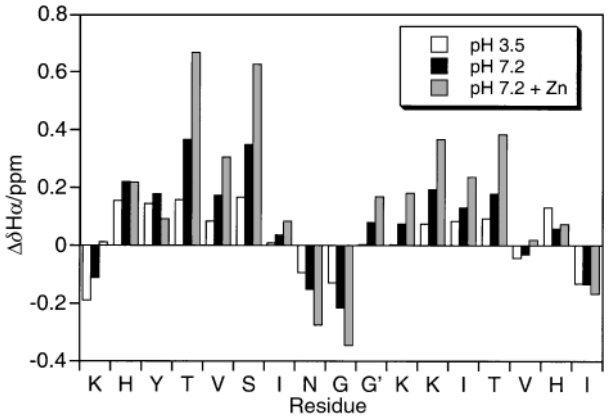

Fig. 2 Deviations of Hα chemical shifts from random coil values ($\Delta\delta$Hα, ppm) for **His$_2$**-β in water at pH 3.5 and 7.2 (298 K), and in aqueous solution (pH 7.2) and 1 equiv. of $ZnCl_2$. All $\Delta\delta$Hα values were determined after full assignment of NOESY and TOCSY data collected at 500 MHz.

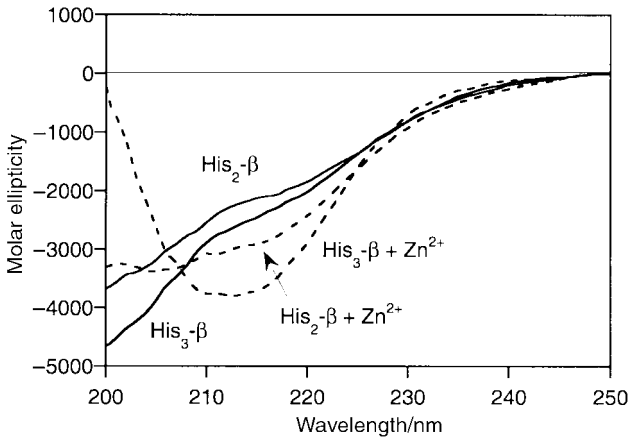

Fig. 3 Far UV-CD spectra of **His$_2$**-β and **His$_3$**-β in aqueous solution (pH 7.2) in the absence of zinc and in the presence of 10 equiv. of $ZnCl_2$. All spectra were recorded on an Aviv 62DS spectrophotometer at 293 K, as previously described.[12]

for the two peptides in the presence of excess $ZnCl_2$ at pH 7.0. In both cases the negative ellipticity at 216 nm becomes more pronounced, however, the effect is greatest for **His$_3$**-β, with the ellipticity also approaching zero at 200 nm. The data imply that Zn^{2+} chelation with **His$_3$**-β induces a greater degree of β-sheet secondary structure.

Significant perturbations to Hα chemical shifts are also consistent with further induction of β-sheet secondary structure by metal binding. In particular, Thr5 and Ser7 are shifted further downfield by > 0.2 ppm ($\Delta\delta$Hα values of 0.67 and 0.63 ppm, respectively for **His$_2$**-β; see Fig. 2); secondly, His Hε resonances are seen to broaden considerably, consistent with metal complexation. The effects of zinc titration on the folding of peptide **His$_3$**-β are equally pronounced but more significant at low concentrations of the metal ion. The Gly residue in the turn sequence has previously proved to be a good indicator of the extent of folding, since the two Hα resonances experience a large difference in chemical shift in the folded state due to the anisotropic effects of neighbouring carbonyl groups.[15] In this case the Gly residue in the turn is well removed from the direct effects of zinc binding. In the presence of Zn^{2+} the Gly Hα splitting for **His$_3$**-β is much larger than for the free peptide (300 *versus* 141 Hz), indicating that chelation of zinc by residues close to the peptide N- and C-termini co-operatively stabilises β-sheet secondary structure along the full length of the hairpin. **His$_2$**-β achieves the same magnitude of Gly Hα splitting but only at much higher metal ion concentrations (>10 equiv.). Using the quantitative methods previously described to estimate hairpin stability from the Gly Hα splitting,[15] we conclude that zinc binding enhances the stability of each hairpin by up to 3 kJ mol^{-1} at 298 K, reflecting the net balance between favourable electrostatic interactions with the metal and opposing entropic effects of organising the peptide backbone and His side chains. Although we cannot state unambiguously that all three His residues of **His$_3$**-β are simultaneously involved in complexation, the observed differences between the two peptides suggest that the overhanging His residues plays some role (dynamic or otherwise) in metal complexation.

In native proteins where Zn^{2+} is used solely in a structural capacity, His_3-Zn^{2+} is less common in the stabilisation of β-sheet structure than alternative His_2-Cys_2 or His-Cys_3 motifs. A recent report of a redesigned zinc-finger motif has shown that His_4-Zn^{2+} co-ordination can be accommodated with two His residues located in the β-sheet,[16] although structural analysis suggests that the short β-hairpin component (only three residues per strand) is distorted by the tetrahedral co-ordination geometry around the Zn^{2+} ion. Here we have used a significantly larger element of β-sheet secondary structure than previously reported with the metal co-ordination site incorporated close to the N- and C-termini to minimise distortions. Our preliminary data from NMR and CD indicate that the integrity of the β-sheet is enhanced although tetrahedral co-ordination around zinc must produce some local distortion.

We thank the EPSRC and Glaxo-SmithKline for financial support through a CASE collaboration, and John Keyte in the School of Biomedical Sciences for peptide synthesis. We are grateful to S. R. Griffiths-Jones and M. Jourdan for helpful discussions.

Received (in Cambridge, UK) 15th February 2001, Accepted 11th May 2001
First published as an Advance Article on the web 8th June 2001

Novel highly efficient Rh-based catalysts with a good regioselectivity in olefin hydroformylation have been prepared by deliberately choosing 11-mercaptoundecanoic acid as a ligating molecule to $[Rh(cod)Cl]_2$ (cod = cyclooctadiene) and a simple recovery process for their recycling was investigated.

Catalyst recovery processes are becoming more important, especially when expensive and toxic heavy metal complexes are employed. Owing to these economic and environmental factors, many attempts have been made to recover homogenous catalysts and recycle them. The homogeneous catalysts are usually recovered by thermal operations such as distillation, which normally leads to thermal stress on the catalyst and seldom yields quantitative recovery. Since the separation of catalyst from products is much simpler in two-phase (or biphasic) systems incorporating a water-soluble catalyst,[1–3] water-soluble organometallic compounds have been studied for many years. They are normally prepared by incorporating highly polar functional groups such as sulfonate salt[4,5] carboxylate salt,[1] amino,[6] or hydroxide[7] into the ligands. Recently, Rh-based catalysts have attracted much attention due to their high activity and selectivity, and some attempts to immobilize these expensive catalysts have also been reported.[6,8–13] In this communication, we will introduce a simple synthetic method of preparing novel water-soluble Rh-based hydroformylation catalysts and discuss their unique solubility and reactivity, which make catalyst recycling much simpler.

$[Rh(\mu\text{-}S(CH_2)_{10}CO_2Na)(cod)]_2$ **1** was prepared in 89% yield as a yellow–orange solid by treating $[Rh(\mu\text{-}Cl)(cod)]_2$ with 11-mercaptoundecanoic acid disodium salt† (Scheme 1). Complex **1** is a very stable solid in air and soluble in water, slightly soluble in MeOH, and insoluble in most organic solvents. This complex shows a very sensitive change of solubility in water when pH values are varied, compared to other known water-soluble organometallic compounds that usually contain sulfonate groups and show no pH-dependent solubility.[4,5] When an aqueous solution of **1** was treated with acid to pH < 4, $[Rh(\mu\text{-}S(CH_2)_{10}CO_2H)(cod)]_2$ **2** was quickly precipitated as a yellow–orange powder from the aqueous solution, this powder being very soluble in polar organic solvents such as THF. Complex **2** can also be quantitatively converted back into **1** by treating with a base such as NaOH aqueous solution. These interconversions between **1** and **2** can be repeated several times without any significant degradation of the complexes (Scheme 1).

The catalytic activity of both **1** and **2** for the hydroformylation of arylolefins was checked, and the large differences in their solubility (depending on the pH) were used to recover the catalyst after the reaction.‡ The water-soluble Rh catalyst **1**, in general, showed a high catalytic activity with the exception of α-methylstyrene (Table 1, entry 1), probably due to its steric bulkiness preventing the effective binding of the disubstituted styrene onto the Rh catalysts. Although the hydroformylation of aromatic olefins showed very good regioselectivity, the electron donating or withdrawing substituents on styrene (Table 1, entries 2–6) did not give rise to any further enhancement of selectivity. Unlike other reported hydroformylation catalysts,[1] compound **1** showed a very high degree of catalytic activity even towards long alkyl olefins such as oct-1-ene, undec-1-ene, and dodec-1-ene (Table 2). It is expected that the long alkyl chains in 11-mercaptoundecanoic acid themselves behave like a surfactant to enhance the solubility of the long aliphatic olefins in the aqueous catalyst phase. The low regioselectivity resulting from the hydroformylation of aliphatic terminal olefins suggests that regioselectivity is related not only to steric but also to electronic factors. After the reaction, the products were easily separated by extraction with Et_2O and the aqueous layer containing catalyst **1** could be reused without any further treatment. Reaction results from the consecutive usage (five times) of aqueous

Table 1 Hydroformylation results of substituted styrenes by employing water-soluble catalyst **1**

Entry	Olefin	*b*/*l*[a]	Conversion yield (%)[b]

2	Undec-1-ene	48/52	100
3	Dodec-1-ene	78/22	92

Catalytic reaction and analysis process was as for Table 1.

solutions containing catalyst **1** did not indicate any differences in catalytic activity. Further detailed study on the long-term stability of catalyst **1** is under investigation.

When organic-soluble compound **2** was used as a catalyst, the reactions were carried out in homogeneous THF solution. All the reaction results were the same as for the case of catalyst **1**, thereby confirming the high catalytic activity of the new Rh-based catalysts in either a homogeneous or a heterogeneous system. However, the recovery process of catalyst **2** from THF solution was different. It was isolated by treating with NaOH solution to precipitate as **1**, followed by filtering off and dissolving it in water. It was then treated with HCl solution again to precipitate as compound **2**, then filtered off and dried for recycling. Recycled catalyst **2** showed the same activity, but there was always a small amount of weight loss during the filtration and drying procedures. From the practical point of view of recycling, therefore, it is much easier and simpler to use compound **1** in a biphasic (water/organic bilayer) system.

We are quite certain that the present catalyst should exhibit a high degree of regioselectivity toward various olefins. Further experiments to obtain a detailed mechanistic understanding and the application of these novel Rh-catalysts to other types of catalytic reactions such as hydrosilylation and stereoselective hydrogenation reactions, are currently under investigation.

This work was supported by the Korean Science and Engineering Foundation through the Center for Molecular Catalysis at Seoul National University. We are grateful to Dr J. W. Han for his kind technical assistance. T. J. Yoon is also grateful to the BK21 fellowship.

Notes and references

† A mixed solution of NaOH (3 M, 3.06 ml) and $HS(CH_2)_{10}CO_2H$ (1.00 g, 4.58 mmol) in 10 ml of THF was stirred at room temperature for 30 min to precipitate the salt $Na^+{-}S(CH_2)_{10}CO_2{-}Na^+$. The precipitate was filtered off, and then washed with THF in order to eliminate excess NaOH. 0.53 g (2.00 mmol) of dried $Na^+{-}S(CH_2)_{10}CO_2{-}$ Na^+ salt was added to a stirred solution of $[Rh(\mu\text{-}Cl)(cod)]_2$ (0.49 g, 1.00 mmol) in dried MeOH (10 ml). The mixed solution was refluxed with vigorous stirring for 30 min. Solvent was evaporation to dryness, and the residual solid was rinsed with cold CH_2Cl_2 (3×10 ml) and crystallized from H_2O–THF mixed solvent. Solid crystals were filtered off and vacuum dried to give 0.80 g of pure complex **1** (89% yield). ^{1}H NMR (300 MHz, D_2O): δ 2.18 and 2.3 (br, total 8H, cod –C*H*$_2$–), 4.3 (br, 4H, cod =C*H*–), 2.19 (t, 2H, $-O_2CCH_2$–), 1.27 (m, 12H, internal –C*H*$_2$–), 2.53 (t, 2H, –SC*H*$_2$–), 1.51(m, 4H, $–SCH_2CH_2–$ and $–O_2CCH_2CH_2–$). Anal. Found: C, 50.66; H, 7.16; S, 7.12%. Calc. for $C_{38}H_{64}O_4S_2Na_2Rh_2$: C, 50.69; H, 7.12%; S, 7.12%. MS (FAB, negative): 901 (M^+).

‡ Neat substituted styrenes (2.5 mmol) over 5.0 mL of the aqueous solution of catalyst **1** (1.3×10^{-3} M) were hydroformylated with pressurized H_2/CO (500 psi, 2:1 ratio of H_2:CO) gas mixtures in a stainless steel autoclave reactor at 55 °C for 22 h. Structural ratios of aldehyde products were measured by ^{1}H NMR spectroscopy. (*b*: 9.62 ppm, *l*: 9.78 ppm)

A biomimetic synthesis of (−)-$N_{(a)}$-methylervitsine

M.-Lluïsa Bennasar,*[a] Ester Zulaica,[a] Yolanda Alonso,[a] Ignasi Mata,[b] Elies Molins[b] and Joan Bosch[a]

Received (in Cambridge, UK) 2nd March 2001, Accepted 15th May 2001
First published as an Advance Article on the web 8th June 2001

A straightforward, biomimetic synthesis of (−)-$N_{(a)}$-methylervitsine involving the nucleophilic addition of the enolate derived from 2-acetylindole 1 to chiral, non-racemic pyridinium salt 2, followed by (Me_2N^+=CH_2) I^- induced cyclization of the resultant 1,4-dihydropyridine, with subsequent elaboration of the exocyclic 16-methylene and 20*E*-ethylidene substituents, is reported.

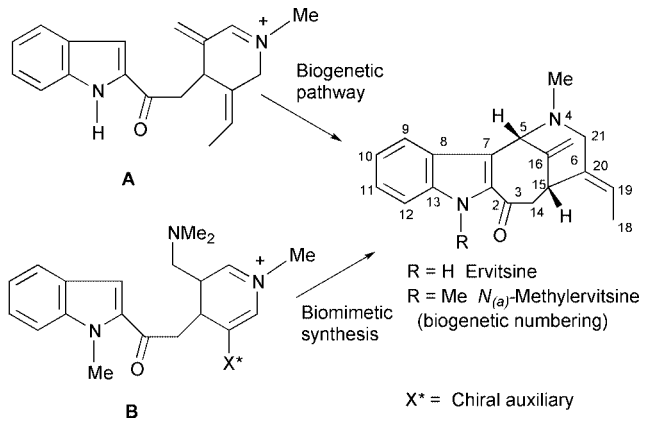
Biomimetic syntheses of natural products reproduce the key steps of their biosynthesis through processes similar to those believed to be occurring in nature.[1] The conjugate iminium cation **A** has been postulated as the key biogenetic intermediate *en route* to ervitsine, a rare 2-acylindole alkaloid isolated from *Pandaca boiteaui*,[2] with a particular skeleton in which the tryptamine carbon atoms C_5–C_6 are in a rearranged situation forming the unusual C_7–C_5–C_{16}–C_6 bond array.[3] Consequently, this bridged alkaloid incorporates a seven membered C ring and a piperidine moiety bearing two different (16-methylene and 20*E*-ethylidene) exocyclic double bonds (Scheme 1).

We report here a biomimetic synthesis of (−)-$N_{(a)}$-methylervitsine *via* the dihydropyridinium cation **B**, which can be envisaged as a synthetic equivalent of the key biogenetic intermediate **A**. This cation incorporates a latent exocyclic methylene group (the dimethylaminomethyl substituent), and *a priori* should be accessible by nucleophilic addition of a 2-acetylindole enolate to the 4-position of a 3-acyl-*N*-alkylpyridinium salt, followed by electrophile (Me_2N^+=CH_2)-induced cyclization of the resulting 1,4-dihydropyridine. The acyl substituent X* would act as a chiral auxiliary, thus allowing the stereoselective generation of the stereocentre at the pyridine 4-position (corresponding to C-15 in ervitsine), and it would then be stereoselectively converted into the exocyclic *E*-ethylidene substituent of the alkaloid. In this approach, taking into account the bridgehead character of C-5 and C-15, the configuration of the latter determines that of the former after the biomimetic cyclization.

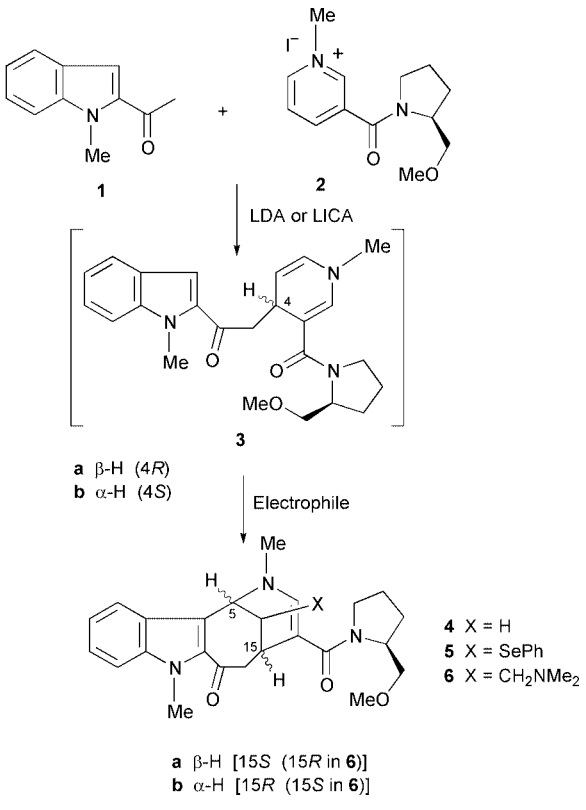
The stereoselective synthesis of chiral non-racemic 1,4-dihydropyridines[4] has been previously achieved by diastereoface-selective addition of suitable organometallic reagents to *N*-acylpyridinium salts carrying chiral auxiliaries, usually at the 3-position of the pyridine ring: oxazoline,[5] aminal,[6] [(η^5-C_5H_5)Fe(CO)(PPh_3)],[7] and amides derived from (*S*)-thiazolidine-2-thiones and (*S*)-oxazolidinones.[8]

In our case, we decided to study the addition of the enolate derived from 2-acetylindole **1** to *N*-methylpyridinium salt **2**, a nicotinic amide derived from (*S*)-*O*-methylprolinol (Scheme 2). The addition of indole-containing enolates to *N*-alkylpyridinium salts bearing an electron-withdrawing group at the 3-position has extensively been used in our laboratory as the initial step of a general scheme for the synthesis of indole alkaloids in the racemic series.[9] However, there are few examples of the use of this methodology for the enantioselective synthesis of alkaloids, and they deal with chiral enolates instead of chiral pyridinium salts.[10]

As can be observed in Table 1, acid induced cyclization of the initially formed dihydropyridine **3** gave a 3:1 diastereomeric mixture of tetracycles **4a** and **4b** (entry 1), whereas PhSeCl (entry 2) or (Me_2N^+=CH_2) I^- (entry 3) induced cyclization afforded 2:1 diastereomeric mixtures of the C-16 substituted tetracycles **5** or **6**, respectively, in which the 15-H β isomers (**a** series) predominated (see below for the determination of the absolute stereochemistry).



Scheme 1



Scheme 2

 DOI: 10.1039/b102010m

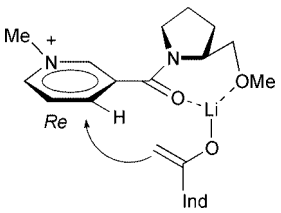
Table 1 Reactions of the enolate derived from **1** with pyridinium iodide **2**[a]

Entry	Electrophile[b]	Product (yield, %)[c]	Diastereomer ratio (a:b)
1	HCl/C_6H_6	**4** (25)	74:26[d]
2	ClSePh	**5** (40)	2:1[e]
3	$CH_2{=}NMe_2\ I^-$	**6** (40)	68:32[d]

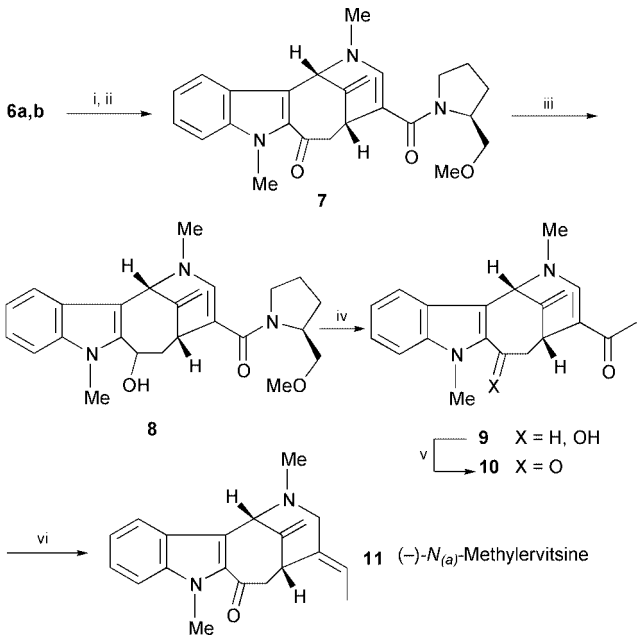
[a] Generation of the enolate with LDA (LICA in entry 3) at −78 °C for 30 min, then interaction with **2** at −30 °C for 1.5 h. [b] Addition at −30 °C to the reaction mixture, then rt for 2 h. [c] Isolated yield of chromatographically pure diastereomeric mixtures. [d] Calculated by HPLC. [e] Approximate ratio calculated by ^{1}H-NMR.

In this way, the tetracyclic ring system of ervitsine has been assembled in a straightforward manner, in a one-pot process involving the formation of three carbon–carbon bonds (C_{14}–C_{15}, C_6–C_{16} and C_5–C_7). This clearly indicates that the interaction of 1,4-dihydropyridine **3** with $(Me_2N^+{=}CH_2)\ I^-$ generates the key biomimetic intermediate **B**, which undergoes the crucial biomimetic cyclization.

The formation of tetracycles **4a**–**6a** as the major products implies that the lithium enolate of **1** preferentially approaches the *Re* face of pyridinium ring **2**, probably after the initial complexation of the lithium cation to both the carbonyl oxygen and the methoxy group of the auxiliary.



The diastereomeric mixture of tetracycles **6a**,**b** was converted into the corresponding 16-methylene derivatives by Cope elimination *via* the respective *N*-oxides in 45% overall yield (Scheme 3). At this point both diastereomers were efficiently separated by crystallization (ether–acetone–hexanes). The absolute configuration of the major diastereomer **7**,[11] coincident with that of natural (−)-ervitsine, was unambiguously determined by X-ray crystallography.[12] Removal of the chiral auxiliary from **7** required the previous chemoselective reduction of the 2-acylindole carbonyl group with lithium borohydride to give alcohol **8** (80%), which was converted into the acetyl derivative **9** by reaction with methyllithium (54%). Finally, after regeneration of the 2-acylindole carbonyl group with MnO_2 (quantitative), the stereoselective elaboration of the 20*E*-ethylidene substituent was accomplished by treatment of **10** with trimethyloxonium tetrafluoroborate followed by controlled sodium borohydride reduction (25%).[13] The ee (> 99%) of the resulting (−)-$N_{(a)}$-methylervitsine (**11**), $[\alpha]_D$ −60.5 (*c* 0.1, $CHCl_3$), was determined by chiral HPLC using racemic $N_{(a)}$-methylervitsine as reference. Finally the NMR spectra of **11** matched those of the racemic material.[9e]



Scheme 3 Synthesis of (−)-$N_{(a)}$-methylervitsine. *Reagents and conditions*: i, 70% *m*-CPBA, CH_2Cl_2, −10 °C, 2 h; ii, toluene, reflux, 1 h, 45%, then separation of diastereomers; iii, $LiBH_4$, THF, rt, overnight, 80%; iv, MeLi, THF, 0 °C, 4 h, 54%; v, MnO_2, CH_2Cl_2, rt, 2 d, quantitative; vi, $Me_3O{\cdot}BF_4$, CH_2Cl_2, rt, 2 h, then $NaBH_4$, MeOH, 0 °C, 1 h, 25%.

Extended scope of *in situ* iodotrimethylsilane mediated selective reduction of benzylic alcohols

Gary A. Cain* and Edward R. Holler

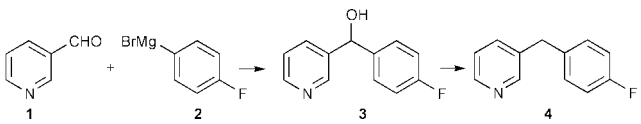
Chemical and Physical Sciences, DuPont Pharmaceuticals Company, P.O. Box 80336, Experimental Station E336/109, Wilmington, DE 19880-0336, USA. E-mail: gary.a.cain@dupontpharma.com

Received (in Corvallis, OR, USA) 14th March 2001, Accepted 7th May 2001
First published as an Advance Article on the web 25th May 2001

Iodotrimethylsilane, generated *in situ* from chlorotrimethylsilane and sodium iodide in acetonitrile, selectively reduces moderately electron deficient benzylic alcohols to the analogous toluenes; other reduction sensitive functional groups such as ketone, aldehyde, nitrile, and nitro are unaffected.

The use of iodotrimethylsilane (TMSI), generated *in situ* from $ClSiMe_3$ (TMSCl) and NaI in dry CH_3CN, is known to be a useful reagent for the reduction of secondary benzylic alcohols.[1–3] Although infrequently utilized, this reagent provides high yields of the deoxygenated toluene products, particularly for electron rich aromatic systems. The near exclusive use of these conditions for electron rich substrates may be associated with the proposed intermediacy of a benzylic stabilized carbocation at the reduction site. We now report that *in situ* TMSI reductions can be extended to moderately electron deficient benzylic alcohols, and that these conditions are selective in the presence of other reduction sensitive functional groups.

Our interest in the area began when we required a preparation of 3-(4-fluorobenzyl)pyridine. Being a previously unknown compound, we envisaged that it should be accessible *via* a Grignard reaction to form the benzylic alcohol, followed by selective benzylic –OH reduction in the presence of the potentially reduced pyridine ring (Scheme 1). In practice, the Grignard reaction, using commercially available 4-fluorophenylmagnesium bromide **1** and 3-formylpyridine **2** in Et_2O at 0 °C, readily provided the benzylic alcohol **3** in 74% yield after flash chromatography. At this stage of our work we followed the *in situ* TMSI benzylic alcohol reduction conditions from the first pertinent literature paper we could locate.[3] This reference used 6 eq. each of TMSCl and NaI with acetonitrile as solvent at 0 °C for 5 min. Under these conditions, however, we did not observe any reduction product. Eventually we found that upon heating the reaction to 55 °C (the boiling point of TMSCl) overnight we obtained a near quantitative yield of the desired reduction product **4** after standard workup (see Table 1, Ex. 1).



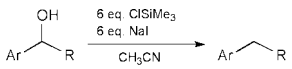
Scheme 1

Upon subsequently conducting a more thorough literature search, we were surprised to find that the defluoro analog of our above example was reported[4] to provide a 0% yield under attempted TMSI reduction. Because this particular paper was mainly concerned with electron rich systems, which proceeded quickly at low temperature, these workers may not have attempted the higher temperature and longer time that we had found necessary. Indeed, when we attempted the reduction of 1-(3-pyridyl)phenylmethanol at 55 °C (Ex. 2), we found that the reduction did proceed, although quite slowly. After 5 days the reduction was observed to be 67% complete by proton NMR.

Having thus established that electron poor 3-pyridyl benzylic alcohols were successful substrates for the *in situ* TMSI reduction, we then explored several other electron deficient examples to begin to understand the scope of the reaction. These results are summarized in the Table 1, Examples 1–8.

It is apparent from these results that moderately electron deficient diarylmethanols are good substrates for this reduction. Comparison of Ex. 3–5 illustrates that increasingly electron deficient systems, as by the sequential introduction of more fluorines onto the rings, led to much slower reactions and poorer yields. The reaction of the 2-pyridyl analog (Ex. 6), with the electron deficient node directly adjacent to the reaction center, failed completely. Strongly electron deficient 4-nitrophenyl

Table 1 *In situ* TMSI reduction of electron deficient benzylic alcohols



Ex. #	Ar	R	Time	Temp/°C	Yield (%)[a]
1	3-Pyridyl	4-F-Ph	18 h	55	99

 DOI: 10.1039/b102495g

groups provide poor substrates, giving a low yield for the doubly aromatic analog Ex. 8, and failing to react for monobenzylic analog Ex. 7.

With this success for the *in situ* TMSI reduction of moderately electron poor benzylic alcohols, we then sought to take advantage of these conditions for selective reductions. Aldehydes, ketones, and nitriles are examples of mild electron withdrawing aromatic substituents which are widely found in the chemical literature. For substrates containing any of these three functional groups, reductive cleavage of a benzylic –OH under more standard conditions,[5] such as catalytic hydrogenation,[6] could be problematic. In fact, a literature search for benzylic alcohol reduction in the presence of an aldehyde or ketone failed to identify any direct methods. As shown in Examples 9–12, we have applied the *in situ* TMSI method to a series of these sensitive molecules. In all cases, the benzylic –OH was reductively cleaved to provide the toluene product and leave the –CN, –Ac, and –CHO groups intact. These conditions, therefore, appear to be suitable for more widespread use.

A self-assembled novel octanuclear Cu(II) 'pin-wheel' cluster exhibiting ferromagnetic coupling

Zhiqiang Xu, Laurence K. Thompson* and David O. Miller

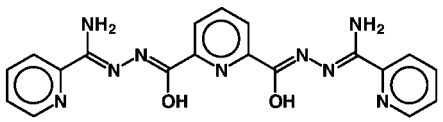
Department of Chemistry, Memorial University of Newfoundland, St. John's, NFLD, Canada A1B 3X7. E-mail: lthomp@morgan.ucs.mun.ca

Received (in Cambridge, UK) 1st March 2001, Accepted 14th May 2001
First published as an Advance Article on the web 5th June 2001

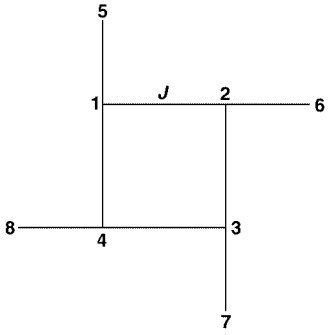
The heptadentate, 'tritopic' ligand 2poapH_2 reacts with $Cu(NO_3)_2$ in the presence of $Gd(NO_3)_3$ to give a novel, self-assembled, ferromagnetically coupled, alkoxide bridged octanuclear Cu(II) cluster in the shape of a pin-wheel, with a central $Cu_4[\mu\text{-}O_4]$ core, and isolated Curie-like $[Gd(NO_3)_4(H_2O)_2]^-$ anions.

Self-assembly reactions with polytopic ligands have led to a number of novel polynuclear cluster complexes, and with the ligand coordination pockets held in a linear array 2D grid structures are produced with tetranuclear,[1–4] hexanuclear,[5] nonanuclear,[6–9] and hexadecanuclear[10] examples. Interest in such systems stems from their ability to produce high nuclearity metallic clusters with pre-determined geometrical arrangements of closely spaced metal centres. With appropriate bridging groups arranged strategically in the ligand backbone magnetic coupling between the metal ions can occur. Examples of alkoxide bridged nonanuclear grids show antiferromagnetic coupling ($M_9(\mu\text{-}O)_{12}$; M = Mn(II), Co(II), Ni(II)), while with copper(II) ferromagnetic exchange prevails due to strict magnetic orbital orthogonality *via* the μ-O bridges.

In an attempt to generate a mixed lanthanide/copper complex of the ligand 2poapH_2 (Scheme 1), with the possibility of enhanced ferromagnetic exchange, $Gd(NO_3)_3$ and $Cu(NO_3)_2$ were reacted with the ligand sequentially.† The resulting green complex, $[Cu_8(2poap)_4(CH_3OH)_4(CH_3CN)_4][Gd(NO_3)_4(H_2O)_2]_2(NO_3)_6\cdot 1.3Cu(NO_3)_2\cdot(H_2O)_{10}$ (**1**),‡ has been shown to contain both copper and gadolinium, but the main fragment consists of a self-assembled octanuclear $Cu(II)_8$ cation accompanied by two isolated $[Gd(NO_3)_4(H_2O)_2]^-$ anions, and a fourth component which has been identified crystallographically as a $Cu(NO_3)_2$ based fragment trapped in the lattice. Fig. 1 shows the octanuclear cation with four opposed ligands in parallel pairs bound *via* terminal coordination pockets to a central square 2 × 2 core of four octahedral Cu(II) centres, which are bridged by alkoxide oxygen atoms, in an arrangement common to other $[M_4(\mu\text{-}O)_4]$ square grids[4] with the ditopic ligand poapH (M = Mn(II), Co(II), Ni(II), Cu(II), Zn(II)). The other ends of the four ligands radiate from the core to create a pin-wheel structure with the external coppers connected to the core by alkoxide bridges. The external tridentate ligand pockets fill only three copper coordination sites, and other sites at these square pyramidal copper centres are occupied by solvent molecules (CH_3OH, CH_3CN from solvent used to produce crystals). The core structure showing the alkoxide bridging connections is illustrated in Fig. 2. Cu–O–Cu angles overall fall in the range 139.0–142.0°. Cu–Cu distances within the core fall in the range



2poapH2



Scheme 1

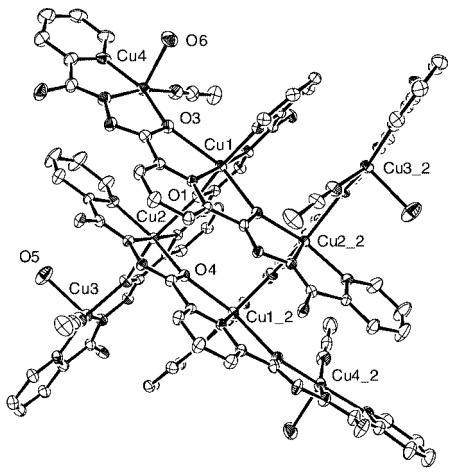


Fig. 1 Structural representation of the cation $[Cu_8(2poap)_4(CH_3OH)_4(CH_3CN)_4]$ in (**1**) (40% probability thermal ellipsoids). Cu(1)–O(4)' 2.307(4), Cu(1)–O(1) 2.020(4), Cu(2)–O(1) 2.283(4), Cu(2)–O(4) 2.030(4), Cu(3)–O(2) 1.969(5), Cu(3)–O(5) 2.215(6), Cu(2)–O(2) 2.340(4), Cu(1)–O(3) 2.404(5), Cu(4)–O(3) 1.983(5), Cu(4)–O(6) 2.224(6), Cu(1)–Cu(2) 4.082(2), Cu(2)–Cu(1)' 4.038(2), Cu(2)–Cu(3) 4.038(2), Cu(1)–Cu(4) 4.151(2), Cu(3)–Cu(3)' 12.805(2), Cu(4)–Cu(4)' 12.676(2) Å; Cu–O–Cu 139.0–142.0°.

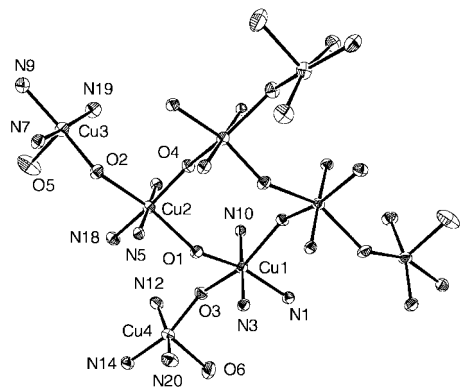

Fig. 2 Structural representation of the octanuclear core in **1**.

 DOI: 10.1039/b101966j

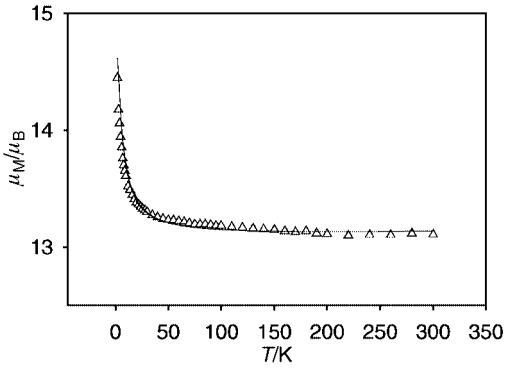

Fig. 3 Magnetic properties of **1** plotted as μ_{mol} *vs.* temperature. The solid line is the best fit of the data to eqn. (1) (see text for fitting parameters).

4.03–4.09 Å, and in the range 4.03–4.15 Å outside. The diagonal external Cu–Cu distances exceed 12.6 Å. The coppers within the core are six-coordinate, with elongated tetragonal stereochemistry. The long contacts involve all the ring oxygen bridging atoms and all *trans* related oxygens (*e.g.* Cu(2)–O(1) 2.283(4) Å; Cu(2)–O(2) 2.340(5) Å). The external square pyramidal coppers have short contacts to the oxygen bridges (Cu(3)–O(2) 1.969(5) Å, Cu(4)–O(3) 1.983(5) Å), and long axial contacts to the weakly bound methanol molecules (Cu(3)–O(5) 2.215(6) Å, Cu(4)–O(6) 2.224(6) Å). This leads to a unique arrangement of the copper atoms, in which all the oxygen bridging connections involve strict metal magnetic orbital ($d_{x^2-y^2}$) orthogonality, resulting in unique ferromagnetic properties (*vide infra*). A related, antiferromagnetically coupled complex $[Cu_8(dpd-2H)_4(\mu\text{-}O_2CMe)_4\{pyOH\}_4](ClO_4)_4$ (**2**) (dpd−2H = dianion from the *gem*-diol $(py)_2(OH)_2$; pyOH = 2-hydroxypyridine), reported recently has a $Cu_4(\mu\text{-}O)_4$ core and four pendant copper centres linked by carboxylate bridges.[11]

Fig. 3 shows the profile of molar magnetic moment *vs.* temperature for **1**, with a moment rising slightly from 13.1 μ_B at 300 K to 13.3 μ_B at about 25 K, followed by a sharp rise to a maximum value of 14.5 μ_B at 2 K.§ Given the fact that the isolated Gd(III) and Cu(II) centres should behave as Curie components the overall magnetic behaviour of **1** indicates the presence of a ferromagnetically coupled cluster. The magnetic data were fitted to an isotropic exchange expression based on a spin Hamiltonian [eqn. (1); Scheme 1],

$$H = -J(S_1S_2 + S_2S_3 + S_3S_4 + S_1S_4 + S_1S_5 + S_2S_6 + S_3S_7 + S_4S_8) \quad (1)$$

reflecting equivalent exchange interactions (J) between adjacent copper(II) centres. The total spin states, and their energies, were calculated using the normal spin vector coupling method,[12] and substituted into the van Vleck equation in the usual way. Curie components corresponding to 2 Gd(III) ions and 1.3 Cu(II) ions identified in the X-ray structure were included. An excellent data fit was obtained using a non-linear regression procedure, and the solid line in Fig. 3 was calculated for g_{av} = 2.113(2), J = 5.0(2) cm^{-1}, TIP = 0.000500 emu mol^{-1}, θ = −0.10 K (R = 1.0%) (θ is a Weiss-like corrective term, TIP = temperature independent paramagnetism). The positive J confirms the intramolecular ferromagnetic behaviour, with a value comparable to related 2 × 2 and 3 × 3 grid systems,[4,8,9] and illustrates another example in which there appears to be a spontaneous tendency for the closely spaced magnetic planes to tilt away from each other in the alkoxide bridged cluster. Magnetization *vs.* field data at 2 K showed incomplete saturation at 5 T, with a value of 24.8 $N\beta$ at 5 T. This is consistent with the sum of the ferromagnetically coupled Cu_8 cluster, and the Curie-like Gd(III) and Cu(II) centers.

The novel ferromagnetically coupled Cu_8 pinwheel cluster forms in a mixed metal self-assembly reaction. Gd(III) is assumed to influence the cluster self assembly, possibly by a pre-coordination step at one end of a ligand, prior to formation of the central square core, followed by displacement of the Gd(III) by Cu(II) ions. Similar reactions are being studied with other first row transition metals.

This research was supported by NSERC (Natural Sciences and Engineering Research Council of Canada). We thank Dr. R. McDonald, University of Alberta, for X-ray crystallographic data.

Notes and references

† $2poapH_2$ was synthesized by a published procedure.[7] $2poapH_2$ (0.40 g, 1.0 mmol) was added to a warm methanol solution (25 mL) of $Gd(NO_3)_3\cdot 6H_2O$ (0.23 g, 0.5 mmol) and the mixture stirred for several minutes until the ligand dissolved, forming a clear yellowish solution. CH_3CN (20 mL) was added and the solution refluxed, and a warm solution of $Cu(NO_3)_2\cdot 3H_2O$ (0.75 g, 3.1 mmol) in methanol (10 mL) added slowly. A brownish powder formed initially, which then dissolved forming a clear deep green solution. Well formed dark green crystals, suitable for X-ray analysis, were produced from the filtered solution after several days (yield 85%). Found (vacuum dried sample): C, 25.87; H, 2.56; N, 19.53. Calc. for $(C_{19}H_{15}N_9O_2)_4\text{-}Cu_8Gd_2(CH_3CN)_4(CH_3OH)_4](NO_3)_{14}\cdot 14H_2O\cdot 1.3Cu(NO_3)_2$: C, 25.87; H, 2.86; N, 19.41. ν_{max}/cm^{-1} (Nujol) 3436 (H_2O), 3343, 3172 (NH), 1665 (C=N) and 1026 (py). λ_{max}/nm (Nujol) 700. $\mu_{(RT)}$ = 13.1 μ_B (mol).

‡ *Crystal data* for $[Cu_8(2poap)_4(CH_3OH)_4(CH_3CN)_4][Gd(NO_3)_4\text{-}(H_2O)_2]_2(NO_3)_6\cdot 1.3Cu(NO_3)_2\cdot(H_2O)_{10}$ (**1**): $C_{44}H_{52.5}N_{27.3}O_{31.65}Cu_{4.65}Gd$ **1**; M = 1922.9, monoclinic, space group $C2/c$ (no. 15), a = 26.647(1), b = 18.1576(9), c = 30.423(2) Å, β = 90.282(1)°, U = 14720(1) Å^3, Z = 8, D_c = 1.735 g cm^{-3}, T = 193(1) K, μ(Mo-Kα) = 23.12 cm^{-1}. 954 parameters were refined with 10976 unique reflections ($I > 2.0\sigma(I)$) to give $R1$ = 0.057, $wR2$ = 0.178 (15062 independent reflections, R_{int} = 0.041) (Bruker P4/CCD with graphite-monochromatized Mo-Kα X-radiation, and a rotating anode generator). Hydrogen atoms were introduced in calculated positions with isotropic thermal parameters set 20% greater than bonding partners and were not refined. A total of six hydrogens from the gadolinium waters and the methanol molecules were omitted from the model. One methyl group from a bound methanol was fixed for the final round of refinement. CCDC reference number 160557. See http://www.rsc.org/suppdata/cc/b1/b101966j/ for crystallographic data in CIF or other electronic format.

Adsorption of cinchonidine on a platinum model catalyst studied by *in situ* ATR-IR spectroscopy revealed that the adsorption mode depends on surface coverage and is affected by concomitant adsorption and fragmentation of solvent molecules.

Heterogeneous asymmetric hydrogenation on chirally modified catalysts is a promising route for producing chiral molecules with high optical purity from prochiral reactants. At present, tartaric acid modified Ni catalysts[1,2] and cinchona modified Pt based catalysts[3–5] are the most successful systems for the hydrogenation of β-keto esters and α-keto esters, respectively. With respect to the latter, the adsorption mode of cinchonidine (CD) is a critical factor, and still a matter of debate. Direct spectroscopic information is available only from earlier XPS and LEED[6] and recent NEXAFS[7] studies of the adsorption of 10,11-dihydrocinchonidine on Pt(111) under UHV conditions. At 298 K the quinoline ring was found to lie almost parallel to the metal surface, whereas a tilting angle of *ca.* 60° was found at 323 K. However, these studies fail to describe the adsorption under reaction conditions, *i.e.* in the presence of both the solvent and H_2. With the present work we aim at closing this gap by studying the adsorption of CD using attenuated total reflection IR spectroscopy (ATR-IRS)[8] close to reaction conditions. For this purpose we have developed a model system based on a Pt/Al_2O_3 coated Ge internal reflection element.[9] In the following it will be shown that the presence of a solvent acting as a competing adsorbate is a crucial factor for modifier adsorption. Adsorption of CD on Pt/Al_2O_3 turns out to be complex. Several adsorption modes of CD can be distinguished, depending on coverage and time similar to recent findings for the Ni–tartrate system.[10]

ATR spectra of cinchonidine (CD) adsorbed from H_2-saturated CH_2Cl_2 solvent on Pt/Al_2O_3 are shown in Fig. 1.† Before recording the ATR spectra the Pt/Al_2O_3 film was treated with hydrogen saturated CH_2Cl_2 which results in a cleaning of the Pt.[9] After this the background spectrum was recorded. Upon admitting a H_2-saturated solution of CD to the sample positive and negative signals were immediately observed in the ATR spectra. The positive signals arise from molecules, which are added to, negative signals from molecules, which are removed from the interface, with respect to the reference spectrum. We assign the positive signals to adsorbed CD, whereas the negative signals are due to simultaneous removal of adsorbed solvent decomposition products as well as the displacement of solvent from near the interface, as detailed below. The spectra exhibit distinct concentration [compare Fig. 1(a) and (c)] and time dependence [Fig. 1 (b) and (e)] and are clearly different from the solution spectrum as a consequence of the interaction of CD with the Pt/Al_2O_3. By contacting quinoline (Q, not shown) with Pt/Al_2O_3, the same concentration and time behaviour of the corresponding vibrational bands was observed, indicating that the interaction of CD with the surface is dominated by the quinoline moiety. The change of the relative intensity of the vibrational bands with concentration and time and the appearance of new bands with respect to the solution spectrum can arise due to (i) a chemical reaction of CD or (ii) a change in adsorption geometry. Feasible chemical reactions of the quinoline moiety under the applied conditions are hydrogenation and α-H abstraction. As concerns hydrogenation, several possible hydrogenation products (1,2,3,4- and 5,6,7,8-tetrahydroquinoline and decahydroquinoline) were adsorbed from CH_2Cl_2 on the Pt/Al_2O_3 film. Although for most of them adsorption could be observed, none of them exhibited the vibrational bands shown in Fig. 1 and hence we exclude adsorbed hydrogenation products as the origin of the bands in Fig. 1. To our knowledge no analysis of the vibrational spectrum of quinoline (intact and/or after α-H abstraction) on Pt has been reported so far. On the other hand for the chemically related pyridine on Pt detailed analysis exists.[11] Intact pyridine and pyridine after α-H abstraction can clearly be distinguished. After adsorption of pyridine from hydrogen-saturated CH_2Cl_2 we predominantly observed the bands which have been associated with intact pyridine in a tilted orientation and bound *via* the N-atom.[11] Although α-H abstraction is feasible, we conclude that it is not a dominant process under the applied conditions. On the other hand the absence of the signal at 1635 cm^{-1} corresponding to ν(C=C) of the vinyl moiety indicates that CD is hydrogenated at this site.

Based on the above mentioned results we conclude that the observed positive bands are mainly associated with chemically intact CD and that the changes in relative intensity of the bands in Fig. 1 are associated with changes in adsorption geometry. At

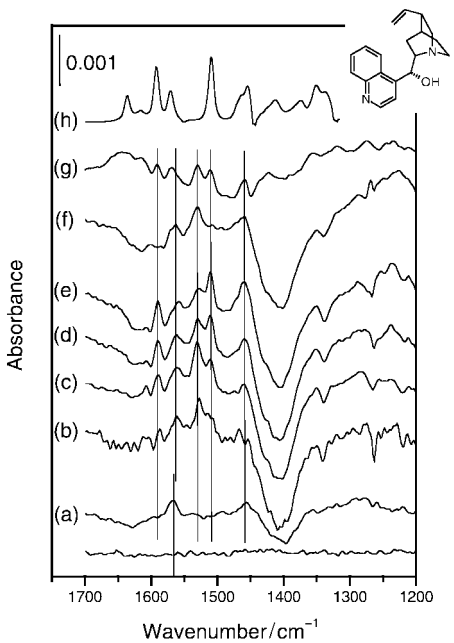

Fig. 1 ATR-IR spectra of cinchonidine adsorption on Pt/Al_2O_3 at 283 K from (a) 10^{-7} mol l^{-1} and (b)–(e) 10^{-3} mol l^{-1} solution in CH_2Cl_2 (recorded after 2, 3, 42 and 122 min, respectively), (f) followed by neat solvent flow; (g) from a 10^{-4} mol l^{-1} solution in cyclohexane at 293 K; (h) scaled (1:80) transmission spectrum of cinchonidine in CH_2Cl_2.

 DOI: 10.1039/b102884g

least three different adsorption geometries of CD (in the following termed 'species') can be distinguished by analysing the spectral region between 1500 and 1650 cm^{-1}, associated with the quinoline ring vibrations. A first species associated with only one band in this region at 1567 cm^{-1} predominates at 10^{-7}–10^{-6} mol l^{-1} [Fig. 1(a)]. At higher solution concentration, signals at 1610, 1590, 1567, 1530, 1511 and 1460 cm^{-1} are observed, having relative intensities changing with adsorption time. A slight red-shift is observed for the signal at around 1570 cm^{-1} upon increasing the concentration above 10^{-6} mol l^{-1} together with the appearance of the signal at 1530 cm^{-1}. The features at 1530 and 1567 cm^{-1} dominate the spectrum: (i) when slowly increasing the concentration of CD from 10^{-7} to 10^{-5} mol l^{-1}, (ii) at the very first stages of adsorption when flowing higher concentration ($> 10^{-5}$ mol l^{-1}) of CD [Fig. 1(b)], and (iii) when flowing neat solvent after saturating the sample [Fig. 1(f)]. They are attributed to a second species that is therefore strongly adsorbed. A third species is associated with strong bands at 1511 and 1590 cm^{-1} with a spectrum resembling that of CD in solution [Fig. 1(h)]. This species appears only at later stages of adsorption and at high concentration [Fig. 1(c)–(e)] and disappears when flowing neat solvent. This species is therefore only weakly bound, which is in line with the fact that its spectrum very much resembles the (unperturbed) solution spectrum. Interestingly, the intensity of the bands associated with the second and third species are anticorrelated, which is best seen by comparing the signals at 1511 and 1530 cm^{-1} in Fig. 1(b)–(e). Such behaviour is consistent with mutually interconverting species, the driving force for this process being the solution concentration. The signal at 1460 cm^{-1} observed for all three species is associated with the quinuclidine moiety of CD as the adsorption of quinuclidine (QD) on Pt/Al_2O_3 clearly indicated (not shown).

Knowledge of the direction of the dynamic dipole moment of a selection of vibrations (from *ab initio* calculations) combined with the metal surface selection rule[12] allows information to be gained about the local adsorbate orientation. Fig. 2 shows that the vibration at 1509 cm^{-1} in the solution spectrum is polarised roughly along the long axis of the quinoline moiety, whereas the mode at 1570 cm^{-1} is polarised perpendicular to it.

In line with the calculated polarisation of the bands, the following interpretation of the spectra can be given: the species associated with only one strong signal at 1567 cm^{-1} has the long axis of the quinoline moiety nearly parallel to the surface with a degree of tilting of the short axis, probably induced by the quinoline-N and the O–H group. For the second species the appearance of a second band at 1530 cm^{-1} indicates a change in orientation. We tentatively assign the band at 1530 cm^{-1} to the 1509 cm^{-1} band in solution, which is blue-shifted due to an interaction with the surface. A similar blue-shift of the corresponding bands was observed for pyridine on Pt adsorbed through the N atom in a tilted orientation.[11,13] The pyridine spectrum recorded in the presence of H_2 and CH_2Cl_2 shows bands with A_1 and B_1 symmetry,[11] indicating that none of the molecular axes are oriented parallel to the surface. Hence, the observed blue-shift of the 1530 cm^{-1} band, in analogy with adsorbed pyridine under our conditions, and the calculated polarisation of the 1530 cm^{-1} band are consistent with the interpretation that for the second species the long axis of the quinoline moiety is no longer parallel to the surface. The weakly bound third species does not show significant orientation preferences.

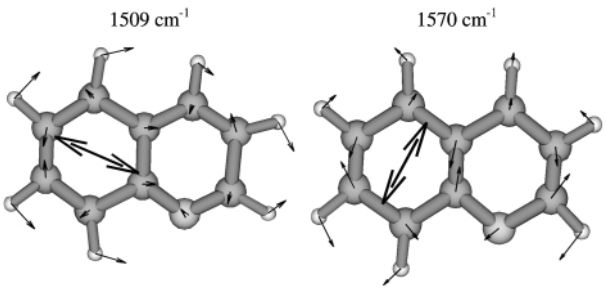

Fig. 2 Schematic of two of the vibrational modes of quinoline used to identify adsorption orientation. Arrows indicate atomic displacement vectors and the direction of the dynamic dipole moment, respectively. The corresponding experimental IR frequencies for cinchonidine in CH_2Cl_2 are also given.

As a general trend the quinoline moiety of CD is tilted more with increasing solution concentration and coverage. This is consistent with an increase of the average thickness of the adsorbate layer (defined as the distance between the Pt/adsorbate and the adsorbate/solution interfaces) and thus the displacement of solvent from very near the interface. This effect is directly observed in the ATR spectra. The negative peak at 1260 cm^{-1} corresponds to the strongest solvent vibration. Upon adsorption of CD (increasing the thickness of the adsorbate layer) this peak becomes negative, since, with respect to the reference spectrum, less solvent is probed by the electromagnetic field. The other negative signals at around 1635, 1400, 1338 and 1120 cm^{-1} (not shown) are associated with removal of water, CH_x and ethylidyne (CCH_3), respectively, from the adsorbate layer. CH_x fragments (1400 cm^{-1}) are formed from CH_2Cl_2 decomposition.[14] Upon admission of a solution of CH_2Cl_2 in cyclohexane on the Pt/Al_2O_3 sample the band was also observed supporting this view. Ethylidyne (1338, 1120 cm^{-1}) is likely formed by recombination of CH_x fragments, which is supported by the observed evolution of ethene on Pt/Al_2O_3 in contact with CH_2Cl_2.[14] CD adsorption from cyclohexane solvent afforded the same positive signals associated with CD, but not the negative signals associated to CH_x fragments and ethylidyne [Fig. 1(g)].

The ATR spectra clearly show that the adsorption mode of CD is coverage dependent and that CD competes with solvent decomposition products for adsorption sites. This observation adds an important new facet to the interpretation of the 'solvent effect' in enantioselective hydrogenation over cinchona-modified platinum.

Notes and references

† *In situ* experiments were carried out with a home-made stainless steel flow through cell by recording spectra at 283 K and co-adding 200 scans at 4 cm^{-1} resolution with a Bruker IFS/66 spectrometer equipped with a liquid-N_2-cooled MCT detector. Adsorption was carried out from H_2-saturated millimolar solutions in CH_2Cl_2 solvent (if not otherwise specified) after cleaning of the metal surface with H_2-saturated solvent. ATR spectra are presented in absorbance units with the last spectrum recorded during H_2-cleaning serving as reference. Pt/Al_2O_3 model films were prepared as described elsewhere.[9] Density functional theory (B3PW91 / cc-pvtz) was used to calculate frequencies and determine the dynamic dipole moment of each vibration.

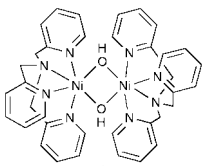
Received (in Irvine, CA, USA) 27th February 2001, Accepted 15th May 2001
First published as an Advance Article on the web 8th June 2001

Acetonitrile reacts with a dinuclear nickel(II) complex $[Ni_2(\mu\text{-}OH)_2(tpa)_2](ClO_4)_2$ [tpa = tris-(2-pyridylmethyl)-amine] in solution forming a novel square-planar nickel(II) complex $Ni\{HN{=}C(Me){-}N{=}C(Me){-}NH\}_2$.

Acetonitrile is one of the common solvents that is widely used to study processes in solution. With most 3d-transition metal ions acetonitrile behaves as a relatively weak monodentate ligand, providing inorganic chemists with a perfect media for numerous reactions.[1] However, transition metal complexes are well known to catalyze and promote the reactions of nitriles, *e.g.* their reduction, redox coupling, hydrolysis, and addition of nucleophiles.[2,3] In some cases nitrile, R–C≡N, adds to a ligand (L^- or LH) yielding a new composite ligand (L–C(R)=N^- or L–C(R)=NH) within the coordination sphere of a metal ion.[2,4] Here we report the first case of a reaction, in which acetonitrile undergoes self-condensation into an efficient bidentate ligand (*N*-acetimidoylacetamidine) under the action of a metal complex, $[Ni_2(\mu\text{-}OH)_2(tpa)_2](ClO_4)_2$ **1**.



1

Metal complexes with the tripodal tetramine ligand tpa and its homologs have been widely used in metalloenzyme modeling.[5,6] In particular, complex **1** was found to be a good catalyst for transesterification and carbon dioxide hydration.[7,8]

We prepared complex **1** by a simplified, one-pot procedure adapted from the original method proposed by Ito and Takita.[7] Its identity was established by elemental analysis, mass spectrometry, and UV–VIS spectroscopy.§ Solid **1** gives a blue solution in acetonitrile. When stored in a tightly sealed container at room temperature, this solution very slowly (within months) turns dark-purple and precipitates an orange–yellow crystalline material. If the acetonitrile solution of **1** is kept at 75 °C, the transformation is completed in 2 days. Recrystallization from acetonitrile and drying under vacuum gives pure diamagnetic complex **2** with the formula $Ni(C_4H_8N_3)_2$.¶

A single crystal X-ray diffraction study of solvated complex **2**·$2H_2O$ revealed that tpa and hydroxide ligands around Ni(II) ions are lost and substituted by a new unexpected ligand, *N*-acetimidoylacetamidine (Fig. 1).‖ Each Ni(II) ion is coordinated by two bidentate *N*-acetimidoylacetamidinate anions, forming the mononuclear molecular complex **2**. A molecule of **2** contains two six-membered flat metallocycles (deviation of atoms from the mean plane < 0.02 Å, and < 0.05 Å, if methyl groups are taken into account). The Ni–N bond lengths (1.85 Å) are similar to other Ni(II) square planar low-spin complexes with imine nitrogen donor atoms.[1] In the crystal lattice of **2**·$2H_2O$, individual molecules of **2** are connected *via* hydrogen bonding with water molecules (Fig. 1; Table S1†).

A mass spectrometry study showed that *N*-acetimidoylacetamidine originated from the solvent (acetonitrile). The crude reaction solution after heating complex **1** in acetonitrile shows signals at *m/z* 255, 291, 347, 407 and 447, which can be ascribed to the molecular ions of $\mathbf{2}^+$, $[tpaH]^+$, $[Ni(tpa)]^+$, $[Ni(tpa)(MeCO_2)]^+$ and $[Ni(tpa)(ClO_4)]^+$, respectively, according to their positions and the relative intensities of isotope satellites. When the reaction is carried out with CD_3CN instead of regular acetonitrile, the peaks of $\mathbf{2}^+$ and $[Ni(tpa)(MeCO_2)]^+$ are shifted 12 and 3 daltons up, respectively. Therefore, the source of the four methyl groups in the molecule of **2** is acetonitrile. There is a concomitant formation of acetate from acetonitrile. The tpa ligand remains intact in the course of the reaction and is partially released in the free form. The stoichiometry of the overall transformation can be tentatively expressed by eqn. (1)

$$2[Ni_2(OH)_2(tpa)_2]^{2+} + 6MeCN \rightarrow Ni(C_4H_8N_3)_2 + 2Ni(tpa)(MeCO_2)^+ + Ni(tpa)^{2+} + tpa \quad (1)$$

The role of **1** as a nickel complex promoting the acetonitrile transformation is specific. In separate experiments under similar conditions, no reaction with acetonitrile was observed, if complex **1** was substituted by $NiX_2{\cdot}6H_2O$ (X = Cl, ClO_4, NO_3), $Ni(MeCO_2)_2{\cdot}4H_2O$, $Ni(ClO_4)_2{\cdot}6H_2O$ + py (1:4), or $Ni(ClO_4)_2{\cdot}6H_2O$ + tpa (1:1).

There are only scarce reports of metal complexes with protonated *N*-acetimidoylacetamidine ligand

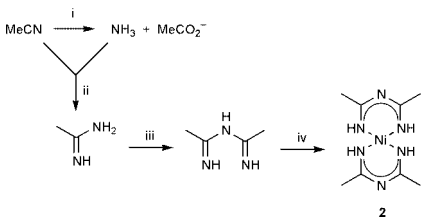
[HN{C(Me)=NH}$_2$, HL]. Two copper(II) complexes ($CuCl_2$·*n*HL, *n* = 1, 2) have been prepared, but not characterized in detail.[9] The only compound characterized by X-ray diffraction is a protonated form of complex **2**, namely green **2**·1.5HCl·3H_2O, formed upon self-condensation of acetamidine [MeC(=NH)NH_2] and $NiCl_2$·6H_2O in methanolic solution.[10] The structures of both complexes with square-planar Ni(II) centers are very similar. The C–N bond lengths in **2** are more uniform than in the protonated complex in agreement with more 'aromatic' character of the chelate metallocycle. Complex **2** seems to be the first molecular *N*-acetimidoylacetamidinate metal complex prepared to date. This is in contrast to the chemistry of metal acetylacetonates, which have been extensively studied and found numerous practical applications.[1] *N*-Acetimidoylacetamidinate is isoelectronic with acetonylacetonate, but has a significantly stronger ligand field. As a result, **2** and **2**·2H_2O have low-spin square-planar Ni(II) ions, while [Ni_3(acac)$_6$] and [Ni(acac)$_2$(H_2O)$_2$] are high-spin pseudo-octahedral Ni(II) complexes with bridging acac ligands and coordinated water molecules, respectively.[1,11]

Based upon known literature precedence, we can propose a sequence of events resulting in the overall transformation of acetonitrile into the acetimidoylacetamidinate complex and acetate (Scheme 1).



Scheme 1 Tentative mechanism of formation of complex **2** from acetonitrile and complex **1** (see text for the explanation of steps).

(i) Acetonitrile reacts with the hydroxide ligands of complex **1** or with trace water forming acetamide and, subsequently, acetate and ammonia. Catalytic activity of transition metal complexes in the hydrolysis of nitriles is well documented.[2] On the other hand, complex **1** is known to be a potent catalyst of transesterification.[8]

(ii) Acetonitrile and NH_3 yield acetamidine. This reaction is also known to be catalyzed by metal ions.[12]

(iii) *N*-Acetimidoylacetamidine is formed upon condensation of an acetamidine molecule with acetonitrile, acetamide, or another acetamidine molecule. Templated condensation of acetamidine in the presence of $NiCl_2$·6H_2O in methanolic solution to form **2**·1.5HCl·3H_2O has been reported.[10]

(iv) *N*-Acetimidoylacetamidine, which is isoelectronic with acetylacetone, but apparently has a much stronger ligand field, can act as a good new ligand for Ni(II). The net result of the reaction is the total displacement of the old ligands in complex **1**, including the tetradentate tpa, and the formation of a new complex Ni{HN=C(Me)–N=C(Me)–NH}$_2$ **2**.

Some other precedence for the reaction exists. Coupling of alkyl nitriles into 3,5-dialkyl-1,2,4-triazoles promoted by a dicopper complex has been reported.[3] Oligomerization of CF_3CN and CCl_3CN in the presence of transition metal complexes leads to the formation of the corresponding halogenated *N*-acetimidoylacetamidines, but acetonitrile is unreactive under the same conditions.[13,14] To the best of our knowledge, the transformation of a non-halogenated nitrile into an *N*-imidoylamidine promoted by a metal complex has not been observed before.

The behavior of dinickel(II) complex **1** can be contrasted to its diiron(III) analog, [Fe_2(μ-O)(tpa)$_2$(OH)(H_2O)]$^{3+}$, which reacts with MeCN to form a complex with a bridging acetamide ligand [Fe_2(μ-O){μ-OC(Me)NH}(tpa)$_2$]$^{3+}$.[5] In that case, the transformation of acetonitrile stops on acetamide, probably because the amidate [Fe_2^{III}(μ-O)(μ-OC(R)NH)(tpa)$_2$]$^{3+}$ complexes are coordinatively saturated and stable towards hydrolysis or dissociation.[15] In an additional experiment we found that complex **1** does not bind acetamide in solution as its diferric analog does.

In conclusion, we have demonstrated that a dinuclear hydroxo-bridged nickel(II) complex promotes self-condensation of acetonitrile into *N*-acetimidoylacetamidine, which acts as an efficient acetylacetone-like bidentate ligand, displacing the old ligands around Ni(II) and forming a new molecular homoleptic bis(*N*-acetimidoylacetamidinate)nickel(II) complex. This reaction shows that possible side-reactions should always be considered in studies involving metal complexes and acetonitrile.

First published as an Advance Article on the web 8th June 2001

Ultra-fine NaX zeolite crystals of dimensions *ca*. 20–100 nm have been synthesized with a novel, efficient, organic-additive-free hydrothermal approach.

The synthesis of nanometer-sized zeolites has received much attention recently owing to their utility in fundamental studies of zeolite crystal growth, in the preparation of ultra-thin zeolite films and nano-composites, and as supports for catalytic and photochemical reactions.[1–10] Reduction of the particle size from the micrometer to the nanometer scale can improve the mass- and heat-transfer in catalytic and sorption processes, thereby enhancing their catalytic selectivity and reducing coke formation in some petroleum reactions.[11] Furthermore, zeolite nano-crystals can be used to fabricate ordered porous structures.[12] Zeolite nano-crystals are usually synthesized *via* hydrothermal procedures using clear aluminosilicate solutions, most commonly in the presence of organic additives as templates. Nano-crystalline faujasite (FAU) zeolites have been synthesized using tetramethylammonium (TMA) as a template.[1–3,6] However, the conditions have to be critically controlled in order to get pure FAU crystals, as TMA is also a template for growth of zeolite A; furthermore, removal of the templates can lead to an irreversible aggregation of nano-crystals into larger solid particles.[13] Moreover, organic additive template routes are not suited for nano-scale synthesis, whereas the 'build-the-bottle-around-the-ship' method (or one-step approach) can directly synthesize the zeolite host matrix around guest molecules, as very pure and homogeneous nano-composites.[14,15] We are interested in developing novel organic-additive-free routes to ultra-fine FAU zeolites. These materials could have very different physical properties from microcrystalline zeolites, and could provide insights into nucleation and crystal growth during the hydrothermal process. Here we report an efficient, organic-additive-free synthesis of NaX zeolite with particle sizes in the range 20–100 nm.

The hydrothermal synthesis was conducted in a shaker with a temperature controller. Aluminosilicate gel was prepared by mixing freshly prepared aluminate and silicate solutions together in the molar ratio 5.5 Na_2O : 1.0 Al_2O_3 : 4.0 SiO_2 : 190 H_2O. Typically, an aluminosilicate gel containing 5.34 g NaOH, 2.42 g $NaAlO_2$, 3.43 g SiO_2 and 50.0 g H_2O was used. $NaAlO_2$ was freshly prepared from $Al(OH)_3$ and NaOH. SM-30 colloidal silica (Aldrich), silica fume (Sigma), and TEOS (tetraethyl orthosilicate, Aldrich) were chosen as the silicate sources, with no significant difference observed in the final particle size-distribution. For TEOS, the hydrolysis was controlled at 0 °C in order to obtain nanometer-sized aluminosilicate gel. Hydrothermal crystallization was conducted at 60 °C for 2–4 days in a shaker with a rotation rate of 250 rpm. The powder product, henceforth referred to as NaX-*nano*, was recovered *via* centrifugation, washed with DI water until pH < 8, and then dried at room temperature for 24 h. In a control experiment, larger particle sizes of FAU zeolite, here denoted NaX-μ, were synthesized with exactly the same aluminosilicate gel composition, but the hydrothermal crystallization was performed at 90 °C for 2 days with no shaking.

Powder X-ray diffraction (XRD) diagrams of as-synthesized zeolite samples and commercial micron-sized FAU zeolite (from Aldrich) are shown in Fig. 1. The XRD patterns of the two synthesized samples and the commercial FAU powder match very well, demonstrating that our approach can indeed be used to synthesize pure FAU crystals. The XRD peaks for the NaX-μ sample are almost the same as for the commercial sample, in both intensity and width. However, the diffraction lines of the NaX-*nano* sample are significantly less intense and much broader, indicating that the crystals are much smaller. From the diffraction peaks (2θ) at 6° [111], 16° [331], and 27° [642] and Scherrer's equation, we calculate an average crystal dimension of 23 ± 4 nm.[2,16] XRD patterns taken after different hydrothermal synthesis periods reveal that NaX-*nano* is more than 95% crystalline after two days of shaking at 60 °C. Longer crystallization times might slightly increase the particle size. The Si/Al ratio was found to be 1.25 ± 0.05 for NaX-*nano* (by X-ray fluorescence) and 1.3 ± 0.1 for NaX-μ (from ^{29}Si solid state NMR). These values fall in the Si/Al range of 1–1.5 for NaX zeolites. Therefore, both synthesized samples are NaX. The as-synthesized samples have slightly lower 2θ values than the commercial sample, as would be expected for reduced Si/Al ratios.

Uncoated NaX-*nano* and NaX-μ samples were imaged with a Hitachi S-4700 cold-field emission scanning electron microscope (SEM) operated at 1 kV. A typical micrograph of NaX-*nano* (Fig. 2) clearly shows that most particle sizes of NaX-*nano* are in the range 20–100 nm. This is one of the smallest faujasite particle sizes reported.[1–4,6] This size distribution is consistent with the results calculated from the XRD patterns, proving that our method does indeed successfully synthesize ultra-fine NaX

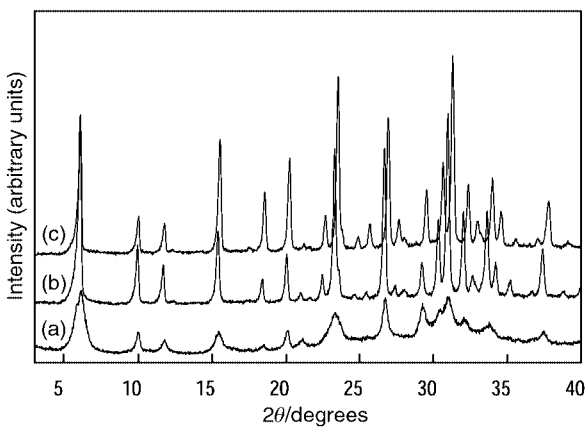

Fig. 1 XRD powder patterns for (a) NaX-*nano*, (b) NaX-μ and (c) a commercial NaX sample (Aldrich). The XRD data were recorded on a Rigaku Miniflex System using Cu-Kα radiation, 30 kV, 15 mA with a scanning speed of 1° (2θ) min^{-1}, T = 20 °C.

 DOI: 10.1039/b102733f

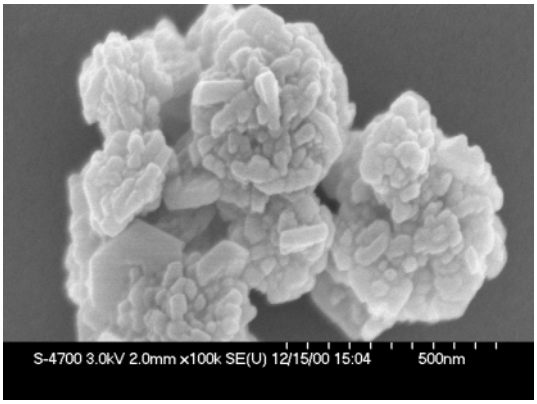

Fig. 2 SEM images of NaX-*nano* (HITACHI S-4700 cold-field emission SEM, 1 kV).

crystals without the assistance of any organic additives. The micrographs of NaX-μ show the particles to be in the micron range (*ca*. 0.8 μm). The significant decrease in particle size from NaX-μ to NaX-*nano* indicates that lower crystallization temperatures and strong shaking conditions, which would together accelerate the nucleation process and lower the crystal growth rates, are key factors in controlling the size of zeolite crystals obtained. By controlling the crystallization temperature, shaking time and silicate source (and its particle size), we successfully synthesized several NaX zeolite samples with average particle sizes ranging from 20 nm to 1 μm.

Both NaX-*nano* and NaX-μ were further characterized by FT-IR and ^{29}Si solid-state NMR. In the FT-IR spectra, three features were noted. First, a symmetric stretching band at 744 cm^{-1} was observed in NaX-*nano*,[17,18] with a corresponding peak at 750 cm^{-1} in the NaX-μ sample. Secondly, the double-ring vibration at 566 cm^{-1}, characteristic of faujasite zeolites, appears as two bands at 608 and 566 cm^{-1} in NaX-*nano*. Thirdly, a new broad band at 860 cm^{-1} was observed in the ultra-fine sample, and it can reasonably be assigned to the silanol (Si–OH) bending mode associated with the Q^3 silicon species (Si connected to three O that have connections to Si or Al),[17] detected with ^{29}Si solid-state NMR. The existence of an abundance of silanol groups in NaX-*nano* is attributed to the large total particle surface area, associated with the reduction to the ultra-fine particle size. From a simple calculation assuming cubic particles, one would expect about 12% Q^3 from the external surface in an NaX zeolite with a 50 nm particle size. Q^3 species could also be formed at internal defects. It was reported that about 20% of Si was in the silanol form in an 18–100 nm particle-size silicalite-1 zeolite studied by solid-state NMR.[5] With both single-pulse and cross-polarization ^{29}Si solid-state NMR techniques, we found all four Q^3 bands and five Q^4 bands in the NaX-*nano* sample. To our knowledge, this is the first time that Q^3 bands have been observed in a nanometer-sized NaX sample. This finding agrees well with the observation of silanol bending modes in the vibrational spectroscopy experiment. On the other hand, only the five Q^4 bands, located at −84.8, −89.5, −94.2, −99.3 and −103 ppm, were detected in the larger-particle NaX-μ sample, as expected.

In conclusion, a novel organic-additive-free approach has been developed to synthesize nanometer-sized faujasite NaX. The XRD pattern of the as-synthesized NaX-*nano* sample matches very well with the commercial micron-sized FAU, but it is broader and less intense. The average crystal size of 23 nm calculated from XRD is in accord with SEM images. The crystal size depends critically on the synthetic conditions, *e.g.* temperature and shaking. In comparison with the micron-sized zeolite, ultra-fine NaX shows a broad silanol vibration peak at 860 cm^{-1}, associated with the Q^3 silicon detected in ^{29}Si solid-state NMR.

Received (in Cambridge, UK) 5th March 2001, Accepted 14th May 2001
First published as an Advance Article on the web 30th May 2001

The proposed two-step preparation route for rare earth polyborates, *i.e.* dehydration of boric acid in the presence of rare earth oxide at low temperature followed by careful annealing at 700 °C, led to, for the gadolinium case, a new gadolinium pentaborate (GdB_5O_9) that can not be prepared by conventional high-temperature reaction.

The structural chemistry of borates is characterized by a variety of discrete and condensed BO_3 and BO_4 groups;[1] as a general rule, the tendency to form polyborates is increased by decreasing cation valence.[2] This promotes stability and a wide variety of polyborate structures with 1+ and 2+ valence cations have been produced. The rare earth borates, on the other hand, usually consist of isolated borate anions (BO_3 or BO_4) or low polymerized borate groups; thus, in the Ln_2O_3–B_2O_3 (Ln = rare earth) system[3] only three compounds, oxyborate,[4,5] orthoborate[6] and metaborate,[7] have been identified; the more borate-rich phases remain unknown. Recently, we found that, in the flux of boric acid, hydrated rare earth polyborates are formed by the reaction of boric acid and rare earth oxides at low temperature. Subsequent annealing of the hydrated polyborates yields anhydrous rare earth polyborates. We describe herein our exploratory syntheses in this area.

The synthesis of hydrated gadolinium polyborate was carried out in a sealed Teflon autoclave at 260 °C for 5 days, starting from H_3BO_3 and Gd_2O_3 in a 20 : 1 ratio. The product **1**, isolated by dissolving the excess boric acid in water, consists of colorless well-crystallized polycrystals. Chemical analysis (ICP) reveals that the approximate atomic ratio Gd : B is about 1 : 6.2, and the IR spectrum indicates the presence of both BO_3 and BO_4 groups in this compound. Fig. 1a shows the X-ray diffraction pattern of **1**. Structural analysis using X-ray powder diffraction techniques[8] established that the product **1** is a hydrated gadolinium polyborate with the composition $H_3GdB_6O_{12}$; it crystallizes with a rhombohedral structure in the space group *R*3*c* with lattice constants a = 8.4076(2) and c = 20.7427(5) Å. The synthesis reaction is:

$$12H_3BO_3 + Gd_2O_3 \xrightarrow{260\ ^{\circ}C} 2H_3GdB_6O_{12} + 15H_2O \quad (1)$$

$H_3GdB_6O_{12}$ is stable at low temperature and decomposes at high temperature. X-Ray powder diffraction studies carried out at high temperatures indicate that the decomposition of $H_3GdB_6O_{12}$ occurs at about 650 °C; it transforms to an amorphous form between 650 °C and 700 °C. During the decomposition, significant weight loss (6.04 wt%) was observed *via* TGA. Therefore, the decomposition reaction is essentially the dehydration of $H_3GdB_6O_{12}$. Careful annealing at 700 °C for 5 days resulted in another new phase (**2**) as shown in Fig. 1b.

The structural study by X-ray powder techniques established that **2** is a rare earth pentaborate GdB_5O_9. It crystallizes in a body centered tetragonal cell (a = 8.2439(4), c = 33.6671(2) Å) in the space group $I4_1/acd$.[9] The basic borate fragments in GdB_5O_9 are B_4O_9 and BO_3 units. The B_4O_9 is a common structure unit in many borates. For example, isolated and 1D chains of B_4O_9 are present in borax ($Na_2[B_4O_5(OH)_4]\cdot 8H_2O$) and $Na_2[B_4O_6(OH)_3]$ respectively.[1] In the structure of GdB_5O_9, the B_4O_9 units form 1D chains by sharing the oxygen atoms of the BO_4 groups (Fig. 2); the 3D-polyborate framework is composed of 1D chains linked by additional BO_3 groups. Fig. 3 shows an overview of the structure of GdB_5O_9, where the triangles and tetrahedra represent BO_3 and BO_4 groups respectively. The decomposition reaction of $H_3GdB_6O_{12}$ is then expressed as:

$$2H_3GdB_6O_{12} \xrightarrow{650-700\ ^{\circ}C} 2GdB_5O_9 + 3H_2O + B_2O_3 \quad (2)$$

The expected weight loss from eqn. (2) is 6.473 wt%, which agrees reasonably well with that observed in the TGA study (6.04 wt%). Moreover, GdB_5O_9 is not stable at higher temperatures; further annealing at 900 °C yielded gadolinium metaborate and another unknown phase. Therefore, this compound cannot be synthesized by conventional high temperature solid state reaction.

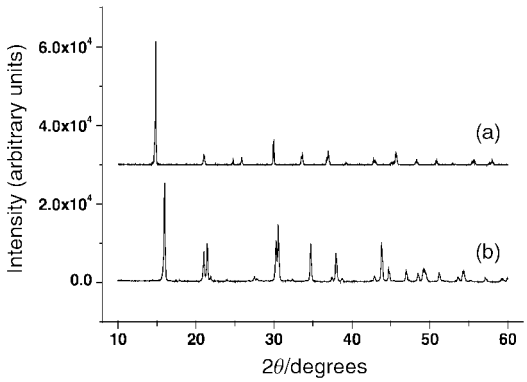

Fig. 1 X-Ray powder diffraction patterns (a) of the hydrated gadolinium polyborate $H_3GdB_6O_{12}$ (**1**) and (b) of the anhydrous gadolinium polyborate GdB_5O_9 (**2**) after annealing at 700 °C for 5 days.

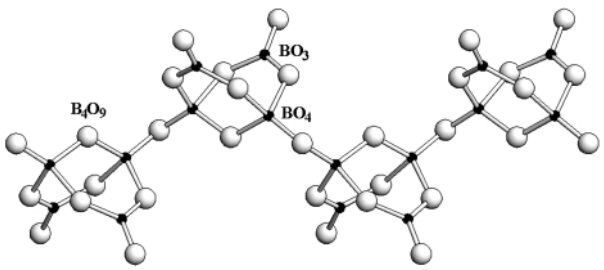

Fig. 2 One-dimensional chain formed by B_4O_9 groups in the structure of GdB_5O_9.

† Electronic supplementary information (ESI) available: crystallographic, TGA/DTA, IR and XRD profile fits for $H_3GdB_6O_{12}$ and GdB_5O_9. See http://www.rsc.org/suppdata/cc/b1/b102045p/

 DOI: 10.1039/b102045p

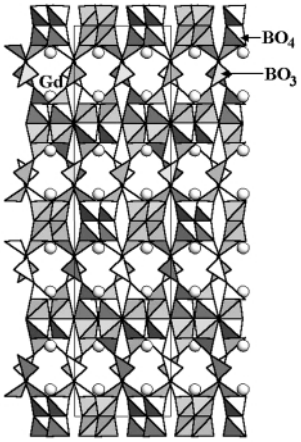

Fig. 3 A projection of the crystal structure of GdB_5O_9 (**2**); triangles and tetrahedra represent BO_3 and BO_4 groups.

In summary, although polyborate is an important resource for functional materials, such as nonlinear optical and luminescent materials, our knowledge of rare earth polyborates was limited due to the instability of these phases at high temperatures. In this communication, we have demonstrated that careful dehydration of a hydrated rare earth polyborate may lead to the anhydrous rare earth polyborate. We believe that the proposed preparative strategy will be very useful in exploiting new polyborate materials for rare earth systems.

We are grateful for the financial support from NSFC (29731010), Rhodia Rare Earth Co. and State Key Basic Research Program of China.

8 The X-ray powder diffraction pattern was collected for $H_3GdB_6O_{12}$ (**1**) on a Rigaku D/max-2000 diffractometer and indexed by using TEROR90.[10] $H_3GdB_6O_{12}$ crystallizes in a rhombohedral system with lattice constants a = 8.4076(2) and c = 20.7427(5) Å. The systematic absences of reflections indicated that the space group is either $R3c$ or $R\bar{3}$. Optimal estimates of the individual reflection intensities were extracted by a profile-fitting method using the EXTRA program.[11] The gadolinium positions in the structure were obtained by direct methods (Sirpow92[12]). The Rietveld refinement (GSAS)[13] and subsequent difference Fourier analysis identified the oxygen and boron positions. During the structure determination, both space groups $R3c$ and $R\bar{3}$were used, but only $R3c$ led to a chemically reasonable solution. The final refinement using the X-ray diffraction data in the range of 20–120° yielded R_p = 0.089 and R_{wp} = 0.115. The structure analysis was not able to locate the hydrogen atoms; the hydrogen component in **1** was estimated by charge balance of the compound, as well as the weight loss in TGA analysis.
9 The lattice constants of GdB_5O_9 (**2**) were established by using TREOR90.[10] **2** crystallizes in the tetragonal space group $I4_1/acd$ with lattice constants a = 8.2380(1), c = 33.6372(6) Å. Similar to **1**, the gadolinium positions were located by direct methods (Sirpow92[12]); subsequent Rietveld refinement and different Fourier analysis revealed the oxygen and boron positions. The final refinement yielded R_p = 0.069 and R_{wp} = 0.098.

First published as an Advance Article on the web 8th June 2001

Unit cell parameters and space group symmetry have been determined for the two main phases of the MoVTeNbO catalysts; models of their structures are proposed based on electron micrographes, EDX data and comparison with other crystal structures.

New processes of production of acrylonitrile by ammoxidation of propane will be implemented on the industrial scale in the coming years.[1] Two catalytic systems, AlVSbWO and MoV-TeNbO have been shown to be effective and will most likely be used. The former has been extensively described in the literature whereas the latter has mostly been covered in the patent literature.[1–4]

The presence in the MoVTeNbO catalyst of two major phases, denoted M1 and M2, has been shown to be key to obtain high yields.[5] Very little is known about these phases whose presence has been verified almost exclusively employing X-ray diffraction. The role of these phases remains under debate mainly because none of these phases have been synthesised and studied independently.

We have synthesised a MoVTeNbO catalyst using a method described in the literature[5] and characterised it by electron microscopy and X-ray diffraction. The catalyst was prepared from an aqueous slurry comprising Mo, V, Te and Nb in the ratios Mo:V:Te:Nb = 1:0.33:0.22:0.11, ratios most frequently reported in patent examples. The slurry was evaporated to dryness at 423 K and successively calcined at 573 K under air and 873 K under nitrogen for 2 h.

Powder X-ray diffraction patterns were obtained using a Siemens D5005 diffractometer and Cu-Kα radiation. They were recorded with 0.02° (2θ) steps over the angular range 3–88° with 16 s counting time per step. High-resolution electron microscopy was performed with a JEM 2010 (C_s = 0.5 mm). The accelerating voltage was 200 kV with a LaB_6 emission current, a point resolution of 0.195 nm and a useful limit of information of 0.14 nm. The instrument was equipped with an EDS LINK-ISIS (spatial resolution: 1 nm). An EDX study was conducted using a probe size of 25 nm to analyse isolated grains of the phases and avoid simultaneous analysis of grains of the two phases. Standard deviations were evaluated for atomic ratios from at least 20 analyses.

The X-ray diffraction pattern of the synthesised catalyst showed the sets of peaks reported in the literature for the two phases,[1] the more intense corresponding to the M2 phase. The electron diffraction spectra of the two phases have been indexed (Figs. 1 and 2). The M1 phase crystallises in the hexagonal system with possible space groups *P*6*mm*, *P*$\bar{6}$*m*2, *P*622 or *P*6/*mmm* while phase M2 crystallises in the orthorhombic system. Extinction conditions observed for the latter are only compatible with the space group $P2_12_12$. The data obtained by electron microscopy made it possible to index the X-ray diffraction powder pattern of the phase mixture and to refine the cell parameters of the phases. The cell parameters of the M1 and M2 phases are, respectively, a = 2.61(2), c = 0.403(1) nm and a = 2.1207(8)(3), b = 2.6831(1) and c = 0.8047(4) nm.

The structure of M1 is isomorphous to that of the phase $Sb_{0.4}MoO_{3.1}$ reported by Parmentier *et al.*[6] and corresponds to a hexagonal tungsten bronze structure.[7] Although the structure is only partial; it can be schematized as shown in Fig. 3. Tellurium occupies the sites in the channels formed by the MO_6

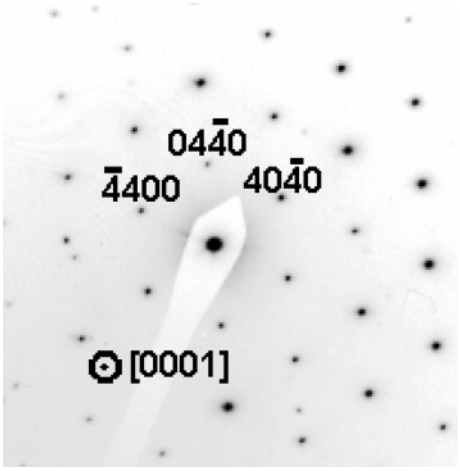

Fig. 1 Indexed electron diffraction pattern of the phase M1.

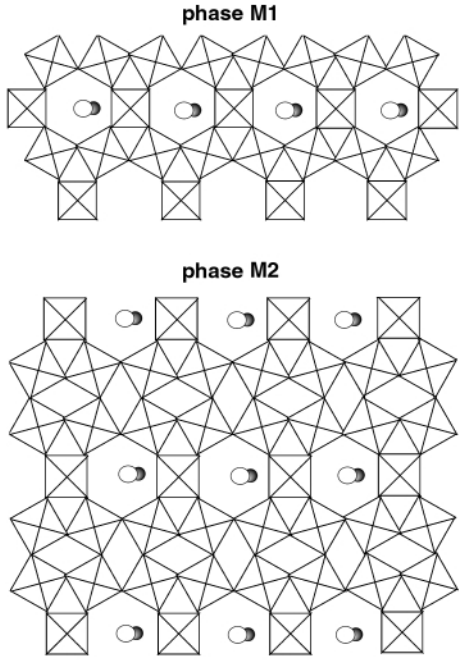

Fig. 3 Representation of the structures of the phases M1 and M2 along the *c* axis.

octahedra (M = Mo, V, Nb). In the case of the antimony bronze, it was proposed that Sb partially occupies the M sites which was not possible with Te, due to steric hindrance. Consequently the stoichiometry of the M1 phase should correspond to $Te_{0.33}MO_3$. Such stoichiometry is in accord with that calculated from EDX analyses (Table 1).

Table 1 EDX analyses of the two phases; standard deviations are given in parentheses

Phase	Te/Mo	V/Mo	Nb/Mo	Te/(Mo + V + Nb)	(Te + Nb)/(Mo + V)
M1	0.32(2)	0.30(2)	0.07(1)	0.23(4)	
M2	0.11(2)	0.23(2)	0.14(5)	0.08(4)	0.20(4)

The structure of M2 shows similarities with those of $TeMo_5O_{16}$ and $Sb_2Mo_{10}O_{31}$ (Table 2) and should present the atomic arrangement of $TeMo_5O_{16}$ (Fig. 3). A lattice image of the phase M2 taken with the incident beam parallel to the *b* axis shows an array of intense fringes having a separation of 1.04 nm (*i.e.* half of the *a* parameter) with in between streaks forming two less intense lines (Fig. 4). These fringes can respectively be attributed to the planes containing tellurium and molybdenum cations and molybdenum cations, as they appear in the structure model of $TeMo_5O_{16}$. The *a* parameters of the two phases (M2 and $TeMo_5O_{16}$) are quite similar, the *c* parameter of the former corresponds to twice that of the latter and the *b* parameter is *ca*. four times larger. These features could be related to a more

Table 2 Comparison of the unit cell parameters of the phase M2, $Sb_2Mo_{10}O_{31}$ and $TeMo_5O_{16}$

Phase	*a*/nm	*b*/nm	*c*/nm	Space group	Ref.
M2	2.1207(3)	2.6831(1)	0.8047(4)	$P2_12_12$	This study
$Sb_2Mo_{10}O_{31}$	2.023(1)	0.809(1)	0.717(1)	*Pma*2	8
$TeMo_5O_{16}$	2.0010(1)	0.72254(4)	0.40650(2)	*Pma*/2	9

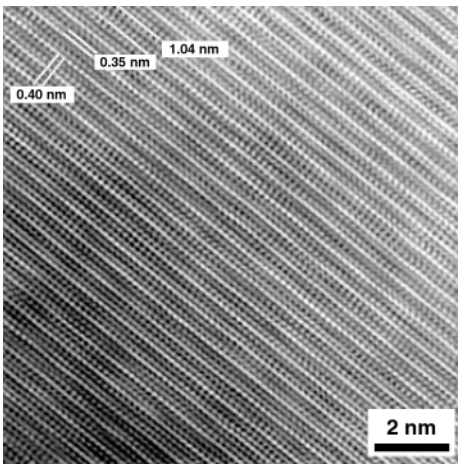

Fig. 4 High-resolution transmission electron imaging of the phase M2.

complex chemical composition of the M2 phase. Such a complex chemical composition should result from both the high degree of substitution of the molybdenum cations by the smaller vanadium cations and a possible ordering of the M cations on the sites. These features may also be due to the possible intergrowth of M2 and M1 structures as proposed earlier for $TeMo_5O_{16}$.[10] The stoichiometry of the phase M2 should correspond to $Te_{0.2}MO_{3.2}$ (with M = Mo, V and Nb). The stoichiometry calculated from EDX data with 0.08 Te per M cation does not agree well with this stoichiometry. It may be possible that niobium, which is in a larger amount in this phase, partially occupies the hexagonal window sites. The sub-stoichiometry in oxygen observed in the case of antimony is due to the absence of infinite chains $[Te–O]_\infty$ in the [001] direction caused by a different orientation of the free electron pairs. This limits to three instead of four the number of oxygens neighboring the Sb cation. The presence of infinite chains could be an important parameter in the formation of this structure and explain the difficulties encountered when preparing the same catalysts with antimony in place of tellurium.

From the data generated from this study, the structures of the two phases can be described on the basis of two closely related stacking models. These models are built up from simple or double sheets of MO_6 (M = Mo, V, Nb) separated by rows of hexagonal windows occupied by tellurium cations (Fig. 3). These structures correspond to the same general formula $Te[MO_3]_{2n+1}$ with $n = 1$ for M1 and $n = 2$ for M2. This feature should explain why the two phases are systematically formed concomitantly.

First published as an Advance Article on the web 13th June 2001

A [2]catenane consisting of 41-membered interlocking rings is formed quantitatively, following a two metal based [Cu(I) and Pd(II)] strategy; the compound is obtained as the thermodynamic product.

Catenanes are experiencing a spectacular revival in relation to topology as well as switches, machines and motors at the molecular level.[1–4] Copper(I) has been extensively used as templating metal centre, allowing the preparation of simple to complex interlocking or knotted topologies.[5] The use of coordination bonds to construct interlocking rings has been recently proposed.[6,7] It is especially attractive when the metal-to-ligand bond is labile and the catenane is obtained as the thermodynamically most stable product, thus leading to quantitative yields of the desired species. In this respect, palladium(II) has turned out to be particularly well adapted.[6]

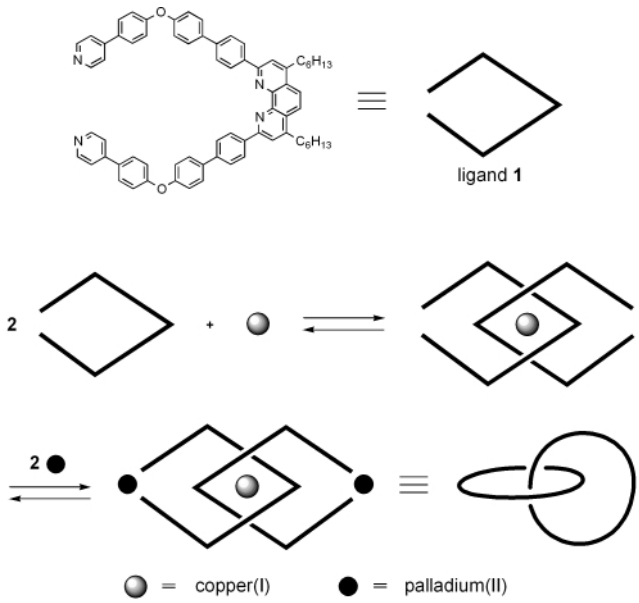
By combining copper(I) and palladium(II) in the same assembly, it has been possible to make a doubly-interlocking molecule, *i.e.* a 4-crossing [2]catenane.[8] This unexpected structure was obtained because the organic ligand used was too short to afford a ring incorporating a single palladium(II) atom.

We would now like to report that, by utilising a sufficiently large bridging ligand, quantitative formation of a [2]catenane was observed. The strategy is depicted in Scheme 1.

According to CPK models, ligand **1** is perfectly adapted to the strategy of Scheme 1. **1** is relatively rigid, and, in particular, the distance between the two oxygen atoms of **1** is more or less fixed and does not depend on rotation about C–C bonds (O···O ~16 Å). After coordination of $enPd^{2+}$ (en = 1,2-diaminoethane) two interlocking 41-membered rings are obtained. The size of the palladium(II) containing cycles is such that the final [2]catenane should not be strained, even if one considers that solubilizing groups (C_6H_{13}) have been attached at the back of the phen units.

The real reactions are represented in Fig. 1. Ligand **1** was obtained by a double Ullmann coupling reaction[9] between 4,7-di-*n*-hexyl-2,9-bis[4-(4-hydroxyphenyl)phenyl]-1,10-phenanthroline[10] and 4-(4-bromophenyl)pyridine.[11] The latter reaction was performed in refluxing toluene in the presence of Cs_2CO_3 and excess $Cu(CH_3CN)_4{\cdot}PF_6$ over 3 days. After demetallation of the crude reaction mixture with KCN and purification by chromatography over silica gel, **1** was obtained in 10% yield as a pale yellow glass. It could be fully characterized by ^1H NMR and mass spectroscopy.

The reaction of **1** (0.010 mmol) and $Cu(CH_3CN)_4{\cdot}PF_6$ (0.005 mmol) in MeCN–DMF (1:1) solution (1 ml), immediately afforded **2**, which is the precursor to catenane **3**. To this solution, $enPd(NO_3)_2$ (0.010 mmol) was added and the reaction was stirred for 1 h at rt. In solution, **3** was obtained quantitatively. It was isolated in 85% yield as a red micro-



Scheme 1 Ligand **1** can be regarded as an open lozenge. The 1,10-phenanthroline (phen) site reacts with copper(I) to afford an entwined complex. Cyclisation is carried out by completing the two interlocking lozenges, the 'clipping' metal being palladium(II).

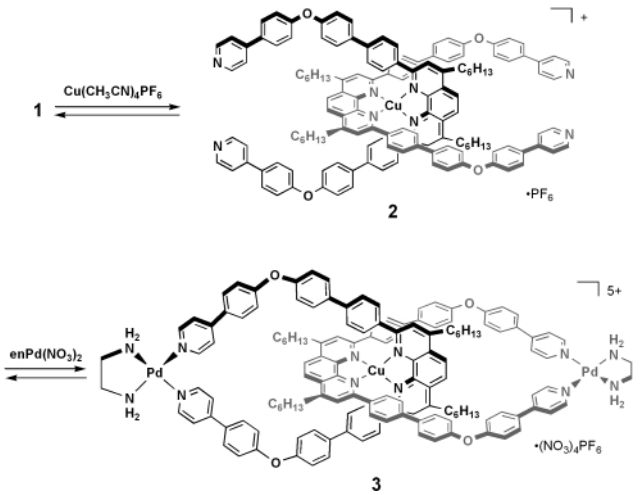


Fig. 1 Quantitative formation of catenane **3** in two steps from **1**, by successive addition of Cu(I) and Pd(II).

 DOI: 10.1039/b102373j

crystalline solid by addition of diethyl ether. **2** and **3** are formed as thermodynamic products since copper(I) complexes and, especially palladium(II) compounds are substitutionally labile.

The formation of **2** and **3** as single products was confirmed by both ^{1}H NMR and CSI-MS (Cold Electro Spray Ionization Mass Spectroscopy).[12] The ^{1}H NMR spectrum of **2** in CD_3CN–DMF-d_7 solution showed the expected signals for the aromatic protons, in accordance with the symmetric structure of **2**, except for the protons borne by the two pyridine nuclei which are probably too broad to lead to clear signals. CSI-MS of **2** in MeCN–DMF solution showed a prominent peak at *m/z* 2046, $[M\text{-}(PF_6)]^+$.

The ^{1}H NMR spectrum of **3** in CD_3CN–DMF-d_7 is also in agreement with its structure. The chemical shifts of the peaks are slightly different from those of **2**. Not surprisingly, the pyridinic protons α to the Pd(II)-coordinated N atoms appear at low field (δ = 9.67). CSI-MS of **3** in CH_3CN–DMF solution at 20 mM concentration showed predominant peaks for $[M\text{-}(PF_6)\text{-}(NO_3)_n]^{(n+1)+}\cdot(dmf)_m$: *e.g. m/z* 548, $[M\text{-}(PF_6)\text{-}(NO_3)_4]^{5+}\cdot(dmf)_5$; 646, $[M\text{-}(PF_6)\text{-}(NO_3)_3]^{4+}\cdot(dmf)_2$; 834, $[M\text{-}(PF_6)\text{-}(NO_3)_2]^{3+}$. Interestingly, **3** is obtained quantitatively, regardless of the concentration of **2** and $enPd(NO_3)_2$. This is in contrast with other previous examples for which catenane dissociation to simple rings was observed at low concentration.[13] In MeCN–DMF, **3** does not dissociate over the concentration range investigated (0.005 to 20 mM). This particularly high stability suggests that no dissociation takes place during the MS measurements. It is probably due to the excellent fit of the ligand to coordination of Pd(II) and especially to the appropriate length of the 4 sides of the constitutive 'lozenges' of **3**.

The results presented in this work together with those discussed in reference 8 (synthesis of a 4-crossing [2]catenane) highlight the utmost importance of the nature of the ligands used in directed syntheses involving both copper(I) and palladium(II) coordination. The balance between the structural parameters (length, angles, flexibility, steric hindrance) of the ligands and stereoelectronic requirements of both metals clearly appears highly crucial and narrow, therefore dictating irrevocably the very nature of the molecular assembly generated by means of such methodology.

We thank the CNRS for its financial support.

Unique structural isomerism involving tetrazole and amide/azide derivatives of gallium

Ned J. Hardman and Philip P. Power*

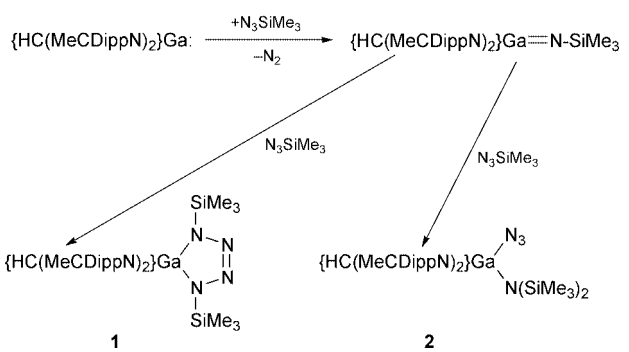
Department of Chemistry, University of California, Davis, One Shields Avenue, Davis, CA, 95616, USA. E-mail: pppower@ucdavis.edu

Received (in Irvine, CA, USA) 1st January 2001, Accepted 3rd May 2001
First published as an Advance Article on the web 13th June 2001

The reaction between {HC(MeCDippN)$_2$}Ga: (Dipp = C$_6$H$_3$Pr$^i_2$-2,6) and N$_3$SiMe$_3$ afforded the tetrazole {HC(MeCDippN)$_2$}GaN(SiMe$_3$)NNN(SiMe$_3$) 1 and its amide/azide isomer {HC(MeCDippN)$_2$}Ga(N$_3$)N(SiMe$_3$)$_2$ 2 whose stabilities are due to the unique steric properties of the [HC(MeCDippN)$_2$]$^-$ ligand.

Recent investigations of derivatives of the sterically encumbered β-diketiminate ligand [HC(MeCDippN)$_2$]$^-$ (Dipp = C$_6$H$_3$Pr$^i_2$-2,6) have shown that it can stabilize a wide variety of species with unusual coordination numbers and bonding throughout the Periodic Table.[1] In particular, its use in connection with low-valent heavier group 13 elements has resulted in the isolation of the monomeric, two-coordinate M(I) species {HC(MeCDippN)$_2$}M: (M = Al[2] or Ga[3]) which contain a stereochemically active lone pair of electrons at the metals. Previous work on less hindered, weakly associated M(I) species such as Cp*M (Cp* = C$_5$Me$_5$; M = Al[4] or Ga[5]) has shown that they can react with azides to give dimeric imides such as Cp*AlN(AlCp*$_2$)Al{N(SiMe$_3$)$_2$}N{Al(Cp*)N(SiMe$_3$)$_2$}[6] or {Cp*GaN(C$_6$H$_3$Me$_2$-2,6)}$_2$[7] under elimination of N$_2$. We reasoned that the more crowded Ga(I) species {HC(MeCDippN)$_2$}Ga: might react with the simple azide N$_3$SiMe$_3$ to afford a monomeric imide {HC(MeCDippN)$_2$}Ga=NSiMe$_3$ which could have a GaN multiple bond. We now report that, although unassociated products were obtained from this reaction, neither of these involved a terminal gallium imide moiety. Instead, the isomers **1** and **2**, involving the reaction of 2 equivalents of N$_3$SiMe$_3$ with {HC(MeCDippN)$_2$}Ga:, were isolated and characterized.

The reaction of {HC(MeCDippN)$_2$}Ga: with N$_3$SiMe$_3$ afforded the products **1** and **2** in accordance with Scheme 1.† It is probable that the species {HC(MeCDippN)$_2$}GaNSiMe$_3$ is generated initally, and this is prevented from dimerizing to give [{HC(MeCDippN)$_2$}GaNSiMe$_3$]$_2$ for steric reasons. Instead, {HC(MeCDippN)$_2$}GaNSiMe$_3$ reacts with a further equivalent of N$_3$SiMe$_3$ to give the tetrazole **1**‡ and the amide/azide product **2**. Solution ^{1}H NMR spectroscopy of the reaction mixture shows that both **1** and **2** as well as unreacted {HC(MeCDippN)$_2$}Ga: and N$_3$SiMe$_3$ are detectable after stirring for 30 min at *ca*. 25 °C. Heating at *ca*. 75 °C results in a *ca.* 1:3 ratio of **1** and **2** which can be isolated in 73% overall yield. Both **1** and **2** were obtained as colorless crystals. However, the solubility of the tetrazole **1** is considerably less than that of **2**, so that the products can be separated quite easily by crystallization. The compound **1** is thermally robust having a melting point > 200 °C. It decomposes at *ca.* 235 °C to a red solid with N$_2$ elimination. Compound **2** melts at a lower temperature (161–163 °C) and also decomposes at *ca*. 230 °C to give a red solid and N$_2$ evolution.§



Scheme 1 Reactions of {HC(MeCDippN)$_2$}Ga: (Dipp = C$_6$H$_3$Pr$^i_2$-2,6) with N$_3$SiMe$_3$ to give **1** or **2**.

Compounds **1** and **2** were characterized by ^{1}H and ^{13}C NMR spectroscopy, by C,H,N analysis and by X-ray crystallography.¶ The structure of the tetrazole **1** (Fig. 1) features GaN$_4$ and GaN$_2$C$_3$ rings that are fused at gallium. The metal has distorted tetrahedral geometry and the Ga–N bonds [av. 1.947(2) Å] to the β-diketiminate nitrogens N(1) and N(2) are significantly longer than the average distance of 1.875(16) Å to the tetrazole nitrogens. The longer pair of Ga–N distances is consistent with equal components of normal and dative character in these bonds.[8] These Ga–N bond lengths also resemble those observed in other Ga(III) β-ketiminate species.[9] The shorter Ga–N distances involving the tetrazole nitrogens are in agreement with known values for bonding between four-coordinate gallium and terminal amide groups.[10] The gallium tetrazole ring is essentially planar, and the N(4)–N(5) distance of 1.265(3) Å is consistent with NN double bonding. In contrast, the gallium β-diketiminate ring is folded along the N(1)···N(2) axis such that Ga(I) lies *ca.* 0.34 Å from the averaged N$_2$C$_3$ plane. This structural feature is common to many bulky β-diketiminate derivatives.[1] The folding of the ring results in different magnetic environments for the two SiMe$_3$ groups (as well as slightly different bond lengths for Ga–N(3) and Ga–N(6)) which is manifested in different ^{1}H NMR chemical shifts for the SiMe$_3$ resonances.

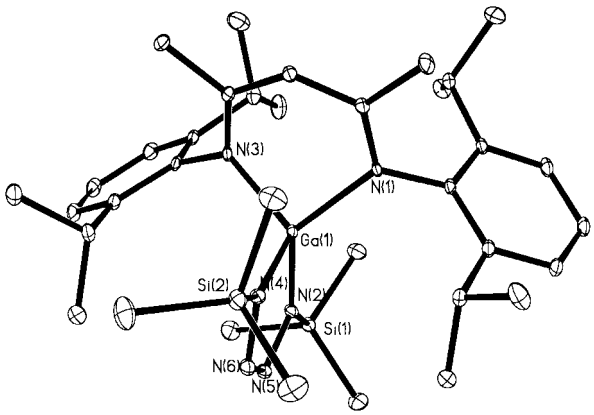


Fig. 1 Thermal ellipsoid (30%) plot of **1** with H atoms not shown. Selected bond distances (Å) and angles (°): Ga(1)–N(1) 1.945(2), Ga(1)–N(2) 1.949(2), Ga(1)–N(3) 1.858(2), Ga(1)–N(6) 1.891(2), N(3)–N(4) 1.402(3), N(4)–N(5) 1.265(3), N(5)–N(6) 1.406(2), Si(1)–N(3) 1.737(2), Si(2)–N(6) 1.750(2); N(1)–Ga(1)–N(2) 95.40(8), N(3)–Ga(1)–N(6) 85.74(7), N(1)–Ga(1)–N(6) 117.49(8), N(2)–Ga(1)–N(6) 115.64(8), N(1)–Ga(1)–N(3) 126.41(8), N(2)–Ga(1)–N(3) 118.11(8).

 DOI: 10.1039/b100466m

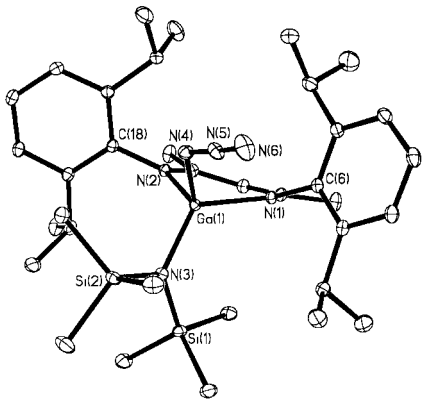

Fig. 2 Thermal ellipsoid (30%) plot of **2** with H atoms not shown. Selected bond distances (Å) and angles (°): Ga(1)–N(1) 1.946(1), Ga(1)–N(2) 1.958(1), Ga(1)–N(3) 1.884(1), Ga(1)–N(4) 1.918(1), Si(1)–N(3) 1.746(1), Si(2)–N(3) 1.751(1); N(1)–Ga(1)–N(2) 98.28(5), N(3)–Ga(1)–N(4) 111.82(6), N(1)–Ga(1)–N(3) 122.45(5), N(2)–Ga(1)–N(3) 113.23(5), Ga(1)–N(3)–Si(1) 123.39(7), Ga(1)–N(3)–Si(2) 115.32(7).

The structure of amide/azide compound **2** (Fig. 2) also features gallium bound to four nitrogens in a distorted tetrahedral fashion. The Ga–N(β-diketiminate) bonds [av. 1.952(7) Å] have very similar lengths to the corresponding bonds in **1**. The β-diketiminate ring is folded along the N(1)···N(2) axis such that Ga(I) lies *ca.* 0.21 Å from the averaged N_2C_3 plane. The Ga–N($SiMe_3$)$_2$ bond length [1.884(1) Å] is close to the 1.872(2) Å reported for {Cp*{(Me_3-Si)$_2$N}Ga(μ-N_3)}$_2$.[7] The Ga–N(azide) bond length, 1.918(3) Å, is essentially the same as the 1.921(4) Å observed in a bulky aryl-substituted bis(azide) of gallium.[11] Within the N_3 moiety, the N–N distances are similar to those previously observed in gallium azides.[12] Like **1**, compound **2** displays two different resonances for the $SiMe_3$ peaks—probably due to restricted rotation of the amide moiety around the Ga–N bond as a result of steric effects. Rotational barriers as high as 18.6 kcal mol^{-1} have been observed for group 13 metal–nitrogen bonds in sterically congested systems.[13] Variable temperature ^{1}H NMR studies of **1** or **2** in toluene did not result in the collapse of the $SiMe_3$ signals to a single resonance.

The isolation of tetrazole–amide/azide isomers appears to be unique.‖[14] Their stability can be rationalized on the basis of the size of the [HC(MeCDippN)$_2$]$^-$ ligand which prevents dimerization of the intermediate {HC(MeCDippN)$_2$}GaNSiMe_3, but allows reaction with a further equivalent of the less hindered N_3SiMe_3. Owing to the multipolar nature of the NNNSi array, this reaction proceeds by two distinct pathways to afford **1** and **2**.

We thank the National Science Foundation for Financial Support.

‡ Professor H. W. Roesky has informed us that a similar reaction involving {HC(MeCDippN)$_2$}Al: and N_3SiMe_3 affords the aluminium analog of **1**. The contrasting behavior of the gallium system, with its preference for the amide/azide over the tetrazole product, is another illustration of the differences between aluminium and gallium chemistry.

§ Attempts at thermal interconversion of **1** and **2** have so far been unsuccessful.

Ethylene oligomerisation in ionic liquids gives predominately alk-1-ene products with better reactivity and selectivity than in conventional solvents; turnover frequencies are correlated with polarity data obtained using solvatochromic dyes.

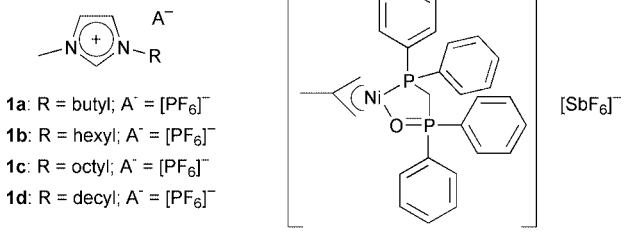
Ionic liquids are salts/salt mixtures with melting points below ambient temperature. The first use of ionic liquids in homogeneous catalysis was reported in 1990 for dimerisation[1] and polymerisation[2] reactions. Since then, a rapidly growing number of transition metal catalysed reactions have been described in various ionic liquids (for general reviews see ref. 3). Several papers describing the oligomerisation of ethylene and higher olefins in ionic liquids have been published.[1,4] However, all work described to date has used chloroaluminate ionic liquids, giving a high degree of isomerisation, and the formation of mainly internal olefins. For example, 9% of but-1-ene, but 91% of but-2-enes are obtained in the C_4-fraction from the reaction of ethylene with $[Ni(MeCN)_6][BF_4]_2$ in chloroaluminate ionic liquid at room temperature.[4c]

Higher α-olefins (HAOs) represent an important group of industrial chemicals. Depending on chain length, they are used as intermediates for plastics, plasticizers, lubricants and surfactants. HAOs can be obtained from ethylene *via* oligomerisation processes, such as those practised by BP Amoco (alkylaluminium catalyst) and Shell (SHOP, neutral nickel/phosphine catalyst). The latter is a biphasic process, the catalyst being dissolved in butane-1,4-diol, and the products forming a second layer easily removed by phase separation.

Besides the neutral nickel/phosphine compounds used in SHOP, cationic Ni complexes have attracted some attention as highly active catalysts for ethylene oligomerisation.[5] The positive charge means that they usually possess a more electrophilic Ni centre, often resulting in higher oligomerisation activity. To our knowledge, no example of biphasic ethylene oligomerisation to HAOs with cationic Ni complexes could be realised to date owing to the lack of a suitable solvent for the catalyst.

Here, we report the use of ionic liquids **1a**–**d** as catalyst solvents in the biphasic oligomerisation of ethylene to higher α-olefins using the cationic Ni catalyst **2**.[5a] Ionic liquids **1a**–**d** were synthesised by reacting the appropriate chloride salt[6] with HPF_6, following a method described by Fuller *et al.*,[7] or purchased from Solvent Innovation GmbH, Cologne, Germany.[8] It was important that the liquids were completely free of water and chloride ions for **2** to exhibit good activity. The catalytic experiments were carried out under a constant pressure of ethylene in a 150 ml autoclave specially designed for biphasic ethylene oligomerisation (four paddles, stirrer with special gas inlet, baffles).

Catalyst **2** is found to be highly active in ionic liquid **1a**, selectively forming HAOs *via* a biphasic reaction (Table 1, entry 1). The products separated as a clear and colorless organic layer from the ionic catalyst solution after reaction (catalyst leaching being < 0.1% (detection limit)), with high selectivity for linear alk-1-enes. Previously, internal isomers have been the major components in reactions of this type.[4] The ionic catalyst solution was recyclable with little change in selectivity, although with somewhat lower activity (Table 1, entries 2 and 3). Since catalyst **2** is very sensitive to traces of water, the deactivation may be assigned to the practical problem of quantitative transfer back into the autoclave under completely inert conditions. In contrast, almost no ethylene conversion was observed in butane-1,4-diol, presumably due to catalyst deactivation (Table 1, entry 4). Butane-1,4-diol was chosen since this solvent is used successfully in biphasic reactions with neutral Ni complexes (*e.g.* SHOP). Following these observations, we decided to investigate the polarity and coordination properties of **1a** in comparison to butane-1,4-diol.



1a: R = butyl; A⁻ = $[PF_6]^-$
1b: R = hexyl; A⁻ = $[PF_6]^-$
1c: R = octyl; A⁻ = $[PF_6]^-$
1d: R = decyl; A⁻ = $[PF_6]^-$

Solvatochromic dyes have been widely used to help quantify solute–solvent interactions.[9] Many different scales exist, but most probe only particular interactions of a given solvent. Defining the 'polarity' of ionic liquids is made difficult by the wide range of interactions possible within systems like **1a**. The

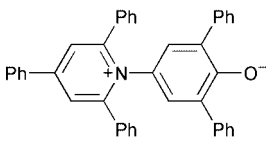
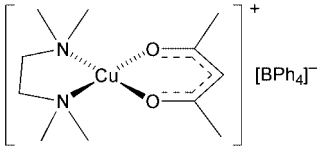
few studies reported to date suggest that ionic liquids are low dielectric materials,[10] whose apparent 'polarity' depends on the probe molecule employed.[11]

One of the most widely quoted scales of solvent polarity is the E_T scale, based on the position of the charge transfer band of betaine dyes such as **3**.[9] This molecule displays an extremely large wavelength shift in its charge-transfer band between non-polar solvents (λ_{max} = 810 nm for Ph_2O) and polar solvents (λ_{max} = 453 nm for H_2O). The position of the CT band is most strongly influenced by specific interactions with the highly basic phenoxide oxygen atom.[12] When **3** is dissolved in **1a** (*ca.* 1 mM), which had been dried under vacuum at 70 °C for several hours, λ_{max} = 547 nm [$E_T(30)$ = 52.3 kcal mol^{-1}],† approximately the same as that obtained for butane-1,4-diol [$E_T(30)$ = 53.5 kcal mol^{-1}]. Karl–Fischer titration measurements indicated a water content of *ca.* 6.0×10^{-3} M in the dried **1a**. It was found that extended drying and different concentrations of **3** resulted in no further change in the value of $E_T(30)$. Clearly the residual water may have some influence on the recorded value of $E_T(30)$, given the similar concentrations of probe molecule and water, but it is likely that removal of all traces of water will be impossible in any synthetic applications. By way of contrast, for undried [bmim][PF_6] (water content *ca.* 0.15 M), λ_{max} = 541 nm [$E_T(30)$ = 52.9 kcal mol^{-1}]. With regard to this polarity scale, **1a** can be regarded as behaving similarly to alcohols, possibly as a result of specific interactions between the hydrogen atoms on the imidazolium ring and the phenoxide oxygen. Thus, these results give no explanation for the difference in ethylene oligomerisation activity between **1a** and butane-1,4-diol.



3



4

Since catalyst activity is most likely to be affected by the solvent basicity, we decided to probe this parameter using **4**, a complex whose d–d absorption band shifts to longer wavelengths as the degree of solvent coordination at the copper atom increases. A relationship has been reported between λ_{max} and the Gutmann donor number of the solvent, allowing **4** to be used as a measure of solvent and anionic basicity.[13]

When **4** is dissolved in dried **1a** ([**4**] = 10–50 mM), λ_{max} = 516.5 nm, while λ_{max} = 598.0 nm for butane-1,4-diol indicating much stronger coordination of the latter to the Cu(II) centre. The same probe in undried **1a** (water content *ca.* 0.15 M) gave a λ_{max} value of 535 nm, suggesting that the presence of water has a more significant effect than is the case for probe **3**. Thus, we conclude that the beneficial properties of **1a** with regard to the ethylene oligomerisation with catalyst **2** can be explained, at least in part, by a unique combination of high polarity and low coordination power displayed by this ionic liquid.

Our data suggested that the coordination strength of **1a** is only slightly higher than that of CH_2Cl_2. Consequently, we applied this solvent to the ethylene oligomerisation reaction with catalyst **2**. In CH_2Cl_2, the reaction is monophasic, thus preventing simple product recovery by phase separation (Table 1, entry 5). More importantly, a comparison with entry 1 reveals a much higher activity of **2** in the ionic liquid. Bearing in mind the similar λ_{max} values, this result seems to be somewhat surprising at first.

Therefore, a comparison of **1a** with other [PF_6]$^-$-based ionic liquids **1b**–**d** was carried out. As expected, measurements with **3** reveal a slight decrease in polarity on increasing alkyl chain length at the imidazolium cation [λ_{max} = 557 nm, $E_T(30)$ = 51.3 kcal mol^{-1} for dried **1c**]. In contrast, **4** displays effectively identical λ_{max}-values for the series **1a**–**d** (λ_{max} = 516.5 nm for dried **1c**), indicating that the strength of interaction at the metal centre is purely anion dependent. All ethylene oligomerisation experiments with catalyst **2** in **1b**–**d** showed enhanced activity compared to the reaction in CH_2Cl_2, but decreasing activity was observed with increasing alkyl chain length at the imidazolium cation. We suggest that weak coordination of the solvent to **2** is a prerequisite for catalytic activity, but is clearly not the only factor to explain the special usefulness of **1a** in this reaction. The greater reactivity may be explained by inhibition of the cationic Ni catalyst **2** by the oligomers formed. This would explain why the oligomerisation activity is reduced by both a monophasic reaction (*e.g.* CH_2Cl_2) and increasing solubility of the products in the catalyst solvent (*e.g.* **1b**–**d**).

Remarkably, the oligomer distribution also shows a strong solvent dependence. The lower α-value of the Schulz–Flory distribution shows that the yield of low molecular weight HAOs is much higher for biphasic reactions in **1a**–**d** than for the reaction in CH_2Cl_2. This observation may be explained by the lower ethylene solubility (25 °C/50 bar) in *e.g.* **1a** (0.110 g ethylene/g **1a**) and **1c** (0.183 g ethylene/g **1c)** compared with CH_2Cl_2 (0.651 g ethylene/g CH_2Cl_2).[14] Since the rate of insertion (k_{ins}) is dependent on the ethylene concentration, while the rate of elimination (k_{elim}) is not, a solvent with lower ethylene solubility shifts the ratio k_{ins}/k_{elim} to lower values since it decreases the relative ethylene concentration at the catalyst.

In conclusion, we believe that our results are of general importance, since many cationic transition metal complexes are excellent catalysts, but are often poorly soluble in non-polar solvents, thus requiring a compromise between the solvation and coordination properties of a solvent. Our investigations clearly show that hexafluorophosphate ionic liquids are very interesting solvents for these applications. We propose to pursue these investigations, and will report our findings in due course.

P. W. and C. H. thank Professor Wilhelm Keim for his continuous interest in this research and many inspiring discussions, and C. M. G. thanks the Royal Society of Edinburgh for funding, and the EPSRC (Grant no. GR/M56852) for a research studentship.

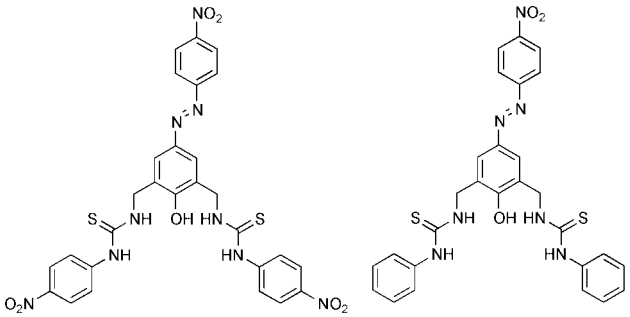
A new anion sensor 1 with an azophenol and *p*-nitrophenyl moieties as chromophores allows for easy colorimetric differentiation of F^-, $H_2PO_4^-$ and AcO^- with similar basicity.

Currently, the development of receptors for biologically important anions is emerging as a research area of great importance.[1] One of the more attractive approaches in this field involves the construction of chemosensors.[2–4] This kind of system is generally composed of two parts. One is the anion-binding part employing various combinations of pyrroles, guanidiniums, Lewis acids, amides and urea/thioureas.[1–5] The other is the chromophore which turns binding-induced changes into optical signals.[2–4] These two parts are either covalently attached[4] or intermolecularly linked.[2a,b,3] Previously, we presented a new chromogenic azophenol–thiourea based anion sensor which allows for the colorimetric detection of F^-, $H_2PO_4^-$ and AcO^-.[6] However, this system is not able to discriminate between $H_2PO_4^-$, AcO^- and F^-.



1 **2**

We now present a dual-chromophore anion sensor **1** with *p*-nitrophenylazophenol[1a,7] and *p*-nitrophenylthiourea moieties as two different chromophores.[8] The anion recognition *via* hydrogen-bonding interactions can be easily monitored by anion-complexation induced changes in UV-vis absorption spectra and with the naked eye.

Synthesis of sensors **1** and **2** is described in the ESI†,[6,7,9a] **1** and **2** contain four thiourea NH groups as hydrogen-bonding donors for anions[9b] and one azophenol OH group as both an additional binding site and a color-monitoring unit.[6] In the case of **1**, the introduction of a *p*-nitrophenyl group to the thiourea moiety as another chromophore enables color differentiation of anions in a cooperative manner, along with an azophenol group upon anion binding. This approach brings together changes in λ_{max} of two chromophores to render colorimetric detection of anions more effective than with only one chromophore.

It turns out that the UV-vis absorption band of **1** in chloroform undergoes a red shift as a phosphate anion is bound. In the absence of anions, the spectrum of **1** is characterized by the presence of one absorption maximum at 339 nm. Upon addition of increasing amounts of $H_2PO_4^-$, the peak at 339 nm decreases while the new peaks gradually move to longer wavelengths finally reaching maximum values at 374 nm (due to a *p*-nitrophenyl group) and 538 nm (due to an azophenol group) (Fig. S1a). Complexation with a series of anions results in similar red shift tendencies. Clear isosbestic points are observed, which demonstrates the existence of two states of a 1:1 complex. As can be expected from the UV-vis data, color change occurs through addition of anions to the solution of **1**. Upon the addition of $H_2PO_4^-$, the color of the solution changes from light yellow to violet. The color change terminates after the addition of 40 equiv. of $H_2PO_4^-$. However, in the case of HSO_4^-, Cl^- and Br^-, no detectable color changes are observed upon excess addition of anions to the solution of **1**.

The qualitative changes explained above are reflected in the quantitative data in the UV-vis absorption experiment. In these chromophores, electronic excitation generally occurs through a charge transfer from the donor oxygen of the azophenol and donor nitrogen of the thiourea to the acceptor substituent ($-NO_2$) of each chromophore. Upon the complex formation of **1** with an anion, the excited state would be more strongly stabilized by anion binding, resulting in a bathochromic shift in λ_{max}.[8] The color discrimination comes from different λ_{max} values in each complex and the relative contribution of the two chromophores (Fig. 1).

The degree of a red shift for **1** was determined to be $H_2PO_4^- \gg AcO^- \approx F^- > Br^- \approx Cl^- > HSO_4^- \approx I^-$. The maximum red-shift value (λ_{max} = 538 nm) for $H_2PO_4^-$ can be understood on the basis of the guest basicity and structure of the complex. According to the basicity of anions,[9b,10] $H_2PO_4^-$, F^- and AcO^- give stronger complexes and thus show noticeable color changes compared to other anions. $H_2PO_4^-$ with four oxygens affects both chromophores *via* multitopic hydrogen bonds to give rise to a pronounced color change, while F^- and AcO^- have a relatively weaker effect on the *p*-nitrophenyl group with respect to inducing color changes. This enables color discrimination between $H_2PO_4^-$, F^- and AcO^-. In the case of sensor **2** with only an azophenol group as the chromophore, λ_{max} values upon complexation with $H_2PO_4^-$, F^- and AcO^- are similar

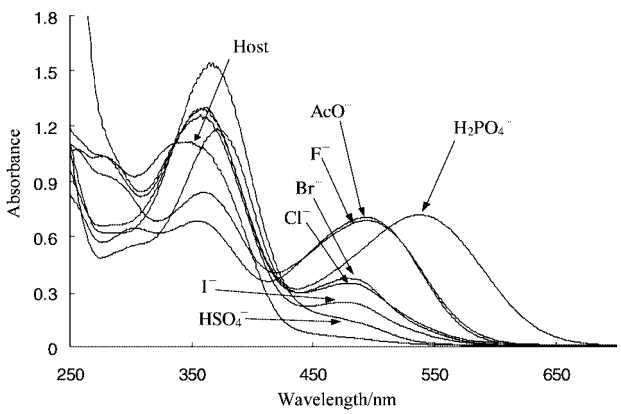


Fig. 1 UV-vis changes of **1** operated in $CHCl_3$ (5.0×10^{-5} M) after the addition of 40 equiv. of anions.

† Electronic supplementary information (ESI) available: experimental details for **1** and **2**, Figs. S1 and S2. See http://www.rsc.org/suppdata/cc/b1/b102187g/

 DOI: 10.1039/b102187g

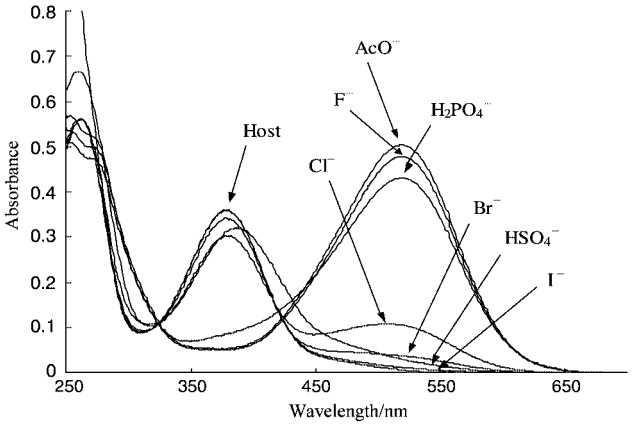

Fig. 2 UV-vis changes of **2** operated in $CHCl_3$ (1.5×10^{-5} M) after the addition of 40 equiv. of anions.

(Fig. S1b and Fig. 2) and thus the color differentiation between $H_2PO_4^-$, F^- and AcO^- is not feasible. This means that the cooperativity of dual-chromophores enables color discrimination of anions $H_2PO_4^-$, F^- and AcO^- with similiar basicity. Considering that an azophenol on its own does not exhibit color changes through addition of anions except for F^-,[11] this result indicates that the introduction of *p*-nitrophenylthiourea groups as an anion-binding site increases the electronic interaction between **1** and the anion, and furthermore results in color discrimination between $H_2PO_4^-$, F^- and AcO^-.

In summary, we have developed a new anion sensor **1** with azophenol and *p*-nitrophenyl moieties as two chromophores. This dual-chromophore system allows for colorimetric differentiation of $H_2PO_4^-$, F^- and AcO^- with similar basicity.

Received (in Cambridge, UK) 5th April 2001, Accepted 18th May 2001
First published as an Advance Article on the web 13th June 2001

The rate for adduct formation between *cis*-[Pt(NH$_3$)(c-NH$_2$C$_6$H$_{11}$)Cl(OH$_2$)]$^+$ and guanine-N7 in d(T$_n$GT$_{16-n}$) decreases gradually from the maximum rate found for platination of the middle position towards both the 3′ and 5′ ends.

Short DNA and RNA fragments are currently of great scientific interest. Modified DNA fragments have emerged as promising candidates for the treatment of both cancers and viral infections.[1] In addition, increasing knowledge about the nature of the interactions between metal ions or naturally occurring proteins and the surface of ribonucleic acids *in vivo* allows for detailed models system studies under well defined conditions *in vitro*.[2] The use of oligonucleotides, rather than extended ribonucleic acids for such studies is, however, likely to change the magnitude of the electrostatic interactions between the oligonucleotide surface and approaching charged or dipolar species.[3–8] A goal for current work in our laboratory is to increase the understanding of how the reduced electrostatic interactions of such model systems influence the overall adduct formation process with charged anticancer active metal complexes. We here present a study that allows for a unique comparison of the kinetic influence from the DNA environment during metalation of the non-charged guanine-N7, G-N7, with that of the previously studied charged phosphorothioate group, p(S).[9,10] The obtained reaction profile reveals a less pronounced kinetic influence from the surrounding DNA, which suggests the distance from the phosphodiester backbone as a parameter of influence on the adduct formation process.

The present study has been designed to obtain detailed information concerning the magnitude of the kinetic influence from the DNA environment as a function of position of G-N7 within a given size DNA fragment. The reaction between *cis*-[Pt(NH$_3$)(c-NH$_2$C$_6$H$_{11}$)Cl(OH$_2$)]$^+$ **1** and a single-stranded 17-mer poly(dT) oligonucleotide with one guanine base at variable position was used as a model system; d(T$_n$GT$_{16-n}$), *n* = 0, 2, 4, 6, 8, 10, 12, 14, and 16. The platinum complex is considered to be the active metabolite of the orally adiministered anticancer active compound *cis*,*trans*,*cis*-[Pt(NH$_3$)(c-NH$_2$C$_6$H$_{11}$)(OC(O)CH$_3$)$_2$Cl$_2$] (JM216).[11–13] Like cisplatin, it preferentially forms intrastrand adducts between adjacent G-N7, but exhibits a reduced preference for formation of the mutagenic AG-lesion.[14,15] Determination of the rate constants for the adduct formation reactions with deoxyguanosine 5′-phosphate, d(pG), was included to illustrate the kinetic influence from the surrounding polymer. A low concentration salt buffer with [cation] = 1.0 mM was used to obtain maximum kinetic resolution between the different positions along the oligonucleotide. The kinetics were studied under pseudo-first-order conditions with a 40-fold excess of **1**. Samples were taken from the thermostated reaction mixture (pH 4.1 ± 0.1, 298 K) at different time intervals, and were analyzed by use of HPLC as described previously.[16] Observed pseudo-first-order rate constants, k_{obs}, were derived by a fit of a single-exponential function to the time dependent decrease or increase of peak areas corresponding to unplatinated and platinated oligomer respectively. During reactions with the oligomers, the concentrations of **1** and DNA were kept constant. The pseudo-first-order rate constants can thus be directly compared and used as a measure of the kinetic influence from surrounding DNA.

The observed rate constants were found to vary significantly with the location of the common G-N7 nucleophile along the oligomer d(T$_n$GT$_{16-n}$), see Fig. 1. The shape of the reaction profile shows that platination is kinetically favoured when the G-N7 site is located in the central part of the oligomer with a maximum for platination of d(T$_8$GT$_8$) with k_{obs} = 6.46 ± 0.04 s^{-1}. The platination rate decreases gradually in both the 5′- and 3′-directions, reaching a similar value at both ends, *viz.* k_{obs} = 1.9 ± 0.5 and 2.48 ± 0.13 s^{-1}, respectively. The observed reactivity of the mononucleotide d(pG) with k_{obs} = 0.27 ± 0.04 s^{-1} is *ca.* one order of magnitude slower compared with platination of the oligomers despite the larger Pt(II)-concentration used (C_{Pt} = 3.2 × 10^{-4} M).

The observed increased reactivity of purine N7 in the DNA environment, compared with the reactivity of its corresponding monomeric form,[17,18] agrees qualitatively well with previous observations made for reactions with the charged p(S)-group.[9,10,19,20] However, the present study shows clearly that the influence from the DNA environment is significantly reduced for reaction with the non-charged G-N7 when the gradient between the concentration of bulk cations and those accumulated on the DNA is increased.[3–8] For example, the second-order rate constant for adduct formation with the d(T$_8$GT$_8$) oligomer is *ca.* 50 times larger compared with that observed for the d(pG) monomer, whereas the reactivity of d(T$_8$p(S)T$_8$) exceeds that of d(Tp(S)T) with a factor of *ca.* 200 at comparable salt concentration.[10] The effect is further

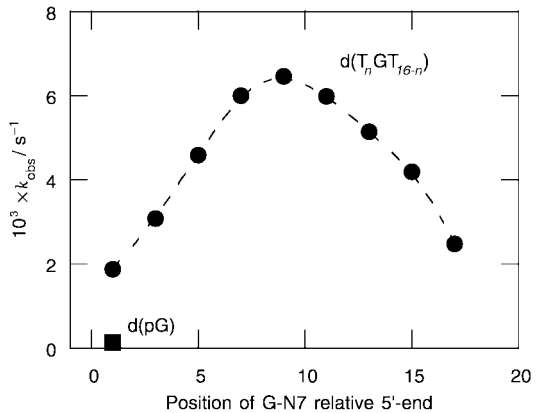

Fig. 1 Observed pseudo-first-order rate constants as a function of G-N7 position with respect to the 5′-end for reaction of **1** with d(pG), and d(T$_n$GT$_{16-n}$); *n* = 0, 2, 4, 6, 8, 10, 12, and 16, *T* = 25 °C, [cation] = 1.0 mM. For reactions with oligonucleotides: C_{Pt} = 1.6 × 10^{-4} M, [DNA] = 4.0 × 10^{-6} M, for reactions with d(pG): C_{Pt} = 3.2 × 10^{-4} M, [DNA] = 3.3 × 10^{-5} M.

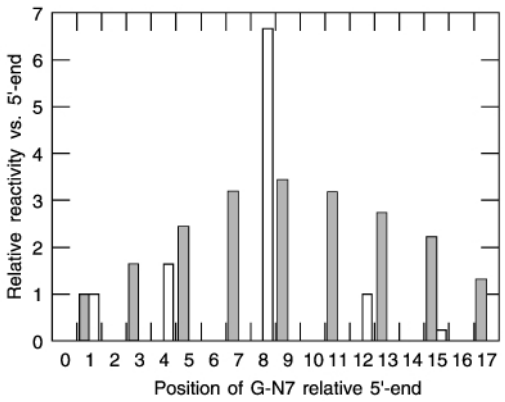

Fig. 2 Relative reactivity for adduct formation of **1** with G-N7 (hatched bars) and p(S) (open bars)[10] as a function of distance from the 5′-end of $d(T_nGT_{16-n})$ and $d(T_np(S)T_{16-n})$.

illustrated by a comparison of the reaction profiles obtained for $d(T_nGT_{16-n})$ and $d(T_np(S)T_{16-n})$, see Fig. 2. The figure reveals a similar overall tendency for a gradual increase of the reactivity towards the middle of the oligomer. Normalization of the reactivity with respect to the rate obtained for the 5′-end positions shows however that the relative change is less pronounced for formation of the platinated G-N7 moiety.

In mechanistic terms, these observations have several implications. First of all, the DNA promoted reactivity is in line with the previously suggested reaction mechanism where an electrostatically driven preequilibrium between the charged metal complex and the oligonucleotide contributes to increase the rate of adduct formation with reactive groups located on the oligomer.[9,10,19,20] Second, the gradual increase of k_{obs} towards the middle of the oligomer rules out a strict sequence dependent influence on the observed reactivity. The common platination environment of the type 5′-T_4GT_4-3′ should be large enough to provide a constant local structural and electrostatic environment around G-N7 in the centrally located positions, *i.e.* $d(T_nGT_{16-n})$; n = 4, 6, 8, 10, and 12 in the absence of other effects. Rather, the similar shape of the reaction profiles speaks in favour of a reaction model where the tendency for preaccumulation varies along the oligomer, in a fashion similar to the one calculated for short double-stranded DNA oligomers.[3,4] The less pronounced influence from such effect in the present investigation, compared with adduct formation with p(S), suggests further that the local concentration of preaccumulated cations decreases with increasing distance from the phosphodiester backbone.‡ To our knowledge, this is the first experimental investigation giving information about the corresponding variation in reactivity for a bimolecular reaction between an external, cationic metal reagent and reactive groups located on the DNA surface.

In summary, the present results support a reaction model where a varying local concentration of preassociated cationic platinum complexes significantly influences the observed reactivity during adduct formation with non-charged groups located on the DNA surface. The lower sensitivity of G-N7, compared with phosphorothioate reactions, can be explained by the larger distance between the electrostatically preferred interaction sites along the phosphodiester backbone and G-N7.[21] These results should be of importance for synthetic strategies and for a fundamental understanding of reaction mechanisms *in vivo* involving interactions between charged species and reactive groups located on small ribonucleic acid fragments or their charged antisense mimics.

Financial support from the Swedish Cancer Society (grant 3308-B00-07XCC, S.K.C.E.) is gratefully acknowledged.

Notes and references

‡ The increased reactivity in the DNA environment can be accounted for by assuming a reaction mechanism where preaccumulation of **1** on the DNA surface contributes to the adduct formation rate by electrostatic condensation and resulting increased local concentration of **1** in the vicinity of G-N7.[10,16,20]

Enantiospecificity of sterol–lipid interactions: first evidence that the absolute configuration of cholesterol affects the physical properties of cholesterol–sphingomyelin membranes

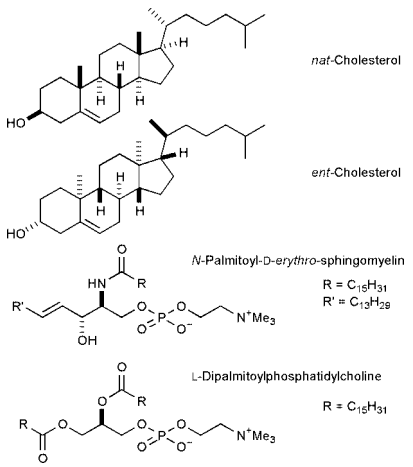
Received (in Columbia, MO, USA) 4th May 2001, Accepted 11th May 2001
First published as an Advance Article on the web 13th June 2001

Results from monolayer studies using the enantiomers of cholesterol (*nat*- and *ent*-cholesterol) and egg yolk sphingomyelin show for the first time that enantiospecific interactions between sterols and lipids can affect the physical properties of membranes.

Because the sterols and lipids of cellular membranes occur in enantiomerically pure form, it is possible that the physical properties of the membranes could, in part, be dependent on enantiospecific sterol–lipid interactions. This possibility has seldom been addressed because the unnatural enantiomers of sterols and lipids are not readily available. Nevertheless, in the few studies that have been performed, where interactions of the enantiomers of dipalmitoylphosphatidylcholine, (or its close structural analogues) with natural cholesterol (*nat*-cholesterol)



were investigated, no enantioselective sterol–lipid interactions were detected.[1] Thus, it is perhaps not surprising that enantiospecific sterol–lipid interactions are widely believed to be too weak to influence the physical properties of membranes. Here, we show that this view is unwarranted for certain sterol–lipid interactions. Specifically, we show that enantiospecific interactions between cholesterol and egg yolk sphingomyelin (SPM) influence the physical properties of cholesterol–sphingomyelin monolayers at the air–water interface in a Langmuir–Blodgett trough.

The *ent*-cholesterol was prepared by us as described previously.[2] Enantioselectivity for the interactions of either *nat*- or *ent*-cholesterol with egg yolk sphingomyelin was investigated by examining the well known condensing effect of cholesterol on the packing of monolayers of cellular membrane lipids on a water surface in a Langmuir–Blodgett trough.[3] At low surface pressures, the rigid steroid acts as a template to orient the lipid hydrocarbon chains into fully extended conformations thereby allowing the lipid to occupy less area on the water surface than it would occupy if the steroid were not present. Thus, enantioselectively for the sterol–lipid interactions is detected as a difference in the plots of surface pressure (Π) *vs.* mean molecular area (mmA) during the compression of mixed monolayers containing the same mol% of either cholesterol enantiomer cospread on the surface with SPM.

In data not shown, the Π–mmA compression isotherms of the cholesterol enantiomers and SPM were recorded. The compression isotherms of the cholesterol enantiomers are identical. A gaseous to liquid ordered phase transition ($\Pi \geqslant 0.5$ mN m^{-1}) occurs at mmA ≈ 42 Å^2 molecule^{-1} and the film collapses when $\Pi \approx 49$ mN m^{-1} and mmA ≈ 36 Å^2 molecule^{-1}. In the absence of cholesterol, SPM monolayers compressed on a water subphase undergo a gaseous to liquid ordered phase transition ($\Pi \geqslant 0.5$ mN m^{-1}) at mmA ≈ 82 Å^2 molecule^{-1}. At collapse, the SPM monolayers have $\Pi \approx 55$ mN m^{-1} and mmA ≈ 35 Å^2 molecule^{-1}. These experimental parameters are in agreement with published values for the compression isotherms of similar cholesterol or SPM films.[4]

Results for the Π–mmA compression isotherms of monolayer films containing 30 mol% of either *nat*- or *ent*-cholesterol and 70 mol% SPM are shown in Fig. 1. Differences in mmA values at all Π are observed and are highly significant ($P < 0.00001$).[5] The *ent*-cholesterol has a greater condensing effect on SPM than *nat*-cholesterol.

In experiments not shown, mixed cholesterol–SPM films containing 10–50 mol% of either cholesterol enantiomer were compressed. Enantioselectivity during compression was observed when the mol% of the steroid was varied in 10 mol% increments between 20 and 40 mol%. Enantioselectivity was greatest at 30 mol% sterol and was not observed at either 10 or

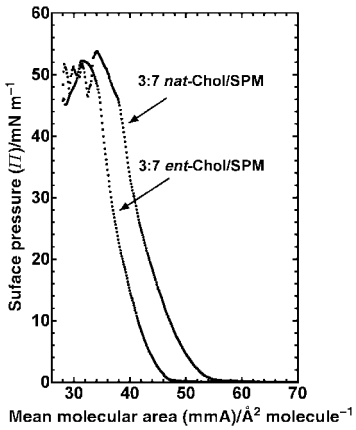


Fig. 1 Pressure–area isotherms for 3:7 mixtures of each cholesterol enantiomer with egg yolk sphingomyelin.

 DOI: 10.1039/b104081m

50 mol% sterol. Also in experiments not shown, mixed cholesterol–DPPC (natural L-dipalmitoylphosphatidylcholine) films containing 10–60 mol% of either cholesterol enantiomer were compressed. These DPPC experiments provide a chirality crosscheck on the earlier reported studies that used DPPC enantiomers. In agreement with the earlier cited studies, we found no enantioselectivity using cholesterol enantiomers and natural DPPC.

The appearance of the 30 mol% *nat*- and *ent*-cholesterol–SPM films during compression was examined using Brewster angle microscopy.[6] Fig. 2 shows micrographs of the films at similar degrees of compression. The SPM film containing *ent*-cholesterol exhibits a greater fraction of the gas (dark) phase than the corresponding SPM film containing *nat*-cholesterol. At this stage of compression the *nat*-cholesterol, but not the *ent*-cholesterol, containing film has undergone the gaseous-to-liquid condensed phase transition (refer to Fig. 1). Thus, the films are visually different at similar degrees of compression. Additionally, there are two phases evident for the *nat*-cholesterol containing film, but three phases present for the *ent*-cholesterol containing film. This difference in the number of phases present also occurs when the films are more expanded and neither film has undergone a phase transition. Further compression of either film after the phase transition has occurred gives uniform films with a similar bright appearance. Although further experiments are needed to characterise the identity of the third phase present in the *ent*-cholesterol containing film, the presence of this additional phase emphasised that the differences between the Π–mmA isotherms of the cholesterol enantiomer–SPM films are not experimental artefacts.

Thus, we confirm that the physical properties of cholesterol–DPPC containing membranes are not measurably influenced by enantiospecific interactions between the sterol and the lipid. In contrast, we report that enantiospecific interactions between cholesterol and SPM do affect the physical properties of these membranes. It is likely that the varying degrees of enantioselectivity observed for DPPC and SPM in their interactions with cholesterol are explained by differences in the hydrogen bonding between the cholesterol hydroxyl group and the polar head groups of the two lipids.

The only chiral center in DPPC is the central carbon in the glycerol backbone of the lipid. Thus, unless the carbonyl oxygen in the ester group attached to this carbon is directly involved in a hydrogen bonding interaction with the hydroxy group attached to the C-3 chiral center in cholesterol, there is little opportunity for the molecules to interact in an enantioselective manner. However, evidence suggests that the DPPC ester carbonyl group and the cholesterol hydroxyl group do not hydrogen bond to each other, but instead hydrogen bond to intervening water molecules.[7,8] Hence, it may not be surprising that cholesterol–DPPC packing interactions are not measurably enantioselective.

The D-*erythro*-sphingosine base of SPM has two chiral centers and a double bond proximate to the zwitterionic choline head group. Additionally, since the polar head group of SPM contains both hydrogen bond donor and acceptor groups it is possible for hydrogen bonding to organise SPM into aggregates in a way that is not possible for DPPC. If hydrogen bonding to cholesterol alters these intermolecular SPM–SPM hydrogen bonding interactions, it seems reasonable that cholesterol could do this in an enantiospecific manner. Further experiments will be needed to investigate this possibility. Nevertheless, the hypothesis seems consistent with published views regarding the idea that intermolecular hydrogen bonding between cholesterol and SPM has important biophysical and biochemical consequences.[8]

This study provides the first evidence that enantioselective interactions between sterols and lipids can affect the physical properties of membranes. In a larger context, *ent*-cholesterol may prove to be a useful reagent for studying cellular cholesterol homeostasis and the role that cholesterol–SPM raft formation plays in the functioning and trafficking of proteins involved in cell-signalling pathways.[9] We have previously used *ent*-cholesterol to demonstrate that the absolute configuration of cholesterol has an effect on the transport of daunomycin by the multidrug resistance transporter P-glycoprotein (Pgp) in human HepG2 and Chinese hamster ovary (CHO) cells.[10] Additional studies to further define the effect that the absolute configuration of cholesterol has on the physical properties of cell membrane lipids and studies of *ent*-cholesterol binding to proteins are in progress.

We thank the NIH for grant GM 47969 that supported this work.

The water-soluble β-cyclodextrin–[60]fullerene complex

C. N. Murthy and K. E. Geckeler*

Laboratory of Applied Macromolecular Chemistry, Department of Materials Science and Engineering, Kwangju Institute of Science and Technology, 1 Oryong-dong, Buk-gu, Kwangju 500-712, South Korea. E-mail: keg@kjist.ac.kr

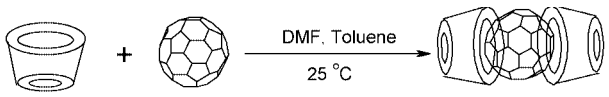
Received (in Cambridge, UK) 7th March 2001, Accepted 21st May 2001
First published as an Advance Article on the web 13th June 2001

A stable inclusion complex of β-cyclodextrin with [60]fullerene is reported for the first time, synthesized by using a novel synthetic procedure; radical scavenging studies of the water-soluble complex indicate that it has potential for a number of medical applications.

The supramolecular chemistry of cyclodextrins (CD) in aqueous solution is a topic of commercial interest with a variety of biomedical applications.[1] Nonpolar drug molecules have been solubilized in water by making their inclusion complexes with cyclodextrins. Among the cyclodextrins, the β-cyclodextrin is the cheapest commercially available, being about four times cheaper than γ-cyclodextrin. [60]Fullerene is a nonpolar molecule and much of the research on the inclusion complexes of cyclodextrins and [60]fullerene has centered on γ-cyclodextrins,[2a–c] as recent research has shown the biological activity of water-soluble [60]fullerene derivatives such as its DNA-cleaving ability and anti-HIV activity.[3] There are only a few reports on inclusion complexation of [60]fullerene.[2] The procedures described are based on heterogeneous reaction media and all have reported that only γ-cyclodextrin forms an inclusion complex (2:1) and β-cyclodextrin or α-cyclodextrin do not form complexes. The reason given is the comparable size of the [60]fullerene and the cavity diameter of the γ-cyclodextrin molecule and that the C_{60} molecule does not intrude deeply into the γ-cyclodextrin cavity. In fact, these reports describe the experimental failure to prepare the inclusion complex of β-cyclodextrin with [60]fullerene.[2b,c]

There are only a few reports on the inclusion complexation of [60]fullerene by CD derivatives.[2d,e] However, when studying the data in detail and conducting molecular modeling studies, it becomes evident that the dimensions of the cyclodextrins do principally not rule out the formation of an inclusion complex between β-cyclodextrin and [60]fullerene. The larger cavity diameter of β-cyclodextrin is 780 pm and the outer rim diameter is 1530 pm on the polar side of the molecule as compared to 950 pm and 1690 pm, respectively, for the γ-cyclodextrin. Thus the cavity diameters are much smaller than the van der Waals diameter of [60]fullerene (~1000 pm). On the other hand, based on crystallographic studies it has been reported that the β-cyclodextrin cavity is suitable for spherically shaped guests such as adamantane derivatives[4] or naphthalene,[5] and the space enclosed by the head-to-head dimer is ~2.5 times wider than the cavity of the single molecule.[6] Consequently, the reason for the unsuccessful attempts to form inclusion complexes of β-cyclodextrin and [60]fullerene is not only the size but seems to also depend on the reaction conditions. Due to the lower cost of β-CD and its widespread applications, there are also considerably more data available on toxicity and other pharmacological studies. Here we report a novel method for a water-soluble, stable β-cyclodextrin–[60]fullerene inclusion complex.

The synthesis of the CD–C_{60} inclusion complex (Scheme 1) was achieved in a mixed organic solvent system containing DMF and toluene (typically 50–90% DMF, v:v), where both the β-cyclodextrin and [60]fullerene formed a homogeneous reaction medium. The inclusion of the fullerene into the CD cavity was monitored over a period of two weeks by UV-Vis spectroscopy (Fig. 1). The CD–C_{60} complex was isolated by removing the organic solvents, and subsequent addition of distilled water, to yield a light yellow aqueous solution. The complex was purified in aqueous solution by membrane filtration using a polymer membrane with a molar mass cut-off of 2 kg mol^{-1} (Yield: 60%, solubility in water: 4 g L^{-1}).[7] The FTIR spectra of the inclusion complex showed the typical band at 527 cm^{-1} assigned to [60]fullerene. The UV-Vis spectrum showed the absorption at 342 nm and the peak broadening beyond 350 nm. Further corroboration for the formation of the inclusion complex was obtained by ^1H and ^{13}C NMR spectroscopy. The complex showed a slight shift in the resonances of the C^3 carbon of the CD unit, but no shift in the resonance of the C^5, indicating that the fullerene does not intrude into the cavity completely. This is supported by the energy minimization calculations (Fig. 2). These studies also showed that the visible and accessible fullerene surface in the complex is increased by a factor of ~8 compared to the γ-cyclodextrin complex, which is very important with respect to biological applications. Under these conditions, in contrast, the α-cyclodextrin did not form an inclusion complex.



Scheme 1 Synthesis of the β-cyclodextrin–[60]fullerene inclusion complex.

Generally, β-cyclodextrin can form a 2:1, 1:1, or 1:2 complex with a guest and the theoretical calculated mass content of β-cyclodextrin in the complex for these three types would be 75.9, 61.2, and 44.1%, respectively. Thermogravimetric analysis of the complex formed showed that the total mass loss of the cyclodextrin at 325 °C was 72.5%. This result clearly indicates that this inclusion complex is of the 2:1 type.

It is known that the two main driving forces for inclusion complexation are the repulsive forces between the included water molecules and the apolar cyclodextrin cavity on the one

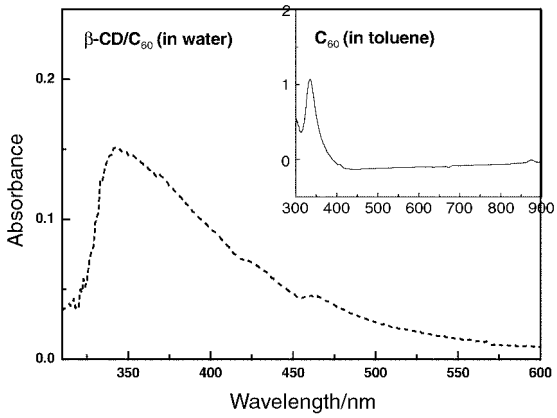


Fig. 1 UV-Vis spectra of C_{60} (in toluene) and the β-cyclodextrin–C_{60} inclusion complex (in water).

 DOI: 10.1039/b102142g

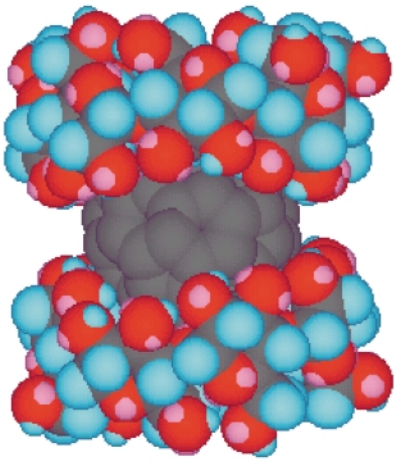

Fig. 2 Energy-minimized molecular model of the β-cyclodextrin–C_{60} inclusion complex (2:1).

hand, and between the apolar [60]fullerene and the bulk water on the other. However, the second factor is not relevant in the dry state and thus the product isolated from the solution could be just a fine dispersion of β-cyclodextrin and [60]fullerene. The X-ray diffraction pattern of the freeze-dried inclusion complex (Fig. 3), however, shows that the product isolated has neither the typical 2θ values of CD nor those of [60]fullerene. It can be seen that the complex has a different structure to the parent β-cyclodextrin (2θ = 9, 12.5, 19.6, 23.0, 27.0, 34.8°) and C_{60}[8] (2θ = 11.0, 17.5, 21.7°), with the total suppression of the crystalline

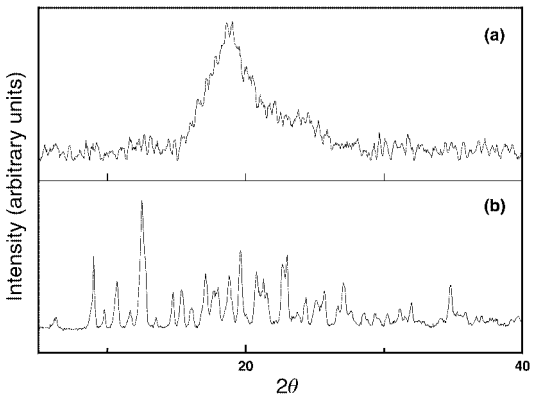

Fig. 3 X-ray diffractograms of (a) the inclusion complex of C_{60} with β-cyclodextrin and (b) the pristine β-cyclodextrin.

structure of β-CD. This is in accord with similar observations for the γ-CD complex.[2b]

Water-soluble fullerene compounds have potential biomedical applications and previous attempts involved its functionalization[9] with a significant modification of the fullerene molecule, which could lead to toxicity problems. The approach adopted here overcomes such problems, as at present only the parent β-CD has been cleared for human consumption. Radical scavenging studies were carried out using a screening test with the stable free radical, 2,2-diphenyl-1-picrylhydrazyl (DPPH), developed in our laboratory.[10] There was a visual bleaching of the purple color of the DPPH solution with time, which was monitored by UV-Vis spectroscopy showing a gradual shift and decrease in the absorbance of the 517 nm peak of the DPPH solution. This shows that the [60]fullerene in the complex with β-cyclodextrin retains its radical scavenging activity in the aqueous solution.

Financial support from the Ministry of Education for the 'Brain Korea 21' project is gratefully acknowledged.

The first application of Selectfluor™ in electrophilic fluorination of amines: a new route to $-NF_2$, –NHF, and >NF compounds

Rajendra P. Singh and Jean'ne M. Shreeve*

Department of Chemistry, University of Idaho, Moscow, ID 83844-2343, USA.

Received (in Cambridge, UK) 21st February 2001, Accepted 18th May 2001
First published as an Advance Article on the web 13th June 2001

Reactions of primary amines, RNH_2 [R = $(CH_3)_3C$–, $(CH_3)_2CH$–, $CH_3(CH_2)_2$–, $(CH_3)_2CHCH_2$–, $CH_3(CH_2)_3$–] and secondary amines, R_2NH [(R = CH_3CH_2–, $CH_3(CH_2)_2$–, $(CH_3)_2CHCH_2$–], with Selectfluor™ in acetonitrile or DMF or DMA result in formation of the corresponding RNF_2, RNHF, and R_2NF in high yields.

The synthesis and reactivity of compounds that contain the nitrogen–fluorine bond have been studied extensively.[1–7] Many methods have been developed to prepare *N*-fluoroamines and *N*,*N*-difluoroamines by using either elemental fluorine or other fluorine-transfer reagents which often gave poor yields of the final products and required extreme precautions. In 1960, Frazer reported the formation of RNF_2 (R = CH_3, C_2H_5) in moderate yields from photolysis of RI + N_2F_4 through Pyrex.[8] Thermolysis of mixtures of alkanes and N_2F_4 at 300 °C resulted in mono and disubstituted difluoroamino compounds.[9] However, with the advent of modern day electrophilic fluorinating reagents, such as CF_3OF, XeF_2, ClO_3F and $CsSO_4F$, as well as fluorine itself, it has been possible to prepare a variety of >NF or −NHF compounds.[9–11] A decade ago we reported the effective synthesis of acyclic secondary and cyclic fluoroamines, in addition to *N*-nitrosoamines, by using trifluoroamine oxide (NF_3O) as the fluorinating agent at < 0 °C.[12]

The application of Selectfluor™ for the electrophilic fluorination of primary and secondary amines provides a powerful straightforward one step route to $-NF_2$ and >NF compounds and, for the first time, the opportunity to prepare –NHF compounds *via* control of reaction stoichiometry. Since the discovery of this reagent, considerable success in the electrophilic fluorination of organic molecules, especially in the formation of C–F bonds, has been realized but the mechanism of the fluorine-transfer step has remained minimally understood.[13-15]

Initially, *tert*-butylamine (3 mmol) was reacted with Selectfluor™ (6.2 mmol) at 0 °C in acetonitrile for 6 h. Analysis of the reaction mixture with GCMS showed complete consumption of the *tert*-butylamine. Separation of *tert*-butyldifluoroamine from acetonitrile was not very clean due to the small difference between the boiling points of the solvent and the product. *tert*-Butyldifluoroamine was characterized spectroscopically in acetonitrile solution. The above reaction was also found to be equally successful when DMF or DMA was used as solvent and was completed within an hour. These solvents were found to be suitable due to their high boiling points which made the separation of the products from the solvent relatively straightforward. In some cases, the formation of $(CH_3)_2NCOF$[16] (≤ 5%) was observed as a byproduct when DMF was used as a solvent. By using similar reaction conditions,† the other primary amines, RNH_2 [R = $(CH_3)_2CH$–, $CH_3(CH_2)_2$–, $(CH_3)_2CHCH_2$–, $CH_3(CH_2)_3$–], were converted in DMA solution into the corresponding difluoroamines in good yields (Scheme 1, Table 1). An attempt to prepare *tert*-butyl fluoroamine [$(CH_3)_3CNHF$] by the slow addition of a DMF solution of *tert*-butylamine (3 mmol) into a stirred suspension of Selectfluor™ (3 mmol) solution in DMF resulted in the formation of a mixture of difluoro and fluoroamine in a 9:1 ratio. However, when the addition of the reagents was reversed, *tert*-butylfluoroamine was formed as the sole product (Scheme 1, Table 1).

Several secondary amines, R_2NH [(R = CH_3CH_2–, $CH_3(CH)_2$–, $(CH_3)_2CHCH_2$–], were reacted at 0 °C to 25 °C with 1.2 equiv. of Selectfluor™ in DMA‡ for 2 h. Separation of

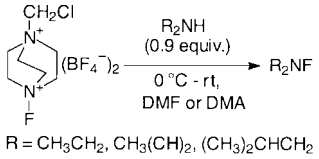
[a] All the reactions were carried out in *N*,*N*-dimethylacetamide (DMA). [b] All the products were characterized by spectroscopic analysis and known compounds were identified by comparing with the spectroscopic data reported in the literature. [c] The yields in entries No. 1–4 were identical when either DMF or DMA was used as solvent. [d] New compounds.

 DOI: 10.1039/b101689j



Scheme 2

the product by low temperature trap-to-trap distillation gave the corresponding *N*-fluoroamines, R_2NF [(R = CH_3CH_2–, $CH_3(CH)_2$–, $(CH_3)_2CHCH_2$–] in good isolated yields (Scheme 2).

The present report describes a powerful and simple method for the preparation of *N*-difluoro and *N*-fluoro compounds (high energy molecules) with some advantages in comparision with some other routes. The stability of these volatile liquids is variable. While all are stable in solution in Pyrex glass containers for several days at 25 °C, various degrees of decomposition occur over time. For example, $(CH_3)_3CNF_2$ was found to be stable in a sealed tube for at least three months under refrigeration, while $CH_3CH_2CH_2CH_2NHF$ decomposed fully after an equal time in Pyrex at 25 °C. A sample of $(CH_3)_3CNHF$ refrigerated in a vial for several months showed no decomposition based on NMR spectral measurements. However, R_2NF compounds are reported to be unstable in Pyrex glass for extended periods.[12]

We are grateful to Dr Robert G. Syvret (Air Products and Chemical, Inc.) for generous gifts of Selectfluor™ reagent. This work was supported by the National Science Foundation (Grant No. CHE – 9720365) and the Office of Naval Research (Award No. N00014-00-1-0721). *Warning*: While no problems arose during these syntheses, adqeuate precautions should be employed since fluoroamines and difluoroamines can be unpredictably shock and thermally unstable.

Notes and references

† To a solution of 3 mmol (1.06 g) of Selectfluor™ in 3.5 mL of DMF or DMA, 1.35 mmol of primary amine or 2.7 mmol of secondary amine in 1.5 mL of DMF or DMA was added dropwise at 0 °C. After 0.5 h stirring, the reaction mixture was stirred for an additional 1.5 h at 25 °C. In general, trap-to-trap distillation under vacuum allowed the separation of the solvent (trap at −20 °C) from the product which may be stopped in a trap at −78 °C or may pass through a trap at −78 °C and stop in a trap at −100 °C. **$(CH_3)_3CNF_2$**:[9] IR (gas phase): 2991 vs, 2944 s, 1485 s, 1375 vs, 1253 m, 1222 m, 980 vs, 880 vs, 587 m cm^{-1}; δ_H (200 MHz, CD_3CN): 1.24 (t, 9H, $J_{H\text{-}F}$ = 1.6 Hz); δ_F (188 MHz, CD_3CN): 28.7 broad singlet; δ_C (50 MHz, CD_3CN): 22.8, 70.6 (t, J = 6.8 Hz); MS (EI) *m/e* (species intensity): 110 (M + H, 1), 94 ($M^+ - CH_3$, 5), 57 ($(CH_3)_3C^+$, 85), 41 (CH_3CN^+, 100). **$(CH_3)_2CHCH_2]_2NF$**:[12] (trapped at −78 °C, passing −40 °C) IR (gas phase): 2986 vs, 2897 vs, 2808 s, 1472 s, 1390 s, 1371 s, 1290 w, 1243 w, 1142 s, 1111 m, 930 w, 833 m cm^{-1}; δ_F (188 MHz, CD_3CN): 0.98 (d, 12H, J = 21 Hz), 2.1 (m, 2H), 2.88 (dd, 4H, $J_{H\text{-}F}$ = 40.8 Hz); δ_F (200 MHz, CD_3CN): −46.5 q ($J_{F\text{-}H}$ = 40.0 Hz); MS (EI) *m/e* (species intensity): 147 (M^+, 6), 127 ($M^+ - HF$, 1), 104 ($M^+ - (CH_3)_2CH$, 63), 57 ($(CH_3)_2CHCH_2^+$, 100).

‡ To a stirred solution of primary amine (3.2 mmol in 2 mL of DMF or DMA), a Selectfluor™ solution (3 mmol in 3 mL of DMF or DMA) was added dropwise at 0 °C. After 0.5 h stirring, the reaction mixture was stirred at 25 °C for an additional 0.5 h. Received (in Cambridge, UK) 25th April 2001, Accepted 24th May 2001
First published as an Advance Article on the web 13th June 2001

A noteworthy three-dimensional framework, obtained by reacting the preformed molecular corner [Cu(2,2′-bipy)]$^{2+}$ (with BF_4^- counter ions) and 1,2-bis(4-pyridyl)ethane (bpetha) in the presence of chlorides, contains molecular square units [Cu(2,2′-bipy)(bpetha)]$_4$ that are linked *via* chloride bridges into a triconnected architecture of unprecedented topology.

In the rational development of new strategies for the crystal engineering of coordination networks[1] and of supramolecular architectures[2] the use of preformed metal-based units has assumed an increasing relevance in recent times. Molecular corners containing transition metals with programmed coordination angles can been employed for the self-assembly of frameworks and, especially, of macromolecular polygons and polyhedral cages,[3] of potential utility for molecular recognition. In particular, *cis*-protected Pd^{II} and Pt^{II} units have been widely employed for the building of molecular squares.[3,4] We are currently studying the use of a different corner unit, namely [Cu(2,2′-bipy)]$^{2+}$ **1** (2,2′-bipy = 2,2′-bipyridyl), that contains two *cis*-equatorial and, possibly, also two axial free coordination sites, and is produced from the parent complex [Cu(2,2′-bipy)Cl_2] by removing the chlorides with different AgX salts of poorly coordinating anions (X = triflate, tetrafluoroborate or nitrate). These [(**1**)X_2] species have already been reacted with a variety of bidentate spacer ligands, mainly affording one-dimensional zigzag polymeric chains.[5] Monochloride species [(**1**)Cl]X, obtained by removing only one half of the chloride content from the parent complex, were also employed, and, interestingly, the reaction of [(**1**)Cl](BF_4) with 1,2-bis(4-pyridyl)ethane (bpetha) has produced the novel polymeric species [{(**1**)(bpetha)}$_2$Cl(BF_4)](BF_4)$_2$·8.5H_2O **2**, containing molecular square units joined by bridging chloride ions into an extended array. We describe here this three-dimensional network, containing large interstitial cavities and exhibiting a topology unprecedented within coordination networks. We report also on a strictly related species, compound **3**, obtained using 1,2-bis(4-pyridyl)ethene (bpethe) as spacer, that, in spite of the similarity of the ligands, shows a completely different frame. Compound **2** is obtained in high yield in a two step process. In the first step the parent [Cu(2,2′-bipy)Cl_2] was treated with $AgBF_4$ in a 2:3 molar ratio in EtOH under stirring for 2 h. The solution was then filtered and layered on a solution of bpetha in CH_2Cl_2 (molar ratio Cu:bpetha from 1:1 to 1:3). After a few days beautiful blue crystals of **2** were obtained. Compound **3**, [{(**1**)(bpethe)}$_2$Cl](BF_4)$_3$·2.5H_2O·CH_2Cl_2, was obtained in the same way, using in the second step the bpethe ligand in CH_2Cl_2 solution. Both species have been characterized by single crystal X-ray analysis.†

The crystal structure of **2** consists of [(**1**)(bpetha)]$_4$ square units interconnected *via* chloride bridges into a three-dimensional non-interpenetrated network. The squares are comprised of [Cu(2,2′-bipy)]$^{2+}$ corners and bpetha edges, with a Cu···Cu separation of 13.23 Å (Fig. 1, top); they are moderately folded about their diagonal axes by *ca.* 27° (Fig. 1, bottom). Similar previously reported macrocyclic motifs, containing Pt^{II} or Pd^{II} corners, are all individual molecules, held together essentially by van der Waals interactions.[4] The peculiar structural feature of **2**, on the other hand, consists in that these square units are organized in an extended architecture sustained by slightly bent chloride bridges [Cu···Cu 5.12 Å, Cu–Cl 2.582(2) Å, Cu–Cl–Cu 164.3(2)°]. Each square is bound to four similar motifs, two

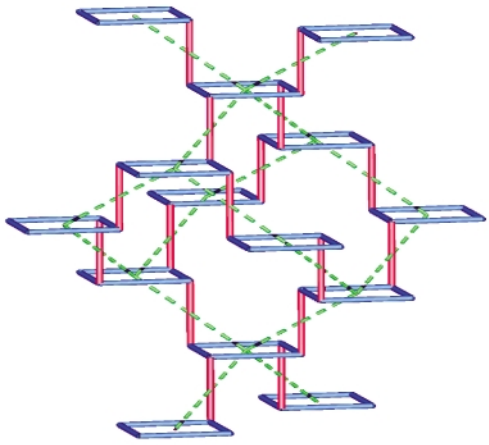

Fig. 2 A schematic view of the three-dimensional network in **2**, with the chloride bridges in red. The broken lines show the underlying diamondoid net, obtained by connecting the baricentres of the squares.

 DOI: 10.1039/b103736f

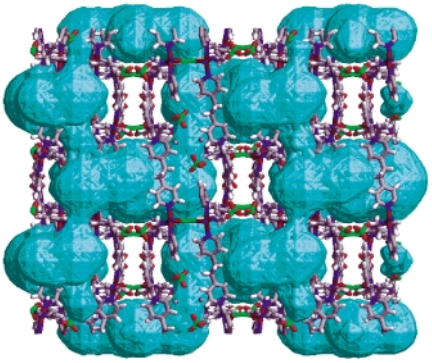

Fig. 3 The overall packing in **2** (down *a*, horizontal *c*) showing the surface of the large interconnected cavities.

above and two below the molecular plane, in an alternate fashion. The Cu^{II} coordination geometry is octahedral, with four equatorial Cu–N(pyridyl) bonds [in the range 2.00(1)–2.04(1) Å], one axial Cu–Cl bond and one axial weak interaction with a BF_4^- anion [Cu–F 2.79(1) Å].

The topology of this uninodal triconnected three-dimensional frame (Fig. 2) is $4{\cdot}14^2$, a relatively simple topological type already considered by Wells in his enumeration,[6] but completely new within coordination polymer chemistry. Interestingly, the baricentres of the squares define a diamondoid network (see Fig. 2), so that the net of **2** can be defined, according to O'Keeffe,[7] as an '*augmented diamond*' net.

The network contains large voids (38% of the cell volume),[8] with connected chambers (Fig. 3) that are filled by water molecules. Samples of **2** start to lose the solvated water at room temperature and TGA analyses show that all the water content (*ca.* 13% weight loss) is completely removed on heating up to *ca.* 120 °C, without demolition of the array (as confirmed by X-ray powder diffraction). Decomposition starts at *ca.* 180 °C, leading to copper metal above *ca.* 400 °C. The desolvated network, however, seems stable as such for an extended period and appears unable to regain solvated molecules to a significant extent even after immersion in different solvents (*e.g.* water, ethanol, isopropyl alcohol, toluene, CCl_4) for some days.

The structure of compound **3**, obtained under reaction conditions quite similar to those leading to **2** but using the bpethe ligand, consists of zigzag polymeric chains all running

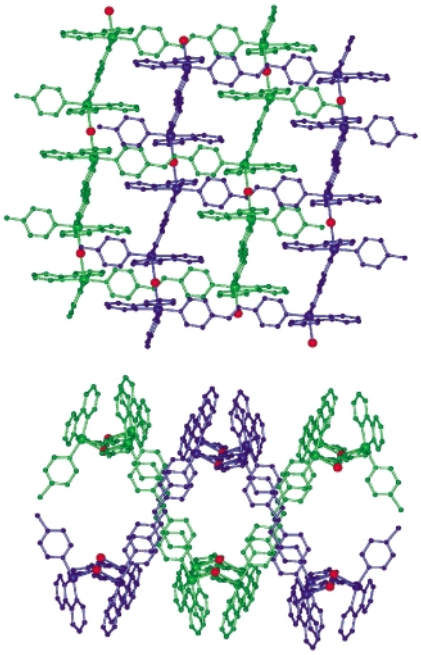

Fig. 4 A side view of the double-layer of **3** (top), showing the highly undulated shape of the sheets, and a view approximately down *b* showing the two-fold interpenetration (bottom). The Cl^- ions are in red.

along the [3 0 1] direction (Cu···Cu contacts of 13.31 Å av.) connected by chloride bridges [Cu–Cl 2.511(1) Å, Cu–Cl–Cu 139.5(1)°] into two-dimensional sheets of six-membered rings (6^3 topology). The Cu^{II} coordination is of the square pyramidal type, with the axial Cu–Cl interaction and four equatorial Cu–N(pyridyl) bonds [in the range 2.012(5)–2.025(5) Å]. The layers are highly undulated, with crankshaft-like sections (Fig. 4, top) and exhibit two-fold parallel interpenetration (Fig. 4, bottom). Moreover, these double-layers are superimposed with high interdigitation involving the nearest neighbours. Again, the array contains large channels along [1 0 0] (28% of the cell volume), located inside the double-layers.

Such different structures for **2** and **3**, in the presence of similar framework stoichiometries, are difficult to rationalize. The higher rigidity of the bpethe ligand and the presence of solvated CH_2Cl_2 molecules in **3** can play some role. While the *ideal* elimination of the chloride ions from **3** leaves polymeric zigzag chains, similar to those recently reported,[5] in the case of **2** this process should result in isolated molecular motifs. However, attempts to disentangle the squares of **2** by dissolution were made impossible by its poor solubility in all common solvents.

Iridium(III) complexes of the new tridentate bis(8-quinolyl)silyl ('NSiN') ligand†

Mark Stradiotto, Kyle L. Fujdala and T. Don Tilley*

Department of Chemistry, University of California at Berkeley, Berkeley, California 94720-1460, USA. E-mail: tdtilley@socrates.berkeley.edu

Received (in Columbia, MO, USA) 22nd March 2001, Accepted 16th May 2001
First published as an Advance Article on the web 13th June 2001

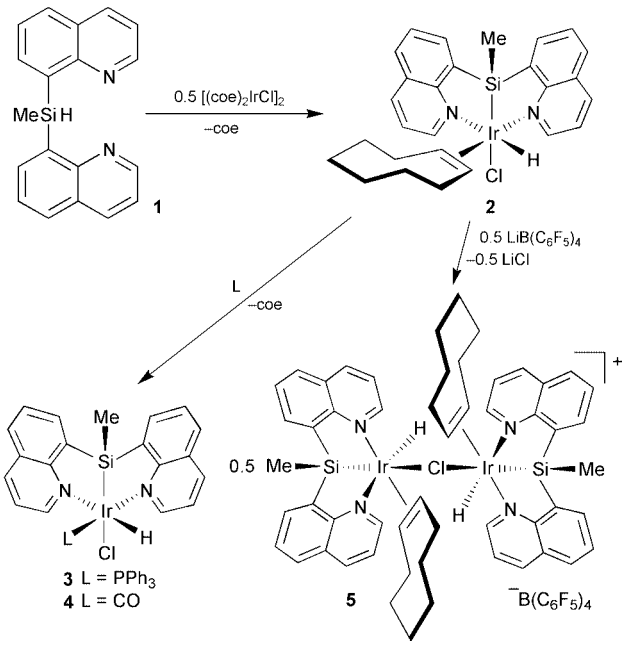
Bis(8-quinolyl)methylsilane reacts cleanly with $[Ir(coe)_2Cl]_2$ (coe = cyclooctene) to give a complex containing an NSiN tridentate ligand, [Ir(NSiN)(coe)(H)(Cl)]; preliminary reactivity studies indicate that the (NSiN)Ir fragment is chemically robust.

Multidentate ligands have featured prominently in the recent development of new transition metal chemistry. Such ligands provide stability to a metal complex, and offer diverse possibilities for the manipulation of steric and electronic properties in controlling reactivity at the metal center. Notwithstanding the significant advances in transition metal–silicon chemistry over the past several years,[1,2] multidentate ligands containing silicon as part of the chelate architecture have received little attention. The incorporation of silicon into such structures may offer certain advantages, given (for example) the high strength of metal–silicon bonds and the strong *trans*-effect for silicon ligands.[1,3] Stobart and coworkers[4] have synthesized a number of metal complexes supported by a PSiP ligand framework; tridentate connectivity is attained in these systems *via* oxidative addition of an Si–H functionality. This general strategy should provide synthetic routes to various silicon-containing multidentate ligands.

With the goal of developing reactive metal fragments supported by new tridentate ancillary ligands, we identified nitrogen-based NSiN chelates as potential synthetic targets. A tridentate system based on the bis(8-quinolyl)silyl framework appeared particularly attractive, since the resulting five-membered metallacyclic rings are expected to stabilize a complex towards reductive elimination of the silyl unit, while providing a rather rigid ligand binding arrangement. Support for the viability of such a ligation strategy comes from the work of Watts and coworkers,[5] who have prepared Rh(III) and Ir(III) complexes of the bidentate (8-quinolyl)dimethylsilyl ligand. In this contribution, synthesis of the tridentate ligand precursor bis(8-quinolyl)methylsilane **1** and Ir(III) complexes supported by this NSiN fragment are reported.

Addition of 0.5 equivalents of methyldichlorosilane to 8-lithioquinoline in THF, followed by purification, provided **1** as pale yellow crystals in moderate yield.†‡ The characterization of **1** is based on IR and NMR spectroscopic data. Notably, the C_S symmetry of this compound results in observation of only one set of quinoline ^1H and ^{13}C NMR resonances.

Treatment of **1** with 0.5 equivalents of $[Ir(coe)_2Cl]_2$ in CH_2Cl_2 resulted in rapid liberation of cyclooctene (coe) and near quantitative formation (by NMR spectroscopy) of the new coordination complex **2** as a *single* diastereomer (Scheme 1). Vapor diffusion of diethyl ether into the reaction mixture permitted isolation of **2** as analytically pure, yellow crystals in 87% yield. As expected, two sets of NMR resonances are observed for the quinoline groups of compound **2**. Evidence for the presence of the hydride ligand in **2** was obtained from IR (2172 cm^{-1}) and ^1H NMR (−15.6 ppm) spectroscopic data.



Scheme 1

The crystallographically determined structure of compound **2** is shown in Fig. 1.†‡ The non-equivalence of the quinoline groups noted in the ^1H and ^{13}C NMR spectra is consistent with the observed facial binding mode of the NSiN fragment. Constraints imposed by this ligand give rise to an Ir(III) center which is distorted considerably from ideal octahedral geometry. The chelate ligand 'bite' angles [N–Ir–N 87.5(3), N–Ir–Si 83.2(3) and 83.2(2)°] are all significantly compressed, underscoring the 'pinned-back' nature of the NSiN chelating framework. Geometric distortions are also observed at the silicon center. For example, the C(Me)–Si–Ir angle [131.2(4)°] is expanded well beyond the normal tetrahedral value. The Ir–Si distance [2.275(3) Å] in **2** can be compared to those in *fac*-tris[(8-quinolyl)dimethylsilyl]iridium (av. 2.30 Å),[5] and falls within the previously observed range (2.235–2.454 Å) for such

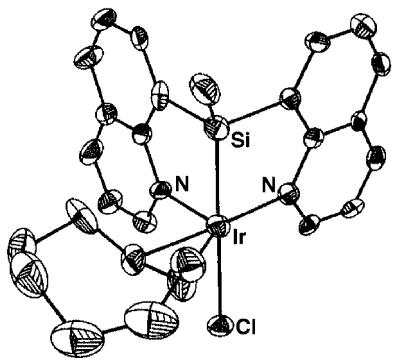


Fig. 1 Crystallographically determined structure of **2**, depicted with 50% thermal ellipsoids; all hydrogen atoms have been omitted for clarity.

† Electronic supplementary information (ESI) available: synthetic and crystallographic details for **1**–**5**. See http://www.rsc.org/suppdata/cc/b1/b102821a/

 DOI: 10.1039/b102821a

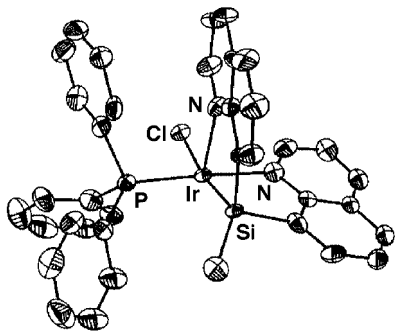

Fig. 2 Crystallographically determined structure of **3**, depicted with 50% thermal ellipsoids; all hydrogen atoms have been omitted for clarity.

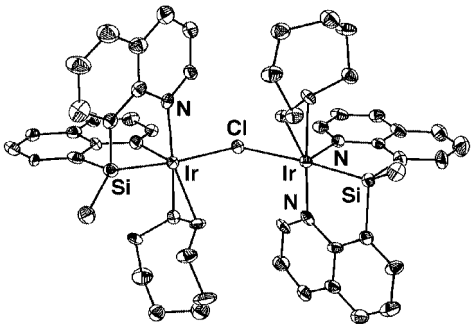

Fig. 3 Crystallographically determined structure of **5**, depicted with 50% thermal ellipsoids; the anion, solvates and all hydrogen atoms have been omitted for clarity. Only one component of the disordered coe fragment is shown.

bonds.[2] In contrast, the *trans*-labilizing nature[1–3] of the silyl group is manifested in a long Ir–Cl bond [2.572(3) Å].[6] The *trans*-influence of the hydride ligand is also indicated by elongation of an Ir–N bond [2.191(9) Å], relative to the other Ir–N bond [2.120(8) Å] in this complex.[7]

Preliminary reactivity studies reveal that the NSiN moiety is a robust ancillary ligand. Treatment of **2** with either PPh_3 or CO resulted in substitution of the coe ligand, yielding compounds **3** and **4**, respectively. Compound **3** gives rise to a singlet (17.0 ppm) in the $^{31}P\{^1H\}$ NMR spectrum and a phosphorus-coupled doublet (−19.1 ppm) in the hydride region of the ^1H NMR spectrum. The solid-state structure of compound **3** (Fig. 2) confirmed that the conversion of **2** to **3** occurs with retention of configuration at the Ir(III) center. In general, the geometric features associated with **3** parallel those described for **2** (*vide supra*). However, the Ir–P distance in **3** [2.234(3) Å] is noteworthy, since it appears to be contracted relative to Ir–P bonds found in related Ir(III) compounds (2.264–2.381 Å).[4,6,7] The coordination of a terminal carbonyl ligand to the Ir(III) center in **4** was confirmed by observation of a strong IR absorption attributed to this fragment (2010 cm^{-1}) and by the presence of a resonance at 169.9 ppm in the ^{13}C NMR spectrum. In contrast to the aforementioned transformations, no reaction was observed when a degassed CD_2Cl_2 solution of **2** was exposed to an atmosphere of H_2—even after prolonged heating (72 h at 90 °C). Collectively, these observations indicate that the Ir–Si linkage in **2** is relatively stable toward reductive elimination of Si–H.

In an attempt to prepare a cationic NSiN complex of iridium, CH_2Cl_2 was added to an equimolar mixture of **2** and $LiB(C_6F_5)_4{\cdot}2.5Et_2O$. Surprisingly, the major product obtained from this reaction was not that resulting from simple anion exchange, but rather the dinuclear complex **5**, which formally results from *in situ* trapping of the anticipated cationic species by an additional molecule of **2**. Complex **5** is formed exclusively as the racemic (C_2-symmetric) diastereomer, as confirmed by X-ray crystallography (Fig. 3).†‡ The overall connectivity pattern in **5** mirrors that found in **2**, with the exception that both of the Ir–Cl distances in the former [2.638(2) and 2.645(2) Å] are significantly longer than the Ir–Cl distance in the latter. Subsequently, compound **5** was prepared in 93% yield *via* treatment of **2** with 0.5 equiv. of the lithium borate. However, slow addition of **2** to an equiv. of $LiB(C_6F_5)_4{\cdot}2.5Et_2O$ under more dilute conditions led to clean formation (by NMR spectroscopy) of a new product, which we assume to be the desired mononuclear complex. Attempts are currently underway to isolate this species in pure form.

In conclusion, Ir(III) complexes containing the new bis(8-quinolyl)methylsilyl ligand have been prepared as single diastereomers in excellent yield. The diastereoselectivity associated with the clean formation of **2** and its derivatives indicates that the NSiN chelating ligand may have a directing effect on transformations at the Ir(III) center.[4] The synthesis and reactivity of various metal complexes supported by NSiN hybrid ligands will be the subject of future reports.

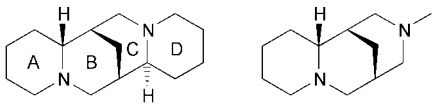
First published as an Advance Article on the web 13th June 2001

Evaluation of a sparteine-like diamine indicates that only the ABC rings of sparteine are required for high enantioselectivity in the lithiation–substitution of *N*-Boc pyrrolidine.

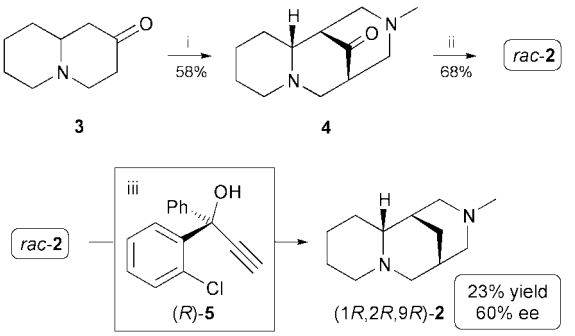
Sparteine **1** is a naturally occurring alkaloid extracted from plants such as Scotch Broom. It is commercially available and has been widely used as a chiral diamine ligand in asymmetric synthesis over the last 30 years.[1] For example, asymmetric lithiation–electrophilic quench using the combination of sparteine and alkyllithiums on a wide range of substrates occurs routinely with > 90% enantioselectivity. The groups of Hoppe[2] and Beak[3] have led the way with pioneering contributions in the applications of sparteine in synthesis. More recently, Hoppe *et al.*[4] and Wiberg and Bailey[5] have carried out theoretical calculations of transition state energies aimed at elucidating how sparteine exerts such high levels of enantiodifferentiation.



One of the main limitations of using sparteine in synthesis is that it is only commercially available in one enantiomeric form. Attempts to find other chiral diamine ligands capable of matching the enantioselectivity of sparteine have been moderately successful.[6,7] With the long term aim of developing a ligand that will function as the enantiomer of sparteine, we have investigated whether diamine **2**, which lacks the D-ring of sparteine as well as one of the chiral centres, mimicks sparteine sufficiently to give high enantioselectivity. Structural comparisons of diamines **1** and **2** complexed to lithium together with a recent calculated transition state for reaction[5] suggested that the D-ring of sparteine was not a key element in the enantiodiscriminating process. In this communication, we provide experimental evidence in support of this conjecture.

Although racemic diamine **2** is a known compound[8] and has found recent application in the functionalisation of terminal epoxides,[9] there have been no reports on the preparation of enantiomerically enriched diamines like **2**. An approach from amino acids investigated in our laboratory[10] was unsuccessful due to unavoidable racemisation in one of the steps. Thus, we resorted to resolution as a means of preparing non-racemic diamine **2** as outlined in Scheme 1.

Racemic diamine **2** was prepared using a published route:[8] double Mannich reaction of ketone **3** gave a single diastereoisomer of **4** (58% yield) which was converted into the required diamine **2** (68% yield) using Wolff–Kishner reduction. Unfortunately, we were unable to develop a resolution protocol for racemic **2** using commercial chiral acids (*e.g.* tartaric acid and derivatives, malic acid and camphorsulfonic acid). However, we had more success with resolution by inclusion complex formation using a method previously described by Toda *et al.*[11] Toda had discovered that it was possible to use naturally ocurring sparteine **1** to resolve racemic acetylinic alcohols such as **5**. Since diamine **2** is structurally similar to sparteine, we speculated that enantiomerically pure **5** could be used for resolution.

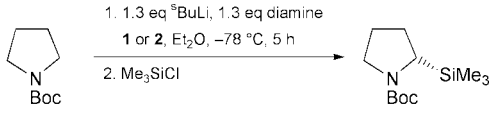


Scheme 1 *Reagents and conditions*: i, $MeNH_2$, $(CH_2O)_n$, AcOH, MeOH, reflux, 16 h; ii, N_2H_4, H_2O, KOH, diethylene glycol, reflux, 2 h; iii, acetone, evaporation over 64 h.†

Thus, Toda's method was employed to synthesise alcohol (*R*)-**5** of 98% ee (by chiral HPLC on an Astec Cyclobond I 2000-RSP column) and it was used in turn to partially resolve diamine **2**. In this way, we obtained a 23% yield of enantiomerically enriched diamine **2**† ($[\alpha]_D$ −15.7 (*c* 0.5 in EtOH); ~60% ee by chiral shift NMR). This resolution was reproducible in the 50–60% ee range and after repeating it a few times, we obtained a sufficient quantity of diamine **2** of ~55% ee. Since alcohol (*R*)-**5** had been obtained *via* crystal formation with sparteine **1**, it seemed likely that resolved diamine **2** (isolated *via* crystal formation with (*R*)-**5**) would have the same *absolute* stereochemistry as the ABC rings of sparteine.

With diamine **2** of ~55% ee in hand, we elected to directly compare it with sparteine **1** using lithiation of *N*-Boc pyrrolidine **6** and subsequent trapping with Me_3SiCl.[6,12] The results are presented in Table 1. Using sparteine **1**, we obtained a 73% isolated yield of silylated pyrrolidine (*S*)-**7** of 95% ee (by chiral GC). Under the same conditions, use of diamine **2** of ~55% ee gave an unoptimised 41% yield of silylated pyrrolidine (*S*)-**7** of 53% ee (by chiral GC).‡ The sense of asymmetric induction was

Table 1 Lithiation–substitution of *N*-Boc pyrrolidine using diamines **1** and **2**



Diamine	Yield of (*S*)-**7** (%)[a]	ee (%)[b]
Sparteine **1**	73	95
(1*R*,2*R*,9*R*)-**2** (~55% ee)	41	53

 DOI: 10.1039/b103220h

the same in both reactions indicating that resolved diamine **2** does indeed possess the same absolute stereochemistry as the ABC rings of sparteine. More importantly, however, the results presented in Table 1 provide the first experimental evidence that only the ABC rings of sparteine **1** are required for high enantioselectivity in the lithiation of *N*-Boc pyrrolidine **6**.

In summary, our results indicate that diamine **2** exhibits essentially the same level of enantioselectivity as sparteine **1** in the lithiation of *N*-Boc pyrrolidine **6**. Thus, we conclude that the sparteine D-ring is superfluous and is not a prerequisite for high enantioselectivity.

We thank the EPSRC and GlaxoSmithKline for the award of an Industrial CASE award (to D. W. P.), The Leverhulme Trust for the award of a fellowship (to J. R. H.) and Dr D. B. Matthews for chiral HPLC and GC analyses.

Notes and references

† *Resolution of diamine rac*-**2**: A solution of freshly distilled diamine *rac*-**2**[8] (742 mg, 3.8 mmol) in acetone (3 cm^3) was added dropwise to a solution of alcohol (*R*)-**5** (929 mg, 3.8 mmol; 98% ee by chiral HPLC on an Astec Cyclobond I 2000-RSP column) in acetone (3 cm^3) at rt. The solvent was allowed to evaporate slowly by standing at rt for 64 h and pale yellow crystals formed. Petrol (5 cm^3) was added and the crystals were collected by filtration and washed well with petrol (3 × 5 cm^3). The crystals were dissolved in Et_2O (15 cm^3) and 2 M $HCl_{(aq)}$ (10 cm^3), the layers were separated and the organic layer was extracted with 2 M $HCl_{(aq)}$ (2 × 10 cm^3). Then, 20% $NaOH_{(aq)}$ was added to the combined aqueous layers until pH 9 and the solution was extracted with Et_2O (3 × 10 cm^3), dried (K_2CO_3) and evaporated under reduced pressure to give diamine (1*R*,2*R*,9*R*)-**2** (171 mg, 23%; ~60% ee by ^1H NMR spectroscopy in the presence of (*R*)-2,2,2-trifluoro-1-(9-anthryl)ethanol) as a colourless oil, $[\alpha]_D$ −15.7 (*c* 0.5 in EtOH). Treatment of the petrol washings in the same way as described above for the crystals gave diamine (1*S*,2*S*,9*S*)-**2** (503 mg, 68%; ~30% ee by ^1H NMR spectroscopy in the presence of (*R*)-2,2,2-trifluoro-1-(9-anthryl)ethanol) as a colourless oil, $[\alpha]_D$ +6.1 (*c* 0.6 in EtOH).

‡ In theory, silylated pyrrolidine (*S*)-**7** of >55% ee could have been generated if a non-linear effect was occurring. Our results clearly indicate the absence of a non-linear effect and are in line with the calculated transition state for reaction[5] which invokes deprotonation by a monomeric complex.

Received (in Cambridge, UK) 26th March 2001, Accepted 15th May 2001
First published as an Advance Article on the web 13th June 2001

A reaction between $Gd(NO_3)_3{\cdot}6H_2O$, $K_3[Cr(CN)_6]$ and dmf or bpy has allowed the synthesis of two new ferrimagnetic Gd^{III}–Cr^{III} chains which are the first low-dimensional 4f–Cr^{III} systems; magnetic susceptibilty data indicate antiferromagnetic coupling between Gd^{III} and Cr^{III}.

The association of 3d–4f ions in cyanide-bridged low dimensional arrays is original and may open new perspectives for the use of the optical properties of rare earth ions included in magnetic molecular media.[1,2] In general, little is known about the nature of the exchange interactions of rare earth ions either with one another or with other magnetic groups. Until recently few simple compounds containing magnetically coupled f-block ions were available. Most of them are Gd^{III}–Cu^{II} or Gd^{III}–radical organic systems.[3,4] Among those with cyanide bridges, several tri-dimensional polycyano metallates(III) (Fe, Co, Cr) with 4f ions[5] and two heteropolynuclear Ln^{III}–Fe^{III} compounds have been reported.[6] Some heterometallic one-dimensional arrays containing cyanide-bridged lanthanide(III) and diamagnetic $[M(CN)_4]^{2-}$ (M = Ni, Pd, Pt) have also been described.[7] In contrast, to the best of our knowledge, discrete or low-dimensional derivatives of $[Cr(CN)_6]^{3-}$ with 4f ions have not been reported. This communication is devoted to the preparation,† characterization including structural determination, and magnetic properties of the two first one-dimensional derivatives from $[Cr(CN)_6]^{3-}$ and Gd^{III}: *cis*-$[Cr(CN)_4(\mu\text{-}CN)_2Gd(H_2O)_2(dmf)_4]_n{\cdot}nH_2O$ **1** and *trans*-$[Cr(CN)_4(\mu\text{-}CN)_2Gd(H_2O)_4(bpy)]_n{\cdot}4nH_2O{\cdot}1.5n$bpy **2**. Fig. 1 shows the X-ray crystal structure of **1**.‡ The crystallographic analysis of **1** revealed that its crystal structure is a one-dimensional (1D) chain polymer. The chain shows an alternation of Gd^{III} and Cr^{III} units linked by cyanide bridges in *cis* geometry with respect to Cr^{III}. The coordination sphere around gadolinium comprises four oxygen atoms of dimethylformamide (dmf) ligands, two oxygen atoms of two water molecules and two nitrogen atoms of the cyanide bridges. The eight-coordinate gadolinium atom lies in a distorted dodecahedral environment. The Gd–Cr intramolecular distance is 5.65 Å and the Gd–Cr–Gd angle is 98.432° indicating the *cis*-geometry. As shown in Fig. 1, the chains are aligned in the *x*-direction where two neighboring chains are linked by water molecules, giving a slipped packing.

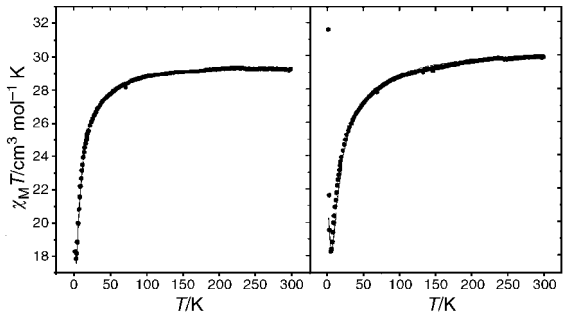

Fig. 3 Left: Temperature dependence of $\chi_M T$ for **1**. The solid line represents the best-fit curve (see text for parameters). Right: Temperature dependence of $\chi_M T$ for **2**. The solid line represents the best-fit curve (see text for parameters).

dral environment. The Gd–Cr intramolecular distance is 5.59 Å and the Gd–Cr–Gd angle is 159.28° indicating the *trans*-geometry. As shown in Fig. 2 the chains are aligned in the *y*-direction. Between two neighboring chains are water molecules and two different bpy crystallization molecules. One of them is not planar showing a dihedral angle between the two pyridine planes of 20° and the other is planar but the same dihedral angle is 180°.

The susceptibility measurements for complexes **1** and **2** are shown in Fig. 3 as $\chi_M T$ *vs.* T respectively. There is no mathematical expression for fitting a one-dimensional system with alternated $S = 7/2$ and 3/2. To fit the experimental data we have assumed a ring of six atoms (three Gd^{III} and three Cr^{III}) (Fig. 4), which should describe the behavior of the infinite chain when J is small. The fit of experimental data was performed according to the following Hamiltonian:

$$H = -J(S_1S_2 + S_2S_3 + S_3S_4 + S_4S_5 + S_5S_6 + S_6S_1)$$

where J corresponds to the coupling through the cyanide bridges. The free parameters were J and g (average). The fit made by the irreducible tensor operator formalism (ITO) using the CLUMAG program[8] gave the following results: $J = -0.52$ cm^{-1}, $g = 2.01$ and $R = 2.07 \times 10^{-5}$ for complex **1** (Fig. 3) and $J = -1.06$ cm^{-1}, $g = 2.05$ and $R = 2.137 \times 10^{-4}$ for complex **2** (Fig. 3). Both complexes show a weak antiferromagnetic interaction between Cr^{III} and Gd^{III} ions to give a ferrimagnetic chain. For complex **2**, the two values of $\chi_M T$ at low temperatures are not fitted because in our model the limit of $\chi_M T$ is that corresponding to three Gd^{III} + three Cr^{III} ($\chi_M T = 21$ cm^3 mol^{-1} K; $S_T = 6$). In the actual structure (one-dimensional complex) $\chi_M T$ tends to infinity, as shown in Fig. 4.

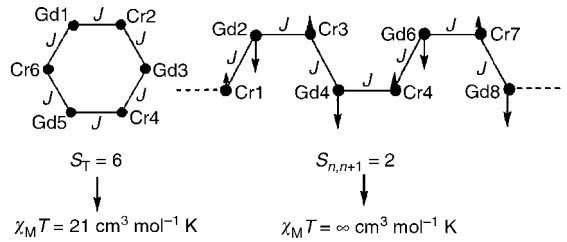

Fig. 4 Left: Scheme of a ring of six atoms used in the fit made by the ITO formalism. Right: Scheme of the spin topology assuming antiferromagnetic coupling.

A simulation of $\chi_M T$ *vs.* T for the ring of six atoms was calculated using the same method as that described above. The g value was fixed as 2.00. The value of J was simulated between 0 cm^{-1} and -2 cm^{-1}. As expected, with these small J values, the variation of $\chi_M T$ *vs.* T is observed only at low temperatures. The theoretical $\chi_M T$ *vs.* T curves are shown in Fig. 5. When the J coupling is more negative the minimum of $\chi_M T$ is shifted to a higher temperature.

This work was supported by the Spanish Dirección General de Investigación Científica y Técnica (project BQU2000-0791).

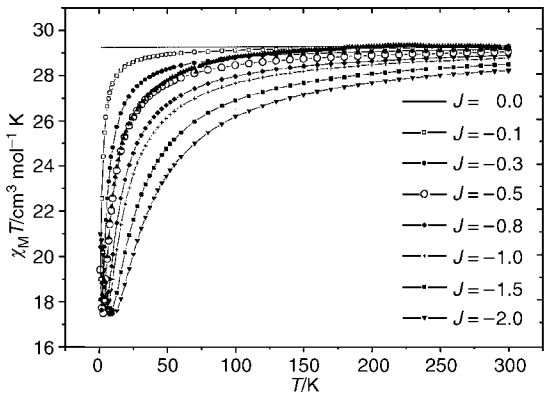

Fig. 5 Theoretical curves obtained by the CLUMAG program for different J values; g was maintained constant and equal to 2.00.

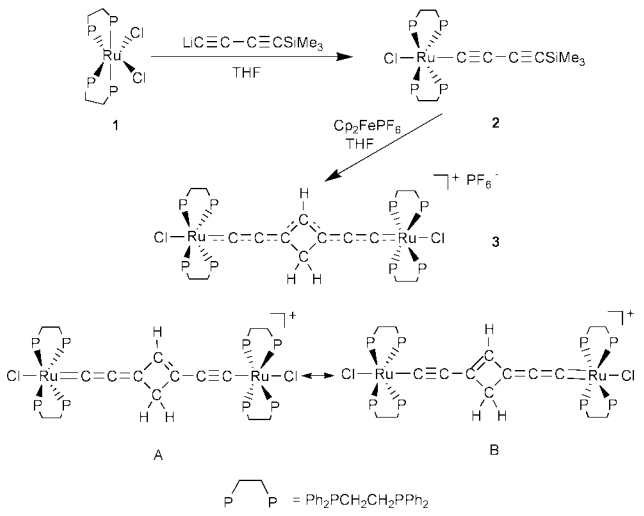
Treatment of $[Cl(dppe)_2Ru–C\equiv C–C\equiv C–SiMe_3]$ with $[Fe(C_5H_5)_2]PF_6$ leads to an unprecedented metal-assisted [2 + 2] coupling reaction on $C^{\gamma}\equiv C^{\delta}$ bonds to obtain $[Cl(dppe)_2Ru–C\equiv C–\overline{C=CHC(CH_2)}=C=C=Ru(dppe)_2Cl]PF_6$ with the charge highly delocalized over seven carbon atoms and including a cyclobutenyl bridge; the crystal structure was solved.

Polynuclear transition metal complexes with unsaturated carbon rich bridges retain much attention,[1,2] for their potential to scale down electronic components *i.e.* to form molecular wires and other nanoelectronic devices.[2] The literature is now extensive for complexes with an even number of conjugated carbon atoms spanning two metal fragments of various structures[1,2] such as $L_nMC_xML_n$ or $L_nM(CH)_xML_n$. By contrast, the synthesis of bimetallic compounds with odd carbon chains has not been extensively explored considering the variety of fragments available. Only few bridges with one, three or five unsaturated carbons capped with two metal moieties have been reported.[3–5] Current extension of the chemistry of vinylidene $[M=C=CR^1R^2]$ and acetylide $[M–C\equiv C–R]$ complexes to obtain new bridges *via* [2 + 2] cycloaddition led to a class of complexes $[M–\overline{C=CR–C(CR^2R^3)}=M]^+$ including rigid cyclic four-membered bridges with a delocalised C_3 path between metals.[4,5] Interestingly, when the reaction was applied to allenylidene[4c] $[M=C=C=CR^1R^2]$ or diyne[4d] $[M–C\equiv C–C\equiv C–R]$ complexes, the resulting ring bears an exocyclic double or triple bond, respectively, with a similar C_3 conjugated path. The formation of these carbon ligands is highly regioselective and the product of addition with the most activated $C^{\alpha}–C^{\beta}$ bond is always obtained. We now report an unprecedented radical-promoted [2 + 2] coupling reaction occurring on the $C^{\gamma}\equiv C^{\delta}$ bonds of a 1,3-diynyl metal derivative to lead to a novel type of metal complex $[M–C\equiv C–C=CHC(CH_2)=C=CM]^+$ including a carbon-rich annelated C_8H_3 bridge with seven conjugated carbons between remote metals.

Previous studies[6] on ruthenium allenylidenes $[Cl(dppe)_2Ru=C=CR^1R^2]$ and acetylides $[Cl(dppe)_2Ru–C\equiv C–R]$ (dppe = 1,2-diphenylphosphinoethane) showed that the bulky ruthenium $[RuCl(dppe)_2]^+$ moiety prevents C^{α} from nucleophilic attack while promoting reactions on C^{γ}. The $C^{\alpha}\equiv C^{\beta}$ bond in diyne complexes such as $[Cl(dppe)_2Ru–C\equiv C–C\equiv C–SiMe_3]$ is sterically protected by the dppe groups and [2 + 2] cycloaddition using this type of complex is likely to occur on the $C^{\gamma}\equiv C^{\delta}$ triple bond. The pale yellow diynyl ruthenium complex *trans*-$[Cl(dppe)_2Ru–C\equiv C–C\equiv C–SiMe_3]$ **2** was obtained (63%) *via* substitution of one chloride of *cis*-$[RuCl_2(dppe)_2]$ **1** with a slight excess (1.5 equiv.) of lithium acetylide in THF (Scheme 1). The *trans* structure was evidenced by ^{31}P NMR spectroscopy showing a singlet at δ 49.09 for the four phosphorus atoms. Upon treatment of complex **2** with half an equivalent of ferrocenium hexafluorophosphate as oxidant a metal-assisted C–C forming reaction took place and dark purple crystals of **3** were isolated after several crystallisations in moderate yield (45%). This compound was fully characterised by NMR, IR, UV–VIS and HR-MS (ESI†). ^{31}P analysis of **3** shows only one singlet at δ 45.2 indicating that (i) the two metal sites are equivalent and (ii) the four phosphorus are also equivalent on each metal centre with the Cl atom and the bridge in a *trans* position. ^{13}C NMR analysis shows only five different signals for the unsaturated bridges linking the two rutheniums. The Ru–C(1) resonance at δ 247.7 (quint, $^2J_{pc}$ 14 Hz) is downfield compared to that of an alkynyl (δ 105.5 for $[Cl(dppe)_2Ru–C\equiv C–CPh_2H]$)[6b] and upfield from that of an allenylidene complex (δ 308.6 for $[Cl(dppe)_2Ru=C=C=CPh_2]$).[6c] The same phenomenon is observed for the C(2) (δ 166.0) and C(3) (δ 147.1) resonances. The ^1H spectrum shows two characteristic resonances for the C_4 ring at δ 2.07 (s, 2H) and δ 5.11 (s, 1H). These NMR studies are consistent with a highly delocalized structure giving a formal half positive charge on each ruthenium as sketched on Scheme 1. The FTIR spectrum shows an intense absorption band at 1909 cm^{-1} indicative of the cumulenylidene character of the system.[6a,c]

X-Ray-structural analysis[7] (Fig. 1) verifies that the complex is formed with two identical bulky ruthenium fragments $[RuCl(dppe)_2]^+$ connected by a C_8H_3 ligand. The Cl atoms adopt a *trans* position with respect to the bridge and the Cl(1)–Ru(1)–bridge–Ru′(1)–Cl(1)′ arrangement is linear. The four-membered ring is planar so giving maximum orbital overlap across the bridge. Owing to the inversion centre which relates the two parts of the complex, the four-membered ring is symmetric. Moreover as the two distances, C(3)–C(4) 1.457(5) Å and C(3)–C(4′) 1.459(5) Å, are identical within experimental error, the four C–C bond lengths are identical within the ring.[7b]



Scheme 1

† Electronic supplementary material (ESI) available: selected spectroscopic data. See http://www.rsc.org/suppdata/cc/b1/b103301h/

 DOI: 10.1039/b103301h

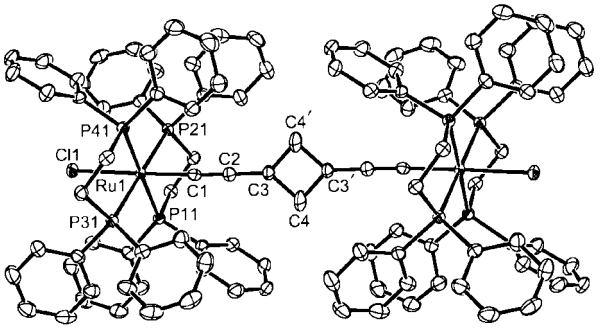


Fig. 1 Molecular structure of **3** (ORTEP view). Ellipsoids represent 50% probability level. Selected distances (Å) and angles (°): Ru(1)–C(1) 1.933(3), C(1)–C(2) 1.225(4), C(2)–C(3) 1.372(4), C(3)–C(4) 1.457(5), C(3)–C(4′) 1.459(5); C(1)–Ru(1)–Cl(1) 178.49(9), C(2)–C(1)–Ru(1) 174.4(2), C(1)–C(2)–C(3) 178.3(3), C(2)–C(3)–C(4) 134.2(3), C(3)–C(4)–C(3′) 88.3(3).

In order to account for the inversion centre, we should consider the occurrence of a fully delocalised system with a disorder between CH and CH_2. Indeed, Ru–C(1) (1.933 Å), C(2)–C(3) (1.372 Å) bonds are found to be shorter than the single bonds in an acetylenic system such as $[Cl(dppe)_2Ru–C{\equiv}C–C_6H_4NO_2)]$[8] (1.986 and 1.442 Å) and longer than the double bonds in an allenylidene system $[Cl(dppm)_2Ru{=}C{=}C{=}C(C_{14}H_{10})]PF_6$[6d] (1.852 and 1.393 Å). On the other hand the C(1)–C(2) bond length (1.225 Å) is intermediate between the values found in these mononuclear systems (1.206 and 1.255 Å, respectively) demonstrating a bond order between one and two for Ru(1)–C(1), C(1)–C(2), C(2)–C(3) bonds indicative of a hybrid structure.

The UV–VIS spectrum of the complex recorded in CH_2Cl_2 exhibits a strong charge transfer band (λ_{max} = 633 nm) with a high absorption coefficient (ε = 141 000 mol^{-1} L cm^{-1}) (ESI†). For comparison, the allenylidene compound $[ClRu(dppe)_2(=C=C=CPh_2)]PF_6$ shows a MLCT band at λ_{max} = 505 nm, ε = 18 000 mol^{-1} L cm^{-1}. The charge transfer is considerably more intense in the bimetallic compound and this can be best rationalized by the two canonical forms A and B. It is of note that **3** shows a stronger absorption than the related 'V' shaped compound $[CpRu(PPh_3)_2{=}C{=}C{=}CH–C{\equiv}C–Ru(PPh_3)_2Cp]BF_4$ (λ_{max} = 600 nm, ε = 72 000 mol^{-1} L cm^{-1}) which exhibits the same type of conjugation between the two remote metals.[3d,9] This is certainly due to the better planarity and rigidity of **3** and subsequent stronger conjugation. Cyclic voltammetry (CV) was used to investigate the electrochemical behaviour of **3** (CH_2Cl_2, $Bu^n_4NPF_6$ 0.1 M 200 mV s^{-1}). The binuclear compound undergoes a well defined one-electron reversible oxidation ($E°$ = 0.42 V *vs*. ferrocene) and an irreversible second oxidation at higher potential (E_{pa} = 0.91 *vs*. ferrocene). It also shows a one-electron reversible reduction ($E°$ = −1.48 V *vs*. ferrocene). The oxidation processes can be attributed to the successive oxidation of the two ruthenium centres[3d,6c,e] due to substantial electronic interaction between the metallic centres.[2] The reduction process can be attributed to the reduction of the C_8H_3 ligand.[3e,6b,e] Indeed, carrying out the reduction of complex **3** with cobaltocene[10] in a THF solution in a capped EPR tube allows the direct observation of the radical species **3**· which generates an intense and persistent feature at 293 K. A signal without detectable hyperfine structure is located in a characteristic region for organic radicals with g = 2.009. The electrochemical behaviour of **3** is in accord with that found for the related 'V' shaped compound $[CpRu(PPh_3)_2{=}C{=}C{=}CH–C{\equiv}C–Ru(PPh_3)_2Cp]BF_4$.[3d]

In summary, we have developed an easy method to prepare a bimetallic complex containing a novel C_8H_3 bridge with new interesting spectroscopic and structural properties. The unprecedented regioselectivity of the addition is explained by the steric hindrance of the bulky diphosphines with only the $C^{\gamma}{\equiv}C^{\delta}$ bond being reactive.[6] Despite the unfavourable potential, the reaction is likely initiated by an electron transfer between ferrocenium and **2** ($E°$ = 0.130 V *vs*. ferrocene) generating an electrophilic organometallic radical. The latter would be able to couple with another molecule of acetylide **2**. This mechanism (and the driving force) remains unverified but we anticipate that the resulting radical incorporates hydrogen atoms from the medium.[11]

We thank the CNRS and the Université de Rennes 1 for support, Drs P. Guenot and O. Maury for helpful discussion and M. Krueger (Erasmus student) for help.

9 The absorptions of the respective mononuclear allenylidenes present similar values of ε, see M. Tamm, T. Jentzsch and W. Werncke, *Organometallics*, 1997, **16**, 1424.

10 The potential of **3** is 150 mV negative to that of $[CoCp_2]$ (−1.33 V *vs*. ferrocene). However, the values are close enough to observe a slight displacement of the equilibrium and to detect the reduced species **3**· using EPR spectroscopy. See N. G. Connelly and W. E. Geiger, *Chem. Rev.*, 1996, **96**, 877.

11 It is likely that **2** is oxidized and further desilylation would lead to a radical species of type $Ru^{\cdot+}–C{\equiv}C–C{\equiv}CH \leftrightarrow Ru^{+}{=}C{=}C{=}C{=}CH^{\cdot}$ that can react with **2** [0.5 equiv. of oxidant is necessary, [2 + 2] coupling reaction]. The resulting cyclic radical would be desilylated and incorporate hydrogen atoms from the medium. It is of note that treatment of **2** with $CuCl_2$ or $FeCl_3$ also leads to **3** and that protonation of **2** with an acid (HBF_4) does not lead to **3** *via* a butatrienylidene intermediate.

Preparation of carbonyltungsten(0) complexes of 2-chloro-3,3-diphenyl-1-(2,4,6-tri-*tert*-butylphenyl)-1,3-diphosphapropene

Shigekazu Ito and Masaaki Yoshifuji*

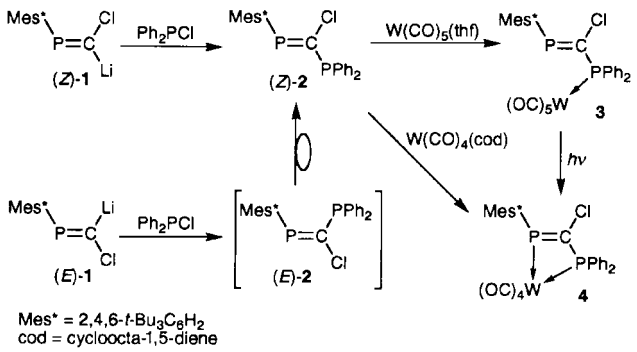
Department of Chemistry, Graduate School of Science, Tohoku University, Aoba, Sendai 980-8578, Japan. E-mail: yoshifj@mail.cc.tohoku.ac.jp

Received (in Cambridge, UK) 27th March 2001, Accepted 10th May 2001
First published as an Advance Article on the web 13th June 2001

(*Z*)-2-Chloro-3,3-diphenyl-1-(2,4,6-tri-*tert*-butylphenyl)-1,3-diphosphapropene was prepared from chlorodiphenylphosphine and 1-chloro-2-(2,4,6-tri-*tert*-butylphenyl)-2-phosphaethenyllithium and used for metal complex formation as a ligand to provide carbonyltungsten(0) complexes.

The 1,3-diphosphapropene system is an attractive ligand system for metal complex formation because two different types of phosphorus atoms are included within the system; *i.e.* a low-coordinated $\lambda^3\sigma^2$-phosphorus atom[1,2] and a common $\lambda^3\sigma^3$-phosphorus atom. However, research on coordination of the 1,3-diphosphapropene derivatives toward transition metals has been limited, whereas several metal complexes of η^3-1,3-diphosphaallyl ligands have been reported so far.[3,4] Indeed, the only reported example concerns the X-ray structural analysis of an iron(0) complex of 1,3-diphosphapropene prepared through an intramolecular cyclization of a bulky 1,3-diphosphaallene by ourselves.[5] There have been no reports on X-ray structural analysis of transition metal complexes of 1,3-diphosphapropene itself. Furthermore, the catalytic abilities of transition metal complexes of low-coordinated phosphorus compounds are of current interest,[6–10] and thus detailed study of the coordination chemistry of the 1,3-diphosphapropene system is crucial. Here we report the preparation and X-ray structural determination of carbonyltungsten complexes of a 1,3-diphosphapropene derivative kinetically stabilized by the 2,4,6-tri-*tert*-butylphenyl group (Mes*) including a selective coordination reaction of either the monodentate or chelate form.

A kinetically stabilized (*Z*)-1-chloro-2-(2,4,6-tri-*tert*-butylphenyl)-2-phosphaethenyllithium (*Z*-**1**) was prepared from 2,2-dichloro-1-(2,4,6-tri-*tert*-butylphenyl)-1-phosphaethene and butyllithium, and was allowed to react with chlorodiphenylphosphine (Scheme 1)[11] to afford the corresponding 2-chloro-1,3-diphosphapropene (*Z*-**2**) in good yield (78%) after silica-gel column chromatographic purification (hexane–toluene, v/v = 5/1). Compound *Z*-**2** was characterized spectroscopically.† In the ^{31}P NMR spectrum, a peak due to the P=C phosphorus atom appeared at low field (δ_P 302.4) with a large $^2J_{PP}$ value (277 Hz), suggesting an *E*-configuration. Similarly, starting from *E*-**1** and chlorodiphenylphosphine,[11a] an attempt was made to prepare *E*-**2**. Although NMR signals due to *E*-**2** were observed in the reaction mixture (δ_P 325.1, 3.0, $^2J_{PP}$ 15 Hz), *E*-**2** was isomerized to *Z*-**2** after the usual work-up procedure, probably due to large repulsion between the Mes* group and the Ph_2P group.



Scheme 1

Next we investigated the coordination property of *Z*-**2** towards tungsten(0). Initially, *Z*-**2** was allowed to react with an equivalent amount of $W(CO)_5$(thf) for 6 h at room temperature to afford the corresponding pentacarbonyltungsten(0) complex **3** in 39% yield as yellow prisms after recrystallisation from hexane (Scheme 1).‡ The coordination on tungsten seemed to occur at the Ph_2P phosphorus atom as suggested by a satellite signal due to the tungsten atom in the ^{31}P NMR spectrum of **3**. The reason for this type of coordination might be explicable taking the stronger basicity of the Ph_2P group into account,[12] while Bertrand and coworkers reported an NMR study to suggest the coordination at the low-coordinated $\lambda^3\sigma^2$-phosphorus atom in a 1,3-diphosphapropene system.[4] In the ^{13}C NMR spectrum, the chemical shift of the P=C carbon atom is similar to that for *Z*-**2**, but the two $^1J_{PC}$ values are quite different (79 and 4 Hz) indicating low electronic interaction between the PPh_2 group and the P=C carbon atom. The structure of **3** was unambiguously determined by X-ray crystallography and Fig. 1 displays an ORTEP drawing.§ The P2–W distance is 2.540(1) Å, which is similar to that for $W(CO)_5(PPh_3)$ [2.545(1) Å].[13] The P1–C(1) distance is 1.675(4) Å, which is a normal value for the P=C bond.[1] The P1, P2, C1, Cl, W atoms are almost coplanar and the tungsten atom is located on the same side of lone pairs of the P1 atom with a P1···W distance of 3.97 Å. Complex **3** did not react with an excess amount of $W(CO)_5$(thf) to afford the bis-tungsten complex, probably due to steric congestion around the P=C phosphorus atom.[4]

The structure of **3** indicates that *Z*-**2** is a good chelating ligand, and therefore we tried to prepare a chelate complex of *Z*-**2** by use of $W(CO)_4$(cod) (cod = cycloocta-1,5-diene) at room

temperature. After 12 h, **4** was obtained in 19% yield as red crystals together with 63% recovery of *Z*-**2**, after purification by gel permeation chromatographic separation (Scheme 1).‡ A trace amount of **4** was also obtained by the reaction of *Z*-**2** and $W(CO)_5$(thf). In the ^{31}P NMR spectrum of **4**, a peak due to the P=C phosphorus atom is observed at a higher field than that for *Z*-**2**, and both of the two phosphorus atoms show satellite peaks due to the presence of the tungsten atom. Moreover, the coupling constant between the P=C phosphorus and the tungsten (213 Hz) is reasonable for a complex with an end-on coordinating mode.[14] On the other hand, Appel and coworkers reported a side-on coordination with Fe(0) on the P=C moiety in the 1,3-diphosphapropene system.[3] In the ^{13}C NMR spectrum of **4**, a peak due to the P=C carbon atom has a higher chemical shift than that for *Z*-**2**, and the two $^1J_{PC}$ values are small (23 and 9 Hz). Two different chemical shifts were observed for CO_{eq} carbons together with two different $^2J_{PC}$ values, probably due to the coordination by two different types of phosphorus atoms. The structure of **4** was unambiguously determined by X-ray crystallography and Fig. 2 depicts an ORTEP drawing.§ The P=C phosphorus atom coordinates in the end-on mode which leads to a large $^1J_{PW}$ value in the NMR spectrum. The P1–W distance [2.489(3) Å] is shorter than the P2–W distance [2.526(3) Å], and the P1–C(1) distance [1.651(10)] is normal for the P=C bond. The P1–W–P2 angle is small with a value of 65.1(1)°. The P1–C(1)–P2 and C(1)–P2–W angles, 93.5(3) and 101.8(5)°, respectively, are smaller than the corresponding angles for **3**.

Chelate complex **4** was also derived by photo-irradiation of **3**. A THF solution of **3** was irradiated with a medium-pressure mercury lamp at 5 °C for 16 h in an NMR tube to afford **4** almost quantitatively. No *E*/*Z* isomerization of **3** was observed probably due to the steric hindrance between the Mes* and Ph_2P moieties.[15]

Compound **2** contains a chlorine atom at the sp^2-carbon atom which can potentially be substituted. We are now attempting to prepare various types of 1,3-diphosphapropenes from **2**, as well as metal complexes of the type **3** and **4**.

This work was supported in part by a Grant-in-Aid for Scientific Research (No. 12042208) from the Ministry of Education, Science, Sports and Culture, Japan.

The first polymer with a fluorosilicate backbone and a non-polar shell

Rudolf Pietschnig* and Klaus Merz

Lehrstuhl für Anorganische Chemie I, Ruhr-Universität Bochum, Universitätsstraße 150, 44780 Bochum, Germany. E-mail: rudolf.pietschnig@ruhr-uni-bochum.de

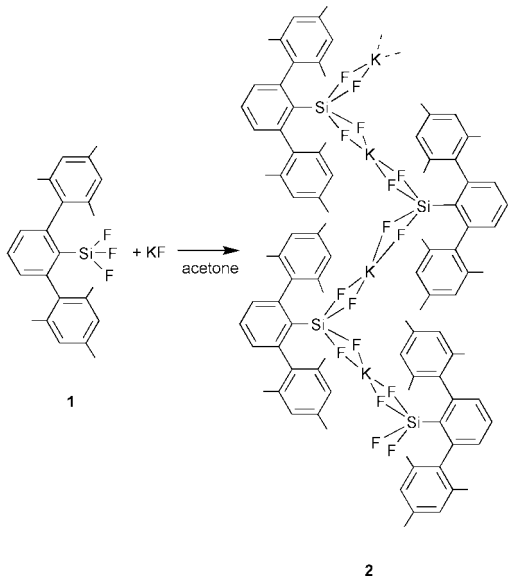
A novel type of linear inorganic–organic hybridic polymer is presented in which terphenyl ligands are covering the inorganic backbone, providing it with a non-polar coating.

Over recent years coordination polymers have attracted considerable interest.[1] Besides their properties and potential application,[2] controlling the self organisation of the monomeric units to build one or higher dimensional frameworks has been a major achievement in this fascinating research area.[3] Most of these inorganic–organic hybrid materials are constructed from metal cations connected by organic ligands, forming a hybrid inorganic–organic backbone.[4] There are also examples of coordination polymers with a completely inorganic backbone showing a wealth of different coordination modes.[5]

Several examples of crystal structures of organo-tetrafluorosilicates are known to date.[6–8] In all of these structures the anions show no direct interaction with more than one counter-cation. Organofluorosilicates with a potassium counter-cation are usually destabilized due to potassium–fluorine interactions. These interactions can be minimised by complexation of the cation with 18-crown-6[7] or completely removed with [2,2,2]-cryptand.[8]

Earlier we reported[9] a globular-terphenyl substituted fluorosilicate in which both tetra- and penta-fluoro silicate units are interconnected in a network built together by the counter-cation interaction. Herein we report the first inorganic fluorosilicate based coordination polymer enveloped by a non-polar organic shell, starting from a multidentate ligand site offering steric control. In order to investigate the balance between electrophilicity and steric protection of the silicon centre in such compounds, we allowed 2,6-dimesitylphenyl trifluorosilane **1** to react with an excess of KF. We exclusively observed the formation of the terphenyl tetrafluorosilicate **2** (Scheme 1) and the product adopts a one dimensional polymeric structure in the solid state (see Fig. 1). To our knowledge this is the first



Scheme 1 Synthesis of **2**.

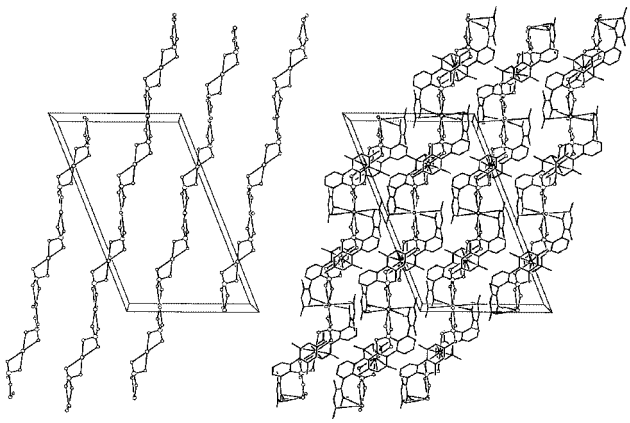


Fig. 1 Inorganic backbone of **2** with (right) and without (left) ligand shell.

structurally characterised potassium organo–tetrafluorosilicate polymer. The interaction of the counter ions leads to association forming a K–F–Si–F–K type of a linear coordination polymer.

Under stoichiometric conditions 2,6-dimesitylphenyl tetrafluorosilicate **2** can be readily synthesised† from the corresponding trifluorosilane **1** and KF. It is a one dimensional coordination polymer the structure of which has been established by X-ray diffraction analysis (see Fig. 2).‡ Polymer **2** is built by organo-tetrafluorosilicate units each of which acts as a bidentate ligand towards two potassium ions. The potassium cations are surrounded by fluorine atoms forming a square planar coordination environment. The axial positions above and below the potassium are occupied by the mesityl substituent of the organic ligand. Additionally one molecule of acetone is present in the coordination sphere of every second potassium ion.

The inorganic backbone consists of four membered SiF_2K rings which are spiro connected at the silicon and the potassium centres. The zig-zag arrangement of the inorganic backbone is shielded by the organic terphenyl ligands attached to each silicon atom. The bulky aryl ligands prevent extensive coordination of solvent to the potassium centres, which instead interact with the π-systems of the mesityl rings of the terphenyl system. This interaction of the cation with the organic shell

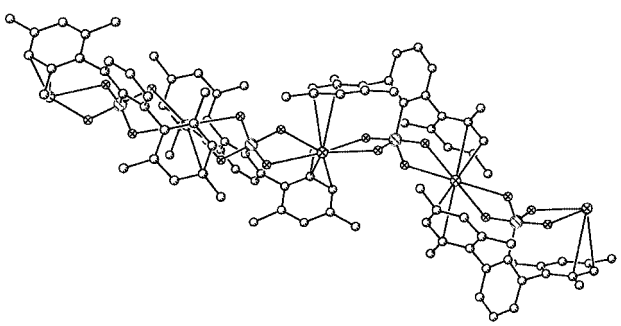

Fig. 2 Detail of the structure of **2**.

 DOI: 10.1039/b102853g

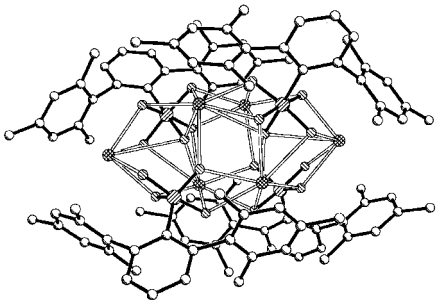

Fig. 3 Crystal structure of **3**.[9]

seems to be crucial for the stability of the polymer, and despite some effort we have not been able to observe similar structures with smaller alkali metal ions.

These findings are in good accordance with previous observations that, due to their preference for increased coordination numbers, the larger alkali metal cations have a tendency to participate in the formation of higher aggregates than smaller alkali metal cations,[10] even though the cation π-system stabilisation energies are smaller for potassium than those observed for lithium.[11,12] The K–C distances in **2** (3.1–3.5 Å) fall in the normal range of such interactions.[6]

The linear polymer **2** is somewhat related to a structural isomer **3** which however shows no polymeric structure but does start a fluorosilicate network in which a globular inorganic core is covered by a shell of organic terphenyl ligands (see Fig. 3).[9] This globular adduct is formed under different kinetic conditions than **2**. The chain **2** forms when both starting materials, dimesitylphenyl trifluorosilane and potassium fluoride, are present in equal concentration in the reaction mixture. In contrast the formation of the globular system **3** is characterised by a large excess of the bulky trifluorosilane in the presence of a small concentration of potassium fluoride. The latter is continuously formed in the course of a slow reductive process.[9] This illustrates how delicately the reaction parameters control the resulting architecture of the polymer. Starting with identical components and controlling reaction conditions globular **3** or linear arrangement **2** can be obtained.

The structure of **2** is not retained in solution as indicated by NMR studies. In acetone solution the coordination polymer dissociates into two species as indicated by ^{19}F-NMR. The main signal at −113.3 ppm is sharp and shows ^{29}Si satellites (214 Hz), while a minor signal at –127.3 ppm is relatively broad ($\nu_{1/2}$ = 30 Hz) probably due to chemical exchange. Simple ^{29}Si-NMR experiments are hampered by the fact that the expected fluorosilicates show their resonance in the same region as the broad resonance of the glass peak of the NMR tube. Moreover the Si–H coupling constants and the number of protons that are close enough to be used for INEPT or DEPT experiments are to small for this purpose. However, with ^{1}H{^{29}Si}-2D-HMQC experiments we have been able to observe ^{29}Si spectra and to assign the data to the respective dissociation products. The predominant species shows a ^{29}Si signal at −123 ppm ($^{1}J_{SiF}$ = 214 Hz) and can be assigned to the monomeric $Mes_2C_6H_3SiF_4^-$ ion. For comparison $PhSiF_4^-$ shows a ^{29}Si resonance at −126 ppm. The ^{29}Si resonance of the other dissociation product appears at −59 ppm (J_{SiF} = 249 Hz), but due to the low signal intensity the multiplet cannot be unambiguously assigned. It should be mentioned that the dissociation process in solution is reversible and the linear polymer **2** forms again on evaporation of the solvent.

For similar reasons as in solution the presence of proton and fluorine nuclei and their dipolar interaction with the silicon nucleus interferes with conventional CP-MAS NMR techniques. More sophisticated experiments with observation of ^{29}Si with simultaneous decoupling of ^{19}F and ^{1}H are in progress. Due to the complexity of these experiments, their results will be reported in context with monomeric organofluorosilanes elsewhere in the future.

We thank PD Dr. Dietrich Gudat (University of Bonn) for recording the HMQC NMR spectra and Prof. Matthias Drieß for intellectual and financial support. Funding for R. P. by the Fonds der Chemischen Industrie (Liebig-fellowship) is gratefully acknowledged.

Novel, covalently bonded hybrid materials of europium (terbium) complexes with silica

H. R. Li, J. Lin,* H. J. Zhang,* H. C. Li, L. S. Fu and Q. G. Meng

Key Lab of Rare Earth Chemistry and Physics, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun 130022, P. R. China. E-mail: jlin@ns.ciac.jl.cn. E-mail: hongjie@ns.ciac.jl.cn

Received (in Cambridge, UK) 7th March 2001, Accepted 14th May 2001
First published as an Advance Article on the web 6th June 2001

New kinds of hybrid materials containing covalently bonded Eu^{3+} (Tb^{3+}) bipyridine complexes in a silica network have been prepared and their luminescence properties reported.

The sol–gel method has been proven to be a suitable approach for the preparation of hybrid materials. One advantage of this method is its low processing temperature, allowing the incorporation of organic moieties that cannot withstand high temperatures into the networks.[1,2] Unfortunately, there are significant drawbacks in using these systems, which include inhomogeneous distribution of both components, leaching of dopants and limitations on the concentrations of dopants used. Covalent grafting of ligands on to the backbone of networks *via* Si–C bonds can greatly overcome the above-mentioned shortcomings.[3,4]

Herein, we present a new compound (denoted as bipyridine–Si) for sol–gelcontaining bipyridine, which plays a double role, *i.e.* as a ligand for lanthanide ions and as a sol–gel precursor. The hybrid luminescent materials were prepared using bipyridine–Si as one of the precursors, which reacted with the tetraethoxysilane (TEOS) by hydrolysis and condensation in the presence of lanthanide ions (see Scheme 1).

The IR spectra for 2,2′-bipyridine-4,4′-dicarboxylic acid (**I**), bipyridine–Si (**II**) and the hybrid material doped with Eu^{3+} (**III**) are shown in Fig. 1(A, B, C), respectively.‡ The absorption band at 1713 cm^{-1} in Fig. 1A corresponds to the asymmetric carbonyl stretch of carboxylic acid. This band is replaced by bands at 1653 and 1638 cm^{-1} due to the absorption of amide groups (CONH) in Fig. 1B and Fig. 1C, respectively, indicating that (3-aminopropyl)triethoxysilane (APS) has been successfully grafted on to 2,2′-bipyridine. Further evidence for this is the presence of the stretching ν(NH, 3379 cm^{-1}) and bending δ(NH, 1542 cm^{-1}) vibration modes, together with the stretching vibration of Si–O at 1094 cm^{-1} and the bending vibration of Si–O at 462 cm^{-1} (from APS) in Fig. 1B. The addition of Eu^{3+}, TEOS and water to bipyridine–Si (**II**) is also responsible for changes in the IR spectra (*cf.* Fig. 1C and Fig. 1B) due to hydrolysis/condensation of TEOS and bipyridine–Si (**II**) together with formation of a complex between Eu^{3+} and bipyridine–Si (**II**). The ν(Si–C) vibration located at 1198 cm^{-1} is still observed in the IR spectra of hybrid materials (Fig. 1C), which is consistent with the fact that no (Si–C) bond cleavage occurs during hydrolysis/condensation reactions. Furthermore, in Fig. 1C the broad absorption band at 1087 cm^{-1}, ν(Si–O–Si), indicates the formation of siloxane bonds.

The excitation spectrum monitored using the Eu^{3+} $^5D_0$–$^7F_2$ transition at 614 nm is dominated by a broad band centered at 336 nm, which is the characteristic absorption of the ligands due to their efficient $\pi \rightarrow \pi^*$ transition. This indicates that an energy transfer occurs from the ligands to the central Eu^{3+}. Upon excitation at the ligands (336 nm), only the emission lines of Eu^{3+} $^5D_0$–^7F_J (J = 0,1,2,3,4) were observed with the hypersensitive transition $^5D_0$–$^7F_2$ (614 nm) as the most prominent group; no emission from the ligands was detected, suggesting that the energy transfer from the ligands to Eu^{3+} is efficient in the hybrid sample. However, when the excitation is at 396 nm (*i.e.* at the $^7F_0$–$^5L_6$ absorption band of Eu^{3+}), the obtained emission spectrum contains not only the emission of Eu^{3+}, but also a broad emission band in the blue region with a maximum at 458 nm. Apparently, the red emission of Eu^{3+} produced in

 DOI: 10.1039/b102160p

this case results from direct excitation into Eu^{3+}. Here it is interesting from the appearance of the broad blue band, which can have no other cause than the excitation of the complex. Because the ligands can by no means be excited at 396 nm, it is obvious that the blue emission originates from an intracomplex due to metal-to-ligand energy transfer, possibly by charge transfer. A similar situation has been reported for Eu^{3+} in bipyridine and PEG200 by Bekiari and Lianos.[5] It can be concluded that both the red and blue emissions originate mainly from an intracomplex energy transfer process because the Eu^{3+} ion does not absorb at 336 nm and the ligand does not absorb at 396 nm, further pointing out the formation of a complex between Eu^{3+} and the ligands in bipyridine–Si.

The decay curve of the hybrid material with Eu^{3+} was singly exponential, confirming that the chemical environment of Eu^{3+} is uniform in the hybrid material, from which the luminescence lifetime was determined to be 123.6 μs. This value is much shorter than that of Eu^{3+} in inorganic solid host lattices (generally in the millisecond range),[6] indicating an important quenching by the OH groups (from the coordinated H_2O) or silanol (Si–OH) groups in the hybrid materials (see Scheme 1).

Very similar results were obtained when the Eu^{3+} was replaced by Tb^{3+} in the hybrid materials, *i.e.* the excitation spectrum was identical to that of Eu^{3+}, and the emission consisted of $^5D_4$–^7F_J (J = 3,4,5,6) transitions of Tb^{3+}, with the $^5D_4$–$^7F_5$ (543 nm) green emission as the most prominent group.

In conclusion, modification of 2,2′-bipyridine with APS results in the formation of a hybrid compound, which can act as both the ligand of lanthanide ions and as a sol–gel precursor.

The hetero-Diels–Alder addition of sulfur dioxide to (*E*)- and (*Z*)-4-(fluoromethylidene)-3-methylene-2,3-dihydronaphthalene follows the *endo* Alder rule. The first example of a crystalline sultine has been obtained. In agreement with high level quantum calculations, (1*SR*,3*SR*)-1-fluoro-1,4,5,6-tetrahydronaphtho[2,1-*d*][1,2]oxathiine 3-oxide adopts a sofa conformation in its ground state.

At low temperature and in the presence of a catalyst, simple alkyl-substituted 1,3-dienes add reversibly to SO_2 *via* hetero-Diels–Alder additions to generate the corresponding 3,6-dihydro-1,2-oxathiine 2-oxides (sultines).[1] They are unstable above −50 °C and undergo fast cycloreversion liberating the starting 1,3-dienes and SO_2 that can undergo the expected chelotropic additions at higher temperature. Until now sultines have been characterised in solution by their NMR data only.[1,2] Because of their instability, none of them have been isolated and better characterised. We report here the successful crystallisation of a fluorosultine and its structure determination by X-ray radiocrystallography. Whereas cyclohexene adopts a *pseudo*-chair conformation in its ground-state that interconverts through sofa transition structures, 6-fluoro-3,6-dihydro-1,2-oxathiine 2-oxides seem to prefer sofa conformation in their ground state with the intra-ring oxygen atom lying in the plane of the four carbon centres. We demonstrate also that the hetero-Diels–Alder addition of SO_2 obeys the *endo* Alder rule.[3]

The fluorodienes (*E*)-**3** and (*Z*)-**3** were derived from **1**[4] as shown in Scheme 1.[5] SO_2 added to (*Z*)-**3** at −80 °C (2 h) giving sultine **4**. When allowed to stand at −40 °C it isomerised into **5**. Above −30 °C, **5** was decomposed, no trace of the corresponding sulfolene could be detected! Diene (*E*)-**3** was less reactive than (*Z*)-**3**. It reacted with SO_2 at −40 °C (15 h) giving sultine **5** that could be crystallised at −50 °C and analysed by X-ray radiocrystallography at −100 °C (Fig. 1), thus establishing its structure unambiguously. That of the *cis*-sultine **4** was deduced from its NMR data and by its isomerization into the more stable *trans*-isomer **5**.[6]

Compound **5** represents the first example of a crystalline sultine.[7] The most striking observation is that it adopts a nearly sofa conformation in the crystalline state. This may not be the unique conformation available in solution as suggested by the ^{1}H NMR spectrum. Assuming validity of the relation $^5J_{H,H} = (5\ \text{Hz})\ (\sin\theta)^2(\sin\theta')^2$ for the coupling constants between the homoallylic proton pairs[8] at C-2 and C-5, a larger value should be measured for ^5J(H-2,H$_t$-5) than for ^5J(H-2,H$_c$-5) since H$_t$ makes a greater angle with the C-2, 1, 6, 5 plane than H$_c$ (see Fig. 1). However, one finds similar values ^5J(H-2,H$_c$-5) < 0.2 Hz, ^5J (H-2,H$_t$-5) = 0.8 Hz and ^5J(F-2,H$_t$-5) = ^5J(H-2,H$_c$-3) = 6.2 Hz suggesting that **5** exists as an equilibrium of several conformers in solution.

We have explored using high-level quantum calculations the potential energy surface (PES) of the Diels–Alder additions of SO_2 to (*E*)- and (*Z*)-1-fluorobutadiene (Figs. 2 and 3). The relative energies were computed using G3 theory[9] with the ΔE(2df,p) contribution estimated at the MP2 level (while the

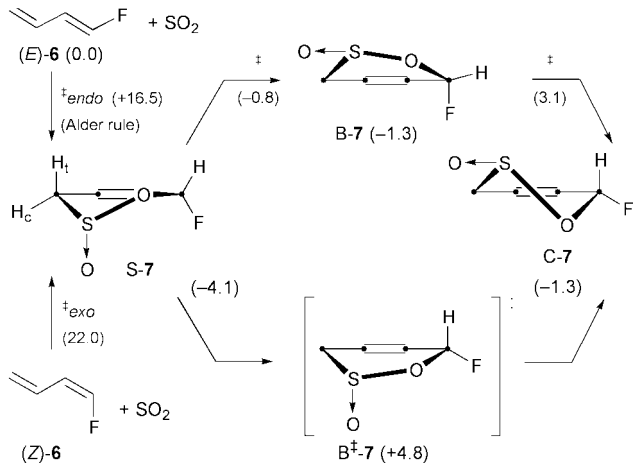

Fig. 2 G3 calculated energies for the hetero-Diels–Alder additions of SO_2 to **6** giving sultine **7** (*cis*). Values (kcal mol^{-1}) given relative to cycloaddends.

CPU times on a NEC SX-4 supercomputer were affected by a factor near 10, a difference of only 0.3 kcal mol^{-1} was found when computing this term for (*S*)-**7** at the MP4 level). The spin-orbit term was not included because of the lack of data for sultines, the zero-point energy was computed from MP2/6-31G(d) harmonic frequencies scaled by a factor of 0.96, and the frozen-core approximation was employed to carry out the geometry optimizations (see ESI†). Both dienes (*E*)-**6** and (*Z*)-**6** prefer the *endo* mode (Alder rule)[3] of addition and (*Z*)-**6** is less reactive than (*E*)-**6**, in agreement with our results with dienes (*Z*)-**3** and (*E*)-**3**, respectively. The calculations predict that *cis*-fluorosultine **7** prefers a sofa conformation S-**7** with *pseudo* axial S=O (Fig. 2). The interconversions of S-**7** and of the pseudo-chair conformer C-**7** can follow two paths. That with the lowest energy barrier involves equilibrium with a boat conformer B-**7**. In the case of the *trans*-fluorosultine **8** (Fig. 3) a sofa S-**8** with *pseudo*-equatorial S=O bond (corresponds to the X-ray structure of **5**) and a 'flattened' *pseudo*-chair conformer C-**8** of similar stabilities are found in agreement with our NMR data for **5**. A boat conformer B-**8** is only 1 kcal mol^{-1} above S-**8** and C-**8** and is reached with an energy barrier of 1.2 kcal mol^{-1}. Alternatively, interconversion S-**8** = C-**8** can operate through a boat transition structure B‡-**8** with an energy barrier of 4.3 kcal mol^{-1} only, suggesting that **8** is more flexible than **7**. If such a flexibility difference should prevail in the cases of **4** and **5**, it could contribute to make **5** more stable than **4**.

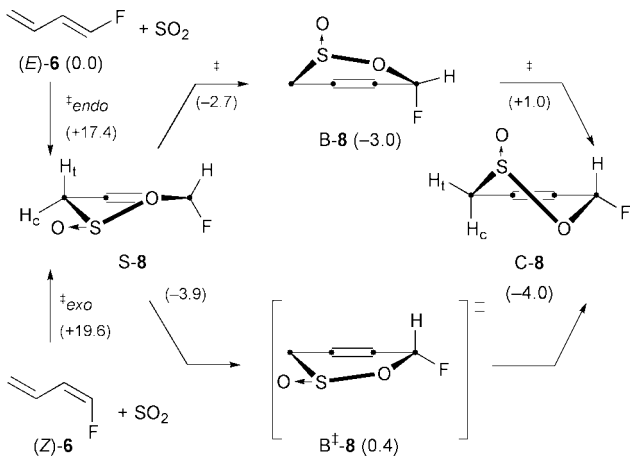

Fig. 3 G3 calculated energies for the hetero-Diels–Alder additions of SO_2 to **6** giving sultine **8** (*trans*). Values (kcal mol^{-1}) given relative to cycloaddends.

We have proposed that sultines are intermediates in our new carbon–carbon forming reaction between electron-rich dienes and enoxysilanes.[10] These species raise fundamental questions concerning their reactivity[11] and, as shown here, about their structure.

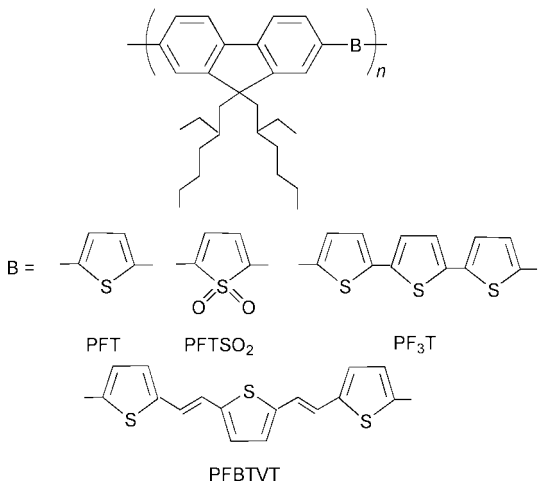
Received (in Cambridge, UK) 10th April 2001, Accepted 25th May 2001
First published as an Advance Article on the web 14th June 2001

We report the synthesis of novel alternating copolymers of the kind A-*alt*-B, where A is a dialkylfluorene unit and B is an aromatic moiety unit which is varied in order to change the position of the frontier energy levels; in particular we find that the B unit thiophene *S*,*S*-dioxide is particularly effective at increasing the polymer electron affinity and ionisation potential.

Poly(9,9-dialkylfluorene)s and derivatives are attracting significant interest in the context of polymer-based optoelectronic devices and in particular for the fabrication of efficient and long-lived light-emitting diodes.[1] Both colour tunability and control of the position of the frontier energy levels (electron affinity, EA, and ionisation potential, IP) are important in order to extend the applicability of this class of polymers, with a view to fabrication of full-colour displays and also to optimisation of charge injection from environmentally stable electrodes. From the synthetic point of view, a successful strategy to achieve this goal is the preparation of copolymers combining the fluorene moiety with other electroactive ones, in an alternating coupling pattern (A-*alt*-B). For example, a moiety of interest is the thiophene *S*,*S*-dioxide, which has been shown to produce an effective increase of EA in oligothiophenes.[2,3]

Here, we report the synthesis and the electrochemical and optical properties of a variety of well-defined A-*alt*-B copolymers, where A is a 9,9-bis(2′-ethylhexyl)fluorene unit and B is either a thiophene unit, a thiophene derivative, an oligothiophene or an oligothienylenevinylene (Scheme 1).

We synthesised the copolymers *via* palladium-catalysed Suzuki coupling[4] from the appropriate dibrominated and boron ester monomers, with a polymerisation yield in the range of 47–58%. The choice of the bulkier 2-ethylhexylfluorene solubilizing substituents, at variance with the more commonly used dioctyl or dihexyl linear chains, is aimed at reducing interchain interactions and ordering. The detrimental role of the interchain excited states on the luminescent polymer properties has been widely reported, in particular for polyfluorenes.[5,6] The polymerisation was carried out in a refluxing tetrahydrofuran–aqueous potassium carbonate solution (2 M) containing $Pd(PPh_3)_4$ as catalyst, for several days, in the dark and under N_2. Copolymers were then purified by dissolution in the minimum amount of $CHCl_3$ and by addition of the filtered solution to a non-solvent (methanol). This process was repeated at least three times, after which the copolymers were dried under vacuum. Monomers and polymers were characterised by standard spectroscopic techniques and elemental analysis. Details of the synthesis and structural characterisation will be reported in a future publication. The molecular weight of the polymers was determined by gel permeation chromatography of their THF solutions, relative to polystyrene standards. The obtained values (Table 1) are typical of the Suzuki type polymerisation reaction.



Scheme 1 Molecular structure of the synthesised copolymers.

We investigated the electrochemical behaviour of the copolymer films by cyclic voltammetry. The ionisation potential (IP) and electron affinity (EA) were estimated from the oxidation and reduction onset potentials determined against a saturated calomel electrode (calibrated against ferrocene, Fc/Fc^+ 0.41 V), considering that the energy level of Fc/Fc^+ is 4.8 eV below the vacuum level.[7] These values are summarised in Table 1. On going from PFT to the copolymers with longer B segments (PF3T and PFBTVT), we observe a decrease of IP whereas EA remains nearly constant. The most significant alteration of these two parameters occurs when the sulfur atom of PFT is functionalised to SO_2; namely, a significant increase of both IP and EA is observed in going from PFT to PFTSO2. The stabilisation of the frontier levels upon such functionalisation was previously reported for oligothiophenes,[2] though, for those systems, the increase of EA was larger than the increase of IP.

The UV-vis absorption of the copolymer films is also dependent on the B unit (Fig. 1). The copolymers'optical gap values, E_g, estimated from the onset of the UV-vis absorption spectra, are given in Table 1. E_g decreases on going from PFT

Table 1 Number-average molecular weight (M_n), polydispersity (M_w/M_n), ionisation potential (IP), electron affinity (EA), optical gap (E_g) and fluorescence quantum yields (Φ_{FL}) determined in solution and in solid films of the investigated copolymers

 DOI: 10.1039/b103179c

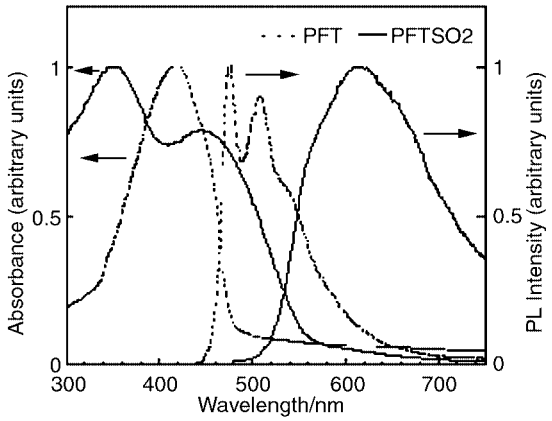

Fig. 1 Normalised UV-vis absorption and photoluminescence (PL) spectra of PFT (λ_{exc} = 408 nm) and PFTSO2 (λ_{exc} = 445 nm) thin films deposited on spectrosil.

to the copolymers with longer conjugated B units, PF3T and PFBTVT, indicating an increase of the conjugation length, despite the decrease of the molecular weight. A similar decrease of E_g is observed upon S to SO_2 functionalisation, showing that such chemical modification of the thiophene unit has a comparable effect to the increase of the number of thiophene rings in the B unit. Furthermore, two distinct bands are observed in the PFTSO2 absorption spectra while a single one is observed for PFT (Fig. 1). Correspondingly, a red-shift of the photoluminescence, PL, spectra is also observed on going from PFT to the other copolymers. Namely, while PFT fluorescence occurs in the green region (λ_{max} = 476 nm), PFTSO2 emits in the orange region of the visible spectrum (λ_{max} = 604 nm). Fluorescence quantum yields (Φ_{FL}) of these polymers were determined both for chloroform solutions and films. Solution Φ_{FL} were calculated by the relative method,[8] by comparing the corrected areas of the fluorescence spectra of a standard and of the sample. As reference substances, we used quinine sulfate in 0.1 M H_2SO_4 (Φ_{FL} = 0.546[9]) and rhodamine 101 in ethanol (Φ_{FL} = 0.89[10]). Solid state Φ_{FL} was determined following the procedure of de Mello *et al.*,[11] using an integrating sphere, upon excitation with the blue line (442 nm) of a He–Cd laser. As shown in Table 1, PFT has the highest solution Φ_{FL}, whereas PF3T shows the highest solid state efficiency. All polymers show a strong reduction of efficiency on going from solution to the solid state, which is indicative of the quenching effects associated to the interchain interactions. We further note that the fluorescence efficiency of PFTSO2 is lower than that of PFT, both in solution and solid state, indicating a detrimental effect of the *S*,*S*-dioxide functionalisation of the thiophene unit.

Φ_{FL} for PFT in solution, 0.51, is comparable to the value of 0.49 reported by Ranger and Leclerc[12] for a similar alternating copolymer combining 9,9-dioctylfluorene and an unsubstituted thiophene unit, prepared by Suzuki coupling. They reported also a decrease of Φ_{FL} to 0.30 when two thiophene rings are used instead of one. Interestingly, we find a higher value of 0.37 for PF3T (which has three thiophene rings), though this value is lower than that of PFT.

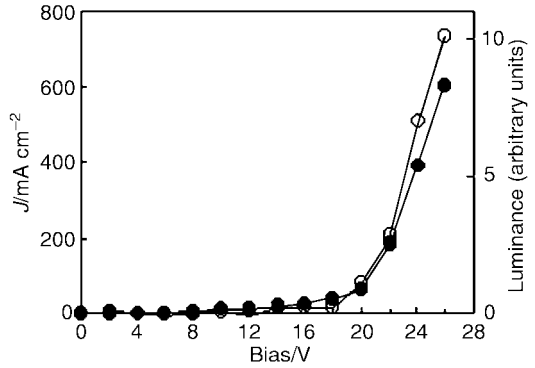

Fig. 2 Current density (J) (-●-) and luminance (-○-), as a function of the applied voltage (V) for an ITO/PEDOT(40 nm)/PFTSO2 (100 nm)/Ca device. The active area of the device is *ca*. 0.02 cm^2.

We fabricated light-emitting diodes using the copolymers shown in Scheme 1 as electroluminescent materials, with Ca cathodes and indium–tin oxide, ITO, or ITO/PEDOT:PSS anodes (where PEDOT:PSS is polyethylenedioxythiophene, doped with polystyrene sulfonic acid) and we found that the electroluminescence spectra are similar to the fluorescence spectra. Fig. 2 shows current density (J) and luminance (L) as a function of the applied voltage (V) for an ITO/PEDOT:PSS/PFTSO2/Ca device. Light-emission starts at about 14 V, and typical external electroluminescence efficiencies of these PFTSO2-based devices are on the order of 10^{-3}%.

In summary, we synthesised well defined alternating copolymers combining fluorene and thiophene-based moieties whose colour emission and position of frontier levels can be tuned upon structural modifications in the thiophene-based aromatic block.

$Zr(OtBu)_4$-catalysed synthesis of acetone aldol adducts and domino aldol-Tishchenko reactions with diacetone alcohol as enol equivalent†

Christoph Schneider* and Markus Hansch

Institut für Organische Chemie der Georg-August-Universität Göttingen, Tammannstr. 2, D-37077 Göttingen, Germany. E-mail: cschnei1@gwdg.de; Fax: (+ 49)551-399660

Received (in Cambridge, UK) 2nd April 2001, Accepted 16th May 2001
First published as an Advance Article on the web 14th June 2001

$Zr(OtBu)_4$ was found to be a potent catalyst for the synthesis of acetone aldol adducts with diacetone alcohol as enol equivalent and for domino aldol-Tishchenko reaction giving rise to 1,3-*anti*-diol monoesters with excellent diastereoselectivity.

Catalytic aldol reactions are currently being intensely investigated. Most processes that have been developed share as a general feature the formation of a silyl enolate in a preceding synthetic operation which in a separate step is then treated with the aldehyde under Lewis acid[1] or Lewis base[2] catalysis. Only very recently few methods for direct, catalytic aldol reactions have been reported.[3] Typically these catalysts exhibit Brønsted base as well as Lewis acid activity to form the metal enolate *in situ* and activate the aldehyde, respectively.

Recently, pharmaceutical chemists aiming at modifying the chemical structure of the immunosuppressant rapamycin reported that the homogeneous stereochemistry of the aldol moiety of the natural product was lost under the action of excess $Ti(OiPr)_4$.[4] They proposed a facile retro-aldol aldolisation process to account for this observation and pointed to the possible use of aldol products as enolate precursors. Inspired by this report we reasoned that a ketone aldol adduct should be an even better source for the *in situ* generation of a metal enolate through a retro-aldol mechanism and selected diacetone alcohol (**1**) as a promising substrate for a direct and catalytic aldol synthesis.[5]

We report here that $Zr(OtBu)_4$ catalyses the synthesis of aldol products from aromatic and α,β-unsaturated aldehydes **2** and diacetone alcohol (**1**) to give rise to the acetone aldol products **3** in typically good yields. Moreover, with most aliphatic aldehydes a rapid $Zr(OtBu)_4$-catalysed Tishchenko reduction of the β-hydroxyketones immediately succeeds the aldol reaction to yield the 1,3-*anti*-diol monoesters **4**/**5**.

In the first step various metal alkoxides (10 mol%) were tested for their catalytic activity in the reaction of benzaldehyde and diacetone alcohol in THF at −20 °C (Table 1). NaO*t*Bu and KO*t*Bu apparently catalysed the reaction but yielded mainly the dehydrated aldol condensation product (entries 1, 2). $Ti(OiPr)_4$ and $Ti(OtBu)_4$ required elevated temperatures for product formation and gave mixtures of **3a** and the condensation product in moderate yields (entries 3, 4). Whereas $Zr(OiPr)_4$ also exhibited poor catalytic activity, $Zr(OtBu)_4$[6] turned out to be the catalyst of choice furnishing the desired aldol adduct **3a** in 80% yield with only traces of the condensation product being formed (entry 6). $La(OtBu)_3$ yielded mainly the direct aldol adduct of diacetone alcohol and benzaldehyde as one might have expected in light of the results reported by Shibasaki (entry 7).[3]

We then subjected a range of aromatic and conjugated aldehydes to the reaction with diacetone alcohol (2 eq.) and $Zr(OtBu)_4$ (10 mol%) in THF at −20 °C which gave rise to the corresponding aldol adducts **3a**–**f** in moderate to very good yields (Table 2).[7] Not unexpectedly, electron-deficient aromatic aldehydes appear to be slightly more reactive than electron-rich ones (entries 2, 3). As byproduct in 5–10% yield we occasionally isolated 1,3-*anti*-diol monoesters comprising two molecules of aldehyde and one acetone fragment which were apparently formed in a $Zr(OtBu)_4$-catalysed Tishchenko reduction[8] of the initially formed β-hydroxy ketones with the aldehyde as hydride source.

This domino aldol-Tishchenko process[9,10] was found to be the dominant reaction pathway in the case of most aliphatic aldehydes (Table 3). Straight chain as well as α-branched aliphatic aldehydes gave the 1,3-*anti*-diol monoesters **4**/**5a**–**e** in good yields upon reaction with diacetone alcohol (1 eq.) and $Zr(OtBu)_4$ (10 mol%) whereas the initial aldol adducts were isolated in < 5% yield. Lowering the amount of aldehyde equivalents resulted in a decrease in yield but did not increase the proportion of the aldol adducts, indicating that the Tishchenko reduction proceeded much faster than the formation of the aldol adducts. Only pivalaldehyde as a sterically very hindered aliphatic aldehyde yielded mainly the initial aldol

Table 1 Metal alkoxide-catalysed synthesis of acetone aldol adduct **3a**

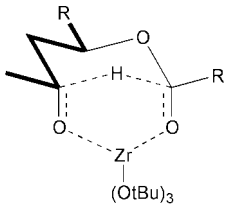
4	iC_3H_7	**4/5d** (9:1)	85
5	cC_6H_{11}	**4/5e** (22:1)	70

[a] Combined yield of both regioisomers; the initial aldol products were formed in < 5% yield.

adduct **3g** in 60% yield along with 6% of the aldol Tishchenko product (Table 2, entry 7).

The initial Tishchenko products **4** suffered partial acyl migration to give rise to mixtures of regioisomeric 1,3-*anti*-diol monoesters which were, however, converted to a single 1,3-*anti*-diol upon hydrolysis with KOH in methanol. ^{13}C NMR analysis of the corresponding acetonides confirmed their *anti*-stereochemistry.[11] The degree of acyl migration was dependent on the steric bulk of the acyl group with straight-chain acyl groups being more readily transferred than α-branched acyl groups. The exclusive (> 97:3 by NMR) formation of the 1,3-*anti*-diol monoesters may be explained through intramolecular hydride delivery of a chelated Zr-hemiacetal alkoxide in transition structure **A** which has been previously put forth for transition metal-catalysed Tishchenko reductions (Fig. 1).[8]

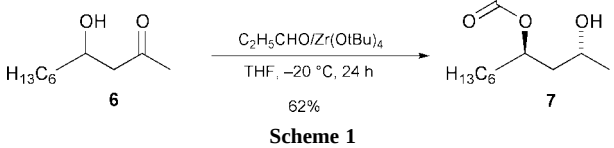


A

Fig. 1

In an additional experiment we treated aldol adduct **6** with propionaldehyde under the typical reaction conditions and obtained the Tishchenko product **7** in 62% yield (15:1-mixture of regioisomers) with no formation of a crossover product being observed (Scheme 1). This result suggests that the Tishchenko reduction proceeded faster than a possible retro-aldol aldolisation process.

At present, we can only speculate about the exact mechanism of the reported aldol synthesis. Although it is very likely that the reaction proceeds stepwise *via* a retro-aldol aldolisation pathway and *in situ* generation of a zirconium enolate, we can not rule out a concerted mechanism analogous to a Meerwein–Ponndorf–Verley reduction.[12] Attempts to detect the presumed zirconium enolate spectroscopically have failed so far which, however, may be due to the very low concentration of the enolate that reacts with the aldehyde as soon as it is formed.



Scheme 1

In conclusion, we have demonstrated that $Zr(OtBu)_4$ is an effective catalyst for the synthesis of acetone aldol adducts using diacetone alcohol as an enol equivalent. With most aliphatic aldehydes $Zr(OtBu)_4$ exhibits a dual activity as an aldol and Tishchenko catalyst. Further studies are aimed at understanding the exact reaction mechanism and expanding the scope of the reaction.

Financial support of this work by the Fonds der Chemischen Industrie is gratefully acknowledged. We thank Professor Tietze for his support.

7 Typical experimental procedure for the aldol synthesis: in a dry flask under nitrogen 0.10 ml (1.00 mmol) freshly distilled benzaldehyde and 0.25 ml (2.00 mmol) of diacetone alcohol were dissolved in 1 ml THF and cooled to −20 °C. At that temperature 39 μl (0.10 mmol) $Zr(OtBu)_4$ were added with a syringe and the reaction mixture remained at −20 °C for 48 h. The reaction was quenched with pH 7 buffer, the product was extracted twice with ether and the organic extracts were dried with $MgSO_4$. Flash chromatography over silica gel with ether–pentane 1:2 furnished 132 mg (80%) of aldol adduct **3a** as a colourless oil along with 18 mg (7%) of the corresponding Tishchenko product. All products gave satisfactory analytical and spectroscopic data.

Received (in Cambridge, UK) 4th April 2001, Accepted 23rd May 2001
First published as an Advance Article on the web 14th June 2001

The easily accessible, enantiopure (*R*)-(+)-2-diarylphosphino-2′-alkoxy-1,1′-binaphthyl 1 bearing three fluorous ponytails is an efficient ligand in the palladium-catalysed asymmetric allylic substitution of 1,3-diphenylprop-2-enyl acetate affording chiral products of up to 87% ee.

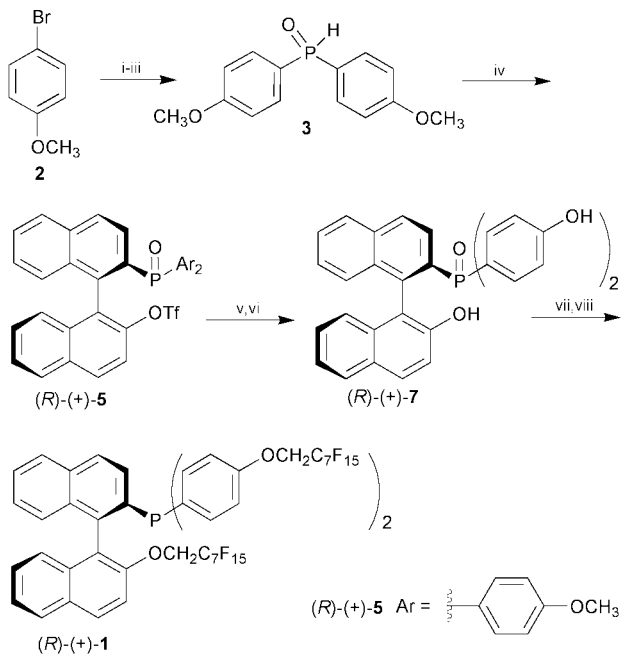
The advantages brought about by the use of CO_2 (supercritical or compressed) or fluorinated solvents in catalytic reactions are well-documented.[1,2] These novel reaction media offer the possibility of cleaner technology for the chemical industry, and might also promote reactions that are not attainable in common organic solvents, along with selectivity improvements related to the unique solvation environment.[3] In both cases, good solubility of the catalyst in the peculiar reaction medium is a major requirement. To reach this goal, several ligands featuring long-chain perfluoroalkyl substituents ('fluorous ligands') have been synthesized,[4] including a few examples of chiral compounds.[5] Indeed, the presence of long-chain perfluoroalkyl substituents increases the affinity of an organometallic compound both for CO_2 and perfluorocarbons. In the latter case, an increasing body of literature data indicates that only a fluorine content of at least 60% can ensure the very high partition coefficients required for the application of the original fluorous biphase strategy.[6] In order to circumvent this limitation, new fluorous techniques have been recently proposed, based on the recovery of fluorinated molecules by liquid–liquid or solid–phase extraction.[7] This makes 'minimally' or 'light' fluorous reagents and catalysts (*i.e.* compounds with a fluorine content below 60%) potentially useful for small-scale and discovery-oriented research.[8]

As phosphorous-based ligands are extensively used in catalytic reactions, many efforts have been devoted to the synthesis of their fluorous analogues.[1,9] However, such enantiopure compounds are not easily available yet.[10] Here we describe the simple synthesis of a fluorous chiral phosphine, namely (*R*)-(+)-2-{bis[4-(1*H*,1*H*-perfluorooctyloxy)phenyl]phosphino}-2′-(1*H*,1*H*-perfluorooctyloxy)-1,1′-binaphthyl (*R*)-(+)-**1**, a new member of this restricted family of compounds.†

Palladium-catalysed coupling of bis(aryl) phosphonic acids with commercially available (*R*)- or (*S*)-1,1′-bi-2-naphthol bis(trifluoromethanesulfonate) provides an easy access to optically pure 2-(diphenylphosphino)-2′-alkoxy-1,1′-binaphthyls.[11] Leitner and Franciò took advantage of this versatile reaction in the synthesis of a chiral phosphine/phosphite ligand bearing two $-(CH_2)_2C_6F_{13}$ ponytails, structurally similar to (*R*,*S*)-BINAPHOS.[10] The introduction of the perfluoroalkyl substituents required the use of a properly functionalised bis(aryl) phosphonic acid at an early stage of the synthesis. In order to increase the flexibility of this approach, we decided to postpone the introduction of perfluorinated residues. This allows the insertion of the required perfluoroalkyl chains onto a preformed ligand structure, thus increasing the number of possible locations. The synthesis of enantiopure (*R*)-(+)-**1** is outlined in Scheme 1.

Bis(4-methoxyphenyl)phosphonic acid **3**, obtained from the corresponding *para*-substituted aryl bromide **2** according to a literature procedure,[12] allowed the easy monophosphinylation of the commercially available (*R*)-(−)-1,1′-bi(2-naphthol) bis(trifluoromethanesulfonate) (*R*)-(−)-**4**. This reaction was carried out in the presence of equimolar amounts of $Pd(OAc)_2$ and 1,4-bis(diphenylphosphino)butane (dppb) in DMSO at 100 °C. Cleavage of the methoxy group of the phosphinyl derivative (*R*)-(+)-**5** with BBr_3 in CH_2Cl_2 afforded the dihydroxy derivative (*R*)-(+)-**6** in 99% yield, after recrystallisation from diethyl ether. Subsequent hydrolysis of the remaining triflate group with aqueous sodium hydroxide in a methanol–dioxane mixture led to (*R*)-(+)-2-[bis(4-hydroxyphenyl)phosphinyl]-2′-hydroxy-1,1′-binaphthyl (*R*)-(+)-**7** in 91% yield. Three fluorous ponytails were then introduced by reaction of the free hydroxy groups of (*R*)-(+)-**7** with 1*H*,1*H*-perfluorooctan-1-ol perfluorobutanesulfonate **8** in DMF, in the presence of caesium carbonate.[13] Phosphine oxide (*R*)-(+)-**9** was obtained in 70% yield after simple flash chromatography (eluent Et_2O). Finally, reduction with Cl_3SiH in boiling toluene afforded pure (*R*)-(+)-**1** in 90% yield.

The partition coefficients for (*R*)-(+)-**1** between *n*-perfluorooctane and three organic solvents (CH_2Cl_2, toluene and



Scheme 1 *Reagents and conditions*: i, Mg, THF, reflux; ii, $ClP(NEt_2)_2$, −20 °C; iii, aqueous 36% HCl, −10 °C; iv, (*R*)-(−)-**4**, $Pd(OAc)_2$, dppb, diisopropylethylamine, DMSO, 100 °C; v, BBr_3, CH_2Cl_2, 0 °C; vi, NaOH, MeOH, dioxane, rt; vii, $C_7F_{15}CH_2OSO_2C_4F_9$ **8**, Cs_2CO_3, 100 °C; viii, Cl_3SiH, toluene, 110 °C.

 DOI: 10.1039/b103074b

Scheme 2 *Reagents and conditions*: Nucleophile (see Table 1), 2 eq.; BSA, 2 eq.; KOAc, 0.1 eq.; $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$, 2 mol%; (*R*)-(+)-**1**, 8 mol%.

CH_3OH) were found to be 0.20, 0.23 and 7.42, respectively. As expected, the new ligand shows a certain affinity for organic solvents, due to the relatively low fluorine content of (*R*)-(+)-**1** (52.4%) and to its aromatic backbone. This mixed behaviour makes (*R*)-(+)-**1** an ideal candidate for the application of 'light fluorous' techniques. Palladium complexes of enantiopure 2-(diphenylphosphino)-2′-alkoxy-1,1′-binaphthyls (MOPs) catalyse several asymmetric transformations.[11] A number of applications of related fluorous compounds could be thus envisaged. It was previously shown that palladium(0)-catalysed allylic substitution reactions can be conveniently performed under fluorous biphase conditions, in the presence of a 'light fluorous' triarylphosphine with a fluorine content of 57%.[14] On the other hand, chiral MOPs have been recently used for the asymmetric allylic alkylation of 1,3-diphenylprop-2-enyl acetate **10** in standard solvents (Scheme 2).[15] We decided therefore to investigate the potentiality of this new fluorous MOP (*R*)-(+)-**1** as a ligand in the same reaction. The results obtained are summarized in Table 1.‡

Table 1 Asymmetric allylic alkylation of 1,3-diphenylprop-2-enyl acetate in benzotrifluoride

Entry	Nucleophile	*T*/°C	*t*/h	Yield[a] (%)	Ee[a] (%)	Conf.[b]

[a] Determined by HPLC analysis (column Chiralpak AD 0.46 × 25 cm). [b] Determined by comparison with an authentic sample. [c] Reaction run in toluene. [d] See ref. 15.

The reaction of **10** with dimethyl malonate using MOP (*R*)-(+)-**1** (8 mol%) and $[Pd(C_3H_5)Cl]_2$ (2 mol%) in the presence of bis(trimethylsilyl)acetamide (BSA, 2 eq.) and potassium acetate (10.1 eq.) in benzotrifluoride (a standard solvent for 'light fluorous' compounds) proceeded quantitatively at rt to give, after 36 h, the corresponding alkylated product in 99% yield with 81% ee (Table 1, entry 1). This value is quite close to the value obtained using toluene as the solvent (Table 1, entry 2). It is to be noticed that non-perfluorinated MOP gave the alkylated product in 95% yield and 99% ee using toluene as the solvent (Table 1, entry 3).

Next we investigated the asymmetric reaction with other carbon nucleophiles. Reaction of **10** with acetylacetone gave the product nearly quantitatively after 1 h with 85% ee (Table 1, entry 4). Substituted dimethyl malonate gave lower chemical yields. Dimethyl methylmalonate gave the alkylated product with 69% yield and 44% ee at 50 °C (Table 1, entry 6), although 76% ee was obtained at rt, but in 7% yield (Table 1, entry 5). Diethyl acetamidomalonate gave also the expected alkylated compound in 67% yield with 85% ee (Table 1, entry 7).

When toluene was used as a solvent, the simple extraction of the reaction mixture with *n*-perfluorooctane (2 × 5 ml) allowed the complete removal of the fluorous ligand and of the corresponding palladium complexes, as shown by the absence of phosphine resonances in the ^{1}H-NMR of the crude product. As pointed out by Curran, this ease of separation together with the possible use of standard reaction conditions could be helpful in discovery-oriented synthesis and parallel synthesis.[8] However, a drawback of this 'light fluorous' approach is the absence of catalytic activity of the recovered fluorous palladium complex. We are currently investigating this problem, which seems to be due to the separation procedure followed. Indeed, recyclability of a 'light fluorous' phosphine used in the same reaction under classical fluorous biphase conditions was feasible.[14]

We thank the Programme Galilée 1999 no. 99023 for financial support.

A dense coordination polymer bearing an extensive and highly intricate hydrogen bonding array†

Timothy J. Prior and Matthew J. Rosseinsky*

Department of Chemistry, Robert Robinson Laboratories, University of Liverpool, UK L69 7ZD. E-mail: m.j.rosseinsky@liv.ac.uk

Received (in Cambridge, UK) 27th March 2001, Accepted 21st May 2001
First published as an Advance Article on the web 14th June 2001

Linking of hydrogen bonded sheets by coordination polymer chains produces a three-dimensional solid derived from two distinct structural components.

Enhanced design strategies for the synthesis of extended molecular solids are of considerable current interest.[1] Existing methods focus on single supramolecular synthons and give rise to solids whose structures are dominated by one specific interaction. Here we describe the use of two molecular tectons, with both coordinative and hydrogen bonding[2] abilities, to construct a phase in which there are two distinct extended structural units.

There are two principal methods for the construction of extended molecular solids: hydrogen bonding or coordinative metal–ligand interactions. The construction of organic hosts from hydrogen bonding moieties has been widely studied.[3] This approach potentially offers excellent control over the construction of materials through the manipulation of the hydrogen bonding interactions. Although hydrogen bonding architectures containing metal ions exist, those exhibiting true coordination polymer units are rare,[4] being limited to frameworks in which the coordination polymer is the primary structural element, subsequently linked by hydrogen bonds. For example several 4,4′-bipyridyl frameworks display this formulation: metal–bipyridyl chains or layers are held together by secondary bipy···water or bipy···nitrate hydrogen bonds.[5]

The tectons selected in this work are trimesic acid (1,3,5-benzenetricarboxylic acid, H_3btc) and 1,4-diaminobenzene (1,4-DAB). Trimesic acid has attracted considerable interest as a host for inclusion compounds, co-crystallising with a wide variety of species.[6] 1,4-DAB is known to act as a rigid spacer between transition metal dimers,[7] although it has not previously been observed linking discrete metal cations. Reaction of these molecular components with Ni^{2+} under hydrothermal conditions‡ affords a dense metal–organic solid, N3DAB, with both coordination polymer and hydrogen bonded structural features.

Analysis of single crystal X-ray diffraction data§ collected using synchrotron radiation shows that N3DAB displays the first example of infinite hydrogen bonded sheets linked by coordination polymer chains (Fig. 1).

The structure is based on nickel centres octahedrally coordinated by three types of ligand, in an '*all trans*' geometry (Fig. 2) allowing the formation of the two distinct sub-arrays: *trans* 1,4-DAB units form coordination polymer chains while *trans* $btcH_2$ units form hydrogen bonded sheets and are locked into the conformation allowing the formation of this infinite sheet by hydrogen bonding to water ligands (Fig. 3). In other systems where two *trans* btc units coordinate to the same metal centre, interligand hydrogen bonding of this type is very important in determining the geometry about the metal and hence the orientation of the btc units. In N3DAB this interaction is clearly also important as shown by the extreme rotation about the C7–C8 bond (ring-carboxylate): the torsion angle defined by C6, C7, C8 and O5 is 156.2°. In the absence of this hydrogen bond the angle would be expected to be very near 180°. The $btcH_2$ units joined to the Ni(1,4-DAB) chain display an unusual mode of coordination, being deprotonated at only one acid functionality. It is the dense and co-operative net of hydrogen bonding interactions which prevents the expected complete deprotonation of the H_3btc under the basic synthetic conditions used.

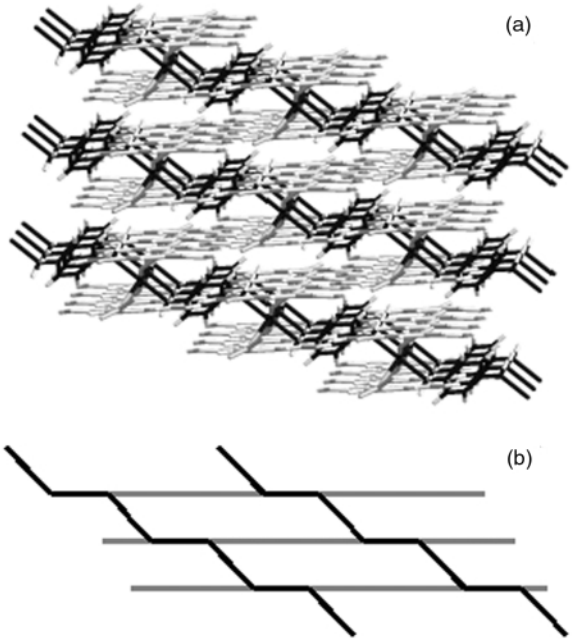

Fig. 1 (a) Infinite 2-D hydrogen bonded decks (grey) linked by 1-D coordination polymer chains (black). (b) Schematic illustration of the two infinite motifs in the structure of N3DAB.

The coordination polymer chains have stoichiometry Ni(1,4-DAB) and run parallel to the crystallographic *b* axis. The Ni–N–C angle is very close to 120° which gives the chain the zigzag arrangement shown in Fig. 2. These chains are decorated with pairs of $btcH_2$ at every nickel centre.

The hydrogen bonded sheets are composed of chains made up from Z-shaped links as shown in Fig. 4. These chains are knit

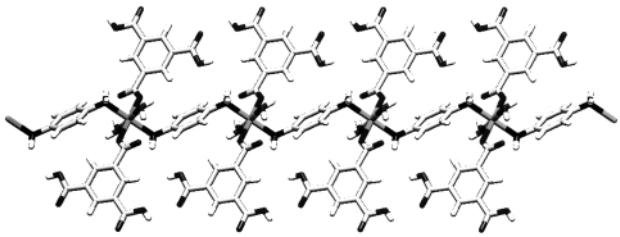

Fig. 2 A single Ni(1,4-DAB) zigzag coordination polymer chain decorated at every nickel with two $btcH_2$ units. Each $btcH_2$ forms part of an infinite hydrogen bonded layer (see Fig. 4).

 DOI: 10.1039/b102809j

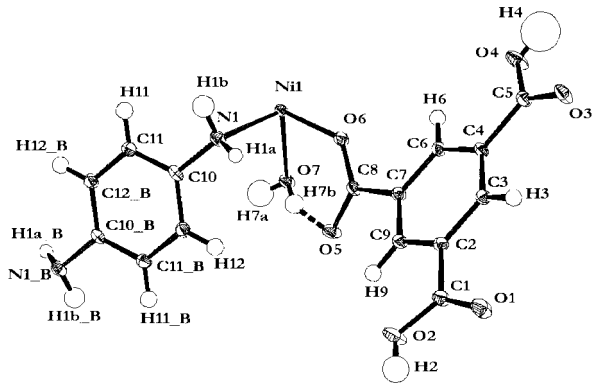

Fig. 3 ORTEP plot of the asymmetric unit of N3DAB. Atoms are shown as 50% thermal ellipsoids. Ni1 lies on the inversion centre. Note the hydrogen bond between O7 and O5 (2.70 Å). Symmetry equivalent atoms appended _B are generated by the symmetry operator $1 - x, - y, 1 - z$.

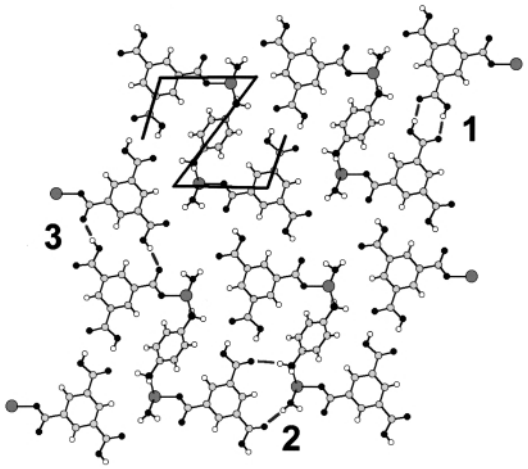

Fig. 4 Part of one of the infinite hydrogen bonded decks composed of Z-shaped links. One such link is highlighted. The three hydrogen bonds responsible for the formation of the infinite sheet are labelled 1, 2 and 3.

together into infinite sheets by further hydrogen bonds. However additional hydrogen bonding networks exist throughout the entire structure and are not constrained to run within the layers, reinforcing the remarkable extent of hydrogen bonding within the structure. Full analysis of the hydrogen bonding is given in the electronic supplementary information (ESI).† The highly electron-rich hydrogen bonded decks lie parallel to each other and their mean separation, 3.324(2) Å (a/2), is sufficiently close to suggest that the $btcH_2$ rings engage in π-stacking.

The unusual mode of coordination of 1,4-DAB offers potential for the formation of a wide range of coordination polymer networks. The coupling of the 1-D chains with different equatorial ligands offers the prospect of novel, potentially porous frameworks. The combination of coordination polymer chains with species known to form extended hydrogen bonded networks opens up a new avenue for synthesis of supramolecular hosts. This two-component approach to synthesis is attractive because of the control which may be exerted through the tectons present.

We thank Dr S. J. Teat for his expert assistance on DL Station 9.8 and the UK EPSRC for a studentship to T. J. P. and support through GR/N 08537.

Notes and references

‡ Very dark purple crystals of N3DAB were grown under hydrothermal conditions. Reagents were purchased from the Aldrich Chemical Company and used without further purification: 0.176 g (0.605 mmol) $Ni(NO_3)_2{\cdot}6H_2O$, 0.2543 g (1.21 mmol) H_3btc, 0.1966 g (1.82 mmol) 1,4-diaminobenzene and 12 ml water were loaded into a 23 cm^3 Teflon-lined stainless-steel reactor which was then sealed. The reactor was heated in an autoclave for 16 h at 150 °C and then cooled to room temperature at a rate of 0.5 °C min^{-1}. Yield 74% (based on Ni). This synthesis affords phase pure N3DAB as demonstrated by the full indexing of powder diffraction patterns given in the ESI† (81 peaks) and chemical analysis (Calc.: C, 46.40; H, 3.58; N, 4.52; Ni, 9.45. Found: C, 46.41; H, 3.58; N, 4.55; Ni, 9.38%).

§ Single-crystal X-ray diffraction data were collected on a Bruker AXS SMART CCD area-detector diffractometer at Station 9.8 of the CLRC Daresbury Laboratory Synchrotron Radiation Source, UK. A dark purple platelet with dimensions 160 × 80 × 60 μm was covered in a thin film of perfluoropolyether oil and mounted on the tip of a two-stage glass fibre. The crystal was cooled to 123 K in an Oxford Instruments nitrogen gas cryostream. Synchrotron radiation of wavelength 0.6941 Å was employed (the wavelength is determined by measurement of unit cell parameters of a known structure). A sphere of data in reciprocal space was collected in three series of ω-rotation exposure frames each with different crystal orientation φ angles: each 1 s exposure employs a 0.15° rotation in ω. Reflection data were integrated using Bruker software.[8] Semiempirical corrections were applied to account for absorption and beam decay.[9] The structure was solved using direct methods in SHELXS-86.[10] Subsequent difference Fourier methods to locate all other atoms and full-matrix least-squares refinement on F^2 was carried out with SHELXL-97.[11] N3DAB, Ni(1,4-DAB)$(btcH_2)_2(H_2O)_2$, crystallises in the centrosymmetric space group $P\bar{1}$ (no. 2). The nickel atom lies in a pseudo-octahedral environment on the inversion centre.

Crystal data: a = 6.6480(18), b = 8.550(2), c = 11.124(3) Å, α = 70.280(6), β = 79.594(6), γ = 76.093(6)°, V = 574.43 Å^3, Z = 2, μ = 0.932 mm^{-1}. Using a single detector position, 5650 intensities were recorded, producing 2987 unique data (θ_{max} 29.38°). R_{int} = 0.0103. Conventional R [$I > 2\sigma(I)$, all data] 0.0462 (0.0526), $wR2$ 0.1256 (0.1279). GOF on F^2 1.135 (1.136). CCDC 162906. Unusual molybdenum mediated C–N bond activation†

Thomas M. Cameron, Khalil A. Abboud and James M. Boncella*

Department of Chemistry and Center for Catalysis, University of Florida, Gainesville, FL 32611-7200, USA. E-mail: boncella@chem.ufl.edu

Received (in Irvine, CA, USA) 27th February 2001, Accepted 24th May 2001
First published as an Advance Article on the web 14th June 2001

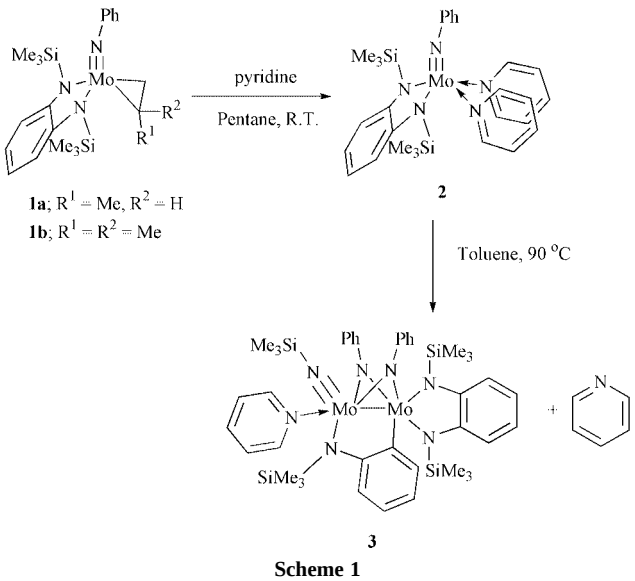
The compounds [Mo(NPh)(η²-olefin){*o*-(Me$_3$SiN)$_2$C$_6$H$_4$}] (olefin = propene 1a or isobutene 1b) react with excess pyridine affording the Mo(IV) bis-pyridine complex, [Mo(NPh)(Py)$_2${*o*-(Me$_3$SiN)$_2$C$_6$H$_4$}] 2 which when heated to 90 °C in toluene undergoes a C–N bond cleavage reaction and is converted to 3, a bimetallic molybdenum species; the crystal structures of both 2 and 3 are reported.

Reactions providing a straightforward example of C–N single bond activation, a most desirable transformation, are rare.[1] The metal-mediated rupture of C–N bonds is for the most part limited to those of strained amines[2] or amidines.[3] Activation of non-activated substrates such as aniline[4] and the ring opening of pyridine[5] has been observed with highly reactive, trivalent, Group 5 metal complexes. A slight variation on this theme involves the recently reported C–N bond cleavage reactivity of a Nb(II) cluster upon ligand replacement by anionic amides.[6] An observation related to this reaction type, made in 1985 by Chisholm *et al.*,[7] involved the isolation of a carbide/imide cluster that may have arisen *via* degradation of an amide ligand. We have recently been able to isolate a bimetallic molybdenum complex **3** arising by C–N activation of the *o*-(Me$_3$SiN)$_2$C$_6$H$_4$ ligand in the bis-pyridine complex [Mo(NPh)(Py)$_2${*o*-(Me$_3$SiN)$_2$C$_6$H$_4$}] **2** (Scheme 1). We herein report the synthesis and solid-state structures of **2** and **3** providing a rare example of C–N activation.

Addition of an excess of pyridine to a stirring pentane solution of **1a** or **1b** resulted in the precipitation of **2** as a purple solid that was isolated by filtration in high yield (Scheme 1).† The room temperature ^{1}H NMR spectrum of **2** displays a significant broadening of the pyridine protons in the 2 and 6 positions. At low temperature (−55 °C) two distinct resonances are observed in the ^{1}H NMR spectrum for these *ortho* protons: one for the two *ortho* protons *syn* to the imido group and the second for two *ortho* protons *anti* to the imido functionality. These observations are consistent with slow rotation of the pyridine rings about the Mo–N bond on the NMR time scale at −55 °C.

An X-ray structural analysis was carried out on a single crystal of **2** grown at room temperature by layering a saturated toluene solution of **2** with pentane. Selected bond lengths and angles are listed in the legend to Fig. 1.‡ The solid-state structure reveals a square pyramidal geometry about the Mo atom, with the imido ligand in the apical position. The Mo–N(4) and Mo–N(5) bond lengths are consistent with a Mo(IV)–Py Lewis acid–base interaction. A space-filling model of **2**, derived from the X-ray study, reveals a sterically congested area around the pyridine ligands due to the presence of the Me$_3$Si groups.[8] It is this steric crowding of the pyridine ligands by the Me$_3$Si groups that hinders their rotation.

The structure of the *o*-(Me$_3$SiN)$_2$C$_6$H$_4$ ligand in **2** differs significantly from that observed in square pyramidal M(VI) complexes containing both NPh imido and *o*-(Me$_3$SiN)$_2$C$_6$H$_4$ ligands. In **2** the C$_6$H$_4$ ring, the N atoms, and the metal center are nearly co-planar. In the related M(VI) complexes the ligand is folded along the N–N vector. This folding has been attributed to π-donation from the NSiMe$_3$ lone pairs to the d$_{xy}$ orbital of the d^0 M(VI) metal center.[9,10] In **2** such π-donation is unfavorable since it would involve a filled–filled interaction between the ligand and the d^2 metal center. The flattened conformation of the *o*-(Me$_3$SiN)$_2$C$_6$H$_4$ ligand in **2** places the SiMe$_3$ groups in the



Scheme 1

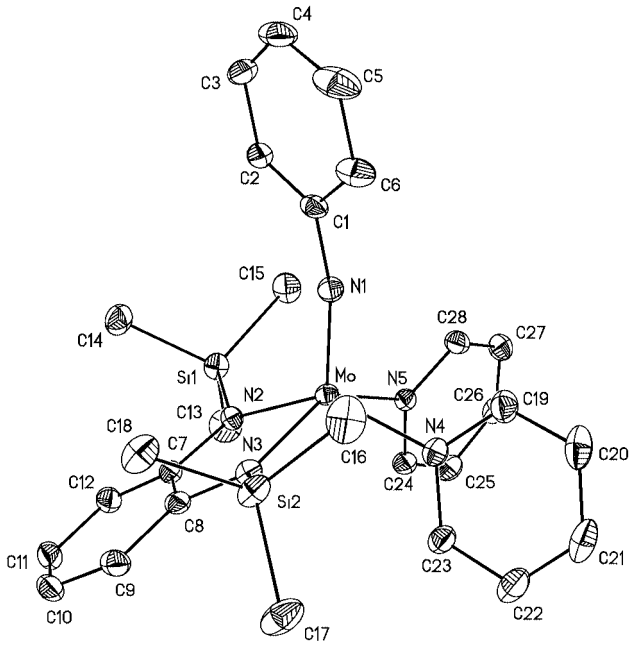


Fig. 1 Thermal ellipsoid plot of **2** (50% probability thermal ellipsoids). Selected bond lengths (Å) and angles (°): Mo–N(1) 1.7476(14), Mo–N(2) 2.0779(16), Mo–N(3) 2.0637(16), Mo–N(4) 2.1247(16), Mo–N(5) 2.1460(16); C(1)–N(1)–Mo 166.35(13).

† Electronic supplementary information (ESI) available: characterisation of complexes **2** and **3**, ^{1}H NMR spectra of **1**–**3** and space-filling diagram of **2**. See http://www.rsc.org/suppdata/cc/b1/b101894i/

 DOI: 10.1039/b101894i

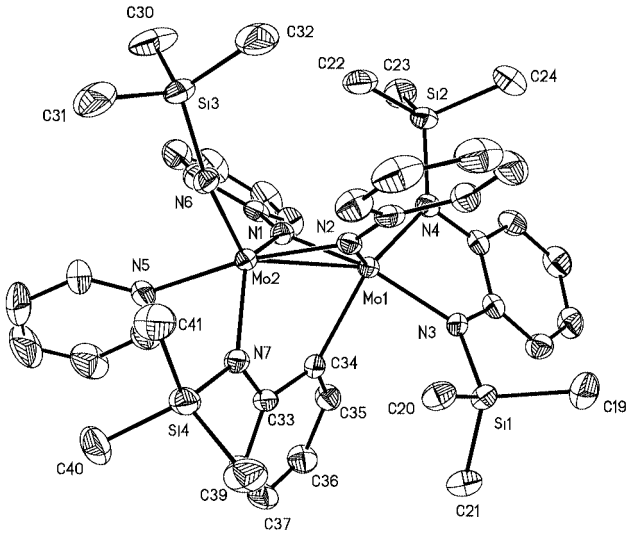

Fig. 2 Molecular structure of **3** (50% probability thermal ellipsoids). The solvating dichloromethane molecules have been omitted for clarity. Selected bond lengths (Å) and angles (°): Mo(1)–Mo(2) 2.5669(4), Mo(1)–C(34) 2.179(3), Mo(2)–N(7) 2.047(2), Mo(2)–N(6) 1.745(2), Mo(2)–N(5) 2.285(3); Mo(1)–N(1)–Mo(2) 80.74(9), Mo(1)–N(2)–Mo(2) 81.48(9).

basal plane of the molecule resulting in steric congestion between the Py and $SiMe_3$ groups which causes the hindered rotation of the Py ligands.

Monomeric **2** is stable at room temperature under an inert atmosphere for extended periods of time. However, when heated to 90 °C in toluene, **2** converts cleanly to the bimetallic compound **3** (Scheme 1) in > 90% yield over the course of 2 h.‡ This air-sensitive, diamagnetic compound is stable in solution for extended periods of time at 90 °C.

A single crystal of **3** was grown from a pentane–dichloromethane solution at −30 °C. Compound **3** crystallizes with two molecules of dichloromethane. An X-ray diffraction study shows that **3** contains two Mo atoms bridged by two phenyl imido groups as well as a $Me_3SiNC_6H_4$ ligand (Fig. 2).§ This unusual $Me_3SiNC_6H_4$ group is apparently formed by cleavage of one $NSiMe_3$ group from an *o*-$(Me_3SiN)_2C_6H_4$ ligand. The $NSiMe_3$ group that was cleaved remains as an additional terminal imido ligand on one of the Mo atoms. The formal oxidation state at each metal center is best described as Mo(V). The Mo(1)–Mo(2) distance of 2.5669(4) Å, although short for a Mo–Mo single bond, indicates the existence of a metal–metal bond, and accounts for the observed diamagnetism of **3**.[11] Four upfield resonances, assigned to the four inequivalent Me_3Si groups, are observed in the ^{1}H NMR spectrum of **3** and this is consistent with the structure as determined by X-ray crystallography.

The unusual C–N bond cleavage reaction that is observed during the pyrolysis of **2** is presumably driven by the formation of the Mo–N triple bond and demonstrates the reactivity of the Mo(IV) moiety towards oxidation. Further reactivity studies of **2** and **3** are currently in progress.

We thank the National Science foundation (CHE 9523279) for funding of this work. K. A. A. thanks the NSF and the University of Florida for funding X-ray equipment purchases.

Notes and references

‡ All reactions and manipulations were carried out using standard Schlenk techniques or in a dry-box under a nitrogen atmosphere. Complexes **1a** and **1b** were synthesized according to published procedures.[12] A representative synthesis of **2**: to a green pentane solution of freshly generated **1b** (1.07 g, 2.18 mmol) was added an excess of pyridine (0.51 g, 6.54 mmol). Upon addition of pyridine, **2** precipitated from solution and was isolated by filtration in 90% yield.

Synthesis of **3**: a toluene solution of **2** (0.200 g, 0.336 mmol) was heated to 90 °C in a sealed ampoule for 2 h. Concentration of the reaction mixture under reduced pressure afforded **3** as a black solid in 92% yield.

§ *Crystal data*: for **2**: $C_{28}H_{37}MoN_5Si_2$, M = 595.75, a = 15.5947(8), b = 10.3170(5), c = 18.4572(9) Å, V = 2969.6 Å^3, orthorhombic, space group $Pna2_1$, Z = 4, μ(Mo-Kα) = 0.547 mm^{-1}, T = 173(2) K, final $R1$ = 0.0218, $wR2$ = 0.0517, GOF (on F^2) = 0.994.

For **3**: $C_{41}H_{59}Mo_2N_7Si_4{\cdot}2CH_2Cl_2$, M = 1124.04, a = 14.4655(8), b = 23.572(1), c = 15.9891(9) Å, β = 104.390(1)°, V = 5280.8(5) Å^3, monoclinic, space group $P2_1/n$, Z = 4, μ(Mo-Kα) = 0.805 mm^{-1}, T = 173(2) K, final $R1$ = 0.0384, $wR2$ = 0.0824, GOF (on F^2) = 0.994.

The structures were solved by direct methods in SHELXTL5,[13] and refined using full-matrix least squares. The non-H atoms were treated anisotropically, whereas the hydrogen atoms were calculated in ideal positions and were riding on their respective carbon atoms. The asymmetric unit of **3** consists of the complex and two dichloromethane molecules, one of which is disordered and refined in three parts. Their site occupation factors were dependently refined until the final cycle of refinement after which they were fixed at 0.50, 0.35 and 0.15, respectively.

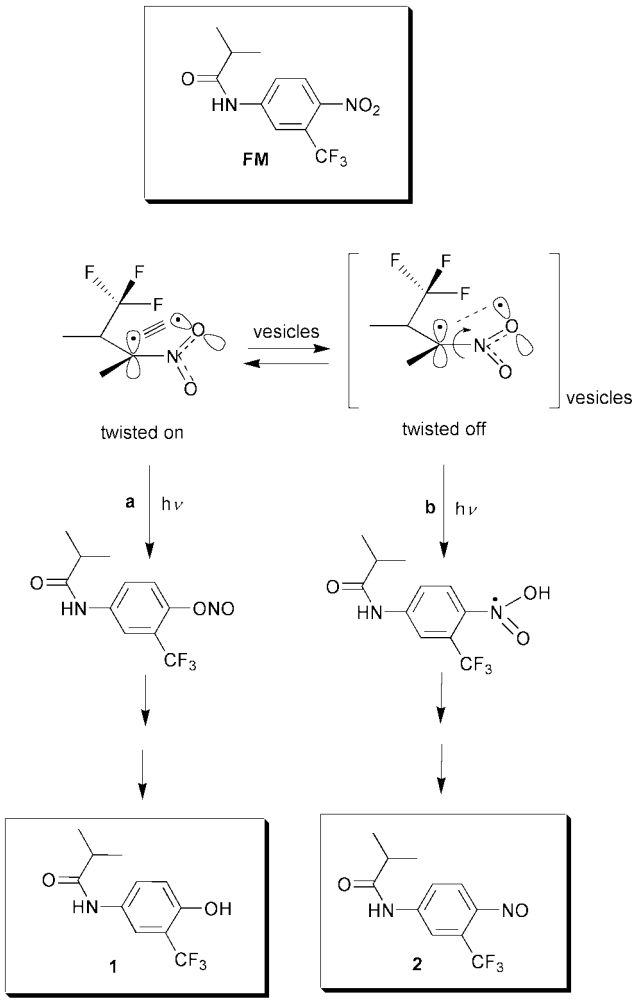
It is shown that structural changes of the phototoxic anti-cancer drug flutamide after its compartmentalization in unilamellar phospholipid bilayer vesicles lead to a highly selective modification of the photochemical outcome, locking the main photodegradation pathways observed in homogeneous media and unlocking a new and more efficient photoreactive channel.

Photochemical investigation of phototoxic drugs in organized assemblies mimicking biological systems is becoming an extremely active area of research in the wide arena of supramolecular photochemistry. Indeed, despite the knowledge of the drug photochemical behavior in homogeneous media is a first step for the understanding of molecular basis of the drug-photoinduced disorders, photoreactivity and phototoxicity are often not directly correlated to each other. The main reasons for these incongruities lie in the fact that real life photoprocesses occur at surfaces, interfaces and in multiphase heterogeneous systems. As a consequence it appears evident that a stepwise approach consisting of the investigation of the drug photobehavior in biologically mimicking systems of increasing complexity, represents an adequate strategy for a more appropriate correlation between phototoxicity and photochemical behavior. Furthermore, from a strictly photochemical point of view, studies concerning the drug photoreactivity in micromedia with particular polarity features in the presence of specific interaction and/or steric constraints provide a useful tool for the understanding of the factors influencing the molecular reactivity in order to control it.

Flutamide (FM), 2-methyl-*N*-[4-nitro-3-(trifluoromethyl)-phenyl]propanamide, is a non-steroidal anti-androgen drug that blocks androgen receptor sites and it is widely used in advanced prostate cancer.[1] Recent reports have shown the capability of FM to induce phototoxic and photoallergic effects in patients after drug treatment.[2,3]

Our recent study performed by using UVA light excitation and dilute FM solutions[4] has shown that the photoreactivity of the drug in homogeneous solvents is almost exclusively characterized by a nitro-to-nitrite photorearrangement leading to the phenol derivative **1** as the main stable photoproduct (path **a** Scheme 1). It has been pointed out that the twisted geometry of the nitro group with respect to the aromatic plane plays a key role in triggering such a photoprocess. Indeed, such 'out of plane' geometry makes the p orbital of the oxygen atom have a constructive overlap with the adjacent p orbital of the aromatic ring in the ground state (see Scheme 1). This kind of molecular conformation determines a lowest excited state triplet state characterized by a low biradical character and, as a consequence, by a considerable inefficiency towards hydrogen abstraction (H-abstraction) even in hydrogen donating solvents[4] contrary to what is commonly observed for nitroaromatic compounds in which the nitro group is conjugated with the aromatic plane.[5,6]

In this study, the photoreactivity of FM (5×10^{-5} M) in unilamellar phospholipid bilayer vesicles (liposomes)[7] of L-α-phosphatidylcholine (10^{-3} M) was analyzed. Such organized systems are smectic mesophases of phospholipids with water interspaced among them and characterized by both high aggregation and occupancy number.[8,9] The general observation was that the self-incorporation of FM into the vesicles leads to a highly selective modification of the photochemical outcome. In fact, the chromatographic analysis† performed after 325 nm



Scheme 1

 DOI: 10.1039/b102359b

irradiation revealed the total absence of **1** being consistent with the dramatic inhibition of the nitro-to-nitrite photorearrangement. On the contrary, the nitroso derivative **2** originated by an unexpected H-abstraction photoprocess was noticed as the sole stable photoproduct (path **b** Scheme 1). Furthermore, the photodegradation quantum yield of FM increased *ca*. 30-fold if compared to aqueous solution ($\Phi_{water} \approx 3 \times 10^{-3}$).[4]

The present scenario cannot be roughly rationalized on the basis of either the presence of the abstractable hydrogen atoms of the bilayer or on its low polarity. Actually, as outlined earlier, the irradiation of FM performed in solvents characterized by good hydrogen donating properties and polarity similar to the vesicles, interior did not activate the photonitroreductive pathway.[4]

We believe that a plausible explanation to account for the inhibition of **1** and the photogeneration of **2** may be consistent with structural changes of FM occurring upon its compartmentalization in the bilayer. In this regard, a less perpendicular geometry of the nitro group with respect to the aromatic ring, more likely caused by steric constrains and specific weak interactions (*i.e.* H-bond involving the CF_3 and/or NO_2) with the close packed lipids, would account well for the obtained results. Such changes in the perpendicularity of the nitro group would lead in fact to a less extended overlap of the p atomic orbital of oxygen with the adjacent orbital of the aromatic ring (see Scheme 1) with consequent loss of the twisted conformation. As well-documented in the literature,[10,11] such a conformation is a prerequisite for the nitro-to-nitrite photorearrangement responsible for the formation of **1**. The consequence of the loss of the twisted conformation is in turn reflected in the logical increase of the biradical character of the n,π* triplet and the consequent high ability of this latter in abstracting hydrogen in the presence of a suitable H-donor. Under these conditions, an intra-vesicles H-abstraction photoprocess involving the nitro group and the hydrogen atoms of the lipid chains might be activated, thus giving rise to the formation of **2** according to the very well known mechanistic pathways (path **b** Scheme 1).[5,6] Our hypothesis is supported well by spectroscopic data combined with theoretical calculations. In fact, from the calculated values of the dipole moments of the ground and first π,π* state, responsible for the first large absorption band (Delta μ about 10 Debyes), one would expect a blue shift of this band going from water to a less polar solvent, such as methanol and isopropyl alcohol (Fig. 1). *Vice versa*, in the vesicles (Fig. 1), where the relative permittivity is similar to that of isopropyl alcohol[9] and where in principle a blue shift should occur, one observes a marked red shift of this band (about 15 nm), consistent with a larger conjugated system which can only occur through a planarization of the NO_2 group.

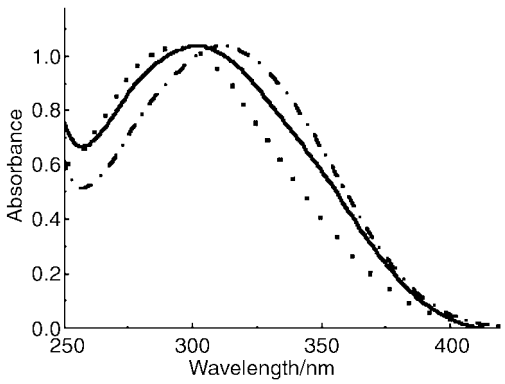


Fig. 1 Normalized absorption spectra of FM in (—) water, (···) isopropyl alcohol and (-·-·-) vesicles.

We believe that these preliminary results may be of chemical, biological and industrial relevance. From a strict chemical point of view, they represent a significant case of photochemical reactions selectively locked and unlocked by conformational changes of the molecular geometry upon substrate confinement in an organized system. From a biological point of view, given the potential of the bilayer in providing an useful model to mimic the biological membranes and by considering that the photogeneration of **2** is mediated by radical pathways[5,6] the obtained results represent a good step forward in understanding the origin of the phototoxic effects displayed by FM. Actually, the compartmentalization of the drug in particular biological sites in the presence of steric constraints and specific interactions, could lead to a relevant increase in the photoproduction of reactive radical species as a consequence of the photogeneration of a new product. Finally, from an industrial point of view, by taking into account the efforts that the scientific community has been making in the development of suitable carrier systems able to increase the FM solubility,[12] our study suggests that in light of the high photolability of the FM–liposome adduct if compared with the free molecule the use of liposome-based drug/carrier systems may not be the right approach to the aforementioned goal.

First published as an Advance Article on the web 27th June 2001

The highly compact and globular shape, as well as the uniform size and plurifunctionality of dendrimers make them ideal molecular building blocks for a wide range of interfacial materials involving self-assembled monolayers, Langmuir films, multilayers, and other surface-confined assemblies. Moreover, the study of the behavior of dendrimers at surfaces and interfaces provides unique insight into their chemical and physical properties. Dendritic macromolecules play an increasingly important role in the materials and surface sciences, where applications utilizing polymer thin films can benefit from their distinctive chemical and physical properties. Recent investigations have highlighted the use of dendrimers as functional surfaces and as interfacial materials for applications in membranes, adhesion, microelectronics or in chemical and biological sensing.

Introduction

Dendrimers constitute a unique class of polymers that are distinguished from all other synthetic macromolecules by their globular shape resulting from their perfectly branched architecture and their monodisperse nature.[1–3] The size, molecular weight, and chemical functionality of dendrimers can be easily controlled through the synthetic methods used for their preparation both by divergent[4] and by convergent[5] methods. With both of these approaches, a branch point is inserted in the dendritic structure at each monomer unit leading to a well-defined macromolecule with a 'degree of branching'[6] (DB) of 100%. This highly branched dendritic architecture causes the molecules to adopt three-dimensional globular conformations to minimize their free energy, with an immediate effect on macromolecular properties. In addition, the chemical composition of the chain-ends of the dendrimers has a determining effect on many of their physical properties such as solubility, glass transition temperature, or intrinsic viscosity. Finally, free energy considerations[2] dictate that the compositional contrast—match or mismatch—between the chain ends and the building blocks of a dendrimer will largely determine whether the chain-ends are mostly peripheral or distributed through their volume.

Over the past 16 years a wide range of 'designer' dendrimers[3] have been developed and synthesized, and their chemical and physical properties as well as their solution behaviors have been studied and well characterized.[3,7] In contrast, it is only recently that interest in the study and use of novel dendrimers for applications at surfaces and interfaces has grown.[7–9] As a result of their compact globular shape and easily controlled size and functionality, dendrimers constitute ideal molecular building blocks for a wide range of surface-related applications. Langmuir monolayers formed from amphiphilic dendrimers have recently been utilized by several research groups in order to probe behaviors such as shape, compressibility, and the localization of end-groups. Moreover, by studying their behavior at the air–water interface, one can gain further understanding of the relationship between physical properties and dendrimer generation. Similarly, the study of self-assembled monolayers of dendrimers on solid substrates has enhanced our understanding of the novel properties that are only accessible through surface confinement. Examples of applications of monolayers and other ultra-thin films assembled from tailor-made dendritic macromolecules have recently begun to appear in mission-oriented research such as functional materials for sensors or for microelectronics. Finally, the globular shape and multifunctional periphery of dendrimers makes them well suited for the construction of multilayer nanocomposite materials. These novel materials have recently been utilized to fabricate chemical and biological sensor devices as well as membranes responsive to external stimuli. The main goal of this article is to highlight the recent activity in both the study and the applications of dendrimers at surfaces and interfaces.

David Tully was born New York in 1973 and grew up in Wisconsin. He graduated cum laude with a B.S. in Chemistry from the University of Minnesota in 1996, where he did his undergraduate thesis research with Professor Larry L. Miller. He recently completed his PhD in Chemistry at the University of California, Berkeley, under the direction of Professor Jean M. J. Fréchet. He currently holds a position as a staff scientist at the Genomics Institute of the Novartis Research Foundation in San Diego, California.

Jean M. J. Fréchet obtained his first degree at the Institut de Chimie et Physique Industrielles (now CPE) in Lyon, France, and PhD degrees from the College of Environmental Sciences and Forestry and Syracuse University. Following academic appointments at the University of Ottawa (1973–1986) and Cornell University (1987–1996), he joined the Department of Chemistry at the University of California in Berkeley where he also heads the polymer program at the Lawrence Berkeley National Laboratory. J. Fréchet received both the American Chemical Society awards in Polymer Chemistry and in Applied Polymer Science; in 2000 he was elected a Fellow of the American Academy of Arts and Sciences, a member of the National Academy of Engineering, and a member of the National Academy of Science.

Dendrimers at the air–water interface

Initial studies of dendrimers at the air–water interface were carried out by Saville *et al.*[8] using convergent Fréchet-type poly(benzyl ether)† dendrons with a hydrophilic alcohol moiety at the focal point and hydrophobic benzyl groups at their periphery. Langmuir films were prepared from a homologous series of dendrons ranging from Generation 2 ([G-2]-OH) through Generation 6 ([G-6]-OH). As expected, surface pres-

† The IUPAC name for poly(benzyl ether) is poly(oxymethylphenylene).

DOI: 10.1039/b104290b

sure *versus* molecular area (*Π–A*) isotherms for this series showed that the higher molecular weight dendrons better resist collapse as the pressure is increased. Within the same series, only the lower molecular weight dendrons, [G-2]-OH through to [G-4]-OH, exhibit surfactant-like behavior while the much larger [G-5]-OH and [G-6]-OH dendrons no longer behave as surfactants. This suggests that the focal point of the larger dendrons is sterically shielded within the interior of the molecule, and, as a result, is inaccessible for association with the water surface, in agreement with the results of solvatochromic studies on comparable dendrons with a dye at their focal point.[10]

Neutron reflectivity studies carried out on Langmuir films prepared from analogous [G-4]-OH dendrons with chain-ends deuterated for additional contrast, support a monolayer structure as shown in Fig. 1. The peripheral benzyl groups are located on the outside of the molecule and away from the water interface, while the alcohol at the focal point is associated with the surface of the water. Further evidence from these neutron reflectivity experiments indicates that the [G-4]-OH Langmuir monolayer collapses easily into a stable bilayer. The bottom layer of dendrons, which afforded full surface coverage at all compressions, contained approximately 25% water. Meanwhile, the top layer, which varied in the extent of coverage from 50 to 100%, contained little or no water. This suggests that the bottom dendrimer layer acts as a hydrophobic barrier and prevents water from penetrating this layer. Furthermore, at low compressions, the [G-4]-OH dendrons within the Langmuir film assumed a spherical shape. However, at higher compressions, the dendrons in the lower layer adopted an elliptical shape with a 2:1 aspect ratio as depicted in Fig. 2. This phenomenon will be discussed in further detail below.

Hawker, White, and co-workers also explored the effect of peripheral group chemistry on the surface activity of dendrimers at the air–water interface.[11] For this study, poly(benzyl ether) dendrons were again synthesized with a single alcohol at the focal point but also included either nitrile or methyl ester functional groups at their periphery. The Langmuir film structure of these dendrimers was also analyzed by neutron specular reflectivity and *Π–A* isotherm measurements. It was found that functionalization of the periphery of the dendrons with polar nitrile and ester functionalities leads to monolayers

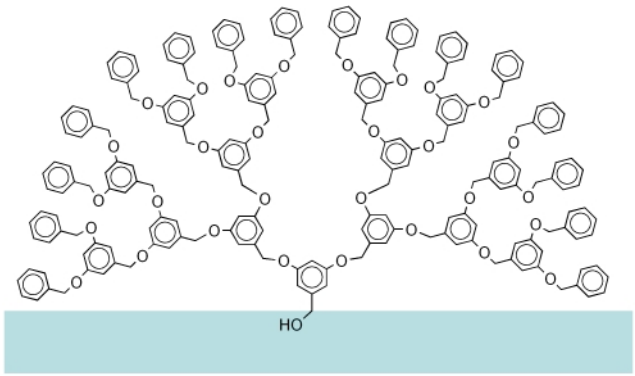

Fig. 1 Idealized structure of [G-4]-OH at the air–water interface.

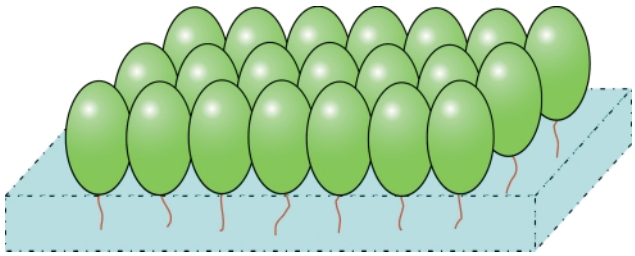

Fig. 2 Poly(benzyl ether) dendrons assume a prolate shape at the air–water interface.

with a structure very different from that of the unfunctionalized, hydrophobic dendrons used in the previous study. In this case the dendrons formed thinner films in which the presence of polar, more hydrophilic nitrile and methyl ester groups increased the affinity of the molecule for the water surface leading to more spreading as the molecules flattened across the interface. In addition, the formation of a bilayer film was not observed as the more polar dendrons tended to move into the water sub-phase under high compression, rather than form bilayers.

A more systematic study was recently carried out by Hawker, Frank and co-workers, in which the researchers examined the Langmuir monolayer structure of a series of dendrimers by changing chemistry at the focal point.[12] Again, Fréchet-type poly(benzyl ether) monodendrons functionalized with benzyl ether groups at the periphery were used for this study. However, this time the chemistry at the focal point of the molecules was adjusted by incorporating oligo(ethylene glycol) chains of varying length. In particular, [G-3] and [G-4] dendrons with mono- through to hexakis-(ethylene glycol) chains at the focal point were used for this study (Fig. 3). Studies of the *Π–A* isotherms for the series of [G-3] dendrons led to the conclusion that the hydrophilic oligo(ethylene glycol) chains extended into the water sub-phase thereby increasing the stability of the monolayer. It was also found that the stability of the monolayers increased with the length of the oligo(ethylene glycol) chain. A similar relationship between monolayer stability and the chain length of the hydrophilic oligo(ethylene glycol) focal point was also observed for the series of [G-4] monodendrons. However, the study concluded that the stability trends for the dendrimer monolayers depended on the relative sizes between the hydrophobic dendron and the hydrophilic focal point chain, as opposed to the absolute size of the oligo(ethylene glycol) unit. The larger [G-4] dendrons produced more stable films, presumably due to the amplified dispersive interactions amongst larger neighboring hydrophobic moieties, which apparently result in a stronger attraction of the hydrophilic focal point for the water sub-phase in the larger dendrons. Previous studies on monolayers consisting of linear fatty acids have also found that monolayer stability was increased by increasing the length of the alkyl chains as a result of the increased attraction between chains.[13]

The comprehensive study by Hawker and co-workers[12] also provided additional insight into the molecular shape of monodendrons assembled into a Langmuir monolayer. The molecular area was measured as a function of molecular weight for the [G-3] through to [G-5] poly(benzyl ether) dendrons, each possessing a hexakis(ethylene glycol) chain at the focal point. A linear relationship was observed for the molecular area as a function of molecular weight [Fig. 4(A)]. However, this measured trend is much smaller than the analogous relationship

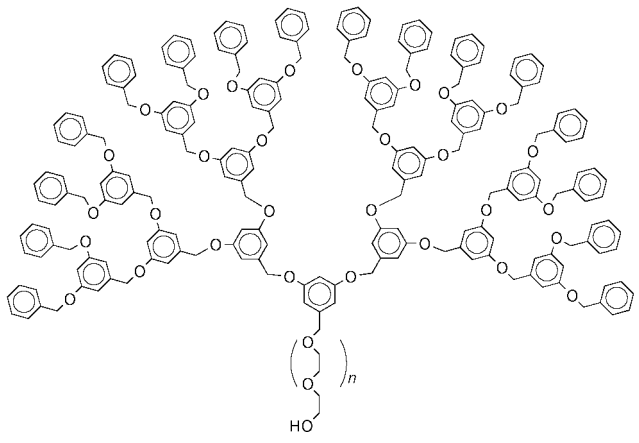

Fig. 3 Hydrophobic poly(benzyl ether) dendron functionalized with a hydrophilic oligo(ethylene glycol) focal point.

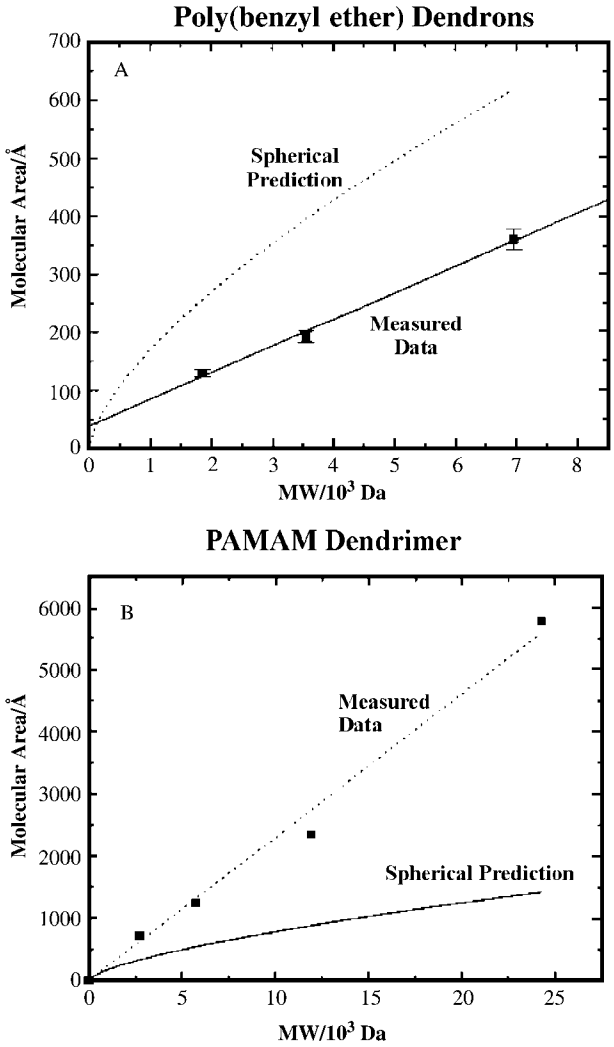

Fig. 4 A. Molecular area (in Å²) of poly(benzyl ether) dendrons as a function of molecular weight. B. Molecular area (in Å²) of PAMAM dendrimers as a function of molecular weight.

predicted for dendrons assuming a spherical shape. Hence, Hawker and co-workers concluded that the monodendrons assumed an ellipsoidal shape at the air–water interface (Fig. 2), in agreement with the conclusions drawn in the earlier studies by Saville *et al.*[8] that involved the same dendrons but with only a single hydroxy group at the focal point. Overall, these studies confirm that once a certain size is reached, poly(benzyl ether) dendrons possess and maintain an overall globular shape than can range from spherical to ovoid depending on the circumstances of their environment. As expected from simple structural considerations, it is only the largest structures or those with considerable steric requirements that can be expected to possess significant rigidity.

Percec and co-workers have used X-ray reflectivity and *Π–A* isotherm measurements to gain additional insight into the molecular structure of a series of functionalized poly(benzyl ether) monodendrons at the air–water interface.[14] In this study, the dendrons' periphery were functionalized with hydrophobic dodecyl chains, while the focal points were substituted with crown ether moieties or oligo(ethylene glycol) units. Their data provide additional evidence that the dendrimer Langmuir monolayers possess a structure consisting of a hydrophilic focal point at or beneath the water surface, and a high density region above the surface consisting of the dendritic block and the peripheral alkyl chains extending upwards from the surface.

The interfacial properties of PEG–poly(benzyl ether) linear-dendritic hybrid block copolymers were also recently examined.[15] Narrow polydispersity poly(ethylene glycol) chains with varying molecular weights were attached to the focal point of [G-2] poly(benzyl ether) dendrons to afford water-soluble hybrid block copolymers. These dendritic-PEG hybrids were then used to modify the surface properties of various polymeric substrates, which were then characterized by water contact angles on polymeric substrates submerged in oil. Treatment of hydrophobic poly(ethylene terephthalate) (PET) surfaces with a dilute aqueous solution of dendritic-PEG copolymer resulted in a marked decrease in the hydrophobicity of the PET surface. This is most likely due to the physisorption of the hydrophobic dendritic block to the lipophilic PET surface, while the hydrophilic PEG chain is extended into the aqueous phase. In contrast, modification of more polar regenerated cellulose resulted in a competitive adsorption between the dendritic head block and the PEG tail also leading to an overall increase in the hydrophilicity of the cellulose surface. These studies have significant implications in the context of stain-proofing fabrics and surface modification in general. They also demonstrate the promising utility of dendrons as modifiers for linear polymer chains as the relatively small dendritic block can impart significant functionality onto the end group of the linear polymer.

Tomalia and co-workers initially examined the behavior at the air–water interface of a series of poly(amido amine) (PAMAM) dendrimers that had been functionalized at the periphery with hydrophobic alkyl chains of varying length.[16] As part of this study, the researchers conducted a series of surface pressure *versus* molecular area isotherm measurements. It was found that the length of the hydrophobic end-group, when varied from hexyl to dodecyl, did not significantly influence the molecular area of the dendrimer at the collapse point in the isotherm. Tomalia and co-workers speculated that the lower generation dendrimers might adopt a conformation in which the hydrophilic dendrimer interior associates with the water surface, while the hydrophobic endgroups either extend upwards and away from the water surface or interdigitate with neighboring molecules. They also proposed a second model in which the dendrimers behaved like hydrophobic spheroids floating on the water surface, in order to account for the observation that the length of the alkyl chains at the periphery did not significantly affect the molecular areas even for the higher generation [G-4] and [G-5] dendrimers.

Shortly after Tomalia's initial account[16] Meijer and co-workers reported on a comprehensive study involving a series of poly(propyleneimine) dendrimers, [G-1] through to [G-5], that were functionalized with a wide variety of different hydrophobic end groups *via* acylation of the peripheral primary amines (Fig. 6).[17] Similar to PAMAM dendrimers, poly(propyleneimine) dendrimers possess a relatively hydrophilic interior due to the presence of a large number of aliphatic tertiary amines. When functionalized at the periphery with either palmitoyl chains (**A**) or long *n*-alkyl chains (**C**) containing an azobenzene chromophore, the amphiphilic dendrimers form stable monolayers, as was shown in a series of *Π–A* isotherms. In addition, the molecular areas of the macromolecules increased linearly with molecular weight, and matched the values that could be calculated for monolayers comprised of palmitoyl chains or alkyloxy–azobenzene chain surfactants alone. Meijer and co-workers concluded that the behavior of these amphiphilic dendrimers could be explained by one model only: namely that the flexible dendrimers assume a flattened conformation in which the hydrophilic dendrimer interior maximizes its association with the water surface, while the hydrophobic end groups are forced upwards and away from the water surface (Fig. 5). Further proof was obtained upon examination of a monolayer that was formed with dendrimer **C** and then transferred to a glass substrate. UV-Vis absorption spectroscopy revealed that the absorption maximum was blue shifted, suggesting the formation of H-type aggregates.[18] This evidence further supports the conclusion by Meijer and co-

workers that the hydrophobic chains adopt a conformation involving a parallel-packed array oriented perpendicular to the water surface.

Although the molecular areas of the series of *n*-alkane-functionalized PAMAM dendrimers at the air–water interface was previously measured and reported by Tomalia and co-workers,[16] the authors did not specifically explore the fundamental relationship between area and molecular weight. Following Meijer's instructive study on poly(propyleneimine) dendrimers,[17] Hawker and co-workers re-examined Tomalia's data concerning the series of epoxy-alkane functionalized dendrimers.[12] They also showed that the molecular area increased linearly with molecular weight (Fig. 4B) in agreement with the data collected earlier for poly(benzyl ether) dendrons.[8,12] However, in contrast to the behavior of the more hydrophobic Fréchet-type dendrons, the measured molecular area for the PAMAM dendrimers was found to be much larger than expected for a spherical model. It appears that the PAMAM dendrimers also assume a flattened, or oblate, conformation when assembled into a Langmuir monolayer (Fig. 5), in a manner similar to the poly(propyleneimine) dendrimers, discovered by Meijer and co-workers.[17] Upon consideration of the chemistry of the three types of dendrimers, these models describing the molecular shapes of dendrimers at the air–water interface can easily be reconciled. Both the PAMAM and poly(propyleneimine) dendrimers possess a polar, hydrophilic interior, resulting from the presence of a large number of amides and tertiary amines. As a result, they minimize their free-energy by association of their polar interior with the water surface, leading to somewhat flattened macromolecules that occupy a larger area than a sphere of comparable volume. Similarly, the hydrophobic chain-ends of the alkyl-modified PAMAM and poly(propyleneimine) dendrimers minimize their free-energy by extending upwards, away from the water surface. Such reasoning, based on simple energy minimization concepts, also explains the initial observation of Tomalia and co-workers that the molecular area of the PAMAM dendrimers does not change upon varying the length of the hydrophobic chain ends from hexyl to dodecyl groups.

In contrast, when poly(propyleneimine) dendrimers were functionalized with bulky adamantyl groups (dendrimer **B**), a different behavior was observed altogether.[17] These dendrimers did not behave like amphiphilic molecules at the air–water interface, but rather formed multi-layers. In addition, the molecular area of these molecules demonstrated a non-linear dependence on molecular weight. As a result, Meijer and co-workers concluded that dendrimer **B** adopts a shape persistent spherical conformation due to the significant steric constraints resulting from the incorporation of bulky peripheral adamantyl groups.

A fifth generation poly(propyleneimine) dendrimer was then randomly substituted with equimolar ratios of palmitoyl chains and azobenzene groups (dendrimer **[G-5]D**).[19] Not surprisingly, this dendrimer also formed stable monolayers with a cylindrical molecular structure similar to that of monolayers formed from the dendrimer series **A** and **C** (Fig. 6). However, while the dendrimers functionalized with 100% azobenzene units (**C**)

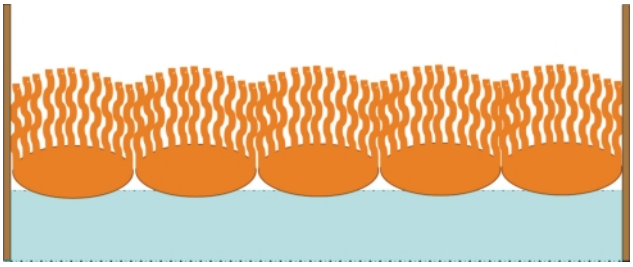

Fig. 5 Peripherally functionalized poly(propyleneimine) and PAMAM dendrimers assume an oblate shape at the air–water interface.

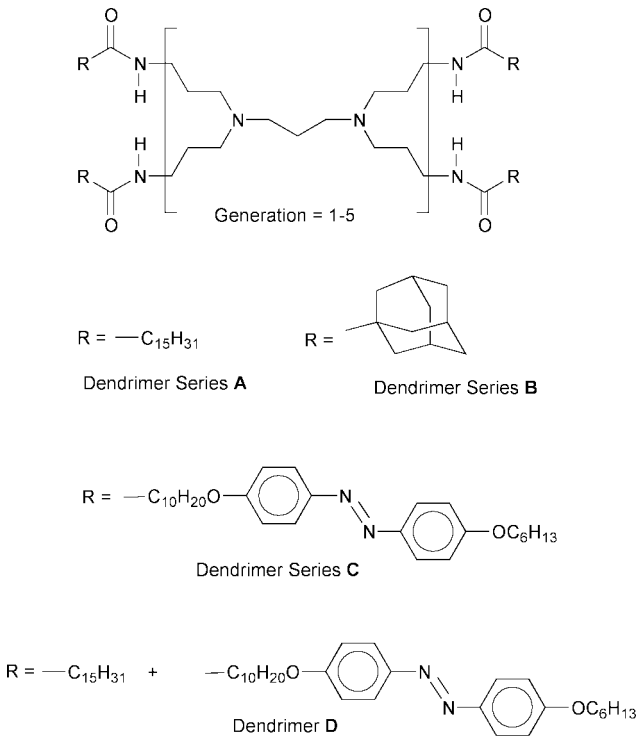

Fig. 6 Functionalized poly(propyleneimine) dendrimers.

exhibited a blue-shifted absorption maximum, indicating favorable π–π stacking among neighboring azobenzene moieties, dendrimer **[G-5]D** did not exhibit this behavior. Presumably the π-stacking of azobenzene groups is prevented by their dilution and solvation by the palmitoyl chains within the monolayer. As a result, reversible photo-switching is enabled for dendrimer **D** with the observation of changes in surface area at constant pressure when the monolayer was alternately irradiated with UV and IR.[19]

McGrath and co-workers have also developed photoresponsive Langmuir monolayers made from functionalized Fréchet-type poly(benzyl ether) dendrons.[20] In this case, the [G-1] through to [G-3] monodendrons were functionalized at their peripheries using *n*-decyl chains while their focal point consisted of an azobenzene unit. Each of the dendrons exhibited amphiphilic behavior and assembled into stable monolayers at the air–water interface. Upon UV irradiation of the [G-1] and [G-2] monolayers, a 10–20% increase in the cross-sectional molecular area A_0, was observed, which was attributed to the photo-switching of the azobenzene moiety from the *trans* to the *cis* isomer. With the monolayers prepared from the larger [G-3] dendrimer, illumination only afforded a minor change in A_0, suggesting that any change occurring within the azobenzene moiety is too small to have a significant effect on the large [G-3] dendron that surrounds it.

Dendrimers have also recently been employed as amphiphilic frameworks for the fabrication of derivatized C_{60} fullerene Langmuir monolayers. Hydrophobic C_{60} does not normally form stable monolayers at the air–water interface, and previous attempts have only led to the formation of ill-defined aggregates. However, in a collaborative effort involving the research groups of Stoddart, Diederich, Echegoyen, and Leblanc, an example of a stable Langmuir monolayer of a fullerene derivative was demonstrated.[21] This was accomplished by attaching C_{60} to hydrophilic glycodendrimer derivatives to afford fullerene–glycodendron conjugates **1** and **2** (Fig. 7). The stable Langmuir monolayers formed by C_{60}-glycodendrons **1** and **2** demonstrated reversible monolayer formation upon successive compression and expansion cycles. The researchers also succeeded in transferring the ordered monolayers onto a quartz substrate and concluded that the bulky

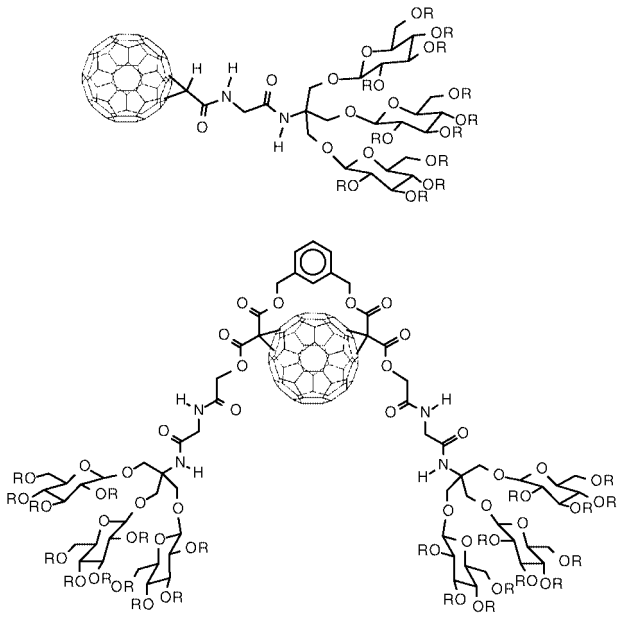

Fig. 7 Fullerene–glycodendron conjugates **1** (upper) and **2** (lower).

dendritic units were responsible for preventing aggregation of the fullerenes, thereby enabling the formation of stable monolayers.

Using an alternative approach, Nierengarten and co-workers functionalized the periphery of polyester dendrons with C_{60} units in order to promote stable monolayer formation at the air–water interface.[22] Upon successive compression and decompression cycles, reversible formation of Langmuir monolayers was observed. The researchers also succeeded in forming stable Langmuir–Blodgett films by transferring the fullerene functionalized dendrimer monolayers onto hydrophobic substrates.

Dendrimer self-assembled monolayers

Self-assembled monolayers (SAMs) of small organic molecules on metal and semiconductor surfaces constitute an area of widespread research.[23] Two systems that have undergone extensive study are alkanethiols on gold and alkylsiloxanes on hydroxylated silicon surfaces. A wide range of different surface chemistries has been employed in applications ranging from lithographic imaging[24–28] and chemical sensing[29] to corrosion passivation[30] and adhesion promotion or inhibition.[31]

The first example of covalent attachment of PAMAM dendrimers to a solid surface was reported by Crooks and co-workers nearly 5 years ago.[32] This was accomplished by forming amide bonds between the peripheral amino-groups of the PAMAM dendrimer and the carboxylic acid groups of a self-assembled monolayer (SAM) of mercaptoundecanoic acid on gold. This, and subsequent research by Crooks and co-workers[33,34] focusing on the development of dendrimer based films as surface-confined chemical sensor arrays has been the subject of a recent review,[29] and will therefore not be covered in detail in this article.

The chemical and physical properties of amine-terminated PAMAM dendrimers adsorbed to gold(111) surfaces have been thoroughly examined by Crooks and co-workers using a variety of analytical techniques.[35–37] When the gold substrate is immersed in a solution of PAMAM dendrimer in ethanol, a stable monolayer is formed presumably due to chemisorption of the terminal amines to the gold surface. PAMAM dendrimer monolayers prepared in this manner were found to be much more stable than monolayers of primary *n*-alkylamine on gold. The polydentate binding interactions between the amine groups of the dendrimer and the gold surface is thought to be responsible for the better stabilization of the dendritic monolayer. The surface-bound conformations of the dendrimers monolayers were also characterized by AFM.[36,37] Monolayer heights for the [G-8] dendrimers were measured to be only approximately 60% of their hydrodynamic diameter, again presumably due to the favorable interactions of the many peripheral amine groups with the gold surface. When the surface is subsequently treated with hexadecanethiol the heights of adsorbed dendrimer monolayers increase although their density on the surface decreases (Fig. 8). The change in height is presumably due to a distortion in the dendrimer shape from a flattened conformation to an upright, prolate shape, or possibly even an agglomeration of dendrimers as the surface amine interactions are replaced by those from a competing hexadecanethiolate monolayer.

Crooks and co-workers also functionalized the periphery of PAMAM dendrimers with varying amounts of thiol groups, and, as expected, these dendrimers formed stable monolayers on gold.[38] X-Ray photoelectron spectroscopy (XPS) suggests that fully thiolated dendrimers are bound to the gold surface utilizing only *ca.* 30% of their terminal thiol groups. Other dendrimers prepared by random functionalization of approximately 20% of their peripheral functionalities with thiol groups form monolayers in which nearly all the peripheral thiol functionalities are bound to the gold surface. This finding attests to the flexibility of the poly(amido amine) dendrimer framework, since randomly distributed peripheral thiols are able to become localized on the same side of the molecule in order to minimize their free energy through interaction with the gold surface.

Self-assembled monolayers of dendrimers on gold were also investigated by Gorman and co-workers,[39] who functionalized the focal point of poly(ether) dendrons with a thiol group. The dendrons, based on the 4,4-bis(4′-hydroxyphenyl)pentanol monomer unit previously developed by our group,[40] were protected at the periphery with hydrophobic benzyl ether groups and then functionalized at the focal point with a benzenethiol moiety (Fig. 9).[41] Self-assembled monolayers were prepared by

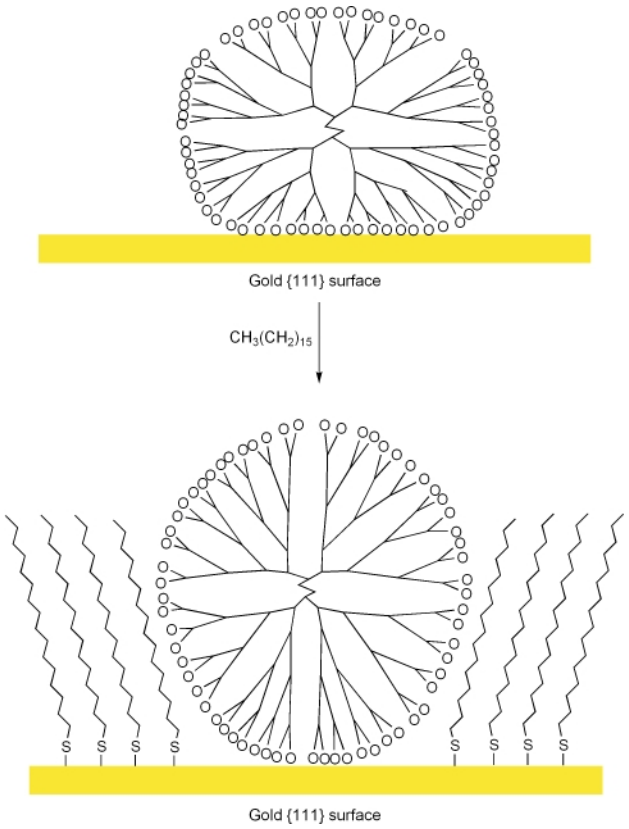

Fig. 8 PAMAM dendrimers adsorbed to gold change shape from oblate to prolate upon co-adsorption of hexadecanethiol.

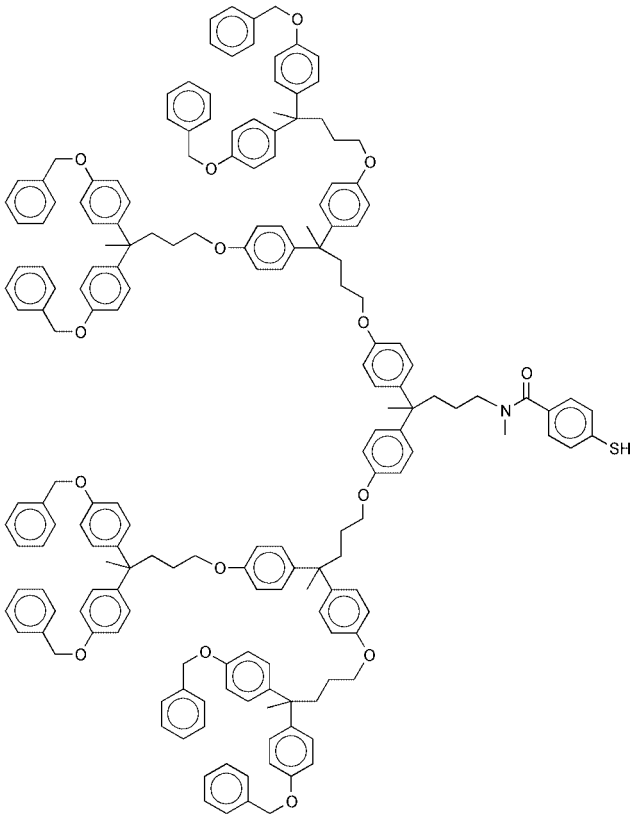

Fig. 9 Poly(ether) dendron with thiol-functionalized focal point.

immersing the polycrystalline gold substrate into a solution of the dendritic thiol. Analysis of the SAM structure by XPS verified that the dendrons were covalently bound to the gold substrate as the aryl thiolate, which is not unexpected considering the relatively flexible nature of the specific dendritic scaffold used. The extent of surface coverage for [G-1] and [G-2] dendrons analyzed by optical ellipsometry was close to 100%. Ellipsometric data for the SAMs formed from [G-3] dendrons showed thinner than expected film thicknesses, indicating either incomplete surface coverage or flattening of the macromolecules. In addition, the relative permeabilities of the dendrimer SAMs were determined using capacitance and redox probe measurements. The capacitance measurements showed that the dendrimer monolayers were more permeable to F^- and Cl^- anions than *n*-alkanethiolate SAMs of comparable thicknesses. This result is not unexpected given the disordered structure of a dendritic SAM in comparison to the ordered quasi-crystalline packing of *n*-alkanethiolate SAMs.

In our own laboratories, we have investigated the preparation of ultra-thin dendrimer films and self-assembled monolayers on silicon surfaces for their possible use as resist materials for scanning probe nanolithography.[42,43] In earlier studies, the scanning probe microscope (SPM) had been used as a direct-write-and-read tool for the lithographic patterning of passivated surfaces with several different chemistries, including self-assembled monolayers on gold[44–46] or silicon,[47–49] and thin polymer films.[50–52]

We first designed modified poly(benzyl ether) dendrimers covalently tethered to a silicon substrate that could serve as passivation resists in scanning probe lithography.[42] The concept of using dendrimers as lithographic resist materials stems from the consideration of their uniform size (several nm in diameter) and globular shape, which might serve as the ideal macromolecular template for a pixel-based approach to lithographic imaging. Specifically, an arrayed monolayer of dendrimers on a surface could act as a resist material for scanning probe lithography by protecting or passivating the surface against a wet etching process. Therefore, we prepared a series of sterically congested, hydrophobic dendrons that could protect the surface of a silicon wafer from an aqueous fluoride etchant. Fréchet-type poly(benzyl ether) dendrons, protected at the periphery with either benzyl ether or *tert*-butyldiphenylsilyl ether groups, were functionalized at the focal point with a covalent tether, consisting of a long alkyl chain derivatized with a terminal chlorosilane coupling agent (Fig. 10). Covalently bound self-assembled monolayers were prepared under anhydrous conditions using these reactive dendrons, and the dendrimer films were characterized by standard analytical techniques.

In addition to covalently bound dendrimer SAMs we have also investigated the synthesis and preparation of ionically bound dendrimer films by an acid/base self-assembly process.[43] In this instance, the poly(benzyl ether) dendrons we designed had a tethered carboxylic acid moiety at their focal point (Fig. 10). A monolayer of dendrons could then be assembled onto an aminated silicon wafer surface prepared by pre-treatment of the clean silicon surface with (3-aminopropyl)triethoxysilane.

We then examined the ability of both types of dendrimer SAMs to serve as etch resists for scanning probe lithography. In the process of scanning probe lithography, the conductive tip of the scanning probe microscope acts as the exposure source (Fig. 11). After the tip is brought into contact with the monolayer surface, a voltage is applied between the tip and the substrate, normally a doped Si(100) wafer. When the process is performed in air, any organic monolayer within the proximity of the intense electric field created between the tip and the substrate undergoes oxidative decomposition. At even higher field strengths, the underlying silicon wafer may also be oxidized, resulting in the formation of raised oxide relief features on the substrate. This occurs as a result of the volume expansion of the silicon wafer due to the incorporation of oxygen into the silicon crystalline lattice. Finally, the latent image in the monolayer can be transferred into the underlying substrate using a selective etch process.

Our experiments have demonstrated that dendrimer monolayers can indeed serve as effective passivation resists for scanning probe lithography. Although these experiments were performed without optimization of either the instrumental or the processing parameters, we were able to successfully create latent patterns on the surface that had feature sizes of *ca.* 35 nm. Furthermore, the dendrimer monolayers efficiently resisted the aqueous fluoride etching process, as evidenced from the lack of any line broadening or pitting in the unexposed regions of the film during the wet etching process. While the dimensions of imaged features far exceed the size of individual dendrimer molecules, it is clear that with optimization of the tip and of the processing conditions could lead to images with sizes in the range of 5–15 nm. Practical implementation would of course also require multiplexing of a very large number of tips.

Other interesting examples of applications involving dendritic SAMs include the use of biomolecule functionalized dendrimer monolayers for the development of affinity biosensors. Kim and co-workers have developed an electrochemical biosensor device that is capable of detecting the avidin–biotin interaction by monitoring the redox properties of free glucose oxidase in a glucose containing electrolyte solution using cyclic voltammetry. Self-assembled monolayers of amine-terminated PAMAM dendrimers were prepared on gold electrodes and the periphery was randomly functionalized with both ferrocenyl groups and biotin analogues.[53,54] In the absence of avidin, an electrochemical signal is generated by the enzymatic activity of glucose oxidase. As the concentration of avidin in the electrolyte solution is increased, the electrochemical signal is decreased due to steric blockage by the avidin adlayer formed on the modified electrode. Finally, the biosensor device can be regenerated by treating it with a solution of excess biotin, which results in desorption of avidin from the biotinylated dendrimer surface.

Multilayer dendrimer films

The earliest known study involving the assembly of dendrimers onto solid surfaces was based on the formation of dendrimer-composite multilayers. Regen and Watanabe[55] first demonstrated this concept by using PAMAM dendrimers to construct multilayers using a method involving coordination chemistry to prepare the thin films. An oxidized silicon surface was treated with (3-aminopropyl)triethoxysilane, followed by adsorption of K_2PtCl_4 from solution to the aminated surface. Next, PAMAM dendrimers, terminated on the periphery with primary amines, were adsorbed to the Pt^{2+} activated surface. This process could be repeated many times over to build up a multilayer of dendrimers with thicknesses of *ca.* 100 nm.

Other examples of PAMAM dendrimer multilayer formation include the formation of dendrimer-polyanhydride composite films on a variety of substrates. Bergbreiter and co-workers developed a multistep process that involves the sequential deposition of orthogonally reactive functional polymers to prepare the composite films that constitute the basis for a variety of ultrathin membrane materials.[56] An amino-functionalized surface is first prepared by treating glass or oxidized silicon with (3-aminopropyl)triethoxysilane. The aminated surface is then treated with a solution of poly[maleic anhydride-*co*-(methyl vinyl ether)] (Gantrez™) that reacts with the surface amines through amide bond formation with the maleic anhydride monomer units. Next, treatment of this modified surface with a solution of amine terminated PAMAM dendrimer results in the grafting of dendrimer molecules onto the surface *via* reaction of the amines with any previously unreacted anhydrides remaining in the first layer of Gantrez. Further sequential deposition of Gantrez and PAMAM dendrimer results in an alternating layer-by-layer build-up of the two polymers. Deposition of the grafted polymers was verified by optical ellipsometry, which demonstrated a linear increase of thickness with each stage of deposition.

These Gantrez–PAMAM composite thin films were shown to function as pH-responsive permeable membranes, as confirmed by a variety of electrochemical experiments.[57,58] The internal chemical composition of the composite films is thought to be homogeneous, and the incorporation of poly(amine) segments and poly(carboxylic acid) segments results in an amphoteric copolymer film. Composite films were coated onto a gold electrode, and cyclic voltammetry was used to monitor the permeability of the films towards cations and anions at different pH. In acidic solution (pH = 3.0), the dendrimer–Gantrez composite films were permeable to anions, such as $Fe(CN)_6^{3-}$, and impermeable to cations, such as $Ru(NH_3)_6^{3+}$. Conversely, in an alkaline solution (pH = 11.0) the films are impermeable to anions and permeable to cations. Furthermore, at neutral pH, the composite films allowed both cations and anions to diffuse through to the electrode. Finally, thermally annealing the dendrimer–Gantrez composite films at 120 °C, for 2 h led to further crosslinking, and resulted in the formation of a new film that was highly impermeable to ionic species over the entire pH range studied.[58] This simple approach to highly-crosslinked, polyfunctional films is quite versatile, and one could easily conceive of variations on this theme that could easily be adapted to other applications. Furthermore, the chemically robust nature and impermeability of the annealed films demonstrates their potential for use as coating materials for the prevention of corrosion.

A recent report from Crooks and co-workers details the use of this sequential deposition technique in conjunction with microcontact printing[24,25] to fabricate patterned PAMAM–Gantrez composite multilayer films.[59] This was accomplished by initial formation of a patterned monolayer of *n*-hexadecanethiol on a gold-coated silicon wafer using a prefabricated poly(dimethylsiloxane) (PDMS) stamp. Next, the substrate was treated with a solution of amine-terminated [G-4] PAMAM dendrimer. A monolayer of this poly(amine) dendrimer was preferentially adsorbed only onto the regions of the gold surface that are not passivated with the *n*-hexadecanethiolate monolayer. Finally, the substrate is treated with a solution

of Gantrez, resulting in the selective deposition of the anhydride containing copolymer only onto the patterned dendrimer regions. This sequential layer-by-layer deposition is repeated in a fashion analogous to the method previously described[56] to build up patterned PAMAM–Gantrez composite films. This method provides a convenient approach to patterned ultrathin organic films for applications in which durable, polyfunctional films are required, such as the patterning of biological molecules or cells.

An alternative method for dendrimer multilayer formation was later developed by Tsukruk and coworkers,[60,61] which hinges on the technique of electrostatic self-assembly developed by Decher.[62] The motivation for this work was said to be related to the development of modified tribological surfaces for boundary lubrication, however no specific applications were reported. Although electrostatic self-assembly is a simple and versatile method for the deposition of polymer multilayers, the resulting films are not as chemically robust as those developed by Bergbreiter and co-workers due to the absence of any covalent bonds among the adjoining layers. Once again, PAMAM dendrimers functionalized with either primary amines or carboxylic acids at their periphery were used for this study. Deposition of an initial layer of amine-terminated dendrimers was performed at pH < 3 to promote adsorption of the positively charged ammonium salts to the anionic silicon surface. A layer of carboxylic acid terminated PAMAM dendrimer was then deposited at pH > 6, a value that favors assembly of the anionic carboxylate salts onto the positively charged ammonium salt layer. Alternating sequential deposition of oppositely charged dendrimers led to a multilayer dendrimer–salt composite film. Thickness measurements of the initial dendrimer layer and subsequent multilayers were performed using atomic force microscopy (AFM). The data showed that the thicknesses of the initial dendrimer monolayers were much smaller than the previously measured hydrodynamic diameters of the PAMAM dendrimers.[2] Furthermore, the thickness of the composite multilayers was also much less than expected for superposed layers of spherical macromolecules. This indicates again that the charged PAMAM dendrimers assume a highly compressed or flattened conformation when arranged on the surface. However, it is also likely that incomplete surface coverage contributes to the lower than expected thickness measurements that were obtained.

Tomalia and co-workers have also used the electrostatic deposition technique to form gold-dendrimer nanocomposite films.[63,64] A layer of cationic poly[dimethyl(diallyl)ammonium chloride] was first deposited onto a negatively charged substrate, followed by the deposition of anionic poly(sodium styrene-4-sulfonate). The bilayer modified substrate was then treated with a solution of positively charged PAMAM dendrimer–gold nanoparticle nanocomposite, which uniformly assembles onto the surface. The authors contend that such materials may be useful for catalysis or optoelectronic applications in which ultrathin nanocomposite films are required, however this concept has yet to be realized.

Dendrimers have also recently been employed as polyfunctional templates for the surface immobilization of biological macromolecules. Anzai and co-workers have recently demonstrated that alternating sequential deposition could be utilized to prepare dendrimer–protein composite multilayer films.[65] This was accomplished by first depositing a layer of fluorescein isothiocyanate-labeled avidin (FITC-avidin) onto a hydrophobic gold or quartz surface. Next, the substrate was treated with a solution of biotin-labeled PAMAM dendrimer, which then assembled onto the surface *via* the well-known avidin–biotin complexation. The sequential deposition process could be repeated to build up dendrimer–avidin composite multilayer films. Although these materials have no distinctive utility by themselves, their preparation constitutes a convenient generalized approach toward functional polymer–biomolecule thin film materials that could potentially incorporate other useful functionalities.

Another example of dendrimer–protein composite multilayers was recently reported by Kim and Yoon.[66] This involves the deposition of an initial layer of periodate treated glucose oxidase (GOx) onto an aminated gold surface *via* the formation of Schiff bases between the aldehyde groups of oxidized GOx with the primary amines on the surface. In the next step, the substrate was treated with a solution of amine-terminated PAMAM dendrimer, which then reacts with any remaining GOx aldehydes also *via* imine formation to covalently bind the dendrimer molecules to the surface. Reductive amination of the Schiff bases was then employed to ensure against dendrimer desorption. Cyclic voltammetry was then used to probe the extent of active enzyme immobilized within the dendrimer–GOx multilayers. It was found that the electrocatalytic response of the electrode was significantly enhanced with respect to multilayer growth, suggesting that sensitivity is tunable by controlling the thickness of the multilayer films. Finally, the film stability with time was investigated, and it was found that over 80% of the initial electrode response was maintained after 20 days.

Solvent cast dendrimer films

There has been considerable interest in the properties and potential applications of dendrimer films prepared by drop- and spin-casting from solution onto solid substrates. A number of groups have focused on investigating the physical properties of dendrimers on solid surfaces using AFM. Sheiko and co-workers first examined the properties of hydrophobic carbosilane dendrimers deposited onto mica and pyrolytic graphite surfaces.[67] The wetting behavior was investigated by spin-casting dilute solutions of the dendrimer onto chemically different surfaces. AFM was then used to analyze the microscopic contact angles of the sub-micron sized droplets of dendrimers formed on the surface. It was found that the hydrophobic dendrimers did not interact specifically with the substrate and the molecules were observed to aggregate into large clusters that behaved like fluid droplets. When the periphery of the carbosilane dendrimers was functionalized with hydroxy groups, the resulting dendrimer possessed an amphiphilic structure with a hydrophobic interior and a hydrophilic periphery, hence leading to a reorganization of the films due to a preferential adsorption of the peripheral hydroxy groups onto the polar mica surface.[68]

Mülhaupt and co-workers used AFM to investigate the film formation of carbosilane dendrimers functionalized at the periphery with mesogenic cholesteryl groups.[69] Films of the mesogen-substituted dendrimers were prepared by drop-casting solutions of varying concentrations onto mica surfaces, followed by evaporation of the solvent. Analysis using AFM showed the formation of both monolayers and multilayers, depending on the initial concentration of the casting solution. Annealing of the lower generation dendrimers led to a reorientation of the molecules on the surface, presumably as a result of the reorganization of the mesogenic peripheral units.

De Schryver and co-workers have also used AFM to probe the physical properties of poly(phenylene) dendrimers.[70] By spin-casting from very dilute solution, poly(phenylene) dendrimers were deposited onto mica surfaces as well separated, individually resolved molecules. Using non-contact mode AFM, the researchers were able to obtain measurements of the dendrimer heights, which were in agreement with the sizes calculated using molecular dynamics simulations. In addition, the adhesion and stiffness properties of individual dendrimer molecules were measured using a pulsed force mode AFM. In comparison with the mica substrate, poly(phenylene) dendrimers and their aggregates exhibited low adhesion and high stiffness, which is not unexpected given the chemical composi-

tion of the hydrophobic, rigid molecular architecture of the poly(phenylene) dendrimer.

Klein and co-workers have used a surface force balance to measure surface interactions and friction in dendrimers adsorbed between mica surfaces. Their first report concerned low surface energy hydrophobic poly(propyleneimine) dendrimers that were functionalized at the periphery with *N*-Boc-phenylalanine.[71] Both shear and frictional forces were measured between two sliding surfaces treated with an adsorbed ultra-thin film of dendrimers. The compressibility of the dendrimer spheres was found to decrease as the molecules were progressively compressed. Furthermore, the researchers concluded that the behavior of these hydrophobic dendrimers was intermediate between that of a solid and a flexible polymer, as they did not exhibit stick–slip sliding. In the following study, Klein and co-workers examined the behavior of a high surface energy, or polar dendrimers under the same conditions.[71] For this comparative study, carbosilane dendrimers terminated with peripheral alcohol groups were used for the surface force balance measurements. In this case, the hydrophilic carbosilane dendrimer behaved more like a rigid sphere. Upon shearing, the molecules underwent relaxation of stored stress. In addition, these dendrimers exhibit stick–slip behavior similar to frozen monolayers of confined liquids.

We have recently investigated the interfacial properties of alkyl chain-modified dendrimers as surface primers for bonding polyolefin substrates. In this study, the end groups of poly(propyleneimine) dendrimers were functionalized with long-alkyl chain aldehydes *via* imine formation followed by reductive amination.[72] A thin film of the alkyl-modified dendrimer was then used as a primer layer for the adhesive joining of a variety of different polyolefin surfaces. Initial studies made use of cyanoacrylate adhesives that are normally incapable of bonding polyolefin surfaces. Block-shear testing of the adhesive strength revealed that in most cases failure could be attributed to substrate rather than adhesive failure, thereby demonstrating that the dendrimer films functioned as highly effective primers for ethyl cyanoacrylate bonding of poly(ethylene) and poly(propylene) substrates.

Recently, there have been a growing number of reports concerning the use of dendrimer-based thin films in a variety of microelectronics-related applications. Dendrimers in the condensed phase display many physical properties that differ significantly from their linear counterparts. We have been interested in exploring some of the unique properties of dendrimers for the development of new materials for applications in microelectronics. While our group has long been active in the areas of photolithography[73] and resist materials,[74] we have recently initiated a study of the various parameters that control resist material performance as a function of polymer architecture. The current state of the art resist materials incorporating chemical amplification[74] are all based on linear polymers as the matrix resin. The use of dendrimers as resist materials for 'next-generation lithography' may prove advantageous when the desired feature sizes approach macromolecular dimensions. In contrast to linear polymers, dendritic polymers are relatively free of chain entanglement. This may have important implications in designing resist materials for ultra-high resolution imaging, where parameters such as line-edge roughness, acid diffusion, and dissolution rates begin to have a serious impact on resist performance.

We have recently reported the first dendrimer-based chemically amplified resist.[75,76] Fréchet-type poly(benzyl ether) dendrimers with Boc (Fig. 12) or *tert*-butyl ester groups at their periphery were synthesized *via* a modification of the convergent route. Resist films were prepared by spin-casting a dendrimer-solution containing a catalytic amount of photo-acid generator (typically a triaryl sulfonium salt) onto a silicon wafer. These dendrimer films, normally several hundred nm thick, exhibited high sensitivity to both deep ultra-violet (DUV) and electron

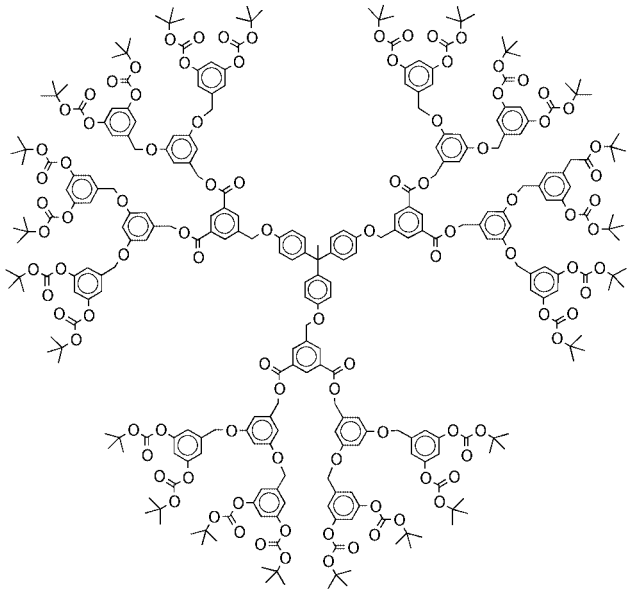

Fig. 12 Boc terminated [G-3] dendrimer.

beam radiation (E-beam). Since we are primarily interested in the performance of dendritic polymers for imaging feature sizes below 100 nm and there is a serious lack of imaging tools capable of such performance, we focused on electron-beam lithography and explored the performance of our dendrimer films as E-beam resists. As expected, these chemically amplified dendrimer resists displayed a high sensitivity to E-beam radiation while allowing image development in either the positive or the negative tone (Fig. 13). The scanning electron micrograph of Fig. 14 shows an example of a line pattern fabricated in a film cast from Boc terminated poly(benzyl ether) dendrimer. Even without optimization of the lithographic

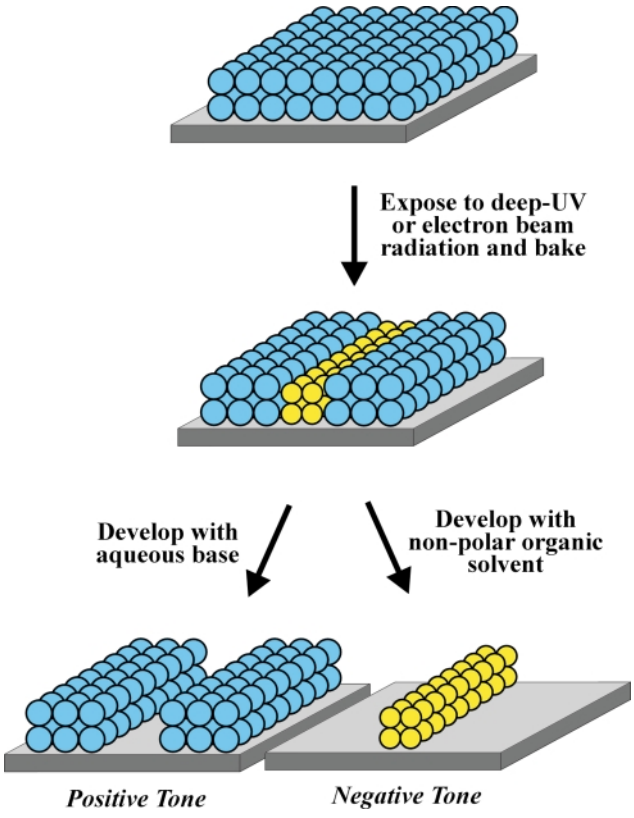

Fig. 13 UV or E-Beam exposure, followed by a bake step removes Boc protecting groups creating a latent, or chemical, image in the film. The dual tone resist can be developed with either aqueous base to afford positive tone images, or with anisole, to produce negative tone images.

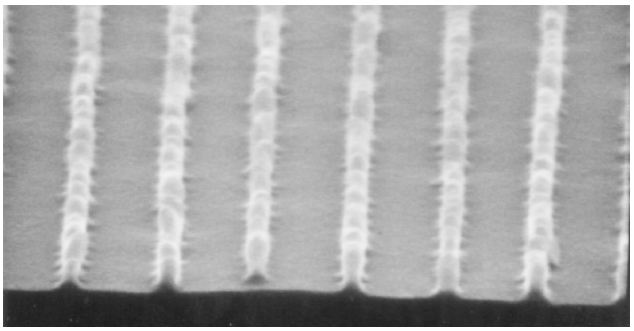

Fig. 14 SEM of negative tone images generated in Boc dendrimer resist. Linewidths: 50 nm; line heights: 100 nm; dose: 15 μC cm^{-2}.

processing parameters, feature sizes below 50 nm could consistently be printed. We are currently involved in the development of several new designs for dendritic polymers that may contribute to vastly enhanced lithographic resist performance. However there are undoubtedly serious limitations in the actual utility of dendrimers as commercial resist materials due to the obvious synthetic difficulty and expense of a multistep convergent dendrimer synthesis. As a result, the performance of a variety of related dendritic structures including hyperbranched polymers as chemically amplified resist materials is also under investigation.[77]

Functional dendritic polymers have also recently been used as templating agents to prepare nanoporous thin films for use as dielectric insulators. Therefore, Hedrick and co-workers have prepared highly branched copolymers by the ring opening polymerization of ε-caprolactone from dendritic initiators.[78,79] Composite films were made by spin-casting a solution of the dendritic polymer and a poly(silsesquioxane) precursor onto a silicon wafer. When the film is thermally annealed at 250 °C, a crosslinked organic–inorganic nanocomposite material is formed. Upon further heating to over 400 °C, the dendritic organic component of the film thermally decomposes into volatile byproducts, leaving behind a closed-cell nanoporous silicate foam. Since a significant proportion of the volume of this new material is occupied by air with a relative permittivity $k \cong 1.0$, an overall bulk relative permittivity below 2.0 is observed, making these materials promising candidates for high-end microelectronic applications where low-*k* dielectric materials are urgently needed. The commercial exploitation of this approach is now well under way.

Other recent applications that make use of dendrimer-based thin film materials include sensor devices that detect volatile organic compounds (VOCs). One such sensor device, developed by Miller and co-workers, detects VOCs on the basis of electrical conductivity changes in a dendrimer-based thin film.[80,81] The periphery of poly(amide) dendrimers was functionalized with oligothiophene derivatives, which function as the charge carriers. Thin films were prepared by first casting the neutral dendrimers from solution, followed by an oxidative doping with iodine vapor. The doped films were stable in air and exhibited true electronic conductivity ($\sigma = 10^{-3}$ S cm^{-1}). Upon exposure to organic vapors, the conductivity of the films was increased by as much as three orders of magnitude. Importantly, the conductivity response was fully reversible, and the magnitude of the response varied uniquely with the identity of the vapor.

The surface chemistry and interfacial properties of related classes of dendritic macromolecules,[2] such as hyperbranched polymers,[82–84] dendritic-linear hybrid block copolymers,[85] and dendronized or dendron-jacketed linear polymers,[86,87] have also recently become an area of growing interest, although they are beyond the scope of this brief review focusing specifically on dendrimers. Finally, the design and application of dendrimers and dendrimer-based films for opto-electronic applications such as light harvesting and light emitting diodes have been the focus of a recent review,[88] and therefore will not be discussed in this article.

Conclusions and outlook

The past several years have seen a considerable growth in the use of dendrimers at surfaces and interfaces. This results from the realization that the unique dendritic architecture of dendrimers can translate into unusual chemical and physical properties. While the demanding methods used for the preparation of dendrimers currently negate their use as commodity materials, it is clear that they are well suited for practical application at surfaces and interfaces where small amounts of materials only are needed. Early work with self-assembled dendrimer monolayers in applications such as resists for scanning probe lithography, affinity biosensors, and chemosensor devices have already demonstrated some of the capabilities of dendrimers. Such findings, coupled to others related to the rheological properties of dendrimers,[89] their ability to encapsulate[90] or harvest and concentrate energy[88] will no doubt continue to fuel interest in numerous 'designer' dendrimers for applications in nanotechnology. Another area of growth for dendrimers will involve their use at biological interfaces as their shape and surface functionality make them ideally suited for accessing, recognizing, coating or penetrating cell membranes. The outlook for continued activity in this field is strong, and many new discoveries and developments in chemistry, materials science, and biology involving dendrimers at surfaces and interfaces can be anticipated.

Acknowledgements

We thank the National Science Foundation (DMR-9816166), Semiconductor Research Corporation (SRC contract 96-LC-460), the Defense Advanced Research Projects Agency (DARPA grant MDA972-97-1-0010), and the AFOSR and ARO-MURI programs for their generous support of our research.

Catalytic enantioselective addition of aromatic amines to enones: synthesis of optically active β-amino acid derivatives

Wei Zhuang, Rita G. Hazell and Karl Anker Jørgensen*

Center for Metal Catalysed Reactions, Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark. E-mail: kaj@kemi.aau.dk

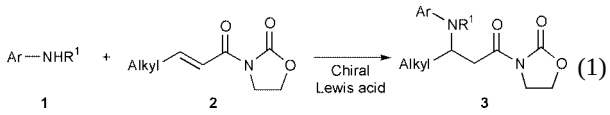
Received (in Cambridge, UK) 12th April 2001, Accepted 18th May 2001
First published as an Advance Article on the web 14th June 2001

A catalytic enantioselective addition of aromatic amines to enones has been developed; the potential of the reaction is shown for aromatic amines reacting with alkyl oxazolidinones in good yield and with moderate to excellent enantiomeric excess, and the transformation of the products to β-amino acid amides.

Optically active β-amino acids are important molecules[1] which show biological activity in their free from, or as present in many different types of molecules, *e.g.* peptides and depsipeptides.[2a] Furthermore, β-amino acid derivatives can easily be converted into important molecules such as β-lactams.[2b]

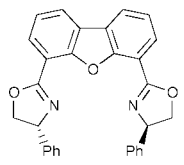
Optically active β-amino acids are traditionally prepared by a diastereoselective approach,[1b,3] while only very few methods are available for the direct formation of these compounds by the addition of nitrogen compounds to α,β-unsaturated carbonyl compounds catalysed by chiral Lewis acids as the catalysts.[4] In these investigations *O*-benzylhydroxylamine, hydrazoic acid or imines were used as the nitrogen source in the presence of different chiral Lewis acids.

In the following we will present the first enantioselective addition of secondary aromatic amines **1** to alkyl oxazolidinones **2** catalyzed by chiral Lewis acids [eqn. (1)].[5] This reaction gives the Michael adduct **3**, which leads to a simple synthetic approach of optically active β-amino acids.

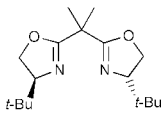


1 2 3 (1)

The reaction of *N*-methylaniline **1a** with 3-[(*E*)-2-butenoyl]-1,3-oxazolidin-2-one **2a** proceeds well in the presence of chiral Lewis acids. The results for the use of DBFOX-Ph[6] (*R*)-**4** and *t*-Bu-BOX[7] (*S*)-**5** as ligands in combination with different Lewis acids are presented in Table 1.



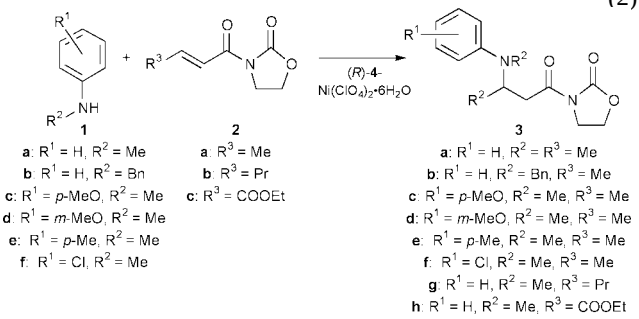
(*R*)-**4**



(*S*)-**5**

The reaction of **1a** with **2a** proceeds with high conversion and **3a** is obtained in up to 90% ee using (*R*)-**4**-Ni$(ClO_4)_2 \cdot 6H_2O$ (5 mol%) as the catalyst (Table 1, entries 1,2).† The solvent effect is notable for the reaction as only 19% conversion is found in THF (entry 3), while much higher conversion is obtained in CH_2Cl_2 (entries 1,2). Other metal salts can also be used in combination with (*R*)-**4** as the chiral ligand with various degree of success (entries 4,5). Surprisingly, the *t*-Bu-BOX (*S*)-**5** ligand in combination with copper salts, which has been found to be an excellent chiral catalyst for reactions of *e.g.* **2**,[7a,c] gave no conversion in the present reaction (entry 6), while the corresponding *t*-Bu-BOX-Zn$(OTf)_2$ catalyst gave moderate conversion and low enantioselectivity (entry 7).

A selection of aromatic amines **1a–f** has been reacted with the oxazolidinones **2a–c** in the presence of (*R*)-**4**-Ni$(ClO_4)_2 \cdot 6H_2O$ (5 mol %) as the catalyst [eqn. (2)] and the results are shown in Table 2.



(2)

The N-substituent is important for the conversion as an exchange of *N*-methyl to *N*-benzyl gives a significant reduction in yield and enantioselectivity (Table 2, entries 1,2). The reaction of *N*-methylanilines, having electron-donating substituents (**1c–e**) with **2a** proceeds in high yield and with up to 89% ee (entries 3–5). It should be noted that applying Ni$(ClO_4)_2 \cdot 6H_2O$ (5 mol%) and varying the equivalents of (*R*)-**4** from 2 to 0.6 relative to the Lewis acid does not alter the yield

Table 1 Screening of chiral ligands, Lewis acids and reaction conditions for the reaction of *N*-methylaniline **1a** with 3-[(*E*)-2-butenoyl]-1,3-oxazolidin-2-one **2a** at room temperature

Entry	Catalyst	Loading (%)	Solvent	Conv.[a] (%)	Ee[b] (%)
1	(*R*)-**4**-Ni$(ClO_4)_2 \cdot 6H_2O$	10	CH_2Cl_2	76	88
2	(*R*)-**4**-Ni$(ClO_4)_2 \cdot 6H_2O$	5	CH_2Cl_2	62	90
3	(*R*)-**4**-Ni$(ClO_4)_2 \cdot 6H_2O$	5	THF	19	84
4	(*R*)-**4**-Mg$(ClO_4)_2 \cdot 6H_2O$	5	CH_2Cl_2	63	39
5	(*R*)-**4**-Zn$(ClO_4)_2 \cdot 6H_2O$	5	CH_2Cl_2	15	64
6	(*S*)-**5**-Cu$(OTf)_2$	10	CH_2Cl_2	—	—
7	(*S*)-**5**-Zn$(OTf)_2$	10	CH_2Cl_2	50	14

[a] Determined by 1H-NMR spectroscopy. [b] Determined by chiral HPLC.

Table 2 Reaction of aromatic amines **1a–f** with the oxazolidonones **2a–c** in the presence of (*R*)-**4**-Ni$(ClO_4)_2 \cdot 6H_2O$ (5 mol%) as the catalyst in CH_2Cl_2 at room temperature

Entry	Amine	Oxazolidinone	Yield[a] %	Ee[b] %
1	**1a**	**2a**	**3a**–62	90
2	**1b**	**2a**	**3b**–6	34

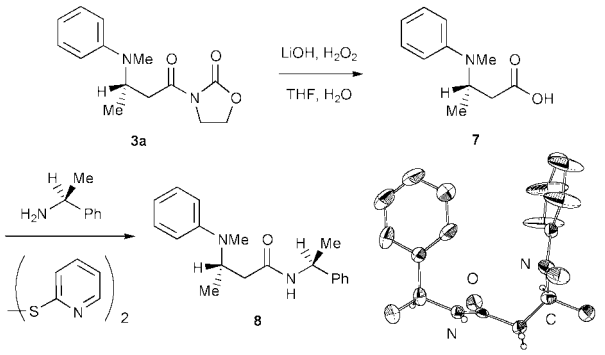

Scheme 1

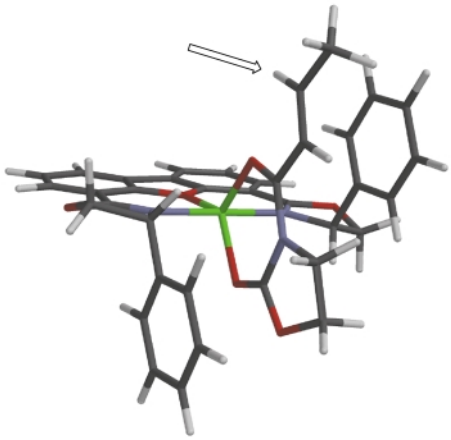

Fig. 1 Proposed intermediate for the catalytic enantioselective addition of secondary aromatic amines to enones catalyzed by (*R*)-DBFOX-Ph-Ni(II).

and enantioselectivity of the reaction of **1c** with **2a**. The reaction of *N*-methyl-*p*-chloroaniline **1f** with **2a** proceeds also with an excellent enantioselectivity, 96% ee of **3f**, however the yield at rt was moderate (entry 6); increasing the reaction temperature to 40 °C improves the yield to 53% and a reduction in enantioselectivity to 60% ee. The reaction of **1a** with **2b** proceeds with an excellent enantioselectivity, 95% ee of **3g** being obtained at rt (entry 7). The yield of **3g** was improved to 52% by performing the reaction in dichloroethane at 60 °C where 69% ee was obtained.

An important aspect of the present chemistry is that the products can be converted easily into various types of β-amino acid ester derivatives. The N-protecting group such as the *p*-methoxyphenyl group can be removed by standard chemistry.[8] In the following we will show that the oxazolidinone in **3** can be removed and exchanged with *e.g.* a chiral amine, which has been used to assign the absolute configuration of the product (Scheme 1). The adduct **3a** was first hydrolyzed with LiOH–H_2O_2 in a THF–H_2O solution giving the carboxylic acid **7**. Condensation with (*S*)-phenylethylamine gave the crystalline diastereomer **8**. The stereochemistry of **8** was assigned by X-ray analysis to be (*S*,*S*) (Scheme 1), *i.e.* the absolute configuration of the stereocenter formed in the addition reaction is (*S*).‡

Based on the absolute configuration of **8** we have proposed the intermediate in Fig. 1. The intermediate has a trigonal bipyrimidal coordination[6] at the metal center with the DBFOX-Ph (*R*)-**4** ligand occupying three sites and the oxazolidinone the remaining two. This intermediate has the β-*Si* face of the alkene shielded by the phenyl substituent of the chiral ligand, while the β-*Re* face is available for approach of the secondary aromatic amine leading to the addition adduct having an absolute configuration consistent with the experimental results.

In summary, a new catalytic enantioselective addition reaction of secondary aromatic amines to enones has been developed. This reaction proceeds in good yields and with moderate to excellent enantioselectivity in the presence of a chiral nickel complex. It was demonstrated that one of the products could be converted into an optically active amide which was used for the assignment of the absolute configuration of the addition adduct. Based on the absolute configuration, a chiral trigonal bipyrimidal nickel complex was proposed as the intermediate.

Double stranded interwound infinite linear silver coordination network†

Bruno Schmaltz, Abdelaziz Jouaiti, Mir Wais Hosseini* and André De Cian

Received (in Cambridge, UK) 27th April 2001, Accepted 4th June 2001
First published as an Advance Article on the web 27th June 2001

Upon self-assembly of a bismonodentate ligand based on two pyridine units interconnected at the *para* position by a hexaethylene glycol fragment using ester junctions and Ag^+ cation, a double stranded interwound infinite linear network was obtained in the crystalline phase; the formation of this unprecedented architecture is a result of the loop type conformation of the connector segment which forms a pseudo-crown ether. The loop surounds the metal cation which is linearly coordinated to two pyridines belonging to consecutive units, thus forming the 1-D network.

The design of molecular networks, in particular in the crystalline phase, can be based on concepts developed in the context of molecular tectonics.[1a] The latter concerns the self-assembly of molecular tectons[1b] or building blocks with programmed information into their structure about the energy of inter- and intra-molecular interactions. For metallo-organic coordination networks[2,3] which are generated upon self-assembly[4] of metal cations with organic ligands and in some cases the anion[5] as tectons, the design principle lies in the match between the requirements of different partners. Under self-assembly conditions, discrete metallo-organic complexes are generated from endo-ligands in the presence of cations. In contrast, the formation of coordination networks, based on translational symmetry of assembling cores, requires the use of exo-ligands *i.e.* organic ligands for which the coordination sites are oriented in a divergent fashion.

When using flexible fragments connecting two coordination poles (composed of one or several coordination sites), depending on the conformation of the spacer, in the presence of metal cations one may expect the formation of either discrete complexes (metallamacrocycle) by an obturation process or infinite coordination networks by iteration (Fig. 1).

Pursuing our efforts to understand the basic principles governing the formation of coordination networks,[6] the above mentioned competition between the formation of discrete and infinite coordination networks was investigated by designing the bis-monodentate ligand **1**. The design of the latter was based on two coordinating pyridine units interconnected by the hexaethyleneglycol moiety using ester junctions. The two coordination sites were connected at the 4 position of the pyridine ring. The latter was chosen as a monodentate coordination site because of its frequent use in the design of coordination networks.[7] Concerning the flexible spacer, this may either be an innocent segment such as a polymethylene chain or a functionalised fragment. Owing to its well known ability to interact with cations, the hexaethylene glycol unit appeared to be the most attractive fragment since it may play both structural and recognition roles.

Here we report the first example in the crystalline phase of an intertwound double stranded linear coordination network based on the self assembly of ligand **1** and Ag^+ cations.

The rather straightforward synthesis of **1** (slightly yellowish oil) was achieved in THF under argon by condensing, in the presence of Et_3N, the commercially available isonicotinoyl chloride **2** with hexaethyleneglycol **3** in 86% yield (Scheme 1).

Depending on the conformation of the polyethylene glycol chain and rotations around the C(O)O bond, compound **1** (Scheme 1) may either behave as an endo-ligand with a convergent orientation of both pyridines or as an exo-ligand for which the two monodentate coordination sites are oriented in a divergent fashion. Thus, in the presence of metal cations adopting a linear coordination geometry, whereas for the first case a metallamacrocycle would be expected, for the divergent orientation an infinite coordination network should be obtained (Fig. 1).

The best suited cation appeared to be Ag^+ due to its extended coordination flexibility, in particular its ability to adopt a linear coordination geometry.

Upon slow diffusion at room temp. of a EtOH solution containing $AgClO_4$ into a PhCl solution of **1**, stable colourless crystals were obtained overnight. X-Ray diffraction‡ on a single-crystal revealed the following relevant features: the crystal (monoclinic system, space group *C*2/*c*) was only composed of **1**, Ag^+ cations and ClO_4^- anions. No solvent molecules were present in the crystal. The combination of **1** and Ag^+ leads to the formation of an infinite polycationic linear coordination network. The latter is obtained by translation of an assembling core composed of a silver cation bridging two consecutive organic tectons. No specific interactions between the polycationic network and the ClO_4^- anions are observed. In a first approximation, the metal cation adopts a linear

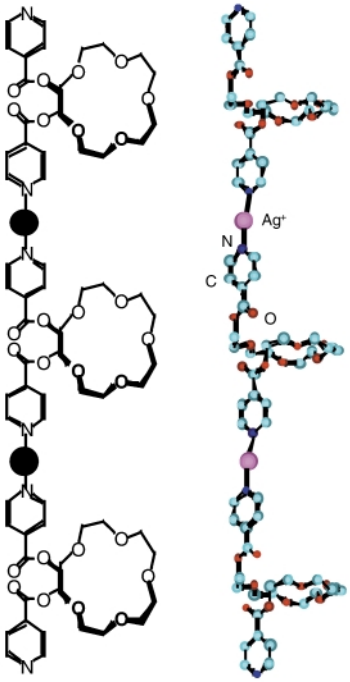

Fig. 2 Schematic (left) and a portion of the X-ray structure (right) of the cationic 1-D network obtained upon self-assembly of ligand **1** and Ag^+. H atoms and anion molecules are omitted for clarity.

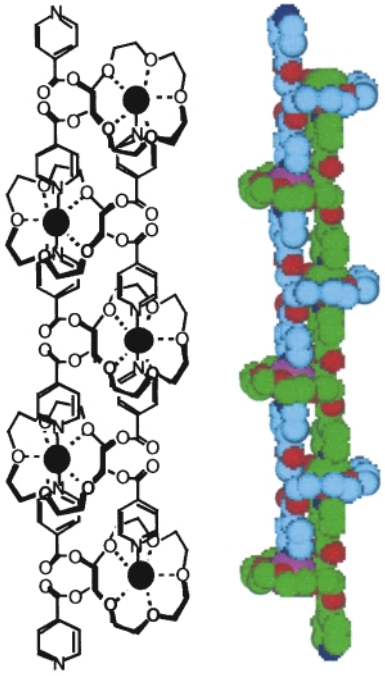

Fig. 3 Schematic (left) and a portion of the X-ray structure (right) of the double stranded cationic interwound 1-D network obtained due to interactions between Ag^+ cations and hexaethylenglycol units adopting a pseudo crown ether type conformation. H atoms and anions molecules are omitted for clarity.

coordination geometry with an N–Ag–N angle of 173.6°. Due to the unsymmetrical environment of the Ag^+ cation, the two N–Ag distances of 2.154 and 2.169 Å are slightly different. The ligand **1** adopts an interesting and particular conformation. The two pyridine units are almost parallel and co-planar but are oriented in opposite directions, thus allowing the formation of the network. Because of the *gauche* conformation of all six OCH_2CH_2O units, the hexaethylene glycol fragment adopts an almost circular conformation which closely resembles crown ether type units (Fig. 2). Furthermore, all pseudo-crown ether moieties adopt the same orientation and are located on the same side of the 1-D network. Of the six OCH_2CH_2O units, only one is disordered.

What was not predicted but is particularly interesting is that two adjacent linear networks are interwoven, leading thus to a double stranded interwound infinite linear network (Fig. 3). The driving force for the formation of such an architecture seems to be the loop type disposition of the polyethylene glycol units leading to interactions between silver cations belonging to one strand and selected ether oxygen atoms of the other strand. Taking into account these interactions, the coordination sphere around the cation may be described as comprising two nitrogen and five oxygen atoms. Among the five O atoms interacting with the cation, there are two rather short Ag–O distances of *ca*. 2.70 and 2.74 Å, one Ag–O distance in the medium range (3.05 Å) and two rather long Ag–O distances of *ca*. 3.26 and 3.44 Å. From this perspective, the assembling core may be regarded as a Ag^+ cation interacting strongly with two pyridine units belonging to one strand and weakly with five O atoms belonging to the other strand. Another curious feature is the orientation of loops within the double stranded interwound network: whereas for one strand all the loops adopt the same type of turn, for example left, for the other strand the opposite turn (right) is observed.

In conclusion, using the neutral acyclic tecton **1** based on two pyridines interconnected by the hexaethylene glycol through two ester junctions and Ag^+ cation, an unusual architecture consisting of a double stranded interwound infinite linear network was obtained unexpectedly in the crystalline phase. This observation opens the way to the design of other systems for which the nature of the coordination site, the connecting segment as well as the metal cation may be varied. Work along these lines is in progress.

Synthesis and application of dimeric *Cinchona* alkaloid phase-transfer catalysts: α,α′-bis[*O*(9)-allylcinchonidinium]-*o*, *m*, or *p*-xylene dibromide†

Sang-sup Jew,* Byeong-Seon Jeong, Mi-Sook Yoo, Hoon Huh and Hyeung-geun Park*

College of Pharmacy, Seoul National University, Seoul 151-742, Korea. E-mail: ssjew@plaza.snu.ac.kr

Received (in Cambridge, UK) 20th March 2001, Accepted 18th May 2001
First published as an Advance Article on the web 20th June 2001

A dimeric *Cinchona* alkaloid ammonium salt, α,α′-bis[*O*(9)-allylcinchonidinium]-*m*-xylene dibromide 4, has been developed as a new efficient phase-transfer catalyst; the catalytic enantioselective alkylation of *N*-(diphenylmethylene)glycine *tert*-butyl ester using 4 provided 7 in a high enantiomeric excess (90–99% ee).

Although phase-transfer catalytic reactions have been widely applied in organic synthesis,[1,2] asymmetric synthetic reactions using chiral phase-transfer catalysts have not been extensively studied as compared to general asymmetric synthetic reactions, such as asymmetric dihydroxylation,[3] asymmetric catalytic reduction,[2] and so on. Since the pioneering work of O'Donnell *et al*. (**1a**),[4] the enantioselective alkylation of a prochiral protected glycine derivative, using *Cinchona* alkaloid ammonium salts, has become a very attractive method for the preparation of both natural and unnatural α-amino acids. Especially, the Lygo[5] and Corey[6] groups independently reported the excellent phase-transfer catalysts, *N*-9-anthracenylmethylcinchonidinium chloride (**2a**) and *O*(9)-allyl-*N*-9-anthracenylmethylcinchonidinium bromide (**2b**), respectively, by replacing the phenyl group of **1** with the bulkier anthracenyl moiety. Recently, the Maruoka group developed very efficient non-*Cinchona* catalysts, the C_2-symmetric chiral quaternary ammonium salts prepared from (*S*)-binaphthol.[7]

In connection with the development of Sharpless asymmetric dihydroxylation, the discovery of ligands with two independent *Cinchona* alkaloid units attached to heterocyclic spacers led to considerable increases in both the enantioselectivity and the scope of the substrate.[3] This dimerization effect prompted us to develop dimeric *Cinchona* alkaloid ammonium salts for enantioselective phase-transfer catalytic reactions. In this communication, we report the preparation of new dimeric catalysts, α,α′-bis[*O*(9)-allylcinchonidinium]-*o*, *m*, or *p*-xylene dibromides **3**–**5**, and their application to the catalytic enantioselective alkylation of *N*-(diphenylmethylene)glycine *tert*-butyl ester **6** under mild phase-transfer conditions (Fig. 1).

Compounds **3**–**5** were prepared in two steps from cinchonidine and α,α′-dibromo-*o*, *m*, or *p*-xylene, respectively. Cinchonidine and α,α′-dibromo-*o*-, *m*-, or *p*-xylene were stirred at 100 °C in EtOH–DMF–$CHCl_3$ (v/v = 2.5:3:1)[8] for 6 h followed by *O*(9)-allylation with allyl bromide and 50% aq. KOH, to give the corresponding dimeric *Cinchona* alkaloid catalysts **3**–**5** in 90–92 % overall yields. The enantioselective efficiency of the prepared catalysts was evaluated by enantioselective phase-transfer alkylation using 5 mol% of catalysts **3**–**5** along with **6**, benzyl bromide, and 50% aq. KOH in toluene–$CHCl_3$[4f,9] (v/v = 7:3) at 0 °C or −20 °C for 2–6 h. Surprisingly, the *meta*-dimeric catalyst **4**‡ showed the highest enantioselectivity (*S*-form, 90% ee at 0 °C; 95% ee at −20 °C) among the three dimeric catalysts **3**–**5** (Table 1). The order of enantioselectivity of the three catalysts along with the monomer catalyst **1b** was as follows: *meta*-dimer (**4**) > *para*-dimer (**5**) ≅ monomer (**1b**) ≫ *ortho*-dimer (**3**). The precise mechanism for the high enantioselectivity of **4** is not clear, but it is thought to be similar to the reported mechanism of **2**.[6a] There are two possible conformations, **4a** and **4b**, as shown in Fig. 2. The **4a** conformer seems to be preferred, because of the steric hindrance between the quinoline and *O*-allyl moieties and the *Cinchona* unit (CD^+) in **4b**. In addition, the dramatic increase in the

[a] Isolated yield of purified material. [b] Enantiopurity was determined by HPLC analysis of the alkylated imine **7** using a chiral column (DAICEL Chiralcel OD) with hexane–propan-2-ol (500/2 for **7a**, **7b**, **7g**, **7h**, **7j**, **7k**, **7l**; 500/1 for **7c**, **7d**, **7e**, **7f**; 500/5 for **7i**) as solvent. [c] Absolute configuration was determined by comparison of the HPLC retention time with the authentic samples independently synthesized by the reported procedure.[4–7]

enantioselectivity from **1b** to **4** implies that the *Cinchona* unit (CD^+) is located near the B site. Consequently, as the direction B is sterically hindered by the counter *Cinchona* unit in **4**, the *E*-enolate of **6** forms an ion-pair with **4** from the less hindered direction A. We expect that as the *re*-face of the enolate can be effectively blocked by the formation of the ion-pair, the alkyl halide can approach only the *si*-face of *E*-enolate, to give the *S*-form. The lack of a difference in the enantioselectivity between the *para*-dimer **5** and the monomer **1b** implies that the *Cinchona* units of the *para*-dimer **5** do not sterically affect each other. In the case of the *ortho*-dimer **3**, the severe steric repulsion between the two *Cinchona* units may lead to a less efficient conformation for enantioselectivity. Generally, the lower temperature (−20 °C) yielded higher enantioselectivity (Table 1). Catalyst **4** was chosen for the further investigation of the enantioselective phase-transfer alkylation with various alkyl halides. Table 2 indicates the results obtained for the alkylation of **6** with various alkyl halides, using catalyst **4** under the same reaction conditions as in Table 1, except for the temperature (−20 °C). The very high enantioselectivities (90–99% ee) shown in Table 2 indicate that catalyst **4** is a very efficient enantioselective phase-transfer catalyst for the synthesis of natural and unnatural α-amino acids.

In conclusion, we prepared the dimeric *Cinchona* alkaloid ammonium salt catalysts **3**–**5** to enhance catalytic efficiency by the dimerization effect. Among the dimeric catalysts, the *meta*-isomer (**4**) showed the highest catalytic activity (90–99% ee) in the alkylation of **6**. The high catalytic efficiency, the easy preparation, and the lower preparation cost relative to **2a,b** could make **4** a practical catalyst in industrial synthetic processes for natural and unnatural chiral α-amino acids. Applications to other various types of phase-transfer catalytic reactions using **4** are currently being investigated.

‡ All new compounds gave satisfactory analytical and spectral data.

Selected data for **4**: mp 181 °C (decomp.); $[\alpha]^{25}_D$ −156 (*c* 0.320, $CHCl_3$); IR (KBr) 3437, 2922 cm^{-1}; δ_H (400 MHz, DMSO-d_6) 9.03 (d, *J* = 4.4 Hz, 2 H), 8.35 (d, *J* = 8.3 Hz, 2 H), 8.15 (d, *J* = 9.0 Hz, 3 H), 7.97 (d, *J* = 7.5 Hz, 2 H), 7.90–7.86 (m, 2 H), 7.81–7.76 (m, 3 H), 7.72 (d, *J* = 4.4 Hz, 2 H), 6.53 (s, 2 H), 6.22–6.16 (m, 2 H), 5.78–5.70 (m, 2 H), 5.49 (d, *J* = 17.2 Hz, 2 H), 5.37–5.28 (m, 4 H), 5.20–5.14 (m, 4 H), 4.99 (d, *J* = 10.5 Hz, 2 H), 4.46 (dd, *J* = 12.5, 5.3 Hz, 2 H), 4.06–4.03 (m, 6 H), 3.82–3.76 (m, 2 H), 3.69–3.64 (m, 2 H), 3.51–3.40 (m, 2 H), 2.84–2.75 (m, 2 H), 2.34–2.26 (m, 2 H), 2.15–2.00 (m, 4 H), 1.92–1.81 (m, 2 H), 1.51–1.42 (m, 2 H); δ_C (100 MHz, DMSO-d_6) 150.6, 148.4, 141.7, 139.3, 138.3, 135.9, 134.6, 130.3, 130.0, 129.9, 128.8, 127.9, 125.4, 124.1, 120.0, 118.0, 116.9, 72.3, 69.7, 68.2, 63.4, 59.3, 51.2, 37.2, 26.3, 24.5, 21.2; MS (ESI): 772 $[M]^{2+}$; HRMS (ESI) calcd for $[C_{52}H_{60}N_4O_2]^{2+}$: 772.4716, found: 772.4739.

Representative procedure for enantioselective catalytic alkylation of **6** *under phase-transfer conditions (benzylation)*: to a mixture of *N*-(diphenylmethylene)glycine *tert*-butyl ester **6** (50 mg, 0.17 mmol) and chiral catalyst **4** (8 mg, 0.0085 mmol) in toluene–$CHCl_3$ (v/v = 7:3, 0.75 mL) was added benzyl bromide (0.1 mL, 0.85 mmol). The reaction mixture was then cooled (−20 °C), 50% aq. KOH (0.25 mL) was added, and the reaction mixture was stirred at −20 °C until the starting material had been consumed (5 h). The suspension was diluted with ether (20 mL), washed with water (2 × 5 mL), dried over $MgSO_4$, filtered and concentrated *in vacuo*. Purification of the residue by flash column chromatography on silica gel (hexane:EtOAc = 50:1) afforded the desired product **7g** (61 mg, 94% yield) as a colorless oil. The enantioselectivity was determined by chiral HPLC analysis (DAICEL Chiralcel OD, hexane:propan-2-ol = 500:2.5, flow rate = 1.0 ml min^{-1}, 23 °C, λ = 254 nm; retention times *R* (minor) 12.2 min, *S* (major) 22.5 min, 95% ee). The absolute configuration was determined by comparison of the HPLC retention time with the authentic sample synthesized by the reported procedure.[4–7]

First published as an Advance Article on the web 20th June 2001

The reaction of substituted spirocyclopropenes 1 with 1-(3,5-dinitrophenyl)-3,4-dihydroisoquinoline 2 in dry ether solution afforded not only the expected THI 4 by 1,5-electrocyclization but also novel fluorenespiroazanorcaradienes 5 which is the first intramolecularly trapped product of the key intermediate in the formation of indolizine photochromics.

The reaction of the easily accessible spirocyclopropenes **1** with isoquinolines **2** has been shown to be an extremely powerful tool to prepare new photochromic dihydroindolizines (DHI), tetrahydroindolizines (THI) and pyrrolopyrrolizidines.[1–4] A vast number of tailormade molecules having interesting properties for applications such as ophthalmic lenses,[5] molecular switches,[6] dental material[7] and potential application in information recording and data storage and holography[8] has been published. We have shown recently that the reaction of 1-styryl-3,4-dihydroisoquinolines with spirocyclopropenes **1** is controlled by substituents to afford a pericyclic reaction to either THI's **4** or azepine derivatives **6**.[9] This reaction is governed by the substituents in the fluorene part and can form in a periselective way THI's **4** or azepines **6**. These results incited us to introduce strongly electron attracting groups (NO_2) which might stabilize the first intermediate in this reaction or even allow isolation of the product directly derived from this—until now—unproved intermediate. In this paper we describe the isolation of fluorenespiroazanorcaradienes **5** the trapped key intermediate in the indolizine formation and their X-ray structure, and also new THIs **4**.

Analogues of **2** with an unsubstituted 2-phenyl-ring, or with halogen or one nitro-group in the ring led only to ring-closed THIs when reacted with spirocyclopropenes **1** (see Table 1). The reaction of spirocyclopropenes **1** with dinitrosubstituted **2** in diethyl ether at rt after 5 d not only afforded the ring-closed THI **4** but a novel product, the azanorcaradiene **5**. Both products were isolated using column chromatography on silica gel (eluent CH_2Cl_2 and CH_2Cl_2–MeOH), their structures were determined *via* elemental analysis, ^{1}H-NMR, ^{13}C-NMR, IR-spectra and X-ray analysis (see ESI†).The general mechanism for the reaction of **2** with **1** is shown in Scheme 1. The reaction of **1** with **2** can proceed in three possible ways. The carbon atoms 2″ and 6″ in the 5′-phenyl ring of intermediate **A** are positively polarised because of the influence of two strong electron withdrawing nitro-groups in *ortho*- and *para*-positions. In the first case (path **a**), after nucleophilic addition of **2** on the double-bond of **1** starting from the intermediate cyclopropylcarbanion **A** by 1,6-electrocyclization through attack of the negative C2′ on the positive C2″ and finally by rearrangement results in **5** which must be regarded as the product of the intramolecularly trapped intermediate **A**. This is the first direct proof of intermediate **A** postulated in the mechanism of indolizine formation. In the second case (path **b**), the intermediate **A** rearranges to the betaine **3** through a cyclopropylallylanion rearrangment, which yields THI **4** through 1,5-electrocyclization. In the third possible case (path **c**), the betaine **3** may form through 1,7-electrocyclization to produce the 7-membered compound **6′**, a reaction not observed here.

Besides spectral data, the structure of products was confirmed by X-ray analysis for the fluorenespiroazanorcaradiene dye **5b** (Fig. S1†) and tetrahydroindolizine **4f** (Fig. S2†).

The green to green-blue dyes **5** have two absorption bands in the visible. The UV–Vis data and color are shown in Table 2.

The novel azanorcaradienes **5** possess acidochromic or halochromic properties, for example the ethanol solution of **5a** has a green color (459 and 655 nm); the color changed at once from green to deep violet (548 nm) after adding a few drops of aqueous sodium hydroxide. This process is reversible with hydrochloric acid many times without decreasing the absorption intensity. It is suggested that the acidochromism of dye **5** giving the anion **5′** (proton abstracted at 4′a position) is due to dissociation of the **4′**a-H atom and the reversible reprotonation

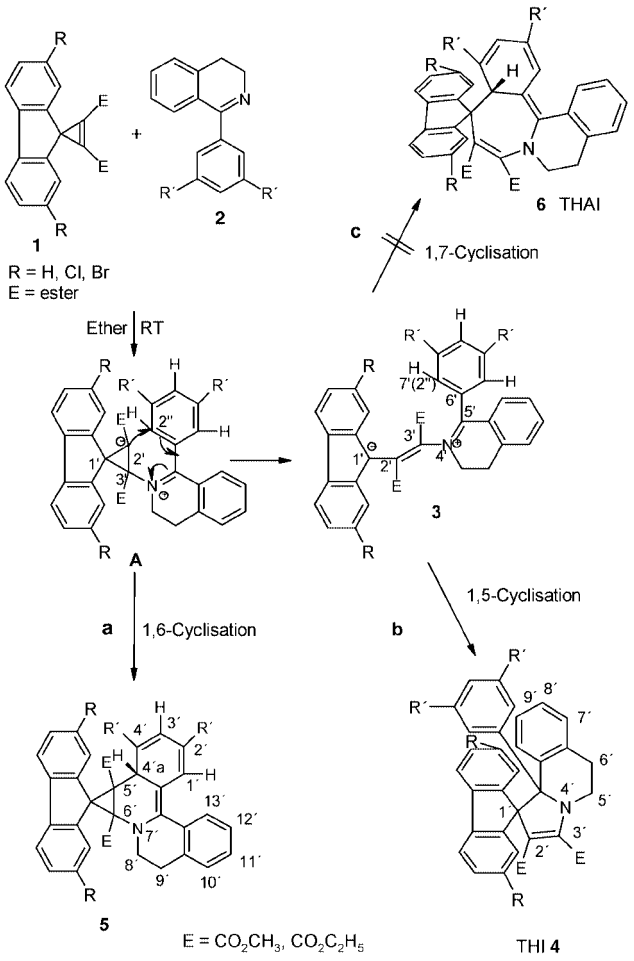

Scheme 1

of the resulting carbanion. This has been proved also by ^{1}H-NMR measurements.

Compound **5a** in CD_3CN shows a singlet for 4′a-H at 5.38 and 1′-H at 8.06 ppm as well as a doublet for 3′-H at 8.27 ppm. The addition of NaOD–D_2O changed the green color to violet, 4′a-H disappeared completely and 3′-H is shifted to 4.74 ppm (s) and 1′-H to 7.59 ppm. The original spectrum appears again after addition of DCl. Thus it is clear that the colored species **5′** is the anion where a proton has been abstracted from the 4′a-position. In summary, the intramolecular trapping of intermediate **A** to afford fluorenespiroazanorcaradienes **5** is the first proof for the mechanism of the cyclopropane anion intermediate postulated[1–4] after nucleophilic attack of **2** to the double bond of **1**. The cyclopropyl anion is intramolecularly trapped to give cyclopropane derivatives **5**. The THI **4** are formed *via* the betaine **3** to its precursor the cyclopropylanion **A**.

A new reaction of cyclohexanone enolate with nitroarenes

Nikolai Moskalev and Mieczysław Mąkosza*

Institute of Organic Chemistry, Polish Academy of Sciences, ul. Kasprzaka 44, 01-224 Warszawa 42, POB 58, Poland. E-mail: icho-s@icho.edu.pl; Fax: +48 22 6326681

Received (in Cambridge, UK) 19th February 2001, Accepted 15th May 2001
First published as an Advance Article on the web 20th June 2001

Reaction of cyclohexanone enolate with some nitroarenes carried out at 60–80 °C proceeds *via* addition to the nitro group followed by a series of transformations giving *o*-hydroxydiarylamines.

Carbanions react with nitroarenes mainly *via* addition to electron-deficient rings, in positions *ortho*- or *para*- to the nitro group giving anionic σ adducts. Addition at positions occupied by nucleofugal substituents X give σ^x adducts rapidly converted into products of S_NAr reaction.[1] Faster and reversible addition at positions occupied by hydrogen produces σ^H adducts,[2,3] which can be converted into products of nucleophilic substitution of hydrogen on a few pathways such as oxidation,[4] vicarious nucleophilic substitution VNS,[5] formation of nitroso compounds[6] *etc*. Direct intermolecular addition of stabilized carbanions to the nitro group is almost unknown, although there are numerous examples of such addition proceeding as intramolecular processes resulting in the formation of heterocyclic systems.[7,8] Addition of indan-1-one enolate to the nitro group of *o*-nitrobenzaldehyde appears to be assisted by initial addition to the carbonyl group, thus being in fact an intramolecular process.[9] Of particular interest in this respect is the observation reported by Scorrano[10] and subsequently by one of us[11] that methyl aryl ketones react with some nitroarenes giving 1,2-diaroyl-1-arylaminoethylenes. The reaction proceeds apparently *via* direct addition of the enolates to the nitro group, although redox process and nitrosoarene intermediates are suggested by Scorrano.[10]

In this communication we report that treatment of some nitroarenes **1a**–**d** with cyclohexanone **2a** and 2- and 3-methylcyclohexanones **2b**,**c** in presence of base results in the formation of substituted *o*-hydroxydiarylamines **3a**–**f** in reasonable yields. Since these anilines are sensitive to oxidation, particularly in basic media, some problems were encountered in isolation and purification, and thus the reaction mixtures were treated with MeI to produce stable *o*-methoxydiarylamines **4a**–**f**, which were then readily isolated and purified.† Some results are collected in Table 1.

The reaction proceeds apparently *via* direct addition of the enolate to the nitro group in nitroarenes and is undoubtedly related to reported earlier formation of 1,2-diaroyl-1-arylaminoethylenes.[10,11] The speculative mechanistic pathway of these complicated processes, which bifurcate at the stage of further transformation of the nitrone intermediate **5**, is shown in Scheme 1.

Direct addition of the enolate to the nitro group produces the anionic adduct converted into nitrone **5**. Nitrone **5a** derived from cyclohexanone undergoes 1,3-proton shift leading to the hydroxylamine derivative, followed by 1,4-dehydration giving the imino ketone which tautomerizes in basic media to form the aromatic system of *o*-hydroxyaniline **3**. In the similar reaction of acetophenone there is no possibility for such proton shift and 1,4-dehydration in the linear nitrone intermediate **5b**, so addition of the second enolate molecule to the nitrone takes place to produce hydroxylamine **6** which upon dehydration and tautomerisation gives the final diaroylethylenes **7**.

The main problem to be clarified is the reason for the observed dichotomy of the reaction course of enolates with nitroarenes. At low temperature, enolates generated by treatment of ketones with base or activation of silyl enol ethers with F^- anions add at the *ortho*- or *para*-position of halonitrobenzenes.[12] Subsequent oxidation of the σ^H adducts leads to nitrobenzylic ketones—products of the oxidative substitution of hydrogen. On the other hand, as has been shown in previous papers[10,11] and in this report, at higher temperature the same enolates add to the nitro group of nitroarenes. Since it is not reasonable to assume that changing the temperature changes the mode of the initial step, one can suppose that also in the latter reaction reversible addition to the ring is a fast initial process. At low temperature the σ^H adducts produced are long lived species and are oxidized, whereas at high temperature the concentration of the σ^H adducts becomes so low that the bimolecular oxidation process does not occur and the reaction proceeds *via* addition of the enolate to the nitro group.

The possibility that the reaction, in analogy to other processes,[13,14] proceeds *via* nitrosoarenes, was excluded by experiments in which *p*-nitroso-*N*,*N*-dimethylaniline subjected to the reaction with cyclohexanone under the identical conditions gave mainly *p*,*p*-bis(*N*,*N*-dimethylamino)azoxybenzene in a fast process, whereas slow introduction of this nitrosoarene to the reaction mixture of *p*-nitrodimethylaniline and cyclohexanone did not improve the yield of the *o*-hydroxydiarylamine, being rapidly converted into the azoxycompound. Direct

intermolecular addition of carbanions to the NO_2 group is a common process when it is connected with oxygen used as a preparative method for nitration of enolates with alkyl nitrates.[15] Such reaction can occur with nitroalkanes provided they are not C–H acids. Thus we found that when *tert*-nitrobutane was allowed to react with cyclohexanone in the presence of KOH in DMSO at 80 °C, *N*-*tert*-butyl-2-hydroxyaniline **3g** was isolated in moderate yield 12%.‡

It is worth stressing that the presented reaction is a useful one-pot alternative to only a few methods designed for the synthesis of diarylamines containing electron-donating substituents in both rings.[16,17]

Cystine-based cyclic oligoureas: a new class of hydrogen-bonding electroneutral anion receptors†

Darshan Ranganathan* and C. Lakshmi

Discovery Laboratory, Indian Institute of Chemical Technology, Hyderabad-500 007, India. E-mail: ranganathan@iict.ap.nic.in; Fax: 040-7173757/7173387

Received (in Cambridge, UK) 23rd March 2001, Accepted 21st May 2001
First published as an Advance Article on the web 20th June 2001

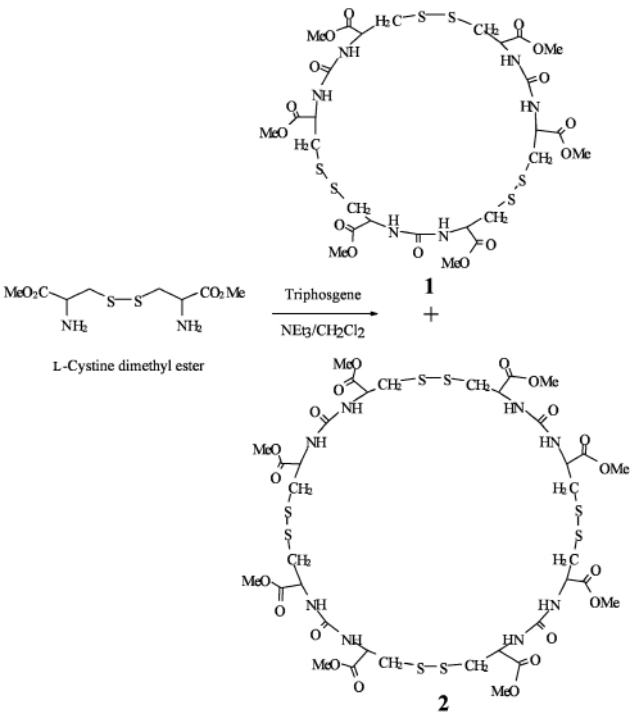
Cystine-based symmetrical cyclic oligoureas, synthesized in a one-pot reaction from L-cystine dimethyl ester and triphosgene, are demonstrated to act as versatile neutral receptors for both inorganic and organic anions operating exclusively through hydrogen bonds; ^{1}H NMR studies have shown that while the cyclic triurea prefers to complex with spherical (halides) and trigonal planar (nitrate) anions, the higher oligomer tetraurea can trap the tetragonal planar squarate dianion with modest efficiency.

Rational design of artificial receptors for anion complexation is an area of intense current interest[1] that has relevance to biology, industry and environment. Considering the intense activity and the vast literature that has accumulated over the past two decades in the field of supramolecular chemistry and the development of preorganization concepts in molecular recognition, it was surprising to find only a handful of designs for cyclic anion receptors and barring few exceptions of neutral cyclic anion hosts,[2] most of these interestingly, centred around the use of protonated macro mono or polycyclic amines.[3] Thus, whereas in Nature it is the neutral anion-binding proteins regulating the transport of anions largely through hydrogen bonds,[4] the synthetic designs of positively charged anion receptors operated mainly through coloumbic interactions. The idea of using amino acid-based macrocycles with multiple hydrogen-bonding pockets, uniformly distributed in the cyclic backbone, appeared an exciting possibility to create neutral receptors that would not only be close to natural systems but may also show high selectivity in multifunctional anion complexation.

In this communication, we provide the first illustration[5] of such a concept and report on the design, synthesis and anion recognition of L-cystine-based cyclic oligourea receptors wherein the multiple urea groups are held as part of the ring framework in a cyclic arrangement. Among the hydrogen bonding groups, the urea unit was particularly favoured because of its double hydrogen bond donor capacity. Choice of cystine unit was based on the consideration that apart from being a neutral amino acid, the presence of S–S linkage in its framework and its 1,ω-diamine nature would facilitate the ring closure to cyclicureas.

For the construction of homocyclic oligomers of cystine ureas, the synthetic strategy envisaged one-step condensation of L-cystine diOMe with triphosgene, a commercially available precursor of phosgene (Scheme 1). The reaction carried out under high dilution conditions afforded a mixture of two products with similar TLC behaviour, which were separated by chromatography on silica gel with dichloromethane–methanol (98 : 2) as eluent. The products **1** and **2** were isolated in yields of 37 and 15% respectively, and were fully characterized by spectroscopic and analytical data.[6] The ES-MS and FAB-MS results (ESI†) confirmed the cyclic trimeric and tetrameric nature of macrocycles **1** and **2** respectively. A noteworthy feature in the cyclization reaction of cystine dimethyl ester with triphosgene was the formation of 27-membered 3 + 3 macrocycle **1** as the major product (37%), followed by 15% of the 36-membered higher oligomer **2**, the 4 + 4 cyclization product. The near complete absence of 9- and 18-membered macrocycles that could arise from 1 + 1 and 2 + 2 cyclization reaction is in agreement with our earlier observations[7] with cystine-containing macrocycles where the most preferred ring size in cyclooligomerization was found to be 26-membered. Our recent finding[8] that 18-membered cyclic bisurea was the only product in the cyclooligomerization reaction of cystamine with triphosgene also supports the notion that the asymmetric cystine unit has more stringent steric demands with respect to the ring size.

The highly symmetrical structure of macrocycles **1** and **2** laced with multiple units of hydrogen-bonding urea functions, positioned equidistant from each other and all converging towards the centre of the cavity, appeared particularly suited for the molecular recognition of anionic substrates with spherical shapes. We also expected these receptors to bind polyoxyanions



Scheme 1 One step condensation of triphosgene and cystine dimethyl ester to give cyclic oligoureas **1** and **2**.

† Electronic supplementary information (ESI) available: ^{1}H NMR of **1** (Fig. S1), **2** (Fig. S2); ROESY NMR of **1** (Fig. S3), **2** (Fig. S4); ES-MS of **1** (Fig. S5), **2** (Fig. S6), FAB-MS of **1** (Fig. S7); NMR titration of **2** with squarate TBA salt (Fig. S8); ^{1}H NMR of **1** in $CDCl_3$ (host alone) (Fig. S9), **1** with Cl^- in 1 : 1 molar ratio (Fig. S10), **1** with Br^- in 1 : 1 molar ratio (Fig. S11), **1** with NO_3^- in 1 : 1 molar ratio (Fig. S12), **2** in $CDCl_3$ (host alone) (Fig. S13), **2** with squarate dianion in 1 : 1 molar ratio (Fig. S14).  DOI: 10.1039/b102720b

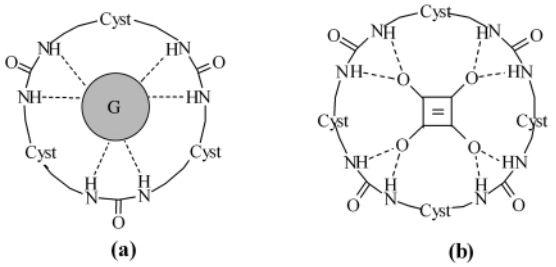

Fig. 1 (a) Proposed hexahydrogen-bonded complex of **1** with Cl^-/Br^- or nitrate anion; G = $Cl^-/Br^-/NO_3^-$; Cyst = L-cystine unit. (b) Proposed octahydrogen-bonded complex of **2** with squarate dianion.

provided their electronic and geometric features are compatible with each other.

Binding studies with halide anions (as tetrabutylammonium (TBA) salts) using ^{1}H NMR, showed that while cyclic triurea **1** showed modest affinity for chloride and bromide ions and no affinity for iodide ion, the macrocyclic tetraurea **2** was unable to bind any of the halide anions. Interestingly, the host **1**, only sparingly soluble in $CDCl_3$, was found to rapidly go into solution upon the addition of chloride or bromide TBA salt, indicating effective host–guest recognition. There was considerable downfield shift ($\sim$0.5–0.8 ppm) of NH protons in **1** suggesting their involvement in hydrogen bonding with the anion. Using NMR titration method,[9] the association constants (K_a) for **1** with chloride and bromide TBA salts were measured as 2.05×10^3 and 2.01×10^2 M^{-1} respectively. The triurea **1** with three-fold symmetry in its structure also suggested a possible complexation with trigonal anionic guests. Thus, while trimesic acid anion was found to be too big for the cavity of **1** to show any detectable NH shift, the trigonal planar geometry of nitrate anion seemed to have a complementary fit with **1** showing appreciable binding in $CDCl_3$ ($K_a = 5.2 \times 10^2$ M^{-1}). In conformity with the above notion, the cyclic tetraurea **2** was demonstrated to act as an excellent host for the squarate dianion $[SQ]^{2-}$, a truly delocalized planar tetraoxyanion[10] with four-fold symmetry. Using NMR titration, the association constant for **2** with squarate TBA salt in $CDCl_3$ was measured as 3.21×10^3 M^{-1}. The significant downfield shift ($\Delta\delta \sim 1.5$) observed for the urea NH protons of **2** is indicative of highly effective hydrogen bonding. The almost 100-fold selectivity of macrocyclic triurea **1** for planar, 3-fold symmetric nitrate anion and of cyclic tetraurea **2** for planar four-fold symmetric squarate tetraoxyanion guest was shown by complete absence of any anion induced shifts in the ^{1}H NMR of **1** and **2** in $CDCl_3$ even with excess molar proportions of the guest substrates. The proposed tris-bidentate or hexahydrogen-bonded structure for complex of **1** with Cl^-/Br^- or NO_3^- [Fig. 1(a)] and octahydrogen-bonded structure for the complex of **2** with $[SQ]^{2-}$ [Fig. 1(b)] is supported by the maximum NH shift at a mole ratio of 1:1 (ESI†).

The cystine-based macrocyclic oligoureas described here represent a new class of electroneutral anion receptors that operate exclusively through hydrogen bonds. The multiple hydrogen-bonding sites distributed symmetrically all over the ring make these macrocycles especially suited for molecular recognition of spherical and polyfunctional anions. Their remarkable affinity for planar polyoxyanions and selectivity according to size complementarity combined with extremely simple synthesis from commercially available materials should open up new challenges in this area. Additionally, the receptor modification through the COOH handles on the cystine unit should provide attractive hosts for membrane anion transport. Studies in this direction are in progress.

We thank Professor S. Ranganathan for valuable discussions. Financial support from DST, New Delhi is gratefully acknowledged. D. R. is also an honorary faculty member of Jawaharlal Nehru Centre for Advanced Scientific Research.

Cambridge Centre for Molecular Recognition, University Chemical Laboratories, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: dhw1@cam.ac.uk; Fax: +44 1223 336913; Tel: +44 1223 336368

Received (in Cambridge, UK) 24th April 2001, Accepted 29th May 2001
First published as an Advance Article on the web 20th June 2001

The biosynthetic pathway to the L-di-*meta*-hydroxyphenylglycine (DHPG) constituent of chloroeremomycin (A82846B), has been investigated by a combination of feeding experiments with ^{13}C-labelled substrates, and expression and assay of HpgT from the chloroeremomycin biosynthetic cluster.

The rising incidence of resistance to vancomycin and teicoplanin[1,2]—currently the antibiotics of last resort for treating many nosocomial infections—necessitates the development of new therapeutic agents. An understanding of the mode of action of vancomycin group antibiotics[3] and the emerging resistance mechanisms[4,5] should facilitate rational design of new antibiotics capable of defeating vancomycin resistant bacteria. Some of our recent research on the vancomycin group of antibiotics has focussed on the biosynthesis of chloroeremomycin **1** (Fig. 1), also known as A82846B and LY264826, which differs from vancomycin in only its appended sugars. A gene cluster from *Amycolatopsis orientalis* A82846 for the biosynthesis of **1** has been sequenced.[6] Protein homologies have suggested roles for many of the putative enzymes encoded therein, and a number of these roles have now been confirmed experimentally.[7–11]

The heptapeptide core of chloroeremomycin contains several unusual amino acids, including four residues with D-stereochemistry at the alpha carbon, and five with non-proteinogenic side chains. Here we report two intermediates and the role of one enzyme, HpgT (*p*-hydroxyphenylglycine transaminase), in the biosynthetic pathway (Scheme 1) leading to L-di-*meta*-hydroxyphenylglycine (L-DHPG) **2**, found as the *C*-terminal residue of **1**. DHPG has previously been shown to be derived from four units of acetate,[12] but the subsequent biosynthetic steps have hitherto been uncertain.

We synthesised two possible precursors to DHPG, di-*meta*-hydroxyphenylacetic acid **3** and (±)-di-*meta*-hydroxymandelic acid **4** (Scheme 1), with ^{13}C-labelled carboxylate groups. These were characterized by NMR and mass spectroscopy; [1-^{13}C]-**3** δ_H (500 MHz, D_2O) 3.44 (2H, d, J^{13}_{CH} = 12 Hz), 6.21 (1H, s), 6.30 (2H, s): δ_C (100 MHz, D_2O, proton decoupled) 41.40 (d, $J^{13}_C{}^{13}_C$ = 54.2), 102.37, 109.56, 137.98, 157.88, 177.48 (^{13}C enriched): *m*/*z* (EI+) [M$^{+\cdot}$] = 169.0454, calculated for $^{12}C_7{}^{13}C_1{}^1H_8{}^{16}O_4$ = 169.0456; [1-^{13}C]-**4** δ_H (500 MHz, DMSO-d_6) 4.74 (1H, d, J^{13}_{CH} = 4.6 Hz), 6.02 (1H, br), 6.23 (2H, br), 9.13 (br): δ_C (125 MHz, DMSO-d_6, proton decoupled) 72.51 (d, $J^{13}_C{}^{13}_C$ = 58 Hz), 101.73, 104.84, 142.25, 158.17, 174.06 (^{13}C enriched): *m*/*z* (EI+) [M$^{+\cdot}$] = 185.0414, calculated for $^{12}C_7{}^{13}C_1{}^1H_8{}^{16}O_5$ = 185.0405. (Details of the syntheses will be published separately.) If incorporated by the producing strain, both should lead to isotopic enrichment at the carbonyl group of L-DHPG. To investigate the uptake of labelled substrates by *A. orientalis* A82846.2 (NRRL 18100), the strain was inoculated into CSM[13] (50 ml) and incubated at 30 °C/250 rpm for 3 days. A 2.5 ml aliquot of this culture was inoculated into FermB medium (50 ml) and incubated at 30 °C/250 rpm for 110 h. Labelled substrates were fed aseptically, in 4 × 5 mg portions, at either 36, 40, 44 and 48 h (for **3**) or 34, 38, 42 and 44 h (for **4**) after inoculation. Cells were removed by centrifugation, and the antibiotics purified from the filtered supernatant by affinity chromatography on sepharose-D-Ala-D-Ala (prepared from Activated CH-Sepharose 4B), desalted by reverse-phase HPLC and lyophilised. Typically, 5–10 mg of purified antibiotic was recovered. The ^{13}C NMR spectra of isolated chloroeremomycin showed enrichment of a peak at 172.1 ppm. The corresponding HMBC spectra, for **1** produced both from **3** and from **4**, showed a cross-peak to a proton at 4.42 ppm, identified as the C_α proton of DHPG, x_7 (see Fig. 1), confirming the identity of the enriched carbon as CX_7. No other cross peaks due to **1** were observed in these spectra. All spectra were run in DMSO-d_6 as **1** does not dimerise in DMSO, thus simplifying the spectra considerably. The natural abundance ^{13}C resonances were too weak to be seen in any of the spectra. Thus **3** and **4** are incorporated in the biosynthesis of DHPG.

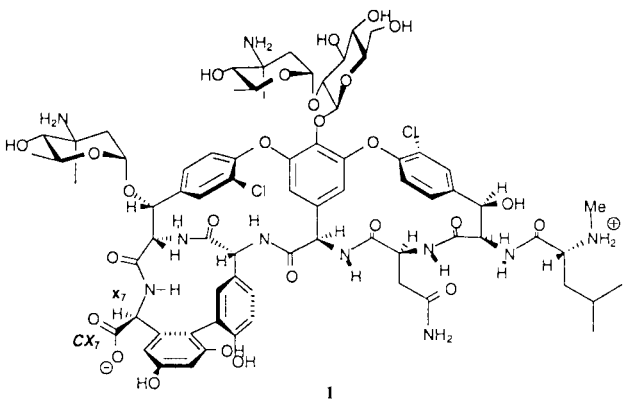

Fig. 1 The structure of chloroeremomycin **1**, showing the carbonyl position of DHPG, CX_7, and the adjacent C_α proton, x_7.

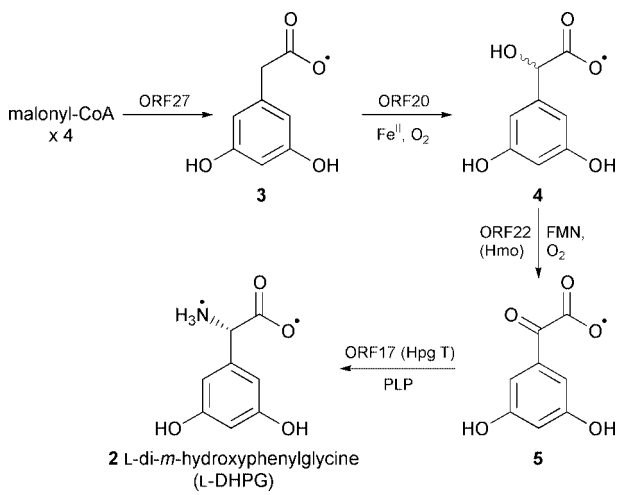

Scheme 1 Proposed biosynthetic pathway to L-DHPG.

 DOI: 10.1039/b103668h

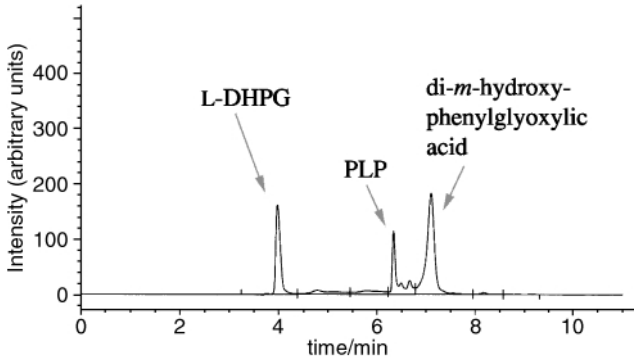

Fig. 2 HPLC trace (monitored at 254 nm) showing the HpgT-catalysed formation of di-*meta*-hydroxyphenylglyoxylic acid **5** from L-DHPG **2**.

To investigate the role of HpgT in the formation of DHPG, *hpgT* from the chloroeremomycin gene cluster was PCR amplified and cloned into the expression vector pET28a(+) (Novagen) as an *N*-terminal His_6-tagged protein. The resulting recombinant plasmid was used to transform the expression host *E. coli* BL21(DE3) (Novagen), and the cells grown for 16 h at 16 °C in 2 × YT medium, following induction by isopropyl β-D-thiogalactoside (IPTG, 1 mM). HpgT was purified using Novagen His-Bind Quick 900 cartridges, and then transferred to Tris-HCl (50 mM, pH 7.5) using Millipore™ centrifugal filters. The purified protein was visualised as a single band by SDS-PAGE, and the relative molecular mass determined by electrospray ionisation (ESI) mass spectrometry to be 49.80 kDa (predicted = 49.808 kDa).

The HpgT catalysed interconversion of **5** (Scheme 1) and L-DHPG was assayed as follows: HpgT (100 μg) was incubated with L-DHPG (1 mM), α-ketoglutarate (2 mM) and pyridoxal phosphate (PLP, 100 μM) in Tris-HCl (300 μl) for 1 h at 30 °C, after which time HPLC analysis showed a new, strongly absorbing peak (Fig. 2). ESI mass spectrometric analysis identified this peak as di-*meta*-hydroxyphenylglyoxylic acid ($[M + H]^+$ = 183.0, calculated for $C_8H_7O_5^+$ = 183.14). These results indicate that, in addition to its previously documented role in *p*-hydroxyphenylglycine biosynthesis,[11] HpgT is responsible for the transamination from **5** to L-DHPG, **2**.

Since another enzyme from the cluster, Hmo, has been shown to oxidise **4** to **5**,[14] the results given here identify the biosynthetic steps and intermediates from di-*meta*-hydroxyphenylacetate to L-DHPG in *A. orientalis* (Scheme 1) except the required benzylic hydroxylation (**3** to **4**). We have shown that ORF27 (a chalcone synthase homologue) produces di-*meta*-hydroxyphenylacetate from malonyl-CoA[15] and propose ORF20 (which shows homology to the P450 family of heme-binding proteins) from the chloroeremomycin biosynthetic cluster as a candidate for the benzylic hydroxylation; experiments are underway to investigate these proposals.

We thank the BBSRC (A. M. S., W. S.), the EPSRC (P. N. K., E. H. C.) and Eli Lilly (S. W. O'B.) for funding. P. Solenberg (Eli Lilly, Indianapolis) is thanked for donating *A. orientalis* A82846.2 and for advice on optimal conditions for antibiotic production. L-DHPG was kindly donated by Professor D. Evans (Harvard University).

Faculty of Chemistry, University of Wroclaw, 14 F. Joliot-Curie Str., 50-383 Wroclaw, Poland. E-mail: drab@wchuwr.chem.uni.wroc.pl

Received (in Cambridge, UK) 28th February 2001, Accepted 30th May 2001
First published as an Advance Article on the web 20th June 2001

The symmetry changes and length of the symmetry independent part of $[Cu(amtrz)_3]_n^{2+}$ (amtrz = 4-amino-1,2,4-triazole) polymeric chains driven by different anions in crystals with BF_4^- (1), BF_4^-/SiF_6^{2-} (2) and SiF_6^{2-} (3) have been studied by single crystal X-ray method.

A variety of coordination compounds with *N*4-substituted 1,2,4-triazoles as a ligand coordinating to first-row transition metal ions have been reported.[1] The interesting magnetic properties of iron(II) and copper(II) compounds with 1,2,4-triazole ligands have been extensively investigated and polynuclear iron(II) 1,2,4-triazole compounds have been found to show spin-crossover behaviour.[2] These ground electronic state related properties depend strongly both on the nature of *N*4-substituent of the ligand[3,4] and non-coordinating anion molecule.[5–7] So far no single crystals suitable for X-ray diffraction were obtained for these iron(II) complexes, however structural information deduced from EXAFS (X-ray absorption fine structure) spectroscopy at the iron K edge indicates the presence of linear chains. On the other hand more detailed analysis of these results leads to ambiguous conclusions. For example, the dependence between the Fe–N bond distances and the size of anions suggested by Erenburg *et al*.[7] were not confirmed by Kojima *et al*.[6] It has been assumed that the copper(II) polymers are isostructural with their iron(II) analogues. Crystallographic studies of copper(II) polymeric chains in different anion environments might reveal the nature of cation–anion interactions. However, only two structures of $[Cu(4\text{-R-trz})_3]A_2$ type crystals have been presented (both with $A = ClO_4^-$ anions).[8,9] The number of data is limited because single crystals of 1-D polymeric metal(II) 1,2,4-triazoles are generally difficult to obtain due to rapid precipitation of the compounds formed.[4]

Because knowledge of the spatial structure of these polymers seems to be necessary to understand the nature of anion–cation interactions we looked for a useful procedure for growing single crystals of copper(II) analogues. Reaction between amtrz in hot MeCN (0.1 mmol in 10 mL) and an aqueous solution of an appropriate copper salt (0.03 mmol, 2 mL) gave a blue amorphous precipitate. The precipitate was filtered off, washed with 5 mL of MeCN and *immediately*[10] dissolved (at least partially) in water giving a light blue solution. After a few weeks $\{[Cu(amtrz)_3](BF_4)_2\cdot H_2O$ **1** and $[Cu(amtrz)_3](BF_4)(SiF_6)_{0.5}\cdot 2H_2O$ **2**$\}$ or days $\{[Cu(amtrz)_3](SiF_6)\cdot 8/3H_2O$ **3**$\}$ well shaped crystals appeared. To obtain **1** the reaction must be carried on in a polyethylene vessel because when glassware is used the mixed anion salt **2** is obtained. It is of note that the synthesis of **2** is reproducible when Pyrex glassware is used. On the other hand, decomposition due to loss of non-coordinated water molecules is observed for compound **3.**† The molecular structures of **1**–**3** were elucidated by X-ray crystallography.‡

The crystals under investigation are composed of linear coordination polymers $[Cu(amtrz)_3]_\infty$ with BF_4 (**1**), BF_4/SiF_6 (**2**) and SiF_6 (**3**) counter ions placed between them as well as different number of water molecules (1, 2 and 8/3, respectively). The μ-N^1,N^2-1,2,4-triazoles act as bidentate ligands bridging copper(II) ions *via* their nitrogen atoms (Fig. 1). The Cu–Cu distances are 3.922 Å in **1**, 3.877 and 3.886 Å in **2**, and 3.855, 3.886 and 3.904 Å in **3**. These values suggest a lack of relation between metal–metal distances and size of counter ion in the crystals. Such a relation was previously postulated for iron(II) triazole complexes on the basis of EXAFS studies.[6]

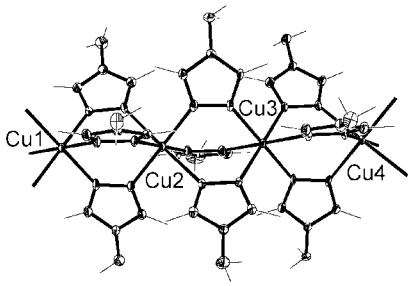

Fig. 1 View of the 1-D coordination polymer in **3**. The anions and water solvate molecules have been omitted for clarity.

In **1**–**3** all copper(II) ions have a distorted (4 + 2), axially elongated octahedral environment (Fig. 2). There are two distinguishable orientations of octahedra along the polymeric chain resulting in alternate *ababa*… order, whereas less regular *abcbab*… order is found for [Cu(4-hydroxyethyl-1,2,4-triazole)$_3$]$(ClO_4)_2\cdot 3H_2O$.[8] In contrast to **1**–**3**, the latter pattern results from intramolecular hydrogen bonds between neighbouring ligands. The above illustrates very well the distribution of elongation of Cu–N bonds due to the Jahn–Teller effect but this distribution is independent of the size of the counter ions in the crystals. In investigating relations between architectures of the chains and size or charge of counter anions we, however, have found a different interesting phenomenon, neither observed nor even postulated for metal–triazole 1-D polymeric complexes.

The *ababa*... order in **1**–**3** does not reflect the distribution of local symmetry of copper(II) ions. In the present structures copper atoms in the crystals occupy inversion centres ($\bar{1}$) or both

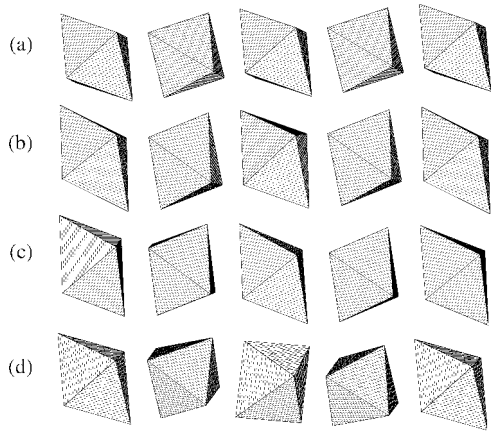

Fig. 2 The orientation of CuN_6 coordination octahedra in polymers of **1** (a), **2** (b) and **3** (c). (d) Shows the orientation detected by Garcia *et al.* for [Cu(4-hydroxyethyl-1,2,4-triazole)$_3$]$(ClO_4)_2\cdot 3H_2O$.[8]

 DOI: 10.1039/b101936h

inversion centres and general (1) positions. In **1** all copper atoms are located at inversion centres and the sequence of point symmetries in the chain is $\bar{1},\bar{1},\bar{1},\bar{1}$, *etc.* whereas in **2** consecutive copper(II) ions form the sequence $\bar{1},1,\bar{1},1,\bar{1}$, *etc.*, and in **3** the observed sequence can be described as $\bar{1},1,1,\bar{1},1,1,\bar{1}$, *etc.* Moreover, the symmetry independent parts of the chains have different lengths. The shortest unit, {Cu(amtrz)$_3$Cu}, is observed with BF_4 ions in crystals of **1**, the longest one, {Cu(amtrz)$_3$Cu(amtrz)$_3$Cu(amtrz)$_3$Cu} with SiF_6 ions for **3**, whereas for the anionic BF_4/SiF_6 mixed salt **2**, an intermediate {Cu(amtrz)$_3$Cu(amtrz)$_3$Cu} unit was observed. The different size of non-coordinated anions should also be reflected in the packing of the crystals. Analysis of crystal packing in **1**–**3** showed that counter ions link polymeric chains *via* N–H···F hydrogen bonds and determine the distances between them. Each polymeric chain is surrounded by four chains in **1** and by six chains in **2** and **3**. Perpendicular distances between neighbouring chains are 10.4 and 10.6 Å in **1**, 10.3, 11.3 and 13.3 Å in **2**, and 10.5, 11.4 and 12.3 Å in **3**. The data calculated for mixed anion crystal **2** clearly show that not only do the larger counter ions determine the distances but that the distances are dependent also on the spatial distribution of all anions and water molecules around the rigid polymeric chains and on the parallel displacement of the chains. Detailed analysis of this distribution shows that the symmetry of polymeric chain is dependent on type of counter ions, though this dependence is very complicated. This relation is a function of several factors, namely number of water molecules, charge of counter ions, hydrogen bond systems *etc*. which directly influence the crystal packing as well as the structure of the polymeric chain.

In summary, we conclude that the symmetry and length of independent units of $[Cu(amtrz)_3]_n^{2+}$ polymeric chains is dependent on the type of counter ions present in the crystals. In view of published results of EXAFS studies on similarities between structures of copper(II) and iron(II) complexes with 1,2,4-triazoles[8] the counter ion dependent symmetry of polymeric chains in the latter seems to be a crucial factor in spin-crossover phenomena.

A novel methodology towards deep desulfurization of light oil effected by sulfimides formation

Yasuhiro Shiraishi, Tomoko Naito, Takayuki Hirai* and Isao Komasawa

Department of Chemical Science and Engineering, Graduate School of Engineering Science, and Research Center for Solar Energy Chemistry, Osaka University, Toyonaka 560-8531, Japan. E-mail: hirai@cheng.es.osaka-u.ac.jp

Received (in Cambridge, UK) 4th April 2001, Accepted 23rd May 2001
First published as an Advance Article on the web 20th June 2001

A novel desulfurization process for light oil, based on *N*-tosylsulfimide formation by the reaction of sulfur compounds with chloramine T (sodium *N*-chlorotoluene-*p*-sulfonamide), has enabled deep desulfurization at ambient temperature.

Much attention has been focused on the deep desulfurization of light oil, since the sulfur oxy-acids (SOx) contained in diesel exhaust gas cause air pollution and acid rain. The sulfur level in diesel fuels is limited presently to 0.05 wt%, both in Japan and Europe. The current technology of hydrodesulfurization (HDS) can desulfurize aliphatic and acyclic sulfur-containing compounds quite adequately, when adopted on the industrial scale. The above process however is limited, when treating dibenzothiophene (DBT), especially DBTs having alkyl substituents on their 4 and/or 6-position.[1] Thus, the production of light oil, of very low level sulfur, inevitably requires severe high energy conditions and specially active catalysts. In the development of any alternative energy-efficient desulfurization process, a radical approach, which is not limited to conventional HDS technology, is required.

Various kinds of sulfur-containing compounds have been reported to react with chloramine T, in hydrogen-donating solvents such as alcohol and water, to give rise at ambient temperature to crystalline powders of the corresponding *N*-tosylsulfimides.[2–5] These sulfimides are highly polarized and are insoluble in nonpolar hydrocarbon solvents. Thus, such a synthetic method, if applied to the desulfurization of nonpolar light oil, might thus be able to remove the DBTs specifically from the light oil under moderate conditions.

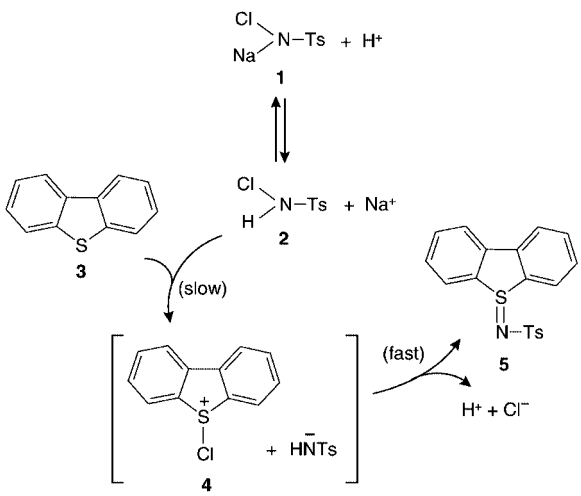
In order to test the feasibility of this idea, a *n*-tetradecane solution (50 ml) containing DBT (11 mmol l^{-1}), corresponding to a sulfur content of 0.05 wt%, was used as a model light oil. An alcohol solution (10 ml), to which a required amount of chloramine T trihydrate was dissolved, was then added to the above tetradecane solution at 323 K. In this procedure, the removal efficiency for DBT from tetradecane, following 3 h of reaction, was however only 5%, as shown in Table 1 (entry 1). As reported[6] and shown in Scheme 1, the sulfimide **5** is formed *via* the chlorination of the sulfur atom for **3** by the free-state chloramine T **2**, produced by the hydrolysis of **1**. The rate of the chlorination is therefore accelerated with decreasing pH of the solution, owing to the acceleration of the hydrolysis of **1**. The desulfurization of DBT, when a small amount of AcOH was added into the reaction mixture, was accelerated significantly (entry 2). The addition of the AcOH improves the desulfurization when used with MeOH, but is ineffective when used with the other solvents such as EtOH and *i*-PrOH (entries 3 and 4). This is because the hydrogen-donation ability of the latter two solvents is lower than that of MeOH. The desulfurization of DBT was also accelerated with increasing the concentrations of chloramine T and AcOH (entries 5–7). Both MeOH and chloramine T are insoluble in the nonpolar tetradecane, such that the resulting tetradecane is recovered easily using a separation funnel. When an equal volume of water to that of MeOH was added into the resulting MeOH solution, the *N*-tosylsulfimide of the DBT precipitated on the bottom of the flask, thus suggesting that the sulfimide formed is removed successively into the MeOH solution during the reaction.

Table 1 Desulfurization yield of DBT from tetradecane following the reaction with chloramine T under differing conditions[a]

Entry	Alcohol	AcOH/ml	Chloramine T/mmol	Desulfurization (%)
1	MeOH	–	1.1	5.0
2	MeOH	1	1.1	70.6
3	EtOH	1	1.1	1.5
4	*i*-PrOH	1	1.1	6.7
5	MeOH	1	5.5	98.5
6	MeOH	1	2.75	95.2
7	MeOH	2	1.1	> 99.9

[a] Temperature: 323 K, time: 3 h, tetradecane volume: 50 ml, alcohol volume: 10 ml, initial DBT content in tetradecane: 11 mmol l^{-1} (0.55 mmol).

The above procedure was then tested for the desulfurization of methyl-substituted DBTs, which are key compounds in the HDS technology.[1] In the present process, as shown in Fig. 1, the desulfurization rates for 4-methyl- and 4,6-dimethyl-DBT from tetradecane were higher than that of nonsubstituted DBT. This tendency differs completely from that obtained by the HDS method.[1] As shown in Scheme 1, the rate-determining step for the present reaction is the chlorination of the nucleophilic sulfur atom for the DBT **3** by **2**. Semiempirical MO calculation[7] showed that the electron density on the sulfur atom for DBTs lies in the order 4,6-dimethyl (5.7597) > 4-methyl (5.7586) > DBT (5.7577), which agrees well with the actual desulfurization reactivity (Fig. 1). The result suggests that the rate of the chlorination depends on the electron density (nucleophilicity) on the sulfur atom for DBTs, and as a result, methyl-substituted



Scheme 1 Formation of DBT sulfimide by chloramine T.

 DOI: 10.1039/b103061m

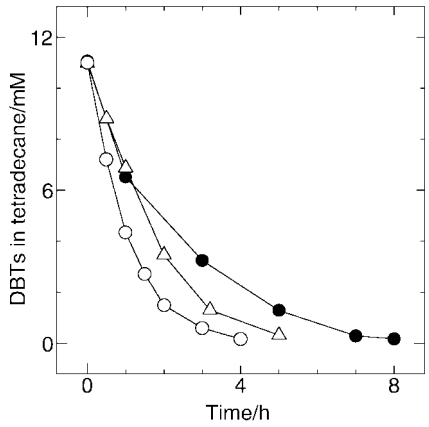


Fig. 1 Time-course variation in the concentration of (●) DBT, (△) 4-methyl-DBT and (○) 4,6-dimethyl-DBT in tetradecane. Temperature: 323 K, tetradecane volume: 50 ml, MeOH volume: 10 ml, AcOH volume: 1 ml, initial DBTs content in tetradecane: 11 mmol l^{-1} (0.55 mmol).

DBTs, having high electron density are desulfurized more easily than the nonsubstituted DBT.

The above process was then applied to the desulfurization of actual light oil containing *ca.* 0.19 wt% sulfur (2.47 mmol), which is just below the previous regulatory value that used to apply in Japan (0.2 wt%). The MeOH solution (50 ml) containing various amount of chloramine T was then added to the light oil (50 ml) in the presence of 2 ml AcOH, and was stirred at 323 K. Upon addition of water to the resulting MeOH solution, a yellow–white solid precipitate adhered to the bottom of the flask. As shown in Fig. 2b, the IR spectrum for the precipitate demonstrated two intense absorption bands at 1180 and 1300 cm^{-1} owing to the sulfonyl group and also a small band at 980 cm^{-1} owing to the S–N bond for the sulfimides. The spectrum is similar to that for *N*-tosylsulfimide of DBT (Fig. 2a), thus indicating that the sulfimides, formed during the reaction, are removed successfully from the light oil into the MeOH solution. As shown in Table 2, the sulfur content of the light oil decreased with increasing the chloramine T concentration. However, the deep desulfurization (0.05 wt%) was hardly achieved, even in the presence of 10-fold molar excess of chloramine T based on the initial sulfur concentration of the feed light oil (entry 3). The desulfurization yields obtained are significantly smaller than those expected from the data for the model light oil, as shown in Fig. 1.

The actual light oil contains a large amount of DBTs, with several types of hydrophobic alkyl substituents on the molecule,

(○) S–N bond, (●) sulfonyl group, (□) aliphatic hydrogen (C–H) and (△) aromatic hydrogen (C–H).

Table 2 Variations in the sulfur content of light oil following (a) reaction with chloramine T and (b) subsequent addition of adsorbents[a]

	(a)		(b)	
Entry	Chloramine T/mmol	Sulfur content/wt%	Adsorbent/g ml^{-1}-oil	Sulfur content/wt%
1	4.65	0.099	—	—
2	11.6	0.079	0.2 (Al_2O_3)	0.054
			0.2 (SiO_2)	0.050
			0.3 (SiO_2)	0.048
3	23.3	0.066	—	—

[a] Temperature: 323 K, time: 10 h, light oil volume: 50 ml, MeOH volume: 50 ml, AcOH volume: 2 mL, initial sulfur content of light oil: 0.190 wt% (2.47 mmol).

and the polarity of the DBTs is decreased with increasing the carbon number of the substituents.[8] The low desulfurization efficiency of the light oil is thus probably because the low polarity sulfimides of DBTs having large carbon number of substituents, formed by the reaction with chloramine T, are not removed into the MeOH solution but remain in the resulting light oil. Since the sulfimides have a higher polarity as compared to the other constituents of the light oil, they might be removed by the addition of solid adsorbents, such as aluminum oxide and silica gel. As shown in Table 2 (entry 2b), the sulfur concentration of light oil was actually decreased by the addition of the adsorbents, with the deep desulfurization (0.05 wt%) being achieved successfully. As shown in Fig. 2c, the adsorbed materials showed absorption bands owing to the sulfonyl group and the S–N bond for sulfimides as also found for the spectrum of the precipitate (Fig. 2b). The spectrum for the adsorbed material also showed a larger absorption band at 1620 cm^{-1}, owing to the alkyl group, as compared to that obtained for the precipitate, indicating that the sulfimides of the DBTs, having a large carbon number of alkyl substituents, are adsorbed successfully.

The present study describes a novel desulfurization process for light oil, based on the removal of *N*-tosylsulfimides produced by the reaction of sulfur compounds with chloramine T. The deep desulfurization was achieved successfully at ambient temperature. The refractory DBTs in the current HDS process are desulfurized easily by the present process, thus showing that the present process is both energy-saving and effective as a new deep desulfurization process for light oil. The sulfimides have been reported to have antimicrobial, diuretic and hypotensive properties on tumor growth and activity as antidepressants and stimulants of the central nervous system.[5] It may thus be interesting to use the recovered sulfimides from the desulfurization process, as novel materials for medicinal supplies.

Unexpected results of enyne metathesis using a ruthenium complex containing an *N*-heterocyclic carbene ligand

Tsuyoshi Kitamura, Yoshihiro Sato and Miwako Mori*

Graduate School of Pharmaceutical Sciences, Hokkaido University, Sapporo 060-0812, Japan

First published as an Advance Article on the web 20th June 2001

Metathesis of enyne having 1,1-substituted alkene, carried out with the new generation of a ruthenium carbene complex containing an *N*-heterocyclic carbene ligand, gave five- and six-membered cyclic compounds in high yield.

In recent synthetic organic chemistry, transition metals play an important role and enable bond cleavage of multiple bonds, such as a double bond or triple bond. A metathesis reaction[1] using a metal carbene complex is quite interesting because multiple bonds are cleaved and, at the same time, a multiple bond is formed. Enyne metathesis[2,3] is particularly attractive, since the double bond of enyne is cleaved and the alkylidene part of the alkene migrates to the alkyne carbon to give a cyclized compound. However, in this reaction, the substituents on the alkyne or the alkene are important. It has been shown that the reaction rate of an enyne having a terminal alkyne is slow because the generated diene moiety coordinates to the ruthenium carbene complex.[3*a*] On the other hand, the effect of the substituent on the alkene is also important. In the case of an enyne having a mono- or 1,2-disubstituted alkene, the metathesis reaction proceeded smoothly and the desired product was obtained.[3*a*]

However, when enyne **2b** (R^3 = Me) having 1,1-disubstituted alkene was treated in a similar manner, no cyclized product was obtained and the starting material was recovered (Scheme 1). This means that ruthenium carbene complex **i** formed by the reaction of the alkyne part of enyne and **1a**[4*a*] does not react intramolecularly with a 1,1-disubstituted alkene. Recently, a new generation of ruthenium carbene complexes containing *N*-heterocyclic carbene ligands was reported.[4*b*,*c*] The reactivity of these complexes is greater than that of **1a**, and the metathesis of an olefin having a 1,1-disubstituted alkene proceeded smoothly using **1b** or **1c** to give a cyclized product having tri- or tetra-substituted olefin. Thus, we decided to use the novel ruthenium carbene complex **1b** or **1c** for enyne metathesis.†

When a toluene solution of enyne **2c** was warmed in the presence of 5 mol% of **1b** at 80 °C for 5 h, two metathesis products, **3c** and **4c**, were obtained in 85% yields along with compound **5c** in 5% yield (Scheme 2). Compounds **3c** and **4c** were obtained as a mixture of two inseparable isomers, and they could be isolated by iterative chromatography on silica gel. Compound **3c** has a five-membered ring, which is usually formed by the reaction of enyne having a mono-substituted alkene and **1a**.[3*a*] On the other hand, the ^{1}H NMR spectrum of **4c** is similar to that of **3c**, and other spectral data such as ^{13}C NMR, HMQC, HMBC and mass spectra supported this structure. This compound should be produced by C–C bond formation between the disubstituted alkene carbon (C7) and the outside alkyne carbon (C2), and the methylene carbon of the alkene migrates to the inside alkyne carbon (C3).

Compound **5c** is formed by reductive elimination from ruthenacyclobutane **III** as shown in Scheme 2. When ruthenium carbene complex **1c** was used for this reaction, the same compounds **3c** and **4c** were each obtained in 32% yield, along with a small amount of **5c**. This indicates that the six-membered ring **4c** was formed from 1,6-ene-yne using ruthenium carbene complex **1b** or **1c**.

A possible reaction course is shown in Scheme 3. It is thought that there are two pathways in the reaction of the alkyne part of the enyne with the methylidene ruthenium carbene complex.[5] If the reaction proceeds through path A, ruthenium carbene complex **II** would be formed.

Intramolecular [2 + 2]cycloaddition affords **III**. Thus, a smaller ring-sized product is formed (five-membered ring). However, when ruthenium metal of the carbene complex bonds to the outside carbon of alkyne, ruthenacycle **IV** would be formed and would be converted into ruthenium carbene complex **V** by ring opening. Then the ruthenium carbene complex reacts intramolecularly with the alkene part to give ruthenacyclobutane **VI**, which affords a six-membered ring compound.[6]

Various enynes were treated with **1b** in a similar manner, and the results are shown in Table 1. In all cases, enyne metathesis

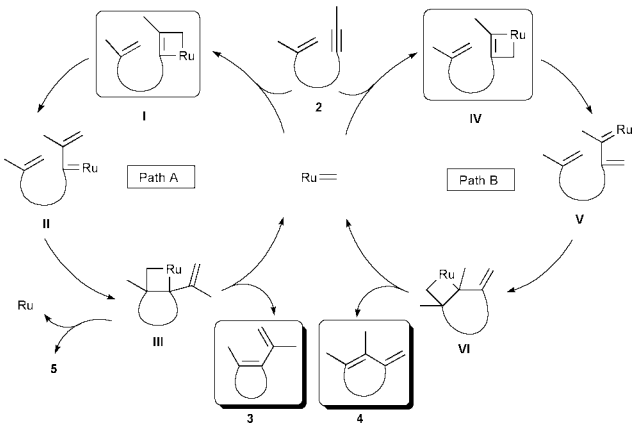
 DOI: 10.1039/b101453f



Scheme 3 Two possible reaction pathways for enyne metathesis.

products **3** and **4** were obtained as an inseparable mixture of two isomers. In some cases, we could isolate each pure compound after iterative of flash column chromatography on silica gel. In each case, a small amount of **5** was produced. Although all spectral data supported the structures of compounds **4**, the structure of a derivative of **4b** was further confirmed by X-ray crystallographic analysis.[7]

Table 1 Enyne metathesis using **1b**[a]

Run	Substrate	Conditions	Products, yield[b]	
1	 **2d**	80 °C 6 h E = CO_2Me	 **3d** 50%	 **4d** 39%
2	 **2e**	80 °C 15 h	 **3e** 47%	 **4e** 27%
3	 **2f**	80 °C 24 h	 **3f** 50%	 **4f** 42%
4	 **2b**	80 °C 6 h	 **3b** 34%	 **4b** 30%
5	 **2g**[c]	50 °C 3 h	 **3g** 41%	 **4g** 30%
6	 **2h**[c]	50 °C 24 h *Si* = TBDMS	 **3h** 29%	 **4h** 17%

[a] All reactions were carried out using **1b** (5 mol%) in toluene. [b] All yields were calculated from ^{1}H NMR spectra after isolation as a mixture of two isomers. [c] 10 mol% of **1b** was used.

Although the reason why the reaction of enyne **2a** with **1a** gave only **3a**,[3a] but enyne **2b** reacts with **1b** or **1c** gave **3b** and **4b** is not clear, the results are quite interesting.

Further studies of enyne metathesis using **1b** or **1c** are in progress.

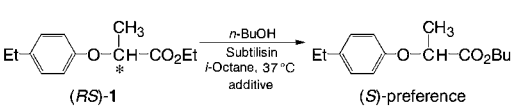
Received (in Cambridge, UK) 8th February 2001, Accepted 21st May 2001
First published as an Advance Article on the web 20th June 2001

For subtilisin-catalysed transesterification of the racemic esters in *i*-octane containing dimethyl sulfoxide as an additive, the relationship between the enantioselectivity and the conformational flexibility of subtilisin estimated from the ESR spectroscopic study provides the first experimental evidence that the enzyme has the optimum flexibility to produce the maximal enantioselectivity toward the given substrates.

The ability of enzymes to discriminate between enantiomers has been applied to the optical resolution of racemates in organic syntheses.[1] Among the strategies to improve the enzyme's enantioselectivity, organic chemists and enzymologists often employ various additives for enzyme-catalysed reactions in organic solvents,[2] because of their simplicity of use. Although the variation of the enzyme's flexibility caused by an additive, such as a small amount of water in organic solvents, is anticipated to control its enantioselectivity,[3] definite information is lacking as to the relationship between the enzyme's flexibility and its enantioselectivity for enzyme-catalysed reactions. According to research done so far, the only reported observation is that the effect on enantioselectivity by the variation of organic solvents is related to the enzyme's flexibility, estimated from time-resolved fluorescence anisotropic study.[4]

In this communication, for subtilisin-catalysed transesterification in *i*-octane, we wish to report the mechanism of enantioselectivity enhancement caused by addition of dimethyl sulfoxide on the basis of the relationship between the initial rates for each enantiomer of the substrates used here and the conformational flexibility of subtilisin estimated from ESR spectroscopic study. Furthermore, the relationship established reveals that the optimum conformational flexibility of subtilisin gives the maximal enantioselectivity.

For subtilisin-catalysed transesterification of ethyl (*R*)- or (*S*)-2-(4-ethylphenoxy)propionate **1** with *n*-butyl alcohol in *i*-octane, we investigated the behaviour of the initial rates for each enantiomer of **1** caused by addition of a small amount of various additives such as water or polar organic solvents (Scheme 1), because this method of enantioselectivity improvement by additives is the simplest one. In a typical subtilisin-catalysed transesterification, the substrate **1** (0.025 mmol) and *n*-butyl alcohol (0.15 mmol) were added to dry *i*-octane (2 ml) containing the additives (0–0.60 vol%), followed by ultrasonic dispersion, and then addition of subtilisin (10 mg).† The reaction mixture was shaken (170 strokes min^{-1}) at 37 °C.



(*RS*)-**1** (*S*)-preference

Scheme 1 Subtilisin-catalysed transesterification of ethyl 2-(4-ethylphenoxy)propionate **1** with *n*-butyl alcohol in *i*-octane.

The effects of the additives (0.45 vol%) on the initial rates as a measure of the enzymatic activity for subtilisin-catalysed transesterification of **1** in *i*-octane were investigated. When a small amount of DMSO (0.45 vol%) was added to the reaction medium, the initial rate for the correctly binding *S* enantiomer was found to be dramatically enhanced (V_S = 20 nmol h^{-1} mg^{-1}), as compared with those for the addition of other general additives such as water (V_S = 0.21 nmol h^{-1} mol^{-1}) or polar organic solvents (DMF, THF, acetone and acetonitrile), although the reaction for no additive conditions did not proceed at all. The effect of DMSO on the enantioselectivity enhancement was also observed for subtilisin-catalysed hydrolysis of **1** in aqueous buffer containing DMSO.[5]

In order to elucidate the optimum amount of added DMSO, the initial rates for each enantiomer of **1** for subtilisin-catalysed transesterification in *i*-octane were determined for a range of added DMSO (0–0.60 vol%). As is seen in Table 1, the initial rate for the correctly binding *S* enantiomer was dramatically enhanced by DMSO added to the reaction medium, as compared with that for the incorrectly binding *R* enantiomer. In particular, upon the addition of 0.45 vol% of DMSO, subtilisin displayed the largest initial rate for the *S* enantiomer, thus resulting in the maximal enantioselectivity (V_S/V_R = 9.6). A serious decrease in the enzymatic activity, however, was produced by addition of an excess amount of DMSO (0.60 vol%). This is probably because the increased flexibility of subtilisin caused by the excess addition of DMSO does not contribute to accommodating the substrate **1** into the subtilisin's binding site, thus leading to the decrease of the enzymatic activity accompanying the loss of the enantioselectivity. This assumption is also supported by the discussion below on the basis of the results obtained from the ESR spectroscopic study.

Furthermore, in order to investigate the DMSO effect on the other substrate, methyl mandelate **2** was submitted to the model reaction. For subtilisin-catalysed transesterification in *i*-octane, subtilisin preferentially catalysed the *R* enantiomer of **2**. The maximal enantioselectivity (V_R/V_S = 7.0) with an increase of

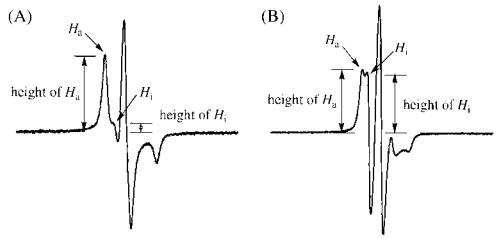

Fig. 1 Typical ESR spectrum of the spin-labeled subtilisin in *i*-octane; (A) no additive condition, (B) 0.45 vol% DMSO.

the enzymatic activity was produced by addition of 0.375 vol% of DMSO. Therefore, our approach using DMSO as the additive was found to be valid for the improvement of the enantioselectivity for subtilisin-catalysed reaction in an organic solvent, although there is the difference in the optimum amount of DMSO between **1** and **2** to obtain the maximal enantioselectivity.

The remarkable enhancement of the enantioselectivity observed is anticipated to be strongly affected by the change of the subtilisin's conformational flexibility caused by addition of DMSO. This view promoted us to investigate the relationship between the initial rates of each enantiomer of **1** and **2**, and the subtilisin's conformational flexibility estimated from ESR spectroscopy. The ESR measurement was carried out under the same conditions as that for the subtilisin-catalyzed transesterification of **1** and **2**, using a spin-labeled subtilisin with 1-oxy-2,2,6,6,-tetramethyl-4-piperidinyl ethoxyphosphorofluoridate prepared by the known method.[6] The spin-labeled subtilisin was indicated by MALDI-TOF MS, in which a fragment (27543) was found which almost corresponded to the sequence of subtilisin (27287) plus the weight of a spin-label (282) less the weight of F (19) and H (1). The spin-labeled subtilisin showed a decrease of enzymatic activity for our model reaction, due to the inhibition by the spin label attached to the active site serine. Fig. 1 shows a typical ESR spectrum, in which two parts of the spectrum are arbitrarily labeled H_a and H_i, respectively. The degree of the subtilisin's conformational flexibility can be monitored roughly by the change in the ratio of the peak height of H_i to $(H_a + H_i)$,[7] because each peak of H_a and H_i represents the anisotropy and the isotropy of the subtilisin's spin-label, respectively.[8] Thus, the increase of the $H_i/(H_a + H_i)$ value reflects that the subtilisin's conformation becomes more flexible. Fig. 2 shows the variation of the $H_i/(H_a + H_i)$ value estimated from the ESR spectra in *i*-octane as a function of the amount of DMSO, in which the increased amount of DMSO in *i*-octane is found to increase the conformational flexibility of subtilisin. In addition, under other additive conditions that give poor enantioselectivity and low enzymatic activity, the ESR signal showed the characteristics of a conformationally rigid enzyme ($H_i/(H_a + H_i)$ = 0.10–0.27).

The plots of the initial rates for each enantiomer of **1** for subtilisin-catalysed transesterification in *i*-octane containing a small amount of DMSO as a function of the $H_i/(H_a + H_i)$ value

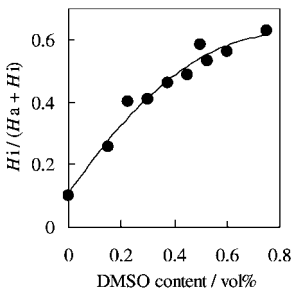

Fig. 2 The variation of the $H_i/(H_a + H_i)$ value estimated from the ESR spectra in *i*-octane as a function of the amount of DMSO.

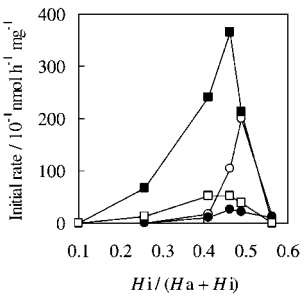

Fig. 3 The relationship between the $H_i/(H_a + H_i)$ value and the initial rates for subtilisin-catalysed transesterifications of **1** and **2** in *i*-octane, ●: **1**-(*R*), ○: **1**-(*S*), ■: **2**-(*R*), □: **2**-(*S*).

are depicted in Fig. 3. The initial rate for the correctly binding *S* enantiomer was significantly enhanced by an increase of the $H_i/(H_a + H_i)$ value. On the other hand, for the incorrectly binding *R* enantiomer, the initial rate is almost unchanged, in spite of the increase of the $H_i/(H_a + H_i)$ value. For subtilisin-catalysed transesterification, the variation of the subtilisin's conformational flexibility caused by addition of DMSO is found to be ascribed to the acceleration of the initial rate for the correctly binding *S* enantiomer, as compared with that for the incorrectly binding *R* enantiomer. Thus, the larger value of the ratio of the initial rates, arising from the marked difference in the flexibility effect on the initial rates for each enantiomer, is significantly responsible for the enhancement of the subtilisin's enantioselectivity.

A serious drop in the initial rates, however, was produced by a small increase of the $H_i/(H_a + H_i)$ value from the optimum flexibility to produce the largest initial rate (Fig. 3). This result is explained by assuming that the subtilisin's flexibility caused by the excess addition of DMSO does not induce the stable association between the substrate **1** and the subtilisin's binding site. Thus, subtilisin is found to display the optimum flexibility to produce the maximal enantioselectivity and the enzymatic activity toward the substrates used here. Furthermore, as is seen in Fig. 3, the change of the substrate from **1** to **2** shows the difference in the optimum flexibility to maximize the enantioselectivity [$(H_i/(H_a + H_i)$ for the largest V_S/V_R value of **1**] > [$H_i/(H_a + H_i)$ for the largest V_R/V_S of **2**], which suggests that the optimum conformational flexibility is responsible for the substrate's structure. Our first observation offers an important insight into the mechanism of the enantioselectivity enhancement for the enzyme-catalysed reactions under the various reaction conditions.

Notes and references

† Because the presence of water is important in the activity of enzymes in non-polar solvents, *i*-octane, *n*-butyl alcohol, and additives used here were dried over Molecular Sieves 4 Å. For our model reactions, however, the enzymatic activity was insensitive to the addition of water (0–0.9 vol%) into *i*-octane.

Received (in Cambridge, UK) 3rd May 2001, Accepted 25th May 2001
First published as an Advance Article on the web 20th June 2001

The catalytic hydroxylation of alkanes by an electron-deficient cobalt(III) porphyrin complex and *m*-chloroperbenzoic acid yielded alcohols as major products with a high k_H/k_D value, > 99% retention of stereochemistry, and a high regioselectivity; a high-valent cobalt–oxo porphyrin complex was suggested as a reactive hydroxylating intermediate.

Cytochrome P-450 enzymes are capable of catalyzing a variety of oxidation reactions, including the most energetically difficult hydroxylation of unactivated C–H bonds of alkanes.[1] Since selective oxygenations of hydrocarbons under mild conditions are of importance in both synthetic chemistry and industrial processes, biomimetic hydroxylation reactions with synthetic metalloporphyrins have been intensively studied over the past two decades.[2] It has been shown that metalloporphyrins containing iron, manganese, and ruthenium ions, especially with electron-deficient porphyrin ligands, are efficient catalysts for the hydroxylation of alkanes by various oxidants.[2,3] However, cobalt porphyrin complexes have been rarely used as catalysts in alkane hydroxylation reactions, since the reactions of cobalt complexes with hydroperoxides often proceed *via* free-radical type of oxidation reactions.[4] In the present study, we report for the first time that an electron-deficient cobalt(III) porphyrin complex catalyzes the hydroxylation of alkanes by *m*-chloroperbenzoic acid (*m*-CPBA) *via* a non-radical type of oxidation reaction.

† Electronic supplementary information (ESI) available: Fig. S1. See http://www.rsc.org/suppdata/cc/b1/b103986p/

The catalytic hydroxylation of alkanes by Co(TPFPP)(CF_3SO_3) [**1**, TPFPP = *meso*-tetrakis(pentafluorophenyl)porphinato dianion] and *m*-CPBA was carried in a solvent mixture of CH_3CN and CH_2Cl_2 at rt.‡ The results in Table 1 show that alcohols were yielded as major products with high alcohol to ketone ratios under mild reaction conditions, indicating that *m*-CPBA is a competent terminal oxidant for the alkane hydroxylations by the cobalt porphyrin complex.§¶‖ The kinetic isotope effect (KIE) for the cyclohexanol formation by **1** and *m*-CPBA was determined to be 8 ± 1 by carrying out intermolecular competitive hydroxylation with cyclohexane and cyclohexane-d_{12} (Table 1, entry 5).[5,6]

The stereochemistry of the alkane hydroxylations by **1** and *m*-CPBA was investigated with *cis*- and *trans*-1,2-dimethylcyclohexane. The alkane hydroxylations were highly stereospecific with > 99% retention; no formation of isomerized alcohol products (*e.g.* the formation of *trans*-1,2-dimethylcyclohexanol in the hydroxylation of *cis*-1,2-dimethylcyclohexane was observed (Table 1, entries 2 and 3). Interestingly, only small amounts of secondary alcohol products such as 2,3- and 3,4-dimethylcyclohexanol were formed in these reactions, and these results are different from those of the hydroxylations of *cis*- and *trans*-1,2-dimethylcyclohexane by iron complexes of porphyrin and non-porphyrin ligands.[6] In the latter reactions, moderate to high amounts of secondary alcohol products were yielded. In a competitive hydroxylation of *cis*- and *trans*-1,2-dimethylcyclohexane, the former was found to react 2.9 times faster than the latter (Table 1, entry 6). The alkane hydroxylation by **1** and *m*-CPBA was also found to be highly

Table 1 Hydroxylation of alkanes by **1** and *m*-CPBA[a]

Entry	Substrate	Products	Yields (%)[b,c]
A. Hydroxylation of alkanes			
1	Cyclohexane	Cyclohexanol	39 ± 4
		Cyclohexanone	8 ± 2
2	*cis*-1,2-Dimethylcyclohexane	*cis*-1,2-Dimethylcyclohexanol	65 ± 5
		trans-1,2-Dimethylcyclohexanol	< 1
		2,3- and 3,4-Dimethylcyclohexanol[d]	5 ± 1
3	*trans*-1,2-Dimethylcyclohexane	*cis*-1,2-Dimethylcyclohexanol	0
		trans-1,2-Dimethylcyclohexanol	43 ± 4
		2,3- and 3,4-Dimethylcyclohexanol[d]	8 ± 2
4	Adamantane[e]	Adamantan-1-ol	53 ± 3
		Adamantan-2-ol	9 ± 2
		Adamantan-2-one	> 1
B. Competitive hydroxylation of alkanes[f]

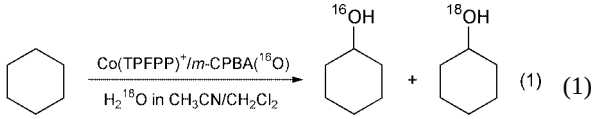
	+		
	Cyclohexane-d_{12}	Cyclohexanol-d_{12}	4 ± 1
6	*cis*-1,2-Dimethylcyclohexane	*cis*-1,2-Dimethylcyclohexanol	41 ± 3
	+		
	trans-1,2-Dimethylcyclohexane	*trans*-1,2-Dimethylcyclohexanol	14 ± 1

[a] See footnote ‡ for detailed reaction procedures. Since the hydroxylation reactions were not affected by molecular oxygen, all the reactions were performed in air. [b] All reactions were run at least triplicate, and the yields reported represent the average of these reactions. [c] Based on the amount of *m*-CPBA added. [d] The yield of 3,4-dimethylcyclohexanol was determined with commercially available 2,3-dimethylcyclohexanol, with an assumption that the response factors for these alcohols are identical. [e] Reaction was run with 0.2 mmol of adamantane in CH_2Cl_2 (0.5 mL) due to the low solubility of adamantane. [f] Equal amounts of competing substrates (1 mmol each) were used.

 DOI: 10.1039/b103986p

regioselective, in which a high degree of selectivity for tertiary C–H bond over secondary C–H bond was observed in the hydroxylation of adamantane (Table 1, entry 4). The ratio of 3°/2° oxygenated products was ~18 after statistical correction; such a high 3°/2° ratio was usually observed in iron and manganese porphyrin-catalyzed hydroxylation of adamantane.[7]

The results presented above demonstrate unambiguously that the alkane hydroxylations by **1** and *m*-CPBA occur *via radical-free* oxidation reactions:[6] (1) the fact that alcohols were the major products with high alcohol to ketone ratios and the ratios of alcohol to ketone products were not affected by the presence of O_2, (2) a high KIE value for the formation of cyclohexanol, and (3) a complete retention of stereochemistry in the hydroxylations of *cis*- and *trans*-alkanes. Then, what is the nature of a hydroxylating intermediate? Is a high-valent cobalt–oxo porphyrin complex involved as a reactive species? Since isotopically labeled water ($H_2{}^{18}O$) experiments are a useful mechanistic probe to test the involvement of high-valent metal oxo intermediates in metal-mediated oxygen atom transfer reactions,[8] the hydroxylation of cyclohexane by **1** and *m*-CPBA was conducted in the presence of a small amount of $H_2{}^{18}O$ [eqn. (1)].** As the results show in Table 2 (entries 1 and 2), some of



(1) (1)

the oxygen in the cyclohexanol product came from $H_2{}^{18}O$ and the percentage of ^{18}O in the alcohol product was dependent on the amount of $H_2{}^{18}O$ present in the reaction media. These results imply that a reactive hydroxylating intermediate generated in the reaction of **1** and *m*-CPBA exchanges its oxygen with labeled water prior to the oxygen atom transfer from the intermediate to cyclohexane.[8,9] For comparison, the ^{18}O-labeled water experiment was carried out with an iron porphyrin complex, Fe(TPFPP)(CF_3SO_3), under the identical reaction conditions, since we have shown previously that an oxoiron(IV) porphyrin cation radical complex was generated as a reactive hydroxylating intermediate in the hydroxylation of alkanes by Fe(TPFPP)(CF_3SO_3) and *m*-CPBA.[10] The degree of ^{18}O-incorporation in the Fe(TPFPP)(CF_3SO_3) reaction was about two times greater than that in the Co(TPFPP)(CF_3SO_3) reaction (Table 2, entries 3 and 4). Since the observation of ^{18}O-incorporation from $H_2{}^{18}O$ into oxygenated products is indirect evidence for the involvement of high-valent metal oxo intermediates in metal-catalyzed oxygenation reactions,[8–10] we suggest that a high-valent cobalt–oxo porphyrin complex participates as a reactive species in the cobalt porphyrin-catalyzed hydroxylation of alkanes by *m*-CPBA.

In conclusion, we have shown for the first time that an electron-deficient cobalt(III) porphyrin complex catalyzes the hydroxylation of alkanes by *m*-CPBA *via* a non-radical type of oxidation reactions. We suggest that a high-valent cobalt–oxo porphyrin complex is generated as a reactive hydroxylating intermediate in the reaction of the cobalt porphyrin complex and *m*-CPBA. Future studies will focus on attempts to understand the exact nature of the reactive intermediate.

Table 2 Percentages of ^{18}O incorporated from $H_2{}^{18}O$ into cyclohexanol product[a]

Entry	Catalyst	Amount (μL) of $H_2{}^{18}O$ present in reaction soln.	Cyclohexanol	
			^{18}O (%)	Yield (%)[b]
1	Co(TPFPP)(CF_3SO_3)	5	5 ± 1	18 ± 2
2		10	10 ± 1	17 ± 3
3	Fe(TPFPP)(CF_3SO_3)	5	11 ± 2	51 ± 4
4		10	18 ± 2	53 ± 4

[a] See footnote ** for detailed reaction procedures. All reactions were run at least triplicate, and the data reported represent the average of these reactions. [b] Based on the amount of *m*-CPBA added.

Notes and references

‡ Reaction conditions: *m*-CPBA (5×10^{-3} mmol, diluted in 20 μL of CH_3CN) was added to a reaction solution containing **1** (1×10^{-3} mmol) and substrate (1 mmol) in a solvent mixture (0.5 mL) of CH_3CN and CH_2Cl_2 (1:1) at rt. After the reaction mixture was stirred for 1 h, the reaction solution was directly analyzed by a Hewlett-Packard 5890 II Plus gas chromatograph with a FID detector and 30 m capillary column (Hewlett-Packard HP-1 or HP-5). Product yields were determined by comparison of peak area with that of decane or dodecane standard.

§ By following the time course of the hydroxylation of cyclohexane by **1** with 5 eq. of *m*-CPBA, we found that the alkane hydroxylation by **1** and *m*-CPBA takes place slowly, and the formation of cyclohexanol lasted for 1 h (data not shown).

¶ A control reaction carried out in the absence of the cobalt porphyrin catalyst did not show the formation of cyclohexanol and cyclohexanone products. Also, other cobalt porphyrin complexes such as Co(TMP)(CF_3SO_3) [TMP = *meso*-tetramesitylporphinato dianion] yielded only small amounts of cyclohexanol (~8%) and cyclohexanone (~2%). All cobalt(III) porphyrin complexes were obtained from Mid-Century and used without further purification.

‖ The catalytic activity of the cobalt porphyrin complex was examined by adding 50 eq. of *m*-CPBA (10 aliquots of 5 eq. of *m*-CPBA each at 1 h time intervals) into a reaction solution containing **1** (1×10^{-3} mmol) and *cis*-1,2-dimethylcyclohexane (1 mmol). Total reaction time was 10 h (see footnote ‡ for detailed experimental procedures). The yield of *cis*-1,2-dimethylcyclohexanol was 40% based on *m*-CPBA added, equivalent to 20 turnovers (see Fig. S1 for a plot of eq. of *m*-CPBA added *vs.* turnover number). By comparing UV-vis spectra of **1** taken before and after the reaction, we found that about 20% of the cobalt porphyrin catalyst was degraded.

** ^{18}O-labeled water experiments were performed under the identical reaction conditions described in footnote ‡ except that $H_2{}^{18}O$ (5 μL, 95% ^{18}O enriched), cyclohexane (0.5 mmol), and 15 eq. of *m*-CPBA (3 aliquots of 5 eq. of *m*-CPBA each at 1 h time intervals) were used. The ^{16}O and ^{18}O compositions in cyclohexanol were determined by the relative abundances of mass peaks at m/z = 57 for ^{16}O and 59 for ^{18}O (HP 5989B mass spectrometer). A control experiment showed that cyclohexanol does not exchange its oxygen with water under the experimental conditions.

First published as an Advance Article on the web 20th June 2001

Specific organization of gold nanorods into anisotropic 3D-aggregates is obtained by DNA hybridisation.

Symmetry breaking and the associated introduction of anisotropy in nanoparticle systems have been a major challenge for chemists and physicists working on nano-materials in recent years. Two distinct approaches have been explored. First, lower symmetries can be obtained by assembling spherical particles in anisotropic environments. Mixtures of different types of particles,[1] microcontact printing,[2] 1D arrays of particles along biolipid tubules[3] or in block copolymers[4] are some examples of this approach. The synthesis of anisotropic nanoparticles constitutes a second strategy. A wide variety of materials has recently been made available in the shapes of elongated rods[5–8] or more complex morphologies.[9] The anisotropy of these building blocks can be transferred to superstructures even by isotropic interactions such as hydrophobicity.[7,10] Although these interactions are efficient in producing large architectures, they are neither specific or selective, thus preventing a rational design of the self-assemblies. In this report, we show how the selective and reversible DNA-driven assembly of nanoparticles can be applied to gold nanorods.

The formation of networks of spherical gold nanoparticles crosslinked by well-defined oligonucleotide duplexes has been recently demonstrated.[11–13] In this approach, two non-complementary strands of DNA are immobilised on the surface of two batches of 13-nm particles. Upon mixing the two populations, no recognition occurs but adding a third strand half complementary to each of the grafted sequences induces hybridisation, which drives the self-assembly.[11,12] Not only is this method selective enough to allow the detection of a single base mismatch in the oligonucleotide sequence,[12] but the self-organisation is also reversible as the DNA duplex can be dissociated by heating.[13] By transferring this technique to non-spherical nanoparticles, we define a method to organise anisotropic materials that may exhibit orientation-dependant physical properties.

Gold nanorods used in this work were prepared by the electrochemical conversion of a gold anodic material into particles in an electrolytic co-surfactant system as described elsewhere.[5] The surfactants were hexadecyltrimethylammonium bromide (CTABr, Sigma, 99%) and tetradodecylammonium bromide (TDABr, Fluka, 98%). After synthesis, the colloidal suspensions were repeatedly centrifuged and washed with deionised water to remove excess surfactant. The concentration of nanorods was then adjusted to an optical density of *ca.* 0.5 at 800 nm in 5-mm lightpath UV cells. The average aspect ratio of the rods was 4.7 (*ca.* 10 nm in diameter and 50 nm in length) as inferred from transmission electron microscopy (TEM) images as well as from the position of the longitudinal plasmon band (850 nm).[5]

Two oligonucleotide systems were examined and all sequences were purchased from Oswell DNA Service, Southampton, UK. The first one, which is shown in the insert of Fig. 2, was identical to the complementary three-strand system reported by Mirkin and coworkers.[12] The second system was composed of two directly complementary strands of thiolated oligonucleotides. The sequence of this duplex is shown in Fig. 3.

Functionalisation of the nanorod surface was performed according to the reported method.[12] Briefly, the thiol group of the DNA strands was activated by treatment in 0.1 M of dithiothreitol (DTT, Aldrich, 99%) at pH 8.4 and room temperature for 1 h. The solutions were then purified through a desalting column (NAP-5, Sephadex G-25 Medium). The different thiolated oligonucleotides were then left to react at room temperature with the nanorod solutions for up to 72 h. Typical final concentrations were *ca.* 5×10^8 nanorods per mL (*i.e.* 1 pM) and 1 nM of DNA. After incubation, the suspensions were centrifuged at 5000 rpm for 20 min, decanted and redispersed in double distilled water to the same concentration.

For hybridisation experiments, identical volumes of equimolar suspensions of functionalised nanorods were mixed in a 5-mm lightpath UV cell at room temperature. Aggregation was monitored by recording UV–VIS spectra as a function of time on a Lambda 11 Perkin-Elmer spectrophotometer. For the complementary two-strand system, duplexation occurred immediately upon mixing the complementary nanorods suspensions. For the three-strand system, aggregation was initiated by adding the free, non-thiolated oligonucleotide, the final concentration of which was typically 10 nM.

As hybridisation progressed, the colour of the suspension changed from red to purple and macroscopic precipitation was observed after 24 h. The nature of the organisation of the nanorods in the purple suspensions was elucidated by TEM. In contrast to as-synthesised or DNA-covered but non-duplexed nanorod suspensions, which showed totally random aggregates when examined under the same conditions, numerous organised aggregates, often several micrometers in size, were observed for the hybridised suspensions. The samples were composed of 3-D bundles of hundreds of nanorods aligned in parallel stacks (Fig. 1). Both alternate and superimposed vertical stacking of the rods could be seen. The inter-particle distance was about

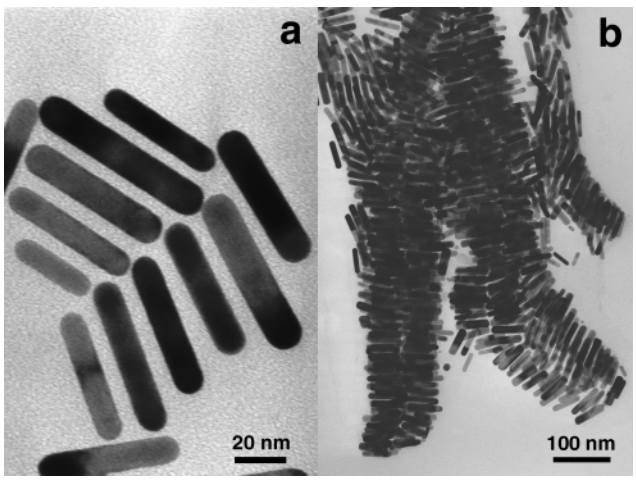

Fig. 1 Transmission electron micrographs of bundles of DNA-linked gold nanorods. Topological characteristics of the three-strand (a) or two-strand (b) DNA linking systems were similar.

 DOI: 10.1039/b102319p

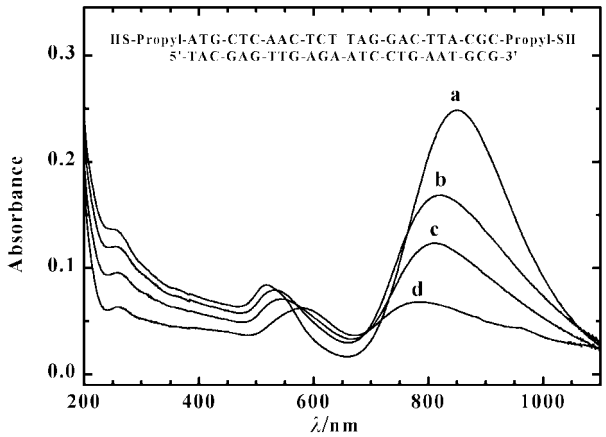

Fig. 2 UV–VIS spectra of a suspension of non-complementary DNA-functionalised nanorods. (a) 0 s, (b) 10 min, (c) 1 h, (d) 2 h after duplex initiation arising from the addition of the third complementary strand. Sequences of the three oligonucleotides are shown in the insert.

6 nm (Fig. 1a), which is longer that an interdigitated CTA bilayer (*ca*. 3 nm)[14] but commensurate with the length of a 24-base pair helix with two propyl spacers (6.5–9.0 nm). This is consistent with an aggregation process resulting from DNA duplex formation rather than from hydrophobic interactions between the CTA alkane chains.

Fig. 2 shows a typical series of spectra taken at various times after the addition of the third complementary oligonucleotide in the three-strand system. The colour change, which the nanorods share with the DNA-driven assembly of isotropic particle suspensions, was confirmed by the decrease in intensity and the red-shift of the transverse plasmon band (520 nm).[12,15] The UV–VIS spectra also showed a longitudinal band at 850 nm that decreased markedly in intensity and was blue-shifted with aggregation. A shoulder peak at 260 nm confirmed the presence of the nucleotides. Moreover, the intensity of this peak was reduced with time, consistent with the onset of base-pairing.[13] In the two-strand system, the decrease in intensity of the three bands upon hybridisation was also observed (Fig. 3, solid and dotted lines). However, the plasmon bands undergo almost no wavelength shift.

Further evidence that the aggregation was driven by DNA duplex formation was given by 'melting' analysis. This consists in dissociating the duplex by heating the sample above a temperature, which, in the case of the three-strand system, is 53 °C.[12] For this purpose, the purple suspensions were heated up to 70 °C by a thermostated bath and UV–VIS spectra were recorded at regular intervals. Hence, upon heating the duplexed suspension of the two-strand system, the intensities of the three bands were essentially recovered at 60 °C (Fig. 3, dashed curve), indicating reversible duplex formation between the complementary nanorod surfaces. Surprisingly, no change in the spectrum of the duplexed three-strand system could be observed and the suspension stayed irreversibly self-assembled.

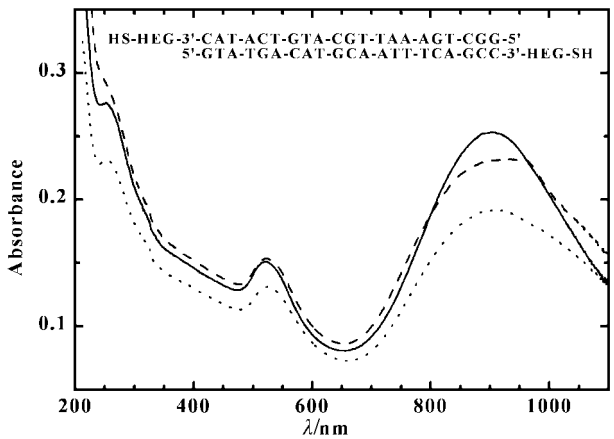

Fig. 3 UV–VIS spectra of the two-strand nanorod system before (—) and after (···) duplexation at 25 °C. The dashed curve was obtained after melting the DNA above 60 °C. The mismatch at higher wavelengths between the initial and denatured spectra is attributed to imperfect background compensation at high temperature. The sequences of the two strands are shown in the insert; HEG = hexaethyleneglycol.

Although further experiments are needed to explain this irreversibility, it is probable that the aspect ratio of the rods and/or the residual CTA molecules on the gold surface play a role. Indeed, whereas the base pairing is certainly the driving force of the self-assembly in both systems, a 12-base oligonucleotide with a propyl spacer (three-strand system) would barely emerge from a residual CTA bilayer. Once the aggregates are formed by duplexation, a multilayered CTA structure could rearrange between neighbouring rods and hydrophobic interactions could then become dominant. Upon heating for the 'melting' experiments, increases in the hydrophobic forces by dehydration of the alkane chains as well as electrostatic interactions between the $-NMe_3^+$ headgroups and the now unpaired DNA strands would reinforce this multilayered structure making rod aggregation irreversible. By contrast, the 21-base HEG-coupled oligonucleotides used in the two-strand system are sufficiently long to extend well beyond a residual CTA bilayer. Thus, in this case, the surfactant layers are not close enough to rearrange and the base pairing is therefore reversible. In addition, as no free DNA strand is released upon 'melting', the multilayered CTA structure would not be stabilised by electrostatic interactions.

In conclusion, this report has shown that large scale uniaxial organisation of metallic nanorods can be tailored by using the specific DNA duplex formation. Beyond DNA, antigen/antibody or protein/substrate bindings can be envisioned to obtain similar programmable assembly of anisotropic building blocks.[16] Systematic organisation of nanorods made of different materials is a straightforward development of this approach that should lead to anisotropic nanomaterials with more complex properties.

We thank Dr C. Murphy, C. Johnson and Dr W. Shenton for valuable discussions and the European Union for a Marie Curie Individual Fellowship (HPMF-CT-1999-00254) to E. D.

A facile and new type of route to the redox-active rigid-rod complex $[\{Mn(dmpe)_2(C{\equiv}CH)\}_2(\mu\text{-}C_4)][PF_6]$ *via* Mn–C_2· radical coupling†

Francisco J. Fernández, Olivier Blacque, Montserrat Alfonso and Heinz Berke*

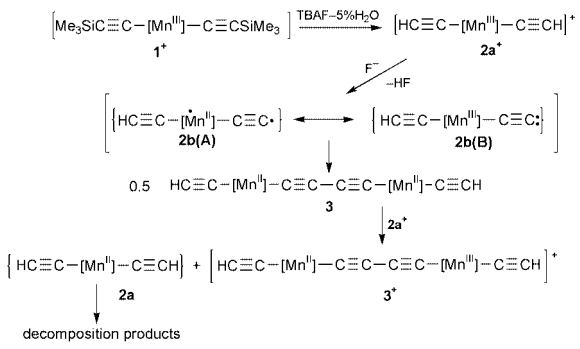
Received (in Cambridge, UK) 14th March 2001, Accepted 29th May 2001
First published as an Advance Article on the web 21st June 2001

The binuclear rigid-rod complex $[\{Mn(dmpe)_2(C{\equiv}CH)\}_2(\mu\text{-}C_4)][PF_6]$ was spontaneously obtained from the reaction of $[Mn(dmpe)_2(C{\equiv}CSiMe_3)_2][PF_6]$ with one equivalent of TBAF.

Di- and oligo-nuclear organometallic complexes, in which two neighboring metal centers are connected by a C_x chain, have recently attracted great interest due to their potential in NLO applications[1] and the possibility to use them as precursors for molecular wires.[2] During the last decade several organometallic research groups therefore focused on the development of facile synthetic routes to ML_n–C_x–ML_n rigid-rod transition metal complexes.[3–7] Studies of the electrochemical properties of these species have demonstrated that for $x = 4$ there is strong metal–metal interaction across the carbon chain. This confers great stability to the corresponding mixed-valent species, as indicated by the value of the comproportionation constant (K_c) which lies in the range of 10^8–10^{12}. This metal–metal interaction decreases with the length of the chain (C_x) and is very small for complexes with values of $x \geqslant 20$.[6a] With regard to the design of new molecular wires particularly great interest arose in new synthetic accesses to short-chain bridged species and polarizable end groups.

We have recently reported the syntheses and characterization of $[\{Mn(dmpe)_2I\}_2(\mu\text{-}C_4)]^{n+}$ ($n = 0, 1, 2$) complexes by the reaction of (MeCp)(dmpe)MnI with 0.5 Me_3Sn–C_4–$SnMe_3$ and dmpe.[7] In order to extend the scope of available versatile routes we initiated reactivity studies on $[Mn(dmpe)_2(C{\equiv}CSiMe_3)_2]^n$ ($n = -1, 0, +1$) complexes.[8] As silyl protected acetylide derivatives they were expected to allow deprotection and recovery of the quite reactive parent acetylide species.

Indeed, the reaction of $[Mn(dmpe)_2(C{\equiv}CSiMe_3)_2]^+$ **1**$^+$ with one equivalent of NBu_4F (TBAF) containing 5% H_2O[9] led to the deprotected species $[Mn(dmpe)_2(C{\equiv}CH)_2]^+$ **2a**$^+$ and subsequent deprotonation of this species produced under the reaction conditions a $[(HC{\equiv}C)Mn(dmpe)_2(C{\equiv}C)]$ intermediate **2b** (Scheme 1).‡ Spontaneous dimerization of **2b** generated $[\{Mn(dmpe)_2(C{\equiv}CH)\}_2(\mu\text{-}C_4)]$ **3** and subsequently the mixed-valent compound $[\{Mn(dmpe)_2(C{\equiv}CH)\}_2(\mu\text{-}C_4)]^+$ **3**$^+$. DFT calculations[10]† performed on the hydrogen substituted model $Mn(dHpe)_2(C{\equiv}CH)(C{\equiv}C)$ simulating **2b** revealed that, of the two possible states, triplet and singlet, the triplet state of **2b(A)** with two unpaired electrons is more stable than the singlet state **2b(B)** by *ca.* 90 kJ mol^{-1}. Furthermore, the computed spin densities of +1.45α and +0.61α, at the manganese atom and at the terminal carbon atom, respectively, clearly indicate that the electronic structure of **2b** is well described by the resonance formula **2b(A)**. The relative stability and therefore longevity of the Mn^{II} free radical apparently supports the C–C coupling process to produce the neutral dinuclear Mn^{II}–Mn^{II} species **3**. Under the given redox conditions, *i.e.* in the presence of the mildly oxidizing **2a**$^+$, **3** is converted to **3**$^+$ with additional formation of the corresponding $Mn(dmpe)_2(C{\equiv}CH)_2$ **2a** which is not stable and decomposes.[8] Indeed, the THF soluble fraction of the reaction contains a mixture of **3** and other not specifically identified Mn^{II} and Mn^{I} complexes.[8]



Scheme 1 [Mn] = $Mn(dmpe)_2$.

Based on **1**$^+$, the new dinuclear mixed-valent complex **3**$^+$ was obtained in about 65% yield, which is almost the ideal yield based on the stoichiometry of Scheme 1. This reaction involving acid–base chemistry in conjunction with the versatile redox properties of the Mn center thus furnishes a new and a facile method to obtain M–C_4–M complexes starting from easily accessible M–C_2SiR_3 units. Mechanistically it appears that there is some relationship of these conversions to the coupling of terminal acetylides with Cu^{II} reagents.[6] However, the intramolecular fashion, along which the redox chemistry of Scheme 1 proceeds, is quite unique. In addition, species **3**$^+$ possesses two reactive terminal acetylenic moieties, which might be utilized in further organometallic substitution processes of the H terminus. Compound **3**$^+$ has been characterized as a violet solid, soluble only in polar and ionizing solvents such as CH_2Cl_2. The ^{1}H NMR spectrum of **3**$^+$ (20 °C, CD_2Cl_2) shows four broad signals for the dmpe protons at δ −0.28, −4.58, −6.49 and −6.65, and a resonance at δ −46.40 due to the C≡CH proton. The paramagnetism is indicated by the broadness of the resonances and more quantitatively confirmed by the contact shift induced Curie–Weiss behavior of **3**$^+$ in the temperature range from −80 to 20 °C. The fact that only one set of resonances was observed for the protons of the dmpe ligands is taken as a strong hint for electron delocalization with both manganese ends equivalent on the NMR time scale (10^{-6} s). In the solid state, **3**$^+$ has a magnetic moment of 2.53 μ_B at 290 K that drops to 1.95 μ_B at 100 K demonstrating strong intramolecular antiferromagnetic interaction comparable to that observed for $[\{Mn(dmpe)_2I\}_2(\mu\text{-}C_4)][BF_4]$.[7]

Cyclic voltammetry (CV) of complex **3**$^+$ in acetonitrile solution displays two fully reversible waves ($\Delta E_p = 0.070$ V and $i_{pa}/i_{pc} \approx 1$ for scan rates of 0.100–0.500 V s^{-1} at 20 °C, *vs.* Fc/Fc^+) at $E_{1/2} = -0.89$ V and $E_{1/2} = -1.46$ V corresponding to the Mn^{III}–Mn^{III} (**3**$^{2+}$)/Mn^{III}–Mn^{II} (**3**$^+$) and Mn^{III}–Mn^{II} (**3**$^+$)/Mn^{II}–Mn^{II} (**3**) redox couples. The difference of these values of $\Delta E_{1/2}$ (= 0.576 V) establishes a comproportionation constant of 7.5×10^9 [$K_c = \exp(F\Delta E_{1/2}/RT)$].[11] Another somewhat irreversible redox couple was identified at $E_{1/2} = -2.29$ V attributed to the Mn^{II}–Mn^{II}/Mn^{II}–Mn^{I} reduction. In accord with this CV behavior the monocation **3**$^+$ could

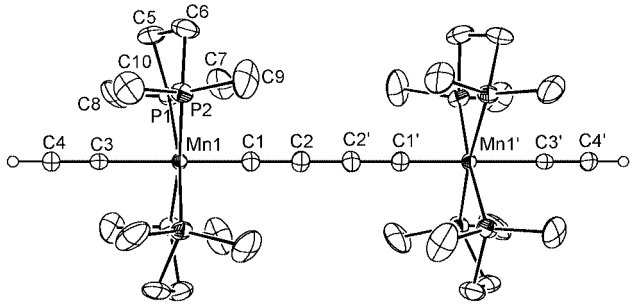

Fig. 1 Molecular structure of $\mathbf{3}^{+}[PF_6]^{-}$. Selected bond lengths (Å) and angles (°): Mn1–C1 1.818(4), Mn1–C3 2.026(5), C1–C2 1.285(6), C2–C2′ 1.307(9), C3–C4 1.189(6); Mn1–C1–C2 180.0(4); the $[PF_6]^{-}$ anion is omitted.

chemically be reduced to the dark-green paramagnetic complex **3** using $Cp(C_6Me_6)Fe$ and oxidized with $[Cp_2Fe][PF_6]$ to give the dark-brown diamagnetic $[\{Mn(dmpe)_2(C{\equiv}CH)\}_2(\mu\text{-}C_4)]^{2+}$ species $\mathbf{3}^{2+}$. Both processes can be fully reversed with $[Cp_2Fe]^{+}$ and Cp_2Co, respectively [eqn. (1)]. Complexes **3** and $\mathbf{3}^{2+}$ were isolated and fully characterized.

$$3 \underset{Cp(C_6Me_6)Fe}{\overset{[Cp_2Fe]^{+}}{\rightleftharpoons}} 3^{+} \underset{Cp_2Co}{\overset{[Cp_2Fe]^{+}}{\rightleftharpoons}} 3^{2+} \qquad (1)$$

The highly symmetric structure of $\mathbf{3}^{+}$ was determined by single-crystal X-ray diffraction (Fig. 1),§ which indeed revealed two equivalent manganese centers adopting pseudo-octahedral geometry. The C1–C2 and C2–C2′ bond lengths show only little alteration and compare very well to those obtained for the related species $[\{Mn(dmpe)_2I\}_2(\mu\text{-}C_4)]^n$ [n = 0, 1.26(2)–1.33(3) Å; n = 1, 1.275(3)–1.313(5) Å and n = 2, 1.289(5)–1.295(5) Å].[7] The C_4 linear chain is thus best described by a cumulenic resonance structure.

Support from the Swiss National Science Fundation and the Fonds of the University of Zürich are gratefully acknowledged. We also thank Dr A. Shengelaya, Institute of Experimental Physics of the University of Zürich, for the magnetic studies of $\mathbf{3}^{+}$.

‡ All operations were performed using standard Schlenck or Glove-box techniches. ^{1}H NMR data for $\mathbf{2a}^{+}$ prepared *in situ* (CD_2Cl_2, 300 MHz, −10 °C), δ −33.0 (br, 8H, PCH_2), −44.0 (br, 24H, PCH_3).

Synthesis of $\mathbf{3}^{+}$ $[PF_6]^{-}$: A 1 M solution of TBAF (0.15 mL) was added to a CH_2Cl_2 solution (15 mL) of $\mathbf{1}^{+}$ (0.1 g, 0.15 mmol). After 1.5 h the dark-green solution was concentrated *in vacuo* to 3 mL. Addition of Et_2O precipitated $\mathbf{3}^{+}[PF_6]^{-}$, which was dried *in vacuo*. Yield 0.046 g, (65%). Anal. Calc. for $C_{32}H_{66}F_6Mn_2P_9$: C, 40.31; H, 6.98. Found: C, 40.01; H, 6.80. ^{1}H NMR (CD_2Cl_2, 300 MHz, 20 °C): δ −0.29 (br, 8H, PCH_2), −4.60 (br, 24H, PCH_3), −6.55 (br, 24H, PCH_2), −6.71 (br, 24H, PCH_3), −46.39 (br, 2H, ≡CH). ^{31}P NMR (121.471 MHz, CD_2Cl_2, 20 °C, 85% H_3PO_4 ext.): δ −145.62 (sept., $^1J_{PF}$ 717.9 Hz, PF_6^{-}).^{19}F NMR (CD_2Cl_2, 282.324 MHz, 20 °C, $C_6H_5CF_3$ ext.): δ −75.09 (d, 717.9 Hz, PF_6^{-}). IR (CH_2Cl_2, 20 °C): 2140s 1819w (C_4 unit), 1960m cm^{-1} [ν(C≡CH)].

Synthesis of $\mathbf{3}^{2+}[PF_6]^{-}_2$: $[Cp_2Fe][PF_6]$ (0.017 g, 0.052 mmol) was added to a CH_2Cl_2 solution (10 mL) of $\mathbf{3}^{+}$ (0.050 g, 0.052 mmol). After 3 h the solution was concentrated *in vacuo* to 3 mL. Addition of Et_2O precipitated $\mathbf{3}^{2+}[PF_6]^{-}_2$, which was dried *in vacuo*. Yield 0.051 g, (90%). Anal. Calc. for $C_{32}H_{66}F_{12}Mn_2P_{10}$: C, 34.99; H, 6.06. Found: C, 34.86; H, 6.06. ^{1}H NMR (CD_2Cl_2, 300 MHz, 20 °C): δ 1.93 (br, 8H, PCH_2), 1.83 (br, 24H, PCH_2), 1.38 (br, 24H, PCH_3), 1.27 (br, 24H, PCH_3), −2.30 (br, 2H, ≡CH). ^{31}P NMR (121.471 MHz, CD_2Cl_2, 20 °C, 85% H_3PO_4 ext.): δ −145.44 (sept, $^1J_{PF}$ 719 Hz, PF_6^{-}). ^{19}F NMR (CD_2Cl_2, 282.324 MHz, 20 °C, $C_6H_5CF_3$ ext.): δ −74.02 (d, 719 Hz, PF_6^{-}). IR (KBr, 20 °C): 1929 cm^{-1} [ν(C≡C)], 2025, 1915, 1920 cm^{-1} [ν(C≡C)$_2$].

Synthesis of **3**: $Cp(C_6Me_6)Fe$ (0.017 g, 0.053 mmol) dissolved in toluene (5 mL) was added to a THF suspension (5 mL of $\mathbf{3}^{+}[PF_6]^{-}$ (0.050 g, 0.052 mmol). After 2 h the solution was filtered and the solvent removed to give **3**. Yield 0.038 g, (90%). Anal. Calc. for $C_{32}H_{66}Mn_2P_8$: C, 47.54; H, 8.23. Found: C, 47.62; H, 8.53. ^{1}H NMR (C_6D_6, 300 MHz, 40 °C): δ −9.47 (br, 8H, PCH_2), −14.89 (br, 32H, PMe_3 + PCH_2), −18.78 (br, 24H, PCH_3), −149.44 (br, 2H, ≡CH). IR: no ν(C≡C) are observed.

§ *Crystal data* for $\mathbf{3}^{+}[PF_6]^{-}$: $C_{32}H_{66}F_6Mn_2P_9$, M = 953.46, dark red block, 0.30 × 0.24 × 0.15 mm, tetragonal, space group $I\bar{4}c2$, a = b = 16.1403(9), c = 18.141(1) Å, V = 4725.9(5) Å^3, Z = 4, D_c = 1.340 Mg m^{-3}, μ = 0.884 mm^{-1}. Data were collected on a STOE IPDS diffractometer [graphite monochromatised Mo-Kα, λ = 0.71073 Å, T = 183(2) K]. 22664 reflections collected, 2924 unique (R_{int} = 0.0202). Refinement converged to R_1 = 0.0303, wR_2 = 0.0732 [$I > 2\sigma(I)$] and R_1 = 0.0529, wR_2 = 0.0777 (all data). CCDC reference number 161685. First published as an Advance Article on the web 21st June 2001

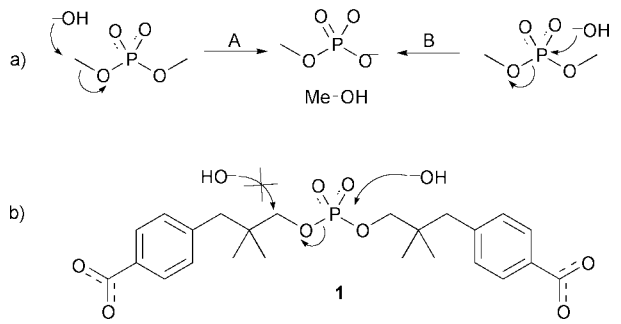
The rate of attack of hydroxide on dialkyl phosphate diesters is far slower than previously estimated, allowing us to estimate the stability of the diester link in DNA and showing that ethylene phosphate is 10^{11} fold more reactive towards attack by hydroxide than an acyclic diester (1000 fold more than previously estimated).

Nature has selected phosphate diesters to hold together the genetic code. This linkage needs to be very stable to keep the sequence of bases intact, but is also the site at which DNA is hydrolysed in the course of its repair and destruction by nucleases.[1] To be able to understand the efficiency of the enzymes (and ribozymes) which catalyse hydrolysis, it is important to quantify the background reactivity. This information will also define the catalytic efficiency which must be achieved by artificial catalysts before they can be used as useful substitutes for natural nucleases. As this is not the most reactive site of DNA,[2] direct measurement of the hydrolysis reaction at phosphorus is not possible and so the hydrolysis of simpler phosphate diesters has to be studied. Here we report the rate of hydroxide catalysed hydrolysis of phosphate diesters with poor leaving groups, revealing that the phosphate diesters in DNA are far more resistant to hydrolysis than has been previously estimated.

The hydrolysis of phosphate diesters with alkoxy leaving groups is extremely slow in the absence of efficient catalysts. Westheimer[3] reported the rate of hydroxide attack on dimethyl phosphate at high temperatures, but Bunton *et al.*[4] used isotopically labeled solvent to show that the majority of the reaction occurs by C–O cleavage (pathway A, Scheme 1a), giving the same products but showing that the attack at phosphorus (pathway B, Scheme 1a) must be slower still. This was confirmed by Westheimer and Haake,[5] and modifying the original rate data to allow for competing attack at carbon gives 6.8×10^{-12} M^{-1} s^{-1} as the best estimate for DNA reactivity with hydroxide at 25 °C.[6] Recently, Wolfenden and Radzicka re-examined the hydrolysis of dimethyl phosphate, and by extrapolating kinetic data from high temperatures arrived at an estimate of 130 000 years as the half life for DNA at pH 6.8 and 25 °C.[7] More detailed study revealed that only pathway A was occurring, and so only an upper limit for the biologically relevant hydrolysis reaction can be derived from these data.[8] These later data also showed that hydrolysis of monomethyl phosphate proceeds only by P–O cleavage and is rapid enough to occur to a similar extent as solvent incorporation under the conditions of the original labeling studies. This could account for the reported isotope labeling results, without involving any P–O cleavage in the initial reaction of dimethyl phosphate. We decided to try and establish the reactivity of dialkyl phosphodiesters to hydrolysis by studying **1** (Scheme 1b) which has a leaving group pK_a comparable to that in DNA.



Scheme 1 (*a*) Pathways for hydrolysis of dimethyl phosphate. (*b*) Compound **1** has pathway A selectively hindered.

Compound **1**† uses the neopentyl effect to prevent attack at carbon without hindering attack at the phosphorus. The steric effect of an alkyl group can significantly retard substitution rates when it is branched α or β to a reaction centre, but the impact of branching at the γ position is minimal.[9] Indeed, the hydrolysis of alkyl 4-nitrophenyl phosphate is only slowed ~2 fold when the alkyl group is changed from methyl to neopentyl.[10] To facilitate analysis by HPLC, we appended aromatic rings, which required the addition of carboxylate groups for solubility in aqueous solution. These anionic groups are distant to the reacting diester, so in a polar, protic solvent such as water, we expect no electrostatic impact on its reactivity; initial studies (using ^{1}H NMR) confirmed that dineopentyl phosphate had the same reactivity as **1**. To study the hydrolysis of **1**, we sealed 0.5 ml aliquots of a 10 mM solution of the diester (with 4-methylbenzoic acid as an internal reference) in 1 M KOH in stainless steel reaction vessels with a PTFE liner and graphite gasket. These were kept at constant temperature by being immersed in a circulating oil bath and removed for analysis at various times.

We investigated the site of reaction by using 94% ^{18}O labeled water. Stopping the reaction after ~50% reaction at 240 °C and analysing the solution by LC-MS revealed that the carboxylate oxygens of **1** and the product alcohol were isotopically labeled at solvent levels, but that the alcohol OH was still at natural abundance—and so the biologically relevant hydrolysis of a phosphate diester mimicking the DNA link is being observed.

Over the range 160–260 °C, we could observe the disappearance of the diester and corresponding appearance of the alcohol product by HPLC analysis of aliquots removed at various time intervals (Fig. 1).‡ Under these conditions, the monoester intermediate does not accumulate to any significant extent. Maintaining the ionic strength at 1 M with KCl, we also measured the rates at 0.33 M KOH, and observed a 3 fold decrease in rate, showing that in 1 M base, the reaction is catalysed by hydroxide.§

In Fig. 2, we plot this data as the log of the second order rate constant for the hydroxide attack against 1/*T* which shows the expected linear relationship. The activation enthalpy is 129 ± 4 kJ mol^{-1} and the activation entropy is −102 ± 9 J mol^{-1} K^{-1}, consistent with a bimolecular reaction and very similar to the entropy of activation (−117 ± 7 J mol^{-1} K^{-1}) measured for the hydroxide catalysed hydrolysis of methyl 4-nitrophenyl phosphate.[11] Extrapolating this data to 25 °C predicts a second order rate constant for attack of hydroxide at the phosphate diester of $10^{-15 \pm 0.5}$ M^{-1} s^{-1}. (*i.e.* half life at pH 14 is ~20 million years!).

If base catalysis is the dominant reaction at pH 7,[12] then the rate of hydrolysis of dialkyl diesters at neutral pH and ambient temperature would be ~10^{-22} s^{-1}. This means that *staphyloccocal nuclease*, which has a turnover number of 95 s^{-1},[13] is

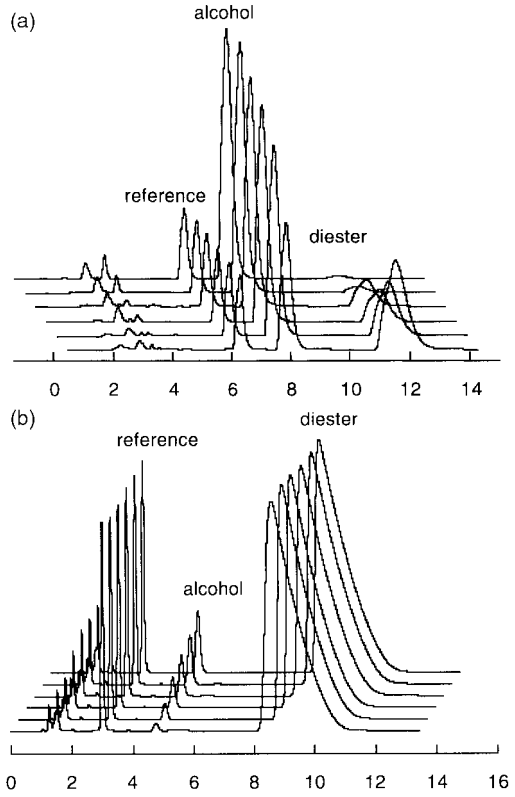

Fig. 1 HPLC traces for the hydrolysis of **1** in 1 M KOH. Upper traces at 240 °C (250 mm column); lower traces at 180 °C (150 mm column). Detection is at 236 nm and retention times are in minutes.

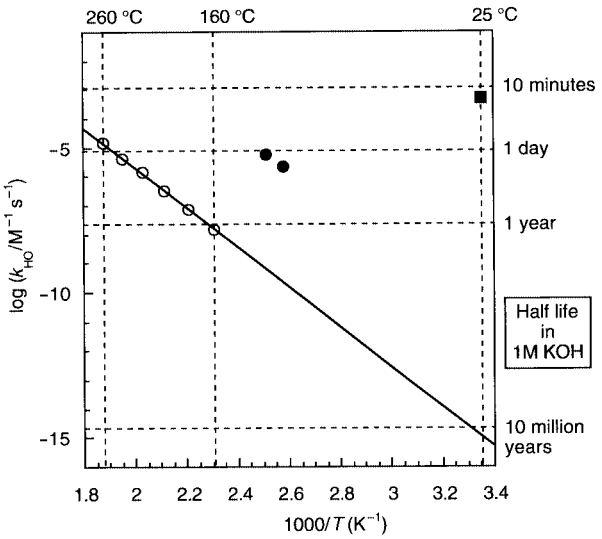

Fig. 2 Arrhenius plot of the second order rate constant for the hydrolysis of **1** (open circles) by hydroxide. The filled circles are the second order rate constant for hydroxide attack on dimethyl phosphate at 125 and 115 °C, and the filled squares for attack on ethylene phosphate at 25 °C.[5]

accelerating the rate of reaction (of the bound diester) by some 23 orders of magnitude. This data also means that the enhanced reactivity of ethylene phosphate is significantly greater than previously estimated. Constraining the ester groups in a 5 membered ring raises the rate constant for attack by hydroxide to 5×10^{-4} M^{-1} s^{-1} at 25 °C.[3] Our data shows that this represents about 10^{11} fold rate enhancement compared to the acyclic compound, 1000 fold more than previously estimated[5] suggesting that rationalisations of this observation will require further study.

Finally, the previously reported rates of reaction of dimethyl phosphate with hydroxide[3] are about 10 000 fold faster than predicted by extrapolating our data (Fig. 2), and so are unlikely to have any significant contribution from pathway B. Approximating the steric effect of the 5′ position of DNA to an isobutyl substituent (which retards S_N2 attack at carbon by an oxyanion in a protic solvent by about 100 fold compared to a methyl substituent[9a]) means that DNA hydrolysis through hydroxide attack at this carbon may be faster than attack at phosphorus. Apparently, biological catalysts have evolved to accelerate attack at phosphorus, rather than the lower energy reaction in solution which would be more energetically efficient.

In conclusion, we have measured the rate of hydroxide attack at the phosphorus of a dialkyl phosphate diester, and found it to be far slower than previously estimated. Consequently, nucleases are considerably more proficient than previously appreciated and the target for making useful artificial nucleases is even more challenging than has previously been appreciated. To be able to artificially manipulate DNA in the same way, catalysts will have to be developed which provide a rate acceleration of about 18 orders of magnitude to reduce the half life to useful levels.

We thank Professor R. Wolfenden for helpful discussion in the course of this work, S. Thorpe for obtaining LC-MS data, the Royal Society and Nuffield Foundation for financial support, and the EPSRC for a studentship to P. W.

12 For diaryl phosphate hydrolysis the pH rate profile between 2 and 10 is made up solely of acid and base terms for leaving groups with pK_a > 8; at pH 7 base catalysis dominates (A. J. Kirby and M. Younas, *J. Chem. Soc. B*, 1970, 510). For intramolecular transesterification in RNA dimers with alkoxy leaving groups, base catalysis also dominates at pH 7 (P. Järvinen, M. Oivanen and H. Lönnberg, *J. Org. Chem.*, 1991, **56**, 5396). Interestingly, extrapolating the pH independent reaction observed for good leaving groups to a leaving group pK_a of 15 predicts a spontaneous reaction of ~10^{-21} s^{-1}, in rather good agreement with our extrapolation for a base catalysed reaction.

Chiral complexes of palladium, 1, with the new tridentate 'pincer' ligand 2,6-lutidinyl-biscarbene (C^N^C), have been prepared; in the solid state they exhibit helical C_2 symmetrical structures which are persistent in solution at least up to 80 °C; the chiral nature of 1 has been established by NMR methods using Pirkle's acid as a chiral discriminating agent; racemic mixtures of 1 are highly active catalysts in Heck coupling reactions.

The use of *N*-heterocyclic carbene transition metal complexes in catalysis is an area of intense current research activity.[1] This has been stimulated by a number of attractive ligand characteristics, including electronic similarity to the alkyl phosphines,[2] formation of strong and inert metal–ligand bonds and ease of electronic and steric tuning. Compared with the electronically similar phosphine ligands, carbenes appear not to dissociate easily from the metal centre and are less prone to metal assisted decomposition leading to catalyst deactivation. Considerable effort has also been directed to the development of new chiral ligands due to the growing importance of transition metal catalysed asymmetric synthesis.[3] Diphosphines, especially those with C_2 symmetry, have proven to be especially useful, resulting in good enantioselective control of the catalytic reactions, although the potential of chiral auxilliary ligands which bind to the metal through nitrogen and carbon atoms is now being evaluated.[4] In sharp contrast, chiral carbene complexes are very rare and have only recently attracted interest, with current examples of ligands including (i) chiral imidazolin-2-ylidenes and imidazol-2-ylidenes [stereogenic centre(s) on the alkyl substituents of the rings],[5] (ii) chiral imidazolin-2-ylidenes (stereogenic centres integrated in the imidazoline ring),[6] (iii) *N*-functionalised imidazol-2-ylidenes and precursors thereof (stereogenic centres on the functional group)[7] and (iv) binaphthyl bridged dicarbenes (stereogenic axis of the binaphthyl framework).[8] Herein we communicate our results on the isolation and full characterisation of the first racemic carbene complexes of palladium as a result of two carbene moieties being linked by a lutidine backbone, together with a preliminary study of their catalytic activity.

As a logical extension of our own work and that of McGuiness and Cavell on the use of pyridine- and picoline-functionalised carbene complexes of palladium[9] we decided to explore the use of tridentate 'pincer' architectures bearing carbene ligands. Toward this end the complexes [(C^N^C)PdCl]X [C^N^C = α,α′-bis-(3-arylimidazol-2-ylidene)-2,6-picoline, **1a**: Ar = 2,6-$Pr^i_2C_6H_3$, **1b**: Ar = mes (2,4,6-$Me_3C_6H_2$); X = Cl^-, $AgCl_2^-$] were prepared by interaction of the analogous silver complexes[10] with (COD)$PdCl_2$ in dichloromethane.

Complexes **1a**, **b** are air stable, colourless high-melting solids (ESI).† The structure of **1a** was determined by X-ray crystallography, and the cationic component is shown in Fig 1.‡ The 'pincer' ligand is coordinated to the square planar palladium centre with the carbene ends disposed *trans* to each other and the lutidine nitrogen *trans* to the chloride. The observed geometrical parameters are similar to those previously reported for analogous complexes.[9] However, as a direct result of the combination of the puckering of the two six-membered chelate rings and the bulk of the aromatic substituents around the carbene moieties a beautiful helical structure is generated with a C_2 proper axis coinciding with the N–Pd–Cl vector. The conformation of the cation is best described by the orientation of the ligand ring systems with respect to each other and to the palladium square plane. Thus, the lutidine ring forms a dihedral angle of 40.04(10)° with the square plane, the N1 and N5 carbene rings form dihedral angles of 42.50(13) and −39.70(11)°, respectively, with the square plane and the carbene rings form dihedrals of 81.93(17) and –79.85(14)°, respectively, with the C1 and C26 Ar moieties. As a consequence of the centrosymmetric nature of the space group ($P2_1/c$), the second enantiomer is generated through the inversion centre leading to a racemic mixture in the crystal lattice.

It is interesting that 'pincer' complexes [(CNC)PdCl]X [CNC = 2,6-bis(3-arylimidazol-2-ylidene)pyridine; **2a**: Ar = 2,6-$Pr^i_2C_6H_3$, **2b**: Ar = mes; X = Cl^-, $AgCl_2^-$] have also been obtained following similar synthetic methods (ESI).† The structure of **2a** was also determined by X-ray crystallography and is shown in Fig.2.‡ The coordination sphere of the metal is

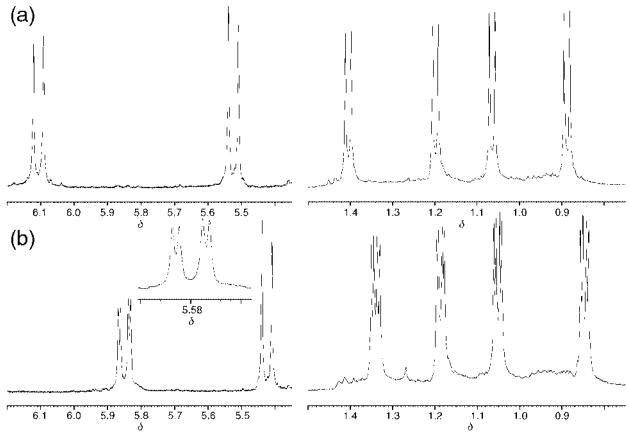

Fig. 3 The isopropyl methyl- and bridging methylene-regions of the ^{1}H NMR spectrum of **1a** before (a) and after (b) the addition of Pirkle's acid.

similar to **1a**. However, the whole molecule is virtually planar, with the Ar groups twisted 76.68(11) and 89.63(22)° out of the plane for rings C12 and C24, respectively. All other geometrical data are very similar to **1a**. It is instructive to view the generation of **1** by desymmetrisation of **2** through a twist deformation around the C_2 axis. The direction of the twist determines the chirality generated. A compound related to **2a** with methyl substituted carbene functionalities has also recently been reported.[11]

The structures of **1a** and **2a** observed in the solid state are persistent in solution. The ^{1}H NMR (CD_2Cl_2) spectrum of **1a** (ESI†) shows four anisochronous doublets which can be assigned to the isopropyl methyl protons. Furthermore, the methylene-bridge protons appear as an AB pattern in the range δ5.5–6.3 [Fig. 3(a)]. In order to demonstrate the chiral nature of **1a** in solution Pirkle's acid. [TFAE, *S*-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol] was used as a chiral discriminating agent.[12] The isopropyl methyl groups and the bridging methylene regions of the spectrum obtained after addition of 3.4 equivalents of TFAE in CD_2Cl_2 solution of **1a** are shown in Fig 3(b). The doubling of the four anisochronous doublets and one of the doublets due to the methylene linkers originates from the strong interaction of the chiral discriminating agent with one of the two enantiomers of **1a** (degree of non-equivalence $\Delta\delta$ *ca.* 0.2 ppm). The conformation of **1a** is rigid at least up to 80 °C as evidenced by variable temperature ^{1}H NMR spectroscopy (C_6D_5Cl). This supports the contention that a high activation barrier exists for enantiomer interconversion, thus leading to the realistic possibility of resolving the racemic mixture by chemical or chromatographic means.

In contrast to **1a,** the spectrum of the planar **2a** contains only two diastereotopic isopropyl methyl protons and remains also unchanged over the temperature range studied.

Preliminary data show that **1** and **2** are active catalysts in Heck coupling reactions (Table S1, ESI†).[9] The catalysts show excellent long term stability at high temperatures. Furthermore, the activity is sensitive to the steric congestion at the reactive site (**1b** is more active than **1a**). It is interesting that aryl chlorides can also be used as substrates. The mechanism and the nature of the active species in these reactions is far from clear. Heck reaction catalysed by 'pincer' phosphine ligated palladium complexes have been reported.[13]

Isolation of the enantiomerically pure complexes and extension of this methodology to other transition metals and their catalytic reactions are currently under way.

We thank Dr J. E. Anderson for a helpful discussion, and acknowledge Mr S. Winston, Mr J. Gonzalez-Outeirino and Mrs J. M. Street for assistance in solving the structure of **1a** and VT NMR spectroscopy, respectively.

Notes and references

‡ *Crystal data*: for **1a**: crystals were obtained by layering a CH_2Cl_2 solution of **1a** with light petroleum (bp = 40–60 °C); $C_{40}H_{45}AgCl_9N_5Pd$, M = 1129.13, monoclinic, space group $P2_1/c$, a = 11.559(2), b = 42.043(8), c = 10.631(2) Å, β = 112.51(3)°, U = 4772.6(16) Å^3, T = 150(2) K, Z = 4, μ(Mo-Kα) = 1.325 mm^{-1}, 28393 reflections collected, 10436 unique reflections, R_{int} = 0.0867), Final R indices: wR_2 = 0.1185 and R_1 = 0.0514 [$F^2 > 2\sigma(F^2)$] and 0.1340 and 0.0897 for all data.

For **2a**: crystals were obtained by layering a CH_2Cl_2 solution of **2a** with light petroleum (bp = 40–60 °C), $C_{36}H_{41}Cl_{4.5}N_5Pd$, M = 809.66, triclinic, space group $P\bar{1}$, a = 8.4782(4), b = 11.8790(6), c = 20.8146(11) Å, α = 75.077(3), β = 83.364(3), γ = 71.322°, U = 1917.65 (17) Å^3, T = 150(2) K, Z = 2, μ(Mo-Kα) = 0.829 mm^{-1}, 14147 reflections collected, 6524 unique reflections, R_{int} = 0.0839), Final R indices: wR_2 = 0.2213 and R_1 = 0.0838 [$F^2 > 2\sigma(F^2)$] and 0.2562 and 0.1316 for all data.

The refinement of both structures was hampered by severe disorder of dichloromethane solvent molecules, and, not unrelated, limited quality data from poor crystals, especially for compound **2a**. At the present stage, the modelling of the disorder is not complete, but the definition of the cation is reliable in each case, with reasonable positional esds and good displacement parameters for all component atoms. Received (in Cambridge, UK) 14th March 2001, Accepted 25th May 2001
First published as an Advance Article on the web 21st June 2001

Equilibrium between neutral hexacoordinate silicon complexes and ionic siliconium chlorides, which is highly temperature, solvent, counterion, ligand and substituent dependent, was observed by low temperature ^{29}Si NMR and confirmed by crystal analysis.

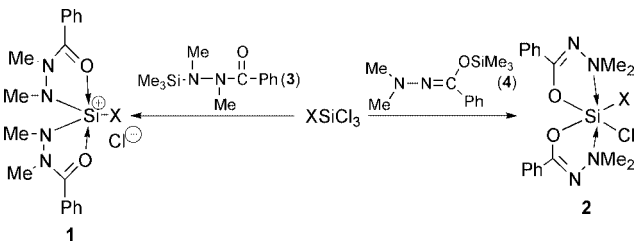
Numerous well established neutral octahedral silicon complexes[1] are now shown to undergo unusual ionic (Si–Cl) dissociation in suitable solvents upon cooling, and consist of equilibrium mixtures with pentacoordinate siliconium chlorides. The only reported similar equilibria are between neutral pentacoordinate and ionic tetra-[2] or pentacoordinate complexes.[3,4] This appears to be the first report of a dissociation–recombination of the Si–Cl bond in hexacoordinate silicon compounds. Substantial temperature, solvent, substituent and counterion effects on the neutral-hexacoordinate/ionic-pentacoordinate population ratio are found.

We have recently reported the unexpected spontaneous formation of ionic pentacoordinate siliconium complexes (**1**), stabilized by two O→Si dative bonds,[5] where neutral hexacoordinate complexes were expected, based on the chemistry of the isomeric N→Si analogs (**2**) (Scheme 1).[1]

In search for dissociation of **2**, to form siliconium complexes analogous to **1**, the ^{29}Si NMR spectra of **2a** in CD_2Cl_2 were measured at low temperature. Line broadening over a large temperature range was observed, followed by the emergence of two signals, at −73.0 and −135.6 ppm, below 200 K, assigned to **5a** and **2a**, respectively (Fig. 1).† Thus, a reversible equilibrium reaction between neutral hexacoordinate complexes (**2a**–**d**) to ionic pentacoordinate complexes (**5a**–**d**) is demonstrated (Scheme 2).

The equilibrium constant K = [**5a**]/[**2a**] changes quite dramatically with temperature, as is shown by the ^{29}Si NMR spectra below 190 K, when *both* signals are narrow (Table 1, Fig. 1). K values above the coalescence temperature were assessed by the temperature dependence of the weighted-average ^{29}Si chemical shift, and are listed in Table 1. Interestingly, the K values cross over from $K < 1$ to $K > 1$ upon a decrease in temperature, *i.e.* at higher temperatures **2a** is predominant, and at lower temperatures **5a** predominates. The K values obtained directly and from the weighted averages (below and above T_c) were used to calculate $\Delta H°$ and $\Delta S°$ (Table 1).

A similar measurement of the temperature dependence of δ^{29}Si of **2b** showed, likewise, line broadening and splitting of the signal, at the slow exchange limit temperature (180 K), to two signals characteristic of hexa- and pentacoordinate silicon complexes (Table 1). However, in sharp contrast with **2a**, the population ratio K = [**5b**]/[**2b**] is barely temperature dependent over the range 180–300 K. It follows that by changing the remote substituent (R) alone, a vast change in equilibrium constant and in its temperature dependence is generated.



Scheme 1

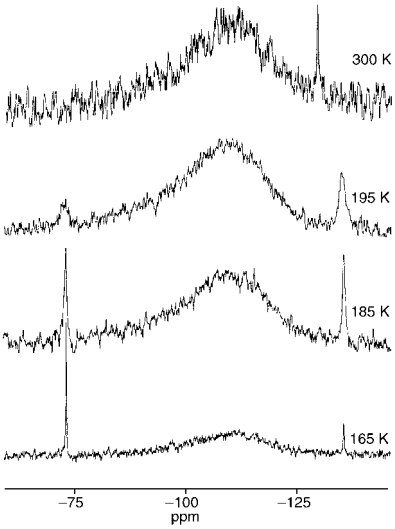


Fig. 1 ^{29}Si NMR spectra (99.325 MHz) of **2a**⇄**5a** in CD_2Cl_2 solution at various temperatures.

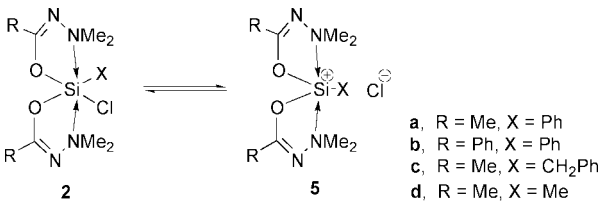

Scheme 2

An even more dramatic manifestation of this effect is found in the equilibrium K = [**5c**]/[**2c**]: K changes from 1 : 25 at 300 K to 30 : 1 at 165 K, *i.e.* from an essentially all hexacoordinate to an essentially all pentacoordinate species (Table 1).

In **2d** the exchange rate is too fast to permit full splitting of the broad signal and evaluation of K down to 165 K. However, the huge temperature dependence of K is evident by the continuous change in δ^{29}Si, from −123.9 at 300 K, to −66.5(br) at 165 K. Like in **2c**, this change indicates an essentially complete turnover from a hexacoordinate to a pentacoordinate complex upon cooling.

The wide temperature ranges over which line broadening took place in the equilibria **2**⇄**5** provided approximate barrier heights, which are summarized in Table 1 It appears that while the equilibrium constant and its temperature dependence are

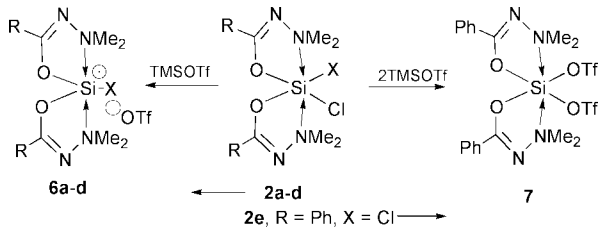
^{a} The large chemical shift difference causes line broadening over a large temperature range, preventing accurate barrier determination. ^{b} Obtained from plots of ln$K$ *vs.* T^{-1}. $R > 0.99$. ^{c} At this temperature only the major component can be observed. ^{d} Barrier too low to permit resolution of the components.

affected primarily by the remote substituent R, the exchange rate constants strongly depend on the ligand X.

The remarkable counter-intuitive temperature dependence of the equilibria (*i.e.* dissociation upon cooling) may result from increased solvent organization around the ions. Alternatively, the N→Si coordination may strengthen upon cooling, in agreement with some observations in pentacoordinate complexes,[1e,2a,b] driving the chloro ligand away as a chloride anion.

Solvent and counterion effects shift the equilibrium: when the apolar toluene-d_8 was used as solvent instead of CD_2Cl_2, the equilibrium shifted toward the hexacoordinate side and only **2** could be observed.‡ When the chloro ligand in **2** was replaced by triflate (OTf), using trimethylsilyl triflate (TMSOTf),[3,4,6] only the pentacoordinate **6a**–**d** were observed (Scheme 3).



Scheme 3

The crystal structure of **6a** (Fig. 2a) features a well separated triflate anion and a distorted trigonal bipyramid geometry, confirming the assigned pentacoordinate siliconium complex structure.§

The pentacoordination of **6** in solution is confirmed by the large downfield changes in ^{29}Si chemical shifts (**6a**, −73.2; **6b**, −72.3; **6c**, −65.3 and **6d**, −61.7 ppm) relative to the parent hexacoordinate **2**. Moreover, these shifts correspond almost exactly to those found for **5a**–**d** at 165 K (Table 1), also confirming the structural assignments of the latter.

A notable exception from the behaviour of **2a**–**d** was found in the low temperature ^{29}Si NMR spectra of **2e** (Scheme 3). Temperature independent ^{29}Si chemical shift, and the absence of exchange phenomena upon cooling, indicated that in this case no ionization took place. Even replacement of the Cl ligands by OTf, which drove the **2**⇌**5** equilibrium completely to the ionic side in **2a**–**d**, failed for **2e** and resulted in the covalent **7**, which was characterized by its crystal structure (Fig. 2b).§ This different behaviour of **2e** relative to **2a**–**d** may be accounted for by the greater electron withdrawing power of the chloro ligand, causing a greater electron defficency at silicon and hence stabilizing the hexacoordinate relative to the pentacoordinate complex.

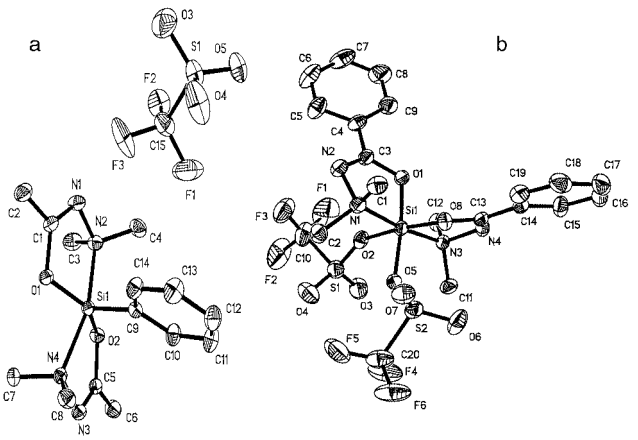


Fig. 2 Crystal structures of **6a** (a) and **7** (b) at 50% probability level. Hydrogen atoms have been omitted for clarity.

We thank Dr Arkady Ellern for the crystallographic analyses. Financial support from the Israel Science Foundation and the German Israeli Foundation (GIF) is gratefully acknowledged.

Notes and references

† These chemical shifts are highly characteristic, respectively, of penta- and hexacoordination in silicon chelates.[1e] The ^{1}H and ^{13}C NMR spectra featured only line broadening, but no splitting.

‡ The use of toluene-d_8 as solvent prevented earlier detection of the dissociation reported here.[1b]

Chemically amplified soft lithography of a low band gap polymer

Jianfei Yu and Steven Holdcroft*

Department of Chemistry, Simon Fraser University, Burnaby, BC, V5A 1S6, Canada. E-mail: holdcrof@sfu.ca

Received (in Cambridge, UK) 5th April 2001, Accepted 25th May 2001
First published as an Advance Article on the web 21st June 2001

A solid state, acid-catalyzed reaction leading to chemically amplified soft lithography is demonstrated with a low band gap conjugated polymer; poly({3-[11-(tetrahydropyran-2-yloxy)undecyl]thiophene-2,5-diyl}-3,4-ethylenedioxythiophene-2,5-diyl).

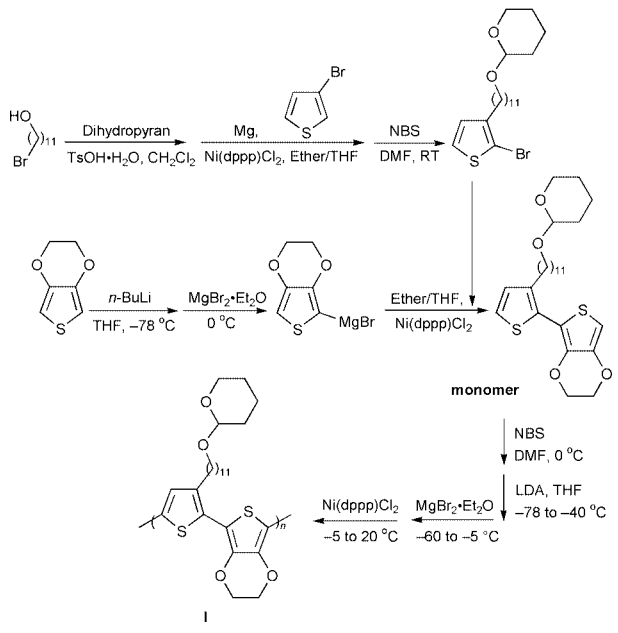
π-Conjugated polymers are promising materials with which to fabricate organic microelectronic and optoelectronic devices.[1–4] Due to their increasing complexity there is a growing need to deposit multi-layers of conjugated polymers in a spatially controlled fashion. Previous reports describing photolithography of conjugated polymers have been based on photocrosslinking, photoinduced doping/dedoping, photochemical structural transformation,[5] and chemically amplification.[6] Inexpensive soft photolithographic techniques[7] including microcontact printing, lift-up and micromolding have also been investigated, as have ink-jet[8] and screen printing.[9]

In this communication, a novel method for patterning conjugated polymer films is described. This technique, we term chemically amplified soft lithography, is demonstrated with a novel regioregular conjugated polymer; poly({3-[11-(tetrahydropyran-2-yloxy)undecyl]thiophene-2,5-diyl}-3,4-ethylenedioxythiophene-2,5-diyl) (**I**). 3,4-Ethylenedioxythiophene-based polymers are receiving considerable attention due to their low band-gap, high conductivity, stability and high transmittance contrast ratio between its reduced and oxidized states.[10]

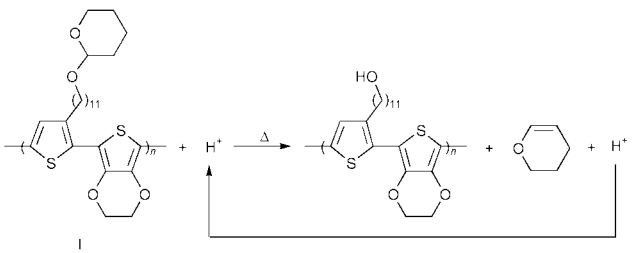
Monomer {3-[11-(tetrahydropyran-2-yloxy)undecyl]thiophenediyl}-3,4-ethylenedioxythiophene and the analogous polymer, **I**, were synthesized according to Scheme 1.† Films of polymer **I** are deep purple in color exhibiting a λ_{max} of 570 nm and a band-gap of ~1.67 eV (740 nm). These values are comparable to that of poly(3,4-ethylenedioxythiophenediyl) (PEDOT).[11]

The presence of the tetrahydropyranyloxy alkyl side chain imparts solubility and reactivity.[12] Similarly to that reported for poly{3-[2-(tetrahydropyran-2-yloxy)ethyl]thiophenediyl} (PTHPET),[13] **I** undergoes a solid state acid-catalyzed reaction depicted Scheme 2. In the absence of acid, thermogravimetric analysis (TGA) (Fig. 1) shows that **I** is stable up to ~230 °C but undergoes an 18% loss in mass between 230 and 270 °C. The observed weight loss is consistent with theoretical value of 17.6% corresponding to cleavage and volatilization of the tetrahydropyranyl moiety as dihydropyran. In the presence of 5% camphorsulfonic acid (mol% based on the thienyl unit) TGA (Fig. 1) indicates that elimination of THP occurs at a much lower temperature. 5 mol% acid is responsible for complete deprotection and thus provides evidence that the reaction is acid catalyzed, *i.e.*, chemically amplified. DSC indicated that the onset of the reaction decreased from ~230 to 85 °C in the presence of acid. Reaction of the polymer was confirmed by FTIR, which showed the emergence of a broad peak at ~3400 cm^{-1} attributed to the formation of ω-hydroxy groups, and a decrease in signals at ~2900 cm^{-1} corresponding to loss of THP-methylene.

In a novel variation of chemically amplified photolithography and soft lithographic techniques, **I** was pattered by spatial deposition of acid onto the surface of a neat film (90 nm thick), followed by heating and development. In this process, shown schematically in Fig. 2, an 'acidic ink' comprising 0.01 M camphorsulfonic acid in THF–hexane was transferred to the



Scheme 1 Synthetic scheme for monomer and polymer.



Scheme 2 Acid-catalyzed elimination of dihydropyran from **I**.

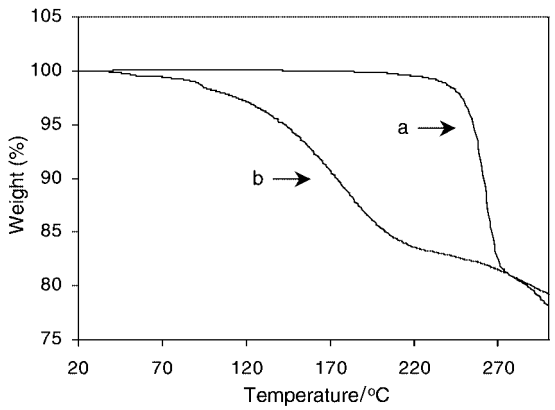


Fig. 1 TGA thermograms of **I**: (a) in the absence of acid and (b) in the presence of 5 mol% camphorsulfonic acid.

 DOI: 10.1039/b103128g

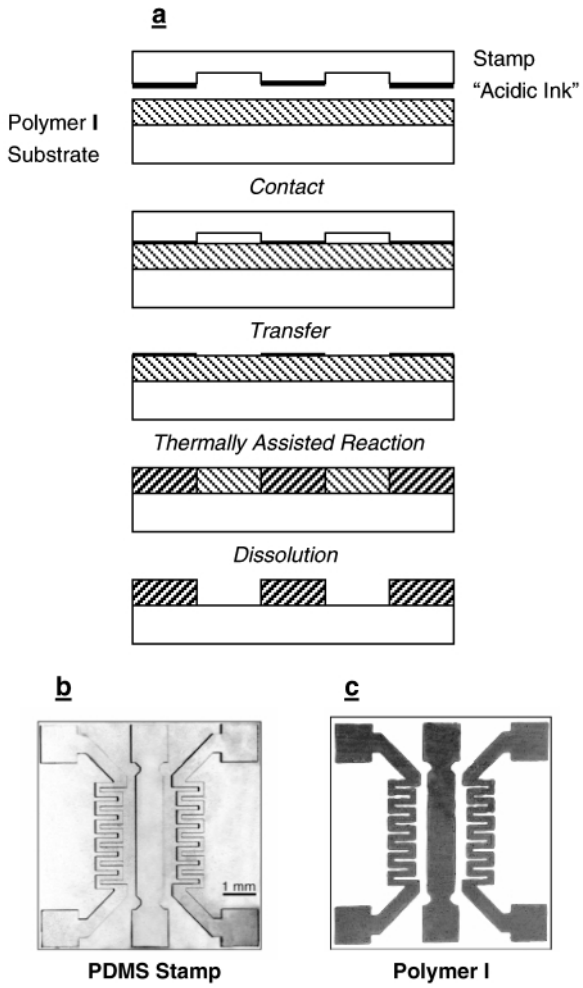

Fig. 2 (a) Scheme depicting chemically amplified soft lithographic process. Micrographs of (b) PDMS stamp and (c) conjugated polymer patterns of **I**.

top of the film by way of a custom-made polydimethylsiloxane (PDMS) rubber stamp. Heating to 130 °C for just 10 s caused elimination of THP in the regions where acid was deposited. No reaction was observed to occur prior to heating as judged by FTIR analysis. The regions reacted were rendered insoluble by virtue of the residual hydroxy group and the overall change in polarity.[6] A positive image of the stamp was obtained by developing the film in solvent (Fig. 2).

Using UV-vis and FTIR spectroscopic analysis, it was found that 2.1 μg cm^{-2} acid was typically transferred to the surface of film using the stamping procedure. The molar ratio of acid to thienyl rings is calculated to be 1 : 4 for a 90 nm thick film. The reaction is thus catalytic in acid and chemically amplified. FTIR of the imaged polymer film indicted a loss of THP and formation of –OH as described previously. UV-vis spectra of the polymeric patterns were similar to **I** indicating that the conjugated polymer backbone is left intact. Furthermore, redox doping of the film with oxidants such as $FeCl_3$ resulted in a color change from deep purple to transparent pale gray and an increase in transmittance from 46 to 91% at 570 nm (for a 50 nm thick film) indicating its potential suitability for patterned electrochromic devices. The conductivity of the doped form is 12 S cm^{-1}, on a par with poly(3-alkylthiophenediyl).

In summary, chemically amplified soft lithography is a non-photolithographic method that circumvents photochemical damage. Films are formed prior to patterning, which may allow for further control of film thickness, morphology, and adhesion over other deposition methods. Furthermore, since the patterned polymer is rendered insoluble, it is possible to deposit multiple layers of similar or dissimilar conjugated polymers. Evaluation of patterned films in field effect transistors, light emitting devices, and electrochromic devices is in progress.

We thank the Natural Sciences and Engineering Research Council of Canada for financial support and Ms Ewa Czyzewska and Mr Bill Woods for their help in the fabrication of the PDMS stamp. We also thank Bayer Corp. for the gift of 3,4-ethylenedioxythiophene (EDOT) monomer.

Synthesis of polyesteramides by a new palladium catalyzed carbonylation–polycondensation reaction

Shrikant M. Kulkarni, Ashutosh A. Kelkar and Raghunath V. Chaudhari*

Homogeneous Catalysis Division, National Chemical Laboratory, Pune – 411008 India. E-mail: rvc@ems.ncl.res.in

Received (in Cambridge, UK) 18th April 2001, Accepted 30th May 2001
First published as an Advance Article on the web 21st June 2001

Alternating polyesteramides are prepared by palladium catalyzed carbonylation–polycondensation reactions of aromatic diiodides and aminohydroxy compounds in the presence of an organic base.

Palladium catalyzed carbonylation–polycondensation reactions are emerging as a new versatile synthetic tool for the preparation of a number of high performance polymers such as polyamides, polyesters, polyimides, polybenzoxazoles, poly(acylhydrazides) *etc.*[1–5] The most rewarding feature of these catalytic reactions is that they allow direct use of carbon monoxide, which is one of the cheapest and most easily available monomers. Conventionally, most of the above polymers are prepared by condensation reactions employing aromatic diacids or their suitable derivatives. One of the major problems associated with conventional condensation reactions is that they use corrosive and moisture sensitive acid chlorides as raw materials. Also, such condensation methods are suitable only if the appropriate diacid is easily available. However, difficulty arises if diacids with less common substitution patterns are required. Thus, it is highly desirable to have a simple alternative synthetic procedure for the synthesis of these polymers which do not require the presence of acid functionalities on the monomer. Palladium catalyzed carbonylation–polycondensation is certainly a promising reaction, at least on the laboratory scale for the preparation of such macromolecules.

We are currently exploring the synthetic utility of transition metal catalyzed carbonylation reactions in the preparation of functional polymers. Here, we report for the first time, on the synthesis of novel alternating polyesteramides by palladium catalyzed carbonylation–polycondensation reactions of aromatic diiodides with aminohydroxy compounds. Polyesteramides contain both ester and amide functions and thus are hybrid structures of polyesters and polyamides. These polymers are of interest because of their good heat resistance and gas barrier properties.[6] Polyesteramides containing mesogenic biphenylene units would be of particular interest because of their liquid crystalline properties. Until now these polymers have been prepared by condensation of diacids or their derivatives with aminohydroxy compounds. The carbonylation route proposed here eliminates the need for diacid derivatives and provides a cleaner synthetic route.

The reaction of aromatic diiodides and aminohydroxy compounds in the presence of carbon monoxide, a catalytic amount of palladium complex and a base leads to carbonylation–polycondensation polymerization to give polyesteramides (Scheme 1).† The carbonylation reactions were carried out under comparatively mild conditions (120 °C and 45 psi of CO pressure) and a variety of polyesteramide derivatives were prepared using this approach. The results are presented in Table 1. Experiments using fully aromatic substrates (Table 1, entries 1 and 5) gave products which were insoluble in common solvents while those obtained from flexible units were soluble in *N*-methylpyrrolidone (NMP). A typical molecular weight of the THF soluble fraction of polyesteramide (Table 1, entry 2) as determined from GPC analysis was 5000 (polystyrene standard). All polymers exhibited distinct and characteristic IR frequencies corresponding to ester carbonyl (around 1720 cm^{-1}) and amide carbonyl functional groups (around 3340 and 1640 cm^{-1}). Thermogravimetric analysis (TGA) indicated that all polymers were stable in air up to at least 350 °C. A typical proton NMR spectrum of the polyesteramide (Table 1, entry 2) shown in Fig. 1 is in accordance with the earlier literature report on similar polymers.[7] The spectrum indicates the absence of any ether or amine linkages, at least in detectable amounts, (arising because of competing *N* and/or *O*-arylation reactions) and confirms the structural homogeneity of the polyesteramide produced by the catalytic carbonylation route.

It was observed that no polyesteramide could be formed in the absence of a base. The organic base employed served as a scavanger for the HI released during the reaction course. Sterically hindered tertiary amines like 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) were particularly effective.

The effect of solvent on the carbonylation–polycondensation was investigated and results are presented in Table 2. It was observed that the highest yield (85%) of polyesteramide was obtained in chlorobenzene as solvent while no polymer was obtained in dichloromethane. Similarly, highest inherent viscosity (0.25 dL g^{-1}) of the polyesteramide was obtained in chlorobenzene solvent.

Scheme 1 Polyesteramide synthesis by carbonylation–polycondensation.

Table 1 Synthesis and properties of polyesteramides[a]

[e] Insoluble in NMP.

 DOI: 10.1039/b103438n

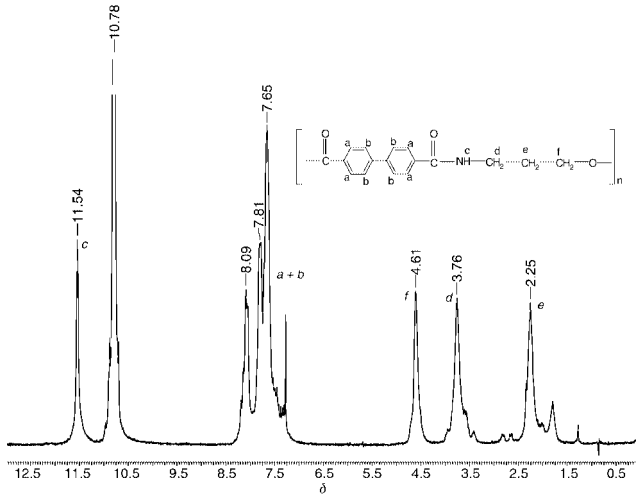

Fig. 1 Proton NMR spectra (200 MHz, trifluoroacetic acid–chloroform-d_1, 20:80) of the polyesteramide prepared by the carbonylation route (Table 1, entry 2).

The effect of temperature on polymer yield and viscosity was also investigated using chlorobenzene as a solvent and the results are given in Fig. 2. There was no significant change in the polymer yield as a function of temperature but the viscosity of the resulting polymer was influenced by the reaction temperature. The viscosity was highest at 120 °C and decreased above or below this temperature.

It is well known that Pd(0) complexes can oxidatively add aryl iodide even in the absence of added phosphine ligand because of the high reactivity of iodo derivatives.[8] However, we preferred adding phosphine ligand during these studies for efficient separation and recycling of the catalyst. The polymers were insoluble in chlorobenzene and therefore could be separated by simple filtration or decantation. The filtrate containing the soluble Pd–phosphine complex was then recycled with fresh reactants. We found that even after four recycles, there was no appreciable loss in the catalytic activity, yield and the inherent viscosity of the resulting polymer.

It was also noted that the dibromoaromatics were less effecive in these reactions and the resulting polymers were obtained in lower yields and with lower viscosities than those obtained with the corresponding diiodoaromatics.

In conclusion, we have successfully demonstrated the application of palladium catalyzed carbonylation–polycondensation reaction for the preparation of polyesteramides. Our studies indicate that a variety of polyesteramides can be prepared efficiently by this method. This approach has three important advantages. First, it eliminates the need for corrosive, moisture-sensitive acid chlorides. Second, literature reports indicate the possibility of preparing a wide variety of diiodoaromatic substrates with high regioselectivity.[9] Third, the catalyst and iodine recyclability is good. The iodide formed during the reaction can be reoxidized to iodine and used in the subsequent iodination to prepare the diiodoaromatics.[1] The only serious problem at present seems to be the fairly low degree of polymerization. We are currently exploring this reaction in more detail to optimize reaction conditions to obtain higher molecular weight polyesteramides.

S. M. K. thanks the Council of Scientific and Industrial Research, New Delhi, India for the award of a Senior Research Fellowship for this work.

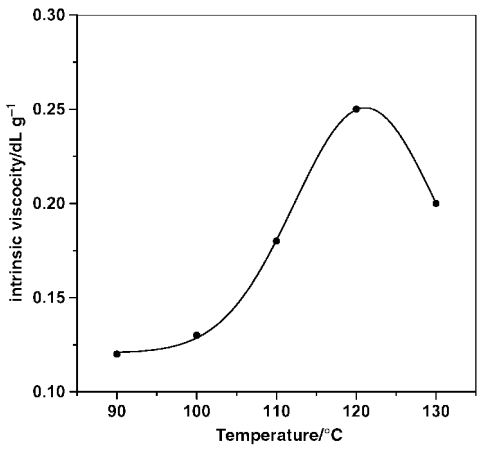

Fig. 2 Effect of temperature on intrinsic viscosity.

Notes and references

† *Experimental procedure*: polymerization reactions were carried out in a 50 mL capacity autoclave. The contents were charged into the reactor and flushed twice with nitrogen to ensure removal of air. The autoclave was then heated to the desired temperature. After the temperature had equilibrated at a set point, CO was introduced at the desired level. During the course of the reaction the CO pressure in the reactor was maintained constant by adding more CO as it was consumed. After completion of the reaction, the reactor was cooled and the excess CO vented. The polymers separated either as solids or viscous oils. The solution containing the catalyst was separated either by filtration or decantation accordingly. The crude polymer was dissolved in NMP and precipitated by methanol, filtered off and dried *in vacuo*.

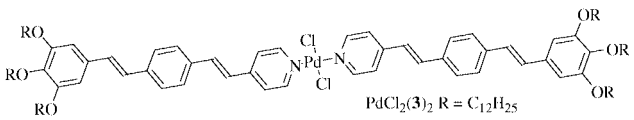
First published as an Advance Article on the web 21st June 2001

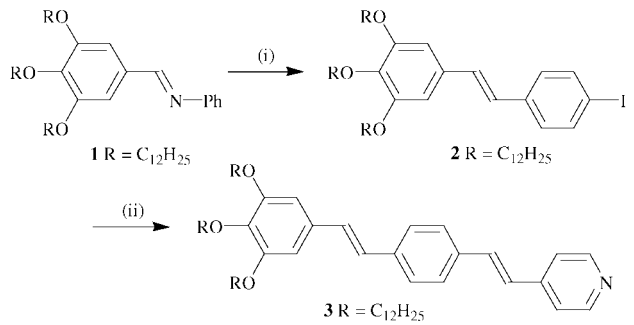
Dimerization of a new styrylstilbazole ligand through non-covalent interactions leads to polycatenar calamitic supramolecular structures with liquid crystalline properties.

The organization of a molecular assembly into a liquid crystalline phase requires a microphase separation resulting from the amphipathic character of two chemically incompatible parts in the molecules, in general a rigid core and paraffinic chains. The self-assembly of building blocks through non-covalent bonds is also able to generate such a structural segregation, thus allowing molecular units without intrinsic mesomorphic properties to form supramolecules presenting liquid crystalline properties.[1–7] The most widely used interactions to obtain self-assembled structures with mesomorphic properties are coordination to a metal center[2–4] (metallomesogens) or hydrogen bonds.[5–7] The use of weaker interactions such as van der Waals or hydrophobic forces have been probed to a much lesser degree.[8] Here we report on the synthesis of a calamitic polycatenar non-mesogenic pyridine containing ligand, and the preparation of supramolecular mesogens by using coordination to a metal and ionic bonds, but also van der Waals forces.



$PdCl_2(\mathbf{3})_2$ R = $C_{12}H_{25}$

The synthesis of **3** is depicted in Scheme 1. Treatment of benzaldimine **1**[7] with 4-iodotoluene under Siegrist conditions gave iodostilbene *E*-**2**. Subsequent Heck coupling of *E*-**2** with 4-vinylpyridine with $Pd(OAc)_2$ as catalyst in Et_3N–toluene in presence of tri-*o*-tolylphosphine (POT) gave **3** in 80% yield. All of the spectroscopic studies and elemental analyses were consistent with the proposed molecular structures.† In particular, coupling constants of *ca*. 16.5 Hz for the two AB systems corresponding to the two sets of vinylic protons in the ^{1}H-NMR spectrum confirmed the *E* stereochemistry of both double bonds in **3**. The electronic absorption and emission of styrylstilbazole



1 R = $C_{12}H_{25}$ **2** R = $C_{12}H_{25}$ **3** R = $C_{12}H_{25}$

Scheme 1 *Reagents and conditions:* i, 4-iodotoluene, *t*-BuOK, DMF, 80 °C, 1 h (50%); ii, 4-vinylpyridine, $Pd(OAc)_2$, POT, Et_3N–toluene, 90 °C, 12 h (80%).

3 are reported in Fig. 1. Compound **3** exhibits a strong absorption (λ_{max} = 367 nm). Interestingly, addition of increasing amounts of TFA to a solution of **3** causes dramatic changes in the absorption spectrum, the peak being completely shifted at *ca*. 10 equivalents of acid added. Isosbestic points are maintained at 313 and 388 nm indicating that a single chemical process occurs, *i.e.* protonation of the pyridine ring. The initially pale yellow solution becomes orange–yellow at the end of titration. The addition of acid also leads to changes in the emission properties (λ_{exc} = 313 nm, isosbestic point). The strong blue luminescence of the ligand (λ_{max} = 501 nm) progressively disappears and a very weak red-shifted emission (λ_{max} = 615 nm) corresponding to the luminescence of protonated **3** is detected at the end of the titration (Fig. 1). Addition of a base (DBU) restores the initial absorption and luminescence properties. Therefore ligand **3** also presents characteristic features that make it an interesting building block for the preparation of new molecular switches.[9]

The observation of **3** under optical microscopy does not reveal any liquid crystalline properties and only shows a melting point at 83 °C. It is well known that metal complexes of polycatenar stilbazole derivatives show mesomorphic properties.[3,4] Ligand **3** is also a suitable building block for the preparation of related metallomesogens. The *trans*-Pd(II) complex of **3** has been prepared according to the procedure developed by Bruce and co-workers.[3] Treatment of **3** with $PdCl_2(CH_3CN)_2$ in a mixture of CH_2Cl_2–CH_3CN 1 : 1 afforded $PdCl_2(\mathbf{3})_2$ in 95% yield.‡

Observation of this Pd(II) complex under a polarizing microscope reveals typical textures of a columnar mesophase from 165 to 234 °C. Differential scanning calorimetry (DSC) analyses and X-ray diffraction patterns recorded for $PdCl_2(\mathbf{3})_2$ at different temperatures were in full agreement with these observations. Indeed, the X-ray pattern is characterized in the small angle region by two sharp reflections in the ratio 1 : $\sqrt{3}$, corresponding to a two-dimensional hexagonal lattice. The

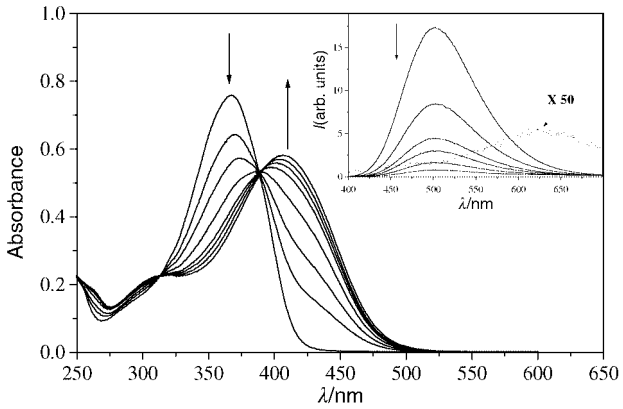


Fig. 1 Absorption and (inset) fluorescence (λ_{exc} = 313 nm, isosb. point) spectra of CH_2Cl_2 solutions of ligand **3** containing 0, 0.5, 1, 2, 4, 6, 10, 100 equiv. of TFA (the emission spectrum recorded after addition of 100 eq. of TFA is multiplied by a factor of 50).

 DOI: 10.1039/b103563k

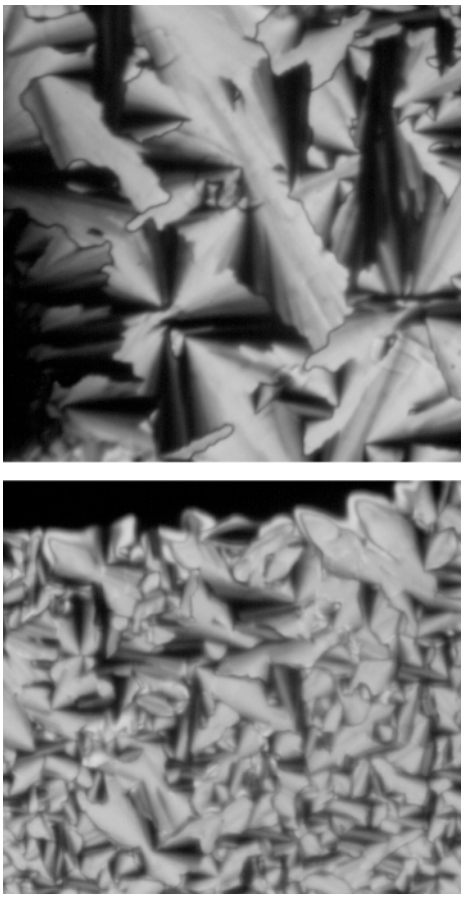

Fig. 2 Top: optical texture observed with a polarizing microscope at 150 °C for the complex prepared from **3** and perfluorosuberic acid. Bottom: optical texture observed with a polarizing microscope at 120 °C for the complex prepared from **3** and TFA.

dimerization of **3** *via* coordination to a metal center is therefore able to produce a polycatenar calamitic supramolecule with liquid crystalline properties.

It has been shown that H-bonding can be used to assemble pyridine derivatives with carboxylic acids to produce linear structures that exhibit liquid crystalline behavior.[5] The treatment of styrylstilbazole **3** with various dicarboxylic acids (oxalic acid, α,ω aliphatic dicarboxylic acids of different lengths and terephthalic acid) was therefore attempted in order to obtain supramolecular derivatives with an appropriate shape to produce columnar mesophases. Unfortunately, homogeneous samples could not be obtained and macrophase separation was observed in all the cases. The interactions (if any) of **3** with these dicarboxylic acid derivatives seem to be too weak to allow the preparation of the desired supramolecular assemblies. This observation prompted us to use a more acidic derivative able to protonate styrylstilbazole **3** in order to produce a stable adduct thanks to the resulting ionic interactions. Slow evaporation of a CH_2Cl_2 solution of **3** and perfluorosuberic acid [HO_2C-$(CF_2)_6CO_2H$; 0.5 equiv.] afforded an orange crystalline solid. The orange color and the presence of a strong band at 1623 cm^{-1} in the IR spectrum (neat) are in good agreement with the formation of a carboxylate salt.

Observation of the resulting complex under a polarizing microscope reveals an optical texture characteristic of a columnar mesophase from 124 to 170 °C (Fig. 2). The dicarboxylic acid and **3** seem therefore able to form a supramolecular dimer stabilized by electrostatic forces with the appropriate polycatenar calamitic shape to produce a columnar liquid crystalline phase.

The treatment of **3** with TFA (1 equiv.) under similar conditions also leads to an orange crystalline solid and the development of typical columnar texture was observed from 70 to 143 °C for the resulting compound (Fig. 2). In addition to the electrostatic interactions among **3** and TFA, it seems that fluorophilic interactions allow the dimerization of the resulting **3** TFA species and, thus are able to direct their self-organization into a columnar liquid crystalline phase. It is worth noting that salts prepared from **3** and inorganic acids such as HCl do not exhibit any mesomorphic properties. The latter observation shows that protonation of **3** alone is not sufficient to produce liquid crystalline derivatives. Thus the fluorophilic interactions must play an important role.

The mesomorphic properties of the complexes obtained from **3** and perfluorosuberic acid or TFA have been studied by DSC and X-ray diffraction. The hexagonal lattice parameters deduced from the X-ray patterns (50 Å at 140 °C for the adduct with perfluorosuberic acid and 48 Å at 140 °C for the adduct with TFA) are similar to that found for the complex $PdCl_2(\mathbf{3})_2$ (45 Å at 160 °C). This observation strongly suggests an effective dimerization of **3** through non-covalent interactions as discussed above.

Treatment of **3** with a palladium salt, perfluorosuberic acid or TFA afforded discrete assemblies with new properties. Effectively, **3** itself does not show any mesomorphic properties, but its dimerization through self-assembling by coordination, ionic or fluorophilic interactions leads to discrete supramolecular structures with liquid crystalline properties.

We thank B. Heinrich for his help with the X-ray measurements and L. Oswald for technical assistance.

Polymers and rings in gold(I) diphosphine complexes: linking gold rings through aurophilic interactions

Marie-Claude Brandys and Richard J. Puddephatt*

Department of Chemistry, University of Western Ontario, London, Canada, N6A 5B7. E-mail: pudd@uwo.ca

Received (in Columbia, MO, USA) 3rd April 2001, Accepted 24th April 2001
First published as an Advance Article on the web 21st June 2001

Gold(I) complex cations of empirical formula $Au[Ph_2P(CH_2)_nPPh_2]^+$ crystallize as rings $[Au_2\{Ph_2P(CH_2)_nPPh_2\}_2]^{2+}$ when n = 3 or 5 but as a polymer $[\{Au[Ph_2P(CH_2)_nPPh_2]\}_x]^{x+}$ when n = 4. In favorable cases, the ring complexes can be connected through aurophilic bonding by addition of $[Au(CN)_2]^-$, and crystals contain pentagold units when n = 3 or polymeric pleated chains when n = 5.

In the context of the rapidly developing field of coordination polymers,[1] and of gold(I) diphosphine complexes that may have interesting photophysical and biological properties,[2] this article reports two new one-dimensional polymers containing gold(I) diphosphine units, one being the first polymer containing linear gold(I) centres with only diphosphine ligands and the other the first to contain gold rings stitched together by using aurophilic attractions.[1,3] The factors that are important in giving self-assembly of polymeric structures are elucidated.

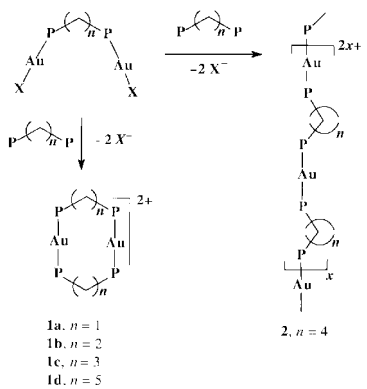
The complexes of empirical formula $AuX[Ph_2P(CH_2)_nPPh_2]$ have been suggested to exist as ring complexes $[Au_2\{\mu\text{-}Ph_2P(CH_2)_nPPh_2\}_2]^{2+}(X^-)_2$,[4] though more complex structures may be formed in cases when the anion X^- is also a ligand to give a higher coordination number than two at gold(I).[1,4] However, it is now shown that the derivatives with X = CF_3CO_2, prepared as in Scheme 1, exist as rings **1** when n = 1, 2, 3 or 5 but as a unique polymeric chain complex **2** when n = 4.

The ring complexes **1** give sharp singlet resonances in the ^{31}P NMR spectra while **2** gives several overlapping and broader resonances.† The complexes were isolated as the trifluoroacetate salts, and complexes **1c** and **2** were characterized by X-ray structure determination (Fig. 1).‡

Why does complex **2** have a structure that is different from the others? The answer is not obvious but can be analyzed in terms of two effects. First, when n = 1 or 2, the ring structure is favored because transannular Au···Au attractions are possible[1–4] and this effect is dominant in these cases. Second, there is a relative preference for the *anti*, rather than *syn*, orientation of the two PPh_2 groups, and hence formation of chains rather than rings, when n is an even integer.[1] Only when n = 4 does the preference for the *anti* conformation prevail and lead to the novel polymeric structure of **2** (Fig. 1). The NMR data suggest, but do not prove, that the solid state structures are maintained in solution.

Can the rings **1** (Scheme 1) be linked to form polymers? The complexes **1** were reacted with potassium dicyanoaurate in the expectation that both ionic and aurophilic attractions between the cationic and anionic gold(I) centres in **1** and $[Au(CN)_2]^-$ would promote association. In solution, these reactions lead to mixtures containing the original ions and the neutral diphosphine gold(I) cyanide complexes **3** (Scheme 2) as established by NMR [^1H, ^{13}C on ^{13}CN enriched samples, ^{31}P; complexes **3** are readily identified by the large coupling $^2J(PC)$].† Crystallization from these solutions gave **3** when n = 1 or 2, but the linked ring complex **4** when n = 3 and the novel polymer **5** when n = 5 (Scheme 2). Both **4** and **5** crystallized as the dicyanoaurate salts and so also contain free $[Au(CN)_2]^-$ anions.‡

The structures of **4** and **5** are shown in Fig. 2. In complex **4** two rings are connected by an $[Au(CN)_2]^-$ ion through aurophilic interactions to give the unit $[\{Au_2(\mu\text{-}Ph_2PCH_2CH_2CH_2PPh_2)_2\}_2\{Au(CN)_2\}]^{3+}$, with only one of the two AuP_2^+ centres of each ring involved in Au···Au bonding. However, in complex **5** all the AuP_2^+ centres are involved in



Scheme 1 P = PPh_2.

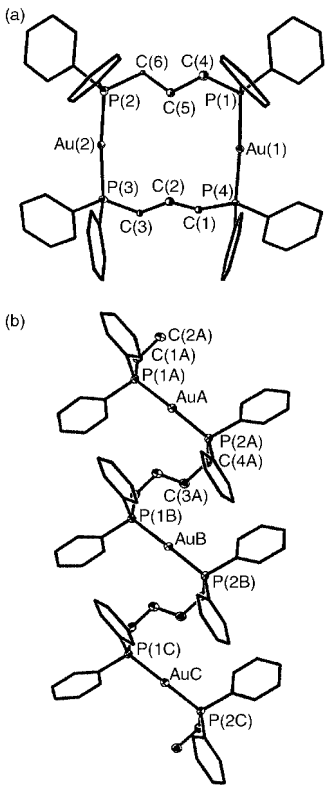


Fig. 1 Structures of the cationic units in (a) the ring complex **1c** and (b) the polymeric complex **2**. For clarity, thermal ellipsoids are not shown for phenyl carbon atoms.

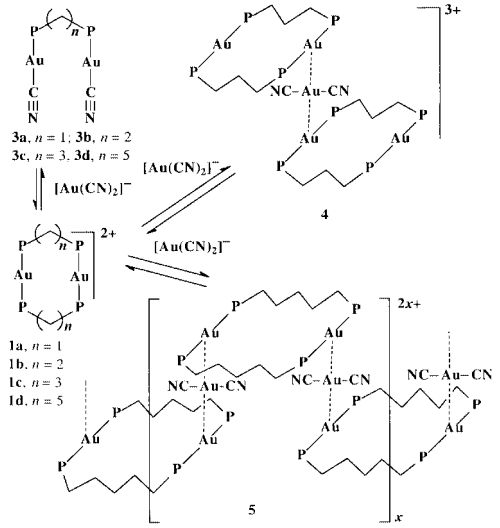
 DOI: 10.1039/b103020p



Scheme 2 P = PPh_2.

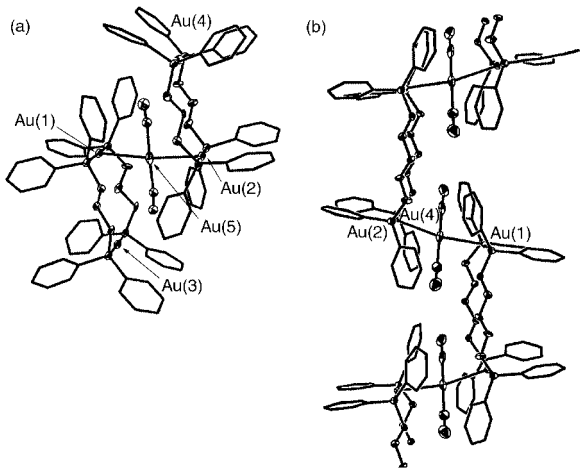


Fig. 2 Structures of the linked ring complex cations in (a) complex **4** and (b) complex **5**. The parameters corresponding to aurophilic attractions are: for complex **4**, Au(1)–Au(5) 3.059(3) Å, Au(2)–Au(5) 3.034(3) Å; Au(1)–Au(5)–Au(2) 172.1(1)°. For complex **5**, Au(1)–Au(4) 2.9906(8), Au(2)–Au(4) 3.0665(8) Å, Au(1)–Au(4)–Au(2) 165.26(3)°.

Au···Au bonding and so the pleated-chain polymeric structure $[\{Au_2[\mu\text{-}Ph_2P(CH_2)_5PPh_2]_2\}_2\{Au(CN)_2\}_2]_x^{2x+}$ results. By inspection of Fig. 2, it is immediately clear that the structure observed for **5** would not be possible for **4** because the transannular Au···Au distance is too short to allow both gold atoms to be linked to approximately collinear $[Au(CN)_2]^-$ units. Phenyl–phenyl repulsions prevent bridging in other ways to link units of **1a**, **1b** or **1c**.

The complexes **4**, **2** and **5**, as the dicyanoaurate salts, give rather similar solid state emission spectra, with maxima at 419, 414 and 411 nm, respectively. This indicates that the extended structures present in **2** (n = 4) and **5** (n = 5) do not greatly affect the photophysical properties of the complexes, when compared to the more limited association in **4**.

The ability to control the self-assembly of extended structures is becoming increasingly important. This article shows how conformational differences in simple, commonly used diphosphine ligands can be used to control whether ring or polymeric structures will be formed in gold(I) complexes and, for the ring compounds, how the distance between phosphorus donors is critical in determining if the rings can be linked to give extended structures.

We thank the NSERC (Canada) for financial support and for a scholarship to M.-C. B. and R. J. P. thanks the Government of Canada for a Canada Research Chair. We thank Dr M. C. Jennings for X-ray data collection.

Molecularly imprinted ionically permeable membrane for uranyl ion

Anael Kimaro,[a] Lisa A. Kelly[a] and George M. Murray*[b]

[a] *Department of Chemistry and Biochemistry, University of Maryland, Baltimore County, Baltimore, MD, USA*
[b] *Johns Hopkins University Applied Physics Laboratory, Laurel, MD, USA. E-mail: george.murray@jhuapl.edu*

Received (in Cambridge, UK) 4th April 2001, Accepted 4th June 2001
First published as an Advance Article on the web 27th June 2001

A polymeric membrane for the separation of specific metal ions can be designed by the application of the molecular imprinting technique.

The transport of metal ions through membranes has been studied as a means of separation, concentration and recovery of both valued and toxic metal ions.[1–5] These efforts are driven by environmental concerns and dwindling natural resources. The development of efficient and selective metal ion transporting systems for use in such operations is of great interest. Two types of membranes are predominant in membrane transport systems: supported liquid membranes and polymeric membranes. The convenience and high flux characteristics of supported liquid membranes have made popular these types of membranes.[5–7] However, the low stability, strength and finite solubility of the active agent used in liquid supported membranes limit their practical application. Polymeric membranes have the physical and chemical stability for practical applications, but are often hampered by low transport flux. In many applications, selectivity is the most important function. The most selective membrane will have a specific transporting or penetrating path, pore or matrix through which only the desired substrate is able to pass. Specific receptor sites in polymeric membranes can be introduced by the molecular imprinting technique.[8]

Molecular imprinting is a process for making selective recognition sites in synthetic polymers. The process employs a target molecule as the template. The template is surrounded by molecular compliments that possess polymerisable functionalities. The template complex is typically copolymerised with a matrix monomer and a cross-linking monomer in the presence of a suitable solvent. The cross-linking monomers add rigidity to the finished polymer and the solvent provides site accessibility. Removal of the template molecules leaves behind cavities that exhibit enhanced affinity for rebinding the target molecule. Previously, using vinylbenzoic acid and vinylsalicyladoxime, we used the molecular imprinting technique to prepare ion exchange resins that are selective for the sequestration of uranyl ions.[9] Recently, Saunders *et al.* reported an imprinted polymer extractant based on chloroacetic acid.[10] However, the utility of a permeable membrane for the selective transport of metal ions has remained relatively unexplored. In this communication, we report our initial results and observations concerning the transport of uranyl ions through an imprinted polymer membrane. The molecular imprinting technique has been exploited in preparing membranes with molecular recognition sites for low weight organic molecules, as reported in a recent review.[11] Mathew-Krotz and Shea[12] reported imprinted polymer membranes for the selective transport of targeted neutral (organic) molecules with fluxes up to 0.5 nmol cm^{-2} h^{-1}. The highest selectivity factor was 3.4 for adenosine *vs*. guanosine with 9-ethyladenine imprinted membrane.

The polymeric membranes were synthesized with ingredients for both selective binding and improved permeability. The selective binding site was prepared by using uranyl ion imprinting. Permeability was addressed using a polyester that associates with the metal ions. The length of the alkyl chain in the diol that was used to make the polyester controlled the spacing of association sites. The polyester was removed from the membrane by the same acid treatment used to remove the uranyl ion. Removal was detected by GC-MS of the membrane acid-wash solutions. The polyester is intended to create channels, directing ion migration to the imprinted sites, thus increasing flux but maintaining selectivity. The addition of polyester to the formula had two significant results: the amount of swelling of the membrane in aqueous solutions was dramatically increased, and in the absence of the polyester there was no detectable migration of ions.

Membranes were prepared using uranyl vinylbenzoate, $UO_2(VBA)_2$, as the ion imprinting complex. Styrene was used as the matrix monomer and divinylbenzene was used as the cross-linking monomer. Membrane synthesis was carried out in a screw-top vial by dissolving the uranyl vinylbenzoate complex (20–150 mg) in 400 μL of 2-methoxyethanol. Nitrophenyl octyl ether (NPOE) as a plasticizer and 22 mg of a polyester, prepared from diglycolic acid and 1,6-hexanediol, was added to the polymerisation mixture. After deaeration with dry nitrogen, 20 mg of a free radical initiator, 2,2′-azobisisobutyronitrile (AIBN) were added. The vial was sealed and placed in a sonicator at 60 °C. The solution was sonicated until viscous and then poured into a Teflon mold. The resultant sample was kept in a sealed container and placed in an oven at 60 °C for 18 h to complete the polymerisation. The thickness of the resulting membranes was approximately 100 microns. Table 1 summarizes the composition of membranes A, Q and R. A reference membrane imprinted with Ni^{2+} was prepared in the same manner as membrane Q. The metal templates and the polyester were removed using a 0.1 M acetic acid solution followed by a 5% nitric acid solution. Metal ions were removed using acid until the entire template was recovered. The membrane was then washed with deionised water until the acid was removed.

Transport studies were carried out in a U-shaped tube consisting of two detachable parts. The membrane, with an exposed cross-sectional area of 0.613 cm^2, was placed between the two halves of the tube. The halves were held together with a screw-actuated clamp that compresses an o-ring seal to tightly secure the connection. Experiments were performed under quiescent conditions and also by stirring the solutions. The time-dependence of uranyl ion transport in quiescent solution is

Table 1 The composition of the membrane in wt% of the total components in the original mixture

Reagent	Membrane A	Membrane Q	Membrane R
$UO_2(VBA)_2$[a]	6.7	1.5	1.5
Divinylbenzene	2.0	14.5	24.5
Polyester	1.8	1.8	1.8
AIBN	0.9	1.6	1.6
NPOE	4.6	8.3	8.3
Styrene	84.0	72.3	62.3

[a] $UO_2(VBA)_2$ was dissolved in 0.4 ml of 2-methoxyethanol in each case.

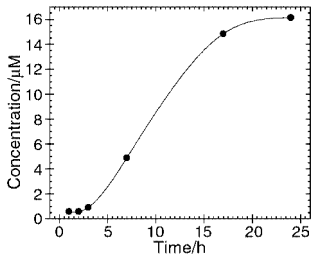

Fig. 1 Transport of uranyl ions across the membrane with time.

given in Fig. 1. The concentration of uranium in the receiving phase was determined by ICP-MS. An experiment performed while stirring the solutions (both the source and the receiving solution) showed that higher fluxes could be obtained by convection. After 24 h of stirring, 25% of UO_2^{2+} in the source solution containing 42 μM UO_2^{2+} was transported through the membrane, compared to 6.5% when the solution was unstirred.

The selectivity of the membrane was evaluated by carrying out competitive transport experiments. A solution containing 0.2 mM of UO_2^{2+}, Ni^{2+}, Cd^{2+}, Cu^{2+} and Zn^{2+} was used as a source solution. After 22 h, a portion of the receiving solution was analysed by ICP-MS to determine the amount of each ion that was transported across the membrane. Fluxes of the competing ions were found to be very small (Table 2). UO_2^{2+} was transported at higher rate, with a selectivity factor (α) ranging from 114 to 152. The selectivity factor is defined as the ratio of the molar concentration of uranyl ion to the molar concentration of the competing metal ions measured in the receiving solution.

Table 2 Transport of uranyl ion through the membrane in the presence of competitors; selectivity

Metal ion	Amount diffused/μM	Flux/nmol cm^{-2} h^{-1}
UO_2^{2+}	11.8 ± 0.1	2.74
Ni^{2+}	0.104 ± 0.002	0.024
Cd^{2+}	0.086 ± 0.001	0.019
Zn^{2+}	0.076 ± 0.001	0.018
Cu^{2+}	none detected	

Membrane A, composition: 6.7 wt% complex, 2 wt% cross-linker.

The origin of selective transport can be attributed to the selective binding of uranyl ion to imprinted sites along channels that span the membrane. The reference membrane prepared by imprinting with nickel showed little permeation of uranyl ions, but higher permeation of some of the competing metal ions. The transport fluxes of UO_2^{2+}, Cu^{2+} and Co^{2+} through the reference membrane were 0.015 ± 0.002, 0.142 ± 0.003 and 0.045 ± 0.001 nmol cm^{-2} h^{-1} respectively. No Ni^{2+} or Zn^{2+} was detected in the effluent, suggesting that the conditions for membrane preparation may need to be established on a case by case basis. The results do show that the Ni^{2+} ion imprinted membrane does not have sites selective for uranyl ions. The selective transport observed in the uranyl ion imprinted membrane arises from a process that involves preferential and reversible complexation for uranyl ion. Metal ion transport across the membrane requires a counter flow of cations in the reverse direction to maintain electroneutrality. A surplus of protons was maintained in the receiving solution by the addition of acid. A scanning electron micrograph of the membrane shows that the surface of the membrane has pores in the micron and submicron range (Fig. 2). Micrographs of the inside of the membranes show an open porous structure. Energy dispersive X-ray emission spectra of the pore area show larger amounts of uranium in the pores relative to the surrounding area, suggesting that the pores are involved in metal ion transport.

The effects of the imprinting conditions on the membrane performance were investigated by preparing membranes with different degrees of cross-linking. Each membrane's performance towards uranyl ion was examined. Using source solutions that contained a range of UO_2^{2+} concentrations from 0.25 to 0.42 mM, the transport fluxes were measured and compared. These results are shown in Table 3.

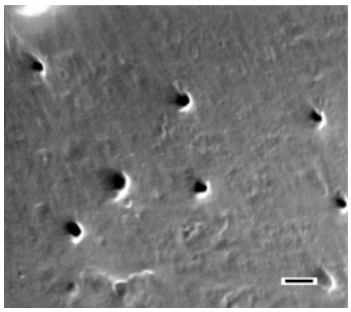

Fig. 2 Scanning electron micrograph of the membrane (bar = 1 μm).

Table 3 Effects of cross-linker and concentration of the source solution on the transport flux

	Flux/nmol cm^{-2} h^{-1}	
UO_2^{2+} (source)/mM	Membrane Q[a]	Membrane R[b]
0.25	0.83 ± 0.03	0.34 ± 0.02
0.34	0.96 ± 0.04	0.68 ± 0.02
0.42	1.21 ± 0.02	0.91 ± 0.03

[a] 1.5 wt% complex, 14.5 wt% cross-linker. [b] 1.5 wt% complex, 24.5 wt% cross-linker.

The membrane with a lower degree of cross linking (Q) exhibited higher fluxes than the membrane with a higher degree of cross-linking (R). The selectivity of the two membranes was verified by the competitive transport test described above. The results show that the membrane with the higher flux also exhibits higher selectivity (α_{Cd} for Q = 56 and for R = 10). Repeated uses of the membranes did not show a loss of selectivity. This result is in agreement with previous work on Pb^{2+} imprinted ion-exchange resins.[13]

In conclusion, the present study demonstrates that a polymeric membrane can be designed for the separation of a specific metal ion from a mixed metal ion solution. The selectivity imparted by the imprinting technique is high.

Received (in Cambridge, UK) 2nd March 2001, Accepted 1st June 2001
First published as an Advance Article on the web 27th June 2001

Cyclic voltammetric examination of $[Co_4O_4(O_2CR)_2(bpy)_4](ClO_4)_2$ cubane complexes 1 (R = various; bpy = 2,2′-bipyridine) in MeCN reveals a one-electron reversible oxidation in the range 0.68–0.86 V *vs.* ferrocene; the one-electron oxidized clusters can be obtained in analytical purity by either controlled potential electrolysis to give $[Co_4O_4(O_2CR)_2(bpy)_4](ClO_4)_3$ 2 or oxidation with $(NH_4)_2Ce(NO_3)_6$ to give $[Co_4O_4(O_2CR)_2(bpy)_4][Ce(NO_3)_6]$ 3.

The ability of hard oxide (O^{2-}) ions to stabilize unusually high metal oxidation states has long been recognized in such textbook species as MnO_4^- and CrO_4^{2-}. More recently, some interesting new examples have been identified in which bridging O^{2-} ions stabilize rare oxidation states of Fe and Cu in non-mononuclear chemistry: apart from their intrinsic importance, such species offer insights into the mode of action of certain metalloenzymes. Thus, the $Fe^{III}Fe^{IV}$ oxidation level, thought to correspond to species X of ribonucleotide reductase,[1,2] has been obtained in oxide-bridged Fe_2 complexes,[2,3] whereas a $2Fe^{IV}$ species is believed to be species Q of methane monooxygenase.[1] Similarly, the $[Cu_2(\mu\text{-}O)_2]^{2+}$ core ($2Cu^{III}$) has been structurally characterized,[4,5] as well as a related species containing the $[Cu_3(\mu_3\text{-}O)_2]^{3+}$ core ($2Cu^{II}$, Cu^{III}).[6] Such species offer valuable insights into Cu-mediated O_2-activation biochemistry. We have now discovered that the cubane $[Co_4(\mu_3\text{-}O_4)_4]^{4+}$ core containing $4Co^{III}$ can be oxidized to a $3Co^{III}$, Co^{IV} form, and we describe the preparation and characterization of several such novel species.

As reported previously,[7] the D_{2d} symmetry complex $[Co_4O_4(O_2CR)_2(bpy)_4](ClO_4)_2$ **1** (R = Me; bpy = 2,2′-bipyridyl) can be prepared by deprotonating $[Co_2(OH)_2(O_2CMe)_3(bpy)_2](ClO_4)$ with Li_2O_2 in DMSO. A series of $[Co_4O_4(O_2CR)_2(bpy)_4](ClO_4)_2$ **1** complexes has now been prepared by ligand substitution with RCO_2H in refluxing MeCN, and electrochemical examination of these $[Co_4O_4]^{4+}$ complexes by cyclic voltammetry (CV) reveals irreversible reductions at $\leqslant -1.4$ V *vs.* ferrocene and a reversible one-electron oxidation at *ca.* 0.7 V *vs.* ferrocene. The CV scan for the R = $C_6H_4NO_2$-4 complex is shown in Fig. 1, and the oxidation potentials as a function of R group are listed in Table 1. The peak separations are comparable with that of the ferrocene/ferrocenium couple used as an internal reference (Fig. 1). Controlled potential coulometry at 0.90 V *vs.* ferrocene for the R = C_6H_4Me-4 and C_6H_4OMe-4 species gave 0.9–1.0 e^-/Co_4 transferred, confirming a one-electron oxidation process. The CV are thus consistent with oxidation to $[Co_4O_4(O_2CR)_2(bpy)_4]^{3+}$, which would contain $3Co^{III}$,Co^{IV} if the oxidation were metal-based. Metal/bpy complexes can often exhibit bpy-based reversible reductions but not oxidations.[8]

Analytically-pure oxidized clusters† were prepared in bulk by two methods: (i) controlled potential electrolysis in MeCN or MeCN–CH_2Cl_2 containing 0.4 M $LiClO_4$ at 0.90–1.00 V *vs.* ferrocene, which caused precipitation of $[Co_4O_4(O_2CR)_2(bpy)_4](ClO_4)_3$ **2** in $\geqslant$ 85% yield as microcrystalline powders; and (ii) oxidation with $(NH_4)_2Ce(NO_3)_6$ in MeCN, which caused precipitation of sparingly soluble microcrystalline $[Co_4O_4(O_2CR)_2(bpy)_4][Ce(NO_3)_6]$ **3**.‡ Complexes **2** can be recrystallized from MeCN–Et_2O. EPR spectra at 5 and 75–100 K of the R = C_6H_4Me-4 and C_6H_4OMe-4 derivatives as powders (**3**) or MeCN–toluene (1 : 1) glasses (**2**) show a broad (*ca.* 800 G) signal at g = 2.20 with no resolved hyperfine, consistent with a S = ½ species and a Co-based oxidation. Solid-state magnetic susceptibility studies at room temperature on the same two derivatives of **2** gave $\mu_{eff} \approx 2.2\ \mu_B$, consistent with one unpaired electron. ^{1}H NMR spectra show paramagnetically shifted and broadened signals for **2**, again consistent with S = ½ oxidized clusters whereas complexes **1** are diamagnetic. Comparison of the spectra for **1** and **2** (R = C_6H_4Me-4), for example, show that only four bpy and three carboxylate signals are observed and that the bpy signals are much more shifted on oxidation than the carboxylate signals,

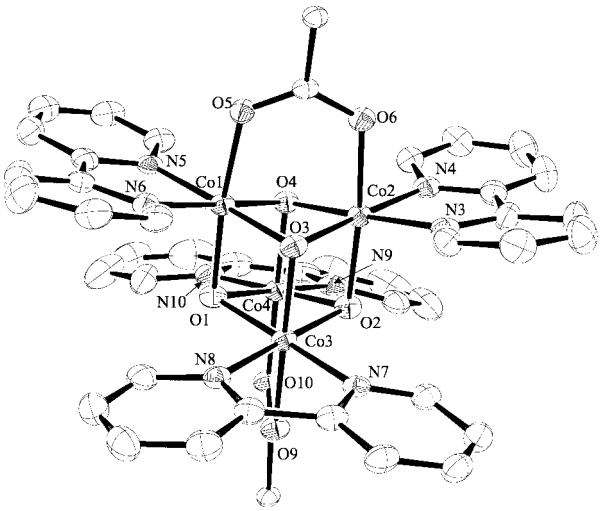

Fig. 2 ORTEP plot of the cation of **2** (R = $C_6H_4NO_2$-4) at the 40% probability level; for clarity, only the *ipso*-C atom of the carboxylate group is shown. Selected distances (Å): Co(1)···Co(2) 2.641(1), Co(1)···Co(3) 2.872(1), Co(1)···Co(4) 2.874(1), Co(2)···Co(3) 2.855(1), Co(2)···Co(4) 2.861(1), Co(3)···Co(4) 2.662(1), Co(1)–O(1) 1.903(4), Co(1)–O(3) 1.882(4), Co(1)–O(4) 1.876(3), Co(2)–O(2) 1.900(4), Co(2)–O(3) 1.877(4), Co(2)–O(4) 1.871(4), Co(3)–O(1) 1.902(4), Co(3)–O(2) 1.878(4), Co(3)–O(3) 1.886(4), Co(4)–O(1) 1.894(4), Co(4)–O(2) 1.882(4), Co(4)–O(4) 1.899(4).

consistent with greater spin delocalization onto the former groups. On the ^{1}H NMR timescale, therefore, the oxidized clusters retain D_{2d} symmetry, which is consistent with electronic delocalization, or detrapping that is fast on the ^{1}H NMR timescale.

The crystal structure‡ of complex **2** (R = $C_6H_4NO_2$-4) was obtained at –100 °C. The cation (Fig. 2) has no crystallographic symmetry, but has virtual D_{2d} symmetry. There is a $[Co_4O_4]$ cubane with a bpy at each Co and a RCO_2^- group bridging two opposite faces; the virtual S_4 axis passes through the latter. Three independent ClO_4^- groups confirm the 3+ charge of the cation. Examination of the bond distances shows that the four Co ions are all equivalent, indicating electronic delocalization and a $Co^{3.25+}$ oxidation state description, even in the solid state at −100 °C. The anisotropic thermal parameters of core Co and O atoms do not appear abnormally large, arguing against a static disorder of a trapped-valence $3Co^{III},Co^{IV}$ system. Protonation of a core O^{2-} ion (and a resulting $4Co^{III}$ description) is ruled out by the absence of Co–O bond lengthening as seen previously[9] in the genuinely protonated species $[Co_4O_3(OH)(O_2CR)_2(bpy)_4]^{3+}$ and $[Co_4O_2(OH)_2(O_2CR)_2(bpy)_4]^{4+}$. Comparison of the structure of **2** (R = $C_6H_4NO_2$-4) with that of **1** (R = C_6H_4Me-4) indicates no significant difference: the largest variation is in the Co–O (carboxylate) distances (average 1.942 Å for **2** *vs*. 1.955 Å for **1**) but these and all the other Co–X distances are statistically the same within the 3σ criterion.

The combined results indicate that the diamagnetic $[Co_4O_4]^{4+}$ core can be oxidized to a paramagnetic (S = ½) $[Co_4O_4]^{5+}$ core that is electronically delocalized, as might be expected for mixed-valence, low-spin Co^{III} (t_{2g}^6), Co^{IV} (t_{2g}^5) species. Cobalt(IV) is still a rare oxidation state, and isolated, well characterized examples that are stable at room temperature are few and all mononuclear,[10] but the combined results above establish that stable $[Co_4O_4]^{5+}$ clusters can be accessed which formally contain $3Co^{III}$, Co^{IV}. Such species could prove useful as a new family of strong oxidizing agents soluble in organic solvents, particularly since their oxidizing strength can be tuned by appropriate choice of organic ligands.

Synthesis and structural characterisation of a boralumoxane capable of activating a zirconocene ethene polymerisation catalyst†‡

Bodo Richter, Auke Meetsma, Bart Hessen* and Jan H. Teuben

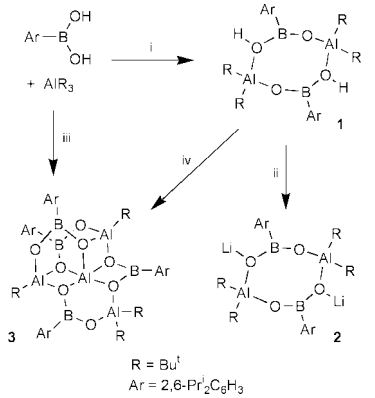
Dutch Polymer Institute/Centre for Catalytic Olefin Polymerisation, Stratingh Institute of Chemistry and Chemical Engineering, University of Groningen, Nijenborgh 4, 9747 AG Groningen, The Netherlands. E-mail: hessen@chem.rug.nl

Received (in Cambridge, UK) 24th April 2001, Accepted 1st June 2001
First published as an Advance Article on the web 27th June 2001

The reaction of Bu^t_3Al with $ArB(OH)_2$ (Ar = 2,6-diisopropylphenyl) leads, *via* the intermediate $[Bu^t_2Al(O)BAr(OH)]_2$ 1, to the crystallographically characterised boralumoxane $Al(Bu^t_2Al)(Bu^tAl)_2(O_2BAr)_4$ 3 which is able to activate Cp_2ZrMe_2 to effect catalytic ethene polymerisation.

The discovery of methylalumoxane (MAO) and its use as a cocatalyst for zirconocene-based olefin polymerisation catalysts[1] has spurred an explosive development of 'single-site' olefin polymerisation catalysts.[2] Despite its widespread use as a cocatalyst for these systems, the actual nature of MAO and the species responsible for its activating ability has still not been unequivocally established. Work by Barron and coworkers on *tert*-butylalumoxane model systems,[3] and various theoretical studies[4] have shown that this property is likely to stem from oligomeric $(MeAlO)_n$ clusters containing four-coordinate Al, that exhibit 'latent' Lewis acidity through ring-opening of strained Al_2O_2 four-membered rings. In several patents it was shown that boronic acids $RB(OH)_2$, boronic esters or boroxines $(RBO)_3$ can act as promotors, enhancing the activating properties of MAO.[5] Boralumoxane materials obtained from reactions of aluminium alkyls with boronic acids or boroxines have been shown to be active as cocatalysts in olefin polymerisation, but these are generally poorly defined species.[6] Very recently, reactions of borinic acids R_2BOH with aluminium trialkyls have yielded some well-defined complexes, but there have been no reports of their properties as cocatalysts.[7] Here we describe the synthesis and structural characterisation of the first well-defined boralumoxane with overall composition $[(RAlO)(R'BO)]_n$, and show that this species is capable of activating zirconocene dimethyl to effect catalytic ethene polymerisation.

In studying the reactivity between trialkylaluminium compounds and boronic acids $RB(OH)_2$ we have focused on Al and B compounds bearing sterically demanding ligands, in order to enhance the possibility of obtaining well-defined species. The reaction of $AlBu^t_3$ with an equimolar amount of the arylboronic acid $ArB(OH)_2$ (Ar = 2,6-diisopropylphenyl) in *n*-pentane solvent at 0 °C initially yielded the species $[Bu^t_2Al(O)BAr(OH)]_2$ **1**, obtained as an analytically pure solid in 83% yield (Scheme 1). The presence of isolated hydroxy groups was established by IR spectroscopy (ν_{OH} 3591 cm^{-1}) and ^1H NMR (OH δ 4.73).[8] It proved difficult to obtain **1** as single crystals suitable for X-ray structure determination. Its formulation as a dimer was supported by its reaction with Bu^nLi followed by the crystallisation of the Li salt $[Bu^t_2Al(O)BAr(OLi)]_2$ **2**, obtained as a benzene solvate. A structure determination§ of **2**·$2C_6H_6$ (Fig. 1) revealed an eight-membered $Al_2B_2O_4$ ring core. Two oxygen atoms on opposite positions on the ring bear Li atoms, that are further stabilised by the proximity of benzene molecules present in the crystal lattice (Li–$C_{benzene}$ distances range over 2.80–3.05 Å). The Al–O–B angle around the unsubstituted oxygen atom O(1) is relatively obtuse, 168.3(2)°, compared to the Al–O(2)–B angle of 128.1(1)°, and the Al(1)–O(1) distance of 1.744(2) Å is clearly shorter than Al(1)–O(2) of 1.821(2) Å. Based on this structure it seems reasonable to formulate **1** as the cyclic species $[Bu^t_2Al(\mu\text{-}O)BAr(\mu\text{-}OH)]_2$.



Scheme 1 *Reagents and conditions*: i, *n*-pentane, 0 °C, 1 h; ii, Bu^nLi, 20 °C, benzene; iii, toluene, 50 °C, recryst. from benzene; iv, hexane, reflux, 2 h.

Allowing a highly concentrated (0.38 M) solution of **1** in benzene-d_6 to stand at ambient temperature and monitoring the sample by ^1H NMR spectroscopy showed that isobutane is evolved gradually, and that various (as yet unidentified) transient species are formed. Eventually, all resonances attributable to hydroxy groups disappear, and a colourless crystalline compound is deposited. This product **3** could be obtained on a preparative scale (Scheme 1), either from **1** by refluxing in hexane for 2 h (48% isolated yield), or from a mixture of

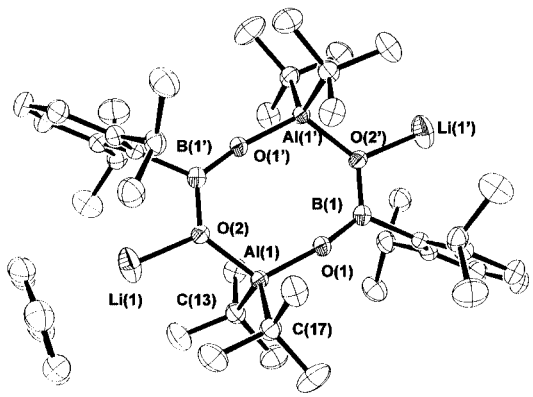


Fig. 1 Molecular structure of **2** (hydrogen atoms omitted for clarity). Selected interatomic distances (Å) and angles (°): Al(1)–O(1) 1.744(2), Al(1)–O(2) 1.821(2), Al(1)–C(13) 1.998(3), Al(1)–C(17) 2.003(2), B(1)–O(1) 1.319(3), B(1)–O(2) 1.380(3), O(2)–Li(1) 1.841(5); O(1)–Al(1)–O(2) 116.20(8), C(13)–Al(1)–C(17) 119.6(1), O(1)–B(1)–O(2) 123.7(2), Al(1)–O(1)–B(1) 168.3(2), Al(1)–O(2)-B(1′) 128.1(1).

 DOI: 10.1039/b103670j

$ArB(OH)_2$ and Bu^t_3Al by warming in toluene at 50 °C followed by crystallization from benzene (79% isolated yield of its benzene solvate). Compound **3** was identified, by a crystal structure determination of its benzene solvate,§ as $Al(Bu^t_2Al)(Bu^tAl)_2(O_2BAr)_4$ (Fig. 2). The overall composition of the compound corresponds to a tetramer of 'Bu^{t}AlOBArO', but it is clear that the remaining *tert*-butyl groups are not evenly distributed over the four Al atoms. The central Al atom bears no alkyl substituent, and is bound to five oxygen atoms. The other three Al atoms are four-coordinate, and all B-atoms are three-coordinate. The structure of **3** may be described as consisting of three six- and three four-membered Al/B–O rings that share the central Al atom. One of the most notable features in the structure is that there are two edge-sharing four-membered rings, containing Al(1)O(2/7)Al(3) and Al(1)O(1/2)B(1), respectively. This arrangement is highly strained, as seen *e.g.* from the angles O(2)–Al(3)–O(7) 83.03(6)°, O(2)–Al(1)–O(7) 81.48(6)° and O(1)–Al(1)–O(2) 71.90(6)°, and may result in 'latent' Lewis acidic behaviour. The longest Al–O distances to four-coordinate Al in the structure are Al(2)–O(1), 1.940(1) Å, a bond to the relatively electron-rich Bu^t_2Al-group, and Al(3)–O(7), 1.890(2) Å, a bond to the Bu^{t}Al group in the edge-sharing four-membered ring assembly. In solution, the structure of **3** appears to be highly fluxional, showing at ambient temperature only two resonances for the Bu^t groups in the ^{1}H NMR spectrum. This fluxionality is likely to be due to rapid decomplexation/complexation of O(1) and O(6) to the central Al(1) atom. This results in an average C_2-symmetry of the complex, with the C_2 axis passing through Al(1) and bisecting the O(7)–Al(1)–O(4) angle.

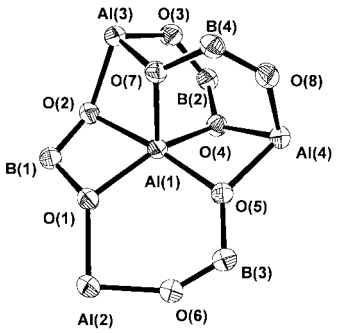

Fig. 2 Molecular structure of **3** (carbon and hydrogen atoms omitted for clarity; each B atom bears one 2,6-diisopropylphenyl group, Al(2) bears two Bu^t groups, Al(3) and Al(4) one Bu^t group each). Selected interatomic distances (Å) and angles (°): Al(1)–O(1) 1.869(1), Al(1)–O(2) 1.924(1), Al(1)–O(4) 1.867(1), Al(1)–O(5) 1.823(1), Al(1)–O(7) 1.851(1), Al(2)–O(1) 1.940(1), Al(2)–O(6) 1.761(2), Al(3)–O(2) 1.827(1), Al(3)–O(3) 1.747(2), Al(3)–O(7) 1.890(2), Al(4)–O(4) 1.873(1), Al(4)–O(5) 1.856(1), Al(4)–O(8) 1.759(1); O(1)–Al(1)–O(2) 71.86(6), O(1)–Al(1)–O(5) 104.00(7), O(4)–Al(1)–O(5) 81.54(6), O(2)–Al(1)–O(4) 97.24(6), O(2)–Al(1)–O(7) 81.48(6), O(1)–B(1)–O(2) 105.8(2), O(1)–Al(2)–O(6) 94.56(7), O(2)–Al(3)–O(7) 83.03(6).

Compounds **1** and **3** were each combined with an equimolar amount of the zirconocene dialkyl Cp_2ZrMe_2 **4** in toluene solvent and exposed to ethene (5 bar), in order to determine whether these species can act as activators for single-site olefin polymerisation catalysts. The combination of **1** and **4** (in an Al : Zr ratio of 2 : 1) did not result in ethene polymerisation activity. In contrast, the combination of **3** and **4** (in an Al : Zr ratio of 4 : 1) readily polymerised ethene to polyethene (M_w = 16600, M_w/M_n = 1.9) with a productivity of 2.59 kg mol^{-1} h^{-1} bar^{-1} (toluene, 5 bar ethene, 23 °C, 30 min run time).

In conclusion, we have shown that the reaction of the boronic acid $ArB(OH)_2$ (Ar = 2,6-diisopropylphenyl) with Bu^t_3Al results in stepwise formation of a well-defined boralumoxane species, $Al(Bu^t_2Al)(Bu^tAl)_2(O_2BAr)_4$ **3**, that is able to act as an activator for zirconocene alkyl olefin polymerisation catalysts. Although **3** contains structural units similar to those in the alumoxanes $[Bu^tAlO]_n$ obtained by Barron and coworkers[3] (six- and four-membered $[(Al/B)O]_n$ rings), it is topologically quite different from these due to three-coordinate B acting as structural element (compared to four-coordinate Al in the alumoxanes). It has in common with these species the presence of edge-sharing four-membered rings, and it is therefore possible that its activating properties are also due to the 'latent' Lewis acidic behaviour of these moieties, as proposed by Barron for the alumoxanes. Further research into the structural and reactivity features of these and related boralumoxanes is expected to shed more light on the nature and activating behaviour of alumoxane-based activators.

Received (in Cambridge, UK) 24th April 2001, Accepted 1st June 2001
First published as an Advance Article on the web 27th June 2001

Intramolecular stacking of the (4′-chloro-2,2′:6′,2″-terpyridine)platinum(II) moieties occurs in *N*,*S*-bis[(4′-chloro-2,2′:6′,2″-terpyridine)platinum(II)]-2-mercaptoimidazole tris-hexafluorophosphate; *N*,*S*-bis[(2,2′:6′,2″-terpyridine)-platinum(II)]thioacetimine trinitrate is slowly transformed in aqueous solution to the molecular propeller-like tris-[(2,2′:6′,2″-terpyridine)platinum(II)]sulfonium ion.

We have recently shown that (2,2′:6′,2″-terpyridine)platinum(II) complexes are cytotoxic to human ovarian carcinoma and that bis[(2,2′:6′,2″-terpyridine)platinum(II)] complexes with short and rigid linkers are particularly effective.[1] This study has been extended to (2,2′:6′,2″-terpyridine)platinum(II) thiolate complexes.[2] Since intercalation into DNA of such molecules may contribute to their antitumour activity we investigated the crystal structure of *N*,*S*-bis[(4′-chloro-2,2′:6′,2″-terpyridine)platinum(II)]-2-mercaptoimidazole tris-hexafluorophosphate **1** in order to determine whether the two (4′-chloro-2,2′:6′,2″-terpyridine)platinum(II) moieties were stacked. If they are, this might be expected to preclude intercalation into DNA.

As seen in Fig. 1 the two (4′-chloro-2,2′:6′,2″-terpyridine)platinum(II) moieties stack virtually parallel to each other, the platinum–platinum distance being 3.2903 Å.‡ The crystals were obtained from water. This stacking of the (4′-chloro-2,2′:6′,2″-terpyridine)platinum(II) moieties in **1**, is maintained in solution,[3] and should preclude it from intercalating into DNA. This supports the conclusion reported recently that DNA is not the principal target for the antitumour activity of these complexes.[2]

The bis-complex **2**, which was characterised spectroscopically (ESI)† is expected to adopt a similar conformation to **1**. However, unlike **1** and its analogue *N*,*S*-bis[(2,2′:6′,2″-terpyridine)platinum(II)]-2-mercaptoimidazole ion (which were stable), it was observed that on storing the bis-complex **2** in aqueous solution over a period of weeks, decomposition occurred ($t_{1/2}$ = 10.5 days at 20 °C) releasing acetamide and a new complex[4] which was shown by electrospray mass spectrometry to have *m*/*z* = 444 (M^{2+} with isotope distribution for two Pt atoms) consistent with the complex **3** (Scheme 1). The thioacetimine moiety in **2** would be activated by the 2,2′:6′,2″-terpyridine platinum(II) complexes and the tetrahedral intermediate formed from **2** by the nucleophilic attack of water would be expected to collapse to **3** and acetamide. The X-ray

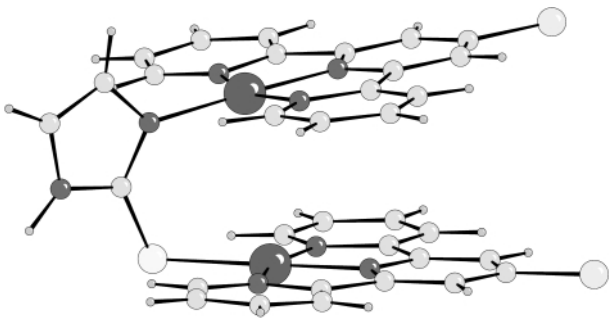

Fig. 1 The X-ray crystal structure of *N*,*S*-bis[(4′-chloro-2,2′:6′,2″-terpyridine)platinum(II)]-2-mercaptoimidazole tris-hexafluorophosphate **1**, showing the stacked (4′-chloro-2,2′:6′,2″-terpyridine)platinum(II) complexes with a Pt–Pt distance of 3.2903 Å and an interplanar angle of 7.5(5)°. The bond lengths to 2-mercaptoimidazole are Pt–S [2.312(4) Å] and Pt–N [2.021(4) Å]. The counter ions and solvent of crystallization are excluded for clarity.

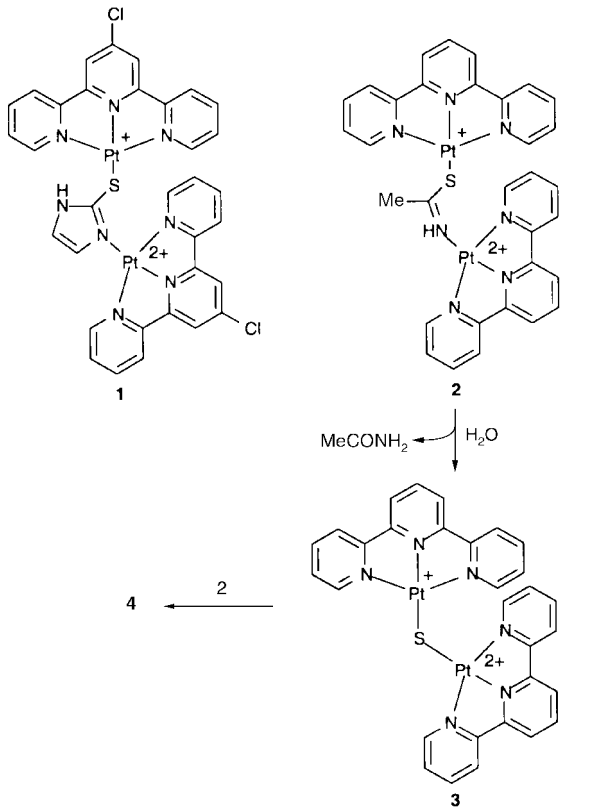

Scheme 1

 DOI: 10.1039/b103637h

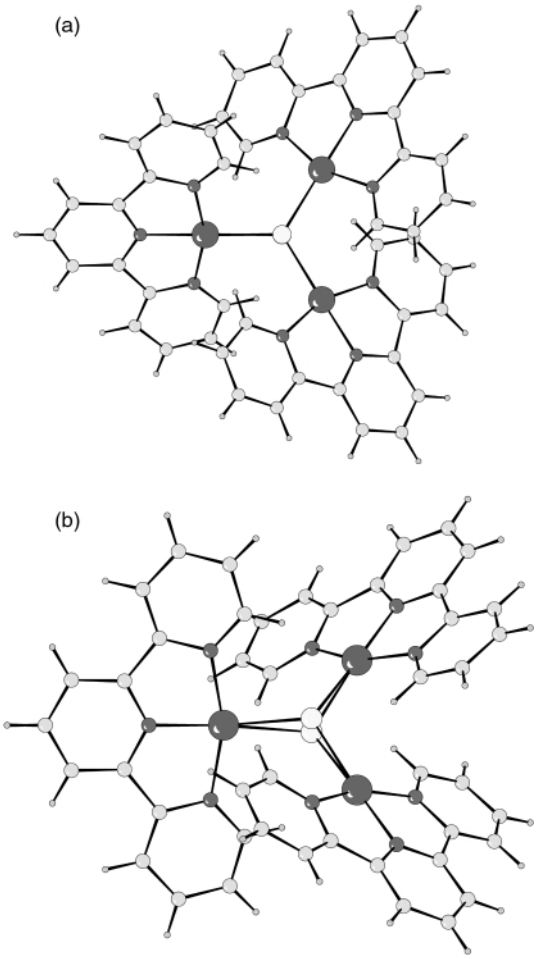

Fig. 2 The X-ray crystal structure of tris[(2,2′:6′,2″-terpyridine)platinum(II)]sulfonium tetra-perchlorate **4**: (a) down the three-fold axis and (b) at an angle to the three-fold axis showing molecules with the same propeller helicity with the sulfur atom above or below the reference plane of the three Pt atoms. The Pt–S bond lengths are 2.32 ± 0.01 Å and the tilt of the three (2,2′:6′,2″-terpyridine)platinum(II) planes is 40 ± 1° to the reference plane of the three Pt atoms. The counter ions and solvent of crystallization are excluded for clarity.

crystal structure of the product [Fig. 2(a)] is clearly not **3**. This tris[(2,2′:6′,2″-terpyridine)platinum(II)]sulfonium salt **4**‡ could be formed from **3** by sulfur abstracting (2,2′:6′,2″-terpyridineplatinum(II) from **2**. Tris[(2,2′:6′,2″-terpyridine)platinum(II)]sulfonium ion **4** would be expected to readily fragment to **3** in the mass spectrometer. Although aliphatic thioethers (*e.g.* methionine)[5] and dimethyl sulfoxide[6] will not ligate to 2,2′:6′,2″-terpyridine)platinum(II) because of the steric hindrance with the 6,6″ hydrogens, the planar nature of the substituents at sulfur in **3** and the longer S–Pt bond compared with the S–C bond make it possible to form **4**.

The X-ray crystal structure shows that the three (2,2′:6′,2″-terpyridine)platinum(II) moieties generate propeller-like helicity which can be right- or left-handed. Sulfur is at the apex of a shallow pyramid, with the S atom 0.354 Å above or below the reference plane formed by the three Pt atoms which are at the apices of an equilateral triangle (Fig. 2). It is not however a stereogenic centre. The three N′–Pt–S bond angles are 172° to accommodate the pyramidalization at sulfur. Thus flipping the molecule through 180° leaves the molecular helicity unchanged but with the sulfur atom on the opposite side of the reference plane formed by the three Pt atoms. Thus each enantiomer (left or right-handed molecular propeller) has crystallised in two orientations in the crystal lattice with equal probability leading to the two positions observed for the sulfur atom [Fig. 2(b)]. The tilt of the (2,2′:6′,2″-terpyridine)platinum(II) moieties from the reference plane of the Pt atoms is 40 ± 1° for each 'blade' of the propeller. Thus the flanking pyridine rings of each (terpyridine)platinum(II) moiety that are on the same side of the reference plane as the sulfur atom are in a different molecular environment from the flanking pyridine rings on the side opposite the sulfur atom. Consequently all ^{1}H resonances of the terpyridines in the NMR spectrum have different chemical shifts and are not resolved.

Propeller-like molecules have been extensively investigated.[7] Because of the necessity for the correlated rotation of the (2,2′:6′,2″-terpyridine)platinum(II) moieties, the tris-[(2,2′:6′,2″-terpyridine)platinum(II)]sulfonium ion forms stable left- and right-handed propeller-like molecules.

We gratefully acknowledge EPSRC/BBSRC support for this work.

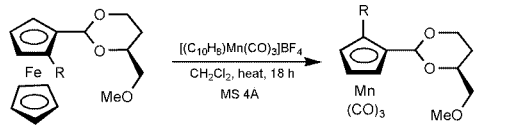
First published as an Advance Article on the web 27th June 2001

Planar chiral ligand transfer reactions can be carried out by the reaction of [(naphthalene)$Mn(CO)_3$]BF_4 with planar chiral ferrocene derivatives.

Ligand transfer from one metal to another is a useful reaction when the complex cannot be easily prepared by conventional methods and is popular in organometallic chemistry.[1] Among these, cyclopentadienyl transfer reactions may be of synthetic interest,[2,3] in particular if cheap substrates such as commercially available ferrocene derivatives can be used as starting materials. However, there have been no reports of ligand transfer reactions from ferrocene derivatives to a manganese moiety to prepare cyclopentadienyl manganese complexes. Such complexes have many notable features such as high thermal stability, lack of substantial air or water sensitivity, kinetic inertness toward substitution reactions, and stereochemical robustness. These characteristics will be useful properties when manganese complexes are used as auxiliaries in other reactions.

Herein we report the synthesis of planar chiral cyclopentadienyltricarbonylmanganese complexes from the reaction of planar chiral ferrocenes with [(η^6-naphthalene)$Mn(CO)_3$]BF_4[4] and their application in asymmetric reactions. Planar chiral chelates of $CpMn(CO)_3$ derivatives are quite rare and hence their use in asymmetric reactions has not been developed. There has been a report[5] of enantioselective allylic substitution of cyclic substrates by catalysis with palladium complexes of *P*,*N*-chelate ligands attached to a $CpMn(CO)_3$ unit.

Refluxing equimolar amounts of a planar chiral ferrocene derivative **1a** and [(η^6-naphthalene)$Mn(CO)_3$]BF_4 in the presence of 4 Å molecular sieves in CH_2Cl_2, followed by standard work-up procedures, led to a 46% yield of the air-stable, planar chiral tricarbonylcyclopentadienylmanganese complex **2a** [eqn. (1)].‡

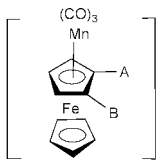


(1)

1a-c

2a R = Me
2b R = $SiMe_3$
2c R = $SiMe_2(CH{=}CH_2)$

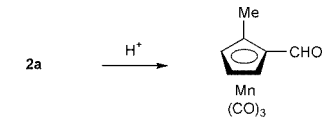
As far as we are aware, this is the first use of a ligand transfer reaction in the synthesis of a planar chiral tricarbonylcyclopentadienylmanganese complex. Interestingly, formation of $CpMn(CO)_3$ was not observed in the reaction products. Birch *et al.*[6] first tested the idea of chirality transfer in the reaction between a chiral donor complex and an unsymmetrical diene ligand. Since then, there have been many reports on the synthesis of chiral organometallic compounds.[7] However, there have been no known reactions on the synthesis of tricarbonylcyclopentadienylmanganese derivatives. Surprisingly, during the transfer reaction, a *complete inversion* of the absolute configuration occurred [eqn. (1)]. This suggests that a bimetallic species [Cp–Fe–Cp–$Mn(CO)_3$]$^+$ **A**, in which one of the Cp rings



A

is coordinated to both metals, occurs as an intermediate in this reaction especially given the recent isolation and characterization of bimetallic complexes [Cp*–M–Cp*–$Mn(CO)_3$]$^+$ (M = Fe, Ru, Os).[8] In the same way, compounds **2b**,**c** were synthesized from the corresponding mixed ferrocenes **1b**,**c**. According to the study of Herberich *et al.*,[9] the migrating Cp is always the unsubstituted ligand. They explained this observation based upon on the electronic structural differences between Cp^- and Cp^{*-}. However, in our case, the substituted cyclopentadienyl ligand always migrated.

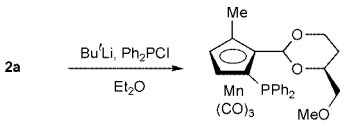
Acid hydrolysis of **2a** yielded the known compound **3** [eqn. (2)];[10] according to the ^1H NMR spectrum of **2a** and the optical rotation of **3**, compound **3** is optically pure.



(2)

3

We investigated whether the triol group in **2** could be used as a directing group in the functionalization of the cyclopentadienyl ring. Deprotonation of **2a** by Bu^{t}Li followed by the addition of PPh_2Cl yielded **4** in 67% yield [eqn. (3)].



(3)

4

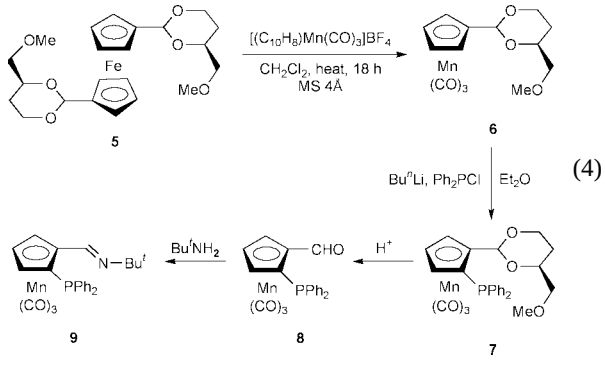
The structure of **4** was confirmed by an X-ray crystal structure determination (Fig. 1).[11] Thus, the diphenylphosphino group was successfully introduced with the aid of the triol group.

We next investigated the use of the ligand transfer reaction in the synthesis of *P*,*N*-ligands and studied palladium-catalyzed asymmetric allylic alkylation. The use of ligands derived from (arene)$Cr(CO)_3$ as a chiral chelating ligand is quite popular.[12] However, the use of $CpMn(CO)_3$ as a chiral chelating ligand is quite rare.[5]

† Electronic supplementary information (ESI) available: characterization of **2b**, **2c**, **4**, **6**, **7**, **8** and **9**, and a typical procedure for Pd-catalyzed allylic alkylation. See http://www.rsc.org/suppdata/cc/b1/b102693n/

 DOI: 10.1039/b102693n

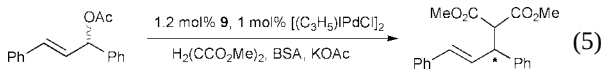
The planar chiral *P*,*N*-ligands **9** were synthesized from **5** [eqn. (4)].



(4)

Ligand transfer reaction of **5** afforded **6** in 74% yield. Deprotonation of **6** followed by the addition of PPh_2Cl and subsequent reaction with acid gave **8** in 75% yield. The condensation reaction of **8** with *tert*-butyl amine gave a *P*,*N*-ligand **9a** in 96% yield. The de of **7** prepared from **6** was 75%. However, after recrystallization, the de of **7** was > 99.5%.

The palladium-catalyzed asymmetric allylic alkylation of *rac*-1,3-diphenylprop-2-en-1-yl acetate with dimethyl malonate was successfully carried out [eqn. (5)].



(5)

Reaction of *rac*-1,3-diphenylprop-2-en-1-yl acetate with dimethyl malonate in the presence of 1 mol% Pd catalyst at 15 °C for 4 h gave the allylic alkylation product methyl-2-carbomethoxy-3,5-diphenylpent-4-enolate in high yields and high ee values (95% yield and 89% ee in CH_2Cl_2; 96% yield and 92% ee in DMSO). Lowering the reaction temperature to −20 °C in CH_2Cl_2 led to an increase of the ee value to 94% with a 74% yield.

In conclusion, we have conducted the first demonstration that a planar chiral ligand transfer reaction can be carried out by the reaction of $[(naphthalene)Mn(CO)_3]BF_4$ with planar chiral ferrocene derivatives and we have shown that the *P*,*N*-ligand prepared in this study can be employed in palladium-catalyzed asymmetric allylic alkylation.

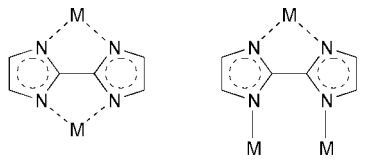
Received (in Cambridge, UK) 4th January 2001, Accepted 4th June 2001
First published as an Advance Article on the web 27th June 2001

Two novel examples of heteronuclear tetrametallic M_2Ag_2 (M = Ru, Os) complexes are described which show strong argentophilic interactions.

The coordination ability of 2,2′-biimidazole is varied and interesting.[1] As a bidentate chelate it can bind as a neutral molecule H_2Biim, the monoanion $[HBiim]^-$ or the dianion $[Biim]^{2-}$. In addition, the mono- and the di-anions also can act as bridging ligands leading to the synthesis of di- and polynuclear complexes. Such polynuclear ruthenium complexes of 2,2′-biimidazolate and its derivatives[2] have received much attention in recent years. Usually the biimidazolate dianion coordinates as a bis-chelating tetradentate ligand (type I). The ligand can also behave as a tetradentate bridge attached to three metal centers (type II). However, the latter coordination mode of bridging $[Biim]^{2-}$ is very limited. As far as we are aware, the rhodium complex, $Rh_4(CO)_8(Biim)_2$ is the only structurally authenticated compound[3] which belongs to this category.



I II

This communication deals with the isolation and characterisation of two novel heterometallic tetranuclear compounds with Ru_2Ag_2 and Os_2Ag_2 cores where the bridging $[Biim]^{2-}$ attaches to three metal atoms (type II).

In a recent publication[4] we have shown that in the presence of a strong π-acid co-ligand 2-(phenylazo)pyridine (pap), the complexes $[M(pap)_2(BiimH_2)]^{2+}$ (M = Ru, Os), exhibit relatively low pK_a values (pK_a: M = Ru, 4.2 and 8.0; M = Os, 3.8 and 6.5). The neutral conjugate bases, $[M(pap)_2(Biim)]$, behave as potential chelating ligands and react with appropriate metal complexes to yield di- and tri-metallic complexes.[4,5] In an attempt to prepare heteropolymetallic M–Ag complexes, methanolic solutions of $[M(pap)_2(BiimH_2)]^{2+}$ were reacted with ammoniacal silver nitrate (Tollen's reagent) in 1:1 molar proportion. It was anticipated that the alkalinity of the Tollen's reagent would be strong enough for the dissociation of biimidazole protons from the above ruthenium/osmium building units. The reaction mixture became blue–violet in an hour. Upon crystallisation of the crude product from acetonitrile–water (1:1), dark crystals of the tetrameric cationic M_2Ag_2 compounds were obtained as their perchlorate salts in high yields (*ca.* 80%) [eqn. (1), M = Ru, Os].

$$[M(pap)_2(BiimH_2)]^{2+} + 2[Ag(NH_3)_2]^+ \longrightarrow [\{M(pap)_2(Biim)\}_2Ag_2]^{2+} \quad (1)$$

The mass spectra of M_2Ag_2 compounds fully corroborate with their formulations. For example, the weak peak at 1514 in the ESIMS spectrum of $[\{Ru(pap)_2(Biim)\}_2Ag_2](ClO_4)_2$ is assigned to $[M_c - X]$, where M_c and X represent the molecule and ClO_4, respectively. The experimental isotopic distributions for the above molecular ions corresponded with the simulated patterns. Representative ESIMS spectra (Fig. S1–S4) are deposited as electronic supplementary information.†

Final authentication of these unusual M_2Ag_2 species, however, were made by X-ray crystallographic characterization‡ of the representative Ru_2Ag_2 compound. The complex cation consists of two approximately octahedral $[Ru(pap)_2(Biim)]$ units which are linked by two silver atoms in a head-to-tail fashion. The asymmetric unit consists of half of the molecule. The other half of the molecule is related by the crystallographic two-fold axis passing through the two silver atoms. The local geometry around each silver atom is nearly linear (N–Ag–N *ca.* 179°). The Ag–Ag distance is 2.8899(19) Å, which is similar to that observed[6] in metallic silver (2.89 Å). An ORTEP plot of $[\{Ru(pap)_2(Biim)\}_2Ag_2]^{2+}$ is shown in Fig. 1. In the solid state the cations are arranged in chains with water molecules present between alternate layers. The small Ag–Ag separation in the compound indicates the presence of argentophilic interactions between the two Ag(I) ($4d^{10}$) ions. The present M_2Ag_2 compounds clearly demonstrate the unique feature of $[M(pap)_2(Biim)]$ as building units, *viz.* their ability to encapsulate two Ag(I) such that these come in proximity giving rise to metallophilic interactions.[7] Heterometallic compounds with

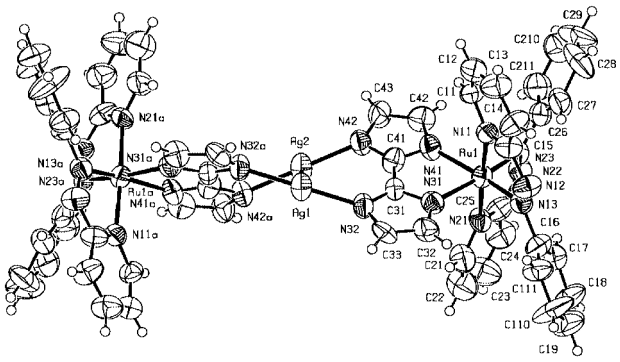


Fig. 1 An ORTEP plot and atom numbering scheme of $[\{Ru(pap)_2(Biim)\}_2Ag_2]^{2+}$ in $[\{Ru(pap)_2(Biim)\}_2Ag_2](ClO_4)_2 \cdot H_2O$. Selected bond distances (Å) and angles (°): Ag(1)–Ag(2) 2.8899(19), C(41)–N(41) 1.329(14), C(41)–N(42) 1.349(14), Ru(1)–N(41) 2.093(10), Ru(1)–N(11) 2.042(9), Ru(1)–N(13) 1.980(9), Ag(1)–N(32) 2.081(10); N(32)–Ag(1)–N(32a) 179.3(5), N(41)–C(41)–C(31) 115.0(11), N(42)–C(41)–C(31) 131.2(11).

† Electronic supplementary information (ESI) available: details of crystal structure solution and refinement: Fig. S1–S4: representative ESIMS spectra. See http://www.rsc.org/suppdata/cc/b1/b100171j/

 DOI: 10.1039/b100171j

such small Ag–Ag separations[8] are unprecedented in the literature. Attractive interactions between formally closed shell (d^{10}) metal centres containing coinage monovalent metals have been known predominantly for gold.[9] In comparison, argentophilic compounds are rare and the M_2Ag_2 compounds, described here are the first examples of heterometallic Ru–Ag and Os–Ag compounds which show metallophilic interactions. In the recent past, however, there have been a few reports[10] on tetranuclear Ru_2Ag_2 compounds in which the Ag–Ag separations are large.

To look for the reason for this mode of binding in the Ru–Ag compound, we compared the separations between the coordinated nitrogen atoms of the biimidazolate ring in the present Ru–Ag heterometallic compound with those in the symmetrical cationic compound,[4] $[\{Ru(bpy)_2\}_2(Biim)]^{2+}$. The separation between the coordinating N(31) and N(41) in $[\{Ru(pap)_2(Biim)\}_2Ag_2]^{2+}$ is 2.622 Å and that between N(32) and N(42) is 3.222 Å. The first pair of nitrogens are attached to the $Ru(pap)_2^{2+}$ moiety as a chelate whereas the other two are coordinated linearly to two Ag(I). This effect is also reflected in the uneven C–N lengths and bond angles in the biimidazolate rings. For example, the bond lengths C(41)–N(41) [1.329(14) Å] and C(31)–N(31) [1.350(13) Å] are shorter than C(41)–N(42) [1.349(14) Å] and C(31)–N(32) [1.371(13) Å], respectively. Moreover, the bond angles N(41)–C(41)–C(31) [115.0(11)°] and N(31)–C(31)–C(41) [117.3(10)°] are narrower than the corresponding angles N(42)–C(41)–C(31) [131.2(11)°] and N(32)–C(31)–C(41) [130.7(11)°]. This wider separation between N(32) and N(42) undoubtedly favours monodentate type II coordination of the $[Ru(pap)_2(Biim)]$ bridging unit over chelate type I coordination. Interestingly, in the symmetrical compound $[\{Ru(bpy)_2\}_2(Biim)]^{2+}$, the reference C–N bond distances, the respective angles and the separation between the coordinated N atoms are very similar.[4]§ In the M–Ag compounds, one half of the bridging biimidazolate is coordinated to M(II) which are known to participate in dπ–pπ interactions very effectively[11] and the other half is attached to two Ag(I) which is known to be a σ-acceptor. The presence of $[M(pap)_2]^{2+}$ moiety together with a preferential affinity of the Ag(I) for a linear coordination[12] are believed to be the two important factors for the trinuclear coordination of the $[Biim]^{2-}$ anion in $[M(pap)_2(Biim)]$.

Finally, we note here that the ESIMS spectral measurements together with experimental results on the reactions of $[M(pap)_2(Biim)]$ with Cu^{2+} indicate a similar binding mode of $[Biim]^{2-}$ resulting in the formation of heteropolymetallic compounds with M_4Cu_2 cores. However, X-ray structural authentication of the products, which are in progress, are essential to make further conclusions. These will be reported in due course.

Financial support received from the Department of Science and Technology, New Delhi is acknowledged.

Notes and references

‡ The M_2Ag_2 compounds appear to be crystalline but, in general, were not suitable for X-ray study. Fortunately, after several trials X-ray quality crystals of $[\{Ru(pap)_2(Biim)\}_2Ag_2](ClO_4)_2\cdot H_2O$ could be formed. Crystals of this compound were found to be weak scatterers and thus the quality of the structure is not very high. However, the structural analysis of the reference Ru_2Ag_2 compound suffices to establish the identity and gross features of the system. Further details of the diffraction experiment are provided as ESI.†

Crystal data: $[\{Ru(pap)_2(Biim)\}_2Ag_2](ClO_4)_2\cdot H_2O$: $C_{56}H_{46}N_{20}O_9Cl_2Ag_2Ru_2$, M = 1631.91, orthorhombic, space group *Pnna* (No. 52), a = 34.037(5), b = 19.467(4), c = 10.0362(12) Å, Z = 4, D_c = 1.630 Mg m^{-3}, crystal dimensions 0.25 × 0.15 × 0.15 mm. Intensity data were collected on an Enraf Nonius CAD4 automatic diffractometer using Cu-Kα radiation (λ = 1.54184 Å) and the ω-scan technique, and corrected for Lorentz and polarisation effects.[13] The number of reflections measured was 7708, of which 6955 were unique and were used for refinement. A semi-empirical absorption correction (ψ-scans) was made.[14] The structure was solved by Patterson and Fourier methods[15] and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters.[16] All hydrogen atoms were located in their calculated positions (C–H 0.93 Å) and were refined using a riding model. The hydrogen atoms of one water molecule, O(1), were not located. The final R indices [$I > 2(\sigma)I$] was 0.078 while $wR2$ for all data was 0.2514. CCDC reference number 156515. See http://www.rsc.org/suppdata/cc/b1/b100171j/ for crystallographic data in CIF or other electronic format.

§ Reference C–N bond distances[4] (Å): 1.322(10), 1.327(10), 1.327(10), 1.322(10); reference N–C–C bond angles (°) : 121.5(7), 121.7(7), 121.7(7), 121.5(7). Separation between the two pairs of coordinating N, N are identical: 2.811 Å.

Formation and ethene substrate reactions of iridium(II) porphyrin metal-centered dπ radicals

Huili Zhai, Andrew Bunn and Bradford Wayland*

Received (in Cambridge, UK) 16th May 2001, Accepted 1st June 2001
First published as an Advance Article on the web 27th June 2001

Monomeric iridium(II) porphyrin complexes of tetrakis-(2,4,6-trialkylphenyl)porphyrin ligands that are generated by photolysis of the Ir–Me derivatives are found to have the $d_{xy}^2\ d_{z^2}^2\ d_{xz,yz}^3$ ground electron configuration which differs from the $d_{xy}^2\ d_{xz,yz}^4\ d_{z^2}^1$ configuration observed for the Co(II) and Rh(II) analogs; reactions of these Ir(II) species with ethene reflect both the metallo-radical reactivity and the varying steric demands for the series of porphyrin ligands.

Monomeric iridium(II) complexes[1] are unusual because of the dominant characteristic for these d^7 species to form diamagnetic Ir^{II}–Ir^{II} bonded dimers.[2] All of the currently reported iridium(II) porphyrin complexes are diamagnetic dimers,[3,4] and the range of thermodynamically favorable substrate reactions is limited by the dimer homolytic dissociation energy. This article reports on the generation of iridium(II) complexes with sterically demanding porphyrin ligands along with studies relevant to the electronic structure and ethene substrate reactions.

Tetramesitylporphyrin (TMP) and derivatives where the mesityl methyl groups in TMP are replaced by ethyl (TTEPP) and isopropyl (TTiPP) provide a series of ligands that require interporphyrin distances too large to support metal–metal bonding.[5,6] Photolysis ($\lambda > 350$ nm) of (octaethylporphyrinato)iridium methyl [(OEP)Ir–Me) gives selective Ir–Me bond homolysis and near quantitative formation of the Ir^{II}–Ir^{II} bonded dimer $\{[(OEP)Ir]_2\}$.[4] Photolysis of (por)Ir-CH_3 (por = TMP, TTEPP, TTiPP) provides an approach to generate iridium(II) porphyrin derivatives that are sterically unable to dimerize by Ir^{II}–Ir^{II} bonding [(eqn. (1)].

$$\text{(por)Ir–Me} \xrightarrow[\lambda > 350\ \text{nm}]{h\nu} \text{(por)Ir}^{II} + \cdot\text{Me} \qquad (1)$$

Photolysis of (por)Ir–Me complexes in C_6D_6 results in the direct observation of $(TTiPP)Ir^{II}$ **1** and $(TTEPP)Ir^{II}$ **2**† and evidence for the formation of $(TMP)Ir^{II}$ **3** through the characteristic reaction with ethene to form (TMP)Ir–CH_2CH_2–Ir(TMP)[eqn. (2)].†

$$2(TMP)Ir^{II} + CH_2{=}CH_2 \rightarrow (TMP)Ir{-}CH_2CH_2{-}Ir(TMP) \qquad (2)$$

The paramagnetism of $(TTiPP)Ir^{II}$ **1** produces shifts and broadening for all of the ^{1}H NMR resonances in **1**† and the high field position for the pyrrole hydrogens [δ_1 (pyr) −20.9 (296 K)] is particularly significant (Fig. 1). The ground electron configuration for both Co(II) and Rh(II) porphyrin complexes is known to be $d_{xy}^2\ d_{xz,yz}^4\ d_{z^2}^1$[7] and downfield pyrrole ^{1}H NMR shifts[8] are observed for these metalloporphyrins which is opposite in sign to that for $(TTiPP)Ir^{II}$ **1**. Upfield pyrrole porphyrin contact shifts are associated with spin density in the porphyrin π orbitals.[9] Low spin (d^5) Fe(III) porphyrin complexes such as $[(TPP)Fe(Im)_2]Cl$ (Im = imidazole)[10] have the $d_{xy}^2\ d_{xz,yz}^3$ ground configuration and upfield pyrrole ^{1}H NMR shift positions comparable to that for **1**.[10] The pyrrole proton contact shifts for **1** clearly indicate that $(TTiPP)Ir^{II}$ has a $d_{xy}^2\ d_{z^2}^2\ d_{xz,yz}^3$ electron configuration which contrasts with the $d_{xy}^2\ d_{xz,yz}^4\ d_{z^2}^1$ configuration observed for the d^7 metalloporphyin complexes of cobalt(II) and rhodium(II).

Plots of the porphyrin pyrrole shifts *vs.* T^{-1} for $(TTiPP)Ir^{II}$ and $(TTiPP)Rh^{II}$ are shown in Fig. 2. Linear dependence of the

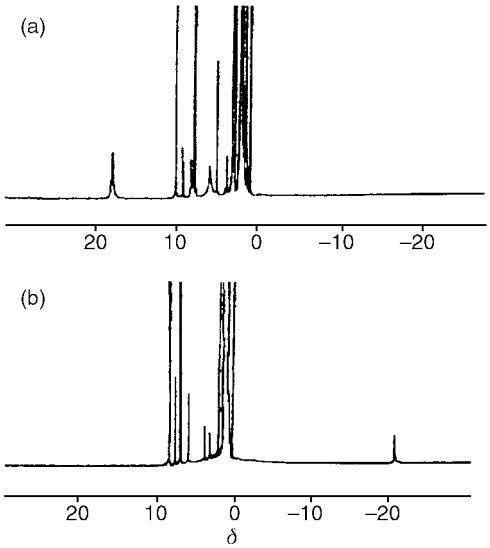

Fig. 1 ^{1}H NMR spectra illustrating the pyrrole resonance (296 K): (a) $(TTiPP)Rh^{II}$, δ_{pyr} +17.5; (b) $(TTiPP)Ir^{II}$, δ_{pyr} −20.9.

paramagnetic shift with T^{-1} for $(TTiPP)Rh^{II}$ is indicative of simple Curie paramagnetic behavior associated with a single contributing state, but curvature of the plot for $(TTiPP)Ir^{II}$ suggests that several states are thermally populated. The deviation from linearity in the shift *vs.* T^{-1} as the temperature is lowered is in the direction of larger upfield contact shift which clearly indicates that the ground configuration has an unpaired electron in the dπ ($d_{xz,yz}$) orbitals. Repeated attempts to determine EPR parameters for $(TTiPP)Ir^{II}$ in toluene glass (20–100 K) did not result in an observed EPR spectrum. The presence of one or more excited states with energy close to that of the ground state may hamper observation of EPR spectra by producing rapid electron spin relaxation.

Differences in steric demands of $(TMP)Ir^{II}$, $(TTEPP)Ir^{II}$ and $(TTiPP)Ir^{II}$ are clearly manifested by the different products that

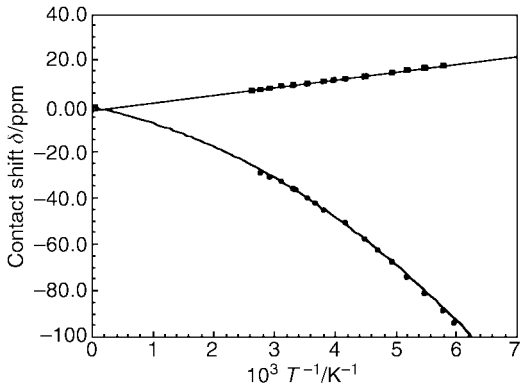

Fig. 2 Plots of the pyrrole ^{1}H NMR contact shifts in toluene-d_8 *vs.* T^{-1} [$(TTiPP)Rh^{II}$ (■); $(TTiPP)Ir^{II}$ (●)].

 DOI: 10.1039/b104301n

result from reactions with ethene. Reaction of (TTEPP)Ir^{II} with ethene produces a four-carbon bridged complex (TTEPP)Ir–CH_2CH_2–CH_2CH_2–Ir(TTEP) [eqn. (3)] without any evidence for the two-carbon ethylene bridged species observed for (TMP)Ir^{II} [(TMP)Ir–CH_2CH_2–Ir(TMP)] [eqn. (1)].

$$2(\text{TTEPP})\text{Ir}^{II} + 2\ CH_2{=}CH_2 \rightarrow (\text{TTEPP})\text{Ir}{-}CH_2CH_2{-}CH_2CH_2{-}\text{Ir}(\text{TTEPP}) \quad (3)$$

The increased steric demands of (TTEPP)Ir compared to (TMP)Ir inhibits formation of the two-carbon bridged complex and an ethene coupling process occurs to yield a four-carbon bridged complex that relieves the steric congestion. The reactions of (TMP)Ir^{II} and (TTEPP)Ir^{II} with ethene to form two- and four-carbon bridged complexes directly parallel reactions of the rhodium(II) derivatives.[6] Further increase in the ligand steric requirements to those of (TTiPP)Ir^{II} inhibits formation of even a four-carbon bridged species which is also a property observed for the rhodium(II) derivative.[6] When a toluene solution of (TTiPP)Ir^{II} is exposed to ethene the porphyrin NMR spectrum disappears, new electronic absorption maxima appear at 444 and 730 nm and an intense EPR signal is observed [$< g >$ = 1.987(290 K); $g_{\|}$ = 1.96, $g_{\perp}$ = 1.998(90 K)]. These spectroscopic changes are indicative of a donor induced intramolecular electron transfer from the Ir^{II} center to the porphyrin ligand π^* which forms an iridium(III) porphyrin anion radical species.[11,12] This behavior differs from (TTiPP)-Rh^{II} which reacts with ethene to form a 1 : 1 complex where the unpaired electron is in a metal centered d_{z^2} molecular orbital.[6] (TTiPP)Rh^{II} requires an excess of a strong donor like pyridine in order to elevate the d_{z^2} above the porphyrin π^* to produce an intramolecular electron transfer.[7] A higher energy position for the iridium d orbitals and or stronger iridium–substrate binding compared to that of rhodium(II) and cobalt(II) is inferred by these results.

Generation of monomeric iridium(II) porphyrins permits study of the fundamental electronic structure of Ir(II) and by removing the thermodynamic restrictions from Ir^{II}–Ir^{II} bonding provides an opportunity to evaluate the full range of Ir(II) substrate reactions.

This research was supported by the Department of Energy Division of Chemical Sciences, Office of Science through grant DE-FG02-86ER-13615.

Notes and references

† The synthesis of iridium complexes of TMP, TTEPP and TTiPP follows the general procedures described by Ogoshi for the synthesis of (OEP)Ir complexes: (por)Ir^{II} (por = TMP, TTEPP, TTiPP) is generated by photolysis of (por)Ir–Me in benzene in a Rayonet photoreactor equipped with RPR-350 nm lamps.

Selected spectroscopic data: (TTiPP)Ir^{II}: $\delta_H(C_6D_6$; 294 K): 8.14 (8H, br s, *m*-H), 5.88 [8H, br, *o*-C*H*$(CH_3)_2$], 3.79 [4H, sept, *p*-C*H*$(CH_3)_2$], 2.08 (24H, br, *p*-CH(C*H*$_3)_2$], 1.73 [48H, br, *o*-CH(C*H*$_3)_2$], −20.89 (8H, br, pyrrole H).

(TTEPP)Ir^{II}: $\delta_H(C_6D_6$; 294 K): 7.62 (8H, br s, *m*-H), 4.08 (16H, br, *o*-C*H*$_2$CH$_3$), 3.23 (8H, br, *p*-C*H*$_2$CH$_3$), 1.83 (12H, br, *p*-CH$_2$C*H*$_3$), 1.61 (24H, br, *o*-CH$_2$C*H*$_3$), −21.46 (8H, br, pyrrole H).

Reaction of (TMP)Ir with ethene in benzene solution produces (TMP)Ir–CH_2CH_2–Ir(TMP), which is identified by ^{1}H NMR spectroscopy by the δ −7.85 resonance characteristic of the –CH_2CH_2– bridge.[6]

Reaction of (TTEPP)Ir with ethene in benzene solution produces (TTEPP)Ir–$CH_2CH_2CH_2CH_2$–Ir(TTEPP). The ^{1}H NMR spectrum displays two high field resonances centered at δ −5.87 and −6.42 that are characteristic of the four-carbon bridge.[6]

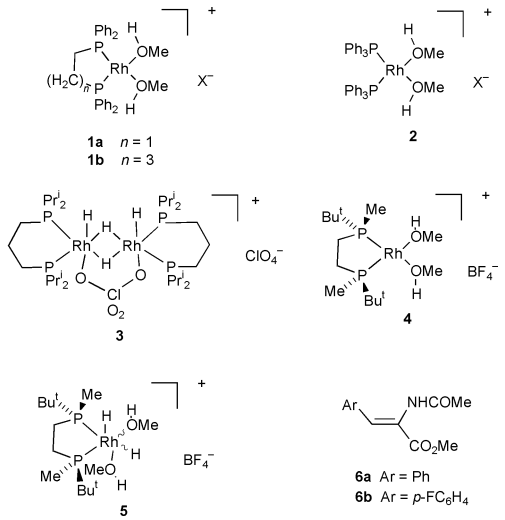
Received (in Cambridge, UK) 12th March 2001, Accepted 24th May 2001
First published as an Advance Article on the web 27th June 2001

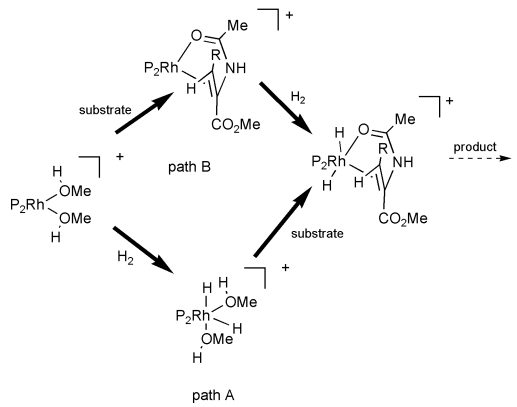
The methanol solvate rhodium(PHANEPHOS) forms a stable dihydride which has been characterised in solution by NMR as a pair of equilibrating diastereomers.

Early experiments designed to elicit the mechanism of asymmetric homogeneous hydrogenation provided a contrast between chelate diphosphine and bisphosphine rhodium complexes. The solvate **1a** showed no tendency to react with

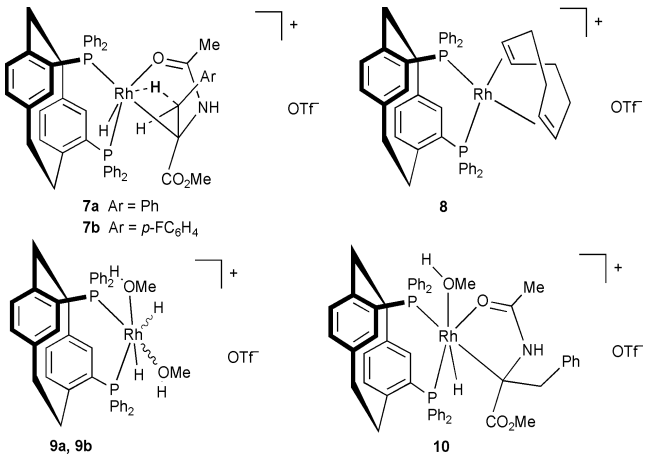


ambient hydrogen, whilst the solvate **2** formed a characterised dihydride;[1] the difference was attributed to a requirement for *trans*-diphosphine geometry in the stable solvate with H correspondingly *trans* to solvent oxygen. This observation has generally been sustained until recently. Aside from reversible *ortho–para* dihydrogen equilibration by complexes **1a** and **1b**,[2] and the likely mediation of a *cis*-dihydride in the formation of the dimeric species **3**,[3] no further progress had been made prior to the work of Gridnev, Imamoto and coworkers.[4] They demonstrated that the corresponding solvate **4** from a simple P-chiral alkylphosphine ligand formed significant quantities of the *cis*-dihydride **5** (20% at −95 °C and ambient pressure), with two diastereomers formed in a ratio of 10:1.[5] Further, this intermediate reacted with the catalytic substrate **6a** to form a Rh alkylhydride,[6] which then underwent reductive elimination at −50 °C to give the hydrogenated product. Taken together with labelling studies, the results are compatible with path **A** in Scheme 1, in contrast to the more generally accepted sequence **B**.[7]

We recently demonstrated the presence of an agostic dihydride intermediate **7** in the hydrogenation cycle of compound **6a** by [PHANEPHOS]Rh$^+$, employing *para*-enriched hydrogen and the precursor complex **8** (or the NBD analogue) to identify the transient at −10 to −30 °C by ^{1}H NMR.[8] When hydrogenation is complete and the substrate exhausted a second species can be observed, however. By carrying out the hydrogenation of the catalyst precursor in the absence of



Scheme 1 The possible paths for addition of dihydrogen to a dehydroamino ester; path **A**: H_2 addition prior to substrate (dihydride route). Path **B**: substrate addition prior to H_2 addition (unsaturate route).



substrate the same intermediate is seen, optimally at −40 °C. The δ and J values are entirely consistent with a *cis*-dihydride structure **9**, with one hydride *trans* to phosphorus (δ *ca.* −11) and one *trans* to one of the two solvent oxygens (δ *ca.* −20). Both the intensity and persistence of the signals indicate that it is a relatively robust species. There are two diastereomers **9a** and **9b** in 2:1 ratio, and their NMR spectra have been fully assigned using PHIP++ [Fig. 1(a)].[9] The chemical shifts are very different from the previous case[4] where the observed major diastereomer resonates at δ −7.7 and −23.0.

When hydrogenation is carried out under conventional NMR conditions at −80 °C, the same dihydride **9** may be observed, along with small amounts of other Rh hydride resonances not seen in the PHIP spectrum. It is stable up to −40 °C [Fig. 1(b)], and a rough estimate based on integration of the high-field ^{1}H NMR signals against the CH_2-region of the ligand indicates that 45% of species **9** is formed at equilibrium, making it more accessible than the previously observed case,[4,5] and to higher

 DOI: 10.1039/b102316k

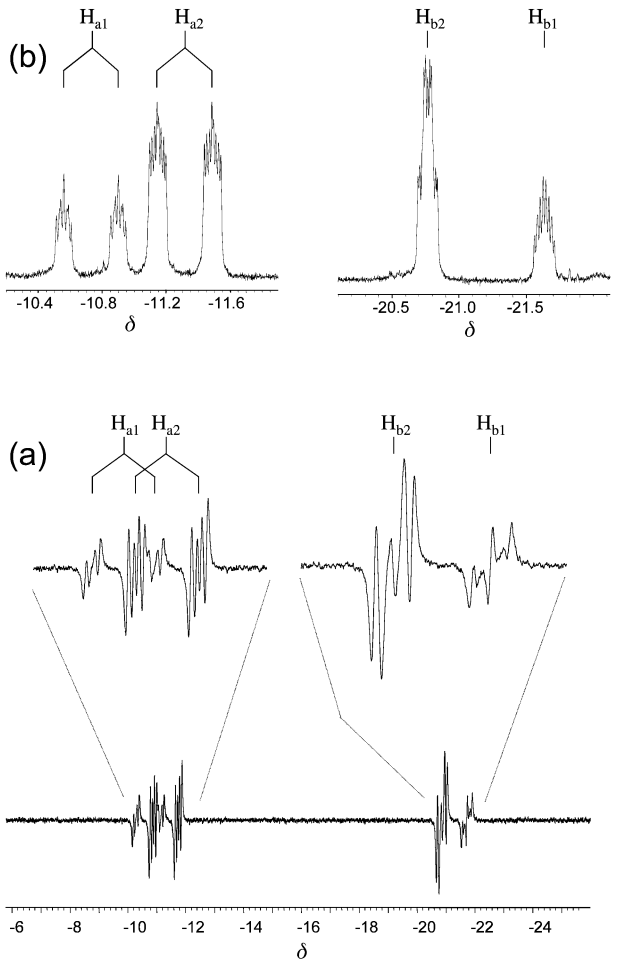


Fig. 1 (a) The PHIP ^{1}H NMR spectrum (CD_3OD, 200 MHz) of dihydrides **9a** and **9b** taken after parahydrogen (98% enriched) passage through a solution of complex **8** in CD_3OD at −40 °C. Minor diastereomer: δ −10.87 (J_{HP} 170, 24, J_{HRh} 14, J_{HH} −9.0 Hz), −21.77, (J_{HP} 32, 12, J_{HRh} 21 Hz); major diastereomer : δ −11.46 (J_{HP} 171, 28, J_{HRh} 15.5, 15, J_{HH} −7.5 Hz), −20.91, (J_{HP} 29, 16, J_{HRh} 22.5 Hz). (b) The ^{1}H NMR spectrum (CD_3OD, 500 MHz) of dihydrides **9a** and **9b** formed in the hydrogenation of complex **8** at −80 °C, taken at −40 °C, with comparable J and δ values.

temperatures. This may be attributed to the high level of electron donation ensuing from the [2.2]paracyclophane backbone,[10] together with the large bite angle of PHANEPHOS,[11] which will favour the dihydride at equilibrium. The two diastereomers are in equilibrium by an unselective mechanism, as indicated by a selective homodecoupling experiment.[12]

When the solution containing complex **9** is held at −80 °C and a solution of compound **6a** in MeOH added, rapid formation of the agostic dihydride **7a** occurs. The signals at δ −2 and −19 are broad at that temperature, and at −70 °C they decay over time without formation of any further observable intermediates. The absence of a 'classical' alkylhydride **10** indicates that **7a** is the only accessible intermediate on the hydrogenation pathway. Further, it must be formed directly from an assumed dihydride precursor rather than by reinsertion of rhodium into the β-CH of **10** after formation of the latter, since the latter pathway would vitiate the earlier PHIP experiment by uncoupling the H–H spins.

In the earlier publication of Gridnev, Imamoto and coworkers,[4] it was suggested that path **A** could be a viable alternative to the accepted reaction mechanism of path **B** (Scheme 1). We

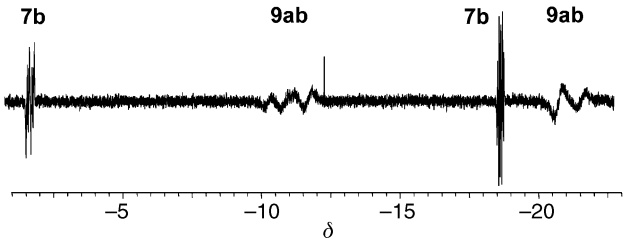

Fig. 2 The PHIP ^{1}H NMR spectrum of the hydrogenation of reactant **6b** in CD_3OD in the presence of Rh complex **8** at −27 °C, after 40 5 s pulses of parahydrogen (98%). Spectra taken earlier in the sequence after 16 pulses show only traces of complex **9**.

observed that when the PHIP experiment was carried out with **6b** as substrate at the lower temperature of −27 °C, the solvate dihydride **9a**, **b** could be observed in significant amount, but only late in the reaction sequence when the substrate concentration was depleted (Fig. 2). This opens up the possibility that path **A** may contribute to catalytic turnover in the PHANEPHOS case. Earlier INEPT experiments demonstrated that the agostic intermediate **7a** is in reversible equilibrium with the solvate complex and substrate.[7] This makes the discrimination between the two pathways quite subtle. Given that both species **7** and **9** are observed in the same experiment under turnover conditions, the result is accessible in principle and a challenge for further work.

We thank Philip Pye and Kai Rossen (Merck, Rahway) for a generous gift of PHANEPHOS, and Johnson-Matthey for the loan of $RhCl_3$. R. G. thanks BASF AG and Studienstiftung des Deutschen Volkes for a Fellowship. JMB is very pleased to acknowledge an unrestricted grant from Merck, Inc. H. H. and J. B. thank the Deutsche Forschungsgemeinschaft for financial support.

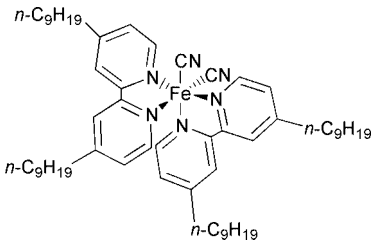
An iron(II) complex with a lipophilic derivative of 2,2′-bipyridine was synthesized and found to aggregate in aqueous solution, yielding vesicles with a mean diameter of 1000 nm; preliminary cyclic voltammetry experiments show that the complex forms redox-active films at the electrode surface.

The design of new amphiphilic molecules incorporating transition metal complexes is a recent topic of interest due to their potential use in catalysis,[1] medicine[2] and materials science.[3] Self-assembling amphiphilic systems containing metal ions are particularly promising since they combine the special solvation and interfacial behaviour of organised media with the rich chemical reactivity of transition metal complexes. Several applications may be envisaged for this type of molecules, such as the development of environmentally friendly catalysts, medical applications such as carriers of diagnostic metals and metal-complex drugs with specific targeting ability, and as models for biological membrane processes. Nevertheless, the special characteristics imparted by metal ions in organised media are much more poorly understood.[4]

In this work we have synthesised and studied the complex *cis*-bis(4,4′-dinonyl-2,2′-bipyridine)dicyanoiron(II) **1**. Complexes of the type $[FeL_2(CN)_2]$, where L is a bidentate diimmine



ligand, have been extensively used as inorganic solvatochromic probes of solvent polarity. In the course of a systematic study on the solvatochromic behaviour of complexes of this type with different hydrolipophilic balance[5] we have prepared complex **1**, using a published procedure with minor modifications.[6] Synthesis of 4,4′-dinonyl-2,2′-bipyridine was performed by reaction of 4,4′-dimethyl-2,2′-bipyridine with lithium diisopropylamide, followed by condensation with 1-bromooctane.[7] The desired complex was obtained by reaction of $(NH_4)_2Fe(SO_4)_2{\cdot}5H_2O$ with three-fold the stoichiometric amount of the ligand, followed by addition of an excess of KCN; purification by chromatography afforded the pure complex.† Its solvatochromic behaviour was studied in a large range of solvents with different properties, from methanol to *n*-pentane. The results obtained are indicative that the solvatochromic sensitivity of **1** is similar to that of the related complex *cis*-$[Fe(bpy)_2(CN)_2]$, which is, however, insoluble in low-polarity solvents. Thus, the introduction of two nonyl chains in the diimmine ligand results in a complex that may act as a solvent polarity probe in lipophilic systems.

In order to evaluate possible preferential solvation effects we have studied the solvatochromic behaviour of complex **1** in water–methanol, water–acetone and water–acetonitrile. The solvatochromic behaviour in water–methanol mixtures is very different from that observed in the two other mixed solvents (Fig. 1). Addition of water to a methanol solution of **1** results in a small but regular decrease of λ_{max}, and thus indicates the absence of preferential solvation. On the contrary, the addition of small amounts of water to acetone or acetonitrile solutions results in a sharp decrease in band maxima, typical of a strong preferential solvation by water.

In the three mixed solvents studied at water content of 33, 40 and 50% (v:v) in methanol, acetone and acetonitrile, respectively, an abrupt increase in λ_{max} is observed with a perceptible colour change from red to deep blue (typical of a very lipophilic environment) accompanied by the appearance of turbidity. Light-scattering of these solutions shows that they contain aggregates with a mean hydrodynamic diameter of *ca.* 1000 nm.‡ Since light-scattering studies and the morphology of the aggregates may depend on the presence of small quantities of organic solvent, we have repeated the analysis using several reported methods for the preparation of lipid aggregates in aqueous solutions,[8]§ and the results were similar. The size of the aggregates was confirmed by electron microscopy (Fig. 2). Several grids were observed and in all of them a regular and relatively homogeneous population of round aggregates were observed with most of them with diameters varying between 870 and 1020 nm.¶

The type of aggregate formed was identified by a well established method,[8b,9] with 4(5)-carboxyfluorescein as a fluorescent probe, that is highly hydrophilic and auto-quenches at high concentrations. Aggregates were prepared in an aqueous 1 M solution of 5(6)-carboxyfluorescein, and separated from unincorporated probe by passing through a Sephadex G-50 column. Elution profiles showed clearly two fluorescent bands, one corresponding to the free aqueous probe and the other to the solution containing the aggregated complex (confirmed by UV–VIS spectroscopy). Addition of TRITON-X to the fraction

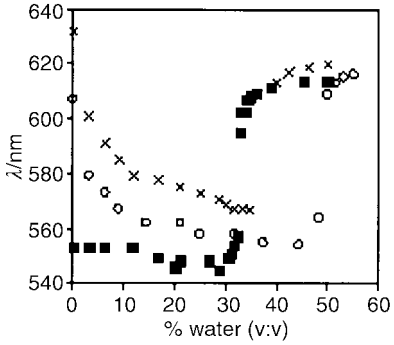


Fig. 1 Variation of λ_{max} of the LMCT band of complex **1** with water content in mixed solvents methanol–water (■), acetone–water (×) and acetonitrile–water (○).

 DOI: 10.1039/b100504i

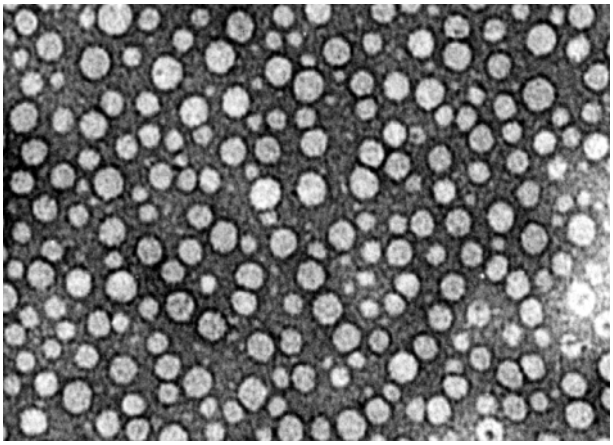

Fig. 2 Negative stain transmission electron micrograph of vesicles at magnification 3000×.

containing the aggregates causes their disruption and an 100-fold increase in fluorescence intensity is observed. This result clearly shows that complex **1** aggregates by forming vesicles—double layer spherical aggregates containing an inner aqueous core.

Preliminary studies of the redox behaviour of this complex in the monomeric and aggregated forms were performed by cyclic voltammetry. Solutions of **1** in acetonitrile show one reversible redox process ($E_{1/2}$ = 0.39 V *vs*. Ag/AgCl,1 M NaCl), a value that is significantly lower than that of $[Fe(bpy)_2(CN)_2]$ obtained in the same conditions ($E_{1/2}$ = 0.49 V *vs*. Ag/AgCl,1 M NaCl), which shows that the introduction of the alkyl chains results in a stabilization of the +3 oxidation state for Fe. Addition of water up to a concentrations of 55% (v/v) does not affect the voltammograms of $[Fe(bpy)_2(CN)_2]$, but for the more lipophilic complex the redox process gradually changes toward more positive potential ($E_{1/2}$ = 0.50 V for 55% H_2O–MeCN). In water rich solvents, where formation of vesicles in solution is observed, immersion of a platinum or vitreous carbon electrode in the solution for 5 min leads to the formation of a redox active film with $E_{1/2}$ = 0.60 V.

The results obtained in this work show that complex **1** is a new metallo-surfactant that readily forms vesicles in water-rich media and with solvatochromic properties that make aggregation self-indicated. This aggregation behaviour provides a simple way to localize metal-ion reactivity in organized media, and the preliminary studies performed by CV show that aggregation, although affecting the redox potential of the iron center, does not inhibit its redox behaviour. Complex **1** is thus a promising compound to test possible synergetic effects of conjugating redox reactivity and the special solvation effects of organized systems, *e.g*. in redox catalysis of lipophilic compounds in water-rich media.

† Chromatography in silica gel 60 (Merck, 230–400 mesh) using acetone and methanol as eluents. δ_H(200 MHz, $CDCl_3$): 0.83–0.90 (m, 12 H, 4 × $-CH_3$); 1.24–1.37 (m, 56 H, 4 × $-(CH_2)_7CH_3$); 2.61 (t, *J* 7.9 Hz, 4 H, 2 × $Ar-CH_2$); 2.77 (t, *J* 7.9 Hz, 4 H, 2 × $Ar-CH_2$); 6.88 (d, *J* 5.8 Hz, 2 H, 2 × 4-Ar-H); 7.12 (d, *J* 5.7 Hz, 2 H, 2 × 3-Ar-H); 7.22 (t, *J* 5.6 Hz, 2 H, 2 × 4′-Ar-H); 7.80 (s, 4 H, 2 × 6,6′-Ar-H); 9.81 (d, *J* 5.6 Hz, 2 H, 2 × 3′-Ar-H). MS (10 keV, FAB$^+$): *m*/*z*: 925 (3) (M^+); 899 (37) [M^+ − CN]; 873 (23) [M^+ − $(CN)_2$].

‡ Dynamic light-scattering was used to determine the diameter of the aggregates, using a Malvern Instrument ZetaSizer 5000, with a 5 mV He–Ne laser operating at 633 nm. Measurements were performed at a scattering angle of 90° at a temperature of 25 °C. All the measurements were performed 2 and 24 h after preparation of the samples. Correlation analysis was performed using CONTIN software from Malvern Instruments.

§ One of the methods more commonly used was the following: 0.1 ml of a methanol solution of the complex (2.0×10^{-4} M) was injected with a Hamilton air-tight syringe into 10 ml of an aqueous solution at 60 °C, under Ar bubbling. After injection the solution was maintained at the same temperature for 5 min with Ar bubbling for complete organic solvent elimination.

¶ A drop of the solution was placed onto 400 mesh copper grids coated with Parlodion (nitrocellulose) film stabilised with vacuum evaporated carbon. After 30 s the excess fluid was drained off with filter paper and a drop of the negative stain added. After 1 min the remainder of the 2% aqueous solution of phototungstic acid with the pH adjusted to 7.2 with 0.1 M NaOH was removed with filter paper and the grid immediately placed in the electron microscope.

First published as an Advance Article on the web 27th June 2001

Polyphenol (p-$HOC_6H_4O)_6W$ is stable with respect to condensation, and formed (4,4′-bipy·$HOC_6H_4O)_6W$ and the 3-D networks $[\{4,4'\text{-}(NC_5H_4)_2(CH_2CH_2)\}_n\{(HOC_6H_4O)_6W\}]_\infty$ (n = 2, 3), when treated with 4,4′-bipy and 1,2-di-4-pyridylethane, respectively.

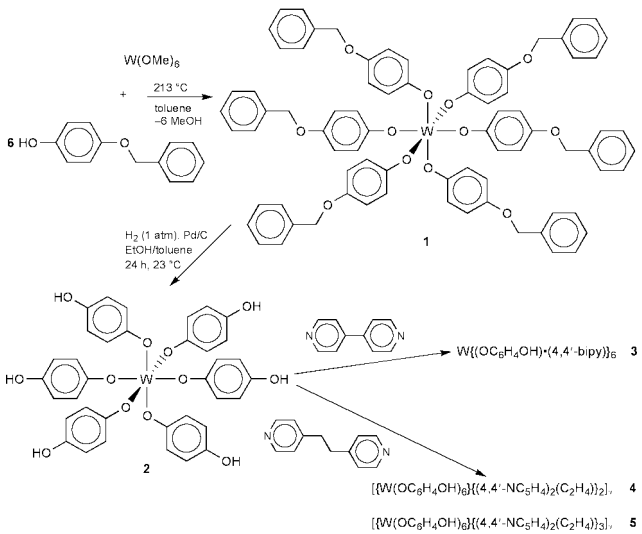
The construction of coordination networks[1] and dendrimeric materials[2,3] often utilizes a polyfunctionalized molecular core from which branches may emanate. While such organic cores exhibit various functionalities, inorganic equivalents are less structurally diverse, and most metals can be considered as Lewis acidic nodes amidst an organic framework. Creating functionality pendant to a metal can be a difficult problem,[4] especially for early transition metals, which are intolerant to many groups. For example, modeling studies indicated that (4-HO-2,6-$C_6R_2H_2O)_4M$ (M = Ti, Zr) would be effectively blocked from self-condensations *via* appropriately sized substituents R, yet trace 4-HO-2,6-$C_6R_2H_2OH$ and rapid alkoxide exchange chemistry hampered all efforts at isolating such species, and oligomeric materials were obtained.

In contrast, $(PhO)_6W$[5] is known to be stable in basic media, and is only susceptible to acid catalyzed phenoxide exchange at elevated temperatures.[6] The innate stability of hexaphenoxidetungsten complexes suggested a route to a polyhydroxylated inorganic core, namely (p-$HOC_6H_4O)_6W$.

As Scheme 1 illustrates, treatment of $W(OMe)_6$, prepared from $W(OMe)_4Cl_2$, MeOH and NEt_3,[7] with p-$HOC_6H_4OCH_2Ph$ in toluene for 24 h at 213 °C in a bomb reactor yielded the polybenzyl ether, (p-$PhCH_2OC_6H_4O)_6W$ **1** (91%).† Deprotection was effected *via* hydrogenation (H_2 (1 atm), Pd/C) in ethanol–toluene, and dark red (p-$HOC_6H_4O)_6W$·2THF·C_6H_6 (**2**·2THF·C_6H_6) was crystallized in 60% yield from THF–benzene.† An intricate, three-dimensional hydrogen-bonding network[8] is observed for **2**·2THF·C_6H_6.‡ Fig. 1. reveals rings of $(p\text{-}OH)_4$ that comprise one connectivity, another loop that alternately involves two p-OH and two phenoxide oxygens, and a single p-OH···THF hydrogen bond. The WO···HO hydrogen bond renders the W–O2 bond long (1.934(4) Å) in contrast to the 1.889(14) Å average distance of the normal tungsten aryloxide bonds.[9] The W–O–C angles range from 136.8(4) to 148.0(4)° to accommodate the network, and little distortion from octahedral coordination is observed in the WO_6 core ($\angle OWO_{cis}$ = 90.0(21)°$_{av}$; $\angle OWO_{trans}$ = 176.7(24)°$_{av}$).

Attempts to generate a hydrogen-bonded network[8] from (p-$HOC_6H_4O)_6W$ **2** and 4,4′-bipyridine failed when efforts to control stoichiometry continually led to the hexa-4,4′-bipyridine derivative (4,4′-bipy·$HOC_6H_4O)_6W$ **3** (Scheme 1, Fig. 2).‡ Hexabasic **3** has a regular core ($\angle OWO_{cis}$ = 90.0(7)°$_{av}$; $\angle OWO_{trans}$ = 178.8(2)°$_{av}$; d(W–O) = 1.901(10) Å$_{av}$; $\angle WOC$ = 137.8(16)°$_{av}$), and packs in hexagonal columns due to face-to-face π-stacking interactions of the bipyridines.[10]

Concern that 4,4′-bipy was rendered an ineffective linker due to the weaker basicity of the second nitrogen upon formation of the initial hydrogen-bond, or its conformational rigidity, prompted a change to 1,2-di-4-pyridylethane. When combined with (p-$HOC_6H_4O)_6W$·2THF·C_6H_6 **2**, two materials of stoichiometry $[\{4,4'\text{-}(NC_5H_4)_2(CH_2CH_2)\}_2\{(HOC_6H_4O)_6W\}]_\infty$ **4** and $[\{4,4'\text{-}(NC_5H_4)_2(CH_2CH_2)\}_3\{(HOC_6H_4O)_6W\}\cdot THF]_\infty$ (**5**·THF) were isolated in *ca.* 1:3 ratio (Scheme 1). Fig. 3(a) reveals the OH···N, N···HO bonds of **4** as a zigzag chain-link motif, while Fig. 3(b) shows how additional phenols interact with the OH groups of these units to form a box.‡ Similar H-bonds connect the boxes and a redundant network interpenetrates to form an overall doubly interpenetrating 3-D network.[1] Again the tungsten core is regular ($\angle OWO_{cis}$ =



Scheme 1

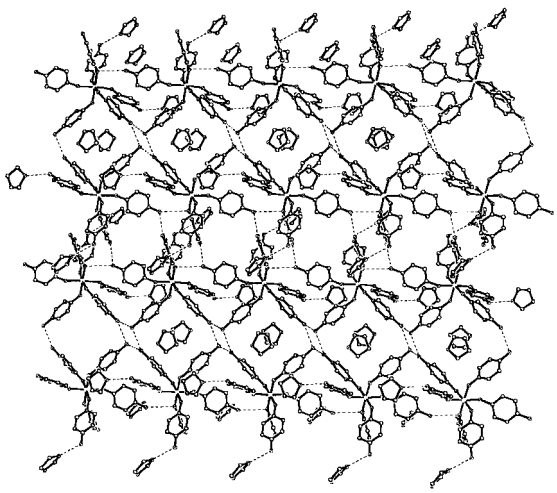


Fig. 1 A sheet of three-dimensional (p-$HOC_6H_4O)_6W$·2THF·C_6H_6 (**2**·2THF·C_6H_6) showing the different H-bonding connectivities.

 DOI: 10.1039/b100561h

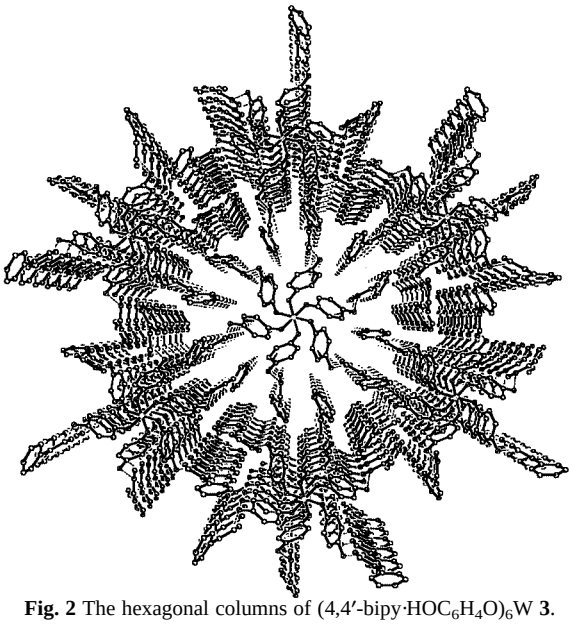

Fig. 2 The hexagonal columns of (4,4′-bipy·$HOC_6H_4O)_6W$ **3**.

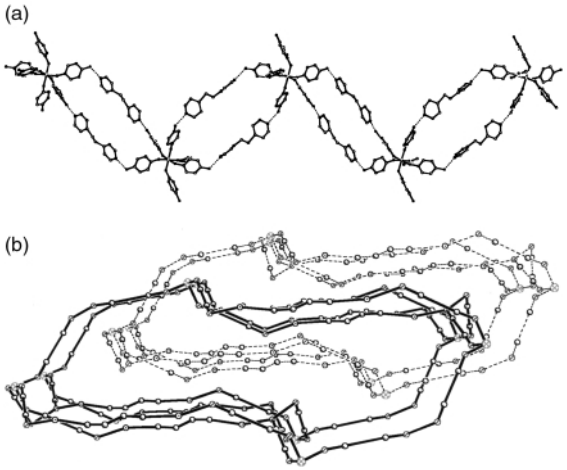

Fig. 3 (a) The zigzag OH···N, N···HO connectivity of [{4,4′-$(NC_5H_4)_2(CH_2CH_2)$}$_2${$(HOC_6H_4O)_6W$}]$_\infty$ **4**. (b) Additional phenolic H-bonds generate the doubly interpenetrating three-dimensional boxes of **4** (W = ⊗, O = ∅, N = ☉, *p*-C and ethane carbons (○)).

90.0(18)°$_{av}$; ∠OWO$_{trans}$ = 178.4(8)°$_{av}$; *d*(W–O) = 1.88(2) Å$_{av}$), but substantial variation in ∠WOC (143.6(54)°$_{av}$) is observed to reflect the constraints of the network.

Fig. 4(a) illustrates the connectivity of [{4,4′-$(NC_5H_4)_2(CH_2CH_2)$}$_3${$(HOC_6H_4O)_6W$}·THF]$_\infty$ (**5**·THF), whose tungsten centers are linked *via* OH···N, N···HO bonds to form an irregular box. The familiar octahedral core of the $(HOC_6H_4O)_6W$ group is evident (∠OWO$_{cis}$ = 90.0(25)°$_{av}$; ∠OWO$_{trans}$ = 177.6(17)°$_{av}$; *d*(W–O) = 1.86(5) Å$_{av}$), yet the W–O–C angles vary greatly (135.7(18)° to 169.4(19)°) to accommodate geometric features of the three-dimensional network. The box described above is voluminous, hence the structure triply interpenetrates[1] [Fig. 4(b)].

In summary, hexaphenol (*p*-$HOC_6H_4O)_6W$ **2** does not self-condense into μ-OC_6H_4O oligomers and can be utilized to form hydrogen-bonded complexes and networks.

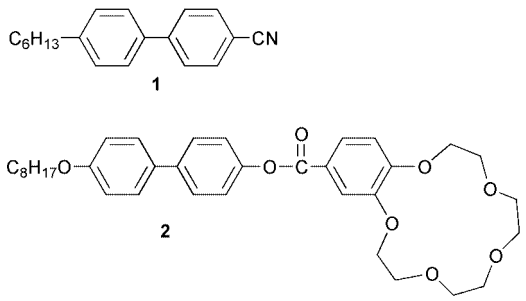
First published as an Advance Article on the web 27th June 2001

Liquid crystallinity of membrane solvent and neutral carriers for potentiometric ion sensors affects the orientation of neutral carrier molecules in the ion-sensing membranes, thus bringing about significant changes in the ion selectivity for the membrane electrodes.

Neutral-carrier-type ion-sensing membranes are very attractive for potentiometric ion sensors such as ion-selective electrodes (ISEs) and ion-sensitive field-effect transistors.[1] The ion selectivities are governed not only by the original selectivity of neutral carriers themselves but also by the kind of plasticizers, because their ion-exchange equilibrium resembles that for liquid–liquid extraction.[2,3] We became very much interested in how the orientation of neutral carrier and solvent molecules affects their ion exchange in the membrane interface. The ion sensor property might be controlled by the orientation of the membrane components. Since liquid crystals possess some molecular orientation as well as mobility, they may be a useful material for PVC-based ion-sensing membranes.[4] We have therefore attempted to use a liquid-crystalline membrane solvent and a neutral carrier as the membrane components for ISEs, expecting some improvement of ion sensor property. Here we report a remarkable liquid crystal effect of membrane solvent and neutral carrier on the resulting membrane electrodes.

In order to elucidate the 'pure' liquid crystal effect on the ion sensor property, we decided to use bulk liquid-crystalline membranes, not PVC-dispersed liquid-crystalline membranes. Bulk membranes consisting of 5.0 wt% neutral carrier, 1.3 wt% potassium tetrakis(*p*-chlorophenylborate) (KTpClPB), and 93.7 wt% solvent were incorporated into the plastic tip of an adjustable pipette (Quality Science Plastics, Q-110) for the neutral carrier-type ion-sensors. For the membrane solvent we employed liquid-crystalline compound, 4-cyano-4′-hexylbiphenyl **1** (K-18, Merck) (Scheme 1), as well as 2-nitrophenyl octyl ether (NPOE) for comparison. The neutral carriers were a liquid-crystalline neutral carrier **2**[5] and [bis(benzo-15-crown-5)-4-methyl] pimelate [bis(benzo-15-crown-5)]. The electrochemical cell for the emf measurements was Ag | AgCl | 1×10^{-3} mol dm^{-3} KCl | ion-sensing membrane | sample solution || 1 mol dm^{-3} CH_3CO_2Li || 3 mol dm^{-3} KCl | AgCl | Ag. The selectivity coefficients of K^+ with respect to Na^+ were determined by a mixed solution method, that is, the fixed interference method (FIM) at the Na^+ background concentration of 1×10^{-2} or 3×10^{-1} mol dm^{-3}.



Scheme 1 Liquid-crystalline solvent (**1**) and neutral carrier (**2**) employed here.

Potassium ion-selective electrodes based on the liquid-crystalline membrane containing liquid-crystalline neutral carrier **2** as well as KTpClPB responded to K^+ activity changes with a Nernstian or near-Nernstian slope in the activity range of 3×10^{-6} to 1×10^{-1} mol dm^{-3} at 25 °C. This was the case for the corresponding liquid membrane systems containing NPOE instead of **1**. There was not any significant difference in the sensitivity at the three measuring temperatures of 19, 25, and 35 °C. The potential response was as fast as that for conventional plasticized-PVC membrane electrodes with t_{90} of several seconds.

The selectivity for K^+ over Na^+ (selectivity coefficient of K^+ with respect to Na^+, $k^{Pot}_{K,Na}$) was measured in the liquid-crystalline membrane systems at the three different temperatures (Fig. 1). It should be noted that the selectivity coefficients depend significantly on the measuring temperatures in the membrane systems containing neutral carrier **2**. On the other hand, little significant change in the selectivity with temperature was observed in the membrane system with bis(benzo-15-crown-5) and without any neutral carrier. The selectivity coefficients of K^+ with respect to Na^+ measured at temperatures of 19 and 25 °C are much smaller than those at 35 °C in the membrane systems containing **2**.

The phase transition temperatures for the above-mentioned membrane systems were followed by differential scanning calorimeter, and are summarized in Table 1. The liquid-crystalline compound **1**, by itself, has a transition from crystal to nematic phase (K–N) at 15.3 °C and from nematic to isotropic phase (N–I) at 29.2 °C. The addition of a small amount of neutral carrier and/or KTpClPB altered the transition temperature to some extent, as anticipated. The drastic temperature dependence of the ion selectivities as shown in Fig. 1 indicates that the higher selectivity for K^+ over Na^+ is attained in the nematic state in the neutral-carrier-type liquid-crystalline membranes of **2**. This means that the highly oriented nematic phase enhances the K^+ selectivity of the 15-crown-5 derivatives over Na^+, as compared with the corresponding isotropic liquid phase. The selectivity coefficients for the membrane system of

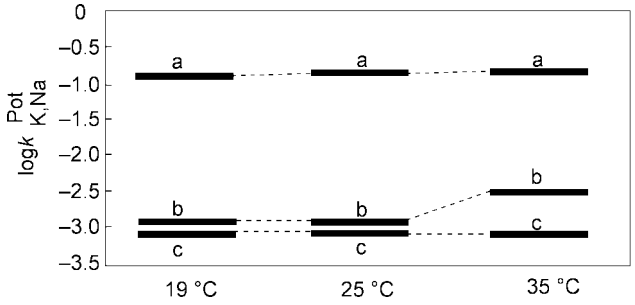


Fig. 1 Temperature dependence of selectivity coefficient for K^+ with respect to Na^+ in the ion-sensing membranes: (a) **1**/KTpClPB (without neutral carrier), (b) **2**/**1**/KTpClPB, and (c) bis(benzo-15-crown-5)/**1**/KTpClPB.

 DOI: 10.1039/b103638f

Table 1 Phase transition temperatures measured by differential scanning calorimetry (°C)

Membrane system	K–N (Crystal-nematic)	N–I (Nematic-isotropic)
1	15.3	29.2
1/KTpClPB	15.2	23.3
2/**1**/KTpClPB	15.3	32.5
Bis(b15C5)[a]/**1**/KTpClPB	15.7	31.1

[a] Bis(b15C5): bis(benzo-15-crown-5) or [bis(benzo-15-crown-5)-4-methyl] pimelate

2/**1**/KTpClPB at 19 and 25 °C are quite comparable to those for the corresponding membrane system containing a bis(benzo-15-crown-5) derivative, bis[(benzo-15-crown-5)-4-methyl] pimelate, instead of **2**. It is well-known that bis(benzo-15-crown-5) derivatives display excellent K^+ selectivity over Na^+ by cooperative action of two adjacent crown ether rings.[6,7] This implies that the highly oriented phase in the membrane urges the monocyclic neutral carriers to aggregate to each other, which in turn allows the neutral carriers to behave as if they were bis(crown ether) neutral carriers.

Even when the bis(benzo-15-crown-5) derivative was employed for the neutral carrier of the liquid-crystalline membrane (**1**/KTpClPB), the K^+ selectivity over Na^+ hardly depended on the temperature over the range from 19 to 35 °C. Also, no significant temperature dependence on the K^+ selectivity over Na^+ was found when NPOE, a well-known plasticizer for PVC-based ion-sensing membranes, was applied as the membrane solvent instead of the liquid- crystalline solvent **1**. This confirms that the enhanced K^+ selectivity over Na^+ for the liquid-crystalline membrane system is quite specific to the highly oriented state of neutral carrier in the membrane.

Thus, the present results suggest that the ordered orientation of neutral carrier molecules in ion-sensing membranes modifies their ion-sensor selectivities to a great extent. The orientation control of neutral carriers not only by temperature but also other external stimuli, such as electric field and light, would switch their membrane ion selectivity. Further study is now under way.

Synthetic equivalents of alkynyl and propargyl radicals

Peter Boutillier and Samir Z. Zard*

Laboratoire de Synthèse Organique associé au CNRS Ecole Polytechnique, 91128 Palaiseau, France. E-mail: zard@poly.polytechnique.fr

Received (in Cambridge, UK) 23rd February 2001, Accepted 4th June 2001
First published as an Advance Article on the web 27th June 2001

Radicals derived from β-ketoesters can, depending on the position of the unpaired electron, represent synthetic equivalents to the high energy and elusive alkynyl radicals or to the stabilised and relatively unreactive propargyl radicals by application of the xanthate transfer reaction followed by nitrosative cleavage of the corresponding isoxazolinones.

Retrosynthetic disconnections of acetylenic targets and intermediates almost never encompass the possibility of using synthons equivalent to propargyl or alkynyl radicals. Synthetic plans rely mostly on the corresponding hypothetical anionic or cationic species and on organometallic coupling or methathesis reactions.[1] Propargylic radicals are stabilised species and are relatively unreactive: although they do undergo ring-closure to non-activated olefins, *intermolecular* additions require activated olefins for success.[2] Alkynyl radicals, in contrast, are highly energetic species, accessible only with great difficulty[3] and, as far as we know, have very rarely been used in synthesis. One notable example is the photochemical generation of phenylethynyl radical from phenyliodoacetylene and its capture by aromatic compounds.[4] The instability of alkynyl radicals is reflected in the strength of the corresponding C–H bond, estimated to be around 130 kcal mol^{-1}, nearly 20 kcal mol^{-1} higher than that of an alkene C–H bond.[3] In view of the central role played by acetylenes in organic chemistry, it seemed worthwhile developing a route which would be an overall synthetic equivalent to either alkynyl or propargyl radicals.

Our approach is based on combining two reactions we have developed in recent times: the nitrous acid mediated cleavage of isoxazolinones[5] with the intermolecular radical addition of xanthates.[6] As shown in the top sequence in Scheme 1, addition of a radical located in position 2 of a β-ketoester and derived from the corresponding xanthate **1** to olefin **2** gives an adduct **3**, where a new C–C bond has been formed in an intermolecular manner. Reductive removal of the xanthate, formation of the isoxazolinone **5** (only one tautomeric form is drawn),[7] and cleavage with nitrous acid finally provides the desired alkyne **6**. This compound corresponds formally to the addition of the inaccessible alkynyl radical **7** to the starting olefin **2**. If the initial radical is located at position 4 of the β-ketoester (*i.e.* starting with xanthate **8**), the overall sequence leading to acetylene **10** is equivalent to the addition of a propargyl radical **11** to the olefin. This approach, involving an electron attracting α-acetonyl radical, complements the use of the propargyl radical itself which, as was stated above, has a rather nucleophilic character and therefore requires an olefin activated by an electrophilic group as partner.

The examples collected in Table 1 give an idea of the scope of the sequence corresponding to the overall addition of an alkynyl radical. Both the radical addition and the nitrosative cleavage occur under mild conditions and are tolerant of various functional groups commonly encountered in organic synthesis. In the case of the isoxazoline **5e** derived from *N*-tosylallylamine **2e** (entry 5), *N*-nitrosation occurred to give **6′e** (**6**, R′ = $-CH_2N(NO)Ts$) in 46% yield, in addition to the 'normal' alkyne **6e**, itself formed in 20% yield. The *N*-nitroso group in **6′e** could be removed by warming with triethylamine in aqueous THF, thus bringing the overall yield of alkyne **6e** to 47%.[8]

For convenience, the xanthate group in the adduct was reductively removed either by treatment with a stoichiometric quantity of lauroyl peroxide in isopropanol (yields with an asterisk in Table 1)[9] or, more conventionally, with tributylstannane; its presence, however, allows the insertion of another radical transformation, namely cyclisation onto an aromatic ring.[10] This is illustrated by the synthesis of the 3-alkynyl indoline pictured in Scheme 2. Thus, addition of xanthate **1c** to *N*-allyl-*N*-mesyl-*p*-bromoaniline **2e** gave the expected adduct **12** in a reasonable yield (43%, along with 28% of recovered xanthate). Exposure of this adduct to stoichiometric amounts of lauroyl peroxide (added portion-wise over several hours) in refluxing 1,2-dichloroethane resulted in ring-closure to indoline **13** (86%). Finally, conversion into the corresponding isox-

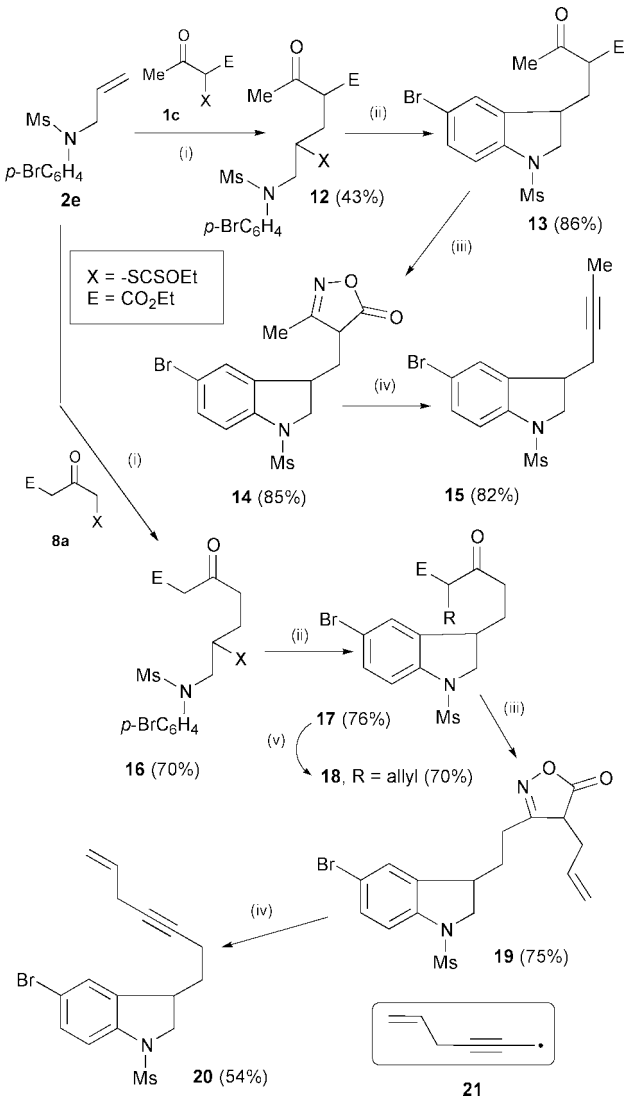
Me	**1c**	$-(CH_2)_9OPiv$	**2c**	**3f** (75)	**4f** (72)*	**5f** (81)	**6f** (60)

 DOI: 10.1039/b101751i



Scheme 2 *Reagents and conditions*: (i) lauroyl peroxide (5–30 mol%), 1,2-dichloroethane, reflux; (ii) lauroyl peroxide (100–110%), 1,2-dichloroethane, reflux; (iii) $NH_2OH.HCl$, AcONa, EtOH, reflux; (iv) $NaNO_2$, $FeSO_4$, AcOH, H_2O, RT; (v) allyl bromide, K_2CO_3, acetone, reflux.

azolinone and nitrosation furnished the desired alkyne **15** in 70% yield for the two steps.

A similar sequence can be used to illustrate the case of a propargyl radical equivalent. As shown in the bottom part of Scheme 2, radical addition of xanthate **8a** to the same olefin **2e** and similar ring closure provided indoline **17** in 42% overall yield. Allylation of the ketoester with allyl bromide, formation of the isoxazolinone, and nitrosative cleavage gave compound **20** containing the delicate, skipped enyne motif. This sequence corresponds to effecting the addition of stabilised and unreactive propargylic radical **21** to the unactivated olefin present in **2e**. Incidentally, the elaboration of a β-ketoester in the 4-position under neutral conditions *via* xanthate **8a** is worth underlining. Usually, it is necessary to resort to the highly basic di-anion[10] or to the bis-silylenol ether under Lewis acid catalysis[11] in order to functionalise position 4 without affecting the much more acidic position 2 of the ketoester.

In summary, the present approach complements existing methods by allowing the rapid assembly of a variety of otherwise inaccessible alkynes. It also brings a practical solution to the longstanding problem of finding synthetically useful and tame surrogates for the unavailable and unruly alkynyl radicals.

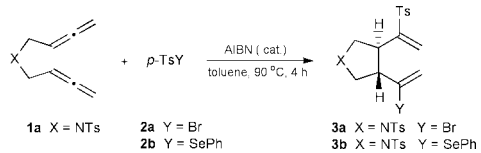
Received (in Cambridge, UK) 27th February 2001, Accepted 30th May 2001
First published as an Advance Article on the web 28th June 2001

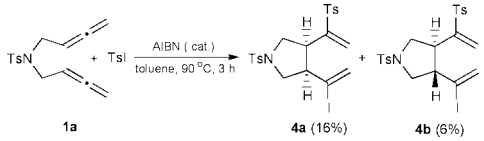
The regio- and stereoselective toluene-*p*-sulfonyl-mediated radical cyclization of bis(allenes) with *p*-TsBr and *p*-TsSePh was carried out in the presence of a catalytic amount of AIBN to afford the *trans*-fused five-membered ring containing vinyl sulfones and bromide or selenide functionalities.

Recently the use of radical cyclization for carbon–carbon bond forming reactions has become widespread in organic chemistry[1] for the construction of carbocyclic and heterocyclic natural products.[2] The majority of commonly employed methods utilize tributyltin hydride to induce homolysis of an organic halide or alcohol derivative in forming the reactive carbon radical species. An alternative approach is to use the addition of a free-radical to two carbon–carbon double bonds, one double bond and one triple bond, or two triple bonds, which has the advantage of incorporating some useful additional functional groups into the cyclized products. The utility of this type of method using dienes,[3,4] enynes,[3a,5] and diynes[5e,6] with sulfonyl halides, thiols, sulfonyl selenides, and tin hydrides *etc*. has been demonstrated. However the radical reaction of allenic derivatives has received little attention,[7,8] because the addition reaction to allenes will be complicated in terms of chemo-, regio-, and stereoselectivity. To the best of our knowledge the radical induced cyclization of bis(allenes) is not known and we reasoned that the radical cyclization addition reaction of bis(allenes) is appealing because useful functionality is introduced in one simple step in which new carbon–carbon bond formation occurs stereoselectively coupled with two unsaturated appendages with distinguished reactivity.[9] The resulting cyclic compounds would be particularly useful to allow further synthetic transformations. Here we report the diastereoselective tosyl-mediated radical cyclization[10] of bis(allenes) **1** with *p*-tosyl bromide[11] and TsSePh[12] in the presence of a catalytic amount of AIBN to afford the *trans*-fused cyclopentane compounds **3**,† in which vinyl sulfones and vinyl bromides, or selenophenyl functionalities are introduced (Scheme 1).



Scheme 1

Our initial work began with TsCl and benzoyl peroxide (BPO).[3b] However, it turned out to be unpromising. The reaction of **1a**[9] with TsI and AIBN in a sealed tube gave the cyclized products **4a** and **4b**‡ as a separable mixture in a low (22%) yield in the ratio of *cis* and *trans* (8:3). With sulfonyl iodides the chain transfer step seems to be too fast to allow efficient stereoselective cyclization (Scheme 2).



Scheme 2

Although with *p*-TsBr and AIBN simple heating did not give the clean product, by the use of a pressure tube (30 mL) capped

Table 1 Radical cyclization of bis(allenes) with TsBr and TsSePh in the presence of AIBN

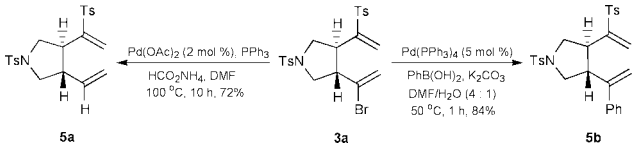
7	 **1d**	**2a**	 **3g**	63

[a] All reactions were carried out at 90 °C for 4 h with AIBN (20 mol%) in toluene.

 DOI: 10.1039/b101870l



Scheme 3

with a teflon screw§ the reaction of **1a** with TsBr (1.1 equiv.) and AIBN (0.2 equiv.) in toluene at 90 °C for 4 h afforded the *trans*-fused cyclized product **3a** as the sole product in 73% isolated yield (entry 1 in Table 1).¶ The *trans* stereochemistry of the cyclized product **3a** was confirmed by the coupling constant (J = 9.6 Hz) for the protons (δ 2.97 and 2.87 ppm) at the ring junction in COSY experiments and 2D-NOESY experiments of the two protons at ring juncture and two *ortho* protons of the *p*-tosyl group in ^{1}H NMR.[13] It is presumed that the addition of tosyl radical to the central carbon atom of the allene moiety gives the allylic radical intermediates in the propagation step followed by cyclization with the other tethered allene moiety in a *trans* fashion stereoselectively to give the energetically more favorable and more stable *trans* product **3a** (entry 1 in Table 1). More clearly the *trans* stereochemistry of **3a** was determined by X-ray crystallography.

The cyclized product **3a** was transformed to the compounds **5a** and **5b** by the palladium-catalyzed reductive hydrogenolysis and Suzuki coupling reaction, respectively (Scheme 3).

Using *p*-TsSePh[12] as the radical source[14] in a pressure tube with AIBN in toluene, the *trans* cyclized selenide **3b** was obtained as the only isolated product in 59% yield (entry 2 in Table 1). The *trans* stereochemistry of **3b** was confirmed by X-ray crystallography.

We have applied this radical cyclization to the other bis(allenes) **1b**, **1c**, and **1d**, summarized in Table 1. The *N*-phenyl-substituted bis(allene) **1b** was treated with TsBr and TsSePh to give the cyclized products **3c** and **3d** in 48 and 65% yields, respectively (entries 3 and 4). For the bis(allenyl) ether **1c** the radical cyclization with **2a** and **2b** gave oxacycles **3e** and **3f** in 64 and 55% yields, respectively (entries 5 and 6). The *trans* stereochemistry of **3f** was determined by the coupling constant (J = 8.8 Hz) for the protons (δ 3.10 and 3.20 ppm) at the ring junction in COSY experiments. The diphenyl-substituted bis(allene) **1d** was smoothly cyclized to furnish vinyl bromide **3g** in 63% yield (entry 7).

In conclusion, *p*-tosyl-mediated radical cyclization of bis(allenes) with *p*-TsBr and *p*-TsSePh was accomplished stereoselectively in the presence of a catalytic amount of AIBN to afford the *trans* cyclized rings containing vinyl sulfone and vinyl bromide or vinyl phenylselenide.

The authors wish to acknowledge financial support by KOSEF-CMDS (Center for Molecular Design and Synthesis).

Notes and references

† A solution containing *p*-TsBr **2a** (94 mg, 0.40 mmol), bis(allene) **1a** (100 mg, 0.36 mmol) and AIBN (0.20 equiv.) in 4.0 mL of toluene was degassed and heated in a pressure tube at 90 °C for 4 h and toluene was evaporated *in vacuo*. The crude product was separated by column chromatography (hexanes–ethyl acetate = 2 : 1). Spectral data for (**3a**), yield: 135 mg, 73%; white solid; TLC, SiO_2, R_f 0.31 (2 : 1 hexane–EtOAc); mp 158 °C; IR (neat) ν = 3061, 2925, 1596, 1338, 1171, 1012, 812 cm^{-1}; ^{1}H NMR (500 MHz, $CDCl_3$): δ = 2.45 (s, 3H), 2.48 (s, 3H), 2.87 (ddd, 1H, J = 7.8, 8.9, 9.6 Hz), 2.97 (ddd, 1H, J = 8.0, 8.9, 9.6 Hz), 3.04 (dd, 1H, J = 8.9, 10.5 Hz), 3.18 (dd, 1H, J = 8.9, 10.4 Hz), 3.61 (dd, 1H, J = 8.0, 10.4 Hz), 3.65 (dd, 1H, J = 7.8, 10.5 Hz), 5.33 (d, 1H, J = 2.2 Hz), 5.46 (d, 1H, J = 2.2 Hz), 5.77 (d, 1H, J = 1.4 Hz), 6.46 (d, 1H, J = 1.4 Hz), 7.31 (d, 2H, J = 8.1 Hz), 7.37 (d, 2H, J = 8.0 Hz), 7.64 (d, 2H, J = 8.1 Hz), 7.70 (d, 2H, J = 8.0 Hz); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 22.3, 22.4, 43.0, 52.0, 53.2, 54.4, 121.2, 125.0, 128.4, 129.2, 130.5, 130.6, 130.7, 134.1, 135.6, 144.6, 145.5, 149.7; HRMS for $C_{22}H_{24}BrNO_4S_2$; calcd: 509.0330; found: 509.0343.

Spectral data for (**3b**), yield: 59%; white solid; TLC, SiO_2, R_f 0.21 (3 : 1 hexane–EtOAc); mp 100–102 °C; IR (neat) ν = 3058, 2954, 1598, 1347, 1311, 1163, 814 cm^{-1}; ^{1}H NMR (500 MHz, $CDCl_3$): δ = 2.44 (s, 3H), 2.48 (s, 3H), 2.91 (m, 3H), 3.08 (m, 1H), 3.62 (m, 2H), 5.01 (d, 1H, J = 0.9 Hz), 5.23 (d, 1H, J = 0.9 Hz), 5.57 (d, 1H, J = 1.5 Hz), 6.38 (d, 1H, J = 1.5 Hz), 7.26–7.35 (m, 9H), 7.65 (m, 4H); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 21.6, 21.7, 42.2, 50.9, 52.6, 54.1, 120.0, 123.8, 127.6, 128.1, 128.4, 128.6, 129.5, 129.8, 130.0, 133.6, 134.5, 135.1, 138.7, 143.8, 145.1, 149.5; HRMS for $C_{28}H_{29}NO_4S_2Se$; calcd: 587.0703; found: 587.0715.

‡ The *trans* configuration was deduced by the coupling constant of the two protons (J = 9.8 Hz) (δ 2.72 and 2.55 ppm) at the ring junction.

§ The pressure tube (made of borosilicate glass) was purchased from Aldrich Chem. Co., Inc. (Catalog Number Z18,109-9 type B).

¶ However when the same reaction was conducted with *p*-TsBr at threefold higher concentration for a shorter reaction time (1 h), we could isolate the *trans* product **3a**, the kinetic *cis* product and the monoadduct in the ratio 5 : 1 : 0.6 in 34% total yield and there remained 46% of the starting material.

Ring-opening of lactides and related cyclic monomers by triaryltin(IV) alkoxides and amides†

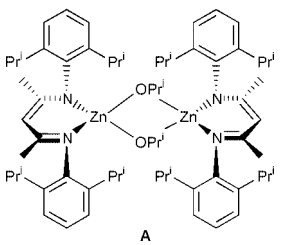
Malcolm H. Chisholm* and Ewan E. Delbridge

Department of Chemistry, The Ohio State University, 100 W 18th Avenue, Columbus Ohio, 43210-1185, USA. E-mail: chisholm@chemistry.ohio-state.edu

Received (in Cambridge, UK) 29th March 2001, Accepted 5th June 2001
First published as an Advance Article on the web 27th June 2001

Ar_3SnX, where Ar = *p*-MeC_6H_4, *p*-$CF_3C_6H_4$ or Ph and X = OBu^t or NMe_2, are catalyst precursors for the ring-opening of lactides in benzene at 80 °C and the rate of ring-opening of lactides and a variety of related cyclic monomers is influenced by Ar and X such the chemistry of the ring-opening event and the initially formed product may be examined.

The ring-opening polymerization of lactides (L, D, *rac* and *meso*) by well-defined coordination complexes is a topic of current interest since polylactides (PLAs) have numerous applications ranging from bulk packing materials[1] to drug delivery reagents,[2] artificial sutures[2,3] and scaffolds[4] for tissue engineering. There have been some exciting recent reports documenting stereoselective polymerization of *rac*- and *meso*-lactides to give heterotactic, isotactic and syndiotactic PLAs.[5] Much remains to be learned at this time, however, since very little is known about the details of factors controlling the rate of ring-opening, the stereoselectivity of this event and the deleterious side reactions of both intra- and inter-chain transfer and transesterification reactions, which can lead to loss of control of stereochemistry and molecular weight of PLAs. For example, the β-diiminate complex $[(BDI)Zn(OPr^i)]_2$ shown in **A** is reported to give >90% heterotactic PLA from *rac*-lactide



A

at 25 °C in CH_2Cl_2[5c] whereas the related magnesium complex gives atactic polymer under similar conditions with rapid transesterification.[6]

The stereocontrol in the polymerization of *rac*-lactide by $[(BDI)Zn(OPr^i)]_2$ has been attributed to end-group control which is fostered by the bulky BDI ligand, yet even bulkier ligands such as pyrazolylborate LMOR complexes [L = $(3\text{-}Bu^tpz)_3BH$, M = Mg and Zn] show little stereoselectivity.[7] We reasoned that much might be learned from studies of the kinetics of reactions employing Ar_3SnOR catalyst precursors since, unlike trispyrazolylborate ligands or other tridentate ligands, reversible bond breaking is not likely for the Sn–C and Sn–O bonds under mild conditions. Moreover the influence of electronic and steric factors can be examined by the use of *para*- and *meta*-substituents on the aryl ligands. We report here on initial findings from studies involving Ar_3SnX precursors, where Ar = *p*-MeC_6H_4, *p*-$CF_3C_6H_4$ or Ph and X = OBu^t or NMe_2.

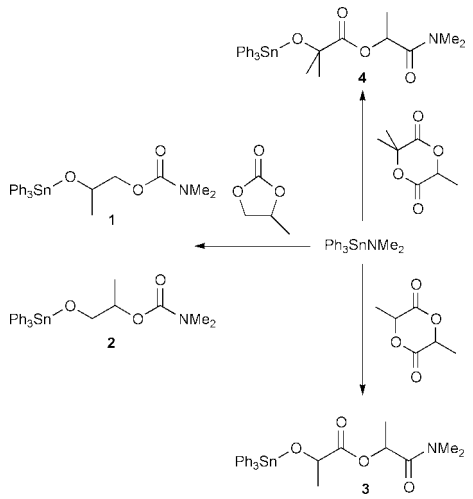
† Electronic supplementary information (ESI) available: additional experimental data. See http://www.rsc.org/suppdata/cc/b1/b102896k/

The compounds Ar_3SnX were prepared from either metathetic reactions involving the respective Ar_3SnCl compound and $LiNMe_2$ or by an alcoholysis reaction involving Ar_3SnNMe_2 and Bu^tOH in hydrocarbons.‡ The compounds are white, hydrocarbon-soluble, microcrystalline materials with the exception of $(p\text{-}MeC_6H_4)_3SnNMe_2$ which is a colorless oil. These compounds were characterized by ^1H, $^{13}C\{H\}$ and ^{119}Sn NMR spectroscopy (and for Ar = *p*-$CF_3C_6H_4$ by ^{19}F) together with mass spectrometry, IR spectroscopy and elemental analysis. These compounds were found to be kinetically inert at 80 °C in benzene, conditions under which ring-opening polymerization (ROP) of lactides was subsequently studied.

In a typical polymerization reaction 50 equivalents of lactide was allowed to react with the Ar_3SnX compound in C_6D_6 at 80 °C (or in some instances at 52, 67 and 70 °C) and the reaction was monitored with time by NMR spectroscopy. Reactions were quite slow requiring *ca.* 3 days to approach 90% conversion. From the plots of $-\ln(A/A_0)$ *vs.* time (where A = concentration of lactide) we can estimate the rates of consumption of lactide to be $k_{obs} = 2.8(1) \times 10^{-6}$ and $2.0(1) \times 10^{-6}$ s^{-1} for X = NMe_2 and Ar = *p*-$CF_3C_6H_4$ and Ph, respectively. In reactions between Ph_3SnOBu^t and L-lactide, we can also obtain a reasonable estimate of the rate of the initial ring-opening event, $k_{ro} = 2.8(1) \times 10^{-6}$ s^{-1} which is faster than the rate of propagation $k_{prop} = 1.4(1) \times 10^{-6}$ s^{-1}. From studies of the rates of polymerization reactions with temperature we have obtained estimates of the enthalpy and entropy of activation for the ring-opening event for Ar = Ph and X = NMe_2 at a [lactide]:[catalyst] ratio of 50 to 1: $\Delta H^{\ddagger} = 12(1)$ kcal mol^{-1} and $\Delta S^{\ddagger} = -51(5)$ cal K^{-1} mol^{-1}. The rather large entropy of activation is consistent with a bimolecular reaction with a highly ordered transition state. However, the role of solvation has not been examined. It is noteworthy that these polymerization reactions are slower than those recently reported for a tin(II) catalyst system employing $(BDI)SnOPr^i$[8] as an initiator and also that whereas the latter shows a preference for heterotactic, *rmr* and *mrm*, tetrads in the polymerization of *rac*-lactide, no such preference is found in reactions employing Ar_3SnX precursors. The rate of polymerization is probably influenced by the relative polarity of the Sn–OR bond which is greater for Sn(II) than Sn(IV) but, given the relative size of Sn(II) *vs.* Sn(IV) (0.69 Å),[9] the stereoselectivity attributed to end-group control involving the SnOC*HMeC(O)OC*HMeC(O)OP unit of the growing polymer chain must arise from the pocket created by the two 2,6-diisopropylphenyl ligands in the (BDI)M(OR) catalyst systems.

Although the Ar_3SnX precursors are kinetically inert at 80 °C in benzene-d_6 for several days and the system that is initially active in the polymerization can be reasonably represented by $Ar_3Sn(OP)$, where OP represents the growing polymer chain, with the onset of polymerization, Ar_4Sn compounds are formed (as identified by ^1H, ^{13}C and ^{119}Sn NMR as well as electrospray mass spectrometry). Ar_4Sn compounds are inactive and the systems that are believed to be catalytically active are $Ar_{3-n}Sn(OP)_n$, where n = 1 or 2. The formation of Ar_4Sn clearly implicates the facility of chain transfer and, in addition, from studies of molecular weight distributions with time, we

 DOI: 10.1039/b102896k



Scheme 1

observe extensive transesterification. Thus, even the seemingly simple and kinetically slow system for the ROP of lactides employing Ar_3SnX precursors has proved to be complicated.

One important point to emerge from these studies is the rate of ring-opening of lactide and related monomers occurs much more rapidly when X = NMe_2 than for X = OBu^t. Thus, *at room temperature*, Ph_3SnNMe_2 in benzene ring-opens the cyclic oxygenates shown in Scheme 1. The regiochemistry of the ring-opening event can be reliably determined from NMR studies.‡ The Sn–O^{13}C carbon shows coupling to ^{119}Sn and the amide methyl protons appear as two singlets due to the restricted rotation about the C–NMe_2 bond. Notable here is the ring-opening of propylene carbonate (PC) to give **1** and **2** (Scheme 1) a required step in the ring-opening decarbonation polymerization of PC by tin catalysts at higher temperatures.[10]

The ring-openings shown in Scheme 1 convert an Sn–NMe_2 group to an Sn–OR group and at 25 °C no further insertion/ring-opening occurs. The compounds are, however, not indefinitely persistent in solution. The compound $Ph_3SnOCHMeC(O)OCHMeCONMe_2$ **3** which we can represent as $Ph_3Sn[OCHMeC(O)]_2NMe_2$ is labile to transesterification reactions as represented by eqn. (1).

$$Ph_3Sn[OCHMeC(O)]_2NMe_2 \rightarrow Ph_3Sn[OCHMeC(O)]NMe_2 + Ph_3Sn[OCHMeC(O)]_nNMe_2\ (n \geqslant 3) \quad (1)$$

Reaction (1) is also accompanied by chain transfer and phenyl migration yielding Ph_4Sn. The compound $Ph_3Sn[OCMe_2C(O)OCHMeC(O)NMe_2]$ **4** is less labile to transesterification of the type shown in eqn. (1), presumably because of the bulky *gem*-dimethyl group, but still enters into chain/aryl group transfer. However, **4** does react with $Ph_3Sn(OBu^t)$ to give $Ph_3SnOCHMeC(O)NMe_2$ and $Ph_3Sn[OCMe_2C(O)OBu^t]$, products of transesterification. $Ph_3SnOCHMeC(O)NMe_2$ is formed from the reaction between Ph_3SnNMe_2 and lactide (2 : 1 ratio) in benzene as the major kinetic product in eqn. (2).

$$Ph_3Sn[OCHMeC(O)OCHMeC(O)NMe_2] + Ph_3SnNMe_2 \rightarrow 2Ph_3Sn[OCHMeC(O)NMe_2] \quad (2)$$

Reactions employing $Ph_2Sn(NMe_2)_2$ and lactide (1 : 1 ratio) yield $Ph_2Sn[OCHMeC(O)NMe_2]_2$ by consecutive ring-opening of lactide followed by intramolecular attack on the chain, eqn. (3).

$$Ph_2Sn(NMe_2)[OCHMeC(O)OCHMeC(O)NMe_2] \rightarrow Ph_2Sn[OCHMeC(O)NMe_2]_2 \quad (3)$$

In conclusion, these initial studies reveal that this seemingly most simple system for ring-opening polymerization of lactide is complicated by mischievous side-reactions. Insight into the latter, namely ligand exchange and transesterification and the ring-opening event can be gleaned from studies of model reactions such as those shown in reactions (1), (2) and (3).

We thank the Department of Energy, Office of Basic Science, Chemistry Division for financial support.

Notes and references

‡ *General considerations*: the synthesis of R_3SnNMe_2 and $Ph_2Sn(NMe_2)_2$ complexes was based on the reported synthesis[11] of Ph_3SnNMe_2 and $Ph_2Sn(NMe_2)_2$. See ESI for additional spectroscopic data.†

$SnPh_3[OCHMeC(O)OCHMeC(O)NMe_2]$: δ_H(400 MHz, C_6D_6): 0.99 [d, CH*Me*C(O)NMe_2, 3H], 1.53 (d, SnOCH*Me*, 3H), 2.11 (s, NMe_2, 3H), 2.47 (s, NMe_2, 3H), 4.75 (q, SnOC*H*Me, 1H), 4.83 [q, C*H*MeC(O)NMe_2, 1H], 7.16 (m, *m*- and *p*-H, 9H), 7.80 (dd, *o*-H, 6H, J_{HH} 7.9, 1.5 Hz, $^{119/117}$Sn satellites J_{SnH} ^{117}Sn 64, ^{119}Sn 49 Hz).

$SnPh_2[OCHMeC(O)NMe_2]_2$: δ_H(400 MHz, C_6D_6): 1.43 (d, SnOCH*Me*, 6H), 1.87 (s, NMe_2, 6H), 2.26 (s, NMe_2, 6H), 4.87 (q, SnOC*H*Me, 2H), 7.21 (t, *p*-H, 2H), 7.35 (t, *m*-H, 4H), 8.37 (dd, *o*-H, 4H, J_{HH} 7.6, 1.2 Hz, $^{119/117}$Sn satellites J_{SnH} ^{117}Sn 75, ^{119}Sn 59 Hz).

$SnPh_3[OCMe_2C(O)OCHMeC(O)NMe_2]$: δ_H(500 MHz, C_6D_6): 1.06 (d, CH*Me*C$ONMe_2$, 3H), 1.56 (s, SnOC*Me*$_2$, 3H), 1.65 (s, SnOC*Me*$_2$, 3H), 2.12 (s, NMe_2, 3H), 2.47 (s, NMe_2, 3H), 4.87 [q, C*H*MeCO)NMe_2, 1H], 7.17 (m, *p*-H, 3H), 7.23 (m, *m*-H, 6H), 7.87 (dd, *o*-H, 6H, J_{HH} 8.2, 1.3 Hz, $^{119/117}$Sn satellites J_{SnH} ^{117}Sn 64, ^{119}Sn 48 Hz).

Polymerization reactions: standard solutions of the appropriate R_3SnX complex (0.027 M) and L- or *rac*-lactide (0.338 M) were prepared in C_6D_6 and stored in a dry-box. Aliquots (100, 50, 25 and 12.5 μL for 25 : 1, 50 : 1, 100 : 1 and 200 : 1, respectively) of R_3SnX solutions were transferred along with an aliquot (200 μL) of either L- or *rac*-lactide to a J. Young® NMR tube. The total volume was made up to 800 μL with C_6D_6 to ensure a constant lactide concentration (0.084 M). Rates of polymerization were determined from ^{1}H NMR data where the sum of the area of monomer and polymer peaks (CH and CH_3) was assumed to be 100% and rates of disappearance of monomer were calculated by the subtraction of the integral of the polymer peaks from the integral of the monomer peaks and dividing by the concentration of monomer at t = 0. The natural log of this ratio was then plotted against time with a straight line being indicative of pseudo-first order kinetics. The gradient of this plot was used to determine values of k_{obs}.

A new architecture, comprising two interpenetrating chains of rings, has been discovered in the first organometallic polyrotaxane; the synthesis combines the techniques of organometallic chemistry, coordination chemistry and self-assembly through hydrogen bonding.

Functional polymers having novel architectures are of great current interest and polyrotaxanes are viewed as particularly significant. Admirable synthetic strategies have been developed to polymers with the rotaxanes on the main chain or side chain,[1–5] (**A** and **B** in Chart 1), and potential applications

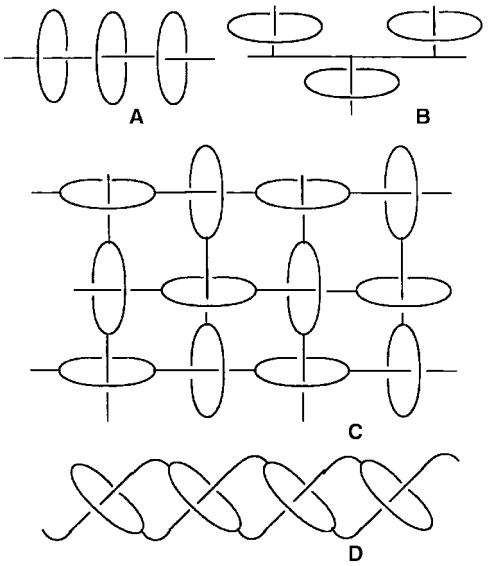

Chart 1 Polyrotoxanes.

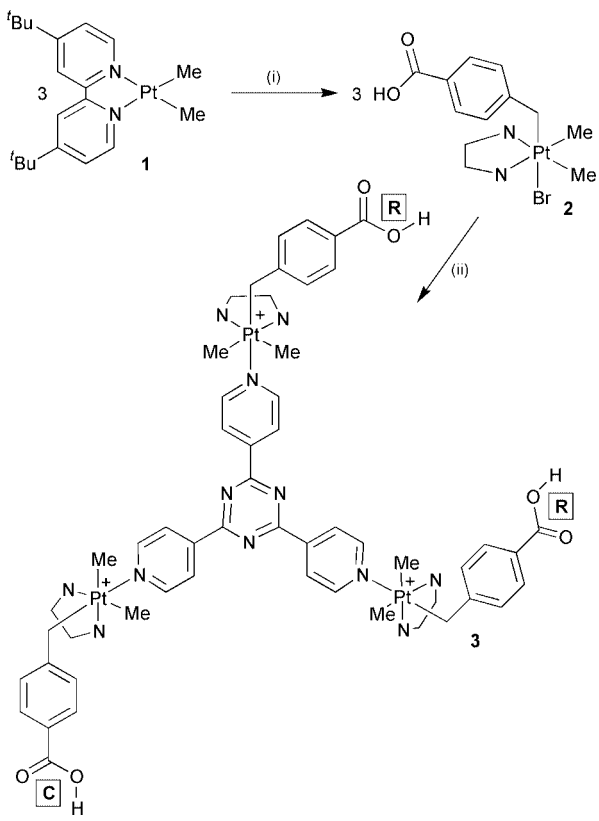
ranging from drug delivery vehicles[6] to sensor devices[7–9] have been identified. If polymeric chains also contain ring components, then interpenetration can occur and this has been demonstrated in a two-dimensional sheet polyrotaxane (**C** in Chart 1).[10] This paper describes a new polyrotaxane architecture in which a related form of interpenetration occurs to give a one-dimensional polyrotaxane of type **D** (Chart 1). The synthesis involves introduction of a hydrogen-bonding group by oxidative addition (organometallic chemistry), assembly of three of these units at a tridentate templating ligand (coordination chemistry) and then formation of the polyrotaxane product by self-assembly through the hydrogen-bonding substituents. The combination of these interdisciplinary methods has great potential for forming new functional materials but has very rarely been used in the past.[11,12]

The reaction of $[PtMe_2(Bu_2bipy)]$, **1**, (Bu_2bipy = 4,4′-di-*tert*-butyl-2,2′-bipyridine)[11] with α-bromo-4-toluic acid gave the complex $[PtBrMe_2(Bu_2bipy)(CH_2C_6H_4CO_2H)]$, **2**, containing a carboxylic acid functional group designed to take part in intermolecular hydrogen bonding (Scheme 1). Three of these organoplatinum(IV) units were assembled at a tridentate ligand by substitution of bromide ligands by the pyridyl donors of *sec*-tris(4-pyridyl)triazine, Py_3T, which is known to give interesting structures in coordination chemistry.[13] The bromide abstraction step in the synthesis was effected by use of $AgPF_6$, to give the product $[\{(HO_2CC_6H_4CH_2)(Bu_2bipy)Me_2Pt\}_3\{(\beta\text{-}NC_5H_4)_3(C_3N_3)\}]^{3+}$, **3**, as the hexafluorophosphate salt. In the successful crystallization, 0.5 equiv. of HPF_6 and five acetone molecules were incorporated for each complex $\mathbf{3}[PF_6]_3$.[14]

The ions **3** self-assemble into chains of rings in the following way: the two carboxylic acid groups labelled **R** in Scheme 1 hydrogen bond to the group of a neighbouring molecule to form 56-membered rings and the group labelled **C** hydrogen bonds to the equivalent carboxylic acid group of a second neighbouring molecule to make a chain. Part of the one-dimensional polymer, comprised of rings connected by chains, that results from this self-assembly is illustrated in Fig. 1. Most remarkably, two of these polymeric units interpenetrate, with each ring section of one polymer penetrated by the chain section of the other, to form a new type of polyrotaxane (**D**, Chart 1) as illustrated in Fig. 2.

The infrared spectrum of **3** as a Nujol mull contains peaks due to ν(O–H) in the range 2545–2672 cm^{-1}, and the O···O distances between the hydrogen-bonded carboxylic acid groups in **3** are in the range 2.6–2.7 Å, Fig. 1, indicating the presence



Scheme 1 NN = Bu_2bipy. *Reagents*: (i) 3 $BrCH_2C_6H_4CO_2H$; (ii) 3 Ag^+, $C_3N_3(C_5H_4N)_3$, −AgBr.

 DOI: 10.1039/b103967a

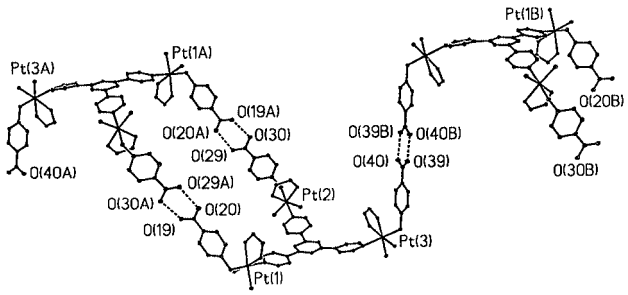


Fig. 1 The structure of complex **3**. The hydrogen bonding to give chains [O(39)···O(40B) = 2.60 Å] of rings [O(20)···O(29A) = 2.64 Å, O(19)···O(30A) = 2.70 Å] is illustrated for a central molecule and its two neighbours. Only the NCCN atoms of the Bu_2bipy ligands are shown for clarity.

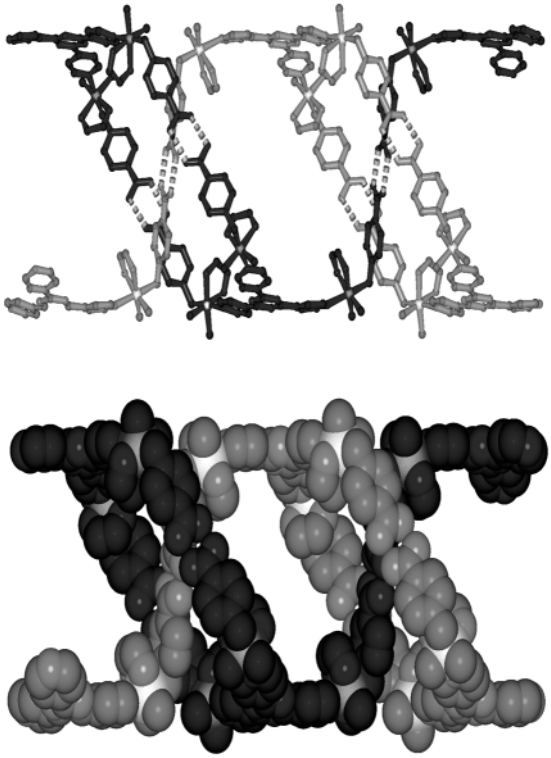

Fig. 2 A section of the polyrotaxane structure formed by two interpenetrating polymer units; only the central NCCN atoms of the Bu_2bipy ligands are shown for clarity. Above, ball and stick and, below, space filling representations.

of strong hydrogen bonds.[15] Are these hydrogen bonds maintained in solution? In acetone-d_6 solution, the ^{1}H NMR spectrum of **3** contains two methylplatinum resonances and two *tert*-butyl resonances in an approximately 2 : 1 intensity ratio, that are tentatively assigned to organoplatinum units within rings and chains respectively, suggesting that at least fragments of the structure are maintained in solution.

Complex **3** appears to be the first organometallic polyrotaxane and it has a unique structure of type **D** (Chart 1). Its formation involves three easy steps, using organometallic chemistry to introduce the hydrogen bonding group, coordination chemistry to assemble three hydrogen bonding groups around a central bridging ligand, and then the final self-assembly of the polyrotaxane through hydrogen bonding. Similar procedures have the potential to lead to many new and interesting forms of molecular architecture.

β-Cyclodextrin dimers as potential tumor pretargeting agents†‡

W. Barry Edwards,[a] David E. Reichert,[a] D. André d'Avignon[b] and Michael J. Welch*[a]

A β-cyclodextrin dimer binds a di-*tert*-butylbenzyl–Cu–cyclen with high affinity, demonstrating potential as a receptor/ligand system for tumor pretargeting with monoclonal antibodies.

Monoclonal antibodies (Mabs) have advantages for the delivery of a radioisotope (or toxin) to tumor sites due to their high affinity and specificity for their antigen.[1,2] However, the results of radioimmunotherapy of solid tumors have been disappointing because radiolabeled Mabs targeted to cell surface antigens impart a high radiation dose to normal organs causing toxicity.[3] In part, this is due to the long circulating times for Mabs.

Successful imaging or therapy with radiolabeled Mabs depends not only on the concentration of the Mab at the targeted site but on clearance rates from normal tissues relative to that from the tumor. Imaging studies in humans have shown that maximum concentrations of Mabs at the tumor site are attainable within 24 h, but several more days are required before the concentration of the radiolabeled Mab in the circulation decreases to levels low enough for successful imaging to take place.[4] Pretargeting techniques seek to maintain high accumulation of the radionuclide at the target site while minimizing non-target tissue toxicity (see reviews[1,2]). One current approach at pretargeting utilizes a Mab conjugated to a receptor with a high affinity for a ligand bearing the radionuclide. The most often utilized receptor/ligand system is avidin (or streptavidin/biotin).[5] After the Mab-receptor conjugate has localized at the tumor site, a low molecular weight radiolabeled ligand, one that is rapidly excreted *via* the kidneys, is administered to visualize the tumor. To be effective, the ligand must be rapidly excreted from the body to provide the desired high tumor accumulation with relatively low non-target accumulation.

An alternative receptor for tumor pretargeting could be a β-cyclodextrin dimer. Breslow *et al.* studied a series of β-cyclodextrin dimers and achieved some of the highest affinities reported to date.[6,7] While the best match between a guest molecule and single cyclodextrin subunit will provide affinities on the order of 10^{-4} M, cyclodextrin dimers can increase affinities to 10^{-8} to 10^{-10} M.[8] With affinities of this magnitude, β-cyclodextrin dimers could serve as receptors for tumor pretargeting. A potential strategy for pretargeting is the development of a radiometal-binding macrocycle containing pendant hydrophobic groups with the appropriate geometry for inclusion into the cavity of the cyclodextrins. Ultimately, the β-cyclodextrin dimer would be concentrated at the tumor site by conjugation *via* a covalent bond to a Mab. Radiometals such Cu-64 [$t_{1/2}$ = 12.7 h; $E_{\beta max}$ = 0.653 MeV (17.4%); $E_{\beta max}$ = 0.573 MeV (40%)] and Cu-67 [$t_{1/2}$ = 62 h; $E_{\beta max}$ = 0.392 MeV (56%)] have been used previously in imaging[9] and therapy[10,11] of tumors. To demonstrate the feasibility of this new approach, Cu–BBC (Scheme 1) and a β-cyclodextrin dimer (Scheme 2) were synthesized and affinities determined in an equilibrium binding assay. A fluorescent dye, BNS, was synthesized as previously described.[12]

Breslow *et al.* reported binding affinities for a β-cyclodextrin dimer with a single linkage in the low nanomolar region for substrates bearing two *tert*-butylphenyl substituents.[6] Therefore, a β-cyclodextrin dimer with a single linkage, was synthesized to serve as a host for a copper chelate-complex bearing two *tert*-butylphenyl substituents. The dimer **1** was prepared from commercially available tosyl-β-cyclodextrin and 2,6-naphthalene dithiol[13] (Scheme 2). The cyclodextrin dimer was purified by HILIC then by silica-gel chromatography.[14] Analysis by ^{1}H, ^{13}C, HMQC, COSY NMR and MALDI-MS confirmed the dimeric structure of the cyclodextrin.

Cyclen was chosen as the chelator because of its high stability (log K_f = 24.6) for copper(II).[15] Based on synthetic methodology for selectively protecting the 1 and 7 nitrogens of tetraazamacrocycles,[16] alkylation of the nitrogens with commercially available *tert*-butylbenzyl bromide appeared to be the most expedient way of introducing a pair of hydrophobic substituents onto the chosen chelator (Scheme 1). Molecular modeling showed that a distance of *ca.* 16 Å is attainable between the two tertiary carbons of the *tert*-butyl groups and between the midpoints of the β-cyclodextrin subunits of dimer **1** when the faces containing the primary hydroxyl groups are opposed to each other.[17]

Equimolar amounts of copper(II) acetate and BBC resulted in the quantitative formation of Cu–BBC. While Cu–BBC and BBC co-eluted on a C-18 column, a diphenyl column resolved a co-injected mixture of the two. Analysis of the reaction

Table 1 Affinities of BNS and Cu–BBC for β-cyclodextrin and dimer **1**

Guest	Host	Calculated affinities	95% CI
BNS	β-Cyclodextrin	K_{D1} = 14 μM	10–18 μM
		K_{D2} = 1.6 mM	0.6–2.6 mM
BNS	Dimer **1**	K_D = 388 nM	112–664 nM
Cu–BBC[a]	Dimer **1**	K_i = 18 nM	12–28 nM
		IC_{50} = 120 nM	76–189 nM

[a] BNS was included. Cu–BBC was a competitive ligand with varying concentration.

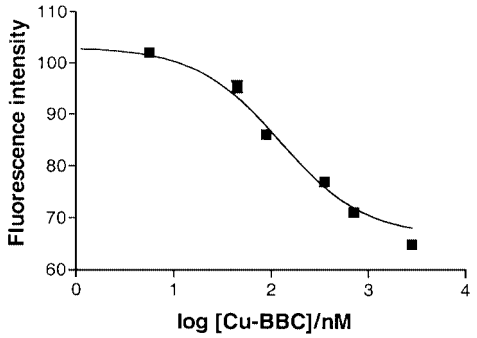

Fig. 1 Heterologous competitive binding assay between Cu–BBC and BNS for dimer **1**.

mixture on the diphenyl column showed that BBC accounted for < 1% of the total peak area observed (λ = 215 nm, Cu–BBC and BBCs strongest absorbance). Analysis by ES-MS confirmed that the component observed by HPLC was Cu–BBC.

Affinity constants for β-cyclodextrin dimers and their substrates are often ascertained by fluorescence spectroscopy§ since saturation binding will be attained at concentrations too low to utilize NMR and UV spectroscopy. Therefore a fluorescent dye, BNS, was synthesized. BNS fluoresces weakly in water, but its inclusion into a hydrophobic environment, such as that of the cavity of β-cyclodextrin, enhances its fluorescence. This dye has been used extensively in the characterization of other β-cyclodextrin dimers (see review[8]). Curve fitting with commercially available software will then yield the affinity of dye. After the affinity of dye for its host has been quantified, a heterologous competitive binding assay between the dye and another guest can provide the affinity of the guest. These approaches were taken to evaluate the affinity of BNS and Cu–BBC for dimer 1 (Table 1).

BNS exhibited an enhancement of fluorescence in aqueous solution when interacting with the β-cyclodextrin subunits. The interaction was characteristic of a receptor–ligand (host–guest) complex because of its saturable and reversible nature. The observed affinity of BNS agrees with the previously determined value of K_D = 20 μM.[12] Previous affinities of BNS observed for β-cyclodextrin dimers with a single linkage have ranged from *ca.* 3 μM to 100 nM.[18,19] The increase in affinity of BNS is consistent with previously observed increases when two β-cyclodextrin subunits are linked face to face.

Because the fluorescence of Cu–BBC is unaffected by the presence of dimer **1**, its affinity must be determined by competition with BNS. The log-dose dependent displacement of BNS from dimer **1** with Cu–BBC indicates that both Cu–BBC and BNS have formed a complex with dimer **1** (Fig. 1). By substituting the value of the IC_{50} of Cu–BBC and the K_D of BNS into the Cheng–Prussof equation, the K_i of Cu–BBC is obtained.[20] This remarkably strong affinity bodes well for the success of dimer **1** and Cu–BBC as a receptor/ligand system for tumor pretargeting.

In conclusion, a β-cyclodextrin dimer with a naphthalene linker, dimer **1**, was synthesized for evaluation as the receptor in a new approach to tumor pretargeting. Dimer **1** showed a higher affinity for a fluorescent dye, BNS, than did β-cyclodextrin. BBC, a derivative of cyclen, was synthesized and Cu–BBC was prepared. Cu–BBC was strongly bound to dimer **1** (K_i = 18 nM relative to BNS). With affinities in the low nanomolar region, Cu-64–BBC and dimer **1** could serve as a receptor/ligand system for tumor pretargeting.

This work was supported by the United States Department of Energy (DE-FG02-87ER60512).

Notes and references

§ *Determination of affinity constants*: Utilizing GraphPad Prism® software (GraphPad Software Inc., San Diego, CA), the data were fit by non-linear regression to: $F = (F_{max})[BNS]/(K_D + [BNS])$ where F is the observed fluorescence intensity generated from incorporation of BNS into the hydrophobic interior of β-cyclodextrin (corrected for background fluorescence from unincorporated BNS or dimer **1**) to determine values for K_D.[21,22] To determine the IC_{50} value, the data were fit by non-linear regression to: $F_{obs} = T + (T - B)/1 + 10 \exp(\log[Cu–BBC] - \log IC_{50})$, where T and B are the top and bottom plateaus of the fitted curve and F_{obs} is the observed fluorescence.[21,22] To calculate K_i for Cu–BBC, the value obtained for the K_D of BNS and Cheng–Prussof equation were utilized.[20–22] The data were fit to both one or two binding sites in all experiments and the results for two binding sites are reported when $P < 0.05$. The error is represented in terms of 95% confidence interval (95% CI).

Nonenzymatic kinetic resolution of β-amino alcohols: chiral BINAP mediated S_N2 displacement of hydroxy groups by halogens through formation of an aziridinium ion intermediate

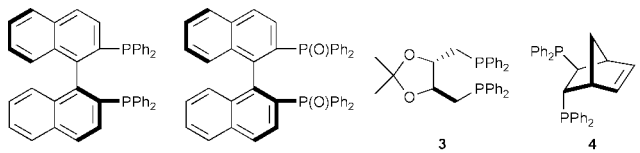
Govindasamy Sekar and Hisao Nishiyama*

School of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi, Aichi 441-8580, Japan. E-mail: hnishi@tutms.tut.ac.jp

Received (in Cambridge, UK) 15th March 2001, Accepted 6th June 2001
First published as an Advance Article on the web 27th June 2001

A series of optically active cyclic *trans*-β-amino alcohols were obtained (up to 97% ee) from nonenzymatic kinetic resolution of corresponding racemic amino alcohols using commercially available (*S*)-BINAP and NCS by halogenation of hydroxy groups through formation of a *meso*-aziridinium ion intermediate.

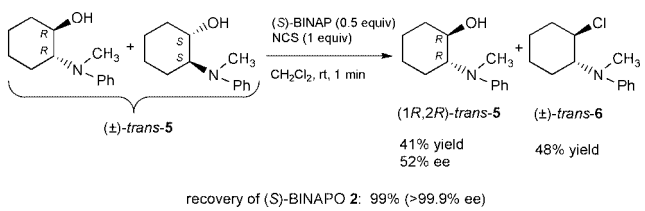
Enantiopure β-amino alcohols are an important class of organic compounds that have found much use in asymmetric synthesis[1] and medicinal chemistry,[2] and can be produced by reduction of optically active α-amino acids.[3] Kinetic resolution of β-amino alcohols through enzyme-catalysed acylation or deacylation is also one of the most efficient methods for the synthesis of chiral β-amino alcohols.[4] Nonenzymatic kinetic resolution (NKR) is the alternative for the enzymatic process, which is considered to be a challenging issue in organic synthesis.[5,6] Very recently, we reported the NKR of secondary alcohols by S_N2 displacement of the hydroxy groups by halogens using chiral BINAP (**1**).[7] In



1 **2** **3** **4**

this communication, we report highly enantioselective NKR of racemic *trans*-β-amino alcohols by halogenation of the hydroxy groups through an aziridinium ion intermediate.

First, we have chosen racemic *trans*-2-(*N*-methyl-*N*-phenylamino)cyclohexanol, (±)-*trans*-**5**, as a model substrate, which was subjected to kinetic resolution with NCS (1 equiv. compared to (±)-*trans*-**5**) and (*S*)-BINAP (0.5 equiv.) in CH_2Cl_2 at room temperature [eqn. (1)]. The reaction was found



(1)

to be extremely fast with moderate selectivity. After 1 min, 41% of optically active amino alcohol (1*R*,2*R*)-*trans*-**5**[8] (52% ee) and 48% of racemic *trans*-β-amino chloride (±)-*trans*-**6** were isolated. BINAP was recovered as BINAP dioxide **2** in quantitative yield without any racemization (> 99.9% ee),[9] which can be reused after reduction.[10] In this reaction, the hydroxy group of the (1*S*,2*S*)-enantiomer of the racemic amino alcohol was selectively replaced by chloride ion through double S_N2 reactions (intramolecular S_N2 displacement of hydroxy group by amine followed by intermolecular S_N2 attack by chloride ion) to produce racemic *trans*-β-amino chloride **6**.

In order to improve the enantioselectivity of the kinetic resolution, the reaction was carried out in a wide range of solvents and the effect of other commercially available C_2-symmetric diphospine ligands were also examined (Table 1). Comparatively the reaction was very much faster and higher enantiomeric excess was obtained for recovered (1*R*,2*R*)-*trans*-**5** when the reaction was carried out in polar solvents than in non-polar solvents. THF turned out to be the solvent of choice among the solvents examined as it provided (1*R*,2*R*)-*trans*-**5** in 87% ee (entry 5). When the NKR was carried out with other commercially available C_2-symmetric diphospine ligands such as (+)-DIOP **3** and (+)-Norphos **4** the ee of (1*S*,2*S*)-*trans*-**5** dropped to 52 and 40%, respectively (entries 8 and 9). Lowering the reaction temperature to −10 °C–rt slightly improved the ee to 89% but longer reaction times discouraged us from doing the reaction at that temperature (entry 10). Surprisingly, the ee of (1*R*,2*R*)-*trans*-**5** dropped to 82% when the reaction was carried out at −74 °C–rt (entry 11). We next studied the effect of other halogenating agents such as *N*,*N*-dichlorocarbamic acid ethyl ester, NBS, *N*-bromosuccinimide, and *N*-bromoacetamide for the kinetic resolution of (±)-*trans*-**5** with (*S*)-BINAP in THF at room temperature. Although all the reactions proceeded smoothly to give corresponding products, a very poor ee was obtained for recovered (1*R*,2*R*)-*trans*-**5** (5–12%).

Using the optimized conditions, a series of racemic cyclic *trans*-β-amino alcohols[11] were resolved and the results are summarized in Table 2. When the kinetic resolution was allowed for 60–70% conversion, excellent enantiomeric excess was obtained for all the six- and seven-membered cyclic β-

Table 1 Effect of solvents, temperature and various diphosphine ligands in NKR of (±)-*trans*-**5**

Entry	Diphosphine	Solvent	Time	Yield of **6** (%)[a]	Recovery of **5** (%)[a]	Ee of recovered **5** (%)[b]
1	**1**	Hexane	1 day	11	68	7
2	**1**	Benzene	30 min	47	43	38
3	**1**	Toluene	5 h	25	49	19

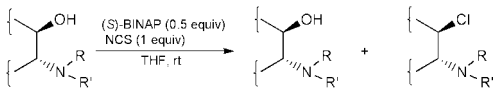
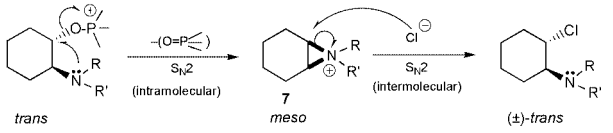
Table 2 NKR of variety of cyclic β-amino alcohols with (*S*)-BINAP and NCS[a]



Entry	β-Amino alcohol	Time	Recovery of β-amino alcohol (%)[b]	Ee of recovered β-amino alcohol (%)[c]
1		20 min	27	87
2		30 min	29	80
3		20 min	27	94
4		25 min	26	89
5		25 min	26	97
6		2 h	33	73
7		30 min	38	72
8		2 h	33	76
9[d]		25 min	38	72
10		15 min	25	59
11		10 min	35	86

[a] To a mixture of (*S*)-BINAP (0.125 mmol) and NCS (0.25 mmol) was added β-amino alcohol (0.25 mmol) in THF (2 mL) at room temperature. The white turbid reaction mixture turning to a colorless or slightly brown homogeneous solution shows the completion of the reaction. In all the reactions (±)-*trans*-β-amino chlorides were obtained in 42–69% isolated yield. [b] Isolated yield (the theoretical maximum yield in a kinetic resolution is 50%). [c] Determined by HPLC using chiral columns. [d] 2 equiv. of NCS were used.

tertiary amino alcohols (72–97% ee, 25–38% yield). Moderate enantiomeric excess was obtained for the five-membered β-amino alcohol (59% ee, entry 10). When the reaction was carried out with an acyclic amino alcohol such as racemic 1-(*N*-methyl-*N*-phenylamino)octadecan-2-ol, the (+)-amino alcohol was recovered in 34% yield with poor ee (15%).[12]



Scheme 1

Although at this moment the mechanism of the present reaction is not very clear, we assume that the reaction proceeds through an ionic phosphonium alkoxide intermediate (quaternary phosphonium salt) in which the amino group attacks the alkoxide by an intramolecular S_N2 reaction (neighboring group participation) to provide *meso*-aziridinium ion **7**. This is followed by an intermolecular S_N2 attack of *meso*-aziridinum ion **7** by chloride ion to provide racemic *trans*-β-amino chloride and dioxide **2** (Scheme 1). This phenomenon was supported as the dioxide **2** was recovered after the reaction and the product β-amino chloride was racemic with *trans* stereochemistry rather than optically active with *cis* stereochemistry. Formation of optically active β-amino chloride from the kinetic resolution of acyclic amino alcohol confirms the formation of an aziridinum ion intermediate. However, detailed mechanistic studies are under progress.

In conclusion, we have demonstrated highly enantioselective nonenzymatic kinetic resolution of racemic *trans*-β-amino alcohols using commercially available chiral BINAP and NCS. When the reaction was allowed for 60–70% conversion, excellent enantiomeric excess was obtained for all cyclic β-tertiary amino alcohols (up to 97% ee).

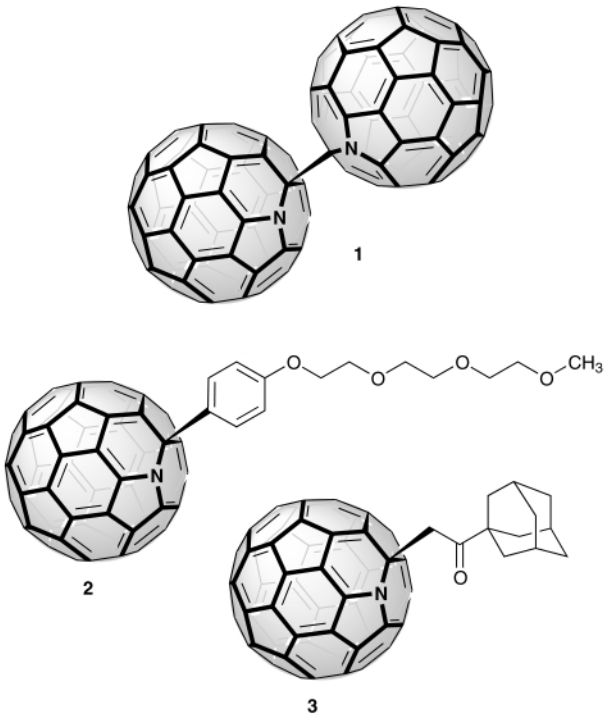
First published as an Advance Article on the web 27th June 2001

The treatment of monomeric azafullerene derivatives $RC_{59}N$ with an excess of diethyl bromomalonate in the presence of DBU and dimethylanthracene leads to the regioselective formation of azafullerene pentamalonates with an octahedral C_s symmetrical addition pattern.

The organic chemistry of the parent azafullerene $C_{59}N$ in the form of its dimer **1**[1] has been so far restricted to the synthesis of monoadducts $RC_{59}N$. In these azafullerene derivatives the addend R is always bound to the cluster C-atom which forms a [6,6]-bond to the heteroatom.[2–5] We have shown recently, that monomeric derivatives $RC_{59}N$ such as **2** and **3** are easily



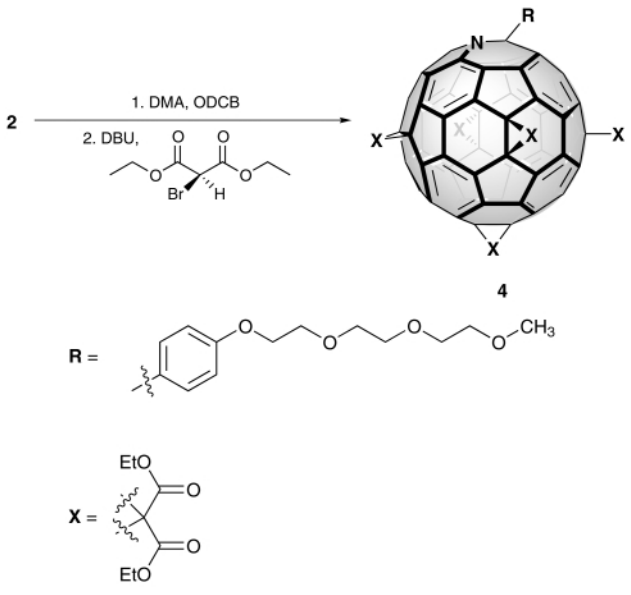
available by treatment of the dimer **1** with electron rich aromatics or enolizable carbonyl compounds in the presence of oxygen and *p*-TsOH.[3–5] The only example of a multiple adduct of $C_{59}N$ is the tetrachloride $Cl_4ArC_{59}N$ containing a pyrrole moiety within the fullerene cage.[6]

Here we report on the first multiple functionalisation of $C_{59}N$ with organic addends. As a model reaction the template mediated generation of oligomalonates, which we developed for the highly regioselective functionalisation of octahedral sites within C_{60} has been chosen.[7] This approach allows us to synthesize pentakisadducts of $RC_{59}N$ containing a C_s symmetrical addition pattern and a cage π-electron system consisting of eight isolated benzenoid rings.

After stirring a solution of the monoadduct **2** and a fivefold excess of dimethylanthracene (DMA) in 1,2-dichlorobenzene (ODCB) for 3 h, a tenfold excess of DBU and diethyl bromomalonate was added (Scheme 1). After stirring this reaction mixture for 2 days a colour change of the olive green solution into orange was observed.

After purification by HPLC using a Buckyclutcher column and toluene–ethyl acetate (8:2) as eluent, the pentamalonate **4** was obtained in 20% yield. The other regioisomeric multi-adducts could not be separated by chromatographic methods.

The complete structural characterisation of **4** was carried out by ^{1}H NMR, ^{13}C NMR, UV-Vis and FT-IR spectroscopy as well as by mass spectrometry.† The ^{1}H NMR spectrum shows two doublets for the aromatic AB spin system at δ 7.95 and 7.00. The methyl group of the polyether side chain resonates as a singlet at δ = 3.31. The signals for the methylene groups of the polyether side chain are found in the region between δ = 4.25–3.45. The four different methylene groups of the malonate function resonate as a broad multiplet at δ = 4.2 and the signals for the four different methyl groups of the malonate function can be found as a broad multiplet at δ = 1.25. The determination of the symmetry was unambiguously carried out by ^{13}C NMR spectroscopy. The ^{13}C NMR spectrum of **4** (Fig. 1) shows five signals for the ten carbonyl groups at δ = 164 with one signal showing double intensity. For a C_s symmetrical pentamalonate six signals are expected. In the sp^2 region between δ = 115–160 28 signals are found, four of which belong to the aromatic addend. The remaining 24 signals are due to the sp^2 C-atoms of the C_s symmetrical fullerene cage. The most striking evidence for a C_s symmetrical adduct can be found in the region between δ = 42–48 where four signals appear, one having double intensity. These are the signals of the methano C-atoms of the malonate bridges. Three of those C-atoms are located on the mirror plane of the molecule giving rise to three



Scheme 1

 DOI: 10.1039/b103169b

well resolved signals. The other two methano C-atoms in equatorial positions are chemically equivalent due to the C_s plane, causing the appearance of just one signal with double intensity. The C-atoms of the methylene groups give rise to just one signal at δ = 62.81 and one signal at δ = 45.37. The methyl groups of the malonate addends resonate at δ = 14.04. The signals of the six different fullerene sp^3 C-atoms and the sp^3 C-cage atom which is adjacent to the N-atom appear as seven different signals in the region between δ = 62.81–77.88. The UV-Vis spectrum of the orange pentakisadduct **4** is completely different from those of monomeric derivatives $RC_{59}N$.[2–5] The characteristic fullerene absorption at λ_{max} = 320 nm has disappeared. Similarly to hexakisadducts of C_{60} containing a T_h-symmetrical addition pattern[7] the most intensive absorption is shifted to λ_{max} = 281 nm.

The reaction of the adamantyl derivative **3** applying the same reaction conditions afforded compound **5**. The structural characterisation of this azafullerene derivative was carried out by ^{1}H NMR, ^{13}C NMR, UV-Vis and FT-IR spectroscopy. In the ^{13}C NMR spectrum no symmetry can be detected; *e.g.* each of the five methano C-atoms gives an individual signal in the region between δ = 42–48. The FAB-MS clearly shows a peak for M^+ at *m/z* 1769. This peak displays the characteristic Br isotope pattern. In the ^{1}H NMR spectrum the methine proton resonates at δ = 5.6, which is characteristic for an α-bromo ketone. Again the resonances for the methylene protons of the malonate addends can be found in the region between δ = 4.1–4.5 forming a broad multiplet. The individual protons for the adamantyl group resonate in the region between δ = 1.2–2.0 and the methyl groups of the malonate addends can be found as a broad multiplet at δ = 1.3. Significantly, the UV-Vis spectrum of **5** is similar to that of **4**, indicating that the same addition patterns are involved. Obviously, the five-fold cyclopropanation of **3** in octahedral positions is accompanied by bromination of the methylene group of the ketone addend. As a consequence, a chiral center is introduced, which causes symmetry lowering to C_1. The facile formation of **5** clearly demonstrates that the α-methylene protons of azafullerenated ketones such as **3** are very acidic. Their deprotonation with DBU used as base generates an intermediate enolate which is able to attack diethyl bromomalonate to efficiently form an α-brominated ketone.

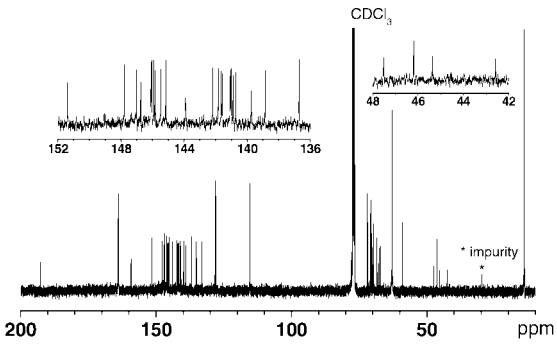


Fig. 1 100 MHz ^{13}C NMR spectrum of **4**.
