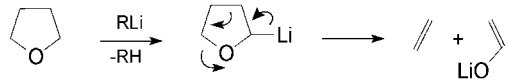
First published as an Advance Article on the web 14th August 2001

A single ethylene oxide anion derived from the ether cleavage reaction of thf with Bu^{t}Li is stabilised by the inverse podant $[Li_3(NBu^t)_3S\}]^+$ to give a high- and a low-temperature polymorph with a considerable difference in conformation and packing.

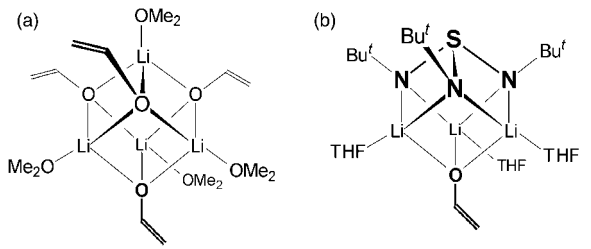
The ether cleavage reaction is one of the most common side reactions in organometallic chemistry as the RLi starting material is often dissolved in ethers.[1] Apart from the mostly unintended reaction to side products, cyclic ethers are deliberately employed in this reaction[2–5] as they give synthetically important lithium enolates[6] by an α-metalation followed by a [π4s + π2s]-cycloreversion. In this reaction the most common cyclic ether tetrahydrofuran (thf) gives lithium ethylene oxide and ethene (Scheme 1).



Scheme 1 Ether cleavage reaction of thf by lithium organics: α-metalation is followed by a [π4s + π2s]-cycloreversion to give lithium ethylene oxide and ethene.[1]

Recently it was found that ethene can insert in the Li–C bond of non-reacted Bu^{t}Li, to give *n*-hexyllithium $[(thf)LiCH_2\text{-}CH_2Bu^t]_4$.[7] Because the ionic character of the Li–O bond lithium enolates tend to aggregate in the solid state as solvated dimers, tetramers or even hexamers.[6] Although heteroatoms, like in the mixed lithium enolate/chiral amide structures[8] or adjacent double bonds,[9] help to coordinate the lithium atoms and to decrease the degree of aggregation, structurally characterised ethylene oxides generally form complex cage like structures.[2–5,10] The S_4 symmetric tetrasolvated tetramer $[(Me_2O)(LiOCH{=}CH_2)]_4$ was computed to be the most stable oligomer (Scheme 2(a)).[11]

Here we report the solid state structure of $[(thf)_3Li_3(OCH{=}CH_2)\{(NBu^t)_3S\}]$ **1**. Formally it derives from the tetramer $[(Me_2O)(LiOCH{=}CH_2)]_4$ by replacement of the top $[(Me_2O)(LiOCH{=}CH_2)_3]^{2-}$ dianionic fragment by the diimido sulfite dianion $[S(NBu^t)_3]^{2-}$(Scheme 2(b)). This tripodal dianion templates the Li_3 triangle required for the oxygen atom of the single ethylene oxide ion to be η^3 metal coordinated. By analogy to Mulvey's inverse crowns[12] like $[M_2Mg_2(NR_2)_4]^{2+}$, M = Li, Na, K, the $[Li_3(NBu^t)_3S\}]^+$ cationic motif in **1** can be regarded an inverse podant, capable of single-anion coordination to *e.g.* methanide.[13] In the attempted coordination of *tert*-butanide from Bu^{t}Li we isolated and crystallised **1** in a high-temperature (**1a**; D_c = 1.036 Mg m^{-3}) and a low-temperature phase (**1b**; D_c = 1.073 Mg m^{-3}).† For the first time an *in situ* generated, industrial important product is stabilised by the diimido sulfite dianion.



Scheme 2 The computed S_4 symmetric cubic tetramer $[(Me_2O)\text{-}(LiOCH{=}CH_2)]_4$ is the most stable lithium enolate solvate (a).[11] $[(thf)_3Li_3(OCH{=}CH_2)\{(NBu^t)_3S\}]$ **1** mimics the same aggregation by replacement of the top $[(Me_2O)(LiOCH{=}CH_2)_3]^{2-}$ dianionic fragment by the triimido sulfite dianion $[S(NBu^t)_3]^{2-}$ (b).

Both phases contain the cap shaped triimido sulfite dianion coordinated to three lithium atoms close to the SN_2 bisectors. The single ethylene oxide anion is η^3 coordinated *via* the oxygen atom to those three metal centres (Fig. 1). Thus, the oxygen atom forms one corner of a SN_3Li_3O cube. In both polymorphs the $H_2C{=}CHO$ group is disordered. In **1a** it slots in between the three thf molecules with a 0.8/0.1/0.1 site occupation factor (SOF) each. In **1b** the ethylene group is only disordered over two positions: staggered between Li2 and Li3 (0.8 SOF) and eclipsed to Li1 (0.2 SOF). The average S–N bond lengths of 165.3 and 166.4 pm for **1a** and **1b**, respectively, are almost identical. The Li_3N_3 array is not a regular chair-shaped ring but shows alternating long and short Li–N bonds. The average Li···Li distances in the cap shaped $[Li_3(NBu^t)_3S]^+$ cation are 264.3 pm in **1a** and 265.5 pm in **1b** and are only marginally longer than the distances found in parent tetrameric lithium organics (241 ($[Bu^tLi]_4$),[14a] 253 ($[EtLi]_4$),[14b] 259 pm ($[MeLi]_4$)).[14c] The bond lengths similarities in both structures indicate that the different phases are not a result of severe changes in bond distances. However, the conformation of both molecules changes quite dramatically.‡

The most obvious difference between **1a** and **1b** is the more dense packing of the molecules in the low-temperature phase

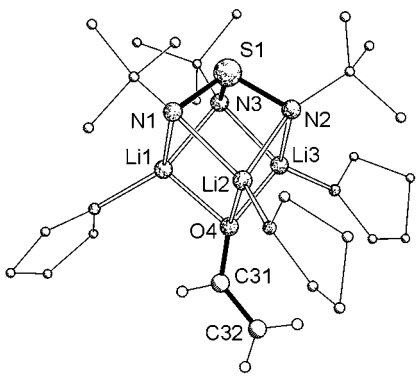


Fig. 1 Solid-state structure of $[(thf)_3Li_3(OCH{=}CH_2)\{(NBu^t)_3S\}]$ **1**. Selected average bond lengths (pm) and angles (°) [**1b** in square brackets]: S–N 165.3(3) [166.4(2)], long Li–N 210.9(7) [211.0(5)], short Li–N 202.3(7) [200.4(5)], Li–OCH=CH$_2$ 195.7(8) [196.4(11)], Li···Li 264.3(10) [265.5(6)], C31–O4 135.8(6) [133.1(6)], C31–C32 136.5(13) [132.1(5)]; N–S–N 100.4(2) [100.38(11)].

 DOI: 10.1039/b105429p

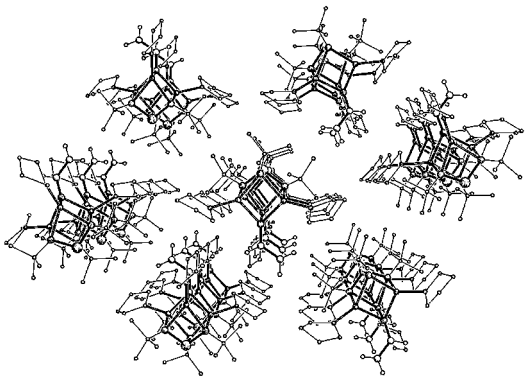

Fig. 2 Wide packing of the molecules in the high-temperature polymorph of **1a** with no interlocking at the periphery.

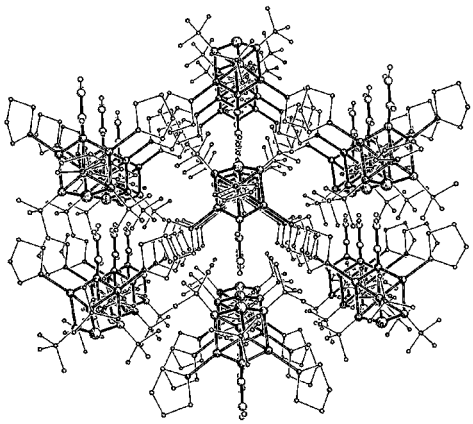

Fig. 3 Dense packing of the low-temperature polymorph **1b**, with the thf donors zipping the molecular rods. The ethylene oxide moiety is locked in a groove provided by an adjacent rod.

compared to the high-temperature polymorph.[15] The average intermolecular distances in **1a** give the molecules considerably more room than in **1b**. Virtually no interlocking of the molecular periphery in the packing of **1a** tolerates the disordered orientation of the ethylene oxide over three positions, although the depicted one is favoured by eight of ten molecules (Fig. 2). In the packing of **1b** the molecular rods are zipped together by interlocking thf molecules (Fig. 3). This causes the ethylene oxide to slot in to the groove formed by two *tert*-butyl groups of an adjacent rod. The channel permits only two disordered orientations of the ethylene oxide group in **1b**. The position with the smaller SOF is disfavoured by the orientation of the CH_2 group eclipsed towards Li1.

Evidently the beginning of the chain of cause and effect between the change in conformation and different packing can not be identified. The question whether the different packing causes the conformation or *vice versa* remains open. However, at temperatures lower than −36 °C the ethylene oxide group clicks into the space between two thf molecules while it has more rotational freedom at higher temperatures.[15c]

We gratefully acknowledge the continued financial support of the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Notes and references

† *Preparation* of $[(thf)_3Li_3(OCH{=}CH_2)\{(NBu^t)_3S\}]$ **1**: to a solution of 5.0 g $[(thf)Li_2\{(NBu^t)_3S\}]_2$ (8.46 mmol) in 20 mL thf, 4.97 mL of a 1.7 M solution of *tert*-butyllithium (16.92 mmol) were slowly added at −78 °C and stirred for 1 h. The mixture was stirred for 2 h at room temperature. The solvent was reduced by half under vacuum. Crystallisation at room temperature gives colourless pyrophoric crystals of the high temperature phase **1a**. Storage of the solution at −36 °C for several days affords colourless pyrophoric crystals of **1b**; destructive phase transition from **1b** to **1a** was observed at −30 °C; spectroscopic data for both phases are identical (2.6 g, 78%). ^{1}H NMR (400.4 MHz, C_6D_6): δ 1.37 (12H, thf), 1.54 [s, 27H, $C(CH_3)$], 3.71 (12 H, thf), 4.03 [d, 2 H, $OCHCH_2$], 7.45 (t, 1 H, $OCHCH_2$); ^{13}C NMR (100 MHz, C_6D_6): δ 25.52, 68.40 (thf), 33.89 [$C(CH_3)_3$], 52.99 [$C(CH_3)_3$] 82.15 ($OCHCH_2$), 159.68 ($OCHCH_2$); ^{7}Li NMR (155.5 MHz, ext. sat. LiCl solution) δ 1.35, (br s, 3 Li).

‡ *Crystal data* were collected from shock-cooled crystals on a STOE IPDS (**1a**) or a Bruker SMART-APEX CCD diffractometer (**1b**) (Mo-Kα radiation, λ = 71.073 pm) at 193(2) and 173(2) K, respectively (D. Stalke, *Chem. Soc. Rev.*, 1998, **27**, 171). The structure of **1a** was solved by direct methods (SHELXS-97) and refined by full-matrix least squares methods against F^2 (SHELXL-97); (G. M. Sheldrick, *Acta Crystallogr., Sect. A*, 1990, **46**, 467; G. M. Sheldrick, SHELXL-97, program for crystal structure refinement, 1996, Göttingen). The low-temperature phase **1b** crystallised as a non-merohedral twin. The matrices of both domains were determined and every domain was integrated independently. Subsequently, the structure was solved with the data of one domain by direct methods; *R* values defined as $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$, $w = [\sigma^2(F_o^2) + (g_1P)^2 + g_2P]^{-1}$, $P = 1/3[\max(F_o^2,0) + 2F_c^2]$.

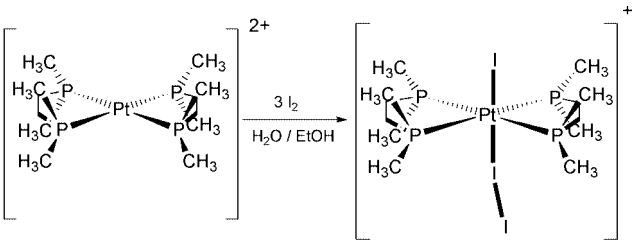
Received (in Cambridge, UK) 24th April 2001, Accepted 20th July 2001
First published as an Advance Article on the web 7th August 2001

The present paper deals with a rare platinum(II) complex containing the κ-I_2 ligand, which is an unusual example of a six-co-ordinated octahedral platinum(II) complex.

Platinum(II) strongly demands a square-planar co-ordination geometry and very few six-co-ordinate complexes have so far been characterized.[1] *Trans*-[PtI_2(diars)$_2$] (diars = *o*-phenylenebis(dimethylarsine)) has been the only example of a six-co-ordinate platinum(II) complex determined by X-ray study.[1b] However, Pt–I bonds in this complex seem to be weak because of long Pt–I distances of 3.50 Å. Here, we present a novel octahedral platinum(II) complex, [PtI(dmpe)$_2$(κ-I_2)]I_3 (dmpe = 1,2-bis(dimethylphosphino)ethane) in which the neutral molecular iodine co-ordinates to the platinum(II) ion. This is a quite rare example of the platinum(II) complex having clearly short Pt–I bond distances.

Treatment of [Pt(dmpe)$_2$](SCN)$_2$ **1**[2] with a 3 molar amount of iodine gave black needle crystals formulated as [PtI(dmpe)$_2$(κ-I_2)]I_3 **2** (Scheme 1, yield 21%).†

The molecular structure of complex **2** is displayed in Fig. 1, with partial labeling.‡ Complex **2** is a mononuclear complex with Pt1, I1, I2, and I3 atoms located on a crystallographic mirror plane that is coincident with mirror symmetry of the complex. The I4, I5 and I6 atoms of I_3^- anion are located on a crystallographic mirror. The co-ordination geometry around the platinum atom is octahedral with 4P and 2I donor atoms, with two iodine atoms having *trans* geometry. The bond distances between platinum and iodine atoms are 2.811(1) and 2.817(1) Å for Pt1–I1 and Pt1–I2, respectively. These values are considerably shorter than those in the complex *trans*-[PtI_2(diars)$_2$] **3** (here the bond length of Pt–I is 3.50 Å).[1b] Compared to **3**, complex **2** can be undoubtedly considered to be a six-co-ordinate octahedral platinum(II) complex. Furthermore, it is worthy of note that the neutral molecular iodine co-ordinates to the platinum(II) ion by end-on type (Pt1–I2–I3 = 171.58(3)°), and the I2–I3 bond distance of 3.061(1) Å is much longer than that of 2.715(6) Å in free diiodine molecules.[3] This means that the electrons on the central platinum(II) flow into the κ-I_2 ligand, which is attributable to a d_{z^2} (Pt) to σ* (I_2) donation.[4]



Scheme 1

Van Koten and coworkers have reported five-co-ordinate platinum(II) complexes containing the κ-I_2 ligand, [PtI{C_6H_3(CH_2NMe_2)$_2$-2,6}(κ-I_2)] **4a** and [Pt(κ-I_3)(κ-I_2){C_6H_3(CH_2N(*t*-Bu)Me)$_2$-2,6}] **4b**.[5] The Pt–I_2 bond distances of 2.895(1) and 2.906(2) Å in **4a** and **4b**, respectively,[5d] are longer than 2.817(1) Å in **2**, showing that a stronger platinum–molecular iodine bond is realised in **2**. The I–I bond distances in these complexes show a marked difference: the I2–I3 distance of 3.061(1) Å in **2** is much longer than that of 2.822(1) and 2.793(1) Å in **4a** and **4b**, respectively. This elongation is attributable to the existence of the ligand on a *trans* position of the κ-I_2 ligand. The bond distances between platinum and co-ordinated phosphorus in **2** are 2.369(2) and 2.374(2) Å for Pt1–P1 and Pt1–P2, respectively. These values are longer than that of starting square-planar complex **1** with a Pt–P of 2.317(1) Å.[6]

The formal oxidation state of the platinum ion in **2** is expected to be +2. To confirm this, X-ray photoelectron spectroscopy (XPS) measurements were performed.§ Binding energies of the Pt 4f region given in Table 1 were determined by a conventional deconvolution procedure. The XPS spectrum of **2** shows a doublet, whose binding energies are coincident with the values of Pt(II) binding energies.[5c,7] From XPS measurements, the platinum ion in complex **2** was found to have the +2 oxidation state.

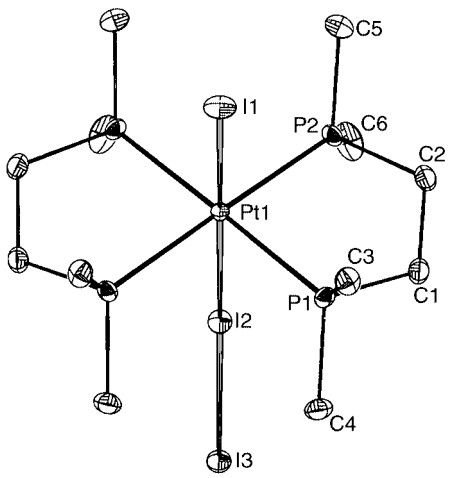


Fig. 1 The structure of **2**. Selected bond distances (Å) and angles (°): Pt1–I1 2.811(1), Pt1–I2 2.817(1), Pt1–P1 2.369(2), Pt1–P2 2.374(2), I2–I3 3.061(1), P1–C1 1.82(1), P1–C3 1.80(1), P1–C4 1.80(1), P2–C2 1.82(1), P2–C5 1.82(1), P2–C6 1.80(1), C1–C2 1.52(1); I1–Pt1–I2 177.75(3), I1–Pt1–P1 89.73(5), I1–Pt1–P2 92.45(5), I2–Pt1–P1 91.78(5), I2–Pt1–P2 86.04(5), P1–Pt1–P2 84.46(6), Pt1–I2–I3 171.58(3).

The ^{31}P MAS NMR spectral data for **1** and **2** in the solid state and in CD_3CN or D_2O solution are given in Table 2. In the ^{31}P MAS NMR spectrum of **2**, a signal appeared at δ 11.9 ppm with satellites due to the coupling with ^{195}Pt (1758 Hz). The smaller coupling constant $^1J_{Pt-P}$ in **2** compared with 2173 Hz in **1**, is explained by the difference in the co-ordination number.[8] $^1J_{Pt-P}$ of 2173 Hz in **1** is a normal value compared with analogous platinum(II) square-planar co-ordinate complexes.[9] On the other hand, in CD_3CN solution, the observed $^1J_{Pt-P}$ of 2172 Hz in **2** was very close to 2162 Hz observed in D_2O solution for **1**. This result indicates that complex **2** has a square-planar geometry caused by the dissociation of iodine in CD_3CN solution.

Nickel porphyrin nanotweezers†

Stéphanie Gazeau, Jacques Pécaut and Jean-Claude Marchon*

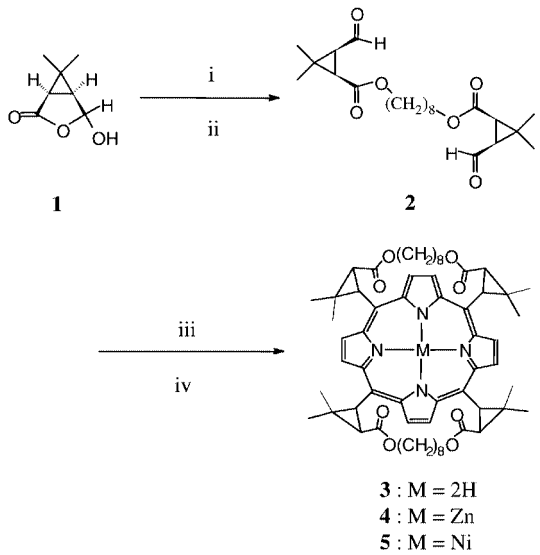
Laboratoire de Chimie Inorganique et Biologique (CEA, CNRS, UJF), Département de Recherche Fondamentale sur la Matière Condensée, CEA-Grenoble, 38054 Grenoble cedex 9, France. E-mail: jcmarchon@cea.fr

Received (in Cambridge, UK) 30th May 2001, Accepted 9th July 2001
First published as an Advance Article on the web 7th August 2001

A strapped chiroporphyrin free base with two 8-methylene chains linking two adjacent meso-substituents was synthesized as the α⁴ conformer; insertion of Ni(II) triggered a complete conversion to the αβαβ complex, and demetallation totally regenerated the strapped free base in the α⁴ conformation.

Metalloporphyrin compounds which have a rigid concave shape can trap molecular guests by coordinative or non-covalent interactions; recognition of the guest is due to complementarity in size, shape and functional groups.[1] A 'Venus flytrap' zinc porphyrin that reversibly swings between an open and a closed form upon binding and dissociation of pyridine has also been reported.[2] We have now designed a strapped chiroporphyrin whose shape can be controlled at will by exploiting the specific coordination requirements of nickel(II). The forces which operate this molecular metamorphosis might be useful in the design of nanoscale tweezers.

Deprotonation of (1*R*)-cis-hemicaronaldehyde **1** by sodium hydride, followed by nucleophilic attack[3] on 1,8-diiodooctane, led to the diester-strapped dialdehyde **2** in 99% yield (Scheme. 1). The latter was reacted with pyrrole according to a literature method[4] to afford the bis-strapped chiroporphyrin **3** in 5% yield.‡ In contrast to the first-generation chiroporphyrins devoid of straps, which are always obtained as the αβαβ atropisomer,[5] **3** shows an α⁴ conformation with the two 8-methylene straps linking adjacent *meso* substituents on the same face of the porphyrin. This unusual conformation is apparent in the C_2 symmetry of the NMR spectra of **3** [*e.g.* two AB systems for the pyrrole protons, Fig. 1(a)], and in the large upfield shifts of the methylene groups of the straps. The zinc complex **4** exhibits the same spectral symmetry [Fig. 1(b),§ and its α⁴ conformation was confirmed by its X-ray structure shown in Fig. 2.[6]



Scheme 1 *Reagents and conditions:* i, NaH, THF, 10 °C, 30 min under Ar; ii, 1,8-diiodooctane in DMF, 25 °C, 24 h under Ar (99%); iii, pyrrole, TFA, CH_2Cl_2, 25 °C, 6 days; iv, DDQ, 4 h (5%).

† Electronic supplementary information (ESI) available: spectroscopic data for **3**–**6**. See http://www.rsc.org/suppdata/cc/b1/b104715a/

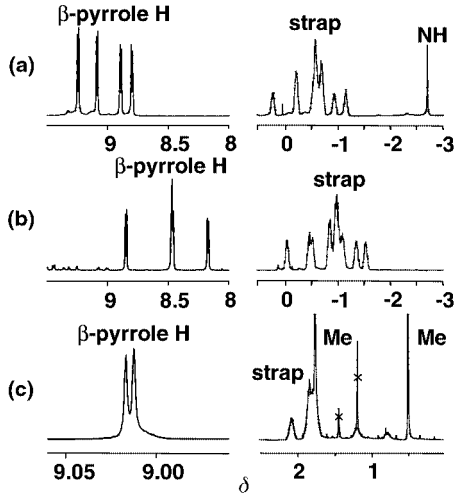


Fig. 1 ¹H NMR spectra (400 MHz, $CDCl_3$, 298 K) for (*a*) the free base chiroporphyrin **3** with two 8-methylene straps in the α⁴ conformation; (*b*) its α⁴ zinc(II) complex **4**; and (*c*) its αβαβ nickel(II) complex **5**; crossed peaks correspond to $CDCl_3$ solvent impurities.

Much to our surprise, metallation of α⁴-**3** by Ni(II) triggered a major conformational change. The nickel complex **5** shows a D_2-symmetric ¹H NMR spectrum [*e.g.* two singlets for the pyrrole proton resonances, Fig. 2(*c*) in which the chemical shifts of the methylene protons are in the normal alkyl range, unambiguously indicating an αβαβ conformation in which the straps now link the adjacent *meso* substituents on opposite faces of the porphyrin.¶ The conversion was complete, and no intermediate could be detected. This unprecedented conformation of a strapped porphyrin[4] was confirmed by the X-ray structure of **5** illustrated in Fig. 3.

Several experiments were carried out to try and remove the nickel(II) center from the porphyrin, in the view of examining

the conformation of the resulting free base. Among several acids which were tried, only trifluoromethanesulfonic acid was found strong enough to transfer protons to the very weakly basic nitrogen atoms of **5** and release the nickel(II) ion. Short reaction times (15 min, resulting in *ca*. 50% demetallation) were required with such a strong reagent, which also hydrolyzes the ester groups upon prolonged contact. The resulting free base exhibited α^1H NMR spectrum identical to that of the starting material **3**, indicating the same α^4 conformation. Thus the $\alpha^4 \rightarrow$ αβαβ conformation change is entirely reversible upon nickel(II) insertion and extrusion (see Graphical Abstract).

Metal insertion in a porphyrin generally induces modest distortions of the core, such as the *sad*, *ruf*, *dom*, *wav* and *pro* types or combinations thereof,[7] but usually it does not affect the orientation of the macrocycle substituents. The intriguing $\alpha^4 \rightarrow$ αβαβ conformation change which is observed upon Zn(II) → Ni(II) substitution in the strapped chiroporphyrin may be related to the coordination requirements of the two metals and to the constraints induced by the short straps. While Zn(II) with its full d^{10} complement shows long Zn-N bonds (average 2.036(5) Å for the two independent molecules) compatible with the flat porphyrin core of α^4-**4**, square-planar d^8 Ni(II) with its vacant antibonding $d_{x^2-y^2}$ orbital requires short Ni–N bonds [average 1.916(5) Å for the two independent molecules] which are obtained by ruffling of the core of **3**. In this distorted core conformation, the 8-methylene straps apparently are too short to stride over their adjacent cyclopropyl substituent, which are forced to rotate toward the opposite face of the porphyrin. The low rotation barrier usually observed in ruffled nickel(II) porphyrins[8] may facilitate this motion, which results in the αβαβ complex **5**.

Nearly complete conversion to a paramagnetic piperidine adduct **6** was obtained by dissolution of **5** in neat $C_5D_{10}ND$, as judged from the UV–VIS spectrum.[9,10] The 500 MHz ^{1}H NMR spectrum of the resulting solution showed a broad peak near 40 ppm at room temperature for the pyrrole protons of the high-spin Ni(II) complex **6**, typical of a $d_{z^2}{}^1\, d_{x^2-y^2}{}^1$ configuration.[9,11] A pair of singlets was also observed at δ 7.44 and 7.61 for the pyrrole protons of the residual diamagnetic species **5**. The fact that **5** and **6** are not in fast exchange on the NMR time scale stands in contrast to the rapid equilibrium between Ni(TPP) and its high-spin piperidine adduct which has been observed earlier.[9] These observations suggest that **5** and **6** have quite different conformations, and they are consistent with the expected structural consequences of the singly occupied $d_{x^2-y^2}$ orbital in **6**. High-spin nickel(II) porphyrins usually exhibit an expanded core [average Ni–N bond length 2.04–2.07 Å] and reduced non planar distortion relative to their parent low-spin complex (average Ni–N bond length 1.89–1.93 Å).[12] The expanded porphyrin core of the piperidine adduct **6** is incompatible with the αβαβ conformation which imparts short Ni-N bonds. Thus this adduct is prone to undergo a structural change to the α^4 conformation which allows near planarity of the porphyrin core similar to that of the zinc complex **3**. The piperidine ligand located between the two straps is probably held by mechanical forces in addition to the coordination bond.

The strong effects of $d_{x^2-y^2}$ orbital occupancy on molecular shape and dynamics in this system could be exploited in the design of molecular machines such as motors and switches.

We thank Nathalie Gon, Colette Lebrun and Pierre-Alain Bayle for assistance, and Dr Pierrette Battioni for experimental details on the use of trifluoromethanesulfonic acid.

Local ordering of hydroxy groups in hydroxyapatite

N. H. de Leeuw

Department of Chemistry, University of Reading, Whiteknights, Reading, UK RG6 5XE. E-mail: n.h.deleeuw@reading.ac.uk

Received (in Cambridge, UK) 4th June 2001, Accepted 11th July 2001
First published as an Advance Article on the web 7th August 2001

Density functional theory calculations of hydroxyapatite identified the oxygen and hydrogen positions of the hydroxy groups in the crystal structure to be well defined, alternating in a column in the *c*-direction, and we predict that the experimentally found oxygen and hydrogen disorder is due to the presence in the crystal of differently oriented locally ordered domains, a finding which is important for studies of crystal growth and surface reactivity.

Apatites $Ca_{10}(PO_4)_6(F,Cl,OH)_2$ are a diverse class of minerals, which are becoming increasingly important as likely candidates for use as biomaterials. They are the most abundant phosphorus-bearing minerals and are found extensively in igneous, metamorphic and sedimentary rocks, mainly in the form of fluor- or chlor-apatite.[1] More recently, hydroxyapatite has increased its prominence due to its biological role as one of the main constituents of mammalian bones and teeth enamel.[2] As such, hydroxyapatite may be immensely valuable in the manufacture of artificial bones, while another possible application is to use ceramic implants as a support for the crystallisation and layer growth of hydroxyapatite, which can then bond to living bone, aiding the acceptance by the body of the implant material. It is necessary for the success of these and other applications, such as the replacement of the hydroxy groups by fluorine ions to strengthen tooth enamel and prevent caries,[3] that we obtain a detailed knowledge of the structure of hydroxyapatite. Although crystallographic studies of the mineral have elucidated the locations of the heavier atoms in the hexagonal crystal structure,[4,5] the oxygen and hydrogen ions of the hydroxy groups are found to be disordered, each partially occupying two possible sites, and little is known about the hydroxy group environment in the crystal structure, *e.g.* whether the constituent atoms are completely disordered over the positions or whether there is local ordering of the groups within domains. It is important for the investigation of hydroxyapatite surfaces, *i.e.* in studies of crystal growth, interfacial bone/ceramic behaviour and interactions between natural bone material and organic matrices, that we have a good understanding of the sites and interactions of the hydroxy groups within the apatite crystal.

Computational methods are well placed to calculate at the atomic level the geometry and relative energies of the various possible hydrogen locations in apatite, investigations which are at present inaccessible with experimental techniques. The approach we have used is to employ quantum mechanical calculations based on density functional theory (DFT) to study the hydroxy groups in hydroxyapatite. The DFT methodology, often used within the generalized gradient approximation (GGA) and employing pseudo-potentials, is well established and has been successfully applied to the study of structural and electronic properties of complex materials, *e.g.* magnesium silicates[6] and microporous aluminium phosphates.[7] The VASP program[8–10] was employed to calculate the structure and total energies of a number of hydroxyapatite structures with different configurations for the hydroxy groups. We used a cut-off for the planewave energy of 500 eV, together with a $2 \times 2 \times 2$ k-point mesh, which led to a convergence of the total energy to within 0.01%.

Although a monoclinic form of hydroxyapatite is known, biological and synthetic hydroxyapatite has a hexagonal crystal structure with space group $C6_3/m$ and $a = b = 9.432$, $c = 6.881$ Å, $\alpha = \beta = 90$, $\gamma = 120°$.[1,2] After full electronic and ionic optimisation, the structure with the lowest energy configuration of the hydroxy groups relaxed to $a = b = 9.563$, $c = 6.832$ Å, $\alpha = \beta = 90$, $\gamma = 120°$, in excellent agreement with the experiment (discrepancy $\leqslant$1.5%). The F^- or OH^- ions in apatite structures are located one above each other in a column parallel to the *c*-axis (into the paper in Fig. 1), where the F^- ions in fluorapatite are located at a crystallographic symmetry position (0, 0, 0.25), while the hydroxy groups in hydroxyapatite are located either above or below the symmetry position in the *c*-direction (oxygen at 0, 0, 0.2008, hydrogen at 0, 0, 0.0617). The deviation of the hydroxy group away from the symmetry position, leading to four possible locations in the unit cell, on either side of two symmetry positions, causes disorder of the oxygen and hydrogen ions. In this work, we investigated whether the occupancy of the oxygen and hydrogen sites is likely to be completely random or whether we could identify local ordering in domains. To this end, we calculated four possible configurations for the oxygen and hydrogen ions in hydroxyapatite, shown in Table 1, where for clarity the (Cartesian) symmetry positions are identified together with the hydroxy group positions above and below the symmetry position in the *c*-direction. Table 1 further shows which of the oxygen and hydrogen positions are occupied in the different calculations with their final coordinates in the *c*-direction, where the unit cell shown is periodically repeated in three dimensions. In configuration 1, both hydroxy groups are located at the two sites corresponding to one symmetry position, while configurations 2 and 3 have the hydroxy groups located at sites corresponding to both symmetry positions. In configuration 2, all hydroxy groups are lined up with the hydrogen and oxygen ions alternating along the *c*-axis, whereby each OH^- group forms one O–H bond of 0.957 Å and one rather long O···H hydrogen bond of 2.483 Å, while configuration 3 forms a column of pairs of OH^- groups, with the hydrogen ions pointing towards each other at a separation of only 0.849 Å and an O···O separation of 4.117 Å. Finally, in configuration 4 we investigated whether the oxygen and hydrogen ions of hydroxy groups were likely to be found separated in the apatite structure, by splitting up one OH^- group into its constituent atoms, whereby the hydrogen atom of the remaining hydroxy group

can form a hydrogen bond to the separated oxygen atom at 1.806 Å, while the separated hydrogen is in a position to form one short and one long hydrogen bond with the oxygen atoms at 1.634 and 2.483 Å.

After electronic and ionic relaxation, the total energies of the structures are compared (Table 1). We find that starting configuration 1, where two hydroxy groups were located either side of a single symmetry position, did not lead to a stable structure. Configuration 3 led to a stable structure, but the positions of the hydroxy groups had shifted away from the experimental locations by about 0.3 Å to the positions shown in Table 1, due to repulsion between the two neighbouring hydrogen ions, which leads to an increase in the distance between the hydroxy groups of 0.65 Å. The structure has somewhat expanded from the experimental structure in the *a* and *b* directions to $a = b = 9.551$ Å and contracted in the *c*-direction, $c = 6.868$ Å. Configurations 2 and 4 are the most stable structures, with practically identical energies ($\Delta E < 0.4$ kJ mol^{-1}). On inspection of Table 1, we see that the hydrogen and oxygen ions in configuration 2 remain virtually at their initial positions with lengthening of the O–H bond lengths from 0.957 to 0.998 Å. The *a* and *b* vectors increase to $a = b = 9.564$ Å, but contraction occurs again in the *c*-direction, $c = 6.831$ Å, which causes the apparent shift of the oxygen and hydrogen ions away from their initial position. In configuration 4 ($a = b = 9.563$, $c = 6.832$ Å), the dissociated hydroxy group in the initial structure has recombined upon geometry optimisation, and is located at the same site as in configuration 2, with a final O–H bond length of 0.998 Å, forming a series of hydrogen-bonded interactions down the *c*-axis at alternating O···H distances of 2.335 and 2.500 Å. If we compare these hydrogen bonds to configuration 2 (Fig. 2), where we find all O···H interactions down the *c*-axis at 2.42 Å, it is clear that configuration 2 is a more regular structure even though energetically identical. Contour plots of the electron density in the plane of the hydroxy groups (Fig. 2) show that the O–H bond has covalent character, but bonding of its oxygen atom to neighbouring calcium ions is fully ionic, as is the interaction between calcium ions and the oxygen atoms of the phosphate groups. Bonding within the phosphate groups is found to be covalent in character, in agreement with quantum chemical calculations of aluminium phosphates.[11]

Our calculations of different possible configurations of hydroxy groups within the hydroxyapatite structure have shown that there is a preferred arrangement of the hydroxy groups, where the energetically most favourable configurations (2 and 4) have all OH$^-$ groups lined up with oxygen and hydrogen ions alternating in a column parallel to the *c*-axis (Fig. 2). These columns of aligned OH$^-$ groups can of course be found in two directions, either up or down the *c*-axis, and hence we predict that the hydroxyapatite structure will consist of local domains of these well-ordered OH$^-$ columns. When the OH$^-$ groups have

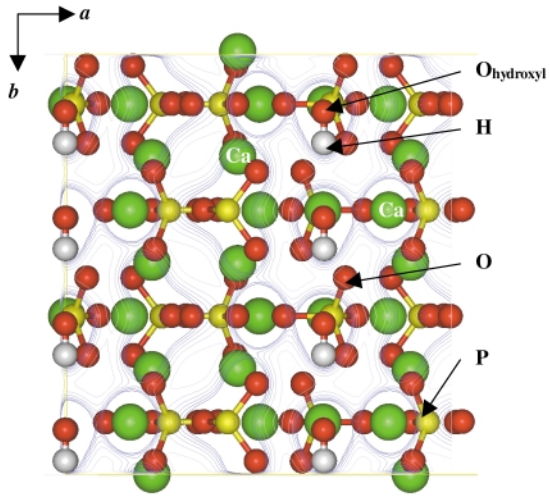

Fig. 2 Relaxed apatite crystal with OH$^-$ configuration 2, showing electron density contour plots in blue (O = red, Ca = green, P = yellow, H = white, contour levels from 0.05 to 0.30 e Å^{-3} at 0.05 e Å^{-3} intervals).

neighbouring oxygen ions (configuration 1) the structure is not stable, while introducing a pair of hydroxy groups with hydrogen ions in neighbouring positions (configuration 3) costs approximately 42 kJ mol^{-1} (0.436 eV/OH pair). A change in the ordering of the hydroxy groups within columns is therefore not energetically impossible, and may be promoted by the presence of anionic impurities such as F$^-$.

N. H. d L. thanks the Mineral Physics and Materials Consortia for provision of computer time on the Cray T3E.

$Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ and $Cs_{1.5-3x}Bi_{9.5+x}Se_{15}$ crystallize in a new structure type which does not belong to but is closely related to the members of the homologous series $A_m[M_6Se_8]_m[M_{5+n}Se_{9+n}]$; the new phases reveal a third dimension of structural evolution for this series according to the formula $A_m[M_{1+l}Se_{2+l}]_{2m}[M_{1+2l+n}Se_{3+3l+n}]$.

Recent efforts[1] in our laboratory aimed at defining new chemical concepts[2] identified the grand homologous series of phases $A_m[M_6Se_8]_m[M_{5+n}Se_{9+n}]$ (A = alkali metal, M = heavy group IV or V element). Members of this series include β-$K_2Bi_8Se_{13}$,[3] $K_{2.5}Bi_{8.5}Se_{14}$,[4] $K_{1+x}Sn_{4-2x}Bi_{7+x}Se_{15}$,[5] $K_{1-x}Sn_{4-x}Bi_{11+x}Se_{21}$[6] and $K_{1-x}Sn_{5-x}Bi_{11+x}Se_{22}$,[7] which exhibit a close structural and compositional relationship. This homology has predictive properties leading to charge-balanced hypothetical members that can be easily generated by the general formula. In fact, the following members of this series, $K_{1+x}Sn_{3-2x}Bi_{7+x}Se_{14}$,[8] $K_{1-x}Sn_{3-x}Bi_{11+x}Se_{20}$,[8] and $K_{1-x}Sn_{9-x}Bi_{11+x}Se_{26}$,[9] have been successfully targeted for synthesis *after* their compositions and structures had been predicted. The construction of each member of the homologous series is modular and assembled by two different modules, $[M_{5+n}Se_{9+n}]$ ($NaCl^{111}$-type) and $[M_6Se_8]_m$ ($NaCl^{100}$-type)[10] of variable dimensions defined by *n* and *m*, which are linked to an anionic framework with tunnels that accommodate the alkali ions (A_m). The terminology of 'homologous series' was given by Magnèli[11] to characterize chemical series that are expressed by general formulae and built on common structural principles, that are found in transition metal oxides.[12] The Aurivillius phases $Bi_2A_{n-1}B_nO_{3n+3}$ (A = Na, K, Ca, Sr, Ba, Pb. Ln, Bi, U, Th *etc* and B = Fe, Cr, Ga, Ti, Zr, Nb, Ta, Mo, W *etc.*)[13] and the Jacobson–Dion phases $A[A'_{n-1}B_nO_{3n+1}]$ (A = Li, Na, K, Rb, Cs, Tl, NH_4; A′ = Ca, Nd, B = Nb)[14] are examples of known homologous series in solid state chemistry. The structures of the lamellar oxides are related to the rutile and perovskite type, where the integer *n* determines the thickness of the slabs.

In contrast to these homologies which evolve in only one dimension, the above mentioned series presents two integers *n* and *m* that can be changed independently and therefore cause evolution of the structure in two different dimensions. While the thickness of the $NaCl^{100}$-type units is controlled by *m*, the shape of the $NaCl^{111}$-type units is induced by *n*. Interestingly, the width of the $NaCl^{100}$-type modules in $A_m[M_6Se_8]_m[M_{5+n}Se_{9+n}]$ is constant for all members. Here we report $Cs_{1-x}Bi_{9+x}Se_{15}$ and its isostructural ternary analog, $Cs_{1.5-3x}Bi_{9.5+x}Se_{15}$, both revealing a novel structure type that is closely related to the known members of the grand homologous series but are not members themselves because they differ in the *width* of the $NaCl^{100}$-type modules. In fact, $Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ represents structural evolution of the series in a *third* dimension. Therefore the general formula has to be expanded to the superseries $A_m[M_{1+l}Se_{2+l}]_{2m}[M_{1+2l+n}Se_{3+3/+n}]$ where now the additional integer *l* determines the width of the building modules. The mineral cannizzarite, $Pb_{46}Bi_{54}S_{127}$, represents one end member of this new homologous series with $l = \infty$, $m = 1$ and $n = 5$. $Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ shows the same motif of assembling the fundamental building units that is found for the members of the homologous series (now a sub-series) we described earlier. Therefore we had to introduce a third integer to account for the structural evolution by changing the width of the $NaCl^{100}$- and $NaCl^{111}$-type units. In order to achieve the next step of the evolutionary ladder in this new direction two MSe equivalents and one M_2Se_3 have to be added. For $l = 2$ this formula is reduced to $A_m[M_6Se_8]_m[M_{5+n}Se_{9+n}]$. This homologous superseries predicts the structure and composition of countless compounds by modifying the three independent integers *l*, *m* and *n*. Fig. 1 depicts the different ways the structure can develop. $Cs_{1-x}Sn_{3-x}Bi_{11+x}Se_{20}$ ($l = 2$, $m = 1$, $n = 3$) evolves by changing only one integer at a time leading to $Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ ($l = 1$, $m = 1$, $n = 3$), $Cs_{1+x}Sn_{3-2x}Bi_{7+x}Se_{14}$ ($l = 2$, $m = 2$, $n = 3$) and $Cs_{1-x}Sn_{9-x}Bi_{11+x}Se_{26}$ ($l = 2$, $m = 1$, $n = 9$). It will be interesting to attempt to prepare further compounds that can be predicted, for example $CsSn_7Bi_9Se_{21}$ ($l = 1$, $m = 1$, $n = 9$),

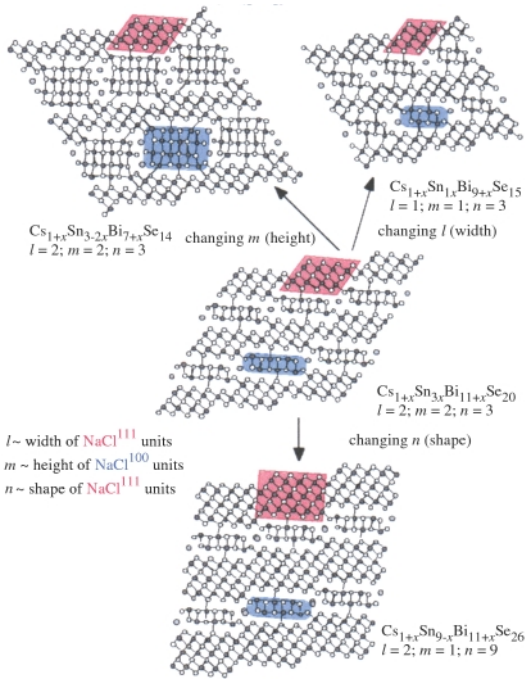

Fig. 1 Structural evolution of the homologous superseries $A_m[M_{1+l}Se_{2+l}]_{2m}[M_{1+2l+n}Se_{3+3l+n}]$ (A = alkali metal, M = heavy group IV or V element) in three different dimensions by varying the independent integers *l*, *m* and *n*. The $NaCl^{111}$-type units are highlighted in red and the $NaCl^{100}$-type units in blue. Small white spheres: Se, large light-gray spheres: A medium-gray spheres: M.

 DOI: 10.1039/b103870m

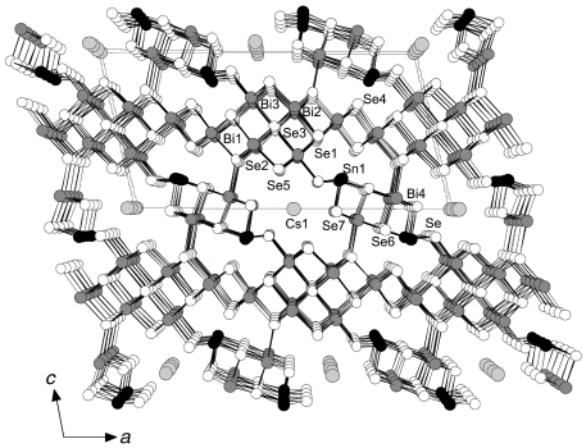

Fig. 2 Projection of the structure of $Cs_{0.65}Sn_{0.65}Bi_{8.35}Se_{15}$ with atom labeling. The tunnels in the anionic framework accommodate the Cs ions in distorted tri-capped trigonal prismatic sites. In $Cs_{1.5-3x}Bi_{9+x}Se_{15}$ the Sn1 site is occupied by Cs and Bi.

$Cs_2Sn_2Bi_{12}Se_{21}$ (l = 1, m = 2, n = 3) and $CsSn_6Bi_{12}Se_{25}$ (l = 3, m = 1, n = 3).

$Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ was prepared involving Cs_2Se, Bi_2Se_3, Sn and Se (ratio 1 : 2 : 11 : 2) in a sealed evacuated carbon coated quartz ampoule. The tube was heated within 24 h to 800 °C and kept at this temperature for 24 h, followed by slow cooling to 400 °C at a rate of 0.1 °C min^{-1} and then to 50 °C in 10 h resulting in a silver, shiny, polycrystalline ingot of $Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ as the major phase with $Cs_{1-x}Sn_{3-x}Bi_{11+x}Se_{20}$ as impurity (about 10%). EDS analyses of selected needles gave the average composition $Cs_{1.1}Sn_{0.9}Bi_{9.3}Se_{15}$. The ternary phase $Cs_{1.5-3x}Bi_{9.5+x}Se_{15}$ was obtained as follows. A mixture of 0.040 g (0.116 mmol) Cs_2Se and 0.380 g (0.580 mmol) was transferred to a silica tube which was flame-sealed under vacuum. The tube was placed under the flame of a natural gas-oxygen torch until the mixture melted and then was removed from the flame and let to solidify. The product consisted of a silvery chunk with needles growing across its surface. $Cs_{1.5-3x}Bi_{9.5+x}Se_{15}$ is the main phase with $CsBi_{3.67}Se_6$[15] as a minor phase as evidenced by X-ray powder diffraction.

The isostructural $Cs_{1.5-3x}Bi_{9.5+x}Se_{15}$ and $Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ crystallize in a new structure type as expected from $A_m[M_{1+l}Se_{2+l}]_{2m}[M_{1+2l+n}Se_{3+3l+n}$.[16] The crystal structure is shown in Fig. 2. Similar to the known members of the homologous series (l = 2) the structure is assembled by two distinct building units of the $NaCl^{111}$-type and $NaCl^{100}$-type, respectively, forming a three-dimensional anionic framework with tunnels running along the b axis which are filled by Cs ions. In $Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ three $BiSe_6$ octahedra wide and two octahedra thick fragments of the $NaCl^{111}$-type form a step-shaped layer by two adjacent units sharing an octahedra face. The distorted 3 + 3 coordination of Bi with interatomic distances in the range 2.74–3.07 Å is caused by the lone pair of Bi. In contrast to $A_{1-x}M_{3-x}Bi_{11+x}Se_{20}$ which shows the same linkage of the $NaCl^{111}$-type units to a step-shaped layer, the units in $Cs_{1-x}Bi_{9+x}Se_{15}$ represent a narrower cut out of a Bi_2Se_3-layer. In order to adjust to the narrower $NaCl^{111}$-type $[M_6Se_9]$ blocks in $Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ the $NaCl^{100}$-type $[M_4Se_6]$ units are shorter as well. They are two $(Bi,Sn)Se_6$ octahedra wide parallel to the direction of the $NaCl^{111}$-type layers and one octahedron high perpendicular to this direction while these units are three octahedra wide in $A_{1-x}Sn_{3-x}Bi_{11+x}Se_{20}$. M–Se interactions between the $NaCl^{100}$-type blocks and the stepped-shaped $NaCl^{111}$-type layers cause the formation of a three-dimensional anionic framework with tunnels along the b-direction that accommodate the Cs ions. Besides positional disorder a high thermal displacement parameter indicates possible 'rattling' of Cs ions in their partly occupied sites.

Preliminary charge transport measurements on polycrystalline ingots of $Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ reveal moderate electrical conductivity (370 S cm^{-1}) and Seebeck coefficient (−70 μV K^{-1}) at room temperature. The negative sign indicates electrons as the main charge carriers. The compound is a narrow gap n-type semiconductor with a band gap of *ca.* 0.53 eV.

In summary, $Cs_{1-x}Sn_{1-x}Bi_{9+x}Se_{15}$ and $Cs_{1.5-3x}Bi_{9.5+x}Se_{15}$ help reveal a new superseries $A_m[M_{1+l}Se_{2+l}]_{2m}[M_{1+2l+n}Se_{3+3l+n}]$ that presents three different and independent compositional variables. The new integer l controls the width of both building units, while the shape of the $NaCl^{111}$-type block is given by n and the thickness of the $NaCl^{100}$-type fragment by m. According to our results the systems A/M/Bi/Se, M = Sn, Pb, seems to be *infinitely adaptive*[17] and the identification of this broad series will permit considerable control in the design of new compounds based on phase homologies.

10 $NaCl^{111}$ is meant to indicate that this fragment derives from a section of the NaCl lattice perpendicular to the (111) direction. $NaCl^{100}$ refers to a section of the NaCl lattice perpendicular to the (100) direction. In previous publications,[6–8] we addressed the ($NaCl^{111}$) and ($NaCl^{100}$) fragments as Bi_2Te_3-type and NaCl-type, respectively. We now realize this is inadequate for large values of n as for $K_{1-x}Sn_{9-x}Bi_{11+x}Se_{26}$.

First published as an Advance Article on the web 15th August 2001

The first nitride mixed halides have been synthesised by disordered intercalation of anions between the positively charged layers of subnitride hosts.

Intercalation reactions are used extensively in solid state chemistry not only to access new compounds or polymorphs, but also in the synthesis of a wide range of commercially important materials such as zeolites and layered transition metal oxides and sulfides. The dominating pattern in this area of chemistry is the insertion of cationic guests into neutral or ostensibly negatively charged 2D or 3D hosts. The ability to intercalate negatively charged species is restricted to a relatively small and exclusive group of host materials, of which graphite and its intercalation compounds (GICs) are well-known examples. In fact, graphite is exceptional in its capacity to act as both electron acceptor (*e.g.* C_8K) and electron donor (*e.g.* C_8Br).[1] Furthermore, the hydrotalcite group of clays are unusual examples of 2D hosts containing formally positively charged layers.[1,2]

Intercalation in nitride chemistry is relatively undeveloped and is largely limited to the insertion of lithium and other alkali metals. Most notable has been the intercalation of Li^+ into Zr(Hf)NCl to induce superconductivity at *ca* 25 K,[3] although other isolated examples exist (*e.g.* 3D insertion in the $Na_xTa_3N_5$ system).[4] One interesting aspect of nitride chemistry, however, is the propensity for compounds to form *anti*-structures; frameworks that are the antithesis of some of the most common 'normal' structures seen in oxide chemistry (*e.g. anti*-perovskites, M_3NX; *anti*-fluorites $(Li,M)_2N$ *etc.*).[5] These *anti*-structures can be exploited for new synthetic and materials chemistry. Here we report our initial investigations of mixed *anion* intercalation in subnitride hosts with layered *anti*-$CdCl_2$ structures to produce the first examples of nitride mixed halides.

Nitride halides $A_2N(X,X')$ (A = Ca, Sr; X, X′ = Cl, Br, I) were synthesised by reaction of the binary alkaline earth nitrides (Ca_3N_2, Ca_2N or Sr_2N), AX_2 and AX'_2 at elevated temperatures (typically 800–1200 °C) under anaerobic conditions. Binary nitrides were prepared first by reaction of the alkaline earth metals under nitrogen in liquid sodium solvent as described previously.[6,7] We also observed that A_2NX species spontaneously form at lower temperatures by reaction of the subnitride with halogen (*e.g.* shaking together Sr_2N and I_2) or an anhydrous transition metal halide salt (*e.g.* grinding Ca_2N and $FeCl_3$ in a mortar in an Ar-filled glove box). Both these processes begin at room temperature and are highly exothermic. The former process leads to a crystalline powder with a powder X-ray diffraction (PXD) pattern that cannot yet be indexed, the latter to microcrystalline Ca_2NCl and iron powder.

Nitride halides were initially characterised by PXD using a Philips Xpert diffractometer with Cu-Kα radiation.‡ Analysis and subsequent indexing of powder data revealed continuous solid solutions existing in the A_2N(Cl, Br) systems (A = Ca, Sr). The hexagonal *anti*-α-$NaFeO_2$ structure (filled *anti*-$CdCl_2$ structure) is retained across the entire solubility range ($A_2NCl_{1-y}Br_y$; $0 \leqslant y \leqslant 1$) with no evidence of superstructure reflections (Table 1). We see no evidence of staging or ordering in these $A_2N(X,X')$ compounds and Cl and Br statistically occupy the 3a (0,0,0) site within the van der Waals type gap of the subnitrides.

Preliminary Rietveld refinement of PXD data collected for $Sr_2NCl_{1-y}Br_y$ (y = 0, 0.33, 1) compounds using the GSAS package[7] confirms that the nitride halides crystallise in space group $R\bar{3}m$ with the *anti*-α-$NaFeO_2$ structure with Cl^- and Br^- disordered on the 3a site between $[Sr_2N]^+$ layers in the y = 0.33 compound. The Sr–N 2D ionic framework does not change dramatically as a function of intercalant concentration. Sr–N bond length increases slightly [2.618(1) to 2.626(1) Å] and $[Sr_2N]^+$ layer thickness decreases (*via* angular compression of NSr_6 octahedra) from 2.68 Å in Sr_2NCl (R_{wp} = 11.51%, R_p = 8.26%, χ^2 = 2.91) to 2.63 Å in Sr_2NBr (R_{wp} = 11.29%, R_p = 8.04%, χ^2 = 2.81). The ionic layers thus separate to accommodate the larger anion and the interlayer gap increases (from 4.31 Å in Sr_2NCl to 4.65 Å in Sr_2NBr).

A detailed structural description of the Ca_2N(Cl,Br) system was obtained by GSAS[8] refinement of time of flight (ToF) powder neutron diffraction (PND) data collected using the high intensity diffractometer POLARIS at ISIS, Rutherford Appleton Laboratory. Diffraction data were collected for $Ca_2NCl_{1-y}Br_y$ (y = 0, 0.6, 1) at 298 K and additionally at 150 and 75 K for $Ca_2NCl_{0.6}Br_{0.4}$. Full details of the refinements of these and other related compounds will be presented elsewhere. A profile plot for $Ca_2NCl_{0.6}Br_{0.4}$ data collected at 75 K is shown in Fig. 1. Ca_2NCl and Ca_2NBr crystallise with the *anti*-α-$NaFeO_2$ structure as previously reported in a single crystal X-ray diffraction study.[9] $Ca_2NCl_{0.6}Br_{0.4}$ (Fig. 2) also adopts this structure, with Cl^- and Br^- disordered on the 3a site at 298 K and there is no evidence for a phase transition to an ordered halide anion arrangement at lower temperature. The structure is one of $[Ca_2N]^+$ layers of edge sharing NCa_6 octahedra lying parallel to the *ab* plane stacked along the *z*-direction between which are inserted halide anions $(Cl,Br)^-$. This thus creates

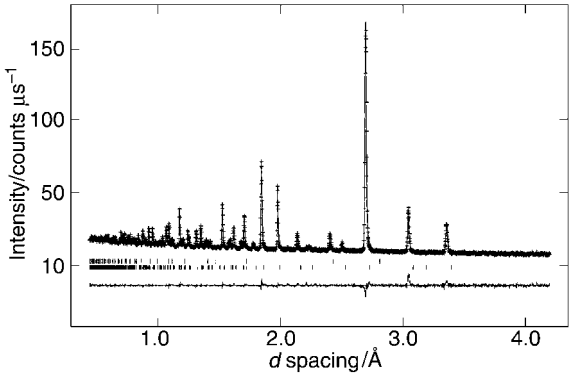

Fig. 1 Observed (crosses), calculated (solid line) and difference (below) profile plot for $Ca_2NCl_{0.6}Br_{0.4}$ PND data collected from the 90° detector bank at 75 K. Tick marks denote the major phase and CaO impurity.

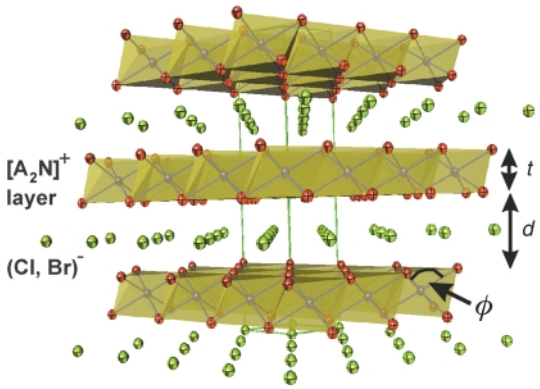

Fig. 2 Structure of $Ca_2N(X,X')$ indicating layer thickness (t), interplanar distance (d) and Ca–N–Ca angle, ϕ.

alternating edge sharing layers of NCa_6 and $(Cl,Br)Ca_6$ octahedra.

The Ca–N bond lengths in the $Ca_2NCl_{1-y}Br_y$ nitride halides are typical of the distances found in Ca containing nitrides. These are 2.4462(2), 2.4574(2) and 2.4679(2) Å for y = 0, 0.6 and 1 respectively, compared to 2.46 Å in α-Ca_3N_2 and 2.4426(4) Å in the subnitride host itself, Ca_2N.[7,10] As in the $Sr_2N(X,X')$ compounds, the $[Ca_2N]^+$ framework is fairly robust. As the average size of the anionic intercalant increases, so the $[Ca_2N]^+$ layer compresses along z through angular distortion of the N–Ca octahedra. The Ca–N–Ca angle, ϕ (see Fig. 2) increases from 97.09(1)° in Ca_2NCl to 97.77(1)° in Ca_2NBr. As a result the intralayer Ca–Ca distances increase [to 3.7187(1) Å along layers and 3.246(1) Å across layers in Ca_2NBr] but remain shorter than that in Ca metal (3.94 Å).[11] In turn the layers separate to accommodate the larger halide and Ca–X distances increase; y = 0: 2.9542(3) Å, y = 0.4: 3.0226(2) Å, y = 1: 3.0818(2) Å. The ratio of layer thickness, t, to interlayer distance, d thus changes from 0.65 in Ca_2N[7] through 0.59 (Ca_2NCl) and 0.57 ($Ca_2NCl_{0.6}Br_{0.4}$) to 0.55 in Ca_2NBr.

Whereas mixed halide compounds themselves are quite prevalent [*e.g.* $Sr(Br,I)_2$, $InBrI_2$ *etc.*][12] and disorder of multiple halides is seen in oxyhalides [*e.g.* $BaCuO_2(Br,I)$, $WOCl_3Br$],[13] these compounds are the first examples of nitride mixed halides. The $A_2N(X,X')$ nitrides are also, more generally, the first examples of heteroanionic intercalation of any sort in A_2N subnitride hosts. The $[A_2N]^+\cdot(e^-)$ formulation describing ionic layers constraining free electrons within van der Waals gaps suggests a highly reactive environment for intercalation. The potential electron donor properties of these hosts are obvious and the ready incorporation of halides at room temperature is testament to the stability of the filled structures (both relative to the hosts and to AX_2). Interestingly, despite the rigidity of the A–N framework with respect to Cl, Br and I intercalation and in contrast to many examples of cation substitution in normal structured 2D chalcogenides, reaction with smaller spherical anions (*e.g.* H^-) or non-spherical species (*e.g.* CN_2^{2-}) can lead to a collapse of A–N layers and formation of 3D structures.[14] This is in contrast however to incorporation of gold (Ca_2NAu) or diazenide (SrN) where more subtle modifications of the A_2N framework allow retention of 2D structure.[15,16]

The electronic properties of the A_2N subnitrides and their intercalates are by no means well elucidated, although the expectation is that the subnitrides are 2D metals which become more insulating (less conducting) with increased intercalation of X^- (X=H, halide). Preliminary magnetic measurements were performed on powders of Ca_2N, Ca_2NCl and Ca_2NBr using a Cryogenic S100 SQUID magnetometer in the range 4–298 K. Data show weak temperature independent paramagnetism, indicating apparently little difference in magnetic behaviour between intercalated compounds and their Pauli paramagnetic hosts. More comprehensive studies of the (de)intercalation chemistry, crystal structures, magnetic and transport properties of these and other A_2N derived nitrides will be published elsewhere.

We thank Dr R. I. Smith for assistance in collecting PND data, Dr M. O. Jones for SQUID data and Dr P. Hubberstey for useful discussions. D. H. G. would like to thank the EPSRC for the award of an Advanced Research Fellowship and for funding this work and the Nuffield Foundation for the award of an undergraduate bursary to P. V. M.

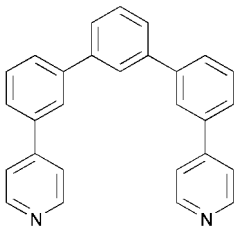
First published as an Advance Article on the web 15th August 2001

Complexation of the ligand 1 with $Pd(NO_3)_2$ leads to the self-assembly of a very stable M_2L_4 type macrotricyclic cage that encapsulates a nitrate ion inside its cavity.

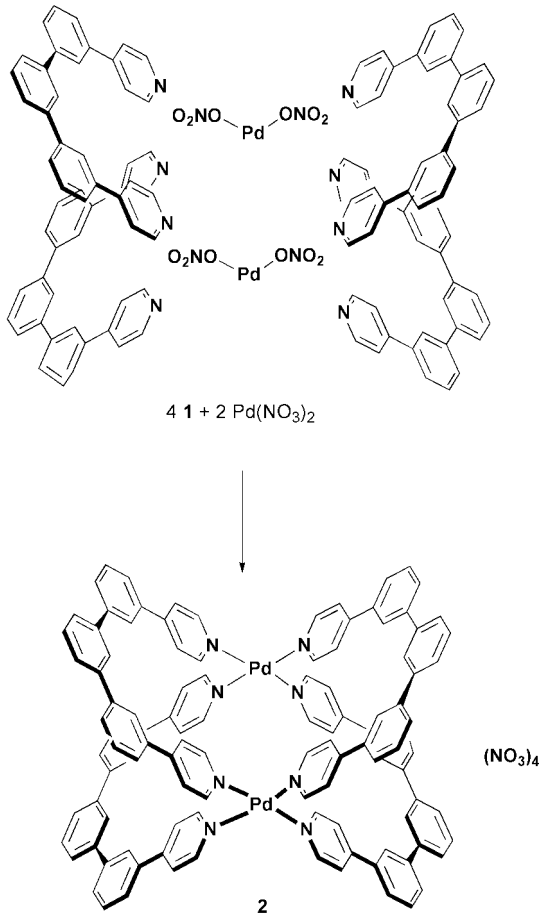
Construction of discrete and well-defined molecular architectures using organic ligands and cleverly selected metal ions through the self-assembly route has received much attention during the last decade.[1] Desired species having predetermined structural and functional properties can be obtained by simply mixing the participating components under suitable conditions.[2] The self-assembled structures formed *via* a metal-driven self-assembly path can be classified logically under M_xL_y types (where M and L denote metal ions and ligands involved, respectively) with varying values of *x* and *y*. While previously reported cage structures are mostly formulated as M_3L_2,[3] M_6L_4,[4] or M_4L_6,[5] there is a scarcity in the series of M_2L_4 type cages[6] in the literature. Atwood and coworkers have reported an early example of a M_2L_4 cage[6a] where two octahedral copper(II) ions are bridged by four units of a bidentate ligand. While all the four equatorial positions of each copper ions are coordinated with the terminal pyridyl groups of the ligand strands, the axial positions are occupied by water molecules. Dinuclear copper(II) complexes of the M_2L_4 family having twisted structures and including chloride[6c] and perchlorate[6d] anions in between the metal centers are also reported. Another analogus structure is a dinuclear Pd(II) cage,[6b] with inclusion of hexafluorophosphate ion inside the cavity. However, in none of the cases the complexation reaction leading to the cage was directly monitored using NMR spectroscopy unlike our study in this work. Herein, we report the self-assembly of a novel macrotricyclic



1

cage molecule from ligand **1** and $Pd(NO_3)_2$, the pivotal positions of the cage being occupied by Pd(II) ions. A nitrate ion is included inside the cavity in a cascade fashion bridging both the metal centers.

Ligand **1** was synthesized by Suzuki coupling of 1,3-bis(3-bromophenyl)benzene with 2-(4-pyridyl)-4,4,5,5-tetramethyl-1,3-dioxaborolane[7] using K_3PO_4 as base and $Pd(PPh_3)_4$ as catalyst.‡ The ligand **1** was mixed with $Pd(NO_3)_2$ at a ratio of 2:1 in DMSO and stirred at 90 °C for 1 day. Subsequently, addition of diethyl ether precipitated a pale yellow powder which was separated by filtration, washed with MeOH, and



Scheme 1

dried *in vacuo* to obtain the complex $[(Pd)_2(\mathbf{1})_4(NO_3)_4]$ **2**§ as a white solid in 74% yield (Scheme 1).

Ligand **1** and complex **2** were characterised by ^1H and ^{13}C NMR. All the peaks were further completely assigned using H–H COSY and C–H COSY techniques. The signals for complex **2** as compared to ligand **1** in its proton NMR spectrum, particularly for py_α and py_β protons, were remarkably downfield shifted due to the complexation. A simple pattern of the spectrum suggests the formation of a discrete species (Fig. 1). Similarly ^{13}C NMR data also supports the assumed structure.¶ All the findings indicate that the four arms in complex **2** are equivalent and that four-fold symmetry axes pass through the metal centers in solution.

The same complexation reaction was also carried out in DMSO-d_6 and the solution was directly monitored by NMR spectroscopic means without isolating the complex. The spectrum obtained matched exactly that of the isolated complex. No peaks other than due to complex **2** were observed which establishes the quantitative self-assembly of **2**. When the metal

† Electronic supplementary information (ESI) available: Crystallography section; Figs. S1–8: ^1H, ^{13}C, H–H and C–H COSY NMR spectra for **1** and **2**. See http://www.rsc.org/suppdata/cc/b1/b104853h/

 DOI: 10.1039/b104853h

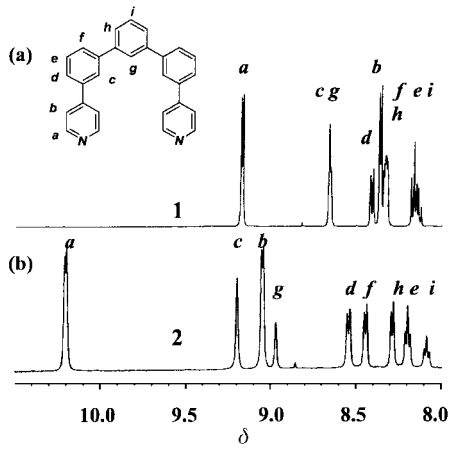


Fig. 1 ^{1}H NMR spectra of (a) ligand **1** and (b) macrotricyclic cage **2** (500 MHz, DMSO-d_6, 25 °C, TMS as an external standard).

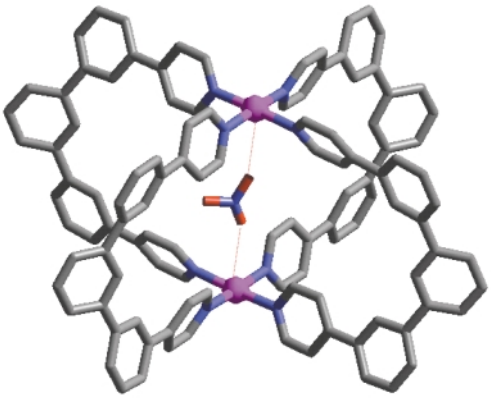

Fig. 2 Representation of $[(Pd)_2(\mathbf{1})_4(NO_3)]^{3+}$ in the crystal structure of **2** (Pd: ball mode and others: cylinder mode). The disorder of the nitrate anion is not shown. Key: palladium (magenta); nitrogen (blue); oxygen (red); carbon (gray).

salt was added in a lesser amount than the required stoichiometry for the complexation, all the signals of complex **2** were still observed, without any indication of any impurity, along with additional signals corresponding only to the uncomplexed free ligand. Also, by adding excess of the metal salt, no other new structures were suggestive from the NMR pattern. All these findings support the remarkable thermodynamic stability of **2**.

Finally, the structure of complex **2** was determined unambiguously from an X-ray diffraction study.‖ Needle-shaped crystals, suitable for X-ray diffraction analysis, were obtained in 2 days by layering diethyl ether over a solution of **2** in DMSO. A perspective view of the molecule is shown in Fig. 2. The crystal structure consists of the complexed cation $[(Pd)_2(\mathbf{1})_4(NO_3)]^{3+}$, three nitrate anions, nine DMSO and two diethyl ether molecules. Each Pd(II) has a square planar geometry with Pd–N bond distances in the range 2.024(7)–2.030(6) Å. The size of the 3-D cavity is *ca.* 11.1 × 10.2 × 8.4 Å which is defined by the arms of the rectangular array formed from four hydrogen centers, H_g (see Fig. 1 for labelling and Fig. 2 for comparison) and Pd–Pd separation. The cavity size after correcting for the van der Waals radius of the H centers is 8.7 × 7.8 × 6.0 Å . While three out of four nitrate ions stay outside of the cavity, one nitrate ion is encapsulated inside by ionic interactions, the Pd–O distance being 3.135(7) Å.

Analysis of crystal packing displayed the extension of intermolecular interactions in a linear manner, where three DMSO molecules lie in the intermolecular cavity formed in between two consecutive $[(Pd)_2(\mathbf{1})_4(NO_3)]^{3+}$ units (Fig. 3). The Pd–Pd axes of adjacent cages adopt a perpendicular geometry to each other making a hydrophobic pocket.

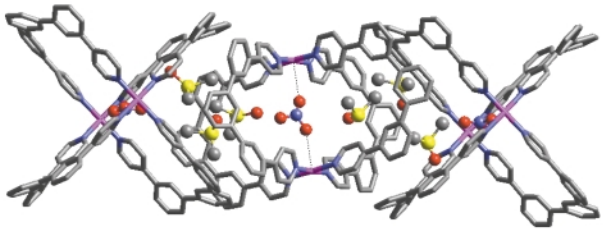

Fig. 3 Linear chain in the crystal structure of **2**. Three DMSO molecules are trapped in each of the intermolecular cavities. Key: palladium (magenta); nitrogen (blue); oxygen (red); sulfur (yellow); carbon (gray). The disorders of the nitrate anions and DMSO molecules are not shown.

The activation of molecular oxygen by horseradish peroxidase with sodium sulfite†

Shin-ichi Ozaki,* Seiko Watanabe, Sachiko Hayasaka and Megumi Konuma

Faculty of Education, Yamagata University, Kojirakawa, Yamagata 990-8560, Japan. E-mail: ozaki@ke-sci.kj.yamagata-u.ac.jp

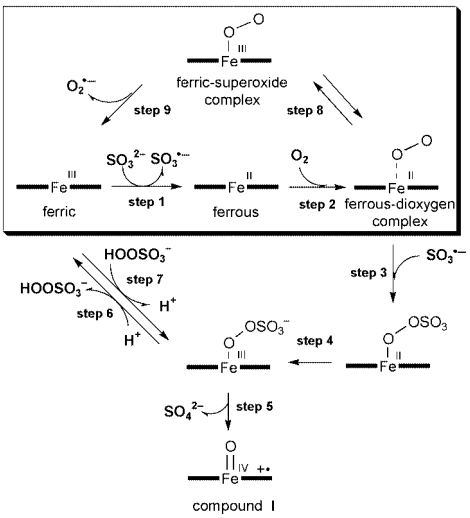
Received (in Cambridge, UK) 22nd May 2001, Accepted 23rd July 2001
First published as an Advance Article on the web 16th August 2001

Horseradish peroxidase (HRP) utilizes molecular oxygen (O_2) with sodium sulfite (Na_2SO_3) to oxidize thioanisole and styrene at the exterior of the heme pocket.

Horseradish peroxidase (HRP) bearing iron protoporphyrin (IX) as the prosthetic group normally utilizes hydrogen peroxide (H_2O_2) as an oxidant to generate an oxoferryl species ($O{=}Fe^{IV}$) paired with porphyrin radical cation, so-called compound **I**.[1] Compound **I** is reduced back to the ferric state by either sequential one-electron transfer from typical phenolic substrates such as guaiacol or by ferryl oxygen transfer to thioethers.[2–4] Since HRP is known to react with racemic hydroperoxides to afford chiral hydroperoxides and alcohols in high enantioselectivity, the enzyme is also used for kinetic resolutions.[5–9] In contrast to P450 monooxygenases, HRP does not efficiently activate O_2 with a reductase and NADH or NADPH because the peroxidase does not mediate the electron transfer from external electron sources on the protein surface to the heme iron buried inside.[10] However, the direct electron transfer from sulfite (SO_3^{2-}) to the ferric heme iron would produce $SO_3^{\cdot}$ (step 1 in Scheme 1), which could initiate the activation of O_2 to oxidize the substrates.[11,12] In order to explore transition metal promoted oxidative reactions with sulfite, we have investigated one- and two-electron oxidation by HRP with SO_3^{2-} and O_2.

Thioanisole is oxidized to methyl phenyl sulfoxide by HRP in the presence of sodium sulfite and ambient O_2 at a rate more than four times faster than the value obtained in the incubation with H_2O_2 as an oxidant (Table 1). Not more than a trace amount of the sulfoxide product is detected when the reaction is performed under anaerobic conditions. The results clearly indicate that HRP together with sulfite can activate molecular oxygen to produce a potential oxidant for the monooxygenation reaction. Interestingly, sulfoxidation with SO_3^{2-} and O_2 does not proceed enantioselectively as observed in the reaction with H_2O_2 (Table 1); therefore, compound **I** does not seem to be a catalytic species in the HRP–SO_3^{2-}–O_2 system (*i.e.* pathway step 3 → 4 → 5 in Scheme 1 is not dominant). Since the oxidation of thioanisole with monoperoxysulfate (HSO_5^-) has been found to afford a racemic mixture of sulfoxide in the presence or absence of HRP, we speculated that monoperoxysulfate released from the heme pocket would be involved in sulfoxidation with sulfite and molecular oxygen.

In order to investigate the mechanism further, we have performed the sulfoxidation reaction in the presence of superoxide dismutase (SOD) and catalase. The reaction is subject to significant inhibition (97%) although SOD and catalase do not decelerate the chemical sulfoxidation by monoperoxysulfate (Table 2). By contrast, the rate of sulfoxidation is reduced by < 18% in the presence of $OH^{\cdot}$ radical scavengers such as methanol or *tert*-butyl alcohol and $SO_4^{\cdot-}$ radical quenchers like ethanol (Table 2). The results imply that (a) superoxide ($O_2^{\cdot-}$) is involved in the production of monoperoxysulfate and (b) the lack of inhibition observed in the presence of ethanol, methanol or *tert*-butyl alcohol argues against the involvement of $SO_4^{\cdot-}$ or $OH^{\cdot}$ radicals in the catalysis. The ferrous–dioxygen and ferric–superoxide complex of HRP are in equilibrium (step 8 in Scheme 1). Thus, the recombination of $O_2^{\cdot-}$ and $SO_3^{\cdot-}$ generated in step 9 and 1 (Scheme 1), respectively, could produce SO_5^{2-}, which is subsequently protonated to produce monoperoxysulfate (HSO_5^-). The release of HSO_5^- from the intermediate by Fe–O



Scheme 1 Reaction scheme for the HRP–SO_3^{2-}–O_2 system. The catalytic cycle postulated by our results is indicated inside the square; $SO_3^{\cdot-}$ and $O_2^{\cdot-}$ generated by step 1 and 9, respectively, would mediate the oxidation reaction outside of the active site under the conditions described here.

HRP	H_2O_2	1.1	77[b]
HRP	sulfite and O_2	1.2	0

[a] The reaction mixture containing HRP (5 μM) and thioanisole (2 mM) was incubated with either H_2O_2 (0.6 mM) or sodium sulfite (0.6 mM) at 25 °C in sodium phosphate buffer (50 mM, pH 7.0). The sulfoxide product extracted with CH_2Cl_2 was analyzed by HPLC equipped with a Dicel OD chiral column as reported in ref. 4. The reported values are the average of two independent experiments. For anaerobic experiments, the vessel containing the reaction mixture was frozen, evacuated and then filled with nitrogen. The procedure was repeated three times to remove dissolved oxygen. Sulfoxidation was then performed under a nitrogen atmosphere. [b] The *S* isomer is the major product.

 DOI: 10.1039/b104529f

Table 2 Inhibition of thioanisole oxidation by additives[a]

Additive	Relative activity (%)
—[b]	100
SOD and catalase[c]	3
Methanol[d]	96
Ethanol[d]	82
tert-Butyl alcohol[d]	96

[a] Reactions were conducted with HRP (5 μM), thioanisole (2 mM), sodium sulfite (0.6 mM) and additive(s) in sodium phosphate buffer (50 mM, pH 7.0) at 25 °C for 10 min. The reported values are the average of two independent experiments. SOD and catalase did not inhibit chemical oxidation of thioanisole by monoperoxysulfate (0.6 mM). [b] No additive. [c] SOD (10 units) and catalase (11 units) added to the reaction mixture. [d] The concentration of additive is 25 mM.

bond cleavage (step 6 in Scheme 1) is excluded because superoxide is not involved in the catalytic cycle (step 1 → 2 → 3 → 6 in Scheme 1) and the observed inhibition in the presence of SOD and catalase can not be rationalized.

Plots of sulfoxidation rate *vs.* pH examined in the range pH 5–10 reveal that the reaction with sulfite does not proceed below pH 5, and the optimum pH is found to be 7 (see ESI†). The trend here is similar to that observed for nickel-catalyzed oxidative deamination with sulfite under aerobic conditions[13] but differs from the pH profile for the HRP–H_2O_2 system, which can produce sulfoxide even below pH 6. The result is consistent with our hypothesis that the oxidation mechanism is altered when SO_3^{2-}–O_2 instead of H_2O_2 is utilized.

Styrene and guaiacol oxidations by HRP with sulfite and oxygen provide further support for the proposed reaction scheme (Scheme 1). In contrast to sulfoxidation, the epoxidation reaction by compound **I** requires interactions of the two vinyl carbons with a ferryl oxygen atom. Since the active site of HRP is sterically hindered, it was previously reported that compound **I** of HRP could not efficiently oxidize styrene.[2,4] However, styrene oxide is detected in the mixture of HRP–styrene–SO_3^{2-}–O_2 (Table 3) although the rate of oxidation is slow. In addition, phenylacetaldehyde, which is normally observed as a side product of compound **I** mediated epoxidation by other hemoproteins, is not produced.[14–18] The results indicate that monooxygenation reactions in the HRP–SO_3^{2-}–O_2 system do not proceed *via* compound **I** but occur outside of the heme pocket by monoperoxysulfate. Significantly, slow one-electron oxidation of guaiacol exhibited by HRP with SO_3^{2-} and O_2 also indicates that the intermediate formation

Table 3 Epoxidation of styrene

Experiment	Protein	Oxidant	Rate
1[a]	HRP	H_2O_2	ND[c]
2[a]	HRP	Sulfite and O_2	200[b]
3[d]	—	Monoperoxysulfate	250[b]
4[e]	—	Sulfite and O_2	ND[c]

[a] Styrene (1 μL) was added to HRP (5 μM) in 0.5 mL of sodium phosphate buffer (50 mM, pH 7.0). The concentration of styrene was expected to be 17 mM, but the reaction mixture appeared to be slightly turbid. To the styrene-saturated solution, either H_2O_2 (0.6 mM) or sodium sulfite (0.6 mM) was added to initiate the reaction at 25 °C. Products were extracted with CH_2Cl_2 and analyzed by GC on a Shimadzu CBP1 capillary column. The reaction time varied from 20 to 120 min to obtain the time *vs.* epoxide formation plot. A linear relationship was observed for 120 min, and the rate was determined as the slope of the plot. The quoted values are the average of two independent experiments. [b] pmol of epoxide min^{-1}. [c] Not detected.[d] The reaction was performed with monoperoxysulfate (0.6 mM) in the absence of HRP. Since the exact concentration of monoperoxysulfate in the HRP–sulfite–O_2 solution can not be determined, direct comparison of the rates in experiments 2 and 3 would not be appropriate, however, the results indicated that the epoxide could be produced from styrene with monoperoxysulfate. [e] Oxidation was also performed with sodium sulfite (0.6 mM) with styrene aerobically in the absence of HRP, but the epoxide product was not detected.

(step 3 in Scheme 1) or/and the heterolytic cleavage of the O–O bond in Fe(III)–SO_5^{2-} species (step 5 in Scheme 1) is not an efficient process since guaiacol can not be oxidized by monoperoxysulfate but only by compound **I**. The addition of an excess of monoperoxysulfate to ferric HRP (step 7 in Scheme 1) somewhat facilitates compound **I** formation to improve the one-electron oxidation activity (4.1 turnover min^{-1}); however, the rate is 6500-fold slower than the value obtained in guaiacol oxidation with H_2O_2. It was previously reported that high valent metal–oxo species generated from water-soluble porphyrins and oxygen atom donors ($KHSO_5$, H_2O_2, … *etc.*) mediate the oxidation of alcohols, olefins or DNA,[19–23] but the active site of HRP may not be large enough to accommodate HSO_5^- as a good oxidant.

In summary, we report that HRP can utilize SO_3^{2-} and O_2 to oxidize thioanisole and styrene, but the catalytic species is not compound **I** as established in the oxidation with H_2O_2. Our mechanistic studies imply that monoperoxysulfate (HSO_5^-) generated from $O_2^{\cdot-}$ and $SO_3^{\cdot-}$ mediates the oxidation reaction outside of the heme pocket. A similar mechanism might be involved in the metalloprotein associated biological toxicity of sulfite inhaled from industrial emissions or ingested as a preservative in foods.[24]

We thank Drs Naohiko Masuda, Minoru Ishii and Yoshihito Watanabe for their technical support. Financial support of this work by Grant-in-Aid for Scientific Research (No. 10680575) and Mitsubishi Chemical Corporation Fund for S. O. is gratefully acknowledged.

Reversible *trans–cis* photoisomerization of azobenzene-attached bipyridine ligands coordinated to cobalt using a single UV light source and the Co(III)/Co(II) redox change

Shoko Kume, Masato Kurihara and Hiroshi Nishihara*

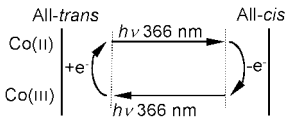
First published as an Advance Article on the web 16th August 2001

The *trans*/*cis* ratio of the azobenzene-attached bipyridine ligands in a cobalt complex is reversibly altered by a combination of photoirradiation with a single UV light source and the reversible redox change between Co(II) and Co(III).

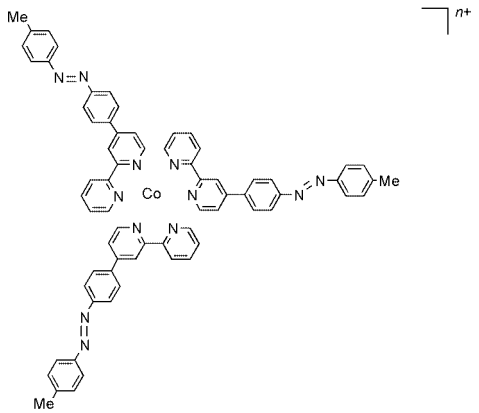
The photoisomerization of organic azobenzenes is a subject of current research interest with regard to information storage and photo-switching molecular devices.[1] Molecular motion induced by isomerization of the azo group can be controlled by a combination of UV- and visible-light irradiation, where the former (π–π* transition) achieves the *trans*-to-*cis* isomerization and the latter (n–π* transition) promotes the reverse isomerization.[2] Thus, use of two different light sources to achieve reversible molecular motion is an essential factor in the development of molecular devices.[3] An exception, which made use of a photochemical–electrochemical hybrid system, has been reported by Fujishima and coworkers.[4] Transition metal-conjugated azo compounds[5,6] can provide new advanced molecular functions utilizing combination of the photoisomerization and redox change of the metal center. In this communication, we report the first example of reversible *trans–cis* isomerization of the azo group achieved through a combination of photoirradiation and a redox cycle between Co(II) and Co(III), that makes possible both forward and backward isomerization in response to irradiation with a single light source (Scheme 1). A novel tris(azobenzene-attached bipyridine)cobalt complex was employed in this system, since both the Co(II) and Co(III) complexes are fairly stable in air under ambient conditions.



Scheme 1

A tolylazophenylbipyridine ligand, azobpy, was synthesized through the coupling of 4-(4″-anilino)-2,2′-bipyridine and 4-nitrosotoluene.[7] The Co(II) complex of azobpy, $[Co^{II}(azobpy)_3](BF_4)_2$, was obtained by reaction of $Co^{II}(NO_3)_2$ with azobpy in dichloromethane at room temperature, followed by exchange of the counter ion with NEt_4BF_4. The oxidation of $[Co^{II}(azobpy)_3]^{2+}$ was carried out with $AgCF_3SO_3$ and $[Co^{III}(azobpy)_3](BF_4)_3$ was precipitated through the addition of an excess amount of NH_4BF_4.† In the ^1H NMR spectrum, two distinct signals of the terminal methyl group and complicated signals of aromatic ring protons were derived from a mixture of *mer*- and *fac*-isomers of $[Co^{III}(azobpy)_3]^{3+}$ with respect to three tolylazophenyl groups.

In a cyclic voltammogram of $[Co^{II}(azobpy)_3](BF_4)_2$, a reversible Co(III)/(II) redox wave and a quasi-reversible Co(II)/(I) redox wave were observed at −0.15 and −1.27 V *vs.* ferrocenium/ferrocene (Fc^+/Fc) in dichloromethane, respectively.



UV–VIS absorption spectra of azobpy, $[Co^{II}(azobpy)_3](BF_4)_2$ and $[Co^{III}(azobpy)_3](BF_4)_3$ showed π–π* bands due to the azo group at λ_{max} = 345 nm ($\varepsilon = 3.5 \times 10^4$ mol^{-1} dm^3 cm^{-1}), 360 (1.1×10^5) and 374 (9.7×10^4), respectively. An increase in the electron-withdrawing effect on the azo group in response to the oxidation of Co(II) to Co(III) resulted in a lower energy of the π–π* band.[8] Upon irradiation to the dichloromethane solution of azobpy with UV light at 366 nm,‡ the π–π* band decreased and the n–π* band of the azo group at 445 nm increased in intensity, showing a typical *trans*-to-*cis* isomerization of the azobenzene moiety [Fig. 1(a)]. The molar ratio of the *cis*-form reached 92% in the photostationary state (PSS). The spectral change of $[Co^{II}(azobpy)_3](BF_4)_2$ in dichloromethane is essentially similar to that of azobpy upon irradiation with the 366 nm light, and 40% of the *trans*-azobenzene moiety was found to be changed into the *cis*-form in PSS [Fig. 1(b)]. The irradiation with 438 nm light reversed the spectral change, indicating a *cis*-to-*trans* isomerization. Intriguingly, almost no decrease in absorbance of the π–π* band of $[Co^{III}(azobpy)_3](BF_4)_3$ was observed under the same 366 nm light irradiation, suggesting that the *cis*-to-*trans* back-reaction of the Co(III) complex is much more effective than that of the Co(II) complex in PSS (*vide infra*).

The difference in the *cis*-form concentrations in PSS between Co(II) and Co(III) described above indicates the possibility of a reversible *trans–cis* conversion with single monochromatic light irradiation by changing the redox state between Co(II) and Co(III). To test this hypothesis, we carried out the following experiments. A dichloromethane solution of the *trans*-form of $[Co^{II}(azobpy)_3](BF_4)_2$ was irradiated with 366 nm light to reach PSS, and the resulting mixture of *trans*- and *cis*-forms was oxidized with a stoichiometric amount of 1,1′-dichloroferrocenium hexafluorophosphate, $[Fe(\eta^5\text{-}C_5H_4Cl)_2]PF_6$ ($E^{0\prime}$ = 0.19 V *vs.* Fc^+/Fc).[5] The ratio of the *cis*-form remained constant after the oxidation, the thermal isomerization to the *trans*-form proceeding very slowly in the dark [the recovery of absorbance of the π–π* band was not pronounced in intensity over 30 min

 DOI: 10.1039/b104381c

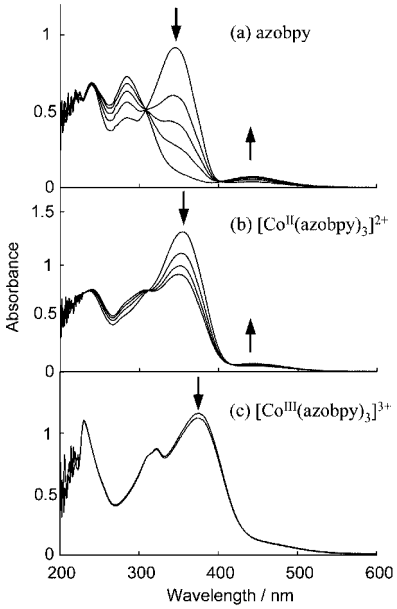


Fig. 1 UV–VIS absorption spectral change of azobpy (2.62×10^{-5} mol dm^{-3}) (a), [Co^{II}(azobpy)](BF$_4$)$_2$ (1.17×10^{-5} mol dm^{-3}) (b), and [Co^{III}(azobpy)](BF$_4$)$_3$ (1.20×10^{-5} mol dm^{-3}) (c), in dichloromethane upon irradiation with 366 nm light.

Fig. 2(b)]. When the oxidized solution was exposed again to 366 nm light, the *cis*-to-*trans* photoisomerization promptly occurred to create the *trans*-rich PSS which is characteristic of the Co(III) state, accompanied by a fast increase in the absorbance of the π–π* band within a few minutes [Fig. 2(a)]. The Co(III) complex in PSS upon irradiation with 366 nm light was re-reduced with a stoichiometric amount of 1,1′-acetylcobaltocene, [Co(η^5-C$_5$H$_4$COMe)$_2$] ($E^{0\prime}$ = −0.76 V *vs.* Fc$^+$/Fc)[9] and the exposure to the same 366 nm light resulted in a *trans*-to-*cis* isomerization to reach the different PSS that is characteristic of the Co(II) state. These results suggest that a reversible *trans–cis* isomerization can be achieved by a combination of the reversible redox change between Co(II) and Co(III) and irradiation with a single UV light source, which is a novel route differing from the reversible isomerization of general organic azobenzenes with a combination of π–π* and n–π* excitation employing UV and visible light, respectively (Scheme 1).

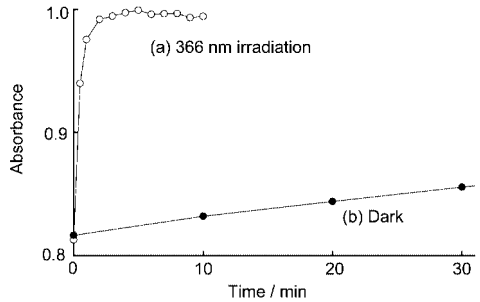

Fig. 2 Change in absorbance at 360 nm with time upon irradiation with 366 nm light (○) and in the dark (●) after a dichloromethane solution of [Co^{II}(azobpy)$_3$](BF$_4$)$_2$ (1.04×10^{-5} mol dm^{-3}) was first irradiated with 366 nm light to reach PSS and then oxidized with [Fe(η^5-C$_5$H$_4$Cl)$_2$]PF$_6$.

The redox-coupled photoisomerization system described above may enable continuous control of total conversion to the *cis*-form of azobenzene moieties in PSS by means of a continuous change in Co(II) to Co(III) complex molar ratio upon irradiation with monochromatic 366 nm light. Solutions consisting of various molar ratios of the Co(III) complex, *x*, were prepared by the addition of *x* equivalents of [Fe(η^5-C$_5$H$_4$Cl)$_2$]PF$_6$ to the solution of [Co^{II}(azobpy)$_3$](BF$_4$)$_3$, which was then irradiated with 366 nm light. After reaching PSS within a few minutes, the Co(II) component was oxidized with

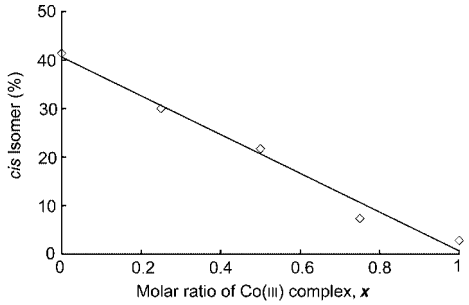

Fig. 3 Correlation between the conversion ratio of the *cis*-form and the molar ratio, *x*, of the Co(III) complex.

$1 - x$ equivalents of [Fe(η^5-C$_5$H$_4$Cl)$_2$]PF$_6$ to estimate the total formation ratio of the *cis*-azobenzene moiety by using the absorbance of the π–π* band normalized as the Co(III) complex (Fig. 3). The contribution of thermal *cis*-to-*trans* isomerization to the *cis* ratio can be neglected, as the process proceeds very slowly compared to the photo-process, as already mentioned. The conversion ratio of the *cis*-form was found to linearly correlate with the ratio *x* within 0–40%. A similar continuous control of the conversion ratio of the *cis*-form for organic azobenzenes can be achieved by tuning the relative intensities of two different monochromatic light sources or by selection of a suitable excitation wavelength closely associated with overlapping of the π–π* and n–π* bands. Compared with these photochemical methods, the combination of the photoisomerization and the redox processes of the metal complex-conjugated azobenzene is a more facile and precise pathway to adjust the *cis* conversion ratio.

In conclusion, reversible *trans–cis* isomerization has been achieved by a combination of the reversible redox reaction between Co(II) and Co(III) and single UV-light irradiation. This method should provide a new design for photochemical and electrochemical hybrid molecular devices. We are currently expanding the method developed in the present study to a modified electrode system in which the redox state of Co can be controlled electrochemically.

Received (in Cambridge, UK) 23rd March 2001, Accepted 11th July 2001
First published as an Advance Article on the web 16th August 2001

A novel luminescent acetylenediide-bridged tetranuclear copper(I) complex $[Cu_4(\mu\text{-}Ph_2Ppypz)_4(\mu_4\text{-}\eta^1,\eta^2\text{-}C{\equiv}C)](ClO_4)_2$ [Ph_2Ppypz = 2-(diphenylphosphino-6-pyrazol-1-yl)pyridine] has been synthesized and structurally characterized by X-ray crystallography.

Metal acetylides have been subjected to intensive study for many years.[1] The interest mainly stems from: (i) the ability of the acetylide group to bond to transition metals, forming a growing number of mono- and poly-nuclear complexes that display an unusually rich variety of structures; (ii) the versatile reactivity of the coordinated acetylide group in its complexes, which serve as useful precursors for the synthesis of other target organometallic compounds. In contrast to the plethora of ethynyl complexes containing acetylenide ligands of the type R–C≡C$^-$, ethynediyl complexes containing the acetylenediide ligand, C_2^{2-}, that exhibits the known coordination modes[2] shown in Fig. 1 are relatively rare.

The group 11 metal acetylides M_2C_2 exhibit properties that are characteristic of covalent polymeric solids. They are insoluble in many common solvents, and highly explosive and sensitive to mechanical shock when completely dried. Some examples of (μ-C≡C)bis[(phosphine)gold(I)] complexes have been reported.[3] In these complexes, the C_2^{2-} anion coordinates a pair of gold atoms by σ-bonding to form a linear molecule. Double salts of silver(I) acetylide were studied over half a century ago,[1a] and recently several novel triple and quadruple salts have been synthesized.[5d,e] Their structures exhibit a variety of polyhedral silver cages each encapsulating a C_2^{2-} anion ($C_2@Ag_n$, n = 6, 7, 8, 9).[5] In the context of the chemistry of copper(I) acetylide, development has been hampered by its insolubility in common solvents and the lack of general methods for the synthesis of its derivatives. To date, there is only one known ethynediyl copper(I) complex, namely $[Cu_4(\mu\text{-}dppm)_4(\mu_4\text{-}\eta^1,\eta^2\text{-}C{\equiv}C)](BF_4)_2$ [dppm = bis(diphenylphosphino)methane] **1** where the C_2^{2-} anion coordinates four rectangularly arranged copper atoms by distinct σ and π bonding, and this planar **D**(1) coordination mode is illustrated in Fig. 1.[6a] Here we report the synthesis, structure and luminescence properties of a related complex $[Cu_4(\mu\text{-}Ph_2Ppypz)_4(\mu_4\text{-}\eta^1,\eta^2\text{-}C{\equiv}C)](ClO_4)_2$ [Ph_2Ppypz = 2-(diphenylphosphino-6-pyrazol-1-yl)pyridine] **2**, in which the coordination mode of C_2^{2-} is **D**(2), with the metal atoms arranged about it in a butterfly configuration.

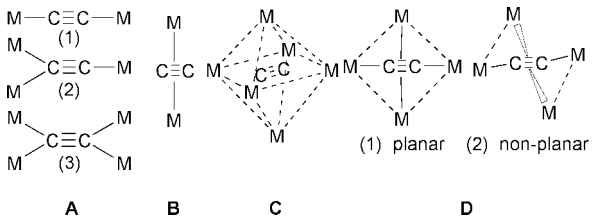

Fig. 1 Coordination modes of C_2^{2-} to metal atoms. In mode **A**, the metal centers are bridged by the C_2^{2-} anion through σ bonds.[1g,2b,c,3] In mode **B**, the C_2^{2-} anion is π-bonded to a pair of metal atoms.[4] In mode **C**, the C_2^{2-} species is encapsulated in a polyhedral metal cage.[5] In modes **D**(1) and **D**(2), the metal atoms are bridged by the C_2^{2-} anion through distinct σ and π bonds in a planar[6] and non-planar[5b] configuration, respectively.

The synthesis of **2** is shown in Scheme 1. In the first method, 1 equiv. Bu^{n}Li was added at room temperature to a solution of 0.5 equiv. $Me_3SiC{\equiv}CH$ in pre-dried, degassed THF under an inert nitrogen atmosphere, and 1 equiv. $[Cu_2(\mu\text{-}Ph_2Ppypz)_2(MeCN)_2](ClO_4)_2$ was then introduced with stirring. After evaporation to dryness, the resulting solid was extracted with CH_2Cl_2. Subsequent diffusion of diisopropyl ether into the concentrated solution gave air-stable orange crystals of **2**·3CH_2Cl_2. In the second method, 0.45 equiv. NaC≡CH was added to a solution of 1 equiv. $[Cu_2(\mu\text{-}Ph_2Ppypz)_2(MeCN)_2](ClO_4)_2$[7a] in degassed THF at −78 °C under an inert atmosphere of nitrogen, and the solution was stirred for 24 h at room temperature. The work-up was similar to that in the first method. However, the yield of the second method is very low (< 10%) due to formation of Cu_2C_2 as the major product. The much higher yield by the first method (60%) is attributable to the gradual release of C_2^{2-} from $Me_3SiC{\equiv}C^-$. Complex **2** gave satisfactory C,H,N analyses, and was subsequently characterized by $^{13}C\{^1H\}$ NMR spectroscopy and X-ray crystallography.† In the $^{13}C\{^1H\}$ NMR (CD_2Cl_2) spectrum, the resonance for carbon in the –C≡C– group appeared at δ 68.65, comparable with that in C_2H_2 (δ 71.90). Although the C≡C stretching vibration is IR active in coordination mode **D**(2), the intensity is weak and scarcely observable in the IR spectrum.

Fig. 2 shows a perspective drawing of the tetranuclear cation in **2**·3CH_2Cl_2 with the atomic numbering scheme. The cation has crystallographic C_2 symmetry. Its structure consists of a butterfly-shaped tetranuclear Cu_4C_2 core in which the acetylenediide anion bridges a pair of Cu_2 sub-units in both η^1 and η^2 bonding modes. The normal electron count requires that the C_2^{2-} anion acts as a six-electron donor according to the covalent model. While the interaction of the C_2^{2-} anion with each Cu_2 sub-unit resembles that found in other μ-η^1,η^2-acetylido complexes, best overlap of the two π orbitals of the C_2^{2-} ligand with the metal orbitals would require that the two Cu_2 sub-units be orthogonal to each other. As shown in Fig. 2, the Cu(2)–C(1)–C(1A)–Cu(2A) system is approximately linear, and the dihedral angle between the planes Cu(1)–C(1)–C(1A) and Cu(1A)–C(1)–C(1A) is 129.0(3)°, which is very distinct

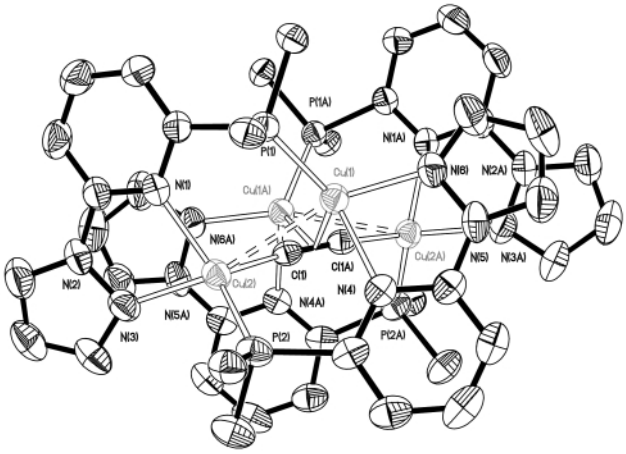

Fig. 2 Perspective drawing (thermal ellipsoids at 35% probability level) of the tetranuclear copper(I) cation in **2**·3CH_2Cl_2 with the atomic numbering scheme. Hydrogen atoms and phenyl rings have been omitted for clarity. Selected bond lengths (Å) and angles (°): Cu(1)–C(1) 2.143(6), Cu(1)–C(1A) 2.215(6), Cu(2)–C(1) 1.931(6), Cu(1)–Cu(2) 2.843(1), C(1)–C(1A) 1.26(1), Cu(1)–P(1) 2.220(2), Cu(1)–N(4) 2.244(5), Cu(1)–N(6) 2.050(5), Cu(2)–P(2) 2.217(2), Cu(2)–N(1) 2.116(5), Cu(2)–N(3) 2.104(5), Cu(1)–C(1)–C(1A) 76.3(5), Cu(2)–C(1)–C(1A) 160.9(7), dihedral angle between planes Cu(1)–C(1)–C(1A) and Cu(1A)–C(1A)–C(1) 129.0(3)°. Symmetry code: A $-x, y, \frac{1}{2} - z$.

from the planar Cu_4C_2 core in **1**. A plausible reason is that the pyridinopyrazole group has less steric hindrance than the dppm group. The C≡C bond in **2** [1.26(1) Å] is identical to that in **1** but longer than those (1.15–1.22 Å) in the ethynediyl silver and gold complexes. The shortest copper–copper distance Cu(1)–Cu(2) 2.843(1) Å lies between those in $[Cu_2(\mu\text{-}Ph_2Ppypz)_2(\mu\text{-}C{\equiv}CPh)](ClO_4)$ [2.516(1) Å] and **1** [3.264(2) and 3.245(2) Å], which is suggestive of cuprophilic interaction between the copper(I) centers.[8] The coordination number of each copper atom in **2** is four, in contrast to the coordination number of three in **1**. The reason can also be attributed to the difference in steric bulk of the two ligands. The dppm ligand is soft and bulky, and the binuclear complex $[Cu_2(MeCN)_4(dppm)_2](BF_4)_2$ readily reacts with halide or $RC{\equiv}C^-$ to form a trinuclear complex.[9] On the other hand, Ph_2Ppypz is more rigid and $[Cu_2(MeCN)_2(Ph_2P\text{-}pypz)_2](ClO_4)_2$ reacts with halide or $RC{\equiv}C^-$ to form other binuclear products.[7]

The electronic absorption and emission spectra of complex **2** in CH_2Cl_2 are shown in Fig. 3.‡ The electronic spectrum exhibits absorption bands at *ca.* 340–400 nm (λ_{max}^{abs}/nm (ε_{max}/dm^3 mol^{-1} cm^{-1}), 345sh (100 000), 364sh (63 827), 373 (37 675), 396 (28 400)). A similar band is also observed in **1** at 374 nm. Such bands most likely involve the Cu_4C_2 core, so they are assigned to LMCT bands of $[(C{\equiv}C)^{2-}{\rightarrow}Cu_4]$. Excitation of

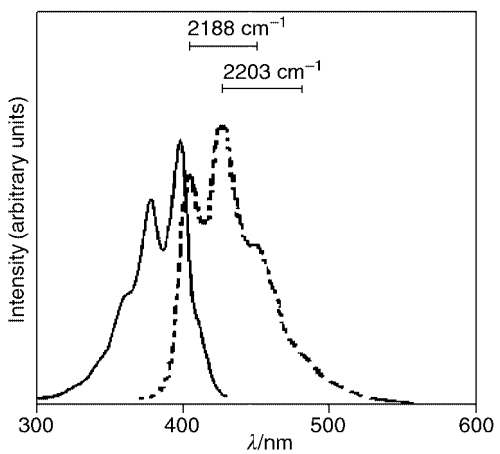

Fig. 3 Excitation spectrum (left, ——) and emission spectrum (right, - - - -) of **2** in CH_2Cl_2 at 298 K.

2 in dichloromethane at λ > 350 nm produces blue–green luminescence (408, 430, 448sh, 475sh nm). Vibronically structured bands with two progressional spacings at 2188 and 2203 cm^{-1}, characteristic of the ν(C≡C) stretch,[9b–d] were observed. The appearance of vibrational progressions is suggestive of involvement of the C_2^{2-} unit in the excited state. The overlap of the emission bands with the low-energy excitation bands and a quite small Stokes shift, quite distinct from the case in **1**, are assigned to the rigid and unsubstituted aromatic ring of Ph_2Ppypz. A possible origin of the emission involves emissive states derived from $[(C{\equiv}C)^{2-}{\rightarrow}Cu_4]$ LMCT mixed with d→s character. Similar assignments have been proposed for other alkynyl/alkynediyl copper(I)/silver(I) systems.[9]

Subtlety in the reactivity of a diketo phosphorus ylide towards mercuric halides: the unprecedented O-coordination of α-acetyl-α-benzoylmethylenetriphenylphosphorane to Hg(II)†

Received (in Cambridge, UK) 9th May 2001, Accepted 20th July 2001
First published as an Advance Article on the web 6th August 2001

The reactions of the title ylide with HgX_2 (X = Cl, Br or I) lead to the regiospecific binding of the acetyl oxygen to soft Hg(II), producing a chloro complex with (2 + 2) coordination and isostructural dimeric bromo and iodo complexes containing halogen bridges with tetrahedral configurations around the metal centres.

The ambidentate resonance stabilized ylide, $Ph_3PCHCOPh$ coordinates through carbon and oxygen to Hg(II)[1,2] and U(VI),[3] respectively. The diketo ylide, α-acetyl-α-benzoylmethylenetriphenylphosphorane (ABPPY) has an additional oxygen site for coordination and can utilize different bonding modes. The symmetrical bidentate O-coordination of the carbonyl groups had been recently observed by us in its reaction with uranyl nitrate.[3] We present herein the regiospecific coordination of the diketo ylide to the soft metal center, Hg(II) *via* the acetyl oxygen. This paper represents the first report of O-coordination of any keto phosphorus ylide to Hg(II).

The parent ylide was prepared by the action of acetic anhydride on $Ph_3PCHCOPh$ and spectrally characterized as published.[4] The action of HgX_2 on an equimolar methanolic solution of the ylide afforded the complexes $HgCl_2(ABPPY)_2$ (**1**), $[HgBr_2(ABPPY)]_2$ (**2**) and $[HgI_2(ABPPY)]_2$ (**3**) which were formed as crystals, on cooling the concentrated solution. Elemental analyses of the products revealed their stoichiometry. In the FTIR spectra of the products, the ν_{CO} for the COMe group observed at 1537 cm^{-1} for ABPPY is shifted to 1526, 1573 and 1575 cm^{-1} in **1**, **2** and **3**, respectively. The corresponding frequencies for the COPh group occur at 1566, 1568, 1600 and 1596 cm^{-1} in the above molecules. It is significant that the ν_{CO} values are very similar in **2** and **3** as expected for the identical environment of their two carbonyl groups. In the $^{13}C\{^1H\}$ NMR spectra of the products in $CDCl_3$, the resonance due to the ylidic carbon at δ 86.35 as well as the $^1J_{PC}$ of 101.8 Hz observed for the free ylide is not very much shifted in the products. The ^{31}P NMR spectra contain a single signal around δ 17 for the ylide and each of the complexes. This suggests the presence of a single isomer in all the complexes, with the oxygen being bonded to the metal. In contrast, the C-coordination which implies a change in the hybridization for the ylidic carbon is characterized by its upfield ^{13}C chemical shifts[5] and also by the downfield shifts of ^{31}P NMR signals.[1] That the bonding of the ylide to Hg(II) in the chloro complex is much weaker than in the bromo and the iodo complexes is indicative in the ^1H NMR spectra in which the methyl group resonances appear at δ 1.80, 1.81, 1.70 and 1.71 for the free ylide and complexes **1**, **2** and **3**, respectively.

In order to establish the region and mode of coordination, single crystal X-ray analysis‡ of the complexes has been undertaken. The solid state structure of **1** shows that it adopts a square planar geometry with two collinear strong covalent Hg–Cl bonds referred to as 'characteristic coordination.' The preference for a characteristic coordination number of two for mercury in its complexes with electronegative ligands, as observed in **1** has been attributed to relativistic effects.[6] The Hg–O bond lengths are distinctly longer in the chloro complex and denoted[7] as 'secondary bonds.' The importance of such inter-species interactions has been realized in solid state architecture, molecular recognition, prototype 'ionic liquids' and biological chemistry.[8] Semiempirical calculations at the PM3 level[9] corroborate the geometry and bond parameters of **1**, discerned from X-ray crystallography. In particular, the calculated values, 173.9 and 179.2°, for O–Hg–O and Cl–Hg–Cl angles, respectively, are comparable to the experimental values (Fig. 1). Mulliken population analysis[10] on the title ylide shows that the oxygen of the COMe group possesses a higher negative charge (−0.47) than the oxygen of the COPh group (−0.38). The linear disposition of secondary bonds in **1** is traceable to the electrostatic interactions caused by the bulky ylide ligands precluding any weak covalent interactions involving p orbitals. The latter type of interactions is indicated by B3LYP[11]/LANL2DZ[12] calculations for the identical Hg–O bonds in $HgCl_2(HCHO)_2$[13] and likely to be present in the crystal structure of $HgCl_2$(chd) (chd = cyclohexane-1,4-dione) complex[14] with an observed O–Hg–O angle of 86°. The Hg(II) in each of the molecules **2** and **3** has a tetrahedral coordination environment with two unsymmetrically bridging Hg–X bonds. The oxygen of the acetyl group is oriented *cis* to the phosphorus

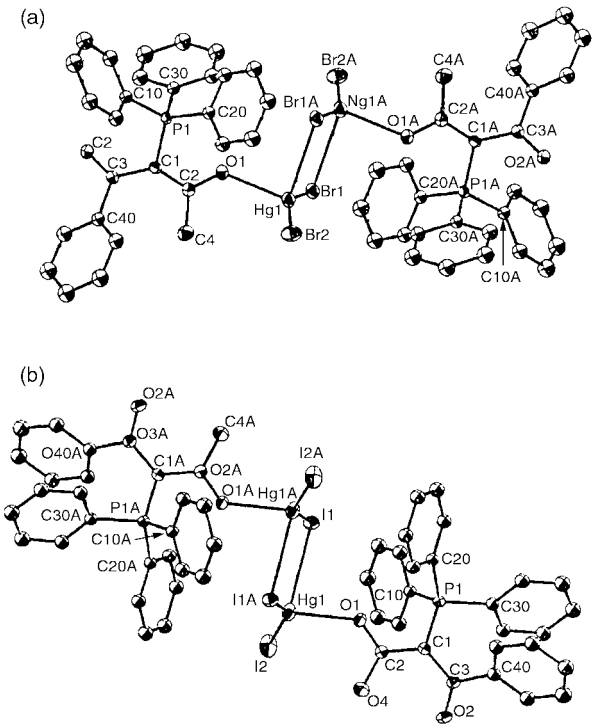

Fig. 2 ZORTEP view of **2** and **3** with 50% probability thermal ellipsoids and selected atom labelling scheme. The hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): for **2**: Hg1–O1 2.397(3), Hg1–Br1 2.4693(5), Hg1–Br2 2.4420(5), Hg1–Br1A 2.9997(5), O1–C2 1.270(5), O2–C3 1.239(5), P1–C1 1.770(4); O1–Hg1–Br1 100.86(7), O1–Hg1–Br2 105.87(7); O1–Hg1–Br1A 87.67(7), Br1–Hg1–Br1A 90.76(2), Hg1–O1–C2 128.9(3). For **3**: Hg1–O1 2.370(3), Hg1–I1 3.120(1), Hg1–I2 2.615(1), Hg1–I1A 2.676(1), O1–C2 1.269(5), O2–C3 1.223(5), P1–C1 1.766(4); O1–Hg1–I1 81.37(8), O1–Hg1–I2 104.05(8), O1–Hg1–I1A 102.80(8), I1–Hg1–I1A 92.49(1), Hg1–O1–C2 129.6(3).

in all the three complexes as is evident from the P–C–C–O torsion angles of 0.0 and 6.1° in **1**, 0.8° in **2** and 8.31° in **3**.

We conclude that novel bonding modes to Hg(II) could be mediated by the flexidentate ylide, ABPPY. It is significant that $HgCl_2$ prefers to form the 1:2 complex, *albeit* with secondary Hg··O interactions. The coordination of the ylide to mercury in **2** and **3** through the lone pair on the unpolarized acetyl oxygen is shown by the C2–O1 and C1–C2 bond lengths, by the bond angles around the trigonal acetyl oxygen (Fig. 2) and also by the upward shifts for the ν_{CO} of COMe group in the IR spectra of the products. This type of bonding that involves the canonical keto form of the ylide contrasts with the enolate bonding of $Ph_3PCHCOMe$.[15] We ascribe this keto-coordination of the ylide found in both **2** and **3** to the symbiotic effects of the softer halogens.

P. L. thanks the Council of Scientific and Industrial Research, Government of India for the award of Senior Research Fellowship [9/475(92)/99-EMRI]. The authors thank the Ohio Crystallographic Consortium, funded by the Ohio Board of Regents 1995 Investment Fund [(CA)-075] located at the University of Toledo, Instrumentation Center in A&S, Toledo, OH 43606, USA for X-ray data collection, the Sophisticated Instruments Facility, Indian Institute of Science, Bangalore, India, for recording ^{13}C NMR spectra for the samples and Dr Mariappan Manoharan, Post-Doctoral Fellow, Centre for Computational Quantum Chemistry, University of Georgia, Athens, GA 30602-2525, USA for DFT calculations.

Received (in Cambridge, UK) 4th April 2001, Accepted 11th July 2001
First published as an Advance Article on the web 6th August 2001

The addition of diethylamine to Stille alkylation reactions using stannanes improves yields by reducing β-hydride elimination and reduction reactions, it also serves as a substitute for other additives such as Cu(I)I.

The Stille reaction is a member of a large family of palladium-catalysed cross-coupling reactions. However, its generality and high degree of success have made it popular among synthetic chemists. One obvious reason for such popularity is the reaction's versatility.[1] It is frequently used in the total syntheses of large polyfunctional molecules for the coupling of complex subunits.[2,3] However, it is sometimes found that it is not universally applicable and that many substrates require specific reaction conditions for cross-coupling to be successful.[1–5]

There are relatively few examples of the successful introduction of alkyl groups employing Stille cross-coupling reactions described in the literature,[6] and for α-iodocyclohexenones the reported yields are only moderate. This is probably due to failure resulting from competing β-hydride elimination when employing stannanes with alkyl groups bearing β-hydrogens and to the low reactivity of the system. A further problem often encountered is the competing reduction of vinylic or aromatic halides to the corresponding hydrocarbon. This can be a serious problem where the halide is unreactive.

Several reports have appeared relating to the importance of intramolecular participation by amino groups in Stille cross-coupling reactions. For example, it has been reported that alkyl derivatives of 1-aza-5-stannabicyclo[3.3.3]undecane were reactive in Stille couplings with aryl and alkenyl halides,[7,8] without β-hydride elimination. It was suggested that intramolecular tin–nitrogen coordination could be the reason.

A difficult case for Stille coupling is represented in Scheme 1 (Table 1) where the highly substituted aryl iodide **1** having an amido group reacted readily with allyl triphenylstannane in the presence of Pd to form the expected product **3** in good yield (95%). The ester **2** under a wide range of normally successful conditions afforded a maximum of 36% of **4**.

Table 1 Stille coupling at polysubstituted aromatic compounds **1** and **2**[a]

Cpd	Pd cat	Ligand	LiCl	Et_2NH	Prod.	Time	Yield
1	$Pd(PPh_3)_2Cl_2$	PPh_3	Yes	No	**3**	2 h	95%
2	$Pd(PPh_3)_2Cl_2$	PPh_3	Yes	No	**4**	1 h	36%
2	$Pd(PPh_3)_2Cl_2$	PPh_3	Yes	Yes	**4**	1 h	87%

[a] The solvent employed was DMF.

† Electronic Supplementary Information (ESI) available: Tables—Stille coupling of α-iodoenone **5** with Et_4Sn and Me_4Sn, and general procedure. See http://www.rsc.org/suppdata/cc/b1/b103072h/

Assuming that the nitrogen atom of the amide was facilitating the aryl transfer process for **1** by intramolecular chelation,[9] we added diethylamine to the reaction mixture, containing ester **2**, to ascertain if the corresponding intermolecular process was possible. This resulted in a 87% isolated yield of the expected allyl compound **4**. No amination[10] or amidification products were isolated. We next applied these findings to other cases.

Alkylation of the iodoenone **5** under 'normal' Stille conditions with tetrabutylstannane gave none of the expected butylated compound **6** but high yields of the reduced product **9** (Scheme 2). The addition of diethylamine to this reaction

Scheme 3

resulted in the formation of the butylated compound **6** in good yield (Table 2). This was also the case for tetraethylstannane and for tetradecylstannane. The products **7** and **10** were obtained in good yield. Without added diethylamine, the reduced product **9** was formed exclusively.

Having shown that diethylamine did influence the outcome of these reactions we next proceeded to approach optimisation by studying several variables for this reaction (Tables 2, 3). Thus, the influence of using Pd(0) or Pd(II) as catalyst sources, the effect of the Pd ligands (PPh_3, $P(o\text{-Tol})_3$ and $AsPh_3$), the presence of CuI as cocatalyst and the additon of LiCl for the aromatic substrates were analysed. We have concluded that both Pd(0) and Pd(II) were equally effective, as expected. The catalytic role of the Pd species was largely influenced by the ligand. $AsPh_3$ and $P(o\text{-Tol})_3$ were found to be the best ligands tested while PPh_3 was considerably less effective. Remarkably, we have observed that for the Stille coupling of iodoenone **5** with tetramethyltin, CuI could effectively be replaced by diethylamine. When this reaction was carried out in the presence of diethylamine the workup was considerably simplified and the yields consequently higher. Analogous reactions reported in the literature used involatile NMP as the solvent.

Studies on the electron poor aromatic substrate **11** were also carried out. For this compound the reaction conditions as used for the iodoenone, had to be changed and DMF became the solvent of choice. The use of diethylamine again prevented reduction, as seen for the reaction of **11** with tetrabutyltin. The yield of the coupling product **12** was not improved over that of the same reaction without added amine but starting material was recovered when Et_2NH was present, whereas several other products were formed in its absence (Scheme 3 and Table 4). The addition of LiCl[11] alone simplified the product distribution but did not avoid reduction and the yield of coupling product was zero or low. When both LiCl and Et_2NH were included in the mixture the coupling product **12** was produced in low yield and starting halide **11** was recovered as the only other product.

The function of the amine is not yet clear but we suspect that it augments the activity of the phosphine ligand in maintaining the Pd(0) in solution. This complexation with the Pd atom of intermediates may also reduce the ability to undergo β-hydride elimination reactions, once it has bonded with the alkyl group by exchanging with the tin.

In conclusion, the addition of diethylamine clearly prevented β-hydride elimination/reduction in the Stille alkylation reactions tested when employing alkylstannanes with β-hydrogens, a problem frequently reported in the literature.[1] Its addition permits the use of more volatile less polar solvents in some cases and can reduce reaction times, as is well exemplified in the case of tetramethyltin.† In this case too the work up and purification of the reaction products was facilitated and the need to use cocatalytic CuI was eliminated. This method permits the efficient introduction of alkyl side chains into the synthetically useful α-iodoenones,[12] which are particularly difficult substrates for this kind of Stille cross-coupling[13] reaction.

Recent reports[14] highlighting the use of organozincs and organoboranes for the alkylation of α-iodoenones and vinyl halides have been described. Reduction and/or β-hydride elimination not a problem in these cases. The mechanism of Pd catalysed coupling reactions[15] may change with the type of coupling reaction depending upon the metal or non-metal present.

We thank Fundação para a Ciência e a Tecnologia for generous financial support (PCTI/1999/QUI/36536) and for grants (Praxis XXI) awarded to M. R. V. and M. I. M.

A new Hg^{2+}-selective chromoionophore based on calix[4]arenediazacrown ether†

Mi Jung Choi, Mi Yee Kim and Suk-Kyu Chang*

Department of Chemistry, Chung-Ang University, Seoul 156-756, Korea. E-mail: skchang@cau.ac.kr; Fax: +82 2 825 4736; Tel: +82 2 820 5199

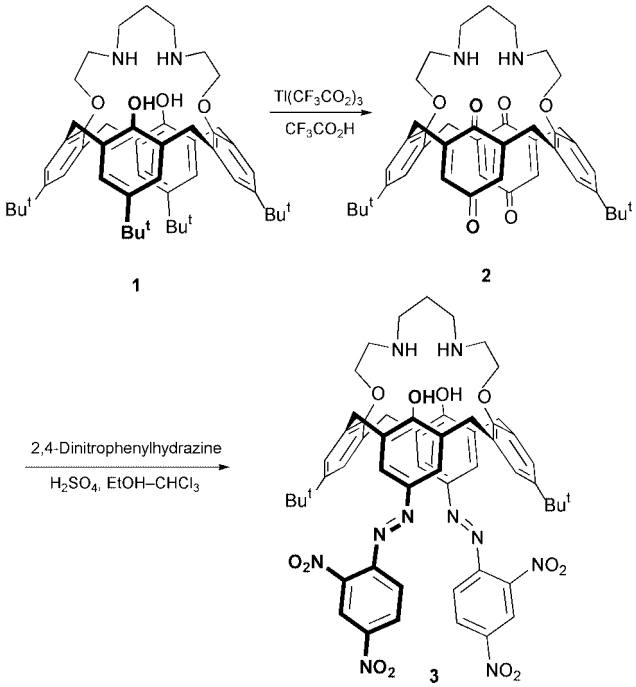
Received (in Cambridge, UK) 1st February 2001, Accepted 12th July 2001
First published as an Advance Article on the web 6th August 2001

A new azophenol type chromogenic ionophore based on the *p-tert*-butylcalix[4]arenediazacrown ether was prepared: the ionophore exhibited a pronouncedly selective chromogenic behaviour toward Hg^{2+} ions among the surveyed guests of alkali, alkaline earth, transition and heavy metal ions in liquid–liquid extraction experiments.

Selective signaling of heavy metal ions is a very important topic for the detection and treatment of the toxic metal ions in various chemical systems including living systems.[1,2] There are, however, relatively few examples of designed sensors for the heavy metal ions in comparison with the variety of compounds developed for the alkali and alkaline earth metal ions.[3] For the selective recognition of soft heavy metal ions, nitrogen binding sites might be a choice as is well exemplified with classical azacrown ethers.[4] Obviously, a suitably designed calix[4]-areneazacrown ether derivative might be a good candidate. This can be realized by combining the azacrown ether moiety as a binding site with the molecular framework of a calix[4]arene as a handle for the elaborate further functionalization to endow the signaling properties.[5] Recently, sensitive ionophores having chromogenic and fluorogenic functions have begun to be devised for heavy metal ions.[6–11] Azophenol groups are one of the most frequently employed functions as a signaling device for the design of chromogenic ionophores and a lot of derivatives based on the crown ethers and calixarenes showed unique chromogenic behaviours toward a variety of guest species.[12] Here, we report the synthesis of a new chromogenic ionophore having 2,4-dinitrophenylazophenol functions derived from the *p-tert*-butylcalix[4]arenediazacrown ether and its selective chromoionophoric behaviour toward Hg^{2+} ions in liquid–liquid extraction systems.

The azophenol derivative was prepared from diazacrown ether **1**,[13] as shown in Scheme 1. Oxidation of the diazacrown ether **1** with $Tl(CF_3CO_2)_3$ in TFA gave the diquinone **2** (61%).‡ Reaction of the resulting diquinone **2** with 2,4-dinitrophenylhydrazine (EtOH–$CHCl_3$, with trace H_2SO_4)[14] afforded 2,4-dinitrophenylazophenol derivative **3** (44%). The resulting product was purified by column chromatography (silica gel, CH_2Cl_2–MeOH, 9:1) followed by recrystallization from CH_2Cl_2–MeOH.

The chromoionophoric properties of the azophenol **3** were investigated by the liquid–liquid extraction of metal ions from buffered aqueous solution into chloroform. The azophenol **3** itself showed a typical UV spectral behaviour of 2,4-dinitrophenylazophenol derivatives and revealed a distinct colour change from yellow (λ_{max} = 424 nm) to blue (λ_{max} = 619 nm) around pH 8.5 as the pH of the aqueous phase increases. The metal ion extraction experiments were performed at pH 6 buffered with morpholin-4-ylethanesulfonic acid (MES) to prevent the possible complications in chromogenic responses of **3**. The aqueous solution containing varying amounts of target metal ions (up to 0.05 mol dm^{-3}) was extracted with the chloroform solution containing azophenol ionophore ([**3**] = 2 × 10^{-5} mol dm^{-3}) at 25 °C. After extraction, the organic phase



Scheme 1

was separated and the UV spectra of the solution were measured. The guest ions surveyed were representative alkali (Li^+, Na^+, K^+, Rb^+), alkaline earth (Mg^{2+}, Ca^{2+}, Ba^{2+}), transition metal (Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}) and heavy metal ions (Cd^{2+}, Hg^{2+}, Pb^{2+}) in perchlorate.

The ionophore showed pronounced chromogenic responses to Hg^{2+} and Cd^{2+} ions among the tested metal ions (Fig. 1). Upon interaction with 100 equiv. of Hg^{2+} ions, the colour of the ionophore solution changed distinctly from yellow (λ_{max} = 424 nm) to red (λ_{max} = 500 nm). With Cd^{2+} ions, a more dramatic change in the UV spectrum was observed and the λ_{max} of **3** was significantly red-shifted and transformed into two bands (from

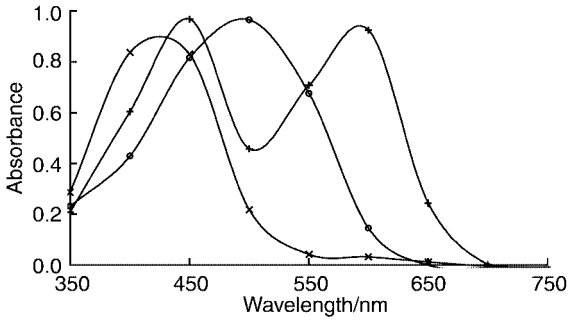


Fig. 1 Absorption spectra of **3** in $CHCl_3$ upon extraction with aqueous metal ion solution. [**3**] = 2 × 10^{-5} mol dm^{-3} in $CHCl_3$. [M^{2+}] = 2 × 10^{-3} mol dm^{-3} in MES buffer at pH 6: (×) **3**, (+) **3** with Cd^{2+} and (○) **3** with Hg^{2+}.

† Dedicated to Professor Iwhan Cho on the occasion of his 65th birthday.

 DOI: 10.1039/b101112j

Table 1 Spectral responses of **3** upon interaction with varying chemical stimuli

Initial form[a]	Reagent added[b]	Final form
3–Hg^{2+}	Cd^{2+}	**3**–Hg^{2+}
3–Hg^{2+}	EDTA	**3**[c]
3–Cd^{2+}	Hg^{2+}	**3**–Hg^{2+}
3–Cd^{2+}	EDTA	**3**

[a] Formed by the extraction with 50 equiv. of guest metal ions. [**3**] = 2×10^{-5} mol dm^{-3} in $CHCl_3$. [b] Concentration of reagents added = 5×10^{-3} mol dm^{-3}. [c] Transforms relatively sluggishly compared with **3**–Cd^{2+}–EDTA system.

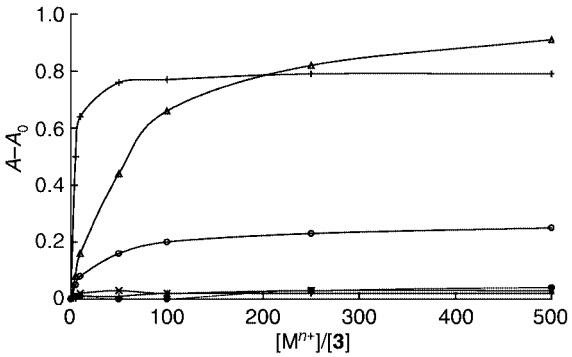

Fig. 2 Changes in absorbance of **3** induced by metal ions. ΔAbs at 500 nm with the addition of (×) Na^+, (*) Mg^{2+}, (●) Zn^{2+}, (○) Cd^{2+} and (+) Hg^{2+} ions. (△) ΔAbs at 591 nm with Cd^{2+} ion addition. [**3**] = 2×10^{-5} mol dm^{-3}. ΔAbs = (Abs of **3** in the presence of metal ion − Abs of **3**).

424 to 457 and 591 nm). Interestingly, the changes in spectral pattern induced by Cd^{2+} ions are quite different from Hg^{2+} ions, which suggests that the two metal ions can be discriminated, even visually, with the present chromogenic ionophore system. Other guest ions of alkali, alkaline earth, and transition metal ions revealed almost no changes in the chromogenic behaviour of **3** at the present extraction conditions of pH 6.

The selective chromogenic behaviour of **3** toward Hg^{2+} ions was further evidenced by the competitive extraction experiments. The ionophore **3** showed a pronounced Hg^{2+}-selectivity even in the presence of a large excess of other metal ions. For example, the absorption spectrum of **3**–Hg^{2+} (obtained by the extraction of 2×10^{-5} mol dm^{-3} of **3** with 50 equiv. Hg^{2+} ions) in $CHCl_3$ was almost unaffected by the addition of 500 equiv. of alkali, alkaline earth, transition metal, and Pb^{2+} ions. Even with Cd^{2+} as competitive guest ion, the chromogenic behaviour of the **3**–Hg^{2+} system was retained up to 250 equiv. of Cd^{2+} ions (Table 1). In contrast to this, the spectral behaviour of **3**–Cd^{2+} was changed upon addition of 2 equiv. of Hg^{2+} ions, and the spectrum was progressively converted into almost that of **3**–Hg^{2+} system by treatment with 30 equiv. of Hg^{2+} ions. These observations clearly showed that the ionophore **3** has much higher affinity toward Hg^{2+} than Cd^{2+} ions, that is in good agreement with the transport results of parent calix[4]-arenediazacrown compound **1** reported earlier.[13]

To have more insight for the selectivity and sensitivity of the present ionophore system, the effects of metal ion concentration in aqueous phase on the absorption spectrum of **3** were investigated. Fig. 2 shows the changes in absorbance of **3** induced by the most responding ions among the surveyed alkali, alkaline earth, transition and heavy metal ions. The selectivity ratios for Hg^{2+} over other representative metal ions, estimated from the ratio of the metal ions required for the same ΔAbs value at 500 nm, were as follows: Na^+, 830; Mg^{2+}, 480; Zn^{2+}, 250; Cd^{2+}, 28. Upon interaction with as low as 4 equiv. of Hg^{2+} ions, visibly discernible changes in chromogenic behaviour were observed for **3**. With Cd^{2+} ions, similar colour change from yellow to violet was observed with around 10 equiv. of guest ions, that can also be easily detected visually. From these measurements the detection limits of **3** for Hg^{2+} and Cd^{2+} ions were estimated to be 1×10^{-5} mol dm^{-3} (at 500 nm) and 8×10^{-5} mol dm^{-3} (at 591 nm), respectively. One more thing to note is the facile regeneration of the ionophore by simple treatment with EDTA solution, that suggests the reusability of the compound as a reversible sensor material. The ionophore solution **3**–Hg^{2+} and **3**–Cd^{2+} fully restored the spectrum of free **3** by the back extraction of extracted guest metal ions with 0.1 mol dm^{-3} EDTA solution at pH 6 (Table 1). In this case, however, the **3**–Hg^{2+}–EDTA system restores the free **3** spectrum relatively sluggishly compared with the **3**–Cd^{2+}–EDTA system, which also implies that Hg^{2+} interacts more strongly with **3** than Cd^{2+} ions.

In conclusion, we have developed a new azophenol type chromogenic ionophore having high selectivity toward Hg^{2+} and possibly Cd^{2+} ions *via* metal ion induced deprotonation of the azophenol moieties. Although ionophore **3** needs more optimization for the practical applications in terms of selectivity and sensitivity, we believe that this compound can be utilized, along with many intriguing systems developed up to now,[15,16] for the detection of toxic Hg^{2+} and Cd^{2+} ions which are of general interest in the treatment of industrial waste streams.

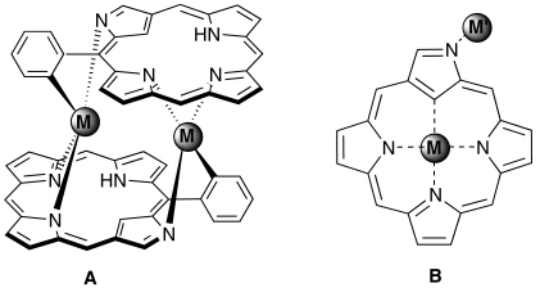
Received (in Cambridge, UK) 4th May 2001, Accepted 20th July 2001
First published as an Advance Article on the web 15th August 2001

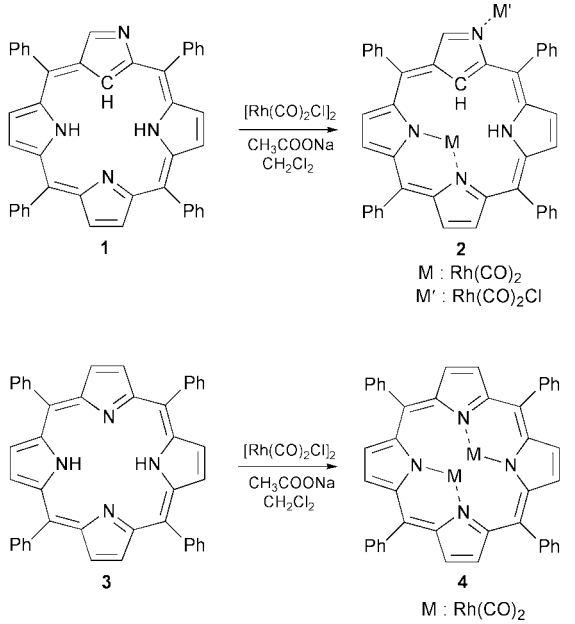
An inner- and outer-*N* coordinated bis-Rh(I) metal complex was obtained from the reaction of *N*-confused porphyrin and $[Rh(CO)_2Cl]_2$ in CH_2Cl_2 and the structure was confirmed by a single crystal X-ray analysis.

N-Confused porphyrin (NCP) is a porphyrin isomer in which one of the pyrrole rings is *confused* or *inverted*.[1,2] Because of the unique NCP structure, which has peripheral nitrogen and inner core carbon atoms, entirely different coordination chemistry from the parent porphyrin system has been expected and revealed gradually.[3–5] Recently, we reported a new type of double-decker Pd NCP dimer complex that used both the inner- and outer-N coordination sites with the help of a carbon–metal bond from an *ortho*-position of a *meso*-aryl ring (**A**).[6] At that



point, it was really a question whether outer-*N* coordination was general and whether the complex formed could be stabilized without any assistance from the surroundings (**B**). Such coordination, if manipulated easily, would be of particular interest for potential use in metal catalysts.[7] Herein, we report the X-ray structure of a bis-Rh(I) NCP complex where the Rh(I) metal atoms are coordinated to the inner- and the outer-nitrogen atoms. For comparison, the X-ray structure of the bis-Rh(I) tetraphenylporphyrin (TPP) complex is also presented.[8] To the best of our knowledge, the structures are the first examples of bis-Rh(I) complexes of *meso*-phenylporphyrin and NCP.

When *N*-confused tetraphenylporphyrin (NCTPP, **1**) was treated with 1 equiv. of $[Rh(CO)_2Cl]_2$ in the presence of 10 equiv. of sodium acetate in refluxing CH_2Cl_2 for 2 h, bis-Rh(I) NCTPP complex **2** was obtained as a blue-greenish solid in 53% yield. Using the same procedure with TPP (**3**), bis-Rh(I) TPP complex **4** was obtained as a purple solid in 36% yield (Scheme 1). FAB mass spectra of **2** and **4** showed molecular ion peaks at *m/z* 967.5 and 930.6, respectively, indicating the presence of two Rh metal ions connected with a chloride and four carbonyl ligands in **2** and the absence of the chloride ligand in **4**. ^{1}H NMR spectral peaks of complex **2** in $CDCl_3$ appeared distinctly in the region from −4 ppm to 9 ppm. The appearance of peaks corresponding to inner β-CH, outer α-CH and an inner NH at −3.83, 8.89 and 1.06 ppm, respectively, proved that they do not participate in the metal coordination and further confirms that only two pyrrolic nitrogens are coordinated to the Rh metal in



Scheme 1 Syntheses of bis-Rh(I) metal complexes.

the cavity. Relative to NCTPP (**1**), there is significant shielding of the inner α-CH and the outer β-CH signals ($\Delta\delta$ = 1.28 and 0.11 ppm) suggesting that the peripheral nitrogen also participates in the metal coordination. In contrast, the absence of NH signals for complex **4** inferrs that all four nitrogens are involved in the metal coordination.

The absorption spectrum of **2** in CH_2Cl_2 displays a Soret-like band at 488 nm and four Q-type bands in the region of 545–780 nm (Fig. 1). In general, the metal complexation is accompanied by a red-shift of both the Soret and Q-type bands.[9] The bis-metallic complex of **2** also shows 50 nm and 44 nm red-shifts of the Soret and the Q-type bands, respectively, as compared to **1**. This proves that the peripheral nitrogen coordination should not perturb the π electron delocalization much, while the Rh coordinated inside the cavity is expected to perturb the

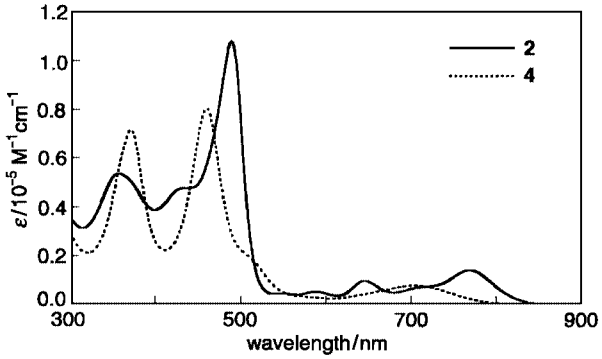


Fig. 1 Electronic absorption spectra of **2** and **4** in CH_2Cl_2.

† Electronic supplementary information (ESI) available: synthetic procedures and X-ray structure information for **2** and **4**. See http://www.rsc.org/suppdata/cc/b1/b104004a/

 DOI: 10.1039/b104004a

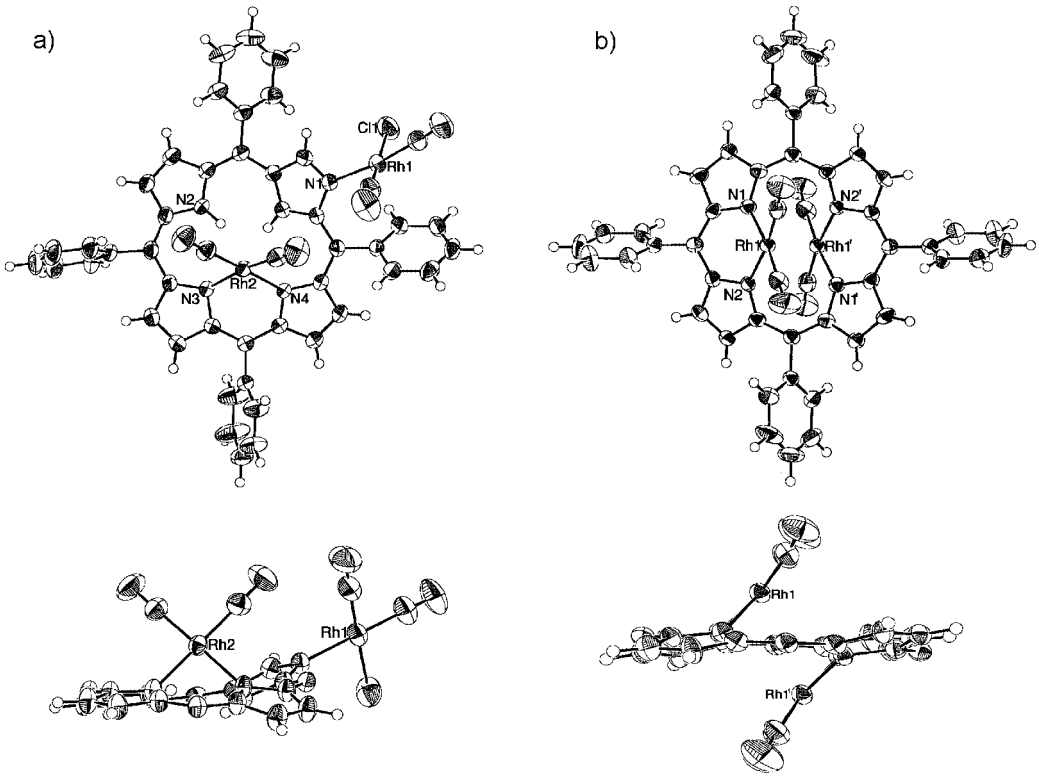

Fig. 2 X-Ray structures of (a) **2** and (b) **4**. The *meso*-aryl rings are omitted for clarity in the side views (bottom). Selected bond lengths (Å) for **2**: Cl1–Rh1, 2.349(3); Rh1–N1, 2.104(6); Rh2–N3, 2.099(6); Rh2–N4, 2.0877(6); and for **4**: Rh1–N1, 2.067(6), Rh1–N2, 2.074(6).

delocalization pathway, and this is reflected in the larger optical absorption band shifts. This trend is further confirmed by the absorption spectrum of **4** where both the Rh are coordinated inside the cavity leading to strong distortion of the molecule and resulting in bands at 371, 460 and 704 nm (Fig. 1).

The explicit structural details of the bis-Rh(I) complexes **2** and **4** were derived from the single crystal X-ray diffraction analyses (Fig. 2).[10] As predicted from the above observations, in the bis-metallic complex of **2**, there are two Rh atoms attached in the NCP skeleton. One imino (N3) and one amino (N4) nitrogen of the macrocycle are coordinated to the Rh2 ion and the other two coordination sites are occupied by the carbonyl ligands. The other Rh1 ion is coordinated to the periphery nitrogen (N1) and the remaining coordination sites are occupied by a chloride and the two carbonyl ligands. Both the Rh(I) ions are located above the NCP plane and the geometry around the metal centers is close to square planar (Cl1–Rh1–N1, 87.6(2)°; N3–Rh2–N4, 85.7(2)°). The angles between the planes containing the Rh1 and the Rh2 with their coordinated atoms and the mean NCP plane are 117.29° and 61.30°, respectively, and the distance between the two Rh metal centers is 6.286 Å.

On the other hand, the metalloporphyrin of **4** is centrosymmetric and the two Rh(I) metal ions are bonded to two dipyrromethene units, one above and one below the macrocyclic plane. Like **2**, the geometry around the metal centers is close to square planar (N1–Rh1–N2, 84.9(2)°). The angle between the plane containing the Rh(1) with its coordinated atoms and the mean TPP plane is 131.59° and the distance between the two metal centers is 3.166 Å, which is considerably longer than the Rh(I)–Rh(I) single bond (2.617–2.705 Å).[11] These results are comparable with the bis-Rh(I) octaethylporphyrin (OEP) complex.[8]

In conclusion, we have synthesized two new bis-Rh(I) metal complexes and disclosed their solid state structures. Inner- and outer-metallation is characteristic of NCP ligands, thus, for **2**, rich and diverse coordination chemistry similar to the parent porphyrin (**1**) can be expected. The present study has also exploited the interaction of only Rh(I) metal ions, but other metal ions are likely to interact with the macrocycle, especially at the peripheral nitrogen. Studies on the synthesis of such hetero bis-metal NCP complexes are currently underway.

Photoluminescence of open-framework phosphates and germanates

Pingyun Feng

Department of Chemistry, University of California, Riverside, CA 92521, USA.
E-mail: pingyun.feng@ucr.edu

Received (in West Lafayette, IN, USA) 27th June 2001, Accepted 9th July 2001
First published as an Advance Article on the web 16th August 2001

Upon excitation by long wavelength UV radiation, strong room temperature luminescence is observed in a family of metal-activator-free zeolite-type materials; the luminescent output from the large cage UCSB-8Mg structure is independent of temperature from 298 K until at least 77 K.

The development of less-expensive and non-toxic luminescent materials for lighting and display technology represents a research area that could have significant commercial impact. In particular, efficient phosphors that could convert low energy UV radiation (340 to 400 nm) into visible light may lead to the replacement of toxic mercury widely used in fluorescent lamps. So far, the synthetic design of inorganic phosphors usually involves the doping of crystalline host lattices with metal activators that can be either expensive or toxic.[1]

Open-framework materials have been known for several decades and have undergone an explosive growth since the discovery of zeolite-type aluminophosphates.[2] Previous efforts to generate luminescent materials using crystalline porous materials were either by incorporating organic dyes or by doping with metal activators.[3] For example, laser action was observed when organic laser dye molecules, pyridine 2 {1-ethyl-4-[4-(*p*-dimethylaminophenyl)-1,3-butadienyl]pyridinium perchlorate}, were inserted into the pores of $AlPO_4$-5 crystals.[4] To our knowledge, dye-free or metal-activator-free open-framework phosphates or germanates that display luminescent properties have not been reported. Furthermore, no open-framework materials were previously known to display both fluorescence and phosphorescence. Here, a class of efficient luminescent crystalline open-framework materials that do not contain metal activators are described.† Some of these phosphors can display visually observable green afterglow with a lifetime up to 15 s.

One particularly interesting example is UCSB-8Mg (Fig. 1 and Table 1).[5] UCSB-8Mg is built from stacking of large cages, each of which has as many as 64 tetrahedral atoms (*i.e.* Mg, Al, P) and 128 oxygen atoms. Clear, transparent square plates of UCSB-8Mg can be synthesized by the low temperature hydrothermal synthesis. When illuminated with a long wavelength UV lamp (365 nm), the sample displays a strong bluish color. Surprisingly, the luminescent output from UCSB-8Mg is independent of temperature until at least 77 K, suggesting that there might be no thermal non-radiative decay, even at room temperature. The lack of thermal non-radiative decay, could lead to a reasonably high quantum efficiency for UCSB-8Mg. The method of using the temperature dependence of the light output of a luminescent material to estimate the quantum efficiency was described earlier.[6] For open-framework materials, in addition to the possible intensity increase at lower temperatures, the luminescence bands also show a noticeable blue-shift (Fig. 2).

Another example is UCSB-10Mg (Table 1) with large cages and a framework topology closely related to that of faujasite.[5] Excited at 340 nm, the room temperature luminescence of UCSB-10Mg gives an emission band at λ_{max} = 402 nm (Fig. 1). The fit to a biexponential equation gives τ = 7.2 ns and 2.0 ns. The strong luminescence of UCSB-10Mg is persistent even at

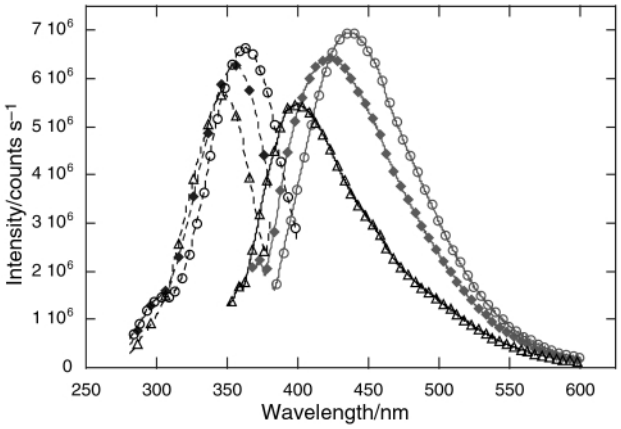

Fig. 1 The excitation (dashed curves) and emission spectra (solid curves) for selected open-framework materials. (△): UCSB-10Mg; (◆): UCSB-7AlGe; (○): UCSB-8Mg. Intensity data for UCSB-10Mg and UCSB-8Mg are multiplied by 5 and 3, respectively. Fluorescent spectra were measured on a SPEX Fluorolog-3 Tau3 system equipped with a 450 W xenon lamp and double monochromators on both excitation and emission sides. Data were collected with a step size of 1 Å and an integration time of 1 s per step.

Table 1 Photoluminescent properties of selected open-framework materials

Name	Framework composition	Guest type[a]	Structure type[b]	Emission λ_{max}/nm
UCSB-10Mg	$MgAlP_2O_8$	R4710	SBT	402
UCSB-10Zn	$ZnAlP_2O_8$	R4710	SBT	407

 DOI: 10.1039/b105715b

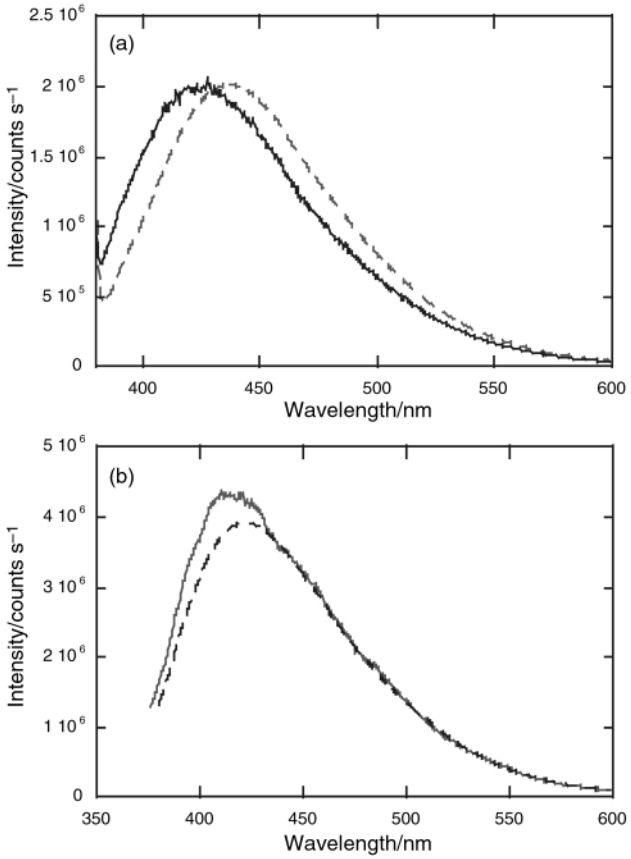

Fig. 2 The emission spectra at room temperature (dashed curves) and at liquid nitrogen temperature (solid curves). (a) UCSB-8Mg (excited at 360 nm); (b) UCSB-7AlGe (excited at 355 nm). Low temperature spectra were collected with the sample tube immersed in a quartz liquid nitrogen Dewar.

high temperatures, *e.g.* 200 °C, below or at which crystalline microporous materials are usually synthesized. Whether the observed photoluminescent phenomena can be used in a screening method for the rapid detection of crystalline open-framework materials represents an interesting question for further studies. In our synthesis, we have frequently found it convenient to detect crystalline open-framework phases with a UV lamp even in the presence of a large amount of amorphous phases because amorphous gel phases are generally not photoluminescent.

Other open-framework materials with efficient luminescence include UCSB-7GaGe and UCSB-7AlGe (Table 1) that are amine-templated gallo- or aluminogermanates with two sets of continuous helical channels separated by a gyroid minimal surface.[7–9] Strong bluish luminescence has also been observed for other open-framework materials with different guest amines, framework compositions and topologies (Table 1). The compositional diversity is advantageous because less expensive and more environmentally benign starting materials may be selected for the synthesis of phosphors reported here and it also offers opportunities for the fine tuning of emission wavelength and bandwidth.

The luminescent mechanism for these open framework materials is not unambiguously known at this stage. For insulating solids without metal activators, the luminescence is often attributed to the presence of various kinds of lattice defects such as oxygen vacancies. Such a defect mechanism is also possible for materials reported here. However, it is also observed that some closely related open-framework materials do not exhibit any photoluminescence. For example, gallogermanate UCSB-7 can be synthesized with either alkali metal cations or different organic amines. Fluorescence measurements show that purely inorganic UCSB-7 structures[7] (those templated with either K or Na cations) do not exhibit luminescence at all while those directed by protonated amine molecules show visible photoluminescence. In addition, it is noteworthy that open-framework materials templated by TMA (TMA = $N(CH_3)_4^+$) such as $(TMA)ZnGa_2X_3O_{12}$ (X = P or As) sodalites[10] do not have any observable photoluminescence when measured on a spectrofluorometer. These preliminary results suggest that the luminescence may also be related to the highly negatively charged inorganic framework and the presence of protonated guest amine molecules.

Considering the great variety of open-framework materials,[11] it is anticipated that additional novel properties will be discovered in the future, which might make it possible to use open framework materials for applications beyond traditional catalytic or adsorptive areas. The interesting luminescent phenomenon observed in open-framework oxides suggests that the investigation of non-oxide open-frameworks such as sulfides, selenides, halides, cyanides *etc*. might be desirable in order to achieve a broader range of emission spectral characteristics.

The financial support of this work by UC Riverside Startup Fund is appreciated. Samples of UCSB-7K and ZnGaP-SOD were prepared by Thurman E. Gier at Prof. Galen D. Stucky's laboratory at University of California, Santa Barbara.

Notes and references

† The following is a typical synthesis procedure, using UCSB-10Mg as an example. Slurry A was prepared by adding aluminium isopropoxide (1.40 g, 98%, Aldrich) and H_3PO_4 (1.43 g, 85 wt% in water) into ethylene glycol (7.52 g). The mixture was stirred for 1 week. Solution B was prepared by mixing 1.19 g magnesium hydrogenphosphate trihydrate (99%, Aldrich) with H_2O (7.16 g) and H_3PO_4 (0.84 g, 85 wt% in water) and was stirred for 1 h. To the mixture of A and B, 3.01 g of 1,13-diamino-4,7,10-trioxatridecane was slowly added with stirring. The final pH of the mixture was 8.12. The mixture was stirred for 5 h at room temperature, transferred into a 23 mL autoclave, and heated in an oven at 170 °C for 4 days. The product was filtered off, washed with distilled H_2O and ethanol, and further purified by repeated sonication of the sample in deionised water and decanting off the cloudy solution. Hexagonal-shaped clear crystals were obtained.

Dehydrogenative coupling of phenanthroline under hydrothermal conditions: crystal structure of a novel layered vanadate complex constructed of 4,8,10-net sheets: [(2,2′-biphen)Co]$V_3O_{8.5}$

Cai-Ming Liu,† Song Gao* and Hui-Zhong Kou

State Key Laboratory of Rare Earth Materials Chemistry and Applications & PKU-HKU Joint Laboratory on Rare Earth Materials and Bioinorganic Chemistry, College of Chemistry and Molecular Engineering, Peking University, Beijing 100871, P. R. China. E-mail: gaosong@pku.edu.cn

Received (in Cambridge, UK) 12th April 2001, Accepted 17th July 2001
First published as an Advance Article on the web 8th August 2001

2,2′-Biphenanthroline (2,2′-biphen) formed from 1,10-phenanthroline when a new two-dimensional layered vanadium oxide metal coordination complex, [(2,2′-biphen)Co]$V_3O_{8.5}$, which contains novel 4,8,10-net sheets, was hydrothermally synthesized.

Increasing attention has been paid to organic–inorganic hybrid materials due not only to their intriguing structure diversity but also their potential applications in areas of molecular adsorption, catalysis, electromagnetism and photochemistry.[1] The role of organic components in hybrid materials is of great interest. Usually, organic amines act as structural directors to construct inorganic frameworks, compensating charges and filling space; on the other hand, they may also function as ligands, coordinated directly to the oxide scaffolding or to the secondary metal centers. [2] As examples of the latter, many hybrid organic–inorganic vanadium oxides have recently been found to be coordinated by transition metal complexes,[3–7] which have discrete cluster, one-dimensional (1D) chain and layer structures. However, few examples involving the self-reaction of the organic component have been reported. Herein, we present a novel two-dimensional (2D) layered vanadium solid state complex [(2,2′-biphen)Co]$V_3O_{8.5}$ **1**, where 2,2′-biphenanthroline (2,2′-biphen) formed automatically from 1,10-phenanthroline (phen) under hydrothermal reaction conditions. To our knowledge, the dehydrogenative coupling of 1,10-phenanthroline during hydrothermal reaction has not been described to date though there are hybrid organic–inorganic structures reported in which 1,10-phenanthroline coordinates to metal centers.[7,8] Complex **1** is the first vanadate complex containing a tetradentate ligand.

Dark red block crystals of **1** were synthesized hydrothermally from a mixture of NH_4VO_3, H_3BO_3, $Co(NO_3)_2{\cdot}6H_2O$, phen and H_2O (molar ratio 1:1.5:1:2:1000) in a polyfluoroethylene-lined stainless steel bomb (25 ml capacity) under autogenous pressure heated to 160 °C for five days (yield 50% based on vanadium).‡ H_3BO_3 is necessary for this reaction though boron is not incorporated into the structure of **1**. H_3BO_3 might have adjusted the pH value of the mixture (the pH value changed from 6 to *ca.* 5 after adding of H_3BO_3), however, **1** did not form in the presence of other acids such as $H_2C_2O_4$ or HCl instead of H_3BO_3.

The formation mechanism for 2,2′-biphenanthroline is not yet known, but probably arises from the polymerization catalysis role of the cobalt complex.[9] High temperature and pressure have also been proved to be effective for the dehydrogenation of pyridine when suitable transition metal salts are present,[10] but require strictly anhydrous conditions[10*a*] or dioxygen as oxidant.[10*b*] Gillard and Hall suggested the 2-(or 4-) position of pyridine becomes polarized upon coordination to metal ions and so facilitating oxidition.[10*b*] A similar situation may occur in the formation of 2,2′-biphenanthroline in our reaction system. Interestingly, no 2,2′-biphenanthroline was observed in the products when $Ni(NO_3)_2$ instead of $Co(NO_3)_2$ was used under the same hydrothermal conditions.[11]

The coordination sphere of the cobalt(II) site in **1** is defined by four nitrogen donors of a biphen ligand and two vanadate oxygen donors in the apical position leading to a distorted CoN_4O_2 octahedron (Fig. 1).§ The two phenanthroline planes of the 2,2′-biphenanthroline ligand are coplanar (mean deviation from the plane defined by N1, C12, C11, N2, C10, C13, N3, C24, C23 and N4 is 0.0209 Å; all 2,2′-biphenanthroline planes are parallel to the *ab* plane) with a C10–C13 bond distance of 1.459(7) Å. The N1–Co1, N4–Co1 bond distances (2.197(2) and 2.189(2) Å, respectively) are slightly larger than those for N2–Co1 (2.111(2) Å) and N3–Co1 (2.110(2) Å), and the bond angle of N1–Co1–N4 (135.40(9)°) is larger than that of N2–Co1–N3 (72.49(10)°) for the tetradentate 2,2′-biphenanthroline ligand. Similar bond angle trends have also been observed in tetradentate Schiff base complexes.[12]

The structure of **1** consists of a 2D neutral framework, where (2,2′-biphen)Co units are covalently linked to the vanadium oxide V_6O_{17} chains (Fig. 2). Each V_6O_{17} chain is constructed from V_4O_{12} tetramer rings and V_2O_7 units arranged alternately by edge- and corner-sharing interactions, while (2,2′-biphen)Co units connect, in a *trans* fashion, V_4O_{12} tetramer rings and V_2O_7 units of neighboring V_6O_{17} chains to form an extended 2D network structure with a unique 4,8,10-net as shown in Fig. 3. It is noteworthy that **1** is the first 2D layered vanadium oxide metal coordination complex constructed of 4,8,10-net sheets.

$[(bipy)_2Zn]_2V_6O_{17}$ also possesses a $V_6O_{17}^{4-}$ component but this exhibits a quite different 2D layer structure,[3*a*] where within each VO layer there are roughly circular rings, defined by

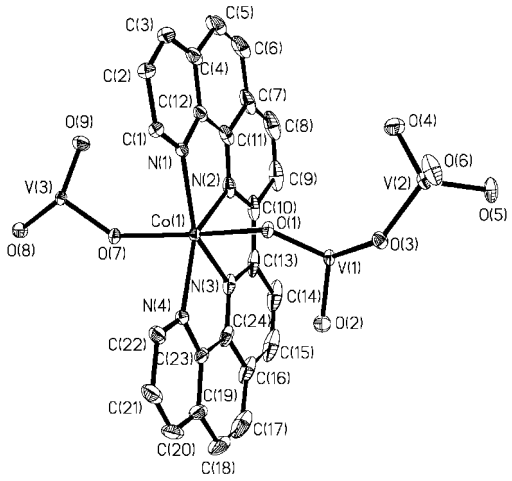

Fig. 1 A fragment of the net with the atomic labeling scheme (30% probability ellipsoids) in complex **1**.

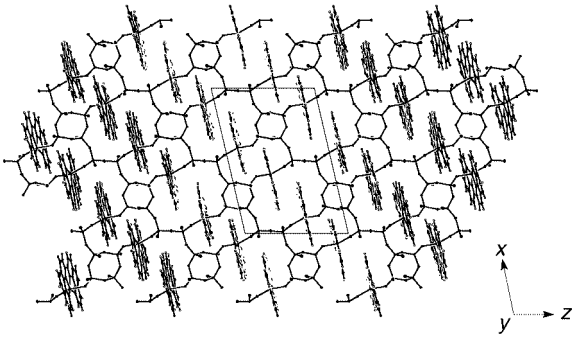

Fig. 2 View of the 2D layer in **1** along the *b*-axis direction.

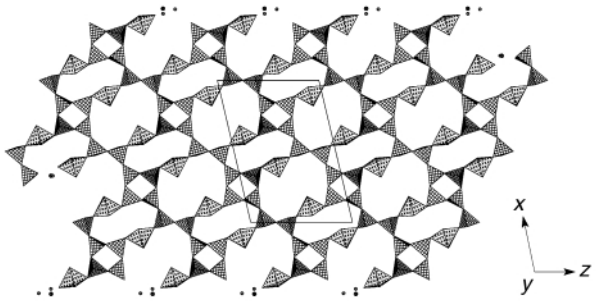

Fig. 3 Polyhedral representation of complex **1** packed along the *b*-axis; all C and H atoms are omitted for clarity.

fourteen corner-sharing VO_4 tetrahedra and two $Zn(bpy)_2$ moieties which are bonded in a *cis* fashion to two second-nearest neighbor VO_4 groups on opposite sides of each ring. It is clear that two oxygen atoms of vanadate connected to the $Zn(bpy)_2$ moiety adopting *cis*- rather than *trans*-orientation give rise to the structure difference of $[(bipy)_2Zn]_2V_6O_{17}$ from **1**. Another quite recently reported vanadium solid state complex with a $V_6O_{17}^{4-}$ component is $[Co_4(2\text{-pzc})_4(V_6O_{17})]\cdot xH_2O$ (2-pzc is the anion of 2-pyrazinecarboxylic acid),[13] where $V_6O_{17}^{4-}$ forms double chains, and each chain connects four $[Co_4(2\text{-pzc})_4]$ chains to form a 3-D chiral structure.

In conclusion, this study illustrates that even organic ligands can undergo self-reaction under hydrothermal conditions, which suggests more novel structures can be obtained by hydrothermal or solvothermal methods even with common ligands.

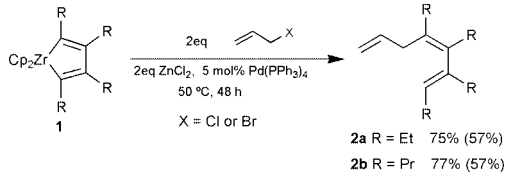
Zirconaindenes reacted with allyl halides in the presence of ZnX_2 (X = Cl or Br) and a catalytic amount of $Pd(PPh_3)_4$ to give naphthalene derivatives in good yield.

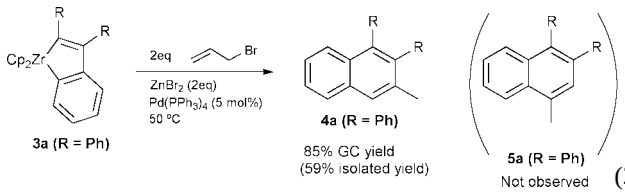
It has been believed for a long time that zirconacyclopentadienes are inert toward C–C bond formation reactions. Recently, we found that transmetalation reactions of zirconacyclopentadienes to copper,[1] nickel[2] and lithium[3] could open a way to various carbon–carbon bond formation reactions. In this paper we would like to report the novel naphthalene formation reaction[4] of zirconaindenes in the presence of ZnX_2 and a catalytic amount of $Pd(PPh_3)_4$.[5]

When we investigated novel transmetalation to Zn, we tried the allylation reaction of zirconacyclopentadienes, since double allylation of zirconacyclopentadienes[1] proceeded in the presence of either a catalytic or stoichiometric amount of CuCl.[1] When only the zinc salts were used, the reactions were very sluggish. However in the presence of a catalytic amount of $Pd(PPh_3)_4$ the reaction dramatically changed. Monoallylation products were clearly formed. The formation of double allylation products was not observed [eqn. (1)].



(1)

This is in sharp contrast to the allylation in the presence of CuCl.[1] Then our attention was turned to the allylation reaction of zirconaindenes. It is interesting to note that, when zirconaindene[6] **3a** was used, substituted naphthalene **4a** was clearly formed as a single product [eqn. (2)].† The formation of



(2)

regioisomer **5a** was not observed. The use of only a catalytic amount of $Pd(PPh_3)_4$ without zinc salt did not give a clean reaction, although **4a** was formed in 33% GC yield.

The structure of the compound **4a** was confirmed by X-ray analysis.‡ It clearly shows that the allylation reaction proceeded selectively at the benzene-carbon attached to Zr. When $MeOC_6H_4$- and MeC_6H_4- were used as substituents instead of the Ph group, the similar perfect regiocontrol was observed as shown in Table 1. This perfect regioselectivity is attributed to the high reactivity of the benzene-carbon attached to Zr compared with the carbon of the –C(Ph)=C(Ph) group attached to Zr. It is interesting to note that when the nucleophilic property

[a] GC yields. Isolated yields are given in parentheses.

of the carbon in the –C=C group attached to Zr was enhanced by introducing alkyl groups such as the Et group and the Pr group instead of the Ph groups, carbon–carbon bond formation with allyl halides at the –C(R)=C(R), R = Et or Pr, was observed. The isomers **5d** and **5e** were obtained in the case of **3d** and **3e**, respectively.

A possible mechanism of the naphthalene formation involves (i) transmetalation of the Zr-phenyl carbon bond to Zn giving **6**, (ii) transmetalation of **6** with an allylpalladium halide formed by oxidative addition of allyl halide to a Pd^0 complex, (iii) reductive elimination to give allylated intermediate **7**, (iv) transmetalation of the second Zr–C bonds to Pd forming **8**, (v) insertion of the vinyl group into the Pd–C bond (vi) β-hydrogen elimination to give *exo*-methylene derivative **10** that isomerizes to the corresponding naphthalene **4** (Scheme 1).

Further investigations on mechanism and selectivity are currently in progress.

† *Typical procedure*: to zirconaindene **3a** prepared according to the literature were added 2 eq. of $ZnBr_2$, a catalytic amount of $Pd(PPh_3)_4$ (5 mol%) and 2 eq. allyl bromide. The mixture was stirred at 50 °C for 12 h. Only **4a** was formed in 85% GC yield. After isolation and purification by column chromatography, **4a** was obtained in 59% isolated yield.

Powerful Claisen condensation and Claisen–aldol tandem reaction of α,α-dialkylated esters promoted by $ZrCl_4$–$^iPr_2NEt$

Yoo Tanabe,* Ryota Hamasaki and Syunsuke Funakoshi

School of Science, Kwansei Gakuin University, 1-1-155 Uegahara, Nishinomiya, Hyogo 662-8501, Japan

Received (in Cambridge, UK) 14th May 2001, Accepted 19th July 2001
First published as an Advance Article on the web 7th August 2001

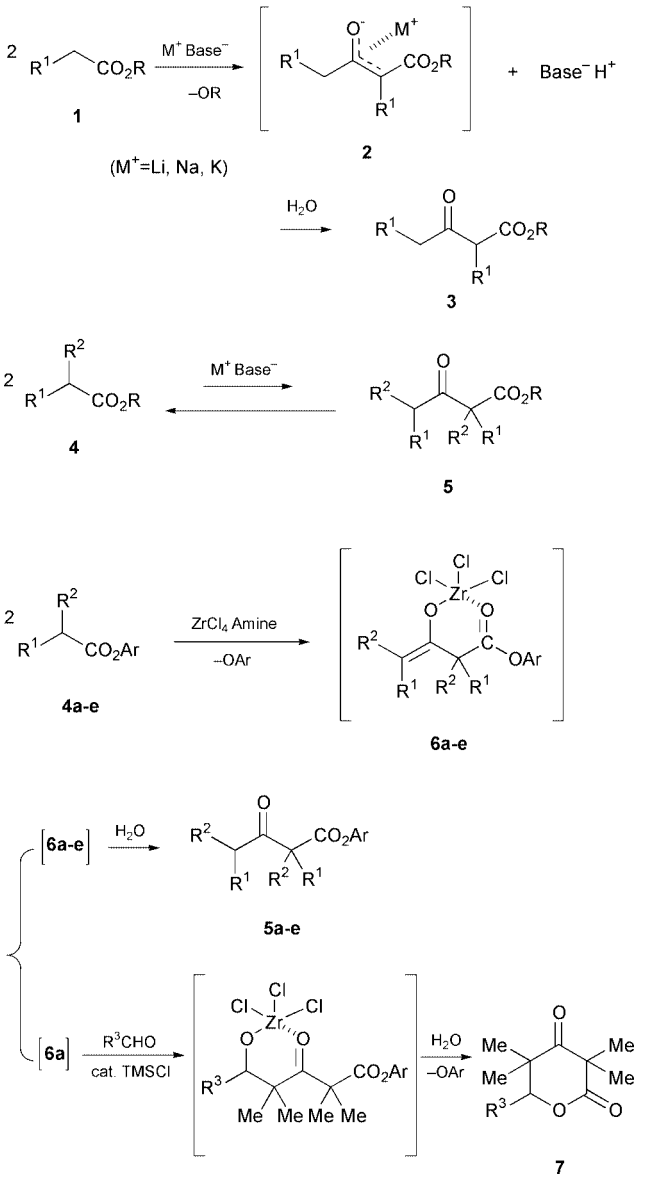
Powerful Claisen ester condensations of α,α-dialkylated esters mediated by $ZrCl_4$–$^iPr_2NEt$ were performed to give the corresponding thermodynamically unfavorable α,α-dialkylated β-ketoesters, and Claisen–aldol tandem reactions between an intermediary Zr-enolate of a α,α-dialkylated β-ketoester and aldehydes also proceeded.

The Claisen ester condensation is recognized as a fundamental and useful C–C bond-forming reaction.[1] Traditional Claisen condensations using alkali-metal basic reagents such as NaOR, NaH, LDA and LiHMDS are widely applied to α-monoalkylated esters **1** giving the corresponding dimeric β-ketoesters **3** (Scheme 1). However, α,α-dialkylated esters **4** could not undergo this type of the condensation, because **4** lacks the ability to force the formation of a stable enolate.[1,2] Actually, the reversible equilibrium barely shifts from **4** to the unfavorable production of the β-ketoesters **5**. Thermodynamics dictate that the starting α,α-dialkylated esters **4** are more stable than the desired β-ketoesters **5**, namely, the retro-Claisen condensation of esters **5** should predominate.[1,2] Although two methods for the Claisen condensation of alkyl 2-methylpropanoate using strong bases ($Ph_3C^-\cdot Na^+$ or KH)[3,4] have been reported, the yields were moderate to low (~35%).† In addition, these methods describe the sole example of the condensation of alkyl 2-methylpropanoate.

Recently, Ti–Claisen condensations were demonstrated[5–9] and proved to be more reactive and practical between α-monoalkylated esters than the representative method using NaH or LDA.‡ However, this method is unfortunately limited to the case of α-monoalkylated esters **1**. Here we introduce the powerful Claisen ester condensation of α,α-dialkylated esters **4** promoted by the $ZrCl_4$–$^iPr_2NEt$ reagent and its extension to the Claisen–aldol tandem reaction.

First, the Claisen condensation of α,α-dialkylated esters is described. Although ethyl 2-methylpropanoate was inert (no reaction) to $ZrCl_4$–amine (Et_3N, Bu_3N, or $^iPr_2NEt$) reagent, successful results were obtained using a slightly more acidic substrate, phenyl 2-methylpropanoate (**4a**). Treatment of **4a** with $ZrCl_4$–$^iPr_2NEt$ afforded the desired phenyl 2,2,4-trimethyl-3-oxopentanoate (**5a**) in 72% yields under optimized conditions.§ Table 1 summarizes the results of the Zr–Claisen condensation of α,α-dialkylated esters **4a**–**e**. Replacement of phenyl ester **4b** for 4-chlorophenyl analog **4e** increased the yield. On the other hand, $TiCl_4$–Bu_3N agent (with or without cat. TMSCl *or* cat. TMSOTf) failed to drive the reaction (no reaction).

Phenyl esters are readily prepared by several methods and, in addition, are smoothly hydrolyzed under milder conditions compared with alkyl esters.[10] A little higher acidity of phenyl esters than that of alkyl esters is suggested by the following two experiments: (a) ^1H NMR chemical shifts of α-hydrogen of **4a**



Scheme 1

4-MeO-Ph	**7d**	57	^{i}Pr	**7h**	31 (61)

[a] In CH_2Cl_2 at −15 to −20 °C for 3 h. Molar ratio; **4a**–$ZrCl_4$–amine–aldehyde = 1.0:2.0:3.0:1.0. [b] Parentheses indicate the yields using catalytic TMSCl (0.05 equiv.).

and ethyl 2-methylpropanoate were located at 2.80 and 2.53 ppm, respectively; and (b) when equimolar mixtures of **4a** and ethyl 2-methylpropanoate in THF were treated with 1 equiv. of LDA at 0–5 °C for 1 h, followed by quenching with D_2O, the ratio of α-deuterated esters was *ca*. 9:1 by the ^{1}H NMR measurement.

The successful results using the Zr reagent suggest that the strong chelation effect of zirconium toward two carbonyl oxygens and longer bond length between Zr–O than that between Ti–O contribute to drive the reactions, releasing steric constraint around the crowded Zr-intermediate **6**.

Next, the intermediary Zr-enolate **6a** was utilized for further C–C bond formation. Namely, the first Claisen–aldol tandem reaction between 2 equiv. of phenyl 2-methylpropanoate **4a** and several aldehydes successfully proceeded in a one-pot manner through intermediary Zr-enolate **6a**, eventually affording pyran-2,4-diones **7** with a concomitant lactonization.¶ Table 2 summarizes these results. It should be noted that catalytic TMSCl significantly affects the second aldol addition step for some aldehydes.[7]

Thus, we achieved an efficient, powerful and practical Zr–Claisen condensation and the first Claisen–aldol tandem reaction of α,α-dialkylated esters **4**.

This work was partially supported by a Grant-in-Aid for Scientific Research on Priority Areas (A) "Exploitation of Multi-Element Cyclic Molecules" and on Basic Areas (C) from the Ministry of Education, Culture, Sports, Science and Technology, Japan.

Notes and references

† In the first method,[3] preparation of the $Ph_3C^{-}\cdot Na^{+}$ reagent includes a tedious procedure from a practical and green chemical standpoint: *ca*. 9.3 g of 1% Na(Hg) *vs*. 0.28 g (1 mmol) of Ph_3CCl is used for ethyl 2-methylpropanoate (0.21 g, 1.8 mmol). The second method[4] using KH lacks generality; this reaction failed to proceed in several of our experiments when ethyl 2-methylpropanoate was employed as the substrate.

‡ For an example of the Claisen condensation of methyl dec-9-enoate using NaH by the reported method,[11] the desired β-ketoester was obtained in *ca*. 75% (DME, reflux, 20 h). The Ti–Claisen condensation proceeded with a 93% yield (toluene, 0–5 °C, 1 h).[8] Accordingly, the Ti–Claisen condensation clearly has the advantage of a high yield, mild conditions and a shorter reaction time. Related Dieckmann condensation using $AlCl_3$ is also reported.[12]

§ A typical procedure is as follows. $^{i}Pr_2NEt$ (388 mg, 3.0 mmol) in CH_2Cl_2 (0.5 cm^3) was added to a stirred suspension of $ZrCl_4$ (466 mg, 2.0 mmol) and phenyl 2-methylpropanoate (164 mg, 1.0 mmol) in CH_2Cl_2 (2.5 cm^3) at −15 to −20 °C. After stirring at the same temperature for 3 h, the mixture was quenched with water (5 cm^3) and extracted twice with ether. The combined organic phase was washed with water, brine, dried (Na_2SO_4) and concentrated. The obtained crude oil was purified by SiO_2-column chromatography (hexane–ether = 30:1) to give phenyl 2,2,4-trimethyl-3-oxopentanoate (84 mg, 72%). Colorless oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ 1.17 (6H, d, J = 7.2 Hz), 1.53 (6H, s), 3.01–3.11 (1H, m), 7.05–7.09 (2H, m), 7.22–7.26 (2H, m), 7.37–7.41 (2H, m). ^{13}C NMR (100 MHz, $CDCl_3$) δ 20.42, 21.85, 36.98, 56.33, 121.11, 126.08, 129.51, 150.51, 172.35, 212.12. IR (film) 2980, 2938, 1763, 1717, 1196, 1121 cm^{-1}.

¶ A typical procedure is as follows. In place of quenching with water, TMSCl (0.006 cm^3, 0.05 mmol) and isobutyraldehyde (72 mg, 1.0 mmol) were successively added to a stirred reaction mixture at 0–5 °C. The mixture was stirred for 2 h, and was then quenched with water (5 cm^3) and extracted twice with AcOEt. The combined organic phase was washed with water, brine, dried (Na_2SO_4) and concentrated. The obtained crude crystals were purified by SiO_2-column chromatography (hexane–AcOEt = 20:1 → 10:1) to give 3,3,5,5-tetramethyl-6-(1-methylethyl)pyran-2,4-dione (65 mg, 61%). Colorless crystals; mp 34.0–34.5 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ 1.08 (3H, d, J = 6.8 Hz), 1.13 (3H, s), 1.14 (3H, d, J = 6.8 Hz), 1.22 (3H, s), 1.43 (3H, s), 1.44 (3H, s), 2.08–2.16 (1H, m), 4.12 (1H, d, J = 3.2 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ 17.15, 18.21, 20.60, 22.50, 23.88, 25.63, 28.93, 47.59, 50.03, 83.97, 174.79, 211.36. IR (film) 2978, 2942, 1750, 1711, 1290, 1152, 1024 cm^{-1}.

Niobium and vanadium iminophosphinimide complexes†

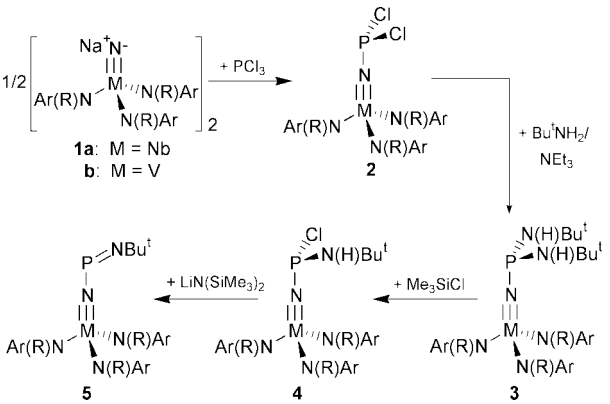
Justin K. Brask, Michael G. Fickes, Preeyanuch Sangtrirutnugul, Víctor Durà-Vilà, Aaron L. Odom and Christopher C. Cummins*

Department of Chemistry, Room 2-227, Massachusetts Institute of Technology, Cambridge, MA 02139-4307, USA. E-mail: ccummins@mit.edu

Received (in Purdue, IN, USA) 25th June 2001, Accepted 18th July 2001
First published as an Advance Article on the web 16th August 2001

The iminophosphinimide complexes $[Ar(R)N]_3M(NPNBu^t)$ (M = V, Nb) were prepared from the corresponding anionic nitride species $\{[Ar(R)N]_3M{\equiv}NNa\}_2$ by way of a four-step synthetic strategy.

Unusually stable Group 5 arylazide complexes were recently isolated and their reactivity probed, *e.g.* $Cp_2Ta(Me)N_3Ph$[1] and $[Ar_F(Bu^t)N]_2V(I)N_3Mes$ (Ar_F = 2-F-5-MeC_6H_3).[2] Upon heating, these species gradually lose N_2 to form the corresponding arylimido complexes.[1,2] An iminophosphinimide ligand resembles the organoazide functionality, with substitution of phosphorus in the β-position. Although several main group compounds with an iminophosphinimide framework have been reported, *e.g.* [Li][Mes*NPNMes*][3] and $[Bu^tNP(\mu\text{-}NBu^t)_2PNBu^t]Ga(Bu^tNPNBu^t)$,[4] this ligand-type has not been supported on a transition-metal platform, *i.e.* $L_nM(N–P{=}NR)$ (R = organic group). Of particular interest is the possibility of N≡P extrusion as a consequence of organoimide formation. Herein we report characterization of the Group 5 iminophosphinimide derivatives $[Ar(R)N]_3M(NPNBu^t)$ [Ar = 3,5-$Me_2C_6H_3$; M = Nb, R = $C(CD_3)_2CH_3$; M = V, R = Bu^t], as constructed in several steps from the corresponding anionic nitride complexes (Scheme 1).



Scheme 1

In a demonstration of the versatility and controlled reactivity of the nitride dimer $\{[Ar(R)N]_3NbNNa\}_2$ (**1a**), reported previously by us in this journal,[5] the addition of PCl_3 to a THF solution of **1a** gave the pale yellow dichlorophosphine complex $[Ar(R)N]_3Nb(NPCl_2)$ (**2a**) in 86% isolated yield. The ^{31}P NMR spectrum for **2a** consists of a broad resonance at 158 ppm ($\Delta\nu_{1/2}$ = 160 Hz).‡ It is important to note that although **2a** was obtained exclusively upon addition of ⩾ 1 equiv. PCl_3, a second substitution reaction of the niobium nitride on phosphorus occurred cleanly when **1a** was added to **2a**.

Employing the synthon **2a**, design of a primary aminochlorophosphinimide functionality, *i.e.* –NP(Cl)($NHBu^t$), was pursued, since dehydrohalogenation of said species would deliver the desired iminophosphinimide ligand. The addition of 1 equiv. Bu^tNH_2 (10% solution in NEt_3) to **2a**, however, did not result in the formation of $[Ar(R)N]_3Nb[NP(Cl)(NHBu^t)]$ (**4a**), but rather a 1 : 1 mixture of $[Ar(R)N]_3Nb[NP(NHBu^t)_2]$ (**3a**) and unreacted **2a**. The yield of yellow di-*tert*-butylaminophosphinimide **3a**, for which the ^{31}P NMR spectrum contains a singlet at 101 ppm ($\Delta\nu_{1/2}$ = 85 Hz), was optimized (92%) upon addition of excess (*ca.* 4.4 equiv.) Bu^tNH_2/NEt_3 to **2a**. In an alternative approach, **4a** was generated by treating **3a** with a large excess of Me_3SiCl. As a caveat, however, the selective substitution of one *tert*-butylamino group on **3a** by chloride, as monitored by ^{31}P NMR spectroscopy, has characteristics of an equilibrium. The ratio of **3a**:**4a** decreased asymptotically when the number of silane equivalents was increased, but partial regeneration of **3a** occurred upon removal of all volatile materials *in vacuo*. This behavior is presumably due to the presence of the by-product $Me_3Si(Bu^t)NH$, which likely drives the equilibrium back towards **3a**. Treatment of **3a** with Me_3SiCl in three stages, between which all volatiles were removed *in vacuo*, conquered this dilemma and yielded **4a** as a yellow microcrystalline solid (73%). The ^{31}P NMR spectrum for **4a** consists of a single resonance at 146 ppm ($\Delta\nu_{1/2}$ = 101 Hz) and the ^1H NMR spectrum exhibits a doublet for the *tert*-butylamino protons, due to 1.5 Hz coupling with the ^{31}P center.

Dehydrohalogenation of **4a** was indeed achieved by treatment with 1 equiv. $LiN(SiMe_3)_2$ in pentane, yielding the *tert*-butyliminophosphinimide complex $[Ar(R)N]_3Nb(NPNBu^t)$ (**5a**) as bright yellow microcrystals in 66% yield. Interestingly, **5a** exhibits a 1 : 1 : 1 triplet centered at 318 ppm ($^1J_{14N–31P}$ = 61 Hz) in its ^{31}P NMR spectrum, due to coupling with one of the adjacent nitrogen atoms.‡ As this phenomenon was not observed for compounds **2a**–**4a**, it is speculated that the imino nitrogen experiences a more symmetric electric field gradient than its imido counterpart and is therefore the more likely source of $^{14}N–^{31}P$ coupling.[6] During recrystallization of **5a** from pentane it was observed that an orange solid started to form, with complete conversion in 24 h at 23 °C. A singlet at 240 ppm ($\Delta\nu_{1/2}$ = 72 Hz) in the ^{31}P NMR spectrum was recorded for this new orange species.‡ X-Ray diffraction analysis revealed the complex $[Ar(R)N]_3NbNP(\mu\text{-}NBu^t)_2PNNb[N(R)Ar]_3$ (**6**), the product of a [2 + 2] cycloaddition reaction involving two molecules of **5a** (Fig. 1).§ The two halves of dimeric **6** are related by a center of inversion, with a planar P_2N_2 core containing pyramidal phosphorus centers and nearly planar nitrogen centers. Selected bond distances and angles are provided in the caption to Fig. 1.

Main group iminophosphinimide compounds tend to form oligomers when lacking sufficiently bulky substituents.[4a] In the case of **5a**, the $[Ar(R)N]_3Nb$ platform apparently does not provide enough steric protection to totally encumber dimerization. It was anticipated that the vanadium analogue of **5a**, with an expected shorter metal–imide bond, would be less susceptible to oligomerization. In order to employ the same synthetic procedure as used for **5a**, however, we set out first to prepare the vanadium nitride complex $\{[Ar(Bu^t)N]_3VNNa\}_n$ (**1b**). Two related anionic vanadium(v) nitride species, $\{[(Me_3SiNCH_2CH_2)_3N]VNLi\}_n$[7] and $(Ph_2N)_3VNLi(THF)_3$,[8] were previously produced *via* deprotection or deprotonation strategies,

 DOI: 10.1039/b105584b

respectively, involving neutral imide precursors. Another approach involved the reductive cleavage of dinitrogen.[9] In the present case, treatment of the readily available vanadium(III) trisanilide $[Ar(Bu^t)N]_3V$[10] with NaN_3 in THF, and subsequent dissolution in pentane followed by drying *in vacuo*, yielded bright yellow **1b** in 88% yield. By analogy with **1a**, unsolvated **1b** is thought to be dimeric (n = 2) in the solid state, with intramolecular solvation of the Na^+ ions provided by the aryl substituents of the –N(Bu^t)Ar groups.[5]

The vanadium iminophosphinimide $[Ar(R)N]_3V(NPNBu^t)$ (**5b**) was indeed successfully generated from **1b** by the methodology illustrated in Scheme 1, with yields for complexes **2b**–**4b** similar to those obtained for their niobium counterparts. The ^{31}P NMR chemical shift values for these intermediates are also similar to those recorded for **2a**–**4a** (*vide supra*), but the resonances are considerably broader, likely due to unresolved long-range ^{51}V coupling.‡ Complex **5b** was isolated from diethyl ether as red crystals in 56% yield. The ^{31}P and ^{51}V NMR spectra for **5b** in D_6-benzene both consist of single broad resonances at 341 ($\Delta\nu_{1/2}$ = 332 Hz) and −151 ($\Delta\nu_{1/2}$ = 123 Hz) ppm, respectively.‡ In contrast to **5a**, coupling with a ^{14}N nucleus was not resolved in the ^{31}P NMR spectrum. An X-ray structure determination confirmed the monomeric nature of **5b**, but is not of publishable quality due to severe disorder in the –N(Bu^t)Ar groups.§ Significantly, dimerization of **5b** to form the vanadium analogue of **6** was not observed, even upon heating to 60 °C in hexane for a period of 18 h.‡ Shortening of the $V–N_{imide}$ bond in **5b**, as compared with **5a**, presumably draws the iminophosphinimide functionality deeper into the sterically protective pocket formed by the three anilide ligands at the metal center,[11] hindering P_2N_2 ring formation.

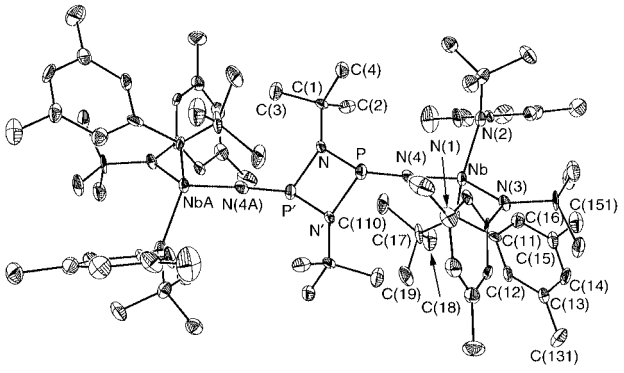

Fig. 1 Molecular structure of $[Ar(R)N]_3NbNP(\mu\text{-}NBu^t)_2PNNb[N(R)Ar]_3$ **6** (35% probability ellipsoids). Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and bond angles (°): Nb–N(1) 2.005(8), Nb–N(2) 2.050(8), Nb–N(3) 2.037(7), Nb–N(4) 1.790(7), P–N 1.734(7), P–N′ 1.727(8); Nb–N(4)–P 167.0(5), N(4)–P–N 108.7(4), N(4)–P–N′ 105.1(4), N–P–N′ 79.9(4), P–N–P′ 100.1(4).

In summary, two examples of a transition-metal supported iminophosphinimide ligand have been prepared by way of a dehydrohalogenation strategy. In the case of **5a**, dimerization occurs *via* cycloaddition of this moiety while a monomer is retained for **5b**, making possible an exploration of the reactivity of the novel M(NPNR) functionality. It is noteworthy that N≡P extrusion to give the corresponding imides was not observed for either complex, illustrating the robust nature of this ligand.

Waterman award to C. C. C.), and the David and Lucile Packard Foundations. J. K. B. thanks NSERC (Canada) for a post-doctoral fellowship.

Notes and references

‡ ^{31}P NMR chemical shift values were calculated (DFT) for models of the complexes **2a**, **5a**, **6**, and **2b**–**5b**. Remarkably good agreement between the experimental and theoretical values lends further support to the structural assignments of these species. Additionally, the chemical shift calculated for **5b** compared with that derived for the hypothetical product of dimerization of **5b**, *i.e.* the vanadium analogue of **6**, substantiates designation of this complex as a monomer. See ESI for details.†

Trimagnesium-bridged trinuclear ferrocenophanes cocomplexed with solvated mononuclear alkali metal amide molecules†

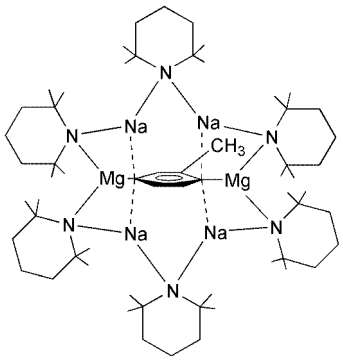
Kenneth W. Henderson, Alan R. Kennedy, Robert E. Mulvey,* Charles T. O'Hara and René B. Rowlings

Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, UK G1 1XL. E-mail: r.e.mulvey@strath.ac.uk

Received (in Cambridge, UK) 6th June 2001, Accepted 25th July 2001
First published as an Advance Article on the web 16th August 2001

Three prototypes of the remarkable new class of compound referred to in the title have been synthesised by treating ferrocene with the same mixed lithium (or sodium)–magnesium amide recipes as those used previously to make s-block metal inverse crowns.

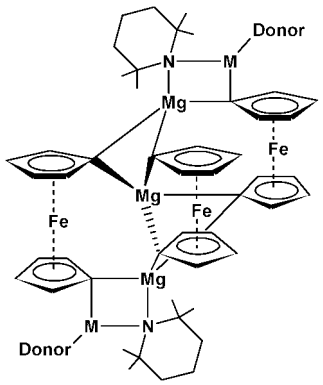
A recent feature article[1] highlighted the special synergistically driven chemistry that can be activated by pairing two distinct metal atom types (Li, Na or K from Group 1 with Mg or Zn from Group 2 or 12) within the same molecular amide environment. Arene molecules such as toluene can undergo selective dideprotonation at thermodynamically unfavourable ring sites to generate dianions which are locked within the central cavities of these so-called 's-block metal inverse crowns'. A representative example germane to the new work described herein is **1**.[2]



1

Derived from the sterically demanding amine 2,2,6,6-tetramethylpiperidine (TMPH) and formulated as $[Na_4Mg_2(TMP)_6\{C_6H_3(CH_3)\}]$, **1** displays a twelve-membered polymetallic ring, comprising alternate NaNMg and NNaN units, which stabilises the encapsulated arenediide through a combination of Mg–C σ bonds and Na–C π bonds (aligned parallel and perpendicular, respectively, to the arene ring plane). This interplay of σ and π bonding prompted the possibility of introducing cyclopentadienyl-based ligands into this developing area of heterometallic chemistry. Here, as a first attempt towards this goal we have subjected ferrocene to the same mixed sodium–magnesium amide recipe as that used to prepare **1**. The surprising product of this reaction is the trinuclear ferrocenophane disodium trimagnesium amide $[\{Fe(C_5H_4)_2\}_3\{Na_2Mg_3(TMP)_2\cdot(TMPH)_2\}]$ **2**. We have also been successful in synthesising two lithium analogues $[\{Fe(C_5H_4)_2\}_3\{Li_2Mg_3(TMP)_2\cdot(TMPH)_2\}]$, **3** and $[\{Fe(C_5H_4)_2\}_3\{Li_2Mg_3(TMP)_2\cdot(pyridine)_2\}]$ **4**, and so herein report the prototypes of a remarkable new class of structure.

In the preparation of **2**, freshly prepared Bu^nNa and commercial Bu_2Mg (10 mmol of each) were stirred together in a hexane–heptane mixture in an argon-filled Schlenk tube. The congealed brown mass obtained was then treated with TMPH (30 mmol) and the mixture was stirred until complete dissolution had occurred. Next, ferrocene (5 mmol) was introduced and the mixture was heated to reflux for 90 min. This produced a red powder which only partially dissolved on addition of hot toluene (40 ml), so what remained was collected by filtration. Left to cool overnight in a Dewar flask of hot water, the filtrate deposited a crop of red crystals. Both the powder and crystals were identified as **2**.‡ Substituting Bu^nLi for Bu^nNa in a similar procedure afforded the lithium analogue **3**.‡ Note that TMPH is available as a ligand here because it is the byproduct of ferrocene deprotonation by amido anions (TMP). Isolated **3** can be smoothly converted to **4**‡ by re-dissolving it in toluene solution and adding several molar equivalents of the stronger donor pyridine.



2/3/4

Each Mg atom independently stitches together the three ferrocene-1,1′-diyl units of **2** (Fig. 1). The distorted tetrahedral coordination sphere of centric Mg(1) comprises four C atoms, belonging to the 'top', 'bottom', and 'top' and 'bottom' C_5H_4 rings attached to Fe(1A), Fe(1) and Fe(2), respectively. This unique third ferrocenyl unit is disordered over two sites. Unfortunately this disorder would prejudice any discussion of dimensions pertaining to **2**, though it has no bearing on the connectivities within the structure which are unambiguous. A crystallographic C_2 axis runs through Mg(1) and Fe(2). The fourth coordination site of symmetry partners Mg(2)/Mg(2A) is filled by an amido N atom [N(1)/N(1A)]. Essentially planar (CMgNNa) rings, solvated at Na by TMPH molecules, complete the architecture. Of special significance therein is the Na(1)–C(1) bond [length 2.526(4) Å] as, to the best of our knowledge, it represents the first direct contact between Na and a ferrocenyl unit.

Detailed discussion of the structure is confined to that of **4** (Fig. 2) because there is no disorder within its molecular structure though there are disordered solvent molecules in the extended structure. Its connectivity pattern follows that of **2**, though the C_2 symmetry about the Mg(2)···Fe(2) axis is only approximate in this case. Mimicking the role of the TMPH

 DOI: 10.1039/b105009p

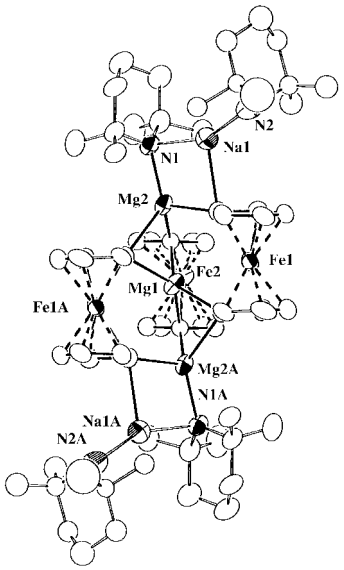

Fig. 1 Molecular structure of **2** without H atoms and disorder component.

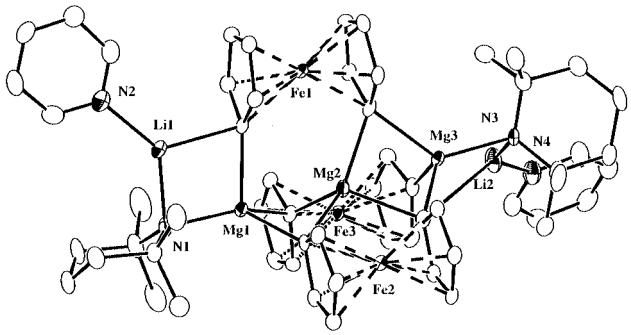

Fig. 2 Molecular structure of **4** from an alternative view to that given for **2** in Fig. 1. H atoms and solvent molecules of crystallisation have been omitted. Key dimensions (Å): Li1–N1 2.031(8), Li1–N2 2.050(8), Li1–C1 2.279(8), Li2–N3 2.027(8), Li2–N4 2.049(8), Li2–C26 2.243(8), Mg1–N1 2.072(3), Mg1–C1 2.187(4), Mg1–C11 2.224(4), Mg1–C21 2.344(4), Mg3–N3 2.094(3), Mg3–C6 2.304(4), Mg3–C16 2.221(4), Mg3–C26 2.194(4), Mg2–C6 2.224(4), Mg2–C11 2.352(4), Mg2–C16 2.307(4), Mg2–C21 2.219(4).

molecules in **2**, pyridine molecules bind terminally to Li at the periphery of the structure. Centric Mg(2) bonds asymmetrically to the ferrocenyl units: the pair of Mg–C bridging bonds to the Fe(2) unit are longer than their single terminal counterparts to the Fe(1) and Fe(3) units (mean lengths, 2.339 and 2.234 Å respectively). Significantly the shortest such bonds in the structure [Mg(1)–C(1) 2.187(4) Å, Mg(3)–C(26) 2.194(4) Å] lie almost parallel with their attached C_5H_4 ring [torsion angles: Mg(1)–C(1)–C(2)–C(3) 176.6(3)°, Mg(3)–C(26)–C(27)–C(28) −176.3(3)°] implying a high degree of σ character. All three Mg atoms deviate substantially from a tetrahedral geometry, with distortion most pronounced for the exclusively ferrocenyl-bound Mg(2) [range of bond angles 90.04(14)–140.42(15)°]. Another salient feature is the near-planarity of the four-element (CMgNLi) rings (sum of endocyclic bond angles, 359.05 or 360.05°). The quasi perpendicular approach of the Li atoms towards the C_5H_4 ring [*e.g.* Li1–C1–C2–C3, 103.6(3)°] signifies a large π contribution to the Li–C bonding. Finally it should be noted that each ferrocenyl unit has essentially eclipsed C_5H_4 rings, and that the staggered positioning of the three ferrocenyl ligands with respect to the Mg···Mg axis gives each molecule a chiral nature.

No precedent exists for this extraordinary class of hetero-trimetallic complex, either in terms of composition or structure. The closest analogy, also reported in 2001,[3] is the homo-main group-metallic gallium-bridged species $[\{Fe(C_5H_4)_2\}_3\{Ga\cdot(pyridine)\}_2]$. Made by a condensation reaction from a methylgallium precursor as opposed to the novel synergic metallation approach used here, it possesses a similar chiral 'carousel' arrangement of ferrocenyl units linked by two end-positioned Ga atoms [*à la* Mg(1) and Mg(3) in **4**], but is 'missing' a centric metal atom and metal amide component. A trinuclear ferrocenyl unit was first observed in the homometallic lithium-bridged species $[\{Fe(C_5H_4)_2\}_3Li_6\cdot(TMEDA)_2]$,[4] but the bridges are exclusively μ_2-Li–C in this case. While no other trinuclear examples are known, there has been a recent report[5] of a dinuclear ferrocenyl complex containing both lithium and magnesium; however, $[(FcN)_2Li_2Mg(Br)_2\cdot(OEt_2)]$ (where FcN is a dimethylaminomethylferrocenyl unit) bears little structural resemblance to **4**.

Returning to the original theme of the work, while **2**, **3** and **4** are clearly not inverse crown ring systems (*à la* **1**) they do nonetheless contain component parts thereof. In particular, their bimetallic MNMg (where M is an alkali metal) fragments are essential building blocks of all the known 8-, 12- and 24-membered inverse crown ring systems. Furthermore the ferrocene-diyl units can be likened to the arene-diyl units encountered in the 12-membered inverse crown **1**. Where **2**, **3** and **4** are truly unique in the context of heterometallic s-block chemistry, is in having a (centric) Mg atom stripped naked of amido ligands. With this atom acting as a fulcrum for supporting the three ferrocenyl units, it should be possible to build supramolecular assemblies of multiple trinuclear ferrocenophane molecules by exploiting the metathetical reactivity of the peripheral alkali metal amide fragments. Such redox-active assemblies could possess a range of interesting electrochemical, electronic and magnetic properties.

We thank the EPSRC for funding this research (through grant award no. GR/M78113).

Notes and references

‡ **2**: Yield (based on ferrocene consumption) 49%; mp decomp. from 200 °C; pyrophoric; satisfactory C, H, N analyses; δ_H (400 MHz, C_5D_5N), 4.83/4.77 (α- or β-H, C_5H_4), 1.58 (γ-H, TMP/H), 1.30 (β-H, TMP/H), 1.12 (α-Me, TMP/H), NH resonance was not observed. **3**: Yield, 68%; mp 174–176 °C; non-pyrophoric, satisfactory C, H, N analyses; δ_H (400 MHz, C_5D_5N). 4.85/4.80 (α- or β-H, C_5H_4), 1.57 (γ-H, TMP/H), 1.29 (β-H, TMP/H), 1.12 (α-Me, TMP/H), NH resonance was not observed. **4**: Yield, 63%; mp 166–168 °C; non-pyrophoric, satisfactory C, H, N analyses; δ_H (400 MHz, C_5D_5N), 8.74 (α-H, pyr), 7.59 (γ-H, pyr), 7.23 (β-H, pyr), 4.84/4.80 (α- or β-H, C_5H_4), 1.58 (γ-H, TMP), 1.29 (β-H, TMP), 1.12 (α-Me, TMP). All samples are extremely sensitive to hydrolysis as shown by trace amounts of ferrocene at δ 4.20. Note that solubility problems were encountered when the reactions were repeated using the stoichiometry consistent with the formulas of **2**, **3** and **4**. However, in all cases the same products were again observed.

Received (in Cambridge, UK) 25th May 2001, Accepted 23rd July 2001
First published as an Advance Article on the web 16th August 2001

Single crystals of $Ba_9Rh_8O_{24}$, grown from a molten potassium carbonate flux, crystallize in the spacegroup $R\bar{3}c$ with lattice parameters of a = 10.0899(4) and c = 41.462(2) Å. Magnetic measurements on oriented single crystals reveal the existence of magnetic anisotropy.

During recent years, there has been much interest in the preparation and investigation of oxides structurally related to the 2H hexagonal perovskites, the prototype of which, Sr_4PtO_6, was first prepared by Randall and Katz[1] and forms in the K_4CdCl_6 structure type. As shown by Darriet and Subramanian,[2] and more recently by Darriet and Perez-Mato,[3] the structures of these oxides can all be described as resulting from stacking sequences of $m[A_3O_9]$ layers and $n[A_3A'O_6]$ layers, with the subsequent filling of the interstitial octahedral sites. The general formula that can be derived from the stacking of such layers is: $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ (n, m = integers, A = alkaline earth; A′, B = large assortment of metals including alkali, alkaline earth, transition, main group, and rare earth metals). The structures are characterized by one-dimensional chains of face-sharing trigonal prisms and octahedra along the *c*-axis of the hexagonal unit cell.

Sr_4PtO_6 is the n = 1, m = 0 member of this family and consists of chains of alternating face-sharing octahedra and trigonal prisms. While many n = 1, m = 0 members are known, for example Sr_3NaRhO_6,[4] $Ca_3Co_2O_6$,[5,6] and Ca_3CuIrO_6,[7] far fewer oxides with higher integer values of n and m have been prepared and structurally characterized. In addition, until recently, most structure determinations were based on Rietveld refinements of polycrystalline powders and few single crystals of any members, and in particular very few members with higher integer values of n and m, have been grown and structurally characterized. A recent example of the latter type includes $Ba_8CoRh_6O_{21}$ corresponding to the m = 5, n = 3 member.[8] Other examples include $Ba_6Ni_5O_{15}$,[9] $Sr_4Ru_2O_9$,[10] and the incommensurate phases of $Ba_{1+x}(Cu_xRh_{1-x})O_3$ (x = 0.1605 and 0.1695) whose average structure is that of the n = 3, m = 4 member with a repeat sequence of five octahedra and one trigonal prism.[11] In this communication we report the first structural characterization of the m = 2, n = 1 member $Ba_9Rh_8O_{24}$ and the investigation of its magnetic properties.

Single crystals of $Ba_9Rh_8O_{24}$ were grown from a molten potassium carbonate flux. $BaCO_3$ and Rh metal powder (6:1 molar ratio) were mixed with a 10 fold mass excess of K_2CO_3. The alumina crucible was heated in air to 1050 °C, held for 48 h, and then quickly cooled to room temperature. The crystals were isolated manually by dissolving the flux in water.

An approximate [110] view is shown in Fig. 1. The structure is characterized by infinite chains containing groups of seven face-sharing RhO_6 octahedra separated by one face-sharing RhO_6 trigonal prism. These chains are in turn separated from one another by chains of Ba cations. The metal–oxygen bond distances [Rh1–O1 2.020(6), Rh2–O2 2.008(6), Rh2–O1 2.035(6), Rh3–O3 2.003(7), Rh3–O2 2.035(6), Rh4–O4 1.969(10), Rh4–O3 2.048(7), Rh5–O4 2.012(12) Å] are typical for oxides of this type. Intrachain Rh–Rh bond distances [Rh1–Rh2 2.523(1), Rh2–Rh3 2.455(1), Rh3–Rh4 2.637(2), Rh4–Rh5 2.750(1) Å] can be considered non-bonding.

$Ba_9Rh_8O_{24}$ represents the first structurally characterized m = 2, n = 1 member of this family, and more interestingly one of only a few single crystal compositions which are commensurate and not of the n = 1, m = 0 structure type. It is worth noting that this compound consists of the longest octahedra repeat sequence structurally characterized to date and structurally approaches the other end member of this family, n = 0, m = 1, the $BaNiO_3$ hexagonal perovskite structure. Compounds with chains consisting of 5 ($Sr_6Rh_5O_{15}$[12]) and 6 ($Ba_8CoRh_6O_{21}$) face-sharing octahedra separated by one face-sharing trigonal prism are known. In these and related oxides,[6] large magnetic anisotropies have been observed as a function of crystal orientation. To investigate the magnetic behavior of $Ba_9Rh_8O_{24}$, susceptibility measurements were obtained using a large single crystal weighing 5.53(1) mg.†

The plot of susceptibility as a function of crystal orientation measured at 2 K is shown in Fig. 2. A beautiful regular sinusoidal variation in the susceptibility is clearly evident. The maxima in the susceptibility correspond to a parallel alignment of the hexagonal *c*-axis (*i.e.* the $[Rh_8O_{24}]_\infty$ chain direction) with the applied field and the minima correspond to a 90 degree rotation from that position, or a perpendicular orientation of the *c*-axis relative to the magnetic field. Susceptibility measurements with the crystal oriented parallel and perpendicular with respect to the magnetic field are shown in Fig. 3, where the two curves diverge below *ca.* 100 K, indicating the onset of the

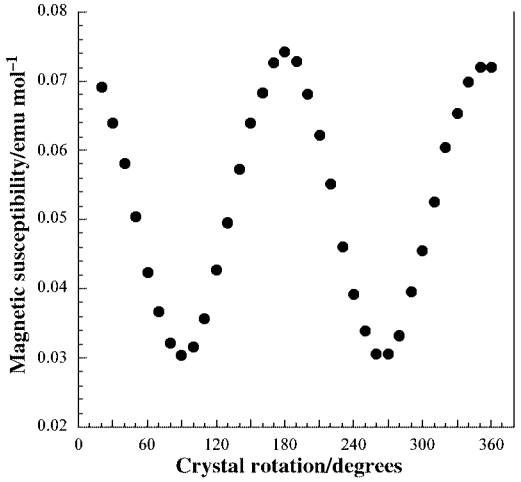

Fig. 2 Magnetic susceptibility of a single crystal of $Ba_9Rh_8O_{24}$ as a function of crystal orientation with respect to the applied magnetic field measured at 2 K and 5 kG. The maxima occur for the crystal's *c*-axis aligned parallel with the applied field.

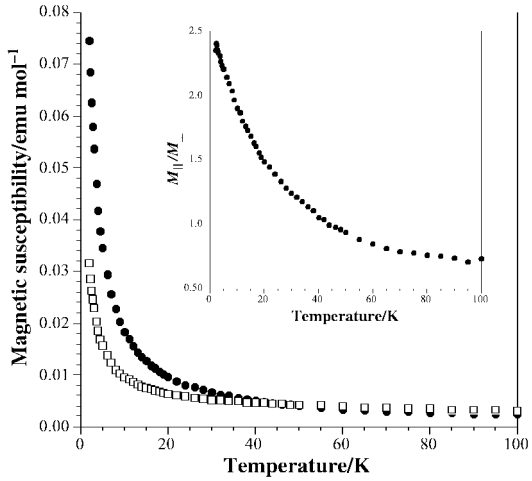

Fig. 3 Temperature dependence of the magnetic susceptibility of a single crystal of $Ba_9Rh_8O_{24}$ oriented parallel (●) and perpendicular (□) with respect to the applied field at 5 kG. Inset: temperature dependence of the magnetic anisotropy (defined as the ratio between the susceptibility of a single crystal oriented parallel and perpendicular with respect to the applied field).

magnetic anisotropy. The inset in Fig. 3 is a plot of the magnitude of the magnetic anisotropy, $M_{\|}/M_{\perp}$, as a function of temperature.‡

The issue of oxidation states for the rhodium and their location in this chain structure is currently not possible to resolve. In order to charge balance $Ba_9Rh_8O_{24}$, oxidation states can be distributed as six Rh^{4+} and two Rh^{3+}. A bond valence analysis proved inconclusive, and so one might hope to gain insight into the oxidation states from the magnetic susceptibility data. Assuming low spin rhodium in octahedral coordination, the Rh^{4+}, d^5, would each contribute one unpaired electron, while Rh^{3+}, d^6, would contribute no unpaired electrons. Unfortunately, the magnetic data cannot be fit to Curie-type behavior, making it impossible to check the above assignment.

Finally, the presence of the non-magnetic Rh^{3+} in the chain, would break any exchange interactions between Rh^{4+} sites, leading to a disruption of magnetic interactions within the chain. This should result in the formation of small magnetic units along the chain. The anisotropy that is observed at low temperature can potentially be due to an anisotropy in the exchange interaction between rhodium atoms in these small units or, alternatively, by irregular Rh^{4+} octahedra, resulting in different *g*-factors for $g_{\|}$ and $g_{\perp}$. This is an area of further investigation and beyond the scope of this communication.

Financial support from the National Science Foundation through Grant DMR:9873570 is gratefully acknowledged.

‡ *Magnetism*: Magnetic measurements were collected on a single crystal of $Ba_9Rh_8O_{24}$ weighing 5.53(1) mg using a Quantum Design MPMS XL SQUID magnetometer. Aligned crystal measurements were performed using a Quantum Design Single Crystal Rotator attachment. The crystal was affixed to the rotator using standard vacuum grease. The crystal was rotated in 10° steps through 360° at 2 K with an applied field of 5 kG; knowing the initial orientation makes it possible to correlate the maxima and minima to the crystal alignment. Temperature dependence measurements were taken at a position corresponding to a maximum and a minimum in susceptibility at 5 kG. The moment of the sample holder was corrected for using the Automatic Background Subtraction software by Quantum Design.

Oxidative cyclisation of cinnamyl ethers mediated by CAN: a stereoselective synthesis of 3,4-*trans* disubstituted tetrahydrofuran derivatives

Vijay Nair,*[a] Lakshmi Balagopal,[a] V. Sheeba,[a] Sreeletha B. Panicker[a] and Nigam P. Rath[b]

[a] *Organic Chemistry Division, Regional Research Laboratory (CSIR), Trivandrum 695 019, India. E-mail: gvn@csrrltrd.ren.nic.in; Fax: +91-471-491712*

Received (in Cambridge, UK) 5th April 2001, Accepted 6th July 2001
First published as an Advance Article on the web 16th August 2001

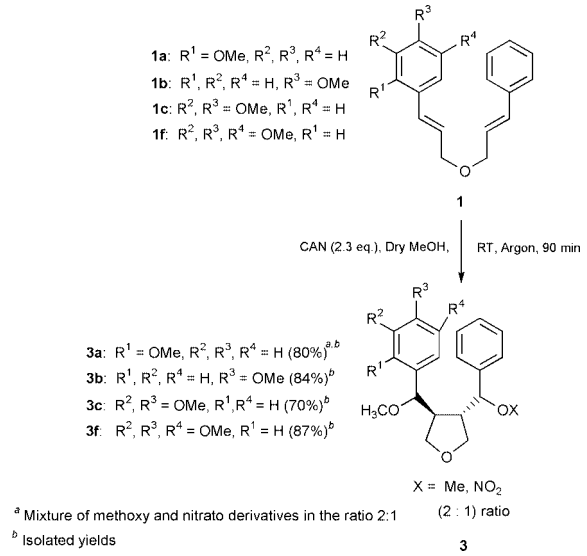
The oxidative cyclisation of cinnamyl ethers mediated by cerium(IV) ammonium nitrate results in the stereospecific formation of 3,4-*trans* disubstituted tetrahydrofuran derivatives in moderate to good yields.

Cerium(IV) ammonium nitrate (CAN) has been found to be a very efficient reagent for carbon–carbon bond formation especially in reactions involving the oxidative addition of 1,3-dicarbonyl compounds to alkenes.[1a,b] In spite of its success in this and a variety of other highly efficient intermolecular reactions of value in organic synthesis,[1] CAN has found very little use in intramolecular C–C bond formation;[2] this is in contrast to the general acceptance of Mn(III) in intramolecular cyclisations.[3] In view of this and prompted by our recent observation of CAN induced dimerisation of alkoxy styrenes,[4] we surmised that appropriately tethered alkoxy cinnamyl ethers would undergo CAN mediated cyclisation leading to tetrahydrofuran derivatives. It is noteworthy that a chemical electron transfer mediated intramolecular cyclobutanation of dicinnamyl ethers using triarylaminium salts has been reported by Bauld *et al*.[5]

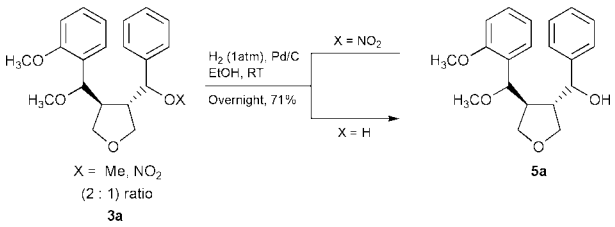
Our studies were initiated by the reaction of 2-methoxycinnamyl cinnamyl ether **1a** with CAN in methanol under an oxygen atmosphere. In the event, the reaction afforded a tetrahydrofuran derivative **2a**, in moderate yield. The reaction was found to be general and applicable to similar substrates (Scheme 1).

Interestingly, when the reaction of **1a** with CAN was carried out under argon atmosphere, instead of the ketone, a mixture of the methoxy and nitrato derivatives **3a**, in the ratio 2:1, was obtained in high yield. Similar results were obtained with other substrates (Scheme 2).

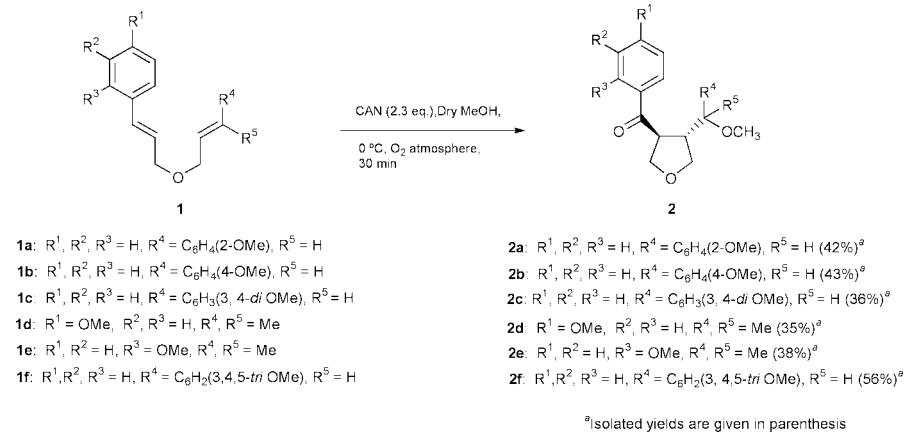
Catalytic hydrogenation of the mixture of methoxy and nitrato derivatives **3a** effected the selective conversion of the latter to the corresponding alcohol **5a** (Scheme 3).



Scheme 2



Scheme 3



Scheme 1

 DOI: 10.1039/b103111m

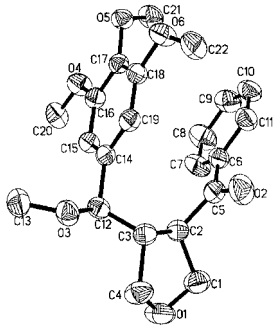


Fig. 1 X-Ray crystal structure of compound **2f**.

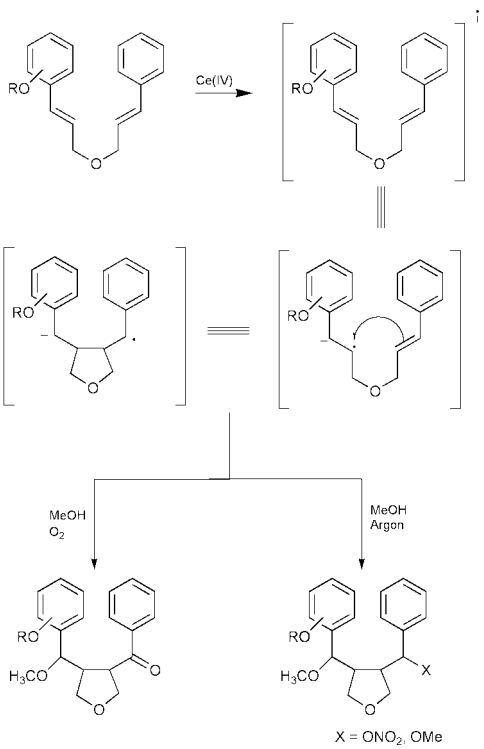
Relevant spectral data (IR, ^{1}H NMR, ^{13}C NMR, DEPT-135 NMR) of the products are in good agreement with structures assigned.† The stereochemistry of the 3,4-disubstituted-tetrahydrofuran derivative has been confirmed to be *trans* with the aid of single crystal X-ray analysis of compound **2f** (Fig. 1).‡

A mechanistic rationale for the formation of the product can be depicted along the following lines (Scheme 4).

A radical cation initially formed from the methoxy styrene unit of the substrate can add in an intramolecular fashion to the adjacent styrene moiety to form a distonic radical cation. The cationic center is quenched by methanol, whereas the radical center is prone to two different transformations.[1c,d] Under oxygen atmosphere, the radical site is quenched by molecular oxygen yielding the keto product *via* the initially formed peroxy radical. Under argon atmosphere, the radical site is quenched by nitrate by ligand transfer from CAN; alternatively, it can undergo oxidation by CAN to the benzylic cation with subsequent addition of methanol yielding the dimethoxy product.



Scheme 4

In conclusion, we have devised a novel and efficient route towards the stereospecific construction of 3,4-*trans* substituted tetrahydrofurans from relatively simple precursors, which assumes importance in view of the fact that substituted tetrahydrofurans feature in many natural products of biological importance,[6] especially lignans. Further studies are currently in progress.

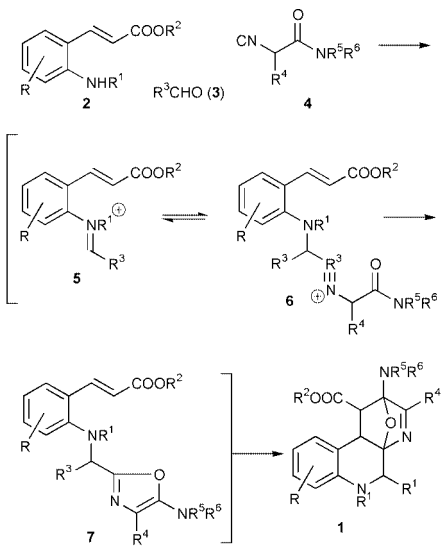
First published as an Advance Article on the web 16th August 2001

Bridged tetracyclic tetrahydroquinoline is synthesized by a novel one-pot three component condensation of an *ortho*-amino cinnamate, α-isocyano acetamide and an aldehyde.

Maximizing synthetic efficiency by designing complexity-generating multicomponent domino processes is gaining more and more importance in organic synthesis and in drug discovery endeavour.[1–4] In connection with our ongoing project, a novel one-pot three component synthesis of tetracyclic tetrahydroquinoline[5] was envisaged. The sequence of events, hinged upon our recently developed synthesis of 5-aminooxazole,[6] is outlined in Scheme 1. Thus, reaction of an aniline, an aldehyde and an α-isocyano acetamide should give the aminooxazole *via* an iminium, then a nitrilium ion intermediate. Cycloaddition of oxazole as an aza-diene with a properly predisposed dienophile would then produce a bridged tetrahydroquinoline-containing polycycle that, *a priori*, would undergo further fragmentation to provide phenanthroline.[7] While domino Ugi/Diels–Alder cycloadditions starting from diene- and dienophile-containing building blocks have been elegantly developed,[8] the multi-component reaction (MCR)/cycloaddition sequence involving *en route* generation of a transient diene, to the best of our knowledge, was unknown.[9] The realization of this concept as well as the documentation of the remarkable thermostability of cycloadduct **1** is the subject of this communication.

Using *ortho*-amino methyl cinnamate (**2a**), heptanal (**3a**) and α-isocyano α-benzyl acetamide (**4a**) as inputs, reaction conditions were surveyed varying the solvent (MeOH, CF_3CH_2OH, benzene, toluene), the temperature (rt to 110°C), and the promotor (LiBr, $BF_3{\cdot}OEt_2$, $Yb(OTf)_3$, $Sc(OTf)_3$, $MgSO_4$). After a considerable number of experiments, conditions were worked out for the domino 3 component reaction (3CR)/intramolecular Diels–Alder cycloaddition process. Thus, under the optimal conditions (**2a** and **3a**, LiBr, in toluene, 2h then **4a**, 70 °C), tetracyclic tetrahydroquinoline **1** was isolated in 94% yield as a mixture of two separable diastereomers (ratio of **1a**:**1a′** = 3:1, Scheme 2). Without LiBr, **1a** and **1a′** were isolated in less than 6% yield under otherwise identical conditions.[10] The identification of 5-aminooxazole intermediate **7** (where NR^5R^6 = NEt_2) provided evidence that the reaction indeed proceeded as programmed. It is worthy of note that one C–N, one C–O and three C–O bonds were formed with the concomitant creation of five asymmetric centers in this one-pot process. The efficiency of this reaction was thus truly remarkable if one looks at the yield per bond formation.



Scheme 1

The stereochemistry of compound **1a** and **1a′** was deduced from both mechanistic consideration and NMR studies. The observed coupling constant between H_a and H_b ($J_{Ha\text{-}Hb}$ = 4.6 Hz for **1a** and 4.4 Hz for **1a′**) indicated a *gauche* relationship of these two protons in both compounds. For the inherent ring strain imposed by the connecting bridge, only the aryl-*exo*-ester-*endo* mode of cycloaddition was possible leading to the observed compounds. This model of ring formation is also indicative of a concerted rather than a stepwise process, since one could expect the formation of aryl-*exo*-ester-*exo* diastereomers if the latter mechanism was operating. The relative stereochemistry of the major adduct **1a** was deduced from the observation of a strong NOE cross peak between H_b and H_c in its NOESY spectrum and corroborated by X-ray analysis (Fig. 1).‡

Control experiments showed that the observed stereoselectivity was a thermodynamically controlled process. Indeed, re-submitting the diastereomerically pure compound **1a** to the reaction conditions led to the formation of a mixture of **1a** and **1a′** with the ratio identical to that resulting from the reaction mixture. The same is true for **1a′**. While the thermo-equilibrium can be interpreted by a sequence of heterocycloreversion/

cycloaddition, the relatively high stability of compound **1** with a strained aminal function was nevertheless intriguing.

Selected structures synthesized in this preliminary study are listed in Fig. 2.§ The reaction conditions have not been individually optimized. As is seen, all substituents at the periphery of the tetracyclic ring system can be varied. The *ortho*-amino cinnamate with either electron donating or electron withdrawing group participated in the reaction, as did the *N*-alkylated derivatives. The α-branched aldehydes, as well as the α-alkyl and α-aryl substituted α-isocyano acetamides took part in this reaction. When cyclooctyl aldehyde was used, a single diastereomer was isolated. Since the nitrogen bearing the asymmetric center was the one that controlled the facial selectivity of the subsequent aza-Diels–Alder cycloaddition, the observation is thus understandable. As expected for Ugi type reaction, racemic tetrahydroquinoline was obtained even when enantiomerically pure isonitrile **4** (R = Bn, or phenyl) was used as input. At this stage of the development, the failure of aromatic aldehyde to enter the reaction cascade constituted the limitation of the present methodology.

In conclusion, we have developed a novel multicomponent domino process for the synthesis of oxa-bridged tetrahydroquinoline starting from simple and readily accessible linear precursors. Besides its synthetic efficiency and potential application in diversity oriented synthesis, we demonstrated, to the best of our knowledge, for the first time that Ugi-type condensations can be performed in toluene in the presence of LiBr without concurrent occurrence of a Passerini-type reaction.

Financial support from CONACYT (E. G.-Z.) and CNRS are gratefully acknowledged. We thank Mr M. De Paolis for helpful discussion.

First published as an Advance Article on the web 16th August 2001

Heteropoly acids such as $H_3PW_{12}O_{40}$ are exceptionally active catalysts in the synthesis of diphenylmethane from benzene and formalin (aqueous formaldehyde) in a biphasic system and can be recycled simply by drying the aqueous phase at room temperature.

Diphenylmethane ($PhCH_2Ph$) is an important intermediate in spices, pharmaceutics and other fine chemicals[1] and its alkylated compounds can be used as insulators in place of PCB.[2] $PhCH_2Ph$ has commercially been synthesized by the Friedel–Crafts reaction with benzyl chloride and benzene, using aluminium-amalgam, $AlCl_3$, or $ZnCl_2$ as catalyst.[3] However, both the materials and the catalysts are environmentally unfriendly. Moreover, harmless solid acids like HY zeolite,[4] H-ZSM-5,[5] and sulfated ZrO_2[6] were reported to be of insufficient activity.

Synthesis of $PhCH_2Ph$ by condensation of benzene with formalin [eqn. (1)] is very attractive, since the direct use

$$2C_6H_6 + HCHO\ (\text{in water}) \rightarrow PhCH_2Ph + H_2O \qquad (1)$$

of formalin is economical and the only by-product of the reaction is water. There are several reports describing reactions between aromatic compounds and paraformaldehyde (water-free oligomers of HCHO) catalysed by liquid acids,[7] solid acids like HY zeolite,[8] and SiO_2-composites of polymer resins.[9] However, when formalin was used instead of paraformaldehyde, no reaction occurred under the same conditions,[7,9] due to serious inhibition by water. There is no report detailing a catalyst effective for the reaction of benzene with formalin. In this communication, we report that $H_3PW_{12}O_{40}$ is unusually active and recyclable for this reaction in a biphasic system. Similar biphasic catalytic systems have been reported for cyclotrimerization of propionaldehyde catalysed by heteropoly acid[10] and for nitration of benzene by lanthanide triflates.[11]

The reaction was performed at 433 K in a stainless steel autoclave (*ca*. 100 cm^3, TAIATSU TECHNO, Japan) with 40 cm^3 of benzene (450 mmol), 6.72 cm^3 of formalin (Wako Chem. Co., HCHO 90 mmol, H_2O 222 mmol, methanol (as stabilizer) 18.2 mmol), and the catalyst (2.3–16.6 mol% with respect to HCHO). The vapor phase was analyzed with a TCD gas chromatograph (Shimadzu, GC-8A) with an active carbon column. Each liquid phase was analyzed with an FID gas chromatograph (Shimadzu, GC-14B) with a 15 m capillary column of cross-linked 5% PhMe siloxane (HP-5, USA) for the aromatic compounds and a Porapak P column for methyl formate and methanol. The TCD-GC with an APS-201 (Flusin T) column was also used for HCHO, HCOOH, and H_2O. All liquid acids (except for *para*-toluenesulfonic acid) were exclusively present in the aqueous phase. When the reaction solution was cooled to room temperature after the reaction (2 h), the solution consisted of two phases, a benzene phase (the upper) and an aqueous phase (the lower), and a phase boundary was apparent.

As Table 1 shows, the conversions of HCHO reached over 93 mol% with $H_3PW_{12}O_{40}$ and $Sc(CF_3SO_3)_3$. It should be emphasized that only $H_3PW_{12}O_{40}$ gave an appreciable amount of $PhCH_2Ph$ (the yield was 35.3% under these conditions), which accumulated in the benzene phase. In addition, dibenzylbenzene ($(PhCH_2)_2C_6H_4$), methyl benzyl ether ($PhCH_2OMe$), and methyl formate (HCOOMe) were detected in the benzene phase, and formic acid, methanol, and excess HCHO in the aqueous phase. For the formation of $PhCH_2Ph$, the following steps are considered:[8] $H_2{}^+COH$ is generated from HCHO and the proton attacks the benzene ring to form, initially, benzyl alcohol. Benzyl alcohol can be transformed to the benzyl cation *via* protonation and dehydration. $PhCH_2Ph$ is produced by the attack of the benzyl cation on the benzene ring. With $H_3PW_{12}O_{40}$ as catalyst, two competitive reactions of HCHO proceeded: (i) attack of the benzyl cation on benzene to form $PhCH_2Ph$ and (ii) dimerization of HCHO to HCOOMe (Tichenko reaction).

On the other hand, $Sc(CF_3SO_3)_3$ efficiently catalysed dimerization of HCHO to HCOOMe, but was inactive for the formation of $PhCH_2Ph$. *para*-Toluenesulfonic acid (PTS) was also active for the dimerization of HCHO, but less active than $H_3PW_{12}O_{40}$ for $PhCH_2Ph$ formation. Mineral acids like H_2SO_4, H_3PO_4, and HNO_3 showed no activity for the formation of $PhCH_2Ph$ and CF_3COOH was also inactive for this reaction. It was confirmed that HCOOMe did not react with benzene under these conditions with any of these catalysts.

A series of other heteropoly acids were examined as catalysts for the synthesis of $PhCH_2Ph$ from benzene and formalin (Table 2). All these heteropoly acids showed activities: $H_4SiW_{12}O_{40}$ and $H_3PMo_{12}O_{40}$ were effective, but $H_6P_2W_{18}O_{62}$ and H_4Si-

$H_4SiMo_{12}O_{40}$	(4.2)	92.0	3.6	77.1	3.9 (33.9)	0.7

Reaction conditions were the same as given in the footnotes of Table 1. [a] On the basis of HCHO. The figures in parentheses are the selectivities for $PhCH_2Ph$ among the aromatic compounds ($PhCH_2Ph$ + $(PhCH_2)_2CH_2$ + $PhCH_2OMe$). [b] Turnover number defined as (mol of $PhCH_2Ph$)/(mol of catalyst).

Table 3 Recycled $H_3PW_{12}O_{40}$[a]

Run	Conversion (%)	Total yield of aromatics[b] (mmol)	Selectivity (mol%)[c]	
			$PhCH_2Ph$	TON[d]
1	83.5	31.4	79.1	4.5
2	74.7	23.8 (75.6%)	76.2	2.9
3	72.2	21.1 (68.4%)	73.4	2.4
4	64.1	17.8 (56.7%)	70.6	1.7
5	63.1	17.6 (56.1%)	66.7	1.6

Reaction conditions: benzene 40 cm^3 (450 mmol), formalin 6.72 cm^3 (HCHO 90 mmol, H_2O 222 mmol, methanol 18.2 mmol), $H_3PW_{12}O_{40}$ 4.2 mmol, 160 °C, and 30 min. [a] Between the runs, the aqueous phase of $H_3PW_{12}O_{40}$ was dried in the ambient atmosphere. The recovered solid $H_3PW_{12}O_{40}$ was reused without any treatment. [b] Total yield of $PhCH_2Ph$, $(PhCH_2)_2CH_2$ and $PhCH_2OMe$. The figures in parentheses are the percentage yield relative to that of the first run. [c] Selectivity for $PhCH_2Ph$ among the aromatic products on the basis of HCHO. [d] Turnover number defined as (mol of $PhCH_2Ph$)/(mol of catalyst).

$Mo_{12}O_{40}$ were less efficient. With $H_3PW_{12}O_{40}$ as catalyst, when the ratio of HCHO/benzene was reduced from 1:5 to 1:10, keeping the amount of benzene (450 mmol) the same, the yield of $PhCH_2Ph$ became higher (42%) with 43% selectivity and 97% conversion. However, the amount of $PhCH_2Ph$ produced was still higher at 1:5 ratio.

IR spectroscopy showed that, while the Keggin structure of $SiMo_{12}O_{40}^{4-}$ decomposed to some extent after the reaction, the structures of the other polyanions were retained. The pH values of the aqueous phases of these heteropoly acids (pH = 0.10, 0.58, 0.61, 0.79, and 0.96 for $H_3PW_{12}O_{40}$, $H_4SiW_{12}O_{40}$, $H_3PMo_{12}O_{40}$, $H_6P_2W_{18}O_{62}$, and $H_4SiMo_{12}O_{40}$, respectively) were close to those of $Sc(CF_3SO_3)_3$ (pH = 0.90), H_3PO_4 (pH = 1.25), HNO_3 (pH = 0.65), and H_2SO_4 (pH = 0.19). Thus the exceptionally high activities of the heteropoly acids are due to not only the strong acidity of the solution, but also the soft basicity of the heteropoly anion, which has been proposed by Izumi *et al.*[12] The cationic intermediates are probably stabilized by the heteropoly anions.

The results of five successive reactions are summarized in Table 3, where used $H_3PW_{12}O_{40}$ was recovered simply by drying the aqueous solution at room temperature. The recovered $H_3PW_{12}O_{40}$ was found to be active in the repeated runs, although the conversion of HCHO and yield of aromatics decreased somewhat. As shown in Table 3, the conversion and the total yield of aromatics reached plateaus after the fourth run. These changes in the conversion, yield, and selectivity are due to the remaining carbonaceous species on the heteropoly acid. Elemental analysis showed that the amount of carbon on the used $H_3PW_{12}O_{40}$ was 2.1%, which corresponds to 0.4 molecules of $PhCH_2Ph$ per heteropoly anion at the fifth run. IR spectroscopy of $H_3PW_{12}O_{40}$ revealed that the Keggin structure was completely retained after repeating the reaction five times.

In conclusion, $H_3PW_{12}O_{40}$ is a highly active and recyclable catalyst for use in the synthesis of diphenylmethane from benzene and formalin in a biphasic system. This is a novel example for direct use of formalin in clean organic synthesis with solid acid.

A series of disulfides containing bicyclo[2.2.2]octane moieties have been synthesised and their self-assembled monolayers (SAMs) on Au(111) have been characterized using scanning tunnelling microscopy (STM).

SAMs consisting of thiols and disulfides chemisorbed on Au(111) have been extensively studied owing to their stability and ease of preparation. Among organosulfurs on gold, *n*-alkanethiols and their substituted analogues are considered the simplest case due to their linear structure of saturated hydrocarbon chain and degree of freedom in the process of self-assembling.[1,2] The first structural study of alkanethiols having a bulky end group was reported in 1992.[3] STM topographs of these SAMs exhibited a ($\sqrt{3} \times \sqrt{3}$)R30° lattice in spite of the bulky end group that sterically hinders the ($\sqrt{3} \times \sqrt{3}$)R30° structure. Later study of other bulky thiols showed incommensurate lattices.[4] Furthermore, new classes of SAMs consisting of spiro-alkanethiols[5] (organic) or polyhedral borane derivatives[6] (inorganic) have been recently investigated. In these reports, the authors attempted to control the film properties by designing the molecular structure of adsorbates. Detailed microscopic structures, however, remain unsolved.

In the present work, we focused on the preparation of well-defined thin rigid films. As a new class of adsorbates, structurally simple and symmetric molecules (bicyclo[2.2.2]octane derivatives) were synthesized. In comparison with *n*-alkanethiols and their substituted analogues, sulfur compounds with bicyclo[2.2.2]octane moieties are expected to have unique properties. First, the overall shape of the molecule is roughly spherical and the size is *ca*. 0.60 nm, which is larger than the nearest neighbour spacing (0.50 nm) of the ($\sqrt{3} \times \sqrt{3}$)R30° structure. Owing to the bulkiness of the bicyclo[2.2.2]octane moieties, they are expected to be oriented perpendicularly to the surface and thus the formation of domain structure due to the tilt of adsorbates can be avoided.[1,2] Second, three ethylene chains are linked at both terminals of this moiety and the structure of the bulky end group itself is rigid. Third, formation of rigid thin films is expected due to the stronger van der Waals interactions between bicyclo[2.2.2]octane moieties compared to those of *n*-butane moieties of *n*-alkanethiols with the same height. The chain ordering in the films with such short *n*-alkane chains is known to be disturbed appreciably by their vigorous thermal motion at room temperature.[1]

Compounds **1a** and **1b** (Fig. 1) were derived from 4-methoxybicyclo[2.2.2]octane-1-carboxylic acid[7] in 20–30% overall yields by a 6–7 steps procedure.† As desired adsorbates, disulfides were synthesized taking their stability and ease of purification into account. Au(111) surfaces for STM studies were prepared by thermal evaporation of gold (99.99%) onto freshly cleaved mica *in vacuo* with a background pressure of $< 5 \times 10^{-7}$ Torr. SAMs [**1**/Au(111) in Fig. 1] were prepared by dipping the Au substrates for 10–72 h in 0.5 mM ethanol solutions of **1a**, **1b**, or **1a** + **1b**. All STM measurements were performed using a constant-current mode with a tungsten tip in the atmosphere at room temperature and the images were unfiltered.

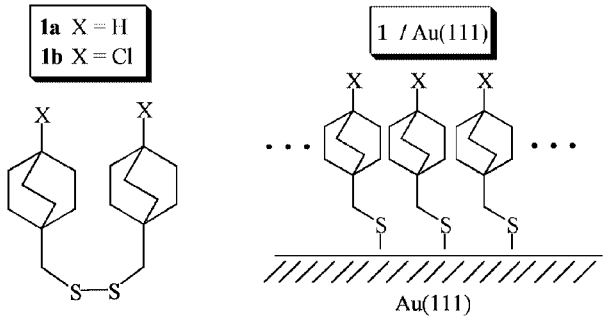

Fig. 1 Bicyclo[2.2.2]octane derivatives (**1a** and **1b**) synthesized in this study and schematic structure of their SAMs [**1**/Au(111)].

Fig. 2 shows a constant-current STM image of a 20 × 20 nm area of a SAM of **1a**/Au(111). In the same way as with *n*-alkanethiols, single Au atom deep pit defects and a hexagonal close-packed lattice were found as shown in Fig. 2. We also investigated a SAM image of a short chain *n*-alkenethiol (pentanethiol) with a carbon number in the vertical direction equal to that of **1**. In the pentanethiol SAM, disordered structure and domains including a *c*(4 × 2) superlattice of a hexagonal lattice[1,2] were found. Periodicities of topographic differences found in the superlattice are considered to reflect the difference in azimuthal orientation. In Fig. 2, such periodicities of topographic differences are not seen and the nearest spacing is 0.59 ± 0.03 nm. This spacing is larger than the ($\sqrt{3} \times \sqrt{3}$)-R30° structure (Au spacing is 0.288 nm). It is also clear from Fig. 2 that rows of molecules are not always straight and that such deviations are not due to thermal drifts.

We also imaged the underlying Au(111) lattice by mechanically removing part of the SAM with the STM tip. It was found that the hexagonal lattice of the adsorbate was rotated *ca*. 30°

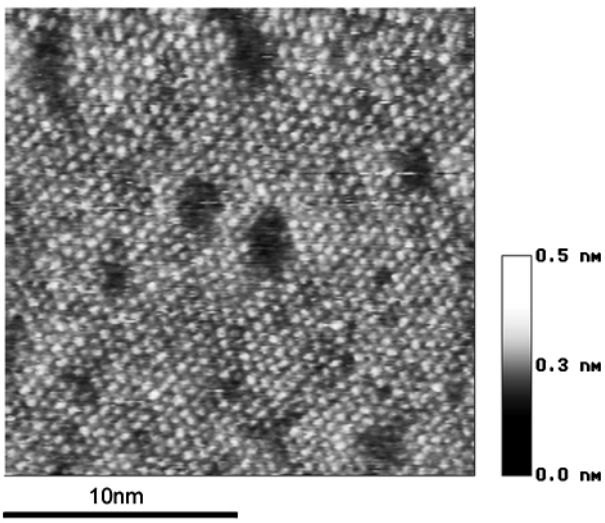

Fig. 2 Constant-current STM image of a 20 × 20 nm area of a SAM of **1a** (tunnelling current = 50 pA, sample bias voltage = +1 V).

 DOI: 10.1039/b104703p

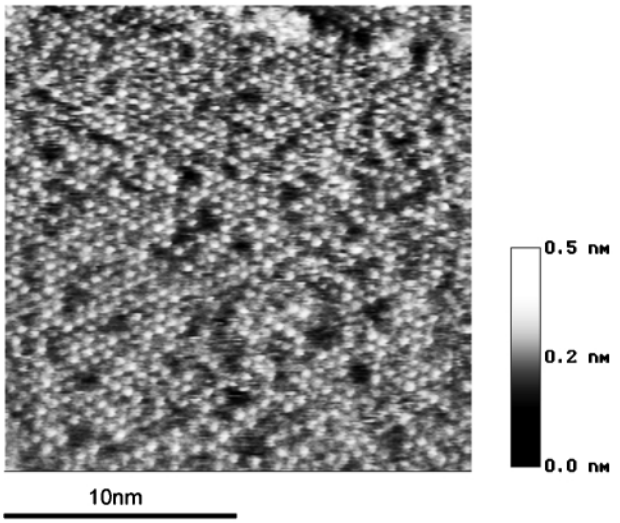

Fig. 3 Constant-current STM image of a 20 × 20 nm area of a SAM of **1b** (tunnelling current = 30 pA, sample bias voltage = +1 V).

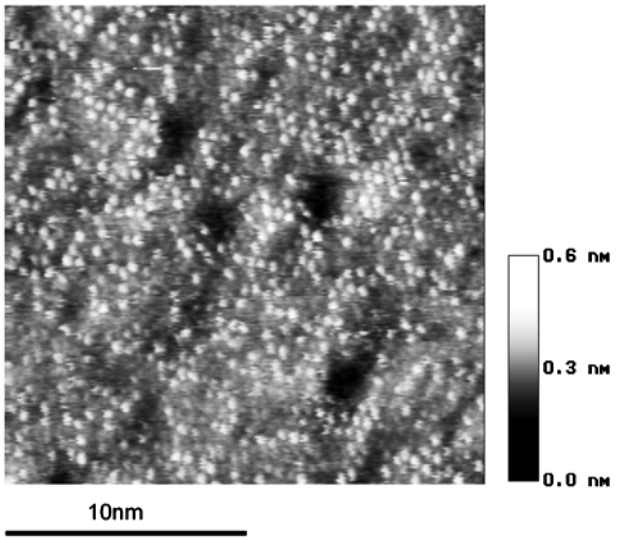

Fig. 4 Constant-current STM image of a 20 × 20 nm area of a SAM of **1a** + **1b** (tunnelling current = 50 pA, sample bias voltage = +1 V).

over that of Au(111). The molecular rows in the same direction went across steps and pits.

Although the shape of a bicyclo[2.2.2]octane moiety is roughly spherical as stated above, it also possesses a three-fold axis. A shorter distance of closest approach between the two bicyclo[2.2.2]octane moieties may be achieved when an ethylene chain of one moiety is located between two chains of the other moiety. We are now undertaking a study of annealing effects to obtain detailed information on the unit cell.

Fig. 3 shows a constant-current STM image of a 20 × 20 nm area of a SAM of **1b**/Au(111). This film shows a slightly different feature. The depressions (pits), that are usually observed in SAMs of *n*-alkanethiols and also in a SAM of **1a**/Au(111) in Fig. 2, are not observed clearly in Fig. 3. Instead, the organic overlayer itself is more poorly ordered. Since there are tip convolution problems for imaging small size depressions, we should take care when discussing this result. This feature probably results from strong short-range interaction, *i.e.* dipole–dipole interactions among C–Cl end groups on the bicyclo[2.2.2]octane moieties, oriented perpendicularly to the Au(111) surface [**1b**/Au(111) in Fig. 1]. For this upright orientation of the terminal groups, the bridgeheads of the moieties play an important role.

Finally, we carried out adsorption of a mixture of two components (compounds **1a** and **1b**). We prepared an ethanol solution of a 1:1 mixture of **1a** + **1b**. Fig. 4 shows a constant-current STM image of a 20 × 20 nm area of a SAM of the mixture on Au(111). The two components were molecularly dispersed. We assigned bright features (*ca*. 0.1 nm protrusions) to chloride end groups on the basis of insertion experiments of **1b** to the matrix containing **1a** carried out separately. This result clearly indicates that dots on the lattice of the STM image correspond to individual molecules and a distinction of the small difference between the H and Cl terminal atoms can be possible by STM. The observed distinction is afforded by the high structural order in the organic surface film which is, in turn, the result of interactions between the rigid sphere-shaped molecules. Most of the bright features seemed to be pairing, indicating that lateral diffusion of dissociated thiolates occured upon chemisorption of **1a** and **1b** from the 0.5 mM mixed solution was slow.

In summary, we have investigated the structure of novel bicyclo[2.2.2]octane derivatives chemisorbed onto Au(111) from 0.5 mM ethanol solutions using STM. Owing to their rigid structure, small differences between the end groups, *e.g.* between H and Cl, were distinctive. This distinction of individual molecules, to the best of our knowledge, represents one of the highest resolutions of organic monolayers on solid surfaces.[8] Although our knowledge of SAMs of these novel adsorbates is still limited in comparison with that of the widely used *n*-alkanethiols, the well-defined structure and the ease of detection and distinction described above will be useful for further investigation of these adsorbates and their substituted analogues. For example, their application to rigid bases for oriented dipoles, rigid spacers for molecular single electron devices, hexagonally close-packed host matrices for insertion experiments, markers for lateral diffusion dynamics, *etc*. are expected. As spacers, dimers and trimers of the bicyclo[2.2.2]octane unit will be useful.

Notes and references

† 4-Methoxybicyclo[2.2.2]octane-1-carboxylic acid was synthesized according to a previously reported procedure.[8] Disulfides used for SAM formation were characterized by ^{1}H and ^{13}C NMR spectra and elemental analysis giving satisfactory results. Details of the syntheses will be reported elsewhere.

Dynamic equilibration of η¹-carbene and η²-alkyne moieties within an alkynylcarbene dimanganese complex†

Yannick Ortin, Yannick Coppel, Noël Lugan,* René Mathieu and Michael J. McGlinchey‡

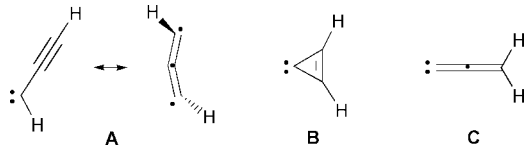
Received (in Cambridge, UK) 30th May 2001, Accepted 24th July 2001
First published as an Advance Article on the web 16th August 2001

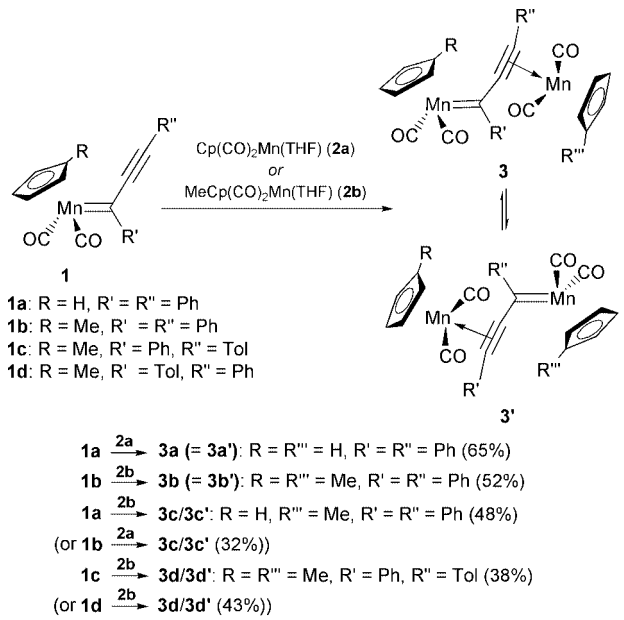
The coordination of an additional [$Cp(CO)_2Mn$] fragment to the alkyne linkage of an alkynylcarbene complex of the type $Cp(CO)_2Mn{=}C(R')C{\equiv}CR''$ yields a highly fluxional molecule, in which the [η¹-carbene] and [η²-alkyne] moieties are seen to exchange rapidly on the NMR time scale.

The energy surface of the C_3H_2 system continues to attract considerable attention.[1] Among the numerous possible isomers that can exist and interconvert are propynylidene **A**, cyclopropenylidene **B**, and allenylidene **C**, and many such species have



been isolated as stable organometallic complexes. In continuation of our studies on manganese carbene complexes,[2] our current work has focussed on non-heteroatom-substituted alkynylcarbenes of the type $(RC_5H_4)Mn{=}C(R')C{\equiv}CR''$, where R = H, Me.[3,4] A recent report by Casey *et al.*[4] that related rhenium systems undergo a fascinating dimerization[4] prompts us to present our own findings in this area.

The alkynylcarbene complexes $(RC_5H_4)Mn{=}C(R')C{\equiv}CR''$ **1** shown in Scheme 1 were synthesised in a straightforward manner and in high yields (81–85%) upon treatment of the corresponding carbyne complexes $[(RC_5H_4)Mn{\equiv}CR'][BPh_4]$ with the appropriate alkynyllithium reagents $LiC{\equiv}CR''$.† With the general idea of inducing remote activation of the carbene carbon atom by coordination of a transition metal to the alkyne function in alkynylcarbene complexes, **1a** was treated with $Cp(CO)_2Mn(THF)$ **2a**, at room temperature. This yielded **3a**, whose IR spectrum showed four bands in the *ν*CO region, strongly indicative of a polymetallic structure.



Scheme 1

The structure of **3a**, as determined by X-ray diffraction§ (Fig. 1) shows that, as anticipated, the molecule consists of a Mn alkynylcarbene complex in which the alkyne is coordinated to an additional $Cp(CO)_2Mn$ fragment. Both $Cp(CO)_2Mn$ units are bonded in the conventional fashion so as to maximise the overlap between the frontier orbitals of the metal fragments and of the carbene and alkyne units, respectively.[5] Indeed, the interplanar angle {cent1–Mn1–C3}–{Mn1–C3–C4} is 2.4° (ideal 0°), whereas the corresponding value for {cent2–Mn2–cent3}–{Mn2–C4–C5} is 83.6° (ideal 90°) [cent1 and cent2 are the centroids of the Cp rings attached to Mn1 and Mn2, respectively, and cent3 is the middle of the C4–C5 vector]. The angle between the plane containing the two alkyne carbon atoms and Mn2, and the plane of the carbene unit attached to Mn1 is 74.6°. The Mn1–C3 distance compares well with the Mn=C bond distance found in mononuclear non-heteroatom-substituted Mn carbene complexes.[6] The alkyne moiety is coordinated to Mn2 in an unsymmetrical fashion, whereby the Mn2–C4 and the Mn2–C5 distances represent, respectively, the longest and the shortest Mn–C bonds ever reported for an alkyne η²-coordinated to a $Cp(CO)_2Mn$ fragment.[7]

The variable-temperature $^{13}C\{^1H\}$ NMR spectra of **3a** are particularly informative. At 183 K, the spectrum is in full agreement with the X-ray crystal structure; in particular, the carbene carbon atom, C3, and two carbon atoms of the alkyne moiety, C4 and C5, are observed at δ 317.9, and 76.9 and 106.3,

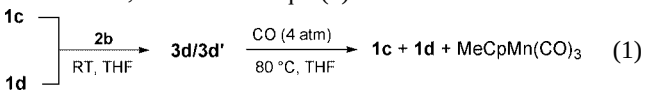
 DOI: 10.1039/b104712b

respectively. As a consequence of the lack of symmetry, the Cp rings appear as two sharp singlets at δ 91.9 and 85.9, the CO ligands give rise to four resonances at δ 235.6, 235.4, 232.6 and 231.4, and the signals due to each of the Ph rings are clearly differentiated. However, as the temperature is gradually raised, the signals for the two Cp rings coalesce (T_c = 213 K), as do the pairs of Ph ring absorptions as well as the four CO resonances. Over the same temperature range, the signals attributed to the C3 and C5 sites rapidly collapse, ultimately giving a barely observable broad resonance centred at δ 212 at 298 K. Clearly, the molecule executes a dynamic process that averages the two Mn environments. Additional spin saturation transfer experiments, performed at 188 K, confirmed the exchange between the C3 and C5 sites. In other words, the results indicate that equilibration of the [η^1-carbene] and the [η^2-alkyne] moieties in **3a** occurs readily on the NMR time-scale, as depicted in Scheme 1. The coalescence behaviour of the Cp ring resonances (both ^{13}C and ^{1}H) yields an activation energy barrier of 9.3 ± 0.5 kcal mol^{-1}.

The MeCp analogue, **3b**, behaved similarly, and the non-dissociative character of the exchange was established by a crossover experiment, whereby no trace of the mixed Cp/MeCp product was detected when **3a** and **3b** were mixed. In fact, the mixed Cp/MeCp complex can be obtained by reaction of *either* **1a** with **2b**, *or* **1b** with **2a**, as a mixture of interconverting isomers **3c**/**c′**, and this provides additional support for the equilibration process shown in Scheme 1.

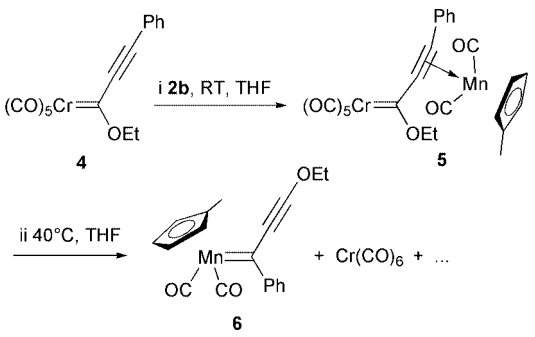
Likewise, complexes **3d**/**d′**, in which an η^3-PhCCCTol ligand bridges two MeCp(CO)$_2$Mn fragments, is preparable by reaction of *either* **1c** *or* **1d** with **2b**. Gratifyingly, subsequent reaction of **3d**/**d′** with carbon monoxide gave a 1 : 1 mixture of **1c** *and* **1d** through loss of the alkyne-bonded Mn fragment in each isomer, as shown in eqn. (1).



(1)

These observations raise the possibility of alkynylcarbene transfer from a metal fragment to an other one upon a bond shift isomerism within a transient bimetallic bridging η^3-alkynylcarbene complex. We now report that this can be realized in the case of (CO)$_5$Cr=C(OEt)C≡CPh **4**, for which treatment with **2b** yields MeCp(CO)$_2$Mn=C(Ph)C≡COEt **6**, through the intermediacy of **5** (Scheme 2). This rearrangement is readily accounted for by the same mechanism that gives rise to fluxionality in the **3**/**3′** system; the difference lies in the fact that the MeCp(CO)$_2$Mn=C linkage is favored over the (OC)$_5$Cr=C moiety, and that (OC)$_5$Cr[η^2-alkyne] complexes are unstable, thus rendering the isomerization irreversible.

This may also be relevant to the postulated alkynyl carbenoid rearrangement observed in the Rh(II)-catalysed cyclisation reaction of dialkynyl-substituted α-diazoketones, reported by Padwa *et al.*[8] Moreover, it is not inconceivable that the slow equilibrium between isomeric monometallic Re alkynylcarbene complexes briefly mentioned by Casey *et al.*[4] may be mediated by traces of a dirhenium complex analogous to the Mn systems described here.



Scheme 2

A more complete analysis of the transition state for these processes must await the full DFT study that is currently under way, however, the variable-temperature NMR data provide some insight. At the low-temperature limit, the ^{13}C spectrum of **3a** exhibits *four* different CO environments but, as the temperature is raised, these signals coalesce into a *single* peak. This implies that the molecule passes through a highly symmetrical conformation allowing the pairs of carbonyls bonded to each manganese to lose their diastereotopic character. Planar transition states of C_{2h} or C_{2v} symmetry, such as those shown below, in which the central carbon possesses carbene character with some stabilisation provided by the two manganese fragments, would be consistent with the NMR data. We favour the C_{2h} conformation on steric grounds, and hypothesize that the reaction proceeds by a stretching of the alkyne-bonded manganese fragment—evidenced by the elongated Mn2–C4 bond in the X-ray structure of **3a**—while the carbene-bonded Cp(CO)$_2$Mn unit approaches the central carbon atom. We emphasise, however, that unlike a conventional organic S_N2 process in which the incoming nucleophile and the leaving group maintain a rectilinear relationship, this process involves a quasi-helical, twisting motion since in the initial and final structures, the planes bisecting the Cp(CO)$_2$Mn fragments adopt mutually almost orthogonal orientations.

Ruthenium catalysed cross metathesis with fluorinated olefins

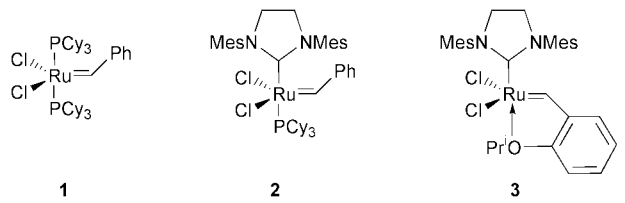
Sonia Imhof, Stefan Randl and Siegfried Blechert*

Institut für Chemie, Technische Universität Berlin, Strasse des 17. Juni 135, D-10623 Berlin, Germany. E-mail: Blechert@chem.tu-berlin.de

Received (in Cambridge, UK) 7th June 2001, Accepted 25th July 2001
First published as an Advance Article on the web 16th August 2001

The *E*-selective cross metathesis (CM) of fluorinated olefins with various functionalised alkenes in good to excellent yields is reported.

In the last decade ruthenium catalysed olefin metathesis has emerged as a powerful synthetic tool for the formation of carbon–carbon bonds.[1] There is growing interest in fluorinated molecules, with their particularly interesting chemical, biological and physical properties.[2] For instance, a high electronegativity together with an atomic size close to hydrogen have made these compounds useful components of both pharmaceuticals and agrochemicals. This, in addition to the selective solubilities of perfluorinated molecules and the advent of new possibilities with fluorinated phases,[3] encouraged us to prepare fluorine-substituted olefins *via* a CM methodology. There has been one report concerning this subject, however the yield of the cross product was modest.[4] Recently we have demonstrated[5,6] that reactivity and selectivity in Ru-catalysed CM reactions depend strongly on the electronic properties of both the ligand and Ru–carbene complex. In line with this earlier work, we



1 **2** **3**

Cy = cyclohexyl Mes = 2,4,6-trimethylphenyl

expected that phosphine-free catalyst **3**[6,7] would show superior activity and stability in CM reactions involving electron deficient fluoroalkenes than either **1** or **2**.[8]

Herein we report the CM of various functionalised olefins with 3,3,3-trifluoropropene **4**† and 3,3,4,4,5,5,6,6,6-nonafluorohexene **5**,‡ as models for molecules with varying degrees of fluorine substitution using catalysts **1**, **2** and **3**. Preliminary experiments using terminal olefins **6**–**12**[9] (Scheme 1) with up to five equivalents of **4** in a closed flask at 45 °C under atmospheric pressure, resulted in quantitative dimerisation of the more electron rich substrates. In order to suppress the dimerisation reaction in the presence of **4**, the flask was equipped with a balloon containing 10 equivalents of **4**. In the case of **5**, 10 equivalents of nonafluorohexene were used as a solvent to achieve good yields of the products **20**–**26**. It was found that α,α,α-trifluorotoluene could be used successfully as an additive to overcome the insolubility of **1**, **2** and **3** in **5**. Using **2**, best results were achieved stirring the reaction mixture at 60 °C for 4 h, whereas reactions catalysed by **3** gave higher yields of CM products under milder conditions (45 °C, 3 h). The results of these experiments are presented in Table 1.

Using substrates **6**–**10** with ester, carboxylic acid, ketone and hydroxy functionalities (Scheme 1), general conversions to CM products (**13**–**17** and **20**–**24**) and dimers were good to excellent. CM reactions with the fluoroolefin were generally favoured over dimerisation, except where the substrate contained a hydroxy group; this effect could be due to the poor solubility of these substrates in the fluorinated media. The nitrile derivatives **11** and **12**, which contain both electron deficient and relatively electron rich terminal double bonds, were chosen to investigate chemoselectivity. Irrespective of the catalyst, fluoroalkene substrates or reaction conditions, the nitrile derivatives with an unprotected hydroxy group were not converted to CM products, giving only starting materials in all cases. The corresponding acetylated derivatives **11** and **12** gave good to excellent conversions, however **11** showed disappointing yields of CM products (**18**, **25**) due to competitive ring-closing metathesis (RCM), giving a ratio of about 50% of RCM in three cases and 6% of RCM using the combination of catalyst **2** and fluorinated olefin **5**. In the case of the larger homologue **12**, formation of the eleven membered RCM product is unfavourable, and hence

 DOI: 10.1039/b105031c

higher yields of the CM products **19** and **26** could be obtained.

These CM reactions proved to be chemoselective, *i.e.* only coupling between the fluorinated olefins and the more electron rich, monosubstituted double bond was observed in all cases.

No difference in reactivity or selectivity was found when the fluoroolefin was varied from **4** to **5**, with the exception of when **10** was used as the CM partner. In this case the poor solubility of **10** in **5** (also observed with the unprotected forms of **11** and **12)** possibly explains the lack of activity with this substrate.

Consistent with our earlier findings,[6] **3** gave superior conversions and higher yields of CM products than **2**. Bisphosphine complex **1** proved inactive in these systems, giving neither CM nor dimerisation products regardless of the reaction conditions.

CM processes are generally known to exhibit a moderate *E*-selectivity,[10] favoured when the substrates contain bulky substituents.[4] We found that all CM products (**13**–**26**) had an *E*/Z ratio of $\geqslant 20:1$. The stereoselectivity of fluorinated olefins with a variety of functionalised alkenes should further increase the synthetic utility of this reaction.

In summary, we have shown that stereoselective CM reactions between **4** and **5** with a variety of alkenes are possible in good yields. With the exception of hydroxy substrates, catalysts **2** and **3** both gave good conversions to CM, dimerisation and RCM products, whereas **1** proved unsuitable for these purposes. Product ratio analyses show that **3** is a better catalyst for CM than **2** in this system.[6]

Further studies in the use of selective CM reactions are underway in our laboratories. The results of these investigations will be reported in due course.

Support for this work from the 'Freiwillige Akademische Gesellschaft, Basel' (S. I.) and the 'Graduiertenkolleg: Synthetische, mechanistische und reaktions-technische Aspekte von Metallkatalysatoren of the TU Berlin' (S. R.) is gratefully acknowledged. We would also like to thank Dr S. Connon for useful comments and suggestions.

Notes and references

† Procedure for CM reactions with **4** and **2** or **3**: to a solution (0.05 M) of **6** (78 mg, 0.410 mmol) and catalyst **3** (12.6 mg, 5 mol%) in trifluorotoluene (10 mL) under N_2 was added gaseous **4** (100 mL, 4.46 mmol) *via* a needle, the atmosphere being maintained by a balloon. The resulting solution was stirred at 45 °C for 3 h (60 °C for 4 h for **2**). Removal of the solvent *in vacuo* gave a brown oil which could be purified by flash chromatography (hexane–EtOAc).

‡ Procedure for CM reactions with **5** and **2** or **3**: to a mixture of **6** (80 mg, 0.420 mmol) and **5** (1.033 g, 4.200 mmol) was added catalyst **3** (12.9 mg, 10 mol%) in trifluorotoluene (61.3 mg, 0.420 mmol) under N_2. The resulting solution was stirred at 45 °C for 3 h (60 °C for 4 h for **2**). Removal of the solvent *in vacuo* gave a brown oil which could be purified by flash chromatography (hexane–EtOAc). The excess of **5** could be recovered by distillation.

Received (in Cambridge, UK) 17th January 2001, Accepted 6th July 2001
First published as an Advance Article on the web 15th August 2001

Poly(acrylic acid-*co*-methyl methacrylate)–cetyltrimethylammonium bromide (P(AA-*co*-MMA)–C_{16}TAB) complex has shape memory behavior due to the formation of crystalline aggregates among the long alkyl chains of C_{16}TAB in the complex, and can be regarded as a novel shape memory network.

During recent years, shape memory materials have received increasing attention on account of their interesting properties and potential applications, especially thermally stimulated shape memory materials.[1–3] The mechanism of shape memory behavior with temperature can be schemed briefly as outlined below where L is the initial state of material and L′ is the

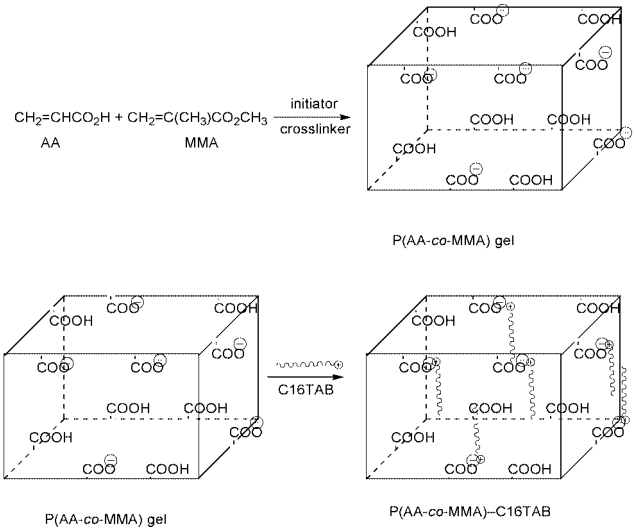
$$\mathrm{L}\xrightarrow[\text{deformation}]{T > T_g \text{ or } T > T_m}\mathrm{L}+\mathrm{L}'\xrightarrow[\text{fixation}]{T < T_g \text{ or } T < T_m}\mathrm{L}+\mathrm{L}'\xrightarrow[\text{recovery}]{T > T_g \text{ or } T > T_m}$$

deformation of material. These materials have a two phase structure, namely, the fixing phase remembers the initial shape and the reversible phase shows a reversible soft and rigid transition with temperature. Based on this principle, some polymers were discovered that had shape memory behavior.[4–9]

Among shape memory materials, copolymer networks[6,7] containing long alkyl side chains were reported due to a reversible order–disorder transition of long alkyl side chains. Below the transition temperature, these side chains form a crystalline aggregate structure, and behave as hard plastic. While above this temperature they transfer to the amorphous state and the material abruptly becomes soft and flexible.

It is well known that many beneficial properties of polyelectrolyte–surfactant complexes[10,11] result from the highly ordered structures[12–14] formed by the self-assembly of surfactant molecules inside the complexes. The supermolecular formation was driven by both electrostatic interactions between charged components and hydrophobic interactions between the polymer backbones and the surfactant alkyl chains.

The research works mentioned above served as a great source of inspiration to us in designing the polyelectrolyte network–surfactant complexes for shape memory networks. Up to now, any similiar research work has not been reported. Hence the polyelectrolyte network–surfactant complexes may broaden the list of shape memory polymers. In this paper, we synthesized poly[(acrylic acid)-*co*-(methyl methacrylate)] (P(AA-*co*-MMA)) networks and the complex of P(AA-*co*-MMA)–(cetyltrimethylammonium bromide) (P(AA-*co*-MMA)–C_{16}TAB). The composition and the structure of the network and complex were characterized. And the surface microstructure before and after deformation was also studied.



Scheme 1 Synthesis of P(AA-*co*-MMA)–C_{16}TAB complex.

Scheme 1 shows the synthesis and the expected structure of P(AA-*co*-MMA)–C_{16}TAB. The crosslinked P(AA-*co*-MMA) network was designed as the fixed phase, while C_{16}TAB was designed as the reversible phase for shape memory networks. Fig. 1 is the FTIR spectra of P(AA-*co*-MMA) before and after complexation with C_{16}TAB. The curves of P(AA-*co*-MMA) and P(AA-*co*-MMA)–C_{16}TAB both give a wide peak from 3100 to 3600 cm^{-1} indicating the stretching of –OH groups of polyacrylic acid (PAA). The relative intensity of the peak at 2955 cm^{-1} due to the stretching of the $-CH_2$ groups of P(AA-*co*-MMA)–C_{16}TAB is slightly higher than that of P(AA-*co*-

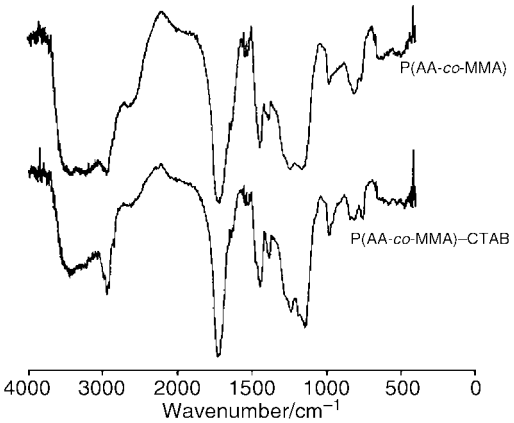


Fig. 1 FTIR spectra of P(AA-*co*-MMA) and P(AA-*co*-MMA)–C_{16}TAB complex.

 DOI: 10.1039/b100625h

MMA). Comparing the C or H content between P(AA-*co*-MMA) and P(AA-*co*-MMA)–C_{16}TAB, the C_{16}TAB : AA ratio can be calculated from eqn. (1) where n_{CTAB} and n_{AA} is the mole content of C_{16}TAB and AA in the complex, respectively.

$$n_{CTAB}/n_{AA} = 0.432 \times [(\%_{complex} - \%_{P(AA\text{-}co\text{-}MMA)})/(\%_{CTAB} - \%_{complex})] \times 100\% \quad (1)$$

$\%_{complex}$, $\%_{P(AA\text{-}co\text{-}MMA)}$ and $\%_{CTAB}$ are the C or H content of P(AA-*co*-MMA)–C_{16}TAB, P(AA-*co*-MMA) and C_{16}TAB, respectively. The calculated value of n_{CTAB}/n_{AA} was 15.4%, which is higher than the pK_a of the PAA segment which is *ca.* 5.[15] Hence, the complexation of C_{16}TAB with P(AA-*co*-MMA) was driven not only by electrostatic interactions but hydrophobic interactions among long alkyl chains of C_{16}TAB and between C_{16}TAB and polymer chains of the network.

The most important key to a shape memory network for P(AA-*co*-MMA)–C_{16}TAB is whether the long alkyl chain of C_{16}TAB could form a highly ordered structure or crystalline phase in the P(AA-*co*-MMA) network. Table 1 gives the DSC data for P(AA-*co*-MMA) and P(AA-*co*-MMA)–C_{16}TAB. A glass transition temperature (T_g) attributed to the PAA segment was obtained for both the polymer network and complex. A melting point (T_m) and crystalline point (T_c) was found only in complex. These facts mean the long alkyl side chains of C_{16}TAB form a crystalline phase in P(AA-*co*-MMA)–C_{16}TAB. This is the necessary condition for P(AA-*co*-MMA)–C_{16}TAB to adopt a shape memory network.

The T_g should be greater than or equal to the melting point of P(AA-*co*-MMA)–C_{16}TAB, 98.26 °C. Hence, 100 °C was chosen to observe the deformation and recovery of the complex. Fig. 2 shows the shape memory phenomenon of P(AA-*co*-MMA)–C_{16}TAB. The straight strip sample was heated to 100 °C, deformed as an 'e' shape and then cooled to rt. The complex is rigid and retains the 'e' shape. On heating again to 100 °C, the complex becomes soft and recovers it's original strip shape. This phenomenon may be attributed to the formation of crystalline aggregates among the long alkyl chains of C_{16}TAB in the complex that locks the new shape. When the deformed complex is heated again above T_g, the crystalline aggregates become amorphous and the complex recovers its original size and shape.

In order to give further support for the shape memory behavior of P(AA-*co*-MMA)–C_{16}TAB, the surface variation of P(AA-*co*-MMA) and P(AA-*co*-MMA)–C_{16}TAB before and after deformation were also observed on an optic microscope and recorded by a PC digital camera. Fig. 3 shows the microphotographs of P(AA-*co*-MMA) and P(AA-*co*-MMA)–C_{16}TAB under different conditions. The initial surface of P(AA-*co*-MMA)–C_{16}TAB is rougher than that of P(AA-*co*-MMA). Those concavo-convex flecks on the surface of P(AA-*co*-MMA)-C_{16}TAB are due to the shrinkage caused by the complexation of P(AA-*co*-MMA) with C_{16}TAB. The surface of P(AA-*co*-MMA) after deformation shows many tiny streaks, while the surface of P(AA-*co*-MMA)-C_{16}TAB shows the extension flecks along the tensile direction. The surface of P(AA-*co*-MMA) is significantly different after recovery from the initial state, which means P(AA-*co*-MMA) cannot recover its initial microstructure. In contrast, the surface of P(AA-*co*-MMA)–C_{16}TAB is very similiar in both the initial and recovery states. In other words, the complex can recover its initial microstructure. The recovery ratio is about 85%, calculated from the difference in length of the test sample in the initial and recovered states.

Table 1 DSC data of P(AA-*co*-MMA) and P(AA-*co*-MMA)–C_{16}TAB

Sample	T_m[a]/°C	T_c[b]/°C	T_g[c]/°C
P(AA-*co*-MMA)	—	—	115.54
P(AA-*co*-MMA)–C_{16}TAB	98.26	68.98	128.12

[a] Melting point. [b] Crystalline point. [c] Glass transition temperature.

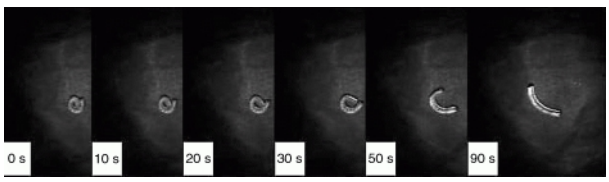

Fig. 2 Shape memory phenomenon of P(AA-*co*-MMA)–C_{16}TAB. (The initial straight stripe was heated to 100 °C and deformed as an 'e' alphabet, then cooled to room temperature under constrained conditions. After withdrawal of the external force, the 'e' shape sample was put into a glass container and kept at a constant temperature of 100 °C. At the same time the snapshot was captured by a digital camera every 2 s.)

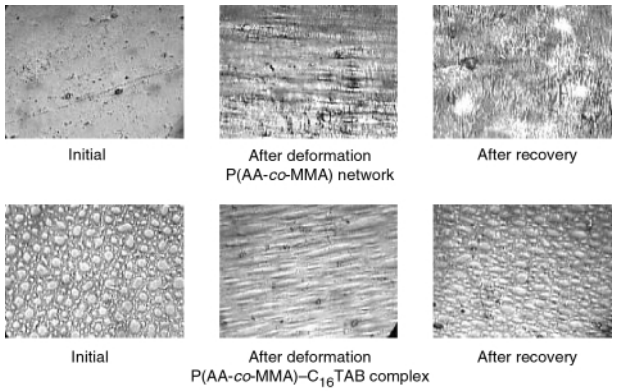

Fig. 3 Microphotographs of the surface of (a) P(AA-*co*-MMA) and (b) P(AA-*co*-MMA)–C_{16}TAB under different conditions at rt. (The enlargement multiple was 160. Initial: initial state of sample. After deformation: sample were drawn at 100 °C under a constant tensile force of 0.05 N until the elongation rate was 150% and then cooled to room temperature. After recovery: samples after deformation were heated to 100 °C and kept at constant temperature for 30 min, then cooled to room temperature.)

In conclusion, although the reversible temperature is high, 100 °C, and the recovery ratio is not 100%, the shape memory phenomenon of P(AA-*co*-MMA)–C_{16}TAB shows that the well designed polyelectrolyte network–surfactant complex can be considered as a kind of novel shape memory network.

Nafion-H catalysed sulfonylation of aromatics with arene/alkenesulfonic acids for the preparation of sulfones[1a]†

George A. Olah,* Thomas Mathew and G. K. Surya Prakash*

Loker Hydrocarbon Research Institute and Department of Chemistry, University of Southern California, Los Angeles, CA 90089-1661, USA

Received (in Corvallis, OR, USA) 21st May 2001, Accepted 17th July 2001
First published as an Advance Article on the web 16th August 2001

Synthesis of both symmetric and unsymmetric diaryl/aryl alkyl sulfones is easily achieved by Friedel–Crafts type sulfonylation of aromatics with suitable arene- or alkanesulfonic acids in the presence of Nafion-H, a perfluorinated resinsulfonic acid catalyst.

The wide use of organosulfones as very versatile synthons in organic synthesis is well known for the past few decades.[1b–d]

Scheme 1

Diaryl sulfones are important drugs active against malaria, leishmaniasis, infections in patients with AIDS and discoid lupus erythematosus.[2–4] Various methods for the synthesis of sulfones involve the conventional Friedel–Crafts type sulfonylation of aromatics using sulfonyl halides,[5] oxidation of the corresponding sulfides,[6] reactions of sulfonyl fluorides with organolithium compounds or Grignard reagents,[7] *etc*. Recently, effective synthesis of sulfones from aryl trifluoromethyl sulfone using Grignard reagents and sulfonyl halides and anhydrides using metal triflates and zeolites as catalysts[8] have been reported. Thus far no convenient synthetic method is available for the synthesis of sulfones using sulfonic acids directly.

In this communication, we would like to report an efficient preparation of aromatic sulfones directly from arene- or

Table 1 Nafion-H catalysed sulfonylation of aromatics using sulfonic acids

Sulfonic acid	Substrate	Time/h	Yield (%)	Sulfone
	Benzene	20	48		Toluene	20	52		p-Xylene	16	82		m-Xylene	16	80		Chlorobenzene	20	52		Benzene	20	50		Toluene	20	57		p-Xylene	8	78		m-Xylene	8	70		Chlorobenzene	20	55	CH_3SO_3H	*p*-Xylene	8	30	
 DOI: 10.1039/b104603a

alkenesulfonic acids with the use of Nafion-H, a solid perfluorinated resinsulfonic acid polymer as a catalyst. We have previously found that Friedel–Crafts type intramolecular acylation with suitably *ortho* substituted benzoic acids in the presence of Nafion-H affords ketones in good yields.[9] Nafion membranes have also been found to allow permeation of sulfonating reagents such as SO_3 and 20% oleum during sulfonation reactions.[10] Preparation of aromatic symmetric and unsymmetric sulfones could be achieved in good yields (30–80%) by intermolecular Friedel–Crafts type sulfonylation of arenes with suitable sulfonic acids (Scheme 1).

Nafion-H has been found to be a suitable solid acid catalyst with high selectivity and catalytic activity giving good yields of sulfones. The reaction with the use of Nafion-H conveniently eliminates the use of volatile or noxious reagents. After the reactions with Nafion-H, the catalyst is easily regenerated.[11] This solid resin catalyst is more convenient and environmentally friendly in comparison with corrosive acid catalysts (liquid acids) generally used in reactions involving strong acids.

The sulfonylation reactions were carried out by refluxing a stirred mixture of the corresponding arene- or alkanesulfonic acid and excess arene in the presence of the solid Nafion-H catalyst. The arenes act as both the substrate and the solvent. The products were isolated after filtering the reaction mixture and distilling off the excess arene.[12]

The sulfonylation reactions are general for sulfonic acids such as benzenesulfonic acid, toluenesulfonic acid and methanesulfonic acid. Activated aromatics such as *p*-xylene and *m*-xylene afforded the corresponding sulfones in good yields (~ 80%). The yield of the corresponding sulfones from benzene and toluene were, however, low (5–15%) due to the insufficient activation of Nafion-H under the used relatively mild refluxing conditions. On the other hand, when the reactions with benzene and toluene were conducted under pressure at 160–165 °C, the product yields increased considerably (48–57%). Along with the product and the unreacted starting material, minor amounts of side products due to alkylation and dealkylation were also observed.

Azeotropic removal of water using a Dean–Stark trap increases the yields. As shown in Table 1, the present method provides an easy approach to sulfones with no undesired side products. Sulfonylation of toluene and chlorobenzene, afforded *para* substituted sulfones as the major product indicating a typical electrophilic aromatic sulfonylation. The method developed is simple, uses readily available arene- or alkanesulfonic acids instead of sulfonyl halides, anhydrides, *etc.*, used in Friedel–Crafts reactions. The substitution of the typical Friedel–Crafts type catalyst with this resin and its convenient regeneration bodes well for the protocol and its overall applicability.

Support of our work by Loker Hydrocarbon Research Institute is gratefully acknowledged.

12 Typical sulfonylation procedure is as follows: to a solution of dry benzenesulfonic acid (790 mg, 5.0 mmol) in dry *p*-xylene (40 mL), Nafion-H (400 mg, 50 wt%) was added and stirred. The flask was fitted with a Dean–Stark trap and the solution was refluxed continuously with stirring for 16 hours (water formed during the reaction was removed completely by introducing dry molecular sieves, ≈2.0 g, in the trap). The reaction mixture was filtered and washed with 10% $NaHCO_3$ solution to remove any amount of unreacted sulfonic acid. After washing with water and drying with anhydrous Na_2SO_4, excess *p*-xylene was distilled off and the residue was recrystallized from a mixture of dichloromethane and *n*-hexane (1:2) to afford 2,5-dimethylphenyl phenyl sulfone as a white crystalline solid, (1.0 g, 82%) mp 101–103 °C.

Lanthanide triflate-catalyzed three component synthesis of α-amino phosphonates in ionic liquids. A catalyst reactivity and reusability study

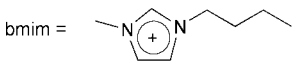
Sang-gi Lee,*[a] Jung Hwan Park,[a] Jahyo Kang[b] and Jae Kyun Lee[a]

[a] *Life Sciences Division, Korea Institute of Science and Technology, PO Box 131, Cheongryang, Seoul 130-650, Korea. E-mail: sanggi@kist.re.kr*
[b] *Department of Chemistry, Sogang University, Seoul 121-742, Korea*

Received (in Cambridge, UK) 5th June 2001, Accepted 24th July 2001
First published as an Advance Article on the web 9th August 2001

The catalyst reactivity and reusability for the lanthanide triflate-catalyzed three component synthesis of α-amino phosphonates have been examined in room temperature ionic liquids, [bmim][X], in which the catalytic activities were very dependent on the counter anion, X, as well as on the phosphorus nucleophile, and moreover, the catalyst immobilized in an ionic liquid was reused several times without any loss of activity.

The use of environmentally benign reaction media is very important in view of today's environmentally conscious attitude. In connection with this, room temperature ionic liquids that are air and moisture stable have received a good deal of attention in recent years as novel solvent systems for organic synthesis. A number of reactions such as Friedel–Crafts reactions, Diels–Alder cycloadditions, hydrogenation, and Heck reactions have employed ionic liquids as solvents.[1] More recently they have been introduced in halogenations of alkenes and alkynes[2] and in asymmetric epoxidation[3] and asymmetric hydrogenations.[4] Here we report lanthanide triflate-catalyzed three component reactions in room temperature ionic liquids, [bmim][X], to give α-amino phosphonates.



X = PF_6^-, SbF_6^-, BF_4^-, OTf^-

α-Amino phosphonates are an important class of compounds in modern pharmaceutical chemistry. Consequently, their synthesis has received an increasing amount of attention.[5] It has been recently reported that ytterbium triflates[6] and indium trichloride[7] are effective catalysts for three component reactions of aldehydes, amines, and diethyl phosphonate in organic solvents to give α-amino phosphonates. Kobayashi discovered that similar three component reactions using triethyl phosphite were also efficiently promoted by a catalytic amount of scandium-surfactant-combined catalysts in water to give α-amino phosphonates.[8] To examine the catalytic activities of lanthanide triflates as well as indium trichloride in ionic liquids, we carried out the three component reactions of benzaldehyde, aniline and diethyl phosphonate, $HP(O)(OEt)_2$, in the presence of 10 mol% of catalyst at 20 °C for 27 h. The results are summarized in Table 1.†

It has been found that, using anhydrous lanthanide triflates as catalysts, the reactions in [bmim][PF_6] proceeded highly efficiently (entries 1–4 in Table 1). Among the anhydrous lanthanide triflates catalysts, $Sm(OTf)_3$ is superior to other catalysts in an ionic liquid (entry 4 in Table 1) whereas $Yb(OTf)_3$ is more effective in an organic solvent.[6] More interestingly, although it has been known that the lanthanide triflates are generally stable and function well in water,[9] the yields decreased greatly with hydrated catalysts, $Yb(OTf)_3{\cdot}H_2O$ (entry 5 in Table 1) and $La(OTf)_3{\cdot}H_2O$ (entry 6 in Table 1). The catalytic activity of $Sm(OTf)_3$ was retained even at 1 mol% (95%, entry 7 in Table 1). However, the activity of the recovered catalyst immobilized in ionic liquid decreased (74%, entry 8 in Table 1) which may be due to water generated during

the reaction. The counter anion of the ionic liquids affected the catalytic activity considerably (entries 9–11), thus, only 18% of product was obtained upon using BF_4 anion (entry 10 in Table 1). By employing indium trichloride as a catalyst in [bmim][PF_6], the reaction also proceeded efficiently (entry 12 in Table 1). However, the reaction in dichloromethane solvent using $Sm(OTf)_3$ afforded product only in 70% yield (entry 13 in Table 1).

We expected that employing triethyl phosphite, $P(OEt)_3$, as a phosphorus nucleophile could overcome the drawback of catalyst recycling in the three component reactions. Mechanistically, the water generated during formation of imine could be used for the hydrolysis of phosphonium intermediate[10] to give α-amino phosphonates and EtOH as shown in Scheme 1.

The use of $P(OEt)_3$ instead of $HP(O)(OEt)_2$ changed the catalytic activities of the lanthanide triflates. In this reaction system, $Sc(OTf)_3$ exhibited the highest catalytic activity (97%, entry 1 in Table 2), and the reaction was completed within 2 h. The $Sc(OTf)_3$ can be used five times without any loss of catalytic activity (entry 1 in Table 2). In second cycle reactions, as we expected, the catalytic activities of the recovered catalysts except $InCl_3$ (entry 5 in Table 2) were almost retained.

The three component reactions of various aldehydes and aniline with $P(OEt)_3$ in the presence of 1 mol% $Sc(OTf)_3$ in ionic liquid, [bmim][PF_6], gave the corresponding α-amino phosphonates in excellent yields as shown in Table 3.

In summary, the catalytic activities of various lanthanide triflates as well as indium trichloride were examined for the three component reactions of aldehydes, amines and phosphorus nuleophiles, $HP(O)(OEt)_2$ and $P(OEt)_3$, in room temperature ionic liquids. The catalytic activities were very dependent on the counter anion, X, as well as on the phosphorus nucleophile. The catalysts immobilized on ionic liquid can be reused several times without any loss of activity.

Notes and references

† *General procedure for the three component reactions and catalyst recycling*: aniline (0.25 mmol), an aldehyde (0.25 mmol) and a phosphorus nucleophile, $HP(O)(OEt)_2$ (1 mmol) or $P(OEt)_3$ (1 mmol), were successively added to a solution of catalyst (0.25×10^{-2} mmol) in an ionic liquid (1 mL) at 20 °C. The mixture was stirred at the same temperature for 27 h for $HP(O)(OEt)_2$ or 2 h for $P(OEt)_3$. The mixture was extracted with benzene (4 mL × 5) and concentrated. Purification by silica gel chromatography afforded the desired product. More reactants (aldehyde, aniline and $P(OEt)_3$) were added to the ionic liquid solution remaining in the vessel. This was the start of the second cycle.

A crucial factor in realising a green chemical process in solution involves the choice of a safe, non-toxic and cheap solvent. Water is the obvious choice. Despite solubility problems, considerable interest has developed recently in organic chemistry in water. This interest also results from the fact that association and chemical reactions often benefit noticeably from the special properties of water, resulting mainly from its small molecular size, its three-dimensional hydrogen-bond network and hydrophobic interactions which are so unique for liquid water. Here we discuss organic reactions and assembly processes in water, largely taken from experiments performed in the authors' laboratories. We show that non-covalent interactions in water can be utilised for fine tuning organic reactions in aqueous media.

Introduction

For a very long time, water has been recognised as essential for all life processes and indeed life support on planet Earth. For example, at the dawn of western scientific thought, Thales (from Milete, B.C. 640–548) said: '*All things are produced from water*'. This statement was one of the first attempts to formulate a generalisation; *i.e.* referring all things to a common origin. In ancient Chinese thought, water was frequently used as a root metaphor for natural and civilised behaviour.[1] K'ung Tzu said: '*Water, which extends everywhere and gives everything life without acting (wuwei) is like virtue (de) . . . That is the reason that when a gentleman (junzi) sees a great river, he will always look upon it . . .*'

In all major religions and philosophies, water plays an important role. In chemical research, a long-standing interest exists in the properties of water[2,3] and in chemical reactions between solutes taking place in this fascinating liquid. However, water is rarely seen as the solvent of choice in which to carry out synthetic chemistry. In this review we illustrate some of the key features involved in understanding the role of solvent water for chemical reactions involving small molecules and then for processes involving larger molecules and large molecular assemblies including micelles and vesicles. We emphasise that water is not just a 'green' solvent, but that the special properties of the liquid give rise to intra- and intermolecular non-covalent interactions leading to novel solvation behaviour and assembly processes.

Professor Jan B. F. N. Engberts graduated with a PhD degree from the University of Groningen, The Netherlands (1967). After a stay at the University of Amsterdam with Prof. Th. J. de Boer (ESR spectroscopy) Jan returned to Groningen and was appointed as a Professor of General Chemistry in 1978 and as a Professor of Physical Organic Chemistry in 1991. Fascinated by the peculiar properties of water as a medium for organic reactions and aggregation processes, much emphasis has been placed on hydrolysis reactions in water in the presence of hydrophobic addenda, surfactant aggregation, vesicle fusion, and, most recently, development of DNA carrier systems for application in gene therapy. In these studies, thermodynamics always played an important role, and these interests brought Mike and Jan together, more years ago than both care to remember.

Professor Mike Blandamer is an Emeritus Professor at the University of Leicester, having retired in 1999. Mike graduated with BSc and PhD degrees from the University of Southampton who awarded Mike the degree of DSc in 1984. Following post-doctoral research at NRC in Ottawa (Canada), Mike joined the staff at the University of Leicester. Mike and Jan share a common interest in aqueous solution chemistry, good food, good wine and New Orleans jazz music. They were coauthors on a paper published in 1985 followed over 26 years by 50 joint papers and reviews. For part of their period of cooperation, Mike was a Visiting Professor at the University of Groningen.

Aqueous solutions: general features

Introductory chemistry textbooks reviewing the properties of water stress the importance of intermolecular hydrogen bonding, leading to the conclusion that water is an associated liquid. The high relative permittivity is consistent with the idea that water is a polar liquid and therefore a good solvent for salts such as sodium chloride. $E(T)$30-values, as defined by Reichardt, which are particularly useful microscopic solvent micropolarity reporter values, confirm that water is a polar solvent.[4] The absence of strong ion-pairing in aqueous solution allows unambiguous mechanistic studies of reactions that proceed *via* highly polar or ionic intermediates. We also note that water has one of the highest heat capacities per unit volume for a liquid; *e.g.* for water, C_p = 4.18 J K^{-1} cm^{-3}; for ethanol C_p = 1.92 J K^{-1} cm^{-3}. This high heat capacity is important in moderating possible extremes of temperature on planet Earth.

This emphasis on molecular association should be set against the fact that water has a modest (shear) viscosity; the liquid pours easily, quite different from, say, glycerol.

Granted the properties of water, including its volumetric properties (*e.g.* a temperature of maximum density near 277 K) are complicated, the expectation is that the properties of aqueous solutions are also complicated. This is indeed the case. Nevertheless important features of water and aqueous solutions can be understood in the following general terms.[2]

A cluster of non-intermolecularly hydrogen bonded, but closely packed water molecules has high density–low molar volume coupled with weak cohesion. A cluster of inter-

molecularly hydrogen-bonded water molecules has low density–large molar volume with strong cohesion. In other words, strong cohesion is coupled with large molar volume. The latter is a consequence of the structural requirements of hydrogen bond formation which for a simple dimer has a *trans*-near linear configuration. To an important extent hydrogen bonding is both cohesive and repulsive, the latter reflecting the tendency to hold apart the centres of mass of water molecules. This situation is reflected in the low internal pressure of water.[5] In the context of describing the properties of aqueous solutions, we might speculate that any process (*e.g.* chemical reaction) which enhances water–water hydrogen bonding leads to an increase in molar volume. This rather unusual situation (compared to organic solvents) accounts in part for the complexity of the properties of aqueous solutions.

Experimental

This review focuses on the results obtained in the laboratories of the two authors using two major experimental techniques: (i) chemical kinetics, and (ii) titration microcalorimetry.

Determination of rate constants for chemical reactions in aqueous solutions using spectrophotometric techniques is considerably helped by computer-based data capture and data analysis programs, coupled with good thermostatting of solutions. In recently published kinetic studies from Groningen we routinely monitor chemical reactions for up to six half-lives leading to rate constants having standard errors of better than 1%. This precision is important in the determination of standard enthalpies ($\Delta^{\ddagger}H^0$) and entropies ($\Delta^{\ddagger}S^0$) of activation as defined by Eyring transition-state theory.

Titration microcalorimetry[6] has proved an extremely important technique particularly in the context of our investigations into the properties of surfactants in aqueous solutions. In this technique (see Fig. 1 of ref. 7) a micro-syringe under computer control injects at pre-selected time intervals a small volume (*e.g.* 5×10^{-6} dm^3) of an aqueous solution into another aqueous solution held in the sample cell, volume *ca.* 1.5 cm^3. A reference cell for the systems discussed here contains water. The reference cell is heated, raising the temperature very slowly. The computer-based control system monitors the temperature of reference and sample cells, adjusting the power to heaters of both sample and reference cells in order to hold the two cells at the same temperature. The recorded quantity is the rate of heating of the sample cell over the time required to bring both sample and reference cells on to the same temperature ramp. In effect the outcome is a plot of the ratio $(q/\delta n_j^0)$ {where heat q results from adding δn_j^0 moles of chemical substance j to the solution in the sample cell} against either injection number or concentration of chemical substance j in the sample cell.

The thermodynamic analysis is based on the following set of equations. The extensive state variable enthalpy H for a closed system is defined by the three independent variables, T, p, ξ where ξ describes the composition of the system. Thus,

$$H = H[T,p,\xi] \tag{1}$$

The complete differential of eqn. (1) yields an equation for the change in enthalpy; eqn. (2)

$$\mathrm{d}H = \left(\frac{\partial H}{\partial T}\right)_{p,\xi} \cdot \mathrm{d}T + \left(\frac{\partial H}{\partial p}\right)_{T,\xi} \cdot \mathrm{d}p + \left(\frac{\partial H}{\partial \xi}\right)_{T,p} \cdot \mathrm{d}\xi \tag{2}$$

Then at constant temperature and pressure the heat q recorded by the calorimeter between injection numbers I and $(I+1)$ following injection of δn_j^0 moles of chemical substance j at injection number I is given by eqn. (3).

$$\left[\frac{q}{\delta n_j^0}\right]_I^{I+1} = \left[\left(\frac{\partial H}{\partial \xi}\right)_{T,p} \cdot \frac{\delta \xi}{\delta n_j^0}\right]_I^{I+1} \tag{3}$$

The left-hand side of eqn. (3) is the measured quantity recorded as a function of injection number. Eqn. (3) shows that the measured ratio $(q/\delta n_j^0)$ is given by the product of two terms which are not known *a priori*. We indicate below some important cases where analysis of the thermodynamic properties of the solutions in the sample cells and injected aliquots yields important information concerning a given system, *e.g.* micelle formation.[7] The thermodynamic properties commented on in this review are Gibbsian[8] in that they are generated by differentials of Gibbs energies with respect to the variables T and p.

Aqueous solutions: general properties

Enderby and coworkers[9] using neutron inelastic scattering techniques have published detailed information for the structures of hydrated metal cations and halide ions in aqueous solutions. For cations, the results are in line with the structures predicted on the basis of secondary evidence; *e.g.* ionic mobilities. Thus for Ni^{2+}, the oxygen atom is adjacent to the cation but the $Ni^{2+}\cdots$O–D(H) angle is less than 2π; the water molecules undergo a wagging motion.

For many years there was intense speculation concerning the arrangement of water molecules around, for example, chloride ions. Two models were often proposed; (i) a bifurcated structure such that the water dipole moment is co-linear with the centre of the anion, and (ii) a linear structure for $Cl^-\cdots$H–O(H). The latter turns out to be the favoured structure. However, the systems are quite dynamic in that water molecules in the primary hydration sheath exchange with water molecules in the bulk solvent although the hydrogen-bond dynamics of water molecules in the hydration shell are slow compared to those for pure water.[10]

Again the fact that water is a polar liquid is often stated to account for the fact that apolar molecules such as rare gases and hydrocarbons are sparingly soluble in water. Even here complexities emerge. The solubilities of argon, methane, ethane and butane in cold water are higher than predicted on the basis of the cohesive energy density of water.[11] For almost 50 years the low solubilities of apolar solutes in water were attributed to the loss of entropy by the solvent accompanying enhancement of water–water hydrogen bonding.[12] The structures of solid clathrate hydrates were taken as models for the H-bond structure of water around apolar solutes.

In general terms the standard enthalpy of solution for neutral solute j (*i.e.* gas phase to solution) $\Delta_{\mathrm{sln}}H^0$ is negative (*i.e.* exothermic). But the solution process is dominated by a negative $\Delta_{\mathrm{sln}}S^0$ such that $\Delta_{\mathrm{sln}}G^0 > 0$ where $\left|T\Delta_{\mathrm{sln}}S^0\right| > \left|\Delta_{\mathrm{sln}}H^0\right|$. Interestingly, thermodynamic parameters such as limiting isobaric heat capacities C_{pj}^{∞}(aq) and limiting partial molar volumes V_j^{∞}(aq) for neutral solute j in aqueous solution can be expressed in terms of group contributions, a form of analysis which seemed to support the clathrate hydrate model.[13] A similar clathrate model[14] was advanced for the hydration of alkylammonium salts, $R_4N^+X^-$.

Serious doubt was thrown on the clathrate model (and the general concept of structure making) for hydration of apolar solutes (including alkylammonium salts) by the results of neutron inelastic experiments. Neutron diffraction data for $(CH_3)_4N^+Cl^-$ in aqueous solution show no evidence for enhancement of water–water interactions over that in pure water.[15] The negative entropy change for dissolution of apolar gases apparently arises largely from a pronounced preference for tangentially oriented water O–H groups with respect to the apolar solute rather than from more or stronger H-bonds in the hydrophobic hydration shell. Apart from neutron scattering, supporting evidence comes from MD computer simulations,[16] thermodynamic analyses,[17a] and quantum chemical calculations.[17b] However, 'whether or not the H-bond structure in the

hydrophobic hydration shell is significantly different from that in water?' is a question still not fully answered.[18]

Analysis of the properties of polyfunctional solutes in aqueous solution is not straightforward. In the case of, for example, monosaccharides account must be taken of the possible multitude of conformations for these solutes. Such is the complexity that it is difficult to formulate general rules although we return in a later section to these systems. Similar complexities emerge in the case of aqueous solutions containing proteins.[19]

Intermolecular interactions in water

The properties of aqueous solutions reflect both (i) solute–water interactions, and (ii) solute–solute interactions. Certainly for concentrated solutions the two sets of interactions cannot be considered independent.

In the context of understanding solute–solute interactions the simple calculation described by Robinson and Stokes[20] has considerable merit leading to intermolecular solute–solute centre-to-centre distances d as a function of solute concentration, c_j; eqns. (4) and (5), where c_j is expressed in mol dm^{-3} and N_A is the Avogadro constant.

$$\text{neutral solutes: } d = (10^3 N_A c_j)^{1/3} \quad (4)$$

$$1:1 \text{ salts: } \quad d = (2 \times 10^3 N_A c_j)^{1/3} \quad (5)$$

The results are summarised in Table 1 for solutions prepared

Table 1 Inter-solute distances[a]

c_j/mol dm^{-3}	10^{-4}	10^{-3}	10^{-2}	0.1	1.0	10.0
Neutral solutes (*e.g.* urea) d/nm	26	12	5.4	2.6	1.2	0.55
1:1 Salts (*e.g.* NaCl) d/nm	20	9.4	4.4	2.0	0.94	0.44

[a] The distances are calculated on the basis that each solute molecule (ion) is at the centre of a cube, volume d^3. The difference between calculated distances for a neutral solute and a 1:1 salt is a consequence of the fact that each mole of a 1:1 salt yields, with complete dissociation, 2 moles of ions.

using a simple solute (*e.g.* urea) and using a 1:1 salt. Distance d provides an indication of the number of solvent molecules between solute molecules, a number which dramatically decreases with increase in solute concentration.

A useful concept was introduced by Gurney[21] who identified a cosphere of water around each solute molecule (ion). The organisation of water in the cosphere differs from that in bulk water. Then the properties of real aqueous solutions of neutral molecules (*e.g.* urea) differ from the properties of the corresponding ideal solutions as a consequence of 'communication' through the intervening water molecules between solute molecules plus their cospheres. Quantitatively this communication is described by the Gibbs–Duhem equation which requires that (at fixed T and p) for an aqueous solution containing water (1) and solute (j), the chemical potentials μ_1(aq) and μ_j(aq) are not independent but closely linked.

$$n_1 \mathrm{d}\mu_1(\text{aq}) + n_j \mathrm{d}\mu_j(\text{aq}) = 0 \quad (6)$$

In these terms the extent and nature of the differences between the properties of real and ideal aqueous solutions (at fixed T and p) are a function of the organisation of water in the cospheres. Then for a given solution, molality m_j, the differences between Gibbs energies of real and ideal solutions can be expressed in terms of an excess Gibbs energy G^E. Moreover the latter property for dilute solutions can also be expressed in terms of pairwise solute–solute interaction parameters[22] g_{jj} as shown in eqn. (7) where $m^o = 1$ mol kg^{-1}.

$$G^E = RTg_{jj}(m_j/m^o)^2 \quad (7)$$

Interaction parameter g_{jj} is a member of a family of such parameters which includes volumetric v_{jj}, enthalpic h_{jj} and entropic s_{jj} pairwise interaction parameters. For ideal solutions h_{jj} is zero and so the enthalpy of dilution of a given aqueous ideal solution is zero. This is not the case for real solutions as is readily demonstrated using a titration microcalorimeter. We can compare the recorded traces for two experiments. In both cases the sample cell at the start of the experiment contained water. In one experiment the syringe contained urea(aq); in a second experiment the syringe contained *N*-ethylurea(aq) at the same molality, 0.8 mol kg^{-1}. The point to note is that in terms of the model discussed above (*cf.* Table 1) dilution simply means that the inter-solute distance increases. We find that for urea(aq), separation is *endothermic* whereas for monoethylurea(aq) separation is *exothermic*, showing a dramatic impact on the properties of the solutions by replacing a hydrogen atom in urea by an ethyl group.[23] The latter comments signal the possibility that these pairwise solute–solute interaction parameters can be decomposed into pairwise group–group interaction parameters. Wood and coworkers[24] developed this method of analysis leading to a significant increase in the understanding of the properties of aqueous solutions containing neutral solutes (Savage–Wood Additivity of Group Interactions, SWAG, approach).

Kinetics of organic reactions in water containing inert cosolutes

If a substrate X undergoes spontaneous hydrolysis in very dilute aqueous solutions at fixed temperature and pressure, the (first-order) rate constant k(aq;id) (id = ideal, *i.e.* in the absence of a cosolute) is determined by the standard Gibbs energy of activation, $\Delta^{\ddagger}G^0$.

When an inert cosolute j is added, the rate constant changes reflecting the impact of solute j on the chemical potentials of X in both initial and transition states. The rate constant k(aq) is sensitive to the molality of added solute m_j as determined by the impact of solute j on the hydration properties of solute X in both initial and transition states. The changes in the latter two states depend on the hydration properties of solute j. In addition, account must be taken of the fact that in real solutions properties of the solvent are not ideal. The final equation[25] takes the following form where ϕ is the practical osmotic coefficient for the solvent, molar mass M_1.

$$\ln[k(\text{aq})/k(\text{aq;id})] = (2/RT)[1/m^o]^2 G_c m_j - \phi M_1 m_j \quad (8)$$

Here G_c is a compact representation of the effect of added solute j on the chemical potentials of initial and transition states for reacting solute X. For most dilute aqueous solutions it can be assumed that ϕ is unity. Then $\{\ln[k(\text{aq})/k(\text{aq;id})]\}$ is a linear function of the solute molality m_j such that if added solute lowers the rate constant, G_c is negative. This model was originally tested using kinetic data describing the effects of added monohydric alcohols on the water-catalysed hydrolysis of 1-acyl-1,2,4-triazoles[26] and the effects of added ureas on the neutral hydrolysis of *p*-methoxyphenyl dichloroethanoate,[25] Fig. 1 and 2, respectively.

In both cases kinetic data at low concentrations of cosolute followed patterns in which G_c parameters can be understood in terms of pairwise interactions describing added solute–substrate interactions. With increase in hydrophobicity of both added cosolute and reacting substrate, G_c decreases. Hence in terms of the substrate, the hydration characteristics of the initial state rather than the transition state are important. In the context of the model, interaction between added cosolvent and initial state is envisaged as taking place *via* the cooperative hydrogen-bonding interactions within the solvent; that is *via* cosphere–cosphere communication.

This kinetic analysis of the effects of added solutes is illustrated by kinetic data for the following reactions:

(i) Hydrolysis of [(*p*-nitrophenyl)sulfonyl]methyl perchlorate;[27] Fig. 3.

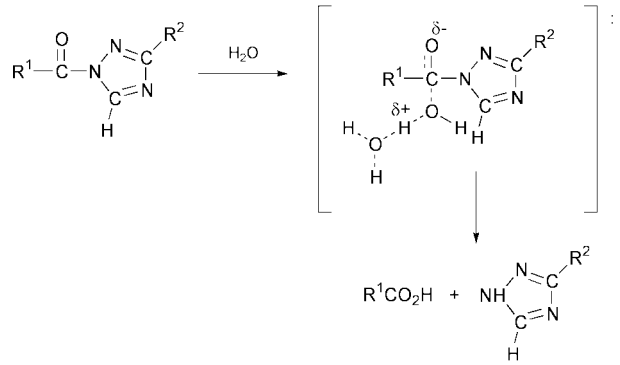

Fig. 1 Neutral hydrolysis of 1-acyl-3-substituted-1,2,4-triazoles.

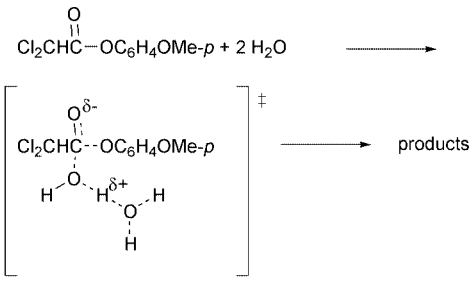

Fig. 2 Mechanism of the water-catalysed hydrolysis of acyl-activated esters.

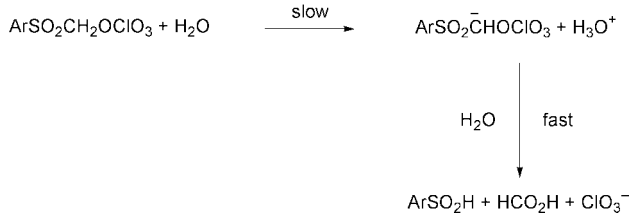

Fig. 3 Water-catalysed hydrolysis of covalent arylsulfonylmethyl perchlorates.

(ii) Hydrolysis of 1-benzoyl-3-phenyl-1,2,4-triazole in aqueous solution containing monohydric alcohols. No alcoholysis of the kinetic probes occurs under the reaction conditions. Group interaction parameters for polyhydric alcohols are strongly dependent on the positions of the hydroxyl groups in the alcohols.[28]

(iii) Hydrolysis of eighteen 1-acyl-(3-substituted)-1,2,4-triazoles in aqueous solutions containing ethanol and propan-1-ol. Although the SWAG analysis is reasonably satisfactory, stereochemical effects also play an important role.[29] The latter feature is also shown by the effects of added monosaccharides on rate constants for hydrolysis of 1-benzoyl-3-phenyl-1,2,4-triazoles.[30]

(iv) For the hydrolysis of *p*-methoxyphenyl dichloroethanoate in aqueous solutions, the elegance of the SWAG approach is shown by the additivity of G_c for carboxamides, ureas, sulfonamides and sulfoxides.[31]

(v) The kinetics of hydrolysis of 1-benzoyl-1,2,4-triazole in aqueous solutions is accounted for in terms of pairwise solute interactions in solution containing amphiphilic solutes below their critical micellar concentrations.[32]

The additivity pattern does break down if salts are added to the solutions in solvents comprising alcohol + water mixtures.

There are interesting and important exceptions to the SWAG additivity concept as shown in the dramatic retardation by added α-phenylalanine of the hydrolysis of activated amides in contrast to the rate acceleration induced by alanine.[33] Similar non-additivity is observed for the effects of isomeric aliphatic α-amino acids on the kinetics of hydrolysis of 2-(4-nitrophenoxy)tetrahydropyran and of alkylammonium salts on the hydrolysis of 1-benzoyl-1,2,4-triazole.[34]

Camouflage effects

Quite generally solutes in aqueous solutions can be classified as either hydrophilic or hydrophobic. However, we noted above that the properties of hydrophilic solutes in aqueous solutions are quite complicated. Indeed the properties of mono- and polyhydroxylated solutes point to key influences of the structure and stereochemistry of the functional groups. This conclusion is confirmed by limiting partial molar volumes and apparent molar isentropic compressions $\phi(K_{Sj};\ \mathrm{def})^{\infty}$ of carbohydrates in aqueous solutions.[35] However we note that $\phi(K_{Sj};\ \mathrm{def})^{\infty}$ is a complicated property[8,36] being for the most part based on an extrathermodynamic assumption.[37]

Hydration of carbohydrates is crucially governed by the relative positions of OH groups in a given carbohydrate. Their hydration characteristics depend on the matching fit between OH-groups in a given carbohydrate and either nearest neighbour (*e.g.* D-talose) or next nearest-neighbour oxygen; Table 2. A

Table 2 Kinetic medium effects and related properties of D-galactose and D-talose in aqueous solutions at 298.15 K

Property	D-galactose	D-talose
$G_c{}^a$/J kg mol^{-2}	−142	−280
$\phi(K_{Sj};\mathrm{def})^{\infty b}$/cm^3 mol^{-1} bar^{-1}	−20.14	−11.9
$n_S{}^c$	8.7	7.7

[a] G_c; see eqn. (6). [b] $\phi(K_{Sj};\mathrm{def})^{\infty}$; defined limiting apparent molar isentropic compression for solute *j* in aqueous solution; see ref. 37. [c] n_h; hydration number.

further feature emerges from analysis of isobaric heat capacity data which can be understood in terms of solute–solute interactions. For a 'probe' solute *j* in an aqueous solution containing a carbohydrate, we might ask how solute *j* 'reacts' to the presence of the carbohydrate. The evidence suggests that if the OH groups of a carbohydrate match into the three-dimensional hydrogen-bond structure of water, solute *j* is unaware of their presence—they have been camouflaged by the solvent. Indeed solute *j* may characterise the carbohydrate solute as hydrophobic.[38] The dependence of the hydration of monosaccharides on the detailed stereochemistry of the OH moieties has also been noted for single-tailed nonionic surfactants with sugar head groups.[39]

Hydrophobic inhibition

The thermodynamic properties of solute X in real solutions containing neutral solute *j* can be described in terms of the activity coefficient of solute X which can in turn be expressed in terms of Gibbs energy interaction parameters. This analysis leads to the description of the effects of added neutral solutes (*e.g.* alcohols) on rate constants for ester hydrolysis in terms of $G(c)$ parameters. This line of argument envisages that the chemical potential of a given solute X in aqueous solution is sensitive to the nature and hydration properties of other solutes by virtue of the communication through intervening water molecules; *i.e.* cosphere–cosphere interactions. This type of explanation is based on the proposal that the properties of a given solute molecule X in solution are perturbed by the sum of individual effects of all other solute molecules in solution.

In an alternative explanation the properties of a given solute molecule X are strongly influenced by intense interaction with a single neighbouring solute molecule *j* in a specific solute–solute interaction. The possibility that the latter model could account for the effects of added solute on the rate of ester hydrolysis was raised by a molecular dynamics simulation.[40]

The latter indicated that an encounter complex[41] involving ester and added solute could be formed. Moreover the cosolute *j* blocks the reaction centre from attack by water in the hydrolysis reaction. In these terms the first-order rate constant for ester hydrolysis $k(m_j)$ in the presence of solute *j*, molality m_j, is related to the equilibrium constant K_{ec} using eqn. (9); (ec = encounter complex).

$$k(m_j) = k(m_j = 0) / [1 + K_{ec}m_j] \quad (9)$$

In the limit that $K_{ec}m_j < 1$, $\ln[k(m_j)]$ is predicted to be a linear function of molality m_j, with slope K_{ec}. Kinetic data for the hydrolysis of three activated esters show that the model accounts satisfactorily for the observed patterns.[42]

Diels–Alder reactions in water

Relatively apolar solutes in aqueous solutions can form encounter complexes which are stabilised by hydrophobic interactions. This can occur for two solutes that can react to form a product if the orientation of both reactions in the encounter complex is suitable for bond making/bond breaking processes. An important example is provided by the formation of an encounter complex that consists of a diene/dienophile pair. The relative stability of the encounter complex in aqueous solution then leads to a rate acceleration compared to the reaction in organic solvents, primarily because the larger number of intermolecular collisions in the complex will favour the cycloaddition reaction. If, in addition to this effect, the activated complex is also stabilised by increased hydrogen-bond interaction relative to the initial state, substantial rate enhancements in water can be realised.[43]

Even in 1931 Diels and Alder used water as a solvent for their famous reaction. However it was the communication by Rideout and Breslow[44] that aroused particular interest in Diels–Alder (DA) reactions and other organic reactions in water. It was reported that the DA reaction of methyl vinyl ketone with cyclopentadiene (CP) was 290 times faster in water than in cyanomethane and that the preference for the *endo* adduct was significantly increased, Fig. 4. Later we found that the second-order rate constant for the DA reaction of 5-methoxy-naphthoquinone with CP was about 1.3×10^4 times higher in water than in *n*-hexane.[43] Detailed examination of aqueous solvent effects on the otherwise solvent-insensitive DA reactions showed that *enforced hydrophobic interactions* between diene and dienophile and *hydrogen bonding* of water to the polarised carbonyl moieties in the activated complex play a major role in the large aqueous rate acceleration.[45] The enhanced preference for the *endo* reaction product (mentioned above) is understood in terms of the smaller solvent accessible surface area for the activated complex leading to this stereoisomer. Computational studies support the interpretation of the beneficial effect of water on these electrocyclic reactions.[46] Aqueous rate acceleration for DA reactions is quite general and has been employed in many synthetic applications. Of course, the magnitude of the effect depends on the contribution of both hydrophobic and hydrogen-bonding interactions.The hydrogen-bonding effect of water can be replaced by Lewis-acid catalysts such as Cu(II) ions with particularly successful applications for bidentate dienophiles,[47] Fig. 5. Relative to the uncatalysed cycloaddition with CP, 0.01 mol dm^{-3} $Cu(NO_3)_2$ in water leads to a rate enhancement of *ca.* 8×10^4. Lewis-acids Ni^{2+}, Co^{2+} and Zn^{2+} are less effective. Water does not enhance the *endo*-selectivity for these reactions, consistent with the view that the stereochemistry is influenced by enforced hydrophobic interactions.

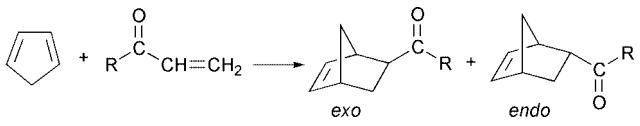

Fig. 4 Diels–Alder reaction of cyclopentadiene with alkyl vinyl ketones.

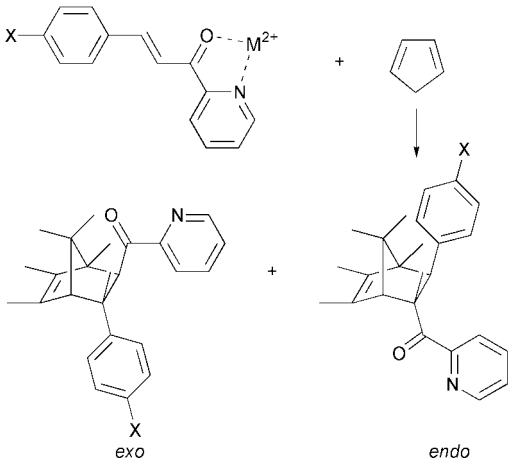

Fig. 5 Lewis-acid catalysed Diels–Alder reaction of 3-*para*-substituted-phenyl-1-(2-pyridyl)-2-propen-1-ones with cyclopentadiene to provide the *endo* (major product) and *exo* (minor product) cycloadducts. (a) X = NO_2, (b) X = Cl, (c) X = H, (d) X = CH_3, (e) X = OCH_3, (f) X = $CH_2SO_3^-$ Na^+, (g) X = $CH_2N^+(CH_3)_3Br^-$.

The same DA reactions have also been performed in the presence of diamine and α-amino acid ligands. Interestingly, ligand-accelerated catalysis of the reaction in the presence of Cu^{2+} ions was observed for a series of (chiral) aromatic α-amino acid ligands. In the case of N^{α}-methyl-L-tryptophan, 74% enantioselectivity was found. Smaller selectivities were found when organic solvents were used. The enhanced catalytic effect and the enantioselectivity are consistent with arene–arene interactions between the pyridine ring[48] of the dienophile and the aromatic ring of the α-amino acid ligand bound to Cu^{2+}, Fig. 6.

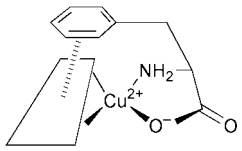

Fig. 6 Ligand-induced hydrophobic bonding of the Lewis acid to the dienophile.

Combination of Lewis-acid catalysis with micellar catalysis leads to exceptionally efficient catalysis.[49] For example, the DA reaction with copper didodecyl sulfate micelles shows a rate acceleration of 1.8×10^6, again compared to the uncatalysed cycloaddition in cyanomethane. The major factor responsible for this huge catalytic effect is the essentially complete complexation of the dienophile to the Cu^{2+} ions at the surface of the micelles. A similar vesicular-catalysed reaction is somewhat less effective (rate acceleration *ca.* 10^6), but the maximum catalytic effect is obtained at significantly lower surfactant concentration, which is important from the view point of 'green chemistry'.[50] Lewis-acid–surfactant-combined catalysts have a definite potential for green organic synthesis in aqueous media as demonstrated by Kobayashi *et al.* for several carbon–carbon bond-forming reactions.[51] The detailed studies of the aqueous rate accelerations of DA reactions have set the stage for extensive application of organic synthesis in water.[50]

Surfactant aggregation

Micelles

The story is told[52] how McBain's original proposal[53] concerning the possibility that surfactants might aggregate in water above a critical micellar concentration was met with the reply, 'Nonsense, McBain'. Of course it is now recognised that in

aqueous solutions up to 100 monomer surfactant monomers may associate to form micelles. Nevertheless the actual structure of micelles is still a matter for debate.

Interest in these systems not only stems from their use in detergent formulations but also for their general ability to solubilise chemical substances in aqueous systems and to act as catalysts for their chemical reactions. Thermodynamic description of the equilibrium between micelles and monomers in solutions is generally based on one of two models, both recognising that micelle formation is a strongly cooperative process, with hydrophobic interactions as the major driving force.[54]

According to the closed association model, a chemical equilibrium exists between monomers and micelles. This is the mass action model.[55] Thus if N is the aggregation number for surfactant S,

$$N\mathrm{S(aq)} \rightleftharpoons \mathrm{S}_N\mathrm{(aq)} \quad (10)$$

Hence, the equilibrium constant is,

$$K = [\mathrm{S}_N\mathrm{(aq)}]/[\mathrm{S(aq)}]^N \quad (11)$$

Numerical analysis shows that with an increase in aggregation number N and with increase in concentration of surfactant, the change in composition of the solution at the critical micellar concentration becomes sharper.

According to the phase separation model,[54] micelles form a separate phase in the aqueous system with surfactant in the micellar phase in equilibrium with surfactant in aqueous solution at the critical micellar concentration. Thus the equilibrium for surfactant j is described as follows; c_r = 1 mol dm^{-3}.

$$\mu^*(\mathrm{micelle};N\mathrm{S}) = N[\mu^0(\mathrm{aq}) + RT\ln(\mathrm{cmc}/c_r)] \quad (12)$$

Then the standard Gibbs energy for micelle formation $\Delta_{mic}G^o$(aq) is given by the following equation.

$$\Delta_{mic}G^o(\mathrm{aq}) = \mu^*(\mathrm{micelle};\ N\mathrm{S}) - N\mu^0(\mathrm{aq}) = NRT\ln(\mathrm{cmc}/c_r) \quad (13)$$

The right-hand site of eqn. (13) contains two important quantities, N and cmc of which only the cmc is readily determined. This point signals that there are complications in the thermodynamic analysis of micellar systems.[56] The way ahead defines a standard Gibbs energy of micelle formation per monomer, $\Delta_{mic}G^o$(aq;mon) [$= \Delta_{mic}G^o(\mathrm{aq})/N$].

Then,

$$\Delta_{mic}G^o(\mathrm{aq;mon}) = RT\ln(\mathrm{cmc}/c_r) \quad (14)$$

If the monomer surfactant is a 1:1 salt (*e.g.* hexadecyltrimethylammonium bromide; CTAB) then the standard Gibbs energy of micelle formation per monomer is given by the following equation.

$$\Delta_{mic}G^o(\mathrm{aq;mon}) = \Delta_{mic}H^o(\mathrm{aq;mon}) - T\Delta_{mic}S^o(\mathrm{aq;mon}) = 2RT\ln(\mathrm{cmc}/c_r) \quad (15)$$

Here $\Delta_{mic}H^o$(aq;mon) is the standard enthalpy of micelle formation per monomer. We have used the latter two equations in an extensive study of the thermodynamics of micelle formation using a titration microcalorimeter. In these experiments the syringe contains an aqueous solution of, for example, CTAB, at a concentration above the cmc whereas the sample cell contains, initially, water. Over the first set of injections of aliquots, the calorimeter records the heat associated with the break up (*i.e.* deaggregation) of the injected micelles to form monomers.[57] However gradually the concentration of surfactant in the sample cell increases, eventually approaching the cmc. At this stage the recorded heat is close to zero in that a micellar solution is being injected into a micellar solution. The resulting plot, an enthalpogram, of the ratio $[q/\delta n_j^0]$ against injection number I is step-shaped such that the ratio $[q/\delta n_j^0]$ effectively yields the enthalpy of micelle formation because $[q/\delta n_j^0]$ at high injection numbers is close to zero. A more detailed analysis takes account of the fact that CTAB is a 1:1 salt. The cmc is calculated using the van Os method[58] in which $\sum_{I=1}^{I=N}[q/\delta n_j^0]$ is plotted against the concentration of CTAB in the sample cell at injection number N. The points generate two straight lines which intersect at a point corresponding to the cmc.

With decreasing alkyl chain length (*e.g.* C_{16} to C_{10} trimethylammonium bromide) the enthalpograms become more complicated indicating that account has to be taken of the thermodynamic properties of the monomer salt and ionic micelles together with the extent of counter ion binding.[59]

An interesting study exploited the structural variations in the cation using 1-alkyl-4-pyridinium surfactants in aqueous solutions.[60] For 1-alkyl-4-methylpyridinium halides, the standard enthalpy of micelle formation becomes more exothermic with an increase in alkyl chain length by -2.6 ± 0.2 kJ mol^{-1} per CH_2 group at 303 K. For 1-methyl-4-*n*-dodecylpyridinium surfactants prepared using aromatic counter ions, the enthalpograms point to different degrees of penetration of the counter anions into the cationic micelles.[61]

Interpretation of the enthalpograms generated by different surfactants is often complicated by the fact that enthalpies of micelle formation are strongly temperature dependent leading in some cases to a change in sign of the standard enthalpy of micelle formation.

In fact there are further complications as shown by the change in sign of the enthalpy of micelle deaggregation of CTAB(aq) when pentanol is added.[62] Titration calorimetric data for non-ionic carbohydrate-derived surfactants[63] show interesting but complicated patterns in the contributions to standard Gibbs energies and enthalpies of micelle formation. A similar comment applies to aqueous solutions containing alkylpolyoxyethylene glycol ethers.[64] The enthalpograms are complicated by the presence of two processes when aliquots are injected into the sample cell, namely micelle deaggregation and declustering of micellar aggregates. The impact of additional methylene groups in the alkyl chain on going from CTAB to octadecyltrimethylammonium bromide is dramatic. The enthalpograms show that the sign of deaggregation changes with a change in concentration of surfactant in the injected aliquots, again pointing to the influence of micellar aggregation.

Analysis of the enthalpograms for mixed alkyltrimethylammonium bromide surfactants turns out not to be straightforward.[65] The effective cmc of a given mixture, as signalled by an enthalpogram, is a function of the mixture concentration. The mixed micellar phase is treated as resembling a binary liquid mixture characterised by rational activity coefficients for both components together with enthalpic interaction parameters treated along the lines used in the treatment of binary liquid mixtures.[66] Monomer–monomer surfactant interaction in both aqueous solution and mixed micellar phase are important in determining the properties of a mixed surfactant. For solutions containing high concentrations of surfactants, the presence of large aggregates is confirmed by a DSC scan for concentrated aqueous solutions of hexadecyltrimethylammonium bromide and chloride.[67]

Vesicles

Whether a surfactant molecule preferentially undergoes molecular assembly to form a micelle or a (closed) bilayer, depends, in a first approximation, on the architecture of the amphiphilic molecule.[68] This shape-dependent association signals a tendency for the most efficient intermolecular overlap of hydrophobic hydration shells with a maximum release of these water molecules to the bulk aqueous solution. The thermodynamics of vesicle formation have also been examined using a titration microcalorimeter.[69] The results emphasise the importance of the nature of the counter ion and reveal a large temperature dependence of the enthalpy of vesiculation as anticipated for a

process involving hydration shell overlap.Gel-to-liquid crystalline phase transitions in vesicular bilayers can be studied using a differential scanning microcalorimeter.[70] The design of the latter is similar to that for a titration microcalorimeter except that the syringe system is absent and the sample cell sealed under nitrogen gas. Both cells are gradually heated from 5 to 90 °C under computer control. The system records the differential amounts of heat required to raise together the temperatures of sample and reference cells. A plot is obtained of the relative isobaric heat capacity of a given vesicular aqueous system as a function of temperature. These scans are extremely informative concerning the factors controlling the thermal characteristics of vesicular bilayers. We have concentrated attention on two classes of vesicular systems, dialkyldimethylammonium bromides[71] (*e.g.* DOAB = di-*n*-octadecyldimethylammonium bromide) and sodium dialkylphosphates[72] (*e.g.* DDP = sodium di-*n*-dodecyl phosphate).

The DSC experiments show that the transitions responsible for extrema in isobaric heat capacities involve patches of between 100 and 200 monomers which melt cooperatively. The extent of cooperative melting in each patch involves but a small fraction of the total number of monomers in each vesicle. The melting temperature (as revealed by the maximum in isobaric heat capacity) depends on the vesicle both in terms of the dialkyl component and the counter ion.[72] The melting has a dynamic feature. For some vesicular systems no extremum in isobaric heat capacity is detected in the second scan if the latter is recorded shortly after the first. In other words there is an element of kinetic control to the repacking of the dialkyl chains forming the gel state from the liquid crystal state.[73]

DSC scans for mixed vesicular systems indicate that when the differences in alkyl chain lengths are small, the chains can assemble in reasonably ordered fashion leading to well defined features in the DSC scans. When the lengths of the dialkyl chains differ considerably, the DSC scans are complicated indicative of domains having different compositions; *cf.* partial miscibility.[74]

For vesicles formed by a series of three sodium dialkylphosphates having identical chain lengths, their thermal stability is strongly dependent on the degree of unsaturation in the alkyl chains. In general, vesicles are stabilised by alkyl–alkyl group cohesion and destablised by charge–charge interactions in the ionic head groups. The thermal stability of the bilayers is very sensitive to added salt,[75a] and other cosolutes including surfactants,[75b] α-amino acids,[75c] sodium dipicolinate[75d] and poly(sodium acrylate)s.[75e]

Conclusion and outlook

Chemical reactions and aggregation processes in water are strongly determined by the properties of the aqueous medium, *i.e.* by the three-dimensional hydrogen-bond network that combines strongly intermolecular interactions with low density. Because water molecules are small and each molecule can form up to four hydrogen bonds (twice as a donor and twice as an acceptor), changes in the H-bond network are associated with large entropy changes (often largely compensated by changes in enthalpy) and with large temperature effects. There appears to be little doubt that in the coming years the unique solvent properties of water will be frequently employed for tuning of desired chemical processes. In particular hydrophobic interactions provide rich possibilities for this purpose. Mother Nature was the first to recognise the potential of such medium-induced control of chemical reactivity.

Acknowledgements

We are much indebted to our coworkers, mentioned in the references, for their enthusiasm and important contributions to the work discussed herein. Special thanks are due to Niek Buurma for his help in processing the manuscript.

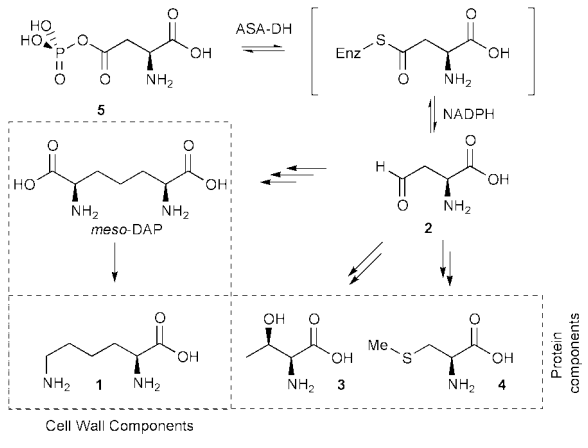
First published as an Advance Article on the web 10th August 2001

The difluoromethylene analogue of aspartyl phosphate 6 has been prepared by the fluoride catalysed coupling of diethyl trimethylsilyldifluoromethyl phosphonate with an appropriate aldehyde followed by Dess–Martin oxidation and deprotection; the deprotected compound inhibited (K_I 95 μM) aspartate semi-aldehyde dehydrogenase, a key enzyme involved in bacterial amino acid and peptidoglycan biosynthesis.

Bacterial resistance to current classes of antibacterial compounds is increasing alarmingly.[1,2] Many successful antibiotics target bacterial cell wall biosynthesis, and the efforts of our group have concentrated on attempts to design and synthesise inhibitors of enzymes from this pathway.[3] We have focussed on inhibitors of L-lysine **1** biosynthesis since L-lysine and its precursor, diaminopimelic acid (DAP), form the strength bearing cross-links of the peptidoglycan layer of bacterial cell walls (Scheme 1).[4] One of the earliest enzymes on the pathway, aspartate semi-aldehyde dehydrogenase (ASA-DH, EC 1.2.1.11) forms the key intermediate L-aspartate semi-aldehyde **2** the precursor of DAP and also L-threonine **3** and L-methionine **4**. Inhibitors of ASA-DH would therefore block dual key bacterial metabolic processes forming proteins and peptidoglycan.

The mechanism of ASA-DH is believed to involve an active site nucleophilic cysteine.[5] γ-Aspartyl phosphate **5**, is bound at the active site. Thiolester formation then occurs with concomitant loss of phosphate. NADPH then transfers its 4-*proS* hydride to reduce the thiolester, releasing the aspartate semi-aldehyde **2** and regenerating the nucleophile (Scheme 1). The 3D crystal structure of ASA-DH has recently been solved, but as no substrates were bound in the structure little information is available regarding the active site geometry and potential binding sites.[6] We decided to synthesise specific ASA-DH inhibitors. Ideally these compounds would mimic the natural substrate and contain an electrophillic centre for covalent attachment to the active site nucleophile.



Scheme 1 Bacterial pathways to cell wall and protein components.

Difluoromethylene phosphonates have found use as phosphate mimics in numerous applications.[7] The difluoromethylene unit effectively mimics oxygen and the pK_a of difluoromethylene phosphonates closely matches that of the analogous phosphates.[8] Compounds such as **6** could form effective inhibitors of ASA-DH. Additionally the difluoromethylene α to the carbonyl would have the effect of making it an excellent electrophile and likely target for thiol attachment.

Berkowitz has reacted difluoromethylene anions such as **7** with methyl esters to prepare ketones directly.[9] We attempted to follow this methodology for the synthesis of **6** (Scheme 2). L-Aspartic acid **8** was selectively protected at the γ-ester using methanol and thionyl chloride to form the mono ester **9**. BOC protection to give **10** followed by formation of the α-*tert*-butyl ester then gave the required methyl ester **11**. However this ester was unreactive under the reaction conditions of Berkowitz[9] and we considered that the mono-protected amine could be the source of an acidic proton. Formation of the doubly BOC protected aspartate **12** was achieved, but this also could not be transformed to the required phosphonate. The bis(methyl ester) **13** was also synthesised by parallel methodology, but was similarly unreactive towards anion **7**.

We next attempted to add **7** to aldehydes (Scheme 3).[10] Treatment of **13** with DIBAL-H yielded a mixture of the corresponding alcohol **14** (22%) and aldehyde **15** (68%);[11] **14** could be converted to **15** by treatment with the Dess–Martin periodinane.[12,13] When **15** was treated with excess **7** (*ca.* 7.5 eq.) at −78 °C we were able to isolate the mixture of diastereomers **16a** and **16b** in very low yield—no products were

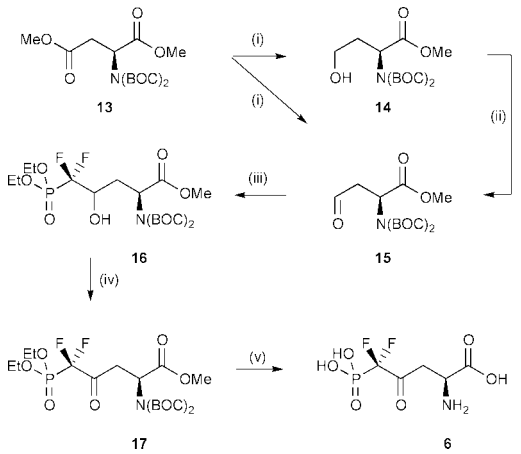
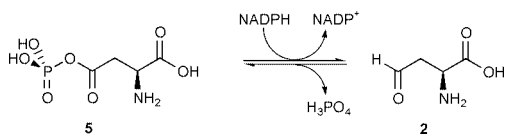
 DOI: 10.1039/b103988c



Scheme 3 *Reagents and conditions*: (i) DIBAL-H, THF, −78 °C, 68%; (ii) Dess–Martin periodinane, CH_2Cl_2, RT, 75%; (iii) $(EtO)_2P(O)CF_2SiMe_3$, THF, 10 mol% TBAF, −60 °C RT, 55%; (iv) Dess–Martin periodinane, CH_2Cl_2, RT, 69%; (v) TMSI, then aq. KOH, then Dowex AG50 WX8, 95%.

formed with lower excesses or stoichiometric amounts of **7**. Under milder conditions treatment of **15** with $(EtO)_2P(O)CF_2SiMe_3$ in THF at 0 °C in the presence of a catalytic fluoride source such as CsF, TBAF or TBAT ($Bu_4N^+SiPh_3F_2^-$) yielded the required products. The most favourable conditions required the use of 1.3 eq. of $(EtO)_2P(O)CF_2SiMe_3$, 10 mol% TBAF and one equivalent of **15**. This reaction yielded a mixture of diastereomers **16a** (2*S*,4*S*) and **16b** (2*S*,4*R*)[14] in 3 : 1 ratio in overall 55% (Scheme 3) with the remaining mass balance being unreacted aldehyde. The alcohols were smoothly converted to the ketone **17**. A two-step deprotection involving treatment of **17** with 5 eq. of TMSI (Me_3SiI) followed by KOH treatment to remove the methyl ester yielded **6** in excellent yield as a 45 : 55 mixture of keto- and hydrate forms.[15] After purification by ion exchange chromatography, **6** was used in inhibition assays using recombinant *E. coli* ASA-DH.

The ASA-DH assay (Scheme 4) requires that the enzyme be run in the 'reverse' direction as aspartyl phosphate is unavailable whereas aspartate semi-aldehyde is obtained by reductive ozonolysis of allyl glycine in 1 M aqueous HCl. In the assay, reaction is observed at 340 nm as NADPH is formed from $NADP^+$ (150 μM). In order to ensure satisfactory reaction rates the other substrates (PO_4^{3-} and ASA) must be present in large excess (15 and 0.35 mM respectively). In initial inhibition reactions under these conditions **6** showed little observable effect. However in pre-incubation reactions in which ASA-DH was incubated with **6** *prior* to addition of the other assay components clear inhibition was observable varying with time (Fig. 1A) and concentration (Fig 1B). Based on this assay a K_I of 95 μM was measured.[16] The rate of inhibition of ASA-DH by **6** was diminished in the presence of phosphate (Fig. 1B) indicating that inhibition occurs at the active site. The inhibition appears to be slowly reversible as indicated by the regeneration of activity upon dilution of the inhibited enzyme into the assay cuvette. This behaviour is consistent with that expected for a slow binding model of inhibition and is most likely caused by covalent bond formation between **6** and the active site thiol of ASA-DH.



Scheme 4 Assay of ASA-DH. In the reverse reaction phosphate and ASA are present in large excess.

Thus we have shown that a rational approach can successfully be used for the design and synthesis of ASA-DH inhibitors. The route should enable the synthesis of a range of related compounds designed to probe the mechanism and active

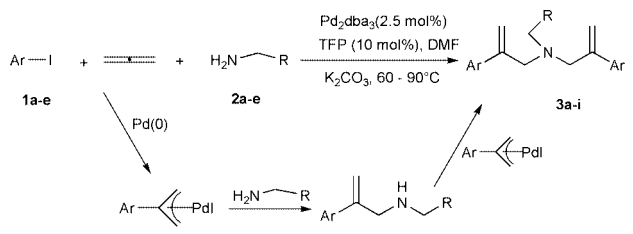
Received (in Cambridge, UK) 26th June 2001, Accepted 20th July 2001
First published as an Advance Article on the web 29th August 2001

A 3-component cascade synthesis of bis(2-arylallyl) tertiary amines from aryl iodide, allene and primary aliphatic amines is described; chiral amines give analogous products with no detectable racemisation; mixtures of two different aryl iodides can be utilised to give the mixed tertiary amines as the sole, or major, product; the reaction is sensitive to stereoelectronic effects which lead to mono(2-arylallyl) secondary amines.

π-Allylpalladium species react with both carbon- and heteroatom-centred nucleophiles with formation of carbon–carbon or carbon–heteroatom bonds and catalytic versions of these processes have been widely utilized in organic synthesis.[1] Heteroatom nucleophiles, including RCO_2H,[2] H_2O,[3] ROH[4] and amines[5] (primary and secondary), have proved particularly valuable in complex molecule synthesis. The reaction of nitrogen nucleophiles with π-allylpalladium(II) species are amongst the most widely used in organic synthesis. The efficiency of intermolecular amination and its tolerance of a wide range of functional groups has encouraged extensive applications including the synthesis of carbocyclic nucleoside analogues.[6] Aryl, acyl and hydropalladation of allenes are additional versatile routes to π-allylpalladium species which have been imaginatively exploited in harness with nucleophilic attack.[7–9]

Most reported cases of reactions with amines involve one π-allylpalladium species reacting with a primary or secondary amine to form a secondary amine or tertiary amine respectively. The sequential transfer of two allyl groups from Pd(II) to a primary amine to form a tertiary amine in a one pot reaction has not, to our knowledge, been reported. Herein we report the first cases where primary amines react with π-allylpalladium(II) species, generated from allene, to form tertiary amines. The three component reaction can be carried out under mild conditions in the presence of a palladium catalyst in good yield (Scheme 1) (Table 1) and involves formation of two carbon–carbon bonds and two carbon–nitrogen bonds. The palladium(0) catalyst Pd_2dba_3 (2.5 mol%) in combination with tris(2-furyl)phosphine (TFP) together with allene gas (1 bar) proved effective at 60–90 ° C over 1–2 d.[10]

A range of aryl/heteroaryl iodides and primary amines were evaluated and good yields were obtained in all cases (Table 1). The reaction also works well for vinyl iodides (Table 1, entries 4 and 9) and for a range of primary aliphatic amines. Reaction of primary aliphatic amines with 1 : 1 mixtures of two different aryl iodides gives the desired mixed product as the major or, in some cases, the sole product. Two typical examples are provided by reaction of (−)-myrtanylamine **4** with 1 mol eq. of 4-methoxyiodobenzene and 4-(*N*,*N*-diethylaminocarbonyl)iodobenzene which affords **5** (56%) as the sole product whilst amine **6** reacts with 4-methoxycarbonyliodobenzene and 3,5-di-



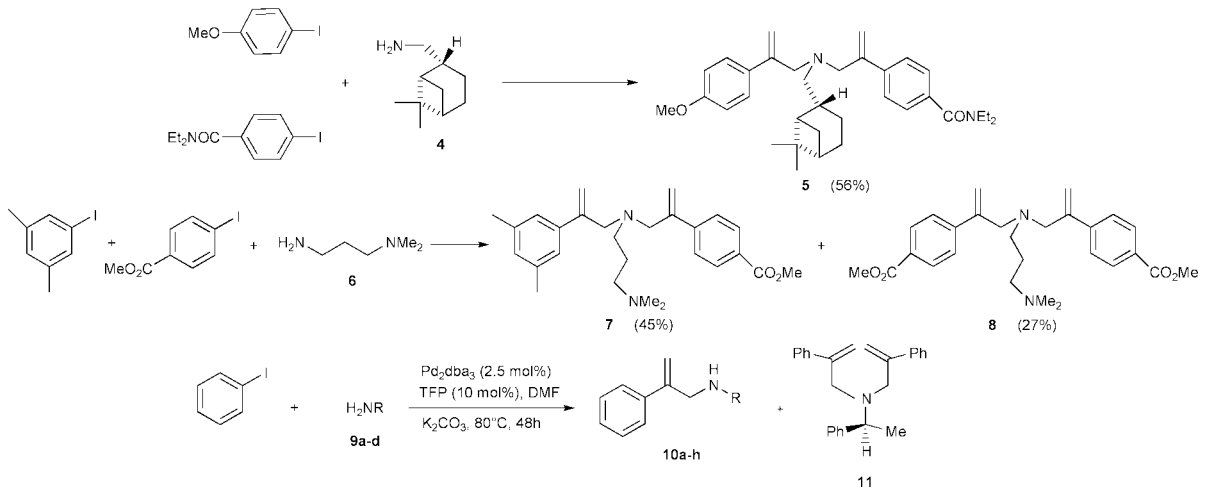
Scheme 1

Table 1 3-Component cascade synthesis of symmetrical bis(2-arylallyl) tertiary amines (**3a–i**)[a]

Entry	Ar-I	Amine	Temp/°C[b]; Time/d	Product	Yield[c] (%)
1	 1a	 2a	85; 2	**3a**	82
2	 1b	 2a	60; 2	**3b**	82
3	 1c	 2a	90; 1	**3c**	70
4	 1d	 2a	90; 2	**3d**	80
5	 1a	 2b	90; 1.5	**3e**	78
6	 1a	 2c	80; 2	**3f**	70
7	 1a	 2d	80; 1	**3g**	62
8	 1a	 2e	85; 2	**3h**	72
9	 1d	 2d	80; 2	**3i**	71

[a] All reactions were run in DMF at 60–90 °C over 1–2 days in the presence of 2.5 mol% Pd_2dba_3, 10 mol% $(2\text{-furyl})_3P$, allene (1 bar) and K_2CO_3(4 mol eq.) in a Schlenk tube. [b] Oil bath temperature. [c] Isolated yield.

 DOI: 10.1039/b105567b



Scheme 2

Table 2 3-Component cascade synthesis of 2-arylallyl secondary amines (**5a–h**)[a]

Entry	Amine	Product	Yield(%)
1	 **9a** (·)	 **10a**	92
2	 **9b**	 **10b**	88
3	 **9c** (S) –	 **10c**	72
4	 **9d** (S)	 **10d**	73[b]
5	 **9e**	 **10e**	73
6	 **9f**	 **10f**	95
7	 **9g**	 **10g**	48[c]
8	 **9h**	 **10h**	83

[a] All reactions were run in DMF at 80 °C for 48 h. Catalyst and additive as for Table 1. Iodobenzene was the aryl iodide unless otherwise noted. [b] In addition the tertiary amine **6** was obtained. [c] 2-Iodothiophene replaced iodobenzene.

methylbenzene to afford a mixture of **7** and **8**. Clearly there is scope for considerable optimisation in these cases.

The reaction is also sensitive to stereoelectronic factors as demonstrated by Scheme 2 and Table 2.

The monoallylated α-branched primary amines **10a–d** (Table 2, entries 1–4) fail to undergo a second allylation due to substantial steric hindrance. The primary amines **9e–h** (Table 2) are orders of magnitude less basic [11] and nucleophilic than **2a–d** and are also sterically more hindered. These two factors conspire to prevent the second allylation under the specified conditions.

The secondary and tertiary amine products of these cascades are unusual derivatives of the bioactive β-aryl/heteroaryl-(ethyl)amine pharmacophore. Bis(2-arylallyl) tertiary amines have also found applications as additives in copolymer latexes[12] and in endoperoxide[13] chemistry.

We thank the ORS and Tetley and Lupton for scholarships (to X. Gai) and Johnson Matthey and Leeds University for support.

Ion-exchange of [Ti,Al]-beta with quaternary ammonium acetates greatly enhances the epoxide selectivity in the oxidation of alkenes with hydrogen peroxide; this is due to the selective poisoning of the acid sites without suppressing the oxidation activity of Ti sites.

Since the first report of TS-1 by Taramasso *et al*. in 1983, titanosilicates have attracted the attention of many researchers.[1] Ti-beta zeolite has a three-dimensionally connected pore system with 12-membered-ring channels and is verified to be more active towards bulky substances such as branched and cyclic alkanes and alkenes using aqueous H_2O_2 or *tert*-butyl hydroperoxide (TBHP) as an oxidant than medium pore TS-1 because of the reduced diffusion restriction imposed by the large pores. A small amount of Al (Si/Al < 200), as crystallization-promoting agent, is generally needed in the conventional hydrothermal synthesis method for Ti-beta using tetraethylammonium hydroxide (TEAOH) as a structure-directing agent (SDA).[2,3] The presence of Al leads to the formation of acid sites, which promotes the successive ring-opening solvolysis of the epoxide generated in the catalytic reactions to lower its selectivity extensively.[4] Afterwards, several novel synthesis methods for Al-free or low-Al Ti-beta were also developed, such as the seeding method,[5] cogel method,[6] fluoride method[7,8] and dry-gel conversion method;[9,10] however none of these were very efficient for enhancing epoxide selectivity in alcoholic solvents. This is probably because the very complex, severely intergrown nature of the beta structure results in high concentration of weak acid sites such as silanol groups at defect sites. Although ion-exchange with alkaline or alkaline earth metal cations inhibits the acidity of titanosilicates, it also suppresses the oxidation activity of Ti species.[11,12] We report here a new method for dramatically enhancing the yield of epoxide in the alkene oxidation reactions catalyzed by Ti-beta even in protic alcoholic solvents without losing its oxidation activity.

[Ti,Al]-beta zeolite was hydrothermally synthesized by modifying the method reported by Camblor *et al*.[2,3] Tetrabutyl orthotitanate [$Ti(OBu)_4$] was employed as a Ti source instead of tetraethyl orthotitanate [$Ti(OEt)_4$] and was hydrolyzed in aqueous H_2O_2 before adding to the SDA solution to suppress the formation of extraframework anatase TiO_2. The mother gel composition was SiO_2:0.33 TiO_2:0.005 Al_2O_3:0.56 TEAOH:12.5 H_2O. The crystallization was carried out by agitating the gel in a Teflon-lined stainless steel autoclave at 413 K for 4 days. The resultant [Ti,Al]-beta was calcined at 793 K for 10 h in a stream of O_2 (30 ml min^{-1} g-$solid^{-1}$) to remove the SDA. Calcined [Ti,Al]-beta was treated with 1 M aqueous solutions of various ammonium acetates (NR_4OAc, R = Me, Et, Pr and H) or 1 M aqueous potassium acetate (KOAc) solution at 353 K for 4 h and then filtered off, washed, dried and finally calcined of 473 K for 10 h. The liquid phase epoxidation of alkenes with H_2O_2 was performed in a flask.

Table 1 shows the results of epoxidation of alkenes. Calcined [Ti,Al]-beta exhibited a low selectivity to epoxide for oxidation reactions of cyclohexene and hex-2-ene (entries 1 and 2). The products were mainly diol and monomethyl glycol ether produced by the acid-catalyzed solvolysis of epoxide, together with a small amount of allylic oxidation products. The negligible formation of epoxide strongly indicates that there were a considerable amount of acid sites in [Ti,Al]-beta, which contributed to the solvolysis of epoxide.

When the catalyst ion-exchanged with tetramethylammonium acetate was employed (entries 4 and 5), the epoxide selectivity was greatly enhanced owing to the suppression of ring-opening reactions, and the selectivity to the allylic oxidation did not change significantly. The enhancement was more obvious for hex-2-ene which gave an epoxide/glycol ratio of 28. Solvent effects were also tested. It is generally known that aprotic solvents such as acetonitrile enhance the selectivity to the epoxide. Employment of the weakly basic solvent, acetoni-

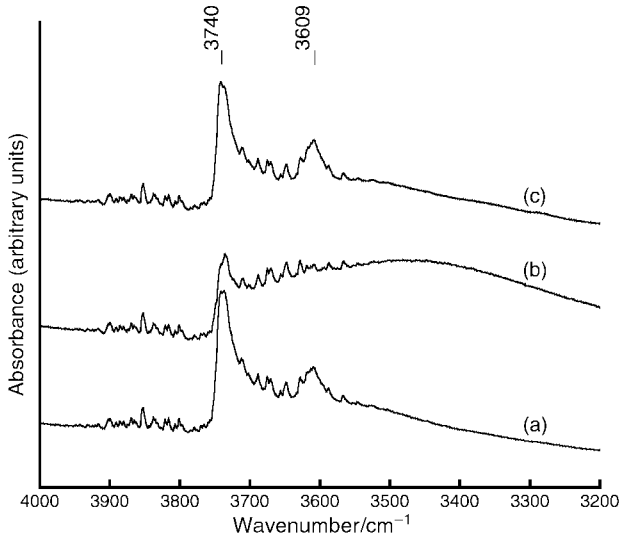

Fig. 1 FTIR spectra of Ti-beta in the OH region; (a) without ion-exchange after evacuation at 773 K, (b) ion-exchanged with NMe_4OAc and evacuated at 473 K, (c) ion-exchanged and evacuated at 773 K.

trile, further enhanced the epoxide selectivity (entries 3 and 6).

Use of larger quaternary ammonium cations led to decreased activity, probably because the bulky cations hinder the reactant molecules from approaching the Ti sites (entries 4, 7 and 8). Ammonium acetate treatment led to no enhancement of the epoxide selectivity (entry 9). FT-IR spectra of the ion-exchanged [Ti,Al]-beta taken before and after the catalytic runs indicated that NH_4^+ was oxidatively degradated while NMe_4^+ remained intact. Ion-exchange with KOAc also increased the selectivity to the epoxide; however the oxidation activity was adversely affected (entry 10). This is consistent with the observations that ion-exchange with sodium carbonate (Na_2CO_3) or sodium azide (NaN_3) on Al-containing TS-1 gave rise to a higher epoxide selectivity but a very low activity in allyl alcohol oxidation,[11] that ion-exchange with potassium carbonate severely lowered the oxidation turnover in unsaturated alcohol oxidation[12] and that TS-1 synthesized in the presence of large amounts of alkali and alkaline earth ions showed low oxidation activity.[13] Elemental analyses indicated that ion-exchanged catalyst contained NMe_4^+ cations in excess of Al, which suggests that the NMe_4^+ blocks not only all the bridging hydroxy groups but also other less acidic sites.

Calcined [Ti,Al]-beta exhibited two bands in its FTIR spectra in the OH vibration region [Fig. 1(a)]. A peak at 3609 cm^{-1} is assigned to bridged hydroxy groups [Si–(OH)–Al] and the other peak around 3740 cm^{-1} to terminal silanols (SiOH) composed of several types of silanol groups:[14] silanols of amorphous silica–alumina species (3747 cm^{-1}), silanols of amorphous silica (3745 cm^{-1}) and terminal silanols attached to the zeolite lattice (3736 cm^{-1}) After ion-exchange with NMe_4OAc followed by calcination at 473 K, the bridged hydroxy groups band disappeared and the silanol bands significantly decreased in intensity [Fig. 1(b)]. When the ion-exchanged sample was calcined at 773 K, the intensities of these bands were almost recovered [Fig. 1(c)]. The pH of aqueous NMe_4OAc used for the ion-exchange was high enough (pH ~ 9) to allow the silanol groups to be exchanged with NMe_4^+ cations since the isoelectric point of SiO_2 is 1.0–2.0. These findings indicate that a part of silanol groups with weaker acidity as well as all of the bridged hydroxy groups with strong acidity were ion-exchanged with NMe_4^+.

The pH of the NMe_4OAc solution was varied from 8 to 12 to control the ion-exchange ratio. The oxidation activity gradually increased with increasing pH. Treatment at high pH resulted in the formation of mesopores, as revealed by N_2 adsorption measurements, which could promote the diffusion of the substances. However, the catalyst ion-exchanged at high pH exhibited low selectivity for epoxide; probably the zeolite framework dissolves to form silanol groups, which would catalyze undesirable reactions.

When the ion-exchanged [Ti,Al]-beta catalyst was reused for the oxidation of cyclohexene after the catalyst was calcined at 473 K for 10 h, the epoxide selectively was retained, although the oxidation activity gradually decreased to 37% for the third run probably because of the blocking of the Ti species by unremovable reaction products such as polymers with high boiling points. Nevertheless, after re-calcination at 793 K and repeated ion-exchange of the deactivated catalyst with NMe_4OAc, both the oxidation activity and the epoxide selectivity were recovered to the initial value, which strongly indicates that the present method is effective in developing an active, selective and reusable catalyst.

Received (in Corvallis, OR, USA) 17th May 2001, Accepted 27th June 2001
First published as an Advance Article on the web 29th August 2001

The reaction of neat 5- or 8-oxobenzopyran-2(1*H*)-ones, 1–3, with a variety of aromatic and heteroaromatic hydrazines, 4, is remarkably accelerated upon irradiation in a household microwave oven in the absence of any catalyst, solid support or solvent thus providing an environmentally friendly route to several heterocyclic hydrazones.

Microwave (MW) irradiation has been used for the rapid synthesis of a variety of compounds.[1] Chemical reactions can be accelerated because of selective absorption of microwave energy by polar molecules, non-polar being inert to the MW dielectric loss. Heterogeneous reactions facilitated by supported reagents on various inorganic surfaces have received special attention in recent years.[2] However, relatively little attention is paid to solventless reactions with neat reactants in the absence of a catalyst or solid support.

From the synthetic point of view hydrazones are important synthons for several transformations[3a–d] and their synthesis from various precursors is well documented.[3a,b] Recently, some hydrazones have been prepared from carbonyl compounds and hydrazine hydrate in ethylene glycol[4a] and toluene[4b] by the application of MW irradiation while some others are synthesized in the presence of silica gel and NaOH.[5]

We report here a general synthesis of several hydrazones **5–15**, which in some earlier preparations required relatively strenuous reaction conditions namely heating substrates for several hours in the presence of an acidic catalyst.[6] The synthetic efforts for these compounds have been previously directed for the selective design of the benzopyran-2-one ring at the positions 5 and 8 as well as for the new transformation into the corresponding quinoline derivatives. The conformational analysis has been accomplished for some of these derivatives by applying molecular modelling techniques based on experimentally determined NOE distance restraints in order to determine their structure in solution.[6a,d] These studies have been stimulated, in part, due to potentially significant biological activity associated with a variety of 2*H*-1-benzopyrans and quinolines.[6d] For the above reasons and in view of our general interest in the development of environmentally friendlier synthetic alternatives using microwaves,[2] we became interested in an expeditious synthesis of these compounds. In all the reactions reported in this paper we worked with neat starting materials, 1-benzopyran-2(2*H*)-ones **1**,[7a,b] **2**,[7a,b] **3**[7c] and hydrazines, **4**, wherein the reactions are completed within minutes and in high yields (61–98%, Scheme 1, Table 1)‡ using an unmodified household MW oven. Remarkably, reactions proceeded well even when both the starting reactants were solids and the reaction temperature was maintained below the melting points of both components; recently some comments have been made on the preparation of phthalimides starting from solid components, phthalic anhydride and amino compounds.[8a] In view of the unprecedented nature of this reaction, we examined the synthesis of the products **10** and **14** in detail. Since a conventional household MW oven is used with no accurate temperature control,§ we decided to measure the temperature of the alumina bath (used for housing the reaction vessel in the MW oven) with a calibrated thermometer immediately after completion of the reaction. In a controlled experiment, concurrently, we also heated the lower melting reactant in a second glass beaker to obtain visual information about the integrity of the solid materials upon exposure to microwaves.

For the synthesis of **10**, the starting benzopyran **2**[7a,b] (mp 179–179.5 °C) and 3-chloro-6-hydrazinopyridazine[9a] (mp 135–137 °C), were admixed in the ratio 1 : 2 (Table 1). When the reaction mixture was irradiated with MW for 5.5 min the highest temperature of the alumina recorded was 120–122 °C. The reaction mixture remained solid and no reaction was observed. After heating for 6 min, however, the temperature of the bath reached 130–132 °C and the reaction mixture was completely in

† Dedicated with deep respect to Professor Miha Tišler, University of Ljubljana, Slovenia on the occasion of his 75th birthday.

 DOI: 10.1039/b104508n

liquefied form affording hydrazone **10** in 85% isolated yield (see Table 1). The 3-chloro-6-hydrazinopyridazine kept in the same bath barely melted (~5% as estimated visually) at that temperature. With the critical temperature information in hand, we embarked on a comparative study and heated the above reaction mixture in the same proportions using a preheated oil bath. Heating for 12 min at 133 °C gave a mixture (liquid with some suspended solid material). NMR analysis revealed that the molar ratio between hydrazone **10** and starting benzopyran **2** was approximately 3.3:1. Prolonged heating of the reaction mixture for 1 h at 133 °C resulted in the formation of the liquid with no suspended solids. The work-up (as in general procedure) and NMR analysis revealed that the ratio between **10** and **2** in the isolated product was 92:8. Obviously, the unreacted benzopyran derivative contaminated product **10**, while under MW conditions we observed complete conversion to a single product (Table 1).

For the synthesis of **14** starting from **3**[7c] (mp 248–250 °C) and 4-nitrophenylhydrazine[9b] (mp ~157 °C with decomp.) we performed an experiment with the reactants in the ratio 1:2.6 respectively. The commercially obtained hydrazine derivative, however, contained 10–15% of water for stabilization and as such slightly melted at 130 °C. Upon MW irradiation for 5.5 min the same temperature (120–122 °C) was attained and the reaction mixture was completely melted while the 4-nitrophenylhydrazine in the second beaker was only barely melted. NMR analysis of the crude mixture showed no presence of the benzopyran derivative **3**, and the work-up resulted in hydrazone **14** in 94% yield. On the other hand, heating the same reaction mixture for 1 h at 128 °C in an oil bath resulted in a mixture of product **14** and starting **3** in the ratio 4.3:1, as discerned from the ^{1}H NMR spectrum of the crude reaction mixture. It should be mentioned that in this case the reaction mixture at the end of the heating period remained solid but attained a brownish color presumably as a result of partial decomposition.

This comparative study of the reactions taking place in an oil bath in the absence of MW heating revealed a substantial rate enhancement for reactions conducted under MW irradiation conditions, presumably due to the increase in polarity after change from the solid to the liquid phase.[8a] Such bimolecular reactions[2d,e] will have polarity enhancement as a result of ensuing intermediate transition state and consequently may display a pronounced microwave effect.[8b] Further, the reactions could be visibly monitored since no reaction occurs without formation of a melt. This methodology allows for performing rapid syntheses of a variety of hydrazones¶ below melting points of starting materials used. This could be explained by the lowering of the melting point by the formation of the eutectic;[10] such methodology seems to be especially useful when starting from substrates, which decompose at the normal melting point.

In conclusion, we have shown an expeditious, easy-to-handle and environmentally friendlier approach to the synthesis of a variety of non-easily-available hydrazones using MW irradiation that can be extended to other systems.

The authors wish to thank the Ministry of Education, Science and Sport of the Republic of Slovenia for financial support (P0-0503-103). Dr B. Kralj and Dr D. Žigon ('Jožef Stefan' Institute, Ljubljana) are acknowledged for mass spectra.

Notes and references

‡ The starting benzopyran-2(2*H*)-ones, **1**–**3**, and 3-chloro-6-hydrazinopyridazine were prepared as described in the literature.[7,9a] A household microwave oven operating at 2450 MHz was used at its full power, 650 W, for all the experiments.

*General procedure for the synthesis of hydrazones **5**–**15***: a neat mixture of benzopyran derivative **1**–**3** (1 mmol) and hydrazine **4** (1.2–3 mmol; see Table 1) in a 10 mL glass beaker was thoroughly mixed for about 5 min, then it was placed in an alumina bath inside the household microwave oven and irradiated. Maximum temperature reached in the alumina after 10 min was about 150 °C. After cooling, methanol (~4 mL) was added to the mixture and the separated solid was filtered off and washed with a small amount of methanol. Reaction conditions and yields are given in Table 1 for products, **5**–**15**, which conform to the NMR and elemental analyses.

§ There are commercial microwave devices available that provide adequate mixing and control of reaction parameters such as temperature, pressure.

Iron polynitroporphyrins bearing up to eight β-nitro groups as interesting new catalysts for H_2O_2-dependent hydrocarbon oxidation: unusual regioselectivity in hydroxylation of alkoxybenzenes

Received (in Cambridge, UK) 11th June 2001, Accepted 26th July 2001
First published as an Advance Article on the web 29th August 2001

A series of iron porphyrins bearing one to eight β-nitro substituents were synthesized and evaluated as catalysts for hydrocarbon oxidation with H_2O_2; iron porphyrins bearing five or six β-nitro groups were the best catalysts for cyclooctene epoxidation and adamantane or anisole hydroxylation without need of a cocatalyst, and led to very different regioselectivities with either H_2O_2 or PhIO as oxidants, as shown by an unusual *ortho*-hydroxylation of alkoxybenzenes highly favored in the H_2O_2-dependent oxidations.

Three successive generations of Fe(III) porphyrins have been developed during the last fifteen years as catalysts mimicking cytochromes P450.[1–3] Recently, iron porphyrins bearing electronegative substituents have been shown to catalyze olefin epoxidation and alkane hydroxylation with H_2O_2 in aprotic solvents without cocatalysts.[4] However, iron porphyrin–H_2O_2 systems efficient for other difficult P450-type monooxygenations, such as aromatic hydroxylation, remain to be found.

Quite recently, we have reported a new general method for selective polynitration of a Zn(II) porphyrin which affords a full series of zinc porphyrins bearing one through to eight β-nitro groups in high yields.[5] This opens the way towards metalloporphyrins with a remarkably wide span of redox potentials.[5] This communication reports a first comparison of the catalytic properties of a full series of new iron(III) β-polynitroporphyrins, that became available by this method,[6] in oxidations of hydrocarbons with H_2O_2. It shows that some of them catalyze not only alkene epoxidation but also alkane and aromatic hydroxylation with H_2O_2, without the need of any cocatalyst, and with chemo- and regio-selectivities very different from those of the corresponding oxidations with PhIO.

Eqn. (1) shows the procedure that was used for preparing the

$$\text{Zn(TDCPP)} \xrightarrow[\text{HNO}_3,\ \text{CF}_3\text{SO}_3\text{H}]{(\text{CF}_3\text{SO}_2)_2\text{O}} \text{Zn(TDCPN}x\text{P)} \xrightarrow[\text{iii } \text{O}_2,\ \text{HCl}]{\text{i } \text{H}^+ \text{ ii } \text{FeBr}_2} \text{Fe(TDCPN}x\text{P)Cl} \quad (1)$$

eight iron porphyrins, Fe(III)(TDCPN*x*P)Cl bearing one through to eight β-nitro substituents (x = 1–8), from Zn(TDCPP).[7] The key step is a reaction of Zn(TDCPP) with increasing amounts of a HNO_3–CF_3SO_3H–$(CF_3SO_2)_2O$ mixture which leads to each compound of the Zn(TDCPN*x*P) series with yields between 50 and 95%.[5] All Zn(II) and Fe(III)Cl complexes of the TDCPN*x*PH_2 porphyrins were completely characterized by mass spectrometry, UV–VIS, ^{1}H NMR and EPR (for the iron complexes) spectroscopy; their detailed synthesis and characteristics will be published elsewhere. The reduction potential of the Fe(III)Cl complexes vary from −225 (for x = 0) to +660 mV (for x = 8) (*vs.* SCE[7]).

As shown in Table 1, Fe(TDCPP)Cl is a poor catalyst for cyclooctene expoxidation with H_2O_2 in CH_2Cl_2–MeCN, in accord with previous literature data.[3] Increasing the number of β-NO_2 substituents of the porphyrin led to a spectacular increase of the epoxidation yield from 5 to 90%. This optimal yield was obtained with Fe(TDCPN$_5$P)Cl, a further increase of the number of β-NO_2 substituents leading to much lower yields. Fe(TDCPN$_5$P)Cl was also the best catalyst for hydroxylation of adamantane with H_2O_2 with a total yield (1- and 2-adamantanols) of 35% based on starting H_2O_2. For this alkane, very low yields were found for Fe(TDCPP)Cl, with a progressive increase of the yield with catalysts bearing one through to four β-nitro groups and optimum yields for Fe(TDCPN$_5$P)Cl and Fe(TDCPN$_6$P)Cl.

A similar trend was observed for aromatic hydroxylation of anisole with H_2O_2 catalyzed by this iron porphyrin series. Fe(TDCPP)Cl is almost inactive for this reaction, whereas iron porphyrins bearing from three to six β-NO_2 substituents led to the formation of *ortho*- and *para*-hydroxylated products with total yields between 13 and 17% (Table 1). Interestingly, the regioselectivity of these Fe(TDCPN*x*P)Cl-catalyzed aromatic hydroxylations varies significantly as a function of x (Table 1). The *ortho*:*para* ratio is in favor of *para*-hydroxylation for x = 0, 1 and 2, whereas it progressively increases to values up to 5.5 for Fe(TDCPN$_6$P)Cl. This remarkable change of regioselectivity as a function of x should be due to a change in the nature and/or reactivity of the active species formed in these reactions. Possible involvement of further oxidations of *o*- and *p*-phenols in determining the *ortho*:*para* ratio is unlikely because of the

Table 1 Oxidation of cyclooctene, adamantane and anisole with H_2O_2 in the presence of the Fe(TDCPN$_x$P)Cl catalysts

Catalyst Fe(TDCPN*x*P)Cl		x = 0	1	2	3	4	5	6	7	8
Reaction		Yield[d] (%)								
Cyclooctene epoxidation[a]		5	20	48	68	80	90	15	6	2
Hydroxylation	ol-1	1.5	3	1.5	2	7	26	25	17	4
of adamantane[b]	ol-2	1	1.5	1	0.5	2.5	9	10	7	2
Hydroxylation	*p*-OH	1	2	3	5	6	3	2	1	2
of anisole[c]	*o*-OH	<1	<1	1.5	9.5	11	13.5	11	3	9
	o/*p*			0.5	1.9	1.8	4.5	5.5	3	4.5

[a] *Conditions*: catalyst:H_2O_2:cyclooctene molar ratio = 1:300:100 in CH_2Cl_2–MeCN (1:1) for 2 h at 20 °C, with [catalyst] = 1 mM. [b] *Conditions*: catalyst:H_2O_2:adamantane molar ratio = 1:40:300 in CH_2Cl_2–MeCN (1:1) for 2 h at 20 °C; [catalyst] = 1 mM. Small amounts of adamantan-2-one were also detected (yield < 1%). [c] *Conditions*: catalyst:H_2O_2:anisole molar ratio = 1:20:3000 in H_2O–MeCN (1:9); [catalyst] = 2 mM. *p*-OH and *o*-OH are used for *p*- and *o*-hydroxyanisole. [d] Yields are based on starting H_2O_2 except for cyclooctene epoxidations for which H_2O_2 was used in excess relative to substrate; yields for cyclooctene epoxidation were thus based on cyclooctene.

[a] *Conditions*: Fe(TDCPN$_5$P)Cl : oxidant : adamantane molar ratio = 1 : 40 : 300 in CH_2Cl_2–MeCN (1 : 1) for 2 h at 20 °C; [catalyst] = 2 mM; o1-1, ol-2 and one-2 denote adamantan-1-ol, -2-ol and -2-one. [b] *Conditions*: Fe(TDCPN$_5$P)Cl : oxidant : limonene = 1 : 40 : 800 in CH_2Cl_2–MeCN (1 : 1). Carveols and carvone are the products resulting from allylic hydroxylation of limonene (at position 6).[3a] [c] *Conditions*: Fe(TDCPN$_5$P)Cl : oxidant : alkoxybenzene = 1 : 20 : 3000 in CH_2Cl_2–MeCN (1 : 1). *o*-OH and *p*-OH are used for the *ortho*- and *para*-hydroxylation products. [d] Yields are based on starting H_2O_2 or PhIO. All the experiments described in Tables 1 and 2 were usually performed under aerobic conditions. However, it is noteworthy that many experiments were also done under anaerobic conditions (under Ar) and gave almost identical results, showing that the observed regioselectivities were not affected by the presence of O_2.

huge excess of substrate used in these reactions (catalyst : H_2O_2 : substrate = 1 : 20 : 3000). Moreover, identical experiments performed under stoichiometric conditions (iron porphyrin : H_2O_2 : substrate = 1 : 1 : 3000) led to almost identical regioselectivities for anisole hydroxylation. It is noteworthy that the Fe(TDCPN*x*P)Cl catalysts were stable under the conditions described in Table 1. This was shown by their visible spectra that were found to be unchanged at the end of the reactions, and by their catalytic activity that remained almost identical after a further addition of H_2O_2 in the reaction medium.

The aforementioned results show the particular efficiency of iron porphyrins bearing around five β-nitro substituents to catalyze alkene epoxidation and alkane and aromatic hydroxylations with H_2O_2 in the absence of a cocatalyst. In order to have a first idea of the nature of the major active species responsible for these oxidations, we compared the oxidations of several substrates with H_2O_2 and Fe(TDCPN$_5$P)Cl to those performed with PhIO and the same catalyst under identical conditions. Table 2 clearly shows marked differences in the chemo- and regio-selectivities of the H_2O_2- and PhIO-dependent oxidations. This changes from small significant albeit small differences in the regioselectivity of adamantane hydroxylation (ol-1/ol-2 molar ratio of 2.9 with H_2O_2 *cf.* 2.1 with PhIO) and in the regioselectivity of limonene epoxidation (1,2 oxide/8,9 oxide = 2.7 *cf.* 1.9) to more dramatic differences in the regioselectivity of anisole and ethoxybenzene hydroxylations (major formation of *ortho*-hydroxylated products with H_2O_2 instead of almost exclusive *para* hydroxylation with PhIO).

Several years ago, a similar comparison between the chemo- and regio-selectivities of the oxidations of alkenes and alkanes with either PhIO or H_2O_2, in the presence of the Mn(TDCPP)Cl catalyst and imidazole cocatalyst, led to the conclusion that both systems involve the same active oxygen species, presumably a high-valent Mn=O complex.[3a] The results of Table 2 strongly suggest that the Fe(TDCPN$_5$P)Cl–H_2O_2 and Fe(TDCPN$_5$P)Cl–PhIO systems involve different active oxygen species. If one assumes that the active species formed with PhIO is a (por$^{+\cdot}$)Fe(IV)=O intermediate, as has been proposed for many other iron porphyrins,[1] one is led to the conclusion that different active species are involved in the H_2O_2-dependent oxidations. Several authors have already mentioned the possible formation of a ferric–hydroperoxo complex as an intermediate towards the high-valent iron–oxo species, in reactions of H_2O_2 with iron porphyrins[1,8] [eqn. (2)]. *Ortho*-hydroxylation of anisole from

$$(por)Fe^{III} + H_2O_2 \xrightarrow{-H^+} [(por)Fe^{III}\text{–}OOH] \xrightarrow[-H_2O]{+H^+} [(por^{+\cdot})Fe^{IV}{=}O] \quad (2)$$

transfer of the terminal oxygen atom of such a ferric–hydroperoxo complex should be less sterically restricted than the transfer of the oxygen atom of a high-valent (TDCPN*x*P) iron–oxo intermediate.[9] Preferential involvement of a Fe(III)–OOH intermediate in reaction of H_2O_2 with iron–β-polynitroporphyrins, which should be less prone to stabilize high-valent iron–oxo species, is likely and could explain the surprising regioselectivity observed in the hydroxylation of anisole and ethoxybenzene. However, additional experiments are necessary to determine the nature of the active intermediate(s) involved in reactions using H_2O_2 and iron–β-polynitroporphyrins. Nonetheless, the preliminary results reported here indicate that the Fe(TDCPN*x*P)Cl complexes with $x \geqslant 4$ are interesting catalysts for alkane and aromatic hydrocarbon oxidation with H_2O_2 without need of a cocatalyst, that lead to new regioselectivities, especially in the hydroxylation of aromatic molecules.

ITQ-16, a new zeolite family of the beta group with different proportions of polymorphs A, B and C

Avelino Corma,* Mª Teresa Navarro, Fernando Rey and Susana Valencia

Instituto de Tecnología Química, UPV-CSIC, Universidad Politécnica de Valencia, Avda. de los Naranjos s/n, 46022 Valencia, Spain. E-mail: acorma@itq.upv.es

Received (in Cambridge, UK) 13th June 2001, Accepted 1st August 2001
First published as an Advance Article on the web 29th August 2001

ITQ-16 is a new zeolite family formed by polymorphs A, B and C of the beta intergrowth in which the proportion of polymorph C can be controlled by changing the organic structure directing agent and/or by changing the Ge content of the synthesis gel; ITQ-16 can be synthesised either in fluoride or fluoride-free medium and Al can be introduced in the framework giving a material with very strong Brönsted acidity.

Beta is the only high silica zeolite with a three-dimensional system of 12-membered ring pores (MRP) that has found commercial applications up to now.[1] Zeolite beta is formed by an intergrowth of polymorphs A and B which gives the typical XRD pattern of this zeolite (Fig. 1).

Over 20 years ago, Newsam *et al*.[2] predicted that a third polymorph with a closely related structure should also exist. We have showed that polymorph C not only exists, but can be synthesised as a unique phase by working in either fluoride[3] or in OH^- fluoride free media.[4] The structure of polymorph C is formed by a three-dimensional system of rectilineous 12 MRP channels, and the corresponding XRD pattern is shown in Fig. 1.

In the present work, we show that it is possible now not only to synthesise the pure polymorph of C (ITQ-17), but also a new family of materials (ITQ-16) can be prepared where the three polymorphs A, B and C exist and the ratio C/(A + B) can be varied as desired. This can be achieved by using different organic structure directing agents (OSDAs) in the synthesis, and also by working in different ranges of gel compositions and crystallization conditions. It will be shown here that ITQ-16 can be synthesised in fluoride as well as in a fluoride-free media.

The general synthesis conditions employed in this work for the experiments in fluoride media were as follows:

$(1 - x)\ SiO_2 : x\ GeO_2 : 0.5\ R^1OH : 0.5\ HF : 8\ H_2O$ and
$(1 - x)\ SiO_2 : x\ GeO_2 : 0.25\ R^2(OH)_2 : 0.5\ HF : 8\ H_2O$

where R^1 and R^2 are the OSDAs shown in Scheme 1 and x was varied between 0.0196 and 0.1667. The OSDAs were prepared according to methods reported in the literature.[5] ITQ-16 zeolite was also synthesised in alkaline media, starting with the following gel compositions:

$(1 - y)\ SiO_2 : y\ GeO_2 : 0.5\ BzDOH : 3.5\ H_2O$ and
$0.8333\ SiO_2 : 0.1667\ GeO_2 : 0.25\ p\text{-}XydD(OH)_2 : 3.5\ H_2O$

where y was 0.0625 and 0.1667. For ITQ-16 synthesised by the alkaline route, 3 wt% (with respect to the total weight of SiO_2 and GeO_2) seeds of pure ITQ-17 zeolite were added to the synthesis gel in order to promote crystallisation.

The gels were autoclaved at 150 °C for different crystallisation times and the solids were recovered by filtration and then were extensively washed with distilled water and dried at 100 °C, overnight. Table 1 shows the synthesis conditions studied in this work as well as the crystalline phase obtained in the final solids.

Syntheses 1–5 show that the level of polymorph C present in the final solid obtained from the same starting synthesis gel can be varied by using different organic structure directing agents. In this way, p-$XydD^{2+}$ (sample 2) and BzD^+ (sample 1) give pure polymorph C, while BzQ^+ (sample 3) gives a mixture of the three polymorphs (Fig. 2). ITQ-16 can also be obtained with other OSDAs, such as $dPyrrP^{2+}$ and in this case a different ratio of C/(A+B) polymorphs is observed (Fig. 2, sample 4). It is noted that polymorph C is not detected when using TEA^+ (sample 5) as the OSDA in the same synthesis conditions.

The ratio of the three polymorphs in ITQ-16 can also be controlled by modifying the cation composition of the synthesis gel. For instance, when using BzD^+ as the OSDA, it can be seen in Fig. 3 that the proportion of polymorph C increases when increasing the Ge content of the synthesis gel (Table 1; samples 1, 6–9).

ITQ-16 can also be synthesised in fluoride-free alkaline media. In this case, highly concentrated gels and longer crystallisation periods are required for the synthesis of ITQ-16 (Table 1; samples 10–12). The formation of ITQ-16 in alkaline

Table 1 Synthesis conditions and zeolitic structures obtained using different OSDAs and Ge contents in the crystallisation gel

Sample	Crystallisation time	OSDA	Ge/(Si + Ge)	Structure	Percentage of polymorph C[a]
1	13 h	BzD^+	0.0625	ITQ-17	100
2	19 h	*p*-$XydD^{2+}$	0.0625	ITQ-17	100
3	20 h	BzQ^+	0.0625	ITQ-16	46
4	12 d	$dPyrrP^{2+}$	0.0625	ITQ-16	31
5	24 h	TEA^+	0.0625	Beta	0
6	14 h	BzD^+	0.1667	ITQ-17	100
7	15 h	BzD^+	0.0385	ITQ-16	85
8	48 h	BzD^+	0.0278	ITQ-16	52
9	13 h	BzD^+	0.0196	ITQ-16	27
10[b]	5 d	*p*-$XydD^{2+}$	0.1667	ITQ-16	66
11[b]	6 d	BzD^+	0.1667	ITQ-16	48
12[b]	7 d	BzD^+	0.0625	ITQ-16	40

[a] The percentage of polymorph C was estimated from the XRD patterns as the integrated area below the characteristic peaks at *ca.* 7.0 and 9.5° with respect to the total area in the range 5–12°. [b] Syntheses carried out in alkaline fluoride-free gels.

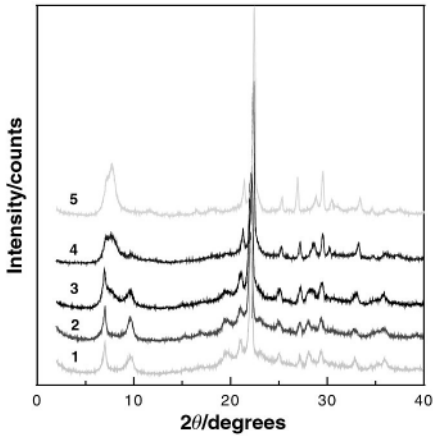

Fig. 2 X-Ray diffraction patterns of as-prepared ITQ-16 zeolites synthesised with different OSDAs (samples of Table 1).

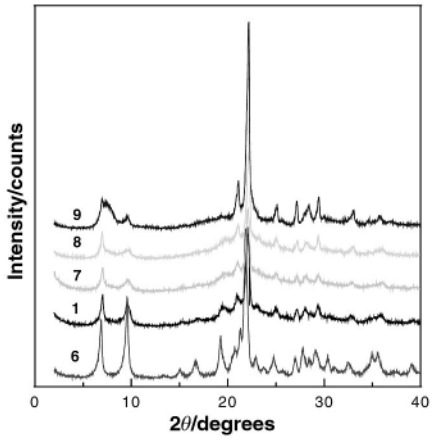

Fig. 3 X-Ray diffraction patterns of as-prepared ITQ-16 zeolites synthesised from gels with different Ge content (samples of Table 1).

media requires lower Si/Ge ratios than when the synthesis was carried out in fluoride media. Thus, it appears that Ge plays a very important role in driving the synthesis towards the formation of polymorph C between the other possible polymorphs which constitute the beta zeolite intergrowth.

For practical catalytic uses it is interesting to introduce acidity in the samples. We have succeeded in incorporating isomorphically Al into the ITQ-16, and one of the possible synthesis gel compositions is given below.

$$0.9375\ SiO_2 : 0.0625\ GeO_2 : 0.5\ BzDOH : 0.5\ HF : 20\ H_2O : 0.02\ Al_2O_3$$

An Al-ITQ-16 material was obtained after 10 days of crystallisation at 150 °C. The resulting Al-ITQ-16 shows a unique resonance peak at 53 ppm in the ^{27}Al MAS NMR spectrum assigned to the presence of Al in tetrahedral coordination.

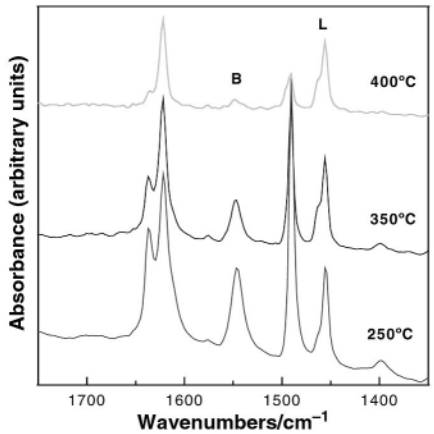

Fig. 4 IR spectra of adsorbed pyridine of the Al-ITQ-16 sample at different desorption temperatures (B and L indicate the characteristic IR bands of pyridine adsorbed on Brönsted and Lewis acid sites, respectively).

Acidity was measured after calcination of the sample at 500 °C, by means of pyridine adsorption–desorption. The IR spectra of adsorbed pyridine (Fig. 4) indicate the formation of pyridinium ions (*ca.* 1545 cm^{-1}) associated with the presence of Brönsted acid sites, as well as a band of pyridine coordinated to extraframework or partially dislodged Lewis acid Al atoms generated upon calcination (*ca.* 1450 cm^{-1}). It can be seen in Fig. 4 that Brönsted acid sites have been generated by the introduction of framework Al, and some of these sites can retain pyridine upon desorption at 350 and 400 °C and 10^{-2} Torr, indicating the presence of very strong acid sites in Al-ITQ-16.

In conclusion, ITQ-16 is formed by polymorphs A, B and C, and the proportion of polymorph C in the sample can be controlled by changing the organic structure directing agent and/or by changing the Ge content of the synthesis gel. ITQ-16 can be synthesized either in fluoride or fluoride-free medium and Al can be introduced in the framework giving a material with very strong Brönsted acidity.

Enantioselective deprotonation reactions using polymer-supported chiral magnesium amide bases†

Kenneth W. Henderson,* William J. Kerr* and Jennifer H. Moir

Department of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, Scotland, UK G1 1XL. E-mail: w.kerr@strath.ac.uk

Received (in Cambridge, UK) 18th May 2001, Accepted 25th July 2001
First published as an Advance Article on the web 28th August 2001

Novel and readily accessible polymer-supported chiral magnesium amide reagents have been prepared and shown to be effective in the asymmetric deprotonation of a series of prochiral cyclohexanones, affording good to excellent levels of both conversion and enantiomeric ratio (up to 93:7); the Merrifield-based chiral amine species has been shown to be readily recyclable.

The application of chiral lithium amide base reagents within asymmetric organic synthesis is widespread.[1] Additionally we have recently disclosed the preparation of a novel homochiral magnesium amide base and have shown it to be particularly effective in the desymmetrisation of both 4-substituted and 2,6-disubstituted cyclohexanones; the initially reported processes afforded the corresponding silyl enol ethers in up to 95:5 er.[2] Consequently, with a view to gaining the practical and economic advantages offered by solid phase chemistry,[3] we envisioned that tethering the chiral amine, and ultimately the Mg-amide, to a polymer support[4] would provide a convenient and potentially recyclable enantioselective reaction source. Furthermore and at least as importantly, based on our drive to alter the nature of the base itself, we believed that this approach would also allow the establishment of a library of supported chiral amines and, in turn, resin-bound Mg-amides, which would enable an effective assessment of the key structural requirements for the optimisation of such enantioselective reagents. Herein, we report our initial studies in this area and, more specifically, the first use of a polymer-supported chiral Mg-amide base to mediate enantioselective deprotonation processes.

At the outset of this programme, the simple and readily accessible Merrifield resin **1**[5] formed an attractive starting point for direct functionalisation with (*R*)-α-methylbenzylamine. The process shown in Scheme 1 cleanly afforded the supported chiral amine (*R*)-**2**.‡

Having established a practically efficient approach to the preparation of (*R*)-**2**, its use as a Mg-amide derivative was then evaluated in the enantioselective deprotonation of **3a**. Optimum formation of the requisite Mg-amide species occurred following reflux of (*R*)-**2** with dibutylmagnesium for 90 min in THF.§ On cooling the resin-bound base to −78 °C, we were pleased to observe the first asymmetric deprotonations with our new supported reagent. As shown in Scheme 2, in the presence of 0.5 mol equiv. of DMPU and excess TMSCl, good levels of both conversion of **3a** to (*S*)-**4a** (78%) and enantiomeric ratio (74:26 er) were achieved.†

Based on this experimental protocol, we moved on to consider the desymmetrisation reaction of a series of alternative prochiral cyclohexanones **3** using our Merrifield-based chiral

amine resin (*R*)-**2** (Table 1). At −78 °C the 4-substituted cyclohexanones **3a–d** all showed good levels of conversion and gave enol ethers (*S*)-**4a–d** with enantiomeric ratios of up to 75:25. With the 2,6-disubstituted substrates, higher temperatures were required to achieve acceptable levels of conversion. However, when all ketones (**3a–f**) employed here are considered, it should be noted that at room temperature higher conversions were achieved in almost every instance with, at worst, only small reductions in the recorded enantiomeric ratios. Indeed, the enantioselection observed upon reaction of *cis*-**3e** and *cis*-**3f** appears largely independent of temperature. Furthermore reaction of *cis*-diisopropylcyclohex-

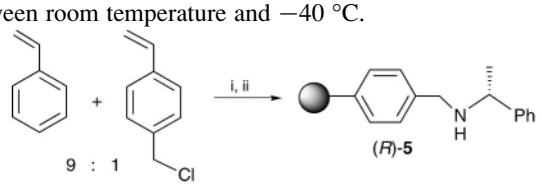
anone *cis*-**3f** gives a 97% conversion and an outstanding er of 93:7 even at room temperature. As such, this method affords us a practically convenient method by which to generate high levels of asymmetric induction in the deprotonation of specific 2,6-disubstituted cyclohexanones.¶

In addition to establishing the initial deprotonation strategies using our Merrifield-based Mg-amide, we were also keen to develop an efficient recycling protocol. In this respect, following completion of reaction, the parent polymer-bound chiral amine (*R*)-**2** was readily regenerated by consecutively washing the resin with a 2:1 mixture of THF–HCl (1 M) and then, to liberate the amine from the HCl salt, with 10% $^{i}Pr_2NEt$ in DMF. This process opened up the possibility of re-using the supported chiral amine and, as such, we can now report that (*R*)-**2** can, indeed, be recycled up to and over 5 times. More specifically, in a series of deprotonations of **3a** to afford (*S*)-**4a**, no appreciable drop in conversion was noted and the enantiomeric ratio remained consistent throughout (Table 2). Furthermore, after 5 cycles at room temperature, the resin was also able to show a return to the enhanced levels of asymmetric induction observed at −78 °C (Cycle 6), thus demonstrating the durability of the tethered amine.‖

Having successfully optimised our deprotonation strategy using the accessible and readily recyclable Merrifield-based chiral amine resin (*R*)-**2**, we moved on to explore the effects of alternative polystyrene supports on the enantioselective potential of the resin-bound Mg-amide, In this respect, a soluble polystyrene resin[8] was prepared and, subsequently, functionalised with (*R*)-α-methylbenzylamine to afford the supported amine (*R*)-**5** (Scheme 3).‡ With this material in hand, we went on to assess the performance of (*R*)-**5**, as the Mg-amide, in the enantioselective deprotonation reaction of a selection of ketones. Pleasingly, as can be seen in Table 3, with **3a** and **3d** this new soluble resin-bound species provided excellent reaction conversions and, moreover, delivered enhanced levels of enantiomeric ratio at both room temperature and at −78 °C. One again, (*S*)-**4f** was formed in excellent er and with no appreciable difference in enantioselection being observed between room temperature and −40 °C.



Scheme 3 *Reagents and conditions*: i, AIBN, toluene, 70 °C, 40 h; ii, (*R*)-α-methylbenzylamine (3 eq.), NaI (1 eq.), DMF, 48 h.

In conclusion, we have successfully prepared two distinct polymeric species posessing chiral amino functionality and, in turn, chiral Mg-amide units and both of these have been shown to be effective in the enantioselective deprotonation reaction of a variety of 4-substituted and, more particularly, 2,6-disubstituted cyclohexanones. Moreover, moderate to high levels of asymmetric induction (up to 93:7 er) were observed, even during reactions performed at room temperature. In addition, the supported chiral amine derived from Merrifield resin was found to be efficiently recycled for further use within the

Table 3 Enantioselective deprotonations using soluble supported amine (*R*)-**5**[a]

		rt	2	>99	93:7

[a] *Reagents and conditions*: i, (*R*)-**2** (2 eq.), Bu_2Mg (1 eq.), THF, reflux, 90 min; ii, TMSCl (4 eq.), DMPU (0.5 eq.), ketone (0.8 eq.), THF. [b] This result is comparable with that observed in our unsupported base studies (−78 °C, 6 h; 89% conv., 90:10 er); see ref. 2.

deprotonation protocols. Indeed, it is envisaged that this facet of the supported Mg-amide chemistry disclosed here will be of considerable benefit when employing more precious chiral amines, which are either commercially unavailable or have required multi-step generation. The application of this methodology to the preparation of a library of chiral Mg-amide reagents and the use of other resins is underway and will be reported in due course.

Wathey at Organon Laboratories, for many helpful discussions and the generous donation of materials, and the EPSRC Mass Spectrometry Service, University of Wales, Swansea for analyses.

Notes and references

‡ The amine loading level was established by derivatisation with FmocCl, followed by UV analysis of the subsequent cleavage reaction.[6] This routinely showed an amine loading of 1.30–1.40 mmol g^{-1} for (*R*)-**2** and 1.00 mmol g^{-1} for (*R*)-**5**.

§ It should be noted that whilst the production of a resin-bound Mg-bisamide reagent is supposed, the possible formation of some alkyl(Bu)-Mg-amide species must also be recognised. A control experiment performed between Bu_2Mg and **3a** gave no reaction, even at room temperature. Based on this observation, it is believed that the presence of such an alkyl–Mg intermediate would have no adverse affect on the deprotonation process.

¶ Enantiomeric ratios were determined by GC analysis. Additionally, the absolute configuration of the major and minor enantiomers for **4a**, **4b**, **4d**, and **4e** were assigned by correlation of optical rotation measurements with those of Koga and co-workers (ref. 7); for **4c** and **4f** the major and minor isomer configurations were tentatively assigned by comparison with **4a**, **b**, and **d**, and **4e**, respectively. All compounds also exhibited satisfactory analytical and spectral data.

‖ It should be noted that resin (*R*)-**2** was also effectively recycled following the initial reaction of *cis*-**3f** at room temperature, and afforded a >99% conversion and 93:7 er.

Generation of chromioenamines by reduction of *O*-acetyloximes with chromium(II) and their application†

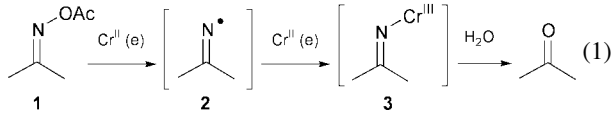
Kazuhiko Takai,* Noriko Katsura and Yuji Kunisada

Department of Applied Chemistry, Faculty of Engineering, Okayama University, Tsushima, Okayama 700-8530, Japan. E-mail: ktakai@cc.okayama-u.ac.jp

Received (in Cambridge, UK) 19th June 2001, Accepted 24th July 2001
First published as an Advance Article on the web 13th August 2001

Chromioenamines can be generated by treatment of *O*-acetyloximes with chromium(II) *via* two steps of one-electron reduction and successive isomerization, and the species react with aldehydes to give γ-amino alcohols after reduction with $LiAlH_4$.

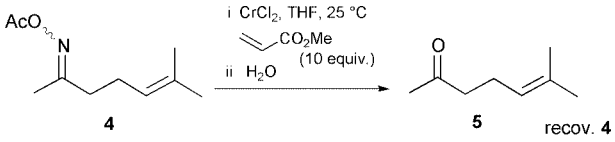
Treatment of *O*-acetyloximes **1** with low valent metals such as Cr(II) and Ti(III) under aqueous conditions is a mild deoximation procedure.[1] The process includes the reductive cleavage of N–O bonds leading to *N*-metal imines **3**[2] *via* iminyl radicals **2**,[3] and the hydrolysis of the formed imines to obtain ketones [eqn. (1)].



1 2 3 (1)

In order to examine the utilization of the formed reactive species **2** or **3** for carbon–carbon formation, we conducted the chromium(II)-mediated deoximation in aprotic solvents.[4]

The *O*-acetyloxime **4** was treated with 2 equiv. of chromium(II) chloride in the presence of 10 equiv. of methyl acrylate to give the corresponding deoximated ketone **5** in 88% yield after hydrolysis [eqn. (2)]. Nitrogen-containing five-membered



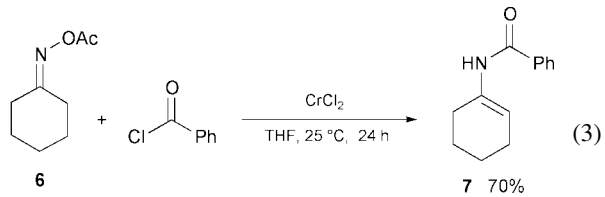
4 5 recov. 4

$CrCl_2$	2.0 equiv.	88%	0%
	1.0 equiv.	44%	44%

(2)

ring compounds derived *via* intramolecular radical cyclization were not observed,[3] and no coupling product between **4** and the acrylate was obtained. When the amount of chromium(II) chloride was reduced to 1 equiv. of the oxime **4**, the ketone **5** was obtained in 44% yield and **4** was recovered in 44% yield. These results suggest that the second one-electron reduction of the iminyl radical **2** to the *N*-chromium imine **3** proceeds faster than the first reduction of **1** to **2**.

Trapping of the formed *N*-chromium imine **3** was examined. Although the reduction of the cyclohexanone *O*-acetyloxime **6** with $CrCl_2$ in the presence of Me_3SiCl resulted only in deoximation leading to cyclohexanone, the reduction in the presence of the benzoyl chloride gave **7** in 70% yield along with benzamide in 8% yield [eqn. (3)].[1b] The expected *N*-acyl imine



6 7 70% (3)

† Electronic supplementary information (ESI) available: experimental section. See http://www.rsc.org/suppdata/cc/b1/b105357b/

derived from *N*-chromium imine **3** was not obtained, and instead a chromioenamine was trapped as **7**.

Thus, carbon–carbon bond formation with this chromioenamine[5] was investigated in the presence of an aldehyde in the aprotic solvent. Treatment of a mixture of acetone *O*-acetyloxime (**8**, 2 equiv.) and benzaldehyde with $CrCl_2$ (8 equiv.) in THF at 25 °C for 24 h followed by hydrolysis with water gave 4-phenyl-4-hydroxybutan-2-one (**9**) in 23% yield. The quenching procedure affected the yields considerably, probably due to the strong chelation of the adducts to chromium(III). The yield was improved to 88% by quenching with aqueous NaF solution (Table 1 run 2).[6–8] Although the reaction proceeded more slowly in the case of aliphatic aldehydes, addition of a catalytic amount of $NiCl_2$ accelerated the reaction rate and improved the yields.[9]

A possible mechanism is shown in Scheme 1. One electron reduction of an *O*-acetyloxime with chromium(II) gives the

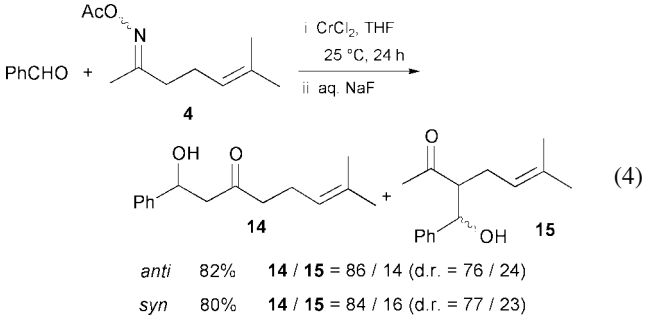
 DOI: 10.1039/b105357b

imine radical **2**,[3] which is then subjected to the second one electron reduction to give **3**. The imine **3** is isomerized to chromioenamine **10**,[1d,10] and the chromioenamine reacts with an aldehyde to give **11**.[11] Hydrolysis of **11** gives the aldol adduct **12**. Metalloenamines are usually prepared by deprotonation of imine derivatives with strong bases,[5] however, the procedure does not require such bases. Attempts to reduce the amount of chromium(II) with manganese and Me_3SiCl resulted in deoximation probably due to the fast trapping of the chromium imine **3** or the chromioenamine **10** with Me_3SiCl.[12]

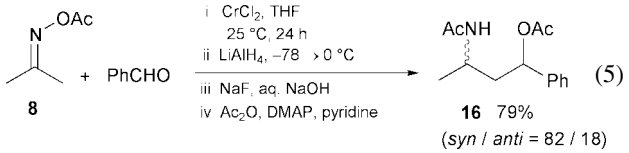
When *anti*- and *syn*-**4** were employed in the reaction, almost the same product distributions were observed [eqn. (4)]. The



(4)

major product was an aldol adduct **14** at the less hindered carbon. This result supports the proposed Scheme 1, in which the two reactions involve the same iminyl radical as the intermediate.

In order to utilize the nitrogen-containing adduct **11**, reduction of **11** leading to a γ-amino alcohol **13** was examined.[13] A mixture obtained from **8** and benzaldehyde was treated with $LiAlH_4$ (10 equiv.) at −78 °C, and the temperature of the mixture was gradually raised to 0 °C. Quenching of the mixture with alkaline NaF solution followed by acetylation gave the acetylated γ-amino alcohol **16** in 79% yield [eqn. (5)].[14,15] The yield was increased by addition of a catalytic



(5)

amount of $NiCl_2$. The results of the preparation of γ-amino alcohols from *O*-acetyloximes and aldehydes with $CrCl_2$ and $NiCl_2$ are summarized in Table 2.

In conclusion, chromioenamines are generated by treatment of *O*-acetyloximes with chromium(II) *via* sequential reduction and isomerization. These react with aldehydes to obtain γ-amino alcohols after reduction with $LiAlH_4$. The reaction proceeds under mild conditions and does not require strong bases such as LDA.

This work was supported by a Grant-in-Aid from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

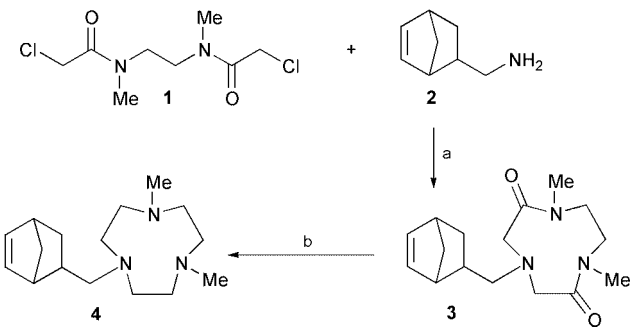
New polymers containing 1,4,7-triazacyclononanes have been synthesised by means of ring opening metathesis polymerisation (ROMP); their complexes with Mn(II) catalyse the oxidation of simple olefins by hydrogen peroxide.

The ongoing interest in environmentally benign processes for oxidations of simple organic molecules has led to the development of various catalytic systems for the activation of H_2O_2. Among these, manganese–triazacyclononane complexes have received considerable attention in recent years.[1] Simple protocols allow epoxidations to be performed in water–cosolvent mixtures using catalytic amounts of such complexes and hydrogen peroxide as stoichiometric oxidant. However, separation and recycling of the catalysts are still major challenges, and several strategies have already been investigated. For example, triazacyclononanes (TACNs) have been linked to silica affording heterogeneous systems, which can easily be recovered by filtration.[2] Alternatively, perfluorinated side chains were introduced onto the TACN in order to allow for fluorous biphasic catalysis (FBC).[3] Unfortunately, most of these approaches led to systems with reduced catalytic activity and lower product selectivity. Thus, a feasible immobilization strategy which allows maintenance of the positive attributes of the 'free' triazacyclononane–manganese system is still missing. In this work, we now present the synthesis of polymeric structures bearing a dense arrangement of 1,4,7-triazacyclononane moieties by application of ROMP.[4] With hydrogen peroxide as terminal oxidant manganese complexes of such polymeric ligands efficiently catalyse epoxidations of simple olefins exhibiting activities and selectivities which are comparable to those of the monomeric systems. Allylic and benzylic alcohols are also oxidised. In the case of conjugated alkenes, other oxidation products (*e.g.* diols) are formed as well.

Monomer **4** containing a polymerisable norbornene‡ element and a 1,4,7-triazacyclonane unit was readily assembled from norbornenylmethylamine (**2**) following a well-established bis-(chloroacetamide) cyclisation–reduction sequence (Scheme 1).[5]



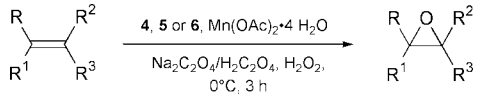
Scheme 1 Synthesis of the monomer **4**. *Reagents and conditions*: (a) Na_2CO_3, LiBr, CH_3CN, reflux, 12 h; (b) $LiAlH_4$, THF, reflux, 6 h.

† Electronic supplementary information (ESI) available: experimental details. See http://www.rsc.org/suppdata/cc/b1/b105560g/

Purification *via* column chromatography or high-vacuum distillation afforded **4** in 15% overall yield.

Attempted polymerisation of monomer **4** with Grubbs's catalyst[6] failed, probably due to interference of the multiple amine groups present in the molecule. Protonated **4** gave polycationic polymers, which, unfortunately, only showed negligible catalytic activity in the epoxidation of olefins when combined with manganese salts and hydrogen peroxide. To our delight, Schrock's molybdenum based catalyst[7] reacted with the free triamine **4** rapidly and efficiently, allowing the preparation of desired polymer **5** in quantitative yield (Scheme 2). In these preliminary studies, 5 mol% of the catalyst was employed in all runs, setting the number of triazacyclononane units per molecule (*n*) at about 20. The terminal ends of the polymer were capped by treatment of the reaction mixture with pivaldehyde after complete consumption of the monomer. Diimide mediated hydrogenation afforded saturated polymer **6** (with a degree of hydrogenation of *ca.* 86%) in 70% yield.

The performance of manganese catalysts derived from polymers **5** and **6** in olefin oxidations with hydrogen peroxide was investigated under the conditions indicated in eqn. (1).§



(1)

In all runs, 1 mol% of active catalyst (based on 3.7 mmol TACN units per g of polymer) formed *in situ* from $Mn(OAc)_2{\cdot}4H_2O$ and **4**, **5**, or **6** was employed. Both the ligand and the manganese complexes were soluble in aqueous acetone–methanol–H_2O_2 mixtures. The presence of sodium oxalate as co-ligand proved essential for the efficiency of the reaction.[8] Noteworthy is the fact that the conversion of the substrates was negligible in the absence of the triazacyclononane-containing polymers. The most significant results of this study are summarised in Table 1.

The performance of the polymeric systems in catalysing the oxidation reactions was in most cases comparable or even superior to that of the corresponding monomeric azacycle. Simple aromatic olefins were converted efficiently to the corresponding epoxides (entries 1–4). In the cases of α-methylstyrene and indene notable amounts of diols were

15	2-Phenylethanol	41	31	21

[a] Calculated as the ratio of epoxide yield and conversion. [b] A notable amount (11–27%) of the corresponding diol is produced. Other byproducts include benzophenone and 2-phenylpropionaldehyde. [c] The main byproduct is indan-2-one (10–24%). A notable quantity (6–11%) of the corresponding *cis*-diol is also produced. [d] + 17% of the corresponding *trans*-epoxide. [e] + 8% of the corresponding *trans*-epoxide. [f] 0.03 M oxalic buffer was employed. [g] A considerable amount (21–27%) of the corresponding α,β-unsaturated aldehyde is formed in this reaction. [h] Notable amounts (13–17%) of the corresponding α,β-unsaturated aldehyde are formed in this reaction. [i] The main products are benzaldehyde (18–29%) and benzoic acid (22–55%).

formed. Most probably this result is due to a subsequent epoxide hydrolysis under these reaction conditions.¶ Aliphatic alkenes were also epoxidised. In particular, internal (*Z*) systems reacted more effectively than terminal or (*E*) olefins (entries 5–9). In the case of (*Z*)-hex-3-ene, a significant amount of *trans*-epoxide was produced. α,β-Unsaturated carbonyl compounds showed poor reactivity (entries 10, 11). Hydroxy groups in the allylic or benzylic position were oxidised. In the case of allylic alcohols, both the epoxy alcohol and the corresponding α,β-unsaturated aldehyde were formed (entries 12, 13), with the epoxidation being the main reaction pathway. The two products did not undergo further transformations. The possibility of converting alcohols to conjugated systems was demonstrated by the oxidation of benzyl alcohol to benzaldehyde and benzoic acid (entry 14) as compared to the relatively less efficient transformation of 2-phenylethanol, which gave the corresponding aldehyde in low yield (7–11% of the reaction mixture) (entry 15). Finally, the procedure described herein was successfully performed of a 100 mmol scale with styrene as substrate, and no variation in conversion or selectivity was observed.

In conclusion, the possibility of generating polymeric systems with a high density of 1,4,7-triazacyclononane units by ROMP has been demonstrated. The corresponding manganese complexes are catalytically active in oxidation reactions with hydrogen peroxide as terminal oxidant. Currently, we are studying alternative polymeric systems based on the model presented with improved characteristics regarding catalyst stability and recovery.

‡ The IUPAC name for norbornene is bicyclo[2.2.1]hept-2-ene.

§ General experimental procedure: a solution of 1 mmol of substrate in acetone (GC quality, 1 mL) is cooled to 0–2 °C and treated with the ligand (for **4**: 2.7 mg in 48 μL of MeOH, 0.01 mmol; for **5** or **6**: 2.7 mg in 48 μL of MeOH, 0.5 μmol) and $Mn(OAc)_2{\cdot}4\,H_2O$ (2.5 mg in 141 μL of H_2O, 0.01 mmol). The mixture is stirred for 15 min. Oxalic buffer (0.15 M, 0.133 mL, 0.02 mmol) is added, followed within 1–2 min by H_2O_2 (30%, 0.4 mL, 4 mmol). After stirring for 1.5 h at 0–2 °C, another aliquot of H_2O_2 is added (0.2 mL, 2 mmol). After a reaction time of 2.5–3 h, the excess oxidant is destroyed by adding a small quantity of MnO_2, the reaction mixture is diluted with approx. 2 mL of CH_2Cl_2 and the organic phase is separated and analysed by gas-chromatography (see ESI).

¶ Samples of pure α-methylstyrene oxide were converted to the corresponding diol when exposed to the reaction conditions.

Novel synthesis of cyclobutanone derivatives *via* dimetalation of iminium ions with the $TiCl_4$–trialkylamine reagent system†

Mariappan Periasamy,* K. Natarajan Jayakumar and Pandi Bharathi

Received (in Cambridge, UK) 5th April 2001, Accepted 24th July 2001
First published as an Advance Article on the web 28th August 2001

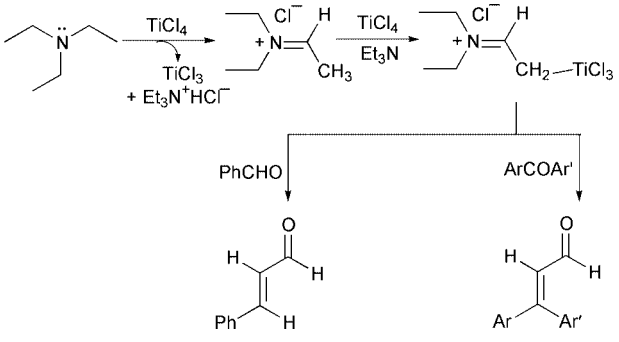
Iminium salts are generated *in situ*, react with $TiCl_4$–trialkylamines, and diaryl ketones to produce 3,3-diarylcyclobutanones in moderate to good yields.

The $TiCl_4$–R_3N combination is well-known to mediate aldol type condensation reactions[1] and oxidative coupling of certain ester enolates.[2] We have reported that the $TiCl_4$–R_3N reagent system is useful for the oxidative coupling of aryl methyl ketimines to 2,5-diarylpyrroles,[3a] for the direct metalation of alk-1-ynes,[3b] for the reductive coupling of imines and aromatic aldehydes,[3c] and for the oxidative coupling of *N,N*-dialkylarylamines.[3d] Also, it was observed that trialkylamines are oxidized to iminium ions by $TiCl_4$ with concomitant formation of $TiCl_3$.[3c,4] Herein, we wish to report that the iminium ions generated *in situ*,[5] undergo metalation followed by reaction with diaryl ketones to produce the corresponding 3,3-diarylcyclobutanones in moderate to good yields.

Metalation of iminium ions using $TiCl_4$ and its further reaction with PhCOPh produce α,β-unsaturated aldehydes (Scheme 1).[4]

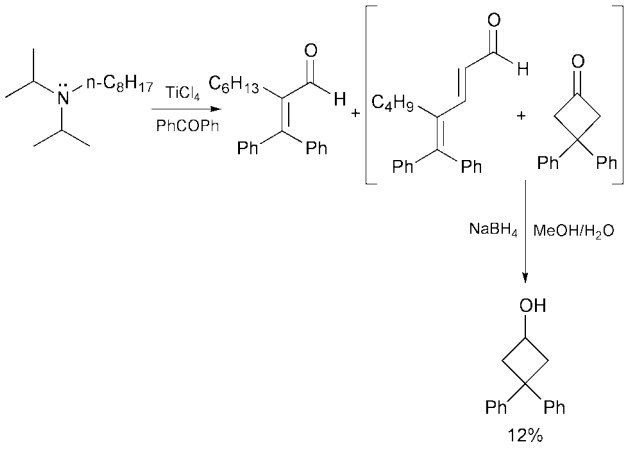
We have examined the reaction of *N,N*-diisopropyl-*N*-ethylamine under these conditions. In this case, an inseparable mixture of the corresponding α,β-unsaturated aldehyde derivative and the cyclobutanone derivative was obtained. The use of *N,N*-diisopropyl-*N*-octylamine produced a better yield of the product mixture (Scheme 2).

Fortunately, the corresponding cyclobutanol could be readily separated after the reduction of the product mixture with $NaBH_4$–MeOH–H_2O (overall yield 12%). Attempts to optimize the reaction conditions to obtain better yields of the cyclobutanones using various *N,N*-diisopropyl-*N*-alkylamines were not fruitful. Therefore, we have examined the reactions of iminium ions prepared *in situ* using other methods. It was found that the iminium ions prepared through the oxidation of *N,N*-diisopropyl-*N*-benzylamine with I_2 gave better results. For example, in the reaction of the iminium ions with $TiCl_4$–*N,N*-diisopropyl-*N*-benzylamine and PhCOPh, the cyclobutanone derivative was obtained in 76% yield (Scheme 3).[6]



Scheme 1

† Electronic supplementary information (ESI) available: ^{13}C NMR spectra of compounds **1a**, **2a**, **3a**, **4a**, **5a**, **6a**, **7a** and **7b**. See http://www.rsc.org/suppdata/cc/b1/103112k/



Scheme 2

When benzaldehyde was used as electrophile, the expected 3-arylcyclobutanone was not formed. Instead, only the dihydroxy ketone **7a** and the divinyl ketone **7b** were obtained in 58 and 11% yields respectively, besides some unidentified products. Earlier, such a reactivity was reported when the (2-siloxyallyl)silane was used as synthetic equivalent of acetone α,α′-dianion in the $TiCl_4$ mediated reaction with aromatic aldehydes.[7]‡

We have carried out several experiments to examine the scope and limitations of this transformation (Table 1). It was observed that the use of TMEDA in the place of *N,N*-diisopropyl-*N*-benzylamine gave the cyclobutanone derivative in poor yields (6%). Addition of PhCOPh initially or after the formation of the iminium ion gave no significant change to the results. Though the reaction works well at 25 °C, the yields of cyclobutanone are slightly better (10 to 20% more) under refluxing conditions. Dichloroethane was found to be the best solvent compared to CH_2Cl_2 and $CHCl_3$. When acetophenone was used as substrate, a complex mixture of products was obtained, possibly due to competing aldol type reactions.[8]

The formation of a cyclobutanone derivative may be tentatively explained by a mechanism involving the dimetalated iminium ion intermediate (Scheme 3). The reaction of 2 eq. of 3° amine and 1 eq. of I_2 would give the iminium iodide.[5] Deprotonation of the β-hydrogen atoms of the iminium ion using *N,N*-diisopropyl-*N*-benzylamine and further metalation with $TiCl_4$ could give the 1,3-dititanated iminium ion intermediate. The reaction of 1,3-dimetalated species with diarylketone would give the corresponding cyclobutanone (Scheme 3). However,

7	 **7**	 **7a**	58
		 **7b**	11

[a] The products were identified by ^1H, ^{13}C NMR, mass spectral and physical constant data and comparison with the reported data.[8] [b] The yields are based on the amount of ketone/aldehyde used.

the possibility of an alternative mechanism involving sequential metalation–addition reactions cannot be ruled out.

In conclusion, simple one pot methods of conversion of diaryl ketones to 3,3-diarylcyclobutanones from readily available starting materials have been developed. Previously, syntheses of such cyclobutanone derivatives have been reported *via* methods such as (i) the 2 + 2 cycloaddition of ketenes to diazomethane,[9] (ii) the 2 + 2 cycloaddition of dichloroketene to olefins,[10] and (iii) the 2 + 2 cycloaddition of ketiminium salts to olefins.[11] The one pot conversions described here involving a 1,3-dimetalated iminium ion intermediate, is a simple alternative to hitherto known methods of synthesis of cyclobutanone derivatives.[12] Moreover, it is anticipated that the interesting reactivity pattern of the titanium intermediates reported here should stimulate further research activities in this area.

The first 1,3-digermyla-2-nickela-carboranylene and the Ni-catalyzed double germylation of unsaturated organic substrates

Junghyun Lee,[a] Chongchan Lee,[a] Shim Sung Lee,[b] Sang Ook Kang[a] and Jaejung Ko*[a]

[a] *Department of Chemistry, Korea University, Chochiwon, Chungnam 339-700, Korea. E-mail: jko@tiger.korea.ac.kr*

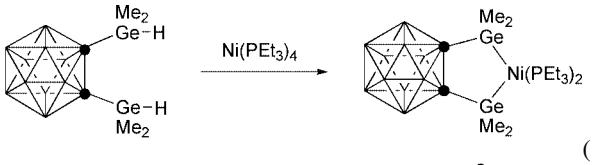
Received (in Cambridge, UK) 7th June 2001, Accepted 23rd July 2001
First published as an Advance Article on the web 29th August 2001

The reaction of *o*-bis(dimethylgermyl)carborane with $Ni(PEt_3)_4$ in pentane affords the reactive intermediate, $[o\text{-}(GeMe_2)_2C_2B_{10}H_{10}]Ni(PEt_3)_2$ 2: the facile double germylation of unsaturated organic substrates catalyzed by 2 is reported.

Although the transition metal-catalyzed double silylation of unsaturated organic substrates has been well documented for three decades,[1] metal-catalyzed double germylation is quite limited.[2–5] Reactions were carried out mainly in the presence of $[Pd(PPh_3)_4]$ as a catalyst. In the catalytic cycle, bis(germyl)-complexes have been implicated as important intermediates. However, there are only a few precedents for such species[6] and only bis(chlorogermyl)platinum has been structurally characterized by Tanaka and coworkers.[7] However, the reactivity towards unsaturated organic substrates was not studied. We found that the bis(germyl)nickel complex is the most efficient and reactive catalyst for the double germylation reaction. We now describe (i) the isolation of the most reactive intermediate cyclic bis(germyl)nickel compound with a bulky *o*-carborane unit; (ii) the facile double germylation of alkyne catalyzed by the intermediate under mild conditions; and (iii) the double germylation of an alkene, aldehyde and nitrile by stoichiometric reacion with the intermediate.

Addition of 1.1 equiv. of *o*-bis(dimethylgermyl)carborane, prepared from $1,2\text{-}Li_2C_2B_{10}H_{10}$ and 2 equiv. of $GeMe_2Cl_2$, followed by reduction by $NaB(CN)H_3$, to $Ni(PEt_3)_4$ in pentane gave a red solution. Standard work-up and crystallization from toluene–pentane gave $[o\text{-}(GeMe_2)_2C_2B_{10}H_{10}]Ni(PEt_3)_2$ **2** as a spectroscopically pure, red crystalline solid very sensitive to air and water in 60% yield [eqn. (1)].†



1 **2** (1)

The ^1H, ^{13}C and ^{31}P NMR spectra for **2** support the proposed structure. The structure of **2** was unambiguously established by a single-crystal X-ray analysis (Fig. 1).‡ Complex **2** has a distorted tetrahedral geometry with the dihedral angle between Ge(1)–Ni–Ge(2) and P(1)–Ni–P(2) being 84.60°. This bis(germyl)nickel complex is the first as indicated by a search of the Cambridge Crystallographic Database. As expected, the average Ni–Ge bond length [2.3290(5) Å] is slightly longer than that of 2.248(1) Å in $CpNi(PPh_3)GeCl_3$.[8] The Ni–P bond distance [2.2188(10) Å] is consistent with those observed in other phosphine nickel compounds.

Intermediate **2** was found to be an efficient reactant for the double germylation reaction under mild conditions. The reaction of *o*-bis(dimethylgermyl)carborane **1** with hex-1-yne (1 equiv.) in the presence of a catalytic amount of **2** (0.03 equiv.) at room temperature for 14 h afforded the double-germylated

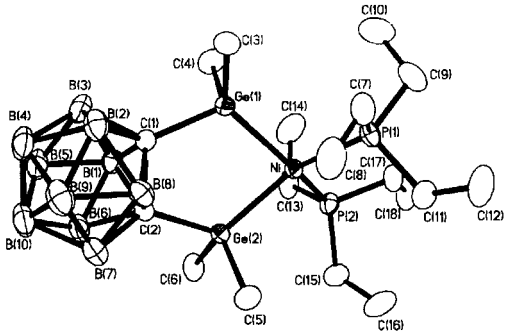


Fig. 1 Molecular structure of **2**. Selected bond lengths (Å) and angles (°): Ge(1)–C(1) 2.028(3), Ge(2)–C(2) 2.035(3), Ge(1)–Ni 2.3316(5), Ge(2)–Ni 2.3264(5), Ni–P(1) 2.2146(10), Ni–P(2) 2.2230(10); C(1)–Ge(1)–Ni 116.01(10), C(2)–Ge(2)–Ni 116.52(9), P(1)–Ni–P(2) 103.10(4), P(1)–Ni–Ge(2) 146.73(3), P(2)–Ni–Ge(2) 92.08(3), Ge(2)–Ni–Ge(1) 84.231(8).

product **3** in 62% yield. All the spectral data of **3** were consistent with the proposed formulation.§ A key feature in the ^1H NMR spectrum includes a singlet at δ 6.24 assigned to the vinyl proton. A characteristic high-field ^{13}C NMR signal at δ 142.82 provides evidence for a tethered carbon atom of the two germanium moieties. Formation of the digermyl ring compound **3** can be related to nickel-catalyzed double silylation.[9]

The reaction of **2** with 1 equiv. of 4-vinylanisole takes place at room temperature and affords a moderate yield of the five-membered digermyl ring compound **4** (Scheme 1). One doublet (δ 2.80) in the ^1H NMR spectrum of **4** is assigned to the methine proton. A low-frequency ^{13}C NMR resonance at δ 55.41 provides evidence for the tethered carbon atom of the two germanium moieties. The structure of **4** has been determined by X-ray crystallography (Fig. 2).‡ The formation of **4** may

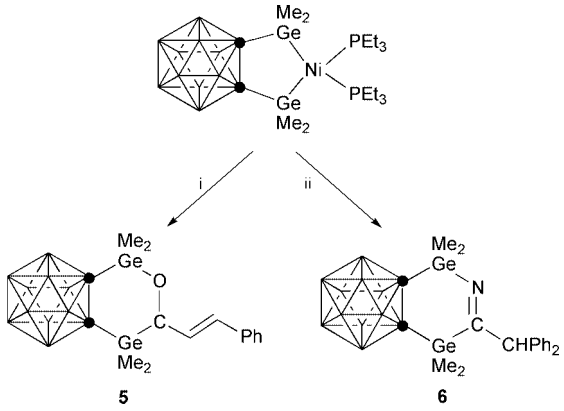
involve an initial oxidative addition reaction of an olefinic C–H bond to the nickel center, followed by the shift of a phenyl group from the nickel atom to one of two germanium atoms. Such a C–H activation has been observed in Ni-catalyzed double silylation.[10] Treatment of **2** with 1 equiv. of *trans*-cinnamaldehyde at room temperature gave the 1,2-double germylation product **5** (Scheme 2). The ^{1}H NMR spectrum of **5**¶ contained a distinguishing low-field methine resonance (δ 4.61) as a doublet of doublets which was used to monitor its formation. This result is in contrast with that of double silylation which gave the insertion product of two carbonyl ligands into the C–Si bond.[11]



Scheme 2 *Reagents and conditions*: i, PhCH=CHCHO (1 equiv.), **2** (1 equiv.), toluene, 25 °C, 70%; ii, Ph_2CHCN (1.3 equiv.), **2** (1 equiv.), toluene, 25 °C, 66%.

When diphenylacetonitrile is employed in the reaction with **1**, the six-membered digermyl ring compound **6** is isolated as colorless crystals in 74% yield. All the spectral data of **6** were consistent with the proposed formulation.‖

In summary, we have isolated a reactive intermediate, a cyclic bis(germyl)nickel complex, which readily reacts with unsaturated organic substrates such as alkynes, alkenes, aldehydes and nitriles, generating a new class of heterocyclic compounds. This potential has been further exploited in a series of novel chemical transformations with this system.

We are grateful to KOSEF (2001) for generous financial support.

Direct NO group transfer from *S*-nitrosothiols to iron centres

Anthony R. Butler,*[a] Susie Elkins-Daukes,[a] David Parkin[b] and D. Lyn H. Williams*[b]

[a] *Department of Chemistry, University of St. Andrews, St. Andrews, Fife, UK KY16 9ST*
[b] *University of Durham, South Road, Durham, UK DH1 3LE. E-mail: D.L.H.Williams@durham.ac.uk*

Received (in Cambridge, UK) 21st June 2001, Accepted 30th July 2001
First published as an Advance Article on the web 29th August 2001

A number of *S*-nitrosothiols react rapidly with the Fe(II) complexes of 2,3-dimercapto-1-propanesulfonic acid (DMPS) and of *N*-methyl-D-glucamine dithiocarbamate (MGD), transferring the NO group directly to the iron centres.

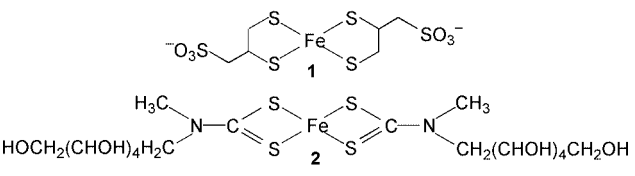
S-Nitrosothiols (RSNO) are now widely believed to be important species in the storage and transport of nitric oxide *in vivo*.[1] Since they generally show the same physiological properties as does nitric oxide itself (notably the induction of vasodilation and inhibition of platelet aggregation[2]), it has been generally assumed that RSNO species act in this way by first releasing nitric oxide. Release of NO from an RSNO can be brought about by at least three routes: (a) a spontaneous thermal reaction, which is too slow at ambient temperatures to be important, (b) a photochemical reaction, which is also unimportant in the absence of appropriate incident radiation, and (c) a rapid copper(II) catalysed process.[3] For reaction (c) it has been shown[4] that decomposition is brought about by Cu^+ generated by thiol reduction of Cu^{2+}. Even low $[Cu^{2+}]$ at the impurity level are effective. Cu^+ can also be obtained by reduction from Cu^{2+} bound to proteins and peptides.[5] Complexation of Cu^+ in biological experiments results in loss of some biological function.[6] Low levels of [RSH] always present in equilibrium with RSNO[7] are sufficient to bring about the reduction. All three decomposition pathways initially generate nitric oxide and the corresponding disulfide, [eqn. (1)] although in the

$$2\mathrm{RSNO} \rightarrow \mathrm{RSSR} + 2\mathrm{NO} \qquad (1)$$

presence of oxygen oxidation of nitric oxide occurs and the final product in aqueous buffer is nitrite ion.

In addition, *S*-nitrosothiols react readily with many nucleophiles transferring the NO group in the NO^+ sense to, for example, amines, thiols and ascorbate[3] directly, without it ever becoming free, *i.e.* they can act as electrophilic nitrosating agents. Many of the biological properties of NO are believed to occur by activation of the enzyme guanylate cyclase, through the binding of NO to a haem iron atom in the enzyme. This leads to elevated levels of cyclic guanosine monophosphate (cGMP) which effects smooth muscle relaxation. It is an interesting and pertinent question as to whether RSNO compounds can achieve this without NO formation, *i.e.* whether they can transfer the NO group directly to an iron atom.

We have chosen initially to look at a simple non-haem iron compound. Iron(II) readily forms a complex $[Fe(DMPS)_2]^{4-}$ with 2,3-dimercaptopropane-1-sulfonate (DMPS) shown as **1**.[8]



This is stable in solution under anaerobic conditions and the solution is red with absorbance maxima at 358 and 509 nm. This iron complex has a strong affinity for NO and has been used industrially as a scrubber of flue gases to remove NO. The nitrosyl complex has been characterised.[9]

The complex is readily prepared in aqueous solution from Fe^{2+} and a two-fold excess of DMPS. Addition of *S*-nitrosoglutathione (GSNO), generated in solution from equimolar quantities of nitrous acid and glutathione, to a solution of **1** at physiological pH 7.4 resulted in the rapid disappearance of the absorbance at 509 nm. The final absorbance spectrum was identical with that obtained when NO gas was reacted with $[Fe(DMPS)_2]^{4-}$ and is taken to be that of $[Fe(DMPS)_2NO]^{3-}$. Kinetic measurements, noting the decreasing absorbance at 509 nm, were made with [GSNO] >> $[Fe(DMPS)_2{}^{4-}]$. Each individual run followed the first-order law and there was also a first-order dependence on [GSNO], leading to a second-order rate constant value k [defined by eqn. (2)] of 24 $dm^3\ mol^{-1}\ s^{-1}$

$$\mathrm{Rate} = k\,[\mathrm{Fe(DMPS)_2}^{4-}]\,[\mathrm{RSNO}] \qquad (2)$$

at 25 °C. The *S*-nitroso derivatives of *N*-acetylcysteine, cysteine, homocysteine and captopril (all generated *in situ*) behaved similarly yielding comparable k values (6.1, 71, 16 and 7.5 $dm^3\ mol^{-1}\ s^{-1}$ respectively). The nitrosyl complex from *S*-nitrosocysteine was identical (spectrally) with that derived from GSNO.

An HPLC analysis of the final solution from the reaction of GSNO with the iron complex showed that the other product of reaction between GSNO and the iron complex was glutathione (GSH) in > 80% yield. This oxidised slowly to give some of the disulfide GSSG on standing in air for several hours. Initial (essentially quantitative) formation of glutathione indicates that the NO group is being transferred as NO^+ rather than as NO. That the same complex is formed by reaction with NO itself means that there must be an oxidation step in that process. It is not unknown in the synthesis of metal nitrosyls for the formal oxidation state of the nitrosyl ligand in the product to be different from that in the reactants.[10]

GSNO also reacts rapidly with the Fe^{2+} complex of *N*-methyl-D-glucamine dithiocarbamate (MGD) shown as structure **2**. The reaction is rapid and much faster than the 'spontaneous' release of NO from GSNO under the same conditions. The Fe^{2+} complex of MGD is EPR active and has been used recently as a trap for NO.[11] Reaction occurs rapidly with NO generated in solution giving the NO complex with a characteristic EPR spectrum. We find that the same UV-Visible spectrum is generated from the reactions of GSNO and NO with the Fe^{2+} complex of MGD. Strangely here in our reaction, the other product is GSSG and not GSH as in the DMPS case. This implies that with the DMPS complex NO is delivered in the NO^+ sense, whereas with the MGD complex it appears that it is in the NO sense. Our principal conclusion is that a direct bimolecular process occurs in the reactions of RSNO compounds with these two iron complexes and there is no prior release of NO. Our product studies also show that this NO-transfer reaction can occur in the NO or NO^+ sense depending presumably on which is the more favoured ligand in the resulting nitrosyl complex. Both reactions are far too rapid for the results to be explained mechanistically in terms of prior breakdown of RSNO to yield NO.

Our results indicate that when considering the reaction of an *S*-nitrosothiol with a biological target, the possibility of a direct

 DOI: 10.1039/b105460k

bimolecular process must be considered. Transfer may occur as either NO or NO^+.

We thank the EPSRC for a research studentship to D. P., and for an equipment grant.

Control over directional metal–metal charge transfer in cyanide-bridged dimanganese complexes: effects of μ-CN linkage isomerism and ancillary ligand set†

Kirsty M. Anderson, Neil G. Connelly, Estefania Llamas-Rey, A. Guy Orpen and Rowena L. Paul

School of Chemistry, University of Bristol, Bristol, UK BS8 1TS. E-mail: Neil.Connelly@bristol.ac.uk

Received (in Cambridge, UK) 6th June 2001, Accepted 28th June 2001
First published as an Advance Article on the web 29th August 2001

Synthesis and characterisation of cyano-bridged complexes of the form [(η-C_5R_4Me)L(ON)Mn(μ-XY)Mn(CO)$_2$-L′(dppm)]^z (X,Y = C,N; z = 1–3) shows that systematic variation of the orientation of the CN bridge and the nature and geometric arrangement of the ancillary ligands affords control of the direction and energy of metal–metal charge transfer in the mixed valence dications.

While much of the current wide interest[1,2] in cyanide-bridged complexes centres on structural properties[1,3] deriving from the (usually linear) M(μ-CN)M′ unit, other important effects (optical,[4–6] magnetic,[1,7] *etc.*) depend on the facility with which intramolecular metal–metal charge transfer (MMCT) occurs in mixed valence complexes.

In order to understand more fully the nature of the MMCT process, and how its energy and direction (through the bridge) might be controlled, there is a need to prepare and study kinetically inert cyanide-bridged species, *i.e.* species in which linkage isomerisation, from M(μ-CN)M′ to M(μ-NC)M′, does not occur. Many systems, often constructed from classical coordination complex units, do isomerise.[1,8] However, by using low valent transition metal building blocks (*e.g.* organometallic or metal carbonyl units) we[9] and others[6,10] have isolated stable cyanide-bridged complexes and, in some cases, linkage isomers.[4,11–14]

Electrochemical studies[11,13,14] which probe the effects of linkage isomerism on redox potential are of particular relevance, especially those on the asymmetric species {$(OC)_5$Cr(μ-CN)Fe(dppe)(η^5-C_5H_5)] and [$(OC)_5$Cr(μ-NC)Fe(dppe)(η^5-C_5H_5)] (each oxidised in two one-electron steps, at $E^{\circ\prime}{}_1$ and $E^{\circ\prime}{}_2$). These isomers show quite different redox behaviour, with $E^{\circ\prime}{}_1$ and $E^{\circ\prime}{}_2$ 0.28 and 0.97 V for the former and 0.46 and 0.91 V for the latter, $\Delta E^{\circ\prime}$ ($\Delta E^{\circ\prime} = E^{\circ\prime}{}_2 - E^{\circ\prime}{}_1$) is 0.68 and 0.45 V, respectively. The difference in $\Delta E^{\circ\prime}$ for the two neutral complexes implies different MMCT behaviour for the corresponding monocations [$(OC)_5$Cr(μ-CN)Fe(dppe)(η^5-C_5H_5)]$^+$ and {$(OC)_5$Cr(μ-NC)Fe(dppe)(η^5-C_5H_5)]$^+$ although a direct comparison on the electronic properties of the two was not possible.[14]

Here we describe a new and highly versatile series of stable cyanide-bridged linkage isomers, [(η-C_5R_4Me)L(ON)Mn(μ-XY)Mn(CO)$_2$L′(dppm)]$^+$, in which the pseudo-tetrahedral unit Mn$^{\rm I}$X(NO)L(η-C_5R_4Me) (generalised as Mn$_{\rm tet}$, R = H or Me) is joined to octahedral *cis*- or *trans*-[Mn$^{\rm I}$Y(CO)$_2$L′(dppm)] (generalised as Mn$_{\rm oct}$) by the bridge XY (X,Y = C,N). The potentials for, and order of, the sequential one-electron oxidations of the two metal centres in Mn$^{\rm I}$(μ-XY)Mn$^{\rm I}$ to Mn$^{\rm I}$(μ-XY)Mn$^{\rm II}$ and Mn$^{\rm II}$(μ-XY)Mn$^{\rm II}$, vary not only with the orientation of the cyanide bridge but also with the cyclopentadienyl ring substituents R, the ancillary ligands L and L′ and the geometry of the Mn(CO)$_2$ unit (*cis* or *trans*) at Mn$_{\rm oct}$. Thus, the energy and direction of MMCT within the Mn$^{\rm I}$Mn$^{\rm II}$ species {(η-C_5H_4Me)L(ON)Mn(μ-XY)Mn(CO)$_2$L′(dppm)]$^{2+}$ can be systematically controlled.

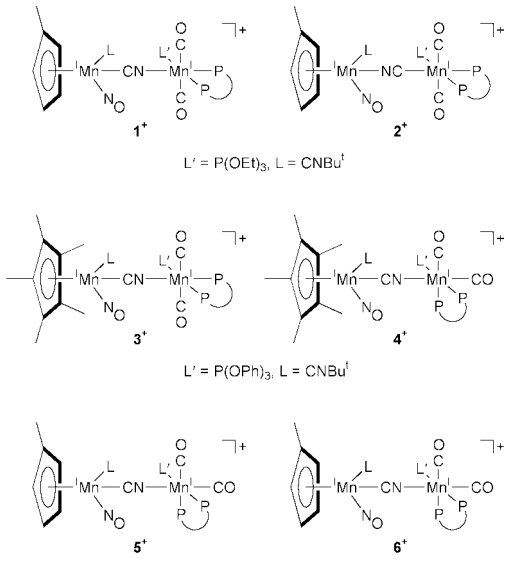
† Electronic supplementary information (ESI) available: Table S1: IR and electrochemical data. See http://www.rsc.org/suppdata/cc/b1/b104998b/

The complexes [(η-C_5R_4Me)L(ON)Mn(μ-XY)Mn(CO)$_2$-L′(dppm)][PF_6] [X,Y = C,N; R = H or Me; L = PPh_3, $P(OPh)_3$ or CNBu^t; L′ = $P(OR')_3$ (R′ = Et or Ph); dppm = $Ph_2CH_2PPh_2$], with either *cis*- or *trans*-Mn(CO)$_2$ units, are prepared as their [PF_6]$^-$ salts by reacting [Mn(CN)(CO)$_2$-L′(dppm)] with [MnI(NO)L(η-C_5R_4Me)] or [MnBr(CO)$_2$-L′(dppm)] with [Mn(CN)(NO)L(η-C_5R_4Me)] in the presence of $TlPF_6$.‡ Representative examples are shown in Scheme 1 and Table S1 (ESI†).

The order in which the two Mn$^{\rm I}$ sites of the binuclear complexes are oxidised is indicated by cyclic voltammetry; assignment of each oxidation site is aided by observing the effects of altering the ancillary ligands L and L′ on redox potential (better donors L and L′ shift oxidation waves to less positive potentials) and noting that a *cis*-[Mn$^{\rm I}$Y(CO)$_2$L′(dppm)] unit undergoes oxidative isomerisation, giving rise to an irreversible oxidation wave coupled with a reversible oxidation wave for the *trans* product.[15] The assignments based on cyclic voltammetry are supported by the results of IR spectroelectrochemistry (see below).

The effect of CN linkage isomerism on redox behaviour is demonstrated by [(η-C_5H_4Me)(Bu^{t}NC)(ON)Mn(μ-CN)-Mn(CO)$_2${P(OEt)$_3$}(dppm)-*trans*][PF_6] **1**$^+$[PF_6]$^-$ and [(η-C_5H_4Me)(Bu^{t}NC)(ON)Mn(μ-NC)Mn(CO)$_2${P(OEt)$_3$}(dppm)-*trans*][PF_6] **2**$^+$[PF_6]$^-$, the X-ray structures of which are virtually identical; that of the cation **1**$^+$ is shown in Fig. 1, together with important bond lengths and angles for the two isomers.§

Both **1**$^+$ and **2**$^+$ show two reversible oxidation waves in their cyclic voltammograms, IR spectroelectrochemistry¶ confirming that the first oxidation occurs at Mn$_{\rm oct}$ (Table 1). Thus, on electrolysis at $E_{\rm applied}$ = 0.6 (for **1**$^+$) or 0.75 V (for **2**$^+$), ν(CO) increases by *ca.* 70–80 cm^{-1} while ν(NO) and ν(CNBu^t)



Scheme 1 P–P = dppm.

 DOI: 10.1039/b104998b

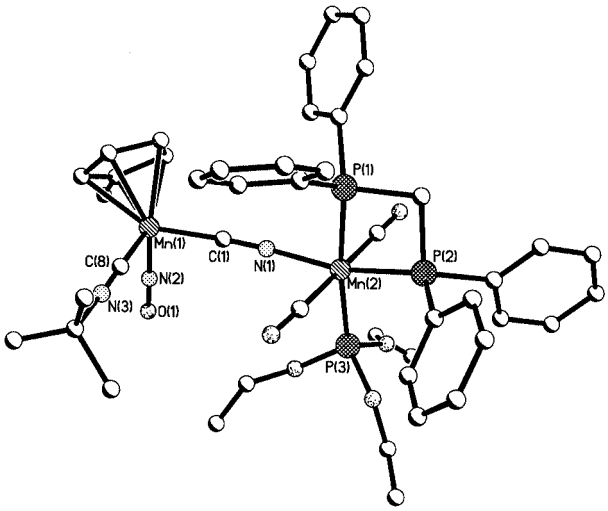


Fig. 1 Structure of the cation of $[(\eta\text{-}C_5H_4Me)(Bu^tNC)(ON)Mn(\mu\text{-}CN)Mn(CO)_2\{P(OEt)_3\}(dppm)][PF_6]$ $\mathbf{1}^+[PF_6]^-$ (hydrogen atoms omitted for clarity); the structure of $[(\eta\text{-}C_5H_4Me)(Bu^tNC)(ON)Mn(\mu\text{-}NC)\text{-}Mn(CO)_2\{P(OEt)_3\}(dppm)][PF_6]$ $\mathbf{2}^+[PF_6]^-$ is virtually identical. Important bond lengths (Å) and angles (°) for $\mathbf{1}^+$: Mn_{tet}–CN 1.951(3), Mn_{oct}–NC 2.010(3), C–N 1.153(4), Mn_{tet}–NO 1.656(3), Mn_{tet}–CNBu^t 1.916(4), Mn–P {*trans* to $P(OEt)_3$} 2.296(1), Mn–P (*trans* to $NCMn_{tet}$) 2.275(1); Mn_{tet}–C–N 176.9(3), Mn_{oct}–N–C 171.6(2). For $\mathbf{2}^+$: Mn_{tet}–NC 1.968(3), Mn_{oct}–CN 1.955(3), C–N 1.151(4), Mn_{tet}–NO 1.665(3) Mn_{tet}–CNBu^t 1.922(3), Mn–P {*trans* to $P(OEt)_3$} 2.283(1), Mn–P (*trans* to $CNMn_{tet}$) 2.290(1) Å; Mn_{tet}–N–C 173.6(2), Mn_{oct}–C–N 175.0(2).

increase by much smaller amounts (*ca.* 13–20 and 6–7 cm^{-1}, respectively), consistent with oxidation at the *trans*-$Mn(CO)_2$ terminus. [Further electrolysis of $\mathbf{1}^{2+}$, at 1.45 V, results in increases in ν(CO), ν(NO) and ν(CNBu^t) of 16, 101 and 62 cm^{-1}, this time consistent with oxidation at Mn_{tet} to give $\mathbf{1}^{3+}$]. Thus, in the isomeric mixed valence dications $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$, Mn^I to Mn^{II} MMCT occurs in the opposite sense with respect to the cyanide bridge, *i.e.* from Mn^I to CN to Mn^{II} in the former and from Mn^I to NC to Mn^{II} in the latter.

Cyanide bridge isomerisation leads to very different values of $\Delta E^{\circ\prime}$ for $\mathbf{1}^+$ and $\mathbf{2}^+$ (0.81 and 0.49 V respectively) and thence to a large difference in the MMCT band energy for the mono-oxidised complexes. Thus, UV–VIS spectroelectrochemistry¶ shows the growth of a MMCT absorption band at 890 nm on oxidation of $\mathbf{1}^+$ to $\mathbf{1}^{2+}$ and a similar band at 1360 nm on oxidation of $\mathbf{2}^+$.

Further control of the direction (and energy) of MMCT is possible simply by varying the geometry (*cis* or *trans* dicarbonyl) of the Mn_{oct} unit. Thus, the positional isomers $[(\eta\text{-}C_5Me_5)(Bu^tNC)(ON)Mn(\mu\text{-}CN)Mn(CO)_2\{P(OPh)_3\}(dppm)\text{-}trans]^+$ $\mathbf{3}^+$ and $[(\eta\text{-}C_5Me_5)(Bu^tNC)(ON)Mn(\mu\text{-}CN)Mn(CO)_2\text{-}\{P(OPh)_3\}(dppm)\text{-}cis]^+$ $\mathbf{4}^+$ are first oxidised at Mn_{oct} and Mn_{tet} respectively, an assignment confirmed in the latter case by IR spectroelectrochemistry; electrolysis (E_{appl} = 1.0 V) leads to a large increase in enery for ν(NO) (94 cm^{-1}) and only a small increase in ν(CO) (Table S1, ESI†). Similar behaviour has been inferred from the CVs of $[(\eta\text{-}C_5H_5)(dppe)Fe(\mu\text{-}XY)(Mn(CO)_2\text{-}\{P(OPh)_3\}(dppm)][PF_6]$ (X, Y = C, N).[11]

Finally, the direction of MMCT can be controlled by varying the ligands L and L′. Thus, replacing PPh_3 at the *pseudo*-tetrahedral site of $[(\eta\text{-}C_5H_4Me)(Ph_3P)(ON)Mn(\mu\text{-}CN)Mn\text{-}(CO)_2\{P(OPh)_3\}(dppm)\text{-}cis]^+$ $\mathbf{5}^+$ by $P(OPh)_3$, giving $[(\eta\text{-}C_5H_4Me)\{(PhO_3P)(ON)Mn(\mu\text{-}CN)Mn(CO)_2\{P(OPh)_3\}\text{-}(dppm)\text{-}\ cis]^+$ $\mathbf{6}^+$, leads to the site of first oxidation changing from Mn_{tet} (first oxidation wave reversible) to Mn_{oct} [isomerisation of the *cis*-$Mn^I(CO)_2$ unit at the first oxidation step].

In summary, cyclic voltammetry and spectroelectrochemistry (IR and UV–VIS) on a range of stable linkage isomers shows that the order of oxidation of the two Mn^I sites in the $Mn^I_{tet}(\mu\text{-}XY)Mn^I_{oct}$ (X,Y = C,N) unit can be controlled by the orientation of XY, by the geometry at Mn^I_{oct} and by the ancillary ligands at either metal centre. In this way, the direction and energy of MMCT, from Mn^I to Mn^{II} through a cyanide bridge, may be systematically and selectively controlled.

We thank the University of Bristol for Postgraduate Scholarships (K. M. A., E. L.-R.), the Leverhulme Foundation for a Postdoctoral Fellowship (R. L. P.) and Professor M. D. Ward for help with the spectroelectrochemistry.

The first example of catalytic *N*-oxidation of tertiary amines by tungstate-exchanged Mg–Al layered double hydroxide in water: a green protocol†

B. M. Choudary,* B. Bharathi, Ch. Venkat Reddy, M. Lakshmi Kantam and K. V. Raghavan

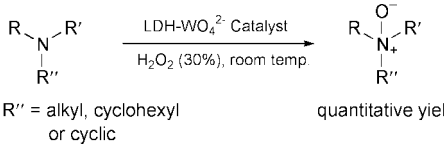
Indian Institute of Chemical Technology, Hyderabad-500007, India. E-mail: choudary@iict.ap.nic.in

Received (in Cambridge, UK) 31st May 2001, Accepted 23rd July 2001
First published as an Advance Article on the web 28th August 2001

A green process, using a recyclable tungstate-exchanged Mg–Al layered double hydroxide (LDH-WO_4^{2-}) heterogenised catalyst and aqueous H_2O_2 oxidant in water, leads to *N*-oxidation of aliphatic *tert*-amines to amine *N*-oxides in quantitative yields, at a high rate at room temperature.

Aliphatic *tert*-amine *N*-oxides are essential and major components for ubiquitously used materials such as hair conditioners, shampoos, toothpaste, laundry detergent powders, fabric softeners, toilet soaps and cosmetics as well as in biomedical applications.[1] Amine oxides are compounds of increasing interest as potential cytoximes which are hypoxia-selective for the treatment of solid tumors.[2] These *N*-oxides are also used as stoichiometric oxidants to accomplish catalytic cycles in important reactions such as osmium catalysed dihydroxylation of olefins,[3a,b] ruthenium catalysed oxidation of alcohols[3c] and Mn–salen catalysed epoxidation of olefins.[3d] Amine *N*-oxides are currently prepared *via* a non-catalytic oxidation of *tert*-amines with H_2O_2 in a slow reaction.[3a,4] Other oxidants employed to hasten the oxidation of *tert*-amines include peracids,[5a] magnesium monophthalate,[5b] 2-sulfonyloxaziridines,[5c] α-azohydroperoxides[5d] and dioxiranes,[5e] which are not only expensive, but also generate large amounts of effluent during the reaction. The biomimetic oxidation of *tert*-amines is induced by 4a-hydroperoxyflavin in the presence of H_2O_2 as oxidant.[6] This forms the sole example of a catalytic reaction to the best of our knowledge. There is a strong need to develop a '*greener technology*'[7] with higher throughput, and in order to conform to the above, we accordingly designed and developed an eco-compatible process utilising a recyclable heterogeneous catalyst in aqueous medium. We report here, an efficient and heterogeneous tungstate-exchanged layered double hydroxide catalyst (LDH-WO_4^{2-}), for the oxidation of aliphatic *tert*-amines in water as solvent using aqueous H_2O_2 as oxidant which leads to excellent yields for the first time (Scheme 1).

Layered double hydroxides (LDHs)[8] have recently received much attention.[9] LDHs consist of alternating cationic $M^{II}_{1-x}M^{III}_x(OH)_2^{x+}$ and anionic $A^{n-}\cdot zH_2O$ layers. The positively charged layers contain edge-shared metal M^{II} and M^{III} hydroxide octahedra, with charges neutralized by A^{n-} located in interlayer spacings or at edges of the lamellae. Small hexagonal LDH crystals of composition $Mg_{1-x}Al_x(OH)_2Cl_x\cdot 2H_2O$ were synthesized following existing procedures (here $x = 0.25$).[9a] The anionic species tungstate, molybdate and vanadate were exchanged with LDH-Cl to give LDH tungstate, molybdate and vanadate, respectively. The Mg–Al LDH (3 : 1) tungstate (cat **1**) was prepared according to the reported procedure.[9c] 1 g of Mg–Al–Cl LDH was stirred in 100 ml of an aqueous solution of 1.87 mM (0.616 g) sodium tungstate at 293 K for 24 h. The solid catalyst was filtered off, washed with deionised and decarbonated water and lyophilized to dryness. Similarly, the Mg–Al LDH molybdate (cat **2**) and Mg–Al LDH vanadate (cat **3**) were prepared. The preparation of LDH-{$PO_4[WO(O_2)]_4$} (cat **4**) was carried out according to the literature procedure.[10] To a solution of 0.46 mmol of isolated (NBu^n_4){$PO_4[WO(O_2)_2]_4$} in acetone (3 ml) was added 1 ml of H_2O_2 [35% (w/w) aqueous solution] and 1 g of Mg–Al–Cl LDH and the mixture was stirred for 16 h at room temperature. The obtained material (cat **4**) was treated consecutively with water–acetone (1 : 1) and acetone.



Scheme 1 Oxidation of *tert*-amines to amine *N*-oxides catalysed by tungstate-exchanged Mg–Al LDH.

All these catalysts were well characterised by powder-XRD, TGA–DTA and chemical analysis. The X-ray powder diffraction patterns of the LDH and LDH-WO_4^{2-} (cat **1**), LDH-MoO_4^{2-} (cat **2**), LDH-VO_3^- (cat **3**), LDH-{$PO_4[WO(O_2)]_4$} (cat **4**) scarcely differ in the range 2θ = 3–65°. These data clearly indicate that the above anions are not intercalated but lie on edge-on positions of LDH in the solid catalyst. Chemical analysis of the catalysts revealed the tungstate (%) content in cat **1** as 11% and cat **4** as 21% while the molybdate content in cat **2** was 9.9%, and vanadate content in cat **3** was 7.8%. The thermogravimetric profiles and the relative derivative curves (TGA and DTA) for the tungstate, molybdate and vanadate exchanged LDH catalysts cat **1**–**4** show two stages of weight loss associated with two endotherms characteristic of LDHs. These results provide evidence that there is no structural disorder after the ion-exchange.

The exchanged LDH catalysts (cat **1**–**4**) and their homogeneous analogues were evaluated in oxidation of aliphatic *tert*-amines with H_2O_2 in order to identify the best catalysts (Table 1). The *tert*-amine is oxidised with aqueous hydrogen peroxide (30% w/w) using water as a solvent in the presence of catalyst at room temperature under continuous stirring, while monitoring the progress of the reaction by TLC. The order of activity of

Table 1 Catalytic *N*-oxidation of *N*-methylmorpholine to *N*-methylmorpholine *N*-oxide catalysed using various metal ion-exchanged LDH catalysts and their homogeneous analogues

the LDH exchanged catalysts is: cat **1** > cat **2** > cat **3** = cat **4** and thus LDH-WO_4^{2-} (cat **1**) is inferred to be the best catalyst in the oxidation of *tert*-amines. The heterogeneous catalysts provide superior performance over their homogeneous counterparts. The efficacy in increasing the rate of *N*-oxidation is evident from Table 1, in which LDH-WO_4^{2-} affords 96% conversion in 1 h *cf.* 25% in 24 h in the absence of a catalyst.

In an effort to understand the scope of the reaction, several other amines having different R groups attached to the tertiary nitrogen atom were subjected for oxidation using the best catalytic LDH–WO_4^{2-}–H_2O_2 system to give excellent yields and ≅ 100% selectivity (Table 2). No other by-products were observed in these reactions. Water proved to be the best solvent in terms of activity in the *N*-oxidation of *tert*-amines. When the dodecylbenzenesulfonic acid sodium salt is employed as an additive, the rate of the *N*-oxidation reaction is increased 2–3 fold except in the case of *N*-methylmorpholine (Table 2). This may be due to the high hydrophilicity of the latter, when compared with other *tert*-amines used. The present *N*-oxidation reaction takes place under liquid–solid–liquid triphasic conditions, comprising of organic *tert*-amine, solid catalyst and aqueous phase. We assumed that the main role of the surfactant is to increase the contact area of the interface between the aqueous and organic phases and to enhance the transfer of the lipophilic amine from the organic to the aqueous phase. The amine *N*-oxides thus obtained are useful additives for the surfactants,[11,12] for example, the product in Table 2, entry 18 is sold under the trade name *Barlox 10S*.[1a] The benzylic amine *N*-oxides (Table 2, entries 14, 16 and 21) serve as substrates.[13]

Table 2 Oxidation of *tert*-amines catalysed by LDH-WO_4^{2-} (cat **1**)[a]

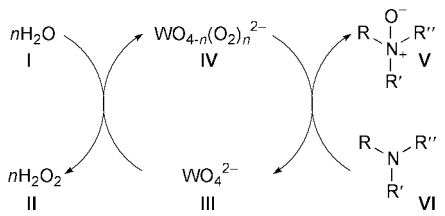
[a] Reaction conditions as in Table 1 (footnotes *a* and *b*). [b] Isolated yields (all the products were characterized by ^{1}H NMR and mass spectrometry). [c] Yield after sixth cycle.



Scheme 2 Plausible catalytic cycle for the *N*-oxidation of *tert*-amines to amine *N*-oxides by tungstate-exchanged Mg–Al LDH.

Furthermore cat **1** can be reused for six cycles (see Table 2, entry 23) without loss of activity and selectivity. The reaction did not proceed when conducted with the resulting filtrate after separation of the solid catalyst from the previous batch. This indicates that the active ingredient has not leached out of the solid catalyst during the reaction.

A plausible catalytic cycle in the oxidation of amines to amine oxides as described in Scheme 2 involves formation of peroxotungstate, **IV** on interaction of tungstate LDH **III** with hydrogen peroxide **II**.[9c] A shift of λ_{max} 250 (LDH **III**) to 325 nm (**IV**) according to UV-DRS confirms the formation of peroxotungstate species. The peroxotungstate **IV** species transfers its electrophilic oxygen to an amine **VI** forming the amine *N*-oxide **V** with regeneration of the active catalyst **III**.

In conclusion, the present process represents the sole example for synthesis of *N*-oxides wherein the heterogenised tungstate-based Mg–Al LDH is used as a catalyst. The potential for its commercial application is strengthened by the high throughput of the product, lower process inventories and use of an aqueous phase reaction system.

Controlled aging of TiO_2 nanoparticles blended with diblock copolymers and processed into dip-coated thin films led to ordered mesostructures with cubic and hexagonal symmetries that can be transformed into mesoporous TiO_2 by calcination.

There has been much interest in porous titania for its potential applications in areas such as photocatalysis,[1] photovoltaics,[2] and proton conducting membranes.[3] However, attempted syntheses of mesoporous titania so far have achieved only limited success.[4] On the other hand, many of the possible applications of mesoporous titania require thin films with accessible pores from the film surfaces, which is not possible with the common 2D hexagonal phases that form channels parallel to the film surfaces; a bicontinuous cubic phase would be desirable. Recently, Yang *et al*. have developed a generalized method to synthesize mesoporous oxides of many non-silicon metals utilizing non-hydrolytic condensation reactions of metal halides with alcohols and Pluronic block copolymers as the structure directing agents.[5] They have synthesized mesoporous titania with a cubic structure as well as 2D hexagonal structure. However, this seemingly simple method actually involves many different reactions occurring simultaneously including condensation of metal ions and self-assembly of the block copolymer templates that are sensitively affected by the reaction conditions. Slight variations of the reaction environments often produce totally different results making this method not highly reproducible. We have sought solutions for this problem by utilizing pre-synthesized nanoparticles instead of inducing the condensation of metal halides in the presence of surfactant molecules to alleviate the system's sensitivity, and thus to make the method simpler and more reproducible. In this paper, we report our results on the synthesis of mesoporous titania films using TiO_2 nanoparticles.

The synthesis of mesoporous titania is achieved in four steps of (1) synthesis of nanoparticles, (2) blending nanoparticles with template molecules into thin films, (3) aging the blended mixtures into mesostructures under appropriate conditions, and (4) calcination to remove the organic templates. Stock solutions of TiO_2 nanoparticles were prepared according to the literature procedure with slight modifications:[6] Titanium chloride, $TiCl_4$, was dissolved in absolute ethanol to a final $TiCl_4$ concentration of 20 wt%. A mixed solution of conc. HCl and 35% H_2O_2 in a 4/1 ratio (v/v) was added and the solution was refluxed at 80 °C for 2 h. The nanoparticles so obtained have anatase structure according to electron diffraction and transmission electron microscopy (TEM, JEOL-3011, 300 keV) studies† with sizes of *ca*. 1.6–2.0 nm based on the absorption edge of 305–325 nm from UV–VIS spectroscopic data.[7] A Brij-type diblock copolymer, $C_nH_{2n+1}(OCH_2CH_2)_yOH$ (C_nEO_y) with n/y = 16/20, 16/10, or 12/4, was dissolved in the TiO_2 stock solution and stirred for 10 h at room temperature. The molar composition of the final solution was $TiCl_4/C_nEO_y/HCl/H_2O_2/EtOH/H_2O$ = 1/0.083/3.8/0.97/6.1/15. The solution was dip-coated on silicon substrates at a pulling rate of 6 cm m^{-1}. The films were dried/aged either at 10 °C for 8 d or at 18 °C for 7 d under a controlled humidity of 80%. The progress of mesostructure formation of the materials in the as-synthesized films was monitored by powder X-ray diffraction (XRD, Rigaku D/max-RC). After the film materials ordered into cubic or hexagonal mesostructures (according to XRD), the films were calcined at 450 °C for 5 h in air. The as-synthesized films had some chlorine impurity (Cl/Ti = 0.3 by EDX/TEM), which was completely removed by calcination. The film thickness was typically about 300 nm for the as-synthesized and about 100 nm for the calcined films by SEM (JEOL-35 CF) and ellipsometry (Woollam VASE instrument). The crack-free, uniform and transparent (to the naked eye) TiO_2 mesoporous thin films so obtained were characterized by XRD and TEM.

The as-synthesized film prepared with $C_{16}EO_{20}$ block copolymer formed a mesostructure after aging at 10 °C for 7 d as evidenced by the XRD peak with d = 5.8 nm [Fig. 1(a)]. The XRD patterns were featureless up to 6 d of aging, indicating the sluggish nature of the self-assembly kinetics of the film materials. The XRD peak was shifted to d = 4.1 nm upon calcination indicating a lattice contraction by about 30% [Fig. 1(b)]. Although the XRD patterns do not reveal the details of the structure with only one peak present, the TEM image of the calcined material, in Fig. 1(c), can be explained by a pseudo-cubic structure with the [100] axis parallel to the viewing direction. The repeating distance of 4.3 nm of this image is in accord with the d-value from the XRD pattern. With the limited information available from these data, we cannot determine the structure of this material. However, the coinciding d-values from the XRD and TEM data suggest that the material has a primitive cubic unit cell. The one-peak nature in the XRD

 DOI: 10.1039/b104699n

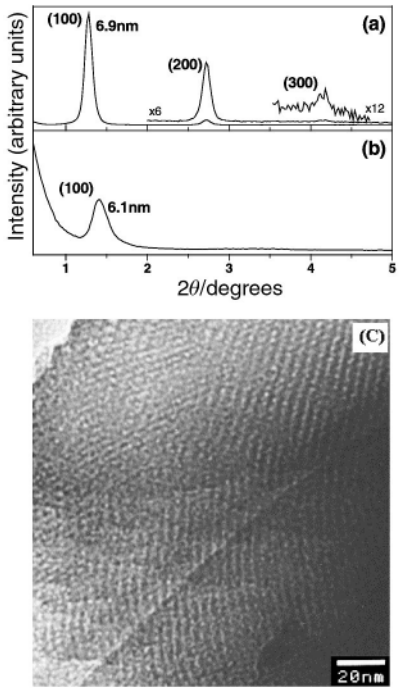

Fig. 2 XRD patterns of (a) an as-synthesized thin film prepared using using $C_{16}EO_{10}$ surfactant as the structure directing agent and aged at 18 °C for 4 d and (b) the calcined thin film. (c) TEM image of the calcined thin film that shows a 2D hexagonal structure preferentially oriented with the [100] axis parallel to the viewing direction.

pattern and the off-perpendicular axes in the TEM images suggest that the material is distorted from the ideal cubic structure, probably because the ordering of the materials is not perfect. The anisotropic lattice contraction during the calcination may also be responsible for the distorted mesostructure in the TEM image. Reflectance UV–VIS spectroscopic data on a calcined thin film shows an absorption edge of 360 nm that corresponds to a size of 3.0 nm for the anatase nanoparticles. This value agrees with the wall thickness measured from the TEM images and implies that the particle size is increased upon calcination. We have attempted to obtain better ordering of the materials by aging for longer periods of time up to 14 d, but the XRD patterns did not reveal any further peaks. Notwithstanding, it is clear that thin films of mesoporous titania with accessible pores from the film surfaces can be obtained by this procedure.

If the as-synthesized film was aged at 18 °C for 4 d instead of 10 °C for 7 d and calcined, the XRD pattern did not show any peak, indicating that a lamellar structure was not obtained. However, when $C_{16}EO_{10}$ was used instead of $C_{16}EO_{20}$ and aged at 18 °C, an XRD pattern with high order peaks that could be indexed with a 2D hexagonal or a lamellar mesostructure was obtained [Fig. 2(a)]. The XRD pattern was maintained after calcination with peaks shifted to higher angles [Fig. 2(b)] indicating a 2D hexagonal phase. The lattice parameters were a = 6.9 and 6.1 nm before and after calcination. The TEM image of the calcined sample also confirmed the hexagonal structure with channels with a repeating distance of 3.7 nm in agreement with the expected value of 3.5 nm (= $a/2$) based on the lattice parameter from XRD measurements.

Unfortunately, our TEM and XRD data did not provide any evidence of crystalline TiO_2 in the mesoporous films, probably because the particles were not well crystallized or were too small in size. Attempts to improve the crystallinity of the wall TiO_2 by calcining at higher temperatures than 450 °C caused collapse of the mesostructures, although anatase peaks were observed in the XRD patterns.

Because of the limited amount of samples available from thin films, we were not able to perform any other characterization studies such as surface area measurements. However, with the XRD and TEM data provided, it is clear that the materials we have obtained are mesoporous TiO_2.

The present system requires optimization of the reaction conditions. When different templates such as $C_{16}EO_{10}$ or $C_{12}EO_4$ were used instead of $C_{16}EO_{20}$ and aged at 10 °C, lamellar or disordered mesostructures were formed. Synthesis using $C_{12}EO_4$ and aging at 18 °C produced a lamellar structure whose lattice collapsed upon calcination. Thin films from solutions with different molar ratio of $TiCl_4/C_nEO_y$ from those given above formed poorly ordered mesostructures. However, the synthesis results are reproducible once the conditions including the composition, aging temperature and atmosphere are controlled as described. The nanoparticles in the solutions, with or without surfactant molecules, are very stable so that thin films prepared from solutions stored for up to 2 weeks under ambient conditions produce the same results.

Even after the mesostructures were formed by aging, the film materials are washed out when immersed in alcohols, indicating that the nanoparticles are not condensed into a 3D framework structure by aging alone. This observation and the strong dependency of the final mesostructure to the aging temperature resemble those of liquid crystals. Therefore, the mesostructures in the as-synthesized films can be explained by the self-assembly of the block copolymer and TiO_2 nanoparticles which, together, behave as a liquid crystal.

The method used in this paper has many advantages over those reported in the literature. First, by using block copolymers with large molecular weight and nanoparticles, the resulting mesostructures have large pores and thick walls, which can be of benefit for the utilization of semiconducting properties of transition metal oxides. Second, the results in this paper are highly reproducible as long as the conditions described are met since the complex condensation reactions of the inorganic precursors were eliminated. Third, the principles used in this work are simple and can be easily adapted to other metal oxide systems. Fourth, the mesoporous thin films of transition metal oxides with accessible pores from the film surfaces can be used for long sought applications such as photocatalysis, photovoltaics and membranes.

This research was financially supported by KOSEF (SRC, CNNC). We thank Mr J. S. Ju at Central Research Facilities, SKKU for the TEM data.

Aggregation greatly boosts emission efficiency of the silole, turning it from a weak luminophor into a strong emitter.

Many chromophoric organics and polymers are highly emissive in their dilute solutions but become weakly luminescent when fabricated into thin films.[1] This is believed to be caused by aggregate formation: in the solid state, the molecules aggregate to form less emissive species such as excimers, leading to a reduction in the luminescence efficiency. The chromophoric molecules are practically utilised in solid state commonly as thin films, and mitigation of the aggregation quenching has been a goal of research.[1,2] Many groups have attempted to obstruct aggregate formation through elaborate chemical, physical, and engineering approaches, which have, however, met with only limited success. Aggregation is in some sense inherent in film formation and it would be ideal if a molecule can emit intense light in its aggregation state. We here report such an unusual molecule, whose isolated species are faintly emissive but whose aggregates are strongly luminescent.

In our search for highly emissive linear and hyperbranched polymers,[3] we are attracted by a group of molecules called 'siloles', whose linearly drawn chemical structures appear to be conjugated, an example of which is shown in Fig. 1. During the purification process of the silole compound 1-methyl-1,2,3,4,5-pentaphenylsilole (**1**),[4] we noticed an intriguing phenomenon: when a drop of a solution of **1** was placed on a TLC plate, the wet spot could hardly be visualised with a UV lamp, but the dried spot (after solvent evaporation) was clearly visible upon UV illumination. This suggests that **1** does not luminesce when dissolved but does so upon aggregation. This rare observation prompted us to further study its luminescence behaviours.

When a dilute ethanol solution of **1** was excited at 381 nm, almost no photoluminescence (PL) signals were recorded by a spectrofluorometer (Fig. 2A). The 100-times magnified data gave a noisy spectrum; that is, **1** is indeed a weak emitter when it is molecularly dissolved in a good solvent. In contrast, when large amounts of water were added to its ethanol solutions (the final concentrations being kept unchanged at 10 μM), intense PL spectra were recorded under identical measurement conditions. Water is a non-solvent of **1** and the silole molecules must have aggregated in the solvent mixtures with high water contents. The 'solutions' were, however, macroscopically homogenous with no precipitate, suggesting that the silole aggregates are of nanodimension. A thin film of **1** prepared by vapour deposition also gave a strong PL spectrum. The spectroscopic analyses thus confirmed our visual observation described above.

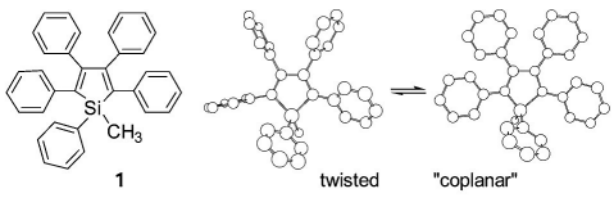

Fig. 1 Molecular structure and conformational rotamers of **1**.

To have a quantitative picture, we estimated the PL quantum yields (Φ_F) of **1** in ethanol and water–ethanol mixtures, using 9,10-diphenylanthracene as the reference. The Φ_F value for the ethanol solution was 0.63×10^{-3} (Fig. 2B), falling in the range of the literature values ($0.31–5.13 \times 10^{-3}$) of their close cousins.[5] The Φ_F value remained almost unchanged when up to 50% water was added to the ethanol solution but started to swiftly increase afterwards. When the water fraction was increased to 90%, Φ_F rose to 0.21, which is 333 times higher than that of the ethanol solution. The trajectory of the Φ_F change suggests that the molecularly dissolved **1** starts to congregate at a water fraction of 50% and the population of the aggregate continues to increase as the water fraction increases. Similar results were obtained when water was added into THF solutions of **1**. The change of the PL spectrum with solvent composition may be regarded as a special type of solvatochromism, and the sensitive on/off switching of the light emission by aggregation/deaggregation may find potential applications in optoelectronics systems.

To gain an insight into the cause of the unique PL behaviours of **1**, we checked its UV absorption spectra. The spectra of **1** in ethanol and 50% water–ethanol mixture were almost identical (Fig. 3). Its absorption bands in the 60% water–ethanol mixture, however, rose in intensity and moved to longer wavelengths. A level-off tail is seen in the visible spectral region; such tails are commonly observed in nanoparticle suspensions,[6] confirming the existence of nanoaggregates of **1** in the solvent mixture. The spectrum was further intensified as the water fraction increased. The differential spectra shown in the inset clearly manifest the growth of the red-shifted bands with an increase in the water fraction. The new peaks at ~291 and 400 nm are obviously due to the nanoaggregate absorption. When the silole molecules cluster together, its effective concentration decreases and the absorbance should also decrease. The increase in the absorbance thus indicates that the nanoaggregates are better conjugated than their counterparts of isolated species.

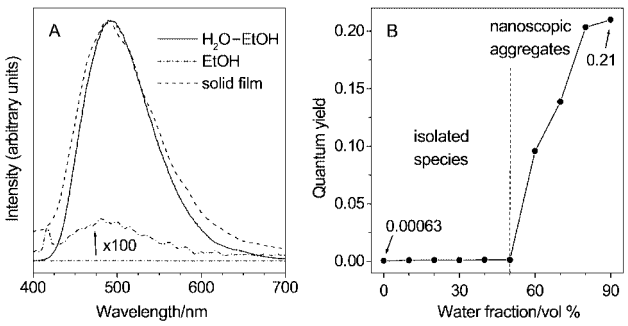

Fig. 2 (A) PL spectra of **1** in water–ethanol mixture (90 : 10 by volume), absolute ethanol, and solid film; concentration of **1**: 10 μM; excitation wavelength (nm): 381 (for solutions), 325 (for film). (B) Quantum yield of **1** *vs.* solvent composition of the water–ethanol mixture.

 DOI: 10.1039/b105159h

The silole may exist mainly as a twisted conformer when it is molecularly dissolved in a good solvent. A twisted rotamer of **1**, whose energy was minimised by the MM2 method in a CS Chem3D Pro program, is given in Fig. 1. The phenyl peripheries linked to the silole core are obviously out of coplanarity. It has been proposed that coplanarisation of chromophores can be induced by aggregation.[7] When **1** aggregates, coplanarisation of its peripheries and core may be induced to a certain extent. It is well known that coplanar and twisted conformers have different resonance energy: when the rings are on the same plane, the degree of conjugation is at a maximum; when the rings rotate to 90° to one another, the conjugation drops to a minimum. The best-known example of this is biphenyl (**2**) and its non-coplanar 2,2'-dimethyl homologue (**3**), which exhibit quite different electronic properties (*e.g.* $\varepsilon_2/\varepsilon_3 > 20$). The coplanarisation of **1** induced by the aggregation leads to a better conjugation between its peripheries and core, thus intensifying and red-shifting its absorption and emission bands. The silole molecules in the nanoaggregates cannot, however, assume a perfect coplanar conformation due to the involved steric crowdedness, and the phenyl rings may still rotate to some degree to cope with the steric repulsion. Such rotation will preclude co-facial alignment of the molecules and hinder excimer formation.[7] Aggregation quenching thus cannot operate in the luminescence process of **1**.

To further verify that aggregation quenching is not involved and to prove the usefulness of the novel luminescence property, we carried out a solid-state 'dilution' experiment and prepared a series of composite films of **1** and poly(methyl methacrylate) (PMMA). The compatibility of **1** and PMMA enabled us to cast thin films of optical quality from its chloroform solutions. The progressive red-shift of the PL spectrum with an increase in the content of **1** manifests the formation and population of the nanoaggregates in the solid 'solutions' (Fig. 4A). The linear increase of the luminance with the content of **1** testifies that the light emission is not quenched by aggregation. The composite film with 90% of **1** emitted a blue light of 492 nm with a high luminance of ~24000 cd m^{-2}. We built an electroluminescence (EL) device of ITO/CuPc/TPD/**1**/Mg-Ag,† which emitted a blue light of 496 nm. When an Alq_3† layer was introduced, the device ITO/CuPc (20 nm)/TPD (50 nm)/**1** (50 nm)/Alq_3 (10 nm)/LiF-Al showed a low turn-on voltage (3.4 V), high emission efficiencies (9234 cd m^{-2}, 12.6 lm W^{-1}, and 12 cd A^{-1}) and external quantum yield (8%). When the thickness of the Alq_3 layer was optimised (7 nm), the power efficiency was boosted to 20 lm W^{-1}. The silole is thus an excellent light-emitting material for the device application.

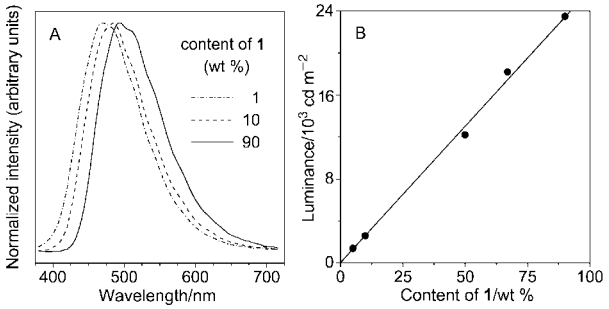

Fig. 4 (A) PL spectra of **1**–PMMA composites (excited at 325 nm). (B) Luminance of the composite film *vs.* its content of **1**.

In summary we revealed the uncommon emission behaviours of a silole (**1**) in this study. It has been a common 'law' that aggregation quenches light emission. What we observed here is exactly the opposite: light emission is induced by aggregation. The aggregation increased the emission efficiency of **1** by as high as two orders of magnitude (333 times). This is exceptionally rare, if not unprecedented, for small organic molecules.[8] Aggregation quenching has been the thorniest problem in the development of organic light-emitting diodes with high efficiencies. Our finding of aggregation-induced emission may stimulate new molecular engineering endeavours in the design of luminescent organics and polymers with highly emissive aggregation states.

We thank the Hong Kong Research Grants Council for financial support (HKUST 6187/99P and 6062/98P).

One-step synthesis and redox properties of dodecahydro-3a,9a-diazaperylene—the most easily oxidized *p*-phenylenediamine

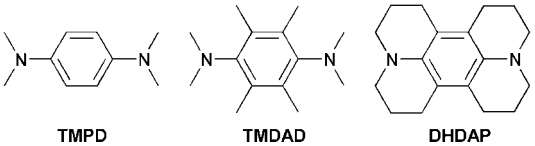
Received (in Corvallis, OR, USA) 29th May 2001, Accepted 17th July 2001
First published as an Advance Article on the web 29th August 2001

Dodecahydro-3a,9a-diazaperylene (DHDAP) was prepared in one step from *p*-phenylenediamine and 1-bromo-3-chloropropane, and its first redox potential is 292 mV more negative than the first redox potential of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD), thus becoming the most easily oxidized *p*-phenylenediamine homologue.

The quest for structure–function relationships in redox chemistry finds an expression in tuning and control of redox potentials. In this context, alkylation is known to increase the electron density and render aromatic systems more easily oxidized. For example, the redox potentials of decamethylmetallocenes are shifted by about 0.5 V to more negative values relative to the corresponding metallocene–metallocenium couples.[1] Similarly, conducting polymer precursors such as *N*-methylpyrrole and 3-methylthiophene are easier to oxidize by 0.06 and 0.20 V relative to pyrrole[2] and thiophene,[3] respectively.

N,N,N′,N′-tetraalkyl-*p*-phenylenediamines, and particularly *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD), are among the most well-known redox systems, typically undergoing two well-separated (*vide infra*) chemically and electrochemically reversible one-electron oxidations.[4] Consequently, this class of compounds has been considered for fundamental studies in electrochemical[5] and photoinduced electron transfer,[6] as derivatizing agents for electrodes in conjunction with redox mediation of biological reagents,[7] as electrochromic materials,[8] and more recently as flow indicators in electrochemically generated magnetohydrodynamic convection.[9] The structures of three representative *p*-phenylenediamines pertinent to the ensuing discussion are:



In general, the various derivatives of the parent *p*-phenylenediamine demonstrate the typical pattern of lower redox potentials as the degree of methylation increases (Table 1). TMPD has been the easiest to oxidize homologue in that series of compounds, and in fact it is one of the most easily oxidizable organic compounds. Importantly, methylation of the phenyl ring of TMPD does not lower the redox potential any further: *N,N,N′,N′*-tetramethyl-3,6-diaminodurene (TMDAD) is not only more difficult to oxidize than TMPD, but also according to Evans and Hu,[10] the second one-electron oxidation occurs at a less positive potential than the first one, so electrochemical oxidation of TMDAD yields directly the two-electron oxidized form. Evans and co-workers have proposed that this redox potential reversal is due to large conformational changes occurring during the oxidation of TMDAD, but not of TMPD. The essence of Evans' theory is that if any of the redox forms of TMDAD were planar, the H-atoms of the *N*-methyl groups would compete for space with the H-atoms of the aromatic methyl groups. The neutral form of TMDAD avoids these steric repulsions by twisting the dimethylamino groups out of planarity with the aromatic system. This is supported by the blue-shifted absorption spectrum of TMDAD relative to that of TMPD (Table 1). The two-electron oxidized form of TMDAD avoids the steric repulsions by adopting a boat-like conformation.[10] At this point, we reasoned that if the *N*-methyl and the aromatic methyl groups of TMDAD were bridged by a single atom, the competition for space by the aforementioned H-atoms would no longer exist, and the steric reasons for the abnormal behaviour of TMDAD would be eliminated. The resulting molecule, DHDAP, should demonstrate redox chemistry analogous to that of TMPD, but it should be much easier to oxidize than the latter. These expectations are justified fully by the following results.

Table 1 Redox and electronic absorption data for various *p*-phenylenediamines in acetonitrile[a]

Compound[b]	$E_{1/2}(1)$, V ($\Delta E_{p\text{-}p}$, V)	$E_{1/2}(2)$, V ($\Delta E_{p\text{-}p}$, V)	λ_{max}/nm ($\varepsilon \times 10^{-3}$/M^{-1} cm^{-1})		
p-Phenylenediamine	−0.106 (0.063)	0.429 (0.068)	321 (2.6)	251 (9.9)

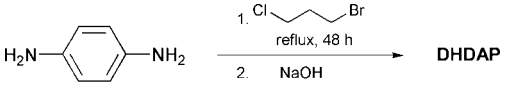
TMDAD	−0.068 (0.443)		264 (3.6)	218 (13.0)	
DHDAP	−0.573 (0.066)	−0.037 (0.065)	338 (27.6)	280 (65.6)	220 (193)

[a] All redox data were determined by cyclic voltammetry in CH_3CN–0.1 M *n*-$Bu_4N^+ClO_4$ (applying 80% compensation for the solution resistance), and are reported *versus* ferrocene. The $E_{1/2}$ values are the mid-points between the anodic and cathodic peak currents. [b] *p*-phenylenediamine, 3,6-diaminodurene, and *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) were commercially available and sublimed before use. *N,N,N′,N′*-tetramethyl-3,6-diaminodurene (TMDAD) was prepared according to the literature.[10] Dodecahydro-3a,9a-diazaperylene (DHDAP) was prepared in this study.†

The previously reported preparation procedure for DHDAP involves multistep synthesis.[11] Here, DHDAP was synthesized in high yield from *p*-phenylenediamine and 1-bromo-3-chloropropane in one step (Scheme 1).† DHDAP is stable as a solid,



Scheme 1

and in oxygen-free solutions. Its solubility in CH_3CN is in the 2–3 mM range, but in CH_2Cl_2 is significantly higher. Like TMPD, in non-degassed solvents DHDAP is oxidized slowly, yielding blue solutions. In further analogy to TMPD, DHDAP shows two successive one-electron oxidations, but both of its

 DOI: 10.1039/b104991g

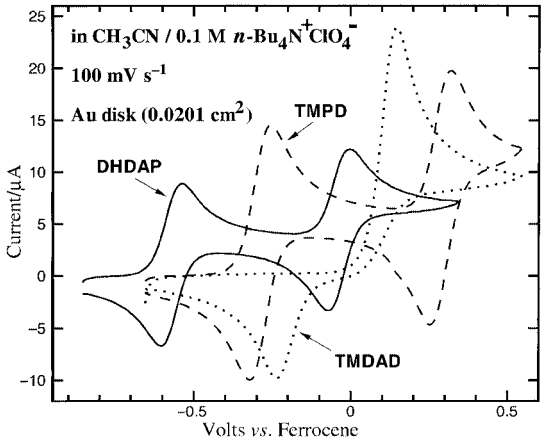


Fig. 1 Cyclic voltammograms of TMPD (1.71 mM), TMDAD (1.59 mM) and DHDAP (1.38 mM) in Ar degassed solutions.

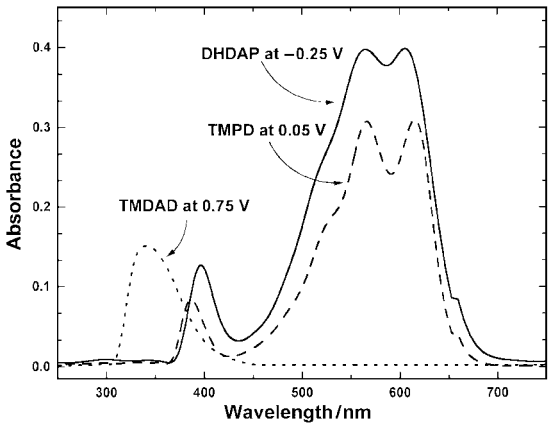

Fig. 2 Absorption spectra of TMPD (10.6 mM), TMDAD (11.1 mM), and DHDAP (7.9 mM) recorded with a dual ITO-electrode thin-layer cell in Ar degassed CH_2Cl_2–0.1 M n-$Bu_4N^+ClO_4^-$.

cyclic voltammetric (CV) waves are negative-shifted relative to those of TMPD, by 292 mV for the first and 331 mV for the second (Fig. 1). By comparison, TMDAD (its CV is also included in Fig. 1) is oxidized 0.213 V more positive than TMPD, reflecting its twisted geometry, which limits the extent of conjugation. The anodic-to-cathodic peak current ratios for both waves of DHDAP are equal to 1.0, indicating chemical reversibilty. Bulk electrolysis to $DHDAP^{\cdot+}$ and then back to DHDAP under the conditions of Fig. 1 led to 100% recovery of DHDAP (by ultramicroelectrode voltammetry), showing that $DHDAP^{\cdot+}$ is a stable species. The same experiment yielded the following diffusion coefficient data: $D_{DHDAP} = 1.52 \times 10^{-5}$ $cm^2\ s^{-1}$ and $D_{DHDAP^{\cdot+}}/D_{DHDAP} = 0.89$. By comparison, $D_{TMPD} = 2.58 \times 10^{-5}$ $cm^2\ s^{-1}$ and $D_{TMPD^{\cdot+}}/D_{TMPD} = 0.79$,[12] reflecting the somewhat smaller size of TMPD. (The different sizes of the CV waves of DHDAP and TMPD in Fig. 1 can be accounted for completely by the small differences in the concentrations and the diffusion coefficients.) Bulk electrolysis to $DHDAP^{2+}$ in CH_3CN–0.1 M $NaClO_4$ led to *ca.*. 80% recovery of DHDAP. The peak-to-peak separation of DHDAP is 66 ± 1 mV (*vs.* 59 mV for ferrocene) indicating a nearly reversible redox couple. Indeed, fitting the CV data with the Perkin–Elmer COOL™ software package we obtained as electron transfer coefficient for the first wave, $\alpha = 0.546$ (indicating an almost symmetric transition state) and a relatively high value for the standard rate constant, $k^\circ = 10.7$ cm s^{-1}.

The 292 mV negative shift of the first oxidation wave of DHDAP relative to TMPD indicates that the HOMO of the former is significantly higher in energy. Also, the two lower energy absorptions of DHDAP are red-shifted by only 7–23 mV (6–14 nm) relative to TMPD's (Table 1), suggesting that the HOMO and the LUMO of DHDAP are destabilized simultaneously by comparable amounts of energy.

The blue $DHDAP^{\cdot+}$ and $TMPD^{\cdot+}$ radicals were generated quantitatively in transparent thin layer electrochemical cells,[8] and their absorption spectra are shown in Fig. 2 alongside the spectrum of $TMDAD^{2+}$. The spectrum of $DHDAP^{\cdot+}$ is identical to the spectrum of $TMPD^{\cdot+}$, indicating analogous structures and identical chromophores. Similarly, the spectrum of the yellow $DHDAP^{2+}$ in CH_3CN–0.1 M $NaClO_4$ (not shown here) is identical to the spectrum of $TMDAD^{2+}$. Although energy minimization (AM1 method) yields a boat-like structure for $TMDAD^{2+}$,[10] and a planar structure for $DHDAP^{2+}$, the fact that their absorption spectra are identical implies that the differences in their geometry are not important. In both cases the iminium groups are electronically isolated from one another, probably due to the perturbation imposed by the positive *N*-atoms.

In summary, the preparation of DHDAP has been straightforward. DHDAP demonstrates two well-separated one-electron oxidation waves, shifted negatively by about 300 mV compared with the corresponding waves of TMPD. DHDAP is expected to render itself a main stream redox-active substance, with utility in redox staircases, and as a charge transfer quencher.

This research was supported by the Petroleum Research Fund, administered by the ACS (Grant No. 35154-AC5). A. M. M. Rawashdeh thanks ICSC-World Laboratory for a scholarship.

Notes and references

† *Synthesis of dodecahydro-3a,9a-diazaperylene*‡ *(DHDAP)*: *p*-phenylenediamine (0.50 g, 4.6 mmol, Aldrich, purified by sublimation) was added to 1-bromo-3-chloropropane (25 ml, 0.25 mol) and the resulting yellow solution was refluxed under Ar for 48 h. During this time a precipitate was formed and the color of the reaction mixture changed to orange. It was then cooled to rt, filtered under Ar and the pale orange solid was washed with diethyl ether and dried *in vacuo* to give DHDAP2H$^+$Br$^-$Cl$^-$ (1.51 g); ^{1}H NMR (400 MHz, D_2O): δ = 7.35 (s, 2H), 3.39 (t, J = 5.7 Hz, 8H,), 2.66 (t, J = 6.9 Hz, 8H), 2.10 (quint, J = 5.7 Hz, 6.9 Hz, 8H). A solution of the latter in 1 M HCl (50 ml, argon degassed) was made basic with 10% NaOH (argon degassed) and then extracted with diethyl ether (3 × 100 ml). Concentration of the pale yellow ether extracts after adding charcoal (rt) and drying over solid NaOH yielded 0.40 g (32%) of DHDAP as colorless platelets;§ mp 188–190 °C (lit.[11a] mp 190–191 °C; lit.[11b] mp 189–190 °C); ^{13}C NMR (100 MHz, argon degassed $CDCl_3$): δ = 136.4, 119.6, 50.4, 24.9, 22.9 ppm; anal. calcd. for $C_{18}H_{24}N_2$ (268.19): C, 80.55; H, 9.01; N, 10.44; found: C, 80.37; H, 9.06; N, 10.23.

‡ In ref. 11, the name of this compound was reported incorrectly as 1,2,3,3a,4,5,6,7,8,9,9a,10,11,12-tetradecahydro-3a,9a-diazaperylene.

§ The isolation of protonated DHDAP may be bypassed by extraction of the reaction mixture with water, basification and isolation of DHDAP as above.

[b] *State Key Laboratory of Ultrafast Laser Spectroscopy, Zhongshan University, Guangzhou 510275, People's Republic of China*

Received (in Cambridge, UK) 28th March 2001, Accepted 4th July 2001
First published as an Advance Article on the web 28th August 2001

Two novel photochromic compounds were designed and synthesized; the two-photon absorption (TPA) cross section of both were measured with a nanosecond laser pulse; their TPACS (δ) values are around 25 $\times$ 10^{-46} cm^4 s photon^{-1} molecule^{-1} in acetonitrile; the molecular structure of the target compounds have a 3-methyl-1-benzothiophen-2-yl moiety, which can greatly enhance the two-photon absorption cross section.

In the early 1930's two-photon absorption (TPA) of an atom was introduced into the literature as a new concept by Göppert-Mayer.[1] The TPA can be defined as the simultaneous absorption of two photons through a virtual state in a molecule or medium. Theoretical studies have been done to define a unit of two-photon absorption cross section (δ) as GM.

$$1\ \mathrm{GM} = 1 \times 10^{-50}\ \mathrm{cm^4\ s\ photon^{-1}\ molecule^{-1}}$$

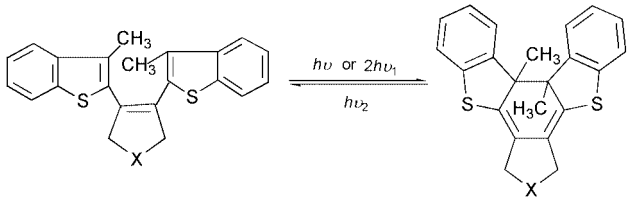
After that, the experimental studies were not developed very well for about forty years. In the 80's and especially in the 90's an upsurge of research on TPA followed the fast development of various lasers and advanced techniques in different fields, such as three dimensional (3D) optical storage;[2–4] the pioneer work being contributed by Rentzepis *et al.*[2] Other fields included 3D fluorescence imaging,[5,6] 3D microfabrication,[7,8] optical limiting[9–11] and two-photon photodynamic cancer therapy.[12,13] Most of the advanced techniques are interlinked between different sciences and techniques. Most of them are based on TPA or multi-photon absorption (MPA).

Studies of TPA can be carried out by nanosecond, picosecond or femtosecond laser pulses. TPA or MPA are based on nonlinear properties of a molecule or medium. The main advantage of TPA is that the excitation spatial area can be selected accurately in a volume medium through a tightly focused laser beam, so volume (3D) or multi-layer devices can be exploited.

It is well known that systematic research on photochromism was started from the 1950's. Until the end of the 1980's photochromism was studied basically on molecules and systems.[14] Two-photon induced photochromism was studied from 1989.[2] Recently, Belfield and Fan *et al.*[15] used a femtosecond laser to study one beam two-photon induced photochromism of 2-[1-(1,2-dimethyl-1*H*-indol-3-yl)ethylidene]-3-isopropylidene succinic anhydride (indolyl fulgide). The TPACS (δ) was measured through a Z-scan technique. The δ value of indolyl fulgide is 10.3 $\times$ 10^{-48} cm^4 s photon^{-1} molecule^{-1}. It is almost the same as that of the D-π-D type molecule, 1,4-bis{[4-(4-dibutylamino)phenyl]buta-1,3-dienyl}-2,5-dimethoxybenzene[7] (as large as 12.5 $\times$ 10^{-48} cm^4 s photon^{-1} molecule^{-1}), but indolyl fulgide is a D-π-A type molecule.

Unfortunately, design and synthesis for molecules with a large TPA cross section have not been well developed. It is well known that a large δ value of a medium is a fundamental property to make 3D or multilayer volume devices. The study of the relationship between molecular structure and δ value is quite important. Some molecular models are designed as D-π-D, D-π-A-π-D or A-π-D-π-A.[7,16] Kim *et al.*[17] studied π systems and they found that the dithienothiophene chromophore as the center π system can greatly enhance the TPA.

We find the connecting chromophore (D or A) can also greatly affect the TPA. Two novel kinds of photochromic compounds will be reported in this communication. The chemical structure of these compounds has been identified by NMR, MS and elemental analysis. They are 3,4-bis(3-methyl-1-benzothiophen-2-yl)-2,5-dihydrofuran (**I**) and 3,4-bis(3-methyl-1-benzothiophen-2-yl)-2,5-dihydrothiophene (**II**). The photochromic reaction is described as follows.



I, X = O; **II**, X = S — **C-I**, X = O; **C-II**, X = S

$h\upsilon$ is UV light; $h\upsilon_1$ is visible light, it is a 532 nm laser beam in this paper;

$h\upsilon_2$ is blue light. **C-I** and **C-II** are the colored forms of **I** and **II**.

The target compounds can be defined as 1,2-diarylethenes,[18] but the 3,4-bis(3-methyl-1-benzothiophen-2-yl)heterocyclopentene derivatives having photochromic properties have never been reported before and never studied as TPA materials.

The one-photon absorption spectra were measured by a spectrometer (Hitachi F-4500). Their maximum wavelengths (λ_{max}) are listed in Table 1.

In the transmittivity measurements, the second harmonic wave of a Q-switched Nd:YAG laser (Spectra-Physics GCR Series) with pulse duration of 10 ns was used as a pump source, and a laser energy meter (Laser Precision Corp., Model Rj-7200) with double detector was used as a recorder. The light beam from the laser was firstly divided into two beams by an optical splitter. The weaker one was used as a reference beam, which entered directly into the detector of the laser energy meter

in order to monitor the intensity of the pump beam. The other beam was focused into the solution of the compounds, and the transmitted energy was measured by another detector of the same laser energy meter. The diameter of the laser beam in the sample was 0.6 mm.

The TPACS are calculated by a method in the literature.[10] The results are collected in Table 2.

Compound **I** can be assigned as a D-π-A-π-D type molecule based on the difference of electronegativity between oxygen and sulfur. The benzothiophenyl could act as an electron donor and the oxygen as an acceptor. On the other hand, there is no difference in electronegativity of heteroatoms in compound **II**. It is difficult to say how the photoinduced electron transfer between different moieties of the molecule occurs. The δ values of studied compounds are almost the same in spite of the difference in the centre moiety between dihydrofuran and dihydrothiophene. In fact, the moieties on the left and right hand side of the target molecules are the same, 3-methyl-1-benzothiophen-2-yl.

The conclusion is that 3-methyl-1-benzothiophen-2-yl can greatly enhance the TPA cross section of a molecule. Based on papers we have checked in the literature, the δ values of the target compounds are the largest in acetonitrile. The reason for the TPA enhancement of the 3-methyl-1-benzothiophen-2-yl moiety could be owing to the lone election pairs of 3p electrons on the sulfur atom. We propose that the enhancement mechanism of dithienothiophene chromophore[17] could also be the same as that of 3-methyl-1-benzothiophen-2-yl. The magnitude of the δ value is a fundamental property of a molecule or medium in making three dimensional optical devices.

The selective formation of *p*-xylene is shown in toluene disproportionation using a new catalyst which is surrounded with a permselective membrane.

New technologies using inorganic membrane reactors have become of interest with the development of preparation methods for metal and ceramic membranes. The basic concept of the membrane reactor is a coupling of a catalyst with a membrane that gives (1) selective addition of reactants to the reaction zone and (2) selective removal of products from the reaction zone. Although the preparation of zeolite membranes on porous supports has been extensively studied,[1–9] the number of reports regarding membrane reactors combined with zeolite membranes is still small.[10,11] Recently, titania plate-supported platinum catalysts covered with a silicalite layer have been developed by van der Pauil *et al.*[12–14] who used titania/Pt/silicalite composites for hydrogenation of linear and branched alkenes. They showed that the yield of the hydrogenation of linear alkenes was much higher than that of branched alkenes because of a high diffusivity (D) of linear alkenes through the silicalite layer.

In this study, we developed catalyst particles coated with a permselective membrane. The reaction models for the potential applications using this type of catalyst particle are shown in Scheme 1. In the first example, if the diffusivity of reactant A is much larger than that of B, reactant A selectively diffuses to a catalyst particle through a membrane. The undesired reaction B to S or the adsorption of B as a poison on the catalyst can be prevented. In the second example, the reaction has a limited yield or selectivity controlled by the reaction equilibrium according to thermodynamics. The selective removal of desired product R from the catalyst particle gives enhancement of selectivity when the diffusivity of product R is much greater than S.

A catalyst with a permselective membrane has a larger membrane area per unit reactor volume compared to conventional membrane reactors. This is one of the most advantageous points of this catalyst considering practical applications since the membranes with large membrane areas without pinholes or cracks are difficult to prepare in many cases.

In this study, a silica-alumina catalyst covered with a silicalite membrane was used for disproportionation of toluene to produce benzene and xylene isomers, which is an example of the reaction shown in Scheme 1(b). An amorphous acid catalyst, silica-alumina, was first used in the industrial process of toluene disproportionation.[15] Following this, zeolite catalysts such as mordenite, faujasite and ZSM-5 were reported to be very active in catalyzing toluene disproportionation. However, the selectivity of *p*-xylene production was close to the thermodynamic equilibrium. To overcome this, various improvements have been carried out using medium pore zeolites, such as dealuminated MCM-22[16] and ZSM-5[17] modified with P and Mg. The high *para*-selectivity over modified MCM-22 and ZSM-5 can be explained by 'restricted transition-state selectivity' or 'product selectivity' inside the zeolite pores.

The silica-alumina/silicalite catalyst was prepared as follows: silica-alumina particles (Nikki Chemical Co., Ltd.) with composition of 82 wt% SiO_2 and 13 wt% Al_2O_3 were crushed to *ca.* 1 mm in size. The starting sol for the zeolite coating consisted of colloidal silica (Nissan Chemical Industries, Ltd.), tetrapropylammonium bromide (TPABr) and tetrapropylammonium hydroxide (TPAOH) (Wako Pure Chemical Industries Co., Ltd.) and deionized water. The silica-alumina particles were placed in the bottom of the sol with a molar ratio of 3 SiO_2:0.3 TPABr:0.3 TPAOH:130 H_2O. The crystallization was carried out in an autoclave at 453 K for 24 h. The product was calcined in air at 773 K for 5 h with a heating rate of 0.8 K min^{-1} and characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM) and catalytic tests.

XRD patterns of silica-alumina particles and zeolite-coated silica-alumina particles are shown in Fig. 1. No amorphous phase was observed in the XRD pattern of the silicalite-coated sample. The observed peaks are similar to the reported XRD patterns of silicalite powder, indicating that randomly oriented polycrystalline silicalite was formed on the silica-alumina particles. Fig. 2 shows SEM images of the obtained particles with different magnifications. The size of the silicalite crystals formed on the silica-alumina was about 5 μm.

The disproportionation of toluene was performed using a fixed-bed reactor (i.d. 4 mm) with a continuous flow system under atmospheric pressure. The feed rate of toluene was 2.16 mg min^{-1}. The catalyst weight and the flow rate of helium carrier were 1.3 g and 10 ml min^{-1}, respectively. Reaction

temperatures used were 723 and 823 K and the products were directly introduced to an FID gas chromatograph.

Table 1 lists the yields of the xylene isomers and the fraction of each xylene. The distribution of xylene isomers was very close to their equilibrium value over the silica-alumina catalyst without silicalite coating. On the other hand, the fraction of *p*-xylene in xylene isomers (*para*-selectivity) over the silicalite-coated catalyst largely exceeded the equilibrium value of about 22%. The selective permeation of *p*-xylene through silicalite membranes has been reported by several groups.[18–20] The high *para*-selectivity in the toluene disproportionation is caused by the selective removal of *p*-xylene from the silica-alumina particles, which leads to an apparent equilibrium shift between xylene isomers. The activity of the silicalite-coated catalyst was lower than that of the non-coated catalyst because of diffusion resistance through the membrane. A remarkable increase in the yield of xylenes was found at high temperature (823 K) owing to an increase in activated diffusivity of xylene through the silicalite membrane. When silicalite crystals without silica-alumina particles were used for the reaction, no catalytic activity was observed. Therefore, the silicalite membrane on the catalyst is believed to act not as a catalyst but as a separator.

High *para*-selectivity over shape-selective zeolite catalysts has been reported previously[16,17] (listed in Table 1). However, the mechanism of selective *p*-xylene production in this study is different from those observed in shape-selective zeolite catalysts. Here, the high *para*-selectivity does not result from 'product shape-selectivity' but from the selective removal of the produced *p*-xylene as seen in membrane reactors. The great potential of catalyst particles coated with a permselective membrane has been shown.

We would like to thank GHAS laboratory at Osaka University for the XRD and SEM measurements.

Ab initio study of oxygen atom transfer from hydrogen peroxide to trimethylamine†

Gianluca Ottolina* and Giacomo Carrea

Istituto di Biocatalisi e Biconoscimento Molecolare, Via Mario Bianco 9, 20131 Milano, Italy. E-mail: ottolina@ico.mi.cnr.it; Fax: 39 02285 0036; Tel: 39 02285 0021

Received (in Cambridge, UK) 4th June 2001, Accepted 27th July 2001
First published as an Advance Article on the web 28th August 2001

Unlike what has been theoretically proposed for ammonia oxidation with hydrogen peroxide, trimethylamine oxidation occurs with a concerted mechanism, which is favored even when an explicit water molecule is added or continuum solvent (water) is simulated.

Tertiary amines can be oxidised to their corresponding *N*-oxides using a large variety of oxidants, one of the most widely used of which is hydrogen peroxide. However, despite the simplicity of this reaction, there is a lack of published *ab initio* calculations of oxygen transfer from hydrogen peroxide to tertiary amines.

By means of such calculations, Bach *et al*. have extensively studied the transfer of an oxygen atom from organic and inorganic peroxy acids,[1] dioxiranes,[2] hydroperoxides[3] and hydrogen peroxide[4] to a broad array of substrates (reactions which involve the cleavage of an oxygen–oxygen σ bond), but the *N*-oxidation of tertiary amines by means of hydrogen peroxide is still not completely understood. Such an understanding would be extremely useful because this reaction can be considered a model for its biological counterpart, which involves the hydroperoxy-enzymes that are currently the subject of intense fundamental and applied research.[5]

Bach has also reported that the oxidation of ammonia by hydrogen peroxide is a 2-step process dominated by a 1,2-hydrogen shift, which is followed by a simple S_N2-like displacement to afford H_3NO and water: *i.e*. the transition state seems to be controlled by the formation of the water oxide (H_2OO) during the reaction.[4b] Furthermore, investigation of the role of solvation showed that a molecule of water stabilised the transition state. This differs from the generally accepted mechanism,[6] which assumes that hydrogen peroxide is attacked by the substrate with a direct nucleophilic displacement of the β-peroxy oxygen. In this study, we investigated this last mechanism by means of *ab initio* calculations, using the model reaction of trimethylamine (TMA) oxidation to the corresponding *N*-oxide (TMAO).

Table 1 shows the optimised geometries and related energies of the reagent complex (TMA–H_2O_2), transition state (TS-1) and product complex (TMAO–H_2O) obtained using the 6-31+G* basis set at different levels of theory.[7] The TMA–H_2O_2 complex was obtained through the hydrogen bond between the hydrogen of H_2O_2 and the TMA nitrogen. Differences in geometry (mainly in the torsion angle ∠HOOH) and energy can be found using HF, B3LYP or MP2 calculations. Significant differences in energy were also found in TS-1, which had only one negative eigenvalue in the Hessian matrix, and ΔE values ranging from 72.24 kcal mol^{-1} (HF) to 36.86 kcal mol^{-1} (B3LYP). Initial TS-1 geometries were obtained from several relaxed PES scans and refined with the eigenvalue-following methodology. It has been reported that the activation energy involved in the oxidation of ammonia by means of water oxide is regulated by the formation of the water oxide itself (56 kcal mol^{-1} MP4SDTQ/6-31G*//MP2/6-31G*),[4a] but our calculated activation barriers were in the range of 36–39 kcal mol^{-1} for B3LYP and MP2 (without ZPE), and thus far below the energy of water oxide formation. This suggests a concerted mechanism for the oxidation of TMA by means of hydrogen peroxide. Another important aspect for all of the transition states (TS-1) is that the hydrogen is not partially shifted towards the distal oxygen as in the concerted transition state mechanism found by Bach in the case of the oxidation of ammonia.[4a]

In our calculations, the 1,2-hydrogen shift occurs with the transfer of oxygen by cleavage of the O–O bond after the activation barrier is crossed. This was also demonstrated by far-reaching intrinsic reaction coordinate (IRC) calculations along the reaction pathway.[8]

In the TMAO–H_2O complex, the water was in staggered disposition to the methyl group in TMAO and had a strong hydrogen bond (~ 10 kcal mol^{-1} for each case), as has already been shown for the TMAO–H_2O complex.[9]

Oxidations with hydrogen peroxide are typically carried out in aqueous solution, and so specific solvent effects were calculated including one explicit water molecule. The transition state (TS-2) parameters (together with the TMA–H_2O_2–H_2O and TMAO–H_2O–H_2O complexes) are summarised in Table 2.

The geometric and energy parameters obtained from the optimised structures indicate the presence of hydrogen bonds.

Comparing the energies obtained from the optimised TMA–H_2O_2 and TMA–H_2O_2–H_2O complexes with those of the isolated reactants, the energy of the water-induced hydrogen bond stabilisation was 6–9 kcal mol^{-1}, and further increased in the transition state: the ΔE values for TS-2 were 8–10 kcal mol^{-1} below the TS-1 values. The overall barrier from the isolated reactants was also reduced by about 16–20 kcal mol^{-1} (ΔE_{IR} in Tables 1 and 2) by the action of one molecule of water.

TS-2 optimisation and IRC indicated that the water molecule did not act as a proton relay, but was involved in a relatively strong hydrogen bond linking the complex. This finding is very important because it excludes the alternative mechanism of the 1,4-hydrogen shift that has been proposed for ammonia oxidation *via* hydrated water oxide.[4b] The 1,4-shift barrier for hydrated water oxide at MP4SDTQ/6-31G*//MP2/6-31G* was 37.4 kcal mol^{-1},[4b] whereas we calculated a barrier of 30.89 kcal mol^{-1} for TS-2 at MP2/6-31+G*. These results suggest that the concerted mechanism is preferred even when one molecule of water is added.

We also studied the effect of a continuum bulk solvent, and analysed its consequences on the geometric and energetic characteristics of the reaction. Our attempts to calculate the bulk solvent effect using polarised continuum model (PCM) approaches were unsuccessful,[10] and so we adopted the Onsager model.[11] The results obtained at the B3LYP level (summarised in italics in Table 1) show that the solvent induced only small geometric changes. The main effect was a decrease in the imaginary frequency associated with the transition state, which indicates that this is significantly looser in aqueous solution than in the gas phase. Despite the small difference between some of the geometric parameters optimised in the gas phase and solution, there was a significant difference in the implied energy. Comparison of the energy in the gas phase and solution clearly showed that the transition state was stabilized (8.62 kcal mol^{-1}) as a result of the electrostatic effect of the solvent. On the other hand, the TMA–H_2O_2 complex was destabilized by 0.15 kcal mol^{-1} and the TMAO–H_2O complex stabilized by 2.47 kcal mol^{-1}.

Comparison of the optimised structures in bulk solvent and with one explicit water molecule revealed that the geometric differences were mainly localised to the transition state and, to a lesser extent, to the product complex: *e.g.* in the transition state, the N–O distance was lengthened in solution by 0.110 Å and the O–O bond simultaneously shortened by 0.07 Å.

In brief, unlike what has been proposed for ammonia, our results show that the 1,2-hydrogen shift follows the oxygen transfer in the case of TMA oxidation by means of hydrogen peroxide. The concerted mechanism was favoured at the studied theoretical levels even when an explicit water molecule was added or continuum water was simulated.

We thank the BVMO project (Biotechnology Programme of the European Commission BIO4-CT98-0267) for its financial support.

Received (in Cambridge, UK) 5th April 2001, Accepted 1st August 2001
First published as an Advance Article on the web 28th August 2001

The induction period of dehydroaromatization of methane to benzene over Mo/HZSM-5 had been investigated in real-time by the resonant-enhanced two-photon ionization (RE2PI) technique; it is remarkable that there is a small amount of benzene formed in the early stage of the induction period; we suggest that the trace amount of benzene was caused by the reduction of the original Mo^{6+} ion during the induction period and the Mo^{6+} species has a slight catalytic activity for methane–benzene conversion.

Direct conversion of methane to higher hydrocarbons, particularly to aromatics such as benzene, toluene, and naphthalene under non-oxidative conditions has received considerable recent attention.[1–3] The dehydroaromatization reaction of methane to benzene over the Mo/HZSM-5 catalysts in flow reactors has been carried out and achieved some attractive results, such as a methane conversion of 7–8% with 70–80% selectivity to benzene. Although a similar catalytic performance has been reported by several groups[2,4–7] for methane conversion over Mo/HZSM-5, differing active sites, reaction mechanisms and reaction intermediates have been proposed by various investigators. Xu *et al.*[6] suggest that MoO_3 may be involved as the catalytically active center, and that dimerization of a CH_2=MoO_3 species occurs to produce ethylene as the reaction intermediate. Later they further proposed that the active center was partially reduced molybdenum oxide species $MoO_{(3-x)}$. Lin *et al.*[7] supposed that the activation of methane to form CH_3· radicals occurred *via* a synergistic action between MoO_x and the Brønsted acid site, and the CH_3· radicals dimerized to form ethane as the primary product. Wang *et al.*[8] reported that the reaction is characterized by an induction period, prior to the initiation of benzene formation, during which Mo_2C is formed and coke deposition occurs, as revealed by X-ray photoelectron spectroscopy (XPS) measurements. Solymosi *et al.*[9] suggested that Mo_2C–MoO_2 with an oxygen deficiency was responsible for the production of ethylene from methane, and ethylene was then converted to benzene on the acidic sites of HZSM-5 support. This reaction is characterized by an induction period, prior to the initiation of benzene production, during which the catalyst surface undergoes physical and chemical changes and gradually forms catalytic active sites, so it is without doubt that the amount of the reaction products varies with time and different detective methods will give rise to different reaction mechanisms.

The resonant-enhanced multi-photon ionization (REMPI) spectrum technique has a high sensitivity and good selectivity. It has been widely used to study spectrum structures and energy-transfer dynamics of atoms, molecules and free radicals.[10,11] In REMPI, we exploit a tunable laser to selectively ionize the product molecules and collect the signals of the resulting photoelectrons *via* electrodes. Based on the ion signals of specified reactant or products, we can instantly monitor the changes of the content of the objective species in the reaction product mixture, monitoring the course of catalytic reaction. In this paper, we investigated in real-time the induction period of the reaction by RE2PI (resonant-enhanced 2-photon ionization) technique and new phenomena have been observed.

According to the resonant-enhanced two-photon ionization spectrum of benzene, we use UV light at 259.5 nm obtained from the frequency-doubled output by the BBO crystal of a dye-laser (Lambda-Physick model FL2002) operating with Coumarin 503 dye, which is pumped by XeCl (Xe/HCl/He) excimer. A Photodiode was used to monitor the wave of laser energy. Through the amplifier and BOXCAR, ion signals produced by the two electrodes were collected by microcomputer. Typical dye laser pulse energy was attenuated to ~50 μJ, before accessing detection windows. All ionization signal measurements were an average of 6 laser pulses, in order to remove pulse to pulse signal variations caused by fluctuations of pump laser energies.

The catalyst was prepared by impregnating an aqueous solution containing the desired amount of ammonium heptamolybdate [$(NH_4)_6Mo_7O_{24}$] in a vacuum environment at rt for 24 h, followed by drying for 4 h at 120 °C and then calcining for 4 h at 500 °C in air. The calcined samples were crushed and sieved to 60/80 mesh granules. Since all of the Mo-containing solution was deposited onto HZSM-5 support during drying, the Mo content in the final catalyst was assumed to be the same as the total Mo content of the solution.

Reactions were carried out in a fixed bed continuous up-flow quartz reactor with an inter diameter of 7 mm and using 0.1 g of catalyst. The upper section of the reactor is a pair of detection electrodes and detecting windows and the middle is a catalyst bed. Temperature was measured by a type K thermocouple located inside a quartz sheath in contact with the catalyst bed. The reactor effluent was sampled using transfer lines held at 400 K, avoiding gas-product condensations. The hourly space velocity of methane was 1500 ml g^{-1} h^{-1}. Reactant and flush gases which included 50% CH_4–Ar, Ar (99.99%), respectively, were used with further purification and gas flows were regulated by mass flow controllers. The catalyst was first heated under the flow reactor in a stream of Ar from rt to 973 K for 1 h, maintained at a temperature of 973 K for 0.5 h, and then the 50% CH_4–Ar reactant gas mixture was introduced into the reactor. The reaction mixtures were also analyzed by online Gas Chromatography (Shanghai Xianchuang Instrument Factory, Model GC-8810) using a column SE-30 and hydrogen flame ionization detector. All studies were carried out at atmospheric pressure and at 973 K.

The aromatization reaction of methane over 6 wt% Mo/HZSM-5 was studied at 973 K by RE2PI techniques and experimental results are shown in Fig. 1. It is obvious to see from Fig. 1(A) that the dehydroaromation reaction of methane to benzene over Mo/HZSM-5 zeolite does have an induction period for CH_4 activation. The results of RE2PI are almost the same as the results of GC, which proves that REMPI is a reliable technique to study this reaction. But it is noteworthy that there

 DOI: 10.1039/b103083n

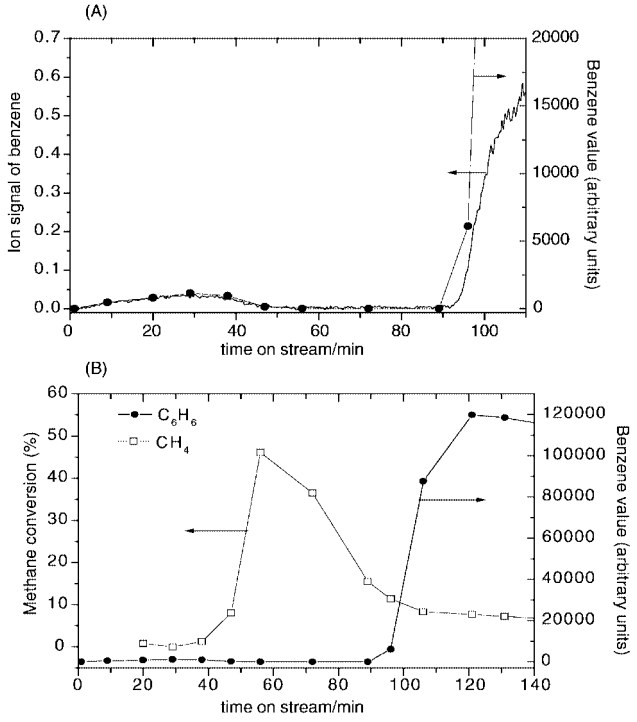

Fig. 1 (A) Benzene RE2PI and GC results *versus* reaction time over 6 wt% Mo/HZSM-5 at 973 K, 1 atm and GHSV = 1500 h^{-1}. — denotes ion signal results by RE2PI, — ● — denotes GC results. (B) Methane conversion and benzene relative peak area by GC method over 6 wt% Mo/HZSM-5 at 973 K, 1 atm, and GHSV = 1500 h^{-1}.

is a small amount of benzene formed at the very beginning of the reaction. Though compared with the amount of benzene after the induction period, the amount of benzene in the early stage of the induction period is negligible; it is an important hint for the reaction mechanism. This phenomenon has never been reported in previous studies. According to Fig. 1(A), we divided the induction period into two continuous sections; one is from 0 to 50 min and the other is from 50 to 90 min. In section one, when reactant gases were contacted with the catalyst, benzene was immediately formed. With the increase of reaction time, the benzene signal grows slowly. After reaching its highest point at about 27 min, the benzene signal began to decrease steadily. At the end of section one, there is no benzene signal. In section two, there is no signal of benzene. From Fig. 1(B), we see that the conversion of methane in these sections is totally different. In section one, the conversion of methane is 1–2%; in section two, the conversion of methane increases with time and reaches its highest point, 31%, at about 52 min, and then decreases. After section two, a significant amount of benzene was produced, while the conversion of methane almost keeps constant at ~7%. The signal of benzene from GC in Fig. 1(B) is the same with in Fig. 1(A), except the unit. Under the same reaction conditions, we repeated the experiment with 3.5 wt% Mo/HZSM-5 and 12 wt% Mo/HZSM catalysts and achieved similar results. The only differences are the lengths of induction period for the three catalysts.

As to the mechanism of methane aromatization reaction to benzene over Mo/HZSM-5 catalyst without oxidant, we suggest that the limited generation of benzene in the induction period section two was produced during the reduction of the original Mo^{6+} species. Less than 2% of the incoming methane was converted and only a trace amount of benzene was formed, showing that the Mo^{6+} species has a slight catalytic activity for methane–benzene conversion. The Mo^{6+} ion was reduced to lower oxidation state Mo species in this section. However in section two, a large amount of methane interacted with the catalyst without generation of benzene, suggesting that large amounts of carbon deposited on the catalyst in the course of high temperature methane conversion. The catalytic active sites were converted from Mo^{6+} species, which are unstable and easily reduced, to lower oxidation states of Mo species, which are very stable in a non-oxidizing atmosphere.

Characterisation of a hydroxymandelate oxidase involved in the biosynthesis of two unusual amino acids occurring in the vancomycin group of antibiotics†

Tsung-Lin Li, Oliver W. Choroba, Elizabeth H. Charles, Alan M. Sandercock, Dudley H. Williams and Jonathan B. Spencer*

Cambridge Centre for Molecular Recognition, Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: jbs20@cam.ac.uk

Received (in Cambridge, UK) 19th April 2001, Accepted 24th July 2001
First published as an Advance Article on the web 28th August 2001

ORF22 from the chloroeremomycin gene cluster has been cloned, expressed and characterised as a hydroxymandelate oxidase (HmO) that is involved in the formation of both (*S*)-4-hydroxyphenylglycine and (*S*)-3,5-dihydroxyphenylglycine.

The glycopeptide antibiotics vancomycin (**1**, Fig. 1) and teicoplanin are currently the treatment of last resort against methicillin-resistant *Staphylococcus aureus*.[1] The continued rise of vancomycin-resistant bacteria has heightened the need for new therapeutic agents. Manipulation of the biosynthetic gene cluster of glycopeptide antibiotics may be a potential route to new antibiotics. To explore this approach we have set out to elucidate the function of the genes involved in chloroeremomycin biosynthesis, another important member from the vancomycin family (**2**, Fig. 1).[2] In this communication we report the overexpression of the protein coded for by *orf*22 from the chloroeremomycin gene cluster, and its characterisation as a flavin-dependent oxidase catalysing the conversion of 4-hydroxymandelic acid and 3,5-dihydroxymandelic acid to their corresponding keto acids.

(*R*)-4-Hydroxyphenylglycine, found at positions 4 and 5 of the heptapeptide backbone of chloroeremomycin, is one of a number of rare amino acids in glycopeptide antibiotics. The peptide synthetase involved in the biosynthesis of chloroeremomycin contains epimerase domains for amino acids 2, 4 and 5, which suggests that (*S*)-4-hydroxyphenylglycine is the precursor of (*R*)-4-hydroxyphenylglycyl units at positions 4 and 5. Recently we have determined that *orf*21 codes for a dioxygenase involved in the pathway to (*S*)-4-hydroxyphenylglycine.[3] This enzyme, 4-hydroxymandelic acid synthase (HmaS), catalyses the production of 4-hydroxymandelate (**4**) (4HMA) from 4-hydroxyphenylpyruvate (**3**) (4HPP) (Fig. 2). Based on this discovery, it was postulated that ORF22, which shows homology to a known glycolate oxidase[4] (50% similarity and 40% identity) might oxidise 4-hydroxymandelic acid to its keto-acid derivative (**5**) followed by transamination, possibly by ORF17, to give (*S*)-4-hydroxyphenylglycine (**6**) (Fig. 2). During the preparation of this manuscript, Hubbard *et al.* published a paper independently establishing parts of the results presented here.[5]

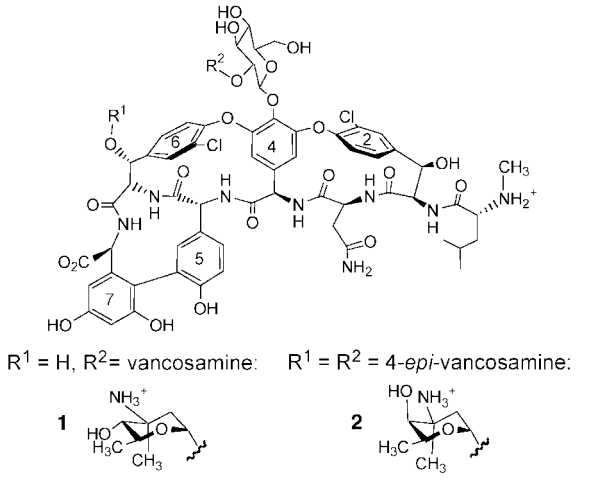

Fig. 1 Structures of vancomycin (**1**) and chloroeremomcyin (**2**).

In order to confirm the proposed pathway for the formation of 4HPG, *orf*22 was amplified by polymerase chain reaction (PCR) and cloned into the expression vector pET28a(+) (Novagen) as an *N*-terminal His_6-tagged protein. The resulting plasmid was used to transform the expression host *E. coli* BL21(DE3). Overexpression was carried out at 37 °C in 1 L 2 × YT medium with induction by isopropyl β-D-thiogalactoside (IPTG, 1 mM). The protein was recovered as an ammonium sulfate precipitate and further purified on Ni^{2+}-NTA agarose resin. The resulting protein was then transferred into 50 mM HEPES buffer, pH 7.6 using Millipore centrifugal filters. The purified protein showed a single band on a SDS-PAGE gel. The relative molecular mass was determined by ESI-MS to be 39863 ± 5 Da which was in excellent agreement with that calculated from the protein sequence (39864 Da). The enzyme contained a cofactor which was released when the protein was denatured by heat. This was determined to be FMN by HPLC analysis.

The enzyme (50 μg) was incubated with commercially available racemic 4HMA (20 mM) in HEPES buffer (50 mM, pH 7.6, 0.5 mL) in the presence of molecular oxygen, flavin mononucleotide (FMN, 0.5 mM) and catalase (1600 IU) at 25 °C for 16 h. The reaction was then quenched with 100 μL 6 M HCl and extracted with ethyl acetate (3 × 1 mL). The combined organic phases were dried with N_2 gas and the products converted to their methyl esters using diazomethane. The mixture was analysed by ammonia chemical ionisation GC-MS. The GC trace clearly shows that a new compound had been produced with a retention time of 16.0 min (Fig. 3, the substrate had a retention time of 16.0 min). The newly formed product

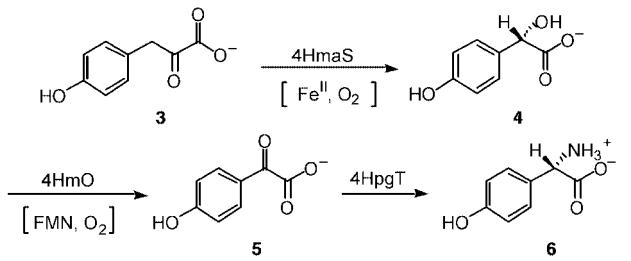

Fig. 2 Proposed biosynthetic pathway for 4-hydroxyphenylglycine (**6**): 4HmaS, 4-hydroxymandelate synthase; 4HmO, 4-hydroxymandelate oxidase; 4HpgT, 4-hydroxyphenylglyoxylate transaminase.

† Electronic supplementary information (ESI) available: SDS-PAGE analysis of HmO and molecular weight analysis of HmO protein by ESI-MS and GC/CI-MS of the enzymatic conversion of 3,5DHMA with HmO. See http://www.rsc.org/suppdata/cc/b1/b103548g/

 DOI: 10.1039/b103548g

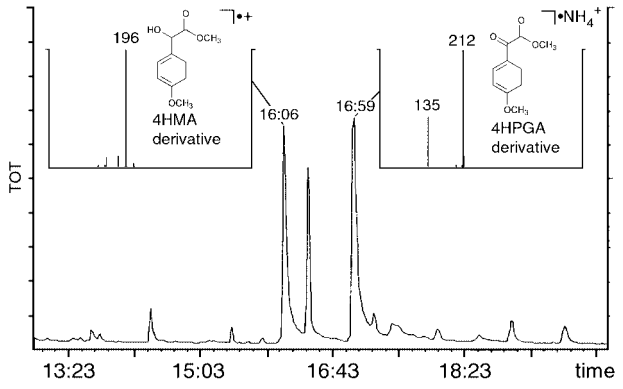

Fig. 3 GC trace and CI mass spectrum of an enzyme reaction of 4HMA with HmO after derivatisation by diazomethane showing 4-hydroxyphenylglyoxylic acid (4HPGA, product) and 4-hydroxymandelic acid (4HMA, substrate).

was identified as 4-methoxyphenylglyoxylate methyl ester (identical retention time and fragmentation pattern to standard material). This identifies *orf*22 as a hydroxymandelic acid oxidase (HmO) and strongly suggests that it is involved in the formation of (*S*)-4-hydroxyphenylglycine.

The stereochemistry of the substrate was elucidated using a racemic mixture of 4HMA and determining the optical rotation of the enantiomer remaining at the end of the incubation. Thus, the 4-hydroxymandelic acid isolated from the reaction had a negative optical rotation ($[\alpha]_D^{25}$ −5.1°, c = 2.5, ethanol) which corresponds to the same sign as synthetic (*R*)-4HMA ($[\alpha]_D^{25}$ −10.2°, c = 0.98, H_2O).[6] The enzyme was also found to oxidise commercially available (*S*)-mandelic acid but not (*R*)-mandelic acid. These combined results lead to the conclusion that (*S*)-4HMA is the natural substrate for the enzyme. Previous studies had determined that (*S*)-3,5-dihydroxyphenylglycine, another rare amino acid found in glycopeptide antibiotics, was formed from acetate *via* a polyketide pathway.[7,8] Analysis of the gene cluster reveals *orf*27 to be homologous to a number of chalcone synthases (polyketide synthases found mainly in plants). Recent work suggests that the pathway to (*S*)-3,5-dihydroxyphenylglycine involves the formation of 3,5-dihydroxyphenylacetic acid by ORF27[9a] followed by hydroxylation at the benzylic position, oxidation to the keto-acid and transamination to (*S*)-3,5-dihydroxyphenylglycine. The last two steps in this pathway are the same as those for (*S*)-4-hydroxyphenylglycine. Therefore it is tempting to suggest that ORF22 might also participate in this pathway and catalyse the oxidation 3,5-dihydroxyphenylmandelate to its keto-acid derivative. To test this, racemic 3,5-dihydroxymandelic acid[9b] was incubated with HmO as described previously (a shorter incubation time was used in this case) and the products analysed by GC-MS. The results show that 3,5-dihydroxymandelic acid is oxidised by the enzyme to give 3,5-dihydroxyphenylglyoxylic acid. This provides strong evidence that HmO is involved in the formation of both (*S*)-4-hydroxyphenylglycine and (*S*)-3,5-dihydroxyphenylglycine. The reaction catalysed by HmO can therefore be summarised as shown in Fig. 4.

Flavin-dependent enzymes are normally divided into two classes, oxidases and dehydrogenases.[10] Oxidases use molecular oxygen to oxidise the flavin after each reaction cycle with the formation of hydrogen peroxide, whereas dehydrogenases re-oxidised the flavin through electron transfer from proteins, such as ubiquinine or cytochrome b_5. To determine whether HmO is an oxidase or dehydrogenase the incubation mixtures were tested for the presence of hydrogen peroxide using a coupled assay of horseradish peroxidase (HRP) and *o*-dianisidine.[11,12] HRP generates *o*-dianisidine radicals which combine with 4HMA to give a product with an absorbance maximum at 550 nm (Fig. 5, trace a). When HmO was incubated with HRP and *o*-dianisidine an increase in absorbance at 550 nm was observed (Fig. 5, trace b). This determines that HmO is formally a flavin dependent oxidase.

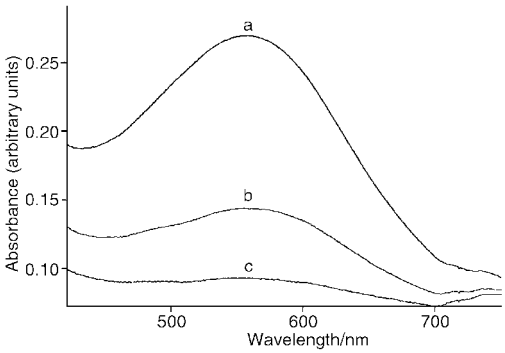

Fig. 5 Visible spectra probing the generation of H_2O_2 during HmO catalysis. a: enzymic reaction of horseradish peroxidase plus H_2O_2, *o*-dianisidine and 4HMA, b: enzymic reaction of HmO plus *o*-dianisidine and horseradish peroxidase, c: blank reaction omitting HmO.

In summary, we have identified the enzyme coded for by *orf*22, as a hydroxymandelate oxidase (HmO) which carries out the oxidation of both 4-hydroxymandelic acid and 3,5-hydroxymandelic acid. This provides strong evidence that it is involved in the pathway to both (*S*)-4-hydroxyphenylglycine and (*S*)-3,5-dihydroxyphenylglycine and sheds new light on how these important antibiotics are biosynthesised.

We thank the Royal Society for a Research Fellowship (J. B. S.), the Ministry of Education, Taiwan, for a Research Fellowship (T.-L. L.), the European Union for a TMR Marie-Curie Research Fellowship (O. W. C), St. John's College, Cambridge for a Junior Research Fellowship (O. W. C.), and the BBSRC for financial support. We thank Hwi Hong, in particular, for her help in GC-MS analysis.

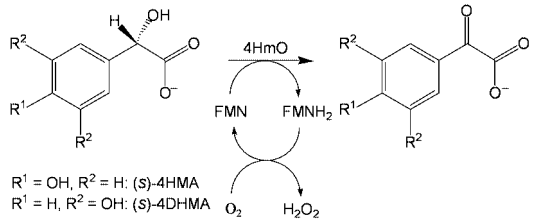

Fig. 4 Oxidation of (*S*)-4-hydroxymandelate ((*S*)-4HMA) and (*S*)-3,5-dihydroxymandelate ((*S*)-4DHMA) to 4-hydroxyphenylglyoxylate by 4HmO in the presence of FMN and molecular oxygen.

Addition of β-Ga_2O_3 to H-ZSM-5, as a physical mixture, enhances the formation of aromatic hydrocarbons in the methanol to hydrocarbons reaction.

Methanol conversion to hydrocarbons has been extensively studied using zeolite catalysts[1] since Chang and Silvestri reported this reaction for the zeolite H-ZSM-5.[2] The reaction has been demonstrated over a range of zeolites and microporous materials, *e.g.* zeolite Y,[3] zeolite β,[4] mordenite,[5] Me-APO-5,[6] SAPO-34,[7] as well as non-microporous catalysts e.g. WO_3–γ-Al_2O_3.[8] During these studies most attention has focussed on the reaction mechanism for the formation of the first carbon–carbon bond.[1] In addition, significant attention has been given to the control of the product distribution e.g. the formation of light alkenes or gasoline.[1] In all these previous studies it is surprising that no attention has been given to the use of composite catalysts in which an oxide and zeolite are mixed together. We have now addressed this, and we have found that the addition of β-Ga_2O_3 to H-ZSM-5 can dramatically enhance the yield of aromatic hydrocarbons and in this communication we present our preliminary results.

H-ZSM-5 (Si : Al mol ratio = 80; calcined at 350 °C, 3 h; PQ Corporation) and β-Ga_2O_3 (Aldrich, 99.99%) were obtained commercially and used without further purification or treatment. The methanol to hydrocarbons reaction was carried out using a standard laboratory microreactor. Methanol was fed using a calibrated syringe pump to a vaporisor, mixed with helium diluent (60 ml min^{-1}) and was reacted over the catalyst (0.25 g) in the heated zone of a tubular microreactor (id = 9 mm). Product analysis was carried out using on-line gas chromatography and the lines to and from the reactor were heated to avoid condensation of the products.

H-ZSM-5 and β-Ga_2O_3 were separately reacted with methanol (400 °C, 3.1 g methanol g $catalyst^{-1}$ h^{-1}) and the results are shown in Table 1. It is apparent that β-Ga_2O_3 is not active for this reaction under these conditions (experiment 3), whereas, as expected H-ZSM-5 gives complete conversion of the methanol to hydrocarbons (experiment 1).

Subsequently, the zeolite (0.125 g) and β-Ga_2O_3 (0.125 g) were mixed together as a physical mixture. This was achieved by mixing either the powders or pellets (β-Ga_2O_3, 250–300 μm; H-ZSM-5, 600–1000 μm) together in a glass tube without crushing. This simple physical mixture gave a significantly higher yield of aromatic compounds and lower yields of $C_4 + C_5$ hydrocarbons, when compared with the same mass of H-ZSM-5 alone (experiment 4). A blank experiment in which BN (0.125 g), a material that is totally unreactive for the conversion of methanol under these reaction conditions, was physically mixed in the same way with H-ZSM-5 (0.125 g) gave no enhancement in the yield of aromatic hydrocarbons (experiment 2). In a subsequent set of experiments, separate beds of β-Ga_2O_3 (0.125 g) and H-ZSM-5 (0.125 g) were reacted with methanol. In these experiments the two beds were separated by glass beads so that there was no physical contact between the two materials. The results (experiments 5 and 6, Table 1) show that no enhancement in the yield of aromatic compounds was observed. This indicates that the effect is the result of physical contact between the two materials. To demonstrate this, an experiment was carried out using a physical mixture of H-ZSM-5 pellets (0.125 g, particle diameter = 600–1000 μm, prepared by pelleting and sieving the zeolite) and β-Ga_2O_3 powder (0.125 g, particle diameter < 80 μm). The results for methanol conversion (400 °C, 3.1 g methanol g $catalyst^{-1}$ h^{-1}) are shown in Fig. 1, and a yield of aromatic hydrocarbons > 20 wt% is observed. After 270 min time on line, the flow of methanol was stopped and the catalyst was cooled in He to ambient temperature. Once cooled, the β-Ga_2O_3 (powder)–H-ZSM-5 (pellets) mixture was sieved to separate the β-Ga_2O_3 from the zeolite. Analysis of the two components by powder X-ray diffraction indicated that no changes had occurred during the reaction to the crystallinity of these materials, althouth it is recognised that this technique cannot provide information on the formation of nano-crystalline material. In addition, analysis of the zeolite pellets using atomic absorption spectroscopy confirmed that it did not contain any gallium. Both materials were retested for methanol conversion using the same conditions that had been used for the previous

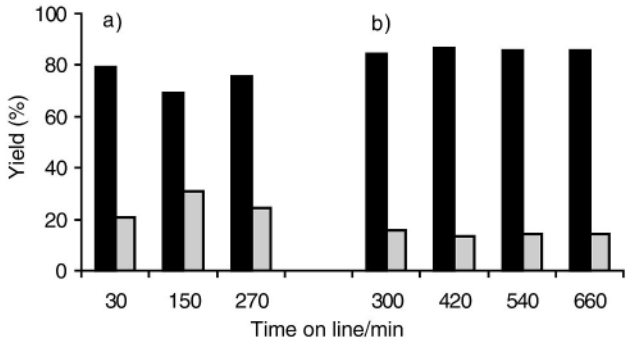

Fig. 1 Methanol conversion to hydrocarbons over (a) β-Ga_2O_3 (powder)–H-ZSM-5 (pellets) physical mixture until 270 min time-on-line and (b) H-ZSM-5 (pellets) following removal of β-Ga_2O_3 (powder) by sieving. Reaction conditions: 400 °C, 3.1 g methanol g catalyst^{-1} h^{-1}. Key: black = aliphatic hydrocarbons, grey = aromatic hydrocarbons. All data recorded at 100% methanol conversion.

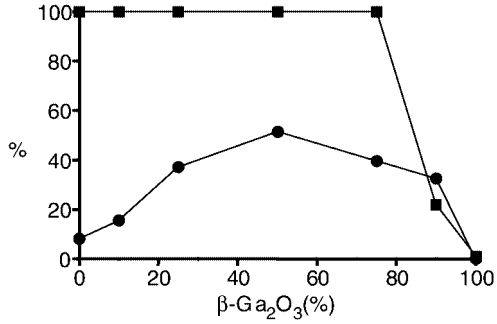

Fig. 2 Methanol conversion to hydrocarbons over β-Ga_2O_3–H-ZSM-5 physical mixtures prepared by grinding as a function of H-ZSM-5 (wt%). Reaction conditions: 400 °C, 0.7 g methanol g catalyst h^{-1}. Key: ■ methanol conversion, ● aromatic yield.

physical mixture experiment. The β-Ga_2O_3 was found to be inactive. The results for the H-ZSM-5 pellets (Fig. 1) show that the yield of aromatic hydrocarbons was now much lower (typically 13–14 wt%), and typical for that expected for H-ZSM-5 alone. This experiment demonstrates that the β-Ga_2O_3–H-ZSM-5 composite catalyst exhibits a new catalytically active site that gives enhanced yields of aromatic hydrocarbons. It is proposed that this new site involves contact synergy between the crystallites of β-Ga_2O_3 and H-ZSM-5. Furthermore, it is apparent that these sites can be removed by separating the physical mixture. To confirm this effect, a further experiment was conducted in which β-Ga_2O_3 (0.125 g) and H-ZSM-5 (0.125 g) were ground together to achieve a uniform intimate mixture. When this intimately mixed material was tested for methanol conversion (400 °C, 0.7 g methanol g catalyst^{-1} h^{-1}) the yield of aromatic hydrocarbons increased to 51.4 wt% (24.2% C_8H_{10}, 20.6% C_9H_{12}). Investigation of other ratios of Ga_2O_3–H-ZSM-5 confirmed that the 1 : 1 physical mixture gives the most marked enhancement in the yield of aromatic hydrocarbon (Fig. 2) which is consistent with the proposal of the active site for enhanced aromatic formation being at the junction of the β-Ga_2O_3 and H-ZSM-5 particles. It is proposed that at this site alkenes are dimerised and aromatised in a similar manner to the aromatisation of propane in the Cyclar process which is observed at temperatures >600 °C using Ga^{3+}-doped H-ZSM-5.[9] Indeed, recently Lunsford and co-workers[10] showed that ethene could be converted to aromatic products using a Ga–H-ZSM-5 catalyst at temperatures in the range 500–550 °C. To demonstrate the generality of the observed effect, we have also investigated β-Ga_2O_3–zeolite β and β-Ga_2O_3–WO_3–γ-Al_2O_3 physical mixture and have observed similar effects of contact synergy. It is therefore considered that composite catalysts, comprising oxides and microporous materials, may generate new types of catalyst for hydrocarbon formation from methanol and these catalysts can be used to control the product distribution.

We thank the EPSRC for financial support.

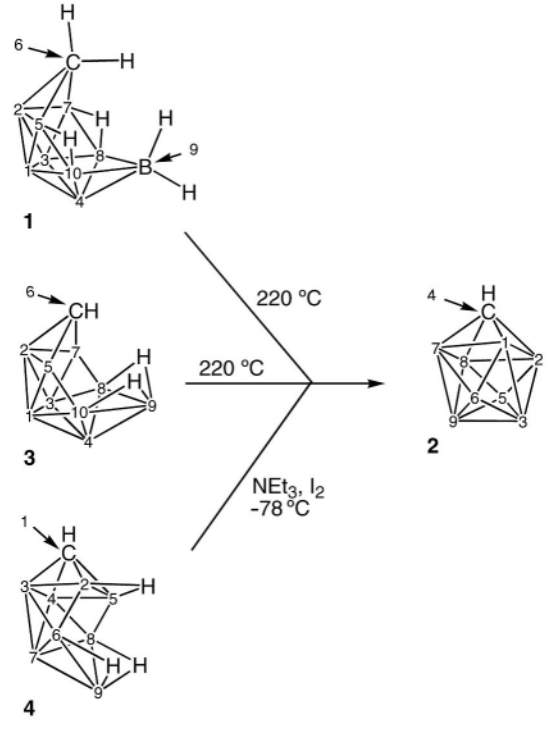
First published as an Advance Article on the web 20th August 2001

Thermolysis in the solid state of $Cs^+[arachno\text{-}CB_9H_{14}]^-$, or of $Cs^+[nido\text{-}CB_9H_{12}]^-$, or the oxidation of *nido*-1-CB_8H_{12} with I_2 in THF at −78 °C in the presence of NEt_3, gives the first nine-vertex *closo* monocarbaborane, the stable [*closo*-4-CB_8H_9]$^-$ anion, in yields of 56, 61 and 75%, respectively.

Although carbaborane chemistry is the most investigated area of polyhedral boron-containing cluster chemistry,[1,2] it is dominated by dicarbaborane chemistry. Monocarbaborane chemistry, by contrast, is sparsely represented,[1] and many of the fundamental cluster types are unreported. Of the classically *closo* $[CB_nH_{n+1}]^-$ monocarbaborane anions, $[CB_5H_6]^-$ (known only as its conjugate acid CB_5H_7), together with the $[CB_9H_{10}]^-$, $[CB_{10}H_{11}]^-$ and $[CB_{11}H_{12}]^-$ anions, have been recognised for some 30 years.[3] Of these, the $[CB_9H_{10}]^-$ and $[CB_{10}H_{11}]^-$ species and their derivatives attract much current attention.[4,5] More recently, the $[CB_7H_8]^-$ species has been reported,[6] but $[CB_6H_7]^-$ and $[CB_8H_9]^-$ have remained elusive. We now report three routes for the preparation of one of these last two missing species, *viz*. the nine-vertex $[CB_8H_9]^-$ anion, in good yields. The first two routes are simple solid-state thermolyses, of $Cs^+[arachno\text{-}6\text{-}CB_9H_{14}]^-$ and of $Cs^+[nido\text{-}6\text{-}CB_9H_{12}]^-$,[7] and the third is the straightforward oxidation of the neutral monocarbaborane *nido*-1-CB_8H_{12}[8,9] with I_2 in the presence of NEt_3. The geometries and numbering systems for the ten-vertex *nido* and *arachno* cages, and for the nine-vertex *closo* and *nido* cages, are shown in Scheme 1: unlettered vertices represent BH(*exo*) units.

In the first method a sample of $Cs^+[arachno\text{-}CB_9H_{14}]^-$ (compound **1** in Scheme 1)[7] is heated at 220 °C for 3 h, followed by dissolution of the product in $(Me)_2CO$, and filtration. Examination of the solution by NMR spectroscopy showed the [*closo*-4-CB_8H_9]$^-$ anion (compound **2**; *ca*. 60%), and smaller quantities of the $[nido\text{-}CB_9H_{12}]^-$ and $[closo\text{-}CB_9H_{10}]^-$ anions (*ca*. 5 and 35% respectively); no starting anion **1** remained. Chromatographic separation on a silica column (30 cm × 2.5 cm) using MeCN–CH_2Cl_2 5:95 as the eluting phase, followed by precipitation with $[PMePh_3]^+Cl^-$, thence resulted in crystalline $[PMePh_3]^+[CB_8H_9]^-$ (56% isolated). The second method consists of a similar heating of $Cs^+[nido\text{-}CB_9H_{12}]^-$ (compound **3**)[7] at 220 °C for 3 h, again followed by dissolution of the product in $(Me)_2CO$ and filtration. Examination by NMR spectroscopy§ again showed the [*closo*-CB_8H_9]$^-$ anion (*ca*. 61% after purification as above), but now with smaller quantities of $[nido\text{-}CB_{10}H_{13}]^-$ (20%) and $[closo\text{-}CB_9H_{10}]^-$ (*ca*. 3%); no starting anion **3** remained. The by-products of the formation of $[CB_9H_{10}]^-$ by these two variants suggest a series of competing reactions. Thus, $[CB_9H_{14}]^-$ may lose H_2 to give $[CB_9H_{12}]^-$, and $[CB_9H_{12}]^-$ may lose H_2 to give $[CB_9H_{10}]^-$. Alternatively, $[CB_9H_{14}]^-$ may lose $\{BH_3\}$ to give $[CB_8H_{11}]^-$ which would be unstable to H_2 loss to give $[CB_8H_9]^-$, and $[CB_9H_{12}]^-$ may lose $\{BH_3\}$ to give $[CB_8H_9]^-$ directly. $[CB_9H_{12}]^-$ may add transient $\{BH_3\}$ to give $[CB_{10}H_{12}]^-$ *via* elimination of H_2, whereas relatively hydrogen-rich $[CB_9H_{14}]^-$ would not add $\{BH_3\}$ so readily. These considerations suggest that the thermolysis conditions may be tailorable to favour between $[CB_8H_9]^-$ or $[CB_9H_{10}]^-$ formation. We currently devise experiments to examine for this possibility.

The other, efficient and fast, route for the preparation of the [*closo*-4-CB_8H_9]$^-$ anion **2** is based on the oxidation of *nido*-1-CB_8H_{12} (compound **4**).[8,9] Treatment of neutral **4** with NEt_3 (3 mol equiv.) and I_2 (1 mol equiv.) in THF solution at −78 °C for



Scheme 1

† Electronic supplementary information (ESI) available: NMR spectroscopy and calculated coordinates for the B3LYP/6-31G* symmetry-locked structure for $[CB_8H_9]^-$. See http://www.rsc.org/suppdata/cc/b1/b103408c/
‡ Systematic IUPAC nomenclature: the *closo*-4-carbanonaborate(1−) anion; characterised crystallographically as its methyltriphenylphosphonium salt.

 DOI: 10.1039/b103408c

1 h, followed by stirring at room temperature for a further hour, resulted in the formation of the $[NHEt_3]^+$ salt of the [*closo*-4-$CB_8H_9]^-$ anion **2**. The reaction is consistent with the stoichiometry as in eqn. (1).

$$1\text{-}CB_8H_{12}\ \mathbf{4} + 3NEt_3 + I_2 \rightarrow 3[NHEt_3]^+ + [4\text{-}CB_8H_9]^-\ \mathbf{2} + 2I^- \qquad (1)$$

The $[NHEt_3]I$ by-product was removed by filtration, the filtrate evaporated to dryness, and then treated with aqueous KOH, followed by aqueous $[PBu^n_4]Br$. Extraction with CH_2Cl_2 and chromatographic separation of the CH_2Cl_2 extract on a silica column (25 cm × 2.5 cm) using MeCN–CH_2Cl_2 5 : 95 as eluting phase, thence gave crystalline $[PBu^n_4]^+$[*closo*-4-$CB_8H_9]^-$ (75%). Mechanistically, the formation of anion **2** as in eqn. (1) seems to agree with a deprotonation of CB_8H_{12} **4** by NEt_3 and thence oxidation of the transient [*nido*-1-$CB_8H_{11}]^-$ anion with I_2. Closure of the nine-vertex *nido* cage by joining the B(9) vertex of **4** with the B(2) and B(5) vertices (Scheme 1), would yield the product configuration of **2**.

The structure of the [*closo*-4-$CB_8H_9]^-$ anion **2** was confirmed by a single-crystal X-ray diffraction analysis of the $[PMePh_3]^+$ salt (Fig. 1).¶ It has the classical tricapped trigonal prismatic structure of $[B_9H_9]^{2-}$, but with a carbon atom in a four-connectivity 4-position. As with the $[B_9H_9]^{2-}$ anion,[10] the edges of the central trigonal prism, at 191.4(4)–200.4(4) pm, are at the longer end of typical interboron cluster bonding distances. NMR spectroscopy on a bulk sample was consistent with the structure derived from the single-crystal work.§¶ Like the $[CB_7H_8]^-$ anion,[6] the new compound is a stronger reducing agent than the $[CB_9H_{10}]^-$ and $[CB_{11}H_{12}]^-$ congeners. It is similarly iodinated at the sites distal from carbon; thus monoiodination with elemental I_2 in CH_2Cl_2 solution gives [3-I-*closo*-4-$CB_8H_8]^-$ and [5-I-*closo*-4-$CB_8H_8]^-$.

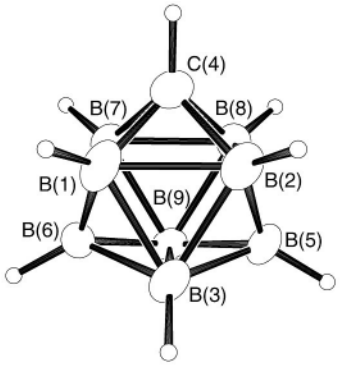


Fig. 1 Crystallographically determined molecular structure of the [*closo*-4-$CB_8H_9]^-$ anion in its $[PMePh_3]^+$ salt. The crystal had two independent $[PMePh_3]^+[CB_8H_9]^-$ units per unit cell. One anion was disordered, the other not. The anion shown here is the undisordered one. Distances (in pm throughout) from C(4) to its adjacent B atoms are in the range 162.8(5)–164.6(5), and the corresponding distances from B(5) and B(6) 'caps' are in the range 165.4(5)–177.4(5). The triangular faces of the internal trigonal prism are longer at 191.4(4)–200.4(4) than the trigonal prism edge distances at 177 6.8(5)–180.0(5); correspondingly, the angles (in degrees throughout) subtended at C(4) fall into two sets: 65.2(2)–66.2(2), and 71.9(2)–75.8(2). Similarly, angles subtended at B(5) and B(6) are in two sets: 63.3(2)–65.0(2) and 67.9(2)–72.5(2).

These results, allied with efficient routes from $B_{10}H_{14}$ to the starting monocarbaboranes **1**, **3** and **4**,[7,9,11] mean that the [*closo*-4-$CB_8H_9]^-$ anion is now one of the most readily accessible *closo*-carboranes. Long the missing link between eight- and ten-vertex [1-$CB_7H_8]^-$ and [1-$CB_9H_{10}]^-$, its chemistry should now contribute substantially to the development of carborane science. For example, the anion could act as a 'weakly coordinating anion' to complement $[CB_9H_{10}]^-$ and $[CB_{10}H_{11}]^-$, and their derivatives:[4] it is also likely to be amenable to substitution and metallacarborane chemistries. We currently work on the optimisation of its synthesis and on the development of other nine-vertex monocarbaborane chemistry.

11 $B_{10}H_{14}$ (12.4 g, 100 mmol) in hexane (200 cm^3) was treated with 15% aqueous NaOH (500 cm^3) with vigorous stirring at room temperature and cooled to 0 °C. 37% aqueous HCHO (containing 36.5 g HCHO, molar ratio $B_{10}H_{14}$: HCHO = 1 : 4.5) was added together with H_2O (30 cm^3) over 1 h. The aqueous layer was separated and extracted with Et_2O (3 × 100 cm^3). Addition of saturated aqueous CsCl (100 mmol) to the combined Et_2O extracts followed by evaporation of the Et_2O, filtration, and recrystallisation of the precipitate from hot H_2O gave $Cs[CB_9H_{14}]$ (44%), as used in the thermolysis. For the CB_8H_{12} route, H_2O (100 cm^3) was added, and the Et_2O removed by rotary evaporation, resulting in an aqueous solution of $Na[CB_9H_{14}]$ [at this stage, precipitation with $[NEt_4]Cl$ can be used to give $[NEt_4][CB_9H_{14}]$ (48%)], which was added dropwise to a stirred mixture of aqueous HCl (*ca*. 4.5 M; 350 cm^3), $FeCl_3·6H_2O$ (65 g) and hexane (200 cm^3), and stirred for 3 h. The hexane layer was separated and evaporated, and the resulting white solid sublimed to give CB_8H_{14} (5.4 g; 47%); which was converted to CB_8H_{12} by dehydrogenation at 350 °C as in ref. 8.

Addition of diprotic nucleophiles to a C_{60}–tetrazine monoadduct: structural reassignment and correction of a novel rearrangement†

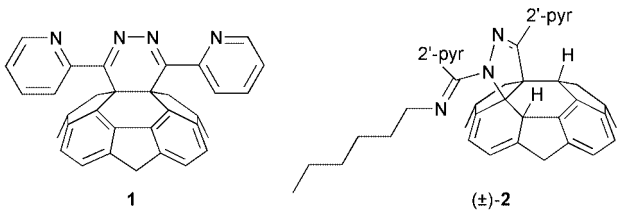
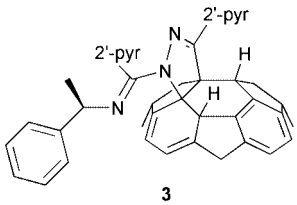
Received (in Corvallis, OR, USA) 9th May 2001, Accepted 18th July 2001
First published as an Advance Article on the web 29th August 2001

C_{60}–tetrazine Diels–Alder adducts bearing electron deficient dihydropyridazine groups undergo chemoselective amination and hydration reactions upon addition of primary aliphatic amines and water, respectively, to form new adducts with 4,5-dihydropyrazole groups nested atop the [60]fullerene skeleton.

Recently, we reported[1] Diels–Alder reactivity between C_{60} and electron deficient 3,6-disubstituted-1,2,4,5-tetrazines. With 3,6-di-2′-pyridyl-1,2,4,5-tetrazine, the corresponding monoadduct **1** bears a 4,5-dihydro-3,6-di-2′-pyridylpyridazine group fused to the [60]fullerene skeleton. Compound **1** behaves as an isolable but reactive intermediate capable of considerable further chemistry. Previously a facile, regioselective 1,4-hydrogenation of **1** was reported.[1] Continued work on this and related compounds shows that the structure reported for the hydrogenated monoadduct was incorrect. Compound **1** does hydrogenate in a 1,4 fashion, but only in concert with a novel rearrangement which effectively converts the fused 4,5-dihydropyridazine function into a 4,5-dihydropyrazole group. The reaction is a net hydration. With the aid of an X-ray crystal structure, we are now able to redefine the chemistry of **1** as it pertains to the addition of diprotic nucleophiles. A variety of nucleophiles including water, alcohols, thiols, and primary and secondary aliphatic amines add smoothly to **1**. Chemoselective additions of the diprotic nucleophiles, primary aliphatic amines and water, are followed in each case by a novel rearrangement reaction on the [60]fullerene surface leading to new compounds bearing fused 4,5-dihydropyrazole groups.[2]



1 (±)-**2**



3
1 of 2 diastereomers

Monoadduct **1** was formed as previously described[1] and reacted with several diprotic nucleophiles including hexylamine and (*R*)-(+)-α-methylbenzylamine. The reactions yield new compounds, (±)-**2** and **3** (as a mixture of 2 diastereomers), respectively. Compounds (±)-**2** and **3** bear 1,3-disubstituted-4,5-dihydropyrazole groups nested atop the corresponding [60]fullerene skeletons.

The structure of **3** was obtained by single crystal X-ray diffraction. Black crystals of **3** ($C_{84}H_{19}N_5{\cdot}2CS_2$) form in the chiral space group $P2_12_12_1$ through vapor diffusion of hexane into a carbon disulfide solution of the compound.‡ The structure is disordered with both diastereomers present, but in unequal amounts. Fig. 1 shows a view of the entire molecule for the major diastereomer, which has a refined population of 0.529(3). (The minor diastereomer has an analogous structure, but the location of the [60]fullerene moiety is switched such that the positions of the 5- and 6-membered rings adjacent to C2 and C3 are reversed relative to those shown in Fig. 1. The ability of these two diastereomers to co-crystallize at a common crystallographic site is related to the orientational disorder seen in many fullerene crystals.[3,4]) Structurally the adduct can be viewed as involving addition to two adjacent 6:6 ring junctions of the fullerene, analogous to a *cis*-1 bisadduct.[5] The C2–C3–N3–N2–C61 ring spans a 6:5 ring junction, protrudes radially from the [60]fullerene skeleton, and is very nearly planar. The hydrogen atoms attached to C1 and C4 were located in a difference Fourier map for both the major and minor diastereomers. As is usual with additions to fullerenes,[6] geometric changes in the carbon cage are localized at the sites of attachment. Thus, the C1–C2 and C3–C4 bond lengths (1.670(8) and 1.712(10) Å in the major diastereomer, 1.720(8) and 1.731(11) Å in the minor diastereomer) are longer than the 1.38 Å distance found for 6:6 ring junction of C60. The C2–C3 bond, 1.622(5) Å, is also long.

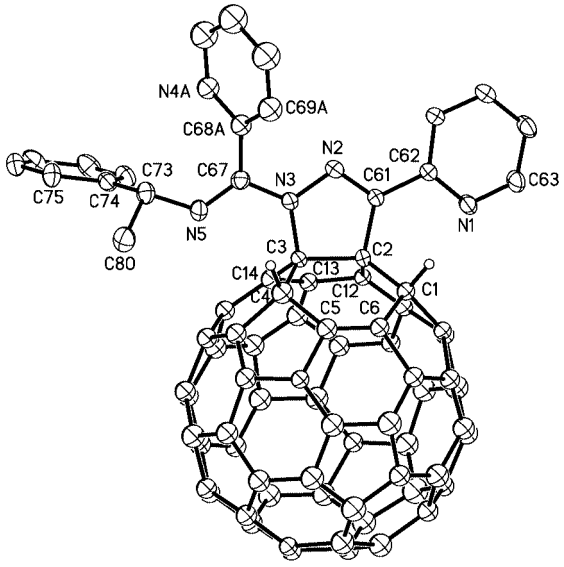


Fig. 1 A perspective view of the major diastereomer (0.529(3) occupancy) of the adduct **3**, $C_{84}H_{19}N_5$, with 50% thermal contours for all non-hydrogen atoms. Only the hydrogen atoms on C1 and C4 are shown.

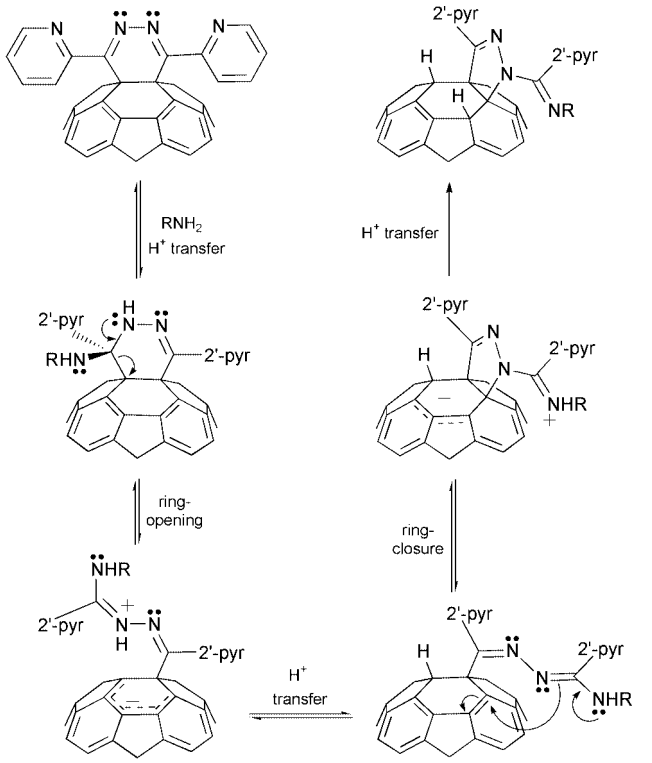


Scheme 1 Possible mechanism for amination of C_{60}–tetrazine monoadduct.

Strong spectroscopic similarities (^{1}H and ^{13}C NMR†) between (±)-**2** and **3** suggest an analogous structure for (±)-**2**.

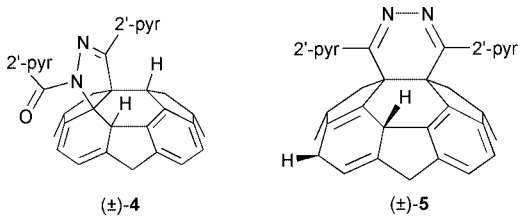
The structures for (±)-**2** and **3** are consistent with amination across a single imine C=N bond of **1** followed by a rearrangement of the amination adducts (Scheme 1). Chemoselective amination across an imine C=N bond of **1** is somewhat surprising considering that C_{60} itself is readily aminated by primary and secondary aliphatic amines.[7] EPR and UV–VIS–NIR evidence[7a,b] suggests that the amination of C_{60} involves initial electron transfer from the amine to C_{60}. In our laboratory, the amination of C_{60} usually requires ambient light when relatively nonpolar organic solvents are employed (*e.g.* toluene, chloroform). This observation is consistent with a mechanism involving electron transfer from amine to photoexcited fullerene (for similar observations involving tertiary amine addition, see refs. 7*f* and 7*g*). However, compounds (±)-**2** and **3** are formed equally well in ambient light or darkness, consistent with but by no means specific to a mechanism involving simple nucleophilic additions (Scheme 1).

Other diprotic nucleophiles show similar reactivity. Water adds to **1** to give the analogous hydration product (±)-**4**. The reaction is catalyzed by weak acid catalysts such as silica gel and requires ambient light.

Compounds (±)-**2** and **3** are formally imine derivatives of (±)-**4**, but do not originate from (±)-**4**. Thus, addition of the appropriate amine to (±)-**4** does not produce (±)-**2** or **3** under otherwise identical reaction conditions employed for the synthesis of (±)-**2** or **3** from **1**. Consequently, (±)-**4** is not an intermediate in the amination reactions leading to (±)-**2** and **3**. Compounds (±)-**2** and **3**, however, are converted to (±)-**4** under harsh hydrolysis conditions (conc. HCl, CH_3CN, 80 °C), thereby confirming the structure of (±)-**4**.

The ^{1}H and ^{13}C NMR spectra for (±)-**4** match those reported previously for a compound assigned structure (±)-**5**.[1]

With an X-ray crystal structure now available for **3**, it is clear that the previously assigned structure (±)-**5** is incorrect and should be replaced with the structure (±)-**4**. The original assignment of structure (±)-**5** was based upon the observations that the reaction leading to hydrogenated product is photoinduced, the reaction requires water adsorbed on glass, and the NMR data are uniquely consistent with a 1,4-hydrogenation



(±)-**4** (±)-**5**

pattern on the fullerene skeleton. Moreover, the completely regioselective nature of the reaction suggested new C–H bond formation in close proximity to the dihydropyridazine group. Indeed, each of these statements holds true for the hydration of **1** leading to (±)-**4**. A key shortcoming of the earlier work was the failure to recognize rearrangement of the dihydropyridazine function, as well as the erroneous incorporation of the tetrazine–dihydrotetrazine redox cycle into the proposed reaction mechanism.

Because the hydration and amination reactions produce structurally similar compounds, it is tempting to conclude that they proceed *via* similar mechanisms. However, the hydration of **1** leading to (±)-**4** requires ambient light while the amination reactions leading to (±)-**2** and **3** do not. By analogy to known photoinduced processes involving C_{60},[7f,g] at least one of the steps leading to (±)-**4** likely involves an electron transfer to a photoexcited [60]fullerene skeleton.

Received (in Cambridge, UK) 10th July 2001, Accepted 30th July 2001
First published as an Advance Article on the web 29th August 2001

The decarboxylation of L-aspartate by *E. coli* L-aspartate-α-decarboxylase (ADC) is shown to occur with retention of configuration; analysis of the protein structure identifies Tyr58 as the proton donor in the decarboxylation mechanism.

ADC catalyses the decarboxylation of L-aspartate to β-alanine.[1] It is one of four enzymes in *E. coli* involved in the biosynthesis of pantothenate (vitamin B_5),[2] the precursor of 4′-phosphopantetheine and coenzyme A. ADC is a tetrameric protein comprising four 14 kDa subunits. The X-ray crystal structure of *E. coli* ADC has been determined, and shows that the active sites are between subunits.[3]

The mechanism of decarboxylation involves formation of an imine between the amino group of aspartate and an integral pyruvoyl group. The pyruvoyl group is formed by an autocatalytic post-translational modification which cleaves the Gly24–Ser25 bond and converts Ser25 into the pyruvoyl group. This reaction is analogous to that which occurs in histidine decarboxylase[4] and *S*-adenosylmethionine decarboxylase.[5]

The proposed enzyme mechanism is depicted in Scheme 1. After formation of the enzyme–substrate adduct (**1**), carbon dioxide is lost to form the extended enolate (**2**). This then reprotonates to form the imine adduct of the product β-alanine (**3**), which is finally released by hydrolysis to regenerate the pyruvoyl group. Evidence for this mechanism comes from trapping of the enzyme–substrate adduct and enzyme–product adduct by reduction with cyanoborohydride, and subsequent detection by electrospray mass spectrometry.[6]

In this paper we report the results of our investigation into the stereochemical course of the decarboxylation reaction catalysed by ADC. Analysis of the crystal structure of ADC suggests that the proton may come from the phenolic group of Tyr58 or the hydroxy group of Thr57, which lie above and below the face of the enzyme–intermediate adduct (**2**) respectively (Fig. 1). If the proton donor were Tyr58, the proton would be added to the *re* face (Scheme 1, path a), corresponding to decarboxylation–protonation occurring with overall retention of configuration. Conversely, decarboxylation–protonation would occur with inversion of configuration if the proton were added from Thr57 to the *si* face of (2) (path b). Alternatively, but less probable, the reprotonation could be non-stereospecific.

The stereochemical course of the reaction can be determined by using ADC to catalyse the conversion of L-aspartate into β-alanine in deuterium oxide. Stereospecific deuteriation of (**2**) will generate chirally-labelled β-alanine which can be charac-

† These authors contributed equally to this work.

 DOI: 10.1039/b106090m

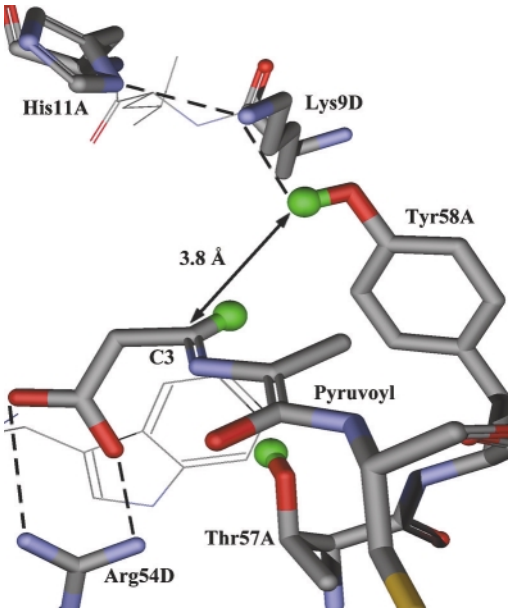

Fig. 1 Active site of ADC with the enzyme-intermediate adduct (**2**) modelled in. The active site is at the interface of subunits and is composed of residues from both subunits (in this case subunits A and D).

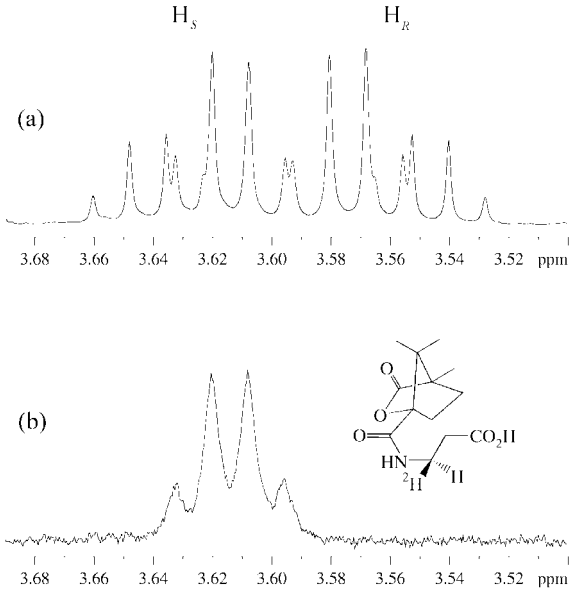

Fig. 2 ^1H NMR (500 MHz, C^2HCl_3) of the C3 protons of β-alanine in (a) *N*-camphanoyl-β-alanine and (b) camphanoyl derivative of the biotransformed material.

terised as its camphanoyl derivative by comparison with previously assigned spectra of (3*R*)- and (3*S*)-*N*-camphanoyl-[3-$^2H_1$]-β-alanine.[7]

The *panD* gene[6,8] in *E. coli* was overexpressed with an *N*-terminal hexa-histidine tag to facilitate protein purification by affinity chromatography on a nickel–nitrilotriacetic acid (Ni–NTA) column. L-Aspartate (50 mg) and His_6-ADC (6 mg) were incubated in phosphate buffer (pD = 7.6, 50 mM) in ^2H_2O for four days at 25 °C. The enzyme was removed by ultrafiltration and the solution lyophilised to dryness. The residue was derivatised with camphanoyl chloride by shaking in a biphasic mixture of 2 M NaOH and toluene for 3 h, followed by extraction with chloroform, drying with Na_2SO_4 and evaporation. Unlabelled *N*-camphanoyl-β-alanine was also synthesised by this procedure. The ^1H NMR spectra of the C3 protons of *N*-camphanoyl-β-alanine and the camphanoyl derivative of the biotransformed material are shown in Fig. 2.[9]

Comparison of the two spectra in Fig. 2 shows that a deuterium atom has been incorporated, leading to loss of the signal for one proton. The geminal ^1H coupling to the remaining proton has been replaced by a smaller ^2H coupling, causing an apparent simplification of the multiplet and broadening of the signals. This confirms that the reprotonation is stereospecific.

In order to determine the absolute stereochemistry of the labelling of β-alanine, the spectra were compared to published data on (3*R*)- and (3*S*)-*N*-camphanoyl-[3-$^2H_1$]-β-alanine, determined as part of a study on the dihydropyrimidine dehydrogenase reaction.[7] The upfield multiplet in Fig. 2a has been assigned to the 3*R* proton. The biotransformed compound, in which this proton has been replaced by a deuteron, is consequently (3*R*)-*N*-camphanoyl-[3-$^2H_1$]-β-alanine. This is the expected product if deuterium is delivered from Tyr58 to the *re* face of (**2**), with the decarboxylation–protonation steps proceeding with overall retention of configuration (Scheme 1, path a).

The enzyme–intermediate adduct (**2**) has been modelled into the crystal structure of ADC (Fig. 1). In this model the distance between the hydroxy proton of Thr57 and the C3 carbon is 3.3 Å. The corresponding distance from C3 to the phenolic proton of Tyr58 is 3.8 Å. Despite being the closest potential donor, Thr57 may not be the most appropriate. It is relatively buried in the active site, and deprotonation of the hydroxy group could destabilise the neighbouring salt bridge between the β-carboxyl of the enzyme–intermediate adduct (**2**) and Arg54. Tyr58 appears to be better placed; in particular it is part of a potential proton relay with Lys9 and His11. All three are conserved residues. As His11 is close to the surface of the protein it could acquire a proton from the solvent.

In conclusion, the stereochemical labelling study and analysis of a model of the putative intermediate bound to the enzyme (**2**), together suggest that the source of the proton in the reprotonation step is the phenolic group of Tyr58.

We would like to thank Drs Martyn Frederickson, Peter Grice and Nick Bampos and the NMR technical staff for their assistance.

Novel silver(I)–organic coordination polymers: conversion of extended structures in the solid state as driven by argentophilic interactions

Long Pan,[a] E. Brice Woodlock,[a] Xiaotai Wang,*[a] Kin-Chung Lam[b] and Arnold L. Rheingold[b]

[b] *Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716, USA*

Received (in Columbia, MO, USA) 27th April 2001, Accepted 13th July 2001
First published as an Advance Article on the web 23rd August 2001

Structurally distinct coordination polymers [Ag(bpp)]ClO_4 1 and [Ag(bpp)]PF_6 2 [bpp = 1,3-bis(4-pyridyl)propane] have been assembled; the conversion of 1 into 2 on treatment with $NaPF_6$ is driven by argentophilic interactions and is the first such transformation reported for silver(I)–organic coordination polymers.

The field of metal–organic coordination polymers[1] has recently attracted intense interest because such supramolecular compounds have potential as smart optoelectronic,[2] magnetic,[3] microporous,[4] and biomimetic materials.[5] The design of coordination polymers takes into account factors such as the coordination nature of the metal ion, the structural characteristics of the polydentate organic ligand, the metal–ligand ratio, and the possible counter ion influence. A subtle alteration in any of these factors can lead to new extended network structures. Thus, a great variety of supramolecular architectures have been ingeniously constructed. These not only have aesthetic appeal, but occasionally exhibit interesting functions. In contrast, there has been a scarcity of information on supramolecular reactivity featuring well-defined conversions of extended structures in coordination polymers.[6] Such transformations may find applications in molecular recognition and chemical sensor technologies. For cationic networks, exchange of anions has recently been reported to induce the interconversion of several silver(I)–polynitrile coordination polymers.[6a] These changes apparently involve the breaking and forming of silver(I)–nitrile coordination bonds, but the driving force and mechanism are not well understood.

The coordination affinity of silver(I) for pyridyl-donor ligands is well known, and the argentophilic d^{10}–d^{10} bonding interactions frequently affect the extended structures of the resulting coordination polymers.[7] The commercially available 1,3-bis(4-pyridyl)propane (bpp) is a bipyridine-type ligand with a flexible $–CH_2CH_2CH_2–$ spacer, and several research groups have reported a few Ag^I–bpp cationic networks where the counter ion is $CF_3SO_3^-$ or NO_3^-.[8] Ciani and coworkers have also mentioned that bpp reacts with $AgBF_4$ or $AgClO_4$ in 2 : 1 molar ratio to form two-fold interpenetrated diamondoid networks.[8a] We have sought to generate novel cationic Ag^I–bpp networks with various counter ions and use such systems for the study of anion-induced transformations of supramolecular structures. Herein we report the assembly of [Ag(bpp)]ClO_4 **1** and [Ag(bpp)]PF_6 **2**, two coordination polymers with novel and distinct cationic network structures. We also describe the well-defined, irreversible conversion of **1** into **2** on treatment with $NaPF_6$. This conversion is unique in that it is driven by forming more and stronger Ag–Ag bonds in the polymeric cation (see below); no such transformations have been previously reported for silver(I)–organic coordination polymers.

Solution-phase reactions of bpp with $AgClO_4$ and $AgPF_6$ in 1 : 1 molar ratio generate **1** and **2**, respectively.† The structures of **1** and **2** determined *via* single crystal X-ray diffraction analysis‡ are shown in Fig. 1. In both **1** and **2**, each Ag^I ion is coordinated by two pyridyl nitrogen atoms of different bpp units in approximately linear geometry, and the Ag–N bond distances fall between 2.114(5) and 2.144(5) Å, as expected for Ag^I complexes with pyridine-type ligands . Despite this similarity in local silver(I)–pyridyl coordination, **1** and **2** have significantly different extended supramolecular structures due to differences in argentophilic interaction.

In the cationic network of **1**, there are two types of crystallographically and chemically equivalent Ag^I ions, both of which form 1-D sinusoidal chains with the bound bpp molecules where each $–CH_2CH_2CH_2–$ spacer adopts a TT conformation.[8a] Adjacent chains containing one type of Ag^I ions are cross-linked through argentophilic bonding to form 2-D layers, as evidenced by the Ag–Ag contact [3.2214(10) Å] that is well below the van der Waals diameter of silver (3.44 Å).[9] The 1-D sinusoidal chains containing the other type of Ag^I ions lack interchain Ag^I–Ag^I interactions because the shortest Ag···Ag separation (4.40 Å) is greater than the van der Waals

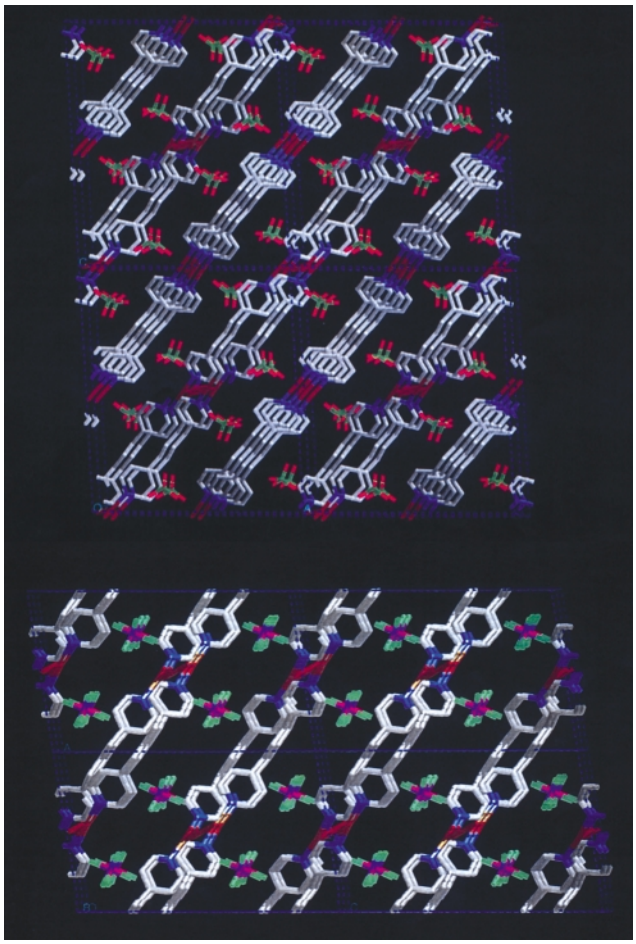

Fig. 1 Cylinder representations of the structures of **1** (top) and **2** (bottom), both viewed approximately along the crystallographic *b* axis. H atoms are omitted for clarity. Color scheme for the cationic networks: Ag, red; N, blue; and C, green.

 DOI: 10.1039/b104074j

diameter. In the entire crystal structure of **1**, the 2-D Ag^{I}–bpp layers and the 1-D Ag^{I}–bpp chains pack the space alternately. The ClO_4^- ions occupy the volume between the 2-D layers and 1-D chains, interacting with the cationic network through predominantly ionic bonding, with the shortest Ag···O(ClO_4^-) separation at 2.78 Å. To our knowledge, the polymeric cation of **1**, consisting of stacked 2-D layers separated by 1-D chains, exhibits an unprecedented structural motif in coordination polymers. Structurally, the polymeric cation of **2** is more straightforward than that of **1**. All silver(I) ions are crystallographically and chemically equivalent and are each coordinated by two pyridyl nitrogen atoms of different bpp units. The sinusoidal Ag^{I}–bpp chains are cross-linked *via* stronger and shorter Ag–Ag bonds [3.0852(9) Å] in comparison with those in **1**. The Ag–Ag bond distance in **2** is comparable to that observed in [Ag(bpy)]NO_3 (bpy = 4,4′-bipyridine).[7e,f] However, adjacent Ag^{I}–bpy chains are perpendicularly linked to afford a 3-D framework whereas the Ag^{I}–bpp chains in **2** are connected approximately in parallel to generate a 2-D layer. The known [Ag(bpp)](CF_3SO_3)·EtOH and [Ag(bpp)]NO_3 display wave-like Ag^{I}–bpp chains similar to **2**, but no interchain Ag–Ag bonds were reported.[8] The 2-D Ag^{I}–bbp layers in **2** are intercalated by the PF_6^- ions and the interaction between $[Ag(bpp)]^+$ and PF_6^- is predominantly ionic, the shortest Ag···F(PF_6^-) separation being 2.75 Å. In both **1** and **2**, π–π interactions between pyridyl rings are very weak.[10,11]

Comparing the extended structures of **1** and **2**, we reasoned that the latter is more stable than the former primarily because of the greater number and strength of Ag–Ag bonds. This rationale prompted us to study the possibility of transforming **1** into **2** *via* anion exchange. Reaction of **1** with $NaPF_6$ affords **2** in quantitative yield [eqn. (1)]:

$$[Ag(bpp)]ClO_4(s) + NaPF_6(aq) \rightarrow [Ag(bpp)]PF_6(s) + NaClO_4(aq) \quad (1)$$

The IR spectrum of the exchanged solid shows the disappearance of the ClO_4^- bands and the appearance of the intense PF_6^- adsorptions at 835 and 561 cm^{-1}. Furthermore, the X-ray powder diffraction (XRD) pattern of the exchanged solid is identical to that of [Ag(bpp)]PF_6 prepared from $AgPF_6$ and bpp (Fig. 2). According to IR and XRD monitoring, no reaction occurred between **2** and $NaClO_4$ even after a sample of **2** was immersed in a large excess of saturated aqueous solution of $NaClO_4$ (*ca.* 14 M) for five days. This result agrees with the observation that **2** has greater structural stability than does **1**.

In conclusion, we have obtained structurally distinct coordination polymers [Ag(bpp)]ClO_4 and [Ag(bpp)]PF_6. Treatment of [Ag(bpp)]ClO_4 with $NaPF_6$ affords [Ag(bpp)]PF_6, and this reactivity is well-correlated with the extended structures of the two compounds. These findings illustrate the structure–property relationship at the supramolecular level. We are currently attempting to extend this study to silver(I) complexes with other pyridyl-donor ligands.

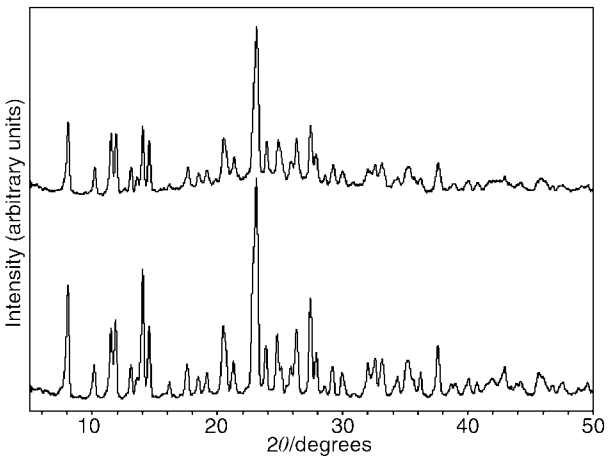

Fig. 2 The XRD patterns of the exchanged solid (top) and [Ag(bpp)]PF_6 prepared from $AgPF_6$ and bpp (bottom).

This work was supported by the University of Colorado at Denver; Research Corporation; and the donors of the Petroleum Research Fund, administered by the American Chemical Society. We thank Dr Jing Li for making X-ray powder diffraction instrumentation available to us. We also thank Drs Jing Li and Robert Damrauer for helpful discussions.

Notes and references

† Under ambient conditions, layering of a methanol solution (4 mL) of bpp (0.10 mmol) over aqueous solutions (4 mL) of $AgClO_4$ and $AgPF_6$ (0.10 mmol) produced colorless crystals of **1** and **2** in 51 and 50% yields, respectively. Compounds **1** and **2** are insoluble in water and common organic solvents. The bulk-phase purities of **1** and **2** were confirmed by comparing their observed and simulated XRD patterns. IR (KBr pellet): for **1**: ν/cm^{-1} 2925m, 2858w, 1609s, 1558w, 1500w, 1429m, 1225w, 1097vs, 808s, 626s, 514m. For **2**: ν/cm^{-1} 2923m, 2856w, 1604s, 1558w, 1500w, 1417m, 1069s, br, 835vs, 561s.

‡ *Crystal data*: for $C_{13}H_{14}AgClN_2O_4$ **1**: M = 405.58, monoclinic, space group $P2_1/n$, a = 16.8826(2), b = 8.6694(2), c = 19.9505(2) Å, β = 93.545(2)°, V = 2914.38(7) $Å^3$, Z = 8, D_c = 1.849 g cm^{-3}, T = 173(2) K, μ(Mo-Kα) = 1.583 mm^{-1}, 3568 data with $I > 2\sigma(I)$, $R(F)$ = 0.040.

For $C_{13}H_{14}AgN_2PF_6$ **2**: M = 451.10, monoclinic, space group $P2_1/c$, a = 11.0925(2), b = 8.4883(2), c = 17.6297(4) Å, β = 99.0826(6)°, V = 1639.12(8) $Å^3$, Z = 4, D_c = 1.828 g cm^{-3}, T = 173(2) K, μ(Mo-Kα) = 1.385 mm^{-1}, 2351 data with $I > 2\sigma(I)$, $R(F)$ = 0.0504.

All data were collected on a Siemens P4 diffractometer equipped with a SMART/CCD detector. The structures were solved by direct methods, completed by subsequent difference Fourier syntheses, and refined by full-matrix least-squares procedures. An absorption correction, using SADABS, was applied to the data for **1** while no absorption correction was required for **2**.

Crystal engineering of microporous 'Chinese-lantern' compounds to improve their ability to reversibly adsorb sulfur dioxide†

Wendy I. Cross, Stephen M. Godfrey, Charles A. McAuliffe and Robin G. Pritchard

Department of Chemistry, UMIST, Manchester, UK M60 1QD. E-mail: Noel.McAuliffe@UMIST.ac.uk

Received (in Cambridge, UK) 8th February 2001, Accepted 4th June 2001
First published as an Advance Article on the web 3rd September 2001

Three new 'Chinese lantern' complexes [XMn(μ-dppO$_2$)$_4$MnX]$^{2+}$2X$^-$·4MeOH·Me$_2$CO [X = Cl, Br, I; dppO$_2$ = 1,3-bis(diphenylphosphinoyl)propane], have been structurally characterised using single-crystal X-ray diffraction and shown to have increasing affinity for SO$_2$ across the series Cl < Br < I *via* thermogravimetric measurements.

The discovery that dppO$_2$ and manganese isothiocyanate self-assemble to form 'Chinese-lantern' shaped macromolecules[1] (Fig. 1) emerged from research into the ability of manganese phosphine oxide complexes to capture sulfur dioxide within their lattices[2,3]

As our earlier work had shown that iodide containing monophosphine oxide compounds retained SO$_2$ more tenaciously than the corresponding isothiocyanates, dppO$_2$ complexes of manganese iodide, bromide and chloride were synthesised,‡ structurally characterised§ and subjected to SO$_2$ adsorption tests. At first sight all the lantern solids appear isostructural as they all crystallise in space group *I*4/*m* and in each case the cations are centred on crystallographic C_{4h} sites. This leads to the structures having a characteristic microporous packing, criss-crossed by tunnels in the *a* and *b* directions (Fig 2).

The tunnels house counter-ions and, in the halide compounds, acetone and methanol guest molecules too. Although, reminiscent of zeolites, whose cages contain cations and water molecules, the tunnels are not rigid and cannot therefore act as molecular sieves. However, the dppO$_2$-based structures achieve steric control by a different means. Once complexed, the dppO$_2$ conformation is locked, as indicated by the near constancy of the torsion angles in all four compounds, Table 1. Effectively, the phenyl rings that surround each manganese atom, act as a rigid calixarene type well.

The molecular shape is maintained by non-classical CH/π hydrogen bonds[4] between phenyl rings on adjacent dppO$_2$ ligands in the lantern cations. These type of bonds are also a feature of the crystal packing (Fig 2) and hence a reason for the four crystal structures being nearly identical.

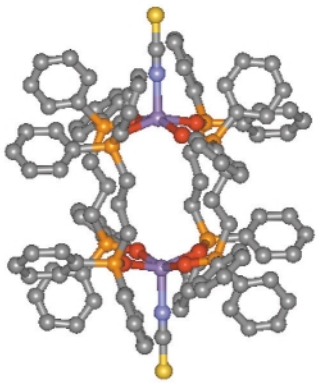

Fig. 1 The cation from [Mn$_2$(μ-dppO$_2$)$_4$(NCS)$_2$]$^{2+}$ 2(NCS)$^-$ **1**.

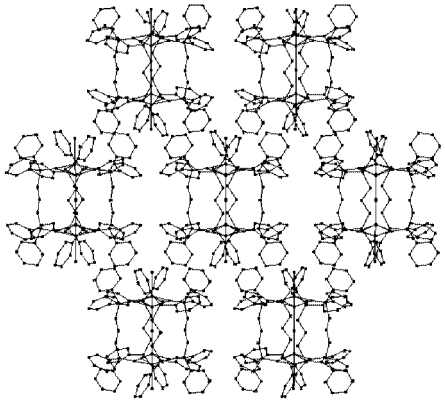

Fig. 2 Crystal packing of the lantern shaped cations, viewed down the crystallographic *b* axis.

Despite the above similarities, closer examination of the manganese and halide atoms lying along the central four-fold axis reveals striking differences between the structures. Importantly, halide anions are smaller than thiocyanate and can be accommodated within the lantern shaped central part of the complex (Cl 100%, Br 100%, I 44%). This difference has ramifications for the manganese atom, which can now occupy two types of sites *ca*. 0.5 on either side of the plane defined by the four coordinated oxygen atoms. This allows an Mn–X bond to form to the central halide atom or, alternatively, to the external capping halide (Table 1).

Table 1 Torsion angles ϕ(°) relative to P=O and Mn displacement from the oxygen plane[a]

				Mn displacement/Å	
Anio	ϕ_1	ϕ_2	ϕ_3	In	Out
NCS	−24.0	9.3	−62.9	—	0.47
C	−26.7	11.2	−68.1	−0.61	0.46
Br	−25.7	13.2	−71.7	−0.59	0.48
I	−23.9	12.6	−69.1	−0.44	0.59

[a] ϕ_1 and ϕ_2 = O=P–C–C$_{Ph}$, ϕ_3 = O=P–C–C$_{prop}$.

These features are manifested in the Cl$^-$ and Br$^-$ X-ray structures as two semi-populated manganese sites and a semi-populated external capping halide site. This leads to the straightforward interpretation that a racemic mixture of the C_4 symmetry molecule illustrated in Fig. 3 occupies each molecular site.

The structures are completed by halide counter-ions, each flanked by two methanol solvate molecules, and disordered acetone, occupying C_{4h} sites above the capping halide ligands. In the halide cases this lead to a total formulation of [Mn$_2$(μ-dppO$_2$)$_4$X$_2$]$^{2+}$2X$^-$·Me$_2$CO·4MeOH.

As the iodide central site is not fully occupied [44.3(1)%], presumably because of the bulk of I$^-$, it is tempting to assume that the molecular site contains a mixture of isothiocyanate and chloride type complexes. However a reasonable match for the crystallographically derived site occupancies cannot be ob-

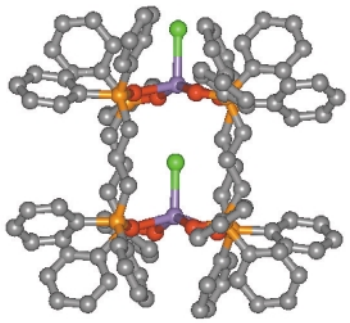

Fig. 3 The cation from $[Mn_2(\mu\text{-}dppO_2)_4Cl_2]^{2+}2Cl^-\cdot Me_2CO\cdot 4MeOH$ **2**, which is isostructural with the bromide analogue **3**.

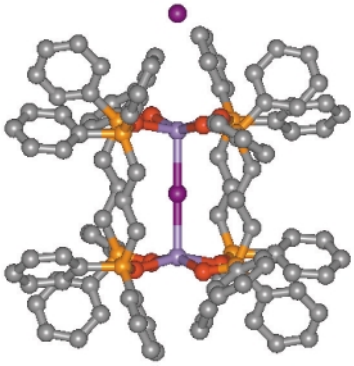

Fig. 4 The cation from $[Mn_2(\mu\text{-}dppO_2)_4I_2]^{2+}$ $2I^-\cdot Me_2CO\cdot 4MeOH$ **4**, showing the central centrosymmetric iodine atom.

tained using this model and 30% of a third molecular configuration must also be used (Fig. 4).

The manganese bonded to the externally capping iodide has flipped to the inner site, allowing the central iodide to bridge the two manganese atoms. This breaks the bond to the capping iodide, which is now held in position by dispersive forces within the calixarene well.

The ability of manganese to occupy the two types of sites is reminiscent of iron in haemoglobin, but the dynamic haemoglobin situation and static disorder cannot be distinguished crystallographically. Nevertheless, a guest molecule diffusing through the microporous tunnels in the iodide crystals would encounter an additional halide bridged Mn type of calixarene site, compared to only the non-bridged types in the bromide and chloride structures.

A series of combined thermogravimetric and X-ray powder diffraction experiments were therefore carried out in order to measure the effect of the above structural variations on SO_2 adsorption. A typical curve shows rapid and fully reversible SO_2 take-up, reminiscent of zeolites. The XRD patterns confirm that all the compounds retain their original crystal structure, although small expansions of the unit cells were observed on adsorption ($<3\%$ at maximum of 4 SO_2 molecules /lantern). Analysis of the isotherms using Hill's adaptation of Langmuir's theory provided a series of equilibrium constants, which were then used to determine the enthalpies of adsorption by means of the Van't Hoff equation. The enthalpy values obtained for the chloride, bromide, iodide and isothiocyanate lanterns were -34, -44, -54 and -39 kJ mol^{-1}, respectively.

As would be expected for compounds that adsorb SO_2 so readily, the energies straddle the physisorption/chemisorption boundary.[5] They are comparable in value to the -50 kJ mol^{-1} determined for $[K(18\text{-crown-}6)]^+[NCS\cdot SO_2]^-$ [5] and fall in the range -20 to -79 kJ mol^{-1} calculated for a series of iodosulfinates, $[I\cdot SO_2]^-$.[6] The order Cl < Br < I is the same as was found in square-planar $Ir(X)(CO)(PPh_3)_2$ complexes,[8,9] where the SO_2 binds loosely to the halide atom, suggesting that this type of interaction also influences the retention of SO_2 within the lantern crystals.

We thank the EPSRC for providing a studentship for W. I. C. and Dr Michael Ruf of Bruker AXS GmbH for collecting the iodide lantern data set.

A space group assignment of ZrP_2O_7 obtained by ^{31}P solid state NMR

Ian J. King,[ab] Franck Fayon,[b] Dominique Massiot,[b] Robin K. Harris[a] and John S. O. Evans*[a]

[a] *Department of Chemistry, University of Durham, Durham, UK DH1 3LE. E-mail: john.evans@durham.ac.uk*
[b] *CNRS-CRMHT, Recherche Scientifique, 1D Av 45071, Orléans Cedex 2, France. E-mail: fayon@cnrs-orleans.fr*

Received (in Cambridge, UK) 18th July 2001, Accepted 25th July 2001
First published as an Advance Article on the web 15th August 2001

2-D ^{31}P dipolar recoupling magic angle spinning NMR has been used to determine the true symmetry of the low temperature structure of ZrP_2O_7 for the first time.

ZrP_2O_7 is often considered to be the parent of the AM_2O_7 family of compounds (A = Sn, Ti, Zr *etc.*; M = P, V, As), which are of interest as several members of the family show low or even negative coefficients of thermal expansion.[1–3] A detailed knowledge of the structure of these materials is of vital importance in understanding this unusual property. The approximate structure of ZrP_2O_7 was reported as being cubic with an ~8.25 Å cell edge as long ago as 1935 by Levi and Peyronel.[4] It can be described as a network of corner-sharing ZrO_6 octahedra and PO_4 tetrahedra, the PO_4 tetrahedra themselves sharing corners to form $P_2O_7^{4-}$ pyrophosphate groups (Fig. 1). It has long been realised, however, that there are problems associated with this simple structure in that the space group symmetry requires linear P–O–P bonds, whereas the energetically preferred bond angle for these linkages is in the region 130–160°. The bending of these linear bonds (and the concomitant lowering of symmetry) is believed to be the driving force behind the phase transition to a low temperature $3 \times 3 \times 3$ superstructure which has been observed for ZrP_2O_7 (and other members of the AM_2O_7 family) by a variety of experimental techniques.[5–9]

The exact nature of these low temperature superstructures is a matter of some debate. Good quality single crystals of these materials can be hard to obtain, and the structural complexity makes detailed interpretation of powder diffraction data difficult. Symmetry considerations show that a $3 \times 3 \times 3$ material can adopt one of 12 possible space groups, containing between 11 ($Pa\bar{3}$) and 216 ($P1$) different unique P sites.[3] Several members of this family have been shown to adopt space group $Pa\bar{3}$; others are known to have lower symmetry.[10,11] In the case of ZrP_2O_7 there has been one previous NMR study, which interpreted the 12 resonances observed in terms of the 11 ^{31}P sites expected for space group $Pa\bar{3}$ and a peak due to an unspecified impurity phase.[3] However, the observation of the same impurity peak by several groups has cast some doubt on this interpretation.[12] Electron diffraction studies[13] have shown extinction conditions consistent with the presence of an *a*-glide, suggesting that the space group is either cubic $Pa\bar{3}$ or orthorhombic *Pbca*. In the former possibility the 11 crystallographically independent P sites give rise to 6 independent $P_2O_7^{4-}$ groups, 4 in general positions, 1 on a 3-fold axis and 1 on an inversion centre (such that the P atoms of the P–O–P linkage are crystallographically equivalent and the bond angle is required to be 180°). For *Pbca* one would expect 27 P sites giving rise to 13 $P_2O_7^{4-}$ groups in general positions and one on a centre of inversion. In the case of SiP_2O_7[14] and TiP_2O_7,[15] two-dimensional (2-D) homonuclear correlation NMR techniques have been shown to be very useful in assigning the space group of these $3 \times 3 \times 3$ superstructures, since they allow the phosphorus connectivity scheme to be probed[16] and give evidence of the presence of different phases in a sample.[17] In this work, we have used various 2-D ^{31}P dipolar recoupling MAS NMR experiments to characterize the ZrP_2O_7 structure.

^{31}P NMR experiments on ZrP_2O_7† were carried out on a Bruker DSX 300 spectrometer operating at a Larmor frequency of 121.48 MHz, using a standard 4 mm Bruker MAS probe. One dimensional (1-D) single-pulse MAS NMR spectra were recorded at spinning speeds of 3, 5, and 10 kHz using a small pulse angle ($\pi/8$) and recycle delay of 80 s to prevent saturation. ^{31}P 2-D MAS exchange NMR experiments were obtained at 10 kHz spinning rate using the RFDR sequence[18] during the mixing time. ^{31}P 2-D MAS double quantum spectra were recorded at a 10 kHz spinning rate using the POSTC7 sequence[19] for excitation and reconversion of double quantum coherences under MAS. The hypercomplex acquisition method[20] was used to obtain pure absorption phase 2-D spectra and the t_1 time increment was synchronised with the rotor period to avoid sidebands in the ω_1 dimension. 160 t_1 increments with 8 and 16 transients per increment were recorded for the MAS exchange NMR spectra and for the MAS double quantum experiment, respectively. The ^{31}P chemical shifts were referenced relative to a 85% H_3PO_4 solution at 0 ppm.

The ^{31}P 1-D MAS NMR spectra of ZrP_2O_7 obtained at different spinning rates are shown in Fig. 2 (centreband region only). These spectra can be seen to contain at least 13 partially overlapping ^{31}P isotropic resonances, corresponding to at least 13 different phosphorus sites. Assuming that these resonances belong to the same phase this is not consistent with space group $Pa\bar{3}$. It can be noted that the positions and linewidths of these resonances vary to different extents with the spinning fre-

 DOI: 10.1039/b106379k

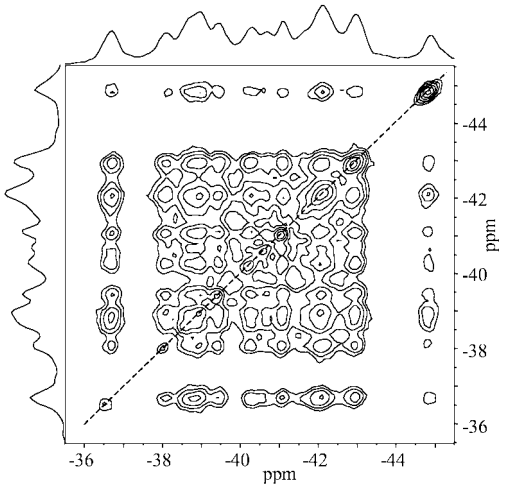

Fig. 3 ^{31}P 2-D exchange MAS spectrum of ZrP_2O_7 obtained with a mixing time of 40 ms at 10 kHz spinning rate, showing that all peaks belong to the same phase.

quency. These effects have also been reported for SiP_2O_7 and TiP_2O_7[15] and may be attributed to the presence of residual dipolar interactions under MAS conditions.

To investigate the possible presence of different phases in our ZrP_2O_7 sample, we have used 2D exchange MAS NMR spectroscopy. In this experiment, the polarisation transfer in the mixing time is driven by the dipolar interaction, allowing one to probe large intra-$P_2O_7^{4-}$ ^{31}P–^{31}P dipolar couplings at short mixing times and weaker long range dipolar couplings at long mixing times. As shown in Fig. 3, the 2-D exchange MAS spectrum of ZrP_2O_7 obtained with a mixing time of 40 ms shows cross-correlation peaks of various intensities between all the individual resonances displayed in the 1-D MAS spectrum reflecting their short and long range spatial proximities. This clearly indicates that our sample contains a single phase with at least 13 different crystallographic sites, ruling out the possibility of the $Pa\bar{3}$ space group to which the ZrP_2O_7 superstructure has previously been assigned.

As well as the number of individual ^{31}P sites, the number of $P_2O_7^{4-}$ groups in the ZrP_2O_7 structure can be used for space group assignement. To characterize the number of $P_2O_7^{4-}$ groups in the $3 \times 3 \times 3$ superstructure, we have used the 2-D MAS double quantum experiment. As shown for other crystalline phosphates,[14,15] short double quantum excitation and reconversion periods of 600 μs allow us to differentiate dipolar coupling between chemically linked PO_4 tetrahedra (~ 750 Hz) and weaker long range dipolar interactions (~ 300 Hz) and thus to identify clearly the P–O–P connectivity scheme. As shown in

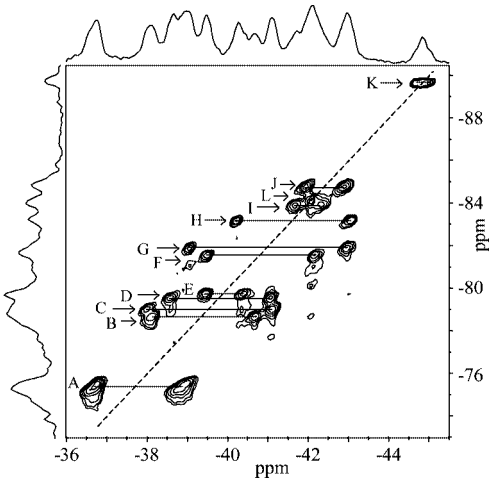

Fig. 4 ^{31}P 2-D MAS double quantum spectrum of ZrP_2O_7 at 10 kHz spinning rate. Cross-correlation peaks are labelled A–K; L is the single auto-correlation peak.

Fig. 4, the 2-D MAS double quantum spectrum of ZrP_2O_7 exhibits one intense auto-correlation peak along the diagonal (L) and 11 pairs of intense resolved cross-correlation peaks (A–K) that reflect the dipolar connectivities between chemically bound PO_4 tetrahedra. The weaker correlation peaks (two lowest contour levels in Fig. 4) correspond to weaker longer range dipolar couplings in the structure. The diagonal auto-correlation peak (L) arises from a single $P_2O_7^{4-}$ group containing two crystallographically equivalent P sites; the remaining 11 paired cross-correlation correspond to $P_2O_7^{4-}$ dimers in which the two P sites are inequivalent. Analysis of the peak intensities in Fig. 4 shows that the paired cross-peaks A are about three times higher than the remaining resonances, suggesting the presence of three overlapping cross-correlation peaks corresponding to three $P_2O_7^{4-}$ groups. Good fits (not shown) of the 2-D double quantum and 1-D MAS spectra were thus obtained with 27 distinct ^{31}P resonances of equal intensity corresponding to 13 $P_2O_7^{4-}$ units (A–K) with two inequivalent P sites, and one $P_2O_7^{4-}$ group (L) with two equivalent P sites. This is entirely consistent with space group *Pbca*.

We therefore conclude that the previously assigned space group of $Pa\bar{3}$ for the ZrP_2O_7 superstructure is incorrect. From the analysis of ^{31}P double quantum MAS NMR spectra, we suggest that the true symmetry of ZrP_2O_7 is *Pbca*. Using this space group excellent agreement with powder X-ray and neutron diffraction data can be obtained.

We gratefully acknowledge support of the EPSRC and CNRS for this work. I. J. K. would like to thank the EU for a Marie-Curie fellowship (HPMT-CT-2000-00169).

Notes and references

† High purity ZrP_2O_7 was prepared from $ZrOCl_2$ and H_3PO_4 (85%) which were mixed in a 1:2 molar ratio in a platinum crucible and heating to 350 °C for 1 h. The resultant powder was washed with distilled water, and heated to 750 °C then 1000 °C for 12 h periods. Powder X-ray and neutron diffraction measurements confirmed sample purity and the presence of $3 \times 3 \times 3$ superstructure reflections.

First published as an Advance Article on the web 28th August 2001

We have first observed clusters for solvated tropylium ions ($Tr^+(ROH)_n$) which were isolated from ROH–CH_3CN (1:1 by vol.; R = Me, Et, and Pr^n) solutions by using a specially designed mass spectrometer and found the clear-cut essential features concerning the solvation structure around Tr^+.

The solvation structure around a carbocation has not thoroughly been clarified in spite of so many investigations from various aspects for a long time[1] owing to few practically available methods for direct observation.[2] Earlier than a decade ago, a specially designed mass spectrometer was devised[3] and utilized to examine the composition of clusters which were isolated from a liquid phase[3,4] and an electrospray source[3a] was introduced to the special mass spectrometer to result in direct observation of species of clusters with a positive charge.[5] Our instruments have the advantage of a splendid isolation of clusters and a hermetic way of working. Then, by using the mass spectrometer and tropylium ion as a stable carbocation, we have examined the compositions of clusters for solvated tropylium ions ($Tr^+(ROH)_n$) to find clear-cut essential features for the solvated carbocation clusters.

The Tr^+–solvent clusters were obtained from a solution containing tropylium ions, by electrospray interface. Since the experimental details on the mass spectrometric analysis of clusters including an ion isolated from solutions containing ionic species has already been reported elsewhere,[5] it is briefly explained here. A sample solution containing ionic species is injected into a five-stage differentially pumped vacuum chamber through the electrospray interface, which leads to the formation of multi-charged liquid droplet flow. The resulting multi-charged liguid droplets fly from the first room to the fifth room through the pressure difference and the electric field in the vacuum chamber. During the flight, the multi-charged liquid droplets are fragmented into the clusters and molecules through the expansion due to the decrease of pressure and the electric repulsion among the ions providing the multi-charge. After the fragmentation of the multi-charged liquid droplets, the strongly interacting cation(s)-molecules were isolated as clusters. However, weakly interacting molecules were vapourized as monomeric molecules. Herein, the clusters with positive charge, by Tr^+, were analyzed by the quadrupole mass spectrometer.

The positively charged clusters were analyzed for a solution of tropylium tetrafluoroborate ($Tr^+BF_4^-$; 4.5×10^{-3} M) in ethanol–acetonitrile (1:1 by vol.). Signals corresponded to clusters containing Tr^+, *e.g.* $Tr^+(EtOH)_2$ to $Tr^+(EtOH)_{17}$, though only up to eight solvent molecules were shown in Fig. 1. No complexes of Tr^+ with CH_3CN were detected. The signal intensity generally decreased with an increase in the number of EtOH molecules which formed clusters with Tr^+, with an exception of those from $Tr^+(EtOH)_4$ to $Tr^+(EtOH)_6$ (Fig. 1). The signals from $Tr^+(EtOH)_4$ to $Tr^+(EtOH)_6$ were somewhat larger than their neighbouring ones. Four to six are 'magic number clusters'.[6] An analogous tendency was observed for $Tr^+(MeOH)_n$, from a solution of Tr^+ ions in MeOH–CH_3CN, and $Tr^+(Pr^nOH)_n$, from a solution of Tr^+ ions in Pr^{n}OH–CH_3CN. The same feature in cluster compositions could be observed for neutral clusters which were isolated from EtOH–CH_3CN (1:1 by vol.) solutions.[7] Theoretical calculation by b$_3$lyp/6-31G** indicated that the binding constant between Tr^+ and five MeOH molecules was larger compared to that for the less or more MeOH molecules.[8]

The relative signal intensities for a solution of Tr^+ in MeOH–EtOH–CH_3CN (1:1:2, by vol.) indicated that the cluster forming ability for Tr^+ was apparently MeOH:EtOH = 1.0:5.2.[9] Similarly, the solution of Tr^+ in EtOH–Pr^{n}OH–CH_3CN was analyzed to show that the cluster forming ability for Tr^+ is EtOH:Pr^{n}OH = 1.0:14.[9] Consequently, the ability for Tr^+ should be MeOH:EtOH:Pr*n*OH = 1.0:5.2:70. The longer the alkyl chain of alcohol molecules, the stronger the cluster forming ability, *i.e.* the solvation ability for Tr^+. Such a tendency might be related to the clustering of the alcohols in acetonitrile, that is, the clustering of alcohols was promoted with an increase in the size of the alkyl group. The binding energy for Tr^+ with an alcohol molecule from theoretical calculations (by b$_3$lyp/6-31G**)[10] was consistent with the observed sequence of cluster forming ability mentioned above. Also, the calculations are in line with the work of Meot-Ner (Mautner) for other ions.[11] The binding energy has a linear relationship with donor numbers[12] for EtOH, MeOH, and CH_3CN suggesting that the Lewis basicity of the alcohol molecule might play a significant role for the carbocation.

In conclusion, we have first observed the solvated cluster compositions for Tr^+ and found that the cluster forming ability (solvation ability) increased with increasing alkyl chain length

Enhanced activity and stability of a Cu/SiO_2 catalyst for the reverse water gas shift reaction by an iron promoter

Ching-Shiun Chen, Wu-Hsun Cheng* and Shou-Shiun Lin

Department of Chemical and Materials Engineering, Chang Gung University, Tao-Yuan 333, Taiwan, Republic of China. E-mail: cheng@mail.cgu.edu.tw

Received (in Cambridge, UK) 15th May 2001, Accepted 30th July 2001
First published as an Advance Article on the web 28th August 2001

An Fe promoter inhibits the sintering of Cu particles and oxidation of the Cu surface, resulting in high catalyst activity and stability.

Carbon dioxide has been attributed to be the main source of the greenhouse effect. The increase of carbon dioxide concentration will strongly influence the global weather. Conversion of CO_2 to CO by catalytic hydrogenation has been recognized as one of the most promising processes for CO_2 utilization. Synthesis gas, H_2 and CO, can be used to produce long-chain hydrocarbons *via* the Fischer–Tropsch reaction.[1,2] The reverse water gas shift (RWGS) reaction is one of the available methods for the production of CO.

Generally, copper catalysts are used for both the water gas shift reaction and the reverse water gas shift reaction.[3–10] There have been many papers reporting the enhanced activity by promoters and the reaction mechanism;[3–7] however, the stability of copper catalysts is little mentioned. The RWGS reaction is an endothermic reaction; therefore, high temperature will facilitate the formation of CO. Nevertheless, copper-based catalysts are not suitable for operation at high temperature because they are significantly deactivated by sintering. In this study, iron is used as a promoter for copper catalysts in order to improve the stability of the catalysts at high temperature.

The 10 wt% Cu/SiO_2 and 0.3 wt% Fe/SiO_2 samples were prepared by impregnating Cab-O-Sil M-5 SiO_2 with an aqueous solution of $Cu(NO_3)_2$ and $Fe(NO_3)_3$, respectively. The $Cu–Fe/SiO_2$ (Cu:Fe = 10:0.3) was prepared by the addition of an aqueous solution of $Fe(NO_3)_3$ to dried Cu/SiO_2 before calcination and/or reduction. These catalysts were calcined in air and reduced in pure H_2 at 873 K for 5 h before reaction. Carbon dioxide hydrogenation was carried out over a fixed bed reactor at atmospheric pressure. 0.1 g samples of catalysts were used for the RWGS reaction by feeding a stream of H_2/CO_2 at 100 ml min^{-1} in a 1:1 feed ratio. Temperature programmed reduction (TPR) of catalysts was performed at atmospheric pressure in a conventional flow system. Samples of 0.06 g of the catalysts were placed in a U-shaped tube reactor and heated in a 5% H_2/N_2 mixed gas stream flowing at 30 ml min^{-1} at a heating rate of 10 °C min^{-1} from 25 to 973 K. The area of the copper surfaces was determined by using TPR of Cu oxidized by N_2O.[11]

The dependence of CO_2 conversion on time on stream for comparison of the RWGS reaction over Cu/SiO_2, $Cu–Fe/SiO_2$ and Fe/SiO_2 are shown in Fig. 1. It was found that the reaction conversion using Cu/SiO_2 was drastically decreased within 120 h: the catalytic activity decreased from 8.5 to 0.3%. The 0.3% Fe/SiO_2 catalyst offered low catalytic activity: its conversion decreased from 2.5 to 0.4% within 120 h. However, when the same experiment was run over the $Cu–Fe/SiO_2$ (Cu:Fe = 10:0.3) catalyst, it was found that CO_2 conversion was significantly increased and initial conversion increased from 8.5 to 15%. On the other hand, the deactivation of $Cu–Fe/SiO_2$ decreased only from 15 to 12% within 120 h. After 40 h, the catalytic activity fluctuated at about 12%. This shows that the Cu-based catalyst could be kept in a stable state by the Fe promoter.

Fig. 2 shows the comparison of surface area of Cu/SiO_2 and $Cu–Fe/SiO_2$ catalysts before and after the reaction. The fresh

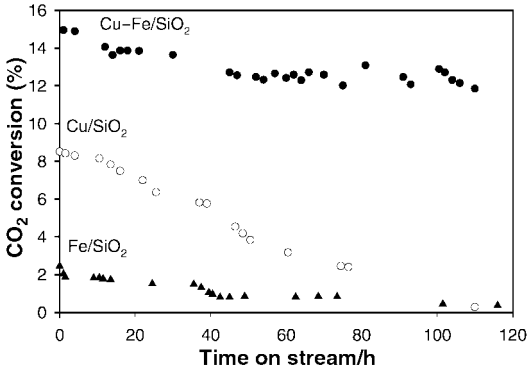

Fig. 1 The dependence of CO_2 conversion on time for H_2/CO_2 with 1:1 ratio over Cu/SiO_2, $Cu–Fe/SiO_2$ and Fe/SiO_2 catalysts at 873 K.

Cu/SiO_2 and $Cu–Fe/SiO_2$ catalysts were pretreated by calcination and reduction at 873 K for 5 h. Obviously, the copper surface area in $Cu–Fe/SiO_2$ was twice as large as that in Cu/SiO_2 [Fig. 2(a) and (b)]. When both catalysts were exposed to the H_2/CO_2 feed at 873 K for 120 h, the copper surface area in Cu/SiO_2 was significantly decreased, but $Cu–Fe/SiO_2$ retained a copper surface area as high as that of a fresh catalyst.

TPR was used to characterize the Cu/SiO_2 and $Cu–Fe/SiO_2$ after H_2/CO_2 reaction at 873 K for 120 h (see Fig. 3). The TPR profile of the Cu/SiO_2 catalyst shows a typical Cu_2O reduction peak at 503 K. A similar result was found in our previous paper, showing that copper can be oxidized in the process of the RWGS reaction.[7] Two peaks are observed in the $Cu–Fe/SiO_2$ catalysts at 723 and 853 K, respectively. The TPR profile of the Fe/SiO_2 catalyst through H_2/CO_2 reaction at 873 K for 120 h was performed to confirm the assignment of iron reduction peaks in the Cu–Fe catalyst. Two peaks are also observed at 723 and 853 K. Comparing these features with earlier literature reports,[1,12] the first peak could be due to reduction of Fe_2O_3 to Fe_3O_4. The second peak is due to reduction of Fe_3O_4 to FeO. Surprisingly, no reduction peak of copper is found in the TPR profile of $Cu–Fe/SiO_2$. The reduced copper particles in $Cu–Fe/SiO_2$ catalyst cannot be oxidized during the reaction process.

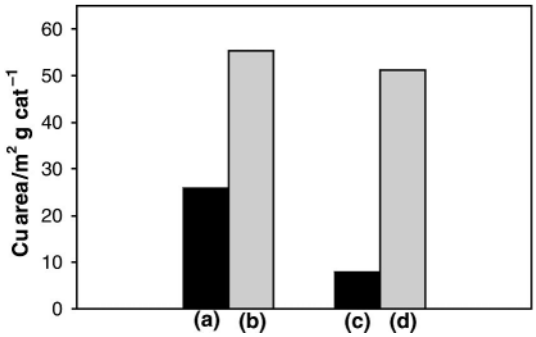

Fig. 2 The copper surface area in Cu/SiO_2 and $Cu–Fe/SiO_2$: (a) fresh Cu/SiO_2, (b) fresh $Cu–Fe/SiO_2$, (c) Cu/SiO_2 after exposure to H_2/CO_2 feed at 873 K for 120 h, (d) $Cu–Fe/SiO_2$ after exposure to H_2/CO_2 feed at 873 K for 120 h.

 DOI: 10.1039/b104279n

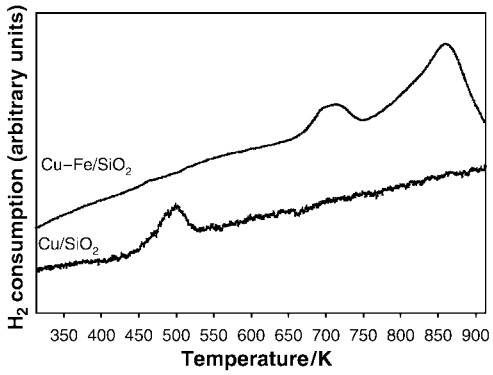

Fig. 3 TPR profiles of Cu/SiO_2 and $Cu–Fe/SiO_2$ catalysts after exposure to H_2/CO_2 feed at 873 K for 120 h.

Two models, redox and formate decomposition mechanisms, were proposed to explain the mechanism of CO formation in the RWGS reaction.[3–7] Cu^0 may be attributed to be the major active site for the RWGS reaction. The higher activity of $Cu–Fe/SiO_2$ compared with Cu/SiO_2 can be explained by the difference in copper surface area values between these two catalysts. When the pretreatment of Cu/SiO_2 was conducted at 773 K for 5 h, the copper surface area was 55 m^2 g cat^{-1}. When the temperature of calcination and reduction increased to 873 K, the surface area of copper decreased markedly due to sintering. By adding 0.3% iron onto the copper catalyst, the sintering of the copper catalyst was successfully inhibited under these high temperature conditions.

A decrease of the copper surface area together with the oxidation of copper caused the decay in catalytic activity for Cu/SiO_2. Iron additives obviously suppressed the decrease of copper surface area and catalyst deactivation. The small surface energy of copper would easily lead to migration of copper under high temperatures. The TPR study showed that iron was oxidized under the reaction conditions. Fe oxides may act as textural promoters which effectively suppress the sintering of Cu.

Instead of the oxidation of copper, an Fe species in the Cu–Fe catalyst was oxidized by the H_2/CO_2 stream. The TPR profile of an Fe_2O_3/zeolite catalyst has been reported: three reduction steps appeared at 695, 850 and 1000 K, respectively, when the catalyst was calcined at 773 K.[12] The lower temperature peak at 695 K corresponds to the reduction of Fe_2O_3 to Fe_3O_4; the middle temperature peak at 850 K is due to the reduction of Fe_3O_4 to FeO; and the higher temperature peak at 1000 K is for the reduction of FeO to Fe^0. FeO can reasonably be deduced to be the major species in the Cu–Fe catalyst after the reduction treatment at 873 K for 5 h in this study. The TPR profile of our $Cu–Fe/SiO_2$ catalyst in Fig. 3 provides strong evidence that FeO can be oxidized to Fe_3O_4 and/or Fe_2O_3 during the reaction.

In summary, we have shown that Fe-promoted Cu/SiO_2 exhibits high activity and stability for the RWGS reaction. The Cu surface area was significantly improved at high temperature by Fe additives. The Fe promoter inhibits the sintering of Cu particles and oxidation of Cu, resulting in high catalytic activity and stability.

We thank the Chinese Petroleum Corporation for financial support of this study.

First published as an Advance Article on the web 20th August 2001

Small hydrophobic pores (channels) in polystyrene latex particles were found by investigating the penetration of pyrene using fluorescence techniques.

Polystyrene latex (PSL) particles are solid nano- or microspheres with functional groups attached on the surfaces.[1] Latexes have many applications in coatings,[2] biomedical diagnostics[3] and drug delivery.[4] They are used also as model systems in colloid research because of their well-defined physicochemical characteristics.[5] Recently we used latex particles as microsubstrates for photoreactions and found that the efficiencies of the reactions are enhanced dramatically.[6,7] This effect is attributed to effective adsorption of the reactants on the particle surfaces. Although all the applications of latex are closely related to the composition and structure of the particle surfaces, some structural details, such as compactness of the polymer chains and penetration of chemicals into the particle, are still unclear.

One particular phenomenon we observed is that the efficiency of photoinduced electron transfer from pyrene (Py) to methylviologen (MV^{2+}) decreases with increase in the loading time (*i.e.* the time of storage after mixing of the reactants with PSL).[7] This result cannot be explained by considering that the reactants are adsorbed only on the surface of the particles. The decrease of the efficiency suggests that there are small channels or pores on the particle surface and Py molecules can go inside the particle to be protected from quenching.

In this work, we report the evidence for small pores in PSL by studying the penetrations of Py, pyrenemethanol (PyM) and 1-pyrenylbutyltrimethylammonium bromide (PBTAB) into PSL particles in aqueous dispersion. This finding will extend the application of PSL as a nano-scale substrate for coatings, drug delivery systems, ammunoassay and so on.

PyM and PBTAB were purchased from Molecular Probes, Inc. and used as supplied. Py was purified by vacuum sublimation. To avoid any aggregate or excimer of the probes, 0.60, 5.0 and 10.0 μM stock solutions were used to prepare samples in the penetration experiments for Py, PyM and PBTAB, respectively. The synthesis, purification and characterization methods of PSL were reported elsewhere.[7,8] The mean diameter of the latex particles used in this work is 212 nm as determined by dynamic light scattering measurements.[8]

Adsorption isotherms of the probes onto the latex particles were measured by ultra-centrifugation.[7,8] Fluorescence spectra were recorded on a Hitachi F-4000 spectrofluorometer. Steady-state fluorescence intensity is expressed in terms of peak heights. Fluorescence lifetime measurements were carried out with a Horiba NAES 1100 time-resolved spectrofluorometer. All Fluorescence measurements were carried out at room temperature with air-saturated samples.

It is well known that the microenvironment of a Py molecule can be measured by the I_1/I_3 ratio in the vibronic fine structure of its fluorescence spectrum.[9] Therefore, the location of a Py probe in a PSL aqueous dispersion can be determined by the I_1/I_3 ratio. Illustrated in Fig. 1 are the loading time effects on the relative fluorescence intensities (a) and I_1/I_3 ratios (b) of Py, PyM and PBTAB in PSL aqueous dispersions. The obvious decrease of I_1/I_3 ratio of Py indicates it was adsorbed from the environment with high polarity (aqueous phase, I_1/I_3 = 1.84)[9] to that with low polarity (polystyrene bulk, $I_1/I_3 \approx 1.05$). However, adsorption equilibrium is usually reached in minutes, the slow process of the decreasing I_1/I_3 ratio with loading time suggests that Py penetrates inside the particle. The homogeneous distribution of Py in poly(methyl methacrylate) latex particles after soaking in a methanolic solution of Py[10] also supports the penetration.

The remarkable increase of Py fluorescence intensity with loading time suggests that the quantum yield or lifetime was increased due to its microenvironmental change. Time-resolved fluorescence measurements suggest that the probes are located in two kinds of environments (Fig. 2). Environment 1 makes Py have a long lifetime (τ_1) and environment 2 makes it have a short lifetime (τ_2). The adsorption isotherm of Py onto PSL shows that more than 99.9% of Py exist in the adsorbed state

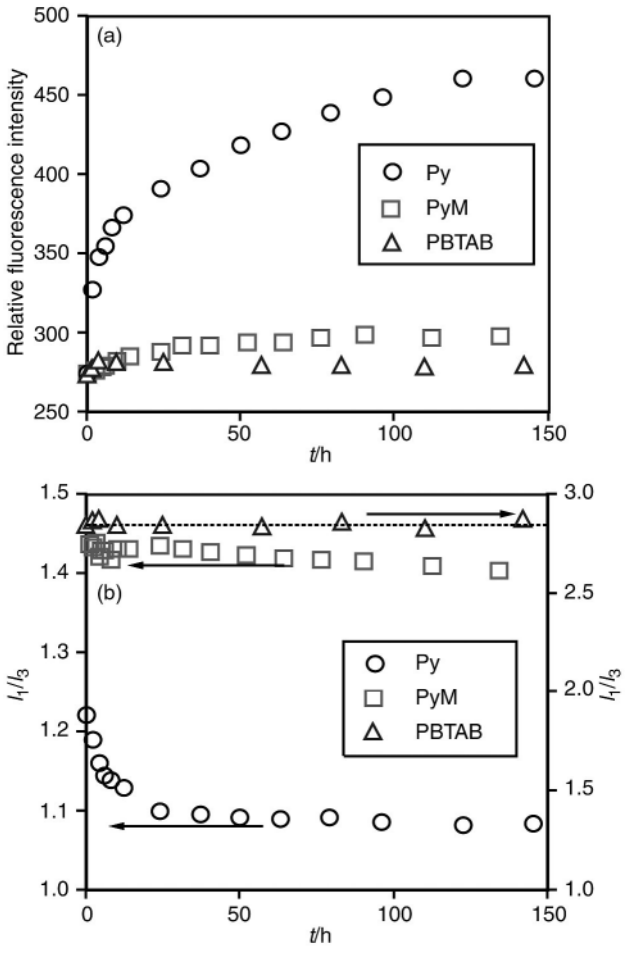

Fig. 1 Loading time effect on the relative fluorescence intensities (a), and I_1/I_3 ratios (b) of Py, PyM, and PBTAB in PSL dispersion at room temperature.

 DOI: 10.1039/b105959a

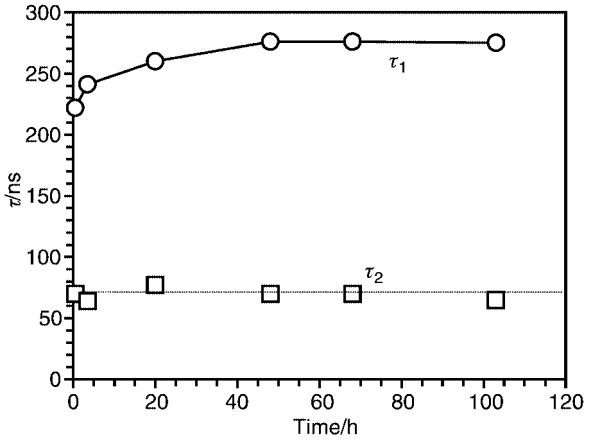

Fig. 2 Loading time effect on the fluorescence lifetimes of pyrene in PSL aqueous dispersion. [Py] = 0.40 μM, [PSL] = 0.40 g L^{-1}.

(data not shown). Therefore, the contribution from the species in aqueous phase is negligible. This means that both of the two environments locate in/on the particle.

The fluorescence lifetime of Py is mainly affected by the mobility of Py and O_2 concentration in the system. In aqueous phase, the fluorescence lifetime of Py decreases from 210 ns in O_2 free solution to 112 ns in air-saturated solution. It is expected in the PSL dispersion that the lifetime will decrease further when Py stays on the PSL surface due to adsorption of both Py and O_2.[11] Actually, we observed the decrease of fluorescence intensity within 2 min of the loading. On the other hand, when Py goes into the inner part of the particle, the lifetime increases due to the reduced mobility of Py. Thus, we ascribe environment 1 to pores or channels inside of PSL particle, and environment 2 to the adsorption sites at the liquid–solid interface.

Py molecules located in environment 2 seem to go gradually to environment 1. This is indicated by the change of fluorescence quantum yields of the two components (data not shown) and the increase of the total fluorescence intensity (Fig. 1a). The microenvironmental change with the loading time is concrete evidence for the penetration of Py.[9] In aqueous solution, the I_1/I_3 ratio of Py is 1.84. After Py was loaded onto PSL, the ratio decreased to 1.22 in 2 min. Then it decreased gradually to 1.08 in 5 d at rt (Fig. 1b). If we assume that the I_1/I_3 ratio of the adsorbed Py is 1.22 at the interface between PSL particle and water, we get some details about the particle surface structure and adsorption mechanism.

First, there are pores or channels in PSL particles through which Py penetrates into the inner part of the particle resulting in the decrease of I_1/I_3 ratio and increase of lifetime. Second, the pore or channel is small and hydrophobic. The hydrophobicity of the channel prevents water molecules and ionic species from penetrating but allows Py to go slowly into the inner part. It is known that a pyrene excimer can be easily formed in confined spaces such as polymer micelles,[12] and zeolites.[13] However, a Py aggregate or excimer was not detected even at high concentration. Thus the dimension of the pore should be slightly larger than the size of Py molecule. Thirdly, the number of the holes should be large because the uptake capacity of Py monomer can be as high as 2% (g/g).

As shown in Fig. 1, the I_1/I_3 ratio of PyM decreases slightly and that of PBTAB is almost constant during the loading. If PyM and PBTAB can go to the inside of the particle, their I_1/I_3 ratios should show obvious change because the I_1/I_3 ratios of PyM and PBTAB are also sensitive to the polarity of the environments.[14] Comparing with that of Py, we conclude that PBTAB does not go inside the particle and PyM goes slightly inside. Here the "passport" for entering into the particle seems to be mainly the polarity of the "passenger".

To confirm the existence of the pores in the latex particles, the control experiments were carried out using PSL and polystyrene cast films. The former was prepared by drying the latex dispersion, and the latter by casting from DCM solution. Both films were annealed at 150 °C for 20 min. The fluorescence intensities of Py from the films immersed in the aqueous solutions decreased and the I_1/I_3 ratio did not decrease below 1.2 as the loading time increased. These results are very different from that of the latex particles. Therefore, we conclude that there exist small hydrophobic pores in the PSL particles.

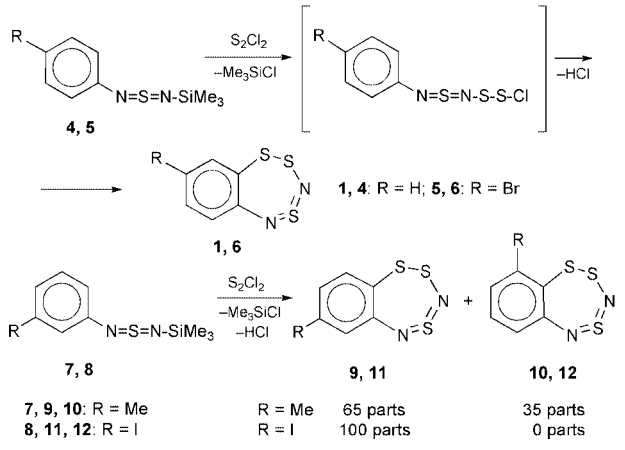
Received (in Cambridge, UK) 6th June 2001, Accepted 2nd August 2001
First published as an Advance Article on the web 3rd September 2001

Previously unknown 1,2,4,3,5-benzotrithiadiazepine 1 was prepared by 1:1 condensation of Ph-N=S=N-SiMe$_3$ with S_2Cl_2 followed by intramolecular *ortho*-cyclization of [Ph-N=S=N-S-S-Cl] intermediate, and hydrolyzed in pyridine to unusual macrocyclic 7*H*,14*H*-dibenzo[*d*,*i*][1,2,6,7,3,8]tetrathiadiazecine 2.

Polysulfur–nitrogen π-excessive heterocycles, especially heterocyclic stable radicals (with the former frequently being precursors of the latter), are of keen interest for contemporary chemistry and materials science.[1–4] Among them, fused trithiadiazepines belong to a little studied system. While 1,3,5,2,4-benzotrithiadiazepine[5,6] **3** is described and subjected to preliminary investigation,[6–8] its non-symmetric isomer 1,2,4,3,5-benzotrithiadiazepine **1** was unknown. The present article deals with the preparation of **1** and its unexpected hydrolysis in pyridine to unusual macrocyclic 7*H*,14*H*-dibenzo-[*d*,*i*][1,2,6,7,3,8]tetrathiadiazecine **2**.

For the synthesis of **1**, the intramolecular electrophilic cyclization of Ar-N=S=N-SiMe$_3$ azathienes into 1,3,2,4-benzodithiadiazines under the action of SCl_2[6,9] was extended to S_2Cl_2. This allows the preparation† of the target heterocycle **1** from C_6H_5-N=S=N-SiMe$_3$ **4** (Scheme 1). The cyclization is also successful with 4-BrC_6H_4-N=S=N-SiMe$_3$ **5** (providing compound **6**, an 8-Br derivative of **1**) and 3-RC_6H_4-N=S=N-SiMe$_3$ (**7**, R = CH_3; **8**, R = I). In the latter case of *meta*-substituted precursors the cyclization is regioselective leading predominantly or even exclusively to 7-R substituted derivatives of **1** (Scheme 1). The ratio of the major 7-R isomer to the minor 9-R one is 65:35 for R = CH_3, as shown by ^{1}H NMR spectroscopy.† With R = I, only the 7-I isomer **11** was observed and its structure has unambiguously been confirmed by X-ray crystallography (Fig. 1).‡

Contrary to the successful synthesis of **1**, an attempt to prepare its symmetric isomer **3**[5,6] by the similar approach from C_6H_5-S-N=S=N-SiMe$_3$ and SCl_2 fails. This result agrees with previously reported[6] one.



Scheme 1

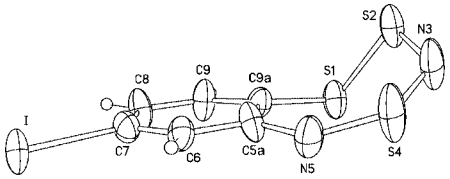


Fig. 1 The X-ray structure of molecule **11**. Selected bond lengths (Å), bond and torsion angles (°): S(1)–S(2) 2.051(6), S(2)–N(3) 1.69(2), N(3)–S(4) 1.52(2), S(4)–N(5) 1.55(1), N(5)–C(5a) 1.41(2), S(1)–C(9a) 1.76(1); C(9a)–S(1)–S(2) 104.6(5), S(1)–S(2)–N(3) 104.2(6), S(2)–N(3)–S(4) 124.6(9), N(3)–S(4)–N(5) 127.1(8), S(4)–N(5)–C(5a) 138(1), N(5)–C(5a)–C(9a) 125(1), C(5a)–C(9a)–S(1) 124(1), C(5a)–C(9a)–S(1)–S(2) −61(1), C(9a)–S(1)–S(2)–N(3) 80.2(8), S(1)–S(2)–N(3)–S(4) −48(2), S(2)–N(3)–S(4)–N(5) 8(2), N(3)–S(4)–N(5)–C(5a) −11(2), S(4)–N(5)–C(5a)–C(9a) 35(3).

According to the data of X-ray crystallography (Fig. 1)‡ and MP2/6-31G* calculations (Fig. 2),‡ the heterocycle of **1** is significantly bent (similar to that of benzopentathiepine)[10] in contrast to the perfectly planar heterocycle of **3**[5b] and its tetrafluoro derivative.[11] The heterocycle conformation (Fig. 1) features the planarity of the C(5a)-N(5)=S(4)=N(3)-S(2) fragment within ± 0.03(1) Å. The S(1) and C(9a) atoms deviate from this plane by 1.35(2) and 0.48(3) Å, respectively. It is seen (Figs. 1 and 2) that the conformation and bond lengths of the title heterocycle are practically the same for a free molecule compared to that packed in the crystal, which is in striking contrast to the situation with related 1,3,2,4-benzodithiadiazines where molecular conformation significantly changes on going from a gas phase to the solid state.[12]

The heteroatom reactivity of **1** differs from that of **3**. For example, it is reported that **3** is stable towards hydrolysis in weak bases and acids[7b] and undergoes fast transformation into 1,3,2-benzodithiazolium chloride under the action of Me$_3$SiCl (a side-product of its preparation).[7a,13] Compound **1** interacts with Me$_3$SiCl to give 1,2,3-benzodithiazolium chloride **13** (Scheme 2) extremely slowly.† However, the most interesting finding is that hydrolysis of **1** in pyridine results unexpectedly in the unusual macrocyclic compound **2** (Scheme 2).† In the absence of pyridine (for example, in THF) the hydrolysis proceeds very slowly if at all. Catalytic or even equimolar

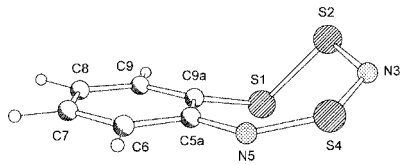

Fig. 2 The MP2/6-31G* structure of molecule **1**. Selected bond lengths (Å), bond and torsion angles (°): S(1)–S(2) 2.086, S(2)–N(3) 1.688, N(3)–S(4) 1.614, S(4)–N(5) 1.594, N(5)–C(5a) 1.381, S(1)–C(9a) 1.757; C(9a)–S(1)–S(2) 106.5, S(1)–S(2)–N(3) 105.0, S(2)–N(3)–S(4) 124.9, N(3)–S(4)–N(5) 126.9, S(4)–N(5)–C(5a) 137.8, N(5)–C(5a)–C(9a) 127.6, C(5a)–C(9a)–S(1) 122.3, C(5a)–C(9a)–S(1)–S(2)–67.1, C(9a)–S(1)–S(2)–N(3) 78.8, S(1)–S(2)–N(3)–S(4) −42.1, S(2)–N(3)–S(4)–N(5) 3.1, N(3)–S(4)–N(5)–C(5a) −2.5, S(4)–N(5)–C(5a)–C(9a) 21.9.

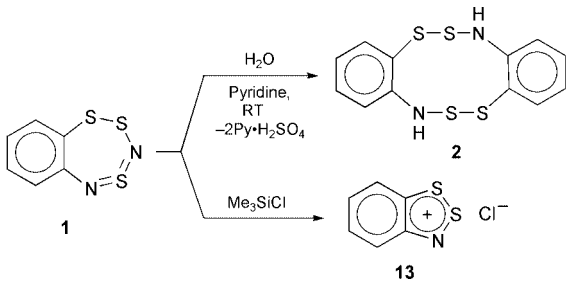
 DOI: 10.1039/b105001j



Scheme 2

amounts of pyridine facilitate the hydrolysis in THF insignificantly.

According to the X-ray diffraction data (Fig. 3) the molecule **2** possesses an inversion center. The macrocycle conformation can be described as a chair featuring two transannular N–H···S hydrogen bonds with a H···S distance of 2.60 Å.

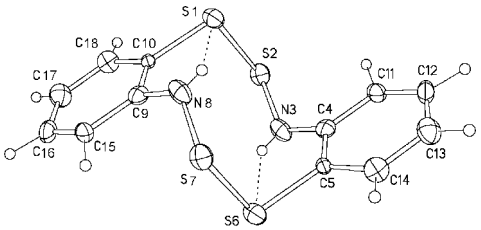


Fig. 3 The X-ray structure of molecule **2**. Selected bond lengths (Å), bond and torsion angles (°): S(1)-S(2) 2.082(5), S(2)-N(3) 1.66(1), N(3)-C(4) 1.42(2), C(4)-C(5) 1.37(2), C(5)-S(6) 1.80(1), S(6)-S(7) 2.082(5); S(1)-S(2)-N(3) 107.1(5), S(2)-N(3)-C(4) 124(1), N(3)-C(4)-C(5) 121(1), C(4)-C(5)-S(6) 121.2(9), C(5)-S(6)-S(7) 100.9(4), C(10)-S(1)-S(2)-N(3) −68.3(7), S(1)-S(2)-N(3)- C(4) −69(1), S(2)-N(3)-C(4)-C(5) 144(1), C(4)-C(5)-S(6)-S(7) −97(1). The dotted lines show N-H···S hydrogen bonds.

Thus, two novel polysulfur–nitrogen heterocyclic systems have been prepared by original approaches and structurally characterized.

After 24 h the precipitate (which consisted of a mixture of **2** and pyridinium sulfate, according to the MS and IR data) was filtered off, washed with pyridine and recrystallized from toluene. Compound **2**, 5 %, colorless crystals, mp 215–217 °C. MS *m*/*z* 309.9729 (M^+; calculated for $C_{12}H_{10}N_2S_4$ 309.9727). IR ν/cm^{-1} (KBr): 3274s, 3050w, 1585m, 1470s, 1443m, 1269s, 901m, 757s, 612s, 575m, 448s. Evaporation of the filtrate under reduced pressure affords viscous oil assumed to be (GC-MS, ^{1}H and ^{13}C NMR) a mixture of 2,2′-diaminodiphenyl disulfide and related polysulfanes.

Compound **13**. To a solution of 105 mg (5.25×10^{-4} mol) of **1** in 4 cm³ of CH_2Cl_2 was added 228 mg (2.1×10^{-3} mol) of Me_3SiCl. After 21 d the precipitate was filtered off and recrystallized from $SOCl_2$–CCl_4 (3:1). Compound **13**, 10%, yellow crystals, mp 194–196 °C (decomp.) MS *m*/*z* 153.9775 ($M^+ - {}^{35}Cl$; calculated for $C_6H_4NS_2$ 153.9785). NMR δ (CF_3CO_2H): ^{1}H: 9.09, 9.00, 8.65, 8.46; ^{13}C: 164.0, 156.2, 139.1, 133.9, 128.1, 123.4; ^{14}N [NH_3 (liq.)]: 406. UV λ_{max}/nm (log ε) (CF_3CO_2H): 426 (3.25), 347 (4.38).

After evaporation of the filtrate under reduced pressure unreacted **1** was recovered in 80% yield.

‡ *X-ray crystallography and ab initio calculations. X-ray structure data for* **2** *and* **11**. *Compound* **2**: $C_{12}H_{10}N_2S_4$, M = 310.46, monoclinic, a = 8.101(2), b = 4.7156(9), c = 16.905(5) Å, β = 95.57(2)°, U = 642.7(3) Å³, space group $P2_1/c$, Z = 2, d_c = 1.604 g cm^{-3}, μ(MoKα) = 0.719 mm^{-1}, 875 reflections measured, 807 unique (R_{int} = 0.037) which were used in all calculations. New high-nuclearity Ni–Pt carbonyl clusters: synthesis and X-ray structure of the ordered $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$ and the substitutionally Ni/Pt disordered $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$ (x = 1.92) tetraanions

First published as an Advance Article on the web 3rd September 2001

The reaction of $[N^nBu_4]_2[Ni_6(CO)_{12}]$ in THF solution with 1.5–2 equivalents of K_2PtCl_4 leads to formation of the $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$ and $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$ ($x \approx 2$) tetraanions, the latter presents a localised substitutional Ni/Pt disorder and an unprecedented close-packed metal structure.

Most high-nuclearity metal carbonyl clusters containing interstitial Ni or Pt atoms, *e.g.* $[Ni_{11}E_2(CO)_{18}]^{n-}$ (E = Sb, Bi),[1,2] $[H_{6-n}Ni_{38}Pt_6(CO)_{48}]^{n-}$,[3] $[H_{6-n}Ni_{36}Pt_4(CO)_{45}]^{n-}$,[4] $[Pt_{19}(CO)_{22}]^{4-}$[5] and $[Pt_{24}(CO)_{30}]^{2-}$,[6,7] display multivalence encompassing several redox changes.[5,8,9] Previously reported Ni–Pd carbonyl clusters, *viz.* $[Ni_{16}Pd_{16}(CO)_{40}]^{4-}$ and $[Ni_{26}Pd_{20}(CO)_{54}]^{6-}$,[10] contain interstitial Pd atoms and are an exception to the above rule. This probably happens because of the weakness of all bonds involving palladium atoms, which may favour fragmentation–condensation processes under redox conditions. On the other hand, it is possible that the above weakness could favour crowding of almost degenerate energy levels in the frontier region and anticipate the size-induced metal–insulator transition,[11] which for metal carbonyl clusters is expected to occur for nuclearities beyond 70.[3] In partial agreement, preliminary magnetic measurements indicate that the even-electron $[Ni_{16}Pd_{16}(CO)_{40}]^{4-}$ displays magnetic behaviour arising from the presence of four unpaired electrons.[12]

The above considerations stirred interest in platinum-rich Ni–Pt carbonyl clusters. As a result, we now report the synthesis and structure of the first examples of such compounds consisting of the substitutionally Ni/Pt crystal disordered $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$ ($x \approx 2$) and the ordered $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$ tetraanions.

Both compounds were obtained by reaction of $[N^nBu_4]_2[Ni_6(CO)_{12}]$ in THF with 1.5–2 equivalents of K_2PtCl_4 and from the residue obtained by evaporation of the reaction solution were separated by differential solubility of their salts. Thus, treatment of the above residue with THF gave a dark-green solution containing a mixture of $[Pt_{3n}(CO)_{6n}]^{2-}$ (n = 3, 4)[13,14] and $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$, and an insoluble dark precipitate. Extraction of the latter with acetone and precipitation with hexane afforded $[N^nBu_4]_4[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]\cdot Me_2CO$ (x = 1.92) (ν_{CO} in MeCN at 2003 s, 1990 sh, 1821 m (br) cm^{-1}) as black prisms. $[N^nBu_4]_4[Ni_{24}Pt_{14}(CO)_{44}]\cdot 6THF$ (ν_{CO} in MeCN at 2008 s, 1877 mw, 1854 m and 1835 mw cm^{-1}) separated out as hexagonal black crystals from the above dark-green THF solution upon concentration. Both compounds have been characterised by elemental analysis and X-ray diffraction studies.†

The overall structures of the $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{12}(\mu\text{-}CO)_{18}]^{4-}$ and $[Ni_{24}Pt_{14}(CO)_{26}(\mu\text{-}CO)_{18}]^{4-}$ tetraanions are shown in Fig. 1 and 2, respectively. The $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$ metal frame is based on an unprecedented *hcp* sequence of M_7, M_{10} and M_7 layers. Interestingly, the closely related homometallic $[Pt_{24}(CO)_{30}]^{2-}$[6,7] is based on a *ccp* fragment deriving from that of $[Pt_{38}(CO)_{44}]^{2-}$[15] by cutting two adjacent hexagonal Pt_7 faces. The metal sites (relative number of metal atoms in parentheses) of $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$ display rather spread metallic coordinations of 4 (4 Ni), 5 (2 Ni/Pt), 6 (1 Pt, 4 Ni/Pt), 7 (6 Ni, 4 Pt), 8 (1 Pt) and 12 (2 Pt). The Ni/Pt substitutional disorder is limited to the two middle-layer sites with metal connectivity of 5 and their adjacent atoms belonging to the top- and bottom-layer and displaying metal connectivity of 6. These were refined as a mixture of Ni and Pt atoms to obtain occupancy fractions of *ca.* 2/3 and 1/3, respectively. All other metal sites could be refined either as nickel or platinum atoms. Analysis of two other crystals, coming from different preparations of $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$, gave rise to slightly different Ni and Pt occupancy fractions in the same substitutionally disordered sites. However, an overall x value of *ca.* 2 was confirmed. This finding is in agreement with the presence of a stoichiometric $[Ni_{10}(Ni_4Pt_2)Pt_8(CO)_{30}]^{4-}$ species having localised substitutional Ni/Pt disorder (as, for instance, $[Fe_2Rh_4(CO)_{16}]^{2-}$).[16] A non-stoichiometric and substitutionally disordered mixture of $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$ species, as exemplified by the recently reported $[Au_6Pd_6(Pd_{6-x}Ni_x)Ni_{20}(CO)_{44}]^{6-}$,[17] seems less in keeping with the available data.

The metal framework of $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$ represents a fragment of *ccp* lattice identical to that displayed by the homometallic $[Pt_{38}(CO)_{44}]^{2-}$ dianion,[15] but different from that of other carbonyl clusters possessing the same metal nuclearity, *viz.* $[HNi_{38}C_6(CO)_{42}]^{5-}$,[18,19] $[Ni_{32}Au_6(CO)_{44}]^{6-}$,[17] $[Ni_{20}(Pd_{6-x}Ni_x)Pd_6Au_6(CO)_{44}]^{6-}$,[17] and $Pd_{38}(CO)_{28}$-

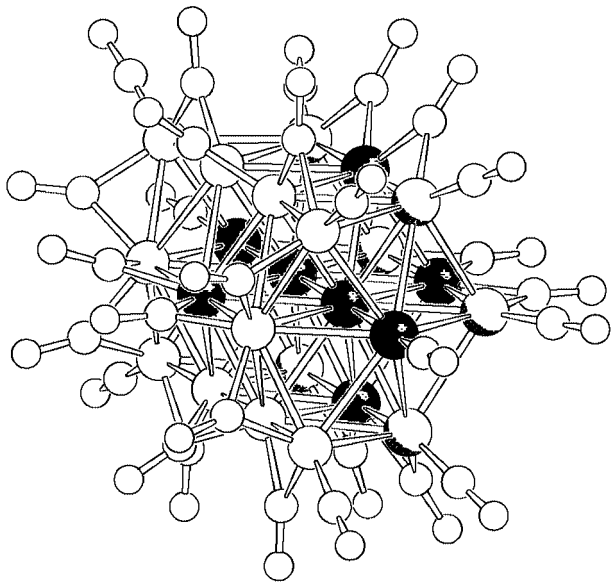

Fig. 1 The $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$ ($x \approx 2$) tetraanion. Pt and Ni atoms are shown as black and open spheres, respectively. Substitutional Ni–Pt disorder is limited to the sites shown as partially blackened spheres. Range of M–M distances: Pt–Pt 2.612(1)–2.817(1), Ni–Pt 2.673(2)–2.854(2), Ni–Ni 2.466(3)–2.815(3), Ni/Pt–Ni 2.705(3)–2.787(3), Ni/Pt–Pt 2.649(2)–2.796(2), Ni/Pt–Ni/Pt 2.732(3)–2.781(3) Å.

 DOI: 10.1039/b103610f

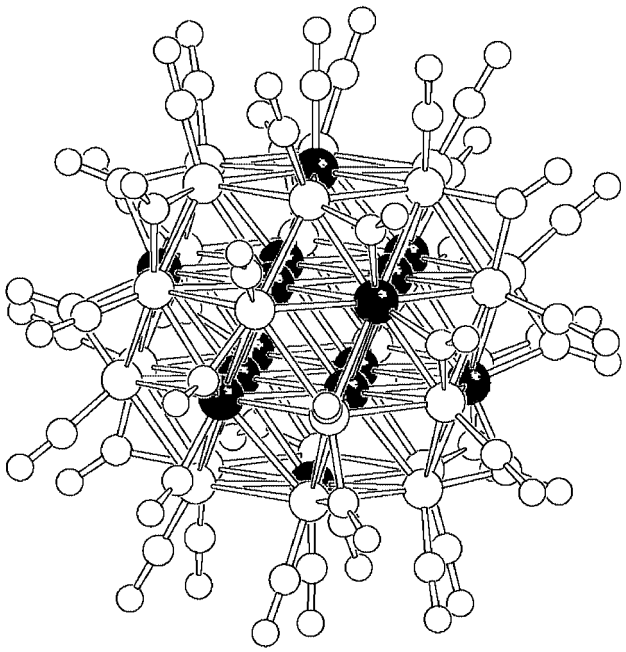

Fig. 2 The $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$ tetraanion (Pt atoms are shown as black spheres). Range of M–M and average M–C distances: Pt–Pt 2.725(1)–2.878(1), Ni–Pt 2.531(2)–2.861(2), Ni–Ni 2.524(3)–2.783(3) Å; $Pt–C_{terminal}$ 1.80(2), $Pt–C_{edge\text{-}bridging}$ 1.99, $Ni–C_{terminal}$ 1.71, $Ni–C_{edge\text{-}bridging}$ 1.85 Å.

$(PEt_3)_{12}$.[20] The 24 nickel atoms occupy the corner sites of the truncated-ν_3-octahedron,[21] whereas the 14 platinum atoms occupy the six vertices of the interstitial octahedron and the centers of the eight hexagonal faces. Such an ordered occupation is probably favoured by the substantial difference in metal coordination (6, 9 and 12) of the three kinds of geometrically equivalent metal sites of $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$.

The carbonyl stereochemistry of $[Ni_{24}Pt_{14}(CO)_{26}(\mu\text{-}CO)_{18}]^{4-}$ represents a variant of that of the non-isoelectronic $[Pt_{38}(CO)_{32}(\mu\text{-}CO)_{12}]^{2-}$ dianion.[15] The tetraanion has 26 terminal ligands (one per each nickel atom and the two platinum atoms centering two opposite Ni_6 hexagonal rings) and 18 edge-bridges (12 onto the Ni–Pt–Ni diagonals of the other six Pt-centered Ni_6 hexagonal faces and six onto one Ni–Ni edge of each Ni_4 square face). Spanning of Ni–Pt bonds rather than a second opposite Ni–Ni edge of each Ni_4 square face reduces the number of short C···C non-bonding contacts and releases the steric pressure among the carbonyl groups. Moreover, an increased number of edge-bridging carbonyl groups with respect to $[Pt_{38}(CO)_{44}]^{2-}$ is in keeping with the increased negative charge of $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$. Regeneration of the carbonyl stereochemistry of the former would only require a concerted terminal–edge site exchange of the 12 edge-bridging carbonyls spanning the Ni–Pt–Ni diagonals of 6 out of 8 hexagonal faces and six terminal ligands bonded to one of the two nickel atoms of the above diagonals.

EHMO calculations with CACAO[22] show that the frontier regions of each of $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$ and $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$ do not feature a well-defined HOMO–LUMO gap. Therefore, it appears possible that both compounds could exhibit a wide range of redox states as their homometallic $[Pt_{24}(CO)_{30}]^{2-}$ and $[Pt_{38}(CO)_{44}]^{2-}$ congeners.[6,7] A further hint is given by the electron counts of both $[Ni_{24}Pt_{14}(CO)_{44}]^{4-}$ and $[Ni_{10}(Ni_{6-x}Pt_x)Pt_8(CO)_{30}]^{4-}$, which exceed by two valence electrons those of the related dianions, $[Pt_{38}(CO)_{44}]^{2-}$ [15] and $[Pt_{24}(CO)_{30}]$,$^{2-}$ respectively.[6,7] Studies devoted to elucidating their magnetic and electrochemical behaviour and the eventual structural changes occurring upon reduction or oxidation are ongoing.

G. L. thanks the MURST (COFIN2000) and the University of Bologna for funding. P. H. S. acknowledges grants from The Wenner-Gren Foundation, Stiftelsen BLANCEFLOR Boncompagni-Ludovisi, född Bildt and Svenska Institutet.

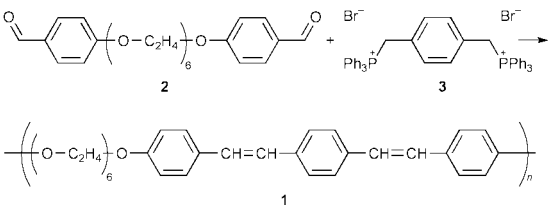
Received (in Cambridge, UK) 10th July 2001, Accepted 3rd August 2001
First published as an Advance Article on the web 3rd September 2001

A block copolymer of distyrylbenzene with sexi(ethylene oxide) spacers displays high solid state photoluminescence efficiency (34%). Single layer light-emitting diodes with calcium or aluminium cathodes exhibit luminances over 2000 cd m^{-2} and efficiencies of 0.5 cd A^{-1}.

Electroluminescence in conjugated polymers was first observed in poly(*p*-phenylenevinylene),[1] PPV, which is made *via* a precursor route and has been the workhorse for investigations of the phenomenon.[2] Most unsubstituted conjugated polymers are insoluble and infusible and consequently not easily processed. Various protocols have been adopted to overcome this fundamental problem including the use of precursor routes, solubilising side chains, formation of block copolymers and polymers containing functional units in side chains.[3] Several groups have demonstrated the use of Wittig condensation as an effective route to copolymers with well-defined conjugated chromophores separated by a non-conjugated unit.[4] In this context oligo(ethylene oxide), OEO, spacers are attractive as they can provide a dramatic enhancement of solubility in both organic and aqueous solvents[5] and avoid the requirement to introduce solubilising side chains directly on the chromophore, which can disrupt planarity. In addition OEOs can provide a significant ionic conductivity that can, in principle, be exploited for fabricating light-emitting electrochemical cells, LECs. Sandman *et al.*[6] and Li *et al.*[7] have described the synthesis of copolymers of distyrylbenzene (DSB) and OEO, but found it difficult to report device characteristics owing to rapid device degradation.[6]

In contrast to these reports, we describe the synthesis and characterisation of a block copolymer of DSB with sexi-(ethylene oxide), SEO, spacers (DSB-*block*-SEO) **1** which displays high solid state photoluminescence (PL) efficiency and good electroluminescence in device structures. In our approach SEO was activated as the bis-tosylate and reacted with 4-hydroxybenzaldehyde to give the flexible linker **2**. The reaction of triphenylphosphine with α,α′-dibromoxylene gave bis(triphenylphosphonium)xylylene dibromide **3** and Wittig condensation of **2** and **3** gave the polymer **1** (see Scheme 1).

The polymer is soluble in chloroform and robust free-standing films can be cast from solution. The ^{1}H-NMR-, ^{13}C-NMR-, FTIR and UV/vis spectra and elemental analysis were consistent with the assigned structure. The ^{1}H-NMR spectrum is reproduced in Fig. 1, in the inset four AB quartets can be identified and assigned;[8] the two with J_{AB} = 16 Hz are assigned to *trans* vinylenes in *trans,trans* and *trans,cis* DSB units and the two with J_{AB} = 12 Hz to *cis* vinylenes in *cis,cis* and *cis,trans* units, the relative intensities of these signals indicating a 50:50 *cis*:*trans* distribution of double bonds.



Scheme 1 Synthesis of polymer DSB-*block*-SEO **1**.

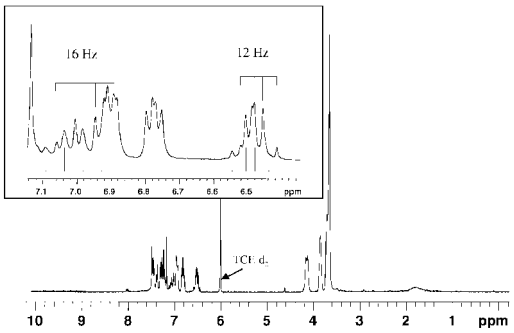


Fig. 1 ^{1}H NMR spectrum of DSB-*block*-SEO in Tetrachloroethane-d_2 (TCE-d_2).

Gel Permeation Chromatography (Viscoteck, RI detector, chloroform eluent, 2 × PL_{gel} mixed bed D 30 cm columns, polystyrene standards, we thank RAPRA for this measurement) indicated a M_n of 5600, a polydispersity of 3 and a degree of polymerisation of about 10 with respect to polystyrene calibration. Ion chromatography (Dionex, DX 120) indicated no traces of Li^+, Na^+, K^+, Mg^{2+} or Ca^{2+} and ^{31}P-NMR showed no phosphorous.

The solid state PL quantum efficiency of polymer **1** is 34%, as measured by exciting a 100 nm thick film on spectrosil inside an integrating sphere, with laser excitation at 325 nm (He-Cd laser). The solid state absorption spectrum is reported in Fig. 2 and shows a maximum at 3.71 eV (334 nm), whereas the solid state PL spectrum (Fig. 3) shows two maxima at 2.34 eV (529 nm) and 2.50 eV (496 nm), *i.e.* in the green region of the visible range. The substantial red-shift (~0.25 eV) with respect to distyrylbenzene oligomers can be explained by taking into

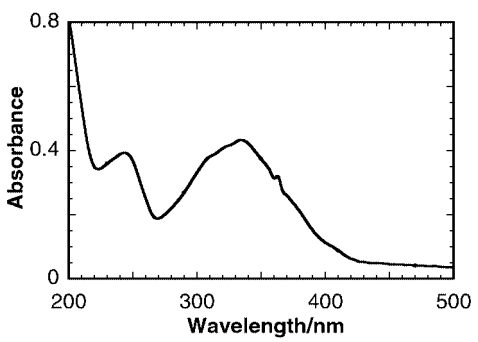

Fig. 2 Absorption spectrum of a DSB-*block*-SEO thin film (100 nm thick) on a spectrosil substrate.

 DOI: 10.1039/b106122b

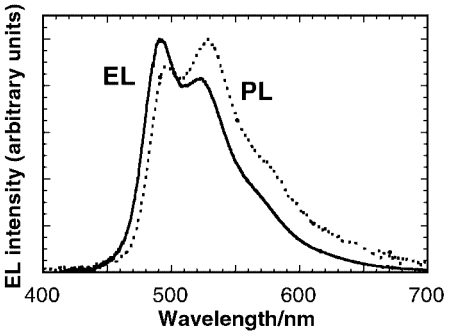

Fig. 3 EL and PL spectra of DSB-*block*-SEO. The EL spectrum is from an ITO/DSB-*block*-SEO/Al diode (2 mm^2 area; 100 nm thick layer). The PL spectrum is obtained by exciting with a He-Cd laser (325 nm) a 100 nm thick film on spectrosil. The relatively broad spectrum with respect to previous reports[6] is likely to be due to a greater disorder, induced by the significant *cis*-content.

account the electron-donating properties of the alkoxy groups in the 4 and 4′ positions.[9] The Stokes shift between absorption and emission is substantial (162 nm).

Light-emitting diodes, LEDs, were prepared on ITO substrates treated with an oxygen plasma prior to spin-coating, in order to increase the work function and surface energy.[10] The active material was spin-coated from a chloroform solution, and the device fabrication completed by thermal evaporation of a calcium and/or aluminium cathode.

Typical current density and luminance *vs*. voltage (IVL) curves for a diode with ITO and Al electrodes are reported in Fig. 4. The turn-on voltage is at 6.5 V, and we obtained luminance values over 2000 cd m^{-2} at 19 V, with luminescence efficiencies up to 0.5 cd A^{-1}. Interestingly, we observed no significant improvement when replacing Al cathodes by Ca cathodes in spite of a much lower work function (2.8 eV *vs*. 4.2–4.3 eV for Al). This is unexpected in view of the position of the frontier levels, found at 5.5 ± 0.1 eV (ionisation potential, IP) and 2.5 ± 0.1 eV (electron affinity, EA), determined by cyclic voltammetry with ferrocene as reference. Relatively high

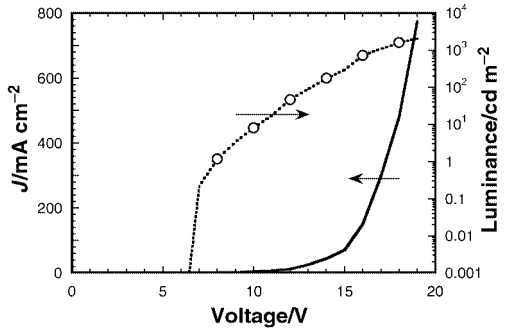

Fig. 4 Current density and luminance *vs*. voltage characteristics of the same ITO/DSB-*block*-SEO/Al device used for the EL spectrum of Fig. 3.

turn-on voltages, even when a poly(ethylenedioxythiophene)–poly(styrenesulfonic acid), PEDOT:PSS, hole-injection layer was used in order to try to increase the anode work function,[11] are consistent with the presence of a significant energy barrier at the anodic interface.

LECs use an electroluminescent polymer, an ion transporting polymer (such as poly(ethylene oxide)) and a salt in order to aid charge injection at the electrodes.[12] Since our polymer comprises both OEO and DSB within its backbone we were able to prepare LECs with active layers made of DSB-*block*-SEO blended with lithium triflate (10 wt%) (ITO/DSB-*block*-SEO(LiTf)/Al). The turn-on voltage was reduced to 3.8 V with emission, as before, in the green and we could observe electroluminescence under reverse bias.

In summary, we have prepared and characterised a solution processable polymer containing distyrylbenzene units having a 50:50 *cis*:*trans* vinylene distribution linked at the 4,4′-positions by sexi(ethylene oxide) units. In contrast to earlier reports on related materials this polymer can be used to construct very efficient LEDs.

We thank EC Network LAMINATE (HPRN-CT-2000-00135) (PWL), the Royal Society and Clare Hall College (FC), the EPSRC, and CDT.

First published as an Advance Article on the web 21st August 2001

The synthesis of a dicationic imidazolium-linked cyclophane and a dimeric silver–N-heterocyclic carbene complex, that is the first silver complex with a N-heterocyclic carbene ligand involved in a π-bonding interaction, is reported.

Our group[1] and others[2] have been exploring the chemistry of silver complexes with mixed-donor N-heterocyclic carbene ligands. Bis(carbene)–Ag complexes with monodentate N-heterocyclic carbene ligands are all structurally similar, with two carbene moieties complexed to a Ag atom in a linear fashion.[3,4] The mixed-donor N-heterocyclic carbene ligands stabilize silver complexes that are quite varied. These complexes can have a combination of Ag–Ag, donor atom–Ag, and bis(carbene)–Ag interactions.

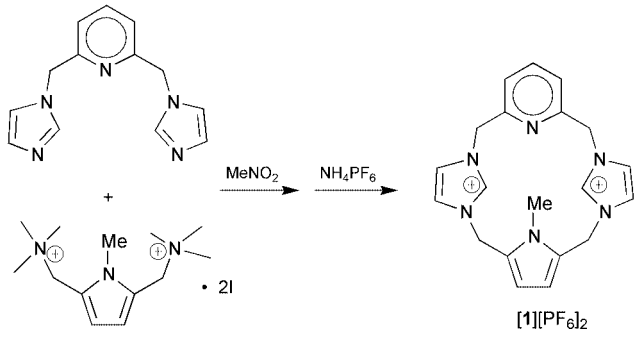
We report herein, the synthesis of the dicationic imidazolium-linked cyclophane **1** and the dimeric silver N-heterocyclic carbene complex $[Ag_4(\mathbf{1}^*)_2][PF_6]_4$ (**2**), where **1*** denotes deprotonated **1**, a bis-carbene-linked cyclophane.[5] Complex **2** is the first silver complex that has a N-heterocyclic carbene ligand involved in a π-bonding interaction. This novel situation facilitates the stabilization of a $[Ag_4]^{4+}$ cluster with four non-coordinating PF_6 anions.

The synthesis of cyclophane **1** is outlined in Scheme 1. The 3 + 1 condensation reaction of 2,6-bis(imidazolmethyl)pyridine[6] and 1-methyl-2,5-bis(trimethylaminomethyl)pyrrole diiodide[7] in nitromethane affords the cyclophane $\mathbf{1}[I]_2$. Treatment of an aqueous solution of $[\mathbf{1}][I]_2$ with ammonium hexafluorophosphate affords $[\mathbf{1}][PF_6]_2$. The ^{1}H and ^{13}C NMR spectra for $[\mathbf{1}][PF_6]_2$ are consistent with the proposed structure of **1**. The most notable features in the ^{1}H and ^{13}C NMR spectra are the resonances for the imidizolium protons at 8.6 ppm and the corresponding imidazolium carbons at 135.4 ppm. Cyclophane **1** in acetone generates $[\mathbf{1}][PF_6]^+$ ions at *m*/*z* 491.3 upon ESI-MS conditions (calculated *m*/*z* 491.2 for $C_{20}H_{22}N_6PF_6$).

Treatment of cyclophane $[\mathbf{1}][PF_6]_2$ with Ag_2O in DMSO at 55 °C affords the N-heterocyclic carbene complex $[Ag_4(\mathbf{1}^*)_2][PF_6]_4$ (**2**) (eqn. (1)). The ^{1}H and ^{13}C NMR data are consistent with the structure of **2**. The most notable feature of the ^{1}H NMR spectrum is the absence of the resonance for the imidazolium protons at 8.6 ppm. In the ^{13}C NMR spectrum for **2**, the carbene resonance appears as two doublets centered at 163.2 ppm ($^1J_{C_\sigma–Ag}$ = 220 Hz, $^1J_{C_\pi–Ag}$ = 47 Hz).[8] The chemical shift and the coupling pattern are consistent with two bonding interactions for the carbene moiety. The larger coupling of 220 Hz is consistent with a σ-bonding interaction between the carbene and a silver atom. Carbene–silver coupling constants have been reported in the range 204–220 Hz (^{109}Ag) and 180–189 Hz (^{107}Ag).[2b,3,4a,b] The smaller coupling of 47 Hz is unprecedented in silver–carbene chemistry, and we assign this value to an unconventional π-bonding interaction between the carbene and a neighboring silver atom. The assignment of each carbene interacting with two different silver atoms, *via* a σ-bonding and a π-bonding interaction, is consistent with the solid state structure for **2**.‡

$$2\,[\mathbf{1}][PF_6]_2 + 4\,Ag_2O \longrightarrow \underset{\mathbf{2}}{[Ag_4(\mathbf{1}^*)_2][PF_6]_4} \qquad (1)$$

The structure of the tetracationic portion of **2** consists of a centrosymmetric dimer with four Ag cations (Fig. 1). The asymmetric unit consists of precisely half of the dimer leading to equivalent bond lengths and angles. With this in mind, we will confine our discussions to only the asymmetric portion of the molecule except in the cases where the inversion center produces additional non-redundant parameters. The four Ag atoms form a central planar core with two Ag cations bridging the Ag–Ag contacts between the other two. The Ag1–Ag1A cross-ring distance (2.9712(11) Å) is slightly longer than the bridging Ag1–Ag2 (2.7680(9) Å) and Ag1A–Ag2 (2.8077(16) Å) interactions. Each bridging Ag atom forms two bonding



Scheme 1

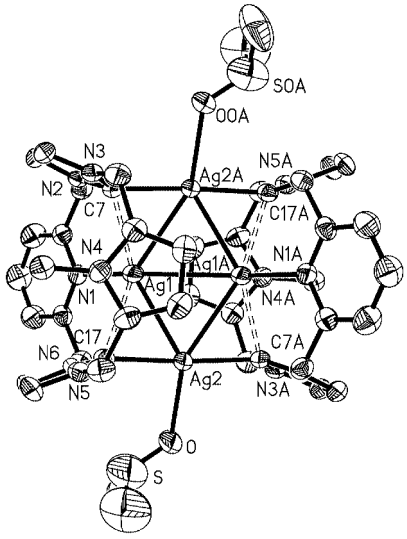


Fig. 1 Molecular structure of the tetracationic portion of $[Ag_4(\mathbf{1}^*)_2][PF_6]_4$ **2** with thermal ellipsoids drawn at 50% probability. Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Ag1–Ag1A 2.9712(11), Ag1–Ag2 2.7680(9), Ag1A–Ag2 2.8077(16), Ag2–C7A 2.148(6), Ag2–C17 2.149(6), Ag1–C7 2.412(5), Ag1–C17 2.516(6); C17–Ag2–C7A 176.2(2).

† Electronic supplementary information (ESI) available: detailed experimental procedures for the syntheses of $[\mathbf{1}][PF_6]_2$ and $[Ag_4(\mathbf{1}^*)_2][PF_6]_4$ (**2**) and details of crystallography. See http://www.rsc.org/suppdata/cc/b1/b105751k

 DOI: 10.1039/b105751k

interactions with the carbene ligands of two neighboring macrocycles at Ag2–C7A (2.148(6) Å) and Ag2–C17 (2.149(6) Å) bond distances and a nearly linear C17–Ag2–C7A (176.2(2)°) bond angle. These values are quite normal when compared to the same parameters reported for other silver–bis(carbene) complexes.[1,3,4a,b] In addition, each bridging Ag atom has a DMSO molecule coordinated to it with a Ag–O distance of 2.401(5) Å. The non-bridging Ag atoms are each coordinated to the pyridine nitrogen atoms of neighboring ligands at a Ag1A–N1A bond distance of 2.360(5) Å. An interesting feature of **2** is the manner in which each carbene ligand tilts inward toward the center of the molecule and interacts with the non-bridging Ag atoms at distances of Ag1–C7 (2.412(5) Å) and Ag1–C17 (2.516(6) Å). Bonding interactions of this type are unprecedented in N-heterocyclic carbene chemistry.[9] We assign this interaction as a π-carbene–silver bond. Our assignment is supported by previously reported silver–arene π-bonding interactions which lie in the range 2.43–2.61 Å.[10] The pyrrole portion of each macrocycle is positioned such that a π–Ag interaction could be envisioned; however, the shortest contact is 3.30 Å (Ag1–N4) and they vary from 3.30–3.89 Å.

Organosilver complexes having inner $[Ag_4]^{4+}$ clusters similar to **2** have been reported.[11] In fact, the structural similarity between **2**, $[Ag(C_6H_4CH_2NMe_2\text{-}2)]_4$ **3**[11a] and $[Ag(C_5H_3CH_2NMe_2\text{-}2)Fe(C_5H_5)]_4$ **4**[11e] is remarkable. For **3**, four Ag–Ag bonds that average 2.738(2) Å are each asymmetrically bridged by an anionic $^{-}C_6H_4CH_2NMe_2$-2 ligand forming two Ag–C bonds that average 2.155(13) and 2.381(13) Å, respectively. For **4**, four Ag–Ag bonds (2.740(2) Å) form a planar core with each of the Ag–Ag bonds symmetrically bridged by an anionic ($^{-}C_5H_3CH_2NMe_2$-2)Fe(C_5H_5) ligand with Ag–C distances of 2.17(2) Å. The structural similarity between **2**, **3** and **4** can be explained in terms of the isoelectronic relationship between the anionic aryl ligands used for **3** and **4** and the N-heterocyclic carbene ligand.

We wish to thank the National Science Foundation, the University of Akron and the Ohio Board of Reagents for financial support. We thank Dr. Judith Gallucci for assistance in the collection of X-ray diffraction data for **2**.

Received (in Cambridge, UK) 20th June 2001, Accepted 6th August 2001
First published as an Advance Article on the web 3rd September 2001

Gold–silver alloy nanoparticles can be produced by pulsed laser irradiation of bulk alloy metals in water, preserving the stoichiometry of the target metals.

The intense research activity in the field of nanoparticles that has been conducted by chemists, physicists, and material scientists is motivated by the search for new materials in order to further miniaturize electronic devices, as well as by the fundamental question of how molecular electronic properties evolve with increasing size in this intermediate region between molecular and solid-state physics.[1] In particular, nanocomposites, *i.e.*, alloy and/or core–shell particles, are attractive materials because of their composition-dependent optical and catalytic properties. Papavassiliou has successfully prepared Au–Ag alloy particles *via* evaporation of Au–Ag alloys.[2] Liz-Marzan and Philipse prepared various bimetallic colloidal nanoparticles (Au–Ag, Au–Pt, and Ag–Pt) by reducing the metal salts in aqueous, optically transparent dispersions of inorganic fibers.[3] Our research group[4] and El-Sayed *et al.*[5] employed simultaneous reduction of gold and silver salts to form Au–Ag alloy particles with 4 and 18 nm diameters, respectively. Very recently, Hodak *et al.*[6] and Chen and Yeh[7] reported the production of Au–Ag alloy nanoparticles by laser irradiation of either the Au–Ag core–shell nanoparticles or the gold and silver colloidal mixtures. This suggests that the interaction between laser light and nano/colloidal particles can result in compositional changes *via* a melting process.[6–8] Herein, we report that homogeneous alloy nanoparticles can be produced even from bulk alloys by laser ablation in water.[9] A gold–silver system is chosen as a model case since both metals are miscible in all proportions in bulk due to their comparable lattice constants. Moreover, UV-vis absorption spectroscopy can readily be applied to differentiate an alloyed structure from a core–shell one for Au–Ag bimetallic particles.[3–5]

Initially, Au–Ag bulk alloys were prepared by inductively heating two metals at high frequency; metals used were in molar ratios of Au:Ag = 3:1, 2:2, and 1:3. Hereafter, we will refer to the metal nanoparticles prepared from the Au–Ag alloys in molar ratios of 3:1, 2:2, and 1:3 as $Au_{0.75}Ag_{0.25}$, $Au_{0.5}Ag_{0.5}$, and $Au_{0.25}Ag_{0.75}$, respectively.† Silver and gold nanoparticles are known to show plasmon absorption bands in the visible region (at ~390 and ~520 nm, respectively[10]). In fact, distinct peaks are observed at 394 and 518 nm in the UV-vis spectra of the Ag and Au nanoparticles prepared from pure metals (see the spectra labeled (a) and (e) in Fig. 1). In Fig. 1 are also shown the UV-vis spectra of the $Au_{0.25}Ag_{0.75}$, $Au_{0.5}Ag_{0.5}$, and $Au_{0.75}Ag_{0.25}$ samples (see the spectra labeled (b), (c), and (d), respectively). Peaks are clearly observed at 427, 460, and 493 nm, respectively, for these samples; all these peaks are located at intermediate positions between the intrinsic Ag and Au plasmon bands. Hence, they must arise from the surface plasmon absorptions of alloyed nanoparticles. It is noteworthy that the plasmon absorptions of the gold–silver composite clusters are linearly red-shifted from that of a monometallic Ag cluster in proportion to the increase in the mol fraction of the Au content. This is demonstrated by Fig. 2, in which the UV-vis absorption peak position is plotted against the mol fraction of Au in the precursor samples. Two plasmon bands would be expected if the clusters consisted of individual Au and Ag particles or of bimetallic composites with a core–shell structure.[4,10] All these UV-vis spectral features suggest that the Au–Ag composite particles prepared in this work are neither a simple mechanical mixture of two different monometallic particles nor bimetallic nanoparticles with a core–shell structure.

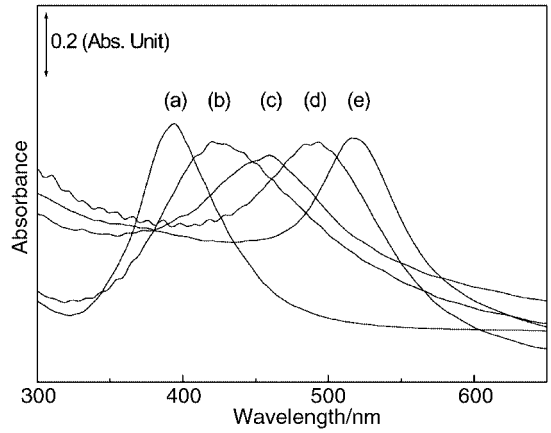

Fig. 1 UV-vis absorption spectra of Au–Ag alloy nanoparticles produced in distilled water with nominal formulae of (a) Ag, (b) $Au_{0.25}Ag_{0.75}$, (c) $Au_{0.5}Ag_{0.5}$, (d) $Au_{0.75}Ag_{0.25}$, and (e) Au.

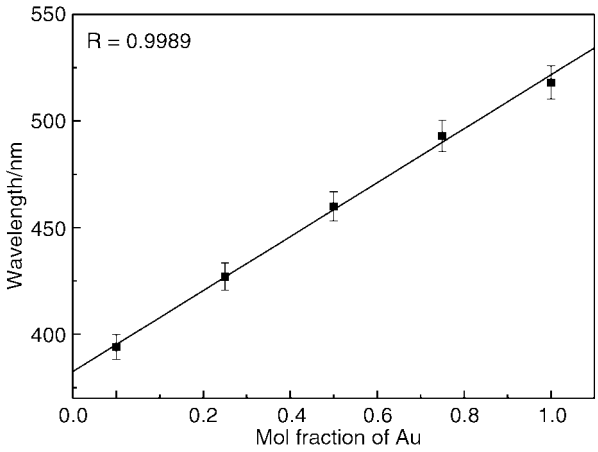

Fig. 2 Positions of surface plasmon bands plotted against the mol fractions of Au atoms in alloy nanoparticles.

Fig. 3(a) shows a typical TEM (JEM-2000 EXII, 160 kV) image taken for a $Au_{0.5}Ag_{0.5}$ sample. As can be seen in the image, most of the particles are not agglomerated and their average size is ~10 nm. Other samples showed similar TEM images. As surmised from UV-vis absorption spectroscopy, the probability of the presence of core–shell particles is proved to

 DOI: 10.1039/b105437f

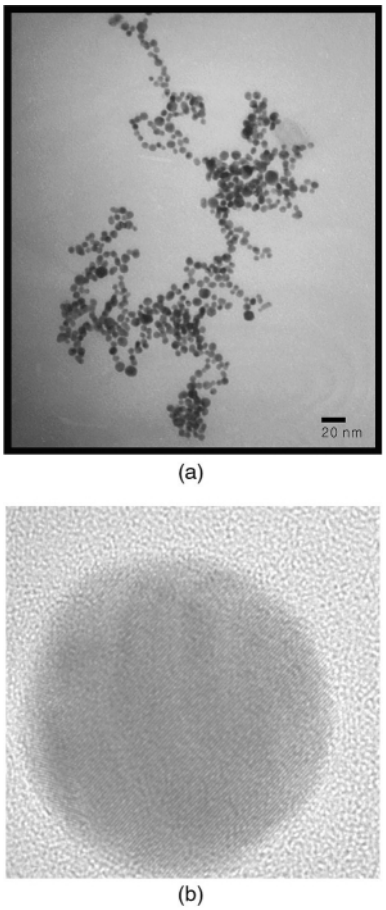

Fig. 3 (a) TEM image of Au–Ag alloy nanoparticles with a nominal formula of $Au_{0.5}Ag_{0.5}$. (b) HRTEM image of a 16 nm diameter Au–Ag alloy nanoparticle with a nominal formula of $Au_{0.5}Ag_{0.5}$.

be very low from the energy dispersive X-ray spectroscopy (EDX) analysis. In the latter analysis, peak integration and normalization were carried out to measure the Au-to-Ag ratio in individual particles, and the data were collected over 10 particles. The EDX analysis on the $Au_{0.75}Ag_{0.25}$, $Au_{0.5}Ag_{0.5}$, and $Au_{0.25}Ag_{0.75}$ particles thus yielded atomic ratios of Au : Ag = 75.79 : 24.21 (±1.65), 49.75 : 50.25 (±1.01), and 25.14 : 74.86 (±1.71), respectively. The results were always comparable to within 2%. These observations indicate that the laser-ablated products are indeed homogeneous alloyed nanoparticles.

Fig. 3(b) is a high-resolution TEM (HRTEM, JEM-3000F, 300 kV) image of the sample in Fig. 3(a). We can estimate from this image that the lattice plane spacing is about 2.35 Å. Much the same value (2.35 ± 0.01 Å) was obtained for other samples with different compositions. In fact, the value obtained herein is very close to those of pure Ag and Au, *i.e.*, 2.36 Å for Ag and 2.35 Å for Au.[11] This may be attributed to the fact that Ag and Au are miscible in all proportions due to their almost identical lattice constants. The unit cell size of Au–Ag alloys changes by less than 1% over the entire range from pure Au to pure Ag, and no superlattice reflections are observed in the alloys.[12]

Let us briefly provide a plausible mechanism for the alloyed particle formation. Immediately after the laser irradiation, the surface of a sample will reach a very high temperature by absorbing pulsed laser energy. As a consequence, atoms and/or small particles should be ejected through vaporization, followed by the build-up of a dense cloud of metal atoms (Au and Ag atoms) near the laser spot. Since the interaction between metal atoms is much greater than that between a metal atom and a solvent molecule, the metal atom(s) will aggregate to produce nanoparticles. Since Au and Ag form nearly ideal solid solutions at all compositions,[13] mixing of the two metals is a thermodynamically favorable process. Therefore, nanoparticles formed must be homogeneous alloy particles.

In summary, we found that Au–Ag alloy nanoparticles could be easily produced by laser ablation of a bulk alloy in water. Formation of homogeneous alloyed particles was clearly demonstrated by UV-vis absorption spectroscopy and TEM and EDX measurements. The simplicity of the procedure is clearly a major advantage of the present method. The size distribution of nanoparticles can be readily controlled by varying the pulse energy and time of ablation. The method is versatile with respect to the kinds of metals and/or solvents employed. The absence of chemical reagents or ions in the final preparation will also be advantageous. The particles can be derivatized with suitable amphiphiles afterwards. Currently, we are attempting to synthesize other alloyed particles such as Au–Pt, Au–Cu, and Ag–Pt.

Notes and references

† For the laser ablation experiments, bulk alloys were placed at the bottom of a glass vessel filled with 10 mL triply distilled water, and then irradiated using a focused beam of a Nd : YAG laser (Continuum Surelite II-10, at 1064 nm). The typical pulse energy, repetition rate, laser pulse duration, and irradiation time were 50 mJ, 10 Hz, 6 ns, and 30 min, respectively. For reference, pure gold and silver nanoparticles were also prepared *via* the same method. Since the produced particles interfere with the subsequent laser pulses, the efficiency of the ablation process gradually decreases as a function of the irradiation time. This can be minimized by stirring the solution phase continuously during the laser ablation process. The extinction spectrum was recorded with a UV-vis absorption spectrometer (SINCO S-2130). Transmission electron microscope (TEM) images of the nanoparticles were acquired by placing drops of sample solutions on copper grids, followed by evaporation of the solvent in a vacuum desiccator.

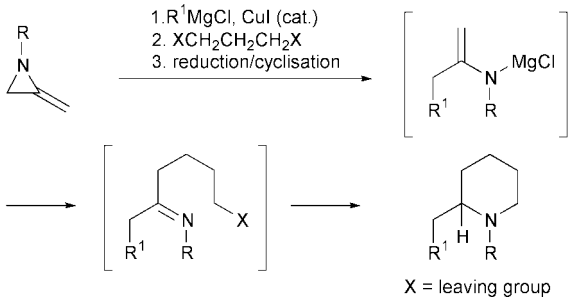
(*S*)-Coniine is made using a reaction which assembles the piperidine ring by the sequential formation of four new chemical bonds and installs the C-2 stereogenic centre with high levels of diastereocontrol (90% de).

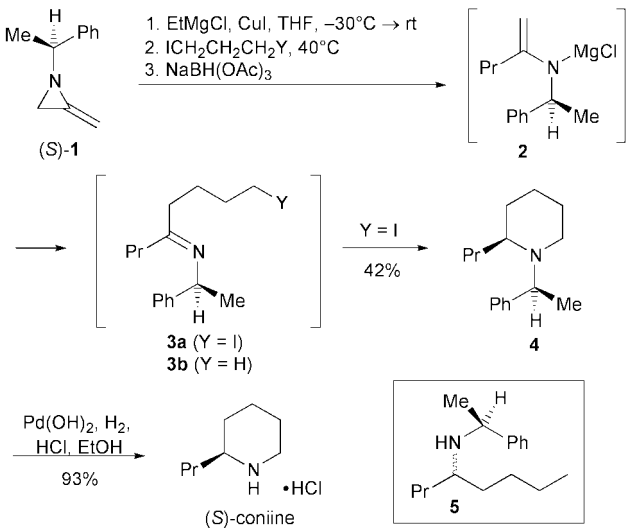
We recently devised a new type of multi-component coupling reaction using 2-methyleneaziridines.[1] Ring opening of this stable and readily accessible heterocyclic system with a Grignard reagent in the presence of copper(I) iodide furnishes a metalloenamine in a regiocontrolled fashion by formation of a carbon–carbon bond. This methodology was originally used to make simple ketones by further *in situ C*-alkylation of the metalloenamine followed by imine hydrolysis. We imagined that by suitable modification, this multi-component coupling reaction could be used to assemble 2-substituted piperidines, important structural motifs in organic chemistry.[2] Our basic approach to these piperidines is depicted in Scheme 1. Alkylation of the initially generated metalloenamine with a 1,3-difunctionalised electrophile ($XCH_2CH_2CH_2X$) followed by reduction of the resultant imine and *in situ* cyclisation was anticipated to lead directly to the piperidine ring system by the sequential formation of two carbon–carbon bonds, one carbon–nitrogen bond and a carbon–hydrogen bond in a single transformation. Furthermore, since 2-methyleneaziridines bearing chiral, nonracemic substituents on nitrogen are known,[3] we hoped that control of the absolute stereochemistry at C-2 of the piperidine ring may be possible by effecting a diastereocontrolled reduction of the intermediate imine using an enantiomerically pure 2-methyleneaziridine starting material.[4] In this communication, we report the successful realisation of these concepts as demonstrated by the enantiocontrolled synthesis of the hemlock alkaloid (*S*)-coniine in a very concise fashion.[5]

We chose to use (*S*)-1-(1-phenylethyl)-2-methyleneaziridine **1** for this study as it is readily accessible in two steps from (*S*)-1-phenylethylamine in good overall yield.[3b] In addition to bearing a group suitable for effecting stereocontrolled reduction of the imine double bond, it possesses the additional attribute that the PhCHMe group can ultimately be removed by cleavage of the benzylic C–N bond. Treatment of (*S*)-**1** with EtMgCl and copper(I) iodide, then 1,3-diiodopropane, and finally sodium triacetoxyborohydride results in the production of piperidine **4** in 42% yield as essentially a single diastereomer (97% de) after chromatography on neutral alumina (Scheme 2).†‡ Slightly larger amounts of the (2*R*)-diastereomer can be detected {(2*S*):(2*R*) = 95:5} by GC analysis prior to chromatography. Piperidine **4** (97% de) was obtained in identical yield using sodium borohydride as the reducing agent, however, the crude diastereomeric ratio was slightly lower {(2*S*):(2*R*) = 88:12}. Metalloenamine **2** must be added to a solution of excess 1,3-diiodopropane (5 equiv.) in THF (inverse addition) to obtain these chemical yields. In this way, additional intermolecular reactions of imine **3a** are suppressed. Using a normal addition mode, quantities of *N*-(1-phenylethyl)-4-decylamine (21%) were produced as a result of displacement of the second iodide by excess ethylmagnesium chloride present in the reaction mixture. Further hydrogenolysis of **4** provides (*S*)-(+)-coniine hydrochloride in 93% yield whose physical and spectroscopic data were in good agreement with those reported previously {mp 212 °C (lit. mp 217 °C[6]); $[\alpha]_D^{25}$ +8.1 (*c* 0.6, EtOH) [lit. $[\alpha]_D^{28}$ + 5.8 (*c* 0.43, EtOH)][6]}. The enantiomeric excess of the synthetic (*S*)-coniine was established to be ⩾95% ee by preparation of the corresponding Mosher amide using (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetic acid chloride.§

Interestingly, when 1-iodopropane was used as the electrophile in this multi-component coupling reaction, amine **5** was isolated in 49% yield as a 58:42 mixture of diastereomers after reduction with $NaBH_4$, indicating that the presence of the remote iodine atom has a significant influence on the diastereoselectivity of the imine reduction. To account for these differences, we suggest that imine **3a** cyclises to iminium ion **6** prior to reduction (Scheme 3). The high level of stereochemical control seen in favour of the (2*S*)-diastereomer can be

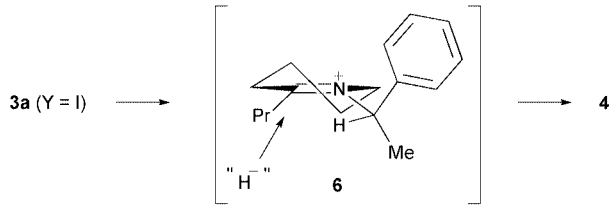


Scheme 1 Planned one-pot piperidine synthesis.



Scheme 2 Asymmetric synthesis of (*S*)-coniine.

 DOI: 10.1039/b106260n



Scheme 3 Rationalisation of diastereoselectivity.

rationalised by assuming this iminium cation adopts a conformation in which allylic 1,3-strain is minimised by projecting the hydrogen atom of the benzylic carbon towards the propyl group, with subsequent hydride addition from the least hindered *Re*-face. In contrast, acyclic imine **3b** has much greater conformation freedom and is reduced in a non-selective fashion to **5**.

In conclusion, we have devised a very short and stereoselective synthesis of the piperidine alkaloid (*S*)-coniine by way of a multi-component coupling reaction. The key step forms four new chemical bonds (>80% efficiency for each) and is highly stereoselective (90% de). Since we have demonstrated that a variety of Grignard reagents (alkyl, aryl, benzyl) ring open 2-methyleneaziridines to metalloenamines,[1] this method should provide a rapid entry to a wide variety of enantiomerically enriched 2-substituted piperidines.

We are indebted to EPSRC and GlaxoSmithKline for their generous financial support of this work. We thank the EPSRC National Mass Spectrometry Centre for performing some of the mass spectral measurements and the EPSRC Chemical Database Service at Daresbury.[7]

† All new compounds have been fully characterised using standard spectroscopic and analytical methods.

‡ *Experimental procedure*: To CuI (72 mg, 0.378 mmol) in THF (6 ml) at −30 °C was added EtMgCl (2.0 M in THF, 2.36 ml, 4.72 mmol) dropwise. After stirring for 10 min, (*S*)-**1** (300 mg, 1.88 mmol) in THF (3 ml) was added. The reaction mixture was allowed to warm up to room temperature and stirred for 24 h. This mixture was then added to diiodopropane (1.09 mL, 9.49 mmol) in THF (2 ml) at 0 °C. A reflux condenser was fitted and the mixture was heated to 40 °C for 18 h. On cooling, the resultant dark green mixture was added to a solution of sodium borohydride (214 mg, 5.66 mmol) in glacial acetic acid (4 ml) at 10 °C. After 2 hours, water (6 ml) was slowly added, then 2 M NaOH (4 ml) and EtOAc (4 ml). After 10 min, the mixture was extracted with EtOAc then washed with aq. NH_4Cl (2 × 20 ml), aq. $NaHCO_3$ (2 × 20 ml) and brine (2 × 20 ml). The organic layer was dried ($MgSO_4$), filtered and the solvent removed *in vacuo*. Column chromatography on alumina (0.1% MeOH in CH_2Cl_2) gave **4** (183 mg, 42%, 97% de) as a pale yellow oil. $[\alpha]_D^{26}$ +14.0 (*c* 0.86, $CHCl_3$); ν_{max} (neat) 2929, 2797, 1445 cm^{-1}; δ_H (400 MHz, $CDCl_3$) 7.45–7.19 (5H, m), 4.02 (1H, q, *J* 6.7 Hz), 2.75–2.73 (1H, m), 2.41–2.36 (1H, m), 2.25–2.17 (1H, m), 1.75–1.25 (10H, m, 5 × CH_2), 1.26 (3H, d, *J* 6.7 Hz), 0.94 (3H, t, *J* 7.2 Hz); δ_C (100.9 MHz, $CDCl_3$) 146.4 (s), 128.0 (d), 127.5 (d), 126.2 (d), 56.8 (d), 55.7 (d), 45.1 (t), 31.0 (t), 29.6 (t), 25.8 (t), 22.7 (t), 18.9 (t), 14.7 (q), 14.6 (q); Observed: 231.1995 (M^+); $C_{16}H_{25}N$ requires 231.1987; Anal. calc. for $C_{16}H_{25}N$: C, 83.06; H, 10.89; N, 6.05%. Oxoanionic or sulfur lone pair attack? The difference in reactivity of hydrogensulfite anion and neutral dimethylsulfite towards $[Bu_4N]_2[MoO_2\{S_2C_2(CN)_2\}_2]$ in the model reductive half reaction of sulfite oxidase

First published as an Advance Article on the web 22nd August 2001

pH dependent reactivity differences of dimethylsulfite towards the title complex 1 demonstrate the crucial need of oxo-anionic coordination of sulfite to the molybdenum centre of 1 in the model reductive half reaction of sulfite oxidase.

Sulfite oxidase catalyzes the physiologically vital oxidation of sulfite to sulfate.[1] It contains molybdenum associated with a molybdopterin dithiolene cofactor and a cytochrome *b*-type heme.[1,2] The two-electron oxidation of sulfite to sulfate occurs at the molybdenum site leading its reduction from Mo(VI) to Mo(IV) and the catalytic cycle is completed by two sequential one-electron oxidations of Mo(IV) to Mo(VI) *via* Mo(V) by cytochrome *c* through the cytochrome *b* site.[3]

The fundamental chemistry catalyzed by sulfite oxidase has been investigated using several model compounds possessing a $\{Mo^{VI}O_2\}$ moiety involving phosphines as model substrates.[4] $[Bu_4N]_2[MoO_2\{S_2C_2(CN)_2\}_2]$ **1** is shown to perform oxidation of HSO_3^- to HSO_4^- both in terms of saturation as well as anionic inhibition kinetics similar to the reductive half reaction of native sulfite oxidase.[5] The initial proposal of oxoanionic attack[5] of HSO_3^- on the Mo center of **1** has been questioned[6] based on the unique experimental results reported by Hille and Brody involving neutral dimethylsulfite as an alternate substrate of the native sulfite oxidase.[7] Nucleophilic attack on one of the Mo=O groups present in **1** by a lone pair of sulfur of HSO_3^-, similar to that of phosphorus in phosphines, have been suggested.[6] Hille and Brody have shown that the methylation of two oxoanions of sulfite reduces the affinity of dimethylsulfite for the active site of the native enzyme. Exhibition of saturation kinetics by dimethylsulfite implies the formation of a Michaelis complex which they interpreted in terms of possible electrostatic interaction between the active site and modified substrate.[7] It has also been reported that sulfite anion contributes 3.4 kcal mol^{-1}. towards the stablization of the E_{ox} S complex which is consistent with the direct coordination to Mo.† Direct oxoanionic coordination of sulfite to the Mo center has also been suggested by Rajagopalan and coworkers.[9] **1** has been shown to respond to saturation kinetics with typical anionic inhibition involving HSO_3^- as substrate.[5] In this communication we furnish proof for the importance of oxo-anionic coordination for such an enzymatic atom transfer reaction by presenting the pH dependent reactivity difference of dimethylsulfite towards **1** which is of relevance to its reaction with native protein.

In order to gain an insight into the reaction of **1** with reductants such as dimethylsulfite, PPh_3 or HSO_3^-; the reactivity of all these oxo-acceptors have separately been examined by following the absorbance change of **1** during the progress of the reaction. In the presence of an excess of dimethylsulfite, **1** in acetonitrile or in acetonitrile–water (pH, 5–7) did not show any change in its electronic spectrum suggesting the inability of dimethylsulfite to reduce **1** [Fig. 1(a)]. Interestingly, dimethylsulfite after standing at pH 8 for a few minutes was found to be capable to reduce **1**, the time-dependent progress of the reaction distinctly showed the formation of the reduced species, $[Bu_4N]_2[MoO\{S_2C_2(CN)_2\}_2]$ **2** [Fig. 1(b)].

The difference in reactivity of dimethylsulfite in the pH range 5–7 and 8 towards **1** was checked by its response to hydrolysis under similar conditions. Thus aqueous solutions of dimethylsulfite at different pH were tested with aqueous $BaCl_2$. In the pH range 5–7 there was no precipitation of $BaSO_3$ over a time period of hours but at pH 8 (and above) precipitation of $BaSO_3$ started to occur within minutes and its identity was confirmed by the standard $BaSO_4$ test.§ The reactions described above clearly demonstrate the inability of neutral dimethylsulfite to react with **1** suggesting the inability of the sulfur lone pair to initiate any redox reaction. Once the neutral dimethylsulfite is base hydrolysed (pH 8) to yield HSO_3^-, the reaction progresses smoothly [Fig. 1(b)].

Interestingly PPh_3 does reduce **1** to **2**; the time-dependent progress of the reaction is shown in Fig. 2.[6]

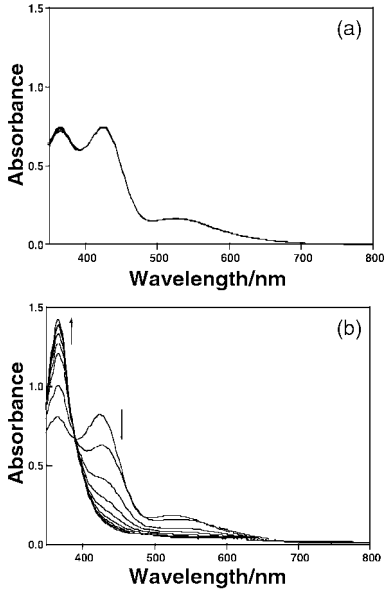

Fig. 1 (a) Spectral changes for the reaction between **1** (1×10^{-4} M) and dimethylsulfite (1.15×10^{-2} M) in acetonitrile. Spectra were taken for 150 min at intervals of 30 min. (b) Spectral changes for the reaction between **1** (1.075×10^{-4} M) and dimethylsulfite (3.4×10^{-2} M) at pH 8 in acetonitrile–water medium.‡ Spectra were taken for 14 min at intervals of 2 min.

 DOI: 10.1039/b105341h

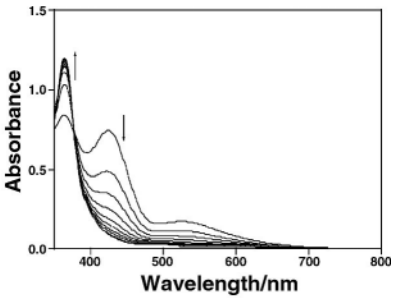

Fig. 2 Spectral changes for the reaction between **1** (1×10^{-4} M) and PPh_3 (5×10^{-3} M) in acetonitrile. Spectra were taken for 150 min at intervals of 15 min.¶

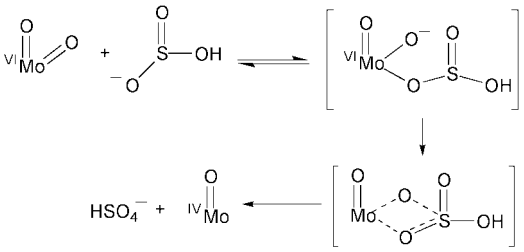
The difference in reactivity between HSO_3^- and PPh_3 should be noted in a sense that for all the reported reactions of model compounds including that of **1**, phosphines invariably respond to oxo abstraction by following second order kinetics (without the involvement of the Michaelis complex) whereas the unique reduction of **1** by HSO_3^- follows enzymatic kinetics (Michaelis complex) similar to that of the native sulfite oxidase.[5] Thus the reactivity of anionic HSO_3^- towards **1** is clearly dependent on the direct coordination of HSO_3^- to the Mo site as proposed earlier.[5] This also explains the observed competitive inhibiton by sulfate,[5] otherwise the lone pair attack of sulfur on the coordinated terminal oxo group and the direct binding of SO_4^{2-} to Mo would have resulted in mixed non-competitive inhibition. The heptacoordinated E_{ox} S type complex, $\{[Bu_4N]_2[Mo(O)(O^-)\{S_2C_2(CN)_2\}_2\{O(OH)SO\}]\}$, generated by the oxoanionic binding of HSO_3^- transforms the $\{Mo(O)_2\}$ group to $\{Mo^{VI}(O)(O^-)\{O(OH)SO\}\}$ moiety which in turn may lead to bidentate coordination of bisulfite to form $\{Mo^{VI}(O)(\mu\text{-}O)_2(OH)S(O)\}$ for the product release step (Scheme 1). This reaction may thus be viewed as being similar to the reductive elimination reaction where the Mo(VI) containing heptacoordinated[11] E_{ox} S complex‖ changed to pentacoordinated Mo(IV) in **2** with the elimination of HSO_4^-.

Funding of this work by DST (New Delhi) and IIT-Kanpur is gratefully acknowledged.



Scheme 1

Notes and references

† The possibility of direct binding of the oxoanion of HSO_3^- to Mo has not been considered in the calculation.[8]

‡ Aqueous dimethylsulfite solution was adjusted to pH 8 by sodium hydroxide and after 5 min its pH was lowered to ~6 by adding acetic acid. This was added to an acetonitrile solution of **1** to monitor the reaction.

§ Aqueous dimethylsulfite in the pH range 5–7 (adjusted by adding acetic acid) does not show any precipitation on addition of $BaCl_2$ over a time scale of hours but at pH 8 and above, precipitation started to occur within minutes. This precipitate readily dissolved in dilute HCl and on addition of Br_2 (aq) to this clear solution insoluble $BaSO_4$ was precipitated. At this point it is important to mention that the rate of hydrolysis of dimethylsulfite in water is 10^{-5} s^{-1} as quoted by Brody and Hille[7] from the work of Guthrie.[10] A careful inspection of the data mentioned in Guthrie's paper reveals that this actually refers to the hydrolysis of the methyl ester of methanesulfonic acid ($CH_3S(O)_2OCH_3$) for which the corresponding acid is CH_3SO_3H (methanesulfonic acid) with $pK_a = -1.92$. For dimethylsulfite ($CH_3OS(O)OCH_3$), the corresponding acid is sulfurous acid (HOS(O)OH) with pK_1 and pK_2 values = +1.90 and +7.25, respectively.

¶ A similar reaction using acetonitrile–water medium showed faster conversion of **1** to **2** compared to that in pure acetonitrile.

‖ Mono-oxoheptacoordinated Mo(VI) or dithiolene coordinated mono-oxoheptacoordinated W(VI) complexes in aqueous media have precedence in the literature.[12]

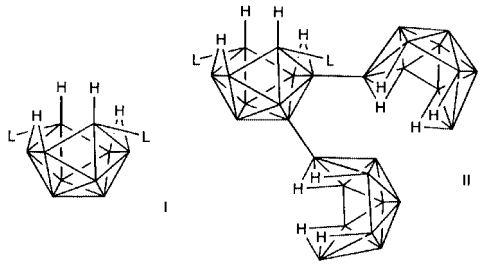
Received (in Cambridge, UK) 26th June 2001, Accepted 1st August 2001
First published as an Advance Article on the web 3rd September 2001

In an attempt to find generic routes to multiple inter-cluster σ-linking, mild thermolysis of [6,9-$(SMe_2)_2$-*arachno*-$B_{10}H_{12}$] 1 in inert hydrocarbon solution gives the tridecaboranyl species [6,9-$(SMe_2)_2$-*arachno*-$B_{10}H_{10}$-1,5-(6′-*nido*-$B_{10}H_{13})_2$] 3 (23%).

There is current activity in the linking together of boron-containing clusters to generate (a) chains, rods and rings of σ-linked clusters,[1] (b) strings and other assemblies in which clusters join with a common metal atom,[2] and (c) macro-polyhedral assemblies of clusters fused with two or more atoms in common.[3] In this context, we have interest in the possibility of multiple σ-linking of several boron clusters to a central boron core for possible precursors to globular 'megaloboranes', of which structures would be based on central boron cluster cores of which, in turn, the peripheral valencies are σ-linked to outer boron–hydride cluster units which are themselves mutually σ-linked to form a boron–hydride skin around the central borons-only nucleus.[4] Here, we thought it useful to examine for activity of the $\{B_{10}H_{12}(SMe_2)\}$ fragment, as it has both 'reactive' and 'unreactive' forms: both forms will electrophilically add to olefins and acetylenes,[5] and thence might add to electrophilically susceptible sites of boron clusters in first steps of a possible synthetic approach involving initial assembly of boron hydride units around a central core. A 'reactive' form of $\{B_{10}H_{12}(SMe_2)\}$, of unestablished constitution, is proposed as a key intermediate in the formation of $\{C_2B_{10}\}$ dicarbaboranes from $[B_{10}H_{12}(SMe_2)_2]$ **1**.[5] A 'stable' form, [5-(SMe_2)-*nido*-$B_{10}H_{12}$] **2** is well established and is generated in yields of 40–60% by heating $[B_{10}H_{12}(SMe_2)_2]$ in the absence of other reagents, other products being unidentified.[6,7] We surmised that these other products might arise from electrophilic attack by the $\{B_{10}H_{12}(SMe_2)\}$ fragments, either 'stable' or 'unstable', on other decaboranyl residues in quasi-auto-fusion processes to generate multidecaboranyl assemblies. We here report preliminary results that are consistent with this idea.

Specifically, a solution of $[(SMe_2)_2B_{10}H_{12}]$ **1** (schematic structure **I**; 107 mg; 440 μmol) in benzene (10 mL) was heated at reflux for 6 h. TLC separation (silica G, hexane–CH_2Cl_2, 3:7) gave known [5-(SMe_2)-*nido*-$B_{10}H_{12}$] **2**[6] (R_F 0.8, 8 mg; 43 μmol, 9%). Closely following **2** on the TLC plate was a faint yellow band (R_F *ca.* 0.7) which was purified by HPLC (Lichrosorb SI 60, 25 cm × 2 cm, hexane–CH_2Cl_2 57:43, 20 mL min^{-1}). The fraction with R_T 1.3 min was the tridecaboranyl species [6,9-$(SMe_2)_2$-*arachno*-$B_{10}H_{10}$-1,5-(6′-*nido*-$B_{10}H_{13})_2$] **3**, (schematic structure **II**; 16 mg, 33 μmol, 23%), characterized by single-crystal X-ray diffraction analysis (Fig. 1)‡ and NMR spectroscopy.‡§ We hope to be able to describe other, lower-yield, by-products in due course.

† Specifically 6,9-bis(dimethylsulfide)-1,5-bis(6′-*nido*-decaboranyl)-*arachno*-decaborane (IUPAC nomenclature).



Obtainable crystals under our conditions were of *ca.* 0.02 × 0.08 mm cross section, and needed synchrotron-generated X-ray radiation for sufficient diffraction intensity for structural analysis.[8] This revealed the *arachno* $\{(SMe_2)_2B_{10}\}$ configura-

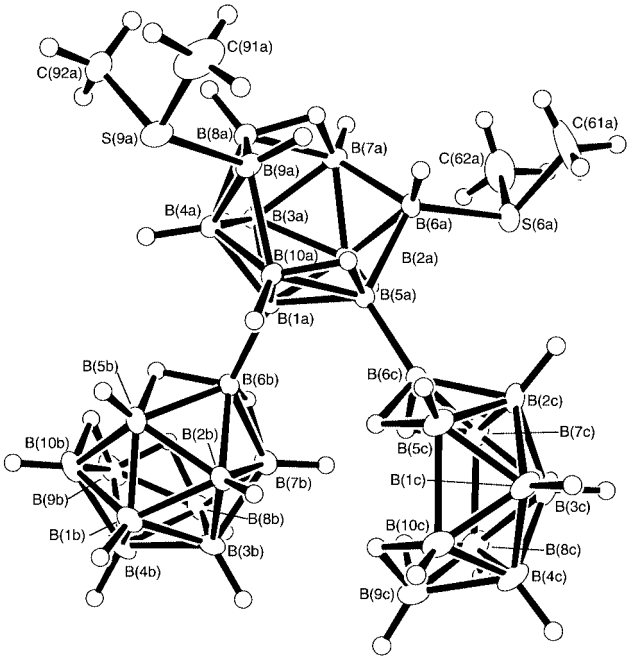


Fig. 1 Crystallographically determined molecular structure of [6,9-$(SMe_2)_2$-*arachno*-$B_{10}H_{10}$-1,5-(6′-*nido*-$B_{10}H_{13})_2$] **3**, drawn with 40% probability ellipsoids for non-hydrogen atoms, and with a small arbitrary radius for hydrogen atoms. The crystal structure had two molecules per unit cell, of which one was disordered over two positions. The undisordered molecule is drawn here. Selected interatomic distances (Å) for the undisordered molecule are as follows: B(6)–S(6) 1.924(3), B(9)–S(9) 1.927(3), B(1)–B(6′) 1.688(5), B(5)–B(6″) 1.676(5), B(5)–B(10) 1.874(5), B(7)–B(8) 1.861(5), B(5′)–B(10′) 1.969(5), B(7′)–B(8′) 1.993(5), B(5″)–B(10″) 1.980(6) and B(7″)–B(8″) 1.979(6).

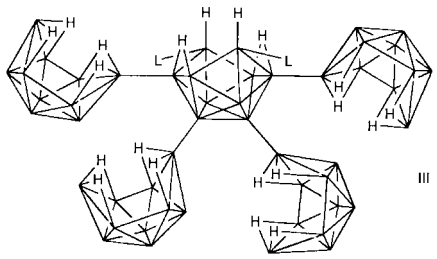
 DOI: 10.1039/b105551h

tion as in compound **1**, but now with two pendant open decaboranyl groups, on the B(1) and B(5) positions. These are established as {*nido*-$B_{10}H_{13}$} moieties by their bridging hydrogen-atom positions, general *nido*-decaboranyl molecular dimensions, and NMR characteristics.‡ Compound **3** is the first tridecaboranyl specifically identified. Although bidecaboranyls are well recognized,[9] as far as we are aware this tridecaboranyl {B_{30}} framework constitutes the biggest molecular all-boron skeletal assembly yet unequivocally characterized. Although $B_{30}H_{38}$, bis(*nido*-decaboranyl)-*nido*-decaborane, [$B_{10}H_{12}$-($B_{10}H_{13}$)$_2$], is formed in the thermolysis of *nido*-$B_{10}H_{14}$ in refluxing toluene with 0.03 mol% [6,9-(SC_4H_8)$_2$-*arachno*-$B_{10}H_{12}$] (a close relative of compound **1**) as catalyst, this product is in low yield (0.2%), and is an unspecifiable mixture of isomers, of which 546 are possible.[10]

The reaction stoicheiometry and product constitution of compound **3** suggest initial dissociation of compound **1** to give {$B_{10}H_{12}(SMe_2)$}, followed by addition into B–H sites by {$B_{10}H_{12}(SMe_2)$} to give B–$B_{10}H_{13}$ units with the elimination of SMe_2 [eqn. (1)].

$$[(SMe_2)_2B_{10}H_{12}]\ \mathbf{1} + 2\ \{B_{10}H_{12}(SMe_2)\} \rightarrow [(SMe_2)_2B_{10}H_{10}(B_{10}H_{13})_2]\ \mathbf{3} + 2\ SMe_2 \qquad (1)$$

The result of one predominant isomer, from three clusters conjoined σ, in good yield for a thermolytic three-molecule conjoining reaction, has interesting auguries. Firstly, the ready attack of a {$(SMe_2)B_{10}H_{12}$} moiety at nucleophilic sites on [$(SMe_2)_2B_{10}H_{12}$] **1** suggests a more general use for compounds **1** and **2** in co-thermolysis reactions with other boranes to link the versatile *nido*-decaboranyl residue to other borane residues. Reaction with the [*closo*-$B_{12}H_{12}]^{2-}$ dianion to give [$B_{12}H_{11}(B_{10}H_{13})]^{2-}$, which might be precursive, *via* further oxidation, to the novel fused-cluster [$B_{22}H_{22}]^{2-}$ anion,[11] would be an attractive target here. Second, the high yield and site specificity for this predominant product suggest preferential activation by the first boron substituent to the addition of the second boron substituent at an adjacent site, which would augur well for the observation of further addition in this and related systems. Third, the observed multiple addition of borane residues to adjacent sites is of potential use in the synthesis of higher more condensed boranes, as mentioned above. Here, the nearness of the *nido*-decaboranyl residues on the central borane unit of compound **3** might imply that coupling reactions among them, with dihydrogen loss, may be readily effected. Thus, for example, establishment of conditions for multiple addition in this type of reaction system to generate species such as in **III**,



III

followed by cross-linking among the pendant $B_{10}H_{13}$ moieties, could engender the type of 'megaloborane' globular species presaged by the structures of very condensed metallaboranes such as [$(PPh_3)_2(PPh_2)Pd_2B_{20}H_{16}Pd(PPh_3)$].[4] Such big 'filled-ball' globular species with borons-only cores surrounded by boron hydride sheaths may well be those that ultimately typify much big borane chemistry.[3,4] Their 'filled-ball' constitution contrasts to the hollow-ball structures of the fullerenes.

We thank the Deutsche Forschungsgemeinschaft and the UK EPSRC (grants nos. J/56929, L/49505 and M/83360) for support and Mr Simon Barrett for assistance with NMR spectroscopy. We gratefully acknowledge the use of the UK CCLRC SRS facility.

Monocarbaborane anion chemistry. The elusive C-arylated $[PhCB_{11}H_{11}]^-$, $[PhCB_9H_9]^-$ and $[PhCB_8H_8]^-$ anions

Tomáš Jelínek, Colin A. Kilner, Mark Thornton-Pett and John D. Kennedy

The School of Chemistry of the University of Leeds, Leeds, UK LS2 9JT. E-mail: johnk@chem.leeds.ac.uk

Received (in Cambridge, UK) 27th June 2001, Accepted 1st August 2001
First published as an Advance Article on the web 3rd September 2001

$B_{10}H_{14}$ and PhCHO yield [6-Ph-*nido*-6-CB_9H_{11}]$^-$ (94%), from which the nine-vertex C-phenyl monocarbaborane anion [4-Ph-*closo*-4-CB_8H_8]$^-$ (68%) can be obtained by heating at 200 °C, and from which the twelve- and ten-vertex analogues [1-Ph-*closo*-1-$CB_{11}H_{11}$]$^-$ (50%) and [4-Ph-*closo*-4-CB_9H_9]$^-$ (25%) can be obtained by heating at 210 °C with $BH_3(NEt_3)$.

There is much contemporary interest in the *closo* monocarbaborane monoanions [1-$CB_{11}H_{12}$]$^-$ and [1-CB_9H_{10}]$^-$, and in their derivatives. This is because their very low basicities, as manifested, for example, in their 'least coordinating anion' properties, enable the investigation and exploitation of species with very high Lewis acidities.[1,2] A considerable focus of current activity derives from the substituent chemistry of these anions, and how their low basicities can be tailored by these substituents for particular purposes. Although C-substitution of $[CB_{11}H_{12}]^-$ and $[CB_9H_{10}]^-$ has engendered a variety of derivatives,[1–3] and, although B-arylation has been achieved,[4] the important target of C-arylation has proved elusive, with no reports in the literature. Here we now report preliminary results on convenient routes to the C-phenylated twelve-vertex [1-Ph-*closo*-1-$CB_{11}H_{11}$]$^-$ anion **1**, and to its corresponding ten-vertex [1-Ph-*closo*-1-CB_9H_9]$^-$ analogue **2**. We also report the nine-vertex [4-Ph-*closo*-4-CB_8H_8]$^-$ anion **3**, which is the C-phenylated derivative of the very recently established 'missing link' [*closo*-4-CB_8H_9]$^-$ monoanion.[5] All three species are characterised crystallographically (Fig. 1),† and by NMR spectroscopy.‡

The synthesis of this series derives from Brellochs' report of the reaction of PhCHO with $B_{10}H_{14}$ in 5% aqueous ethanolic KOH,[6] which we have found to give the [6-Ph-*nido*-6-CB_9H_{11}]$^-$ anion **4** in 94% yield. The method is essentially the same as that for the synthesis of unsubstituted [*arachno*-6-CB_9H_{14}]$^-$ from HCHO and $B_{10}H_{14}$,[5,6] except that, interestingly, the *nido* rather than the *arachno* ten-vertex species is formed. The reaction may go *via* the [*arachno*-B_9H_{14}]$^-$ anion as intermediate. Thence, solid-state thermolysis of the $[NEt_4]^+$ salt of [6-Ph-*nido*-6-CB_9H_{11}]$^-$ **4** at 200 °C for 4 h, followed by column chromatographic separation (silica gel, 30 cm × 2.5 cm, MeCN–CH_2Cl_2 10:90), gave the $[NEt_4]^+$ salts of $[PhCB_8H_8]^-$ (anion **3**, 68%) and [7-Ph-*nido*-7-$CB_{10}H_{12}$]$^-$ (anion **5**, 22%), together with trace quantities of the $[NEt_4]^+$ salt of $[PhCB_9H_9]^-$ (anion **2**). A crystallographic sample of the $[NEt_4]^+$ salt of the $[PhCB_8H_8]^-$ anion **3** was obtained from dichloromethane–diethyl ether. The *nido* eleven-vertex anion $[PhCB_{10}H_{12}]^-$ **5** may be synthesised more specifically in 78% yield by treatment of $[PhCB_9H_{11}]^-$ **4** with $[BH_3(SMe_2)]$ in 1,2-$Cl_2C_2H_4$, and thence converted to the $[PhCB_{11}H_{11}]^-$ anion **1** by treatment with $[BH_3(SMe_2)]$. More conveniently, this last reagent also converts $[PhCB_9H_{11}]^-$ **4** more directly to $[PhCB_{11}H_{11}]^-$ **1**. Thus, $[NEt_4]^+[PhCB_9H_{11}]^-$ (1.65 g, 5 mmol) was suspended in $[BH_3(NEt_3)]$ (2.3 g, 20 mmol), and the mixture heated on an oil bath (210 °C) under nitrogen for 6 h. After cooling to room temperature, the mixture was extracted with benzene (2 × 30 ml), and the solid residue was then decomposed by heating at reflux for 3 h in ethanol–concentrated hydrochloric acid (1:1, 50 ml). The ethanol was evaporated, the mixture mixed with

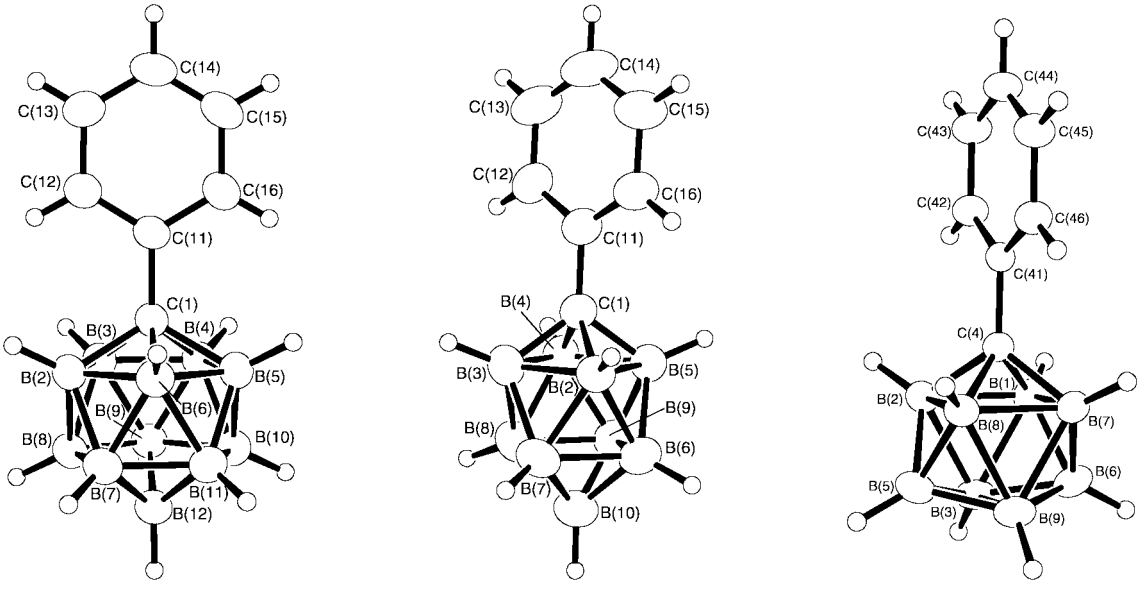

Fig. 1 From left to right, molecular structures of the $[PhCB_{11}H_{11}]^-$ twelve-vertex cluster anion **1**, and its corresponding ten- and nine-vertex $[PhCB_9H_9]^-$ and $[PhCB_8H_8]^-$ analogues, **2** and **3** respectively, as determined crystallographically for their $[NEt_4]^+$ salts.‡ Selected dimensions in Å are as follows: for anion **1**, C(1)–C(11) 1.512(3), C(1)–B(2) 1.729(4), C(1)–B(3) 1.715(3), C(1)–B(4) 1.725(4), C(1)–B(5) 1.722(4) and interboron distances 1.772(4)–1.791(4); for anion **2**, C(1)–C(11) 1.503(4), C(1)–B(2) 1.613(4), C(1)–B(3) 1.606(4), C(1)–B(4) 1.598(5) and interboron distances 1.694(6)–1.843(5); and for anion **3** C(4)–C(41) 1.490(2), C(4)–B(1) 1.623(2), C(4)–B(2) 1.622(2), C(4)–B(7) 1.620(2), C(4)–B(8) 1.623(2) and interboron distances 1.694(3)–1.975(3).

 DOI: 10.1039/b105645j

water (50 ml), and the precipitate filtered off. The latter was a mixture of the $[NEt_4]^+$ salts of $[PhCB_{11}H_{11}]^-$ and $[PhCB_9H_9]^-$ (anions **1** and **2** respectively; molar ratio 2 : 1; combined yield 1.45 g; 76%). Crystallographic samples of these $[NEt_4]^+$ salts of **1** and **2** for diffraction analysis were obtained by fractional crystallisation from dichloromethane–diethyl ether. However, bulk separation of **1** and **2** is better achieved by ion-exchange of $[NEt_4]^+$ for Cs^+, followed by fractional crystallisation of the Cs^+ salts. Thus, a solution of the mixture of the two $[NEt_4]^+$ salts (1.20 g) was dissolved in ethanol–water (4 : 1, 60 ml) and passed through of column of ionex resin (Zerolit 325 in H^+ form, 2.5 cm × 30 cm) using ethanol–water (4 : 1) as eluting liquid. Evaporation of ethanol *in vacuo* from the resulting acidic solution, followed by neutralisation by Cs[OH] to pH 7, gave a white precipitate of the Cs^+ salts of **1** and **2**. This mixture was separated by fractional crystallisation from water, starting with *ca.* 15 ml of hot solution: $Cs^+[PhCB_9H_9]^-$ is much less soluble in cold water (*ca.* 12×) than $Cs^+[PhCB_{11}H_{11}]^-$.

The synthesis of these first of a new generation of C-arylated monocarbaborane anions by simple routes in relatively good yield in two steps from the common polyhedral borane starting material $B_{10}H_{14}$ significantly augments the range of materials available for 'least-coordinating anion' chemistry; the aromatic ring/delocalised cluster conjunction may also have implications for investigation of electronic 'push–pull ' phenomena,[6] and other related interactions between the delocalised cluster and ring systems.[7] The advantage of the method is that it starts with the carbon atom pre-substituted, and thereby avoids complex synthetic carborane carbon-substitution protocols. We currently explore possibilities for other C-substituted monocarbaboranes, and for the generality of this aromatic aldehyde route.

We thank the EPSRC and the DTI for support.

New and easy route to primary cyclopropylamines from nitriles

Philippe Bertus and Jan Szymoniak*

First published as an Advance Article on the web 3rd September 2001

Starting from readily available substrates, we have developed a new synthesis of primary cyclopropylamines. The reaction involves a cooperative Ti(II)- and Lewis acid-mediated coupling of alkanenitriles with Grignard reagents.

Cyclopropylamines are not only versatile synthetic intermediates,[1] but also a variety of biologically active molecules contain a cyclopropylamine moiety.[2] Yet, a few synthetic methods that allow preparation of these important compounds[1,3] often require multi-step reactions. Among the available methods, the recent de Meijere adaptation[4] of the Kulinkovich hydroxycyclopropanation[5] presents a useful synthesis of *N*,*N*-dialkylcyclopropylamines from *N*,*N*-dialkylcarboxamides and Grignard reagents in the presence of $Ti(OPr^i)_4$ or $MeTi(OPr^i)_3$. Here we disclose that primary cyclopropylamines may be easily obtained in one step by a Ti(II)-mediated coupling of Grignard reagents with alkanenitriles.

The idea of transforming nitriles to cyclopropylamines directly was initially based on our recent approach to cyclopropanes from carbonyl compounds *via* Cp_2Zr chemistry.[6] This reaction involves a deoxygenative contraction of an intermediate oxazirconacycle into a carbocycle under Lewis acid activation conditions [Scheme 1, eqn. (1)]. We envisioned that, in an analogous way, nitriles might be converted to cyclopropylamines following eqn. (2).

However, attempts to perform the reaction by using Cp_2Zr(ethylene) invariably led to complex reaction mixtures. Therefore, we investigated the feasibility of the reaction using the *in situ* formed (ethylene)$Ti(OPr^i)_2$[4,5] instead of (ethylene)zirconocene. We noticed that cyclopropylamines were formed by combining the use of this reagent with the subsequent addition of a Lewis acid, $BF_3{\cdot}OEt_2$ or $TiCl_4$. After optimizing the reaction conditions, synthetically useful yields were obtained. In a representative procedure, to a solution of benzyl cyanide (1 eq.) and $Ti(OPr^i)_4$ (1.1 eq.) in Et_2O was slowly added at rt EtMgBr (2 eq., 1 M solution in ether). After stirring for 1 h, $BF_3{\cdot}OEt_2$ (2 eq.) was added, and the reaction mixture further stirred for 0.5 h at rt. Finally, basic workup (10% NaOH aq) followed by extraction with ether and flash chromatography purification afforded (1-benzyl)cyclopropylamine (**2**) in 70% yield.

The following additional observations gave an insight into the reaction: (i) $BF_3{\cdot}OEt_2$ and $TiCl_4$ gave rise to similar results. (ii) The yields of **2** in the reactions employing $BF_3{\cdot}OEt_2$ were similar in THF and in Et_2O. (iii) Cyclopropylamine **2** was also formed in the absence of the additional Lewis acid, however, in this case, the yields were markedly lower in Et_2O (31%) and negligible in THF (7%); in these reactions benzyl ethyl ketone (**3**) was the major product formed (60% yield in Et_2O and 70% yield in THF). (iv) When using more than 2 eq. of EtMgBr the yield of **2** decreased significantly to detriment of the tertiary carbinamine **4**, which was obtained solely in 67% yield with 4 eq. of EtMgBr. (v) Lowering the quantity of $Ti(OPr^i)_4$ below 1 eq. decreased the yield of **2** to the detriment of **3** and **4**.

The competing reactions to afford compounds **2**, **3** and **4** are summarized in Scheme 2. In accordance with our initial hypothesis, and by analogy with the cyclopropanation of carbonyl compounds,[6] the Lewis acid plays a crucial role for the ring contraction leading to cyclopropane **2**. The reaction differs to that of the Kulinkovich and de Meijere reactions, in which the ring contraction occurs in the absence of an additional Lewis acid, spontaneously from the intermediate oxatitanacycle. In our reaction, in the absence of $BF_3{\cdot}OEt_2$ the intermediate azatitanacycle (cyclic titanium iminate) remains unchanged to furnish the ketone **3** on hydrolysis. The minor formation of **2** in this case can be explained by assuming that weak acid species always present in solution (Mg, Ti) operate, to a significantly lower degree, however, in the more coordinating THF (7% yield of **2**) than in the less coordinating Et_2O (31% yield of **2**). In contrast, when a strong Lewis acid is used, the cyclopropanation step proceeds efficiently (70% yield) in both solvents. The competing formation of **4** also deserves some comments. It is known that simple nitriles do not undergo double alkylation by alkyl Grignard reagents.[7] In contrast, the attack of a second equivalent of EtMgBr on the C atom of the titanium iminate (Scheme 2) would be an efficient process. This reaction possibly opens a simple, general way to tertiary carbinamines.

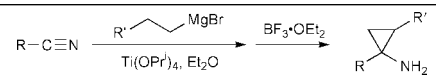
Table 1 Reaction of nitriles with Grignard reagents promoted by $Ti(OPr^i)_4$ and $BF_3{\cdot}OEt_2$



Entry	Nitrile	R′-$(CH_2)_2$-MgBr	Product	Yield[a] (%)
1	 **1**	Et-MgBr	 **2**	70
2	 **5**	Et-MgBr	 **10**	70
3	 **6**	Et-MgBr	 **11**	52
4	 **7**	Et-MgBr	 **12**	53
5	 **8**	Et-MgBr	 **13**	54
6	 **1**	Bu^n-MgBr	 **14**	57 (64:36)[b]
7	 **1**	Bu^s-MgBr	 **14**	54 (55:45)[b]
8	 **1**	Ph$(CH_2)_2$-MgBr	 **15**	51 (68:32)[b]
9	 **9**	Ph$(CH_2)_2$-MgBr	 **16**	54 (68:32)[b]

[a] Yields of isolated products. [b] Mixture of diastereomers.

Furthermore, since an excess of EtMgBr strongly favours the dialkylation over the cyclopropanation reaction, the nucleophilic attack of a Grignard reagent on titanium seems not to be determining the ring contraction.[8]

To further explore the scope of the cyclopropanation reaction we tested other nitriles and Grignard reagents under the optimized reaction conditions. As shown in Table 1, the reaction employing EtMgBr proceeded smoothly from different alkanenitriles to afford the corresponding cyclopropylamines in moderate to good yields (entries 1–5). Both acyclic and cyclic nitriles were used. Particularly, the reaction took place starting from the sterically crowded adamantane-1-carbonitrile (**7**) (entry 4), and the nitrile **8** having the benzyloxy group (entry 5). Benzonitrile and acrylonitrile did not afford the corresponding cyclopropylamines under the conditions used here. The reactions employing other Grignard reagents, namely Bu^{n}MgBr, Bu^{s}MgBr and $PhCH_2CH_2MgBr$, could also be accomplished leading to 1,2-disubstituted cyclopropylamines **14**, **15** and **16** (entries 6–9). Interestingly, starting from the isomeric Grignard reagents Bu^{n}MgBr and Bu^{s}MgBr, the same compound **14** was formed solely (entries 6 and 7). A unique reaction pathway through (but-1-ene)$Ti(OPr^i)_2$ accounts for the totally regioselective formation of **14**. In all cases, a moderate diastereoselectivity of about 2:1 was observed.[9] The very easy separation by flash chromatography of diastereomeric primary cyclopropylamines (**14**, **15** and **16**) is noteworthy,[9] and should be synthetically useful.

In summary, we have presented a new method for the preparation of primary cyclopropylamines. The described reaction involves a cooperative Ti(II) and Lewis acid-mediated coupling of nitriles with Grignard reagents. Simplicity of the procedure, cheap reagents as well as readily available starting materials, and particularly different alkanenitriles, are the major advantages of this method. Studies aimed at further exploring the reaction are currently underway.

A remarkably stable hydrogen-bonded porphyrin·iron(terpyridine) ion pair

Tyler B. Norsten, Kelly Chichak and Neil R. Branda*†

Department of Chemistry, University of Alberta, Edmonton, AB, Canada T6G 2G2

Received (in Columbia, MO, USA) 10th May 2001, Accepted 18th July 2001
First published as an Advance Article on the web 3rd September 2001

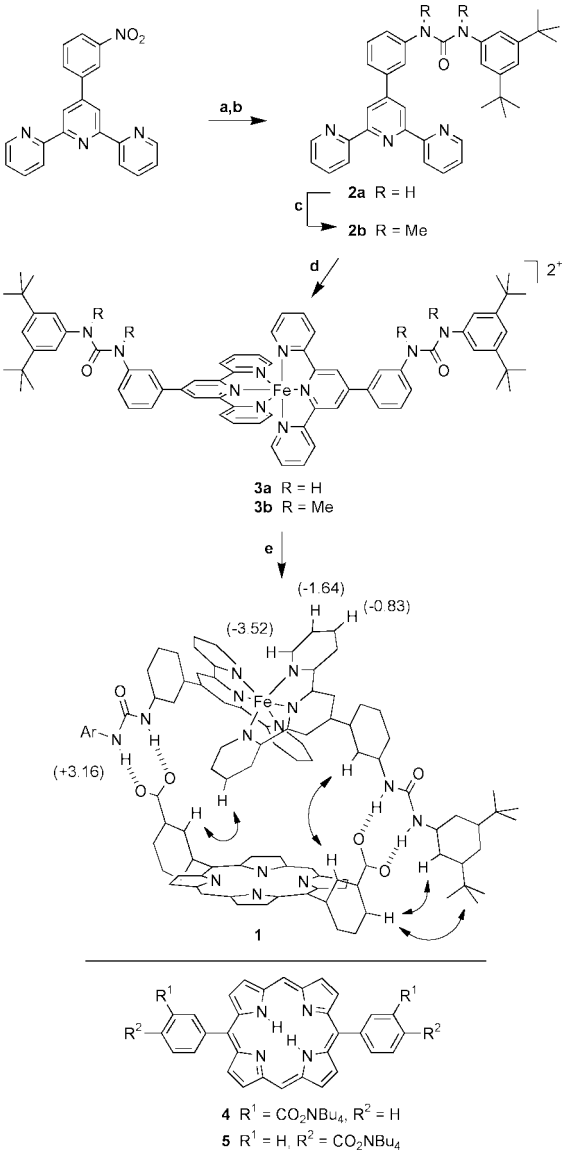
Even in highly competitive solvents such as DMSO, strong bimolecular association and subsequent fluorescence quenching result from the combination of hydrogen bonding and ion pairing between a porphyrinic bis(carboxylate) dianion and an iron(terpyridine) bis(urea).

In naturally occurring light harvesting systems, the relative orientation and proximity of the photoactive components play fundamental roles in the effective operation of the systems. These complex molecular devices rely primarily on non-covalent interactions to place the chromophores in optimal locations to facilitate beneficial electronic communication. Accordingly, significant efforts have been devoted to develop artificial multi-component photoactive arrays, with a particular emphasis on those involving porphyrins.[1–7] Because the photochemical characteristics are ultimately governed by the assemblies' topologies, their fabrication hinges on the tailoring of productive molecular recognition interactions such as coordination bonding,[2,3] ion pairing,[4] π–π stacking[5,6] and hydrogen bonding.[3,7] The hydrogen bond is a particularly serviceable driving force to align building blocks due to its directionality and its ease of tailoring. This is especially true when several hydrogen bonds are united into a multipoint recognition site. The utility of the hydrogen bond is diminished, however, in polar competitive solvents that can better solvate the hydrogen bonding surface. The implementation of cooperative or ionic hydrogen bonding motifs, where the hydrogen bond partners are of opposite charge, can often overcome these destructive solvation effects.[8] Strong complexation is especially critical in order to study energy/electron transfer processes at the low concentrations required by luminescence spectroscopy without having to add excessive quantities of quencher.

We describe here the synthesis and characterization of the novel non-covalently bound porphyrinic assembly **1**. The building blocks were designed to harness the beneficial recognition attributes of both ion pairing and hydrogen bonding interactions. The first interaction is provided by the attraction between the Fe^{2+} dication complex **3a** and the porphyrinic bis(carboxylate) dianion **4**. The carboxylate groups on the porphyrin serve dual roles in that they also act as charged hydrogen bond acceptors for the neutral bidentate urea hydrogen bond donors on the iron(terpyridine) fragment. The result is the self-assembly of neutral complex **1**, which retains both its structural integrity and topology even at low concentrations in polar solvents such as DMSO.

Assembly **1** was prepared by mixing an equimolar mixture of building blocks **3a** and **4** in methanol (Scheme 1). The neutral complex precipitated from the solution and was easily isolated in high purity and in nearly quantitative yield. Owing to the charges balancing in the final complex, 2 equivalents of $[Bu_4N][BF_4]$ were produced in the reaction and were washed away during the filtration. The integration of signals in the ^1H NMR spectrum of the isolated solid supports the claim that the 1:1 complex is the product of the self-assembly process. Electrospray mass spectrometry confirmed this claim as peaks at *m*/*z* 1738.7 and 880.3 corresponding to $[M + Na]^+$ and $[M + 2Na]^{2+}$, respectively, were observed.

Assembly **1** is freely soluble in highly polar solvents such as DMSO and DMF, but is only sparingly soluble in all other common organic solvents. GCOSY and T-ROESY experiments aided in assigning the protons of complex **1**. The complex



Scheme 1 *Reagents and conditions*: (a) $SnCl_2·2H_2O$, EtOH; (b) triphosgene, CH_2Cl_2, then 3,5-di-*tert*-butylaniline, 78% for three steps; (c) NaH, CH_3I, DMF, 50 °C, 99%; (d) $Fe(H_2O)_6(BF_4)_2$, acetone, quantitative; (e) **4**, MeOH, 97%. The double bonds have been removed from structure **1** for clarity. Observed intermolecular nOe's (represented as arrows) and complex induced chemical shifts in the ^1H NMR spectrum (shown in parentheses) are highlighted.

† Current address: Department of Chemistry, Simon Fraser University, 8888 University Drive, Burnaby, B.C., Canada V5A 1S6. E-mail: nbranda@sfu.ca

 DOI: 10.1039/b106430b

induced shift (CIS) values for complex **1** in the ^{1}H NMR spectrum in DMSO-d_6 and the observed intermolecular nuclear Overhauser enhancements (nOe's) are highlighted in Scheme 1. Both experiments support the proposed structure of **1**, where **3a** is straddling across the porphyrin macrocycle and is not lying to its side. The significant downfield shift ($\Delta\delta > 3$ in DMSO-d_6) observed for the urea N–H protons in assembly **1** is indicative of effective hydrogen bonding even in such a polar and competitive solvent. The role of the hydrogen bonds is also to steer the iron(terpyridine) fragment into a position where it lies directly over the porphyrin plane. This guidance is successful as diagnosed by the upfield shifts observed for the hydrogen atoms of **3a** lying directly over the porphyrin plane and within the shielding region of the macrocycle ($\Delta\delta$ are as large as -3.52). The signals for the four hydrogen atoms on the terminal pyridine ring of **3a** are unique in that they appear as broad peaks in the spectrum. We attribute this to the fact that **3a** can be thought of as a 'spit on a barbecue' in which the terpyridine can slowly rotate above the porphyrin ring. The terpyridine protons can, therefore, range in distance from 3.5 to 14.5 Å‡ from the plane of the macrocycle at any given moment affording a variety of possible conformers that can exist within the NMR time-scale. Variable temperature NMR experiments failed to alter the shape of these broadened signals.

The strength of the binding between **3a** and **4** was too large to be accurately measured by ^{1}H NMR spectroscopy even in DMSO-d_6. Isothermal titration calorimetry (ITC) experiments in DMSO, however, indicated a binding stoichiometry of 1 : 1 for **3a** and **4** and an impressive value for the association constant (K_a) of $(2.47 \pm 0.44) \times 10^6$ M^{-1}. When the ITC experiments were repeated replacing **3a** with the *N*,*N*′-dimethylated analog **3b**, that can only associate through ion pairing, the heat released upon binding was so small that the association constant was impossible to estimate. The titration of **5** with **3a** also revealed a similar trend, despite the fact that the **3a**·**5** complex can be isolated as a solid in a similar fashion as for **1**. In this case, the hydrogen bonds are not suitably positioned to operate in unison and direct the formation of a strapped 1 : 1 complex. Although the ^{1}H NMR spectrum in DMSO-d_6 does reveal a 1 : 1 stoichiometry between **3a** and **5**, the signals for the urea N–H protons shift only 1 ppm downfield, and there is no observable shift of the signals corresponding to the C–H protons on the iron(terpyridine) fragment. This indicates that **3a** does not reside over the plane of **5** and the 1 : 1 complex should really be thought of as an aggregate $(\mathbf{3a}\cdot\mathbf{5})_n$. These experiments clearly highlight that ion pairing contributes to the association of **1**; however, the cooperative hydrogen bonds aid in aligning the building blocks into close proximity so that these ion pairing attractive forces can be maximized.

The relative positioning of **3a** and **4** within **1** has a significant impact on the photophysical behavior of the final assembly. Studies using steady-state fluorescence spectroscopy to monitor the changes in the emission intensities of DMSO solutions of **4** and **5** as the porphyrins were treated with aliquots of **3a** are shown in Fig. 1. The immediate quenching of the fluorescence of **4** is most likely a direct result of the straddling nature of the iron(terpyridine) fragment which positions the two chromophores into the most intimate arrangement possible and ensures maximum through-space communication. The fluorescence quenching of porphyrin **4** by **3a** is clearly a result of both strong bimolecular association and optimal spatial positioning of the two chromophores. The *N*,*N*′-dimethylated analog **3b**, on the other hand, only slightly quenched the fluorescence of **4** presumably in a dynamic, collision-based process. A similar low level of quenching was obtained when porphyrin **5** was titrated with **3a**. Despite the fact that both hydrogen bonding and ion pairing are present in the $(\mathbf{3a}\cdot\mathbf{5})_n$ polymolecular assembly, the terpyridine fragment cannot form a strapped arrangement, and any through-space communication between the chromophores is significantly reduced. Impressively, similar photophysical behavior of assembly **1** was observed in a 10% H_2O/MeCN solution attesting to the strength of the association between building blocks **3a** and **4** even in an aqueous environment.

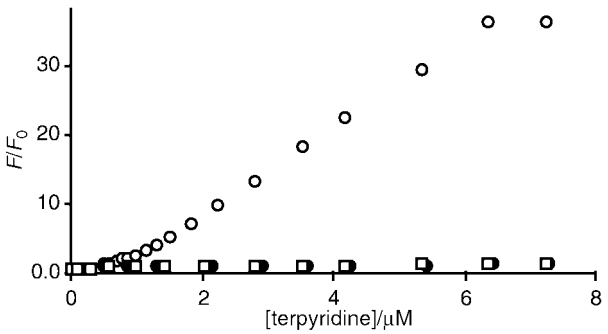


Fig. 1 Stern–Volmer quenching when a DMSO solution of **4** is titrated with **3a** (○), with **3b** (□), and when **5** is titrated with **3a** (●) (λ_{ex} = 415 nm, λ_{em} = 633 nm). Concentrations: [**4**] and [**5**] = 1.0×10^{-6} M, [**3a**] and [**3b**] = 2×10^{-5} M.

Ring opening–cross metathesis of unstrained cycloalkenes

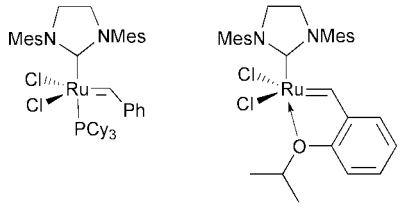
Stefan Randl, Stephen J. Connon and Siegfried Blechert*

Institut für Chemie, Technische Universität Berlin, Strasse des 17. Juni 135, 10623 Berlin, Germany. E-mail: blechert@chem.tu-berlin.de; Fax: +49 30 31423619

Received (in Cambridge, UK) 23rd July 2001, Accepted 3rd August 2001
First published as an Advance Article on the web 4th September 2001

Unstrained cycloalkenes undergo ruthenium-catalysed ring opening–cross metathesis reactions with simple α,β-unsaturated carbonyl compounds under mild conditions.

Over the last decade, olefin metathesis has emerged as a powerful tool for the formation of carbon–carbon double bonds.[1] Due to their excellent activity and functional group tolerance, ruthenium complexes with sterically demanding *N*-heterocyclic carbene (NHC) ligands (**1** and **2**) have proved to be

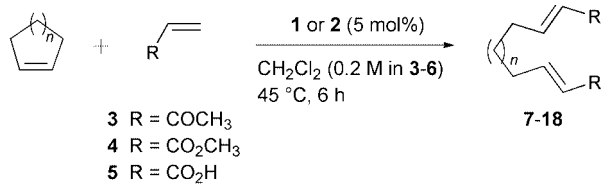


1 **2**

Cy = Cyclohexyl
Mes = 2,4,6-trimethylphenyl

an important development in this field. Our group[2] and others[3] have investigated the catalytic properties of the readily prepared phosphine-free catalyst **2**. In the case of cross metathesis (CM) with α,β-unsaturated carbonyl compounds catalysed by **1**, the formation of the relatively unstable acceptor substituted carbene species was rejected.[4] However, Grubbs *et al*. have demonstrated that β-carbonyl ruthenium carbene species generated from diazoacetate are highly active, reacting in stoichiometric quantities with cyclohexene to afford new ruthenium carbene complexes.[5] Little is known about the ring opening–cross metathesis (ROM-CM) of unstrained cycloolefins,[6] and since **1** and **2** can promote highly efficient CM reactions with α,β-unsaturated carbonyl compounds,[2] we wondered if catalytic ROM-CM reactions of low-strain cycloolefins could be accomplished *via* highly reactive β-carbonyl ruthenium carbene intermediates.

Preliminary studies were carried out with cyclohexene and various electron deficient olefins. We found that methyl vinyl ketone (**3**), methyl acrylate (**4**), acrylic acid (**5**) and acrylaldehyde (**6**) were suitable substrates for ROM-CM, whereas vinyl sulfones, nitriles and amides gave poor results. Encouraged by these findings, we investigated the ROM-CM of unstrained cycloolefins (Scheme 1) such as cyclopentene, cyclohexene and cycloheptene (3.0 eq.), with simple α,β-unsaturated carbonyl compounds **3**–**6**.† It was also decided to compare the activity of catalysts **1** and **2** in these reactions. The results of these experiments are outlined in Table 1.



Scheme 1

In almost all cases moderate to excellent yields of ring opened double-cross products (**7**–**18**) were obtained. In addition, several trends were observed. Firstly, as expected,[2] phosphine-free catalyst **2** gave better cross product yields than **1**; secondly, the order of reactivity of the cycloalkene substrates was cycloheptene ≥ cyclopentene > cyclohexene presumably due to ring strain. In addition, acrylic acid gave especially good results over the range of substrates.

Having established that efficient ROM-CM of unstrained cycloolefins is possible, we wished to extend this methodology to both functionalised and heterocyclic compounds. Thus, **19**–**25** were subjected to ROM-CM conditions, using catalyst **2** (5 mol%) and CM partners **3**, **4** and **5** (Table 2). Given the high reactivity of cyclopentene, the failure of 5- and 6-membered *N*-heterocycles **19** and **20** to give ring-opened products was somewhat surprising. In these reactions, only dimerisation of the electron deficient olefin occurred. At this time it is not known if this lack of ROM reactivity is attributable to either an internal complexation of the heteroatom to ruthenium during the catalytic cycle, or to the electron withdrawing effect of the tosyl-protected nitrogen atom on the 'allylic' double bond. In this regard it is interesting to note that dihydrofuran **23** gave only moderate yields of double-cross product. In the case of **21**, the 7-membered analogue of **19** and **20**, this effect is obviously less important than relief from ring strain, as good CM product yields were obtained. This is supported by the fact that the yields of **32**, **33** and **34** are in good correlation with those of **35**, **36** and **37** derived from **22**, where the olefin double bond is one methylene unit further removed from the heteroatom. Epoxycyclooctene **24** also gave smooth conversion to **41**, **42** and **43**, however bicyclic lactone **25** did not react, possibly due to steric factors.

Given that neither polymeric nor terminal olefinic products were detected even in the presence of excess cycloolefin, it is clear that the first step in the catalytic cycle is reaction between **1** or **2** and the electron deficient olefin to afford reactive carbene intermediates of general type **47**, which then ring-open the substrate to form a second alkylidene **48** (Scheme 2).

Table 1 Performance of **1** and **2** in ROM-CM with electron deficient alkenes

Product[a]	Yield (%)[b] using cat. **2**	Yield (%)[b] using cat. **1**
7 n = 1, R = $COCH_3$	86	62
8 n = 1, R = CO_2CH_3	90	79
9 n = 1, R = CO_2H	83	57
10 n = 1, R = CHO	83	30

12 n = 2, R = CO_2CH_3	66	47
13 n = 2, R = CO_2H	80	38
14 n = 2, R = CHO	45	5
15 n = 3, R = $COCH_3$	87	87
16 n = 3, R = CO_2CH_3	97	80
17 n = 3, R = CO_2H	83	70
18 n = 3, R = CHO	90	75

[a] Only the *E*-isomers were detected in all cases. [b] Determined by ^{1}H NMR using (*E*)-stilbene as an internal standard.

 DOI: 10.1039/b106558k

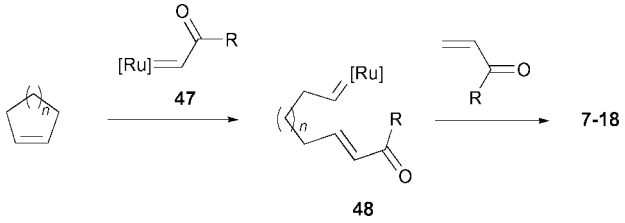
Table 2 ROM-CM of functionalised cycloolefins

Cycloolefin	Products with **3**, **4** and **5** (% Yield)[a,b]			
 **19**		**26**	R = $COCH_3$	(0)
		27	R = CO_2CH_3	(0)
		28	R = CO_2H	(0)
 **20**		**29**	R = $COCH_3$	(0)
		30	R = CO_2CH_3	(0)
		31	R = CO_2H	(0)
 **21**		**32**	R = $COCH_3$	(79)
		33	R = CO_2CH_3	(70)
		34	R = CO_2H	(85)
 **22**		**35**	R = $COCH_3$	(75)
		36	R = CO_2CH_3	(90)
		37	R = CO_2H	(82)
 **23**		**38**	R = $COCH_3$	(42)
		39	R = CO_2CH_3	(0)
		40	R = CO_2H	(60)
 **24**		**41**	R = $COCH_3$	(84)
		42	R = CO_2CH_3	(92)
		43	R = CO_2H	(80)
 **25**		**44**	R = $COCH_3$	(0)
		45	R = CO_2CH_3	(0)
		46	R = CO_2H	(0)

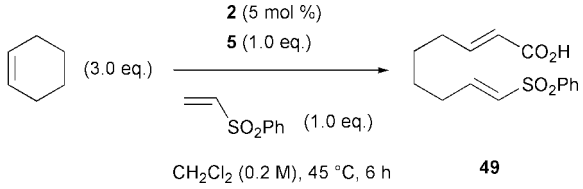
[a] Only the *E*-isomers were detected in all cases. [b] Determined by ^{1}H NMR using (*E*)-stilbene as an internal standard.

The intermediacy of **48** suggested that a ring opening double cross metathesis reaction with two different CM partners could be possible. In order to test this, cyclohexene (3.0 eq.) was ring opened in the presence of **2** (5 mol%), **5** (1.0 eq) and phenyl vinyl sulfone (1.0 eq.) to give 25% yield (by ^{1}H NMR) of double cross product **49** (Scheme 3).

In summary, the novel ROM-CM of relatively unstrained carbo- and heterocycles to give ring opened bis-α,β-unsaturated carbonyl compounds has been described. Phosphine free catalyst **2** has been shown to possess a superior activity



Scheme 2



Scheme 3

compared to **1** in these reactions. The bis-functionalisation of cyclohexene with two different CM partners using a ROM-CM strategy has also been demonstrated. Further investigations along these lines are in progress in our laboratories.

We would like to thank the 'Fonds der Chemischen Industrie' for financial support. S. R. and S. J. C. thank the Graduiertenkolleg "Synthetische, mechanistische und reaktionstechnische Aspekte von Metallkatalysatoren" for their stipends.

Notes and references

† All new compounds were purified by column chromatography and fully characterised. Representative procedure: a solution of cyclohexene (0.40 mL, 3.95 mmol), **2** (125.4 mg, 0.2 mmol) and **5** (0.18 mL, 2.62 mmol) in CH_2Cl_2 (13 mL, 0.2 M in **5**) was stirred at 45 °C for 6 h under a nitrogen atmosphere, after which time the solvent was evaporated and (*E*)-stilbene added as an internal standard. The product yield was determined by ^{1}H NMR analysis of the crude mixture.

Barbier reaction in the regime of metal oxide: the first example of carbonyl allylation mediated by tetragonal tin(II) oxide†

Pradipta Sinha and Sujit Roy*

Organometallics & Catalysis Laboratory, Chemistry Department, Indian Institute of Technology, Kharagpur 721302, India. E-mail: sroy@chem.iitkgp.ernet.in; Fax: +91 3222 82252; Tel: +91 3222 83338

Received (in Cambridge, UK) 22nd May 2001, Accepted 25th July 2001
First published as an Advance Article on the web 4th September 2001

Facile synthesis of homoallylic alcohols is achieved from allyl halides and aldehydes or ketones over an all-oxide heterogenous media involving β-SnO and catalytic Cu_2O.

The reaction of a carbonyl compound and an organic halide in the presence of magnesium metal, trivially known as the Barbier reaction, has carved a distinct niche in synthetic organic and pharmaceutical chemistry.[1] In the hundred years, since its original discovery,[2] this one-pot variant of the Grignard reaction has been demonstrated solely with zerovalent metals, and metal halides.[3] With specific reference to carbonyl allylation *via* tin reagents,[4] both preformed as well as *in situ* generated allylstannanes continue to evoke widespread[5] interest due to their chemo-, regio-, stereo-, and enantioselecivity aspects. Our continuing interest[6] in organotin chemistry and recent interest in heterobimetallic reagents, prompted us to explore a gateway into the Barbier reaction *via* metal oxides. We are delighted to disclose herein a facile carbonyl allylation reaction over tetragonal tin(II)oxide (β-SnO)[7] and catalytic Pt(II), Pd(II), Pd(0), Cu(I) salts/complexes in organic–aqueous or aqueous medium (Scheme 1). *Further extension to β-SnO/catalytic Cu_2O affords an all-oxide reagent in Barbier allylation*. We believe that the results provide new directions in the synthetic and mechanistic issues of Grignard type carbon–carbon bond forming reactions across metal oxides.

The model reaction of 1-bromoprop-2-ene **1a** (2 mM) and 4-chlorobenzaldehyde **2a** (1 mM) in the presence of catalytic $PtCl_2(PPh_3)_2$ **4a** (0.01 mM) and β-SnO (1.5 mM) in THF–water (9 : 1 v/v) at 70 °C for 6 h gives rise to the desired homoallylic alcohol 1-(4-chlorophenyl)but-3-ene-1-ol **3a** in 96% isolated yield (Table 1, entry 3).[8] Under identical conditions, uncatalyzed reaction affords < 15% of the product. Also important is the remarkable effect of water: reaction in the presence of catalyst **4a** but in dry THF yields < 15% of the product, while reaction in water alone gives rise to 55% of the desired alcohol. That there is no phase change of β-SnO before and after treatment with THF–water, is indicated by XRD. Among the other catalysts screened, $NiCl_2(PPh_3)_2$, $PdCl_2(PhCN)_2$ and $Pd_2(dba)_3{\cdot}CHCl_3$ are found unsatisfactory (< 25% yields), but $PdCl_2(PPh_3)_2$, $Pd_2(dba)_3$, and CuCl afford moderate to excellent yields of product. The generality of the reaction has been successfully tested with aliphatic, aromatic and heteroaromatic aldehydes and substituted allyl bromides (Table 2, entry 1–5).

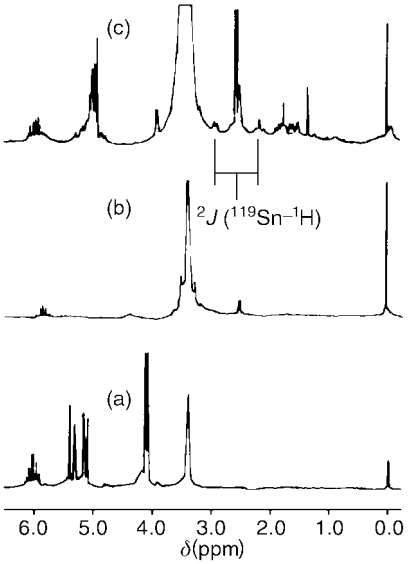

Fig. 1 ^{1}H NMR spectra in DMSO-d_6 of (a) allyl bromide; (b) residue from the reaction of β-SnO–allyl bromide; (c) residue from the reaction of β-SnO–allyl bromide–catalytic $Pd_2(dba)_3$ [dba = dibenzylideneacetone].

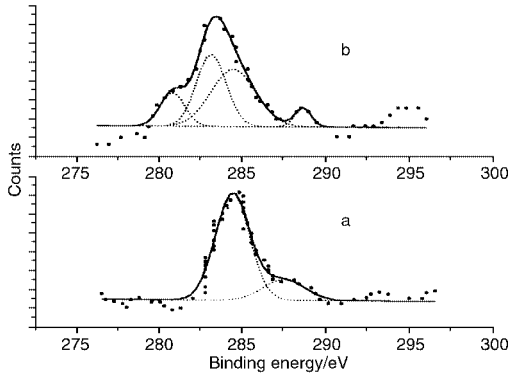

Fig. 2 XPS spectra in the C-1s region of (a) untreated β-SnO/Cu_2O—peaks at 284.5, 287.6; (b) β-SnO/Cu_2O after treatment with allyl bromide—peaks at 280.8, 283.2, 284.5, 288.9.

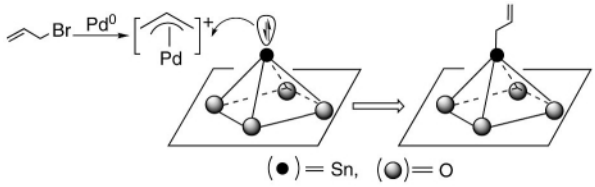
Triggered by the success as above, we wished to attempt *an all-oxide reagent* for carbonyl allylation. The reagent combination of β-SnO and catalytic Cu_2O in refluxing DCM–water (9 : 1 v/v) is adjudged to be the best (Table 1, entry 5–6; Table 2, entry 6–9).

While mechanistic studies are underway in our laboratory, preliminary experiments clearly establish the formation of new tin–carbon bonded species during the course of the reaction. Thus, a mixture of β-SnO (2 mM), catalytic $Pd_2(dba)_3$ (0.02 mM) and allyl bromide (4 mM) in THF–H_2O (99 : 1 v/v) was refluxed for 10 h. Following filtration under argon, and solvent removal, the residue was examined by ^{1}H NMR. The spectrum (Fig. 1, spectrum c) showed the formation of a new σ-allyl tin species[9] characterized by allylic proton signals at 2.55 ppm [^2J(^{119}Sn–^{1}H) = 154 Hz], as compared to that of allyl bromide at 4.1 ppm (spectrum a). No such species was detected in the reaction without catalyst (Fig. 1, spectrum b). On the other hand, reaction of allyl bromide with $Pd_2(dba)_3$ alone, showed signals due to known π-allylpalladium intermediate.[10] We conclude that the latter assists the formation of the σ-allyl tin species (Scheme 2).[11]

Unlike the above, we could not detect any soluble organotin species in the reaction of allyl bromide with β-SnO/catalytic Cu_2O, thereby indicating that the incipient metal–carbon intermediate is formed in the solid phase. To test this hypothesis, narrow scan XPS analysis was performed for β-SnO/Cu_2O before and after its reaction with allyl bromide. Formation of new species is indicated by major shifts in the binding energies of Sn ($3d_{5/2}$, $3d_{3/2}$), Cu ($2p_{3/2}$, $2p_{1/2}$), O (1s) and C (1s) peaks.[12] Multi-Gaussian peak analysis of carbon-1s spectra shows two new peaks at 280.8 and 283.2 eV (Fig. 2, spectrum b) indicative of metal–carbon bonded species. Prior interaction of alkene with copper(I) is likely to promote the formation of an allyltin intermediate.[13] We hope to address this and related mechanistic issues in future studies.



Scheme 2 π-Allylpalladium attacks tetragonal tin(II) oxide.

We thank CSIR, UGC and DST for financial support.

8 Typical procedure: a mixture of **1a** (242 mg, 2 mM) and **2a** (140 mg, 1 mM) in THF (2 mL) was added slowly to a refluxing solution containing β-SnO (202 mg, 1.5 mM) and **4a** (8 mg, 0.01 mM) in THF–H_2O (2.5 mL–0.5 mL) and under argon. Upon completion (TLC monitoring: silica gel, eluent: *n*-hexane–EtOAc 9 : 1), an aqueous solution of NH_4F (15%, 10 mL) was added to the reaction mixture and the organic layer was extracted with diethyl ether (3 × 10 mL), washed with water (2 × 10 mL), brine (2 × 10 mL) and dried over magnesium sulfate. Solvent removal followed by column chromatography (eluent *n*-hexane–ethyl acetate 9 : 1) afforded pure **3a** (175 mg, 96% w.r.t. aldehyde). Similar procedure as above was followed for reactions with Cu_2O as catalyst (14 mg, 0.1 mM), the solvent used was CH_2Cl_2–H_2O (4.5 mL–0.5 mL).

A new enzymatic synthesis of pyruvic acid from acetaldehyde and carbon dioxide has been developed.

Because global environmental pollution has recently become a serious problem, it is advantageous to develop a clean chemical process, which produces low emissions and organic wastes. Biocatalytic reactions attract attention as environmentally safe catalytic reactions in organic synthesis.[1] Several enzymatic processes have been designed and used as alternative organic processes.

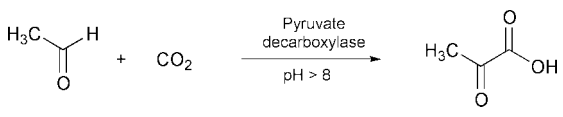
Pyruvate decarboxylase (EC 4.1.1.1) is known as a catalyst of the decarboxylation reaction of pyruvic acid, to produce acetaldehyde. The mechanism of catalytic reaction of pyruvate decarboxylase has been elucidated. This enzyme requires thiamin pyrophosphate as a coenzyme for catalytic activity.[2] As for other thiamin pyrophosphate dependent enzymes, this enzyme has been interesting as a catalyst for carbon–carbon bond formations.[3–5] Pyruvate decarboxylase has been intensively studied as a carboligase for synthesis of chiral α-hydroxy ketones, which are versatile building blocks for organic and pharmaceutical chemistry.

The reverse reaction of this enzyme is also of interest as a catalytic procedure for carboxylation. Several studies have been performed which imitate these enzyme reactions using CO_2 as the reactant.[6–8] A previous study using α-lactoylthiamin showed that production of pyruvate was achieved at higher pH (>10).[8] However, these reactions require organic solvents and severe conditions.

We are interested in the development of novel enzymatic reactions and reactor systems having environmentally safe chemical processes. In the present study, we demonstrate the usefulness of the reverse reaction of pyruvate decarboxylase in the production of pyruvic acid from acetaldehyde and carbon dioxide (Scheme 1).

We chose a sodium bicarbonate buffer system, because not only is this buffer suitable at higher pHs, but it also can be used as the source of carbon dioxide. A typical run was as follows. To a solution of acetaldehyde (100 μM) in sodium bicarbonate buffer (1 ml) in a 1.5 ml microcentrifuge tube, Brewer's yeast pyruvate decarboxylase (1 unit) and thiamin pyrophosphate (the final concentration was 10 μM) were added at 4 °C. The reaction mixture was warmed to 25 °C quickly, and then shaken on a vortex mixer at room temperature. After 1 h, the reaction mixture was chilled on ice, and then subjected to HPLC analysis immediately. The amount of pyruvic acid was calculated from the peak area of HPLC analysis calibrated with commercially available pyruvic acid standards. The yield was estimated based on acetaldehyde.

First, we evaluated the effect of pH on the reaction. The reaction was performed using acetaldehyde (100 μM), thiamin



Scheme 1 Synthesis of pyruvic acid.

(0.1 μM), and pyruvate decarboxylase (1 unit) in 0.1 M $NaHCO_3$–Na_2CO_3 buffer at various pHs (pH 8.5–11.5). The result is shown in Fig. 1. Higher pHs gave a better yield of pyruvic acid. The maximum yield was obtained at pH 11 (61%). The present result agreed well with a previous observation obtained from the hydrolysis of α-lactoylthiamin. In that case, the best yield from hydrolysis was obtained at pH 12. In our case, the best yield was obtained at pH 11, but the yields decreased at much higher pH. Although the hydrolysis proceeds at a maximum rate at pH 12, the enzyme might not be stable over pH 11. Therefore, the maximum yield was obtained at pH 11. Thus, we decided to perform further experiments at pH 11.

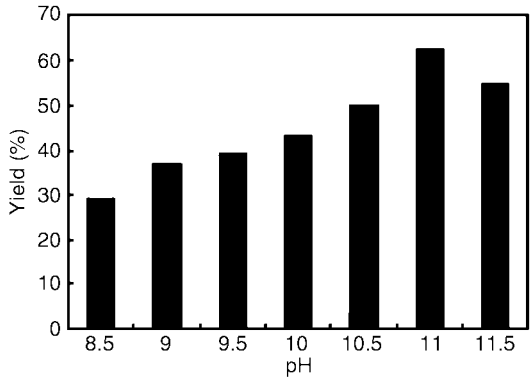


Fig. 1 Effect of pH on pyruvic acid production.

Next, we examined the effects of concentration of bicarbonate buffer on the reaction (Fig. 2). Higher ionic strength of the bicarbonate buffer strongly influenced the yield, as expected. The maximum yield of the reaction was 81% at 500 mM $NaHCO_3$–Na_2CO_3 buffer. This yield was sufficient to use as an organic process, and much higher than that obtained by the reaction in DMF under 20 atm of CO_2.[8] Not only does the latter reaction require multiple steps, but the use of the organic solvent DMF is problematic for environmental safety reasons. The enzymatic reaction does not require any organic solvent and gave a better yield. It has been reported that the thiamin itself

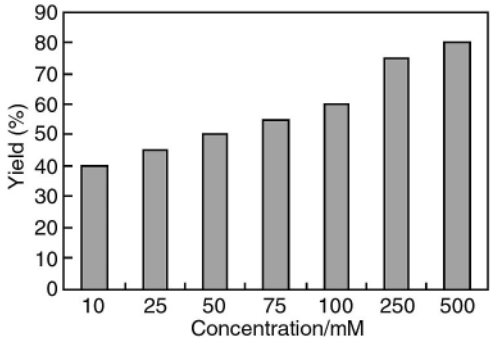

Fig. 2 Effect of ionic strength on enzyme reaction.

 DOI: 10.1039/b104873m

could catalyze a reaction analogous to that of the enzyme, but preparation of the intermediate lactoylthiamin from acetaldehyde was unsuccessful. Thus, it is difficult to reverse the reaction without an enzyme, and pyruvate decarboxylase is the best catalyst for carboxylation of acetaldehyde.

Recently, some enzymatic reactions utilizing supercritical carbon dioxide have been reported.[9,10] In our method, a higher concentration of carbon dioxide is required. The supercritical conditions might be effective at improving the yield of pyruvic acid synthesis, because they should provide a much higher carbon dioxide concentration. The reaction in supercritical carbon dioxide conditions will be our next subject.

Although the effect is much weaker than methane, carbon dioxide is considered to be a greenhouse gas, and therefore its immobilization is desired. The methods currently reported are mainly catalytic or electrochemical reactions, which require much energy.[11–13] One alternative method has been reported, which utilized carbonic anhydrase for the immobilization of carbon dioxide.[14] This biomimetic approach needs almost no energy for the reaction. However, the carbonic anhydrase just improves the solubility of carbon dioxide in aqueous media, and further treatment of dissolved gas is required. Although the reaction requires a large excess of CO_2, our approach can be useful for such a purpose. By our method, the carbon dioxide in the aqueous phase can be condensed with acetaldehyde to produce the pyruvic acid. Because pyruvic acid can easily be converted into lactic acid, which is a constituent of a biodegradable plastic, the carbon dioxide can be immobilized into the biological cycle. An enzymatic reaction by lactic dehydrogenase can be used for hydrogenation of pyruvic acid into lactic acid. Thus, it is possible to design a two-step enzymatic process as a completely environmentally safe method for CO_2 immobilization.

In summary, we have demonstrated the usefulness of the reverse reaction of pyruvate decarboxylase. This reaction might become a recommendable, environmentally safe carboxylation procedure for acetaldehyde. Further studies, such as the reaction utilizing supercritical carbon dioxide, and two-step enzymatic production of lactic acid, are in progress in our laboratories.

We thank Drs Masao Shibata, Tsuyoshi Sakaki, Hiroaki Kodama and Shoji Ando, for their continuous supports.

Received (in Cambridge, UK) 9th May 2001, Accepted 7th August 2001
First published as an Advance Article on the web 5th September 2001

Novel alkenylene-bridged oligosilsesquioxanes composed of half-caged structures with 16- or 17-membered rings as well as a titanium-containing molecule with a twisted 21-membered macrocycle have been synthesized by ruthenium or rhodium-catalyzed ring-closing reactions of silsesquioxanes with bis(allyldimethylsilyl) groups.

Recently, development of novel organic–inorganic hybrid materials, such as organic functionalized micro- and mesoporous materials, has attracted widespread attention because of the novel catalytic activities and physical properties of these substances.[1] Since silsesquioxanes and spherosilicates with cage-like core structures are expected to be candidates for building blocks of such materials, a number of silsesquioxanes with organic functional groups have been synthesized by various methods[2] including ruthenium or molybdenum-catalyzed cross-metathesis.[3] Porous materials are reported to be obtained by the hydrosilylative polymerization of T_8 cubes.[2d,4] Therefore, synthesis of oligosilsesquioxanes with novel core structures is of great importance. On the other hand, the synthesis of silacycloalkenes, which incorporate an alkenylene unit in the ring system, has attracted growing interest from the viewpoint of materials chemistry,[5] and various methods[6] for the synthesis of these compounds by catalytic ring-closing metathesis (RCM) reactions[7] have been developed.

Here we report the synthesis of silsesquioxanes containing novel organic–inorganic hybrid half-caged core structures. The ring-closing reactions of bis(allyldimethylsilyl)-substituted silsesquioxanes in the presence of a catalytic amount of a ruthenium or rhodium complex successfully gave novel alkenylene-bridged oligosilsesquioxanes composed of 16-, 17- and 21-membered macrocycles in high yields.

A silsesquioxane with two allyldimethylsilyl groups **1a** was prepared by the stepwise silylation of silsesquioxane disilanol $(c\text{-}C_5H_9)_7Si_7O_9(OSiMe_3)(OH)_2$ (**2**) by allylchlorodimethylsilane.[8] The RCM reaction of **1a** promoted by stepwise addition of 13 mol% of the ruthenium benzylidene complex, $\{(C_6H_{11})_3P\}_2Cl_2Ru{=}CHPh$ (**3**),[7] at 65 °C for 54 h, followed by column chromatography and reprecipitation afforded the desired novel half-caged oligosilsesquioxane with a 17-membered ring **4a** in an isolated yield of 94% as a mixture of *cis* and *trans* isomers.‡ At present, the major isomer is assigned to be *cis* on the basis of IR and ^{13}C NMR, and the ratio of *cis*:*trans* was estimated to be 4.9:1. The preliminary X-ray analysis of a single crystal of the major isomer established the structure illustrated in Scheme 1 with *cis* configuration of the butenylene bridge,§ although the complete solution of the structure was hampered by poor diffraction in the high angle region ($2\theta > 30°$) and severe disorder at trimethylsilyl and cyclopentyl groups. According to the ^1H NMR spectrum, these single crystals were composed of the major isomer. The undesired intermolecular reaction was not observed. The ^{29}Si NMR spectrum of *cis*-**4a** consists of one set of five peaks in a 1:1:2:2:1 ratio for seven silicon atoms in the silsesquioxane cage, which is in good accordance with the local C_s-symmetry of the siloxane framework. Note that the RCM reaction with a smaller amount of a ruthenium catalyst (reduced to 5 mol%) also gave **4a** in 85% yield (by ^1H NMR).

The treatment of **1b**, which has three allyldimethylsilyl groups, by stepwise addition of 10 mol% of **3** at 65 °C for 36 h afforded **4b**, a silsesquioxane containing both terminal and internal alkenyl groups, in 90% yield as a mixture of *cis* and *trans* isomers in a 5.6:1 ratio.

The synthesis of a titanium-containing silsesquioxane with a more extended alkenylene-bridged macrocycle by the RCM reaction was examined. The RCM reaction of a titanium-containing silsesquioxane having two allylic moieties **6**[8] (prepared by the reaction of an allyldimethylsilyl-substituted silsesquioxane disilanol **5** with tetrakis(diethylamino)titanium) in the presence of 15 mol% of the ruthenium catalyst **3** at 65 °C for 54 h afforded the desired silsesquioxane **7** in 74% yield (*cis*:*trans* = 4.4:1). The product (**7**) which contains an organic–inorganic hybrid 21-membered macrocycle, was fully characterized by NMR, IR, FAB-MS, and elemental analysis. ^1H and ^{13}C NMR measurements indicate the presence of one butenylene unit together with two half-caged silsesquioxane cores in **7**. The ^{29}Si NMR spectrum of *cis*-**7** consists of eight peaks of almost the same intensity for sixteen silicon atoms in the molecule, which indicates the apparent local C_2-symmetry of its siloxane framework.

On the other hand, treatment of **1a** with 10 mol% of the rhodium complex Cp*Rh(ethylene)$_2$ **9** produced a *trans*-propenylene-bridged silsesquioxane **8a** in an isolated yield of 90%, which has a 16-membered ring. There was no sign of the *cis* isomer in the crude reaction mixture. Note that the reaction in toluene instead of ethanol did not proceed at all, strongly suggesting that formation of a rhodium hydride species is crucial for the present reaction. Although the present untypical formation of (*E*)-propenylene-bridges has been reported in the $RuHCl(CO)(PPh_3)_3$ or $RuCl_2(PPh_3)_3$–catalyzed coupling or polycondensation of allylsilanes,[9–11] the use of these ruthenium catalysts in toluene at 80 °C reduced the yield of **8a** drastically (less than 25% by ^1H NMR), where considerable isomerization of **1a** to 1-propenylsilyl-substituted silsesquioxanes occurred. These reactions previously had been explained in terms of isomerization of allylsilanes to 1-propenylsilanes followed by metathesis,[9] but a mechanism including the formation of a silylmetal species *via* the silyl group transfer is now generally accepted.[11,12] Treatment of a titanium-containing silsesquioxane **6** under similar reaction conditions, however, did not give any desired propenylene-bridged product, and only the isomerization of allylic groups was observed.

In conclusion, a series of novel alkenylene-bridged silsesquioxanes with 16- to 21-membered rings were synthesized in high yields by ruthenium or rhodium complex-catalyzed reactions. These molecules are quite interesting as building blocks for new materials or a platform for novel macrocyclic

Equimolar mixtures of ethyl diazoacetate and alkynes can be converted into cyclopropenes in very high yields, at room temperature, through the intermediacy of readily available Cu(I) catalysts containing trispyrazolylborate ligands.

Carbon–carbon unsaturated bonds can be converted into three-membered rings by the intermediacy of metal-based catalysts and the appropriate carbene source.[1,2] Thus, a diazo compound and an olefin lead to cyclopropanes whereas the same carbene precursor and alkynes afford cyclopropenes (Scheme 1). Despite the obvious similarities between both reactions, most efforts have been devoted to the former transformation, the catalytic systems reported to date for the cyclopropenation reaction being reduced to a few, and mainly based on copper and rhodium. Copper bronze, Cu(I) and Cu(II) salts have been employed as catalysts for the cyclopropenation reaction, but high temperatures (90–140 °C) were required and yields were low.[3] At room temperature, $Rh_2(OAc)_4$ has been the catalyst of choice for this transformation, as reported by Hubert *et al.*[4] Related chiral derivatives of the type $Rh_2(L–L^*)_4$ have been developed by Doyle and co-workers,[5] inducing high enantiomeric excesses. However, there are two major drawbacks to address in this field. First, those rhodium catalysts do not operate with internal alkynes, or if so, yields are quite low. Secondly, and despite the use of high alkyne–EDA (ethyl diazoacetate) ratios, only moderate to high conversion yields have been achieved (40–85%), the quantitative conversion being still elusive.

The catalytic capabilities of the homoscorpionate complex Tp*Cu(C_2H_4) (**1**) (Tp* = hydrotris(3,5-dimethylpyrazol-1-yl)-borate (1), towards the alkyne cyclopropenation reaction were reported a few years ago.[6] Those preliminary results showed that both internal and alk-1-ynes could be converted into the corresponding cyclopropenes with moderate yields (40–65%). Complex Tp*Cu[7] (**2**) displays the same catalytic behaviour, with the advantage of its higher stability in comparison with **1**. Complexes **1** or **2** also catalyse the conversion of olefins into cyclopropanes[8] and epoxides,[9] both under homogeneous and heterogeneous conditions, as well as the aziridination of alkenes.[6,9] This remarkable behaviour has been now expanded to the achievement of higher degrees of alkyne cyclopropenation. It is worth mentioning that the main problem in these transformations is the formation of diazoacetate-coupling products: diethyl fumarate and maleate are also formed when EDA is employed as the carbene source. Usually, this is avoided by using a large excess of the alkyne with respect to EDA, and by adding the diazocompound by means of slow-addition devices onto the alkyne and catalyst-containing solution. As a consequence of our knowledge on the olefin cyclopropanation reaction, we have learnt that there is an enormous dependence of the three-membered ring yields on the reaction design, particularly the catalyst concentration and the carbene precursor addition rate. Fig. 1 shows the results of the hex-3-yne cyclopropenation reaction obtained from three experiments at three different concentrations of complex **2**. The initial hex-3-yne concentration was fixed at 0.45 M and EDA (0.15 M) was added with two different addition rates (0.15 and 1.5 mmol h^{-1}). The use of initial [**2**] of 0.0075 M (1:20:60 of [Cu]–[EDA]–[hex-3-yne]) induced the almost quantitative conversion into the corresponding cyclopropene, whereas a third of that value caused a 50% decrease of the product. As expected, an increase in the addition rate of EDA diminished the yields, but the same trend was observed upon varying [Cu]. These results are in accord with the reaction pathway proposed for the related cyclopropanation reaction with this type of catalyst.[10]

With this knowledge, we have tested an array of trispyrazolylborate ligands[11] (Fig. 2) in which R^1–R^3 can be modified to tune the electronic and steric effects induced to the metal centre. The catalysts of general formula $Tp^XCu(I)$ were generated *in situ* by mixing equimolar amounts of CuI and the corresponding potassium or thalium salt of the homoscorpionate ligand. These preliminary experiments were run with a [Cu]–[EDA]–[hex-3-yne] ratio of 1:30:90, that corresponds to [Cu] 0.005 in Fig. 1. As inferred from data in Table 1, the 3-neopentyl and 3-cyclohexyl derivatives showed excellent, unprecedented degrees of conversion into ethyl 2,3-diethylcyclorop-1-enecarboxylate (95 and 97%, respectively) therefore

minimising the formation of EDA-coupling products (ethyl fumarate and maleate). We have recently reported[12] an extraordinarily active and diastereoselective (towards the *cis* isomer) catalytic system for the olefin cyclopropanation reaction, in which aromatic substituents as R^1 provided the best results in comparison with the aliphatic groups in this position. But this situation reverses in the alkyne cyclopropenation reaction, since aliphatic groups as R^1 seem to be required for high conversions. This constitutes a significant difference between these two transformations that traditionally have been described to occur in a similar way.[1,2]

After this initial screening, optimisation of the reaction conditions and expansion to other alkynes afforded more interesting features. Table 2 displays the results of the cyclopropenation reaction of hex-1-yne, 1-phenylprop-1-yne and hex-3-yne with different [Cu]–[EDA]–[alkyne] ratios using the Tp^{Cy} derivative. The observed yields show dramatic improvement over any other reported catalytic system in terms of cyclopropene formation not only for alk-1-yne derivatives, but also for internal ones: the values for hex-3-yne are >90% in all cases and 1-phenylprop-1-yne also undergoes high conversions (73–94%). This remarkable activity is confirmed by data

Table 2 Cyclopropenation of alkynes with $Tp^{Cy}Cu$[a]

in Table 2, entry 5, in which an equimolar EDA–alkyne ratio was employed: yields of cyclopropene fall in the range 80–94%. The lack of alkyne excess in these high-yield transformations has no precedent in the literature: our system has obviated the need for an excess of alkyne to achieve noticeable yields, not only with the cyclohexyl derivative but also with other Tp^X ligands (X = alkyl). Thus, the cyclopropenation of hex-3-yne using an equimolar ratio of the alkyne and ethyl diazoacetate afforded the corresponding three-membered ring in 75–94% yield (Table 3).

Table 3 Equimolar EDA–hex-3-yne cyclopropenation experiments[a]

In conclusion, we have developed an extraordinarily efficient cyclopropenation system in which terminal and internal alkynes can be converted into the corresponding unsaturated rings in very high yields. In addition, no excess of the alkyne is required for those yields to be produced. Work aimed to extend these results to a number of other unsaturated substrates is currently underway in our laboratory.

Notes and references

† Experimental procedure: CuI and an equimolar amount of the MTp^X salt were dissolved in CH_2Cl_2 and the mixture was stirred for 2–3 h. After filtration volatiles were removed under reduced pressure. The residue was dissolved in 20 mL of 1,2-dichloroethane, and the resulting solution was charged with alkyne. A solution of EDA in 1,2-dichloroethane was slowly added with the aid of an automatic syringe pump. All reactions were performed at room temperature. After complete addition, the reaction mixture was analyzed by GC, only cyclopropenes and ethyl fumarate or maleate being detected. Yields are shown in Tables 1–3.

Addition of functional vinylzinc reagents to nitrones: synthesis of (*E*)-*N*-allylhydroxylamines and their rearrangement into (*E*)-*O*-allylhydroxylamines

Shashi Urvish Pandya, Corinne Garçon, Pierre Y. Chavant, Sandrine Py and Yannick Vallée*

Received (in Cambridge, UK) 18th May 2001, Accepted 26th July 2001
First published as an Advance Article on the web 4th September 2001

The vinylzinc reagents derived from hydrozirconation of alkynes and transmetallation add readily to nitrones to yield pure (*E*)-*N*-allylhydroxylamines; some of these rearrange into *O*-allylhydroxylamines.

In the course of our studies on nitrones,[1] we became interested in obtaining (*E*)-allylic *N*-hydroxylamines by the addition of organometallic reagents onto nitrones.

In the past, addition of organolithium or organomagnesium reagents onto C=N bonds[2] was studied to a much lesser extent than the corresponding addition onto carbonyl functions, the major reason being that imines are less prone to nucleophilic addition and more prone to deprotonation. In recent years, there has been a renewed interest in the addition of organometallics onto C=N double bonds because of both the availability of more selective organotransition reagents, and the use of more reactive C=N species. Among the latter, nitrones appear to be an interesting choice as precursors. They are reactive, readily available and stable. Indeed, recent work has dealt with the addition of alkyl,[3] allyl[4] and alkynyl[3,5] lithium, magnesium and zinc reagents onto nitrones.

Comparatively fewer examples of the addition of vinylic organometallics to C=N bonds have been described. Imines do, however, react readily with vinylzinc compounds.[6] It has also been shown that vinylmagnesium bromide adds to tosyl imines.[7] Furthermore, it was demonstrated[8] that vinylmagnesium bromide adds rapidly to nitrones. These results were extended to diastereoselective additions onto chiral nitrones[9] but the results were limited to the simplest ethenyl organometallic reagent.

For our study, we needed adducts from γ-functionalized, pure *E*, vinylmetallic species. Thus, we decided to prepare these reagents according to Wipf's procedure:[10] hydrozirconation of alkynes followed by transmetallation to the (*E*)-vinylzinc species. We found that the resultant organometallic reagents add readily onto nitrones, under mild conditions, to give secondary *N*-hydroxylamines in good yields† (Scheme 1, Table 1).

As expected, only the *E* configuration was observed in the double bond of all the products. Also, excellent conversions were obtained for the addition of the vinylzinc species derived from hex-1-yne onto a variety of nitrones **2**. Steric hindrance in the nitrone (entry **g**, 39% conversion) is a limitation. The more hindered vinylzinc reagent derived from hex-3-yne led to incomplete conversion (entry **h**), and the formation of *N*-benzyl-*N*-(1-phenylpropyl)hydroxylamine (10%), resulting from ethylzinc addition, accompanied the allylic product **3h**. Addition onto the chiral nitrone **2d** led to moderate diastereoselectivity at 0 °C. Functionalized alkynes can also be used in this protocol. The pivalate-protected but-3-yn-1-ol led readily to **3i** and **3j**. In other examples however, the ω-cyanoalkyne (entry **k**), the *O*-protected propynol[11] (entries **l**, **m**, **n**, **o**) and the

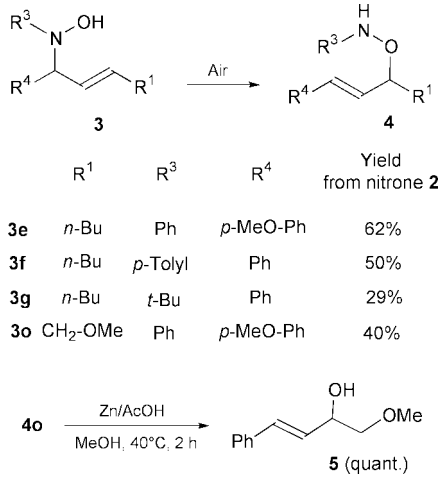
 DOI: 10.1039/b104427n



Scheme 2 Rearrangement of *N*-allylhydroxylamines **3**.

phenylacetylene (entry **q**) all yielded substoichiometric amounts of vinylzinc reagent, presumably due to a less efficient hydrozirconation step. In these runs, the conversions of nitrones **2** were incomplete, and the expected products **3** were contaminated with *N*-propargylhydroxylamines,‡ derived from the addition of the alkyne **1** onto the nitrone **2**.§

All the vinyl adducts freshly obtained from this procedure were the expected (*E*)-*N*-allylhydroxylamines **3**. Surprisingly however, we observed that on standing (at room temperature), some of the samples (neat or in $CDCl_3$ solutions) isomerized slowly, with allylic transposition, to yield (*E*)-*O*-allylhydroxylamines **4** (Scheme 2). This process occurs particularly readily for *N*-arylhydroxylamines. In these cases, the rearrangement was complete within 24 h at 20 °C and consequently, the rearranged adducts were isolated after completion of this step (entries **e**, **f**, **m**, **o**). This rearrangement also occurred in the case of *N*-*tert*-butylhydroxylamine **3g**. The structure of **4o** was confirmed by its reduction to the (*E*)-allylic alcohol **5** (Zn, AcOH–MeOH 1 : 9, 40 °C, 2 h, quant.).

To our knowledge, this rearrangement has not been previously described, although it can be related with several observations, involving allylic N–O bonds, including the Meisenheimer rearrangement of tertiary amine *N*-oxides.[12]

We observed qualitatively that the rate of this rearrangement depends strongly on the nitrogen atom substitution: Aryl > *t*-Bu >> Bn. Several observations hint at a radical mechanism. First, the reaction seems to be initiated by air: in an early experiment, we observed a 50 : 50 mixture of **3o** and **4o** 2 h after working-up the reaction. We repeated the experiment, using for the hydrolytic work-up freshly distilled solvents and freshly boiled water phases, and handling the crude materials with simple anaerobic precautions: the amount of isomer **4o** was then reduced to less than 3% (NMR) of the crude material. Thereafter, exposure to air induced the rearrangement. EPR of the crude materials during isomerization showed a strong signal, with a fine structure consistent with the aminoxyl radical derived from **3**. Obviously, this radical could be the active species, undergoing a Meisenheimer [2,3] rearrangement. We are currently investigating the mechanism, scope, and limitations of this new reaction.

It is important to note that the above isomerization amounted only to traces if the R^3 substituent on the nitrogen atom was a benzyl group: as seen in Table 1, the *N*-benzyl-*N*-allylhydroxylamines **3** can be isolated in good yields. They can be readily reduced to provide the corresponding (*E*)-*N*-benzyl-*N*-allylamines.

In conclusion, we have shown that the sequence: terminal alkyne hydrozirconation, Zr to Zn exchange and addition to nitrones, is a good method to stereoselectively synthesize (*E*)-*N*-allylhydroxylamines, under mild conditions and in good yields. It is noteworthy that this reaction occurs with no need for an external activating agent such as amino-alcohols.[13] We are currently studying an asymmetric version of this reaction by adding chiral zinc ligands to the reaction mixture.

Notes and references

† Typical experimental procedure: to a suspension of zirconocene hydrochloride (1.2 mmol) in CH_2Cl_2 (2 mL) under an N_2 atmosphere at 20 °C was added hex-1-yne (1.8 mmol) using standard Schlenk procedures. The reaction was stirred at 20 °C until a homogeneous solution was formed. All volatiles were then removed under reduced pressure at 20 °C, to give a yellow vinylchlorozirconocene reagent. To the resultant solid was added CH_2Cl_2 (2 mL) and the mixture was cooled to −65 °C. Diethylzinc (1.2 mmol, as a 1.1 M solution in toluene), was added dropwise (over 10 min) at −65 °C and allowed to stir for 15 min at −65 °C. The vessel was then immersed in an ice bath and a solution of (*N*-benzylidene)benzylamine *N*-oxide (1 mmol) in CH_2Cl_2 (2 mL) was added dropwise. After 6 h stirring at 0 °C, the reaction was quenched with saturated $NaHCO_3$ solution (2 mL), and extracted with ethyl acetate. The combined organic extracts were washed with brine, dried over Na_2SO_4, and filtered through a pad of silica. Removal of the solvents under reduced pressure and purification by chromatography (silica, cyclohexane–ethyl acetate 90 : 10) yielded the pure adduct **3**.

‡ The IUPAC name for propargyl is prop-2-ynyl.

§ We found that a mixture of alkyne **1**, nitrone **2** and diethylzinc in CH_2Cl_2 or toluene at rt leads quantitatively to *N*-propargylhydroxylamine adducts, and we are currently studying this reaction. A similar addition of species generated from the reaction of dialkylzinc with terminal alkynes onto aromatic aldehydes has been described previously.[14]

Through billions of years of evolution nature has created and refined structural proteins for a wide variety of specific purposes. Amino acid sequences and their associated folding patterns combine to create elastic, rigid or tough materials. In many respects, nature's intricately designed products provide challenging examples for materials scientists, but translation of natural structural concepts into bio-inspired materials requires a level of control of macromolecular architecture far higher than that afforded by conventional polymerization processes. An increasingly important approach to this problem has been to use biological systems for production of materials. Through protein engineering, artificial genes can be developed that encode protein-based materials with desired features. Structural elements found in nature, such as β-sheets and α-helices, can be combined with great flexibility, and can be outfitted with functional elements such as cell binding sites or enzymatic domains. The possibility of incorporating non-natural amino acids increases the versatility of protein engineering still

Jan van Hest was born in 1968 in the Netherlands. After completing his M.Sc. in polymer chemistry in 1991, he conducted his doctoral research at the Eindhoven University of Technology under supervision of Professor Dr Bert Meijer, for which the Ph.D. was granted in 1996. For this work on molecular architectures based on dendrimers he was awarded the first prize of the DSM technology and chemistry competition in 1995 and the SNS award for the best thesis in fundamental research of the Eindhoven University of Technology in 1997.

Next he investigated as a post-doctoral researcher the possibilities of protein engineering for the preparation of materials under supervision of Professor Dr D. A. Tirrell, at the University of Massachusetts in Amherst till 1997.

He then joined the chemical company DSM, where he worked in the research group New Architectures, first as research scientist and later on as group leader, on the development of innovative material concepts. Specific topics of investigation were controlled radical polymerization and integration of expertise from life sciences and materials.

In 2000 he was appointed as full professor at the University of Nijmegen to set up a new group in bio-organic chemistry. His current interests focus on translating natural structural concepts into bio-inspired materials with the aid of state of the art organic and polymeric chemistry techniques and protein engineering.

David A. Tirrell is the Ross McCollum–William H. Corcoran Professor and Chairman of the Division of Chemistry and Chemical Engineering at the California Institute of Technology. After earning the B.S. in Chemistry at MIT, Tirrell enrolled in the newly-created Department of Polymer Science and Engineering at the University of Massachusetts, where he worked in the laboratory of Otto Vogl, on the synthesis and polymerization of vinyl derivatives of salicylic acid and 2,4-dihydroxybenzophenone. He was awarded the Ph.D. in 1978. During a four-month stay with Takeo Saegusa at Kyoto University, Tirrell developed methods for the synthesis of ionomers based on polymers of ethyl glycidate. He then accepted an assistant professorship in the Department of Chemistry at Carnegie-Mellon University, where he established research programs directed toward the exploration of neighboring group effects in polymer modification reactions, and toward elucidation of mechanistic questions in radical copolymerization processes.

Tirrell returned to Amherst in 1984. He was promoted to Professor in 1987, appointed Director of the Materials Research Laboratory in 1991, and named Barrett Professor of Polymer Science and Engineering in 1992. Tirrell moved to Caltech in 1998. He has served as Visiting Professor at the University of Queensland (1987), at the Institut Charles Sadron in Strasbourg (1991), at the University of Wisconsin-Madison (1995), and at the Institut Curie in Paris. He is a Fellow of the American Institute of Medical and Biological Engineering, and serves on technical advisory boards for Dow Chemical Company and Protein Polymer Technologies, Inc. He was Editor of the Journal of Polymer Science, Part A: Polymer Chemistry from 1988 until 1999, and has served on the editorial boards of many other journals, including Macromolecules, Biopolymers, Accounts of Chemical Research, and Chemical and Engineering News. He chaired the 1994 Gordon Research Conference on Polymers in Biosystems and the 1995 Gordon Conference on Chemistry of Supramolecules and Assemblies.

Tirrell's contributions to teaching and research have been recognized in a variety of ways. He was named Outstanding Teacher in the College of Science at Carnegie-Mellon, and a Sloan Fellow in 1982. He was a Presidential Young Investigator Awardee of the National Science Foundation in 1984, and a Fulbright Senior Scholar in 1987. In 1991, he was recognized by the Carl S. Marvel Creative Polymer Chemistry Award of the American Chemical Society, in 1996 he received the Harrison Howe Award of the Rochester Section of the ACS, and in 1997 he was awarded the Chancellor's Medal of the University of Massachusetts. In 2001, he received the American Chemical Society Award in Polymer Chemistry, and the degree of Doctor honoris causa from the Eindhoven University of Technology.

Tirrell's most important contributions to chemistry have come in three areas: i). radical copolymerization mechanism, ii). biomimetic membrane chemistry, and iii). development of molecular biological approaches to new polymeric materials.

DOI: 10.1039/b105185g

further. It is expected that such methods will have large impact in the field of materials science, and especially in biomedical materials science, in the future.

Introduction

For many years materials scientists have been investigating the possibilities of obtaining higher levels of control in polymer synthesis. Although important progress has been made, especially in recent years with the advance of controlled radical polymerization techniques,[1] the level of control characteristic of biomacromolecules, such as DNA and proteins, remains unsurpassed.

In the nomenclature of polymer chemistry, organisms prepare monodisperse polymers with predetermined chain lengths. But more important is the fact that virtually complete control is achieved over the sequence of the monomeric units, the amino acids. The information stored in the primary sequence results in a three-dimensional folded structure for each protein, which is largely responsible for the most important protein properties. For every specific function, nature has refined protein structures through eons of evolution. It is striking that with the same set of amino acid building blocks such diverse products can be prepared, including globular proteins which function as enzymes as well as fibrous proteins with structural properties, such as collagen. It is the prospect of creating three-dimensional ordered structures by designing the requisite amino acid sequences that motivates much of the current interest in protein-based materials.[2]

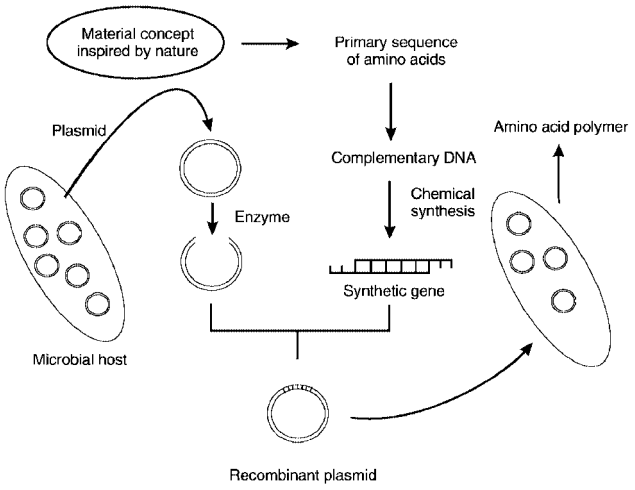
Materials scientists have much to learn from the organizational principles employed in nature, and substantial progress has been made recently in elucidation of the three-dimensional architectures of fibrous proteins such as silks, elastins, and collagens. An important challenge, however, is to translate these concepts into synthetic or bio-inspired materials, which would lead to new kinds of high performance materials.[3] Because of the importance of control at the monomer level, the most promising approach to this target is to use the biosynthetic pathways of (micro)-organisms to synthesize macromolecular materials.

Protein engineering has been used for the design and modification of globular proteins for many years, and standard biological tools have been developed that can now be used to prepare structural proteins.[4] It is remarkable that only in the past decade, and especially in the last 5 years, has this approach to materials design become a serious topic of investigation.

This review is not meant to be comprehensive, but instead will present examples of some of the latest developments in the field of protein engineering directed toward the preparation of high performance materials. After a short explanation of the protein engineering technique, examples will be given of structural proteins found in nature and attempts to use these basic structures for the preparation of new protein-based materials. We will conclude with new methods that allow the scope of protein engineering to be extended to building blocks other than the natural amino acids, developments that promise to make this technique even more versatile in the hands of the materials chemist.

Protein engineering

Scheme 1 shows the overall process of materials synthesis *via* protein engineering.[5] Often—though not always—based on natural structures, amino acid sequences are chosen to create specific folding patterns and desired material properties. The primary amino acid sequence can then be reverse-translated into a corresponding nucleotide sequence. There are 2 methods of obtaining the needed DNA fragments. One possibility is to clone these sequences from an organism that produces the desired structural protein. The second option is to synthesize



Scheme 1 Overview of the protein engineering methodology.

artificial genes by solid phase techniques. The second method of course allows maximum freedom in designing the target sequence. Because many structural proteins are characterized by repetitive amino acid sequences, it is often possible to multimerize a smaller oligonucleotide sequence to prepare an artificial gene that codes for proteins of high molecular weight.

This multimerization process can be considered as a polycondensation, which therefore results in a set of genes with different lengths. After construction of the artificial gene library, each individual gene is incorporated into circular plasmid DNA, which can be used to transform an appropriate bacterial host. Most commonly the bacterial host *E. coli* is used for these purposes. The plasmids are replicated during every division of the bacterial cells. Because there is only one type of plasmid per cell, screening of the plasmids of individual bacterial colonies leads to isolation of specific artificial genes, each encoding a protein-based material with a specific molecular weight.

The selected artificial gene is first analyzed to verify its sequence, and then cloned into a second plasmid which allows protein expression. The expression plasmid contains a promoter site for recognition by mRNA polymerase and a switch that regulates protein production from the gene of interest.

The expression plasmid is re-introduced into the bacterial host, and the host cells are allowed to grow to high cell density. During this stage the plasmid switch is turned off in order to prevent protein production from the artificial gene. Premature protein synthesis can be detrimental to cell growth. After sufficient cell density is reached the switch is turned on (a process called induction) and expression of the desired protein begins. Often the synthesis of other cellular proteins is slowed dramatically after induction.

Spider dragline silk

Among the most thoroughly studied classes of structural proteins is silk.[6] There are many forms of silk, of which that from *Bombyx mori* (Chinese silkworm silk)[7,8] and dragline spider silk of the *Nephila clavipes* (the golden orb weaver) have drawn most attention.[9] Silkworm silk of course is of interest because it is produced in large quantities and used as textile fiber. Spiders produce a large variety of types of silk, each one meant for a specific purpose, such as web construction or trapping of prey. Of all these different types of spider silk, dragline spider silk of *Nephila clavipes* is regarded as nature's high performance fiber, with a remarkable combination of strength and toughness. Values reported for its mechanical properties are an *E*-modulus of 10–50 GPa, elongation to break of 10–30% and tensile strength of 1.1–1.4 GPa. These values are

dependent on moisture content and strain rate. The effect of humidity is of utmost importance. Silk exposed to water can shrink to less than half of its original length, and the supercontracted fibers then show rubberlike behavior.[9] Although this is a desirable feature under natural conditions, because it allows spider webs to reshape in the dewy evening, it is less practical when one wants to apply this material as a high performance fiber. The large variation in properties is a result of the difficulty in maintaining constant conditions under which spiders produce their silk. In recent years important insight has been obtained into the three-dimensional structures of the different types of silk. X-ray diffraction,[10] state of the art NMR techniques[11,12] and IR and Raman spectroscopy[13] have helped to unravel the architectural reasons why this class of structural proteins has its remarkable mechanical properties. Silks from both silkworms and spiders contain repetitive sequences of crystalline and amorphous domains (Fig. 1). The crystalline

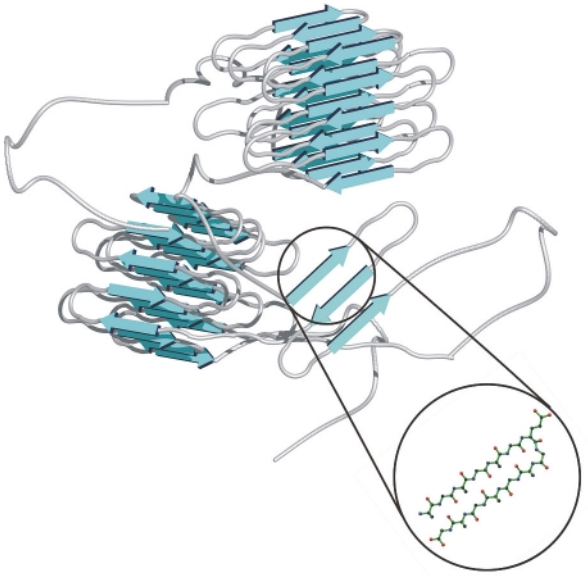


Fig. 1 Schematic representation of the organization of amorphous and crystalline domains in silk fibers. Silk has inspired protein engineers to construct β-sheet materials. A detail of a silk-like peptide sequence $((AG)_3EG)_n$[21,22] is encircled.

domains are responsible for the strength of the material, whereas the amorphous protein matrix: i) allows the crystalline domains to orient under strain to increase the strength of the material, and ii) introduces flexibility to increase the energy to break.

The crystalline domains comprise highly repetitive amino acid sequences consisting of alanine rich β-sheets. In *Bombyx mori* silk the most important repeat sequence is (Ala Gly); for *N. clavipes* dragline spider silk it is predominantly poly Ala.

In contrast to silkworm silk, there is no readily available source for spider dragline silk, and protein engineering techniques have been explored as a means of scaling up production. Furthermore, changes in the silk structure might be made to produce a material less sensitive to water. The combination of bacterial production with a synthetic processing step should allow better control of mechanical properties as compared to natural silk. On the other hand, development of methods of posttranslational silk spinning is not a straightforward process.

The first protein engineering attempts were made by using large parts of the native spider silk genes. After incorporation of these cDNA fragments into *E. coli* expression systems however, difficulties arose from gene and protein stability, and truncated proteins were produced. Clones larger than 2.5 kb proved to be unstable.[14,15] The same behavior was observed for native silkworm silk genes. An explanation for this phenomenon may lie in the highly repetitive nature of these sequences, which renders the coding sequence susceptible to genetic recombination. Differences in codon preferences between the silkworm and the bacterial host could also reduce expression efficiency.[16]

The first attempts using synthetic genes based on the native gene sequence were reported as early as 1990 by Cappello and Ferrari,[17] who used silkworm fibroin analogues. Better results were obtained than when the cDNA genes were used, although the levels of protein production remained relatively low, especially for high molecular weight variants.[18] The best results reported thus far with *E. coli* expression systems were obtained by Winkler *et al.* for spider dragline silk (25–40 mg L^{-1} cell culture)[19] and Krejchi *et al.* for an $(AG)_3EG$[20] repetitive material.[21,22] To increase protein yield, high cell density production was performed, and allowed preparation of multigram quantities of product (25 g protein/35 L culture).[23] Another approach to this problem has involved changes in the production host. O'Brien *et al.* have shown that with the yeast *Pichia pastoris* it was possible to produce spider silk-like material in larger quantity (1 g L^{-1}).[24] Even mammalian hosts are now being investigated, such as Nexia's transgenic goats, which produce milk containing spider silk protein.[25]

Protein production in large quantity is just one of the problems related to obtaining silk-like fibers. An equally difficult aspect is spinning of the polypeptide, to create a material with the correct three-dimensionally ordered structure. Recently, using micro-spinneret techniques, Jelinski *et al.* have succeeded in processing regenerated *Bombyx mori* silk fibers that show similar properties when compared to their native counterparts.[26,27]

Protein engineering can also play a role in improving processing of silk like materials. Introduction of methionine residues flanking the β-sheet domains creates a tool for chemical control of structural organization.[28] By oxidizing the methionine units, β-sheet formation was prevented, which also increased solubility, while sheet formation was restored after reduction. Enzymatic techniques have also been developed to induce this transition. The functional oligopeptide RGYSLG is a recognition site for cyclic AMP-dependent kinase, which phosphorylates the hydroxy function of the serine residue.[19] Introduction of this recognition site into the structural protein allowed Winkler *et al.* to prevent β-sheet formation upon phosphorylation. Sheet formation was restored after dephosphorylation.

Recent insights into the mechanical properties of silk[29] have shown that it is not necessary or desirable to prepare purely β-sheet sequences; a certain amount of disorder should also be introduced to allow reorientation of the β-sheet crystalline domains. With protein engineering this could be accomplished by producing multiblock copolymers of β-sheet structures flanked by random oligopeptides. Such block copolymers have been reported by Conticello *et al.*, who synthesized multiblock copolymers consisting of alanine-rich blocks and elastin-mimetic domains.[30] This method leads to good protein yield (50 mg L^{-1} culture) and a method for controlling β-sheet formation by concentration from an aqueous solution.

With respect to silk-like polymers, protein engineering is probably the only synthetic method that will allow high molecular weight materials to be prepared in sufficient quantity for materials applications. The ability to introduce switches for β-sheet formation as well as the production of multiblock copolymers will ultimately lead to materials with predictable processing behavior and mechanical properties.

Mussel byssus thread

Another masterpiece of a structural material found in nature is the mussel byssus thread. This thread is used to attach the mussel to a surface, and must be tough enough to withstand challenging marine conditions. Extensive investigations by

Waite and coworkers have shown that the thread consists predominantly of a gradient of two pentablock copolymers, which are held together by so-called dovetail proteins, and which provide a graded distribution of strength and structure (Fig. 2).[31–33]

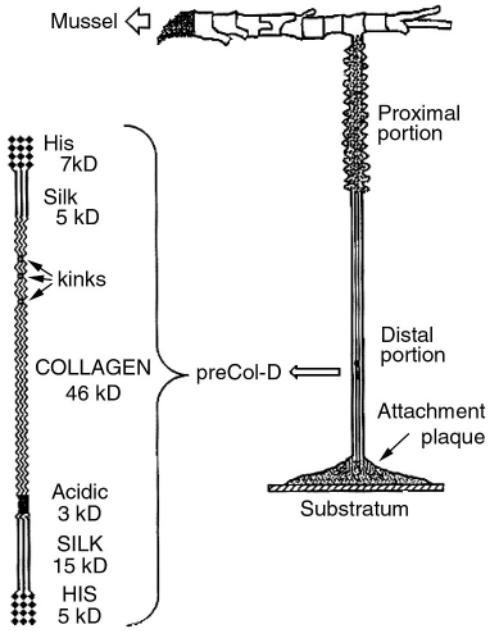

Fig. 2 Schematic view of the mussel byssus thread of *M. edulis*. The enlargement depicts the pentablock copolymer containing β-sheet domains. Reprinted with permission from (33), Copyright 1997 The American Society for Biochemistry and Molecular Biology.

The polymer that is predominant at the proximal end of the thread (*i.e.* closest to the mussel tissue) consists of a central collagen block flanked by 2 elastic domains and 2 polyhistidine sequences. The latter are expected to give rise to metal complexation between the different peptide structures. The elastin fragments introduce flexibility into the structure, whereas the collagen part is responsible for stiffness. Further down the byssus, and therefore closer to the substratum to which the mussel is attached, the elastin fragments are replaced by silk-like β-sheet domains. This structure therefore becomes much more rigid. The entire byssus is built up by a mussel within 5 minutes, and is about five times tougher and more extensible than Achilles tendon. After processing the proteins are also covalently connected. The complexity of a simple mussel byssus thread is thus far greater than that characteristic of materials produced by present-day synthetic polymer processing techniques.

Although this material would be an ideal target for protein engineering, no efforts toward this end have been reported. A possible reason could be the high content of collagen in these structures. Collagens are the most abundant family of structural proteins in the human body, and are an important constituent of ligaments, cartilage and bone. They are generally characterized by the repetitive sequence GXY, in which X is often proline and Y often hydroxyproline. Collagens form triple helices, which provide critical building blocks for higher ordered aggregates.[34] Because of their strong tendency to self-assemble, collagens become insoluble very quickly. The few protein engineering attempts reported thus far have failed for this (or perhaps other) reasons.[35] The need for a protein engineering approach for collagen is also not as pressing as for spider silk, because collagen is available in large quantities from mammalian sources. On the other hand, the repetitive sequence of collagen may be of value as an element in designed peptide-based materials, as shown by the example of the mussel byssus thread.

The mussel byssus contains more surprising peptides. The tendons have to be attached to the substrate under aqueous conditions. Nature therefore has developed a series of extraordinary protein glues, which work even in saline media. Careful analysis of these proteins, which must be done under conditions where the protein hasn't formed a network, shows that the adhesive proteins are rich in proline, tyrosine and lysine.[36] Furthermore, proline and tyrosine are posttranslationally transformed into 4-hydroxyproline and L-3,4-dihydroxyphenylalanine (DOPA), respectively. The DOPA units are expected to contribute to crosslinking *via* radical processes, in order to form networks and assist in adhesion.[37] Researchers intrigued by this phenomenon have prepared synthetic genes and expressed the corresponding $(AKPSYPPTYK)_n$ polypeptides.[38] These model peptides were treated with mushroom tyrosinase to convert the tyrosine units into DOPA, and thereby to induce crosslinking. Because expression yields were low, insufficient material was produced for a thorough evaluation. Furthermore, the question remains whether protein engineering is necessary in this case. Deming *et al*. have used NCA polymerization techniques to prepare copolypeptides consisting of lysine and DOPA residues to investigate the adhesive potential of these structures.[39] Based on the positive results obtained from this research, one can conclude that at least some of the key adhesive properties do not require the specific protein sequence; only the presence of the functional amino acids DOPA and hydroxyproline is essential. For such materials it will be more convenient to pursue the (improved) NCA polymerization routes than protein engineering.[40] More subtle effects of sequence may become apparent upon further analysis of the structure and properties of the adhesive proteins.

Elastin

One of the most versatile materials, especially from a protein engineering point of view is elastin. Elastin is a connective tissue protein that provides a combination of strength and flexibility in the extracellular matrix. Elastins are characterized by simple repeating sequences, and in contrast to silks or collagens, this family of materials does not suffer from significant solubility problems. At low temperatures elastin-like polypeptides are highly soluble in aqueous solutions and adopt random coil conformations. Elastins, however, display lower critical solution temperature (LCST) behavior, which means that the proteins form ordered structures upon raising temperature. The loss of entropy of the protein chain, when the structure folds itself into a β-helix conformation, is compensated by the release of water from the chain. A thoroughly investigated series of elastin proteins is based on the pentapeptide sequence VPGVG.[41–43] The structure and function of elastins are maintained as long as the glycine and proline residues are present, and the second valine residue can be replaced by any other amino acid. This property provides a means to control the temperature of the phase transition. When a more hydrophobic unit, such as tryptophan, replaces valine, the LCST drops significantly, and the transition temperature can be raised by introduction of more polar moieties such as glutamic acid. In the latter case, the phase transition is also made pH dependent. The pioneering work of Urry has shown that changing hydrophobicity leads to a broad spectrum of transition temperatures. The phase transition can also be induced electrochemically. For this purpose nicotinamide adenine nucleotide (NAD) is attached to glutamic acid residues within the peptide sequence. Reduction of NAD to NADH creates a more hydrophobic domain and therefore a lower transition temperature. Elastin materials have been made both by organic chemical techniques, and by microbial protein expression. Although it has been shown that one repeat unit of VPGVG is sufficient to allow the transition from random coil into an ordered β-helix structure,[44] for useful materials properties

higher molecular weight polymers are required. Protein engineering is ideally suited for this purpose, especially because production yields in bacteria are high (50–60 mg L^{-1} culture) when compared to other structural proteins.

Following up on earlier work by Urry, Conticello *et al*. have used protein engineering techniques to synthesize elastin-based block copolymers consisting of hydrophilic and hydrophobic blocks.[45] Protein engineering allows complete control of the composition, sequence and length of the blocks. By careful design, the critical micellization temperatures of these polymers could be controlled, and the resulting materials are under investigation as candidates for drug delivery. A second demonstration of the versatility of protein engineering for the preparation of elastin-based materials has been reported by the same group. Hydrogels are important products in biomedical applications. Ideally one wants to obtain control of mechanical properties by regulating crosslink density and network formation. Using protein engineering, control over monomer composition, and therefore control over distribution of crosslinkable moieties, is achieved easily. Conticello *et al*. synthesized elastin-based materials containing one specific crosslinking point (lysine) per 25 monomer units, allowing a high level of control of crosslink density after reaction with bis(sulfosuccinimidyl) suberate.[46]

Another approach, which takes advantage of additional possibilities of protein engineering was developed by Urry and extended by Panitch *et al*., who reported new materials for tissue-engineered vascular grafts.[47,48] Oligopeptides were introduced that contained either RGD (Urry) or REDV (Panitch) domains, which are known to stimulate endothelial cell binding.[49] This approach yields matrix materials that exhibit mechanical properties similar to those of the arterial wall and that support adhesion of vascular endothelial cells. An extension of the polymer design was made by introduction of lysine moieties, which allowed amine specific crosslinking of the elastin matrix without disturbing the cell binding domains.[50] The combination of structure and function in a well defined manner as demonstrated by this example is almost impossible to achieve by any method other than protein engineering.

Helical polypeptides

Leucine zipper peptides play key roles in the dimerization and DNA-binding behavior of transcriptional regulatory proteins. Related structures can be found within the keratins, the main structural protein of hair and nails. The leucine zipper motif is characterized by a consensus heptad repeat (*abdcefg*), in which *a* and *d* are hydrophobic amino acids, (*d* most frequently leucine) and the moieties at *e* and *g* are usually charged. In the helical form of the zipper peptide, the residues at *a* and *d* are arrayed along a single face of the helix. Exposure of this hydrophobic face to the aqueous environment is reduced by formation of a dimeric coiled-coil structure, while electrostatic interactions between *e* and *g* residues modulate the stability of the dimer. This feature has been exploited to prepare pH dependent peptide-based hydrogels. Triblock copolymers were constructed to comprise a central random coil $(AG_3PEG)_x$, flanked by terminal leucine zipper domains (Fig. 3).[51] These

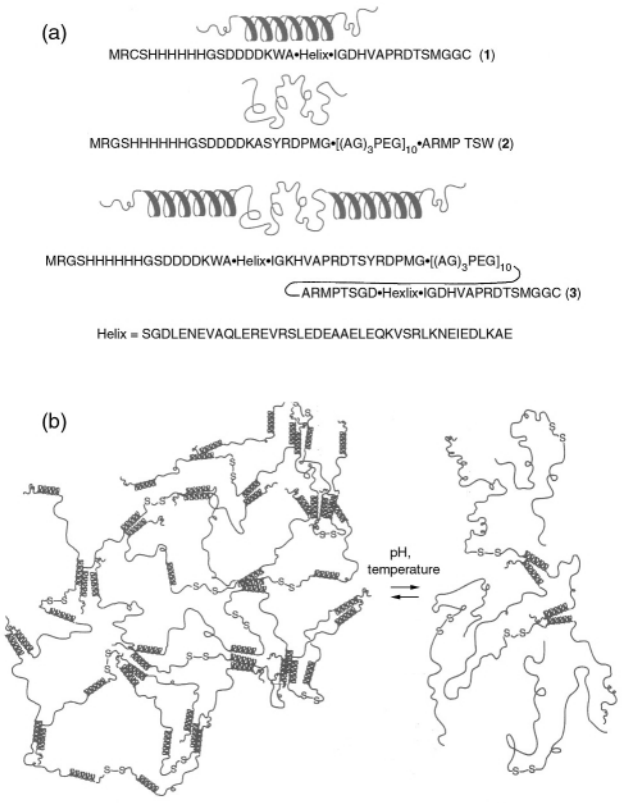

Fig. 3 (a) Amino acid sequence of the leucine zipper triblock copolymer; (b) demonstration of reversible hydrogel formation. Reprinted with permission from W. A. Petka, J. L. Harden, K. P. McGrath, D. Wirtz and D. A. Tirrell, *Science*, 1998, **281**, 389. Copyright 1998 American Association for the Advancement of Science.

domains consisted of six heptad repeats of which the choice of *a*/*d* residues was based on the *Jun* oncogene product. A database developed by Lupas *et al*.[52] was used for the selection of the residues occupying positions *b*, *c* and *f*. Nine of the 12 *e* and *g* positions were occupied by Glu residues, which allowed switching between the aggregated and dissociated states by changes in pH or temperature. At low pH and low temperature the materials formed elastic gels; increases in pH or in temperature resulted in decreased viscosity and loss of hydrogel properties.

Reprinted with permission from (55), Copyright 1998 American Chemical Society.

Each of the examples examined thus far shows the need for control over composition in order to engineer the properties of the products. Molecular weight distribution is a second parameter that is of importance in polymer chemistry, though its influence on material properties is not always easy to anticipate. One striking exception however, is the synthesis of the helical polypeptide polybenzyl-L-glutamate (pBLG) (Fig. 4).

The polydisperse form, which can be prepared by NCA polymerization, has been known for many years to exhibit liquid crystalline behavior.[53] Under most conditions, pBLG forms a cholesteric phase, but certain solvents and temperatures yield a nematic. Because of the broad distribution of molecular weight a clear characterization has always been difficult. Using protein engineering, monodisperse poly L-α-glutamic acid could be synthesized, and posttranslationally modified to yield pBLG. This monodisperse sample showed distinctly different LC behavior. Instead of a nematic or cholesteric phase a twisted smectic mesophase was obtained.[54,55] The fact that all chains were of the same length resulted in ordering in layers, which was not possible in conventional polydisperse samples.

Increasing the scope of protein engineering

The foregoing examples illustrate some of the promise of protein engineering as a tool for material synthesis. Especially in cases where the information encoded in the primary amino acid sequence governs higher ordered structures, and thereby the ultimate material properties, protein engineering clearly outperforms synthetic polymerization techniques.

One of the drawbacks of protein engineering in comparison to the other techniques, however, is that the choice of building blocks might be expected to be limited to the naturally occurring amino acids. Many functional groups, which would be useful in controlling properties or postmodification efforts, such as alkenes, alkynes, or halogens, are not found in natural proteins. The chemical versatility of amino acids containing unsaturated side chains has recently been reviewed.[56] Furthermore, incorporation of halides, especially fluoride, can have dramatic effects on the physical properties of materials. Extension of the set of amino acid building blocks to unnatural analogues that can be utilized by the protein production mechanism of living systems would therefore enlarge the possibilities of protein-based materials.

This idea has intrigued several groups. A first approach is to use stop (nonsense) codons or 4-base codons[57] for the introduction of unnatural amino acids. Suppressor tRNAs can be found that overwrite these termination signals. If unnatural amino acids can be coupled to these tRNA molecules, efficient incorporation of analogues can be accomplished. This technique has been applied *in vitro* for more than a decade.[58] For this approach to succeed *in vivo* it is necessary to introduce a suppressor tRNA that is not recognized by the host enzymes that couple amino acids to tRNAs (the aminoacyl-tRNA synthetases).[59,60] This can be achieved by using a suppressor tRNA from an exogenous source such as yeast.[61,62] Next, a synthetase must be identified or developed to couple the unnatural amino acid to the suppressor tRNA. This synthetase should also be inactive toward other tRNAs. This method allows site-directed insertion of the amino acid analogue at a single position, *e.g.* in he active site of an enzyme. This method will have major impact on the design of proteins that are used for functional purposes

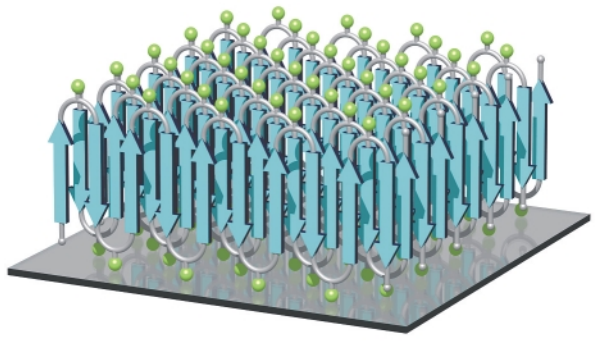

Fig. 5 Schematic representation of the lamellar crystalline phase formed by the peptide sequence $((AG)_3FG)_n$, in which phenylalanine is replaced by *p*-fluorophenylalanine. The green spots indicate amino acid side chains with unnatural functionality, in this case fluorine, at the lamellar surface.

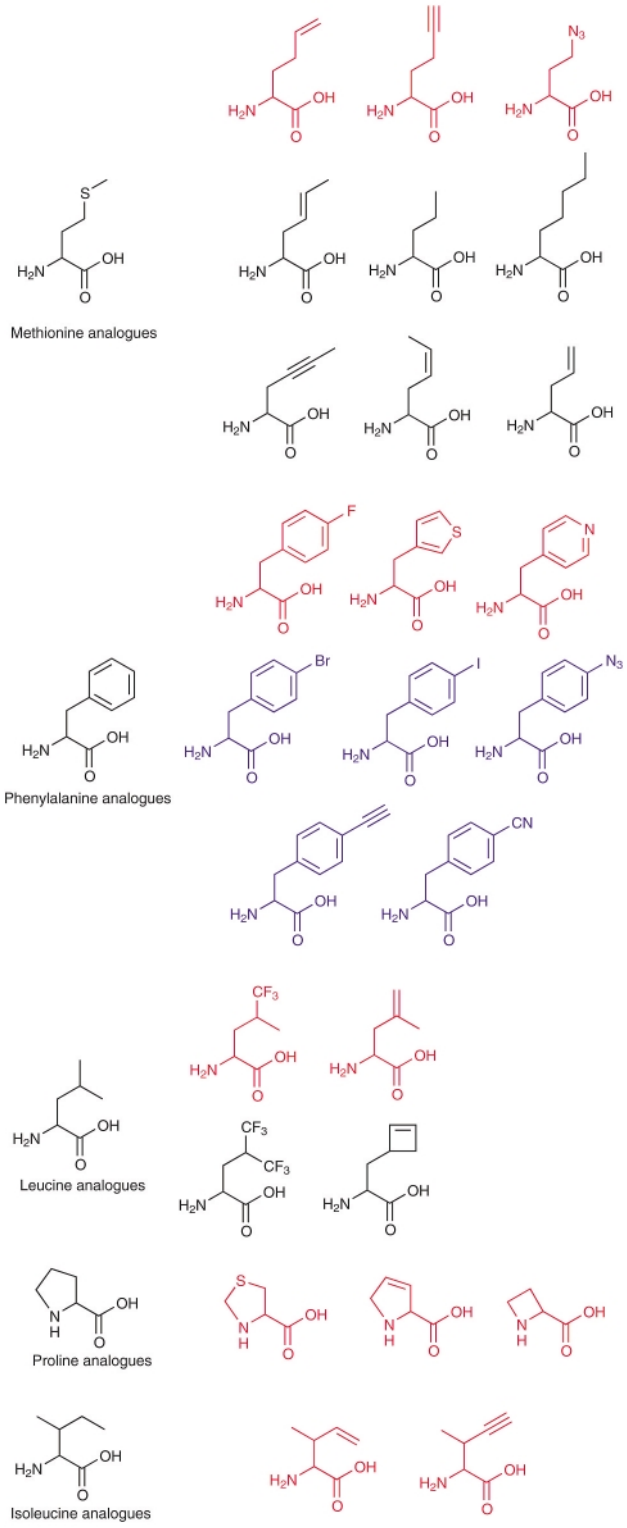

Fig. 6 An overview of the obtained results of Tirrell and coworkers with respect to *in vivo* replacement of natural amino acids by their analogues. Amino acids depicted in red are incorporated *via* standard auxotroph methodologies. Mutant aminoacyl tRNA synthetases have to be applied to be able to build in the blue amino acids. Analogues depicted in black are incorporated after boosting synthetase activity.

such as enzymes, since alteration of the overall physical properties of the macromolecule generally cannot be achieved through modification of a single site. An overview of this technique has been published recently.[63]

An alternative method has been developed by Tirrell *et al.*, based on much earlier work on substitution of natural amino acids by their close structural analogues. This method uses so-called bacterial auxotrophs, *i.e.* bacteria that have lost the ability to produce one of the natural amino acids. Such bacterial strains are dependent on the growth medium for obtaining this specific amino acid. If an analogue is added to the medium, it can be incorporated in place of the natural substrate, if it is recognized by the corresponding aminoacyl-tRNA synthetase.

In order to reduce toxicity, the cells are grown first in a medium containing all of the natural amino acids. When sufficient cell density is reached, the cells are shifted to a new medium which contains the analogue instead of the natural amino acid.

This methodology has proven successful for a large number of amino acids and derivatives thereof. Though the first publications go back for several decades,[64] only in recent years has extensive research allowed replacement of phenylalanine, proline, leucine, methionine, tyrosine and isoleucine with their respective analogues.[65–68]

An interesting application of this method is the incorporation of phenylalanine analogues into the β-sheet element $((AG)_3FG)_n$. This sequence adopts a lamellar crystalline structure, in which the phenylalanine residues are exposed to the surface. Well-defined functional surfaces can now be created. Replacement by *p*-fluorophenylalanine allowed the construction of fluorinated crystalline layers,[65] and β-sheets containing thiophene units from 3-thienylalanine[66] can be regarded as precursors for conducting polymers (Fig. 5).

Replacement of leucine by either trifluoroleucine or 2-amino-4-methylhex-4-enoic acid in leucine zippers causes marked effects on conformational stability. For example, in a leucine zipper peptide characterized by a melting temperature of 48 °C, the transition temperature was elevated to 61 °C by introduction of trifluoroleucine, whereas the native structure was destabilized by the introduction of the unsaturated analogue.[69] This simple example illustrates the extent to which incorporation of amino acid analogues expands the possibilities for engineering protein stability and protein–protein interactions.[70]

The most systematic study to date has concerned introduction of methionine analogues. Homoallylglycine and homopropargylglycine are especially effective as methionine surrogates.[68,71] Although *trans*-crotylglycine is recognized by the methionyl-tRNA synthetase, increasing the synthetase activity of the host is required for protein production.[72,73] The possibility of using mutant synthetases has also been demonstrated for *p*-bromophenylalanine[74] and azatyrosine.[75]

With the methods described in this section, some of the natural limitations of protein engineering are beginning to fade. Tailor-made materials can now be designed with pre-defined structures and properties (Fig. 6). Furthermore, protein engineering is unique in combining structural with functional elements, which can be either of natural origin, such as cell-binding domains, or introduced by incorporation of unnatural amino acids. The versatility and control of protein engineering will make this an important synthetic approach to a new generation of biomaterials.

First published as an Advance Article on the web 31st August 2001

SAMs based on a novel dendron-thiol system, which maintain the alkanethiols' active site, but with the –SH group connected to independently variable groups by a dendron-linker, showed a controllable surface pattern and wetting properties. The precisely tailored structure of dendron-thiols with locally controlled hydrophobic and hydrophilic peripheries allows the formation of designed surface structures on a gold surface, *e.g.* nano-stripes, honeycomb and homogeneous structures.

Self-assembled monolayers (SAMs) with macroscopic physical properties tailored by molecular-scale variation of the chemical structure and constituents are a particularly attractive field. There are two routes that are amenable to realize this goal. One is based on the chemisorption of dialkyl sulfides,[1] the other is the adsorption of an alkanethiol mixture.[2] Both methods permit local control of the surface structure of the adsorbed monolayer to some extent. But the self-assembled monolayers formed from dialkyl sulfides are significantly less densely packed and less ordered than those prepared by adsorption of alkanethiols. Moreover, the monolayers prepared from dialkyl sulfides were not stable at high temperature (*e.g.* 80 °C). As for the adsorption of mixed alkanethiols, there does exist, more or less, phase separation. So, avoiding the above problems to obtain SAMs with controllable constituents and a stable ordered surface structure is a challenge for chemists.

Dendrimers, a type of regular-branched molecule, with structures precisely controlled at the molecular level and having many unique properties,[3] are promising candidates for nano-fabrication.[4] Combining molecular self-assembly techniques and dendrimer chemistry, self-assembled monolayer formation based on the chemisorption of dendron-thiols has been addressed by several groups.[5,6] In our previous studies, we have found that SAMs of Fréchet type dendrons with a thiol group at the focal point can form patterned stripes with nanometer-sized features and long-range order. The patterned stripes were closely related to the size of dendron, and they can be improved by thermal annealing. Here we introduce two types of building blocks with different hydrophobicity into the dendron-thiols' peripheries, and expect that the SAMs formed by this type of dendron-thiol with locally controlled hydrophobicity could exhibit a stable and unique assembly structure. As Fig. 1 shows, dendron-thiols with both hydrophobic and hydrophilic groups at their peripheries have been synthesized, labelled G2REO. Heptane chains and oligo(ethylene oxide) chains were selected as hydrophobic and hydrophilic building blocks respectively. For comparison, dendron-thiols with either hydrophobic or hydrophilic groups at their peripheries were also synthesized. These are labelled G2R or G2EO, as shown in Fig. 1.

Scanning tunneling microscopy (STM) was used to observe the surface morphology of self-assembled monolayers of G2R, G2EO and G2REO on gold surfaces. For the dendron-thiols with a purely hydrophobic periphery (G2R) as the building block, the SAMs on a gold surface displayed a stripe-like ordered structure (Fig. 2a). The width of stripes is about 4 nm. It is presumed that both π–π stacking and hydrophobic interactions of hydrophobic peripheries contribute to the long-range order of G2R. In order to confirm this assumption, we also studied the SAMs of G2EO. In this case, where the dendron-thiol has a hydrophilic periphery, only uniform surface structure (except for few defects) was found on the gold surface rather than high-level ordered packing (Fig. 2b). A plausible reason is that the intermolecular interaction of dendron-thiols is weakened due to the extended conformation of the oligo(ethylene oxide) chain.

As for the case of SAMs of dendron-thiols bearing hydrophobic and hydrophilic (G2REO) groups at their peripheries on gold surface, it can be seen that a type of pore structure has been formed, and in smooth areas, the pores can further self-organize into a well-ordered structure after annealing at 70 °C for 3 h, as shown in Fig. 3. The diameter of the pore was about 5 nm, as measured from STM images. An STM image of G2REO on gold surface with a large scan area depicted the ordered structure extending over a large area. As far as we know, there are few reports concerning the formation of such patterned structures completely based on the self-assembly of organo-sulfur on gold surface. The driving force for the spontaneous formation of the 2D assembly includes chemisorption between dendron-thiols with –SH at the focal point and the gold surface, and combined intermolecular interactions among dendron-thiols. In our system, the chemisorption is similar for the series of samples. Therefore, we can deduce that the chemical structure of dendron-thiol influences greatly the intermolecular interaction, and even the molecular assembly behavior at the interface. Molecular dynamics simulations with quench dy-

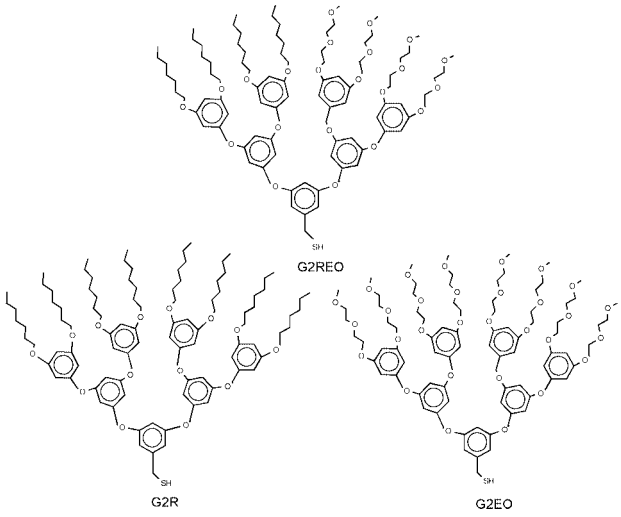

Fig. 1 Chemical structures of dendron-thiols.

 DOI: 10.1039/b103903m

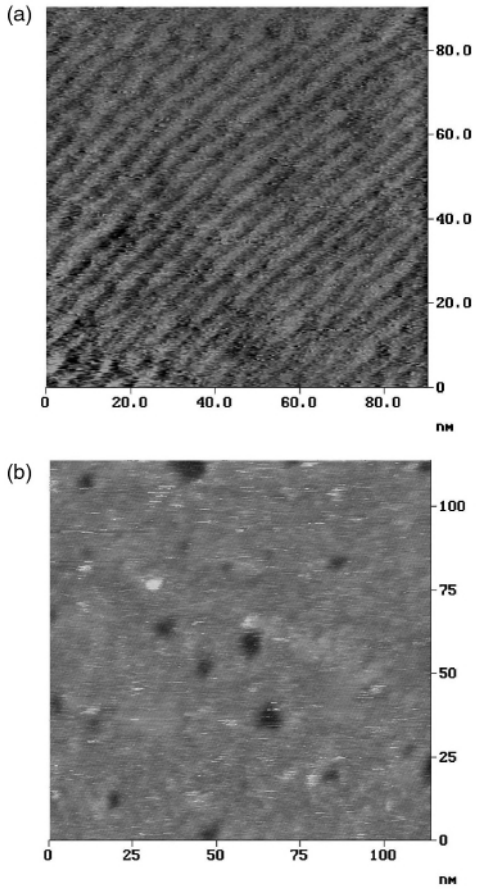

Fig. 2 STM images of self-assembled monolayers of dendron-thiols on gold surface (a) G2R; (b) G2EO.

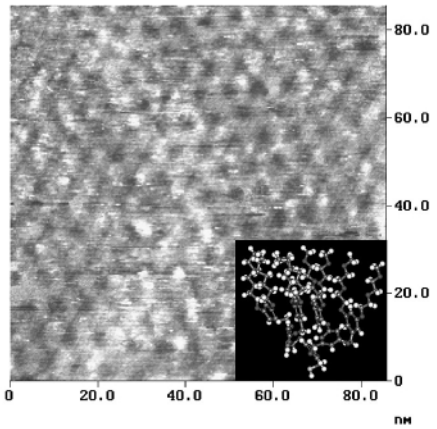

Fig. 3 STM images of self-assembled monolayers of dendron-thiols G2REO on gold surface (height mode, inset: the stable conformation of G2REO obtained by MD simulation).

namics show that the stable conformation of G2REO exhibits local aggregate behavior of the hydrophobic and hydrophilic peripheries based on the like-to-like principle. It indicates that the precisely tailored structure of dendron-thiols with local controlled hydrophobic and hydrophilic peripheries allows a nano-separation in a confined state, leading to the formation of an energetically favorable pore structure.

The process of the adsorption kinetics of dendron-thiol on gold surface was studied by contact angle measurement of water. Fig. 4 shows the relationship between contact angle and assembly time of G2R, G2REO and G2EO on gold surface. For the assembly processes of G2R or G2EO, the contact angles increased with the assembly time, and reached saturated

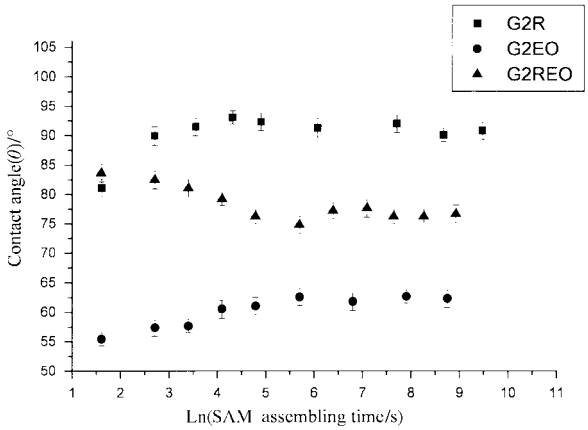

Fig. 4 Relationship between contact angles of water and assembly time of SAMs of dendron-thiols G2R, G2REO and G2EO on gold surface.

adsorption within about 7 min. The values of the contact angle at saturated adsorption were about 92° and 60° for SAMs of G2R and G2EO respectively. The process of assembly of dendron-thiols with hydrophobic and hydrophilic groups at their peripheries exhibited a special character. The contact angle decreased with assembly time at the beginning of the chemisorption and was constant after 11 min. G2REO's hydrophobic and hydrophilic peripheral group parts could both contribute to the wettability of SAMs on gold surface. The value for the contact angle of water on G2REO modified gold surface at saturated adsorption was about 75°, which was just in between the values of G2R and G2EO. The different relationship between contact angle and assembly time of G2REO as compared to that of G2R and G2EO might indicate a different 2D crystallizing process of dendron-thiols on gold surface.

In conclusion, these monolayers represent a successful example of designed modification of surface structure and properties by molecular-scale variation of the structure of molecular constituents. By taking full advantage of dendrimers with precisely controlled structures at the molecular level, many functional groups can be introduced into alkanethiol with a dendron-linker. It is expected that the interplay between dendrimer chemistry and self-assembled monolayers may open a new route for surface engineering.

We thank the support of the Major State Basic Research Development Program (Grant. No. G2000078102), Educational Ministry and National Natural Science Foundational of China. Dr Xi Zhang would like to acknowledge DFG for a one month visit to the University of Muenster in 2000.

Ready protease-catalyzed synthesis of carbohydrate–amino acid conjugates†

Viviane Boyer,[a] Mincho Stanchev,[b] Antony J. Fairbanks*[b] and Benjamin G. Davis*[a]

[a] *Department of Chemistry, Univeristy of Durham, South Road, Durham, UK DH1 3LE. E-mail: Ben.Davis@durham.ac.uk*

Received (in Cambridge, UK) 10th May 2001, Accepted 6th July 2001
First published as an Advance Article on the web 12th September 2001

The protease-catalyzed synthesis of amino acid ester–carbohydrate conjugates as glycopeptide analogues has been achieved in a highly regioselective and carbohydrate-specific manner using amino acid vinyl ester acyl donors and minimally or completely unprotected carbohydrate acyl acceptors, which together probed active sites of proteases to reveal yield efficiencies that are modulated by the carbohydrate C-2 substituent, and that may be exploited to allow selective one-pot syntheses.

Many carbohydrate–peptide conjugates display a wide variety of potent biological activities of potential therapeutic and commercial value.[1,2] For example, glycoproteins act as critical cell surface communication markers,[3] glycopeptide motifs such as the Thomsen–Friedenreich (Tf) antigen are associated with cancer cell lines[4] and an oligomeric sequence of the glycopeptide motif $(AAT[Gal\beta(1,3)GalNAc\alpha])_n$ displays unusual non-colligative antifreeze properties.[5] Access to well-defined carbohydrate–peptide conjugates and their analogues to probe the nature of these properties is essential. A large number of elegant methods have been developed for the synthesis and assembly of *N*- and *O*-linked glycopeptides[2,6] but these methods may be complicated by low glycosylation efficiencies and extensive protection regimes to ensure regioselectivity. To avoid these potential problems we have investigated the utility of enzyme-catalyzed regioselective acylation of carbohydrates as a one-step method. Despite the ready construction of ester–carbohydrate linkages, there have been remarkably few syntheses of amino acid esters of carbohydrates.[7] Furthermore, although the utility of hydrolases as powerful catalysts for regioselective acylation of carbohydrates is well demonstrated,[8] their use in the transfer of amino acids to carbohydrates is, with very few exceptions,[9] neglected. This is all the more surprising given that several biofunctional molecules, such as enkephalin–carbohydrate conjugates that modulate fibroblast and melanoma growth,[10] are themselves α-amino esters of carbohydrates. Moreover, carbohydrate–peptide conjugates connected by potentially metabolisable, sacrificial linkages, such as esters, have high potential utility as prodrugs in which the glycan moiety affords both protection and specific transport properties.[11] We therefore set ourselves the goal of establishing a ready, short route for the creation of such ester-linked glycopeptides.

Initially, we chose the serine protease subtilisin *Bacillus lentus* (SBL, EC 3.4.21.14) as a powerful catalyst for ester synthesis[12] and the representative amino acids phenylalanine **1a**, aspartic acid **2a** and glutamic acid **3a**. Amino acid derivatives (Scheme 1)† were chosen to probe not only the amino acid specificity of SBL but also its tolerance for a variety of amine (Ac, Boc, Fmoc, Z) and ester (Bn) protecting groups. $Pd(OAc)_2$-mediated transesterification[13] of **1–8b** with vinyl acetate (Scheme 1) allowed the preparation of the corresponding Phe, Asp and Glu; α and side-chain vinyl esters **1–8c** as acyl donors that render transesterifications essentially irreversible.[14]

With these acyl donors in hand, we investigated their utility in transesterification reactions with a representative range of carbohydrate acyl acceptors **9a–20a** (Scheme 2, Table 1). After exploring a range of conditions, the use of SBL lyophilised from phosphate buffer (pH 8.0) in anhydrous pyridine at 45 °C proved optimal. Initial variation of parent carbohydrate in the completely deprotected series **9a–12a** revealed exclusive *O*-6 regioselectivity but only low isolated yields of either D-glucose **9b** or D-galactose **10b** 6-*O*-phenylalaninate esters.[15] However, a higher yield of the 6-*O*-phenylalaninate ester of D-mannose **11b** indicated an exciting preference based only on the stereochemistry of the parent carbohydrate. This crucial dependency on carbohydrate acceptor was yet more dramatically confirmed by the complete absence of product from the attempted esterification of *N*-acetylglucosamine **12a** from which only **12a** and the product of acyl donor hydrolysis **1b** were recovered. Next the effect of anomeric substituent was probed. Introduction of a methyl substituent at *O*-1 increased yield only slightly in the case of D-galactose and D-glucose acyl acceptors **13–15a**. Moreover, the near identical yields of α- and β-glucosides **13**, **14b** indicated that, at least in the D-gluco series, anomeric stereochemistry had little or no effect on overall yield. Most notably, the apparent specificity preference of SBL for D-manno acyl acceptors was further confirmed by the higher yield (76%) of ester **16b** obtained here from α-D-mannoside **16a**.

Thioglycosides and selenoglycosides are important glycosyl donors[16] and we next investigated their esterification to provide potential glycopeptide donors, in which the glycosyl unit might be further extended, and as further probes of the effect of anomeric substituent. Consistent with both their larger size and the potential for aromatic aglycones in carbohydrate substrates to interact with protein surfaces,[17] more dramatic results were obtained for the thioglycosides **17–20a**. A trend in the efficiencies of the formation of 6-*O*-phenylalaninate products in the order D-manno > D-gluco > D-galacto > *N*-acetyl-D-gluco emerged. In addition, for the first time, reduced regioselectivity was observed for D-thioglucoside **17a** (3:2, 6-*O* **17b**: 3-*O* **17c**).[18]

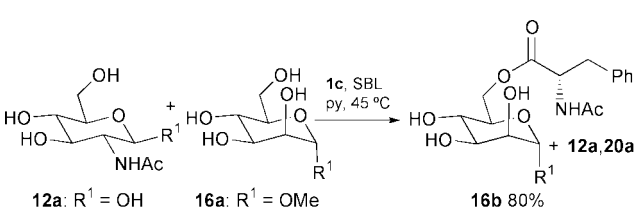
[a] 2 mg ml^{-1} of lyophilized (from pH 8.0, 0.1 M phosphate) SBL preparation, 45 °C, anhydrous pyridine, 120 h. [b] 1 mg ml^{-1} of TL-CLEC, 45 °C, 1 : 25 water–pyridine. [c] All yields are for isolated, purified, single compounds. [d] As for footnote *a* but for 500 h. [e] Yield of 3-*O*-acyl.

Next we investigated the effect of varying the amino acid acyl donor. Disappointingly, but consistent with the observed low affinity of SBL for other amino acid esters,[19] none of the aspartate or glutamate acyl donors were accepted as substrates. In all cases only vinyl esters **4**–**8c** were recovered indicating an absence of acyl–enzyme intermediate formation. This contrasted with the reactions of **1c** from which only transesterification or hydrolysis products were recovered. In order to further assess the utility of **1**, **4**–**8c** as acyl donor probes, we also screened their reactivity with CLEC-thermolysin (TL-CLEC)[20] as a protease with a different substrate specificity profile, that includes β-aspartate esters.[21] However, TL-CLEC also failed to accept **4**–**8c** and again only **1c** was accepted, allowing the preparation of **16b** from **16a** in 48% yield.

Next, the effect of *N*-protection in the acyl donor was investigated using Boc- and Z-protected phenylalanine donors **2**, **3c**, respectively. For **2c** much lower rates of reaction were observed than for **1c** and after a comparable period of time lower yields (32%) for the esterification of **16a** were obtained. However, extended reaction times gratifyingly allowed the preparation of 6-*O*-phenylalaninates **16c**, **e** from **2**, **3c** in 63 and 60% yields, respectively. The utility of **16c**, **e** as glycopeptide building blocks was confirmed through their quantitative *N*-deprotection to methyl 6-*O*-phenylalaninyl-α-D-mannopyranoside **21**, which may be extended at its *N*-terminus.

Finally, the valuable specificity information obtained in these screens was exploited to allow selective one-pot couplings. We were delighted to find that different carbohydrate acyl acceptors successfully competed in one-pot reactions to allow carbohydrate-selective esterification. Thus, in 1 : 1 mixtures of **12a** + **16a** and **19a** + **20a** (Scheme 3) mannosides reacted over *N*-acetylglucosaminides with **1c** in SBL-catalyzed acylations to yield mannoside esters **16**, **19b** exclusively. In both reactions no trace of **12b** or **20b**, respectively, was detected during this highly selective process.

In summary, we have described a ready method for the construction of glycan–peptide conjugates by exploiting a highly regioselective protease-catalyzed transesterification process. The yields for this selective carbohydrate–peptide conjugation of 23–76%, compare well with overall yields of < 34% for alternative routes employing protection–deprotection strategies.[7] The glycopeptides formed are powerful building blocks that will allow sugar reducing end (*e.g.* **17**–**20b**) or peptide *N*-terminal (*e.g.* **21**) extension. In addition, we have probed the substrate specificity of the proteases SBL and TL-CLEC in this reaction using the novel vinyl esters **1**–**8c** and this has indicated a strong preference for phenylalanine but flexibility in the *N*-protection that may be used. Furthermore, we have successfully exploited striking differences in the rate of reaction of carbohydrate acyl acceptors in this system to perform exclusively mannose over *N*-acetylglucosamine selective one-pot acylations. We have recently reported greatly broadened substrate amino acid ester specificities for glycosylated variants of SBL[22] and we are currently exploring transesterifications catalyzed by these glyco-SBLs with **4**–**8c** and other donors the results of which will be reported in due course.



Scheme 3

We thank the BBSRC for generous funding, Genencor International for SBL, and Altus for TL-CLEC. We thank the EPSRC for access to the Mass Spectrometry Service at Swansea and the Chemical Database Service at Daresbury.

Molybdenum-catalyzed episulfidation of (*E*)-cycloalkenes with elemental sulfur†‡

Waldemar Adam and Rainer M. Bargon*

Received (in Cambridge, UK) 18th April 2001, Accepted 13th August 2001
First published as an Advance Article on the web 4th September 2001

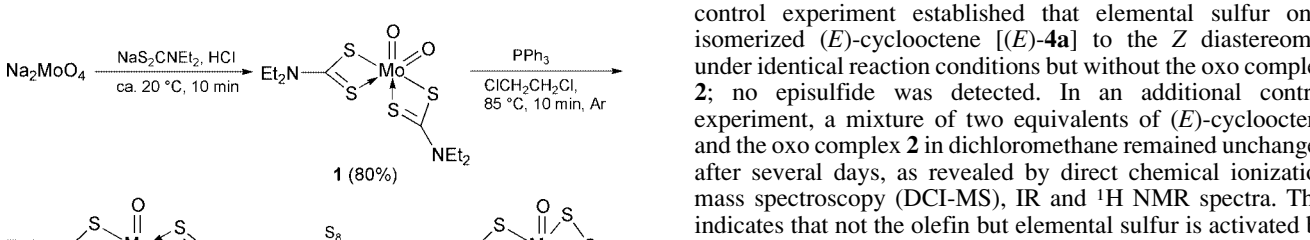
Episulfidation of (*E*)-cyclooctene and (*E*)-cyclononene was achieved with elemental sulfur by using a catalytic amount of a molybdenum oxo complex.

Molybdenum peroxo complexes have been utilized for the epoxidation of alkenes;[1] evidently, the analogous thioepoxidation by structurally related disulfur complexes would be of considerable synthetic value. In this context, Khan and Siddiqui claimed the first catalytic episulfidation of cyclohexene with a ruthenium persulfido complex and elemental sulfur as sulfidation source.[2] Instead of elemental sulfur, Kendall and Simpkins[3] described the rhodium-catalyzed sulfur transfer to norbornene (bicyclo[2.2.1]hept-2-ene), in which propylene sulfide was used as a sulfur source. Recently, Chandrasekaran[4] and coworkers used a molybdenum complex to transform alkyl halides into disulfides, the latter are added to Michael acceptors such as α,β-unsaturated enones.

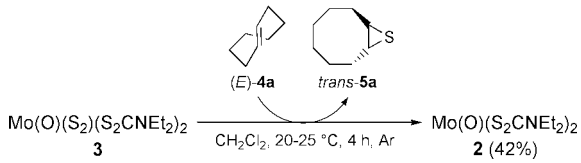
Clearly, literature on sulfur-atom transfer to organic substrates is to date rather scarce. Since the electrophilic character of disulfur complexes has been demonstrated through the desulfuration by various nucleophiles,[5] most effectively by triphenylphosphine,[6] we have explored the feasibility of employing molybdenum disulfur complexes as sulfur-transfer agents for the episulfidation of alkenes. Herein we report the novel *catalytic* episulfidation of (*E*)-cyclooctene and (*E*)-cyclononene by elemental sulfur, mediated by the molybdenum disulfur complex **3**.

Disulfur complex **3** was obtained in three reaction steps from sodium molybdate (Scheme 1). In the first step, the molybdenum dioxo complex **1** is formed in 80% yield from sodium molybdate and sodium diethyl dithiocarbamate in an acidic medium. Deoxygenation by triphenylphosphine resulted in the isolable but air-sensitive molybdenum oxo complex **2** in 80% yield.[7] Complex **2**, when treated with elemental sulfur in refluxing acetone gave the disulfur complex **3** in 87% yield.[8]

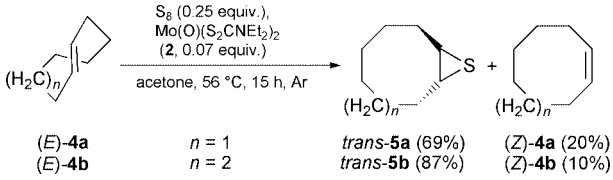
When the disulfur complex **3** was allowed to react with two equivalents of (*E*)-cyclooctene [(*E*)-**4a**], the episulfide *trans*-**5a** was quantitatively formed, as detected by ^{1}H-NMR spectroscopy (Scheme 2). Since the oxo complex **2** was isolated in 42% yield, presumably, the molybdenum oxo complex **2** may be employed directly in a catalytic manner for the episulfidation of suitable olefinic substrates by elemental sulfur. Indeed, the catalytic sulfur-atom transfer to strained (*E*)-cycloalkenes **4** worked well in refluxing acetone (Scheme 3).



Scheme 1 Preparation of the molybdenum oxo complex **2** and its sulfuration to the disulfur complex **3**.



Scheme 2 Stoichiometric episulfidation of (*E*)-cyclooctene [(*E*)-**4a**].



Scheme 3 Catalytic sulfur-transfer reaction with (*E*)-cyclooctene [(*E*)-**4a**] and (*E*)-cyclononene [(*E*)-**4b**].

Thus, with catalytic amounts (0.07 equiv.) of the oxo complex **2**, 69% of the *trans*-cyclooctene episulfide (*trans*-**5a**) and 87% of the *trans*-cyclononene episulfide (*trans*-**5b**) were isolated.§ When 1 mol% of catalyst **2** was used, the yield of episulfide (*trans*-**5a**) decreased to only 15%. Other less strained olefins failed to react under catalytic conditions, but could be episulfidated stoichiometrically by the disulfur complex **3**. Thus, the episulfides of (*Z*)-cyclooctene [(*Z*)-**4a**], norbornene (**4c**), bi(cyclopentadiene) (**4d**), and cyclopentene (**4e**) were isolated in 20, 50, 28 and 16% yields based on complex **3**.§ A control experiment established that elemental sulfur only isomerized (*E*)-cyclooctene [(*E*)-**4a**] to the *Z* diastereomer under identical reaction conditions but without the oxo complex **2**; no episulfide was detected. In an additional control experiment, a mixture of two equivalents of (*E*)-cyclooctene and the oxo complex **2** in dichloromethane remained unchanged after several days, as revealed by direct chemical ionization mass spectroscopy (DCI-MS), IR and ^{1}H NMR spectra. This indicates that not the olefin but elemental sulfur is activated by the molybdenum oxo complex **2**.

In Scheme 4, a mechanism is proposed for this catalytic sulfur-atom transfer, in which first sulfuration of the oxo complex **2** to the disulfur complex **3** takes place, followed by sulfur-atom abstraction from the disulfur bridge to afford the sulfido complex **A** as intermediate. Similar molybdenum monosulfido complexes have recently been isolated and characterized.[9] The subsequent sulfur-atom transfer from the sulfido complex **A** to the cycloalkene regenerates the initial oxo complex **2** and thereby the catalytic activity is sustained. In support of this mechanism for the sulfur abstraction from the

† This work was presented at the XIXth International Symposium on the Organic Chemistry of Sulfur, Sheffield, England, 25th–30th June 2000.

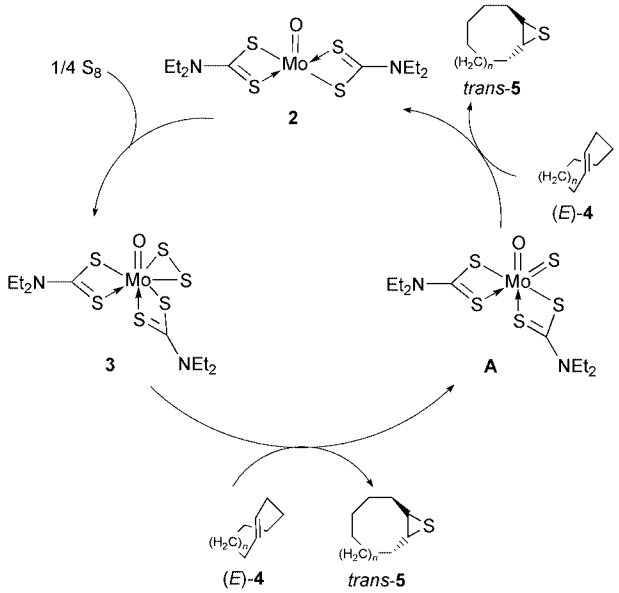

Scheme 4 Catalytic cycle for the generation of the disulfur complex **3** and the sulfuration of (*E*)-cyclooctene [(*E*)-**4a**) and (*E*)-cyclononene [(*E*)-**4b**].

disulfur complex **3** by PPh_3, the intermediary sulfido complex **A** was suggested.[10]

In view of the difficulties with the previous report,[2] presently the first catalytic episulfidation of (*E*)-cycloalkenes with elemental sulfur has been developed, in which the molybdenum oxo complex **2** functions as catalyst and the disulfur complex **3** as sulfur-transfer agent. These encouraging results should stimulate an intense search for more reactive molybdenum disulfur complexes to effect in a general manner the direct episulfidation of olefins with elemental sulfur.

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for generous financial support.

Notes and references

§ *General episulfidation procedure*: in an NMR tube were placed under argon gas 64.2 mg (2.00 mmol) of elemental sulfur and 28.6 mg (70.0 μmol) of molybdenum oxo complex **2** in 0.7 ml of oxygen-free acetone, and 130 μl (1.00 mmol) of (*E*)-cyclooctene [(*E*)-**4**] were added. The tube was sealed with a rubber septum and Parafilm®, then heated for 15 h in an oil bath to 56 °C. After cooling to room temperature, the tube was opened, the suspension transferred to a flask and the solvent evaporated (40 °C/500 mbar). The residue was subjected to silica-gel flash chromatography and 98.0 mg (69%) of *trans*-9-thiabicyclo[6.1.0]nonane (*trans*-**5a**) was isolated, R_f (silica gel, petroleum ether) = 0.33. Nanoparticles of chromium or nickel have been prepared by the reduction of either $CrCl_2$ or $Ni(acac)_2$ (acac = pentane-2,4-dionate) at elevated temperatures in various Lewis base solvents; the effect of the Lewis base, which acts as both a reaction solvent and passivating ligand on morphology are apparent; the nanostructures have been analysed by NMR, IR, TEM and XRD.

Nanoparticles of metals have been known since antiquity and colloids of gold have been the subject of systematic study since 1857.[1] To date, noble metals such as gold and platinum have received most attention as they are intrinsically easier to prepare than metals such as nickel and cobalt; mainly because of their resilience to atmospheric degradation.[2–4] A popular, simple route to high quality alkylthiol passivated gold particles has been reported by Brust *et al*.[5] which has been extended to the preparation of iridium and palladium nanoparticles.[6] Heath and coworkers have also made significant advances in the preparation of noble metal colloids.[7] Nanoparticles of metals such as cobalt or nickel have interesting magnetic properties, which have potential as data storage devices and in ferrofluids. Nanoparticles of cobalt have also been prepared from oil-in-water micelles,[8] by the reduction of metal salts coupled with rapid expansion of supercritical fluid solutions.[9] Nickel nanoparticles have been prepared by the sonification of nickel tetracarbonyl.[10]

Sun and Murray have recently reported a route to high quality monodispersed passivated nanoparticulate cobalt.[11] In this work, cobalt nanoparticles were prepared by reduction of cobalt(II) chloride by superhydride in various coordinating solvents based on the tri-*n*-octylphosphine oxide (TOPO) system. Dinega and Bawendi have also prepared TOPO capped cobalt nanocrystals by thermolysis of dicobalt octacarbonyl.[12] In both cases, a new phase of cobalt was obtained, assigned ε-cobalt (space group $P4_132$), a phase similar to cubic β-manganese. This product could be used as a precursor to the more usual hexagonal close packed cobalt. Whilst single domain particles of nickel and cobalt are known to exhibit ferrimagnetism, chromium is antiferromagnetic and is not expected to have any magnetic applications. However, chromium nanostructures have been investigated.[13] The oxidation of cobalt nanoparticles to cobalt oxide once the protective ligand is removed has previously been reported,[11] and it is hoped that the controlled oxidation of chromium nanoparticles may result in the magnetic phase CrO_2, rather than the usual Cr_2O_3.

Here we report a simple preparation of alkylphosphine/alkylphosphine oxide passivated chromium and nickel nanoparticles. $Ni(acac)_2$ or $CrCl_2$ was reduced with either $LiBH_4$ or $NaBH_4$ in various Lewis base solvent systems in attempts to produce nanoparticles. Lewis bases such as tri-*n*-octylphosphine oxide (TOPO), tri-*n*-octylphosphine (TOP), tri-*n*-butylphosphine (TBP) and tri-*n*-butylphosphine oxide (TBPO) were utilised as both the reaction solvents and passivating ligands. The TOPO used in the experiments was technical grade (Aldrich, 90%), purified as described in the literature.[14] The TBPO was used as received (Aldrich, 95%), as was TOP (Aldrich, 90%) and TBP (Aldrich, 97%).

In a typical reaction, 20 g of trialkylphosphine oxide is heated to *ca*. 100 °C and degassed whilst periodically being flushed with nitrogen. The reducing agent MBH_4 (M = Na, Li) is placed in the reaction flask with the phosphine oxide, mixed, the temperature raised to between 150 and 250 °C and stabilised. (Reaction between the reducing agent and the phosphine oxide may occur. However this has not been investigated and does not appear to hinder the reduction of the metal precursors.) In a separate flask, *ca*. 0.5 g of precursor (either $CrCl_2$ or $Ni(acac)_2$) is dissolved in 5 ml of trialkylphosphine. Rapid injection of the metal precursor solution into the reaction flask results in an immediate dark colouration, consistent with reduction of the precursor. Growth is stabilised at between 150 and 250 °C for 30 min and the flask is removed from the heat and allowed to cool to *ca*. 60 °C. The nanoparticles were either dissolved straight into a solvent (toluene or pyridine) or isolated as a powder by addition of a non-solvent (methanol or light petroleum). The preferred solvent is pyridine, as this polar Lewis base solvent appears to increase the stability of the suspension.

The identity of the materials as the metals was confirmed by XRD. Both chromium and nickel nanoparticles gave reflections consistent with the cubic forms of the metals. The strongest peak in the PXRD of nanosized nickel was at 2θ *ca*. 44°, corresponding to the strongest 111 reflection of bulk nickel.[15] A weaker peak at *ca*. 51° is consistent with the 200 reflection, the second strongest reflection in bulk cubic nickel. The chromium sample gave a set of broad, weak reflections between 2θ = 40 and 50° the region of the 200, 210, 211 reflections of the metal, and another broad reflection between 55 and 70° (220, 310). These reflections are in the regions associated with the strongest reflections for bulk cubic chromium.[16]

Electron microscopy of the metal nanoparticles showed a distinct relationship between morphology and the capping agents. Preparation of chromium nanoparticles in TOPO produced highly monodispersed spherical quantum dots of *ca*. 5 nm in size (Fig. 1). Preparation of nanoparticulate nickel in TBPO showed a mixture of small (2–5 nm) particles and long nanowires up to 20 nm in length. Impurities in the mixed ligand system (TBPO/TBP) are believed to be responsible for the formation of the elongated structures (Fig. 2). The control of metal quantum dot shape and size by the capping ligand has been previously demonstrated with gold nanoparticles.[17] Alivisatos and coworkers have investigated the preparation of elongated semiconductor nanoparticles and rods by synthesis using controlled amounts of 'impurities'.[18,19]

The electronic spectra of metal colloids are well documented, especially for gold.[20] The electronic spectra of nickel and chromium colloids prepared as described above showed unusual features. Colloidal chromium displayed no absorption

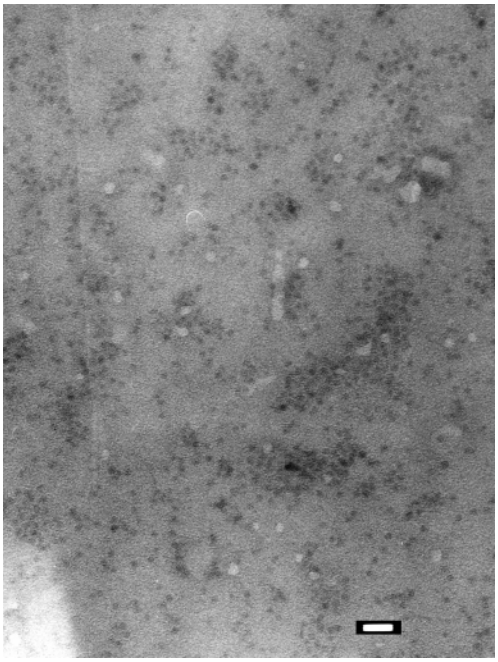

Fig. 1 TEM image of TOPO/TOP capped Cr nanoparticles, bar = 20 nm.

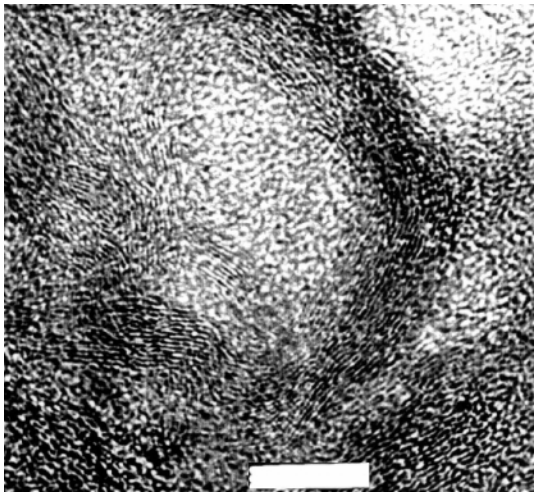

Fig. 2 HRTEM image of TBPO/TBP capped Ni nanowires, bar = 10 nm.

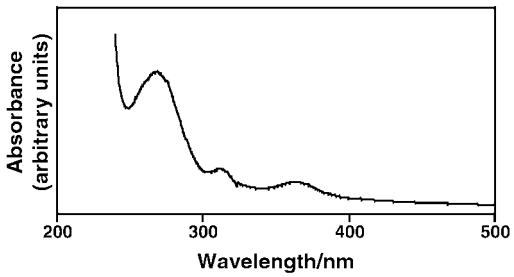

Fig. 3 Electronic spectrum of nickel nanoparticles capped with TBPO/TBP.

bands when prepared, whilst nickel displayed three peaks (Fig. 3). Altering the preparation of chromium nanoparticles by including an amine into the reaction mixture resulted in nanoparticles that displayed two plasmon resonance peaks. The origin of such effects is still under investigation. The effects of a nanoparticle's aspect ratio on optical properties, notably the surface plasmon resonance, has been investigated by El-Sayed and coworkers.[21] The presence of multiple plasmon resonances in metals has also been observed by Lutz *et al*.[22]

Solution ^{1}H and ^{31}P NMR reveals that the ligands are bound to the nanoparticle surface. The broadening of the proton spectra for all samples indicates the inhomogeneous magnetic environment due to restricted molecular motion. The phosphorus spectra reveal a shift in the resonances, consistent with surface shielding effects. TOPO capped chromium nanoparticles show a single resonance at *ca*. 45 ppm, shifted from the unattached ligand resonance at *ca*. 50 ppm.

TBPO capped nickel nanoparticles displayed a distinct resonance at *ca*. 45 ppm, shifted from the free ligand resonance at 59 ppm. Other resonances observed at −18 and −31 ppm were attributed to TBP. Unattached TBP displays resonances at −19 and −32 ppm, as well as minor features at 42, 29, −38 and −70 ppm. These may well be from impurities that encourage nanowire formation in TBPO/TBP capped Q-Ni. FTIR spectroscopy of the TOPO capped chromium particles did not show a shift in the ν(P=O) stretch at 1145 cm^{-1}, but did show a broadening in this feature, which has also been observed with TOPO capped semiconductors. TBPO capped nickel displayed the ν(P=O) stretch at 1128 cm^{-1}, shifted from the free ligand at *ca*. 1152 cm^{-1}.

In conclusion we have demonstrated a simple solution based route to passivated nanoparticulate nickel and chromium. Further work is ongoing to identify the magnetic properties of such materials.

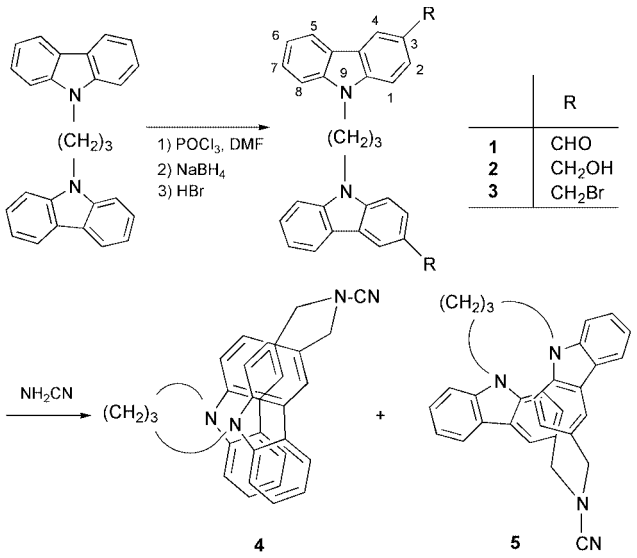
syn- And _anti_-[3.3](3,9)carbazolophanes, which are suitable model compounds for sandwich and partial-overlap excimers, respectively, have been synthesized and characterized; the structures of both singlet and triplet carbazole excimer have been described.

Poly(*N*-vinylcarbazole) (PVCz) has been the subject of intense investigation because of its photoconductive and photophysical properties.[1] In particular, two kinds of excimer, sandwich and partial-overlap excimers, formed in PVCz are of high interest.[2] The excimer formation in PVCz solutions has been extensively studied using bichromophoric compounds such as 2,4-dicarbazol-9-ylpentane.[3] These excimer emissions are also observed even in PVCz solids where conformational change of carbazole (Cz) chromophores is highly restricted. In PVCz solids, electronic excitation energy of Cz monomer migrates efficiently into an excimer-forming site where conformation of two Cz chromophores are sufficiently similar to that of the excimers. Cyclophanes are some of the most attractive molecules for investigating the electronic interactions of face-to-face arranged aromatic molecules in solids as well as in solutions.[4] Here we report the synthesis and photophysical properties of *syn*- and *anti*-[3.3](3,9)carbazolophane derivatives used as model compounds of excimer-forming sites in PVCz films.

Treatment of 1,3-dicarbazol-9-ylpropane with phosphorous oxychloride and DMF gave **1**, which was reduced with sodium borohydride to afford **2** (Scheme 1). Bromination of **2** with excess conc. HBr afforded unstable dibromide **3**. The intramolecular cyclization of **3** with NH_2CN was carried out according to the method developed by one of us (H.T.)[5] to afford *syn*-isomer **4** and *anti*-isomer **5** in 3.3% and 28% yield, respectively.†



Scheme 1 Synthesis of [3.3](3,9)carbazolophanes, **4** and **5**.

The structures of carbazolophanes **4** and **5** were clearly determined by X-ray analyses.‡ Fig. 1 shows that two carbazole rings in **4** completely overlap each other. Their least-squares planes are inclined only 8.7° and the intramolecular distance between carbazole nitrogen atoms in **4** is 3.24 Å. Fig. 2 shows the X-ray analysis of **5**, which clearly indicates the overlap of only a 3-position-bridged benzene ring in the mutual Cz chromophores, just like the proposed partial overlap singlet excimer in the *tt* conformation of the syndiotactic sequence in PVCz,[2] and their least-squares planes are inclined only 6.2°. Thus, it is concluded that **4** and **5** having [3.3] linkages are suitable model compounds for investigating both sandwich and partial-overlap interactions in excimer-forming site in PVCz films, respectively.

(A) in Fig. 3 shows absorption spectra of *N*-ethylcarbazole **6**, **4**, and **5** in THF. The absorption shapes of both **4** and **5** were different from that of **6**, *i.e.*, broadening and red-shift were observed. These features were ascribed to the exciton band splitting as is commonly applied to interpret absorption spectra of cyclophanes.

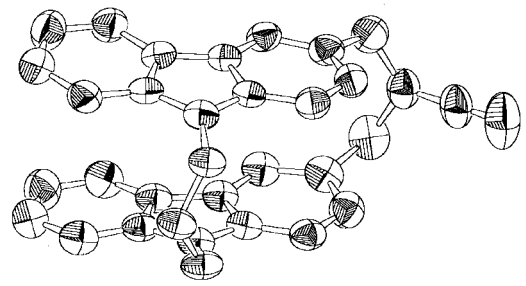


Fig. 1 Crystal structure (ORTEP representation) of **4**.

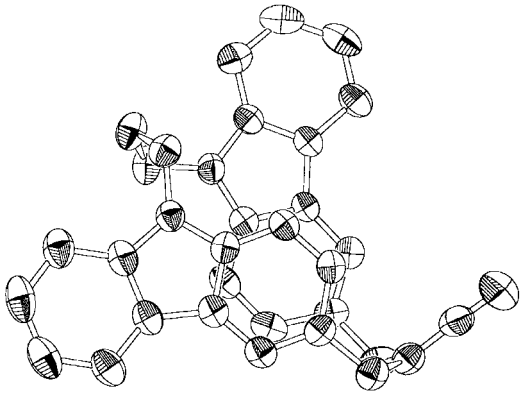

Fig. 2 Crystal structure (ORTEP representation) of **5**.

 DOI: 10.1039/b104101k

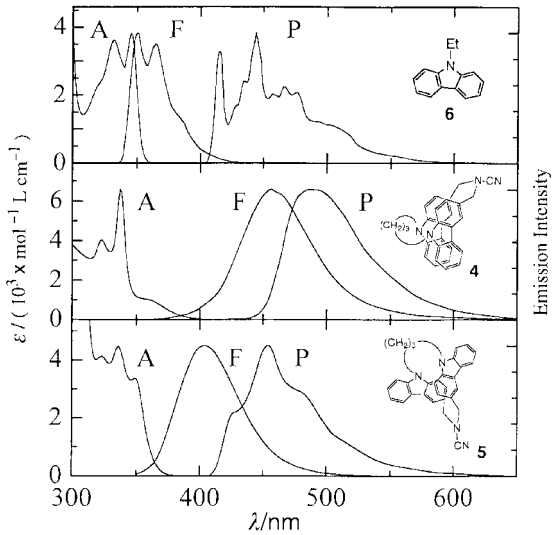

Fig. 3 Absorption (A), fluorescence (F) (λ_{ex} = 340 nm), phosphorescence (P) (λ_{ex} = 340 nm) spectra of **6**, **4**, and **5**: (A) were measured in a THF solution at room temperature; (F) in a MTHF solution at room temperature; (P) in a MTHF rigid matrix at 77 K. Emission spectra of **4** and **5** are normalized at the maximum of each spectrum peak. All samples used for fluorescence and phosphorescence measurements were degassed by the freeze–pump–thaw method. The concentrations of **4**, **5**, and **6** were *ca.* 2.0 $\times$ 10^{-5} M.

The fluorescence spectra of **4**, **5**, and **6** were measured in 2-methyltetrahydrofuran (MTHF) at room temperature indicated by (F) in Fig. 3. Both **4** and **5** exhibit broad structureless emission and large Stokes shifts (7650 cm^{-1} for **4**, 3960 cm^{-1} for **5**). These broad emissions were not due to any impurity, because the excitation spectra for the broad emission of **4** and **5** were almost the same as the absorption spectra. Therefore, two kinds of fluorescence observed from **4** (λ_{max} 457 nm) and **5** (405 nm) correspond to the emissions from the sandwich and partial-overlap excimer-forming sites in PVCz films respectively,[2] although there are slight red-shifts in the peak wavelength. The difference demonstrates that two Cz chromophores in **4** and **5** are located in a suitable geometry for the sandwich and partial-overlap excimer-forming sites in PVCz films.

The phosphorescence spectra of **4**, **5**, and **6** were measured in a MTHF rigid matrix at 77 K indicated by (P) in Fig. 3. The phosphorescence spectrum of **6** consists of a structured monomer phosphorescence with the peaks 414 and 444 nm. On the other hand, **4** exhibits a broad structureless band centered at 487 nm, which roughly agrees with that of PVCz films.[6] The phosphorescence spectrum of **5** consists of a structured band with a maximum at 454 nm, though considerable broadening and red-shift were observed. The excitation spectra for phosphorescence of **4** and **5** were almost the same as the corresponding absorption spectra. In polymeric systems, it is difficult to distinguish between triplet excimer and any impurity emission, because high concentration of the chromophores enhances photosensitization.[7] However, in our system, each carbazolophane is isolated and such sensitized phosphorescence is negligible. Therefore we ascribed the spectral change observed in the phosphorescence spectra to intramolecular electronic interaction in the excited triplet state of carbazolophanes. The structured vibrational band of **5** indicates that triplet interaction in **5** is weak. The broad emission of **4** shows that the sandwich geometry of two Cz chromophores in close proximity can surely interact in the triplet state and form a triplet excimer.

In summary, we are confident that carbazolophanes **4** and **5** will disclose interesting sandwich and partial-overlap interactions in excimer-forming sites in PVCz films. They showed definite dependence of the emission spectra upon the geometry of Cz chromophores. The most striking point of this work is that one of the geometry of triplet excimer in PVCz films is revealed for the first time.

First published as an Advance Article on the web 13th September 2001

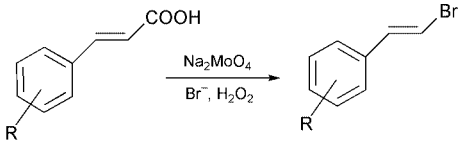
Reaction of α,β-unsaturated aromatic carboxylic acids with KBr and H_2O_2 in the presence of $Na_2MoO_4{\cdot}2H_2O$ in aqueous medium affords β-bromo alkenes in high yield.

The classical Hunsdiecker reaction and its later modifications are efficient for the synthesis of organic halides.[1] However, these reactions have major limitations, such as toxicity and hazard involving use of elemental bromine, salts of Hg(II), Tl(I), Pb(IV), Ag(I). Apart from this, very poor yields of the products are obtained in the cases of α,β-unsaturated aromatic carboxylic acids. Recently, some of these difficulties have been overcome by the use of lithium acetate as the catalyst and *N*-bromosuccinimide as the bromine source, the reaction medium being aqueous acetonitrile.[2] However, low yields were obtained in the cases of α,β-unsaturated aromatic carboxylic acids bearing electron-withdrawing groups in the aromatic ring.

Transition metal peroxo compounds have been shown to be efficient oxidising agents for various organic substrates.[3–6] Some marine organisms use a vanadium dependant enzyme, bromoperoxidase, for the bromination of organic compounds using inorganic bromides and hydrogen peroxide.[6] We have been investigating bromination of organic compounds using vanadium(V) or molybdenum(VI), potassium bromide, and hydrogen peroxide in aqueous medium.[7–9] It was observed that the transition metal peroxo complexes can oxidise inorganic bromide and produce Br_3^- species which is in equilibrium with HOBr and Br_2.

We thought that this biomimetic system could be utilised as an alternative route to the Hunsdiecker reaction. Herein we report the initial results of our studies on the reaction of α,β-unsaturated aromatic carboxylic acids with KBr and H_2O_2 in aqueous medium in the presence of $Na_2MoO_4{\cdot}2H_2O$.

When a suspension of α,β-unsaturated aromatic carboxylic acid (0.02 mol) is stirred with KBr (0.04 mol) and $Na_2MoO_4{\cdot}2H_2O$ (0.001 mol) in water (5 cm^3) and H_2O_2 (15 cm^3, 0.13 mol) is added drop-wise at room temperature (30 °C), a rapid reaction takes place and the temperature rises to 80 °C within 20 min. The reaction mixture was stirred for further 20 min and the product as well as the unreacted acid was extracted with diethyl ether. The corresponding β-bromostyrene was separated from the starting material by column chromatography in good yield (Scheme 1). The yield of the styrene is very good in the cases of α,β-unsaturated aromatic carboxylic acid bearing a substitutent in the 4-position. For example, 3-(4-methoxyphenyl)prop-2-enoic acid and 3-(4-chlorophenyl)prop-2-enoic acid yield the corresponding β-bromo alkenes in 85 and 65% yield respectively. It may be noted that for 3-(4-chlorophenyl)prop-2-enoic acid a larger amount of Na_2MoO_4 (acid–Mo, 10 : 1) is required for better yield. The unsubstituted acid also affords β-bromostyrene in good yield (65%). In the case of an acid bearing substituents in 2-positions, for example, 3-(2-chlorophenyl)prop-2-enoic acid and 3-(2-methylphenyl)-prop-2-enoic acid, the yield of the corresponding β-bromostyrene is very poor (5 and 15%, respectively). The evolution of CO_2 was detected by passing the outcoming gas through limewater. It may be noted that this is the first report of isolation of Hunsdiecker products in water. All the earlier reports deal with the reactions in non-aqueous medium.



R = H or 4-OMe or 4-Cl or 2-Me or 2-Cl

Scheme 1

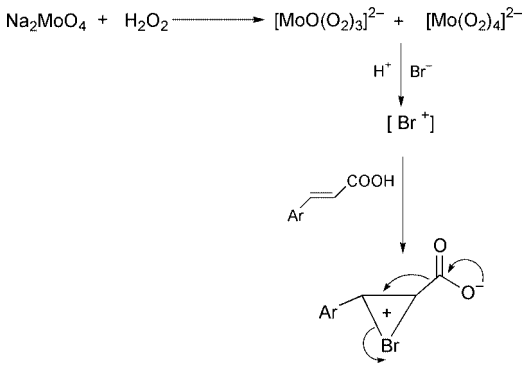
The solution of Na_2MoO_4 (0.001 mol) and KBr in H_2O (5 cm^3) is basic in nature (pH 10). Upon addition of solid acid, the pH of the slurry changes to 4.5. When H_2O_2 (15 cm^3) is added to the reaction mixture, the measured pH is 3.9. The pH of the reaction changes to 9 upon completion of the reaction. It has been shown by Rothenberg and Clark that a proton source is required for oxyhalogenation.[10] Thus in these reactions the proton source is the acid itself.

It has been shown earlier that, MoO_4^{2-} forms a number of peroxo species in solution in the presence of H_2O_2. The ^{95}Mo NMR spectra of a solution of Na_2MoO_4 (0.001 M) in H_2O_2 (15 cm^3) shows a major signal at −336 ppm and a relatively low intensity signal at −509 ppm. These are due to the formation of $[MoO(O_2)_3]^{2-}$ and $[Mo(O_2)_4]^{2-}$ species, respectively.[11] Upon addition of Br^- both the signals at −509 and −336 ppm disappear and two signals at −222 and −37 ppm appear. The signal at −222 ppm can be assigned to $[MoO(O_2)_2]^{2-}$.[11] The signal at −37 ppm may be assigned to a molybdate species coordinated to bromide. The slight shift in the observed ^{95}Mo NMR spectra from those of reported ones[11] may be due to the effect of pH as well as extent of hydration.

A blank reaction, which is a similar reaction without the addition of Na_2MoO_4, did not afford the brominated products. Thus, it is clear that bromide is oxidised by the peroxomolybdate species formed in solution.

The electronic spectrum of a solution (10^{-3} M) of Na_2MoO_4 in H_2O_2 (2×10^{-2} M) shows bands at 445 (ε = 162) and at 293 nm (ε = 1620 mol^{-1} dm^3 cm^{-1}). These are due to the tetraperoxo and triperoxomolybdate species.[11] When KBr is added to this solution an absorbance increase is observed in the region 700 to 290 nm. However, no new band appears. The molar extinction coefficient of the 445 nm band increases to 320 and the band at 293 nm shifts to 298 nm with increase in the molar extinction coefficient (ε = 1833). It may be noted that the oxidised bromide species, Br_2, Br_3^- and OBr^- absorb in the region, 450 to 300 nm. Meister and Butler[12] and our earlier work on the oxidation of Br^- by H_2O_2 in the presence of Mo(VI)[9] have shown that Mo(VI) first forms peroxomolybdate which then oxidises Br^- to form an equilibrium mixture of Br_2, Br_3^- and OBr^-. Thus it clear form the earlier work as well as from the present evidence that the peroxomolybdates generated

 DOI: 10.1039/b104540g



Scheme 2

from the reaction of H_2O_2 and MoO_4^{2-} react with Br^- to produce the equivalent of the Br^+ species, which then react with the unsaturated acid to give bromo alkene.

In order to identify the brominating species, reactions of Br_2 in aqueous KOH (HOBr–OBr^-) (pH = 10) as well as Br_2 in aqueous KBr (Br_3^-) with the acid in aqueous medium were carried out. But in both the cases we could only isolate the starting material. Thus, it is clear that the Mo center plays an important role, and probably the coordination of the acid is required for the conversion as observed in the case of vanadium bromoperoxidase.[13]

From the above spectral evidence, it may be inferred that, the reaction proceeds through an ionic mechanism (Scheme 2). It may be noted that a similar mechanism has been suggested by Roy *et al*. earlier.[2] The reason behind the low yield of the products in the cases of *ortho* substituted aromatic acids may be due to steric crowding of the intermediate bromonium species. The reactions described here show that the Hunsdiecker reaction can be brought about in aqueous medium, contrary to earlier reports, and also this is the greenest route to Hunsdiecker products.

The authors would like to thank Dr Sujit Roy, Department of Chemistry, Indian Institute of Technology, Kharagpur, India for helpful discussions and suggestions.

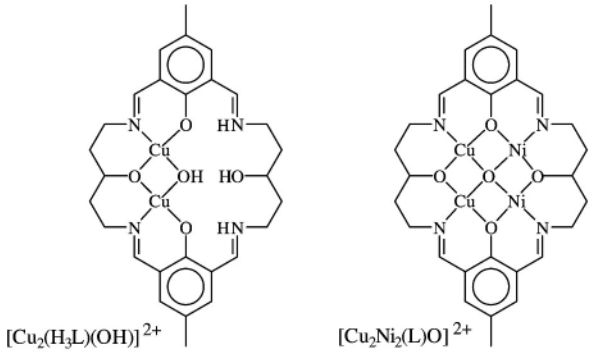
Site-selectivity in a heterotetranuclear macrocyclic complex is controlled by the geometry of the dinuclear intermediate.

Arrays of different interacting metal ions in controlled geometric relationships offer potential access to new reaction chemistry of exogenous ligands on such a bimetallic 'surface' and insights into heteronuclear metal–metal interactions. Synthesis of such complexes requires some mechanism for site-selectivity. Heterodinuclear complexes of phenol-based Robson[1] macrocycles are among the most studied examples[2] and the essential synthetic step is formation of a precursor containing only one type of metal ion. Most commonly, this is achieved by designing ligands with different binding sites and hence different preferences for particular metals. The metal ions are then incorporated sequentially (sometimes the first metal is selectively eliminated from one or more sites before adding the second metal[3]). Similar requirements apply to larger, tri- or tetra-nuclear systems.[4,5] Here we report the structure of a complex incorporating a heterotetranuclear macrocyclic unit in which the macrocyclic binding sites are identical. The geometric arrangement of the metal ions in the tetranuclear product is controlled by the structure of the dinuclear intermediate.

The dicopper(II) species $[Cu_2(H_3L)(OH)]^{2+}$ can be prepared directly in a metal-deficient template reaction. Reaction of



$[Cu_2(H_3L)(OH)]^{2+}$ $[Cu_2Ni_2(L)O]^{2+}$

equimolar amounts of 2,6-diformyl-4-methylphenol (Hdfmp), 1,5-diamino-3-hydroxypentane and $Cu(X)_2{\cdot}6H_2O$ (X = NO_3 or BF_4) in methanol–water (2:1) yields complexes of formula $[Cu_2(H_3L)(OH)]X_2$, each showing characteristic FAB MS spectra (in NOBA), with clusters centred on *m*/*z* values of 616 (100), 635 (20) and 653 (12%) assigned to $\{[Cu_2(H_2L)]\}^+$, $\{[Cu_2(H_3L)(OH)]\}^+$, and $\{[Cu_2(H_3L)(OH)](H_2O)\}^+$, respectively. The presence of two different imine sites is indicated by the presence of two imine stretches in the IR spectra (KBr disc), at 1636 and 1654 cm^{-1}. The stoichiometry suggests that the phenol protons have transferred to the uncoordinated imine groups, a common feature in related systems.[6,7]

The dicopper complexes dimerise on recrystallisation from methanol by slow diffusion of diethyl ether to form crystals† of formula $[Cu_2(H_3L)O]_2X_2{\cdot}nH_2O$ with IR and FAB-MS spectra very similar to the monomers. The centrosymmetric cation from $[Cu_2(H_3L)O]_2(NO_3)_2{\cdot}5H_2O$ is shown in Fig. 1, and comprises two parallel dicopper(II) macrocyclic units. The copper ions are

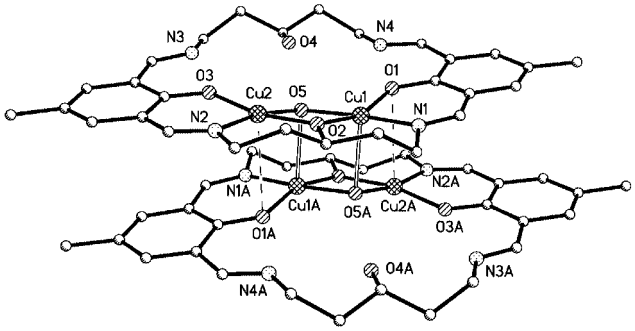


Fig. 1 Molecular structure of the $\{[Cu_2(H_3L)O]_2\}^{2+}$ cation. Selected distances (Å): Cu(1)–Cu(2) 3.0013(7), Cu(1)–O(5A) 2.413(3), Cu(2)–O(1A) 3.084(3).

bridged by one of the ligand alkoxy donors and by an exogenous oxo ligand. The two macrocycles are linked by two symmetry-related Cu–oxo bonds, supported by longer interactions between the second copper ion and a phenolate oxygen from the second ring. The structure of the dimer is markedly similar to that of the fully occupied analogue where tetranuclear and octanuclear forms are interconvertible.[8,9] In each case the dimerisation involves displacement of the OH proton by a copper(II) ion from the second macrocycle.

The alkoxide-bridged, side-by-side geometry of this intermediate complex is the key factor determining the geometry of the heterotetranuclear product described below. There are three possible arrangements of two copper ions between the four potential binding sites. The side-by-side geometry permits the copper ion to bind the largest number of deprotonated donors (an alkoxo, a hydroxo and two phenoxo donors) and is, presumably, favoured for this reason. We have never observed the conventional Robson geometry (dinuclear, bridged by two phenolate groups) in these complexes. The third possibility, a diagonal dinuclear complex in which none of the macrocyclic oxygen donors are bridging, can form[10,11] but requires different conditions.

Reaction of the dinuclear complexes with an excess of nickel(II) acetate yields heterotetranuclear complexes of formula $[Cu_2Ni_2(L)(OH)(OAc)]X_2$. These complexes are identical with those obtained *via* pyrazolate intermediates[7] and consist of olive-green powders which were readily identified from their FAB-MS spectra but which are resistant to crystallisation. However reaction of $[Cu_2(H_3L)(OH)](BF_4)_2$ with an excess of nickel(II) acetate in the presence of excess dfmp yielded small crystals† of $\{[Cu_2Ni_2(L)O(OAc)][Ni_2(dfmp)(OAc)(OH)_3]\}{\cdot}6.5H_2O$. The structure of this neutral complex is shown in Fig. 2, and the metal coordination spheres are illustrated in Fig. 3. The heterotetranuclear $[Cu_2Ni_2(L)O]$ macrocyclic unit is capped on one face by an acetate ion bridging the two nickel ions. Bound to the other face is an assembly comprising two nickel ions coordinated by a diformylmethylphenolate anion, three hydroxo ligands and a second acetate ion, also bridging two nickel ions. There are six bonds linking the macrocycle to the superstructure; four Ni–O bonds and two (longer) Cu–O interactions. The core (Fig. 3) can also be described as based on

a Ni_4O_4 cubane. All the adjacent metal–metal distances are under 3 Å.

The X-ray data do not distinguish between the electron densities of nickel and copper ions, so assignment must be based on other factors. Firstly, the stoichiometry is consistent with the FAB-MS data, which show the presence of species containing two copper ions and four nickel ions. The spectrum (in NOBA) shows four significant clusters at *m*/*z* values of 747 (18), 807 (100), 1199 (41), and 1225 (29%) which are assigned to {[Cu_2Ni_2(L)O] − H}$^+$, {[Cu_2Ni_2(L)(OH)(OAc)]}$^+$, {[Cu_2-Ni_2(L)O(OAc)][Ni_2(dfmp)(OAc)$(OH)_3$] + H}$^+$ and {[Cu_2Ni_2-(L)O(OAc)][Ni_2(dfmp)(OAc)$(OH)_3$] + Na}$^+$, respectively. The clusters at *m*/*z* of 747 and 807 are also the principal features seen in the FAB-MS spectrum[7] of [Cu_2Ni_2(L)(OH)$(OAc)_2$]BF_4. There is no indication of scrambling of the metal ions. Secondly, the observed geometry at the metal sites, square pyramidal at copper and six-coordinate pseudo-octahedral at nickel, is consistent with the present assignment. If copper occupied the sites assigned to nickel, significant Jahn–Teller distortion would be expected and this is not observed.

The structure of the heteronuclear complex demonstrates that the macrocycle retains the metal ions in the side-by-side geometry, reflecting the structure of the dinuclear precursor. Site-selection for the heteronuclear product has been achieved based on the relative stability of one of the three possible dinuclear intermediates, without requiring different sites in the macrocyclic ligand itself.

The additional superstructure demonstrates that it is possible to use the Cu_2Ni_2 array as a platform to bind both further ligands and metal ions. Related synthetic strategies might be used to design larger mixed metal assemblies.

We are grateful to the EPSRC Mass Spectrometry Service Centre, Swansea for FAB(LSIMS) spectra and to the EPSRC for access to Station 9.8 of the SRS at Daresbury.

Notes and references

† Both crystals were too weakly diffracting for data collection using a standard laboratory sealed-tube source and so the data were collected at 150 K on Station 9.8 of the Synchrotron Radiation Source at Daresbury.[12] The structures were solved and refined using the SHELXTL[13] package.

[Cu_2(HL)O]$_2$(NO_3)$_2$·5H_2O: $C_{56}H_{80}Cu_{4.12}N_{10}O_{21}$, triclinic, space group $P\bar{1}$, a = 11.2527(7), b = 13.2136(8), c = 13.8116(9) Å, α = 104.974(1), β = 100.755(1), γ = 111.187(1)°, V = 1758.1(2) Å^3, λ = 0.68900 Å, Z = 1, 10912 reflections measured, 6465 unique (R_{int} = 0.030), $wR(F^2)$ = 0.1581 (all data), $R1$ = 0.0559 [$I > 2\sigma(I)$]. Non-H atoms were assigned anisotropic ADPs except the partial occupancy Cu(II) ions. H atoms bonded to carbon were inserted at calculated positions. The remaining protons were not located or included in the model. There is approximately 3% occupancy of the vacant Cu coordination sites, and the saturated section of the macrocyclic chain on the vacant side is disordered 70:30 between two related conformations. The lattice contains a number of severely disordered water molecules; attempts to model these were only partially successful so the PLATON SQUEEZE[14] procedure was used instead. A single void of 380 Å^3 (21.6% of the cell volume) was located between the cations, the five H_2O molecules given in the formula are based on the estimate of 88 electrons in the void.

{[Cu_2Ni_2(L)O(OAc)][Ni_2(dfmp)(OAc)$(OH)_3$]}·6.5H_2O: $C_{41}H_{61}Cu_2N_4$-$Ni_4O_{21.5}$, monoclinic, space group $C2$, a = 24.1826(1), b = 20.100(1), c = 13.9551(8) Å, β = 93.223(1)°, V = 6773.5(7) Å^3, λ = 0.69410 Å, Z = 4, 21150 reflections measured, 11931 unique (R_{int} = 0.024), $wR(F^2)$ = 0.2459 (all data), $R1$ = 0.0741 [$I > 2\sigma(I)$]. The structure could be solved and refined in either $C2/m$ or $C2$; in the $C2/m$ solution, the molecule lies on a mirror plane with the dfmp component disordered, having 50% occupancy on either side of the mirror. Since this implies that no individual molecule actually possesses mirror symmetry, the solution in $C2$ was preferred. In this space group no major disorder of the complex is exhibited but the structure behaves as a racemic twin. All non-H atoms were assigned anisotropic ADPs; hydrogen atoms bonded to carbon were inserted at calculated positions, those bonded to oxygen were not included in the model. Directly linked dehydropurpurin–porphyrin dyads from Ag(I)-promoted oxidation of *meso*-phenylethynyl substituted zinc(II) porphyrins

Aiko Nakano, Naoki Aratani, Hiroyuki Furuta and Atsuhiro Osuka*

Department of Chemistry, Graduate School of Science, Kyoto University, Sakyo-ku, Kyoto 606-8502, Japan. E-mail: osuka@kuchem.kyoto-u.ac.jp

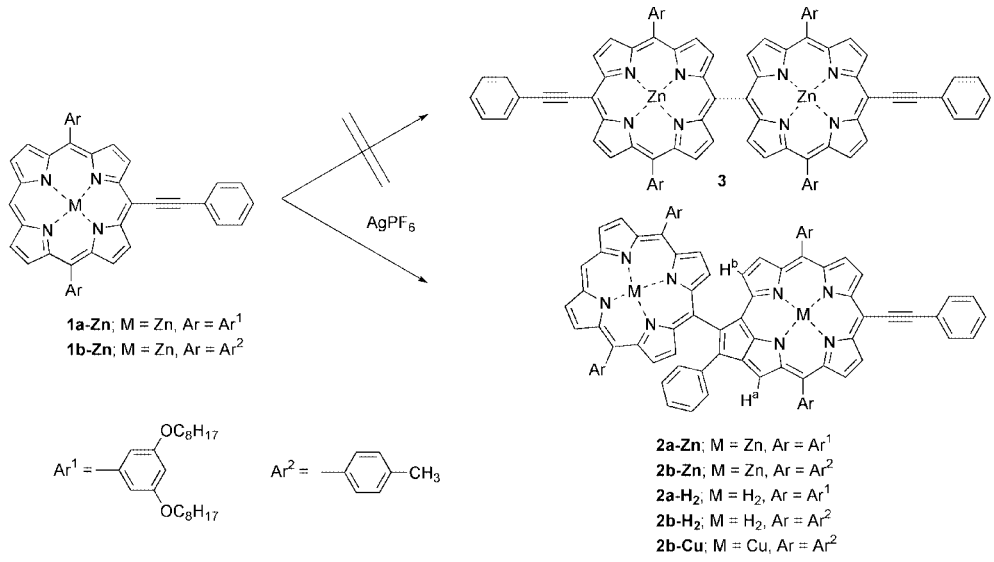
Received (in Cambridge, UK) 9th July 2001, Accepted 21st August 2001
First published as an Advance Article on the web 13th September 2001

Ag(I)-promoted oxidation of (5,15-diaryl-10-phenylethynylporphyrinato)zinc(II) complexes in $CHCl_3$ gave directly linked 12,13-dehydropurpurin–porphyrin dyads, the structures of which were revealed by X-ray analysis.

5,15-Diaryl metalloporphyrins without β-pyrrolic substituents have been shown to be reactive in direct coupling at the *meso*- and/or β-positions under one-electron oxidizing conditions.[1] Along this line, we reported efficient synthetic routes to *meso*–*meso* singly-linked diporphyrins,[2] *meso*–β singly-linked diporphyrins,[3] *meso*–β doubly-linked diporphyrins,[4] and *meso*–*meso*, β–β, β–β triply-linked diporphyrins[5] through the oxidation of metalloporphyrins. The observed metal-dependent coupling regioselectivities are likely to be correlated with the electronic properties of the cation radical intermediates, especially whether the SOMO is derived from the A_{2u} or A_{1u} orbital. In this respect, *meso*-ethynylated metalloporphyrins are of particular interest since their HOMO orbitals are indicated to be extending over the *meso*-ethynyl substituent.[6,7] Here, we report that Ag(I)-promoted oxidation of 5,15-diaryl-10-phenylethynyl-substituted zinc(II) porphyrins gave directly-linked dehydropurpurin–porphyrin dyads.

Treatment of **1a**–**Zn** with 1.0 equiv. of $AgPF_6$ in $CHCl_3$ at room temperature for 6 h followed by separations over size-exclusion and silica-gel columns provided a dimer of **1a**–**Zn** in 34% yield. The molecular weight of the dimer was revealed to be m/z = 2273 (calc. for $C_{144}H_{174}N_8O_8Zn_2$, 2271) by the FAB-MS measurement but its ^{1}H NMR spectrum was compatible not with the structure of symmetric *meso*–*meso* coupling product **3**[8] but with that of **2a**–**Zn**. The ^{1}H NMR spectrum revealed the presence of a symmetric 5-substituted porphyrin subunit by featuring four 2H-equivalent β-protons at 10.31, 9.43, 9.23 and 9.07 ppm, a *meso*-proton at 10.31 ppm, and a set of protons due to the two equivalent 3,5-dioctyloxyphenyl substituents, while the peripheral β-protons in the dehydropurpurin macrocycle appeared as a singlet at 7.56 ppm (H^a); three sets of mutually coupled pairs of doublets were observed of which the most high-field shifted signal appearing at 4.77 ppm was assigned to H^b because of its location in the shielding region of the neighboring porphyrin. In order to obtain an X-ray crystal structure, a similar hybrid dimer **2b**–**Zn** was prepared from **1b** in 19% yield and was converted into the bis-Cu(II) complex **2b**–**Cu**. Fig. 1 shows the X-ray crystal structure of **2b**–**Cu**,[9] which provides firm evidence for the directly-linked porphyrin–12,13-dehydropurpurin dyad. Whereas the *meso*-arylethynyl substituent in the dehydropurpurin moiety is intact, that in the porphyrin is condensed with the unsubstituted porphyrin side to form an exocyclic five-membered ring. The dehydropurpurin macrocycle is nearly flat with a mean plane deviation of 0.119 Å and is directly linked with the porphyrin ring with a dihedral angle of 90.8°. This orthogonal structure well explains the observed ^{1}H NMR spectra mentioned above. It is of interest that the two phenyl rings [designated as Ph^1 and Ph^2 in Fig. 1(a)] are nearly coplanar with the dehydropurpurin macrocycle with dihedral angles of 20.7 and 15.6°, respectively. The mechanism of this dimerization is not fully understood but may be considered to be initiated by one-electron oxidation of the zinc(II)-phenylethynylporphyrin with $AgPF_6$ followed by nucleophilic attack of another neutral porphyrin with its *meso*-position against the ethynyl-carbon adjacent to the *meso*-position.

Although tetrapyrrolic macrocycles with an exocyclic five membered ring are quite ubiquitous both in nature[10] and synthetic studies,[11] the 12,13-dehydropurpurin structure is quite



Scheme 1 Reaction of **1** and $AgPF_6$.

 DOI: 10.1039/b106050n

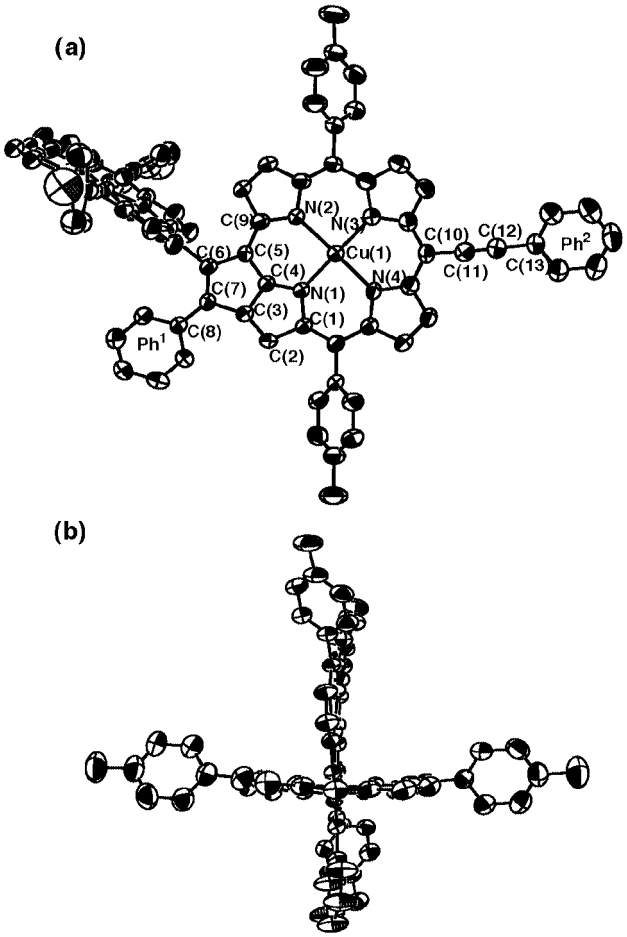


Fig. 1 Molecular structure of **2b–Cu**: (a) top view and (b) side view; solvents and hydrogen atoms are omitted for clarity. Bond lengths of C(6)–C(7) and C(6)–porphyrin *meso*-carbon are 1.38(1) and 1.50(1) Å, respectively.

rare in the literature,[12] and there is much less information on this macrocycle. The ^{1}H NMR spectrum of **2a–H$_2$** revealed the inner NH protons at 3.09 and 5.04 ppm for the dehydropurpurin ring, hence suggesting that its ring current is weaker compared with those in structurally related porphyrins and pheophorbides.

Fig. 2 shows the absorption spectra of **2a–Zn**† and **2a–H$_2$** taken in THF. It is conceivable that the direct connection leads to the strong electronic interaction between the two macrocycles and causes broadening of the absorption bands. Nevertheless, it seems likely that relatively sharp bands at 421 nm for **2a–Zn** and 415 nm for **2a–H$_2$** can be assigned to Soret bands of the porphyrin, and the broad bands at 471 and 498 nm for **2a–Zn** and 482 nm for **2a–H$_2$** can be assigned to Soret-like bands of the dehydropurpurin. In addition, broad Q-like bands are observed at 645 nm for **2a–Zn** and at 674 nm for **2a–H$_2$**. Neither **2a–Zn** nor **2a–H$_2$** exhibits fluorescence, probably reflecting strong electronic interaction between the two macrocycles. These findings may suggest the potential use of such dyads as energy- and electron-transfer functional units. Related detailed studies will be reported elsewhere.

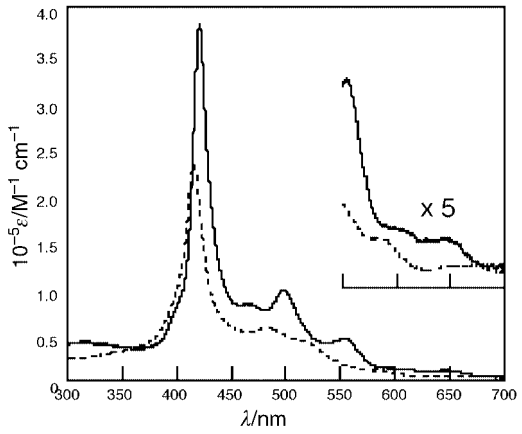

Fig. 2 Absorption spectra of **2a–Zn** (——) and **2a–H$_2$** (- - - - -) in THF.

Received (in Purdue, IN, USA) 15th June 2001, Accepted 12th August 2001
First published as an Advance Article on the web 13th September 2001

Lithiation of $SP[N(H)R]_3$ with $LiBu^n$ produces the dimers $[(THF)LiSP(NR)(NHR)_2]_2$ (R = Pr^i) or $\{[LiSP(NR)(NHR)_2][(THF)LiSP(NR)_2(NHR)]\}_2$ (R = Bu^t) with central Li_2N_2 or Li_2S_2 rings, respectively; further lithiation yields the dianion $[SP(NR)_2(NHR)]^{2-}$ (R = Pr^i) or leads to sulfur extrusion when R = Bu^t.

The first polyimido analogues of the orthophosphate and phosphite anions, *i.e.* $[P(Nnaph)_4]^{3-}$ and $[HP(NC_6H_4OMe\text{-}2)_3]^{2-}$, were reported recently as their lithium derivatives.[1,2] Ambidentate anions involving a combination of hard (N) and soft (S or Se) donor sites attached to a P(v) centre display versatile coordination behaviour[3–6] and some of their alkali-metal derivatives form extended ladder structures.[4,5] For example, the dimers of $[EP(NBu^t)_2]^-$, isoelectronic with metaphosphate PO_3^-, adopt a different bonding mode towards Li^+ than that observed for Na^+ or K^+.[4] Heteroleptic imido/thio analogues of orthophosphate PO_4^{3-} are unknown. As a possible approach to this potentially versatile class of anionic ligands, we have now investigated the reactions of trisamidothiophosphates $SP[N(H)R]_3$ (R = Pr^i, Bu^t) with R′Li reagents. We report here that the steric bulk of R has a marked effect on both the mode of aggregation and the reactivity of partially lithiated derivatives of $SP[N(H)R]_3$.

The reaction of $SP[N(H)Pr^i]_3$ with $LiBu^n$ in a 1 : 1 molar ratio in THF produced the monolithiated derivative $\{(THF)LiSP(NPr^i)(NHPr^i)_2\}$ **1** in 61% yield.† The ^{31}P NMR spectrum of **1** in C_6D_6 showed a singlet at δ 47.9 {*cf.* δ 56.3 for $SP[N(H)Pr^i]_3$}. An X-ray analysis of **1** revealed a centrosymmetric dimer comprised of a step-shaped ladder in the transoid conformation (Fig. 1).‡ The two halves of the dimer are connected by the more polar Li–N bonds rather than the sterically unencumbered Li–S interactions. We note that lithium thioamidates $\{Li[RC(S)NR']\}_n$ invariably aggregate through Li–S bonds.[7] When the same reaction is carried out in a 1 : 2 molar ratio in THF an insoluble product is formed. In the presence of TMEDA, however, this reaction produces the dilithiated complex $\{[(TMEDA)Li]_2[SP(NPr^i)_2(NHPr^i)]\}$ **2**.† Solid state ^7Li and ^{31}P NMR spectra of **2** showed singlets at δ 1.9 and δ 45.7, respectively. An X-ray analysis showed that **2** has a monomeric structure and contains the dianion $[SP(NPr^i)_2(NHPr^i)]^{2-}$ (Scheme 1). Apparently, chelation of Li^+ ions by a TMEDA ligand prevents extensive laddering *via* Li–N interactions (*cf.* $\{[p\text{-}MeC_6H_4N(H)Li\cdot TMEDA]_2\}$);[8] the latter phenomenon may account for the insolubility of the product obtained in the absence of TMEDA.

The reaction of $SP[N(H)Bu^t]_3$ with $LiBu^n$ or $LiN(SiMe_3)_2$ in THF in a 2 : 3 molar ratio produces the complex $\{[LiSP(NBu^t)(NHBu^t)_2][(THF)LiSP(NBu^t)_2(NHBu^t)]\}_2$ **3** in an optimum yield of 82%.† In contrast to the Li–N interactions observed for **1**, an X-ray analysis showed **3** to be a dimer in which the central feature is a cisoid Li_4S_4 ladder (Fig. 2).‡ There is a crystallographic twofold axis through the middle of the central Li_2S_2 ring. The asymmetric unit of **3** is comprised of an aggregate of the mono- and di-lithiated derivatives, $LiSP(NBu^t)(NHBu^t)_2$ and $Li_2SP(NBu^t)_2(NHBu^t)$, respectively, linked by Li–S and Li–N bonds to give a distorted $Li_3PS_2N_2$ cube {bond lengths range from 1.615(6) [P(1)–N(2)] to 2.635(13) Å [Li(2)–S(2)]}. The solid-state ^{31}P NMR spectrum of **3** shows two resonances at δ 28.5 and 25.8. Complex **3** is also generated

Selected bond lengths (Å): Li(1)–S(1) 2.429(12), Li(1)–S(2) 2.541(13), Li(2)–S(2) 2.635(13), Li(3)–S(1) 2.614(13), Li(3)-S(2) 2.614(13), Li(3)–S(1)* 2.449(12), P(1)–S(1) 2.077(2), P(2)–S(2) 2.036(2), P–N (amido) [mean 1.670(14), range 1.651(6)–1.683(6)], P–N (imido) [mean 1.599(24), range 1.566(7)–1.617(6)], Li–N [range 1.937(13)–2.275(13)].

when the reaction of SP[N(H)Bu^t]$_3$ with LiBu^n is carried out in a 1 : 1 molar ratio. In contrast to the behaviour of the Pr^i system, however, the use of a 1 : 2 molar ratio for this reaction results in sulfur extrusion to give the complex [(THF)LiP(NBu^t)$_3$]$_2$ **4** in *ca*. 15% yield. An X-ray analysis revealed that **4** is an $Li_2N_4P_2$ cubane with exocyclic NBu^t groups attached to P, *i.e*. the dimeric lithium derivative of the trisimidometaphosphate anion [P(NBu^t)$_3$]$^-$ (Scheme 1). Monomeric analogues of **4**, *e.g*. the ion-separated complex [Li(THF)$_4$]$^+$[P(NMes*)$_3$]$^-$, have been reported.[9] The P(III) analogue of **4** also has a cubane structure which, in the absence of THF ligands, dimerizes *via* Li–N interactions.[10,11] The facile extrusion of sulfur in this lithiation process is in marked contrast to the formation of Li$_2$[Bu^{t}N(S)P(μ-NBu^t)$_2$P(S)NBu^t] *via* lithiation with LiBu^t in boiling THF.[4b] Further details of this desulfurization process and the X-ray structures of **2** and **4** will be given in a full account of this work.

In summary, we have shown that steric effects influence the mode of aggregation and the reactivity of lithium derivatives of trisamidothiophosphates. The anions in **1** and **2** represent novel examples of multidentate ligands with hard (N) and soft (S) donor sites attached to a P(v) centre.

We thank the NSERC (Canada) for financial support and Dr R. MacDonald (University of Alberta) for the collection of the X-ray data for **1** and **2**.

Notes and references

† *Synthesis* of **1**: a solution of LiBu^n in hexanes (2.5 M, 1.69 mL, 4.21 mmol) was added to a solution of SP[N(H)Pr^i]$_3$[12] (1.00 g, 4.21 mmol) in THF (25 mL) at 23 °C. After 2 h, solvent was removed *in vacuo* and the residue washed with *n*-pentane (2 × 5 mL) to give **1** as a pale yellow solid in 61% yield. X-Ray quality crystals were obtained by layering hexane onto a THF solution at 23 °C. ^{1}H NMR (C_6D_6, 23 °C): δ 3.66 (m, THF), 2.12 (s, 2 H, NH), 1.43 (m, THF), 1.24 [br d, 18 H, CH(C*H*$_3$)$_2$], 3.45 [m, 3 H, C*H*(CH$_3$)$_2$]. ^{31}P{^{1}H} NMR (C_6D_6, 23 °C): δ 47.9 (s); (solid state): δ 55.0 (s). ^{7}Li NMR (C_6D_6, 23 °C): δ −1.2 (s).

Synthesis of **2**: a solution of LiBu^n in hexanes (2.5 M, 3.37 mL, 8.43 mmol) was added to a solution of SP[N(H)Pr^i]$_3$ (1.00 g, 4.21 mmol) in toluene (20 mL) and TMEDA (10 mL) at 23 °C. After 2 h, solvent was removed *in vacuo* and the residue washed with pentane (2 × 10 mL) to give **2** as a white solid in 56% yield. X-Ray quality crystals were obtained by layering *n*-hexane onto a TMEDA–toluene solution at 23 °C. ^{31}P{^{1}H} NMR (solid state): δ 45.7 (s). ^{7}Li NMR (solid state): δ 1.9 (br s).

Synthesis of **3**: A solution of (Et$_2$O)LiN(SiMe$_3$)$_2$ (6.82 g, 28.2 mmol) in THF (15 mL) was added slowly to a stirred solution of SP[N(H)Bu^t]$_3$[13] (5.00 g, 17.9 mmol) in THF (25 mL) at 23 °C. After 18 h solvent was removed and the residue washed with *n*-pentane (3 × 5 mL) to give **3** as a white powder in 82% yield. X-Ray quality crystals were obtained from a THF–hexane solution at 23 °C. ^{1}H NMR (d$_8$-THF, 23 °C): δ 3.61 (m, [O(C*H*$_2$)$_2$(CH$_2$)$_2$]), 1.90 (3 H, NH), 1.76 (m, [O(CH$_2$)$_2$(C*H*$_2$)$_2$]), 1.34 (36 H, Bu^t), 1.17 (18 H, Bu^t). ^{31}P {^{1}H} NMR (d$_8$-THF, 23 °C): δ 33.1 (br s); (solid state): δ 28.5 (s), 25.8 (s). IR (cm^{-1}): 3360 [ν(N–H)].

‡ *Crystal data* for **1**: $C_{26}H_{62}Li_2N_6O_2P_2S_2$, M = 630.76, monoclinic, space group $P2_1/c$ (no. 14), a = 11.0007(16), b = 17.324(3), c = 10.8355(16) Å, β = 114.463(2)°, V = 1879.6(5) Å^3, Z = 2, D_c = 1.114 g cm^{-3}, μ(Mo-Kα) = 2.56 cm^{-1}. Crystal dimensions 0.71 × 0.44 × 0.34 mm. Data were measured on a Bruker AXS P4/RA/SMART 1000 CCD diffractometer at −80 °C using Mo-Kα radiation. The structure was solved by direct methods (SHELXS-97) and the non-hydrogen atoms were refined anisotropically using data that were corrected for absorption (SHELXL97-2). 3030 of the 3837 unique reflections had $I \geqslant 2.00\sigma(I)$. The final agreement factors were R_1 = 0.0488, wR_2 = 0.1420.

Crystal data for **3**: $C_{112}H_{260}Li_{12}N_{24}O_4P_8S_8{\cdot}C_5H_{12}$, M = 2667.12, monoclinic, space group $C2/c$, a = 24.145(4), b = 16.462(4), c = 23.405(5) Å, β = 110.45(1)°, V = 8716(3) Å^3, Z = 2, D_c = 1.016 g cm^{-3}, μ(Mo-Kα) = 2.22 cm^{-1}. Crystal dimensions 0.60 × 0.50 × 0.40 mm. Data were collected at −103 °C on a Rigaku AFC 6S diffractometer and corrected for absorption. The structure was solved by direct methods (SIR92) and expanded using Fourier techniques (DIRDIF 94). One THF molecule was disordered over two sites with unequal site occupancy factors. 3940 of the 7694 unique reflections had $I \geqslant 2.00\sigma(I)$. The final agreement factors were R_1 = 0.0762, wR_2 = 0.2325. CCDC reference numbers 168972 and 168973. Bis[(alkoxy)benzoylsemicarbazides]—a new class of powerful organogelators

Uwe Beginn* and Bernd Tartsch

Department of Organic and Macromolecular Chemistry, Albert-Einstein-Allee 11, D-89069 Ulm, Germany. E-mail: uwe.beginn@chemie.uni-ulm.de; Fax: +49-731-502-2883; Tel: +49-731-502-2884

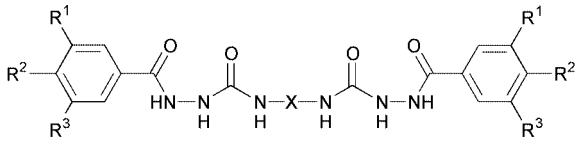
Received (in Cambridge, UK) 10th July 2001, Accepted 10th August 2001
First published as an Advance Article on the web 13th September 2001

Reaction of *N*-[(alkoxy)benzoyl]hydrazides and diisocyanates produces bis[(alkoxy)benzoylsemicarbazides] that allow for 'cold gelation' of organic liquids by mixing low viscous gelator solutions with a large excess of the respective solvent at ambient temperature.

'Organogels' are elastic- or viscoelastic materials consisting of solvents and low molecular weight organic 'gelators'. Most efficient gelation is found from gelators that self-assemble to networks of fibrous structures with large aspect ratios, *e.g.* rods or ribbons.[1] Though organogels have been known for a long time[2] only a few examples of designed gelators have been reported so far.[3,4]

A simple rational concept to construct gel forming molecules is to prepare nearly flat amphiphilic molecules consisting of small polar and bulky non polar parts.[4] According to this idea rod formation was found with tris(alkoxy)benzamides,[5] *N*-sorbitoyl-3,4,5-tris(alkoxy)benzamides,[6] and crown ether amphiphiles.[4] The latter have been used to generate supramolecular ion transport channels.[7] We prepared dumb-bell shaped amphiphiles to increase the thermal- and mechanical stability of the resulting gels.

Urea type hydrogen bonds are known to stabilise gelator assemblies.[8] In extension of this concept bis[(alkoxy)benzoylsemicarbazides] of the general structure **Y**–CO–NHNH–CO–NH–**X**–NH–CO–NHNH–CO–**Y** (Scheme 1) have been prepared. Y represents alkoxyphenyl units, and X denotes either an aromatic or an aliphatic moiety. Bis(semicarbazide) cores have been selected because of (i) their ability to form up to 14 hydrogen bonds per molecule, (ii) their simple preparation† and (iii) their large structural variability. Table 1 summarizes the compounds prepared so far. The thermal stability of the bis(semicarbazides) **1**–**10**, was obtained from TGA, and confirmed by thermo-optical analysis (TOA).



X = 1,4-phenylene, 2,4-tolylene, 2,6-tolylene, 2,6-tolylene, 1,8-naphthylene, 1,6-hexamethylene $R^i = C_nH_{2n+1}O$-, H-

Scheme 1 General formula of the bis[(alkoxy)benzoylsemicarbazides].

Compounds **2**, **3**, **6**, **8** and **9** started decomposing before melting, hence phase transition temperatures were not reproducible on repeated heating of a sample. All semicarbazides melted into optically anisotropic liquids, but isotropisation temperatures could not be obtained due to vigorous decomposition on exceeding 250 °C. The mesophase type is not yet determined.

The solubility of the semicarbazides was tested with solvents of different polarity. Mixtures of 2.5 wt% solute and 97.5 wt% of the solvent were annealed at 20 °C for 2 h, and subsequently heated to the boiling point of the solvent until a clear solution was obtained. The semicarbazides **1**–**5**, and **7**–**10** did not dissolve at ambient temperature in any of the tested solvents, only swelling of the materials was occasionally observed. Swelling most frequently occurred in the presence of THF, $CHCl_3$, styrene, toluene, and hexane. At elevated temperatures the solubilities strongly depended on the molecular structure. The derivatives with a 1,4-phenylene-core (**1**–**7**) were much less soluble than the tolylene (**8**, **9**), and the 1,8-naphthylene (**10**) compounds. With decreasing number of attached alkyl chains the solubility was reduced and the 4-decyloxy derivative **7** could only be dissolved in boiling DMF while all other solvents failed.

Thermoreversible gelation was studied as an indication for the self-ordering to supramolecular structures. Table 2 summarises qualitative tests with 2.5 wt% solutions of **1**–**10**. The hot semicarbazide–solvent mixtures were cooled at a controlled rate (< 6 K min^{-1}) to induce gelation. Three types of gels have been distinguished: (i) transparent–clear gels, (ii) turbid–translucent gels, and (iii) opaque–white gels. Opaque gels were most frequently obtained from the polar solvents, while the non-polar liquids preferably yielded clear gels.

Table 1 Synthesised bis[(alkoxy)benzoylsemicarbazides]

No.	Core	R^1	R^2	R^3	T_d/°C	T_m/°C	ΔH_m[f]

n-Hexane	GC	GC	GC	P	GC	GC	P	GC	GC	GC

[a] 2-Hydroxyethyl methacrylate. [b] *tert*-Butyl acetate. [c] *n*-Hexyl methacrylate. [d] GO = opaque gel, GT = translucent gel, GC = clear–transparent gel, P = preciptate, S = solution, Sη = viscous solution.

Ethanol was a bad solvent for all bis(semicarbazides), opaque gels were formed from ethanol solutions of **2**, **3**, **9** and **10**. The critical gelation concentration was below 1 wt%.

Except for **4** and **7** all semicarbazides formed transparent–clear gels in hexane solutions. Compounds **2**, **5**, **6** and **8** formed clear solutions of high viscosity with hexane that settled to clear gels on cooling to ambient temperature. The gels could not be melted on re-heating the samples to the boiling temperature of *n*-hexane. Clear solutions of high viscosity were also found at 20 °C with **3**–*tert*-butyl acetate, **9**–toluene, **9**–styrene, and **10**–toluene (*cf.* Table 2). In $CHCl_3$ 2.5 wt% of **1** and **2** only partially dissolved, but the heterogeneous mixture gelled upon cooling. Similar observations were made with **2** in toluene and styrene. The gels from such mixtures consisted of swollen gelator particles dispersed in a gelled matrix.

It may be summarised that gelation was most pronounced with relatively non-polar solvents like $CHCl_3$, styrene, toluene, and *n*-hexane, since the solubility of the carbazides was rather limited in non-polar liquids. This orthogonality in solubility and gelation offers intriguing perspectives to induce gel formation by changing the solvent composition ('cold gelation'). Such a situation might be of practical interest as it allows to add a low viscous dissolved gelator to a solution or dispersion that should be gelled, or thickened.

An attempt was made to gel solutions of **1** in DMAc by addition of toluene or *n*-hexane as diluents of lower polarity. At 20 °C up to 33 wt% of **1** is soluble in DMAc without gelation. On diluting the concentrated DMAc solutions, gels were immediately formed. While the toluene gels were slightly turbid, clear gels emerged from *n*-hexane (*cf.* Table 3).

In a similar way hot solutions of DMF and 33 wt% of **2** were gelled by addition of toluene or hexane. Dilution of DMF solutions by means of $CHCl_3$ resulted in turbid inhomogeneous gels on exceeding 4.5 wt% of **2** that became opaque on standing for a prolonged time (> 12 h). Between 2.4 and 0.6 wt% of **2** transparent viscous liquids, containing streaky inhomogeneous regions, were obtained directly after mixing. Within 90 min the inhomogeneities vanished, and simultaneously the mixtures transformed to viscoelastic fluids. The viscoelastic properties have been recognised by the recoil of entrapped air bubbles subsequent to swirling the liquids in a vial.[9] On standing over night the fluid transformed to a turbid soft gel. Similar viscoelastic fluids arised from dilution of 1.2 wt% **2** in THF with petrol ether to an overall concentration of 0.85 wt%.

Table 3 Gelation of **1**–DMAc solutions by addition of toluene, or n-hexane at ambient temperature

[**1**][a]	+solvent	[DMAc][b]	[**1**][c]	10 min	15 h

33.3	Toluene	1.7	0.8	GC	GC
33.3	*n*-Hexane	6.2	3.1	GC	GC
33.3	*n*-Hexane	2.2	1.1	GC	GC

[a] Gelator concentration prior to dilution in wt%. [b] DMAc concentration. [c] Gelator concentration of the final mixture in wt%.

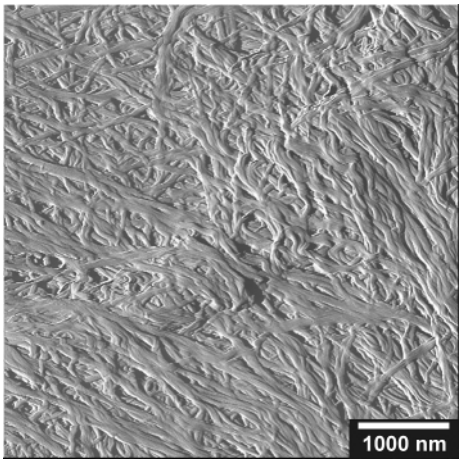

Fig. 1 SFM picture of gel fibres of **2** (0.8 wt%) in THF–PE (2 : 1).

Scanning force microscopy (Fig. 1) resolved the gel network to consist of fibre bundles 90–150 nm in diameter. The bundles contained elementary strings with diameters below 50 nm.

These few examples demonstrate the potential of bis(semicarbazides) to control the mechanical properties of organic liquids. Depending on the molecular structure of the semicarbazide and the solvent composition solid gels, viscoelastic fluids, or viscous liquids can be obtained. Future work will deal with investigation of the gel morphologies, and the kinetics of gelation.

Financial support from the German research foundation (SFB 569, A6) is gratefully acknowledged. The authors want to thank Martin Möller for helpful discussions.

Notes and references

† A solution of 10 mmol diisocyanate in 25 mL THF was added to a solution of 20 mmol *N*-[(alkoxy)benzoyl]hydrazine in 25 mL THF. After 30 min the solvent was removed, the residue taken up with DMF, and precipitated from acetone. The raw compound was crystallised from acetone.

‡ DSC was obtained with a PERKIN ELMER DSC 7 device, calibrated against cyclohexane, water, and indium standards. 5 mg samples were used, the heating rate was 10 K min^{-1}.

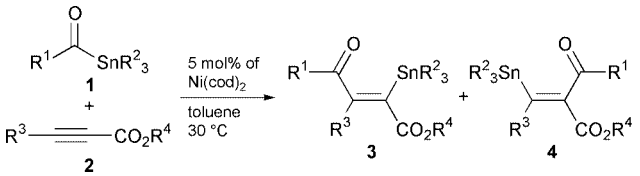
Received (in Cambridge, UK) 3rd July 2001, Accepted 8th August 2001
First published as an Advance Article on the web 13th September 2001

Acylstannanes were found to add to such α,β-unsaturated carbonyl compounds as enones or ynoates in the presence of a nickel or palladium catalyst to give 2-stannyl-4-oxoalk-2-enoates or 1,4-diketones, whereas the three component coupling between acylstannanes, enones and aldehydes provided 2-hydroxymethyl 1,4-diketones.

Well-documented synthetic precursors for five-membered ring compounds are 1,4-dicarbonyl compounds: furans, pyrroles or thiophenes are readily prepared by mixing with an acid,[1] an amine[2] or a sulfur nucleophile,[3] respectively, whereas treatment of 1,4-diketones with a base gives cyclopentenones.[4] On the other hand, alkenes having a carbonyl group at both of the carbon atoms behave as good dienophiles in the Diels–Alder reaction. Although addition of a C–H bond of aldehydes to α,β-unsaturated carbonyl compounds provides a straightforward way to 1,4-dicarbonyl compounds,[5] the reaction is hard to apply to synthesis of structurally complex targets. For this purpose, acylmetalation of α,β-unsaturated carbonyl compounds[6] is apparently beneficial, since metal atoms of resulting organometallic compounds can be replaced by various groups through the reaction with electrophiles. Here we report the nickel-catalysed acylstannylation of ynoates,[7] the palladium-catalysed addition of the acyl group of acylstannanes to enones, and the palladium-catalysed three component coupling between acylstannanes, enones and aldehydes to give 2-hydroxymethyl 1,4-diketones.[8]

We first examined the reaction of benzoyl(trimethyl)tin (**1a**) with methyl oct-2-ynoate (**2a**) in the presence of 5 mol% of bis(cycloocta-1,5-diene)nickel, $Ni(cod)_2$. The reaction in toluene at 30 °C for 2.5 h gave an 88 : 12 mixture of methyl (*Z*)-3-benzoyl-2-trimethylstannyloct-2-enoate (**3a**) and methyl (*E*)-2-benzoyl-3-trimethylstannyloct-2-enoate (**4a**) in 66% yield (Scheme 1 and entry 1 of Table 1). Although the reaction in a more polar solvent such as THF or DMF proceeded with a perfect preference for **3a** over **4a**, a considerable amount of the decarbonylation product, trimethyl(phenyl)tin, also was produced and the yield of **3a** was less than 40%.[9] Acylstannylation of various alkynes with the $Ni(cod)_2$ catalyst was next studied in toluene (Table 1). In addition to aliphatic ynoates, trimethylsilyl- and phenyl-substituted propiolates also can participate in the reaction with **1a** to give regioisomeric mixtures (entries 2–4). The regiochemistry was largely affected by the substituent on propiolate, where an electron-donating silyl group exhibited selectivity much higher than an electron-withdrawing phenyl



Scheme 1

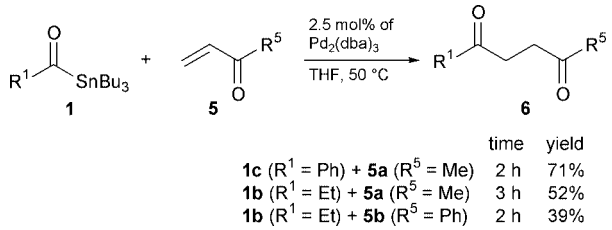
Table 1 Nickel-catalysed acylstannylation of ynoates[a]

Entry	R^1	R^2	R^3	R^4	Time/h	Yield (%)[b]	**3** : **4**[c]
1	Ph	Me	$CH_3(CH_2)_4$	Me	2.5	66	88 : 12
2	Ph	Me	Me_3Si	Et	3	85	98 : 2
3	Ph	Me	Me	Me	1.5	56	91 : 9
4	Ph	Me	Ph	Et	24	58	66 : 34
5	Et	Bu	$CH_3(CH_2)_4$	Me	24	47	79 : 21

[a] The reaction was carried out in toluene (0.4 mL) at 30 °C using an acylstannane (0.30 mmol), an ynoate (0.90 mmol) and $Ni(cod)_2$ (15 μmol). [b] Isolated yield based on the acylstannane. [c] Determined by ^{119}Sn NMR.

group. Tributyl(propanoyl)tin (**1b**) also underwent acylstannylation of **2a** (entry 5).

Enones also were found to react with acylstannanes to give 1,4-diketones. However, a palladium complex showed catalytic activity higher than the nickel complex (Scheme 2). For example, the reaction of benzoyl(tributyl)tin (**1c**) with methyl vinyl ketone (**5a**) proceeded in the presence of tris(dibenzylideneacetone)dipalladium, $Pd_2(dba)_3$, in THF at 50 °C for 2 h to afford 1-phenylpentane-1,4-dione (**6a**) in 71% yield. Propanoylstannane **1b** also added to **5a** or phenyl vinyl ketone (**5b**). An aqueous additive in a stoichiometric amount accelerated the reaction considerably.



Scheme 2

Although the $SnBu_3$ group that should be definitely versatile for further construction of carbon frameworks was lost in the reaction product with enones, *in situ* trapping with an electrophile achieved three component coupling and accordingly indicated the presence of the stannyl group in the product. Thus acylstannanes, enones and aldehydes reacted in the presence of a catalytic amount of $Pd_2(dba)_3$ to give labile 2-hydroxymethyl 1,4-diketones. As the products easily underwent a retro-aldol reaction during purification by silica gel chromatography, the three component coupled products were isolated after acetylation with acetic anhydride–pyridine (Scheme 3 and Table 2).

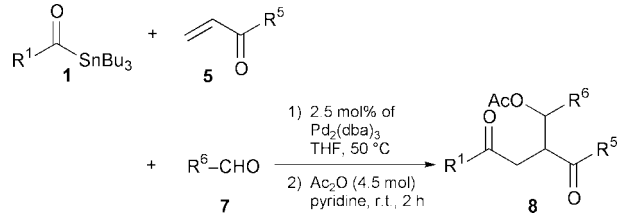
The stannyl group of the ynoate–acylstannylation products can be easily converted into organic groups through the palladium-catalysed cross-coupling reaction with organic halides. Actually, **3a** coupled with ethyl 4-iodobenzoate in the presence of palladium and copper catalysts and gave expected product **9** with retention of configuration (Scheme 4).

 DOI: 10.1039/b105832k

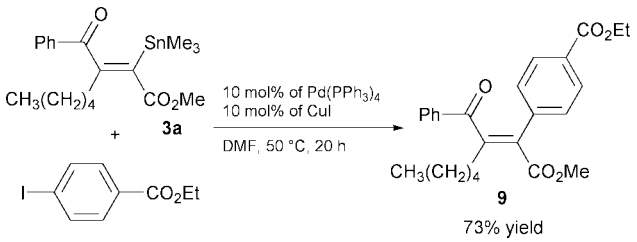
Table 2 Palladium-catalysed three component coupling between acylstannanes, enones and aldehydes[a]

Entry	R^1	R^5	R^6	Time/h	Yield (%)[b]	Diastereomeric ratio
1	Ph	Me	4-$CF_3C_6H_4$	1.5	64	73:27
2	Ph	Ph	4-$CF_3C_6H_4$	24	37	55:45
3	Et	Me	4-$CF_3C_6H_4$	1	62	51:49
4	Et	Ph	4-$CF_3C_6H_4$	1.5	44	53:47
5[c]	Ph	Me	Ph	0.5	44	79:21
6[c]	Ph	Me	$PhCH_2CH_2$	1	38	69:31

[a] The reaction was carried out in THF (0.2 mL) at 50 °C using an acylstannane (0.15 mmol), an enone (0.23 mmol), an aldehyde (0.45 mmol) and $Pd_2(dba)_3$ (3.8 μmol). Then, the reaction mixture was treated with acetic anhydride (0.68 mmol) and pyridine (0.5 mL) at rt for 2 h. [b] Isolated yield based on the acylstannane. [c] The reaction was carried out in the presence of Linde molecular sieves Type 4A (60 mg).

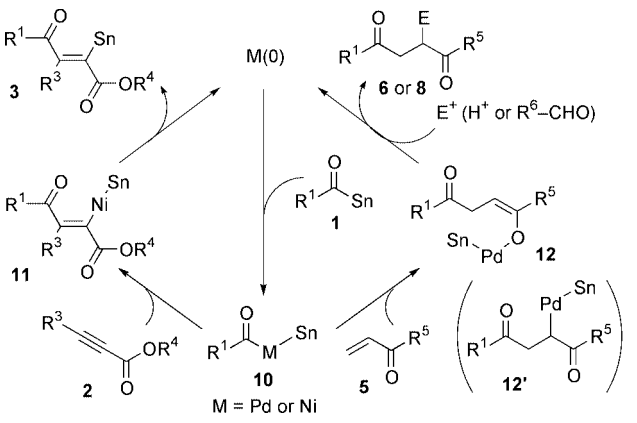


Scheme 3



Scheme 4

The catalytic cycle should be initiated by oxidative addition of an acylstannane to a nickel(0) or palladium(0) complex as we discussed previously,[7] followed by insertion of a C–C unsaturated bond to the C–Ni bond of oxidative adduct **10** (Scheme 5). Insertion of an ynoate should afford relatively stable alkenylnickel complex **11**, which undergoes reductive elimination to give alkenylstannane **3**. In a similar manner, regioisomer **4** also would be produced. On the other hand, insertion of an enone may lead to formation of palladium enolate **12** rather than alkylpalladium complex **12′** owing possibly to relative stability of a Pd–O bond as compared with a Pd–C bond. Reductive elimination of **12** appears to be difficult, but the reaction of **12** with such an electrophile as water or an aldehyde would take place, giving **6** or **8**, respectively.



Scheme 5

In conclusion, we have demonstrated that addition of the acyl group of acylstannanes to ynoates or enones readily takes place in the presence of a nickel or palladium catalyst. The addition products are further transformed into 1,4-dicarbonyl compounds having a complicated structure in a separated step or a tandem reaction. Studies on details of the mechanism as well as synthetic applications to various unsaturated substrates and organostannanes are in progress in our laboratories.

Hierarchic patterning: architectures beyond 'giant molecular wheels'†

Achim Müller,*[a] Ekkehard Diemann,[a] Christoph Kuhlmann,[a] Wolfgang Eimer,[a] Claire Serain,[a] Thomas Tak,[a] Arndt Knöchel[b] and P. Klaus Pranzas[b]

[a] *Faculty of Chemistry, University of Bielefeld, D-33501 Bielefeld, Germany. E-mail: a.mueller@uni-bielefeld.de*

Received (in Cambridge, UK) 24th April 2001, Accepted 16th August 2001
First published as an Advance Article on the web 13th September 2001

Based on symmetry breaking steps under one-pot conditions, simple molybdenum oxide-based building blocks initially assemble to 'giant molecular wheels' in a fast process followed by further slower assembly processes leading stepwise to more complex mesoscopic architectures including spherical ones and finally to those with a size larger than 500 nm.

Molybdenum blue solutions have fascinated chemists for more than 200 years without, however, success in identifying their true chemical nature.[1] One interesting aspect is that a structural hierarchy is obtained in a multi-step process: the initial assembly of very simple building blocks form 'giant molecular wheel' type species within seconds, and subsequent assembly leads to spherical patterns of the final complex architectures, as visualised by SEM. Equally surprising and fascinating, the whole structural hierarchy, which spans over more than four orders of magnitude is built up under one-pot conditions without changing the constituents.

We have used dynamic light scattering (DLS)‡ to characterise such solutions. The first preliminary investigations were done using the structurally characterised 'molybdenum blue' compound $Na_{24}[Mo_{144}O_{437}H_{14}(H_2O)_{56}]\cdot xH_2O$ **1** ($x \approx 250$), which contains nanoscaled wheel shaped units covalently linked to chains.[2] Surprisingly, in non-aqueous media such as methanol or acetone, we observed only a single relaxation process from which the hydrodynamic radius was calculated to be about 40 nm. In particular, it should be noted that the inverse Laplace transformation of the intensity autocorrelation function yields a rather low variance of the size distribution of the particles in solution (Fig. 1). Measurements with different solutions reveal that the variation of particle sizes is always rather small. These results are in agreement with the experiments performed in methanolic and acetonic solutions prepared from $(NH_4)_{28}[Mo_{154}(NO)_{14}O_{448}H_{14}(H_2O)_{70}]\cdot xH_2O$ **2** ($x \approx 350$),[3] which contains the same type of discrete 'giant molecular wheels' with $MoNO^{3+}$ instead of MoO^{4+} groups, and especially from $Na_{15}[Mo_{154}O_{462}H_{14}(H_2O)_{70}]_{0.5}[Mo_{152}O_{457}H_{14}(H_2O)_{68}]_{0.5}\cdot xH_2O$ **3** ($x \approx 400$) which can easily be obtained in crystalline form and high yield in a facile synthesis.[4] With DLS we do not observe an additional much faster relaxation process which would correspond to the translational motion of *monomeric* units in solution, probably due to the much lower scattering power of these particles compared to the aggregate structures. Model calculations were performed for rod-like or oblate ellipsoid particles. To achieve consistency between experimental data and theoretical predictions, we have to assume either very elongated molecules (for example rods of 4 nm diameter and 400 nm in length) or a near spherical ellipsoid shape.

Small angle X-ray scattering (SAXS) experiments‡ on such fresh solutions showed the presence of small particles as obtained from the distance distribution function [Fig. 2(a)] which corresponds clearly to the scattering of isolated single 'giant molecular wheel' units for which structure and form factors are known from the crystal structure analysis. Repeating the measurement on these solutions after about two days displayed significant changes. As shown in Fig. 2(b), the corresponding distance distribution function develops further maxima at larger distances. Supported by some preliminary simulation calculations, this implies that for **1** and **3** chain formation takes place where, within the limits of our present SAXS setup, four-membered assemblies dominate.

Therefore, we assume that the chains of **1** break in solution such that the *monomeric* unit is the 'giant molecular wheel' and a new aggregation process initiates from this particle. This corresponds to the observation that compound **3** which consists of isolated 'giant wheels' already at the beginning also shows this type of aggregation process. USAXS measurements would be required to elucidate also the presence and nature of higher aggregates with more than four members.

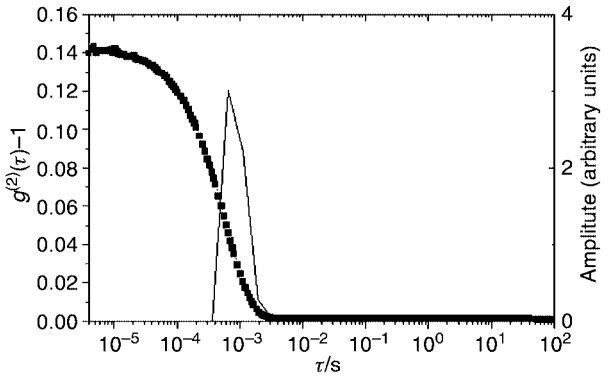

Fig. 1 Intensity autocorrelation function $g^{(2)}(\tau) - 1$ and the corresponding distribution function $G(\Gamma^{-1})$ of **1** or **3** in methanol.

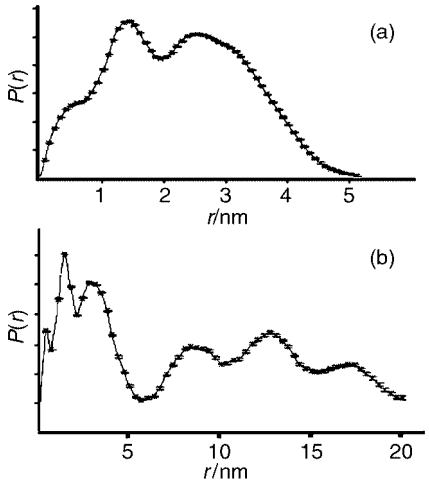

Fig. 2 Distance distribution function $P(r)$ from SAXS data (a) obtained from a fresh solution of **1** (or **3**, *cf.* text) and (b) from the same solution after two days.

† Dedicated to Professor Phillip Gütlich on the occasion of his 65th birthday.

 DOI: 10.1039/b103639b

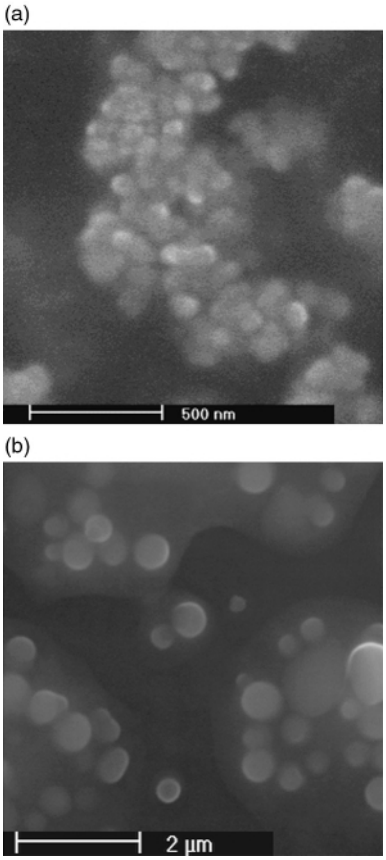

Fig. 3 ESEM images of the spherical aggregates obtained from a solution of **1**, showing further aggregation to form some more complex architecture (a); ESEM image of larger spherical units formed from an acetonic solution of **3** (b).

To obtain more information about the shape of the higher aggregated particles we examined them with an environmental scanning electronic microscope (ESEM). Fig. 3 shows ESEM micrographs‡ of residues obtained by drying off the solvent under water vapour pressure. The observed spherical particles have mainly an apparent diameter of 80–90 nm which is in reasonable agreement with the DLS results. Particularly when acetone instead of methanol is used as solvent even larger and more perfect spheres are obtained. The question whether these spherical units are filled or hollow can probably be answered from future USAXS measurements. EDAX performed on single spheres shows (*via* the carbon signal) the presence of considerable amounts of solvent inside, and, on switching the SEM from the environmental to the high vacuum mode, the spherical assemblies burst, thus implying that hollow spheres were formed. This would also explain the obviously intrinsically limited resolution of the ESEM pictures. Further studies will have to elucidate the thickness and order of the spherical walls, *e.g*. whether of onion type, and how and why they are formed from chain-like building units.

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank E. Krickemeyer for his contributions.

Notes and references

‡ *Experimental*: compounds **1**, **2** and **3** were dissolved in methanol (UV grade) or acetone (p.a.) (c = 0.1 mg mL^{-1} for the DLS, but higher for the SAXS). The solutions were filtered through a filter of 0.2 µm pore size and subsequently centrifuged for 30 min at *ca*. 2000 rpm to remove larger dust particles and to de-gas the solvent. All steps were performed in an Ar atmosphere.

DLS measurements: the light scattering measurements (λ = 488 nm) were performed at low sample concentration and with minimum laser power to avoid any significant heating of the sample due to absorption of the coloured material in the visible region. The experimental data were analysed using the program CONTIN.

Small angle X-ray scattering: the SAXS experiments were carried out at the instrument POLYP at beamline A2 at HASYLAB/DESY in Hamburg.[5] The solutions used for SAXS investigations were the same as those used for DLS and ESEM studies, but with higher concentrations (c = 5 mg mL^{-1}) in order to obtain sufficient scattering statistics, so that the subtraction of the solvent scattering is possible. The solutions were measured in vacuum tight sample cells with a diameter of 1 mm and Kapton windows immediately after preparation. A fixed wavelength of 0.154 nm, distances between sample and detector of 0.49 and 1.91 m and measuring times of 20 min were used.

Scanning electron microscopy: A FEI ESEM XL30 was used at an accelerating voltage of 25 kV under 4.0 mbar water vapor pressure. Acetonic and methanolic solutions were used directly. With the ESEM the sample could be examined in a wet atmosphere. Under these conditions a *fast* destruction of the aggregates is avoided.

Inorganic–organic hybrids derived from oxovanadium sulfate motifs: synthesis and characterization of $[V^{IV}O(\mu_3\text{-}SO_4)(2,2'\text{-bpy})]_\infty$

M. Ishaque Khan,*[a] Sabri Cevik[a] and Robert J. Doedens[b]

Received (in Purdue, IN, USA) 28th July 2001, Accepted 16th August 2001
First published as an Advance Article on the web 17th September 2001

The hydrothermal reaction of V_2O_5, V_2O_3, 2,2′-bpy and Na_2SO_4 in dilute sulfuric acid yields a novel hybrid, $[V^{IV}O(\mu_3\text{-}SO_4)(2,2'\text{-bpy})]_\infty$, which demonstrates the potential of constructing a new class of robust composite solids composed of a $\{V/O/SO_4\}$-based framework decorated with organic functionalities by combining appropriate vanadyl sulfate motifs with a variety of organic ligands.

The amalgamation of oxovanadate moieties with the tetrahedral $\{PO_4\}$ ligand has produced an impressive array of vanadium–oxide–phosphate based systems with fascinating electronic and structural properties.[1–8] Oxovanadiumphosphate-based porous-framework materials containing unprecedented large cavities and channels similar to those observed in conventional zeolites and solids with double-helix structure have been synthesized and characterized in recent years.[7,8] As compared to the $V/O/PO_4$, however, well-defined $V/O/SO_4$-based inorganic materials prepared from the combination of sulfate with oxovanadate units are rare.[9–11]

Since vanadium exhibits extensive coordination chemistry involving a variety of organic ligands,[12] the solids constructed from $\{V/O/SO_4\}$ system may, in principle, incorporate appropriate organic ligands. This offers opportunity for making new inorganic–organic hybrid (composite) phases containing an inorganic $\{V/O/SO_4\}$ backbone decorated with organic functionalities. Such compounds are practically unknown.[10d] We are currently exploring the potential of this approach[13] which, to our knowledge, has not been exploited for materials design and development. This report describes the synthesis and characterization by IR spectroscopy, thermogravimetry, elemental analysis, manganometric titration, bond valence sum calculations, and complete single crystal X-ray structure analysis of a new solid $[V^{IV}O(\mu_3\text{-}SO_4)(2,2'\text{-bpy})]_\infty$ **1**.

Green needle shaped crystals of **1** are prepared in ~78% yield by the hydrothermal reaction of V_2O_5, V_2O_3, Na_2SO_4, 2,2′-bpy and 1 M H_2SO_4 in the molar ratio 0.5 : 0.5 : 5 : 3 : 10 at 180 °C for 48 h.†

The crystal structure‡ of **1** is shown in Fig. 1. It may be viewed as constructed from the centrosymmetric dimer building block, $[V^{IV}_2O_2(\mu_3\text{-}SO_4)_2(2,2'\text{-bpy})_2]$, which contains two $[V^{IV}O(\mu_3\text{-}SO_4)(2,2'\text{-bpy})]$ units linked through sulfate groups. The crystal packing views, which exhibit alternating inorganic ($VOSO_4$) and organic (2,2′-bpy) layers, are aesthetically appealing. The extended structure consists of parallel running inorganic chains decorated by organic ligands. The individual chains contain $\{VO_4N_2\}$ octahedra and $\{SO_4\}$ tetrahedra joined by common vertices. Every sulfate ligand, which uses three oxygen atoms to bond three vanadium centers, bridges three $\{VO_4N_2\}$ octahedra each one of which, in turn, shares vertices with three $\{SO_4\}$ groups. This generates a series of eight-membered {–V–O–S–O–V–O–S–O–} rings that are fused to construct the entire chain. The overall geometry around sulfur is a slightly distorted tetrahedron. All O–S–O angles (105.5–112.7°) and the S–O bond distances are in the normal range. The octahedral geometry around each vanadium center is defined by a terminal oxo group, three μ-O groups from the three adjacent sulfate ligands in the chain, and two nitrogen donor atoms from a chelating 2,2′-bpy ligand. The terminal oxo groups on vanadium centers alternate such that any two adjacent vanadium atoms will have their terminal oxo groups pointing toward the opposite sides of the chain.

The structure and building block units in **1** are significantly different to those observed in our earlier reported compound $[V^{IV}_2O_2(OH)_2(\mu\text{-}SO_4)(2,2'\text{-bpy})_2]$ **2**.[13a] The structure of **2** consists of ribbons constructed from the infinite inorganic chains, $[-\{V_2O_2(\mu\text{-}OH)_2\}(\mu\text{-}SO_4)\{V_2O_2(\mu\text{-}OH)_2\}-SO_4]$, composed of pairs of edge sharing $\{VO_2(OH)_2N_2\}$ octahedra joined by $\{SO_4\}$ tetrahedra, laced by organic (2,2′-bpy) ligands. The metrical parameters of the two $V/O/SO_4$/2,2′-bpy-based hybrid materials (**1** and **2**) are comparable.

The comparison of the two structures may suggest the possible transformation of **2** into **1** by the replacement of the two μ-(OH) groups in **2** by a μ_3-SO_4 group, cleavage of {V–(OH)–V} bonds, and concomitant formation of new {V–(SO_4)–V} bonds accompanied by condensation. So far, we have not achieved the chemical interconversion between **1** and **2**. Compound **1** can, however, be prepared by the slight modification in the reaction used to synthesize **2**. The structure of **1** is strikingly similar to a recently reported compound $[Fe^{III}_2Cl_2(MoO_4)_2(2,2'\text{-bpy})_2]$ **3**[14] in which {FeCl} and tetrahedral $\{MoO_4\}$ groups occupy the positions equivalent to that of {VO} and $\{SO_4\}$ groups, respectively, in **1**. This suggests that $\{Fe^{III}Cl\}$ and $\{Mo^{VI}O_4\}$ groups are topologically equivalent to $\{V^{IV}O\}$ and $\{S^{VI}O_4\}$, respectively.[15a]

The bond valence sum§ calculations[15b] and manganometric titration (of V^{IV} sites) results are consistent with the formulation and charge balance requirements of **1**. Thermogravimetric analysis of **1** reveals its remarkable thermal stability showing no weight loss up to ~420 °C, a two-step weight loss in the range 423–488 °C corresponding to the decomposition of 2,2′-bpy and sulfate ligands, and no further weight change up to 600 °C. The IR spectrum of the black residue exhibits features [at 994w, 738m br, 699(sh), 532m and 439m cm^{-1}] of a reduced vanadium oxide phase that has not been further characterized.

This report underlines the potential of the approach for making new and robust inorganic–organic hybrid phases. In view of the spectacular progress in the design and development of $V/O/PO_4$-based materials, it is clear that many more $V/O/SO_4$-based systems remain to be discovered. The suitable combination of oxovanadate sulfate fragments and organic ligands could yield new composites (and nanocomposites) that may exhibit properties unobserved in purely organic or inorganic phases.

This work was partly supported by a grant to M. I. K. from the American Chemical Society's Petroleum Research Fund (ACS-PRF# 35591-AC5).

Stereoselective total synthesis of (+)-myriocin from D-mannose

Takeshi Oishi, Koji Ando and Noritaka Chida*

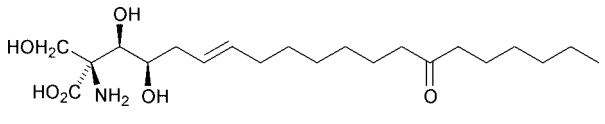
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223-8522, Japan. E-mail: chida@applc.keio.ac.jp

Received (in Cambridge, UK) 4th June 2001, Accepted 21st August 2001
First published as an Advance Article on the web 4th September 2001

The stereoselective total synthesis of myriocin 1 from D-mannose is described; the carbon framework with three contiguous chiral centers including a tetra-substituted carbon with nitrogen was effectively constructed using Overman rearrangement as the key reaction.

Myriocin[1] (also known as thermozymocidin[2] and ISP-I[3]) **1** (Fig. 1) is an α,α-disubstituted α-amino acid derivative isolated from the culture broth of *Myriococcus*,[1] *Mycelia*[2] and *Isalia*,[3] and reported to show antifungal[1,2] as well as immunosuppressive activities.[3] Its promising immunosuppressive properties[4] and unique structure have attracted much synthetic interest, and several total[5] and formal syntheses[6] of **1** have been reported to date. A structural feature of **1** is the unusual α,α-disubstituted α-amino acid framework with three contiguous chiral centers including a tetra-substituted carbon with nitrogen. For construction of the tetra-substituted carbon, previous syntheses adopted the Strecker synthesis,[6a] hydrocyanation of imines,[5a] the Darzen reaction,[5b,6c] Pd-catalyzed hydroxyamination of a vinyl epoxide,[6b] asymmetric aldol reaction of chiral dilactim ethers,[5c] and Lewis acid catalyzed cyclization of an epoxytrichloroacetimidate.[5d] Our previous success in total synthesis of lactacystin, a heterocyclic natural product with an α,α-disubstituted α-amino acid framework, from D-glucose[7] suggested that the rearrangement of an allylic trichloroacetimidate (Overman rearrangement)[8] derived from a furanose with proper functionalities would generate the tetra-substituted carbon stereoselectively. This methodology was also expected to provide an efficient approach to the highly functionalized part in **1**. Here we report the realization of this plan in a total synthesis of **1** from D-mannose.

The known glycal **2**[9] derived from D-mannose in three steps (80% overall yield) (Scheme 1) was converted into α-methyl furanoside **3**† by oxymercuration-reduction followed by acid treatment in 81% yield. The primary hydroxy group in **3** was selectively *p*-methoxybenzylated[10] to afford **4** (95% yield). Swern oxidation of **4** generated ketone **5**, which was submitted to the Horner–Emmons reaction to provide an inseparable mixture of (*E*)-alkene **6** and its (*Z*)-isomer (15 : 1) in 90% yield from **4**. DIBAL-H reduction of the mixture followed by chromatographic separation afforded geometrically pure (*E*)-allyl alcohol **7** and its (*Z*)-isomer in 93 and 6% isolated yields, respectively. Compound **7** was converted into trichloroacetimidate **8**, which, without isolation, was subjected to Overman rearrangement. Thus, a xylene solution of **8** was heated at 140 °C in the presence of K_2CO_3[11] in a sealed tube for 72 h to provide an inseparable mixture of rearranged products **9** and its C(5) epimer in a ratio of 7 : 1 (determined with 300 MHz ^{1}H NMR) in 90% yield from **7**.‡ The newly formed stereochemistry in **9** was determined to be *R* by NOE experiments



myriocin **1**

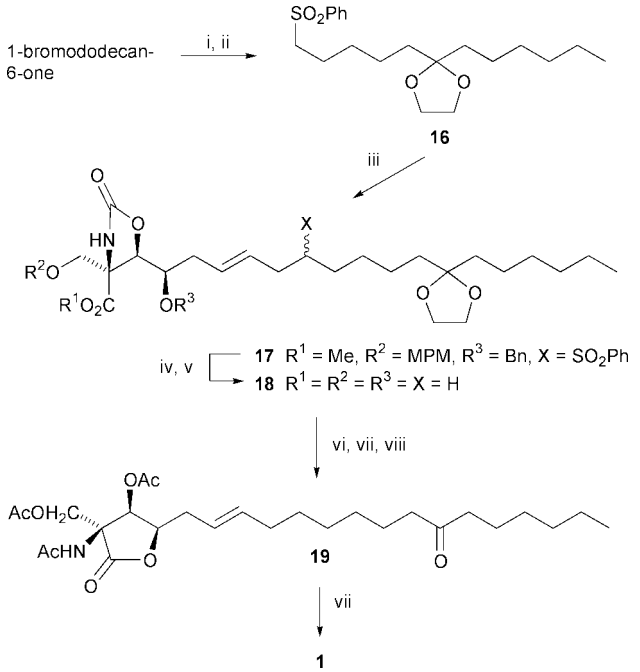
 DOI: 10.1039/b104864n

of bicyclic carbamate **10** derived from **9** in four steps (46% overall yield). Ozonolysis of the mixture of **9** and its C(5) epimer (Me_2S work-up) followed by oxidation and esterification, and subsequent chromatographic separation afforded **11** in a diastereochemically pure form (82% yield from the mixture of **9** and its epimer). Acid hydrolysis of **11** provided an anomeric mixture of lactol, which was then reacted with stabilized ylide to give (*E*)-alkene **12** as a single isomer in 71% yield. When compound **12** was treated with DIBAL-H in THF–toluene at −15 °C, only the α,β-unsaturated ester function was reduced to afford allyl alcohol **13** (75% yield), which was transformed into cyclic carbamate **14** in 86% yield. The observed coupling constant in **14** ($J_{6,7}$ = 15.6 Hz) clearly supported the (*E*)-geometry of the double bond. The primary hydroxy group in **14** was converted into corresponding bromide to furnish the highly functionalized moiety, allyl bromide **15** in 92% yield.

The hydrophobic part of myriocin, sulfone **16**, was prepared by treatment of 1-bromododecan-6-one§ with $PhSO_2Na$, followed by ketalization (82% yield) (Scheme 2). Sulfone **16** was lithiated with *n*-BuLi, and then reacted with the allyl bromide **15** to afford the coupling product **17** in 80% yield. Saponification of **17** and subsequent Birch reduction gave crude carboxylic acid **18**. Removal of the ketal group and carbamate function in **18** followed by conventional acetylation provided the known γ-lactone **19** {$[\alpha]_D^{20}$ +54 (*c* 0.7, $CHCl_3$); lit.[2a] $[\alpha]_D^{24}$ +57 (*c* 1.0, $CHCl_3$)} in 47% yield from **17**. The spectral data for **19** were identical in all respects to those kindly provided by Professor Hatakeyama.[5d] Finally, according to the precedent,[5d] saponification of **19** followed by neutralization with weak acidic resin (Amberlite IRC-76, H^+ form) furnished (+)-myriocin **1** in 82% yield. The spectroscopic (^1H and ^{13}C NMR) data for synthetic **1** were fully identical with those of natural myriocin, and the physical properties of **1** {mp 168–170 °C, $[\alpha]_D^{23}$ +5.1 (*c* 0.17, MeOH); lit.[3] mp 169–171 °C, $[\alpha]_D$ +4.8 (*c* 0.286, MeOH)} showed good agreement with those reported for the natural product.



Scheme 2 *Reagents and conditions*: i $PhSO_2Na$, DMF, room temp.; ii $(TMSOCH_2)_2$, TMSOTf, CH_2Cl_2, room temp.; iii *n*-BuLi, THF, −78 °C, then **15**, −78–0 °C; iv LiOH, H_2O–MeOH, room temp.; v Li, liq. NH_3, THF, −78 °C; vi 4 M aqueous HCl–THF (1:1), room temp.; vii 10% aqueous NaOH–MeOH (1:3), reflux; viii Ac_2O, pyridine, room temp.

This synthesis established an alternative and efficient pathway to myriocin **1** (24 linear steps and 4.9% overall yield from D-mannose), which showed almost the same efficiency as previous excellent approaches (2.4–5.1% overall yield).[5b–d] In addition, this work proved that the novel methodology, Overman rearrangement on a furanose scaffold,[7] is quite effective for the chiral synthesis of both acyclic and heterocyclic natural products possessing highly functionalized α,α-disubstituted α-amino acid structures. Additional applications of this methodology in natural product synthesis are now warranted and will be reported in due course.

We thank Professor Susumi Hatakeyama (Nagasaki University, Japan) for providing us with spectral data of an authentic sample and valuable discussions. Financial support of the Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japanese Government is gratefully acknowledged.

Notes and references

† All new compounds described in this paper were fully characterized by 300 MHz ^1H NMR, 75 MHz ^{13}C NMR, IR and mass spectrometric and/or elemental analyses.

‡ Overman rearrangement of an imidate derived from (*Z*)-allyl alcohol afforded **9** and its C(5) epimer in a ratio of 1:5 in 70% yield.

§ 1-Bromododecan-6-one was synthesized by essentially the same procedure reported by Just and Payette [see ref. 6(*a*)]. In place of cyclooctanone, cyclohexanone was employed as the starting material.

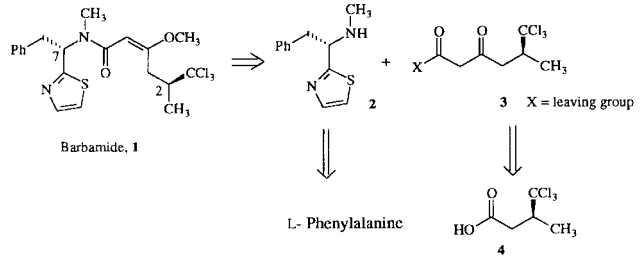
First published as an Advance Article on the web 17th September 2001

The first total synthesis of the trichlorinated natural product barbamide is described. The convergent approach involves coupling (*S*)-3-trichloromethylbutanoyl chloride with Meldrum's acid (2,2-dimethyl-1,3-dioxane-4,6-dione) to give 15 followed by addition of the novel secondary amine *N*-methyl-(*S*)-dolaphenine 2 (prepared in 6 steps and 24% overall yield from *N*-Cbz-L-phenylalanine) to give the β-keto amide 16 which was converted directly to the required (*E*)-enol ether.

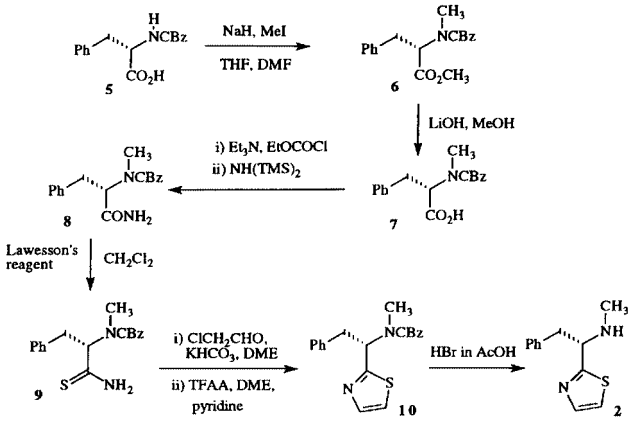
An interesting feature of many biologically active marine-derived natural products is the covalent inclusion of chlorine and bromine. Several compounds which contain a trichloromethyl group have been isolated from sponges of the genus *Dysidea* which have symbiotic association with cyanobacteria.[1] The polychlorinated natural products include, for example, the dysamides,[2] dysidin,[3] dysidenin,[4] herbacic acid[5] and herbamide A.[6] It has been suggested that sponge-based dysidenins are biosynthesised from associated cyanobacteria and indeed in 1996 a new natural product, barbamide, was found in the extracts of the cyanobacterium *Lyngbya majuscula*.[7] From extensive spectrocopic studies, it was proposed that barbamide has the structure **1** encompassing a trichloromethyl group, a thiazole ring as well as the methyl enol ether of a β-keto amide. Barbamide is an intriguing natural product in that the trichloromethyl group derives from the *pro-R* methyl group of leucine without detectable activation to facilitate a potential nucleophilic or electrophilic chlorination process. Hence, we have proposed that biochlorination occurs through a novel process, possibly involving radical chemistry.[8] In the majority of halogenated natural products the halogens are incorporated into positions which are suggestive of their biochemical reaction involving electrophilic species and indeed haloperoxidases which catalyse such reactions have been widely studied.[9]

Herein we report the first total synthesis of barbamide which confirms the structure of the natural product. Degradation studies have indicated that the configuration at C-7 is *S*.[8] Our retrosynthetic analysis is shown in Scheme 1 and involves cleavage of the amide bond to give two fragments: (*S*)-*N*-methyldolaphenine **2** which would be derived from L-phenylalanine and ketone **3** from (*S*)-3-trichloromethylbutanoic acid **4**.

The route for the synthesis of (*S*)-*N*-methyldolaphenine **2** is shown in Scheme 2. Treatment of commercially available *N*-Cbz-L-phenylalanine **5** with an excess of sodium hydride and



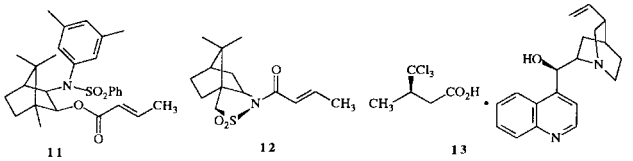
Scheme 1 Retrosynthetic analysis of barbamide.



Scheme 2 Synthesis of (*S*)-*N*-methyldolaphenine.

methyl iodide gave the *N*-methyl methyl ester **6** which was hydrolysed to the corresponding acid **7** in 80% yield over the 2 steps. A modified Hantsch method was used to form the thiazole ring in which the acid **7** was first converted to an amide **8** *via* a mixed anhydride using the approach described by Pellegata and coworkers.[10] Treatment of amide **8** with Lawesson's reagent at room temperature in dichloromethane[11] gave thioamide **9** in 71% yield over the two steps from acid **7**. Reaction of **9** with α-chloroacetaldehyde (prepared from the corresponding dimethyl acetal[12]) in DME in the presence of potassium hydrogen carbonate followed by dehydration using trifluoroacetic anhydride[13] gave (*S*)-*N*-Cbz-*N*-methyldolaphenine **10** as a yellow oil. Finally removal of the Cbz protecting group with hydrobromic acid in acetic acid gave an analytically pure sample of the novel secondary amine **2** with $[\alpha]_D$ −3.02† (*c* 0.65 in $CHCl_3$). To ensure that the stereochemical integrity at C-2 of **2** had been maintained throughout the synthetic route a sample of the (*R*,*R*)-tartrate salt was prepared in $CD_3OD:D_2O$ (4:1).[14] The ^{1}H-NMR spectrum of the product showed a downfield shift of the signal assigned to 2-H from δ 4.22 for amine **2** to δ 4.97 in the salt, there was no trace of the other diastereomer which was clearly apparent in a control experiment with the (*R*,*R*)-tartrate salt of racemic amine.

With the required amine **2** in hand, we next turned our attention to the synthesis of ketone **3** for which multigram quantities of **4** were needed (Scheme 1). Several methods have been reported for the preparation of **4** and the most direct is conjugate addition of a trichloromethyl anion to the chiral crotonyl derivatives **11** and **12**.[15,16] Unfortunately, despite



several attempts to repeat these reactions on a synthetically useful scale, in our hands generation of either trichloromethylmagnesium chloride[15] or trichloromethyllithium[16] at low temperature for reaction with **11** and **12** respectively did not

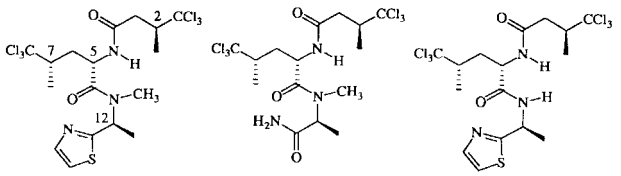
 DOI: 10.1039/b106087m

give acceptable yields of the required product. A more satisfactory approach proved to be resolution of the racemic acid.

Racemic trichloromethylbutanoic acid has been prepared previously *via* radical addition of bromotrichloromethane to crotonic acid followed by treatment of the resultant α-bromo acid with zinc.[17] The acid may then be resolved by separation of the corresponding (−)-(*R*)-α-phenylglycinol derivatives by HPLC giving **4** with 81% ee. However, there is some confusion in the literature with the sign of the optical rotation for (*S*)- and (*R*)-trichloromethylbutanoic acid.[18] Thus, in order to remove any possible ambiguity, the cinchonidine salt of **4** was prepared and repeated crystallisation of the salt from methanol and water[16] gave a single diastereomer as determined by ^{1}H- and ^{13}C-NMR spectroscopy. X-Ray crystallography revealed the (*R*)-configuration for C-3 of the trichloromethylbutanoic acid portion of the salt **13**. Treatment of the salt with potassium hydroxide followed by 2 M HCl gave, after work up, (*R*) (+)-**4** with $[\alpha]_D$ +25 (*c* 1.8 in EtOH).

For the synthesis of **4**, the (4*R*,5*S*)-4-methyl-5-phenyl-2-oxazolidinone[19] derivative of racemic trichloromethylbutanoic acid was prepared and the diastereomers were separated by column chromatography on silica. Following hydrolytic cleavage with lithium hydroxide–hydrogen peroxide the required (*S*)-**4** ($[\alpha]_D$ −28.9, *c* 0.96 in EtOH; lit.[15] −28.09, *c* 2.12 in EtOH) was isolated as well as recovered auxiliary, both in quantitative yield. From the retrosynthetic analysis shown in Scheme 1, the next stage of the synthesis of barbamide required a two carbon homologation of (*S*)-trichloromethylbutanoic acid **4** to give a β-keto acid derivative **3** with a suitable leaving group for reaction with (*S*)-*N*-methyldolaphenine **2**. Several approaches were investigated to achieve these final steps and the most direct route proved to be conversion of acid **4** to the corresponding acid chloride **14** with thionyl chloride followed by coupling **14** with Meldrum's acid to give the intermediate **15** (Scheme 3).[20] Treatment of **15** with **2** gave **16** with the framework of barbamide in 51% yield over the three steps from **4**. Finally, the (*E*)-enol ether was formed by reaction of β-keto amide **16** with sodium hydride and dimethyl sulfate in the presence of HMPA. A 1 : 1 mixture of two products was formed in this final stage of the synthesis due to epimerisation at C-7 under the basic reaction conditions. These compounds were readily separated by HPLC[21] giving the less polar product barbamide **1** and 7-epibarbamide **17**, $[\alpha]_D$ +73.4 (*c* 1.13 in CH_3OH). The ^{1}H- and ^{13}C-NMR and mass spectra of the synthetic material **1** were found to be identical with those of the natural product.[7] The optical rotation of synthetic barbamide was $[\alpha]_D$ −81.9 (*c* 0.95 in CH_3OH) whilst that of an authentic sample of the natural product gave $[\alpha]_D$ −82 (*c* 1.2 in CH_3OH).

Recently three further metabolites (pseudodysidenin **18**, dysidenamide **19** and nordysidenin **20**) containing the 3-trichloromethylbutanyl unit have been isolated from *L. majuscula*.[22] Unlike barbamide which is biosynthesised from L-trichloroleucine and a derivative of L-phenylalanine,[8] it is apparent that these metabolites are assembled from L-trichloroleucine and an L-alanine derivative (as determined by degradation studies). The 2*S*,5*S*,7*S* configurations of **18**, **19** and **20** were assigned by chiral HPLC and comparison of their optical rotations (which were all negative) to other polychlorinated natural products.[22] The synthetic studies described herein confirm that barbamide **1** isolated from extracts of *L. majuscula*, encompasses the (3*S*)-trichloromethylbutanyl unit which is in accord with the assignment of the configuration of the 2*S* and 7*S* stereocentres in these new structurally related metabolites **18**, **19** and **20** which have been isolated more recently from *L. majuscula*.



Pseudodysidenin, **18** Dysidenamide, **19** Nordysidenin, **20**

We are very grateful to Dr Clive Smith, GlaxoSmithKline for his kind assistance in the preparation of (*S*)-3-trichloromethylbutanoic acid and Dr Lee Hall for the X-ray analysis. The University of Bristol is thanked for a Scholarship (to V.-A. N.).

Mesopore immobilised copper bis(oxazoline) complexes for enantioselective catalysis

Richard J. Clarke and Ian J. Shannon*

School of Chemical Sciences, University of Birmingham, Birmingham, UK B15 2TT. E-mail: I.Shannon@bham.ac.uk

Received (in Cambridge, UK) 27th June 2001, Accepted 21st August 2001
First published as an Advance Article on the web 17th September 2001

New supported heterogeneous catalysts have been synthesised through the tethering of copper bis(oxazoline) complexes to the surfaces of MCM-41 and MCM-48 mesoporous materials, and the prepared catalysts shown to be highly active in the enantioselective cyclopropanation of styrene with ethyl diazoacetate.

Bis(oxazoline) complexes have been widely reported as being excellent catalysts for a broad range of organic reactions.[1] The most extensively used bis(oxazoline) ligands have been those containing a single carbon spacer between the oxazoline rings (*e.g.* **1**), enabling the ligand to chelate to a metal centre forming a stable six-membered ring. The ease with which differing bis(oxazoline) ligands may be synthesised, with stereocontrol over the C_2-symmetry of the ligand, combined with their ability to complex a variety of transition metal cations, has enabled catalysts to be tailored to give good yield and selectivity in asymmetric syntheses including Diels–Alder,[2] cyclopropanation,[3] aziridination[4] and oxidation reactions.[5]

With the success and diversity of chiral bis(oxazoline) catalysts in enantioselective reactions in the homogeneous phase, attention has also turned to the development of heterogenised systems which may be of significant industrial interest. Previous studies have seen the encapsulation of bis(oxazoline) complexes within zeolites *via* 'ship-in-a-bottle' type syntheses,[6] and layered aluminosilicate clay materials.[7,8] Both these strategies have met with some success, but have recognised the potential problem of accessibility of reactants to the catalytically active sites due to pore blocking. In both cases the interaction between the complex and the host material is through ionic interactions which, dependent on the nature of support, can lead to problems of leaching of the ligand complex into solution. An alternative strategy which prevents leaching of ligand is to covalently bind the ligand to the substrate, demonstrated for bis(oxazolines) through their attachment to dendritic cores[9] and polymers.[8,10]

We have investigated an alternative method for the development of heterogenised bis(oxazoline) catalysts through the covalent binding of the ligand to the surface of the inorganic mesoporous materials, MCM-41 and MCM-48. These MCM-type materials[11,12] are large pore silicates with high surface areas, which are ideal for use as catalyst supports. The size of the pores (*ca.* 30 Å) is sufficient that, upon catalyst immobilisation, good accessibility to isolated active sites is maintained, while also potentially enabling reactions involving larger substrates than are possible with conventional supports such as zeolites and clays. In many other studies, catalytically active species have been successfully attached to mesoporous solids,[13,14] either through ionic or covalent binding similar to that we use here. To date, however, there have been no reports of the immobilisation of the versatile bis(oxazoline) catalysts within mesoporous materials.

We have synthesised catalysts incorporating methylene-bis[(4*S*)-4-phenyl-2-oxazoline] **1** complexes, supported *via* alkyl tethers on MCM-41 and MCM-48. The mesoporous silica materials were prepared using methods derived from the literature.[12] The modified bis(oxazoline) complexes for tethering were prepared using standard Schlenk techniques in a pseudo-one-pot synthesis (Scheme 1). Typically, 0.13 mmol **1** was reacted with 0.33 mmol (2.5 equivalents) of BuLi in 5 ml dry THF in an isopropyl alcohol–dry-ice bath, before addition of 0.43 mmol of iodopropyltrimethoxysilane. After stirring for several days the colour changed to red–brown, at which point 0.135 mmol of $CuCl_2$ or $Cu(TfO)_2$ was added and the solution further stirred overnight. The solution was then added to 0.65 g of MCM-41 or MCM-48 suspended in 10 ml dry THF, and 0.5 ml Et_3N added. After overnight stirring, the resulting solid was filtered off, washed and Soxhlet extracted with THF to remove any untethered species, and dried.

Analysis by powder X-ray diffraction confirmed that the structure of the mesoporous supporting material remained intact through the tethering procedure and also after catalysis. Cu contents in the final catalysts were determined by AAS; the amount of support was selected so as to give a theoretical catalyst loading of 0.2 mmol Cu g^{-1}, however we found in practice that the true loading was much less than this value (typically 20%). IR data recorded on dehydrated samples of the supported catalysts revealed the presence of an absorption band at *ca.* 1640 cm^{-1} characteristic of the C=N double bond group of the oxazoline ligand. All compounds were pale green–blue, and comparison of the diffuse reflectance UV–VIS spectra of our catalysts with those of the corresponding untethered **1**:$CuCl_2$ and **1**:$Cu(TfO)_2$ complexes revealed that a broad absorption maximum was observed at *ca.* 740 nm, indicating further that we have synthesised the mono-bis(oxazoline) copper complex and not the di-liganded complex.[3] As final

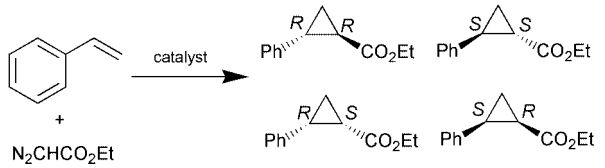

Scheme 2 Cyclopropanation reaction between styrene and ethyl diazoacetate, showing the four products obtained.

Table 1 Catalytic results for the cyclopropanation reaction involving styrene and ethyl diazoacetate[a]

Catalyst	Cu (mol%)	Run	Yield[b] (%)	*trans*/*cis*	ee (*cis*)[c](%)	ee (*trans*)[d](%)
1:$CuCl_2$ (homo)	1	1	19.5	1.99	23	21
1:$Cu(TfO)_2$ (homo)	1	1	46.3	2.05	49	58
2a	0.10	1	38.7	1.89	48	54
		2	23.7	1.80	48	52
3a	0.24	1	47.4	1.95	46	51
		2	46.6	1.78	42	45
2b	0.16	1	36.6	1.69	46	51
		2	27.8	1.63	44	46
3b	0.22	1	32.3	1.93	50	54
		2	31.0	1.79	46	48
4	0.64	1	32	1.61	1	2

[a] All reactions were run at 25 °C. To a stirred solution of 3 mmol of styrene in 2 ml of dichloroethane containing *ca.* 50 mg of catalyst, 50 μl of a 1% phenylhydrazine solution was added, and 10 μl of diethyl adipate was used as standard. 1 mmol of ethyl diazoacetate was then added and the reaction stirred for 40 h (24 h for homogeneous reactions) before filtration, solvent removal and purification by column chromatography. Analysis was carried out on a CE 2000 Series Trace GC using a Chirasil-Dex CB column. [b] Yield is percentage of cyclopropanes formed relative to the theoretical maximum expected for 100% diazoacetate conversion. [c] Major enantiomer for *cis* products is *R,S*. [d] Major enantiomer for *trans* products is *R,R*.

confirmation, ^{13}C MAS NMR of a tethered bis(oxazoline) made in the same manner as above, but to which no $CuCl_2$ or $Cu(TfO)_2$ had been added, showed peaks which matched those seen for the free ligand, with additional peaks seen corresponding to the carbons forming the alkyl chain tether to the mesopore surface. Although NMR did not show the presence of residual methoxy groups, it is known that the reaction between these and the surface silanols is incomplete, resulting in complexes attached to the surface by fewer than the maximum six Si–O–Si linkages.

The supported catalysts prepared were tested for the enantioselective cyclopropanation reaction of styrene with ethyl diazoacetate (Scheme 2). As can be seen from the results in Table 1, the supported catalysts perform favourably compared with the homogeneous catalysts operating under the same reaction conditions. The tethered Cl-catalysts, **2a** and **2b**, performed much better giving higher yield and enantioselectivity than the homogeneous mono-bis(oxazoline) complex equivalent, for significantly lower concentration of active catalyst. The supported TfO-catalysts, **3a** and **3b**, showed enantioselectivity only slightly lower than the homogeneous version.

Interestingly, when in a further comparison the **1**:$Cu(TfO)_2$ complex was immobilised directly onto the surface of MCM-41, **4** (believed to be attached *via* hydrogen bonding between the triflate anion and the surface Si–OH groups in a manner analogous to that described by de Rege *et al.*[15]), the catalyst showed respectable yield but very poor selectivity. This suggests that, for this catalyst, the triflate complex is not leached from the surface (in which case the reaction would be expected to show similar results to the homogeneous system), but that the mode of immobilisation is inferior to the covalent tethering method we have used in generating the other catalysts.

After recovery by filtration, the catalysts were washed with dichloromethane and dried and their structural integrity confirmed by XRD. On reuse, following the same catalytic procedure as above, it can be seen that those made with copper chloride (**2a** and **2b**) have deactivated faster than those from the triflate salt (**3a** and **3b**) which show very little deactivation at all, although there is an accompanying small drop in the ee values and *trans*/*cis* ratio of the products observed. In part this loss of activity and selectivity has previously been attributed to the poisoning of the system by adsorption of by-products on the catalyst's surface,[7] such as the dimer formed from diazoacetate self-reacting or excess styrene, and we are currently tuning the reaction conditions under which catalysis is carried out to further investigate this problem. Another factor under investigation for improving the efficiency of the catalysts is the removal of the residual surface silanol groups which may be acting to trap side-products in the pores.

Although further work is still required to fully optimise conditions for conversion, selectivity and recyclability in the above reaction, the general synthetic methodology proposed here provides the basis for a large family of mesopore supported bis(oxazoline) catalysts to be generated for use in a wide range of organic reactions and in particular in asymmetric syntheses.

We would like to thank EPSRC for support (studentship to R. J. C.)

Received (in Cambridge, UK) 12th June 2001, Accepted 14th August 2001
First published as an Advance Article on the web 4th September 2001

The [2 + 2] photoreaction of (*E*)-diaminostilbene dihydrochloride proceeds with large rate acceleration and high stereoselectivity *via* formation of a stable 1:2 host–guest complex with cucurbit[8]uril in solution.

Bringing two reactants in close proximity and the correct orientation to promote reactions between them in a regio- and/or stereoselective manner is an important research goal. Supramolecular encapsulation of two guest molecules in molecular hosts[1–3] or supramolecular hosts[4] has been studied to achieve this goal. For example, by forming host–guest complexes, cyclodextrins mediate photoreaction of aromatic guests such as anthracene,[5] coumarin[6] and stilbene[7,8] derivatives in solution as well as in the solid state.[8,9] However, few studies reported large rate acceleration and high stereo- and/or regioselectivity in [2 + 2] photoreactions mediated by cyclodextrins in solution.

Cucurbituril (CB[6]), a macrocycle comprising six glycoluril† units, forms stable host–guest complexes with small molecules.[10] Recently, we synthesized the octameric cucurbituril homologue cucurbit[8]uril (CB[8]) with a cavity comparable to that of γ-cyclodextrin. Its large cavity can accommodate two aromatic guest molecules to form 1:2 host–guest complexes,[11] or 1:1:1 ternary complexes.[12] This observation prompted us to study chemical reactions between the two guest molecules included inside the cavity of CB[8]. Here we report a facile, highly stereoselective [2 + 2] photoreaction of (*E*)-diaminostilbene dihydrochloride [(*E*)-**1**, Scheme 1] inside the cavity of CB[8] in solution.

CB[8] and (*E*)-**1** form a stable 1:2 host–guest complex in aqueous medium (D_2O) as confirmed by ^1H NMR spectroscopy (Fig. 1b). Interestingly, when the host and guest are mixed in a 1:1 stoichiometry, the 1:2 complex exists as the major product. The formation constant of the ternary complex in formic acid–water (2:3) was measured to be $(3.8 \pm 0.4) \times 10^4$ M^{-2} by isothermal titration calorimetry.‡ UV irradiation§ of an aqueous solution the 1:2 complex for 0.5 h affords **3a**, almost solely (Fig. 1c). Subsequent treatment of the reaction mixture with a small amount of base (*e.g.*, 1 M NaOH solution) produces the free [2 + 2] adduct, 1α,2α,3β,4β-tetrakis(4-aminophenyl)cyclobutane (*syn*-**4**, where α and β represent either face of the cyclobutane ring) along with a trace amount (< 5 %) of 1α,2β,3α,4β-tetrakis(4-aminophenyl)cyclobutane (*anti*-**4**). No formation of the isomerization product (*Z*)-**1** is observed. In the absence of CB[8], however, the main reaction pathway for (*E*)-**1** upon UV irradiation is the isomerization to (*Z*)-**1** as usually is the case for stilbene derivatives.[13] Therefore, the present result indicates that photodimerization is far more favorable than photoisomerization in the cavity of CB[8]. Furthermore, the facile formation (< 0.5 h) of the dimers with high stereoselectivity (*syn–anti* ratio > 95:5) in the presence of CB[8] is in contrast to the slow formation (72 h) of dimers of a similar stilbene derivative with moderate stereoselectivity (*syn–anti* ratio ≈ 4:1) in the presence of γ-CD in solution.[7]

What is the origin of the high stereoselectivity of the photodimerization mediated by CB[8]? To answer the question we carried out AM1 calculations[14] on the 1:2 host–guest complex between CB[8] and (*E*)-**1**. The most stable conformations for the ternary complex are **2a** ('*syn*') or **2b** ('*anti*') (Scheme 2), in which two guest molecules are included in the host with either '*syn*' or '*anti*' relationship of the olefinic groups. In the two equally stable conformations, half of each guest body is embedded in the host cavity while the remaining parts of the guest molecules stick out into the solution in opposite directions. The high stability of the conformations is due to ion–dipole as well as hydrogen bonding interactions between the ammonium groups of the guests and the portal oxygen atoms of the host, and hydrophobic interaction between the host cavity and the guests. For [2 + 2] photo-cycloaddition to occur, however, the two olefinic double bonds should be in close proximity as in **2a′** ('*syn*') or **2b′** ('*anti*'), which would lead to **3a** or **3b**, respectively, upon photodimerization of the guest. Although **2a′** and **2b′** would also have similar stabilization energies in solution, the concerted [2 + 2] cycloaddition of two guests in CB[8] occurs much more effectively in **2a′** than in **2b′** because of the parallel orientation of the two double bonds in **2a′**.[15] Furthermore, **3a** is more stable than **3b** ($\Delta\Delta E \approx 18$ kcal mol^{-1}) according to the gas phase calculation.[14] Although the calculated energy difference is clearly overestimated, the modeling results provide a possible explanation why the

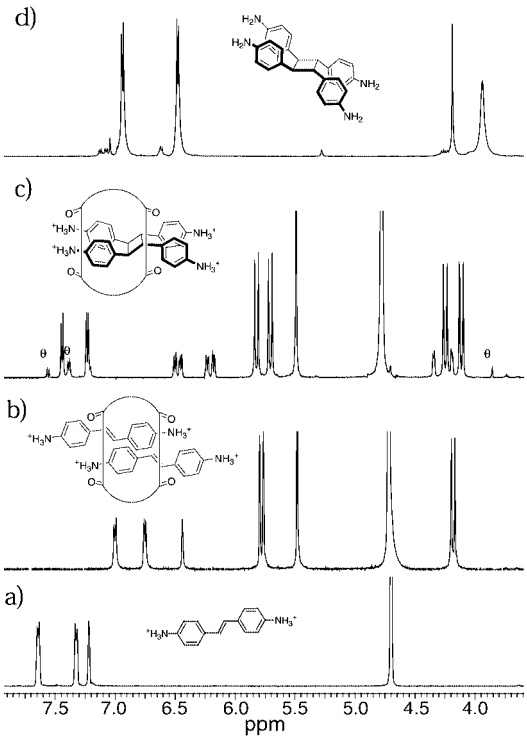

Fig. 1 (a) ^{1}H NMR spectra of (*trans*)-**1** (4×10^{-3} M) in D_2O; (b) after addition of 0.5 equiv. of CB[8]; (c) after irradiation of solution (b) for 30 min. Signals for the *anti* adduct **3b** are marked θ; (d) after isolation, *syn*-**4**–*anti*-**4** > 95:5, in CD_3CN.

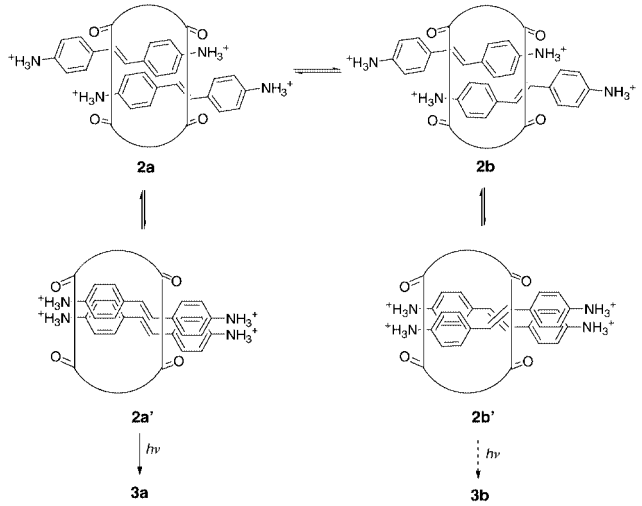

Scheme 2

photodimerization to **3a** ('*syn*') is far more favorable than to **3b** ('*anti*').

In conclusion, [2 + 2] photoreaction of (*E*)-**1** proceeds in solution with large rate acceleration and high stereoselectivity *via* formation of a stable 1:2 host–guest complex with CB[8]. The ability of the host to stabilize the two guest molecules with a parallel orientation of the olefinic groups in close proximity leads to the high stereoselectivity of the photodimerization. This work thus demonstrates a synthetic utility of CB[8] as a reaction 'vessel' in which bimolecular reactions between appropriately designed guest molecules can be facilitated with high regio- and stereoselectivity.

We thank the Korean Ministry of Science and Technology (Creative Research Initiative Program) for support of this work. We also thank Mr Eunsung Lee for synthesizing cucurbit[8]uril and Professor P. K. Bharadwaj for reading the manuscript.

Notes and references

† The IUPAC name for glycoluril is 2,4,6,8-tetraazabicyclo[3.3.0]octan-3,7-dione.

‡ The microcalorimetric titration was carried out using HCO_2H–H_2O (2:3 v/v) as solvent because CB[8] is sparingly soluble in neutral water. Therefore, the formation constant of the ternary complex in a neutral aqueous solution should be higher.

§ A solution of 2(*E*)-**1**–CB[8] complex in D_2O (4×10^{-3} M) in a NMR tube was irradiated at 300 nm in a Rayonet photochemical reactor for 0.5 h. To this solution was added several drops of dilute aqueous NaOH solution to adjust pH ~9, then excess of methanol (10 mL) was added to the mixture. After vigorous stirring for 1 h, the precipitate CB[8] was removed by filtration. The resulting solution was concentrated under reduced pressure to afford **4** in 82% yield as a pale yellow solid. The product distribution was determined by integration of the ^{1}H NMR signals of the crude product in CD_3CN. *Selected data* for *syn*-**4** δ_H (CD_3CN, 500 MHz) 6.92 (d, *J* 8.2, 2H, ArH), 6.46 (d, *J* 8.2, 2H, ArH), 4.16 (s, 1H, CH), 3.91 (br, 2H, NH_2); δ_C (CD_3CN, 125 MHz) 146.0, 130.8, 129.4, 114.9, 47.4; EI-MS: *m*/*z* 210.3 [M^+/2].

Received (in Cambridge, UK) 6th June 2001, Accepted 10th August 2001
First published as an Advance Article on the web 17th September 2001

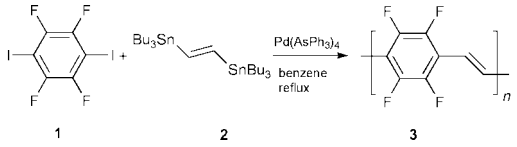
Poly(2,3,5,6-tetrafluoro-1,4-phenylenevinylene) (PTFPV) was prepared for the first time by the Stille cross-coupling reaction and the resulting material was characterized through MALDI-TOF mass spectrometry, employing a novel sample preparation protocol suitable for insoluble compounds; preliminary optical and electrooptical measurements were performed.

In recent years, conjugated organic polymers belonging to the class of poly(1,4-phenylenevinylene) (PPV) have been successfully employed as active materials in several types of devices, the most frequent use being represented by the fabrication of light emitting diodes (OLED).[1,2] However, one of the major limiting factors in the wide commercialisation of polymer based LED devices is their insufficient long term stability, mainly due to the oxidative photodegradation of the organic semiconductor layer.[3]

The replacement of carbon–hydrogen bonds by stronger and less reactive carbon–fluorine bonds has been proposed as a possible approach for increasing the chemical stability of PPVs.[4a,5] Furthermore, fluorine atoms act as electron-withdrawing groups on the π conjugated system and consequently they are expected to have important electronic effects on the light emission properties of the resulting material.[4b,5] For these reasons considerable attention has been attracted by the synthesis and optical properties of various fluorine substituted PPVs and closely related poly(arylenevinylene)s.[4,6] In particular, the synthesis of poly(2,3,5,6-tetrafluoro-1,4-phenylenevinylene) (PTFPV) has been unsuccessfully attempted by the classical soluble precursor route.[6a] The same protocol has been employed for the synthesis of copolymers containing tetrafluorophenylenevinylene with either phenylenevinylene[4a] or dialkoxyphenylenevinylene[4b] units. In the first case, upon increasing the ratio between fluorinated and unsubstituted monomers, a decrease both in the conversion to precursor polymer and in the final yield of conjugated material was observed.[4a] As a consequence, it was not practically possible to prepare PTFPV using only the fluorinated monomer. Oligomeric PTFPVs having three or four aromatic rings were obtained with very low yields, *i.e.* 7 and 0.6% respectively, in the reaction of (*E*)-2-(pentafluorophenyl)ethenyllithium with hexafluorobenzene.[6b] An alternative approach reported in the same paper was represented by a self-polycondensation of (*E*)-2-(pentafluorophenyl)ethenyllithium. However, as admitted also by the authors, it was only possible to present rough proof, *i.e.* an elemental analysis, in favour of the proposed TFPPV structure for the resulting material.

In this communication we present our successful approach to the preparation of such an elusive fluorinated polymer, together with its structural characterization and preliminary measurements of its properties. Our synthesis of PTFPV is based upon a Stille cross-coupling reaction[2a,d,7] (Scheme 1).

1,4-Diiodotetrafluorobenzene **1** and (*E*)-1,2-bis(tributylstannyl)ethene **2**[8] were suitable starting materials and $Pd(AsPh_3)_4$,[9] generated *in situ* from $Pd_2(dba)_3$ and $AsPh_3$, was found to be the most effective catalyst.†



Scheme 1 Polymerization reaction.

Clear evidence that the insoluble yellow powder recovered from our reaction is PTFPV **3** is provided by the TOF mass spectrum performed in negative mode from a matrix of 2,5-dihydroxybenzoic acid after matrix-assisted laser desorption-ionization (MALDI) (Fig. 1).

Despite the complete insolubility of the material in all common organic solvents suitable for the preparation of samples for MALDI analysis, it was possible to get the spectra using a protocol recently described for polyamides.[10] The novel procedure is analogous to the preparation of a KBr sample for infrared analysis, using the matrix and the polymer in a 1:1 mixing ratio. To the best of our knowledge, the present work represents the first application of MALDI analysis to an insoluble conjugated polymer. The spectrum of PTFPV (Fig. 1) consists of peaks with masses ranging from about 500 to 4500 amu. Mass-discrimination phenomena, occurring in particular at higher molecular weight end in the MALDI-TOF spectra of polydisperse polymers,[11] allow only an approximate evaluation of the molecular weights ($M_w \approx 2400$, and $M_n \approx 1700$ with a relatively high polydispersity index $D > 1.4$). On the other hand, an analysis of the MALDI-TOF spectrum enabled us to assign the peaks to PTFPV chains with all the possible terminations as described in Fig. 2.

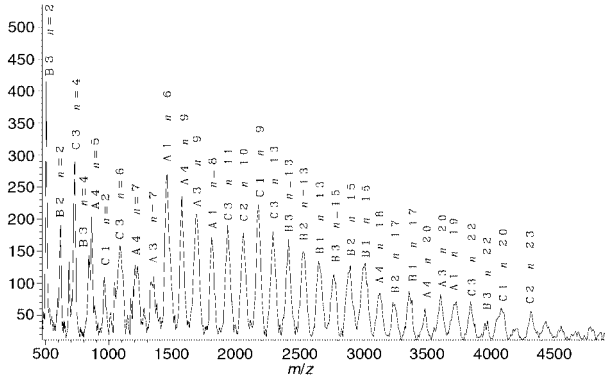


Fig. 1 MALDI-TOF mass spectrum of PTFPV. Ions are generated using a 337 nm nitrogen laser beam. The spectrum presented here is the sum of 300 shots acquired in linear mode. It was baseline corrected for presentation quality and the matrix signals are left outside the mass range reported (see also Fig. 2).

 DOI: 10.1039/b105029j

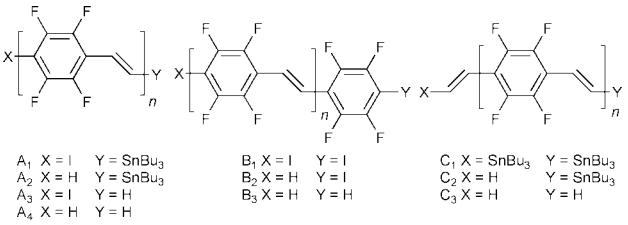

Fig. 2 PTFPV chains with all the possible terminations.

The masses calculated account for the peaks within the limit of the accuracy of about 1%, intrinsically due to the particular sample preparation technique.

As a further characterization of our material, X-ray photoelectron spectroscopy (XPS) elemental analysis was performed on a silicon-supported thin film, obtained as described below. The XPS spectrum shows the presence of carbon, fluorine, tin and iodine in the following atomic percentages: C1s = 69.09; F1s = 30.11; Sn3d = 0.44; I3d = 0.36. The C1s signal was best fitted in three components respectively due to the presence of carbon bonded to fluorine (atom% 44.19) and hydrocarbon carbon (atom% 55.81), and a third component attributable to $\pi \rightarrow \pi^*$ shake up satellites due to the aromatic rings.‡ The average polymerization degree calculated assuming statistical chain termination of an iodine atom and a tributylstannyl group is approximately 17–20 arylenevinylene units.

The Fourier transformed infrared spectrum of the material shows a strong band at 1490 cm^{-1} due to C–F stretching of the aromatic rings. A band at 963 cm^{-1}, assigned to the out of plane bending of the vinylic C–H bonds, is consistent with a *trans* geometry of the vinylene units.

In order to perform the optical and electrooptical characterization of the material, thin films of PTFPV (about 50 nm thickness) were thermally evaporated under high vacuum (10^{-6} mmHg) onto a support of quartz or commercial ITO, respectively.

Absorption and photoluminescence spectra of a PTFPV film were taken. The absorption band is centered at 347 nm. The photoluminescence (PL), in the green region, is centered at 544 nm, showing a considerable Stokes shift.

Single-layer electroluminescent devices, fabricated using PTFPV as emitting layer and aluminium and ITO as cathode and anode respectively, did not yield any emission even at high density current. According to the high electronegativity of the fluorine atom, which should increase the electron affinity of the polymer,[12] this observation can be explained in terms of a high energy barrier for hole injection from the ITO anode, while a significantly lower energy barrier is expected for electron injection from the Al cathode into the conduction band of the PTFPV.

In fact, the introduction of a layer of TPD [*N*,*N*′-bis(3-methylphenyl)-*N*,*N*′-diphenylbenzidine], a typical hole transporter,[13] between the ITO anode and the PTFPV resulted in a working device. The *I–V* and *E–V* curves, showing current density and emitted light power *versus* voltage, for an ITO/TPD/PTFPV/Al LED are reported in Fig. 3, where the inset illustrates the dependence of the light output on the injected current density. The electroluminescence (EL) threshold voltage was 6.5 eV.

The EL spectrum essentially matches the PL one suggesting that the radiative decay of the same exciton is responsible for the emission in both cases.

Summing up, we have described the first synthesis of PTFPV and performed the characterization of this insoluble material by means of MALDI-TOF mass spectrometry, using a novel sample preparation procedure that should enlarge the applications of this powerful analytical technique in the field of conjugated organic materials. Useful information was also obtained by XPS spectroscopy. Preliminary experiments have confirmed that the length and the structure of this polymer are suitable for the fabrication of electroluminescent devices.

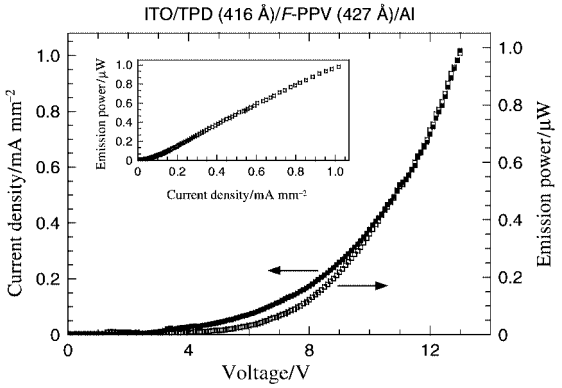

Fig. 3 *I–V* and *E–V* curves and *E–I* output of PTFPV LED. The area of device is ~9 mm^2.

Notes and references

† Experimental procedure: a mixture of 1,4-diiodo-2,3,5,6-tetrafluorobenzene **1** (0.600 g, 1.49 mmol), (*E*)-1,2-bis(tributylstannyl)ethene (0.905 g, 1.49 mmol) **2**, catalyst $Pd_2(dba)_3$ (0.041 g, 0.05 mmol) and ligand $AsPh_3$ (0.110 g, 0.36 mmol) in 24 ml of benzene was refluxed under a nitrogen atmosphere for 7 days. After cooling at room temperature, the solvent was evaporated under reduced pressure. The crude polymer obtained was washed twice with hexane. A greenish solid was recovered by centrifugation. Arsine and low molecular weight fractions were eliminated by extraction in a Soxhlet apparatus with ethanol (24 h) and with chloroform (12 h), respectively, leaving a yellow insoluble residue (0.260 g). The material does not melt up to 300 °C.

‡ XPS elemental analysis performed on powder gave comparable results.

First published as an Advance Article on the web 17th September 2001

A novel method for preparing highly photoactive nano-sized TiO_2 photocatalysts with anatase and brookite phases has been developed by hydrolysis of titanium tetraisopropoxide in pure water or a 1 : 1 EtOH–H_2O solution under ultrasonic irradiation; the photocatalytic activity of TiO_2 particles prepared by this method exceeded that of Degussa P25.

A great deal of effort has been devoted in recent years to developing heterogeneous photocatalysts with high photocatalytic activities for their applications in solving environmental problems.[1–3] In order to commercialize this treatment technique, it is of great importance to improve the preparative methods of titania, because the photocatalytic activity and phase transition behavior of TiO_2 are significantly influenced by the preparative conditions and methods.[4–8] In this study, a novel and simple method for preparing highly photoactive nano-sized TiO_2 photocatalysts with anatase and brookite phases has been developed by a sol–gel method and ultrasonic irradiation in pure water or EtOH–H_2O mixed solution. This is the first report that shows high photocatalytic activity of a photocatalyst containing an 80% anatase and 20% brookite phase.

Sonochemistry arises from acoustic cavitation, the formation, growth, and implosive collapse of bubbles in a liquid.[8–10] The use of ultrasound to enhance the rate of reaction has become a routine synthetic technique for many homogeneous and heterogeneous chemical reactions.[8–10] Sonochemistry has been used to prepare various oxides and amorphous metal powders.[8–12] In the present work, it was found that ultrasonic irradiation could not only accelerate the hydrolysis and crystallization of titania, but also enhances the photocatalytic activity.

To synthesize nano-sized TiO_2 particles, titanium tetraisopropoxide (TTIP, Aldrich) was used as a titanium source. TTIP (0.0125 mol) was added dropwise to 100 mL pure water or EtOH–H_2O mixed solution under vigorous stirring at room temperature. The molar ratio of EtOH to H_2O (R_{EtOH}) was 0, 1 or 10. Sol samples formed by the hydrolysis process were treated with and without ultrasonic irradiation in an ultrasonic cleaning bath (Bransonic ultrasonic cleaner, model 3210E DTH, 47 kHz, 120 W, USA) for 1 h, followed by ageing in a closed beaker at room temperature for 36 h in order to further hydrolyze the TTIP and form mono-dispersed TiO_2 particles. After the ageing, these samples were dried at 100 °C for *ca.* 8 h in air in order to vaporize water and alcohol in the gels and then ground to a fine powder to obtain dried gel samples. The dried gel samples were calcined at 500 °C in air for 1 h to obtain TiO_2 photocatalysts. Their synthesis conditions and physicochemical properties are summarized in Table 1.

The X-ray diffraction (XRD) patterns, obtained on a Philips MPD 18801 X-ray diffractometer using Cu-Kα radiation at a scan rate of 0.05° 2θ s^{-1}, were used to determine the identity of any phase present and its crystallite size. The phase content of titania can be calculated from the integrated intensities of anatase (101), rutile (110) and brookite (121) peaks by the method reported by Zhang.[13] The average crystallite sizes of anatase, rutile, and brookite were determined according to the Scherrer equation. Brunauer–Emmett–Teller (BET) surface areas (S_{BET}) were determined using a Micromeritics ASAP 2000 nitrogen adsorption apparatus. All the samples measured were degassed at 180 °C before the actual measurements.

The photocatalytic activity experiments on TiO_2 particles for the oxidation of acetone in air were performed at ambient temperature using a 7000 ml reactor. The detailed experimental process can be found in ref. 14. The photocatalytic oxidation of acetone is a pseudo-first-order reaction and its kinetics may be expressed as follows: $\ln(C_0/C) = kt$, where k is the apparent reaction rate constant, C_0 and C are the initial concentration and the reaction concentration of acetone, respectively.[1,2]

Fig. 1 shows XRD patterns of the as-prepared TiO_2 gel powders. The TiO_2 gel particles obtained from pure water ($R_{EtOH} = 0$) contain anatase, as the main phase along with brookite. With increasing R_{EtOH}, the intensities of anatase peaks become steadily weaker and the brookite phase disappears.

Table 1 Synthesis conditions and physicochemical properties of TiO_2 particles

Sample	R_{EtOH}[a]	Ultrasonic irradiation	Phase content[b]	Crystallite size[c]/nm	S_{BET}[d]/ m^2 g^{-1}	Porosity[e]	Pore volume[f]/ ml g^{-1}	Pore size[g]/nm

[a] Molar ratios of EtOH to H_2O. [b] Determined by XRD, (A): anatase, (B): brookite. [c] Calculated by XRD using the Scherrer equation. [d] BET surface area calculated from the linear part of the BET plot (P/P_0 = 0.1–0.2). [e] The porosity is estimated from the pore volume determined using the adsorption branch of the N_2 isotherm curve at P/P_0 = 0.995. [f] Total pore volume, taken from the volume of N_2 adsorbed at P/P_0 = 0.995. [g] Average pore diameter, estimated using the desorption branch of the isotherm and the Barrett–Joyner–Halenda (BJH) formula.

 DOI: 10.1039/b105471f

When R_w = 10, the TiO_2 gel particles appear completely amorphous. This is probably due to the fact that EtOH solvent suppresses the hydrolysis of titanium alkoxide and rapid crystallization of the TiO_2 particles by adsorbing on the surfaces of TiO_2 particles.[6,7] Usually, with increasing water content, a stronger nucleophilic reaction between water and alkoxide molecules will occur and more alkoxy groups in the alkoxide will be substituted by hydroxy groups of water.[7] Therefore, the decrease in the quantity of unhydrolysed alkyls in a precursors results in a reduction of steric hindrance by the residual alkyls, preventing crystallization to crystalline anatase. R_{EtOH} and ultrasonic irradiation also has a strong influence on the crystallization behavior of TiO_2 gels at 500 °C. Table 1 shows that with increasing R_{EtOH}, the content and crystallite size of anatase increases. This is ascribed to the fact that the heat produced by the combustion of residual alkyls will promote the transformation of the TiO_2 phase and growth of TiO_2 crystallites. Moreover, ultrasonic irradiation reduces the crystallite size of anatase. This is due to the fact that ultrasound irradiation generates many localized hot spots in the solution and within the gel. The hydrolysis of ≡Ti–OR species is enhanced and the polycondensation of ≡Ti–OH species is promoted. This further causes the homogeneous formation of a large number of seed nuclei, which leads to a smaller particle size.[11]

Fig. 2 shows the pore size distribution curve and the corresponding nitrogen adsorption–desorption isotherms (inset) of sample A. The BET surface area and pore parameters of the samples determined from the nitrogen adsorption–desorption isotherm by the BJH (Barrett–Joyner–Halenda) method are summarized in Table 1. This shows that all samples A–F have a mesoporous structure. The average pore diameter is several nm. The mesoporous structure of TiO_2 particles is attributed to pores formed between TiO_2 particles.[11] It is these mesopores

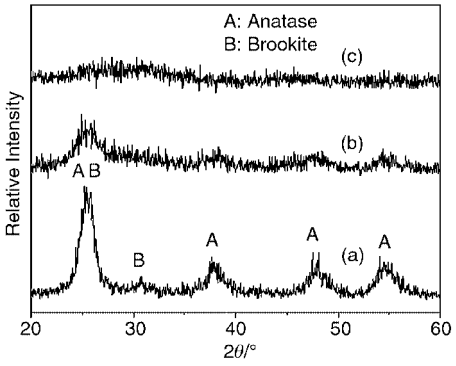

Fig. 1 XRD patterns of the TiO_2 gel powders prepared from the EtOH–H_2O mixed solutions under ultrasonic irradiation with (*a*) R_{EtOH} = 0 (pure water), (*b*) R_{EtOH} = 1 and (*c*) R_{EtOH} = 10; and dried at 100 °C for 8 h.

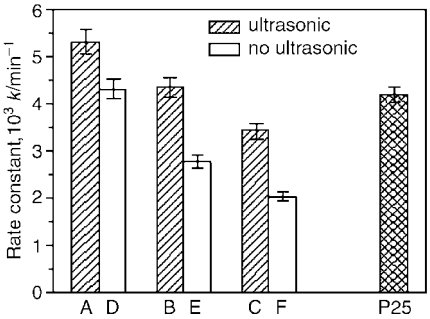

Fig. 3 Comparison of the apparent rate constants of samples A–F and P25.

that allow rapid diffusion of various reactants and products during photocatalytic reaction and enhance the speed of the photocatalytic reaction. It can also be seen from Table 1 that with increasing R_{EtOH}, BET surface area, porosity and pore volume decrease and pore diameter increases, which is attributed to the growth of TiO_2 crystallites.

Fig. 3 shows the comparison of the apparent rate constants (k/min^{-1}) of samples A–F and Degussa P25 (P25). For sample A, the k value (5.30×10^{-3}) is obviously higher than that of P25 (4.19×10^{-3}), which is well known to have a high photocatalytic activity.[1,2] This may be attributed to the fact that the former has a larger specific surface area, smaller crystallite size *etc*. With increasing R_{EtOH} (from sample A to C), the value of k decreases. For example, the k value of sample C is lower than that of P25 and sample B. This is attributed to the fact that it had a smaller specific surface area and a larger crystallite size. On the other hand, P25 and sample A or B are composed of two phases, corresponding to anatase and rutile and anatase and brookite anatase, respectively. Usually, the composite of two kinds of semiconductors or two phases of the same semiconductor is beneficial in reducing the combination of photogenerated electrons and holes and in enhancing photocatalytic activity. Fig. 3 also shows that ultrasonic irradiation obviously enhances the photocatalytic activity of TiO_2 powders whether the solvent is pure water or EtOH–H_2O. This may be ascribed to the fact that ultrasonic irradiation enhances hydrolysis of titanium alkoxide and promotes better crystallization of TiO_2 gel, since ultrasonic cavitation creates a unique environment for the hydrolysis of titanium alkoxide and the formation of seed nuclei of TiO_2.

Received (in Cambridge, UK) 4th June 2001, Accepted 15th August 2001
First published as an Advance Article on the web 17th September 2001

Recombinant β-1,4-galactosyltransferase (β1,4-GalT) and α-2,6-sialyltransferase (α2,6-SiaT) immobilised covalently with activated Sepharose beads were employed for the practical synthesis of a trisaccharide derivative, Neu-5Acα(2→6)Galβ(1→4)GlcNAcβ-O-$(CH_2)_6$-NH_2, on a water-soluble primer having GlcNAc residues through a α-chymotrypsin-sensitive linker.

Synthesis of oligosaccharides using glycosyltransferases is recognized as a promising practical alternative method to chemical synthesis because enzyme-based synthesis has produced highly stereo- and regioselective glycosylations without tedious multi-step protection–deprotection procedures.[1] It has also been known that enzymatic glycosylations of polymer-supported sugars both in solid-phase[2] and in solution[3–5] greatly facilitate synthetic schemes because of easy and simple procedures for purifying products linked with macromolecules. Recently, a variety of recombinant glycosyltransferases for such a purpose are becoming practicable owing to advances in cloning studies of glycosyltransferases.[6] However, these recombinant enzymes are still very expensive and unstable as versatile reagents in chemoenzymatic synthesis, and they cannot be recovered from the reaction mixture by common work-up processes. At present, these biocatalysts are not suited for large-scale and/or combinatorial syntheses of glycoconjugates. Although immobilisation of the glycosyltransferases seems to have become a crucial step for solution of these problems,[7,8] enzymes immobilised on solid materials cannot be used for glycosylation of solid-supported sugars as glycosyl acceptors. Therefore, our interest has been focused on the feasibility of reactions between glycosyltransferases immobilised on solid phase and sugars bound on the flexible polymers showing satisfactory water-solubility as 'primers'. In the present communication, we describe highly practical synthesis of a sialooligosaccharide using immobilised recombinant-glycosyltransferases and a GlcNAc carrying primer involving an α-chymotrypsin-sensitive linker moiety.

In the course of our synthetic studies on the multivalent glycopolymers as models for glycoproteins,[9] we found that these materials can be used for polymer-assisted enzymatic synthesis as convenient 'multivalent substrates' of glycosyltransferases.[10] The success of this new strategy is critically dependent on drastically enhanced affinity of glycosyltransferases for multivalent glycopolymers.[5] Since glycosyltransferases are generally monomeric proteins with a single binding site, the mechanism for the enhancement of binding affinity observed here might be different from the cases where a 'glycoside clustering effect' is found in the proteins with multiple sugar-binding sites.[11] Although this can be explained basically by 'enhanced accessibility' of proteins to the high-density glycoclusters displayed on the flexible synthetic polymers,[12] further physicochemical analyses of the mechanism are still under way. In this study, we firstly checked the

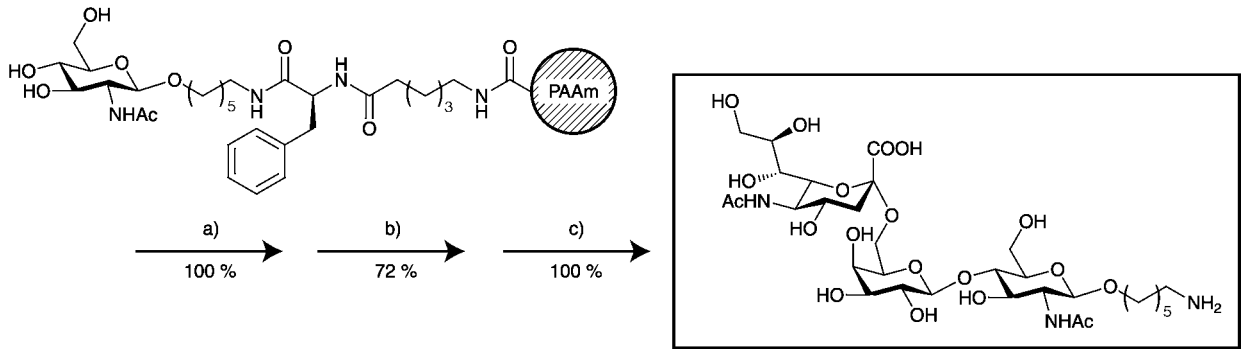
 DOI: 10.1039/b104896c



Scheme 2 (a) i, immobilized β1,4-GalT (0.2 unit, 0.3 mL),† primer (27 mg, 40 mM as GlcNAc residue), UDP-Gal (1.3 eq., 52 mM), 10 mM $MnCl_2$, 50 mM HEPES buffer (pH 7.5), 37 °C, 24 h; ii, gel filtration on Sephadex G-25 with distilled water; (b) i, immobilized α2,6-SiaT (0.08 unit, 0.3 mL),‡ polymer (19 mg, 17 mM as LacNAc residues), CMP-NeuAc (1.5 eq., 26 mM), alkaline phosphatase (40 unit), 10 mM $MnCl_2$, 0.1% Triton CF-54, 50 mM HEPES buffer (pH 7.5), 37 °C, 24 h; ii, gel filtration on Sephadex G-25 with distilled water; (c) i, α-chymotrypsin (3000 U, 1.5 mg), polymer (15 mg, 8.3 mM as SiaLacNAc residues), 10 mM $CaCl_2$, 100 mM Tris–HCl (pH 8.0), 37 °C, 24 h; ii, gel filtration on Sephadex G-25 with distilled water. PAAm: polyacrylamide copolymer (M_r > 300K, sugar–acrylamide = 1:10).

effect of immobilisation of recombinant glycosyltransferases on the affinity with glycosyl acceptor substrates by using the surface plasmon resonance (SPR, IAsys) method. As shown in Fig. 1, it was clearly suggested that recombinant β1,4-GalT immobilised on the SPR-cuvette retained a high affinity for a water-soluble primer and the affinity constant of the immobilised GalT with the glycopolymer bearing GlcNAcs was estimated to be 5.0×10^6 M^{-1}. On the contrary, the affinity of methyl 2-acetamido-2-deoxy-β-D-glucopyranoside (GlcNAc) for this GalT-conjugated SPR cuvette was estimated to be lower than 10^3 M^{-1}. This result prompted us to immobilise GalT and α2,6-SiaT on the polymer supports (Scheme 1). Thus, these glycosyltransferases expressed as fusion proteins with maltose-binding protein (MBP) in *E. coli*[13,14] were directly subjected to the coupling reactions with CNBr-activated§ Sepharose 4B (MBP-GalT) or NHS-activated¶ Sepharose 4FF (MBP-SiaT). As anticipated, immobilised GalT exhibited satisfactory sugar-elongation activity to the primer and the GalT combined beads were found to be recyclable (Fig. 2).

The versatility of oligosaccharide synthesis based on the immobilised glycosyltransferases was demonstrated by constructing a simple trisaccharide derivative that can be applied to further conjugation studies to produce glycodrugs or glycomaterials having interesting bioactivities. Galactosylation (100%) by GalT-Sepharose (0.2 unit, 0.3 mL of beads) and sialylation (72%) by α2,6-SiaT-Sepharose (0.08 unit, 0.3 mL of beads) were achieved on the primer (15.0 mg of polymer, 8.3 μmol of GlcNAc residue) and 4.6 mg of sialylα(2-6)-*N*-acetyllactosamine (72%) was finally obtained by treating the primer with α-chymotrypsin under reported conditions[4] (Scheme 2).

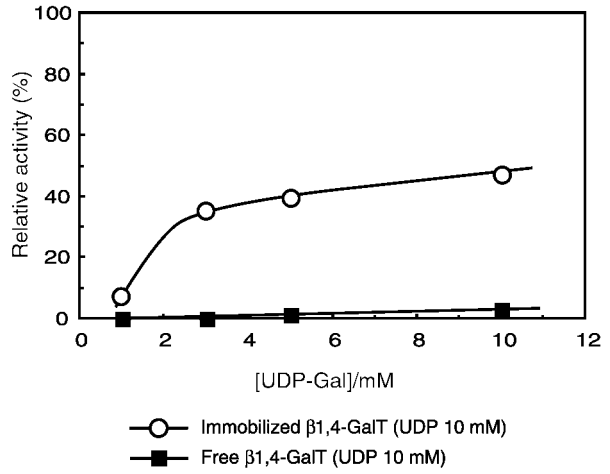


Fig. 3 The effect of UDP on the glycosylation by GalT to primer. (a) immobilised GalT; (b) free GalT. All reactions were carried out in the presence of 10 mM of UDP.

It should also be noted that glycosylation of polymer primers by glycosyltransferases conjugated with macromolecular support proceeds predominantly to afford product even in the presence of a high concentration of inhibitors (nucleotides) as shown in Fig. 3. This result indicates that the inhibitory effect of nucleotide (UDP) generated from UDP-Gal was significantly reduced by immobilisation of enzyme. The availability of the immobilised glycosyltransferases reported herein will greatly accelerate the development of an enzyme-based automated glycosynthesiser.[15]

We are grateful to Dr Fujiyama (International Center of Cooperative Research in Biotechnology, Japan, Osaka University) for gift of the cDNA coding human β1,4-GalT. This work was supported by a grant from the New Energy and Industrial Technology Development Organization (NEDO).

Received (in Cambridge, UK) 20th June 2001, Accepted 7th August 2001
First published as an Advance Article on the web 17th September 2001

The model tripeptide Boc-β-Ala(1)-Aib(2)-β-Ala(3)-OMe 1 [β-Ala: β-alanine, Aib: α-aminoisobutyric acid] forms an infinite parallel β-sheet structure through intermolecular interactions in single crystals and from the SEM diagram of this peptide, it is evident that the compound has fibrillar morphology, a characteristic of neurodegenerative disease causing amyloid aggregate.

The design of short peptide molecules that form an intermolecular β-sheet structure is a newly emerging area. The molecular basis of some fatal, neurodegenerative diseases like prion protein disease[1,2] and Alzheimer's disease[3,4] involve intermolecular β-sheet aggregation and subsequent formation of highly ordered fibrillar structure. So it is important to construct peptide β-sheet assemblage to understand the pathogenesis and therapeutics of these diseases. Until now there have been limited reports describing β-sheet stabilization in crystals and in solution by intermolecular interactions. Most of the previous reports of β-sheet stabilization include unimolecular β-hairpin formation and subsequent stabilization by only intramolecular interactions.[5] Schrader and Kirsten first established β-sheet stabilization using rigid templates like 3-aminopyrazole derivatives that promote the formation and stabilization of β-sheet structures by purely intermolecular interactions.[6] Yamada *et al*. introduced a series of model peptide derivatives that formed an amyloid-like parallel β-sheet assemblage in solution.[7] Kelly and coworkers in a recent study using 2,8-disubstituted dibenzofuran-based peptidomimetics have established that β-sheet mediated self-assembly is essential to form amyloid-like fibrils of highly ordered structures.[8] However, all previously reported peptides or peptide derivatives that participate in intermolecular β-sheet stabilization and/or amyloid-like aggregate formation, used either rigid template or long aliphatic chains. Here, we report for the first time parallel β-sheet aggregation of a short synthetic peptide containing only noncoded amino acids [*viz*. β-alanine (β-Ala) and α-aminoisobutyric acid (Aib)] in crystals and formation of amyloid-like fibrils in the solid state.

The ORTEP diagram with the atom numbering scheme is shown in Fig. 1.† The hydrogen bonding pattern (Fig. 2) in the crystal lattice shows the formation of one infinite parallel β-sheet assembly along the *c* direction. These β-sheets are themselves regularly stacked *via* van der Waals interactions as shown by the projection of the unit cells in the *c* direction (Fig. 3). The hydrogen bonding parameters for **1** are listed in Table 1. There are three intermolecular hydrogen bonds N5–H5···O4, N10–H10···O9 and N15–H15···O16 that are responsible for connecting individual molecules to form and stabilize the sheet assembly. For the peptide **1**, backbone torsions are mostly in fully extended and semi-extended conformations (Table 1), a prerequisite for individual β-strand formation. This peptide has two terminal β-Ala residues, in which inherent conformational flexibility remains and thus terminal parts of the peptide are flexible in nature and might help to adopt extended or semi-extended conformations for the two terminal β-Ala residues. The variations from extended values of torsion angles occur at the centre of the molecule, which is occupied by the conforma-

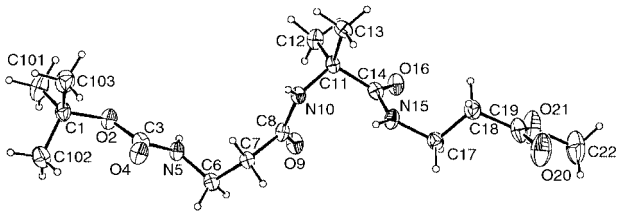

Fig. 1 An ORTEP representation of the molecular structure including atom numbering scheme of the peptide **1**. Thermal ellipsoids are shown at the level of 20% probability.

tionally restricted α-aminoisobutyric acid (Aib) residue that is known to direct helical conformation[9] instead of β-sheet (Table 1). Here, Aib also adopts helical conformation ($\phi = -57.8°$, $\psi = -48.5°$). Some specific torsion angles along the two terminal β-Ala residues, N5–C6, C6–C7 and N15–C17, C18–C19 are in semi-extended conformations (Table 1).

The morphological similarity of the assemblage of the reported peptide with the amyloid fibrils has been studied using a scanning electron microscope (SEM). The SEM image (Fig. 4) of the dried fibrous material clearly shows that the aggregate in the solid state is a bunch of long small filaments.

The peptide **1** (containing noncoded amino acids) self-associates *via* intermolecular hydrogen bonds into a parallel β-sheet assemblage, in which all the intermolecular hydrogen bonds are present between the peptide linkages. Therefore, the present model should be a good model for β-sheet polypeptides. Morphological resemblance of this peptide with Alzheimers-associated Aβ peptides suggests that the fibril model with a parallel β-sheet assemblage will be helpful for examining the structure and function of abnormal peptides such as the prion and the Alzheimer's amyloid. Another remarkable feature of the present result is the formation of a parallel β-sheet structure in a short synthetic peptide containing the centrally-positioned, conformationally-constrained helix-forming Aib residue.

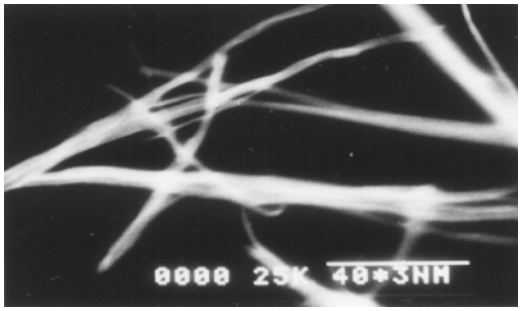

Fig. 4 A typical SEM image showing the fibril aggregate of peptide **1** in the solid state. For the SEM image, dried fibrous material was taken which was grown up from ethyl acetate solution by slow evaporation.

We thank EPSRC and the University of Reading, UK for funds for the Image Plate System. S. K. Maji wishes to acknowledge the Council for Scientific & Industrial research (C.S.I.R), New Delhi, India for financial assistance.

Notes and references

† The compound was synthesized using the fragment condensation method in solution. Single crystals were obtained from 1,2-dichlorobenzene solutions by slow evaporation.

Crystal data for **1**: $C_{16}H_{29}N_3O_6$, $M = 359.92$, orthorhombic, space group *Pccn*, $a = 37.25(4)$, $b = 11.123(19)$, $c = 9.610(14)$ Å, $U = 3981$ Å^3, $Z = 8$, $D = 1.199$ Mg m^{-3}. Intensity data were collected with MoKα radiation using the MARresearch Image Plate System. The crystal was positioned at 70 mm from the Image Plate. 100 frames were measured at 2° intervals with a counting time of 5 min to give 4684 reflections of which 1777 were independent [R(int) = 0.0506)]. Data analysis was carried out with the XDS program.[10] The structure was solved using direct methods with the SHELX86 program.[11] The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. The structure was refined on F^2 using SHELXL.[12] The final R values were $R1$ 0.0747 and $wR2$ 0.1984 for 1255 data with $I > 2\sigma(I)$. The largest peak and hole in the final difference Fourier were 0.358 and −0.317 e Å^{-3}. CCDC 167175. The titled cyclophane (cyclic [6]metaphenylacetylene) with six methoxy groups inside the cavity has a nearly planar carbon framework, forms open-channel structures in the crystal, and exhibits an ammonium-selective ionophoric property in spite of the considerably large cavity.

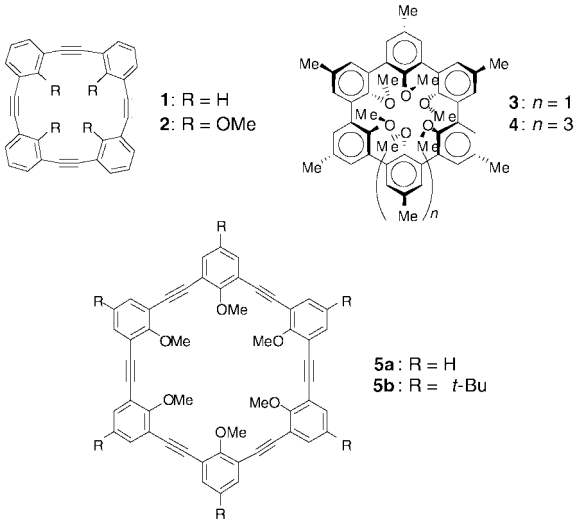
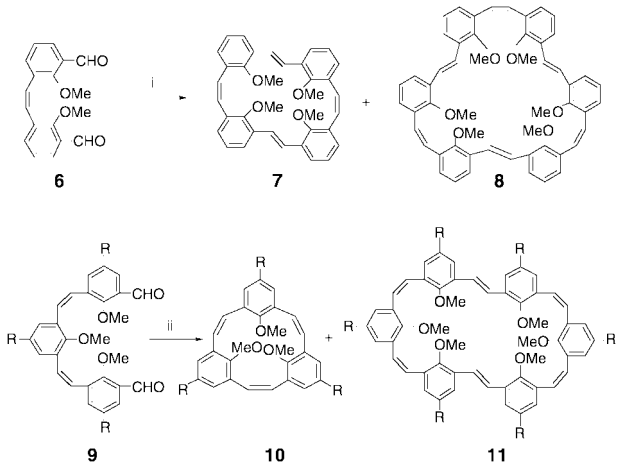
Recently, we have reported the synthesis of [2.4]metacyclophane-1,9,17,25-tetrayne **1** (cyclic [4]metaphenylacetylene, [4]CMPA) and its tetramethoxy derivative **2** where the methoxy groups point inside the molecule.[1,2] CMPA **2** thus has a cavity surrounded by the four methoxy oxygen atoms (1.2 Å in diameter, X-ray analysis) and was found to be a good ionophore for various alkali metal ions probably owing to its well-organized but conformationally somewhat flexible structure.[2] The good ionophoric properties of **2** are rare for this kind of molecule, because host molecules composed of anisole units have hardly shown efficient ionophoric properties except spherands and cavitands such as **3** and **4**.[3] Hexamethoxy-[6]CMPA **5**, a homologue of **2**, would also be of interest from the viewpoints of structure and ionophoric properties. While **2** has a sterically congested cavity and its carbon framework deviates from planarity, **5** would be almost free of steric congestion (PM3 calculation[4]). CMPA **5** can also be regarded as an analogue of spherand **3** extended with acetylenic bonds. Although the parent [6]CMPA and some derivatives bearing functional groups outside the molecules have been reported,[5–7] no [6]CMPAs bearing substituents inside the molecules have been described. We here report on the synthesis, structure, and host properties of **5a** and **5b**.



Hexamethoxy[6]CMPAs **5a** and **5b** were synthesized in a similar manner as for the synthesis of CMPAs **1** and **2**, that is, bromination–dehydrobromination of the corresponding metacyclophane-polyenes prepared by a modified McMurry coupling (Scheme 1).[1,2] The McMurry coupling of 2,2′-dimethoxy-3,3′-diformyl-(*Z*)-stilbene **6**[2] in DME–toluene (5 : 1) afforded (*EZEZ*)-tetraene **7**[2] (23% yield) and (*EZ*)[3]-hexaene **8**† (14%). Similarly, the McMurry coupling of (*Z,Z*)-1,3-bis(5-*tert*-butyl-3-formylstyryl)benzene **9**, prepared from (*Z,Z*)-1,3-bis(5-bromo-3-formylstyryl)benzene through dilithiation (BuLi) and diformylation (DMF), in THF–toluene (5 : 1) afforded (all-*Z*)-triene **10**† (4%) and (*ZEZ*)[2]-hexaene **11**† (15%). The McMurry reactions in DME or THF alone afforded **8** or **11** in poorer yield. Bromination of **8** and **11** with 9 equivalents of Br_2 in chloroform and subsequent dehydrobromination of the crude dodecabromides with 15 equivalents of *t*-BuOK in ether gave the corresponding CMPAs **5a**† (52%) and **5b**† (69%) as stable crystalline substances. Similar to the parent [6]CMPA, **5a** is poorly soluble in organic solvents, but **5b** is a little more soluble to allow the examination of complexation with metal ions and molecular cations.

^{1}H and ^{13}C NMR spectra of **5a** and **5b** are simple in agreement with the high symmetry of the molecules (C_6). The chemical shifts of their sp carbons (δ 89.92 and 89.87 respectively) are in the normal region of unstrained acetylenic carbon [δ 89.85 for bis(2-methoxyphenyl)acetylene].

A single crystal of **5b** suitable for X-ray analysis was obtained from a dichloromethane–hexane solution, and the ORTEP drawing is shown in Fig. 1.‡ The carbon framework of **5b** is nearly planar, and the six methoxy groups point up and down alternately in accord with a theoretical calculation (PM3). The distance between the diagonal oxygen atoms in *ca.* 8.1 Å which is twice as long as that in **2** (4.2 Å). Thus, **5b** (and also **5a**) has a sizable cavity of about 5 Å in diameter surrounded by six oxygen atoms. In the crystal, the molecules of **5b** form displaced sheet structures which stack so as to form open-channels with internal pores of 4.5 Å in diameter running parallel to the *c* axis (Fig. 2). There is little π–π stacking, and the inter-sheet separation is 3.7 Å. Channel formation in crystals of CMPAs has also been reported for hexahydroxy[6]CMPA **12** bearing the hydroxy groups outside the molecule.[7,8] While hydrogen bonding plays an important role in channel formation in **12**, only van der Waals interactions are operative in **5b**.



Scheme 1 *Reagents*: i, $TiCl_4$–Zn–CuI/DME–Tol 5 : 1, rt then reflux; ii, $TiCl_4$–Zn–CuI/THF–Tol 5 : 1, rt then reflux.

 DOI: 10.1039/b104325k

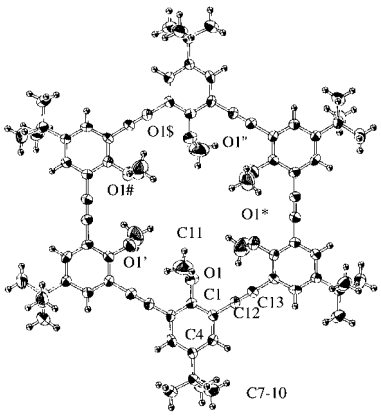


Fig. 1 ORTEP drawing of **5b** (50% probability): C1–C12, 1.457(5); C12–C13, 1.185(4); Cl–O1, 1.370(4) Å. Interatomic distance of diagonal oxygen atoms: 8.1 Å (average).

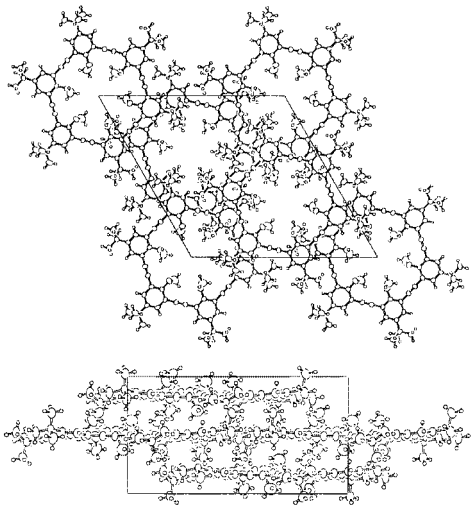

Fig. 2 Crystal packing of **5b**. Top; along *c* axis, bottom; along *a* axis.

The cavity size of **5b** is appreciably larger than the size of a caesium ion (3.4 Å), and in fact **5b** did not show any measurable complexation with alkali metal ions upon solvent extraction experiments (chloroform/aq. picrate salts; the low solubility of **5b** limits the range of detection by absorption spectroscopy). However, it was found that **5b** exhibits good ionophoric selectivity for the ammonium ion in spite of its smaller size (2.86 Å) compared with caesium ion. A plot by Shono's method shows a straight line with a slope of approximately unity, suggesting the formation of a 1 : 1 complex between **5b** and the ammonium ion in solution.[9,10] The association constant obtained for the ammonium ion (log K_a = 7.84) is smaller than that of **2** (9.51[2]) and 18-crown-6 (9.38[11]), but larger than that for the cavitand **4** (6.59[11]). On the other hand, methylammonium ion was extracted poorly (log K_a < 6.5). This large difference in K_a contrasts with small differences in the complexation of **4** with ammonium and methylammonium ion (6.66 and 6.59,[11] respectively). Cavitands have been known to be flexible enough to change the cavity for binding cationic species. The carbon framework of **5b** would be more rigid than cavitands, although some flexibility has been suggested from the low ionophoric selectivity of **2** toward alkali metal ions.

Thus, **5b** is a novel ionophore with a high selectivity for the parent ammonium ion. This selectivity is notable because other host molecules like **2**, **4** and 18-crown-6 can bind both metal cations and ammonium ions of similar size to a similar degree. According to the optimized structure of the complex of **5a** with ammonium ion by PM3 calculation,[4] the ammonium ion occupies a position where three NH bonds point to three oxygen atoms of the host.[12] Therefore, although the distance between the NH nitrogens and MeO oxygen atoms (3.5 Å) is longer than that of a usual hydrogen bond (3.0 Å), there seems weak but triple hydrogen bonding between **5b** and the ammonium ion in addition to electrostatic attraction. On the other hand, a similar structure for the complex of **5a** with methylammonium ion suffers steric repulsion between the methyl groups of the host and guest molecules and the NH bonds no longer point to the oxygen atoms of the host in the optimized structure.

In view of the present results, the phenolic molecule of **5** will be an intriguing compound and attempts to synthesize it are in progress.

We gratefully acknowledge the support of this research by a Grant-in-Aids for Scientific Research of Priority Area (No.10146102) from the Ministry of Education, Japan.

A new tricyclic ring and a nitrogen–sulfur analogue of the tri-pentagon bowl. Substituted 5,6,7,7a-tetrahydropyrrolo[2,1-*b*]-1,3,4-thiadiazole-*endo*-6,7-dicarboxyimides

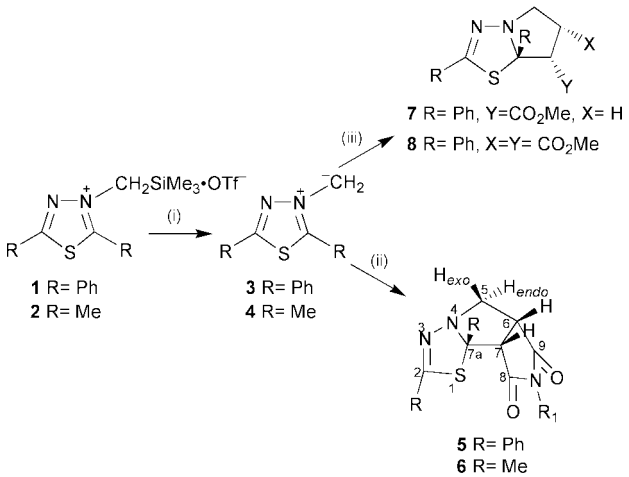
Richard N. Butler,* Georgina M. Smyth, Martin O. Cloonan (in part), Patrick McArdle and Desmond Cunningham

Chemistry Department, National University of Ireland, Galway, Ireland

Received (in Cambridge, UK) 13th June 2001, Accepted 15th August 2001
First published as an Advance Article on the web 7th September 2001

The first examples of a bowl-shaped tricyclic nitrogen–sulfur analogue of the tri-pentagon bowl are reported; substituted 5,6,7,7a-tetrahydropyrrolo[2,1-*b*]-1,3,4-thiadiazole-*endo*-6,7-dicarboxyimides are synthesised by a relatively simple route.

Among the fused 5,5-bicyclic heterocycles a number of simple pyrrolo systems are quite rare. One such case is the pyrrolo[2,1-*b*]-1,3,4-thiadiazole ring,[1] for which there are few reports.[1] Recently we have generated[2] the unstabilised 1,3,4-thiadiazolium-3-methanide 1,3-dipole **3** in solution by desilylation of the salts **1** with CsF, following a literature procedure[3,4] originally developed with Schiff bases (Scheme 1). If the dipole **3** were to cycloadd an alkene it should give the pyrrolo[2,1-*b*]-1,3,4-thiadiazole ring system. The 1,3-dipole **3** was unstable and could only be trapped at −60 °C using reactive electron-poor alkyne dipolarophiles. The alkyne cycloadducts were unstable and rearranged *in situ* by opening of the thiadiazole ring[2] and the likely intermediate pyrrolo-1,3,4-thiadiazole system could not be isolated or detected. Problems with the lesser reactivity and insolubility of alkene dipolarophiles in the high molar excess required at −60 °C prevented trapping with these. The difficulties have now been overcome with a number of alkene systems including *N*-substituted maleimides in reactions of the 1,3-dipoles **3** and **4**. The cycloaddition products† were the stable compounds **5**–**8** (Table 1), providing a new one-pot route to the pyrrolo [2,1-*b*]-1,3,4-thiadiazole system. The preferred stereochemistry of the cycloaddition was *endo*- and it was exclusively *endo*- for the reaction of the dipole **3** with maleimides. These reactions gave derivatives of the new tricyclic rings **5** and **6**. The bowl-shaped structure of these tricyclic products is a nitrogen–sulfur analogue of the tri-pentagon bowl-unit present in the dodecahedron.



R[1] **a** Me; **b** CH_2Ph; **c** ^{t}Bu; **d** 1-admantyl; **e** Ph; **f** *p*-Me-C_6H_4; **g** *p*-Br-C_6H_4

Scheme 1 *Reagents and conditions*: (i) CsF in CH_2Cl_2 at −60 °C; (ii) *N*-substituted maleimides; (iii) methyl acrylate or dimethyl maleate.

The structures of the products were established from microanalyses, IR, ^{1}H and ^{13}C NMR spectra which showed all of the expected signals (Table 1). The 5-H$_{endo}$ proton was strongly deshielded ($\delta \approx 4.8$ ppm) relative to its geminal partner the 5-H$_{exo}$ ($\delta \approx 3.6$ ppm). NOE difference spectra showed enhancements at the 7a-substituent from H-7, H-6 and 5-H$_{exo}$ on the same face of the central ring thereby confirming the *endo*-cycloaddition. This occurred exclusively for the 1,3-dipole **3** even then R′ was a *tert*-butyl or adamantyl group. Small quantities of the *exo*-isomers were detected from cycloadditions with the dipole **4** but the *endo*–*exo* ratio was still ≥6:1. An X-ray crystal structure‡ of compound **5a** illustrates the interesting bowl-type structure of the three fused pentagons containing three nitrogens and a sulfur (Fig. 1). The system relieved strain by significant opening of the angles at the carbon fusion atoms. Thus the angles C(7)–C(7A)–S(1), C(7A)–C(7)–

Ultra highly pure hydrogen and more valuable hydrocarbons are produced directly from methane in one step beyond the thermodynamic equilibrium conversion by integration of the dehydrogenation reaction and hydrogen separation with a Pd–Ag based membrane reactor at mild temperatures, and a highly active catalyst is developed under the non-equilibrium reaction conditions.

Both as an alternative process for production of hydrogen and as a promising method for the production of higher hydrocarbons from natural gas, the dehydrogenation and aromatization reactions of methane on Mo/HZSM-5 and Re/HZSM-5 has attracted increasing attention since 1993. However, the maximum aromatics yield has been reported to be only 7–8% at 973 K on the catalysts by different research groups[1–9] and it seems that this is the thermodynamic equilibrium conversion at this temperature. In addition, the equilibrium reaction conditions make it difficult to develop more active catalysts. In the present communication, direct methane conversion into hydrogen and higher hydrocarbons beyond the thermodynamic equilibrium limit becomes possible by integration of the methane dehydrogenation reaction and H_2 separation with a Pd membrane reactor, and a highly active catalyst has been developed for the production of pure hydrogen and higher hydrocarbons under non-equilibrium reaction conditions.

The catalysts Re/HZSM-5 and Mo/HZSM-5 were prepared by impregnating NH_4ZSM-5 with NH_4ReO_4 and $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ aqueous solution, respectively, followed by drying at 383 K for 4 h and calcination at 773 K for 4 h. The sample was finally pressed, crushed and sorted into 20–40 meshes. Catalytic tests were carried out in a fixed bed continuous-flow Pd–Ag based membrane reactor (5/8 inch diameter × 10 inch height). The membrane reactor contains four membrane tubes (1/8 inch diameter × 7 inch height). H_2 was continuously separated from the product by permeation through the membrane tubes and removed by a vacuum pump. A schematic diagram of the membrane reactor is shown in Fig. 1. The results for methane conversion on Re/HZSM-5 at a low temperature of 858 K and different methane space velocity (SV) values are listed in Table 1. Both hydrogen and higher hydrocarbons are produced from methane dehydrogenation on the catalyst even at such a low temperature. The major hydrocarbon products for methane dehydrogenation include benzene, naphthalene, toluene and C_2 products. When hydrogen is not separated from the dehydrogenation product by H_2 permeation through the membrane, the maximum methane conversion into aromatics and C_2 on Re/HZSM-5 is *ca.* 2.4–2.6% at 858 K (Table 1). The methane conversion changes little even for a wide methane SV range of 120–1440 ml h^{-1} g^{-1}. Therefore, under thermodynamic equilibrium reaction conditions, the yield of aromatics and C_2 is only *ca.* 2.4–2.6% at 858 K. Of most significance is that this thermodynamic equilibrium can be disturbed, leading to much higher conversions than the equilibrium conversion for methane dehydrogenation into aromatics, achieved by continuous separation of hydrogen from the product by hydrogen permeation through the membrane.

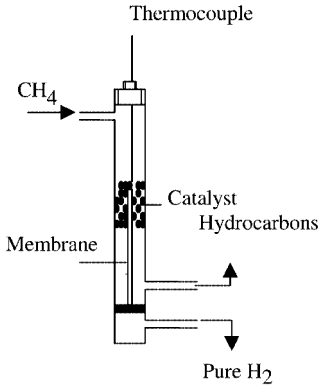

Fig. 1 Schematic illustration of the membrane reactor.

A high methane conversion of 7.5% is attained on Re/HZSM-5 at 858 K when the methane SV is 120 ml h^{-1} g^{-1} at a low temperature of 858 K. This is *ca.* twice as high as the methane equilibrium conversion at the same temperature. At the same time, ultra highly purely H_2 is produced because of the 100% selectivity of the membrane for hydrogen permeation and the pure hydrogen can be directly used in a fuel cell. Fig. 2 shows the activity profile of Re/HZSM-5 catalyst with time on stream when H_2 was separated by selective permeation. The enhanced

 DOI: 10.1039/b105703k

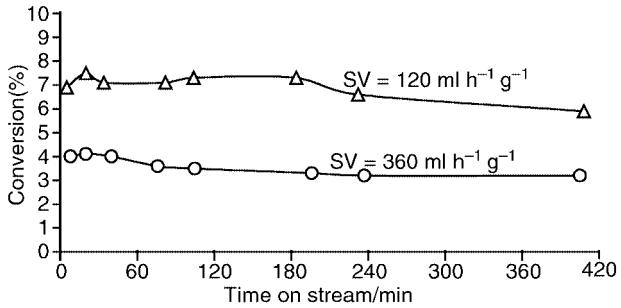

Fig. 2 Activity profile for the Re/HZSM-5 catalyst with time on stream at 858 K and different methane SV when H_2 was separated by selective permeation.

methane conversion declines from 7.5 to 5.9% after 7 h on stream at 858 K at a methane SV of 120 ml h^{-1} g^{-1} as shown in Fig. 2.

On the other hand, it is difficult to compare the activity of the catalysts under equilibrium reaction conditions and therefore, many arguments still exist about activity comparisons between Mo/HZSM-5 and Re/HZSM-5 for the methane dehydrogenation reaction. Use of non-equilibrium reaction conditions makes it more easy to develop highly active catalysts. The results in Table 2 indicate that both the catalysts show similar activity for methane conversion into higher hydrocarbons when hydrogen is not separated from the product. However, the activities of the two catalysts are quite different under non-equilibrium reaction conditions when hydrogen is continuously separated from product by selective permeation of hydrogen in the Pd–Ag based membrane reactor. Re/HZSM-5 clearly shows a higher activity than Mo/HZSM-5 under non-equilibrium reaction conditions as shown in Table 2. The evaluation of the catalysts under non-equilibrium reaction conditions is a useful method for development of highly active catalysts.

Therefore, the higher conversion of methane is dependent on hydrogen permeation and separation through the membrane. To make hydrogen permeation through the membrane and separation from the product more efficient, the effect of reaction pressure on methane conversion was investigated and some results are given in Table 3. It is clear that methane conversion is enhanced further by a small increase of the reaction pressure. This indicates that higher pressures are more favorable for hydrogen permeation through the membrane tube. Thus, a higher methane conversion of 5.8% is achieved at a higher reaction pressure of 200 kPa and a higher methane SV of 360 ml h^{-1} g^{-1} in the membrane reactor.

In conclusion, methane activation into hydrogen and more useful hydrocarbons such as aromatics and C_2 far beyond the thermodynamic equilibrium conversion has been achieved by continuous hydrogen separation from the product using a Pd–Ag based membrane reactor. The highly active Re/HZSM-5 catalyst has been developed for methane conversion at a low temperature of 858 K under non-equilibrium reaction conditions. Ultra highly pure hydrogen and aromatics are produced directly from methane in one step on the developed highly active Re/HZSM-5 catalyst by integration of the dehydrogenation reaction and a hydrogen separation process using a membrane reactor.

Received (in Cambridge, UK) 17th July 2001, Accepted 21st August 2001
First published as an Advance Article on the web 19th September 2001

The first example of a redox controlled hydrogen bonded three-pole switch is described, which exploits both electrochemical oxidation and reduction of the host–guest dyad to modulate the intermolecular recognition properties.

Application of the interplay between molecular recognition and electrochemistry to modulate the interactions between host–guest complexes is a burgeoning field within supramolecular chemistry.[1] The electrochemically controlled gain or loss of an electron by a redox active host (or guest) can profoundly influence the charge and/or electronic distribution of the host–guest dyad, leading to major changes in the magnitude and nature of the intermolecular interactions between these units.[2] Recently, the reversibility and convenience of electrochemically controlled supramolecular interactions have been used to produce molecular switches which utilise redox controlled inclusion,[3] hydrogen bonding[4] and charge-transfer (CT)[5] interactions to control the recognition processes between the complementary host–guest moieties. For most of these systems, however, the switching properties are limited to the modulation of the host–guest binding between two distinct states (two-pole switch). Multi-pole switch systems, on the other hand, provide access to new applications within molecular electronics and photonics, due to their enhanced ability to handle and process information at the molecular level.[3,6]

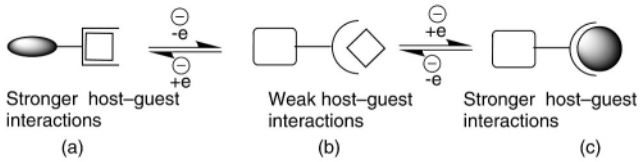

Fig. 1 A redox controlled three-pole switch.

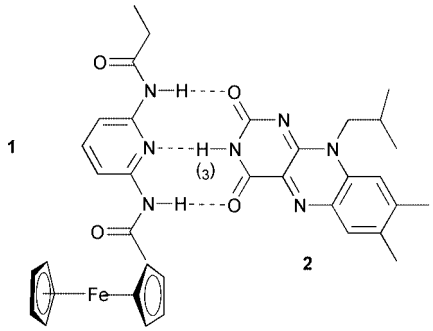
Here, we report the application of dual redox controlled hydrogen bonding interactions between electroactive pyridine host **1** and flavin guest **2**, to produce the first three-pole switch which solely utilises the strength and directionality of hydrogen bonding interactions to control the extent of the intermolecular recognition processes (Fig. 1). In their neutral states [Fig. 1(b)], relatively weak interactions between host **1** and guest **2** are predicted. However, upon electrochemical oxidation of the ferrocene unit of **1** to its ferrocenium state [Fig. 1(a)], an increase in the acidity of the N–H group of the amide moiety of this derivative should result in an increase in the intermolecular hydrogen bond strength between **1** and **2**.[4c] Furthermore, reduction of the flavin moiety of **1**·**2** to its radical anion state [Fig. 1(c)], should give rise to enhanced intermolecular hydrogen bonding interactions due to an increase in the negative charge density of the carbonyl groups of **2**.[7]

The ferrocene host **1** was synthesised by reacting 2-ethylamido-6-aminopyridine with one equivalent of fluorocarbonylferrocene[8] in THF under reflux for two days. Compound **1** was readily purified using column chromatography to afford the host unit in 75% yield.† Flavin **2** was prepared using previously reported procedures.[9]



Hydrogen bond formation between **1** and **2** was confirmed by ^{1}H NMR titration in $CDCl_3$. The smooth downfield shift in the resonance of H(3) of **2** upon the addition of ferroreceptor **1** cleanly fits a 1 : 1 binding isotherm, providing an association constant (K_a) of 45 ± 5 M^{-1}.[10] This is considerably lower than the K_a obtained for the 1 : 1 hydrogen bonded complex of **2** and 2,6-diethylamidopyridine (K_a = 537 M^{-1}),[11] presumably due to the bulky ferrocene unit partially masking the hydrogen bonding site of **1**.

With host–guest complexation verified, we next investigated the electrochemically modulated switching properties of this system using cyclic voltammetry (CV).[12] CV studies on compound **1** gave rise to a reversible single-electron oxidation of $E_{1/2}$ = +0.79 V. Addition of an excess of **2** to a solution of **1**, immediately resulted in a −0.034 V shift in the oxidation potential of the ferrocene moiety of receptor **1** (Fig. 2). This negative shift indicates a stabilization (3.28 kJ mol^{-1})[13] of the ferrocenium state of receptor **1**, and hence corresponds to the flavin unit becoming more strongly bound to **1** (**1**$^+$·**2**, K_a = 169 ± 17 M^{-1}).[14] CV studies of flavin **2** show a single, one-electron reduction peak and two separate re-oxidation peaks (Fig. 3).[4f]

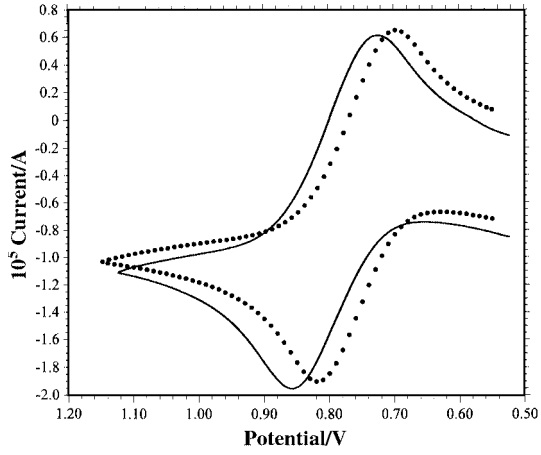


Fig. 2 Cyclic voltammogram of host **1** (——) and in the presence of an excess of **2** (.....).

 DOI: 10.1039/b106342c

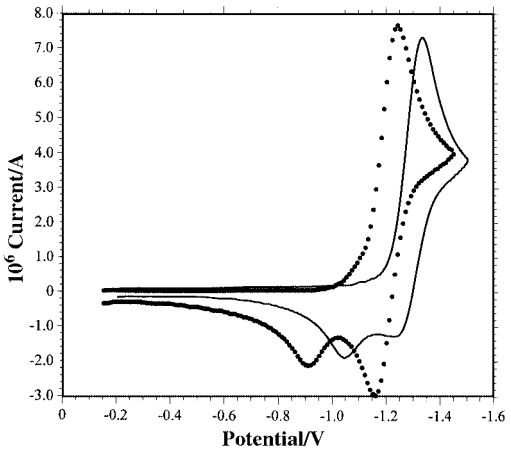

Fig. 3 Cyclic voltammogram of guest **2** (——) and in the presence of an excess of **1** (.....).

Addition of an excess of **1** provides a significant reduction (+0.100 V) in the voltage for both the reduction wave potential and $E_{½}$ for the reversible redox couple, indicating a substantial (9.65 kJ mol^{-1}) stabilization of the radical anion of **2**, which results in a 50-fold increase in the binding strength of the complex (**1**·**2**$^{-\cdot}$, K_a = 2209 ± 221 M^{-1}). In accordance with previously reported data for the hydrogen bonded complex of **2** with 2,6-diethylamidopyridine, the wave corresponding to the re-oxidation of the flavin radical anion is greatly enhanced.[2a] However, the wave due to re-oxidation of the flavohydroquinone anion to the neutral flavin for the **1**·**2** complex is not fully suppressed and is shifted to a more positive potential.

In conclusion, we have produced the first example of a redox controlled hydrogen bonded three-pole switch which exploits the disparate redox properties of the host and guest moieties to modulate their intermolecular hydrogen bonded interactions. Oxidation of the ferrocene moiety results in a four-fold increase in the hydrogen bonding efficiency, whereas reduction of the flavin moiety results in a 50-fold increase in the hydrogen bonding efficiency of **1**·**2**. Structural modification of host **1** is underway (*e.g.* incorporation of moieties capable of increasing the binding efficiency with the reduced flavin *via* donor atom–π interactions) the results of which will be reported in due course.

12 All electrochemical experiments were performed using a CH Instruments CH120A electrochemical workstation. The 0.1 M electrolyte solution was prepared from recrystallised Bu_4NPF_6 using spectroscopic grade dichloromethane and purged with nitrogen prior to use. A three-electrode configuration was used with a Pt working electrode, a Ag wire pseudo-reference electrode and a platinum wire counter electrode. The oxidative scans used decamethylferrocene as an internal standard whilst the reductive scans used ferrocene as an internal standard.
13 Calculated from the relationship: $\triangle\triangle G = -nF\triangle E_{½}$, where n is the number of electrons involved in the redox process, F is the Faraday constant (C mol^{-1}) and $\triangle E_{½}$ is the change in the half-wave potential of the redox active host following the addition of the guest.
14 The redox-based enhancement in recognition can be calculated using a thermodynamic cycle which can be expressed mathematically using: K_a(red)/K_a(ox) = $e^{(nF/RT)[E_{1/2}(\text{bound}) - E_{1/2}(\text{unbound})]}$. K_a(red) and K_a(ox) are the association constants in the reduced and oxidized forms, respectively, and $E_{½}$(bound) and $E_{½}$(unbound) are the half-wave redox potentials in the receptor bound and unbound states.

Received (in Cambridge, UK) 17th July 2001, Accepted 21st August 2001
First published as an Advance Article on the web 18th September 2001

Hexagonal $[(\eta^2\text{-}Cp)_3MnK\cdot1.5thf]$ 1 and ion-separated $[(\eta^2\text{-}Cp)_3Mn]_2[Mg(thf)_6]\cdot2thf$ 2 are obtained from reactions of CpK and Cp_2Mg, respectively, with manganocene, Cp_2Mn; they are the first complexes to be structurally characterised containing the $[Cp_3Mn]^-$ anion.

The greater covalent character of the metal–ligand bonds and the significant involvement of d orbitals in transition metal metallocenes[1] results in some fundamentally different reactivity compared to their main group counterparts.[2] One significant difference is the far greater lability and ionicity of the Cp ligands of main group metallocenes, which are readily displaced by acids and nucleophiles. Nonetheless, although rarely investigated these characteristics have also been found for certain transition metal complexes, such as $[CpCu(PPh_3)]$[3] and $[Cp_2Mn]$.[4,5] The similarity between the ligand reactivity of 17e Cp_2Mn and 14e Cp_2Sn and Cp_2Pb has prompted us recently to investigate the possibility of observing related reactivity at their *metal* centres. We report here, that nucleophilic addition of Cp^- to $[Cp_2Mn]$ gives the first complexes containing the $[Cp_3Mn]^-$ anion, behaviour which is analogous to that of Cp_2Sn and Cp_2Pb.[2]

The complexes $[(\eta^2\text{-}Cp)_3MnK\cdot1.5thf]$ **1** and $[(\eta^2\text{-}Cp)_3Mn]_2[Mg(thf)_6]\cdot2thf$ **2** were prepared by the reactions of $[Cp_2Mn]$ with CpK (1 : 1 equivalents) or $[Cp_2Mg]$ (1 : 2 equivalents), respectively, in thf solvent (Scheme 1).† Spectral characterisation of **1** and **2** was hampered by their paramagnetic nature which made NMR spectroscopic investigations of little value in ascertaining the solution structures. A further complication is the extreme lability of the thf ligands of **1**, which are completely removed by placing the complex under vacuum for even moderately short periods prior to isolation.

Owing to the flaky, laminar nature of crystals of **1** only relatively poor quality X-ray data could be collected (despite repeated attempts).‡ Despite these inherent problems the essential features of the structure were determined unambiguously. The complex consists of $[(\eta^2\text{-}Cp)_3Mn]^-$ anions associated *via* Mn–(μ-Cp)–K interactions into cyclic $[(\eta^2\text{-}Cp)_3MnK]_3$ units, which build into a honeycomb sheet structure (Fig. 1). The extensive static disordering of the K^+ cations and Cp ligands (over two 50 : 50 sites for both; see ESI†) stems from the presence of two crystallographically independent sheets within the structure in which the Cp rings adopt a propeller-like arrangement which is randomly left-handed in half of the sheets and right-handed in the other half. These layers are randomly distributed in the lattice of **1** with an extremely large interlayer spacing between them of *ca.* 9.53 Å. Like graphite, the $[(\eta^2\text{-}Cp)_3MnK]_3$ units of alternate sheets are staggered with respect to each other, with the Mn^{II} cations within a sheet being coincident with the centroid of the $[(\eta^2\text{-}Cp)_3MnK]_3$ units of adjacent layers. The voids between the sheets are occupied by thf molecules {1.5 thf per $[(\eta^2\text{-}Cp)_3MnK]$ monomer unit}. On average, each K^+ cation is solvated by half a thf ligand, with another disordered thf ligand being uncoordinated. The structure of **1** is similar to that of the recently characterised Pb^{II} complex $[(Cp)_2(Cp^{thf})PbNa\cdot0.5thf]$ ($Cp^{thf} = C_5H_4CH_2C_4H_7O$) which also adopts a 'graphite-like' lattice.[6] However, in this case puckered hexanuclear Pb_3Na_3 rings result from the intramolecular coordination of the ligand-bonded ether functionality to the Na^+ cations. The η^5-Cp bonding of three Cp ligands to both of the disordered K^+ sites in **1** [range K–C: 2.968(6)–3.31(2) Å] is similar to that observed previously in the structures of CpK and its Lewis base complexes (*ca.* 2.97–3.13 Å).[7]

The extensive disordering provides a particular complication to the discussion of the metal–ligand bond lengths and metal geometries involved in **1**. However, the significant bonding features of the $[(\eta^2\text{-}Cp)_3Mn]^-$ anion are nonetheless apparent. Most surprisingly, the Mn^{II} centers are clearly coordinated by three η^2-Cp ligands for both of the disordered Cp sites [range

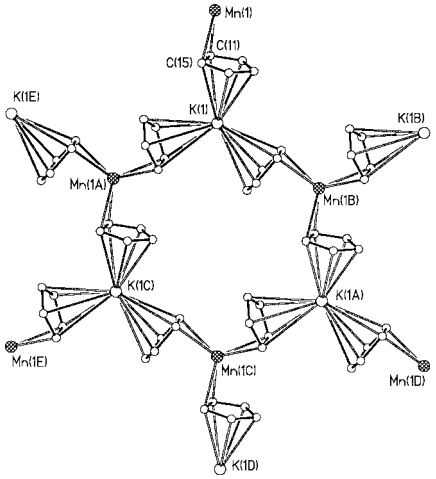

Fig. 1 Sheet structure of **1**, viewed along the *c*-axis. Only one of the sheets is shown {corresponding to anti-clockwise rotation of the $[(\eta^2\text{-}Cp)_3Mn]^-$ anions}. H-atoms and thf ligands have been removed for clarity. Key bond lengths (Å) and angles (°); Mn–C range: 2.36(1)–2.405(4), Mn···η^2-$Cp_{centroid}$(mean) 2.25, K–C 2.96(2)–3.300(4), K···$Cp_{centroid}$(mean) 2.94, K···Mn(mean) 5.26, Mn···Mn 9.09, C–Mn–C(mean) 34.6.

 DOI: 10.1039/b106366a

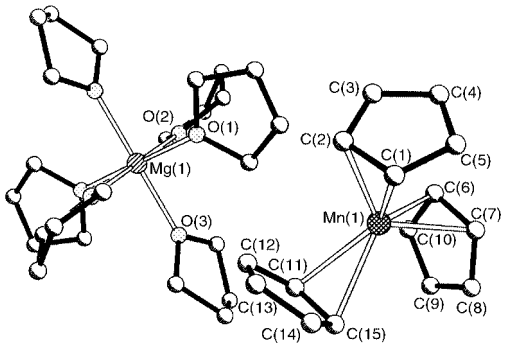

Fig. 2 The ion-separated complex **2**. H-atoms and the lattice-bound thf molecules have been omitted for clarity. Only one of the $[(\eta^2\text{-Cp})_3\text{Mn}]^-$ anions is shown. Key bond lengths (Å) and angles (°): Mn–C range: 2.351(5)–2.392(6) Mn···η^2-$\text{Cp}_{centroid}$(mean) 2.25, Mg–O range: 2.091(3)–2.109(3), C–Mn–C 34.9(2).

Mn–C: 2.36(1)–2.405(4) Å]. This bonding mode is retained in the structure of the ion-separated complex $[(\eta^2\text{-Cp})_3\text{Mn}]_2[\text{Mg(thf)}_6]\cdot 2\text{thf}$ **2** (Fig. 2).‡ Although the three Cp ligands of the $[(\eta^2\text{-Cp})_3\text{Mn}]^-$ anion are crystallographically independent in this case, the Mn–C bond lengths are almost identical to those in **1** [range Mn–C: 2.351(5)–2.392(6) Å]. The outcome of the reaction of $[\text{Cp}_2\text{Mn}]$ with Cp_2Mg is the same as that between Cp_2E (E = Sn, Pb) and Cp_2Mg, producing the ion-separated complexes $[\text{Cp}_3\text{E}]_2[\text{Mg(thf)}_6]\cdot\text{thf}$.[8] However, unlike **2**, ion-separation leads to a change in hapticity from η^5 to η^3 for the group 14 $[\text{Cp}_3\text{E}]^-$ anions, apparently as a consequence of increased p-character in the metal lone pairs.[8]

The only transition metal metallocene anions to be structurally characterised previously have been those derived from d^{10} CpCu^{I}.[9] The $[(\eta^2\text{-Cp})_3\text{Mn}]^-$ anion of **1** and **2** is the first transition metal tris-cyclopentadienide anion[10] and the first containing a paramagnetic metal [(d^5) Mn^{II}]. To our knowledge, the only previous case of η^2-Cp coordination in manganocenes occurs in Cp_2Mn, in which the Mn^{II} centers within the polymer chains are coordinated by three Cp ligands using η^5, η^3 and η^2 bonding modes [C–Mn being 2.44(3) and 2.62(3) Å for the η^2-interactions].[11a] It is interesting that in the previously reported $[\text{Cp}_2\text{Cu}]^-$ and $[\text{Cp}_3\text{Cu}_2]^-$ anions η^2-Cp bonding is also a feature.[9]

Structural investigations of Lewis base adducts of manganocenes indicate that steric factors have a decisive influence on hapticity and ring-slippage.[4a,11] However, there is also some possibility that electronic factors may play a role in the adoption of the η^2-Cp bonding mode in **1** and **2**. Extended Hückel calculations on C_{3v} $[(\eta^5\text{-Cp})_3\text{Ti}]^+$ indicate that only the essentially non-bonding metal d_{z^2} orbital is available for metal electrons.[12] Thus, if a metal has more than 2e these high-energy orbitals must be filled, as would be the case in a 23e $[(\eta^5\text{-Cp})_3\text{Mn}]^-$ anion. The adoption of an η^2-bonding mode therefore avoids an unfavourable electronic situation, by giving the Mn in the $[(\eta^2\text{-Cp})_3\text{Mn}]^-$ anion a 14e count.

Samples of **1** and **2** were examined on a SQUID magnetometer in the temperature range 5–300 K, in an applied field of 700 G.†[13] Both samples show an extremely similar temperature dependence of the magnetic moment. The room-temperature moment of *ca.* 4.8 μ_B is somewhat lower than that expected for an *S* 5/2 paramagnet (5.9 μ_B). On cooling, the effective magnetic moment decreases steadily, reaching a minimum value of 3.7 μ_B at the low-temperature limit of the experiments. The similarity of the behaviour of both complexes strongly suggests that the magnetic properties originate from single-ion effects, rather than intermolecular exchange between Mn^{II} ions. The behaviour of **1** and **2** can be compared to that of Cp_2Mn itself, for which the Mn^{II} centers have been concluded to be antiferromagnetically coupled over a similar temperature range.[11a,14] However, studies of 'magnetically-dilute' Cp_2Mn doped with Cp_2Mg[15] show that the magnetic properties can be explained by zero-field splitting, which is substantially greater than that normally observed for Mn^{II} salts.[15c] Attempts to model the behaviour of **1** and **2** using zero-field splitting alone were unsuccessful.†[13] We therefore conclude that their magnetic behaviour stems from high-/low-spin equilibrium, with a possible component of zero-field splitting. Further detailed magnetic and EPR experiments are planned, to provide a detailed explanation of the electronic structure.

Self-assisted tandem Michael-aldol reactions of α,β-unsaturated ketones with aldehydes

Tadashi Kataoka,* Sayaka Kinoshita, Hironori Kinoshita, Masaru Fujita, Tatsunori Iwamura and Shin-ichi Watanabe

Gifu Pharmaceutical University, 6-1 Mitahora-higashi 5-chome, Gifu 502-8585, Japan. E-mail: kataoka@gifu-pu.ac.jp

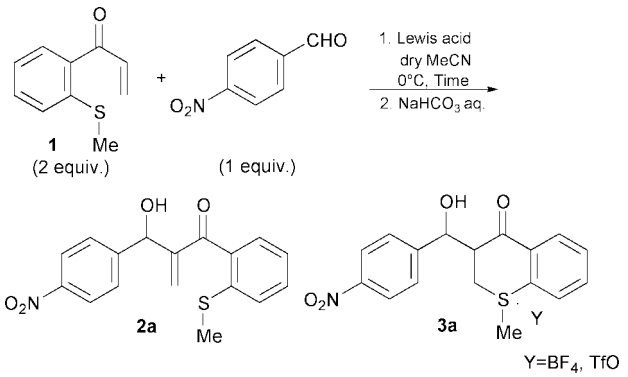
Received (in Cambridge, UK) 11th July 2001, Accepted 24th August 2001
First published as an Advance Article on the web 10th September 2001

The tandem Michael-aldol reaction of 1-[2-(methylsulfanyl)-phenyl]prop-2-en-1-one (1) or the seleno congener 4 with *p*-nitrobenzaldehyde in the presence of $BF_3{\cdot}Et_2O$ gave the Baylis–Hillman adduct 2 or 5 and onium salt 3 or 6, respectively, and selenochromanone 7 from 4.

The Baylis–Hillman reaction is one of the most popular reactions, and a great number of papers have been recently published on it.[1] This reaction is quite slow, and many changes have been made to it to overcome this drawback.[2] We developed the chalcogenide–$TiCl_4$-mediated reactions of electron-deficient alkenes with aldehydes.[3] The reactions had been deemed to be a chalcogenide version of the Baylis–Hillman reaction because the Baylis–Hillman adducts were given after purification of the products by preparative TLC on silica gel. However, a detailed examination of the reactions revealed that the original products were α-chloromethyl aldols and that dehydrochlorination occurred during purification by the preparative TLC on silica gel.[4] Similar reactions using $TiCl_4$ have been reported by other groups.[5] Very recently, we obtained methyl 3-methylsulfanyl-2-(α-hydroxy-*p*-nitrobenzyl)acrylate from the reaction of methyl propiolate with *p*-nitrobenzaldehyde in the presence of $TiBr_4$–SMe_2 as a minor product.[6] This finding implied that SMe_2 worked as a Lewis base and suggested to us that the intramolecular Michael addition of a sulfanyl group to an enone moiety would proceed more efficiently than the intermolecular one. In other words, the sulfanyl substituent assists the intramolecular Michael addition to form a cyclic sulfonium betaine. Cyclisation of enone sulfides with a Lewis acid has been reported from a different viewpoint.[7] These reports encouraged us to conduct the reactions of 1-[2-(methylsulfanyl)phenyl]prop-2-en-1-one with aldehydes in the presence of $BF_3{\cdot}Et_2O$. In this paper, we would like to describe a new type of tandem Michael-aldol reaction of an enone sulfide with aldehydes using a Lewis acid.†

A chloride ion reacted with an α,β-unsaturated carbonyl compound as a nucleophile in the reaction of the enone with an aldehyde using chalcogenide–$TiCl_4$.[4] In order to avoid this reaction and allow a chalcogenide to react with the enone instead of a chloride ion, we selected a Lewis acid such as metal fluoride or triflate, which releases non-nucleophilic anion, although $BF_3{\cdot}Et_2O$ and triflates of the lanthanide metals had been ineffective for the intermolecularly chalcogenide-promoted tandem Michael-aldol reactions.[3]

Various Lewis acids were examined for the reactions of 1-[2-(methylsulfanyl)phenyl]prop-2-en-1-one (**1**)‡ with *p*-nitrobenzaldehyde (Scheme 1). The reaction mixture was quenched with a saturated aqueous $NaHCO_3$ solution. Results of the reactions are summarised in Table 1. Reactions using $BF_3{\cdot}Et_2O$ were monitored by TLC and stopped when *p*-nitrobenzaldehyde disappeared (entries 1–3). The reaction was accelerated with increase of the amount of $BF_3{\cdot}Et_2O$ and the reaction time was shortened. Prolonged reaction time decreased the yield of **3a** and increased **2a** (entries 1 and 4). Reactions using $BF_3{\cdot}Et_2O$–$LiBF_4$ (1:1) or TiF_4 afforded **2a** only in low yields (entries 5 and 6). Reaction catalyzed $Yb(TfO)_3$ gave **2a**



Scheme 1

(21%) and **3a** (42%)§ (entry 7). When 2 equiv. of $BF_3{\cdot}Et_2O$ were used, the highest yields of **2a** (18%) and **3a** (62%)§ were given from the reaction at 0 °C for 1 h (entry 2). The use of lithium perchlorate and aluminium sulfate gave no product, and **1** was recovered without loss.

Other aromatic aldehydes and 3-phenylpropionaldehyde similarly reacted with **1** to give **2** and **3** in low to moderate yields (Scheme 2 and Table 2). Since the reactions of various aldehydes were slower than that of *p*-nitrobenzaldehyde, the reactions were conducted for 2 h and then worked up with aqueous $NaHCO_3$. Seleno derivative **4**‡ reacted with aromatic aldehydes to give α-methylene aldol **5**, aldol selenonium salt **6**§, and 3-(α-hydroxybenzyl)selenochromanone **7**. Demethylation of **6** occurred more easily during the reactions than that of **3** to give **7** as a mixture of diasteroisomers. The *syn*- and *anti*-diastereoisomers were assigned in comparison of the coupling constants of the methine protons [C-CH(OH)-C], *syn*- (0–2.4 Hz) and *anti*-isomer (7.8–8.3 Hz), with those of the cyclohexanone derivative.[8]

^1H NMR spectra of the residues obtained by concentration of the reaction mixtures were measured in order to examine whether α-methylene aldol **2** or **5** was formed *via* the Baylis–Hillman reaction or the β-elimination of **3** or **6** by a work-up with a saturated aqueous $NaHCO_3$ solution. Vinyl proton

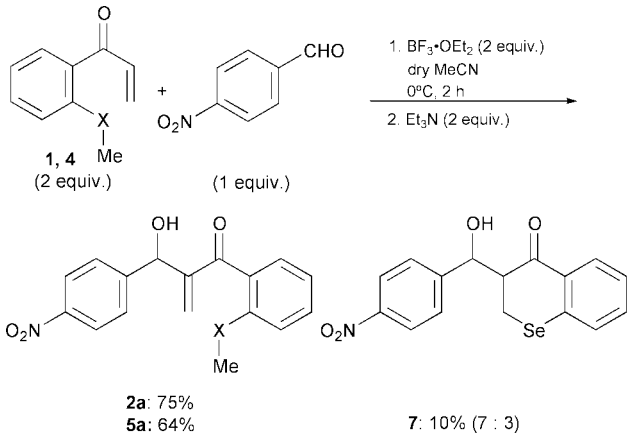
[a] Diastereoisomer ratio (*syn* : *anti*-isomer).

signals of **2** and **5** were observed in the region of δ 5.80, 6.09 and δ 5.76, 6.06, respectively. This indicates that α-methylene aldol **2** or **5** was formed during the reaction. However, the intensities of the $^+$X-Me signals of **3** and **6** were decreased, and those of the X-Me signals of **2** and **5** were increased after treatment with saturated aqueous $NaHCO_3$ solution. Therefore, some of the onium salts **3** or **6** suffered β-elimination by the work-up with the saturated aqueous $NaHCO_3$ solution to form **2** or **5**, respectively.§

Next, the residue obtained from the reaction of **1** or **4** (2 equiv.) with *p*-nitrobenzaldehyde (1 equiv.) using $BF_3{\cdot}Et_2O$ (2 equiv.) as a Lewis acid was treated with triethylamine (2 equiv.) instead of saturated aqueous $NaHCO_3$ solution in order to obtain α-methylene aldol **2** or **5** (Scheme 3). The reaction of sulfide **1** afforded **2a** in 75% yield, but the reaction of the selenium congener **4** gave **5** (64%) and the demethylated product **7** (10%).



Scheme 3

The reaction conditions presented here were not sufficiently optimised, but this methodology will be the starting point for the development of tandem Michael-aldol reactions as well as the Baylis–Hillman reaction.

This research was partially supported by the Ministry of Education, Science, Sports and Culture, Grant-in-Aid for Scientific Research (C), 12672056.

Notes and references

† A typical example: $BF_3{\cdot}OEt_2$ (126 μl, 1.00 mmol) was added to a stirred solution of *p*-nitrobenzaldehyde (76 mg, 0.50 mmol) and 1-[2-(methylsulfanyl)phenyl]prop-2-en-1-one (**1**) (178 mg, 1.00 mmol) in dry MeCN (1.5 ml) at 0 °C. The mixture was stirred at the same temperature for 2 h, and the reaction was quenched by addition of saturated aqueous $NaHCO_3$ (3 ml). The precipitate of the inorganic material was removed by filtration through Celite and washed with MeCN. The filtrate and the washing were combined, and the solvent was evaporated under reduced pressure. The residue was washed with CH_2Cl_2, and crystals were filtered and recrystallised from MeCN–CH_2Cl_2 to give 3-[(4-nitrophenyl)(hydroxy)methyl]-1-methyl-4-oxo-3,4-dihydro-2*H*-thiochromenium tetrafluoroborate (**3a**), as a white powder of a mixture of diastereoisomers: major isomer: δ_H 3.10 (3H, s, SMe), 3.60 (1H, dd, J = 5 and 15), 3.61 (1H, ddd, J = 3, 5 and 10), 4.02 (1H, dd, J = 10 and 15), 4.36 (1H , d, J = 4, OH), 5.79 (1H, dd, J = 3 and 4, benzylic H), 7.71 (2H, d, J = 9, ArH), 7.89–7.94 (3H, m, ArH), 8.29 (2H, d, J = 9, ArH), 8.38 (2H, dd, J = 2 and 7, ArH). The ^{1}H NMR signals of the minor isomer could not be clearly assigned because of the overlapping absorptions. The washing was concentrated to dryness, and the residue was purified by preparative TLC on silica gel (ethyl acetate–hexane = 1 : 2, v/v) to give 2-[(4-nitrophenyl)(hydroxy)methyl]-1-[2-(methylsulfanyl)phenyl]-prop-2-en-1-one (**2a**) as yellow oil: δ_H 2.40 (3H, s, SCH_3), 3.50 (1H, br s, OH), 5.80 and 6.09 (each 1H, s, olefinic H), 5.91 (1H, s, benzylic H), 7.17 and 7.43 (each 1H, t, J = 8, ArH), 7.27 and 7.34 (each 1H, d, J = 8, ArH), 7.66 and 8.21 (each 2H d, J = 9, ArH); δ_C 17.0 (q), 72.4 (d), 123.8 (d), 124.6 (d), 127.3 (d), 127.4 (d), 129.7 (d), 130.1 (t), 131.7 (d), 136.9 (s), 139.3 (s), 147.5 (s), 149.1 (s), 149.2 (s), 198.2 (s); EIMS *m*/*z* 329 (M^+); Found: C, 61.9; H, 4.9; N, 4.0. $C_{17}H_{15}NO_4S$ requires C, 62.0; H, 4.6; N, 4.3%.

‡ Compounds **1** and **4** were prepared in a similar way as for 1-[2-(ethylsulfanyl)-4,5-dimethoxyphenyl]prop-2-en-1-one in Ref. 7*b*.

§ The onium salts **3** and **6** were obtained as mixtures of stereoisomers based on two chiral carbons and a chalcogenide atom. However, their stereostructures and isomer ratios could not be determined. The stereostructures of onium salts **3** and **6** and their reactivity against a base will be described in the full paper.

Peptide conjugation: unexpected ring opening of azacrown ether nucleophiles in the oxazolone-based coupling†

Anatoly M. Belostotskii,* Elisheva Genizi and Alfred Hassner

Chemistry Department, Bar-Ilan University, Ramat-Gan 52900, Israel. E-mail: belostot@mail.biu.ac.il

Received (in Cambridge, UK) 10th July 2001, Accepted 7th August 2001
First published as an Advance Article on the web 10th September 2001

Unexpected cleavage of the macrocyclic ring of secondary azacrown ethers when interacting with the Aib_8 (Aib = α-aminoisobutyric acid) oxazolone indicates the possibility for a new mechanism of peptide racemization due to transformations of the oxazolones formed from the *N*-derivatives of α-amino acids in peptide synthesis.

Peptide–benzocrown ether conjugates have been proposed as metal carriers which are capable of specific membrane penetration.[1] In the framework of developing *a biomembrane active peptide with a C-terminus-attached chelator* we started the synthesis of new peptide conjugates with crown ethers.

As the peptide we chose the octamer of α-aminoisobutyric acid (Aib), Aib_8, since natural and synthetic Aib-enriched peptides (including Aib_8) are capable of strong binding to biomembranes.[2] A preferred approach to preparation of conjugates consists of coupling Aib_8 with derivatives of the desired crown ethers, *i.e.*, of peptide modification in the last synthetic step. We chose the oxazolone-based coupling[3] for the C-terminus modification of this non-racemizing peptide, since other activation of the carboxy group of the C-terminal Aib residues is problematic (see below as well as ref. 4). The oxazolone coupling proceeded smoothly with primary amines but surprisingly led to different products on interaction with secondary amine crown ether nucleophiles.

Basic hydrolysis of octapeptide methyl ester **1a**[4] (NaOH, MeOH–H_2O, 25 °C, 48 h) led to acid **1b**, which was transformed into oxazolone **2** by heating with acetic anhydride (120 °C, 12 h; see Fig. 1). Interaction of oxazolone **2** (as a crude material; NMP, 110 °C, 1–1.5 h) with primary amines **3** and **4c** led to conjugates **5a** and **6a**, respectively, in good yields. Further, Boc-deprotection (TFA, 0 °C, 1 h) afforded peptide trifluoroacetates **5b** and **6b** (isolated by HPLC).[5]

No difficulties were encountered for acylation of azacrown ethers **4a** and **7a** possessing a secondary amino group using different activation methods of the carboxyl group. For instance, derivative **4c** was obtained by triphosgene-assisted coupling[6] of BocGlyOH and **4a** [THF, lutidine, 1 h at 25 °C and then 1 h at 50 °C] followed by acidic deprotection of amide **4b** (see Fig. 2). The PyBOP-provided coupling of **7a** and lithocholic acid **8** (3-fold excess of the amine, DIEA, CH_2Cl_2, 25 °C, 48 h) led to azacrown–steroid conjugate **9** (a steroidal analog of azacrown-based transmembranic carriers).

By contrast, when the coupling of oxazolone **2** with azacrown compounds **4a** and **7b** was carried out under the above conditions, only **10a** and **10b**, respectively, unexpected products of azacrown ring opening, were isolated (as trifluoroacetates)[5] after hydrolysis in TFA (see Fig. 3). No link between the secondary amine **7b** and the sterically hindered carboxyl function of peptide **1b** could be achieved under other conditions employed. For instance, triphosgene-based activation, which has been proposed as an advantageous solution for the often difficult peptide coupling with secondary amines,[6] was unsuccessful, with peptide **1b** being recovered unchanged.

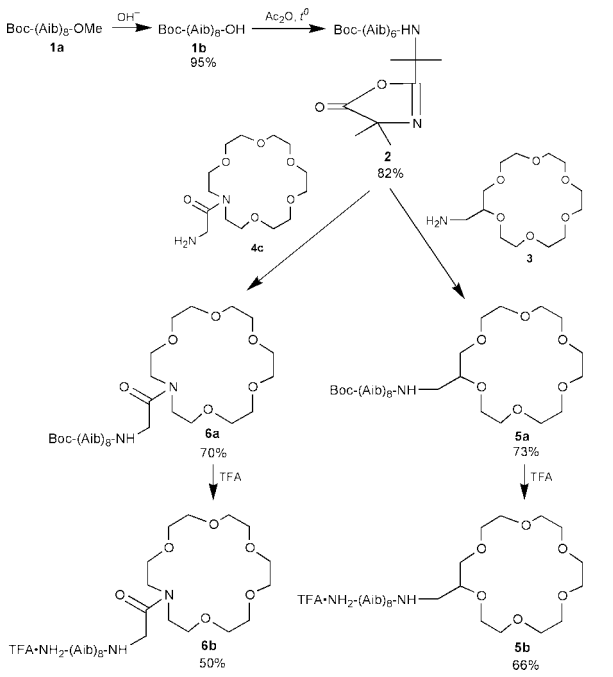

Fig. 1 Synthesis of macrocyclic conjugates **5b** and **6b**.

The drastic difference in the chemical behavior of crown ethers with primary (*e.g.*, **3**) and secondary (*e.g.*, **4a**) amino groups allows us to conclude that different mechanisms are involved in the reaction of these amines with peptide oxazolone **2**. We suggest the scheme in Fig. 3 to account for the azacrown ether ring opening with loss of two carbons.

While formation of conjugates **5a** and **6a** obviously occurs according to the accepted mechanism of nucleophilic cleavage of the peptide oxazolone ring,[7a,b] transformation of intermediate **11** into *O*-alkyl imidonium species **12**[8] under elevated temperatures initiates the azacrown ring opening. The positive charge on the iminium nitrogen atom (stabilized by the highly polar solvent, NMP) facilitates β-elimination of the hydroxy group leading to the cleavage of the macrocyclic ether. It should be noted that in the case of *the primary amine nucleophiles* **3** or **4c**, intermediates of type **12** will be converted in the aprotic

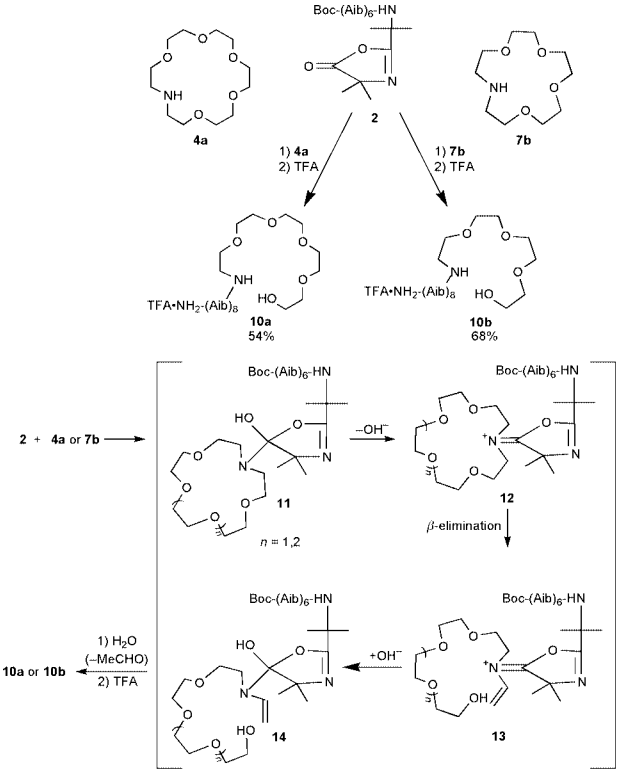

Fig. 3 Azacrown ether ring opening in the reaction of secondary amines **4c** and **7b** with oxazolone **2**.

solvent used into *neutral imidates* (see Fig. 4), which are not capable of β-elimination of alcohols. Imidates **13** afford the corresponding enamines **14** which are hydrolyzed to open chain azacrown compounds **10a** or **10b**.

Oxazolone formation from N-protected amino acids is one of the important factors leading to racemization in peptide synthesis.[7a,9] The observed ring opening indicates a possible *additional mechanism for peptide racemization* through oxazolone derivatives of amino acids (see ref. 7 for the commonly considered mechanisms). If oxazoline intermediates of type **11** are reversibly dehydrated under reaction conditions, the acidity of the 4-H proton is significantly increased due to tautomerization of the imidate structure into the enamine structure (see Fig. 4). Formation of an aromatic oxazole system is the driving force of this bond reorganization.

In order to reveal how reversible the equilibrium between these imine and enamine forms for *N*-Boc derivatives of amino acids is and thus to prove roughly the validity of the proposed racemization mechanism, we estimated the relative stability of the lowest energy conformers for the model tautomers ***I*** and ***E*** using *ab initio* calculations at the MP2/6-31G* level. Conformational space for these tautomers was analyzed using force

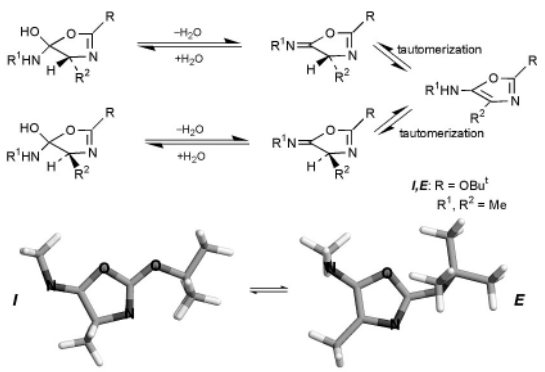

Fig. 4 Intermediate products of reversible transformation of oxazolones which lead to racemization of *N*-acyl of *N*-acyloxy amino acids or peptides. Optimized geometries (MP2/6-31G*) for model imine (***I***) and enamine (***E***) tautomers are shown.

fields Amber, OPLS and MM3 and the Monte-Carlo-based conformational search implemented into the Macromodel 6.0 package. The conformers of ***I*** and ***E*** shown in Fig. 4 were found by these force fields possessing the minimal energy among the conformers of the corresponding tautomer.

Ab initio calculations for the full electron energy (ΔE) of these conformers ***I*** and ***E*** (using also the PCM solvation model, a utility of the Gaussian98 package) demonstrated that imine tautomer ***I*** is more stable than enamine tautomer ***E*** by 6.1 and 5.1 kcal mol^{-1} in the gas phase and in DMSO, respectively. On the other hand, specific intermolecular amine–amide interactions (*e.g.*, H-bond formation) are not included in this solvation model. This high energy H-bonding should stabilize tautomer ***E*** in amidic solvents (*e.g.*, in NMP or DMF). Values of $\Delta H°$ for the H-bond formation are ~5 kcal mol^{-1} in such systems.[9] Taking into account this value and the calculated ΔE values we conclude that tautomers ***I*** and ***E*** should be near in energy in these polar solvents. Therefore, the equilibrium between ***I*** and ***E*** indeed is appreciably reversible (no large energy gap is present for these tautomers). It is known that the racemization in peptide synthesis is promoted by highly polar solvents (NMP, DMF or DMSO).[10] Thus, the above described tautomerization could be involved in the racemization of peptides being prepared in these H-bond-forming solvents.

This research was supported by a grant from the Mallinckrodt Medical B.V., Petten, Holland, and the Israel Ministry of Science and Technology (Grant 1471-1-99).

4 Peptide **1a** was synthesized using Boc and Me-ester protections for amino and carboxyl groups, respectively. Cleavage of these protecting groups afforded oligo(Aib) peptides in yields higher than 90%. A successful PyBOP coupling in solution for preparation of Aib-containing peptides (E. Frerot, J. Coste, A. Pantaloni, M.-N. Dufour and P. Jouin, *Tetrahedron*, 1991, **47**, 259;) was used for the stepwise chain elongation up to the $(Aib)_4$ derivative. In order to minimize the number of synthetic steps in our synthesis of Aib_8, the [4 + 4] fragment coupling was examined as an alternative to the known stepwise elongation (see ; D. S. Jones, G. W. Kenner, J. Prenston and R. C. Sheppard, *J. Chem. Soc.*, 1965, 6227;) of the oligo(Aib) chain. Attempts to perform the [4 + 4] coupling using the DCC–HOBt condensation led to preferential formation of the corresponding oxazolone over octapeptide **1a** (~8:1, respectively). Therefore we converted the acid $Boc(Aib)_4OH$ into the oxazolone, which without purification was opened in a nucleophilic reaction with the amine $NH_2(Aib)_4OMe$ (NMP, 110 °C, 2 h), furnishing the desired octapeptide **1a**.

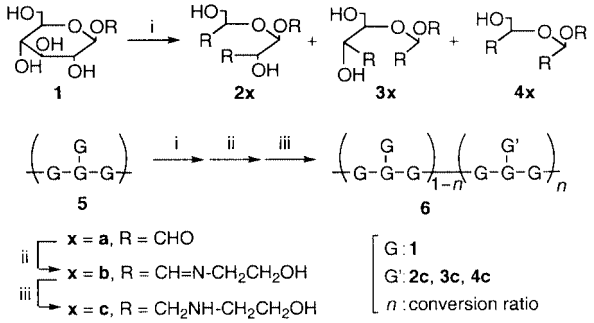
Received (in Cambridge, UK) 26th June 2001, Accepted 24th August 2001
First published as an Advance Article on the web 19th September 2001

Combining oxidation with periodate and reductive amination, the amino group is introduced only in the side chain of schizophyllan and the product can bind to poly(C) with a higher dissociation temperature than that of the unmodified schizophyllan and poly(C) complex.

Schizophyllan (SPG) is a natural polysaccharide produced by the fungus *Schizophyllum commune* and its repeating unit consists of three β(1→3) glucose units and one β(1→6) glucose side chain linked at every third main-chain glucose (see **5** in Scheme 1).[1,2] SPG adopts a triple helix in water and dissociates into a single chain (s-SPG) in dimethyl sulfoxide (DMSO).[3–5] The s-SPG chain can regain the original triple helix by exchanging DMSO for water.[5–7] Recently, we found that when this solvent-exchange process is carried out in the presence of polynucleotides, the resultant triple helix consists of two s-SPG chains and one nucleotide chain.[8,9] Subsequent study reveals that this complexation is characteristic for water-soluble β-1,3-glucans and never observed for other polysaccharides.[10] As far as we know, this is the first clear evidence that a neutral polysaccharide can form a macromolecular complex with polynucleotides. We believe that s-SPG–polynucleotide complexes may provide a new methodology for gene technology, such as gene carriers, affinity separation columns, biosensors, *etc*.[11] Judging from these potential applications, it is advantageous to be able to control the complex stability by chemical modification of SPG. In this paper, we have introduced an amino group into the side chain of SPG by combining periodate oxidation with subsequent reductive amination.

As shown in Scheme 1, oxidation of glucosides by periodate anion (IO_4^-) leads to cleavage of the pyranose ring and converts each cleavage end to a formyl group.[12] The formyl group reacts with 2-aminoethanol and subsequent reduction of the resultant Schiff base produces an amino-appended glucoside (**2c**, **3c**, and **4c**). When this method is applied to SPG, the product is expected to have the chemical structure shown by **6**. Here, *n* is the conversion ratio (or the ratio of cationic monomeric unit), which was estimated to be 2.4 ± 0.3% by nitrogen elemental analysis. Hereinafter, we denote this copolymer as N-s-SPG. Since the ratio of the introduced cationic monomer unit is very low, it is reasonable to consider that the reaction takes place statistically to yield a random copolymer.



Scheme 1 Schematic illustration for the introduction of an amino group into SPG. *Reagents and conditions*: (i) $NaIO_4$, H_2O, 4 °C, 2 days, (ii) 2-aminoethanol, DMSO, rt, 2 days, (iii) $NaBH_4$, DMSO, rt 1 day.

One of advantages in applying this periodate oxidation method to SPG is that the cleavage reaction takes place only at the side chain and the main chain should be intact during the reaction because the main chain does not have any 1,2-diol groups. Therefore, this method can be extended to other 1,3-glucans such as lentinan and scleroglucan.[11] Although not mentioned in this paper, *n* can be controlled by changing the concentration of the periodate anion. Detailed characterisations and the relationship between *n* and the complex stability will be discussed in the corresponding full paper.

The amino group introduced by the above mentioned method forms an ammonium cation in neutral aqueous solutions. Therefore, when N-s-SPG is mixed with polynucleotides, we expect that an ion-pair can be formed between the phosphate anion of polynucleotide and the cation of N-s-SPG. Once the ion pair is formed, this strong attractive interaction is expected to enhance the complex stability.

Fig. 1 compares the CD spectra between poly(C) itself, a mixture of s-SPG and poly(C) (+s-SPG), and a mixture of N-s-SPG and poly(C) (+N-s-SPG), where [θ] is the molar ellipticity. Neither s-SPG nor N-s-SPG has any absorbance in the wavelengths presented in Fig. 1. Therefore, all CD bands are ascribed to the conformational asymmetry of a poly(C) chain. CD bands in this wavelength region sensitively reflect how the cytosine bases are stacked in the helix.[13]

As shown in Fig. 1, the spectrum of +s-SPG is different from that of poly(C) itself; the 275 nm band increases by 50% and a

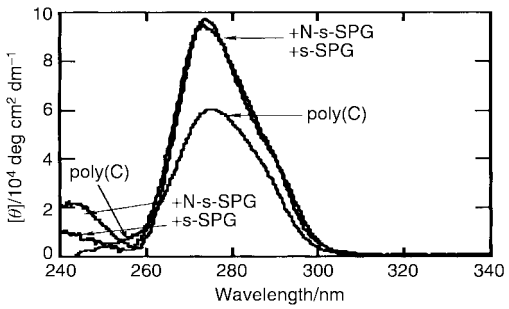


Fig. 1 Comparison of the CD spectra between poly(C), +s-SPG and +N-s-SPG measured at 15 °C in a non-salt solution.

 DOI: 10.1039/b105609n

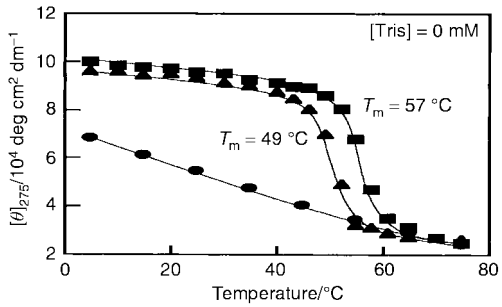

Fig. 2 Comparison of the melting behaviours of the complex between +s-SPG (▲) and +N-s-SPG (■) [Poly(C) (●)].

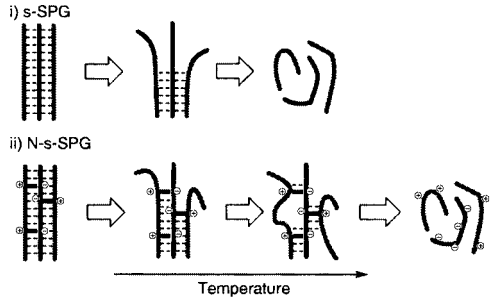

Fig. 4 Schematic illustration of the pinning effect induced by ion-pair formation.

new band arises around 242 nm. According to our previous work,[8,10] these changes can be ascribed to the complex formation between s-SPG and poly(C). The spectrum of +N-s-SPG also has two characteristic bands at 242 and 275 nm, however, the spectrum is slightly different from that of +s-SPG. In particular, the intensity of the 242 nm band of +N-s-SPG is almost twice of that of +s-SPG. Although the origin for the 242 nm band is not clear, this difference should be related to the ion pair formation between the cations in N-s-SPG and the phosphate anions in poly(C). When we measured the CD spectra with increasing Tris concentration, $[\theta]_{242}$ of +s-SPG does not change, whereas $[\theta]_{242}$ of +N-s-SPG merges with that of +s-SPG above 80 mM Tris, where $[\theta]_{242}$ is the molar ellipticity at 242 nm. Since Tris can generate a cationic charge at pH = 8.0, Tris cations presumably can bind to the phosphate anions in poly(C). Therefore, Tris and N-s-SPG cations compete with each other for binding to poly(C) and increasing Tris concentration is favourable for Tris to bind to poly(C).[14] This ion-competition effect can explain why increasing Tris concentration reduces the difference in the CD spectrum between +s-SPG and +N-s-SPG.

Fig. 2 compares the temperature dependence of $[\theta]_{275}$ for poly(C), +s-SPG and +N-s-SPG in a non-salt solution. The melting temperature of the complex (T_m) was determined with a conventional method[15,16] and the resultant values are presented in the figure. The complex of +N-s-SPG dissociates at higher temperature than s-SPG. This feature clearly indicates that the presence of the amino group in s-SPG can stabilise the complex. Fig. 3 plots T_m against Tris concentration for +s-SPG and +N-s-SPG. For +s-SPG, T_m seems to be independent of the Tris concentration, on the other hand, T_m for +N-s-SPG decreases with increasing Tris concentration. This concentration dependence of T_m can be also explained by the ion-competition effect mentioned above. Therefore, we can confirm that the formation of the ion-pair between N-s-SPG and poly(C) enhances the complex stability.

It is interesting that major features of the CD spectrum are common to +N-s-SPG and +s-SPG. This indicates that the poly(C) conformation in the complex is almost same for +s-SPG and +N-s-SPG. The complex of +N-s-SPG melts at 57 °C, whereas that of +s-SPG at 49 °C. This temperature difference of 8 °C approximately corresponds to a difference in enthalpy of 5–10 kcal mol^{-1}. The complex with +N-s-SPG is stabilised compared with +s-SPG in spite of the similarity in their conformation. This phenomenon can be explained by ion-pair formation between the phosphate anion and the ammonium cation. This ion-pair pins the poly(C) chain to the SPG chain to prevent decomplexation. This 'pinning effect' is schematically shown in Fig. 4.

In conclusion, we have successfully introduced an amino group into the side chain of SPG and stabilised the complex. It is undoubted that in the polymer complex the hydrogen-bonding interaction with OH groups and the electrostatic interaction with the amino groups operate synergistically to enhance the complex stability and the latter interaction is selectively reduced by the increase in the Tris concentration. Thus, this result presents a new strategy to control the stability of polynucleotide–polysaccharide complexes.

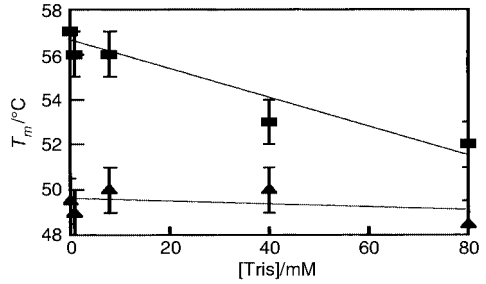

Fig. 3 Tris concentration dependence of T_m for +s-SPG (▲) and N-s-SPG (■).

14 Using inorganic salts such as NaCl and KCl, we found that the salt concentration dependence of the CD spectrum of both +s-SPG and +N-s-SPG, as expected, had a similar effect to that of Tris. However, these inorganic salts stabilise the complex even for the s-SPG system and since this effect takes place more dominantly than the competition effect, we could not see any CD changes due to ion-pair formation.

Functionalised polyolefin synthesis using [P,O]Ni catalysts

Vernon C. Gibson* and Atanas Tomov

Department of Chemistry, Imperial College of Science, Technology and Medicine, Exhibition Road, South Kensington, London, UK SW7 2AY. E-mail: v.gibson@ic.ac.uk

Received (in Cambridge, UK) 20th July 2001, Accepted 21st August 2001
First published as an Advance Article on the web 19th September 2001

Nickel olefin polymerisation catalysts containing bulky phosphino-enolate ligands are shown to give methyl methacrylate end-functionalised polyolefins.

Industrial processes for the manufacture of most polyolefin materials rely on transition metal catalysts which operate at modest temperatures and pressures and allow the properties of the materials to be tuned to their various applications. The past 20 years or so have seen important advances in the design of 'single-site' molecular catalysts which have given rise to an era of more finely controlled polyolefin materials synthesis.[1] A crucially important industrial and academic objective remains, however, and that is to develop catalysts that will allow the copolymerisation of hydrocarbon monomers such as ethylene and propylene with readily available polar monomers such as methyl methacrylate (MMA), alkylacrylates, and vinyl acetate. At present, commercial processes for the copolymerisation of these monomers rely on high pressure free radical polymerisation technology, and the range of materials accessible *via* this technology is severely restricted. There thus exists a compelling technological requirement for new metal-based catalysts capable of copolymerising hydrocarbon and polar monomers, under low temperature/pressure conditions, to give polyolefins with modified surface properties (adhesion, wettability, *etc*.) or bulk properties, or to act as compatibilisers for polyolefins and functionalised polymers.

To date, late transition metal catalysts have provided the most significant advances in polar comonomer incorporation but the majority only incorporate monomers in which the functionality is remote to the polymerisable vinyl group.[2,3] An important advance was reported by Brookhart and coworkers[4] who showed that α-diimine palladium catalysts are capable of incorporating acrylates into highly branched polyethylene, to give materials that bear resemblance to the copolymers obtained by free radical techniques. More recently nickel catalysts bearing salicylaldimine ligands have been shown to copolymerise ethylene with functionalised norbornenes.[3] These catalysts, however, do not incorporate polar monomers with the polar functionality directly attached to the C–C double bond.†

Recently we described a new family of highly active ethylene polymerisation catalysts **1** and **2** (Scheme 1) based on P–O chelate ligands bearing bulky substituents.[5] Here, we describe the use of this catalyst system to incorporate the readily available polar monomer, methyl methacrylate, into polyolefin materials.

The [P,O]Ni catalysts are readily generated by treatment of $Ni(cod)_2$ with the ligand precursors **1a–c**‡ in the presence of MMA. Interestingly, the catalyst does not form in the absence of an olefin (ethylene or MMA) which is presumed to be required to displace a cod ligand from the nickel centre. The polymerisations were carried out by exposing the nickel catalyst/MMA mixture to a continuous feed of ethylene (1–5 bar) in a glass reactor at temperatures in the range 50–70 °C. At the end of each polymerisation the polymer was precipitated with methanol, filtered, dissolved in 1,2,4-trichlorobenzene at 120 °C and precipitated from tetrahydrofuran. This procedure was repeated twice to remove any traces of poly(MMA). *In situ* generated catalytic mixtures as well as the pre-formed catalysts **2** are found to be equally active in the copolymerisation reaction.

The polymerisation results are collected in Table 1. The activities of the catalysts range from 80 to 418 g $mmol^{-1}$ h^{-1},

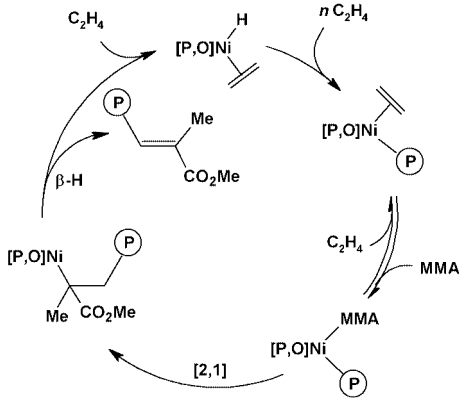
and give a first-order dependence on ethylene concentration, affording number average molecular weights in the range 3000–4000 and with narrow molecular weight distributions.

The isolated polymers were analysed by ^1H, $^{13}C\{^1H\}$ NMR and IR spectroscopies, MALDI-TOF mass spectrometry§ and gel permeation chromatography. In addition to the resonances of linear polyethylene, the $^{13}C\{^1H\}$ NMR spectrum revealed signals consistent with the presence of the methyl methacrylate unit. In particular, resonances at δ 128.2 and 143.0 are attributable to a double bond substituted with an ester functionality, while resonances at δ 169.0 and 51.7 confirm the presence of the methyl ester unit. Comparison of these NMR data with those derived from 2-methylpent-2-enoate (Fig. 1) indicate that the polyethylene chains possesses a methylenoate end-group. The presence of this end-group is confirmed by MALDI-TOF mass spectrometry (Fig. 2) which reveals individual polymer chains [$MeCH_2(CH_2CH_2)_{n-1}CH{=}C(Me)$-$CO_2Me$ (n = 40–60)], each terminated by the methylenoate functionality. In general, MALDI-TOF mass spectrometry would appear to provide a useful direct method of determining whether or not a polar comonomer has been incorporated into the polyolefin, since purely hydrocarbon polyolefins do not generally give good mass spectral data. The presence of the α,β-unsaturated ester functionality can also be observed by IR spectroscopy which affords bands corresponding to the ester group (1720 cm^{-1}) and C=C double bond (1642 cm^{-1}). Methyl methacrylate oligomers can also be incorporated into PE. For example, polymerisation of ethylene in the presence of trimer-MMA affords a PE–t-$(MMA)_3$ block copolymer (Table 1) which is readily identified by NMR and MALDI-TOF mass spectrometry. The presence of the α,β-unsaturated ester groups at the chain ends is consistent with a mechanism involving insertion of MMA or $(MMA)_3$ into the growing polyethylene chain, followed by β-H elimination (Scheme 2) rather than *via* chain transfer to the polar monomer, since the latter, in the



Scheme 2 Proposed mechanism for formation of PE–t-MMA.

absence of chain-walking, would give rise to saturated ester end-groups.

Since this catalyst system has also been shown to be capable of oligomerising propylene with good activities and hex-1-ene with more modest activities,[5] we have also investigated the potential for incorporating MMA into these oligomeric products. Treatment of **1a**/$Ni(cod)_2$ with an equimolar amount of propylene and MMA affords (by GC–MS) the MMA end-functionalised polypropylene oligomers $(C_3H_6)_nMMA$ (n = 1–3) (activity ~12 g $mmol^{-1}$ h^{-1}). In the case of hex-1-ene, a very low activity system (~1 g $mmol^{-1}$ h^{-1}) results in the MMA-functionalised co-dimer and -trimer, $(C_6H_{12})_nMMA$ (n = 1–2).

BP Chemicals Ltd is thanked for financial support. Drs G. Audley and J. Boyle are thanked for GPC and NMR measurements, respectively.

Notes and references

† It should be noted that lanthanide based catalyst systems for the synthesis of ethylene–MMA diblock copolymers have been reported,[6,7] and thiophene end-functionalised polyethylene *via* C–H bond activation[8] has recently been described.

‡ All new compounds gave satisfactory analytical and spectroscopic data.

§ Measured on a Micromass TOFSPEC spectrometer at laser λ_{ex} 337 nm. α-Cyano-4-hydroxycinnamic acid was used as a matrix. It should be noted that MALDI-MS has been shown in certain cases to observe components of lower mass preferentially.[9] This results in M_w being lowered to a greater extent than M_n, consequently affording a lower molecular weight distribution than the true value. The detector response is also known to affect the measured polymer weight distributions.

Heck and Suzuki reactions proceed in good yield in supercritical carbon dioxide in the presence of palladium acetate and tri-*tert*-butylphosphine with both free and polymer-tethered substrates.

The synthesis of organic molecules in the absence of volatile organic solvents remains an important industrial goal and the use of alternative reaction media in synthetic chemistry has attracted widespread attention. Supercritical carbon dioxide ($scCO_2$) has recently attracted much interest as an environmentally benign alternative to many toxic organic solvents.[1–3] It is non-toxic, inexpensive, universally available and affords facile separation from products by simple depressurisation. However, its practical use has been limited by its solvent power. Although $scCO_2$ will dissolve most non-polar compounds of low molecular mass, many catalysts, substrates and reagents are only poorly soluble.

Heck and Suzuki reactions have evolved into one of the most versatile families of reactions, as illustrated in the recent literature.[4,5] Their application in $scCO_2$ media was initially hindered by the poor solubilities of commercially available metal catalysts. In 1998 we[6] and Tumas[7] independently reported the first palladium-catalysed carbon–carbon coupling reactions in $scCO_2$ using fluorinated phosphine ligands to solubilise the palladium complex. To date, although the use of non-fluorinated phosphine ligands has been contemplated, the results have been disappointing, and inferior to the comparable fluorinated system. Rayner[8] reported added advantages in using palladium trifluoroacetate with commercial phosphines and metallocycles in the Heck reaction. Arai and co-workers communicated a Heck reaction in $scCO_2$ using a water soluble catalyst in a biphasic system, in which phase-transfer additives such as ethylene glycol afforded an increased reaction yield.[9] Very recently Bannwarth[10] described the application of perfluoro-tagged triphenylphosphine derivatives in the Stille reaction. Significantly, triphenylphosphine itself was also used as a ligand, with lower overall yields than the fluoro-analogue, but still an improvement over the previously reported work.[7]

Tri-*tert*-butylphosphine [P(*t*-Bu)$_3$] has been shown by Fu to be a highly active catalyst in a variety of palladium-catalysed coupling reactions.[11,12] We now show that the combination of palladium acetate with P(*t*-Bu)$_3$ very effectively catalyses Heck and Suzuki reactions of aryl halides in $scCO_2$. The solubility of triethylphosphine in $scCO_2$ has previously been noted.[13]

We first tested P(*t*-Bu)$_3$ as a ligand in the Heck reaction, a system with which we had previous experience.[6] (Table 1, entries 1a and b). Initial results were promising, and the application of this completely non-fluorous system to the

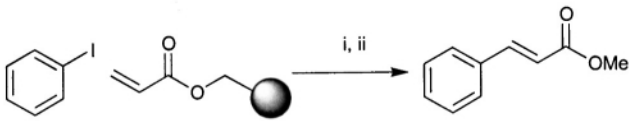

Scheme 1 *Reagents and conditions*: (i) 5 mol% $Pd(OAc)_2$, 10 mol% phosphine **1**, NEt_3, $scCO_2$, 100 °C, 40 h. (ii) NaOMe, MeOH, THF.

Suzuki reaction was also successful (entries 2–4). The yields for these reactions are not yet optimised.†

Both aryl iodides and bromides underwent the Suzuki reaction, although lower yields were obtained with the less reactive bromide coupling partners. A variety of different bases were investigated and shown to be effective in $scCO_2$. Surprisingly these reactions proceeded effectively in the presence of solid tetraalkylammonium acetate salts without addition of any other base. Jeffrey has reported the use of alkylammonium salts for the Heck reaction in conventional solvents.[14] In addition, Bannwarth reported the use of tetra-*n*-butylammonium chloride in a Stille reaction in $scCO_2$.[10] We have found in related cross coupling reactions that the acetate is superior.[15]

Solid phase organic synthesis carried out on a substrate bound to a solid, typically polymeric, support continues to be an area of intense study. The application of solid phase synthesis to palladium-catalysed reactions has been the subject of recent reviews.[16,17] Conducting reactions on a solid support provides an attractive and practical method for clean and efficient synthetic preparations, allowing convenient separation of products from the reaction mixture and forming the basis of combinatorial chemistry. Reactions using polymer supports require the use of a solvent that will swell the polymer and expose reactive sites. The ability of $scCO_2$ to plasticise polymers has been exploited in a number of applications including polymer impregnation, formation of blends and particle formation.[18] We expected therefore that $scCO_2$ would provide a good swelling solvent for polymer supported reagents, allowing access to reactive sites and reducing the amount of excess reagent required to give acceptable coverage.

We now report the successful application of solid supported substrates for palladium catalysed Heck and Suzuki couplings in $scCO_2$. The first pilot reaction employed a catalytic system of palladium acetate with the highly fluorinated phosphine $PhP(CH_2CH_2C_6F_{13})_2$, **1** (Scheme 1).[6] REM resin[19] underwent a Heck reaction with iodobenzene and the modified resin was then cleaved under basic conditions to give (*E*)-methyl cinnamate in 74% yield over the two steps.

After this initial success we then extended the palladium acetate–P(*t*-Bu)$_3$ catalytic system to substrates immobilised on a polymer resin. The Suzuki reaction was applied to a functionalised Merrifield resin and proceeded in good yield, comparable to reactions off resin (Table 1, entries 5a and b). The Heck reaction on REM resin[19] gave a near-quantitative yield (entry 6). These results clearly demonstrate the successful application of the palladium-mediated cross-coupling methodology to a heterogeneous system, and form to our knowledge the first example of the use of polymer supported synthesis in $scCO_2$.

In summary we have shown that the non-fluorinated palladium acetate–P(*t*-Bu)$_3$ catalyst system is highly active in promoting C–C bond forming reactions in $scCO_2$. We have applied this system to the first example of polymer-supported reactions in $scCO_2$.

We thank the EPSRC, AstraZeneca, the Commission of the EU (Brite-Euram Contract BRRT-CT98-5089 'RUCADI') and the Isaac Newton Trust, Cambridge for generous financial support. We thank EPSRC for provision of the Swansea Mass Spectrometry Service.

Notes and references

† Typical procedure for the Suzuki reaction in supercritical carbon dioxide: palladium(II) acetate, (11 mg, 0.05 mmol) and tolylboronic acid (204 mg, 1.5 mmol) were placed in a 10 cm^3 stainless steel cell, which was taken into a nitrogen atmosphere (glove-box) where tri-*tert*-butylphosphine (20 mg, 0.1 mmol) was added, and the cell was sealed, and removed from the glove-box. Iodobenzene (0.204 g, 1 mmol) and *N*,*N*,*N*′,*N*″-tetramethylhexane-1,6-diamine (0.172 g, 1 mmol) were injected through the inlet port. The cell was then connected to the CO_2 line and charged with CO_2 (99.9995%—further purified over an Oxisorb® catalyst) to approximately 880 psi (volume *ca.* 5 cm^3 liquid carbon dioxide). The cell was heated to 100 °C and the pressure was adjusted to 3000 psi by the addition of CO_2. The reagents were maintained at this temperature and pressure for 16 h and the cell was then allowed to cool to room temperature. The contents of the cell were vented into ethyl acetate (100 cm^3), and once atmospheric pressure had been reached the cell was opened and washed out with further ethyl acetate (20 cm^3). The combined organic fractions were concentrated *in vacuo* to give the crude product which was adsorbed onto a flash silica column using CH_2Cl_2 and eluted with hexane to give a white crystalline solid (128 mg, 76%), mp 47–48 °C (lit.[20] 49–50 °C) δ_H (400 MHz; $CDCl_3$) 7.59 (2 H, dd, *o*′-Ph, *J* 7.8, 1.2 Hz), 7.51 (2H, d, *m*-Ar, *J* 8.1 Hz), 7.44 (2 H, dd, *m*′-Ph, *J* 7.8, 7.35 Hz), 7.33 (1 H, td, *p*′-Ph, *J* 7.35, 1.2 Hz), 7.26 (2H, d, *o*-Ar, *J* 8.1 Hz), 2.41 (3 H, s, Ar-CH_3).

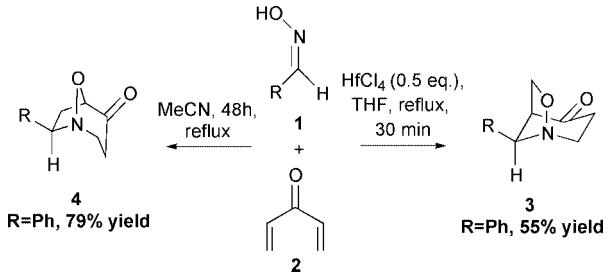
Received (in Cambridge, UK) 26th June 2001, Accepted 23rd August 2001
First published as an Advance Article on the web 19th September 2001

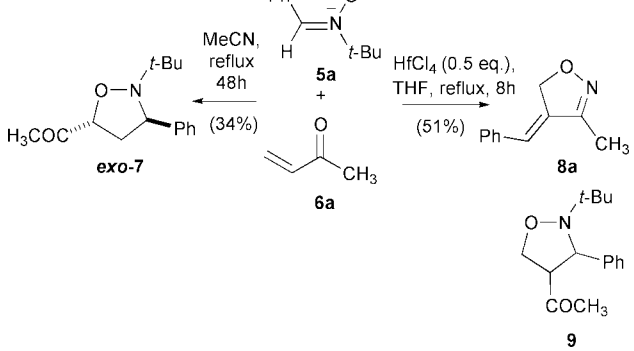
Heating alkyl vinyl ketones and *N-tert*-butylarylmethylideneamine *N*-oxides in the presence of $HfCl_4$ results in the formation of 4-methylene-4,5-dihydroisoxazoles in good yield.

We recently reported that hafnium(IV) chloride is an excellent catalyst for the tandem 1,3-azaprotio cyclotransfer–cycloaddition reaction between aldoximes and divinyl ketone, inducing the formation of the *exo*-isomers of substituted 1-aza-8-oxabicyclo[3.2.1]octan-4-ones **3** and reversing the natural regioselectivity of the thermally promoted cascade (Scheme 1).[1] We proposed that the dramatic effect on regioselectivity was due to coordination of the Lewis acid to the carbonyl moiety of the intermediate nitrone enhancing nucleophilicity at the β-carbon and promoting the formation of **3**.



Scheme 1

To study the effect of $HfCl_4$ on a similar intermolecular 1,3-dipolar cycloaddition we reacted *N-tert*-benzylideneamine *N*-oxide **5a** with methyl vinyl ketone **6a**. Under thermal conditions (MeCN, reflux, 48 h) a 4 : 1 mixture of 5-substituted isoxazolidines ***exo*-7** and ***endo*-7** was obtained in 34% combined yield (Scheme 2). When the same substrates were subjected to the $HfCl_4$ catalysed conditions outlined in Scheme 1 only starting material was obtained after the usual reaction time of 30 min. Increasing the reaction time to 8 h did not result in the formation of the expected 4-substituted isoxazolidine **9** but, instead, furnished 4-methylene-4,5-dihydroisoxazole **8a** (80% conversion of nitrone, 51% yield). The structure of **8a** was determined by X-ray crystallography (Fig. 1).† Anhydrous $Sc(OTf)_3$ also induced the formation of **8a** (0.5 eq. $Sc(OTf)_3$, THF, reflux, 8 h) in slightly lower yield (80% nitrone conversion, 48% yield) whereas the addition of $ZnBr_2$ (0.5 eq.) under otherwise identical reaction conditions did not induce the formation of **8a** (^{1}H NMR indicated that the crude reaction mixture was comprised of starting material and traces of the products of a 1,3-dipolar cycloaddition).



Scheme 2

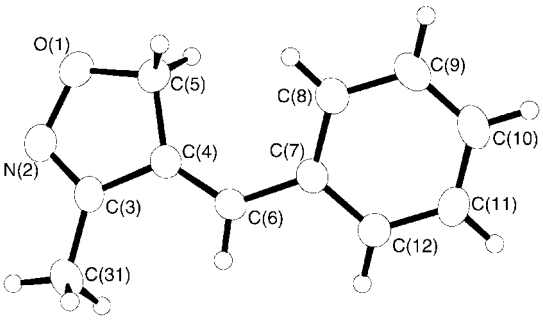


Fig. 1 X-Ray crystal structure of **8a**.†

Further development of this process identified conditions that afford reproducible results (Scheme 3).[2] The methodology encompasses both electron-donating and electron-withdrawing groups on the aromatic ring and variation of the ketone component (**6a–c**) (Table 1). In addition to **8a–h**, which were obtained as single stereoisomers, traces (5%) of the corresponding aromatic aldehydes (from degradation of **5a–f**, *vide infra*) were visible in the ^{1}H NMR spectra of crude products. The stereochemistry of the double bond in compounds **8b–h** was assigned by correlation of the chemical shift and coupling constants of the C=CH and CH_2 moieties in the ^{1}H NMR spectra with those obtained for **8a**.

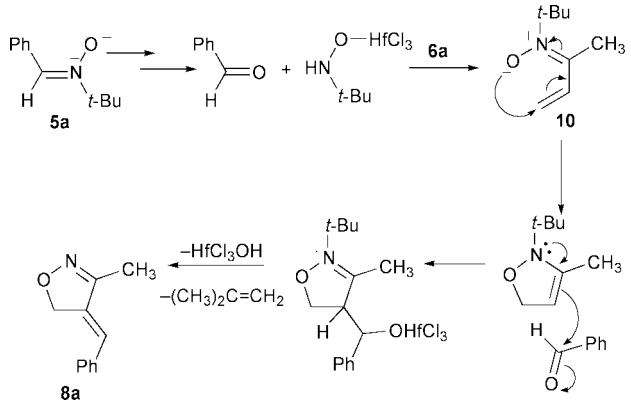
Table 1 Hafnium(IV) chloride mediated synthesis of 4-methylene-4,5-dihydroisoxazoles

Nitrone	Vinyl ketone	Product[a]	Yield[b] (%)
5a	**6a**	**8a**	75
5b	**6a**	**8b**	76
5c	**6a**	**8c**	68
5d	**6a**	**8d**	54
5e	**6a**	**8e**	64
5f	**6a**	**8f**	70
5a	**6b**	**8g**	64
5a	**6c**	**8h**	31

[a] In all cases apart from **5a** + **6a**, small amounts (5–10%) of the corresponding aldehydes were detected by ^{1}H NMR. [b] Yield isolated by flash chromatography.

The mechanism of the reaction is a matter of conjecture at present. $HfCl_4$ catalysed degradation of nitrone **5a** may generate benzaldehyde and a hafnium complexed hydroxylamine if traces of water are present in the system. Indeed small amounts of the corresponding aromatic aldehydes are visible in the ^{1}H NMR spectra of the crude products and the amount of these was found to be proportional to the quantity of catalyst and reaction time. The hydroxylamine may react with **6a** to generate nitrone **10**[3] followed by a 6π-electrocyclisation–aldol condensation–dehydration sequence to generate **8a** (Scheme 4). Analogous 6π-electrocyclisation reactions are well known.[4–6]



Scheme 4

In summary, we report a novel route to 4-methylene-4,5-dihydroisoxazoles from readily available starting materials.[7] The synthetic value of these systems, and conventional methods to generate them are the subject of a recent review by Zecchi *et al*.[8] Further studies of the mechanism and scope of the reaction are in progress.

First published as an Advance Article on the web 19th September 2001

Hollow spheres of MCM-41 mesoporous aluminosilicates, with two small holes on the shell, have been synthesized from a surfactant–aluminosilicate gel composite.

Hollow spherical ceramic materials of micron size have received a lot of recent attention due to their potential applications in drug-delivery, adsorption, and catalysis.[1–3] The standard approach for generating hollow spheres is to use organic polymer beads as the templates which control the size of the void volume.[4,5] However, large entities such as macromolecules usually cannot penetrate such spheres because of the microporous shell. It would be desirable to leave a macro-hole on the shell surface for transporting macromolecules. Furthermore, a mesoporous shell of the hollow sphere would allow simultaneous embedding of smaller molecules.

In this paper, we report a liquid crystalline/sol–gel approach to the synthesis of vesicular mesoporous aluminosilicates MCM-41. Both the diameters of the hollow spheres and the aluminium content of the materials can be controlled. The vesicular hollow spheres of MCM-41 were reasonably supposed to possess a pair of holes of submicron size on exactly opposite sides.

The hollow spheres of MCM-41 aluminosilicates were prepared according to our previously reported delayed neutralization procedure at 27 °C.[6,7] Typically, the surfactant myristyltrimethylammonium bromide, $CH_3(CH_2)_{13}N(CH_3)_3Br$, ($C_{14}$TMAB), as organic template, and butanol (BuOH), as cosurfactant, were dissolved in sufficient water to form a clear solution. Sodium silicate was added and mixed thoroughly. Then 1.2 M H_2SO_4 (aq) was gradually added to adjust the pH value of the gel solution to *ca*. 9.0. Finally, the gel solution was combined with the required amount of sodium aluminate ($NaAlO_2$). The molar ratios of the resulting gels were 1 C_{14}TMAB : 1.50 SiO_2 : 1.20 NaOH : 0.48 H_2SO_4 : (0.02–0.1) $NaAlO_3$: (1.25–1.85) BuOH : 200 H_2O. The vesicular sphere products were obtained by filtering the solution after hydrothermal treatment at 100 °C for 6 h. After washing with deionised water, drying and calcination at 580 °C in air, hollow spheres of MCM-41 mesoporous aluminosilicate were obtained.

In Fig. 1(A), we see that the aluminosilicate spheres were produced in high yield (~95%) and uniform size (5.0 μm). From some broken spheres (broken by the scraper during the SEM sample preparation process), one can easily distinguish that the micrometer-sized spheres are hollow (Fig. 1(B)). Without the use of sodium aluminate, we previously obtained hollow spheres with a center pillar inside.[7] TEM micrographs (not shown here) of microtomed samples also show the hollow insides of the spheres. Careful checking under higher magnification showed that the surface of every hollow sphere contains a tiny hole of *ca*. 0.1 μm in diameter (Fig. 1(C)). The existence of this tiny hole would allow the large internal void space of the sphere to be more accessible to larger entities such as viruses or macromolecules. An ultra-thin film microtome TEM micrograph of the shell of a hollow sphere is illustrated in Fig. 1(D). This enables the mesostructure of the shell to be examined and clearly shows the hexagonal-arrayed honeycomb mesostructures of MCM-41. This well-aligned structure is in agreement with its XRD pattern, which possesses 3–4 sharp peaks (see ESI†).[8,9]

To understand the direction of the nanochannels on the shell of the hollow sphere, we carefully observed the nanochannels near the tiny hole on the shell under a TEM. Fig. 2(A) clearly shows that the nanochannels of the hollow sphere of the MCM-41 mesoporous aluminosilicates are arranged concentrically around the hole. Taking the hole as the north pole of the sphere, the nanochannels are arranged in the latitudinal direction to form the shell. This is in agreement with our previous observation that nanochannels arrange latitudinally in pillar-within-spheres structures except that this time the center pillar is removed, leaving holes in the shell at the bases of the pillar. The

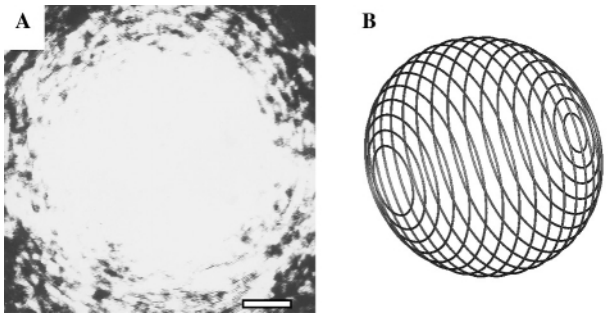

Fig. 2 (A) A HR-TEM micrograph showing nanochannels arranging around the tiny hole. The scale bar in this figure is 110 nm. (B) A schematic diagram of the vesicle-like sphere of aluminosilicates MCM-41.

fact that we can always see only a single hole on the shell leads us to the logical conjecture that every hollow sphere possesses two tiny holes on opposite sides. A schematic diagram of the hollow sphere is shown in Fig. 2(B). Although a direct microscopic observation of both polar holes on a hollow sphere was not obtained, the existence of the tiny holes at both poles can be reasonably explained. The singularity at the pole gives too high an energy penalty to form closed hollow spheres.[10,11] This hollow sphere with two tiny holes at both poles is a novel hierarchical structure that has not previously been identified. Compared with our previous pillar-within-sphere structure,[7] the aluminium component apparently makes the center pillar position of higher energy and the aluminosilicate materials are deposited around the waist to make a thicker shell.

In addition to making hollow spheres with an Si/Al ratio of 30, we can prepare samples with different aluminium contents by simply adding different amounts of sodium aluminate. In the range Si/Al = 15–70, hollow spheres of MCM-41 aluminosilicates with well-aligned mesostructures have been obtained. By examining the ^{27}Al MAS NMR spectra of the uncalcined hollow spheres, we found that only one peak at 54 ppm, referenced to a dilute aqueous solution of $Al(NO_3)_3$, was observed in each sample. This indicates that all the Al atoms are incorporated in the silica framework to form the hollow sphere.[12]

We can also control the size of the hollow spheres. In lyotropic surfactant liquid crystals, the rigidity of the surfactant assembly, such as the membrane, decreases with the amount of cosurfactant alkanol.[13,14] Accordingly, we changed the BuOH/C_{14}TMAB ratio in the reaction mixture. Fig. 3 demonstrates that the diameter of the hollow sphere decreases with an increase of the BuOH/C_{14}TMAB ratio, as we expected. However, the size range can be adjusted only in the range of 2.5 to 7.6 μm using the C_{14}TMAB–BuOH–aluminosilicate–water composition. Outside this range, the morphology will transform into fine particles or tubules-within-tubules structures.[15] We found that

Table 1 The physical properties of the hollow spheres of MCM-41 mesoporous aluminosilicates with different diameters and Si/Al ratio composites

Diameter/ μm	Si/Al	d_{100} value/nm	Pore size[a]/nm	BET surface area/ $m^2\ g^{-1}$	Porosity[b]/ $cm^3\ g^{-1}$
7.5	30	3.25	2.25	960	0.67
5.0	30	3.30	2.30	975	0.65
2.8	30	3.32	2.23	1002	0.62
5.0	60	3.42	2.28	996	0.70
5.0	15	3.25	2.20	952	0.63

[a] The central value of the pore size distribution calculated from the N_2 adsorption isotherm branch using the BJH method. [b] The N_2 adsorption value at $P/P_0 = 0.9$.

the tiny hole size ranges from *ca.* 0.05–0.1 μm and is not apparently dependent on sphere diameter.

Table 1 lists the physical properties of the hollow spheres with various diameters and Al contents. Comparing these data, the surface area, pore size and porosity are not significantly affected by the aluminium content or the diameter. For different Al contents and various sphere diameters, high yields of vesicular hollow spheres of MCM-41 materials with high surface area, uniform pore size and large porosity have been successfully synthesized using a simple self-organization approach.

The discovery of such an intricate hollow spherical topology with two tiny holes at the poles of the sphere will also be interesting to the physics of complex biomineralization processes. It will enrich our ability to build hierarchical complex inorganic–organic composite structures using the bottom-up approach.

Banana-shaped mesogens: observation of a direct transition from the antiferroelectric B_2 to nematic phase†

R. Amaranatha Reddy, B. K. Sadashiva* and Surajit Dhara

Raman Research Institute, C.V. Raman Avenue, Bangalore 560 080, India. E-mail: sadashiv@rri.res.in

Received (in Cambridge, UK) 19th July 2001, Accepted 22nd August 2001
First published as an Advance Article on the web 19th September 2001

The synthesis and characterisation of the first banana-shaped mesogens which exhibit a direct transition from the antiferroelectric B_2 phase to the nematic phase are reported.

During the last couple of years there has been an upsurge in the synthesis and phase transition studies of compounds composed of banana-shaped or bent-core molecules because of the unusual and very interesting mesophases they exhibit. The detection of ferroelectricity in the mesophase of such an achiral compound by Niori *et al.*,[1] which was later determined to be antiferroelectric in the ground state[2–4] by current response measurements, have stimulated further research in this field. Several hundred compounds with a bent molecular shape have been synthesised so far and at least seven different banana (B) phases characterised.[5,6] It has been observed that in many homologous series of compounds only one banana phase exists in one homologue. However, smectic A, smectic C or nematic phases have been obtained either individually or in combination particularly for homologues with short terminal chains. Although the nematic phase has been observed in many series of bent-core molecules,[7–11] there is no example of a compound exhibiting a direct transition from the B_2 phase to nematic. Very recently there was a report of a case in which the B_2 phase and a nematic phase are observed in the same substance and the two are separated by smectic A and smectic C phases.[12] It would be very interesting and useful from an experimental point of view if one could get a direct transition from the antiferroelectric B_2 phase to the nematic phase. We have achieved this objective and report our results in this communication.

The synthesis and characterisation of four compounds composed of banana-shaped molecules, three of which represent the first examples which show a direct transition from the antiferroelectric B_2 to nematic (N) phase transition, is described here. The general method of preparation of the compounds is shown in Scheme 1. As reported[10] by us earlier, 2,7-dihydroxynaphthalene **1** was reacted with 2-fluoro-4-benzyloxybenzoic acid **2** to give the diester **3**. The protective benzyloxy groups were removed using 5% Pd–C as catalyst in an hydrogen atmosphere to yield the diphenol **4**. In the final step (iii) compound **4** was reacted with two equivalents of an appropriate (*E*)-4-*n*-alkoxy-α-methylcinnamic acid to furnish compound **5**.‡ All the compounds were purified by column chromatography (silica gel, 60–120 mesh) and were crystallised several times using suitable solvents.

The liquid-crystalline properties of the compounds were investigated by using optical polarising microscopy and differential scanning calorimetry (DSC). The transition temperatures together with the associated enthalpies are summarised in Table 1. On examination of the samples under a polarising microscope the following are observed. Compound **5**, n = 12, melts into a nematic phase and on cooling the isotropic (I) liquid shows typical schlieren texture. On further cooling, small broken-fan like texture emanates from the nematic phase and the field of view is completely filled with this texture. Fig. 1 shows a typical texture wherein the broken-fans are appearing from the nematic phase and this phase transition is enantiotropic. Compounds **5**, n = 13 and n = 14, are enantiotropic in both nematic and the lower temperature phase while compound **5**, n = 16, is also enantiotropic but without the nematic phase. The N→I transition enthalpy is about 0.4 kJ mol^{-1}. A DSC thermogram obtained for compound **5**, n = 13, is shown in Fig. 2 and all the transitions can be seen clearly.

In order to confirm the nature of the lower temperature phase of these compounds, X-ray investigations were carried out. The X-ray diffraction experiments were conducted using Cu-Kα radiation from a rotating anode generator with a flat graphite crystal monochromator. The diffraction patterns were collected on an image plate (Marresearch). The unoriented sample was contained in a Lindemann capillary and the temperature was controlled to within ±0.1 °C. The diffraction pattern of an unoriented sample of the mesophase of compound **5**, n = 14,

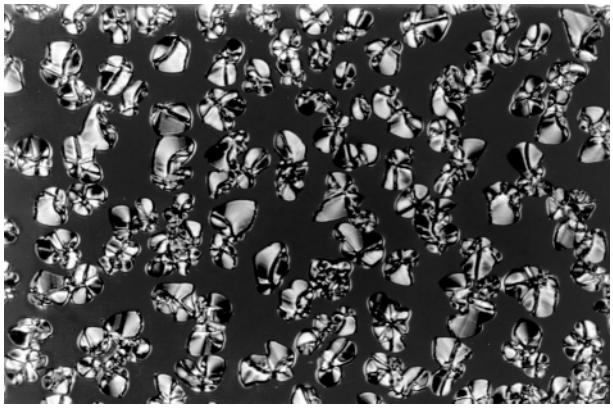

Fig. 1 Photo-micrograph of the B_2 phase appearing on cooling from a homogeneously aligned nematic phase, compound **5**, $n = 13$ (magnification $\times 300$).

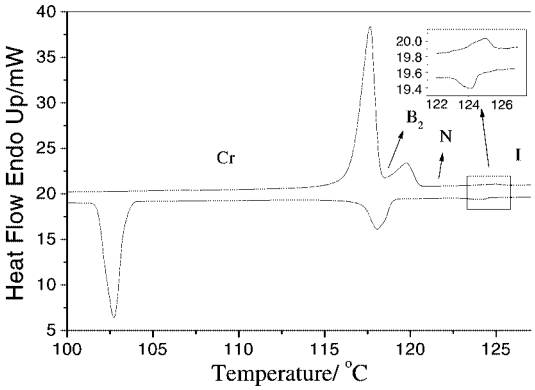

Fig. 2 Differential scanning calorimetric scan of compound **5**, $n = 13$ showing clearly the transition from the B_2 to the nematic phase. The insert shows the amplified N→I transition.

shows a diffuse peak in the wide angle region with $d = 4.6$ Å, indicating liquid-like in-plane order. In addition, three orders of lamellar reflections (in the ratio 1 : 2 : 3) in the small angle region could be clearly seen. From this as well as the textural characteristics we have identified this mesophase to be a B_2 phase.

Finally, the characteristic feature of the B_2 phase, namely the switching current response, was carried out on the mesophase of compound **5**, $n = 14$. An electro-optical switching cell was constructed using two ITO coated glass plates pre-treated with polyimide which enables the sample to align homogeneously. The cell thickness was adjusted to be 6 μm by using appropriate spacers. The sample was filled in the isotropic phase and cooled slowly. A very good alignment of the nematic phase was obtained. On further slow cooling under a low frequency AC triangular voltage, well formed domains of the B_2 phase over the entire field of view were seen. From the visual observations under the polarising microscope, we see colourful circular domains which switch above a threshold voltage. Simultaneously two very sharp current peaks could be seen on the oscilloscope screen for the half period of the triangular voltage (250 V_{pp}). A typical switching current response for this compound is shown in Fig. 3. The current was measured across a 10 kΩ resistance. The apparent 'saturated polarisation' P_s was obtained by measuring the area under the peaks and is about 560 nC cm^{-2}. These observations clearly indicate the antiferroelectric nature of this phase.

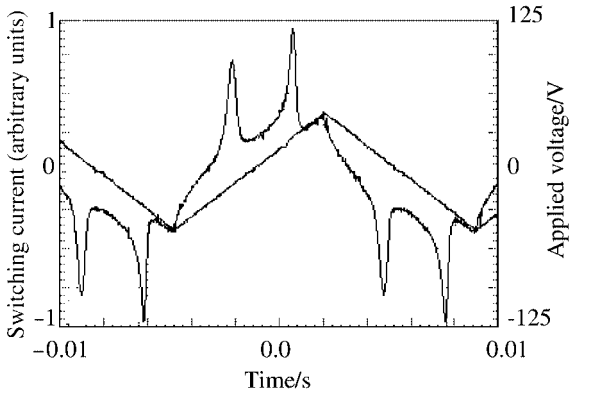

Fig. 3 Switching current response obtained in the B_2 phase of compound **5**, $n = 14$ at 120 °C by applying a triangular voltage (cell thickness: 6 μm, 250 V_{pp}, 29 Hz). (V_{pp} = volt peak-to-peak.)

The presence of this uniaxial nematic phase, as evidenced by numerous $s = \pm 1$ disclinations and fewer $s = \pm\frac{1}{2}$ defects above the B_2 phase helps to align the latter and may contribute to making the measurement of other physical properties of this interesting antiferroelectric phase rather easy.

The authors thank Dr V. A. Raghunathan for help with the X-ray measurements and Mrs K. N. Vasudha for technical support.

Notes and references

‡ The chemical structure of the compounds listed in Table 1 was determined from their spectral data. Typical data obtained for compound **5**, $n = 13$ is given below. γ_{max} (KBr) cm^{-1} 2910, 2850, 1740, 1720, 1605, 1508, 1415, 1250, 1190; δ_H (400 MHz, $CDCl_3$) 8.22 (t, *J* 8.72 Hz, 2H, Ar-H), 7.94 (d, *J* 8.92 Hz, 2H, Ar-H), 7.9 (s, 2H, Ar-CH=C), 7.72 (d, *J* 2.0 Hz, 2H, Ar-H), 7.47 (d, *J* 8.76 Hz, 4H, Ar-H), 7.39 (dd, *J* 2.08 Hz, 2H, Ar-H), 7.13–7.17 (m, 4H, Ar-H), 6.96 (d, *J* 8.68 Hz, 4H, Ar-H),4.01 (t, *J* 6.56 Hz, 4H, 2 × Ar-OCH_2), 2.27 (d, *J* 0.88 Hz, 6H, 2 × Ar-C=C(CH_3)), 1.81 (quin., *J* 6.68 Hz, 4H, 2 × Ar-OCH_2-CH_2), 1.26–1.48 (m, 12H, 6 × CH_2), 0.88 (t, *J* 6.64 Hz, 6H, 2 × CH_3); δ_C (400 MHz, $CDCl_3$) 166.3, 162.1, 161.5, 159.9, 156.4, 149.0, 141.7, 134.3, 133.3, 131.8, 129.7, 129.3, 127.6, 124.2, 121.1, 118.6, 117.8, 115.1, 114.6, 111.4, 111.2, 68.2, 31.9, 29.6, 29.5, 29.3, 29.1, 25.9, 22.6, 14.2, 14.0.

First published as an Advance Article on the web 10th September 2001

β-Cyclodextrin catalyses for the first time the asymmetric reduction of α-azido aryl ketones to corresponding alcohols of great significance using sodium borohydride in water. The azido group appeared to be the best fit among various groups studied. This asymmetric reduction using water as solvent overcomes many of the drawbacks in the existing methodologies.

Chiral vicinal azidohydrins are of great significance in asymmetric catalysis,[1] chemistry of carbocyclic nucleosides[2,3] and also as precursors for a wide range of pharmaceuticals such as β-blockers and agonists in the treatment of cardiovascular disease, cardiac failure, asthma and glaucoma.[4] However, synthetic methodologies reported until recently consist mainly of either asymmetric ring opening of oxiranes in the presence of chiral organometallic complexes[5] or reduction of prochiral ketones catalysed by oxazaborolidines in presence of $BH_3{\cdot}SMe_2$ *etc*.[6] involving the use of anhydrous organic solvents, moisture sensitive catalysts, expensive and toxic reagents. In view of these limitations, there is still a need for a mild, simple and widely applicable alternative approach to these highly valuable compounds. The best choice would be through supramolecular catalysis involving water as solvent, which is environmentally benign, however, this still remained as a goal.

Though the reduction of some substituted aryl alkyl ketones using sodium borohydride in the presence of cyclodextrin have been reported earlier, the results are not encouraging (optical yields up to 36% ee).[7] However, no attempts have been made so far to involve α-azido aryl ketones in supramolecular catalysis to get the versatile azidoalcohols. In our efforts to develop biomimetic approaches for chemical reactions including asymmetric catalysis using cyclodextrins(CDs),[8] we report herein the first biomimetic approach for the asymmetric synthesis of α-azidoalcohols **2** by reduction of the corresponding ketones **1** as their β-cyclodextrin complexes in water using sodium borohydride (Scheme 1).

Cyclodextrins, which are cyclic oligosaccharides, catalyse reactions by supramolecular catalysis through non-covalent bonding by formation of reversible host–guest complexes as seen in enzymes. Cyclodextrins' chirality can also induce asymmetric reactions but the utility of CDs in asymmetric synthesis is still limited.[8a,e,f, 9,11]

In CD catalysed asymmetric reactions, the following criteria are required to be met for chiral induction: a phenyl ring in the substrate to form the CD inclusion complex and a functional group to interact with CD hydroxy groups to attain rigidity for chiral recognition. Since α-azido aryl ketones **1** conform to these criteria, they have been chosen as substrates for chiral asymmetric reduction. The complexes were formed with β-cyclodextrin since it is the most inexpensive and easily accessible of the cyclodextrins.

The reductions were carried out as follows: β-CD (1 mmol) was dissolved in water (15 ml) and heated up to 60 °C until a clear solution was formed. Then α-azido aryl ketone **1** (1 mmol) dissolved in acetone (1 ml) was added dropwise and allowed to come to room temperature. Later, the reaction mixture was cooled in an ice bath and sodium borohydride (5 mmol) was added slowly, brought to room temperature and stirred for 24 h. It was then quenched with hydrochloric acid (2 M, 10 ml), extracted with ethyl acetate, dried and concentrated under reduced pressure. The crude product was purified by column chromatography on silica gel. The yields obtained were good, ranging from 90–96% and the enantioselectivities observed were also impressive in some cases showing up to 81% ee (Table 1). The ratio of β-CD to the substrate **1** appeared to be

Table 2 Effect of concentration of β-CD on enantioselectivity as shown by **2e**

Entry	Ratio (β-CD–**1**e)	Ee(%)
1	1.5 : 1	80
2	1 : 1	80
3	0.75 : 1	37
4	0.50 : 1	14
5	0.25 : 1	0

optimum at 1 : 1 since a lower ratio of β-CD led to a decrease in ee whereas a higher ratio has not shown any improvement in enantioselectivity (Table 2). The enantiomeric excesses (ee) of the products were determined by chiral HPLC analysis. These compounds have been shown to have *S* configuration by comparison of the sign of rotation with those of the known compounds.[6] An interesting feature of this reaction is that the substrates having electron donating substituents on the aromatic ring have shown higher enantioselectivity compared with the electron withdrawing substituents (Table 1). This may be ascribed to additional stabilization of the transition state of carbonyl–borohydride complex by electron donating substituents which can result in better enantioselectivity. However, this will be complimentary to other factors.

Among the compounds studied, compound **2i** with an isopropoxy group has shown the highest enantioselectivity (81% ee) followed by **2e** (80% ee), **2f** (73% ee), **2g** (66% ee), **2h** (53% ee) and **2a** (52% ee) whereas lower enantioselectivities were observed with the rest of the compounds (0–12% ee). To study the effect of substitution on enantioselectivity, the azido group was replaced by H, OH and OTBDMS with increasing bulkiness. Though increase in bulkiness in this series (**2k–q**) has led to enhancement in enantioselectivity (Table 1) with **2p** showing a maximum of 61% ee, the ketones with azide group (**2a–j**) appeared to fit best in the CD cavity for reduction with sodium borohydride giving an ee up to 81% (Table 1).

The inclusion complex formation was observed from ^{1}H NMR spectra[10] and powder X-ray spectra[11] of the solid CD complexes. Hydrogen bonding of substrates with CD hydroxy groups was seen from IR by a shift of the C=O stretch to lower frequency in CD complexes (in the range of 2–53 cm^{-1}) compared with the uncomplexed substrates. Stronger shifts were observed for the substrate–CD complexes which yielded products with higher ee. Thus, the CD induced asymmetric reductions by supramolecular catalysis may involve various factors such as hydrophobic binding, carbonyl exposure to the CD rim of secondary hydroxy groups, a decrease in the degrees of freedom of the guest molecule possibly through hydrogen bonding, favorable control of geometry in the approach of the substrate to the 'active site' *etc*. A balance of these interactions determines the enantioface selectivity.

These CD mediated water solvent reactions are very useful both from economical and environmental points of view and also for the practical convenience of not having to handle flammable anhydrous organic solvents or toxic and expensive reagents. β-Cyclodextrin, apart from being non-toxic, is also considered as metabolically safe.[12] Thus, the present methodology for the synthesis of chiral 2-azido-1-arylethanols of great significance in asymmetric synthesis and medicinal chemistry involving water as solvent may be considered as simple from the practical point of view with great potential for future applications.

MAR thanks CSIR, New Delhi, India for the award of a fellowship.

Acenaphthenic hopanoids, a novel series of aromatised triterpenoids occurring in crude oil

Teresita Carrillo-Hernández, Philippe Schaeffer and Pierre Albrecht*

Laboratoire de Géochimie Organique, Faculté de Chimie, Université Louis Pasteur, 1 rue Blaise Pascal 67 000. Strasbourg, France. E-mail: albrecht@chimie.u-strasbg.fr; Fax: +33-3 90241764; Tel: +33-3 9024 1696

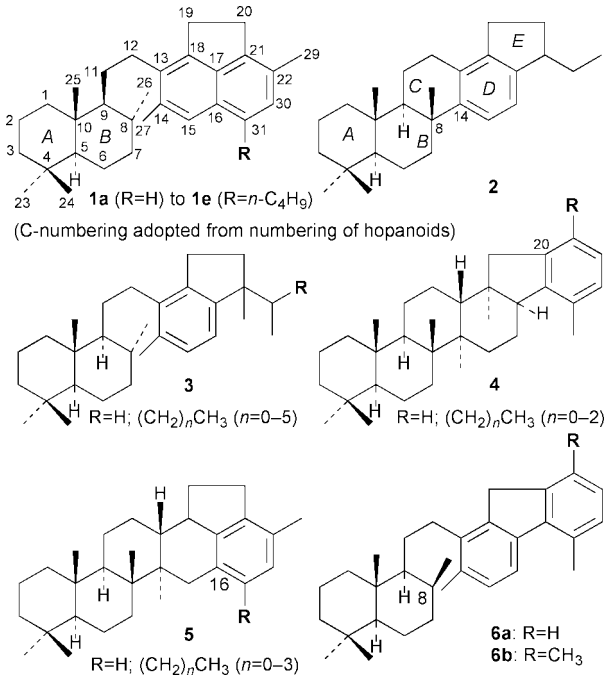
Received (in Cambridge, UK) 13th June 2001, Accepted 30th August 2001
First published as an Advance Article on the web 10th September 2001

A series of diaromatic 8,14-secohopanoids of microbial origin has been characterized in a petroleum by NMR studies, disclosing novel geochemical transformations.

In the course of our studies dealing with the geochemical characterization of Mexican crude oils, coupled gas chromatography–mass spectrometry (GC-MS) investigation of the 'triaromatic' hydrocarbon fraction separated by thin layer chromatography (SiO_2, hexane as developer) from Lacantún petroleum† revealed the presence of a homologous series of 5 compounds **1a–e** with unknown mass spectra.‡ The lowest homologue **1a** is characterized by a molecular ion at 402 ($C_{30}H_{42}$) and a base peak at *m/z* 195 ($C_{15}H_{15}^+$) which could correspond to an alkylated acenaphthene moiety. In the mass spectra of the higher homologues, the major fragment and the molecular ion are shifted upwards by $n \times 14$ mass units (n = 1–4), indicating that this series extends up to the C_{34} homologue (M_w 458). These mass spectral features, together with the fact that the homologous series ranges from C_{30} to C_{34}, suggest that these new compounds may be related to 8,14-secohopanoids bearing an acenaphthene moiety.[1]

To unambiguously establish the structure of these novel aromatic hydrocarbons, isolation of the predominant C_{30} (**1a**, R = H) and C_{31} (**1b**, R = CH_3) homologues was carried out.§

Following HPLC purification, the structure of compound **1a** was determined by exhaustive 1D and 2D NMR studies including ^1H–^1H COSY, NOESY, direct (HMQC) and long-range (HMBC) ^1H–^{13}C correlation experiments (Table 1). The ^1H spectrum shows the presence of 3 aromatic protons (2 doublets at 7.16 and 7.36 ppm and 1 singlet at 7.32 ppm), 2 benzylic methyl groups (singlets at 2.36 and 2.49 ppm), 3 methyls on quaternary carbons and 1 methyl on a tertiary carbon (doublet at 1.08 ppm). The major part of the carbon framework, including notably the dimethylated acenaphthene moiety was unambiguously established from the ^1H–^{13}C long-range ($^{2,3}J$) connectivities (Fig.1).



The connection between the bicyclic aliphatic and the aromatic moieties was determined by the presence of a coupling between H-9 and CH_2-11 in the COSY experiment.

Stereochemical information, notably concerning the *trans* junction of rings *A* and *B*, could be obtained from the NOESY experiment (Fig. 1) and is also confirmed by the chemical shifts of the protons and carbon resonances. For example, the shielded ^{13}C signal and deshielded ^1H signal for H-5 is in agreement with an axial orientation. Similarly, the high-field ^{13}C signal ($\delta < 20$ ppm) of CH_3-25 indicates that this methyl at the ring junction is

axial (presence of γ-*gauche* effects). The equatorial position of CH_3-26 could be established due to the presence of nuclear Overhauser effects between H-8 and CH_3-25, and H-9 and CH_3-26 (Fig. 1).

The ^{1}H NMR spectrum of compound **1b** is almost identical to that of compound **1a**, except for the presence of 1 additional benzylic methyl group superimposed for CH_3-27 at 2.52 ppm and the presence of only 2 aromatic protons. Both protons are uncoupled and resonate at 7.00 (H-30) and 7.39 ppm (H-15), indicating that the methyl group is located at C-31, as expected for a homohopanoid structure.[1]

Aromatisation processes of polycyclic terpenoids are widespread in the sub-surface. Such transformations may be induced by microorganisms at the earliest stages of diagenesis, as demonstrated in the case of higher plant pentacyclic triterpenoids.[2] Alternatively, aromatisation may occur at subsequent stages of dia- and catagenesis *via* abiotic processes, notably driven by thermal stress. Among sedimentary hopanoids, which are molecular fossils of bacteria ubiquitous in geological samples,[1] several aromatic hydrocarbons have been identified. Thus, the presence of functionalities (*e.g.*, double bonds) in intermediates like hop-17(21)-enes or neohop-13(18)-enes may initially trigger aromatisation in ring *D* (*e.g.*, compound **2**) and progress from ring *D* to ring *A*.[3] Aromatisation of ring *D* may also occur in connection with cleavage of the weak C-8(14) bond, yielding monoaromatic 8,14-secohopanes **3**.[4] Aromatisation of hopanoids may also operate at relatively early stages of diagenesis under a different mechanism which involves cyclisation of the hopanoid side-chain at position 20 or 16, leading to the formation of benzohopanes **4** and **5**, respectively.[4,5]

Recently, the aromatic 8,14-secohopanoid **6a** bearing a fluorene moiety has been isolated from the solvent extract of an immature sediment from the Jurassic Kimmeridge Clay Formation and has been characterized by NMR studies.[6] The presence of this compound, which is formed by cleavage of the C-8(14) bond, followed by aromatisation of ring *D* and by cyclization–aromatisation of the hopanoid side chain at C-20, indicates that both aromatisation processes may be operative on the same molecule upon diagenesis or early maturation. In the crude oil from Lacantún, ring *D* monoaromatic 8,14-secohopanoids, **3**, and benzohopanes cyclized at C-20, **4**, occur in relatively high amounts, whereas benzohopanes cyclized at C-16, **5**, are completely absent. Surprisingly, no fluorene hopanoid derivatives such as **6** could be detected, whereas those corresponding to the novel series **1** represent the predominant polyaromatic polycyclic hydrocarbons. It can be proposed that given the relative high maturity reached by Lacantún crude oil, the benzohopanes **5** originally present have been converted into more stable C_{30}–C_{34} hopanoid derivatives belonging to series **1**. This process involves cleavage of the C-8(14) bond and formation of a fused aromatic ring by hydrogen transfer reactions well established to occur in the sub-surface.[7] In contrast, it is likely that compounds **6a**,**b** are not formed by a maturity-driven process, but rather originate from a specific intermediate or precursor.[6] Indeed, these compounds have been characterised in quite immature samples and possess an axial methyl group at C-8, unlike compound **1a** which bears an equatorial methyl at C-8. Furthermore, the C_{32} homologue **6b**, present in trace amounts, represents the highest homologue of this hopanoid fluorene series detected thus far in sediments, whereas benzohopanes **4** usually occur as a series of four homologues (*i.e.*, C_{32}–C_{35}).[4–6] These features seem therefore to indicate that despite some structural similarities, aromatised hopanoids **1** and **6** are formed at different stages of maturity by distinct processes.

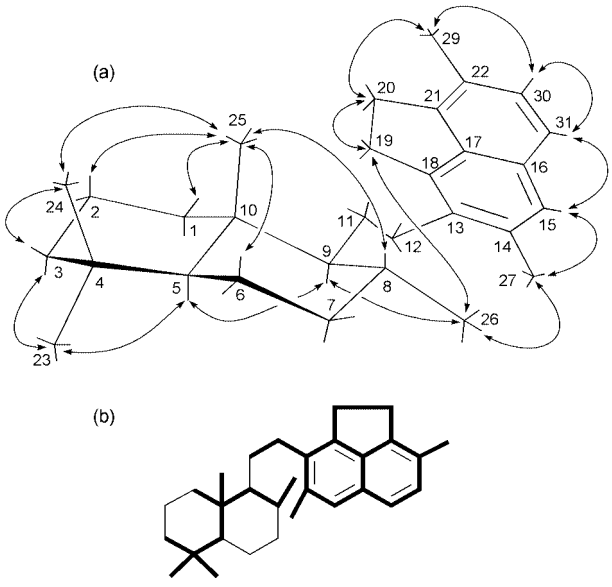

Fig. 1 (a) Spatial representation of **1a** showing the main NOEs observed. (b) In bold: carbon sequence established from the inverse long range ^{1}H–^{13}C (HMBC) correlation experiment.

We thank Drs M. A. Guzmán Vega and J. Connan for providing the crude oil samples from Lacantún, Drs P. Adam and J. M. Trendel for helpful discussions and E. Mastio and Dr R. Graff for their assistance in MS and NMR measurements, respectively. The Instituto Mexicano del Petroleo is acknowledged for financial support (T. C.-H.).

Adsorption and separation of amino acids from aqueous solutions on zeolites

Sven Munsch, Martin Hartmann and Stefan Ernst*

Department of Chemistry, Chemical Technology, University of Kaiserslautern, PO Box 3049, D-67653 Kaiserslautern, Germany. E-mail: sernst@rhrk.uni-kl.de; Fax: +49(0)631-205-4193; Tel: +49(0)631-205-3587

Received (in Cambridge, UK) 18th June 2001, Accepted 21st August 2001
First published as an Advance Article on the web 10th September 2001

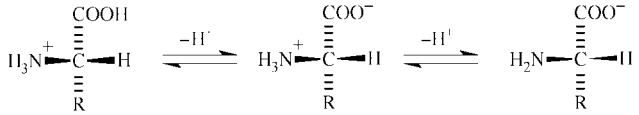
The adsorption of various amino acids on zeolites with different structures was studied with regard to dependence of the pH value of the solution and the aluminum content of the zeolite in order to design tailor-made adsorbents for amino acid separations.

Amino acids are used on a large scale as supplements to stock feed and to improve the quality of proteins in food technology. There are several routes for the production of amino acids, *e.g.*, their extraction from natural primary products (*e.g.* feathers), chemical or enzymatic synthesis and microbiological fermentation. All of these methods require the use of separation techniques in order to recover and purify amino acids with similar chemical properties. Beside several chromatographic techniques,[1] organic ion exchange resins are usually used for the recovery of the desired amino acid.[2] A process for the separation of amino acids from aqueous fermentation broths by bringing these solutions into contact with zeolites was claimed recently.[3] Moreover, several zeolites were tested in the separation of leucine and isoleucine from aqueous solutions,[4] but the fundamentals of the decisive interactions between the amino acids and the zeolite framework are still unknown.

To learn more about these interactions, the adsorption of various amino acids has been studied on different zeolites. For this purpose, zeolites ZSM-22, ZSM-5, ZSM-11, MCM-58, Beta and dealuminated Y were synthesized as described in the open literature, calcined at 813 K, subsequently repeatedly ion-exchanged in NH_4NO_3 solution and finally calcined at 723 K to obtain the protonated forms. Characterization of the adsorbents prior to and after the adsorption process was performed by chemical analysis, powder X-ray diffraction and nitrogen sorption at 77 K. The adsorption experiments were conducted in the liquid phase using the batch method at 298 K. In a typical experiment, 0.3 g of the activated zeolite was brought into contact with 5 g of an aqueous solution of the amino acid or a mixture of amino acids. Adsorption equilibrium was reached within 24 h under continuous stirring. The concentrations of the amino acids at the onset of the experiments and after equilibrium were determined by high performance liquid chromatography (HPLC). The extent of adsorption from the liquid-phase is quantified by the specific reduced surface excess $n_{aa}\sigma(n)/m = n^0(x^0_{aa} - x_{aa})/m$, where n^0 is the total number of moles in the original solution and $(x^0_{aa} - x_{aa})$ the change in the molar fraction of the amino acid (aa) in solution due to adsorption on the adsorbent of mass m.[5] The adsorption isotherms were either recorded using solutions buffered at pH 6 or at varying solution pH adjusted by the addition of aqueous HCl or NaOH.

X-Ray powder patterns (not shown), recorded before and after the adsorption of amino acids show no changes, indicating that the zeolite structure remains unaffected during the course of adsorption. Pertinent nitrogen sorption data for zeolite samples before and after the adsorption of phenylalanine reveal that the micropore volume of, *e.g.*, zeolite Beta decreases from 0.28 to 0.09 $cm^3\ g^{-1}$ and for ZSM-5 from 0.17 to 0.08 $cm^3\ g^{-1}$. The significant reduction of the pore volumes due to the adsorption of phenylalanine on the zeolites indicates that the amino acid molecules are located inside the pores.

α-Amino acids are amphoteric compounds, consisting of an amino group, a carboxyl group, a hydrogen atom, and a distinctive side chain R which are bonded to one carbon atom. The ionization state of an amino acid varies with the pH value (*cf.* Scheme 1). Acidic amino acids, such as glutamic acid, additionally contain a second carboxy group in the side chain, and, hence, have a lower isoelectric point pI compared to amino acids with neutral side chains, like phenylalanine. Basic amino acids, such as lysine, contain a second amino group in the side chain, leading to a higher isoelectric point. The influence of the solution pH value on the uptake of an amino acid with an acidic (glutamic acid, pI = 3.24), a neutral (phenylalanine, pI = 5.48) and a basic side chain (lysine, pI = 9.82) on zeolite Beta (n_{Si}/n_{Al} = 25) is depicted in Fig. 1. Glutamic acid is exclusively adsorbed under acidic conditions and the amount adsorbed diminishes for solution pH values exceeding pI = 3.24. This behavior can be explained by electrostatic interactions between the positively charged amino group and the negatively charged lattice of the zeolite. Phenylalanine shows a similar behavior, but the decrease in uptake starts at higher pH since the isoelectric point of phenylalanine is higher (pI = 5.48). Although lysine is positively charged over the whole investigated pH range, its adsorption is particularly favored under strongly basic conditions. Apparently, the additional positively charged ammonium group in the side chain for lower pH results in a reduced uptake of lysine. In order to examine the influence of the nature of the side chain on the adsorption in detail, the adsorption of four amino acids containing different neutral side chains was studied on zeolites Beta and ZSM-5. The hydrophobic properties of these amino acids increase with the number



Scheme 1

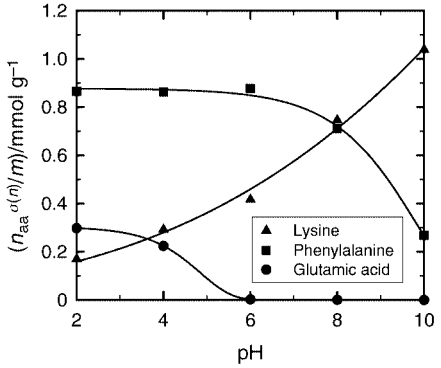


Fig. 1 Influence of the pH on the adsorption of lysine, phenylalanine and glutamic acid on zeolite Beta (n_{Si}/n_{Al} = 25).

 DOI: 10.1039/b105333g

of C-atoms in the side chain, *viz.* in the sequence: alanine (1 C) < valine (3 C) < leucine (4 C) < phenylalanine (7 C). A comparison of the specific reduced surface excesses $n_{aa}{}^{\sigma(n)}/m$ for zeolites Beta and ZSM-5 (Table 1) shows that the loadings achieved for Beta are generally higher than those for ZSM-5, which can be attributed to the different pore volumes (Beta: 0.28 $cm^3\ g^{-1}$, ZSM-5: 0.17 $cm^3\ g^{-1}$). Furthermore, the more hydrophobic amino acids are adsorbed to a considerably higher extent on both zeolites. Therefore, hydrophobic interactions seem to complement the electrostatic interactions of the amino acid with the zeolite. These hydrophobic interactions may either originate from an attraction of the non-polar side chains of the amino acids by siloxane bridges at the zeolite surface or from adsorbate–adsorbate interactions between the hydrophobic side chains of neighboring adsorbate complexes. With respect to the pronounced hydrophobic properties of phenylalanine its adsorption on ZSM-5 is unexpectedly low. The adsorbate–adsorbate interactions between the hydrophobic side chains of neighboring amino acids adsorbed on the zeolite surface are expected to be restricted by the narrow pore system of ZSM-5 and, hence, the bulky phenylalanine molecules interact to a lower extent than in zeolite Beta, which has larger pores. For a closer inspection of the hydrophobic interactions, adsorption isotherms of phenylalanine were recorded on samples of zeolite Beta with different aluminium content from buffered solutions at pH 6 (Fig. 2). The maximum amount adsorbed is nearly the same for all samples, except for the sample with the lowest n_{Si}/n_{Al} ratio of 12 with a slightly lower loading. This can be attributed to an increasing affinity to water due to the high aluminium content. The initial curvature of the corresponding isotherm changes with decreasing aluminium content of the adsorbent. For zeolite Beta with n_{Si}/n_{Al} ratios of 12 and 25, respectively, the isotherms exhibit the common Langmuir-type L-curve, but the shape changes with increasing n_{Si}/n_{Al} ratio to an S-curve. S-curves are characteristic for solutes showing only little attraction to the adsorbent, but possessing stronger intermolecular interactions.[6] At low concentrations, phenylalanine is hardly adsorbed on the surface of the aluminium-free zeolite Beta. This can be rationalized by the absence of aluminium atoms in the zeolite structure, which are the adsorption sites for the amino acids if electrostatic interactions dominate. At higher concentrations, the sudden sharp increase in the amount adsorbed reflects the change in the adsorption conditions: the number of solute molecules is now high enough to form clusters of adsorbed molecules that interact with each other *via* the hydrophobic attractions of their non-polar phenyl-groups and, hence, rapid filling of the zeolite pores with phenylalanine molecules occurs.

Table 1 Adsorption of amino acids with non-polar side chains

Adsorbent	Amino acid	$(n_{aa}{}^{\sigma(n)}/m)^a$/mmol g^{-1}
Beta (n_{Si}/n_{Al} = 25)	Alanine	0.04
	Valine	0.37
	Leucine	0.70
	Phenylalanine	0.84
ZSM-5 (n_{Si}/n_{Al} = 30)	Alanine	0.02
	Valine	0.29
	Leucine	0.40
	Phenylalanine	0.29

[a] Specific reduced surface excess values for equilibrium molar fractions of x_{aa} = 0.001.

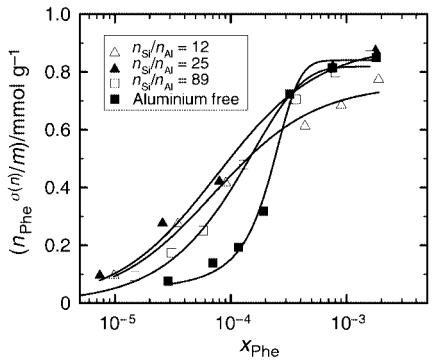

Fig. 2 Effect of the aluminium content of zeolite Beta on the adsorption of phenylalanine at pH 6.

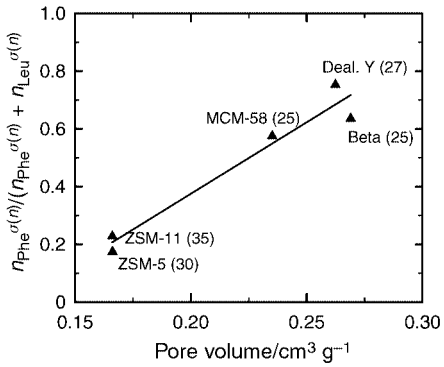

Fig. 3 Separation of leucine and phenylalanine from a mixture of both amino acids in aqueous solution by adsorption on various zeolites.

According to our results, zeolites allow the separation of miscellaneous amino acids from model aqueous solutions. As already demonstrated in Fig. 1 amino acids of different polarity can be separated by adjusting the pH of the solution appropriately. The separation of phenylalanine (Phe) and leucine (Leu) from buffered solutions at pH 6 on various zeolites with n_{Si}/n_{Al} ratios of about 30 is depicted in Fig. 3, where the ratio of phenylalanine adsorbed over the total amount of phenylalanine and leucine adsorbed from the mixture $(n_{Phe}{}^{\sigma(n)}/(n_{Phe}{}^{\sigma(n)} + n_{Leu}{}^{\sigma(n)})]$ is plotted against the pore volumes of the zeolites used as adsorbents. Both amino acids are excluded from the relatively narrow pores of ZSM-22. For ZSM-5, the adsorption of leucine as compared to phenylalanine is clearly favored. Using zeolites with larger pore sizes, the ratio $n_{Phe}{}^{\sigma(n)}/(n_{Phe}{}^{\sigma(n)} + n_{Leu}{}^{\sigma(n)})$ increases and phenylalanine is preferentially adsorbed.

The results obtained for a systematic variation of the side chain of the amino acid, the structure and the aluminium content of the zeolites used as adsorbent and the pH of the solution can be summarized as follows. The adsorption of amino acids seems to be dominated by electrostatic interactions of their positively charged ammonium group with the negatively charged zeolite surface. Moreover, hydrophobic interactions between non-polar side chains of adsorbed amino acid molecules complement the ionic interactions. These two fundamental interactions allow the separation of amino acids from aqueous solutions, as could be demonstrated for a mixture of leucine and phenylalanine.

Enantioselective crystallization of D,L-amino acids induced by spontaneous asymmetric resolution of D,L-asparagine

Shosuke Kojo* and Kyoko Tanaka

Department of Food Science and Nutrition, Nara Women's University, Nara 630-8506, Japan. E-mail: kojo@cc.nara-wu.ac.jp; Fax: +81 742 20 3459; Tel: +81 742 20 3459

Received (in Cambridge, UK) 27th June 2001, Accepted 30th August 2001
First published as an Advance Article on the web 18th September 2001

Racemic D,L-asparagine induced spontaneous asymmetric resolution of co-existing D,L-phenylalanine or D,L-tryptophan by recrystallization from a homogeneous aqueous solution, and the enantiomeric excess of phenylalanine or tryptophan in the resulting crystals correlated linearly with that of asparagine crystallized with phenylalanine or tryptophan.

Although many efforts have been devoted to the elucidation of why and how L-amino acids were selected in the biosphere,[1–3] it is still difficult to explain the origin of the specificity of L-amino acid, and further to elucidate the relationship in selection among 20 L-amino acids with apparently different structures except the configuration of the α-carbon. Since the famous experiment performed by Pasteur,[4] recrytallization has been tried for asymmetric resolution.[5–7] Among amino acids, D,L-asparagine (D,L-Asn) spontaneously forms crystals of either isomer during recrystallization.[8] In this study, we report that D,L-Asn induces asymmetric resolution of co-existing racemic amino acids during recrystallization. This is the first study that shows the spontaneous induction of enantiomeric excess (ee) of coexisting racemic amino acid by a racemic amino acid (in this case, D,L-Asn), although asymmetric resolution by crystallization using chiral additives and crystal interfaces are well documented.[9,10]

In this study, the ee value was determined by a widely used method utilizing high-performance liquid chromatography (HPLC) equipped with a column {Crownpak CR(+) manufactured by Daicel Chem. Ind. Ltd., Tokyo, Japan} which allowed perfect separation of D- and L-amino acids using perchloric acid solution as an eluent as indicated by the supplier. The determination was made by absorption at 200 nm also indicated by the column supplier. When starting racemic materials {D,L-asparagine, D,L-phenylalanine (D,L-Phe), and D,L-tryptophan (D,L-Trp)} taken as an aliquot just after the first filtration of the recrystallization experiments described below were analyzed, ee of either isomer never exceeded 2.5%. Usually the experimental error in chromatographic analysis is assumed to be 2–3%. Therefore, an ee value of less than 2.5% was defined as racemic.

D,L-Asn monohydrate (2 g) was dissolved in water (10 ml) heated in a boiling water bath. After filtration with a glass filter, the solution was stored in a glass vial with a screw cap, and left at room temperature until a measurable amount of crystals were formed. Crystals weighing from 170 to 652 mg were collected by filtration with a glass filter, dissolved in an appropriate amount of water, and directly applied to HPLC analysis. The ee values of L-Asn were 4.8, 11.2, 11.5, 11.7, 15.5, 26.7, 26.8, 27.1, 64.7, 88.9, and −59.7%, showing that L-rich crystals were obtained 10 times and D-rich crystals were formed once among 11 recrystallizations. These results clearly indicate that crystals formed by recrystallization of D,L-Asn show ee as a whole. To elucidate the mechanism of this resolution, the ee of each crystal taken randomly from recrystallization experiments was measured. Among 35 crystals, 3 crystals gave an ee of either isomer at about 70% and that of 32 crystals was more than 90%. This result indicated that each crystal consisted of almost purely one enantiomer and that the ee of the crystals in total was determined by the weight percent of crystals of the enriched isomer.

D,L-Phe (180 mg) was dissolved in 10 ml of water heated with a boiling water bath. After filtration, recrystallization was similarly performed. Crystals weighing from 17 to 41 mg were collected, and dissolved in water, and applied to HPLC analysis, which showed that the resulting samples from 11 independent recrystallizations were all racemic. D,L-Phe (300 mg) and D,L-Asn monohydrate (2.1 g) were similarly dissolved in 10 ml of water at 100 °C. By similar recrystallization, crystals weighing 62–240 mg were obtained, dissolved in water, and analyzed by HPLC. Thirteen independent experiments were carried out. The ee values of L-Asn (abscissa: *x*-axis) and L-Phe (the ordinate: *y*-axis) for each sample solution were plotted as shown in Fig. 1. The maximal ee values of L-isomer were 22.3 and 41.1% for Phe and Asn, respectively. The maximal ee values of the D-isomer were 35.6 and 89.8% for Phe and Asn, respectively (Fig. 1). These results demonstrate that D,L-Asn causes asymmetric selection of Phe to a significant extent. Furthermore, the ee of Phe correlated almost linearly with that of Asn, and the former was less than the latter (Fig. 1). The content of Phe in these crystals was less than 1% of Asn. The ee of each crystal indicated that the ee of Asn of either isomer was nearly 100% and that of Phe of the corresponding isomer was 60–93%. These results suggested that L-Asn crystallized preferentially involving L-Phe, and *vice versa*, and that asymmetric selection resulted from the relative content of crystals enriched with either Asn isomer.

Trp was examined as the second amino acid. D,L-Trp (133 mg) was dissolved in 10 ml of hot water. After filtration, recrystallization was similarly performed. Crystals weighing from 10 to 43 mg were collected, dissolved in water, and applied to HPLC analysis, which showed that the resulting samples from 11 independent recrystallizations were all racemic as expected. Then, D,L-Trp (125 mg) and D,L-Asn monohydrate (2.5 g) were dissolved in 10 ml of hot water. Similar recrystallization yielded crystals weighing 20–250 mg. After dissolving the crystals in water, HPLC analysis was carried out.

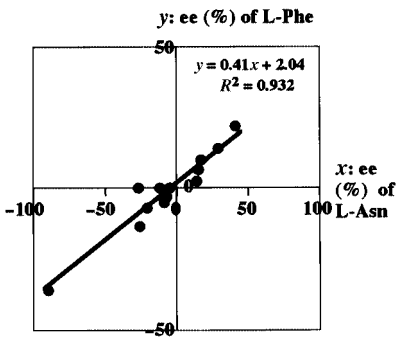

Fig. 1 Plot of ee values of L-phenylalanine and L-asparagine of crystals obtained from recrystallization of D,L-phenylalanine and D,L-asparagine. The ee values of asparagine {Asn: abscissa (*x*-axis)} and phenylalanine {Phe: the ordinate (*y*-axis)} for each sample were plotted as ●.

 DOI: 10.1039/b105663h

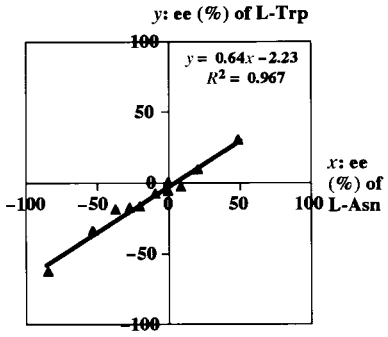

Fig. 2 Plot of ee values of L-tryptophan and L-asparagine of crystals obtained from recrystallization of D,L-tryptophan and D,L-asparagine. The ee values of asparagine {Asn: abscissa (*x*-axis)} and tryptophan {Trp: the ordinate (*y*-axis)} for each sample were plotted as ▲.

Twelve independent experiments were performed. The ee values of L-Asn (the abscissa: *x*-axis) and L-Trp (the ordinate: *y*-axis) for each sample solution were plotted as shown in Fig. 2. The maximal ee values of L-isomer were 30.2 and 48.7% for Trp and Asn, respectively. The maximal ee values of the D-isomer were 62.1 and 83.8% for Trp and Asn, respectively (Fig. 2). These results demonstrate that D,L-Asn also causes asymmetric crystallization of D,L-Trp to a considerable extent. The extent of asymmetric induction in Trp correlated almost linearly with that of Asn, and the ee of the influenced amino acid (Trp) was less than that of the inducer (Asn) (Fig. 2) as in the case of Phe. The content of Trp in these crystals was less than 5% of Asn. Although recrystallization of D,L-Trp with D,L-Asn gave fine powders and a crystal that could be separated with forceps was not obtained, a similar mechanism to the case of Phe was suggested for the optical resolution of Trp.

In conclusion, the present study demonstrates that D,L-Asn can induce a significant enantio-selective crystallization of co-existing amino acids such as Phe and Trp from a homogeneous aqueous solution. Whether the enrichment takes place in L- or D-Asn is accidentally determined. However, once the selection is made, the co-existing amino acid with the same configuration at the α-carbon seems to be preferentially involved in crystals of Asn. This idea may be supported by the observation that the ee of asparagine correlates almost linearly with that of the influenced amino acid (Fig. 1 and 2). These results suggest that the ee of racemic amino acids induced by spontaneous and accidental resolution of co-existing racemic molecules such as D,L-Asn may contribute to the homochirality of L-amino acids in the biosphere.

Sub-ppt detection limits for copper ions with Gly-Gly-His modified electrodes†

Wenrong Yang, David Jaramillo, J. Justin Gooding,* D. Brynn Hibbert, Rui Zhang, Gary D. Willett and Keith J. Fisher

School of Chemistry, The University of New South Wales, Sydney, NSW 2052, Australia. E-mail: justin.gooding@unsw.edu.au

Received (in Cambridge, UK) 25th July 2001, Accepted 30th August 2001
First published as an Advance Article on the web 18th September 2001

An electrochemical metal ion sensor has been developed with a detection limit of less than 0.2 ppt by the covalent attachment of the tripeptide Gly-Gly-His as a recognition element to a 3-mercaptopropionic acid modified gold electrode.

Detecting a number of metal ions at very low concentrations directly in the field is one of the key targets of environmental chemists. Electrochemical sensors have the potential to allow multi-ion analysis in the field because of their small size, low power requirements and the need for little or no sample pretreatment. The majority of research into chemically modified electrodes for the detection of metal ions involves the synthesis and testing of macrocyclic ligands to provide the sensing interface with selectivity for a given metal ion and the ability to pre-concentrate the metal. In nature however, binding metals is achieved with a high degree of selectivity using peptide motifs rather than macrocyclic ligands. Considering the development of biosensors that exploit Nature's methods of selective recognition and the extensive body of literature on the complexation of metal ions with peptides,[1,2] it is surprising how little research has been conducted into the development of solid state metal ion sensors based on peptide ligands.[3] Here we describe an electrode modified with the oligopeptide Gly-Gly-His with an extraordinarily low detection limit in the sub ppt range (pM) for copper ions.

Electrodes modified with Gly-Gly-His were prepared using polycrystalline gold electrodes cleaned as described previously.[4,5] Self-assembly of 3-mercaptopropionic acid (MPA) was achieved by soaking the electrodes in a 1.0 mM MPA solution in ethanol for 12 hours. The carboxylic acid terminated self assembled monolayer (SAM) was activated using a mixture of 15 mM *N*-hydroxysuccinimide (NHS) and 75 mM 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) and 2-(*N*-morpholino)ethanesulfonic acid (MES) buffer solution (pH 5.5) for 30 minutes.[6] The resultant succinimide ester monolayers were reacted for 30 minutes in a solution of Gly-Gly-His (50 mg ml^{-1}) in MES buffer to give the modified electrode shown in Fig. 1 where the tripeptide is attached through the amino group of the first glycine and terminates with the carboxylic acid of the histidine.

Copper was accumulated at the Gly-Gly-His modified electrode (GGHME) in an open circuit potential for 10 minutes in a 0.05 M ammonium acetate buffer solution (pH 7.0) containing copper nitrate. Cyclic voltammetry (using a BAS 100B, Bioanalytical System Inc., USA) measured after removal of the electrode from the copper nitrate solution, rinsing and then placing in a copper free ammonia acetate buffer solution showed reversible electrochemistry with a half-wave potential at −55 mV *versus* Ag|AgCl|3.0 M KCl which was attributed to the half cell Au|$Cu(II)_{complex}$, $Cu(I)_{complex}$ as reported previously for cysteine modified electrodes.[7–9] In the absence of accumulated copper no such electrochemistry was observed. Copper free electrodes could be regenerated by elimination of Cu(II) by holding the working electrode at +0.5 V for 30 seconds in 0.1 M $HClO_4$.

That Cu(II) is tightly bound to the GGHME is demonstrated by no diminution of the peak currents with multiple scans, despite the absence of any copper in the test solution. Furthermore, the peak current varies linearly with scan rate, behaviour indicative of the redox active species being strongly bound to the electrode.[10] Hence we propose the copper is bound to the GGHME as shown in Fig. 1 to give the tetragonal coordination preferred by Cu(II). Evidence for the binding of the copper through the nitrogen on the histidine ring, to give coordination by four nitrogen atoms, was obtained from studies of collision-induced dissociation (CID) using electrospray ionization Fourier transform ion cyclotron resonance mass spectroscopy (FT-ICR MS).† In the absence of copper, the negative ion mass spectrum of Gly-Gly-His in pure methanol showed the pseudo-parent ion [Gly-Gly-His − H] at *m*/*z* 268.11 Da and the most prominent fragment ion at *m*/*z* 154.06 Da which arises from the cleavage of histidine to leave [Gly-Gly]. However, in the presence of Cu(II) the cleavage of histidine is prevented by its role in the complexing of copper. The pseudo-parent ion [Gly-Gly-His + Cu^{2+} − 3H] is observed at *m*/*z* 331.02 Da with the most common fragment ion at *m*/*z* 287.03 Da which corresponds to decarboxylation from the histidine; thus confirming in solution that the binding of the copper is through a deprotonated amine of the peptide bond between Gly and His. These results are consistent with mass spectroscopy results reported previously.[11]

Osteryoung square wave voltammetry (OSWV) was employed with a GGHME for detection of low levels of copper in environmental samples. This technique is more sensitive than cyclic voltammetry.[12] Fig. 2a shows OSWV peaks of a GGHME in 0.05 M ammonium acetate buffer solution (pH 7.0) for a series of copper standards adsorbed for ten minutes from solutions with concentrations in the picomolar range, before

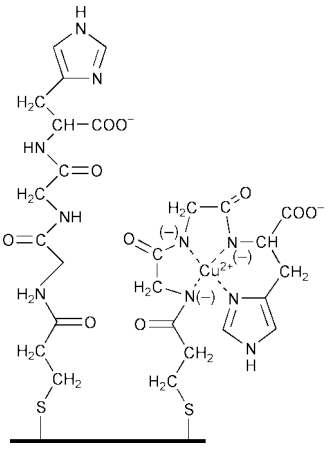

Fig. 1 Schematic of the Gly-Gly-His modified electrode with and without complexed Cu^{2+}.

 DOI: 10.1039/b106730n

transfer to the stripping electrolyte. The 3 pM (0.2 ppt) standard could easily be discriminated from the background in which no Cu(II) was added to the buffer (Fig. 2a). The implied detection limit (*i.e.* <3 pM) is several orders of magnitude below that which we have reported previously for cysteine (1.5 ppb)[9] and polyaspartate (0.2 ppb)[13] modified electrodes. The low detection limit and strong binding of copper reflects the well known affinity for Gly-Gly-His, the so called copper binding peptide, for Cu(II).[1,2]

To the best of our knowledge this detection limit is well below any other reported in the literature [50 pM using the subtractive mode of anodic stripping voltammetry[14] (ASV)] and is also well below that observed for most metal ions using anodic stripping voltammetry or catalytic ASV.[15] A fluorimetric method has achieved 125 pM[16] and electrothermal atomic adsorption spectrometry, where the sample was accumulated *via* sorption in a knotted reactor, detected 100 pM.[17]

The calibration curve (Fig. 2b) shows a linear range up to 10 pM with a slope of 2.1 (standard deviation = 0.1) nA pM^{-1}. The standard error in a measurement of concentration made in the middle of the calibration range was 0.33 pM. The electrodes could be regenerated up to 30 times without any apparent change in performance. Four electrodes fabricated on different days with different batches of reagents gave results with RSDs between 10 and 20%, as indicated by the error bars on points in Fig. 2b. The low saturation concentration again reflects the high affinity of the peptide for copper. The selectivity of GGHMEs to copper was tested by measuring the response of the electrode to a number of metals ions commonly found in waste water, shown in Table S1 in the supplementary information. The case of Ni(II) addition of 10 pM of Ni(II) to a solution of 9.8 pM of Cu(II) resulted in a 6.5% decrease in current. Apart from Ni(II) however, none of the other metal ions showed significant interference with the Cu(II) measurement. The interference of Ni(II) is not unexpected considering Ni(II) is also known to form a 4*N* complex with Gly-Gly-His in solution.[2] Analysis of a local tap water was performed by diluting the sample to bring the copper concentration to within the range of the Gly-Gly-His modified electrode. The measured concentration of free Cu(II) in the tap water, when dilutions were accounted for, was 0.27 ppm (standard deviation = 0.03 for 3 samples (*i.e.* $n = 3$)) which agreed well with the total copper concentration measured using inductively coupled plasma optical emission spectroscopy (ICP-OES) of 0.33 ppm.

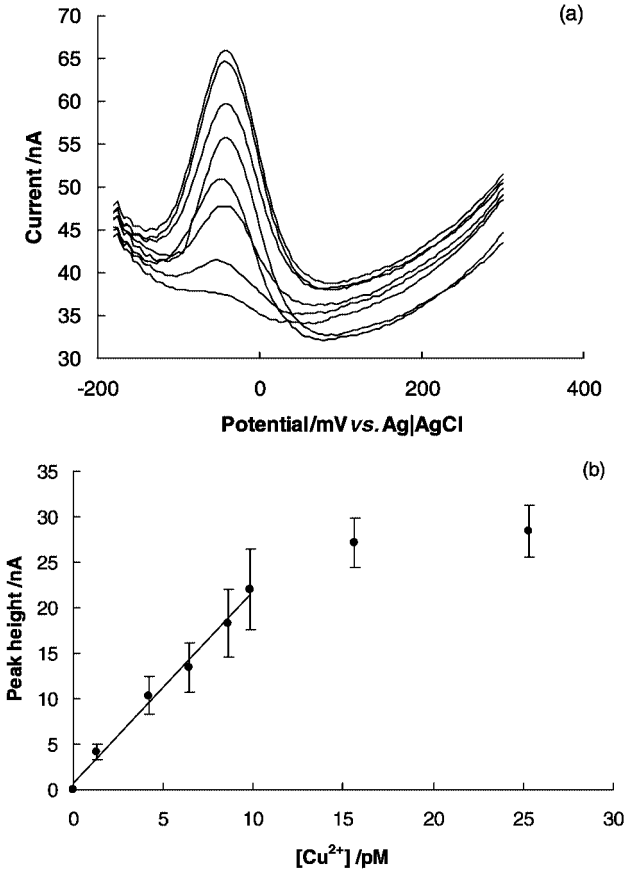

Fig. 2 Response of the Gly-Gly-His modified electrode to complexed Cu(II) (a) Osteryoung square wave voltammetry peaks showing an increase in current with copper concentrations of 0, 1.28, 4.2, 6.4, 8.6, 9.8, 15.6, 25.3 pM and (b) calibration curve derived from the OSWV peaks with error bars as ±1 standard deviation of four electrodes prepared on different days. In all cases Cu(II) was accumulated at the Gly-Gly-His modified electrode in an open circuit over 10 minutes in a 0.05 M ammonium acetate buffer solution (pH 7.0) containing copper nitrate, removed, rinsed and then placed in a copper-free ammonium acetate buffer solution.

These initial results illustrate the potential for peptide-modified electrodes to be used as metal ion sensors with extraordinarily low detection limits. This work is part of our aim to fabricate a multiple metal ion sensor array, based on peptide modified electrodes, where each electrode in the array gives a different response for a given metal ion to produce a characteristic response pattern for different metal ions. Future work involves exploring other peptide modified electrodes for selectivity for other metal ions.

First published as an Advance Article on the web 12th September 2001

The crystal structure of $BiPb_2VO_6$ has been determined from powder diffraction data using a combination of direct methods and the novel approach of applying simulated annealing methods simultaneously to X-ray and neutron data; $BiPb_2VO_6$ is a polar, noncentrosymmetric, second harmonic generation active material and its crystal structure is one of the more complex to be solved *ab initio* from powder diffraction data.

Bismuth vanadates have been widely studied owing to the interesting properties they exhibit. Materials based on $Bi_4V_2O_{11}$ are good oxide ion conductors.[1] $BiVO_4$ is a ferroelastic and has been patented as a yellow pigment.[2,3] Owing to the Bi(III) lone pair stereoactivity, these materials frequently crystallize in noncentrosymmetric space groups and thus are potential nonlinear optical materials and ferroelectrics. Several vanadates of the BiM_2AO_6 family (M = Ca, Mg, Cd, Cu; A = V, As ,P) have been synthesized and characterized by us and others.[4–9] The different members have related, though subtly different crystal structures and three of them have been shown to be second harmonic generation active. $BiPb_2VO_6$ was first reported in 1995 and its diffraction pattern described[10] as complex and apparently unrelated to other phases of the BiM_2AO_6 family.

Our $BiPb_2VO_6$ samples were prepared by solid state reactions of stoichiometric quantities of Bi_2O_3, PbO and NH_4VO_3 at 720 °C. DSC measurements show that between room temperature and its melting point, $BiPb_2VO_6$ undergoes several phase transformations and displays different behaviour on heating and cooling. Although crystals of this phase can be grown, they exhibit complex intergrowths and twinning, making them unsuitable for structural analysis. This is presumably related to the large number of phase transitions.

In order to solve the structure of this material, we therefore resorted to powder diffraction methods. The first attempt to index[11] the diffraction pattern of the room temperature phase was carried out using laboratory X-ray diffraction data collected on a Siemens D5000 diffractometer. The cell obtained gave a figure of merit of 109 and indexed all but a few weak reflections; it corresponded to the unit cell reported by Mizrahi *et al.*,[10] but with the *c* axis halved. By doubling the *c* cell dimension and applying a simple transformation, we obtained a unit cell with $a = 7.7219(2)$, $b = 5.8443(1)$, $c = 29.0762(7)$ Å and $\beta = 94.278(2)°$. Using this cell and the space group *Pn*, an excellent Pawley fit to the observed X-ray data was achieved. This unit cell was later unambiguously confirmed by electron diffraction[12] which suggested possible space groups *Pn* or *P*2/*n*. The absence of an inversion centre in the structure was confirmed by a positive second harmonic generation test,[13] an observed signal of 2–5 × that of quartz was obtained. This leaves *Pn* as the only possible space group choice.

† Electronic supplementary information (ESI) available: fractional coordinates and valence sums, bond distances and angles and virtual reality image of Fig. 2. See http://www.rsc.org/suppdata/cc/b1/b105242j/

X-Ray diffraction data for structure solution were collected at beam line X7A of the Brookhaven NSLS, using a wavelength of 0.57775 Å, in both flat plate and capillary modes. Structure solution was attempted by direct methods[14] in space group *Pn*, using the flat plate data set. A total of 16 metal sites were found, 12 assigned as Bi/Pb and 4 as V. Owing to minor texture effects in the flat plate data, the metal positions obtained were refined against the capillary synchrotron X-ray data until the best possible fit was achieved. To obtain information on the oxygen positions two approaches were used: ^{51}V solid state NMR and neutron powder diffraction measurements.[15,16] ^{51}V MAS NMR provides valuable information on vanadium coordination. A single peak was observed with an isotropic chemical shift of −496 ppm and a very low chemical shift anisotropy. This is consistent with all V sites existing as regular, isolated VO_4 tetrahedra.[17]

Armed with this information, the X-ray derived metal coordinates were used to calculate a difference Fourier map based on the neutron diffraction data, which are more sensitive to oxygen positions. This revealed a number of difference peaks. Eight peaks could be readily assigned as oxygen atoms tetrahedrally coordinated by four Bi/Pb atoms. Other peaks were observed in the vicinity of vanadium sites suggestive of tetrahedrally coordinated vanadium. In fact, charge balance requires a further 16 oxygens in the asymmetric unit. This, together with the ^{51}V NMR data, provides convincing support for four tetrahedral VO_4 groups.

Introduction of the eight tetrahedrally coordinated oxygen sites and a plausible set of oxygens around vanadium atoms followed by Rietveld refinement led to a model showing reasonable agreement with both X-ray and neutron data sets and agreement factors for neutron data of $wR_p = 6.77\%$ and $R_{Bragg} = 7.26\%$. At this stage of the solution, however, there were still some significant discrepancies between the observed and calculated neutron diffraction data. Since the X-ray scattering is dominated by Bi, Pb and V atoms, whereas neutron data are sensitive to Pb, Bi and O (the coherent cross section of vanadium is only −0.40 fm), we decided to adopt a novel approach of simultaneous simulated annealing of the neutron and X-ray diffraction data in order to complete the structure solution.

Simulated annealing calculations were performed[18,19] in which a structural model was generated by the application of random shifts to the positions and rotations of rigid VO_4 tetrahedra and fractional coordinates of other atoms. These shifts were then scaled according to an arbitrary 'temperature'. Several thousand cycles of full Rietveld refinement followed by perturbation of the structural model were then performed, during which the scaling temperature was varied systematically. In this manner a structural model was found showing excellent agreement with both neutron and X-ray data. From this solution, combined Rietveld refinement of both data sets was performed, in which a total of 128 parameters were varied.[20] The final overall agreement factor was $wR_p = 3.83\%$, while the agreement factors for the individual data sets were wR_p =

 DOI: 10.1039/b105242j

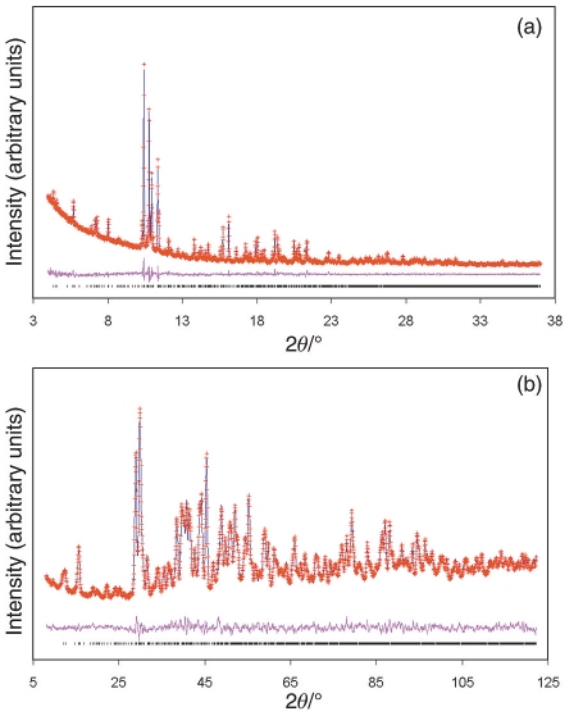

Fig. 1 Final Rietveld plots for (a) X-ray and (b) neutron data.

3.71% and R_{Bragg} = 2.01% for X-ray data [Fig. 1(a)] and wR_p = 3.91% and R_{Bragg} = 3.25% for neutron [Fig. 1(b)].

When rigid VO_4 bodies were allowed to refine freely, the V–O bond lengths refined to values between 1.65 and 1.82 Å and the O–V–O angles to 109 ± 6°, without a significant reduction of the agreement factors. The sensitivity of the data to Bi/Pb occupancies on the various sites of the edge sharing OM_4 tetrahedra was then investigated by perturbing the Bi/Pb distribution several thousand times followed by the full refinement of the model. The data were essentially insensitive to this distribution. By analogy with other BiM_2VO_6 phases we have chosen to assign Bi atoms to the central two positions of the tetrahedral chains of Fig. 2.

Views of the unit cell of $BiPb_2VO_6$ are given in Fig. 2. The structure can be described as containing infinite edge sharing chains of OBi_2Pb_2 tetrahedra similar to those found in fluorite, running parallel to the *b* axis, with isolated VO_4 tetrahedral groups interspersed.

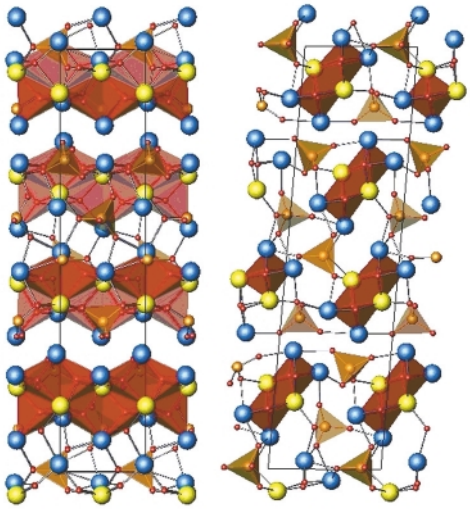

Fig. 2 Views of the $BiPb_2VO_6$ structure down (a) the *a*-axis and (b) the *b*-axis: Bi atoms are depicted in yellow, Pb atoms in blue, V atoms in light brown and O in red; light brown tetrahedra represent VO_4 groups; red tetrahedra represent OBi_2Pb_2 groups which share edges and form chains running parallel to the *b* axis.

Bi and Pb atoms adopt geometrically irregular coordination environments characteristic of lone-pair cations, with coordination numbers between five and seven. Typically, they bond to four oxygen atoms with bond lengths between 2.2 and 2.5 Å and complete their coordination spheres by additional bonds of up to 2.9 Å in length. The VO_4 tetrahedra can be seen to adopt an acentric orientation in accordance with the noncentrosymmetric space group.

More detailed comparison of this structure to other members of the BiM_2AO_6 family and the details of the high temperature structures of $BiPb_2VO_6$ will appear elsewhere.

We wish to acknowledge Dr Pat Woodward of Ohio State University for collecting the synchrotron X-ray diffraction data at Brookhaven National Laboratory, Dr Alan Hewat for the assistance with the neutron diffraction data collection at ILL, Ian King and Dr Franck Fayon of CRMHT-CNRS Orleans for ^{51}V solid state NMR, Dr P. Shiv Halasyamani of The University of Houston for SHG measurements and the EPSRC for a Senior Research Fellowship (J. A. K. H).

First synthesis of a highly symmetrical decakis-adduct of fullerene dimer C_{120}

Koichi Fujiwara and Koichi Komatsu*

Received (in Cambridge, UK) 25th June 2001, Accepted 29th August 2001
First published as an Advance Article on the web 10th September 2001

The highly symmetrical decakis-cyclopropanated derivative of C_{120} was synthesized using template activation and the structure was determined by X-ray crystallography; the decakis-adduct was converted into the eicosa-carboxylic acid derivative that is water soluble.

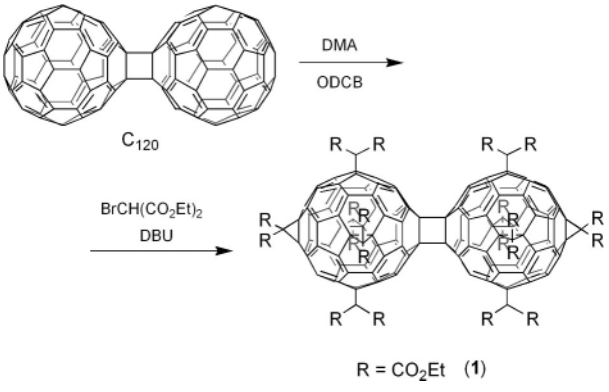
Fullerene is considered as a three-dimensional building block, to which multiple organic addends can be introduced. In particular, detailed studies have been conducted concerning the hexakis-adduct of C_{60} with a T_h symmetric octahedral addition pattern.[1–6] For example, regioselective introduction of different addends to these six positions have been reported,[3] giving applications as a core block of dendrimer molecules,[4] an organometallic ligand,[5] or an investigation of organic LEDs using the emisson property of the hexakis-adduct.[6] We have previously reported a highly selective synthesis of the fullerene dimer C_{120} by the solid-state reaction of C_{60} using a high-speed vibration-milling technique.[7,8] Having the two C_{60} cages directly connected, C_{120} can accommodate a larger number of addends. It seems to be a difficult task to precisely control the multi-addition to this very large molecule. However, we succeeded in the synthesis of the decakis-adduct of C_{120} with D_{2h} symmetry by the use of the Bingel cyclopropanation reaction under the template activation with 9,10-dimethylanthracene (DMA).[2] Here we report the synthesis, structure, and properties of this new highly symmetrical decakis-adduct.

The reaction was conducted by addition of excess amounts of diethyl bromomalonate (17 eq.) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (17 eq.) to a solution of C_{120} and DMA (11 eq.) in *o*-dichlorobenzene (ODCB). After stirring for 3 days, the reaction mixture was roughly separated by flash chromatography over SiO_2 eluted with $CHCl_3$ and washed with diethyl ether to give the D_{2h} symmetric decakis-adduct **1**† as orange crystals in 26% yield (Scheme 1).

In the ^1H NMR spectrum of **1**, four signals (peak intensity 2 : 1 : 1 : 1) corresponding to ethyl groups were observed reflecting the D_{2h} symmetry. In the ^{13}C NMR spectrum, 12 signals were observed in the sp^2 region, which indicated the existence of only two kinds of cyclohexatriene rings on the fullerene cages. In the sp^3 region five signals including a signal for the central cyclobutane ring (71.1 ppm) were observed. The UV-vis spectrum of **1** was similar to that of the T_h symmetric hexakis-cyclopropanated C_{60},[1a] while the extinction coefficients were larger because of the presence of two C_{60} cages. These results clearly support the structure of **1**.

A single crystal of **1** was grown from a $CHCl_3$–chlorobenzene solution (~5 : 1), and its structure was determined by X-ray crystallography‡ as shown in Fig. 1. Four molecules of chlorobenzene were found in the unit cell. With respect to the bond length, the bond alternation between the 6-6 bond (average 1.385 Å) and the 5-6 bond (average 1.424 Å) on the π-system of the C_{60} cages is reduced compared with that of the original C_{120} (6-6 bond, 1.380 Å; 5-6 bond, 1.450 Å).[7a] This is attributed to the presence of the six-membered ring as an isolated π-system (which is somewhat more 'benzene-like') as in the case of T_h symmetric C_{60} hexakis-adducts.[2] The cyclobutane ring connecting the two C_{60} cages lies about an inversion centre and is thus planar; the cyclobutane bond lengths (intra-cage bond length, 1.582(6) Å; inter-cage bond length, 1.579(9) Å) are not significantly different. A similar situation was found in the case of the parent C_{120} (intra-cage bond length, 1.581(7) Å; inter-cage bond length, 1.575(7) Å).[7a]

Just in the same manner as the mother compound C_{120},[7b] the central cyclobutane ring of decakis-adduct **1** in $CHCl_3$ solution slowly underwent cleavage to give C_{60} pentakis-adduct **2** (Scheme 2) with a half-life of 1.5 days under irradiation of room light (*ca.* 100 lux). The same cleavage also took place under thermal conditions: **1** was quantitatively converted to **2** after heating at 200 °C for 0.5 h. This cleavage reaction of decakis-adduct **1** can be regarded as an efficient synthetic method of C_{60} pentakis-adduct **2**, which has only one reactive site left on the C_{60} cage. Thus, **2** is a suitable precursor for the selective synthesis of a hexakis-adduct of C_{60} having different addends. Fullerene **2** was allowed to react with an azomethine ylide,



Scheme 1

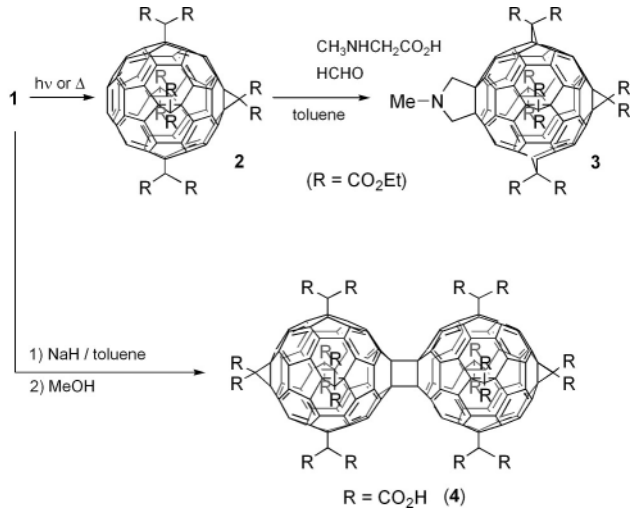
 DOI: 10.1039/b105191c



Scheme 2

generated from *N*-methylglycine and formaldehyde,[9] to give a C_{60} hexakis-adduct **3**§ having two kinds of addends in a high yield (82%).

When treated with NaH in toluene and with methanol,[10] the decakis-adduct **1** having 20 ester groups was transformed into the eicosa-carboxylic acid derivative **4**¶ in high yield (91%). In spite of the carbon-rich framework composed of two C_{60} cages, it exhibited considerable solubility in neutral water (16 mg ml^{-1}) to give a yellow–orange solution, owing to the presence of abundant hydrophilic sites.

In summary, the highly symmetrical decakis-adduct of fullerene dimer C_{120} was synthesized by the Bingel reaction with template activation. This adduct is expected to have an applicability as a core block for dendrimeric compounds and also as a precursor to a C_{2v} symmetric pentakis-adduct.

Synthesis and characterisation of $(C_4N_2H_{12})(UO_2)_2(PO_3H)_2\{PO_2(OH)H\}_2$: a three dimensionally connected actinide framework

Michael Doran, Susan M. Walker and Dermot O'Hare*

Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR. E-mail: dermot.ohare@chem.ox.ac.uk

Received (in Cambridge, UK) 27th July 2001, Accepted 13th August 2001
First published as an Advance Article on the web 18th September 2001

The material $(C_4N_2H_{12})(UO_2)_2(PO_3H)_2\{PO_2(OH)H\}_2$ (MUPH-1) has been prepared hydrothermally; it is a three dimensional structure consisting of four intersecting elliptical shaped one-dimensional channels, the largest channel has dimensions of 13.1 × 7.2 Å.

In recent years we have been interested in developing the solid state chemistry of uranium. In particular, we have been interested in template-directed hydrothermal syntheses of novel uranium-containing phases. Zeolite-like materials built from MX_7, MX_8, or even MX_9 units, where M is a lanthanide or actinide, would be expected to exhibit unusual structural topologies, connectivity and reactivity. We have previously reported a series of layered uranium(IV) fluorides (UFO-*n*) which were prepared under hydrothermal conditions from UO_2, HF and H_3PO_4 by using $H_2N(CH_2)_nNH_2$ (n = 3, 4 or 6) as the structure directing agents.[1] More recently, we reported $(C_4N_2H_{12})U_2O_4F_6$ MUF-1[2,3] which was the first organically templated microporous actinide material. Here we report the phase pure synthesis and crystal structure of an organically templated actinide phosphite which contains a 3D channel network structure.

$(C_4N_2H_{12})(UO_2)_2(PO_3H)_2\{PO_2(OH)H\}_2$ MUPH-1 was synthesised hydrothermally by combining $UO_2(MeCO_2)_2{\cdot}2H_2O$

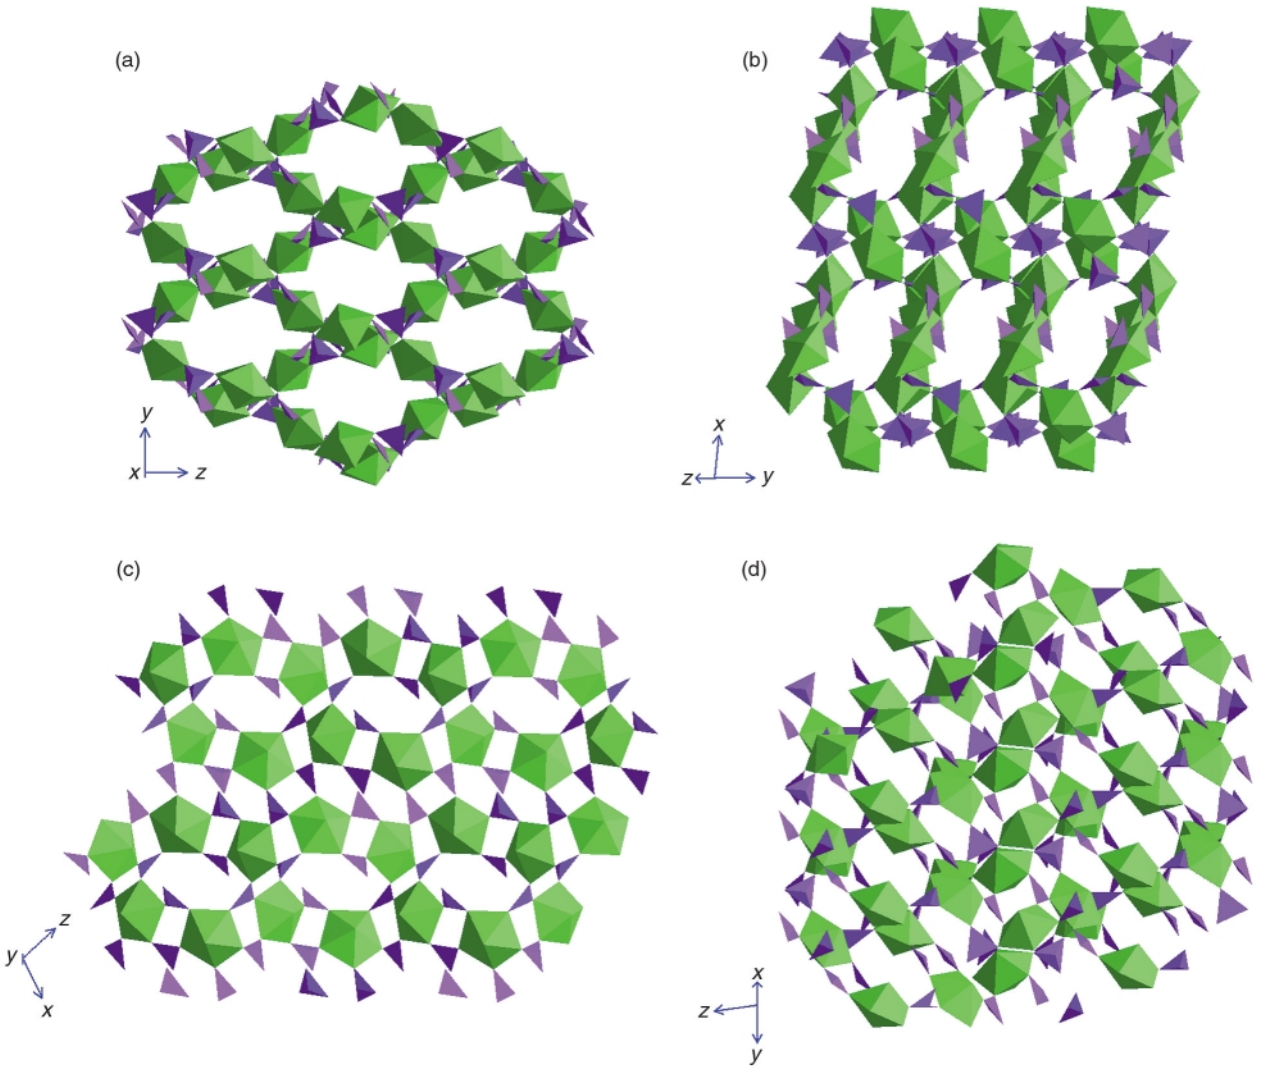

Fig. 1 Views of the structure of MUPH-1 down four crystallographic axes; (a) 100; (b) 011; (c) 010; (d) 110. (Note the piperazine template has been removed for clarity.)

 DOI: 10.1039/b106804k

Table 1 Summary of channel information for MUPH-1

Direction	Shape	Dimensions/Å	Ring size/atoms
100	Elliptical	8.306 × 7.230	12 atoms
011	Elliptical	13.170 × 7.230	12 atoms
010	Elliptical	8.127 × 6.900	8 atoms
110	Elliptical	6.483 × 4.878	8 atoms

(0.406 g, 1.0×10^{-3} mol), H_3PO_3 (Aldrich, 99%) (0.385 g, 4.7×10^{-3} mol), and $C_4N_2H_{10}$ (Aldrich, 95%) (0.043 g, 0.5×10^{-3} mol) in a Teflon-lined, 23 ml stainless steel autoclave. $UO_2(MeCO_2O)_2{\cdot}2H_2O$ was synthesized as previously described.[3] The autoclave was sealed, heated for 1 d at 180 °C, and cooled at 6 °C h^{-1} to room temperature over an additional day. The only product recovered was yellow rods, obtained in 25% yield based on uranium.† The powder X-ray diffraction pattern of this product is in excellent agreement with the pattern generated from the single crystal structure data.‡

MUPH-1 contains two crystallographically unique uranium atoms, both of which adopt seven coordinate, pentagonal bipyramidal geometries. Axially, the uranium atoms are bonded to two oxygen atoms to form uranyl units. The axial U=O bond lengths range between 1.772(10) and 1.780(10) Å, with O=U=O bond angles of 176.2(5) and 176.9(5)°. In the equatorial plane, both uranium atoms are bonded to five oxygen atoms, with U–O bond lengths ranging between 2.321(10) and 2.445(9) Å. The O–U–O bond angles are between 69.4(3) and 75.6(3)°. The uranium polyhedra share all five equatorial vertices with phosphite groups. Bond valence calculations give values of 6.738 and 6.809 for the uranium atoms.[4]

There are four crystallographically distinct phosphorus atoms, each bonded to three oxygen atoms and one hydrogen atom in a truncated tetrahedral environment. Two of the phosphite groups contain three bridging oxygen atoms, while the other two contain two bridging oxygen atoms and one terminal OH group. The bridging P–O bond lengths are between 1.487(13) and 1.533(10) Å whilst the P–OH bond lengths are 1.537(14) and 1.557(11) Å. Bond valence calculations give values between 4.088 and 4.258 for the P–H unit.[5]

The linkages between the polyhedra result in an anionic $[(UO_2)_2(PO_3H)_2\{PO_2(OH)H\}_2]^{2-}$ three dimensional framework, which contains four channels running throughout the structure. These are summarised in Table 1, and shown in Fig. 1. There are two distinct template molecules in MUPH-1, both of which form hydrogen bonds with the inorganic framework. They are found along the 100 channel, stacked in an ABA fashion.

The thermal analysis shows no significant mass loss until between 325 and 400 °C, where 4.5% of the starting mass is lost. This is due to the start of template decomposition. At 400 °C a smoother mass loss of 2% begins, continuing until 725 °C, attributable to further template decomposition and the start of framework breakdown. Between 725 and 850 °C there is a rapid mass loss of 5%, indicating framework breakdown. The final product obtained after heating to 850 °C is UP_2O_7.

The presence of the template is confirmed in the IR spectrum by the N–H stretch at 3024 cm^{-1}, the N–H bend at 1604 cm^{-1} and the C–H bending mode at 1430 cm^{-1}. P–H stretches are observed as sharp peaks at 2426 and 2400 cm^{-1}. P–H bending modes are observed at 1042 and 984 cm^{-1}. A P–O stretch can be seen at 1156 cm^{-1}. The U=O asymmetric and symmetric stretches appear at 950 and 828 cm^{-1} respectively. The MAS ^{31}P solid state NMR spectrum of MUPH-1 exhibits two resonances at 13.4 and 9.2 ppm which is consistent with the crystal chemistry.

We thank the EPSRC for financial support.

Received (in Cambridge, UK) 27th June 2001, Accepted 10th August 2001
First published as an Advance Article on the web 18th September 2001

The first time-resolved *in situ* X-ray diffraction studies of the hydrothermal crystallisation of open-framework zinc phosphates reveal a pathway of sequential crystallisation involving formation of a metastable low dimensional chain phase before the growth of three-dimensional zeolitic architectures.

A great deal of effort is currently focussed on understanding the crystallisation mechanism of microporous solids which can have applications in shape-selective catalysis, separation science, and ion-exchange. It is hoped that an understanding of mechanisms leading to the formation of these zeolite-like solids at the atomic-scale will allow the rational synthesis of new materials.[1,2] The common use of hydrothermal synthesis conditions in the preparation of such open-framework solids requires sealed thick-walled reaction vessels and it is only in recent years that *in situ* probes of hydrothermal crystallisation have been developed to follow reactions under these experimentally-challenging conditions.[3] For example, in a study of the phosphates of gallium using energy-dispersive X-ray diffraction (EDXRD) some of us have observed previously-unknown, transient phases prior to the onset of crystallisation of open-framework phases,[4,5] and Taulelle *et al.* have identified oligomeric 'building blocks' in hydrothermal reaction solutions using NMR spectroscopy.[6] The results of such studies provide a foundation on which to build descriptions of reaction mechanisms.

The first results of an *in situ* EDXRD study of the hydrothermal synthesis of zinc phosphates are described here. This large family of solids has recently been the focus of study by some of us, and an Aufbau principle for the building up of three-dimensional structures from structures of lower dimensionalities proposed.[7] With an aim of gaining further information about crystallisation mechanisms it is crucial to study systems such as these using *in situ* measurements of crystallisation, since it has been established that on arresting a hydrothermal reaction by cooling to room temperature the material recovered is not necessarily representative of the material present under reaction conditions.[4,5] The EDXRD method uses intense synchrotron X-rays which allows the use of a laboratory-sized hydrothermal reaction vessel, mimicking the conditions employed in the synthetic laboratory and permitting rapid data collection (< 1 min) for kinetic studies. An apparatus developed over the past few years by O'Hare and co-workers[8] was used in the current work.†

In the first zinc phosphate system studied we focussed on the reaction between piperazine phosphate ($[C_4N_2H_{12}][HPO_4]\cdot H_2O$, PIP-P) and zinc oxide in dilute hydrochloric acid solution. Fig. 1 shows a stack plot of the time-resolved EDXRD data measured as a reaction mixture of composition ZnO : 1.5 HCl : 1.75 PIP-P : 100 H_2O which was heated to 180 °C in an autoclave at *ca.* 5 °C min^{-1} (detector angle 0.9325°). The use of a three-element energy discriminating detector system[9] allows unambiguous identification of known crystalline phases, owing to the large amount of diffraction data that can be simultaneously recorded.[10] Characteristic Bragg reflections of the phosphate and amine source, PIP-P, are observed only during the first minute before disappearing; presumably this is due to dissolution of this rather soluble species. Remarkably, we observe that characteristic Bragg reflections of a known zinc phosphate, $[C_4N_2H_{12}][Zn(HPO_4)_2(H_2O)]$ (ZnPO–PIP-I),[11] are present in the first spectrum recorded (31 °C), suggesting that this material forms on mixing the chemicals at room temperature. The compound has a 1-D ladder structure (see Table 1 for descriptions of the phases discussed in this paper). After heating to 163 °C new strong Bragg reflections (of a phase not yet identified) are apparent, and these diffraction features, along with those of ZnPO–PIP-I, have constant intensity for 30 min during which time a temperature of 180 °C is reached. Over a period of 10 min, these two phases and the starting material ZnO are replaced by two known zinc phosphates, $[C_4N_2H_{12}][Zn_{3.5}(PO_4)_3(H_2O)]$ (ZnPO–PIP-II)[11,12] and $[C_4N_2H_{12}][Zn_2(HPO_4)_2(H_2PO_4)_2]$ (ZnPO–PIP-III),[11] which are the sole two products after 145 min of heating. ZnPO–PIP-II and ZnPO–PIP-III both have three-dimensional framework structures.

On changing the amount of PIP-P we observed rather different behaviour. For a mixture of composition ZnO : 1.5 HCl : 1 PIP-P : 100 H_2O, held at a constant temperature of 180 °C, the ladder phase ZnPO–PIP-I is present in the first spectrum

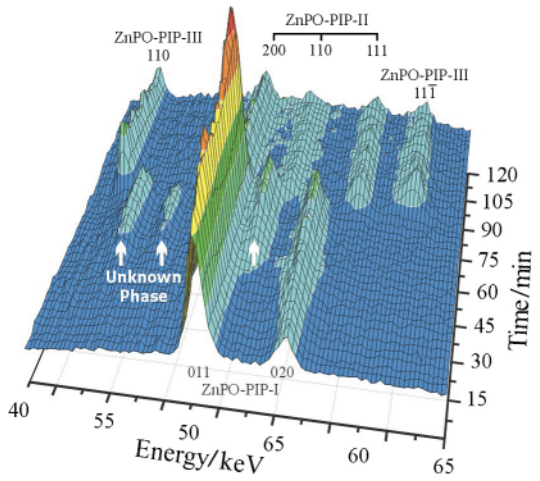

Fig. 1 A stack plot of EDXRD data measured during the sequential crystallisation of zinc phosphates from the reaction mixture ZnO : 1.5 HCl : 1.75 PIP-P : 100 H_2O.

[a] Ref. 11 [b] Ref. 12. [c] Bottom EDXRD detection.

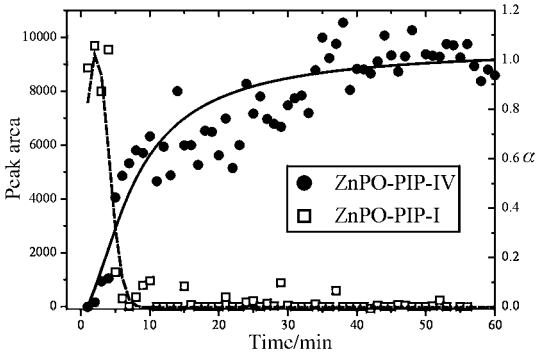

Fig. 2 Integrated peak intensities of ZnPO–PIP-I and ZnPO–PIP-IV during crystallisation from the reaction mixture ZnO : 1.5 HCl : 1 PIP-P : 100 H_2O at 180 °C.

recorded, and almost immediately its Bragg reflections begin to decay. The ladder phase is consequently replaced by a known zinc phosphate with a three-dimensional structure, $[C_4N_2H_{12}][Zn(H_2O)Zn(HPO_4)(PO_4)]$ (ZnPO–PIP-IV).[11] The decay of the precursor phase and growth of the product are not mirrored precisely: integrated peak intensities show that an appreciable amount of ZnPO–PIP-I is consumed before ZnPO–PIP-IV is observed. The decay and growth curves cross at $\alpha \approx 0.3$ of product (α is the extent of reaction; see Fig. 2). This suggests that the transformation of the chain material to the three-dimensional structure is a solution-mediated process involving dissolution of the first phase, rather than a solid-state transformation.

We have presented preliminary results of an *in situ* study of the formation of a large family of open-framework materials. The dissolution of starting materials and sequential crystallisation of a number of open-framework solids was directly observed. In certain cases, crystalline materials with as-yet unknown structures form during the reactions. Given the huge number of zinc phosphate structures that can be formed from reaction mixtures of only slightly differing composition, it is not unexpected to discover new metastable phases. The importance of these crystallisation studies is that for the first time we have observed *under real reaction conditions* the sequential crystallisation of materials with increasing dimensionality. Recently it has been shown that a ladder zinc phosphate, similar to that observed as a transient phase in our *in situ* studies, can be used as a solid precursor to a number of other layered and 3-D phases.[13] Combined with our *in situ* results, such studies of the reactivity of the ZnPO phases provide convincing evidence for the Aufbau principle proposed recently for the building up of 3-D zinc phosphate structures.[7] We are currently extending our *in situ* studies to survey other ZnPO/amine systems in order to understand more fully the nature of the structural transformations taking place.

We thank the EPRSC for funding and provision of beam-time at SRS, Daresbury Laboratory.

Notes and references

† EDXRD experiments were performed on Station 16.4 of the Daresbury Synchrotron Radiation Source ($I \sim 200$ mA, ~ 2 GeV synchrotron). Station 16.4 was illuminated with X-rays in the energy range 5–120 keV from a 6 T superconducting wiggler insertion device. Diffracted X-rays were measured using a three-element germanium solid-state detector; this allowed access to three *d*-spacing ranges, dependant on the angle to which the detector was set. The delay between mixing reagents, sealing in the hydrothermal autoclave and beginning data collection was of the order of 5 min.

Received (in Cambridge, UK) 27th June 2001, Accepted 24th August 2001
First published as an Advance Article on the web 18th September 2001

Novel oligonucleotide analogues, containing a 3′-amino-2′,4′-BNA unit, were successfully synthesized, and they showed superior duplex and triplex forming ability as well as BNA itself, along with remarkable enzymatic stability.

Oligonucleotides for practical antisense and/or antigene molecules should fulfil some requirements, such as a high binding affinity for the target ssRNA or dsDNA, high sequence selectivity, and sufficient enzymatic stability. During the past decade, various chemically modified oligonucleotides have been synthesized, and their properties have been investigated;[1–5] however, an ideal antisense or antigene molecule is still lacking. We recently achieved the first synthesis of a novel nucleoside with a fixed *N*-type conformation,[6] 2′-*O*,4′-*C*-methylene bridged nucleic acid (2′,4′-BNA)[7,8] (Fig. 1) and found that 2′,4′-BNA modified oligonucleotides exhibited strong hybridization ability with complementary strands of RNA and DNA.[9,10] Moreover, these 2′,4′-BNA oligonucleotides appeared to possess high affinity for dsDNA forming a stable DNA triplex.[10–15]

On the other hand, Gryaznov *et al*. reported in numerous papers that oligonucleotide analogues with an N3′→P5′ phosphoramidate linkage show superior properties of hybridization to ssDNA, ssRNA and dsDNA, along with high resistance to enzymatic degradation.[16–19]

Therefore, we became interested in a combination of a BNA structure and an N3′→P5′ phosphoramidate linkage.† Here, we report the synthesis, hybridization properties and enzymatic stability of novel oligonucleotide analogues with a 3′-amino-2′,4′-BNA monomer unit (Fig. 1).

The synthesis of 3′-amino-2′,4′-BNA heterodimer building block **1** was accomplished as shown in Scheme 1. After protection of the 5′-hydroxy group in **2**,[20] the 3′-azido group was successfully reduced to give the 3′-amino derivative **3**. Condensation of **3** with a 5′-phosphoramidite **4**[21] was performed according to the reported procedure.[17,21] The obtained heterodimer **5** was converted to the deisred compound **1** by treatment with tetrabutylammonium fluoride and subsequent phosphitylation. The 3′-amino-2′,4′-BNA oligonucleotides **6–8** were prepared using the phosphoramidite **1**.‡

The duplex-forming abilities of the 3′-amino-2′,4′-BNA modified oligonucleotide **6** with complementary ssDNA and ssRNA were elucidated under physiological conditions on the basis of melting temperatures (T_ms) (Table 1). Replacement of a natural 2′-deoxyribonucleotide by a 3′-amino-2′,4′-BNA monomer in the 12-mer oligonucleotide **9** resulted in significant

Table 1 T_m values for 3′-amino-2′,4′-BNA with complementary DNA and RNA[a]

	T_m (ΔT_m)/°C	
Oligonucleotides	DNA	RNA
5′-GCGTTT**T^aB**TTTGCT-3′ (**6**)	51 (+4)	52 (+7)
5′-GCGTTT**T^B**TTTGCT-3′ (**10**)	53 (+6)	52 (+7)
5′-GCGTTTTTTGCT-3′ (**9**)	47	45

[a] UV melting profiles were measured in 10 mM sodium phosphate buffer (pH 7.2) containing 100 mM NaCl at a scan rate of 0.5 °C min^{-1} at 260 nm. The oligonucleotide concentration used was 4 μM for each strand. The sequence of target DNA or RNA complements is 5′-AGCAAAAAACGC-3′.

 DOI: 10.1039/b105640a

Table 2 T_m values of 3′-amino-2′,4′-BNA with dsDNA[a]

Oligonucleotides	T_m (ΔT_m)/°C	
	+10 mM $MgCl_2$	−$MgCl_2$
5′-TTTTT^{m}CT**T^{aB}**T^{m}CT^{m}CT^{m}CT-3′ (**7**)	55 (+11)	44 (+11)
5′-TTTTT^{m}CT**T^B**T^{m}CT^{m}CT^{m}CT-3′ (**12**)	57 (+13)	44 (+11)
5′-TTTTT^{m}CTTT^{m}CT^{m}CT^{m}CT-3′ (**11**)	44	33

[a] UV melting profiles were measured in 7 mM sodium phosphate buffer (pH 7.0) containing 140 mM KCl without or with additional 10 mM $MgCl_2$. The oligonucleotide concentration used was 1.5 μM for each strand. The sequence of target dsDNA is 5′-GCTAAAAAGAAAGAGAGATCG-3′/3′-CGATTTTTCTTTCTCTCTAGC-5′. ^{m}C means 5-methylcytidine.

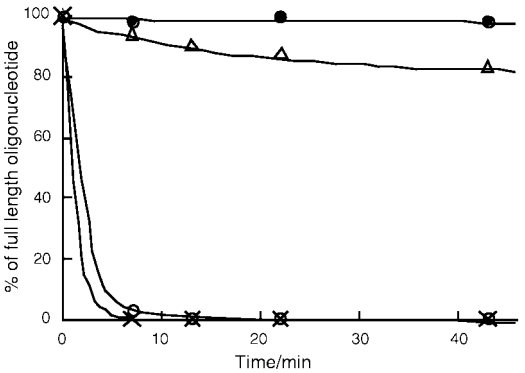

Fig. 2 Enzymatic stability of T_8**T^{aB}**T (**8**) (closed circle), T_{10} (**13**) (cross), T_8**T^B**T (**14**) (open circle) and T_8T_ST (**15**) (triangle). Hydrolysis of the oligonucleotides (10 μg) was carried out at 37 °C in a buffer (320 μl) containing 50 mM Tris–HCl (pH 8.0), 10 mM $MgCl_2$ and SVPDE (0.2 μg). '$_S$' means phosporthioate linkage.

stabilization of the duplexes formed with both complementary DNA and RNA. The increases in T_ms were up to 4 and 7 °C for the duplexes formed with the DNA and RNA strands, respectively. Next, the binding affinity of the oligonucleotide **7** to a homopurine•homopyrimidine dsDNA was also studied and shown to be much higher than that of the natural oligonucleotide **11**. The T_m values of triplex formation for **7** were 55 and 44 °C under neutral conditions with or without 10 mM $MgCl_2$, respectively, which is over 10 °C higher than the corresponding value for **11** as summarized in Table 2.

Thus, the oligonucleotides with one-point modification by 3′-amino-2′,4′-BNA, a combination of the 2′,4′-BNA backbone and N3′→P5′ phosphoramidate linkage, exhibited enhanced hybridizing properties towards complementary ssDNA, ssRNA and dsDNA, compared to the corresponding natural oligonucleotides. These ΔT_m values were almost comparable to those for 2′,4′-BNA singly modified congeners **10** and **12**, and seem to reach the utmost level of hybridization.

The nuclease-resistance of the 3′-amino-2′,4′-BNA modified oligonucleotide **8** was investigated by using snake venom phosphodiesterase (SVPDE), compared with natural and one point modified (2′,4′-BNA or phosphorthioate[22]) oligothymidilate 10-mers **13**, **14** and **15**, respectively. The reaction mixtures were analyzed at several time points by reversed-phase HPLC to monitor the percentage of full length oligonucleotides (Fig. 2). Under the conditions used, the natural T 10-mer control **13** and the 2′,4′-BNA **14** were immediately digested. In both cases, no full length oligomer was detected after 10 min, although the 2′,4′-BNA modification of oligonucleotides was found to be sufficiently resistant to enzymatic hydrolysis in other cases.[10] In contrast, more than 98% of full length 3′-amino-2′,4′-BNA oligonucleotide **8** was unchanged after 40 min, while 83% of **15** was intact after the same time period. It is noteworthy that enzymatic stability of the 3′-amino-2′,4′-BNA **8** was superior to that of the phosphorthioate modified oligonucleotide **15**.[22]

The results presented here clearly demonstrate that the novel nucleic acid analogue, 3′-amino-2′,4′-BNA, was a good candidate for a practical antisense and antigene molecule, due to its potent hybridization ability with DNA and RNA complements and homopurine•homopyrimidine dsDNA, and remarkable enzymatic stability surpassing that of phosphorthioate oligonucleotides. Further investigation of properties of the 3′-amino-2′,4′-BNA is currently under way.

Notes and references

† Recently Wang and Stoisavljevic reported a combination of a phosphoramidate linkage and another type of bicyclic nucleoside, and their modification of oligonucleotides decreased the duplex-forming ability. See ref. 21.

First published as an Advance Article on the web 18th September 2001

We introduce the concept of 'directed assembly' of multilayers on surfaces: the overall process involves the exposure of a surface to a series of solutions containing, alternately, adsorbable cations and adsorbable anions, and these are gradually built up into well-defined multilayer structures.

In the present work we describe a new method of assembling multilayers on surfaces. In contrast to the familiar process of *self-assembly*, which is spontaneous and leads to single monolayers, *directed assembly* is driven by the experimenter and leads to extended multilayers. In a proof-of-concept experiment, described below, we show that it is possible to generate multilayers of Prussian Blue and Ruthenium Purple on gold surfaces by exposing them alternately to positively charged ferric cations and negatively charged $Fe(CN)_6^{4-}$ or $Ru(CN)_6^{4-}$ anions. We also show that this process can be controlled with monolayer precision.

Prussian Blue [iron(III) potassium hexacyanoferrate(II)] has the nominal formula $Fe^{III}K[Fe^{II}(CN)_6]\cdot xH_2O$, but commonly contains extensive cation disorder and variable amounts of water. In industry it is employed as a pigment[1] in the formulation of paints and printing inks. It has also found use as a thallium absorbent in medicine, as an electrochromic material, as a catalyst, and as a sequestrant for heavy metals. In the laboratory, its ability to exchange metal ions with ambient solutions makes it an object of continuing curiosity.[2]

For synthetic work, bulk quantities of Prussian Blue can readily be precipitated from aqueous mixtures of Fe^{3+} and $Fe(CN)_6^{4-}$. For solid state electrochemical measurements, however, more complex preparations must be employed, in which electrode surfaces are coated *in situ* by electrochemical reduction of $Fe(CN)_6^{3-}$ to $Fe(CN)_6^{4-}$ in the presence of Fe^{3+}.[3] This leads to thick polycrystalline films. More rarely, films of Prussian Blue have also been prepared by extensive redox cycling of ferrocyanide[4] or by embedding micrometer sized crystals directly into electrode surfaces using powder abrasion.[5]

In our quest to achieve ultra-thin layers of Prussian Blue, our attention was drawn to some recent work in which polymer heterostructures had been successfully deposited on surfaces using alternate adsorption of anions and cations. For example, Stepp and Schlenoff[6] had prepared polyelectrolyte multilayers of poly(butanyl viologen) dibromide and poly(styrene sulfonate) from alternating positive and negative polyion solutions. Mallouk and coworkers had also reported an ionic–covalent strategy for self-assembly of inorganic multilayer films.[7] These works, and others, inspired us to attempt monolayer-by-monolayer deposition of Prussian Blue using a similar approach. Here, we report the successful implementation of this idea.†

Our monolayer-by-monolayer deposition method for Prussian Blue films is as follows. A gold electrode (A = 0.2 cm^2) is immersed in (a) 40 mM Fe^{3+} in aqueous 0.1 M HNO_3 for 60 s, (b) deionized water for 30 s, (c) 40 mM $Fe(CN)_6^{4-}$ in aqueous 0.1 M HNO_3 for 60 s, and finally (d) deionized water for 30 s again. The Fe^{3+} cations adsorbed during the first immersion react with the $Fe(CN)_6^{4-}$ anions adsorbed during the second immersion to form the first monolayer of Prussian Blue. (This is readily confirmed by cyclic voltammetry, as we show later.) This completes the first treatment cycle. Additional monolayers can be added by repeating the treatment cycle. After about fifty cycles, the characteristic colour of Prussian Blue emerges. A cartoon of the deposition process is shown in Fig. 1.

All the Prussian Blue multilayers deposited by the above method exhibit a characteristic voltammetric reduction response at +0.2 V *vs.* Ag/AgCl, which allows them to be quantified. The response is due to the electrochemical reaction [eqn (1)]:

$$Fe^{III}K[Fe^{II}(CN)_6]\cdot xH_2O + K^+ + e^- \rightleftarrows Fe^{II}K_2[Fe^{II}(CN)_6]\cdot(x-n)H_2O + nH_2O \quad (1)$$

and is completely analogous to the reduction of the bulk material. It is noteworthy that the reaction is accompanied by the insertion of K^+ cations into the Prussian Blue framework in order to maintain charge neutrality, and this is accompanied by a change in the hydration state of the crystal lattice.

Cyclic voltammograms for the reduction and re-oxidation of a series of Prussian Blue multilayer deposits are shown in Fig. 2(a). Corresponding numerical data are compiled in Table 1. Immediately after the first treatment cycle, the characteristic voltammetric response for the reduction and re-oxidation of Prussian Blue is detected. As the number of treatments increases, the charge under the reduction peak increases and the peak positions change. The change in peak position during the first six treatments is evidence that the deposited material is not bulk material: each layer deposits on a slightly different substrate until the influence of the underlying substrate becomes negligible.

The charge under the reduction peak increases linearly with the number of treatments, with a slope of *ca.* 26 μC per treatment cycle [see Fig. 2(c)]. This corresponds to an incremental extension of the deposit by 130 μC cm^{-2}, or 2.6 × 10^{-10} mol. Assuming a roughness factor of *ca.* 1.7 (estimated

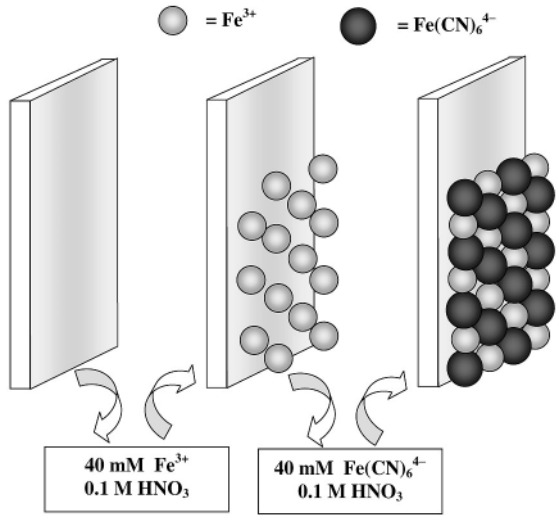

Fig. 1 Cartoon showing the steps involved in the directed assembly of Prussian Blue multilayers.

 DOI: 10.1039/b106616c

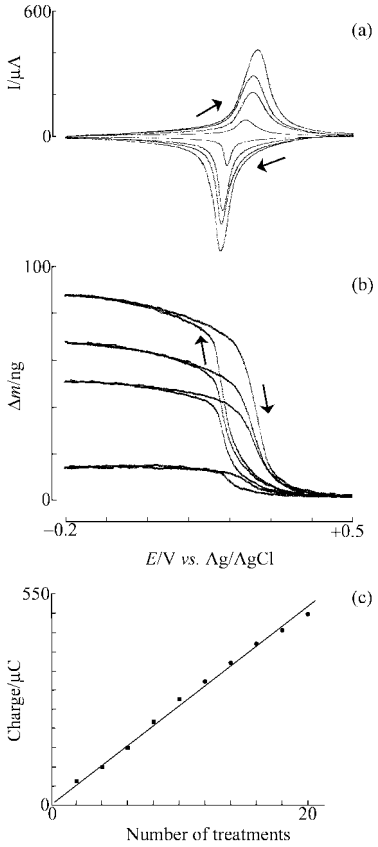

Fig. 2 Cyclic voltammograms (0.5 M KCl, scan rate 0.1 V s^{-1}) for Prussian Blue and Ruthenium Purple formed by layer-by-layer deposition onto a gold plated quartz crystal electrode (area 0.2 cm^2). (a) Cyclic voltammograms for the reduction of Prussian Blue after 4 and 10 treatment cycles and for the reduction of a Prussian Blue/Ruthenium Purple bilayer with 10 treatment cycles of Prussian Blue and with 4 and 10 treatment cycles of Ruthenium Purple. (b) Simultaneous mass changes recorded by quartz crystal microbalance gravimetry. (c) Plot of the charge under the reduction signal *vs.* the number of treatment cycles (Prussian Blue and Ruthenium Purple) with a line indicating 26 μC per treatment cycle.

by SEM), this is as expected for a monolayer quantity of Prussian Blue. The linearity of the plot emphasizes the layer-by-layer nature of the assembly process.

Gravimetric data recorded simultaneously with cyclic voltammetric data provide further insight into the reaction mechanism. By multiplying the total mass change after reduction by Faraday's constant, then dividing by the total charge, the overall mass change per mol of electrons is readily determined (Table 1). This overall mass change per mol of electrons, which stabilizes at *ca.* 17 g mol^{-1}, is clearly inconsistent with the theoretical value for K^+ electroinsertion, 39 g mol^{-1}, but is consistent with the co-expulsion of about 1.2 mol of water for each mol of K^+ inserted.

Table 1 Data obtained from cyclic voltammetry (scan rate 0.1 V s^{-1}) and gravimetry for the reduction of Prussian Blue (treatments 1–10) and Ruthenium Purple (treatments 11–20). Multilayers on a 0.2 cm^2 gold electrode immersed in aqueous 0.5 M KCl

Number of treatments	E_p^{ox}/V	E_p^{red}/V	ΔE_p/ mV	Q_{red}/ μC	Δm/ ng	(ΔmF/ Q_{red})/ g mol^{-1}
Deposition Prussian Blue						
2	0.228	0.199	29	62	4	6.5
4	0.238	0.194	44	99	13	12.9
6	0.246	0.190	56	150	23	15.7
8	0.250	0.184	66	218	36	16.6
10	0.256	0.184	72	272	49	17.9
Deposition of Ruthenium Purple onto Prussian Blue						
10 + 2	0.257	0.184	73	324	58	17.8
10 + 4	0.257	0.181	76	373	66	17.7
10 + 6	0.241	0.168	73	422	72	17.1
10 + 8	0.263	0.179	84	458	78	17.1
10 + 10	0.269	0.177	92	500	86	17.2

Surface analysis by Auger spectroscopy on selected areas of 10 × 10 μm size allowed the elemental composition of the electrode surface to be sampled as a function of the number of treatments. After deposition of 4–6 monolayers of Prussian Blue, strong signals for Fe, K, C, and N were detected in approximately 2 : 1 : 6 : 6 proportions and the signal for Au was considerably diminished. After deposition of 10 monolayers the signal for Au was undetectable, suggesting an even coverage.

Besides creating compositionally uniform structures, the directed assembly technique was also used to create compositionally modulated structures. For example, Ruthenium Purple,[8] $Fe(III)K[Ru(II)(CN)_6]\cdot xH_2O$, has a structure very similar to Prussian Blue (unit cell dimension 1.14 nm)[9] and may also by prepared by directed assembly from solutions of (i) 40 mM Fe^{3+} in aqueous 0.1 M HNO_3 and (ii) 40 mM $Ru(CN)_6^{4-}$ in aqueous 0.1 M HNO_3. Moreover, the reduction of Ruthenium Purple occurs at approximately the same potential as that of Prussian Blue, in accordance with eqn (2):

$$Fe(III)K[Ru(II)(CN)_6]\cdot xH_2O + K^+ + e^- \rightleftarrows Fe(II)K_2[Ru(II)(CN)_6]\cdot(x - n)H_2O + nH_2O \quad (2)$$

Thus, multilayers of Ruthenium Purple could readily be deposited on top of multilayers of Prussian Blue (Fig. 2).

Finally, it should be noted that the voltammetric responses and gravimetric responses shown in Fig. 2 remain sharp even at scan rates above 1 V s^{-1}, and that the charges under the oxidation and reduction peaks are independent of scan rate. This is consistent with very fast insertion of K^+ ions into the multilayers of Prussian Blue, suggesting that the process is field driven rather than diffusion controlled.

In conclusion, we have demonstrated that Prussian Blue multilayers can be formed by *directed assembly* on electrode surfaces. In future, the production of a wide range of compositionally modulated electrode surfaces can be expected, with applications in catalysis, sensors, and electrochromic materials.

Notes and references

† Reagents were of analytical grade. Demineralised water was obtained from an Elgastat purification system (Elga, High Wycombe, Bucks). The simultaneous cyclic voltammetry and gravimetry experiments were carried out with a Princeton Applied Research model 173 potentiostat/galvanostat and an Elchema model EQCN-700 electrochemical quartz crystal nanobalance. For mass balance experiments the working electrodes were *AT*-cut 10 MHz gold plated quartz crystals with geometric electrode areas of 0.2 cm^2. All gold electrodes were pretreated by cycling in 0.1 M HNO_3 between 0.0 and 1.0 V *vs.* Ag/AgCl. Auger spectra were recorded on a JEOL 7100 Auger electron spectrometer and quantified based on a $K_4Fe(CN)_6$ reference sample.

Received (in Cambridge, UK) 5th June 2001, Accepted 17th August 2001
First published as an Advance Article on the web 18th September 2001

The reaction of nona-2,7-diyne, deca-2,8-diyne and hex-1-yne with $[RuCp(PR_3)(MeCN)_2]PF_6$ (R = Cy, Ph, Me) affords, depending on the structure of the alkyne and the substituent of the phosphine ligand, ruthenium metallacyclopentatriene, allyl carbene and/or butadienyl carbene complexes involving either metal-to-ligand-to-metal migration of the phosphine ligand with concomitant C–H activation or a facile 1,2 hydrogen shift.

Transition metal complexes with a vacant coordination site, or bearing weakly coordinating ligands, are known to react with alkynes to form a variety of products such as vinylidene complexes,[1] metallacyclopentadienes,[2] and in some cases metallacyclopentatrienes.[3] We have recently shown[4] that the labile complex $[RuCp(PR_3)(MeCN)_2]PF_6$ [R = Cy (**1a**), Ph (**1b**), Me (**1c**)], which serves as a synthetic equivalent for the 14-electron fragment $[RuCp(PR_3)]^+$, reacts with terminal alkynes to give ruthenium allyl carbene complexes.[5] This conversion is a very complex one involving oxidative coupling of two alkynes and an unusual PR_3 migration. In the course of the reaction, a metallacyclopentatriene complex is a reasonable, though elusive intermediate which is a fascinating entity featuring the cyclic biscarbene structure. Since such species might be important intermediates in various transformations,[6] we set out to modify the reactants with the aim to make such species observable. For this purpose we switched over to using the internal alkynes nona-2,7-diyne and deca-2,8-diyne, the intention being to impede nucleophilic attack at the α carbon of the metallacycle. Along these lines, however, unexpected and novel reactions occurred, which are described herein.

In virtually one case the surmised metallacyclopentatriene intermediate could be isolated, namely when the alkyne was deca-2,8-diyne and the phosphine in **1** was PCy_3. Monitoring the reaction by ^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$ NMR spectroscopy revealed the formation of an intermediate consistent with the cationic metallacyclopentatriene structure $[CpRu\{=C_2(Me)_2C_2(CH_2)_4\}(PCy_3)]^+$ (**2**) (Scheme 1).‡ Thus, the resonances in the $^{13}C\{^1H\}$ NMR spectrum at 325.6 and 170.6 ppm can be associated with the C_α and C_β ring carbons, respectively. The unusual down-field shift of the C_α carbon resonance is in agreement with an unsaturated bis-carbene ligand {*cf.* $RuCp[=C_2(Ph)_2CH_2]Br$, for which the resonances of the C_α and C_β atoms, respectively, are found at 271.1 and 156.0 ppm[3a]}. Finally, the signal at 52.5 ppm is relevant to the methyl carbon atoms. However, this metallacyclopentatriene complex is unstable and transforms directly into the butadienyl carbene complex $[CpRu\{=C(Me)C(CH_2)_4C\text{-}\eta^2\text{-}CH{=}CH_2\}(PCy_3)]PF_6$ **3a** in high yield (for the characterization see below).

The direct step from **2** to **3a** is intriguing in that it involves activation of an α-substituent by an electrophilic carbene (pathway **a**), which is unprecedented for a metallacyclopentatriene. Hitherto, a 1,2 hydrogen shift was known only for electrophilic alkyl carbenes.[7] There is only one other example of a butadienyl carbene as encountered recently in the reaction of an osmacyclopentatriene complex with *tert*-butylamine.[8]

Note that the outcome of the reaction of deca-2,8-diyne with $[RuCp(PR_3)(MeCN)_2]PF_6$ is very sensitive to the substituent of the phosphine ligand. While also with PPh_3 conversion to the butadienyl carbene complex **3b** occurred, although without observing an intermediate, the reaction took another course when PMe_3 was used. In this case, phosphine migration takes place as shown in pathway **b** of Scheme 1, analogously to the reaction of nona-2,7-diyne with $[RuCp(PR_3)(MeCN)_2]PF_6$, independent of the phosphine substituent. Such a phosphine migration results in the formation of the allyl carbene complexes $[CpRu\{=C(Me)\text{-}\eta^3\text{-}C(CH_2)_4CC(Me)PMe_3\}]PF_6$ **4a** and $[CpRu\{=C(Me)\text{-}\eta^3\text{-}C(CH_2)_3CC(Me)PR_3\}]PF_6$ [R = Me (**4b**), Ph (**4c**), Cy (**4d**)] in essentially quantitative yield. This conversion features the same type of reaction that was observed before in the case of terminal alkynes. Products **4** could be readily characterized by their $^{13}C\{^1H\}$ NMR spectra displaying two doublet resonances in the range of 271–252 (J_{CP} 7–4 Hz) and 41–33 ppm (J_{CP} 72–61 Hz) that can be assigned to the carbene carbon atoms and the terminal allyl carbon atoms bearing the phosphine substituent, respectively.

Furthermore, the allyl carbene composition of **4c** proved not to be the most stable one. If a solution of **4c** in acetone-d_6 is kept for several days at room temperature, further rearrangement takes place leading eventually to the butadienyl carbene complex $[CpRu\{=C(Me)C(CH_2)_3C\text{-}\eta^2\text{-}CH{=}CH_2\}(PPh_3)]PF_6$ **3c** in essentially quantitative yield. The ^1H NMR spectroscopic data for **4c** include characteristic resonances centered at 5.42 (dd, H^4, $^3J_{HH}$ 11.4 $^3J_{HH}$ 10.8 Hz), 3.80 (d, H^{5cis}, $^3J_{HH}$ 10.8 Hz) and 1.85 ppm (dd, H^{5trans}, $^3J_{HP}$ 12.0, $^3J_{HH}$ 11.4 Hz) assignable

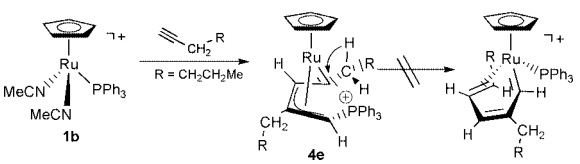
Selected bond lengths (Å) and angles (°): Ru–C(1–5)$_{av}$ 2.245(5), Ru–C(7) 1.934(5), Ru–C(14) 2.212(6), Ru–C(15) 2.265(6), Ru–P(1) 2.358(1), C(7)–C(8) 1.437(7), C(8)–C(13) 1.349(9), C(13)–C(14) 1.471(8), C(14)–C(15) 1.397(8), C(7)–C(8)–C(13) 112.8(4), C(8)–C(13)–C(14) 119.7(5), C(13)–C(14)–C(15) 121.3(6), P(1)–Ru–C(7) 91.8(1).

to the vinyl protons of the coordinated double bond. In the $^{13}C\{^1H\}$ NMR spectrum the characteristic resonance of the carbene carbon occurs as a doublet centered at 330.1 ppm (J_{CP} 15.3 Hz). The uncoordinated and coordinated sp^2 carbon atoms C^2, C^3, C^4 and C^5 of the butadienyl unit exhibit resonances at 199.7, 174.4, 74.4 and 55.1 (d, J_{CP} 5.6 Hz) ppm, respectively. During this conversion, the PPh_3 moiety has re-migrated to the metal center with concomitant C–H bond activation. This may involve either the Me substituent of the carbene carbon atom *via* a 1,2 hydrogen shift (pathway **c**) or the Me group adjacent to the phosphonium moiety (pathway **d**). It is interesting that neither **4a**, **4b** nor **4d** underwent such a rearrangement process.

In addition to a full NMR spectroscopic and analytical characterization of **3a**–**c**,§ the solid state structure of **3b** was determined by single-crystal X-ray diffraction.¶ The solid state structure is depicted in Fig. 1 with important bond distances reported in the legend. Accordingly, **3b** adopts a three legged piano stool conformation with PPh_3 and the two C=C bonds and the carbene carbon atom of the butadienyl moiety as the legs. The most notable feature is the short Ru–C(7) bond distance of 1.934(5) Å, which is in line with a metal–carbon double bond. Furthermore, the butadienyl C–C bonds C(8)–C(13), C(13)–C(14) and C(14)–C(15) show the expected short–long–short pattern (1.349(9), 1.471(8) and 1.397(8) Å, in the same order].

In order to distinguish between the operation of pathways **c** or **d** in Scheme 1, complex **1b** was also reacted with hex-1-yne. The result is depicted in Scheme 2. As expected, the allyl carbene $[CpRu\{=C(Bu^n)(\eta^3\text{-}CHC(Bu^n)CHPPh_3)\}]PF_6$ **4e** was formed in high yield. Owing to the positions of the butyl substituents, however, any rearrangement to the corresponding butadienyl carbene complexes could occur only *via* a 1,2 H shift. Since no such rearrangement was evident, even after a week, it can be concluded that the activation of C–H bonds adjacent to the phosphonium moiety is preferred to a 1,2 H shift. In this context, it is worth mentioning that allyl carbenes can activate alkyl C–H bonds in tertiary phosphine ligands.[5]

In conclusion, we have shown that the reactivity of a cationic metallacyclopentatriene complex varies with the nucleophilicity of the co-ligand and the presence of α-alkyl substituents.



Scheme 2

Ligand migrations give initially allyl carbenes and a 1,2 hydrogen shift gives butadienyl carbenes. Therefore, due to their strong electrophilic character, cationic metallacyclopentatriene complexes are not catalytically active with respect to cyclotrimerizations. Furthermore, the present reluctance with respect of a 1,2 H shift may suggest that allyl carbenes are not electrophilic enough at the carbene carbon. In fact, the carbene carbon of allyl carbenes can be attacked by protons forming η^4-diene complexes.[5]

Dioxygen activation by a neutral β-diketiminato copper(I) ethylene complex†

Xuliang Dai and Timothy H. Warren*

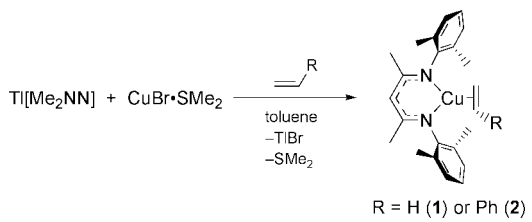
Georgetown University, Department of Chemistry, Box 571227, Washington, D.C. 20057-1227, USA. E-mail: thw@georgetown.edu

Received (in Cambridge, UK) 14th June 2001, Accepted 15th August 2001
First published as an Advance Article on the web 18th September 2001

The synthesis and structure of two thermally stable neutral β-diketiminato copper(I) olefin complexes are presented along with the structure of a Cu(II)$_2$(μ-OH)$_2$ dimer that results from the reaction of the Cu(I) ethylene complex with O_2 *via* the proposed intermediacy of a Cu(III)$_2$(μ-O)$_2$ species.

The diverse biological role copper(I) complexes play motivates a great deal of interest in synthetic nitrogen-ligated systems. For example, the Cu(I)-based ethylene receptor in ETR 1 regulates many facets of plant growth such as fruit ripening, seed germination and even sex determination in some species.[1] Synthetic studies have uncovered that most copper(I)-ethylene complexes are quite labile,[2] with the most robust systems based on very electron-rich neutral donors such as bipyridine[2b] or a recently reported monoanionic iminophosphinamide.[2c] Cu(I) complexes are also responsible for the binding and transport of dioxygen in invertebrates as exemplified by the ubiquitous enzyme hemocyanin whose active site consists of two Cu(I) centers ligated by three histidine residues each.[3] The related enzyme tyrosine is responsible for the selective C–H activation of phenols, ultimately oxidizing them to *ortho*quinones.[4] Whereas much effort has been directed toward a detailed understanding of this biological reactivity,[3] model systems based on bi- and tri-dentate amine donors also offer the synthetic potential for selective C–H bond functionalization.[5] As part of our program to explore the chemistry of electron-rich β-diketiminates of the later first row metals, we report herein our initial results describing a neutral Cu(I) system that both binds olefins and activates dioxygen.[6–8]

Reaction of the thallium β-diketiminate Tl[Me$_2$NN] with CuBr·SMe$_2$ in the presence of either ethylene (1 atm) or styrene (1.2 equiv.) in benzene or toluene provides thermally stable [Me$_2$NN]Cu(alkene) complexes in 60–80% yield as colorless crystals from pentane (Scheme 1) (ESI†). The ^{1}H NMR spectrum of **1** in benzene-d$_6$ shows a significantly upfield shifted resonance (δ 2.91) for bound ethylene. Neither **1** nor **2** is exceptionally labile as exchange with free olefin is slow on the NMR timescale. Reaction of **1** with 1 equiv. styrene at 25 °C in a sealed NMR tube, however, does result in a 1 : 2.3 equilibrium mixture of **1** and **2** after 3 h. Taking the incomplete solubility of ethylene in benzene-d$_6$ into account, styrene complex **2** is actually thermodynamically disfavored over the sterically less hindered ethylene derivative **1** (K = 0.33(2)). Backbonding in **1** and **2** is likely relatively weak as shown by the ethylene $^1J_{CH}$ coupling constant of 158 Hz in **1** and facile rotation about the Cu–styrene bond in **2** ($\Delta G^{\ddagger}$ = 10.7(3) kcal mol^{-1} at 215 K) (ESI†).



Scheme 1 Synthesis of Cu(I) olefin complexes (ESI†).

The X-ray structures of **1** and **2**‡ (Fig. 1) reveal a coplanar orientation of the olefin with the β-diketiminate backbone which chelates the copper center with bite angles of 98.68(6) and 99.0(1)°, respectively. The ethylene and styrene C–C distances in **1** and **2** (1.365(3) and 1.373(6) Å) are similar to that found in the iminophosphinamide [Bu$^t_2$P(NSiMe$_3$)$_2$-κ^2*N*]Cu(C$_2$H$_4$) (1.362(6) Å)[2c] and [(bipy)Cu(styrene)][ClO$_4$] (1.358(10) Å),[9] slightly elongated as compared to the corresponding free olefins (1.337(1)[10a] and 1.346(2)[10b]). While the above data suggest minimal backbonding from the d^{10} copper(I) center, the observed orientation may be favored on electronic grounds due to an enhanced interaction of the olefin π* orbital with the filled Cu d orbital destabilized by the opposing β-diketiminate N donors.

Treating a diethyl ether solution of ethylene complex **1** with several equivalents of dry dioxygen at room temperature ultimately results in the precipitation of paramagnetic {[Me$_2$NN]Cu(μ-OH)]}$_2$ **3**[6,7] (μ_{eff} = 1.39 μ_B in CDCl$_3$) which is isolated in 80% yield as brown crystals (ESI†). The X-ray structure of **3**‡ (Fig. 2) shows two square planar Cu(II) centers separated by 3.0581(3) Å nearly symmetrically bridged by two hydroxo ligands with Cu–O distances of 1.914(1) and 1.923(1) Å. The hydroxo H-atom was found in the Fourier difference map, corroborated by a sharp, high energy band at 3646 cm^{-1} in the solid state IR spectrum of **3**. We suggest that the reaction proceeds *via* the intermediacy of a Cu(III)$_2$(μ-O)$_2$ dimer[5,11] **4** followed by abstraction of some H-atom donor[5] to provide **3**

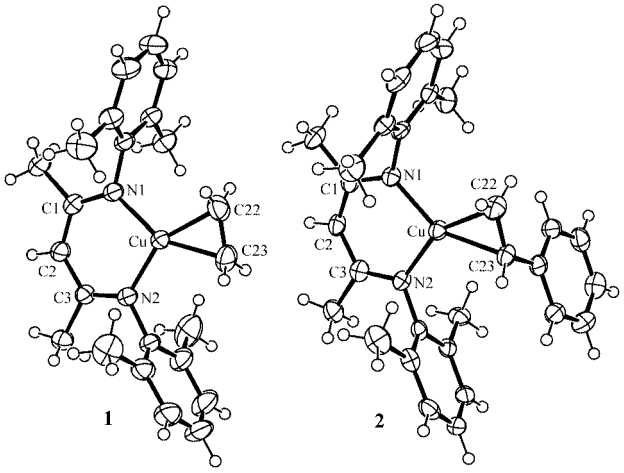


Fig. 1 ORTEP diagrams of the solid state structures of **1** and **2**.‡ Selected bond distances (Å) and angles (°) for **1**·0.5 C$_5$H$_{12}$: Cu–N(1) 1.917(2), Cu–N(2) 1.908(1), Cu–C(22) 1.986(2), Cu–C(23) 1.992(2), C(22)–C(23) 1.365(3), N(1)–Cu–N(2) 98.68(6), C(22)–Cu–C(23) 40.13(9). Selected bond distances (Å) and angles (°) for **2**: Cu–N(1) 1.913(3), Cu–N(2) 1.915(3), Cu–C(22) 1.975(5), Cu–C(23) 2.027(4), C(22)–C(23) 1.373(6), N(1)–Cu–N(2) 99.0(1), C(22)–Cu–C(23) 40.1(2).

† Electronic supplementary information (ESI) available: synthesis of Tl[Me$_2$NN] and **1**–**3** with relevant analytical and spectroscopic details. See http://www.rsc.org/suppdata/cc/b1/b105244f/

 DOI: 10.1039/b105244f

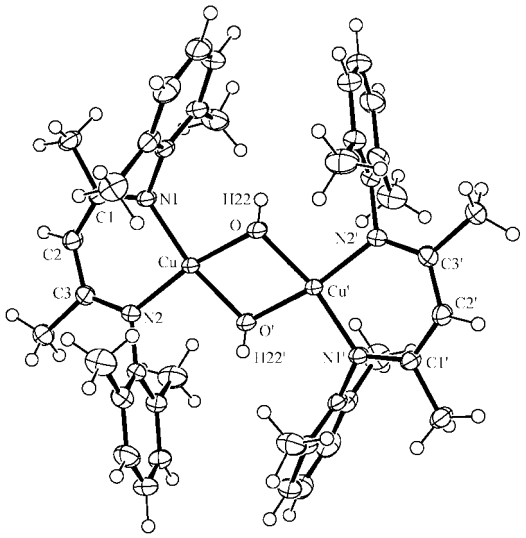

Fig. 2 ORTEP diagram of the solid state structure of **3**.‡ Selected bond distances (Å) and angles (°): Cu–N(1) 1.9446(11), Cu–N(2) 1.9373(11), Cu–O 1.9142(11), Cu–O′ 1.9230(11), Cu–Cu′ 3.0581(3); N(1)–Cu–N(2) 94.83(5), O–Cu–O′ 74.32(5).

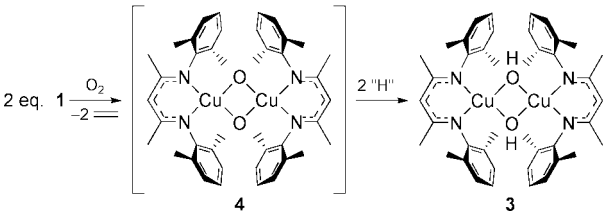

Scheme 2 Proposed formation of **3**.

(Scheme 2). Whereas the source of the hydroxo H-atoms is not yet known, it should be noted that **1** rapidly reacts with H_2O under anaerobic conditions to give the free ligand H[Me_2NN] and an intractable Cu-containing precipitate.

Significantly less thermally stable than the only other reported neutral, iminophosphinamide-based $Cu_2(\mu\text{-}O)_2$ complex which slowly decomposes to an unidentified Cu(II) species,[11a] the enhanced reactivity of proposed μ-oxo dimer **4** has hampered its isolation in pure form. Addition of O_2 to **1** at −78 °C in diethyl ether allows for the isolation of a green microcrystalline material that gradually converts into **3**, even in the solid state. A solution of this freshly isolated green material in CH_2Cl_2 shows an absorption band at 343 nm ($\varepsilon = 2.4 \times 10^4$ M^{-1} cm^{-1}) corresponding to the μ-hydroxo complex **3** as well as two new absorbances at 315 and 420 nm, consistent with characteristic LMCT bands of previously reported $Cu(III)_2(\mu\text{-}O)_2$ complexes.[5,11] Furthermore, oxygenation of **1** with air (THF, 25 °C) results in the initial formation of these bands at 315 and 420 nm followed by their gradual loss in intensity giving rise to the 343 nm band of the μ-hydroxo complex **3** (ESI†).

Low temperature resonance Raman spectroscopy[5,11] in addition to the synthesis of a sterically diverse family of neutral β-diketiminato Cu(I) complexes are underway to uniquely determine the composition of the green intermediate **4** as well as the source of H-atoms that lead to the isolated μ-hydroxo compound **3**. Further protonation studies of the olefin adducts **1** and **2** to yield new cationic β-diimino Cu(I) olefin complexes[6] and their use as cyclopropanation catalysts will also be reported in due course.

We thank the Georgetown University Department of Chemistry for financial support of this work as well as Professor Robert Bachman and Professor K. Travis Holman for assistance with the X-ray structures of **1** and **2**.

Notes and references

‡ Data were collected on a Bruker SMART CCD instrument and the structure solutions were performed using the SHELXTL/PC suite[12a] and XSEED.[12b] Intensities were corrected for Lorentz and polarization effects and an empirical absorption correction was applied to **3** using Blessing's method as incorporated into the program SADABS.[12c]

Gold nanoparticles have been functionalized with thiol dendrons containing three redox active amidoferrocenyl or silylferrocenyl units; using cyclic voltammetry, these dendronized gold nanoparticles recognize $H_2PO_4^-$

The scope of supramolecular chemistry[1] involves nanoscience including dendrimers[2] and nanoparticles[3] with applications to the field of sensors.[1,4] Beer *et al*. have shown various examples of redox anion recognition by amidoferrocenes bound to endoreceptors,[4] a concept that we have extended to dendrimers[5a] and colloids[5b] as exoreceptors. So far, only a few other reports of molecular recognition by nanoparticles have appeared,[6] althought ferrocenylalkylthiol ligands bonded to surfaces in self-assembled monolayers and colloids have been known for some time.[7] Dendrimer-colloid assemblies have also been successfully designed for the fabrication of a new generation of catalysts and sensors.[3b] We now report the synthesis of dendrons containing silylferrocenyl or amidoferrocenyl termini, their functionalization by thiol ligands, fixation of these dendron-thiol ligands onto gold colloids[8] and recognition of $H_2PO_4^-$ by these thiol-functionalized gold colloids.

Our strategy has consisted of performing ligand exchange reactions between alkylthiol–gold colloids of the Brust type[9] and the thiol dendron, a method that keeps the size of the colloids constant during the ligand exchange reactions, thus retaining their narrow polydispersity.[5b,9] The two syntheses of the triferrocenyl dendron–gold particle assemblies are represented in Scheme 1. Both syntheses represent the first routes to ferrocenyl-containing dendrons, although numerous ferrocenyl- and amidoferrocenyl-containing dendrimers are known.[10–13a] The key to rapid entry into the chemistry of such functionalized dendrons is the direct hydrosilylation of the three allyl groups of the dendron **1**[12] using various silanes[11–13] without any protection of the phenol function (Scheme 1).[14] The two air-sensitive thiol dendrons **8** and **10** were fully characterized by elemental analysis, NMR and the molecular peaks in their MALDI TOF mass spectra. We synthesized gold colloids with 2.1 nm diameter core and approximately 108 ± 5 dodecanethiolate ligands using the method of Brust *et al*.[9] Ligand-exchange reactions between these gold–dodecanethiolate particles and the thiol ligands **8** and **10** were carried out under ambient conditions in CH_2Cl_2 using 2/3 equiv. functional thiol per dodecane thiol

 DOI: 10.1039/b106805a

ligand. This led to the dendronized particles **11** and **12**, and the excess of functional ligand was removed by washing **11** and **12** with methanol. The percentage of functional thiolate dendrons introduced as ligands in **11** and **12**, determined by combined HRTEM, ^{1}H NMR spectroscopy and elemental analysis, was 4.8 and 3%, respectively (a little more than five and three dendrons per particle for **11** and **12**, respectively). TEM images confirm that the sizes of the gold cores of the particles remain unchanged after the ligand-substitution reactions.

The cyclovoltammograms of the dendronized colloids **11** and **12** (Pt, CH_2Cl_2, 0.1 M [*n*-Bu_4N][PF_6]) show a chemically (i_a/i_c = 1) and electrochemically ($\Delta E_p \leq 50$ mV) reversible ferrocene/ferrocenium wave.[14] Thus, all the ferrocenyl units appear equivalent in each type of particles, which is due, in particular, to the fact that rotation of the particles is faster than the electrochemical time scale.[15] The separation between the anodic and cathodic peaks is 50 mV for **11**, which almost corresponds to the value expected at 20 °C for a single-electron wave (58 mV). In the case of **12**, however, this peak separation is only 20 mV. This indicates some adsorption, although this phenomenon is not accompanied by an enhanced intensity of the adsorbed species. The $E_{1/2}$ value is 0 V *vs.* $Cp_2Fe^{0/+}$ for **11** and 0.145 V *vs.* $Cp_2Fe^{0/+}$ for **12**.

We then added [*n*-Bu_4N][H_2PO_4] to the electrochemical cell containing **12**, which led to a decrease of the intensity of the amidoferrocene wave of **12** (Fig. 1). The growth of another wave was then observed at a less positive potential until the initial wave had disappeared when the amount of [*n*-Bu_4N][H_2PO_4] added corresponded to 1 equiv. per amidoferrocenyl branch. Thus, the new wave is the signature of a strong amidoferrocenium–$H_2PO_4^-$ interaction. Contrary to the initial wave, it shows the characteristic of slow electron transfer since the ΔE_p value is larger than 60 mV and depends on the scan rate, indicating structural reorganization in the course of the heterogeneous electron transfer.[14] The value of $E_{1/2}$ for each wave does not vary during the titration, the difference remaining equal to 210 ± 10 mV (as for the dendron **8** alone). This corresponds to an apparent association constant K_{app} between the ferrocenium form of **12** and $H_2PO_4^-$ that is 5200 ± 1000 times larger than that between the neutral form of **12** and $H_2PO_4^-$.[16] This shift is very large compared to monomeric amidoferrocenes ($E_{1/2(free)} - E_{1/2(bound)} = 45$ mV) and even to tripodal tris-amidoferrocenes such as PhC{$(CH_2)_3O(CH_2)_3$NHCOFc}$_3$ ($E_{1/2(free)} - E_{1/2(bound)} = 110$ mV), and is about as large as with a nona-amidoferrocene dendrimer.[5a] The known factors involved in the recognition of $H_2PO_4^-$ by amidoferrocenyl-containing receptors are the double hydrogen bonding between this anion and the amido groups, the enhanced electrostatic attraction in the oxidized ferrocenium form and the topographical effect of the receptor.[4]

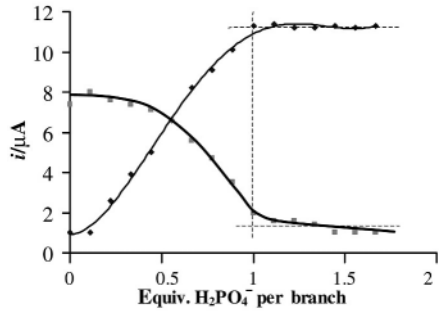

Fig. 1 Titration of **12** (10^{-6} M in CH_2Cl_2) with [*n*-Bu_4N][H_2PO_4] (10^{-2} M in CH_2Cl_2) monitored by CV. Decrease of the intensity of the initial wave at $E_{1/2}$ = 0.145 V *vs.* $FeCp_2^{+/0}$ and increase of the intensity of the new wave at $E_{1/2}$ = –0.065 V *vs.* $FeCp_2^{+/0}$ *vs.* the number of equivalents of [*n*-Bu_4N][H_2PO_4] added per ferrocenyl branch of **12**. [*n*-Bu_4N][PF_6] 0.1 M, 20 °C; internal reference: [Fe(η^5-$C_5Me_5)_2$]; reference electrode: Ag; auxiliary and working electrodes: Pt; scan rate: 0.2 V s^{-1}. A similar response was obtained with **11**.

Interestingly, the silylferrocene-containing colloids **11** also recognize $H_2PO_4^-$. Addition of [*n*-Bu_4N][H_2PO_4] to an electrochemical cell containing **11** provokes the same effect as with **12**, *i.e.* the appearance of a new wave at less positive potential than the original one, while the disappearance of the initial wave is observed for 1 equiv. of anion per silylferrocenyl branch. The difference of potential between the two waves is 110 ± 10 mV, which corresponds to a K_{app} value 85 ± 30 times larger for the ferrocenium form than for the ferrocenyl form. So far, only $H_2PO_4^-$ is recognized, the anions HSO_4^-, Cl^-, Br^- and NO_3^-, for instance, having no significant effect using either **11** or **12**.

It is likely that the supramolecular redox properties of dendronized colloids can be developed for sensoring, catalysis and molecular electronics in the near future.

First published as an Advance Article on the web 17th September 2001

Chlorophyll derivatives possessing triethoxysilyl groups have been synthesized for the first time and grafted on mesoporous silica to construct an efficient energy transfer system between the chromophores.

In natural photosynthesis, chlorophylls (Chls, Fig. 1) play a key role in converting solar energy to chemical energy. Mimicking the highly efficient energy transfer (ET) systems is a subject to be tackled towards the ultimate goal of establishing solar energy conversion systems.[1] Considerable efforts have been directed toward the preparation of donor–acceptor (D–A) systems immobilized in various media (*e.g.* films,[2] surfactant micelles,[3] and lipid vesicles[4]). On the other hand, we have recently proposed the use of FSM-type mesoporous silica as an adsorbent of Chls,[5–7] because mesoporous silica powders possess high adsorption capacity with well ordered mesopores. However, our previous studies revealed that the surface silanol groups on FSM denatured incorporated chlorophyllous pigments.[5] Although surface modification with diols is an effective approach to suppress denaturation of Chls,[5,7] the plane of chlorin macrocycles should probably lie down on the modified silica surface.[6,7] Moreover, the arrangement between neighboring chromophores in mesopores is difficult to control by simple liquid-phase adsorption,[7] resulting in inefficient ET. In order to control the arrangements of macrocycles which should ideally be located in the center of mesopores, Chl derivatives possessing triethoxysilyl groups (Fig. 1) were therefore synthesized and grafted on mesoporous silica. We used Zn–chlorin and Cu–chlorin as the donor–quencher pair, because the fluorescence of Zn–chlorin should be quenched by Cu–chlorin, a non-fluorescent Chl derivative.[2]

Siliceous FSM was synthesized according to a method reported previously.[5] The X-ray diffraction (XRD) pattern (d_{100} = 4.0 nm) and the BET specific surface area (1000 $m^2\ g^{-1}$) were similar to those reported in ref. 5. A prescribed amount of compound **1**‡ (50–200 nmol of **1a**, **1b**, or a mixture of **1a** and **1b**, see Fig. 1) and 3-aminopropyltriethoxysilane (APTES, 4.3 mmol), a modifier to suppress denaturation of Chls, were dissolved in dry CH_2Cl_2 (2 mL). Then FSM powders (0.1 g), preheated at 150 °C for 3 h under vacuum, were dispersed in the solution of **1** and APTES. The mixtures were stirred at room temperature for 24 h in the dark (*i.e.* under mild conditions) to prevent denaturation of the chlorin macrocycles, centrifuged, washed with acetone, and dried under reduced pressure. The APTES–FSM/**1** compounds (*i.e.* APTES–FSM/**1a**, APTES–FSM/**1b** and APTES–FSM/**1a**–**1b**) were found to be green powders after washing. The mesostructure was retained after silylation according to the XRD patterns of APTES–FSM/**1** which was quite similar to that of pristine FSM (d_{100} = 4.0 nm) (ESI).†

Fig. 1 Molecular structure of chlorophyllous pigments (left) and schematic representation of the ET process in mesopores (right).

† Electronic supplementary information (ESI) available: Figs. S1–3: XRD patterns, ^{29}Si CP/MAS NMR and IR spectra. See http://www.rsc.org/suppdata/cc/b1/b104959n/

The cross polarization (CP) and magic angle spinning (MAS) ^{29}Si NMR spectrum of pristine FSM gives a Q^4 ($Si(OSi)_4$) peak with a relatively small Q^3 ($Si(OSi)_3OH$) band.[8] On the other hand, APTES–FSM gave resonance peaks in the region from −50 to −70 ppm assigned to T^1 (R(OR′)(OR″)*Si*(OSi)), T^2 (R(OR′)*Si*$(OSi)_2$) and T^3 (R*Si*$(OSi)_3$) peaks along with Q^3 and Q^4 peaks (ESI).[9]† A decrease in the number of Si–OH groups after silylation was also indicated by a decrease in the IR absorption in the O–H stretching region (*ca.* 3690 cm^{-1}) (ESI).† These findings confirm that APTES formed Si–O–Si bondings with Si–OH groups on FSM. Oligomerization of APTES in mesopores should be negligible, since silylated FSM powders were washed three times to remove residual silanes. The ^{13}C CP/MAS NMR signals due to CH_2 and CH_3 carbons of unreacted ethoxy groups of APTES appeared at *ca.* 56 and 17 ppm in the spectrum (data not shown).[9] Based on the CHN analysis, the number of grafted aminopropylsilyl groups was roughly estimated to be 1.3 nm^{-2} and the number of reacted ethoxy groups per APTES was calculated to be 1.9 nm^{-2}. The degree of grafting was smaller than that of FSM silylated with APTES by refluxing (1.7 groups nm^{-2}),[8] which is ascribed to the mild reaction conditions.

Because the amounts of **1** introduced were much lower than that of APTES molecules to prevent concentration quenching of ET (see below), there is no spectroscopic evidence whether the compounds **1** formed Si–O–Si bondings with FSM. However, all APTES–FSM/**1** powders were scarcely bleached by repeated washing with acetone. This is in sharp contrast with the observation that Chls incorporated into FSM by simple liquid-phase adsorption were easily desorbed from the mesopores by washing with acetone.[5–7] This finding strongly suggests that the compounds **1** were grafted onto the surface of mesopores as well as APTES–FSM.

Fig. 2(top) and (middle) depict the diffuse reflectance visible absorption spectra of **1a** (M = Zn) and **1b** (M = Cu) grafted on FSM. The Soret and Q_y absorption peaks of **1a** onto FSM were located at 426 and 660 nm, respectively. The spectral shape for APTES–FSM/**1a** is similar to the absorption spectrum of Zn–Chl *a* in methanol.[10] The full width at half maximum of the Q_y band (*ca.* 720 cm^{-1}) was broadened to a lesser extent than that of FSM/Zn–Chl *a* (*ca.* 1100 cm^{-1}),[6] indicating that **1a** was well-dispersed in the mesopores. Compound **1b** showed Soret and Q_y absorption peaks at 413 and 655 nm, respectively. The incorporation of Cu–chlorin was successful, which was in sharp

 DOI: 10.1039/b104959n

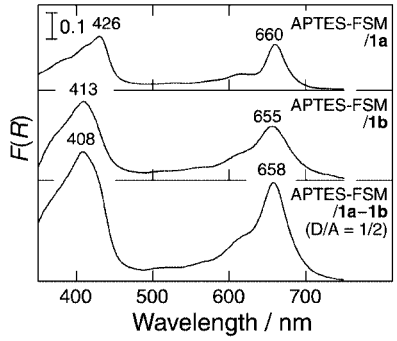

Fig. 2 Diffuse reflectance visible absorption spectra of APTES–FSM/**1** compounds. $F(R)$ refers to the so-called remission function for diffuse reflection measurements; $F(R) = (1 - R)^2/2R$.

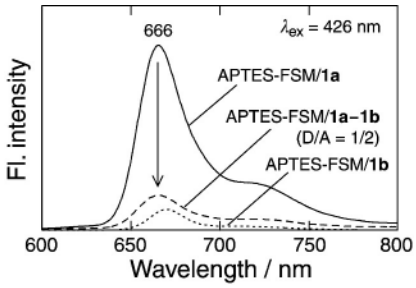

Fig. 3 Fluorescence emission spectra of APTES–FSM/**1** compounds (excited at 426 nm): APTES–FSM/**1a** (M = Zn) (—), APTES–FSM/**1b** (M = Cu) (···), APTES–FSM/**1a**–**1b** (co-adsorption) (– – –).

contrast to the fact that Cu–Chl *a* was scarcely immobilized in APTES–FSM (Furukawa *et al*., unpublished results). In the co-adsorbed state (APTES–FSM/**1a**–**1b**), the absorption band in the Soret region appeared at 408 nm with a small shoulder at 430 nm [Fig. 2(bottom)],[11] which indicates that this absorption spectrum can be roughly interpreted as a summation of those of **1a** and **1b**. This also indicates that the individual chromophores scarcely exhibit any specific interactions in the ground states within the mesopores.

The fluorescence emission spectra of APTES–FSM/**1** powders are illustrated in Fig. 3. Concentration quenching is negligible in all the APTES–FSM/**1** samples since the fluorescence intensity is proportional to the pigment concentration. The amounts of incorporated pigments were also estimated by the difference in the absorption spectra of the supernatant solutions before and after the silylation. The emission peaks of **1a** (M = Zn) and **1b** (M = Cu) on APTES–FSM were located at 666 and 670 nm, respectively. The emission intensity of **1b** was much weaker than that of **1a** in APTES–FSM.[11] The spectral overlap between the donor emission and quencher absorption bands is also relatively large (Figs. 2 and 3). These findings indicate that Förster type donor–acceptor (quencher) ET should occur.[12] In the co-adsorption systems the emission intensity of **1a** (M = Zn) was decreased with an increase in the amount of **1b** (M = Cu). The ET efficiency from **1a** to **1b** was approximately estimated by the considering the decrease in the emission area in the Q_y region in comparison with that of the APTES–FSM/**1a** complex (90% for D/A = 1/2; 50% for D/A = 1/1). In the case of co-adsorption of both Zn–pyroChl *b* and Zn–pyroChl *a* in APTES–FSM, the emission intensity originating from Zn–pyroChl *a* (acceptor) was increased even though there are many NH_2 groups in the mesopores (ET efficiency 75% for D/A = 1/10, Furukawa *et al*., unpublished results). The finding indicates that the NH_2 groups of APTES scarcely act as quenchers in the present system. Based on the pore volume and pore size of APTES–FSM, the critical distance (R_0)[12] between neighboring chromophores is calculated to be *ca*. 12 nm. It is of interest that this efficiency is much higher than the ET efficiency between Chl *b* and Chl *a* in diol modified FSM (70% for D/A = 1/10),[7] though the pigment concentration and R_0 in the mesopores are very similar. Taking into account that fact that highly efficient ET is obtained in this grafted system in comparison to systems obtained by conventional adsorption methods, the planes of chromophores are probably perpendicular to the silica walls in the mesopores. This suggests that the interactions between the chlorin macrocycles and the silica walls are relatively small, and this may be the reason why APTES–FSM/**1a** complexes gave a sharper absorption band in comparison with FSM/Zn–Chl *a*, for which Zn–Chl *a* was incorporated into FSM by liquid-phase adsorption.[6]

We are grateful to Mr T. Shigeno (Waseda Univ.) for his help in NMR measurements. This work was partially supported by a Grant-in-Aid for COE Research, MEXT, Japan. H. F. also acknowledges a Grant-in-Aid for Scientific Research, MEXT, Japan (No. 13750780).

Notes and references

‡ Chl was extracted from spinach tissue and pyrolyzed to suppress denaturation of the chlorin macrocycle.[6] The amidation procedure is as follows: zinc $C13^2$-demethoxycarbonylchlorophyllide *a* (Zn–pyroChlid *a*) was prepared, as described in ref. 13 from Chl *a*. Zn–pyroChlid *a* (60 μmol) was added to a mixture of 3-aminopropyltriethoxysilane (120 μmol), 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (60 μmol) and dimethylaminopyridinium tosylate (60 μmol) in dry CH_2Cl_2 (10 mL).[14] The mixture was stirred for 12 h under N_2 at room temperature. The crude compound was purified by flash column chromatography over silica gel with acetone and by preparative normal-phase HPLC (column: Senshupak Silica-5251N; eluent: ethyl acetate–hexane–acetone = 6 : 1 : 3). *Characterization data* for zinc $C13^2$-demethoxycarbonylchlorophyllide *a* 3-triethoxysilylpropylamide (**1a**, 60%). 11 Taking into account the fact that the absorption maximum in the Soret region of APTES–FSM/**1a**–**1b** was located at a wavelength shorter than that of APTES–FSM/**1a**, the possibility of denaturation (and/or demetalation) of the macrocycle in mesopores cannot be fully excluded. This may be the reason that a weak emission of **1b** was observed (Fig. 3), though Cu–chlorin is normally non-fluorescent.[2] An excitation spectrum of APTES–FSM/**1b** did not resemble that of either pheophytin *a* (free base chlorin) or Zn–Chl *a*, which may also support the possibility of partial pigment denaturation.

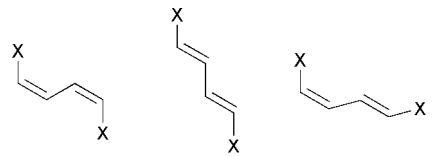
First published as an Advance Article on the web 11th September 2001

One-way *EZ*-isomerization of bis(*n*-butylammonium) (*Z,Z*)-muconate [(*Z,Z*)-hexa-2,4-diene-1,6-dioate] to the corresponding (*E,E*)-isomer quantitatively proceeded in the crystalline state under photoirradiation with a high-pressure mercury lamp, being a new type of crystal-to-crystal reaction.

Organic synthesis performed in the solid state is one of the most intriguing fields of chemistry in recent years, because of the specific features of the solid-state reaction including the excellent selectivity of the reaction compared to those in an isotropic medium, the specific molecular alignment in the solid as the product, and the environmental aspect of a solvent-free process.[1] In contrast to cyclization and rearrangement as the unimolecular reaction in the crystalline state, *EZ*-isomerization is difficult due to a drastic and unenviable change in the size and shape of the occupied space by an olefin molecule during the isomerization.[2] During the course of our recent studies of the topochemical polymerization of diene monomers, we have found that some (*Z,Z*)-muconic derivatives provided a geometrical isomer but not a polymer as the photoproduct in a high yield by UV irradiation in the crystalline state.[3] This isomerization is a crystal-to-crystal reaction with an excellent selectivity, being completely different from ordinary photoreactions. Monoolefins and azo compounds generally induce reversible *EZ*-isomerization and the photoproducts are isolated as a mixture of *cis* and *trans* isomers, whose composition is dependent on the wavelength of light used. In the present paper, we describe the unique one-way *EZ*-isomerization of bis(*n*-butylammonium) (*Z,Z*)-muconate [(*Z,Z*)-hexa-2,4-diene-1,6-dioate] (**1**) to the corresponding (*E,E*)-isomer (**2**) as a new type of solid-state topotactic reaction.



When **1** was irradiated in the crystalline state at room temperature using a high-pressure mercury lamp with a Pyrex filter, the isomerization to **2** proceeded. In this system, no polymer was produced due to the absence of columnar structure appropriate for the topochemical polymerization in the crystals.[3c,d] ^{1}H NMR spectroscopy confirmed that the solid-state photoisomerization is highly stereoselective, *i.e.*, no (*E,Z*)-isomer (**3**) formed during photoirradiation in the crystalline state, in contrast to the photoirradiation in a solution resulting in a mixture of three kinds of isomers, and complementary to the exclusive formation of **3** during thermal isomerization in solution.[4] As summarized in Table 1, the conversion of **1** to **2** achieved 98% for the 10 h irradiation. When **2** was irradiated in the crystalline state under similar conditions, unreacted **2** was recovered. Thus, the isomerization occurs solely one-way from **1** to **2** in the crystalline state, despite similar UV absorption bands of both isomers, *i.e.*, λ = 255 nm and $\varepsilon = 1.77 \times 10^4$ for **1**; λ = 260 nm and $\varepsilon = 2.42 \times 10^4$ for **2**. Similar one-way isomerization was observed for a series of muconic acid derivatives, *e.g.*, *n*-alkyl- and branched alkylammonium salts, alkyl esters, and *N*-alkylamides.

Powder X-ray diffraction has verified that the isomerization occurs *via* a crystal-to-crystal reaction process, and that the diffraction profiles of the crystals after photoirradiation consist of overlapped patterns of the diffraction due to the crystals of **1** and **2** (Fig. 1). This indicates that the crystal domains of each isomer exist simultaneously in the crystals accompanied by crystal phase separation during the photoisomerization. Single crystal structure analysis has disclosed that the crystals of **2** as the photoproduct have a symmetry different from that of the starting crystals of **1** (Fig. 2).† The solid-state photoisomeriza-

tion of **1** proceeds *via* a topotactic reaction mechanism.[5] The isomerization from **1** to **2** in the crystalline state requires not only the movement of atoms but also a change in the crystal symmetry and the reconstruction of the hydrogen bond network pattern. In the crystals of these primary ammonium carboxylates, one-dimensional ladder-type hydrogen bonds are observed, consisting of the primary ammonium cations and the carboxylate anions which act as triple hydrogen bond donors and acceptors, respectively.[3c,6] The isomerization of the (*Z,Z*)-diene to the (*E,E*)-diene is associated with the rotation of carbonyl groups and the change in the hydrogen bond structure (Fig. 3). The reconstruction of the hydrogen bond network during the isomerization is accompanied with an inter-ladder reaction, but not intra-ladder. The quantitative transformation of **1** to **2** in the crystalline state suggests that the molecular motion in the crystals occurred cooperatively with the minimum movement of atoms in the crystals *via* a phase transition from the crystal of **1** to that of **2**. It is possible to accelerate the heterogeneous solid-state reaction in a boundary domain between the mutual crystal phases of **1** and **2**.

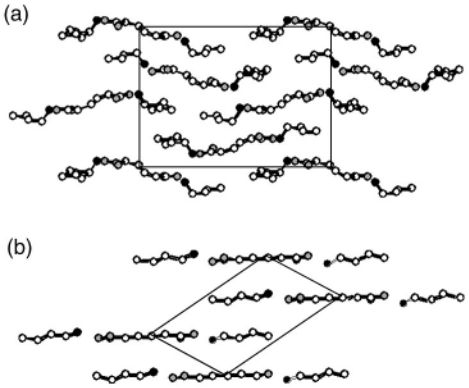

Fig. 2 Crystal structure of (a) **1**, (b) **2** viewed along the crystallographic *a*-axis. Hydrogen atoms are omitted. Hydrogen bond networks run along the crystallographic *a*-axis.

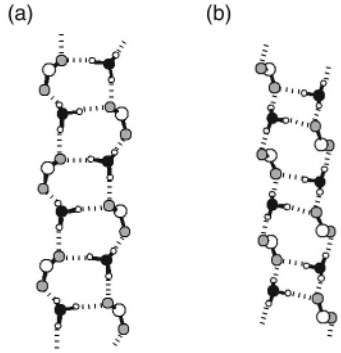

Fig. 3 One-dimensional ladder-type hydrogen bond networks of (a) **1**, (b) **2**.

Topotactic *EZ*-isomerization is advantageous for 1,3-diene derivatives such as muconates, of which both isomers have similar molecular shapes, different from the case of monoolefins. As an exceptional event, unique one-way isomerization of an anthracene-substituted olefin with (*Z*)-configuration has been reported,[7] in which the isomerization to the (*E*)-derivative proceeds during photoirradiation in solution, but the reverse reaction hardly occurs due to the presence of the large aromatic substituent changing in its potential energy surfaces at the excited triplet state. In this work, the excited-state of **1** probably has a conformation similar to that of **2** in the solid state, resulting in a quantitative and one-way isomerization. Further mechanistic studies of the one-way *EZ*-isomerization of the muconic acid derivatives in the crystalline state are now under investigation.

The first structural report of an unprecedented organotellurate(IV) inorganic–organic hybrid macrocyclic host encapsulating a bromide anion guest is described.

In recent years considerable efforts have been directed to gaining an understanding of the fundamental aspects of tellurite glass chemistry because of its potential applications in nonlinear optics and as ionic conductive materials.[1] Tellurites, $(M_2O)_x$-$(TeO_2)_{1-x}$, are glass oxide materials constituted by a network (TeO_2) and a modifier (M_2O, alkali metal oxide). Their remarkable properties arise from the free electron pair in their motif built of TeO_3 or TeO_4 units. In spite of the significant progress in the interpretation of solid state ^{125}Te-NMR spectroscopy data[2] and the structure determination of a few crystalline phases,[3] precise structural data remain elusive due to the amorphous nature of these materials. The development of a 'telluroxane' chemistry of tellurium(IV) as model compounds might be a fruitful approach by analogy to the well-developed chemistry of oligomeric siloxanes, whose importance as molecular precursors and model compounds for zeolitic material is well known.[4] To the best of our knowledge, no comparable oligomeric 'telluroxane' containing exclusively Te–O bonds in their rings has been crystallographically characterized. We present here a novel 'telluroxane' containing a $Te_{12}O_{16}$ ring that can be formally viewed as the condensation product of organotellurium trihydroxides. $[Li(THF)_4][\{(Pr^iTe)_{12}O_{16}Br_4\{Li(THF)Br\}_4\}Br]$ **1** represents the first of a new and potentially rich class of compounds.

Crystals of the title salt† consist of isolated $[Li(THF)_4]^+$ cations, $[\{(Pr^iTe)_{12}O_{16}Br_4\{Li(THF)Br\}_4\}Br]^-$ anions and uncoordinating solvent molecules. The crystals were obtained as colorless air-sensitive trigonal prismatic crystals in a reaction designed initially to prepare a new organotellurium compound, isopropyl hex-1-ynyl telluride,[5] and can be viewed as a partial air oxidation product of a mixture of lithium hex-1-ynyl tellurolate and isopropyl bromide in THF. The structure of this novel tellurium oxide cage compound, with unprecedented molecular macrocyclic character, has been determined by single crystal X-ray diffraction. In the crystalline state, the tellurium oxide framework spherically encapsulates a bromide anion in its cavity. This molecular guest–host entity is stabilized by four Li(THF)Br units and four bromide anions in an outer shell. The capability of entrapping an atomic size guest in its cavity makes it a promising candidate for various applications in chemistry.[6] Moreover, this new example of a self-assembled molecular macrocycle exhibits the remarkably rare[7] property of encapsulating a *negatively* charged ion.

The structure of the skeleton of the anion is shown in Fig. 1. The macrocycle of alternating tellurium and oxygen atoms—constructed of four O–Te–O–Te(μ-O)$_2$Te– monomers attached head-to-tail—folds into a spherical arrangement. With twelve tellurium and sixteen oxygen atoms in a continuous ring the macrocycle is unprecedented for a molecular organotellurate(IV). The closest structural analogs are $[(C_6H_4\text{-}4\text{-}Me)_2Te\{OTe(C_6H_4\text{-}4\text{-}Me)_2\}_2][Te(C_6H_4\text{-}4\text{-}Me)_2OTe(C_6H_4\text{-}4\text{-}Me)_2][CF_3SO_3]_4$ in which Te···O–S–O···Te cation–anion interactions form a 14-membered ring[8] and, the first example of a supramolecular structure of an organotellurium complex, polymeric $[(C_4H_8TeNO_3)_2O]_n$ containing $(NO_3)Te(C_4H_8)$–O–$Te(C_4H_8)(NO_3)$ monomers connected *via* Te···O–N–O···Te secondary semi-bonding interactions.[9]

The arrangement of the Te–O framework around the central bromide anion possesses the point group symmetry D_{2d} and is topologically equivalent to the seams of a tennis ball.[6] The encapsulated bromide anion is located inside a cavity of dimensions 5.0 × 4.1 × 3.2 Å^3, with four long [4.1707(10)–4.2641(10) Å; Te(3), Te(5), Te(9), Te(11)] and eight short [3.5398(9)–3.6625(10) Å; Te(1), Te(2), Te(4), Te(6), Te(7), Te(8), Te(10), Te(12)] Br(9)–Te distances. No bonding interactions are expected for the longer Te···Br distances, which are slightly greater than the sum of van der Waals radii (Te, 2.10 Å; Br, 1.80–2.00 Å).[10] The distance between the central bromide anion and the eight closer tellurium atoms is shorter than the sum of van der Waals radii, but much longer than the sum of the covalent radii (Te, 1.35 Å; Br, 1.14 Å),[10] indicating a stabilizing interaction between guest and host. Similar distances have been ascribed to Te···Br secondary interactions.[11]

The Te–O macrocycle consists of alternating Te(μ-O)$_2$Te and O–Te–O building blocks. In agreement with other Te(μ-O)$_2$Te microcycles[3] the Te(μ-O)$_2$Te rings in **1** possess alternating short [1.916(5)–1.941(5) Å] and long [2.107(5)–2.157(5) Å] bonds between tellurium and oxygen. The shorter ones can be attributed[12] to Te=O bonds, and are slightly shorter than the sum of covalent radii (Te, 1.35 Å; O, 0.73 Å),[10] while the longer ones can be attributed[12] to dative interactions (Te←O). The

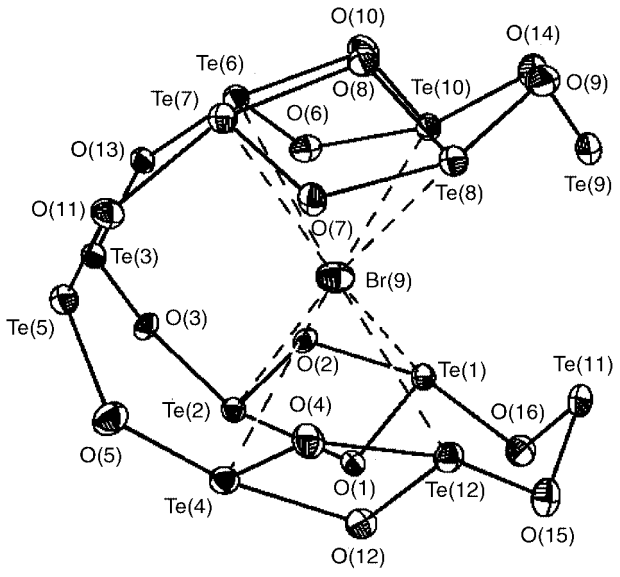

Fig. 1 Labeling scheme of the $Te_{12}O_{16}$ skeleton and the central bromine anion of the anion of **1**. For clarity the Pr^i groups, four Br anions and four Li(THF)Br have been removed.

 DOI: 10.1039/b107147p

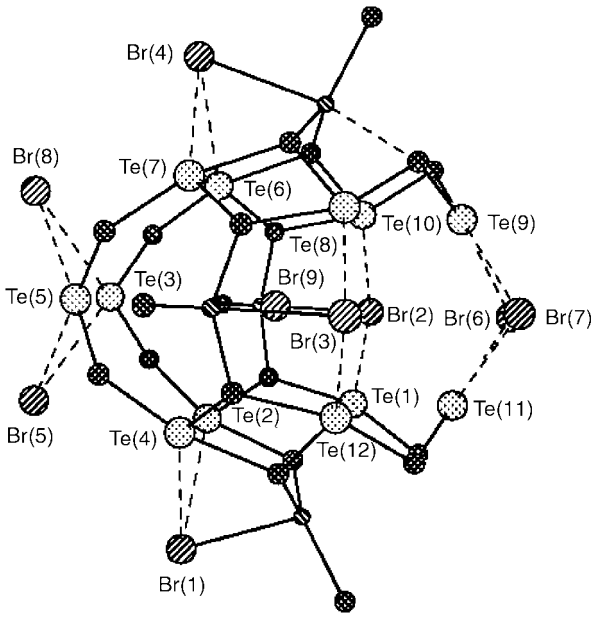

Fig 2 Labeling scheme for the Te and Br atoms of the anion of **1**.

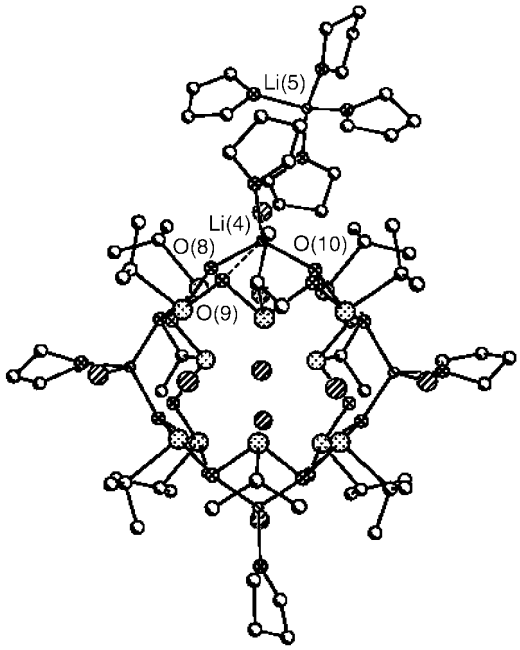

Fig. 3 Drawing showing the $\bar{4}$ symmetry in the title compound.

connection of the four Te(μ-O)$_2$Te rings to the –OTeO– building block occurs by weaker Te–O-interactions [2.091(6)–2.120(5) Å], while the O–Te–O unit itself contains stronger Te–O bonds [1.908(5)–1.924(5) Å]. This sequence of bonding type and the planarity (±0.12 Å) of the Te(μ-O)$_2$Te rings is not uncommon for telluroxides.[12,13]

Stabilization of the spherical $Te_{12}O_{16}$ framework is provided by the nine bromide anions, one inside and eight outside the sphere (Fig. 2). The eight tellurium atoms of the Te(μ-O)$_2$Te microcycle have weak interactions to the central Br(9) and somewhat stronger interactions to the 'outer' bromine atoms [Br(1)–Br(4): Te–Br 3.2444(10)–3.3639(10) Å] of the four Li(THF)Br units in the anion. A stronger set of Te–Br interactions occur between the O–Te–O building blocks and 'outer' bromide anions [Br(5)–Br(8): Te–Br 3.0847(10)–3.1817(11) Å]. Similar Te–Br bridging bonds have been described.[14] Additional stabilization of the $Te_{12}O_{16}$ framework occurs through O–Li–O bridges above the Te(μ-O)$_2$Te microcycles through Li–O [1.914(15)–1.980(15) Å] bonds (Fig. 2). Finally, each tellurium atom bears one Pr^i group with standard Te–C distances [2.132(8)–2.176(8) Å].[15] A [Li(THF)$_4$] cation compensates for the charge of the host–guest assembly in the crystal.

Overall the anion possesses a non-crystallographic $\bar{4}$ symmetry (Fig. 3). A deviation from this point symmetry is most likely caused by packing effects due to the spatial requirements of the [Li(THF)$_4$]$^+$ ion. The proximity of the [Li(THF)$_4$]$^+$ cation to Li(4) causes Li(4) to move toward O(9). As a result one, that attached to Te(9), of the four Pr^i groups on the macrocycle is turned by *ca.* 90°.

First published as an Advance Article on the web 19th September 2001

The formation of dimerized alkenyl carbenium ions, characterized by an IR band at 1513 cm^{-1} and a UV band at 323 nm, was observed by adsorption of 1-methylcyclopentene on HY and DY zeolites at temperatures as low as 150 K.

The formation of alkenyl carbenium ions on zeolites has attracted much attention in the past decade.[1,2] Using *in-situ* NMR, Haw and his coworkers observed the formation of cyclopentenyl cations on zeolites through propene oligomerization on HY at 293 K,[3] by cracking ethene oligomers on HZSM-5 at 523 K,[4] and by adsorption of some cyclic precursors on HY and HZSM-5.[5] These cations are believed to be the true intermediates in aromatics formation and coke deposition, which are undesirable in some reactions. However, very recently, Haw *et al.*[6] found that cyclopentenyl cations not only play a catalytic role but also act as reactive intermediates in methanol-to-olefin (MTO)/methanol-to-gasoline (MTG) chemistry. The critical and distinct roles of these cations are of great importance, and have motivated us to investigate the initial formation of alkenyl carbenium ions using *in-situ* infrared spectroscopy, a powerful technique that is widely used for studying zeolites. In this work, 1-methylcyclopentene, a cyclic olefin with a tertiary carbon, was selected as a probe molecule.

HY zeolite (Si/Al = 2.8) was pressed into a self-supporting wafer and placed in a quartz IR cell connected to a closed gas-circulation system. The sample was first evacuated and oxidized at 773 K and was then treated with H_2 or D_2 at 673 K, followed by evacuation at room temperature. All IR spectra were recorded on a JASCO 7000 FTIR spectrometer with MCT detector at a resolution of 4 cm^{-1} and 64 scans. Only differential spectra are given, obtained by subtracting the spectra taken at different temperatures before adsorption. UV-vis spectra were collected on a JASCO V-560 UV-vis spectrophotometer, the sample for which was treated in a similar manner as for the IR experiments.

Fig. 1 shows the IR spectra of 1-methylcyclopentene adsorbed on DY zeolite. The spectrum of 1-methylcyclopentene adsorbed on SiO_2 is also given as a reference. A small amount (*ca.* 40 μmol) of 1-methylcyclopentene was introduced to the IR cell at below 150 K, and the sample chamber was immediately evacuated in order to avoid rapid oligomerization and to allow the formation of intermediates to be observed clearly. The IR cell was then gradually warmed under evacuation. On SiO_2 (partially deuterated, Fig. 1(a)), 1-methylcyclopentene is only adsorbed molecularly, *via* hydrogen bonds, as indicated by the two broad bands at 3495 and 2592 cm^{-1} attributable to the shift of the isolated OH and OD bands, respectively. The spectrum of adsorbed 1-methylcyclopentene is identical to that of free 1-methylcyclopentene molecules,[7] and the $\nu_{=C-H}$ and $\nu_{C=C}$ bands appear at 3043 and 1650 cm^{-1}, respectively. With increasing temperature, the adsorbed molecules are simply desorbed from SiO_2 under evacuation. The adsorption of 1-methylcyclopentene on to DY (Fig. 1(b)–(g)), however, induced significant changes. At 150 K, four bands at 3032, 2961, 2931 and 2859 cm^{-1} were identified in the ν_{C-H} region. The band at 3032 cm^{-1} is attributed to olefinic C–H stretching, while the latter three are related to the ν_s and ν_{as} bands of saturated C–H bonds. The $\nu_{C=C}$ band shifts to 1637 cm^{-1}, 13 cm^{-1} lower than that of free molecules,[7] suggesting the formation of a π-BAS (Brønsted acid sites) complex.[8] Meanwhile, a negative band appears at *ca.* 2690 cm^{-1}, confirming the consumption of OD groups. In the low-frequency region (1600–1300 cm^{-1}), a new band appears at 1513 cm^{-1}. With increasing temperature, the bands at 2931, 2859 and 1513 cm^{-1} grow in intensity, and the band at 3032 cm^{-1} due to olefinic C–H stretching has almost disappeared by 245 K. Upon heating to 373 K, the 1513 cm^{-1} band reaches maximum intensity and then disappears with further increases in temperature. At 473 K, only the bands at 2931, 2859, 1465 and 1382 cm^{-1} remain, while a band at 1600 cm^{-1} due to aromatic compounds appears.

The formed species are considered to be alkenyl carbenium ions, as characterized by the band at 1513 cm^{-1}. This band is attributed to the asymmetric stretching vibration of the $[C{=}C{-}C]^+$ unit.[2] Because the positive charge of this unit is delocalized within the three carbon atoms, its vibrational frequency occurs in the region between those of the typical C–C and C=C stretching modes. Buzek *et al.*[9] simulated the IR spectrum of the parent allyl cation and predicted a band at 1558 cm^{-1}, which is in agreement with their experimental data in acidic solutions. This assignment is further supported by our theoretical

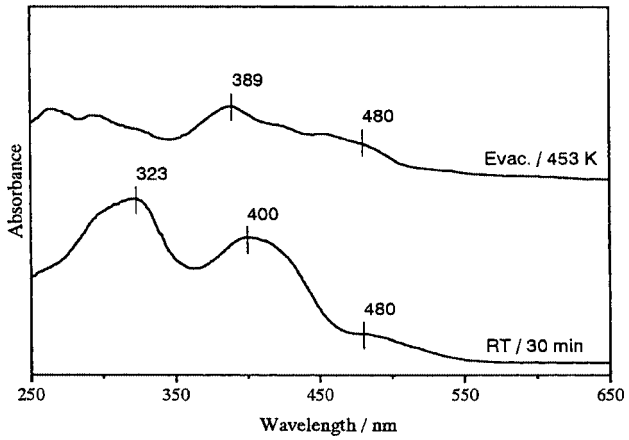

Fig. 2 UV-vis spectra of 1-methylcyclopentene adsorbed on HY at liquid nitrogen temperature and then (a) warmed to RT and maintained for 30 min, and (b) evacuated at 453 K.

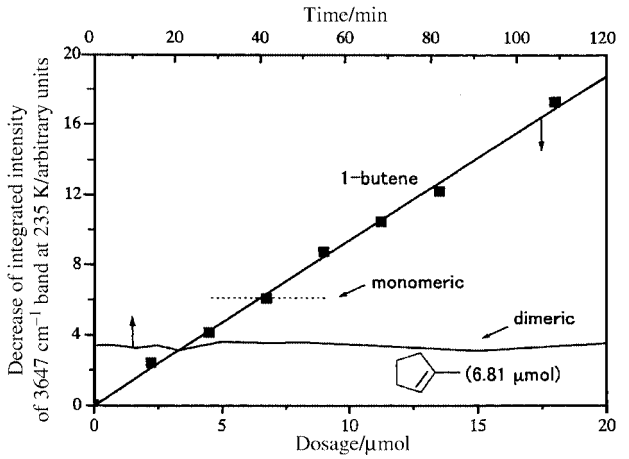

Fig. 3 Calibration of acid sites of HY using 1-butene at 235 K. For comparison, 6.81 μmol 1-methylcyclopentene (0.18 mmol g^{-1} catalyst) was also introduced on HY at 235 K. If monomeric species are formed, the consumption of acid sites should be situated on the dotted line.

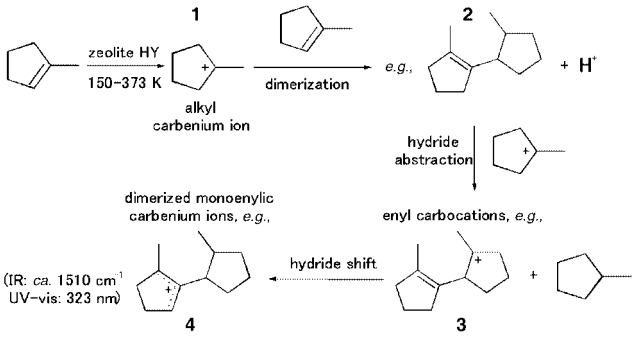

Scheme 1 Possible pathway for the formation of dimerized alkenyl carbenium ions.

calculation of the harmonic IR frequencies of 1-methylcyclopentenyl cations.

UV-vis spectroscopy was also used to confirm the formation of alkenyl carbenium ions, and the results are given in Fig. 2. After 1-methylcyclopentene adsorbed on HY at liquid nitrogen temperature, the sample was warmed to room temperature. Two strong bands appeared at 323 and 400 nm, and a small shoulder could be seen at *ca.* 480 nm. Based on experience with superacid solutions, the bands observed in the ranges 280–330, 360–380 and 430–470 nm have been attributed to π–π* transitions of mono-, di-, and trienylic carbenium ions. Therefore, the three bands observed in our case can be assigned accordingly.[2] The red-shift of the bands is attributed to the formation of branched, *i.e.* alkyl-substituted, carbenium ions. The results clearly show that monoenylic carbenium ions are predominant on the sample, along with a considerable amount of dienylic ones and a small amount of trienylic ones. After evacuation at 453 K, only dienylic and trienylic carbenium ions were left. This is in good agreement with IR results, which show that the 1513 cm^{-1} band disappears at 423 K and above.

To estimate the structure of the species formed on zeolite Y, 1-butene was used to calibrate the acid sites of HY at 235 K. At this temperature, 1-butene is adsorbed only molecularly on the acid sites of HY (forming a 1:1 π-OH complex) without oligomerization.[8] A controlled amount of 1-butene (0.06 mmol g^{-1} catalyst) was then introduced to the IR cell at 235 K. An IR spectrum was taken after 3–5 min of the dosage, and then other doses were given, until saturated adsorption. By measuring the decrease of the integrated intensity of the 3647 cm^{-1} band (stretching vibration of OH groups in supercages), the correlation between the OH band intensity (which represents the amount of acid sites) and the dosage of 1-butene was obtained (Fig. 3). In a separate experiment, 6.81 μmol 1-methylcyclopentene was introduced to the sample, and the weakening of the 3647 cm^{-1} band plotted against adsorption time. If the adsorbed 1-methylcyclopentene species is monomeric, the consumption of acid sites should be the same as for the addition of 6.81 μmol 1-butene, as indicated by the dotted line in Fig. 3. However, only half of the acid sites were consumed, suggesting that the formed species are not monomeric, but dimeric. Of course the formation of trimerized (or even higher) species could not be totally excluded, but their amount should be very small. These results clearly indicate that 1-methylcyclopentene rapidly undergoes oligomerization on zeolite Y even at temperatures as low as 150 K. As a result, dimerized carbenium ions were formed, with a notable absence of monomeric species.

Alkenyl carbenium ions can be formed by hydride transfer between olefin and carbenium ions, or through hydride abstraction from olefins by Lewis acid sites (LAS). Owing to the absence of LAS on our sample, alkyl carbenium ions may act as LAS and abstract hydrogen from olefins or oligomers to form alkenyl carbenium ions. From the integrated intensity of the 1513 cm^{-1} band, it can be deduced that alkenyl carbenium ions have already been formed in high yield at temperatures lower than 298 K. Scheme 1 shows the possible pathway for the formation of dimerized alkenyl carbenium ions. Worth noting is that cation **1** cannot be observed experimentally.

In summary, alkenyl carbenium ions were formed by the adsorption of 1-methylcyclopentene on zeolite Y in high yield at temperatures from 150 to 473 K. The majority of the carbenium ions were present in dimerized form, indicating that the oligomerization of olefins proceeded very rapidly even at temperatures as low as 150 K, and as a result, monomeric forms were not observed.

Received (in Cambridge, UK) 17th July 2001, Accepted 29th August 2001
First published as an Advance Article on the web 19th September 2001

A range of novel, moisture-stable, Lewis-acidic ionic liquids has been prepared by mixing appropriate molar ratios of MCl_2 (M = Zn and/or Sn) and quaternary ammonium salts of formula $[Me_3NC_2H_4Y]Cl$ (Y = OH, Cl, OC(O)Me, OC(O)Ph); the influence of substituent Y and metal M on the physical properties of the melts has been investigated.

Ionic liquids, or room temperature molten salts, have attracted increasing interest over recent years, particularly in the area of green chemistry, due to their advantageous properties including negligible vapour pressure and wide liquid range.[1–3] Work has focussed on liquids formed from dialkylimidazolium halides which are readily prepared from 1-methylimidazole and a slight excess of the desired haloalkane.[4] Addition of a suitable molar ratio of aluminium chloride to these salts gives rise to ionic liquids containing complex metal anions which have been used in a number of applications such as electroplating, electrochemical devices and catalysts for organic synthesis.[1,4–6] The main disadvantage of imidazolium-based liquids is their relatively high cost for bulk applications, whilst chloroaluminate ionic liquids have the additional problem of their low tolerance to moisture, necessitating the use of glove box and Schlenk techniques to prepare and investigate their properties. The former problem may be overcome by using cheaper ammonium salts whereas the latter may be solved by replacing aluminium with less reactive metals.

Recently, Freeman and coworkers have characterised ionic liquids formed from $FeCl_2$ or $FeCl_3$ and 1-butyl-3-methylimidazolium chloride.[7] However, other examples of ionic liquids made from metal chlorides other than aluminium are less well characterised and are mainly cited in conference proceedings[8] or in the patent literature.[9,10] Here we report the synthesis and characterisation of new moisture-stable, Lewis-acidic ionic liquids made from metal chlorides and quaternary ammonium salts that are commercially available or simple to synthesise. These offer the potential to tailor the physical properties *e.g.* melting point, viscosity and conductivity, and to tune the Lewis acidity by choosing a different metal or indeed combinations of metals.

To investigate the parameters necessary for a salt to be liquid at or near room temperature we have heated a range of ammonium salts with zinc chloride in a 1:2 molar ratio and the results are shown in Table 1.‡ Using salts of symmetrical cations, H_4NCl and Me_4NCl, no liquid is formed below 200 °C whereas with the longer chain NEt_4Cl the freezing point was *ca.* 90 °C. It has been established in the imidazolium systems that reducing the symmetry of the cation leads to a lower freezing point for the ionic liquid, thus, we have examined cations of the general formula Me_3NR^+. Using Me_3NEt^+ gives a freezing range of 53–55 °C, *i.e.* a reduction of *ca.* 35 or 140 °C compared with Et_4N^+ and Me_4N^+ respectively. However, we have found that functionalised ethyl chains, $Me_3NC_2H_4Y^+$, give even lower freezing points; *e.g.* if Y = OH or Cl, room temperature liquids are observed with freezing points of 23–25 °C. Even when the substituent is significantly larger, *e.g.* Y = OC(O)Me or OC(O)Ph, the salts formed have lower freezing points than for Me_3NEt^+. These results suggest that both lower symmetry and the presence of a functional group reduce the freezing points of the salts formed, though the exact role of the functional substituent is not yet clear. In all cases the liquids formed are viscous and hygroscopic but moisture-stable so can be easily prepared and stored without the need for specialist equipment.

Since choline chloride, $[Me_3NC_2H_4OH]Cl$, gave the lowest freezing point we have characterised this system in more detail. Heating mixtures of choline chloride and zinc chloride in molar ratios between 1:1 and 1:3 gave rise to clear colourless liquids, with the freezing points varying between *ca.* 65 °C (1:1), 25 °C (1:2) and 45 °C (1:3). Unlike analogous aluminium systems,[4,11,12] ratios with a molar excess of choline chloride, *i.e.* basic melts, do not form ambient temperature liquids in these systems. This would imply that complex zinc anions, in which the charge can be delocalised, are necessary in the formation of these ionic liquids. Further characterisation of the 1:2 liquid is described below.

A ^1H NMR spectrum of the neat ionic liquid was recorded and shows resonances at δ 2.97, 3.34 and 3.94 assigned to the methyl groups, N–CH_2 protons, and the CH_2OH protons, respectively, of the choline cation. All signals were broad and poorly resolved, even at 80 °C, due to the viscosity of the melt. The FAB mass spectrum shows the presence of complex zinc chloride ions $[ZnCl_3]^-$, $[Zn_2Cl_5]^-$ and $[Zn_3Cl_7]^-$. Higher clusters are also detectable but occurred at very low intensities. Similar species have been observed in aluminium chloride-based ionic liquids.[13]

The ionic liquid has a conductivity of 36 μS cm^{-1} at 40 °C and this increases exponentially with temperature, due to a decrease in the viscosity and hence an increase in the mobility of the ions in the melt.† The conductivity is similar to that found in alkylpyridinium-based ionic liquids[14] and is sufficient for them to be suitable media for electrochemical applications such

Table 1 Freezing points for the materials formed from heating a quaternary ammonium chloride and MCl_2 (M = Zn, Sn) in a 1:2 molar ratio

	Cation	M	Freezing point/°C
1	NH_4	Zn	>200
2	Me_4N	Zn	>200
3	Et_4N	Zn	90–92
4	Me_3NEt	Zn	53–55
5	$Me_3NCH_2CH_2OH$	Zn	23–25
6	$Me_3NCH_2CH_2Cl$	Zn	23–25
7	$Me_3NCH_2CH_2OC(O)Me$	Zn	30–32
8	$Me_3NCH_2CH_2OC(O)Ph$	Zn	46–48
9	$Me_3NCH_2CH_2OH$	Sn	43–45
10	$Me_3NCH_2CH_2Cl$	Sn	69–71
11	$Me_3NCH_2CH_2OC(O)Me$	Sn	13–15
12	$Me_3NCH_2CH_2OH$	Zn/Sn[a]	21–23

[a] The ratio $[Me_3NCH_2CH_2OH]Cl:ZnCl_2:SnCl_2$ was 1:1:1.

† Electronic supplementary information (ESI) available: plot of conductivity *vs.* temperature for the ionic liquid formed from zinc chloride and choline chloride (2:1). See http://www.rsc.org/suppdata/cc/b1/b106357j/

 DOI: 10.1039/b106357j

as batteries and metal deposition. The liquids provide an electrochemical window of about 2 V positive from the Zn/Zn^{2+} couple. Further details of the conductivity and electrochemical properties are reported elsewhere.[15]

Having established that the cationic component can be varied we have also investigated changing the metal-containing, *i.e.* anionic, component. Heating choline chloride and $SnCl_2$ in a 1:2 molar ratio provides a viscous liquid which has a freezing range of 43–45 °C. The negative ion FAB mass spectrum shows the presence of $[SnCl_3]^-$ and $[Sn_2Cl_5]^-$; however, no higher ions are observed in this case. For the tin-containing melts the liquid formed from $[YC_2H_4NMe_3]Cl$ (Y = OC(O)Me) gave the lowest melting point. Heating choline chloride : $ZnCl_2$: $SnCl_2$ in a 1:1:1 molar ratio gives a liquid with a freezing point of 21–23 °C, *i.e.* similar to the pure zinc-containing melt but significantly lower than the pure tin-containing one. The FAB mass spectrum of this liquid shows the presence of the individual metal-containing ions and the mixed metal ion $[SnZnCl_5]^-$. Mixed metal melts allow the possibility of tuning the catalytic properties of the liquids, as well as opening up possibilities for electrodeposition of metal alloys.

To conclude, we have shown that heating functionalised quaternary ammonium halides $[Me_3NC_2H_4Y]Cl$ and MCl_2 (M = Zn, Sn) gives materials that are conducting, viscous liquids at or around room temperature. The freezing points are dependent upon the symmetry of the cation and upon the nature of the functionalised side chain. The advantages of these new ionic liquids over presently available metal-containing ionic liquids are that they are insensitive to moisture and are much cheaper than imidazolium-based liquids. In addition, their Lewis acidity can be altered by varying the metal chloride(s) used. The use of these liquids as catalysts for the Diels–Alder reaction of acroleins and dienes will be reported elsewhere.

We thank Scionix Ltd., a joint venture company between Whyte Chemicals and the University of Leicester, for financial support.

Notes and references

‡ The general route for the synthesis of the ionic liquids was as follows: quaternary ammonium salt (20 mmol) was mixed with zinc chloride (40 mmol) and heated to *ca.* 150 °C in air with stirring until a clear colourless liquid was obtained. In contrast with the usual $AlCl_3$-based ionic liquids the reaction appears to be endothermic.

Drying the liquids under vacuum at 100 °C overnight has only a small effect on the freezing point, a few degrees, suggesting that immediately after preparation the liquids do not contain much water. The liquids are at least as thermally stable as $AlCl_3$-based liquids, and can be heated to at least 190 °C.

L-Lysine derivatives of viologens form supramolecular assemblies of fibers and ribbons in some aromatic solvents, and the charge separation reaction in these self-assembling systems proceeds with a similar efficiency to the MV^{2+} system.

One of the keywords in supramolecular chemistry, which utilizes relatively weak, noncovalent interactions such as hydrogen bonding, π–π stacking, electrostatic, and van der Waals interactions, is self-assembly.[1] Self-assembly, which is the spontaneous organization of molecules driven by noncovalent interactions or objects into stable aggregates, has been well recognized in biological systems: lipid bilayers, the DNA duplex, and tertiary and quaternary structure of proteins.[2] In chemical synthesis, self-assembly offers considerable advantages over stepwise bond formation in the construction of large supramolecular assemblies. Many reports have appeared on supramolecular assemblies formed from organic compounds, dendrimers, macromolecules, and coordination compounds.[3]

Ordered, self-assembling aggregates of low molecular weight compounds formed through noncovalent interactions such as hydrogen bonding, van der Waals interactions and π–π stacking have been of great interest.[4] These supramolecular assemblies are to some extent similar to macromolecules, as repeating units linked to each other by either noncovalent or covalent bonds (can be both) give a network structure in various solvents, resulting in gelation or a high viscosity. In contrast to the gels obtained from supramolecules, which can be disintegrated by addition of a cosolvent or by heating, the network structures obtained from macromolecules are decomposed only by breaking chemical bonds. Several low molecular mass compounds which form network structures in organic fluids have been reported.[5,6] Recently, L-lysine derivatives have been found to form supramolecular fibrous network structures on the nanometer scale.[7] Here we describe the formation of self-assembling fibers from new L-lysine derivatives of viologens and their photosensitized charge separation using tris(2,2′-bipyridine)ruthenium(II) [$Ru(bpy)_3^{2+}$] as a photosensitizer.

The viologen derivatives (**1**, **2**) were prepared in high yield according to the synthetically simple approach as shown in Scheme 1. The gelation ability of **1** and **2** was evaluated after allowing solutions to stand at rt for 6 h followed by dissociation into organic solvents with heating. Photosensitized charge separation reactions were carried out in methanol–toluene containing 1.0×10^{-5} M $Ru(bpy)_3^{2+}$, 1.0×10^{-3} M viologen, and 0.1 M triethanolamine (TEOA) under an argon atmosphere. Visible light irradiation was performed using a 300 W Xe lamp equipped with a UV cutoff filter ($\lambda > 440$ nm). The rate constants of the elemental reactions were measured by laser flash photolysis.[8]

Both **1** and **2** were completely dissolved with heating in all organic solvents in which the gelation ability was examined. After dissolution of **1** and **2** by heating, they formed gels in aromatic solvents (benzene, toluene, nitrobenzene, chlorobenzene) and reprecipitated in alcohols. In DMF, DMSO, and chloroform, both **1** and **2** have a high solubility and give an isotropic solution. TEM images of samples prepared from these solvents demonstrated that the viologens formed fibrous assemblies in aromatic solvents and alcohols, but not in chloroform; in alcohols, small fibers of **1** and **2** were observed for samples prepared from the dilute solutions (see ESI†). These facts imply that **1** and **2** hardly interact with each other in chloroform and strongly interact in alcohols, which leads to the isotropic solution in chloroform and reprecipitation in the alcohols. As shown in Fig.1, **1** (A) and **2** (B) prepared from toluene create nanometer scale network structures with *ca.* 250–700 nm width for **1** and *ca.* 300–400 nm width for **2** formed by entangling of fine fibers (*ca.* 30–100 nm width) or ribbons (*ca.* 70–200 nm width).[9] It is noteworthy that the viologens form different nanostructures; a fibrous structure for **1** and a ribbon structure for **2**.

To consider the factor of self-assembling behavior, we measured the FTIR spectrum of **1** and **2**. The FTIR spectra in chloroform, in which no self assembly occurs, show the absorption bands at 3440 and 1665 cm^{-1}, characteristic of non-hydrogen bonded N–H and C=O stretching vibrations. In contrast, the FTIR spectra in toluene show almost the same spectra in the solid state and are characterized by a band at 3320 cm^{-1} which is assigned to N–H stretching vibrations of hydrogen bonded amide groups,[10] which indicates that the driving force for the self-assembly is mainly hydrogen bonding. The fine nanofibers and nanoribbons are entangled in a complex way probably through van der Waals interaction between the terminal alkyl groups and the three-dimensional network

 DOI: 10.1039/b106513k

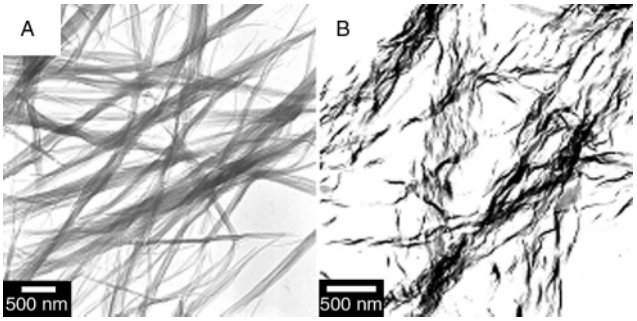

Fig. 1 TEM images of viologens **1** (A) and **2** (B) prepared from toluene solution.

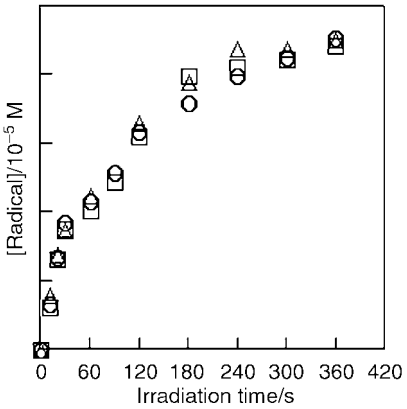

Fig. 2 Viologen radical formation upon visible light irradiation for V1 (○), V2 (□), and MV^{2+} (△) systems.

structure is created, which leads to gelation. Moreover, the shape of the nanostructure is controllable to some extent by the length of alkylene spacer between bipyridine and L-lysine segments.

Next, the photosensitized charge separation reaction was carried out in a mixture of methanol and toluene (1 : 1 v/v).[11] Fig. 2 shows the formation of a viologen radical upon visible light irradiation. Very interestingly, the viologen radical formation in the self-assemblies is the almost the same as in MV^{2+}. In the present systems, the photosensitized charge separation proceeds according to eqns. (1)–(5):

$$\mathrm{Ru(II)} + h\nu \rightarrow {}^*\mathrm{Ru(II)} \quad (1)$$

$${}^*\mathrm{Ru(II)} \xrightarrow{k_0} \mathrm{Ru(II)} + h\nu' + \Delta \quad (2)$$

$${}^*\mathrm{Ru(II)} + \mathrm{V}^{2+} \xrightarrow{k_q} \mathrm{Ru(III)} + \mathrm{V}^{+} \quad (3)$$

$$\mathrm{Ru(III)} + \mathrm{V}^{+} \xrightarrow{k_b} \mathrm{Ru(II)} + \mathrm{V}^{2+} \quad (4)$$

$$\mathrm{Ru(III)} + \mathrm{TEOA} \xrightarrow{k_s} \mathrm{Ru(II)} + \mathrm{TEOAox} \quad (5)$$

where k_0, k_q, k_b, and k_s represent the rate constants for the corresponding reactions. These values are obtained by laser flash photolysis and are listed in Table 1. The rate constants of the quenching reaction (forward reaction), k_q, are almost the same values regardless of the viologens. In contrast, the self-assembling viologens restrict the back electron transfer and accelerate the re-reduction of the Ru(III) to Ru(II) with TEOA. This is probably due to an electrostatic repulsion between the positively charged viologen assembly and the ruthenium(III) complex and a concentration of TEOA in the vicinity of the assemblies.

Table 1 Kinetic parameters obtained from laser flash photolysis

	k_q (M^{-1} s^{-1})[a]	k_b (M^{-1} s^{-1})[b]	k_s (M^{-1} s^{-1})[c]
1	7.0×10^8	1.7×10^{10}	2.7×10^7
2	6.2×10^8	2.3×10^{10}	1.9×10^7
MV^{2+}	6.9×10^8	5.1×10^{10}	1.5×10^7

[a] Stern–Volmer plot (τ_0/τ *vs.* [viologen]) using laser flash photolysis. [b] Rate constants for back electron transfer. [c] The rate constants of re-reduction reaction of Ru(III) with TEOA corresponding to eqn. (5).

In summary, we have found that new L-lysine derivatives of viologens form gels containing nanometre scale organized assemblies in some organic solvents. In particular, the viologens create a network structure by the entangling of nanofibers for viologen **1** and nanoribbons for viologen **2** in some aromatic solvents. In the viologen assembly–$Ru(bpy)_3^{2+}$ systems containing a sacrificial electron donor, the charge separation reaction proceeds with a similar efficiency to MV^{2+}–$Ru(bpy)_3^{2+}$ because of the restriction of the back electron transfer and acceleration of re-reduction of the Ru(III). Furthermore, we find that the nanostructure is controllable by changing the length of the alkylene spacer.

9 Similar TEM images were observed for samples prepared from other solvents that formed gel.
10 In toluene, a hydrogen bonded C=O stretching vibration could not be detected in the FTIR spectra because the toluene's own spectrum overlaps with viologens around 1650 cm^{-1}.
11 To dissolve $Ru(bpy)_3^{2+}$ and triethanolamine (TEOA), the reaction was carried out in methanol–toluene. The viologens did not gel in methanol–toluene under the reaction conditions, but we obtained the TEM images showing that the viologens formed fibrous nanostructures (but not networks).

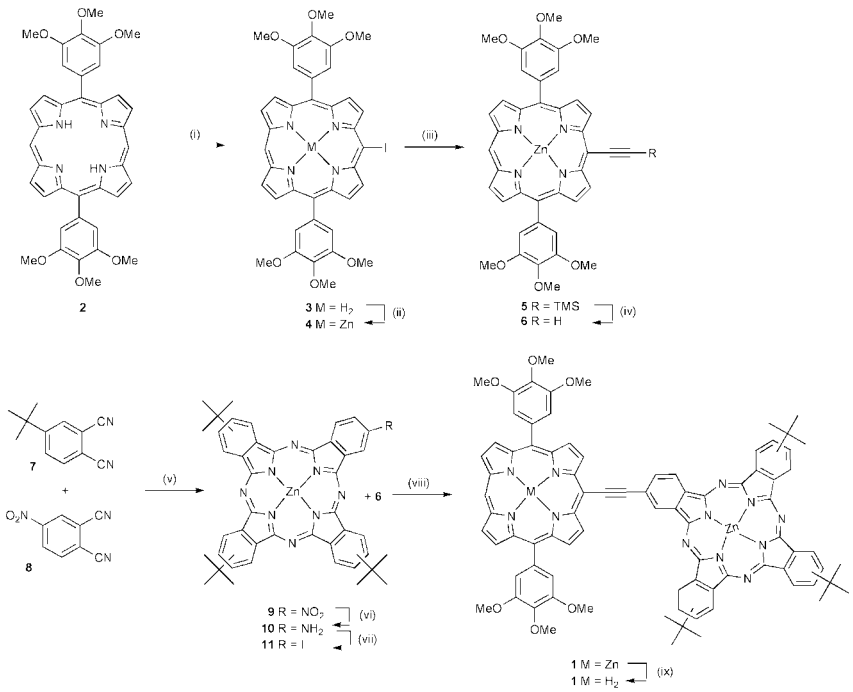
Received (in Cambridge, UK) 3rd July 2001, Accepted 8th August 2001
First published as an Advance Article on the web 19th September 2001

The first synthesis of two porphyrin–phthalocyanine heterodimers with a direct triple bond linkage between the macrocycles, designed for the study of photo-induced energy and electron transfer processes, is presented along with preliminary ground state and fluorescence spectroscopic data.

It is well known that metalloporphyrins which are held together in carefully controlled orientations play important roles in photosynthesis and some metalloenzyme catalysed reactions.[1,2] Spectroscopic evidence has suggested that this careful control of spatial orientation allows optimisation of photon or electron transfer processes,[3] and there is now considerable interest in the generation of compounds that can be used to model such processes. A number of covalently linked porphyrin–chlorin[4] and phthalocyanine homo/hetero-dimers[5] have been prepared successfully, as well as a number of porphyrin–phthalocyanine heterodimers.[6–10] Although most of these examples have shown varying degrees of intramolecular energy transfer, they have involved covalent attachment of both macrocycles using ether, phenylethynyl linkages[11–15] or flexible aliphatic chains. As a result, the π electron system of each macrocycle can orient to minimise p–p orbital overlap with the linker, thus inhibiting conjugation of the two systems through these bonds. This effect is well known for *meso*-aryl porphyrins, where the phenyl rings are typically perpendicular to the macrocycle.

We report here the first synthesis and characterisation of a (Zn)porphyrin–(Zn)phthalocyanine heterodimer **1(Zn)**, and also a (H_2)porphyrin–(Zn)phthalocyanine heterodimer **1(H_2)** produced by selective de-metallation of the porphyrin, in which the two macrocycles are directly linked through an ethynyl group. The direct triple bond linkage fully conjugates the two major π systems, irrespective of the torsional angle between the planes of the porphyrin and phthalocyanine. An initial photophysical investigation of these ethynyl linked heterodimers has also been undertaken.

Scheme 1 shows the strategy used to synthesise heterodimers **1(Zn)** and **1(H_2)**. The convergent synthesis involved the preparation of heterodimer precursors **6** and **11**. Hexamethoxydiphenylporphyrin[16] **2** was selectively monoiodinated at one of the available *meso* positions using I_2/trifluoroacetoxybenzene.[17] The crude reaction, containing impurities of starting material and diiodoporphyrin, in addition to monoiodoporphyrin, was purified by flash silica-gel chromatography. The required monoiodoporphyrin **3** was then metallated with zinc acetate. The zinc monoiodoporphyrin **4** was converted into *meso*-(2-(trimethylsilyl)ethynyl) zinc porphyrin **5** by palladium mediated Sonagashiro coupling with TMS-acetylene. Desilylation of **5** using tetrabutylammonium fluoride afforded the *meso*-ethynyl zinc porphyrin **6**. Phthalocyanine **11**, the second macrocycle required for coupling, was synthesised by condensation of 4-(*tert*-butyl)phthalonitrile **7** with 4-nitrophthalonitrile **8** and $Zn(AcO)_2$, to give a statistical mixture composed primarily of tetra(*tert*-butyl)phthalocyanine and mononitrotri(*tert*-butyl)phthalocyanine **9**.[18] The crude reaction mixture was then treated with sodium sulfide to afford a mixture of



Scheme 1 Conditions: (i) I_2, $PhI(OCOCF_3)_2$, pyridine, 45 min, RT; (ii) $Zn(OAc)_2$, $CHCl_3$ (iii) TMS-acetylene, $[Pd(PPh)_2Cl_2]$, CuI, THF, Et_3N, RT, 16 h; (iv) TBAF, DCM; (v) $Zn(OAc)_2$, fuse 165 °C, 2 h; (vi) $Na_2S{\cdot}9H_2O$, 60 °C, 2 h; (vii) $NaNO_2$(aq), conc.  DOI: 10.1039/b105840c

phthalocyanines containing monoaminotri(*tert*-butyl)phthalocyanine **10**, which was easily separated from the much less polar tetra(*tert*-butyl)phthalocyanine by flash column chromatography.[18] Phthalocyanine **10**, as a mixture of positional isomers, was then converted into a mixture of monoiodotri(*tert*-butyl)phthalocyanine isomers **11** *via* the diazonium salt, using a modified Sandmeyer reaction.[19] A second Sonagashiro palladium mediated coupling between precursors **6** and **11**, under anaerobic conditions, afforded the required heterodimer **1(Zn)** as a mixture of positional isomers in 50% yield. Flash column chromatography of the mixture of heterodimer positional isomers allowed isolation of a greatly enriched sample containing over 75% of the heterodimer **1** as a single positional isomer (the remaining 25% consisting of other positional isomers formed during phthalocyanine condensation). The heterodimer **1(Zn)** could now be characterised by ^{1}H NMR, UV-visible spectroscopy, fluorescence spectroscopy and FAB mass spectrometry.[20] It was then possible to take advantage of the weaker binding of zinc in the central cavity of porphyrins, compared with phthalocyanines, to conduct a facile, and selective, demetallation of the porphyrin component of heterodimer **1(Zn)** using trifluoroacetic acid to give the (H_2)porphyrin–(Zn)phthalocyanine heterodimer **1(H_2)** in quantitative yield.

The UV-visible spectra, in toluene, of heterodimers **1(Zn)** and **1(H_2)** resemble that of an equimolar mixture of porphyrin **6** and phthalocyanine **11**, however a number of differences are apparent (Fig. 1). Firstly, both compound **1(Zn)** and **1(H_2)** show marked bathochromic shifts in their Soret bands of 10 and 13 nm respectively, indicating that effective electronic communication between the two different ring systems occurs. Secondly, the phthalocyanine Q-band in the heterodimer is split as a result of electronic and symmetry effects caused by the porphyrin–ethynyl moiety. Presumably, the closeness of the two ring systems results in a perpendicular, unsymmetrical orientation in solution. Although splitting of the phthalocyanine Q-band has not been reported previously, a broadening of this absorption has been noted in other porphyrin–phthalocyanine dimers[9] and was ascribed to a weak exciton interaction between the two chromophores in the ground state.

An initial examination of the heterodimer **1(Zn)** by fluorescence spectroscopy (Fig. 2) has shown that excitation at the porphyrin Soret band (431 nm) results in an emission spectrum with a major peak between 600–630 nm and a second weaker band at 712 nm. Fig. 2 also shows the effect of solvent polarity on the emission spectrum, where a direct relationship between increasing solvent polarity and the relative intensity of the shorter to longer wavelength emission bands was observed. The solvent dependent behaviour observed here is in accord with spectroscopic data for other porphyrin–phthalocyanine systems[8–10] where it is reported to be indicative of singlet–singlet energy transfer between the porphyrin and phthalocyanine.

Work is currently underway within our laboratory to synthesise a series of metalloporphyrin–(Zn)phthalocyanine heterodimers, by re-metallation of (H_2)porphyrin–(Zn)phthalocyanine **1(H_2)** and to study more closely the influence of the coordinated metal on ground and excited state photochemical processes.

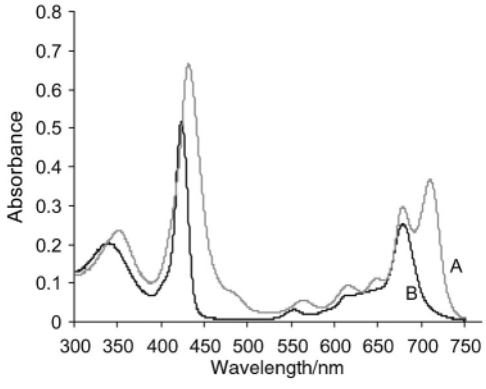

Fig. 1 UV-vis absorption spectra of A: heterodimer **1(Zn)** and B: an equimolar mixture of DPP **6** and PC **11** in toluene.

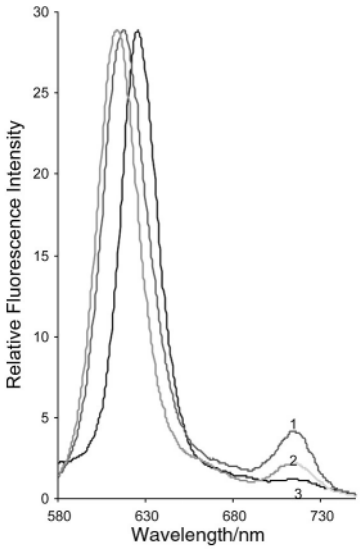

Fig. 2 Fluorescence spectra of heterodimer **1(Zn)** in solvents of different polarity (1–3; toluene/DCM/DMF, respectively).

The authors wish to thank the Wellcome Trust for financial support (052724) and EPSRC Mass Spectrometry Service, Swansea for analyses.

Novel organoaluminium (and gallium) carboxylate-bridged ring systems†

Carl Redshaw*[a] and Mark R. J. Elsegood[b]

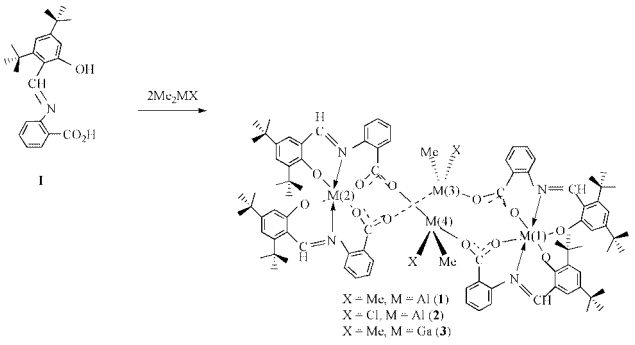
Received (in Cambridge, UK) 10th July 2001, Accepted 24th August 2001
First published as an Advance Article on the web 19th September 2001

Treatment of the Schiff-base ligand [3,5-Bu^t_2-2-(OH)$C_6H_2CHNC_6H_4$-2-(CO_2H)] with either Me_3Al, Me_2AlCl or Me_3Ga affords 16-membered macrocyclic tetramers containing both four- and six-coordinate metal centres.

The chemistry of frameworks that permit the binding of two or more multidentate Lewis acid centres is a rapidly emerging area. In particular, organoaluminium chelate complexes are receiving interest not only for their intriguing structural diversity but also for their co-operative effects in organic chemistry.[1] Neutral and more recently cationic organoaluminium species are also known to act as olefin polymerisation catalysts.[2,3] Despite this growing interest, the non-aqueous chemistry of organoaluminium carboxylates is scant.[4] Indeed, structural studies are limited to only a handful of compounds, but do reveal a preference for a bridging, bidentate carboxylate mode. Similarly, the behaviour of a number of bifunctional amine-alcohols towards aluminium trialkyls has revealed a dependence on the nature of both the alkyl and amine groups present.[5] The latter reactions resulting in the formation of mono-, di- or tri-nuclear products. Recent results in our laboratory have focused on reactions of anthranilic acid, 1,2-(H_2N)$C_6H_4CO_2H$.[6] Crystal structure analyses of a number of transition metal complexes have shown its potential to function as a chelating amidobenzoate, imidobenzoate or as a carboxylate group. Extending these studies to Me_3Al led quite unexpectedly to a remarkable macrocyclic deca-ring system {[$Me_2Al(MeAl)(\mu_3$-O)(μ-O)L]}$_3$ (L = quinazoline ring system) arising from insertion of acetonitrile into the generated Al–N bonds.[7] Such insertion reactions also led to novel ring structures by reaction of Me_3Al with 1,1-disubstituted hydrazines.[8] Considering all of this, we were interested in exploring the feasibilty of forming other large aggregates by utilising the coordination properties of these functional groups. To this end, it seemed interesting to ascertain the detailed structural features of the products arising from the interaction of the organoaluminium reagents Me_3Al and Me_2AlCl (as well as the gallium reagent Me_3Ga) with the potentially tridentate Schiff-base ligand **I**. The products from these reactions are remarkable 16-membered macrocyclic tetramers, see Scheme 1. However, despite being recrystallised from acetonitrile none of the products are the result of MeCN insertion into Al–N bonds.

The Schiff-base ligand **I** is formed readily from anthranilic acid and 3,5-di-*tert*-butylsalicylaldehyde in refluxing ethanol. Its molecular structure exhibits both intra- and inter-molecular H-bonding.[9] Addition of 2 molar equivalents of Me_3Al to **I** in toluene results in rapid evolution of methane and formation of a yellow solution. Following work-up, small yellow prisms of **1**, suitable for an X-ray analysis using synchrotron radiation,[10] were grown from acetonitrile in *ca*. 55% yield. The molecular structure of the acetonitrile solvate is shown in Fig. 1, with



Scheme 1

selected bond lengths given in the caption. The X-ray analysis‡ reveals the product to be a centrosymmetric tetramer. The 16-membered macrocyclic ring is self-filling and comprises four aluminium atoms (two octahedral and two tetrahedral) linked *via* carboxylate groups binding in an *anti*/*syn* fashion. The geometries at the bridging aluminium centres are only slightly distorted from tetrahedral (104–123°). In contrast, the remaining two aluminium centres are octahedral with two tridentate, meridonally coordinated Schiff ligands, binding to aluminium *via* the deprotonated hydroxy oxygen, the imino nitrogen and an oxygen of the carboxylate group (*cis*-oxygens, *trans*-nitrogens). This results in the formation of four six-membered *N,O*-chelate rings per Al centre, each of which adopt a 'boat-like' conformation, the aluminium lying on average about 0.63 Å out of the plane of the other five atoms (which are co-planar to within 0.06 Å). The imino bonds to aluminium are typical [1.986(2)–2.001(3) Å], whilst the C=N bonds (av. 1.31 Å) have clearly retained some double bond character, there being no evidence of significant delocalisation into any of the

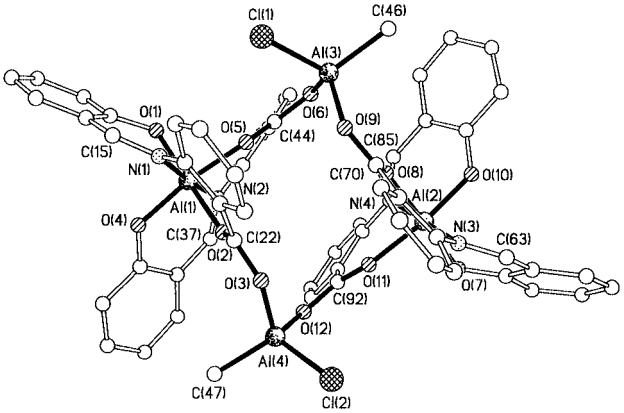

Fig. 2 Molecular structure of **2** with H-atoms, Bu^t groups and MeCN solvent molecules removed for clarity. Selected bond lengths (Å): Al(1)–O(1) 1.826(3), Al(1)–O(2) 1.921(3), Al(1)–O(4) 1.820(3), Al(1)–O(5) 1.915(3), Al(1)–N(1) 2.013(3), Al(1)–N(2) 2.000(3), Al(3)–O(6) 1.802(3), Al(3)–O(9) 1.810(3).

adjoining bonds. The Al–methyl distances [1.940(4)–1.948(4) Å] are typical of others observed in the literature.[11] Despite the apparent inequivalence of the phenyl groups in the structure, the ^{1}H NMR spectrum (ambient temperature, 300 MHz) is relatively simple with only one Al–Me and two *tert*-butyl resonances.

Encouraged by the synthesis of the macrocyclic ring system **1**, we then investigated the reaction of Me_2AlCl with **I**. Addition of Me_2AlCl (2 equivalents) to **I** in toluene, followed by heating to reflux for 12 h, afforded, on work-up, small yellow prisms of **2** suitable for X-ray diffraction in 40% yield. The X-ray analysis‡ reveals the product to be a similar centrosymmetric tetramer (Fig. 2). Again, the 16-membered macrocyclic ring is self-filling and comprises four aluminium atoms (two octahedral and two tetrahedral) linked *via* carboxylate groups binding, as in **1**, in an *anti*/*syn* fashion. The geometries at the bridging aluminium centres are only slightly distorted from tetrahedral (104–106°). The two octahedral aluminium centres are again coordinated by two tridentate, meridonal Schiff ligands, binding to aluminium *via* the deprotonated hydroxy oxygen, the imino nitrogen and an oxygen of the carboxylate group (*cis*-oxygens, *trans*-nitrogens). The resulting four six-membered *N,O*-chelate rings adopt the 'boat-like' conformation seen in **1**, the aluminium lying on average *ca*. 0.61 Å out of the plane of the other five atoms (which are co-planar to within 0.07 Å). The imino bonds to aluminium are typical [2.001(3)–2.012(3) Å], whilst the C=N bonds (av. 1.31 Å) have clearly retained some double bond character, there being no evidence of significant delocalisation into any of the adjoining bonds. The Al–methyl distances [1.939(4) and 1.951(3) Å] are similar to those in **1**; the Al–Cl distances are 2.1169(16) and 2.1015(18) Å. The ^{1}H NMR spectrum of **2** is more complex than that of **1**, doubtless reflecting the increased asymmetry at the bridging Al centres. The ^{27}Al NMR spectra of **1** and **2** consist of two peaks: one in the expected range for six-coordinate aluminium ($\delta \sim 8$) and a second peak which is difficult to interpret ($\delta \sim 120$ (**1**) and 107 (**2**)], but tentatively assigned to the four-coordinate centre. Four- and five-coordinate aluminium centres usually appear at $\delta \sim 150$ and 100, respectively.[12] It is noteworthy that in a related Schiff-base type environment, five-coordinate aluminium is present at $\delta \sim 65$.[13]

The gallium analogue of **1** is readily available in good yield (*ca*. 70%) from the reaction of Me_3Ga (2 equivalents) and **I**. Although compounds **1**–**3** failed to give the expected parent ions in the FAB mass spectra, a number of fragments were consistently observed (see ESI†).

In contrast to the pendant-arm Schiff-base complexes of aluminium reported by Gibson and coworkers (all mono-nuclear),[3d] the present system powerfully illustrates the potential for generating novel macrocyclic ring systems utilising the coordination properties of the carboxylate group. Future studies will focus on further exploiting these coordination properties to access new inorganic ring systems and to examine the catalytic properties thereof.

The first fluorescent sensor for boronic and boric acids with sensitivity at sub-micromolar concentrations—a cautionary tale†

Susumu Arimori, Christopher J. Ward and Tony D. James*

Department of Chemistry, University of Bath, Bath, UK BA2 7AY. E-mail: T.D.James@Bath.ac.uk

Received (in Cambridge, UK) 19th April 2001, Accepted 21st August 2001
First published as an Advance Article on the web 18th September 2001

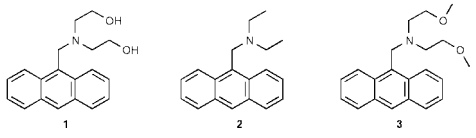
The first reported fluorescent sensor for boronic and boric acids is actually not a sensor for boronic and boric acids but rather is a sensor for protons; the system is also not the first fluorescent sensor since Alizarin has been used as a fluorescent sensor for boric acids since 1936.

We were very interested to read 'the first fluorescent sensor for boronic and boric acids with sensitivity at sub-micromolar concentrations'. The report[1] described how the interaction between an amine and boronic acid could be used to create a fluorescent sensor for boric and boronic acids. It was proposed that compound **1** formed a stable complex with phenylboronic acid and was fluorescent due to a strong B–N interaction, whereas compound **2** does not interact strongly with phenylboronic acid and remains non-fluorescent due to a weak B–N interaction.†

We have also been interested in the use of such B–N interactions in the development of fluorescent sensors for saccharides.[2] The interaction of a neighbouring amine with boronic acid is strengthened on saccharide binding. The strength of this boronic acid–tertiary amine interaction can be used to signal the binding event. Many successful photoinduced electron transfer (PET) sensors have been developed based on this approach.[3–7]

We were interested in the Wang paper[1] since we believed that molecule **1** would make it possible to develop an independent (of saccharide) scale for boronic acid binding efficiency. We believed that such a scale would help in the development of new saccharide receptors.

We easily repeated the reported syntheses of compounds **1** and **2**, and also prepared compound **3**. Compound **3**, like



compound **2**, cannot form a cyclic ester with phenylboronic acid but is a closer structural mimic of **1**. With compounds **1**, **2** and **3** we repeated the titration with phenylboronic acid in methanol (Fig. 1). The relative fluorescence intensity of **1**, **2** and **3** increased with added phenylboronic acid. The results we obtained for **1** and **2** are almost identical to the published results.[1] However, we were intrigued by the fluorescence spectra of **1**, **2** and **3** in methanol. The observed fluorescence intensity of **2** in the absence of phenylboronic acid was much higher than the fluorescence intensity of **1** and **3**. Therefore we decided to investigate the fluorescent properties of **1**, **2** and **3** further.

A fluorescence titration of **1** (1.0×10^{-6} mol dm^{-3}) with phenylboronic acid was carried out in pH 8.21 aqueous methanolic buffer solution [52.1 wt% methanol (KCl, 0.01000 mol dm^{-3}; KH_2PO_4, 0.002752 mol dm^{-3}; Na_2HPO_4, 0.002757 mol dm^{-3})].[8] Surprisingly the fluorescence intensity of **1** only increased slightly with added phenylboronic acid. Why was the result for non-buffered methanol and buffered methanolic aqueous solution different?

In order to investigate the above observations we determined the pK_a values of **1**, **2** and **3** in aqueous methanolic solution. The pH titrations of **1**, **2** and **3** (all 1.0×10^{-6} mol dm^{-3}) were carried out in 52.1 wt% methanolic aqueous solution (sodium chloride 0.05 mol dm^{-3}). The pH was controlled using minimum volumes of sodium hydroxide and hydrochloric acid solutions. The fluorescence intensity *vs*. pH curves are shown in Fig. 2, and pK_a values of **1**, **2** and **3** calculated from the relative fluorescence intensity *vs*. pH titration curves[7,9] are given in Table 1. The pK_a values of **1**, **2** and **3** were also determined in

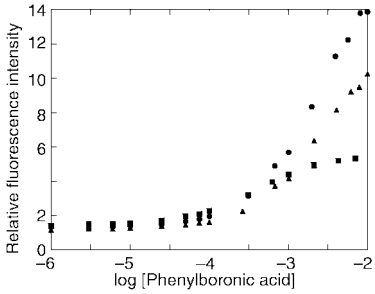


Fig. 1 Relative fluorescence intensity *vs*. log[phenylboronic acid] profile for **1**, **2** and **3** at 25 °C in methanol; [**1**] = [**2**] = [**3**] = 1.0×10^{-6} mol dm^{-3}, [phenylboronic acid] = 0–0.01 mol dm^{-3}: (●) **1**, (■) **2**, (▲) **3**. λ_{ex} = 370 nm, λ_{em} = 417 nm.

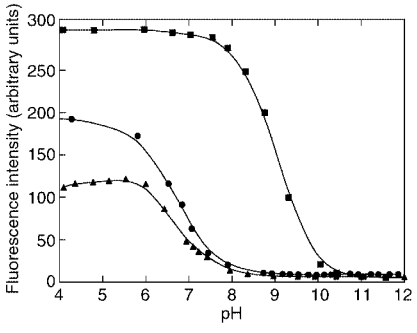

Fig. 2 Fluorescence intensity *vs*. pH profile for **1**, **2** and **3** at 25 °C; [**1**] = [**2**] = [**3**] = 1.0×10^{-6} mol dm^{-3}, 52.1 wt% methanolic aqueous solution in the presence of [NaCl] = 0.05 mol dm^{-3}: (●) **1**, (■) **2**, (▲) **3**. λ_{ex} = 370 nm, λ_{em} = 417 nm.

Table 1 pK_a values of **1**, **2** and **3** with and without phenylboronic acid (PBA)[a]

Compound	pK_a(r^2)	pK_a [PBA (10 mM)] (r^2)
1	6.55 ± 0.03 (1.00)	6.70 ± 0.01 (1.00)
2	9.03 ± 0.01 (1.00)	8.75 ± 0.01 (1.00)
3	6.78 ± 0.03 (0.99)	6.61 ± 0.04 (0.99)

[a] The pH titration was carried out in 52.1 wt% methanolic aqueous solution in the presence of NaCl (0.05 mol dm^{-3}) at 25 °C.

† Electronic supplementary information (ESI) available: PET sensors **1** and **2**, ^{1}H, ^{13}C and ^{11}B NMR data for **1** with and without phenylboronic acid (PBA). See http://www.rsc.org/suppdata/cc/b1/b103533a/

 DOI: 10.1039/b103533a

the presence of phenylboronic acid (0.01 mol dm^{-3}) (Table 1). From Table 1 it can be seen that the pK_a values of **1**, **2** and **3** do not change significantly in the presence of phenylboronic acid. This result indicates that under these conditions **1**, **2** and **3** do not show a significant B–N interaction. From these results it is also evident that **3** (pK_a = 6.78) and not **2** (pK_a = 9.03) should be used as a model for compound **1** (pK_a = 6.55).

The observed lack of a significant B–N interaction was somewhat surprising since Hall *et al.* and ourselves have recently used diethanolamine based polymers to bind with boronic acids.[10,11] However, the loading of diethanolamine based polymers is achieved in THF, which is a non-protic polar solvent.

To confirm these observations we recorded the ^{1}H and ^{13}C NMR spectra of **1** with and without phenylboronic acid, and also the ^{11}B NMR spectra of phenylboronic acid with and without **1** in methanol and chloroform.† The methanol conditions are those employed by Wang *et al.*[1] whereas chloroform is an aprotic solvent that mirrors the conditions used by Hall *et al.* and ourselves for loading boronic acids onto diethanolamine polymers.

^{11}B NMR spectroscopy provides the clearest evidence that no complex is formed in methanol. The boron signal of phenylboronic acid appears at 29.97 ppm and shifts to 30.70 ppm on addition of **1** clearly indicating that the boron remains sp^2 hybridised.[12] In contrast in chloroform the boron signal of phenylboronic acid at 32.27 ppm shifts to 15.90 ppm on addition of **1**, showing that the boron changes hybridisation from sp^2 to sp^3.[12] The ^{13}C NMR spectrum of **1** is also useful since in methanol none of the methylene carbons shift significantly on addition of phenylboronic acid whereas in chloroform the methylene carbon next to the oxygen shifts by 3.03 ppm on addition of phenylboronic acid. The ^{1}H NMR spectrum of **1** is also informative; in methanol none of the methylene protons shift significantly on addition of phenylboronic acid. However, in chloroform the spectrum becomes broad on addition of phenylboronic acid. These NMR measurements indicate that in methanol no complexation with **1** occurs, but in chloroform compound **1** does form a complex with boronic acids.

Wang *et al.*[1] made their conclusions about compound **1** in methanol using model compound **2** and the relative fluorescence intensity. With this research we have shown that compound **3** and not compound **2** should have been used as the model compound. Also, if the data used to produce Fig. 1 is replotted using the raw fluorescence intensity the conclusions drawn about compound **1** are shown to be incorrect. Fig. 3 shows the fluorescence intensity *vs.* log concentration titration curves of **1**, **2** and **3** in methanol with phenylboronic acid. From these curves compound **2** and not compound **1** shows the best response with added phenylboronic acid.

From the experimental pK_a curves (Fig. 2) and the titrations with phenylboronic acid (Fig. 3) an explanation for the observed behaviour of compounds **1**, **2** and **3** is forthcoming. In our experiments we used HPLC grade methanol but took no special precautions to ensure that the solvent was dry. Therefore, it is reasonable to assume that water was present in the methanol. From our observations this water must be sufficiently acidic to partially protonate **2** but not **1** or **3**. This explains why in just methanol, the fluorescence intensity of **1** was much higher than **2** and **3** (Fig. 3). When phenylboronic acid is then added to the methanol solution water molecules present in the methanol coordinate with the boron Lewis acid and become more acidic.[2,13] These more acidic water molecules can now protonate compounds **1** and **3** as well as compound **2**. Because compound **2** is more basic than **1** and **3** it is more sensitive to the addition of phenylboronic acid (Fig. 3). Also, since phenylboronic acid is simply acting as an acid in methanol it is not surprising that the maximum intensities observed in the phenylboronic acid titrations (Fig. 3) mirror the maximum intensities observed in the pH titrations (Fig. 2).

The justification given above explains the observed titration results in methanol and may also explain why in buffered methanolic solution negligible fluorescence changes are observed.

In conclusion, compound **1** in methanol does not act as a fluorescence sensor for boronic and boric acids. The fluorescence increases observed by Wang *et al.*[1] for **1** with added boronic acid are probably due to protonation[14] and not a B–N interaction. If a fluorescence sensor for boronic or boric acid is required the reader is directed to two recent papers where commercial Alizarin Red S has been used.[15,16] In fact Alizarin Red S has been used as a fluorescent sensor for boric acid since 1936.[17]

Non-covalent interactions exert extraordinary influence over conformation and properties of a well-known supramolecular building block

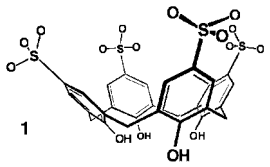
Leonard J. Barbour and Jerry L. Atwood*

Department of Chemistry, University of Missouri–Columbia, Columbia, MO 65211, USA
E-mail: atwoodj@missouri.edu

Received (in Cambridge, UK) 13th June 2001, Accepted 18th July 2001
First published as an Advance Article on the web 18th September 2001

At low pH, and in the presence of 4,4′-bipyridine, *p*-sulfonatocalix[4]arene crystallizes in the 1,3-alternate conformation rather than the expected cone conformation and exhibits remarkable stability.

We and others have conducted extensive studies of the solid-state supramolecular complexes of *p*-sulfonatocalix[4]arene **1**.[1]



Our primary interest in this compound relates to its amphiphilic nature which is of possible relevance to biological systems. The molecule resembles the shape of a truncated cone and possesses strongly hydrophilic upper and lower rims, while the cavity and outer midsection are strongly hydrophobic. Furthermore, *p*-sulfonatocalix[4]arene is usually terta- or penta-anionic, depending on pH, and highly soluble in aqueous media. To date, this tantalizing blend of properties has yielded several different, but related packing motifs of remarkable complexity. Most commonly, the calixarenes arrange themselves in an up–down fashion to form a bilayer with the hydrophobic midsections of adjacent molecules mutually aligned and engaged in intermolecular π-stacking interactions.

Owing to its truncated cone shape, the bilayers of **1** are necessarily planar and the head and tail groups of the individual molecules constitute hydrophilic surfaces on both sides. The hydrophilic region between adjacent layers is occupied by a complex array of hydrogen bonded water molecules and cations. In the presence of suitably sized aromatic guests, the non-polar portions of the guest molecules usually protrude into the calixarene cavities lining the surface of the bilayer. Recently we were able to show that an up–up arrangement of the cones can be induced, thereby affording curvature to the calixarene 'skin'.[2] This results in the formation of nanometer-scale spheres and tubules with hydrophilic interior and exterior regions. Such studies have relied upon the notion that the cone shape of *p*-sulfonatocalix[4]arene is invariant owing to the rigidity imparted by the cyclic hydrogen bonded array at the lower rim. Indeed, a survey of the Cambridge Crystallographic Database reveals that, of the 102 deposited calixarene structures with at least three hydroxy groups at the lower rim, none deviate from the cone conformation. We now present a crystal structure in which the *p*-sulfonatocalix[4]arene molecule assumes the so-called 1,3-alternate conformation despite all four phenolic hydroxy groups being intact. Furthermore, this conformation markedly affects the solubility properties of the molecule.

As part of our ongoing investigation of the inclusion phenomena of calixarenes, Na_4**1** (0.06 mmol) and 4,4′-bipyridine **2**, (0.48 mmol) were dissolved in a mixture of 2 ml water and 1 ml concentrated HCl. After a period of *ca*. two days, bright yellow crystals appeared and their X-ray structure was determined.† The asymmetric unit consists of one quarter of a calixarene molecule, and one half of a diprotonated 4,4′-bipyridine molecule (1 : 2 molar ratio). As shown in Fig. 1, the calixarene is situated on a position of $\bar{4}$ site symmetry and assumes the completely unanticipated 1,3-alternate conformation.[3] As expected at low pH, **1** possesses a charge of −4 which is counterbalanced by the charge on the bipyridinium cations. To the best of our knowledge, this structure represents the first example of a structure involving *p*-sulfonatocalix[4]arene that is completely devoid of solvent water molecules. A detailed inspection of the intermolecular hydrogen bonded pattern (Table 1) of the structure reveals an intricate network of interactions that provide a high degree of stability to the lattice.

Each *p*-sulfonatocalix[4]arene molecule donates four O–H···O–S and eight C–H···O–S hydrogen bonds to a total of eight neighboring calixarenes. Each sulfonate oxygen atom

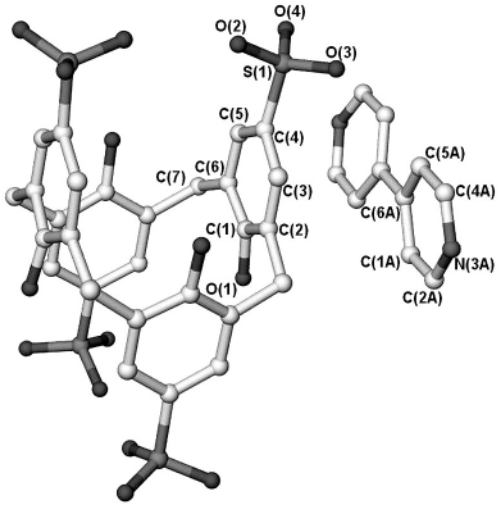


Fig. 1 View of **1** and **2** showing the labeling scheme (only asymmetric unit atoms are labeled) and the 1,3-alternate conformation of the *p*-sulfonatocalix[4]arene molecule. Hydrogen atoms are omitted for clarity.

Table 1 Unique hydrogen bond geometry[a]

No.[b]	D	A	*d*(D···A)	*d*(H···A)	*θ*(D–H···A)
1	O(1)	O(4)^{i}	2.823	1.854	166
2	C(7)	O(4)^{i}	3.290	2.396	150
3	C(7)	O(3)^{ii}	3.500	2.549	161

5	C(4A)	O(1)^{iv}	3.116	2.313	142
6	C(5A)	O(3)^{v}	3.100	2.370	133

[a] Distances and angles are given in Å and °. D = donor, A = acceptor. Symmetry operations: (i) ½ + *y*, *x* − ½, *z* − ½; (ii) ½ − *x*, ½ − *y*, ½ − *z*; (iii) ½ + *x*, ½ − *y*, ½ − *z*; (iv) ½ + *y*, *x* −½, ½ + *z*; (v) 1 − *x*, −*y*, *z*. [b] See Fig. 2 for bond numbering scheme.

 DOI: 10.1039/b105182m

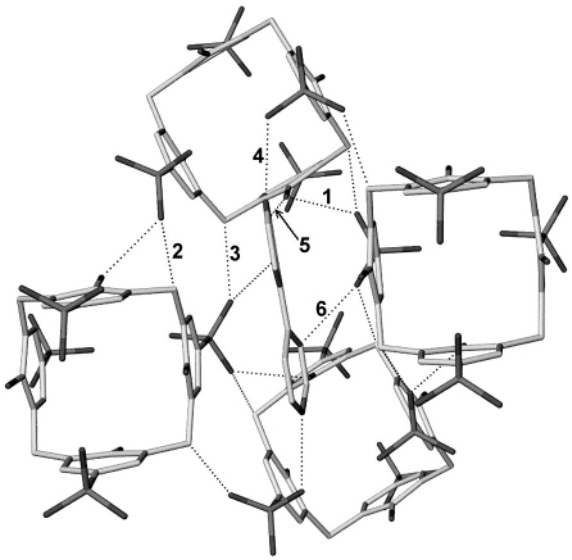

Fig. 2 View showing the hydrogen bonded network. Hydrogen atoms are omitted for clarity (H-bonds are drawn between donor and acceptor atoms). See Table 1 for details of the hydrogen bond geometry.

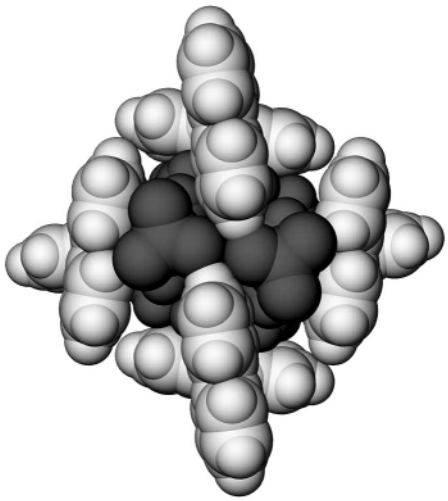

Fig. 3 View along [001] showing the calixarene molecule (dark) surrounded by eight molecules of 4,4′-bipyridine.

O(4) acts as a double receptor of both a strong O–H···O and a moderately strong[4] C–H···O hydrogen bond while each methylene carbon atom C(7) donates its two hydrogen atoms to C–H···O hydrogen bonds to sulfonate oxygen atoms of two separate calixarenes.

The calixarene is surrounded by eight 4,4′-bipyridinium cations. As shown in Fig. 3, four of these are situated about the 4-fold axis while the remaining four protrude into the small clefts beside the sulfonate headgroups. The former interact with the calixarene by means of relatively strong C–H···O hydrogen bonds and face-to-face aromatic π···π interactions (interplanar spacing 3.24 Å) while the latter form strong N–H···O hydrogen bonds to the O(2) atoms of the four symmetry-related sulfonate groups.

A number of additional conformational features of **1** are worthy of mention with regard to the overall stability of the crystal lattice. It is interesting that the sulfonate groups belonging to distal aromatic rings of **1** are aligned such that their O(2) oxygen atoms are separated by a distance of only 2.855 Å. This is well within the van der Waals contact limit and somewhat surprising, considering that the sulfonate groups each carry a negative charge and are thus expected to repel one another strongly.

Furthermore, the phenolic rings deviate significantly from planarity: C(1) and O(1) are at distances of 0.101 and 0.295 Å respectively, from the least-squares plane through C(2)–C(3)–C(4)–C(5)–C(6). The hydroxy groups are pulled away from the $\bar{4}$ axis by the O–H···O hydrogen bond that they donate to a sulfonate oxygen atom of a neighboring calixarene molecule (the methylene carbon atoms C(7) act as hinges to facilitate this motion). However, appropriate angling of the aromatic ring is impeded as the distal sulfonate oxygen atoms O(2) come into close contact with one another as described above. As a result, the aromatic ring is forced to bend outwards near the lower rim.

Finally, since every other known solid-state phase of **1** is highly water-soluble it is noteworthy that the crystals described here are insoluble in water and decompose at *ca*. 344–348 °C. Indeed, it is clear that, in concert, the many intermolecular interactions (*i.e*. O–H···O and C–H···O hydrogen bonds as well as aromatic π···π interactions) impart an extraordinarily high degree of stability to the structure, thereby compensating for the energy involved in disruption of the cone conformation and the strain resulting from close non-interacting O···O contacts and distortion of the calixarene aromatic rings.

We thank the National Science Foundation for support of this work.

A new highly fluorescent probe for monosaccharides based on a donor–acceptor diphenyloxazole

Nicolas DiCesare and Joseph R. Lakowicz*

Center for Fluorescence Spectroscopy, University of Maryland, School of Medicine, 725 W. Lombard St., Baltimore, Maryland 21201, USA. E-mail: cfs@umbi.umd.edu; Fax: +1 410 706-8408

Received (in Covallis, OR, USA) 18th July 2001, Accepted 13th August 2001
First published as an Advance Article on the web 12th September 2001

A diphenyloxazole substituted with a dimethylamino and a boronic acid group showing intramolecular charge transfer in the excited state undergoes large spectral changes in the presence of monosaccharides.

For a decade, the development of synthetic probes for the recognition and analysis of sugar has attracted much attention.[1] Synthetic probes could find useful applications in the food industry as well as in clinical analysis. Detection and monitoring of glucose is particularly important for diabetics.[2] The development of synthetic sensors could be complementary to the present technology of glucose testing by using enzymes.[3] For example, the use of enzymes shows some limitations in the development of implantable sensors for continuous glucose monitoring in blood or in interstitial tissue. Continuous monitoring of glucose blood level is very important for the long term health of the diabetics and synthetic probes could lead to improvements in medical technology such as alarm systems for hypoglycemia and a control device for an insulin pump.

The boronic acids have been known for a few decades for their ability to interact with diols.[4] They have been used for the development of receptor and fluorescent probes for sugars.[1,5–7] The advantages of using boronic acid as chelator group for sugars are the fast and reversible interaction with sugars. In addition, many substituted phenylboronic acids are commercially available allowing the development of a large diversity of synthetic fluorescent probes for sugars with minimal synthetic steps. Different mechanisms have been used to induce spectral change following the interaction of the boronic acid and the sugars. Among these mechanisms, the use of intramolecular charge transfer (ICT) involving the boronic acid is very promising.[6,7] ICT is well known to be very sensitive to small perturbations[8] that can result in spectral shifts, intensity changes and/or lifetime changes. In addition, ICT can be applied to a very large diversity of fluorophores with no limitation of the wavelength range and/or lifetime of the fluorophore.

In an attempt to develop highly effective fluorescent probes for glucose, we synthesized compound **1** (Scheme 1). Compound **1**† is readily synthesized from the reaction between the 2-amino-4′-dimethylaminoacetophenone hydrochloride‡ and 4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)benzoyl chloride, obtained from the commercially available 4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)benzoic acid refluxed in $SOCl_2$, following by the dehydratation of the product in $POCl_3$.[9] Donor–acceptor derivatives of diphenyloxazole are well known to show high fluorescence quantum yields, long wavelength emission and to be very sensitive to small variations affecting the ICT properties of the excited state.[9] In this case, the ICT state is between the boronic acid, the electron-withdrawing group, and the *N*,*N*-dimethylamino group, the electron-donating group. As the boronic acid group changes to its anionic form, **2** in Scheme 2, the electron-withdrawing properties of the boron are removed and then the ICT is affected.[6] As the pH increases, we observe a blue shift (results not shown) and a significant increase in the fluorescence intensity. The emission band of the neutral form **1** appears at 557 nm with a ϕ_F value of 0.03, on the other hand, the emission of the anionic form **2** appears at 488 nm with a ϕ_F value of 0.95. These important spectral changes are interpreted by the loss of the ICT property for the anionic form **2**. The intensity change following the pH change is shown in

Scheme 2 Equilibrium involving pH and sugars.

 DOI: 10.1039/b106763j

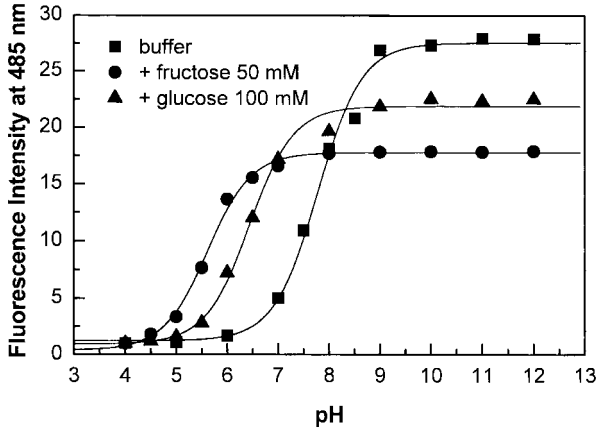

Fig. 1 Titration curves of **1** against the pH in absence and presence of sugars, λ_{ex} = 350 nm.

Fig. 1. Nearly a 30-fold increase in the fluorescence intensity can be observed at 485 nm.

Usually, the effects of sugars are observed since the boronic acid–sugar complex (structure **3** from Scheme 2) has a lower pK_a than the uncomplexed boronic acid. At a selected pH, it is possible to have a predominance of the neutral form (**1**) in absence of sugar and a predominance of the anionic form (**4**) in presence of sugar. This conformational change of the boron group, induced by the presence of sugar, is the origin of the spectral changes observed. Titration curves of **1** in presence of the sugar are displayed in Fig. 1. The observed pK_a of **1** is 7.8 in absence of sugar, pK_as of 5.6 and 6.5 are obtained in presence of fructose and glucose, respectively. Maximum changes between the titration curves with and without sugar are obtained at pH 6.5 and 7.0 for fructose and glucose, respectively. Since the spectral changes induced by sugar are not so different between these two pH values, we performed our measurements at pH 7.0 for all saccharides. It is also interesting to note that large spectral changes could also be observed at a pH higher than 9.0 as seen in Fig. 1. This suggests that probe **1** could also be used for monitoring sugar at high pH.

The effect of fructose on the emission band of **1** is displayed in Fig. 2. As observed for the pH, the presence of the sugar induces a blue shift and an increase in the fluorescence intensity. An isosbestic point is observed at 615 nm showing the equilibrium of the two conformations, the neutral and anionic form of the boronic acid. The same isosbestic point was observed in the pH effects on the emission band. The increase of the emission intensity is about 5-fold in the presence of fructose and about 3-fold in the presence of galactose and glucose. Titration curves of **1** against sugars are displayed in Fig. 3. Dissociation constants (K_D) of **1** were calculated at 1.9 ± 0.1 mM for fructose and 14 ± 1 and 37 ± 3 mM for galactose and glucose, respectively. K_D values are comparable to previous

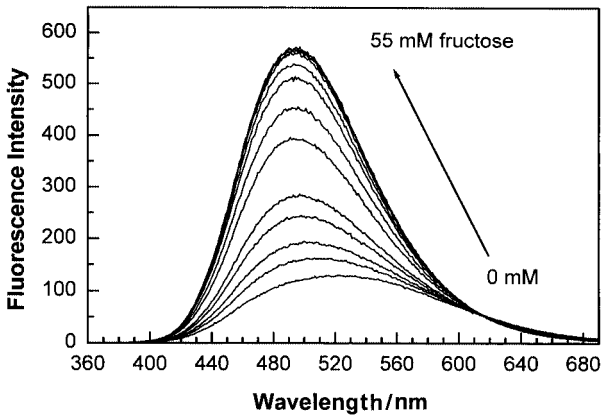

Fig. 2 Effect of fructose on the emission of **1**, measured in phosphate buffer–methanol (2:1 v/v) at pH 7.0, λ_{ex} = 350 nm. Probe concentration: 5 × 10^{-6} M.

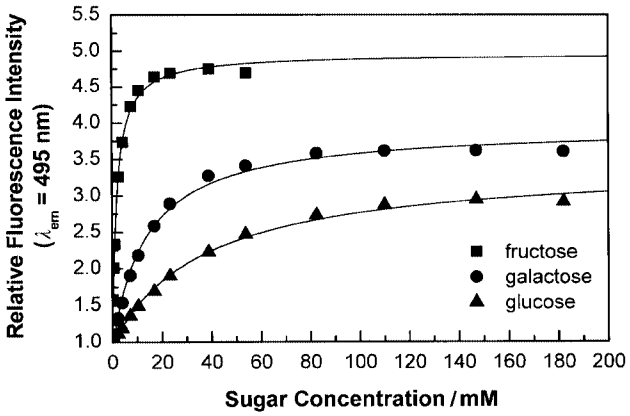

Fig. 3 Titration curves of **1** against sugars, measured in phosphate buffer–methanol (2:1 v/v) at pH 7.0, λ_{ex} = 350 nm. Probe concentration: 5 × 10^{-6} M.

values obtained with donor–acceptor chromophores involving the boronic acid group.[6,7] The higher affinity of the monoboronic acid **1** for fructose in comparison with glucose and the high concentration range of practical usefulness of **1** for glucose would not be suitable for glucose sensing in biological samples and/or in the presence of fructose but could find applications in the food industry and/or in fermentation industry where high concentrations of glucose are used.

In addition to the observed changes in the steady-state emission properties of **1**, we have also observed changes in the fluorescence lifetime of the probes. The neutral structure, **1**, shows a monoexponential fluorescence decay with a lifetime of 1.7 ns while the anionic form **2** possesses a lifetime of 3.7 ns, also monoexponential. At pH 7, the presence of fructose changes the fluorescence lifetime of the probe from 2.8 to 3.6 ns. Fluorescence lifetime changes are useful for sensing and monitoring since they are independent of the total intensity and independent also from the power of the excitation source and the concentration of the probe.[10]

Efficient synthesis of the antigenic phosphoglycans of the *Leishmania* parasite†

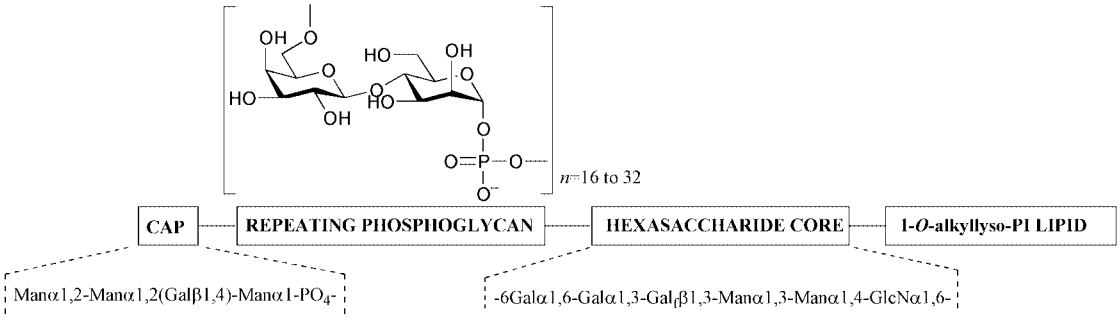
Dipali Ruhela and Ram A. Vishwakarma*

Bio-organic Chemistry Lab, National Institute of Immunology, Aruna Asaf Ali Marg, JNU Complex, New Delhi 110067, India. E-mail: ram@nii.res.in; Fax: +91 11 6162125; Tel: +91 11 6174899

Received (in Cambridge, UK) 23rd July 2001, Accepted 21st August 2001
First published as an Advance Article on the web 12th September 2001

Antigenic phosphoglycan repeats of the *Leishmania* parasite can be assembled in a flexible and efficient manner without involving any glycosidation steps, and the chain can be extended either towards the non-reducing (6′-OH) or reducing (1-OH) end suitable for synthesis of lipophosphoglycan, proteophosphoglycan and analogues.

The protozoan parasite *Leishmania* causes visceral and cutaneous leishmaniases and has a remarkable ability to survive and proliferate in extreme environments during its digenetic life cycle in the sandfly vector and the human host. At all life-cycle stages *Leishmania* species assemble an abundance of a unique class of glycoconjugates named phosphoglycans (reviewed in ref. 1). These include the most abundant surface molecule of infectious promastigote stage, the lipophosphoglycan (LPG), and secreted proteophosphoglycan (PPG) of the amastigote stage. There is substantial evidence[1] that the LPG and PPG are antigenic and multifunctional virulence factors essential for infectivity and survival of the parasite. The role of phosphoglycans in parasite virulence is currently a topic of intense debate[2] in parasite biology.



The intriguing structure of the LPG consists of four distinct domains: (i) alkyllysophosphatidylinositol lipid-anchor; (ii) conserved phosphosaccharide core with internal galactofuranose residue; (iii) variable phosphoglycan repeats and (iv) neutral oligosaccharide cap. The unique feature of LPG is the variable phosphoglycan domain made of phosphodisaccharide $[6Gal\textit{p}\text{-}\beta1,4\text{-}Man\textit{p}\text{-}\alpha1\text{-phosphate}]_n$ repeats linked through phosphodiester between the anomeric-OH of mannose of one repeat and the 6-OH of galactose of the adjoining repeat. PPG molecules are made up of the phosphoglycan repeats linked to a peptide anchor.

The biological, biochemical and biophysical experiments to probe the function, biosynthesis and conformation of the *Leishmania* phosphoglycans, and to exploit them in drug and vaccine design, require efficient chemical synthesis. Since the phosphoglycans are labile molecules, due to the presence of anomeric phosphodiester linkages, their synthesis is particularly challenging. The first synthesis of *Leishmania* phosphoglycans was accomplished[3] by the Dundee group from monosaccharide building blocks, using a suitably protected galactose donor and mannose acceptors. This obviously involved multiple protection, deprotection, glycosidation and purification steps even before the phosphoglycan assembly began through the H-phosphonate chemistry.

In our ongoing work on synthesis[4–7] and biosynthesis[8] of *Leishmania* glycoconjugates, an efficient route to construct phosphoglycans was required for the total synthesis of LPG and vaccine design. To circumvent the usual problems associated with glycosidation and to avoid several protection–deprotection steps required in previous synthesis, we used the readily available disaccharide lactose as starting material. Here we report a new efficient synthesis of phosphoglycans, which does not involve any glycosidation steps, and the phosphoglycan chain can be extended either towards the non-reducing (6′-OH) or reducing (1-OH) end in high yielding iterative steps. The important features of our approach include the glycal chemistry mediated gluco→manno transformation and regioselective 6′-protection to convert lactose (Galβ1,4-Glu) into the suitably protected Galβ1,4-Man building block, extension of PG repeats in either direction by selective deprotection at the non-reducing 6′-position or reducing 1-position and α-phosphitylation, followed by iterative PG coupling cycles.

The first intermediate lactal (**1**) was prepared[6,7] from lactose (Scheme 1) in straightforward steps (acetylation, bromination, reductive elimination and deacetylation), and a high yield could be obtained in the reductive elimination step by the application of Zn–Vitamin-B_{12} reagent.[9] The next task was to selectively protect the 6-position of the galactose residue of lactal (**1**) and this was achieved, after a considerable number of experiments, by dibutyltin oxide mediated silylation (Bu_2SnO–MeOH reflux followed by TBSCl) which led exclusively to 6′-*O*-TBS-lactal (**2**). It should be mentioned here that under similar conditions most other protecting groups (benzyl, *p*-methoxybenzyl and allyl) led to C3′-OH protected lactals. The next step involved stereoselective gluco→manno transformation of 6′-*O*-TBS-lactal (**2**) by MCPBA under biphasic conditions which led exclusively to the manno product 6′-*O*-TBS-galactopyranosyl-(1→4)-β-D-mannopyranose (**3**). The acetylation of **3** gave the key intermediate, 1,2,3,6-tetra-*O*-acetyl-4-*O*-(2,3,4,tri-*O*-acetyl-6-*O*-TBS-β-D-galactopyranosyl)-α-D-mannopyranose (**4**), as the major isomer, which served as a central point to both

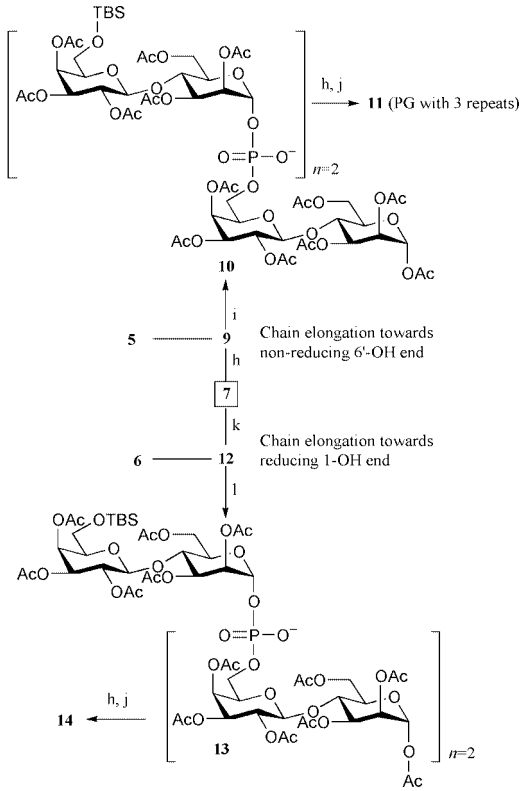

Scheme 2 *Reagents and conditions*: (h) HF–CH_3CN, 0 °C, 2 h, 85%; (i) **5**, pivaloyl Cl, Py, rt 1 h; I_2, 30 min, TEAB work-up, 79%; (j) TEA–MeOH–H_2O, rt, 24 h, 95%; (k) Me_2NH–CH_3CN, −20 °C, 3 h, 95%; PCl_3, imidazole, CH_3CN, 0 °C, 2 h, TEAB, 87%; (l) **6**, pivaloyl Cl, Py, rt, 1 h; I_2, 30 min, TEAB, 79%.

donor and acceptor for iterative assembly of the phosphoglycan repeats. Compound **4** was divided into two parts; the first part was transformed to the PG donor by anomeric deacylation (Me_2NH at −20 °C) followed by phosphitylation (triimidazolylphosphine generated *in-situ* from PCl_3 and imidazole) to provide 2,3,6-tri-*O*-acetyl-4-*O*-[2,3,4-tri-*O*-acetyl-6-*O*-(*tert*-butyldimethylsilyl)-β-D-galactopyranosyl]-α-D-mannopyranosyl H-phosphonate (**5**), isolated as the TEAB salt. The second part of **4** was converted to hepta-acetyl PG-acceptor **6** by removal of the TBS group from the 6-position of the Gal residue. The pivaloyl chloride coupling of PG-H-phosphonate donor **5** with acceptor **6** followed by *in-situ* iodine oxidation afforded fully protected phosphotetrasaccharide **7**; which on full deprotection (HF, NaOMe–MeOH) provided free phosphoglycan **8** (with two PG repeats).

Now the protected phosphotetrasaccharide **7** was well placed (Scheme 2) for further extension of phosphoglycan chain either in the upstream direction (non-reducing 6′-end) or downstream direction (reducing 1-OH end). For upstream extension of the PG domain, the TBS group from the 6′-position of galactose at the non-reducing end of **7** was removed, and the resulting tetrasaccharide **9** was coupled with disaccharide H-phosphonate **5** to provide phosphohexasaccharide **10** in high yield. The global deprotection (HF–CH_3CN and TEA–MeOH–H_2O) led to free phosphoglycan **11** with three PG repeats. For downstream extension of the PG domain, the intermediate **7** was deacetylated (Me_2NH at −20 °C) at the reducing-end anomeric position and converted to H-phosphonate **12** as described above. This was coupled with hepta-*O*-acetyl disaccharide **6** to provide phosphohexasaccharide **13** ready for deprotection or further extension to higher oligomers. The presence of (1→6)-phosphodiester linkages between the PG repeats was confirmed by ^{31}P–^{13}C coupling (doublets, 5 and 7 Hz in ^{13}C NMR) for C-1 and C-2 of the mannose units, and the C-5 and C-6 of the corresponding galactose units; these ^{13}C signals were found to be shifted due to α- and β-phosphorylation effects.

It is obvious from above that the phosphoglycan chain can further be extended to the desired length in either direction, and instead of 2 + 4 (disaccharide + tetrasaccharide) coupling, 4 + 4 coupling can also be carried out for rapid access to desired PGs.

To conclude, a versatile synthesis for rapid assembly of the biologically important *Leishmania* phosphoglycans has been achieved, which does not involve any glycosidation steps and allows the PG chain to grow in either direction. This approach is now being adopted on the solid phase and for the total synthesis of the LPG, which will be communicated shortly.

Authors thank the DST (India) for financial support for this work, and the DBT (India) for core grant to the Institute.

Received (in Cambridge, UK) 5th July 2001, Accepted 3rd September 2001
First published as an Advance Article on the web 12th September 2001

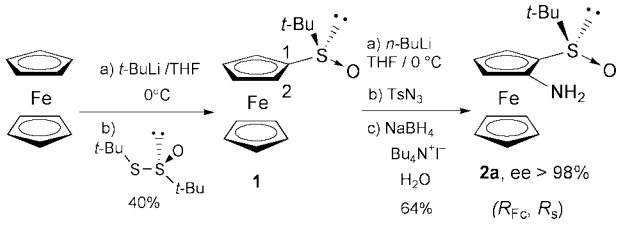
A ready access to a new family of planar chiral ferrocenes, the (R_{Fc},R_S)-2-amino substituted 1-*tert*-butylsulfinylferrocenes, is described; in the case of the sulfonamide series enantioselectivities of up to 96% were obtained in the addition of Et_2Zn to aromatic aldehydes.

During the last two decades the sulfinyl group has been extensively used as a chiral auxiliary in emblematic C–C bond forming reactions, such as Diels–Alder cycloadditions and nucleophile additions,[1] and more recently has started to be applied in transition metal-catalyzed reactions.[2] However, despite the huge interest currently devoted to the development of highly efficient chiral ligands for asymmetric catalysis, usually involving *P*,*P*- *P*,*N*- or *N*,*N*-bidentate metal-coordinating ligands,[3] few examples of chiral ligands based on sulfoxides have been reported,[4] most of them being tested only in asymmetric palladium-catalyzed allylic substitutions. Among the wide structural diversity of chiral frameworks commonly used in asymmetric catalysis, the planar chirality of 1,2-disubstituted ferrocene derivatives has received a great attention.[5] Within this context, we describe herein the synthesis of enantiopure (R_{Fc},R_S)-2-amino substituted *tert*-butylsulfinylferrocenes as a new family of sterically and electronically adjustable chiral ligands and their application to the asymmetric addition of Et_2Zn to aromatic aldehydes.[6]

The synthesis of *tert*-butyl ferrocenyl sulfoxide (**1**) in high optical purity had been previously described by enantioselective oxidation of the corresponding thioether and by sulfinylation of ferrocenyllithium with an enantiopure *tert*-butylsulfinate.[7] Alternatively, we have prepared (*R*)-**1** by direct sulfinylation of ferrocenyllithium (formed *in situ* by deprotonation of ferrocene with *t*-BuLi in THF) with (*R*)-*S*-*tert*-butyl 1,1-dimethylethanethiosulfinate.[8] This one-step procedure is experimentally quite simple (THF, 0 °C), affording ferrocene (*R*)-**1** in 40% yield after flash chromatography (58% of starting ferrocene is recovered). The recrystallization from hexane–ether (1 : 1) yielded (*R*)-**1** in very high optical purity[9] (ee = 99%, HPLC, Daicel Chiralcel OD column).

According to the previously reported cases of highly stereoselective *ortho* C-2 deprotonation of ferrocenyl sulfoxides with strong bases,[7] the treatment of **1** with *n*-BuLi (THF, 0 °C) generated selectively the C-2 lithiated *tert*-butylsulfinylferrocene.[10] This solution was treated with tosyl azide to give the intermediate ferrocenyl azide, followed by *in situ* reduction with $NaBH_4$, which afforded the amino(sulfinyl)ferrocene **2a** (64% yield) in very high optical purity (ee > 98%, HPLC, Chiralpak AS column) (Scheme 1).

In the search of efficient chiral ligands for enantioselective synthesis, the ready access to a wide diversity of substrates with adjustable steric and electronic properties around the metal-coordinating atoms is a crucial point. In this context, having developed a practical two-step procedure for the preparation of enantiopure **2a** in gram quantities from ferrocene, the amino group was readily transformed into a variety of nitrogen



Scheme 1 Synthesis of 2-amino(sulfinyl)ferrocene **2a**.

compounds such as substituted amines (**2b**), amides (**2c–f**) and sulfonamides (**2g–l**) following straightforward reactions of amine derivatization (Scheme 2).

With this family of ligands in hand, we examined their effectiveness as chiral catalysts in one of the most prototypical reactions in chiral ligand screening: the addition of diethylzinc to benzaldehyde.[6] The reactions were performed under typical conditions: 5 mol% of ligand **2**, excess of diethylzinc (200 mol%) in toluene at rt (Table 1). In most cases the complete disappearance of benzaldehyde was observed after 1–4 days, affording in acceptable to good yields the alcohol **3** with enantioselectivities very dependent on the substitution at the nitrogen atom. While a low enantiocontrol occurred using the amine (entries 1 and 2) and amide ligands (entries 3–6), a more interesting outcome was observed in the case of the sulfonamide ligands (entries 7–14), which provided (*R*)-**3** in 42 to 88% ee's. The best ligands were found to be the *p*-tolylsulfonamide **2h** (80% ee, entry 8) and the *p*-methoxyphenylsulfonamide **2i** (82% ee, entry 10). It is worth noting that in both cases the

enantioselectivity of the process was enhanced significantly by performing the reaction at −20 °C instead of rt (entries 9 and 11, 88 and 86% ee, respectively).

In order to clarify whether the enantiocontrol exerted by the chiral ligand was predominantly due to the planar chirality of the ferrocenyl moiety or to the stereogenic sulfur atom, the optimal sulfoxides **2h** and **2i** were reduced to the corresponding thioethers **2m** and **2n** by reaction with NaI–$(CF_3CO)_2O$ in acetone (89 and 74% yields, respectively). Interestingly, the addition of Et_2Zn to benzaldehyde at rt in the presence of both **2m** and **2n** (entries 15 and 16) occurred with an enantioselectivity very similar to that observed for the corresponding sulfoxides **2h** and **2i** (entries 8 and 10), showing that the planar chirality of ferrocene is the main structural factor involved in the asymmetric induction.[11]

Finally, to explore the substrate generality of this enantioselective process, the ligands **2h** and **2i** were tested in the addition of Et_2Zn to differently substituted aromatic aldehydes under the same experimental conditions. As depicted in Table 2, both ligands **2h** and **2i** behaved similarly, affording in all cases the alcohol of (*R*) configuration as the main enantiomer[12] in good chemical yields. With the exception of the case of *p*-nitrobenzaldehyde (entries 1 and 2), moderate to high enantioselectivities were observed with the rest of aldehydes (ee's from 58 to 96%, entries 3–12).

In summary, a novel family of enantiopure ferrocene ligands, the (R_{Fc},R_S)-2-amino substituted 1-*tert*-butylsulfinylferrocenes **2**, has been readily synthesized from ferrocene. Using sulfonamide ligands (especially **2h** and **2i**) moderate to high asymmetric inductions were obtained in the addition of Et_2Zn to aromatic aldehydes. The application of this new type of chiral ferrocene ligand to other asymmetric C–C bond forming reactions is under active investigation.

Interfacial synthesis of hollow microspheres of mesostructured silica

Christabel E. Fowler, Deepa Khushalani† and Stephen Mann*

School of Chemistry, Univeristy of Bristol, UK BS8 1TS. E-mail: s.mann@bris.ac.uk

Received (in Cambridge, UK) 4th June 2001, Accepted 16th August 2001
First published as an Advance Article on the web 18th September 2001

Hollow microspheres with ordered mesoporous walls are synthesised under ambient conditions by a simple procedure involving dilution and neutralisation of an aqueous tetraethoxysilane/cetyltrimethylammonium bromide reaction mixture.

The size and shape selectivity of porous inorganic structures plays a pivotal role in a wide range of industrial and biological applications involving molecular transport, adsorption, catalysis and separation. The scope of these applications could be significantly increased, for example in the parallel or sequential processing of feedstock, by the use of hierarchically organized architectures that exhibit order and functionality across several length scales. Efforts have therefore been made to invent chemically based routes to the synthesis of inorganic materials with structural and morphological complexity.[1] For example, a variety of multiple templating methodologies involving macro- and microscopic structures such as latex particles,[2] colloidal crystals[3] and bacterial superstructures,[4] in association with preformed nanoparticles or reaction solutions containing supramolecular aggregates, have been investigated. Alternatively, confined reaction environments such as emulsion droplets have been employed to prepare porous hollow spheres and inorganic vesicle-like morphologies that could be useful in controlled storage and release.[5] In particular, multilamellar silica colloids have been synthesised using neutral gemini surfactant vesicles[6] or by spray drying of reaction solutions containing cationic surfactant templates,[7] and semi-hollow microspheres of mesostructured silica prepared using a cosolvent,[8] or oil droplets containing tetraethoxysilane (TEOS) dispersed in aqueous reaction solutions.[9]

We now report the facile synthesis of thermally stable micron-size hollow spherical shells with ordered mesoporous walls, approximately 20 nm or less in thickness. The structures were synthesised at room temperature by hydrolysis and condensation of TEOS in an aqueous solution of cetyltrimethylammonium bromide (CTABr), which was subjected to rapid quenching by dilution followed by pH neutralisation after an induction period.‡ Unlike previous studies, the preparation did not necessitate addition of auxiliary cosurfactants or cosolvents, substrates, stringent conditions and/or specialized equipment, and the products were structurally and morphologically well-defined and stable upon calcination.

Samples of the as-synthesised product were obtained as a cloudy suspension at the air/water interface. Scanning electron microscopy (SEM) studies showed a high yield of micrometre-sized (mean diameter = 0.98 μm, σ = 0.4 μm) spherical structures with a uniform and smooth surface texture [Fig. 1(a)]. The size and shape of the microspheres were unchanged upon heating to 540 °C [Fig. 1(b)]. In general, only a few deformed or cracked structures were observed but when imaged these, as well as samples that had been mechanically fractured, indicated that the silica microspheres were hollow, as shown for example in Fig. 1(b). The shell thickness, which was determined from SEM and transmission electron microscopy (TEM) images of the broken microspheres, was highly uniform and less than 20 nm.

† Current address: School of Physical Sciences, University of Kent at Canterbury, UK CT2 7NR.

TEM studies of the as-synthesised and calcined materials showed hollow shells that occasionally collapsed under the high vacuum. High resolution images of the wall structures showed multiple domains of well-ordered lattice fringes with spacings between 4.2 and 5.8 nm (Fig. 2). The spacings were significantly larger than those reported for MCM-41 silica, and although image artefacts could not be ruled out, the reproducibility in the measurements suggested that the as-synthesised walls consisted of a metastable or swollen silica–surfactant mesophase that was replicated in the form of an ordered mesoporous silica shell upon calcination. In general, the lattice fringes were observed as parallel lines running across the surface of the wall, except at the edges of the projected structures where 'dot' patterns were sometimes observed (Fig. 2). The results were therefore consistent with a wall structure in which the mesoporous channels were predominantly arranged parallel to the shell surface. Pseudo-hexagonal patterns were occasionally observed in the central areas of the projected

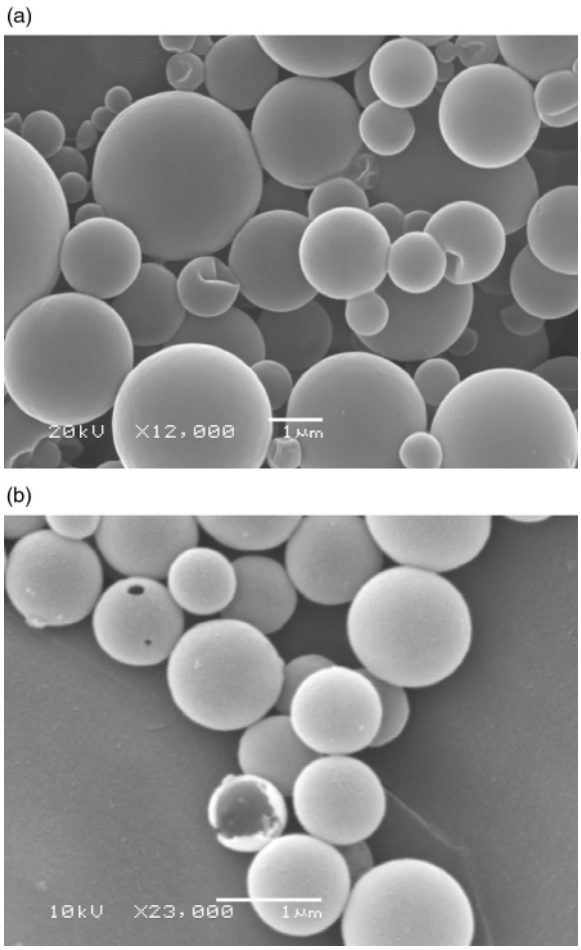

Fig. 1 SEM micrographs showing (a) as-synthesised silica-surfactant hollow mesostructured microspheres; note the partial collapse in the high vaccum of a few of the shells.  DOI: 10.1039/b104879c

images but these were interpreted as fortuitous intersections between different domains rather than regions comprising channels aligned perpendicular to the wall surface.

Small angle X-ray diffraction patterns of the as-synthesised and calcined hollow microspheres showed a single broad reflection centred at approximately 3.7 nm (Cu-Kα, λ = 0.154178 nm). The absence of higher-order reflections was consistent with the limited domain size of the mesostructure imaged by TEM. Surprisingly, thermogravimetric analysis revealed a loss of only *ca*. 2.5 wt% centred at 223 °C that was attributed to removal of surfactant from the shell walls (Fig. 3). This suggests that a significant amount of the micellar template was released *in situ* after formation of the as-synthesised mesophase without loss of the ordered mesostructure. In addition, there was minimal loss attributed to physisorbed water (4 wt% at < 100 °C) or removal of water from the condensation of terminal silanol groups (2 wt% between 400 and 500 °C). Thus, a residual mass of over 90% was obtained after heating at 800 °C for 5 h. This is considerably higher than for bulk mesoporous silica, which for MCM-41 is *ca*. 55 wt%.

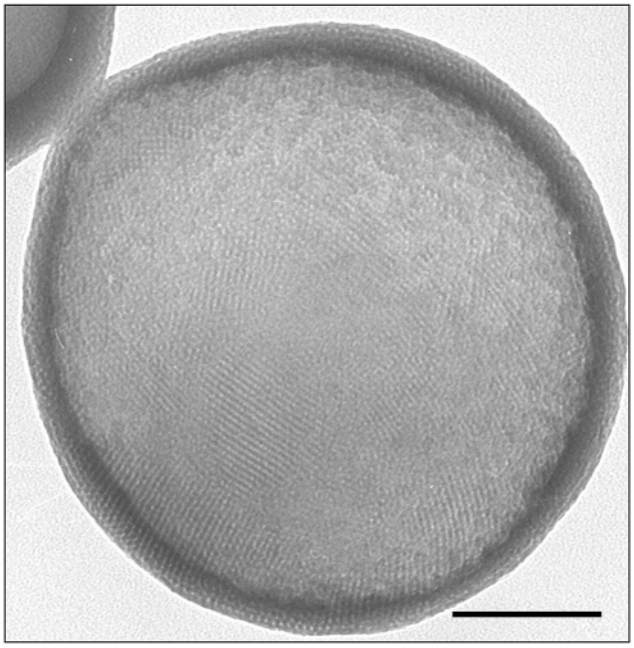

Fig. 2 TEM image of a calcined hollow mesostructured microsphere showing domains of well-ordered lattice fringes with 4.3 nm spacing. Scale bar, 100 nm.

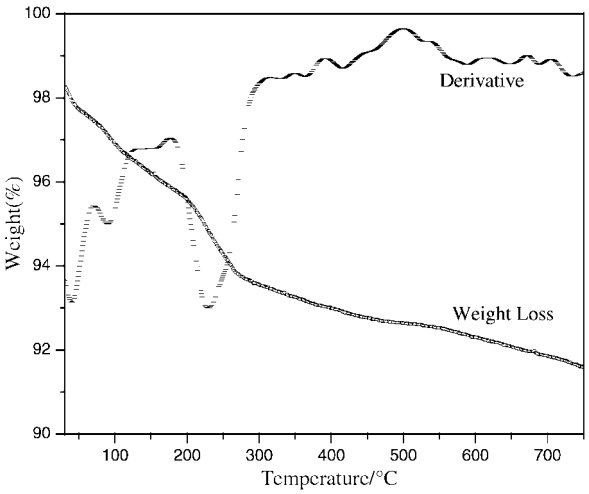

Fig. 3 TGA plot of %wt with increasing temperature and the corresponding derivative curve.

Formation of the mesostructured hollow spheres was sensitive to the stirring conditions, induction time, and time delays between the dilution and neutralisation steps of the synthesis procedure. For the conditions used, TEOS is only partially hydrolysed prior to dilution so droplets of the reactant form in the reaction mixture. These are probably stabilized to some extent by CTABr molecules that partition at the TEOS/water interface. Moreover, as the pH is lowered significantly on dilution and neutralisation, slow hydrolysis and condensation of TEOS at the droplet/water interface is curtailed so that mesostructured spherical shells only 20 nm in thickness are produced. One possibility is that the extremely dilute conditions of the synthesis promote the formation of hemispherical CTABr micelles on the surface of the TEOS droplet,[10] which also promotes the interfacial reactions. However, mesostructured nanoparticles are also formed in the reaction,[11] which indicates that the interfacial synthesis of the hollow microspheres and nucleation of colloidal particles in bulk solution are competitive processes, and explains why the preparation of the mesostructured shells is highly dependent on the reaction conditions.

We would like to thank the University of Bristol and EPSRC for financial support, and Dr C. G. Goeltner for scientific discussions.

Notes and references

‡ Hollow spheres of mesostructured silica were synthesised at room temperature by adding 3.78 g of TEOS to 45 ml of an alkaline solution (0.22 M NaOH) containing 0.049 M CTABr. 40 s after addition of the TEOS, the reaction mixture was poured into an excess of distilled water (300 ml) under slow stirring. The final molar ratio was: 0.12 C_{16}TMABr : 0.5 NaOH : 1.0 SiO_2 : 130 H_2O. When the pH had dropped to *ca*. 10 and the mixture began to appear cloudy (usually 220 s after the dilution step), the reaction was further quenched by the dropwise addition of 2 M HCl. The acid was added with stirring over a period of approximately 1 min until a final pH of 7.0 was attained. The stirring was then stopped and a layer of white product slowly formed at the air/water interface. This layer was recovered after leaving the suspension standing for approximately 2 h. The product was dried overnight under ambient conditions. The solid material was usually calcined by heating to a temperature of 540 °C at a rate of 1 °C min^{-1} although TGA data were recorded up to 800 °C.

An enantio- and stereocontrolled synthesis of (−)-mycestericin E *via cinchona* alkaloid-catalyzed asymmetric Baylis–Hillman reaction†

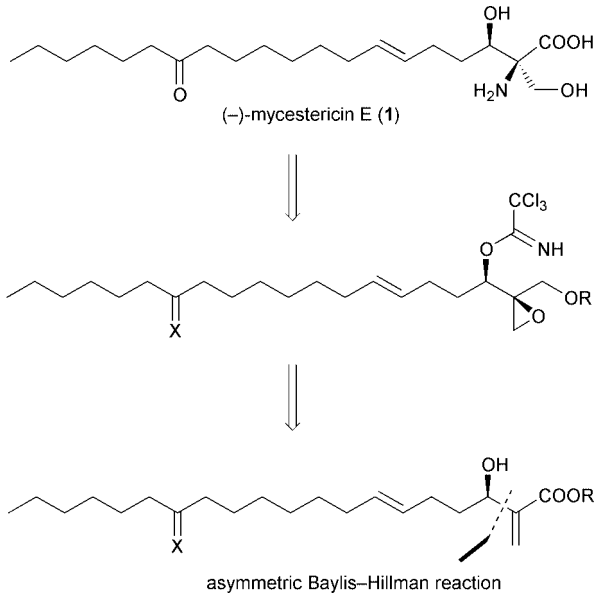
Yoshiharu Iwabuchi, Mariko Furukawa, Tomoyuki Esumi and Susumi Hatakeyama*

Faculty of Pharmaceutical Sciences, Nagasaki University, Nagasaki 852-8521, Japan. E-mail: susumi@net.nagasaki-u.ac.jp

Received (in Cambridge, UK) 1st August 2001, Accepted 29th August 2001
First published as an Advance Article on the web 18th September 2001

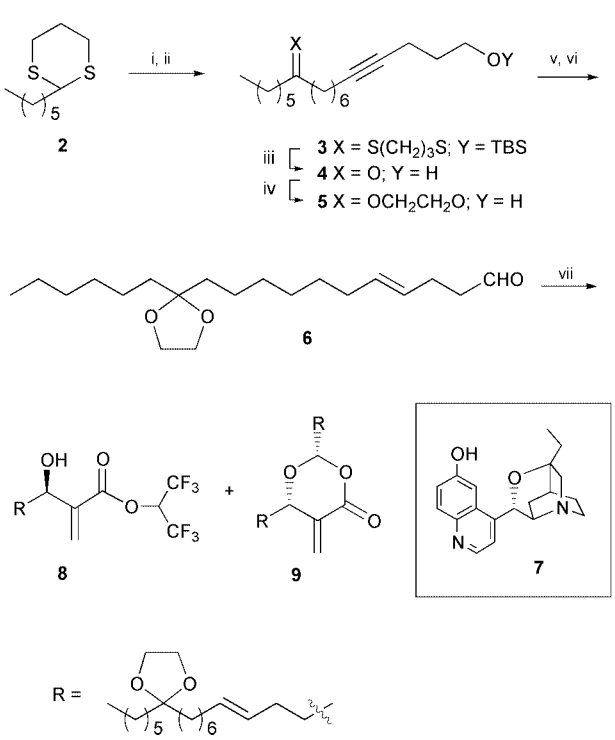
A new enantiocontrolled synthesis of a potent immunosuppressant (−)-mycestericin E has been accomplished by using *cinchona* alkaloid-catalyzed asymmetric Baylis–Hillman reaction of an aldehyde with 1,1,1,3,3,3-hexafluoroisopropyl acrylate and Lewis acid-promoted cyclisation of an epoxytrichloroacetimidate as the key steps.

Recently, we have developed a catalytic asymmetric version of the Baylis–Hillman reaction using an amine catalyst derived from quinidine, which allows us to obtain highly enantiomerically enriched (*R*)-(α-methylene-β-hydroxy)esters.[1] In order to demonstrate the synthetic utility of our methodology, we envisaged its application towards a synthesis of (−)-mycestericin E (**1**), a potent immunosuppressive principle isolated from the culture broth of the fungus *Mycelia sterilia* ATCC 20349.[2] We report herein an enantio- and stereocontrolled synthesis[3] of (−)-mycestericin E (**1**) employing a new strategy which relies on the above-mentioned asymmetric Baylis–Hillman reaction for securing the key chiral framework and Lewis acid-promoted cyclisation of an epoxytrichloroacetimidate[4] for the stereoselective construction of the substituted serine structure with a quaternary centre.



The required long chain aldehyde **6** was prepared from the dithiane **2**[5] in a straightforward manner in 62% overall yield (Scheme 1). Thus, sequential substitution of both terminals of 1,6-diiodohexane with **2** and 5-(*tert*-butyldimethylsilyloxy)-pent-1-yne *via* the lithio-species gave the alkyne **3**. Dethioketalisation with concomitant cleavage of the silyl ether protecting group, followed by ketalisation converted **3** to the dioxolane **5** *via* **4** in good yield. $LiAlH_4$-reduction of **5** in diglyme[6] at 130 °C allowed stereoselective formation of the *E*-olefinic double bond although Birch reduction was unsuccessful in this transformation. Swern oxidation of the reduced product generated the aldehyde **6** quantitatively.

The crucial Baylis–Hillman reaction of **6** thus obtained was investigated using 1,1,1,3,3,3-hexafluoroisopropyl acrylate and the amine catalyst **7** under various conditions according to the procedure we have developed.[1] As a result, we found that our method can be successfully applied to even long chain aldehydes such as **6**. Thus, upon reaction of **6** with 1,1,1,3,3,3-hexafluoroisopropyl acrylate in the presence of the amine catalyst **7** (0.2 equiv.) in DMF–CH_2Cl_2[7] (1 : 1), the (*R*)-ester **8**, $[\alpha]_D^{27}$ +6.9° (*c* 0.72, $CHCl_3$), was produced with excellent enantioselectivity (> 97% ee[8]) in 47% yield together with the dioxanone **9** (14% yield), $[\alpha]_D^{25}$ −2.7° (*c* 1.11, $CHCl_3$), 20% ee (Scheme 1). It is important to note that this reaction could be easily carried out on a multi-gram scale. Interestingly, compared with **8**, the dioxanone **9** again showed the lower optical integrity and the opposite chirality regarding the stereocenter generated in this reaction as we observed previously.[1]

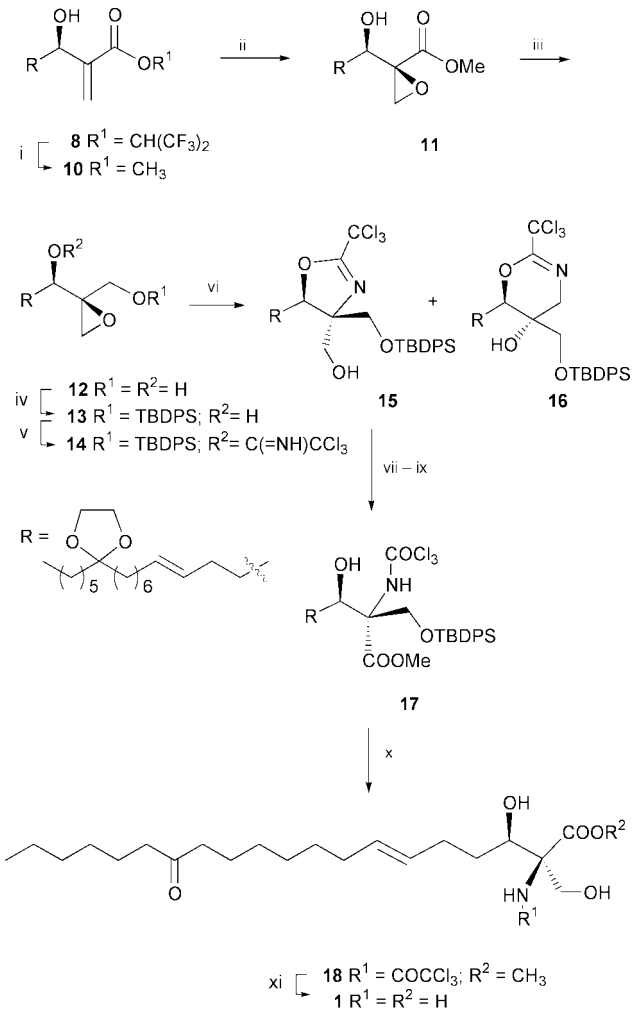


Scheme 1 *Reagents and conditions*: i, *n*-BuLi, THF, −30 °C, then 1,6-diiodohexane, 81%; ii, $LiCC(CH_2)_3OTBS$, THF–HMPA, −20 °C, 87%; iii, MeI, Na_2CO_3, THF–MeCN, sealed tube 70 °C, 91%; iv, ethylene glycol, cat. *p*-TsOH, benzene, 80 °C, 98%; v, $LiAlH_4$, diglyme, 130 °C, 87%; vi, DMSO, $(COCl)_2$, Et_3N, CH_2Cl_2, −78 °C to 0 °C, quant; vii, **7** (0.2 equiv.), 1,1,1,3,3,3-hexafluoroisopropyl acrylate (1.5 equiv.), DMF–CH_2Cl_2 (1 : 1), −55 °C, 24 h, 47% of **8**, 14% of **9**.

† Electronic supplementary information (ESI) available: experimental details. See http://www.rsc.org/suppdata/cc/b1/b106471c/

 DOI: 10.1039/b106471c

With the desired Baylis–Hillman product **8** in hand in almost enantiomerically pure form, we then investigated the construction of the serine structure possessing a quaternary centre. Prior to introduction of the epoxide scaffold, the hexafluoroisopropyl ester of **8** was converted to the methyl ester under methanolytic conditions to give the methyl ester **10**, $[\alpha]_D^{24}$ +9.0° (*c* 1.0, $CHCl_3$), in 95% yield (Scheme 2). Ti(O*i*-Pr)$_4$-mediated epoxidation[8] of **10** was found to proceed with complete diastereoselectivity to furnish the epoxy alcohol **11**, $[\alpha]_D^{17}$ +10.1° (*c* 1.0, $CHCl_3$), in 73% yield. Exposure of **11** to $NaBH_4$ in THF–MeOH allowed chemoselective reduction of the ester functionality to give the diol **12**, $[\alpha]_D^{21}$ +9.7° (*c* 0.95, MeOH), in 79% yield. The primary hydroxy group of **12** was then selectively protected as its *tert*-butyldiphenylsilyl ether to give **13**, $[\alpha]_D^{18}$ −2.6° (*c* 1.0, MeOH), in 95% yield. At this stage stereoselective introduction of a nitrogen atom at the quaternary centre was achieved by taking advantage of Lewis acid-promoted cyclisation of an epoxytrichloroacetimidate which we have previously developed.[4] Thus, the epoxy alcohol **13** was converted to the corresponding trichloroacetimidate **14**, $[\alpha]_D^{22}$ +7.3° (*c* 1.0, $CHCl_3$), in 81% yield by the reaction with trichloroacetonitrile in the presence of DBU. Upon treatment of **14** with 1.0 equiv. of $BF_3{\cdot}OEt_2$[10,11] in CH_2Cl_2 at −23 °C, the cyclisation took place selectively at the quatenary centre of the epoxide with complete inversion of the stereochemistry to produce the oxazolidine **15**, $[\alpha]_D^{23}$ −3.5° (*c* 1.0, $CHCl_3$), in 71% yield along with dihydrooxazine **16** (4% yield). Upon sequential Moffatt oxidation,[12] $NaClO_2$ oxidation,[13,14] and esterification, **15** gave the methyl ester **17**, $[\alpha]_D^{24}$ +26.6° (*c* 1.48, $CHCl_3$), in 55% yield. Treatment of **17** with 47% HF in acetonitrile at 60 °C brought about deprotection of the silyl ether and cyclic ketal protecting groups to give the trichloroacetamide **18** in 87% yield. Finally, saponification of **18**, followed by neutralisation using Amberlite IRC–76 furnished (−)-mycestericin E (**1**). The synthetic substance, mp 183–184 °C, $[\alpha]_D^{27}$ −8.3° (*c* 0.05, MeOH), exhibited spectral properties (^{1}H and ^{13}C NMR, IR, MS) in accord with those reported for natural mycestericin E,[2] mp 184–186 °C, $[\alpha]_D$ −8.6° (*c* 0.06, MeOH).



Scheme 2 *Reagents and conditions*: i, cat. NaOMe, MeOH, rt, then Dowex-50 H$^+$ form, 95%; ii, Ti(O*i*-Pr)$_4$, *t*-BuOOH, 4 Å molecular sieves, CH_2Cl_2, −20 °C, 73%; iii, $NaBH_4$, THF–MeOH (1:1), 0 °C, 79%; iv, TBDPSCl, DMAP, Et_3N, CH_2Cl_2, 0 °C, 95%; v, DBU, CCl_3CN, CH_2Cl_2, 0 °C, 81%; vi, $BF_3{\cdot}OEt_2$, CH_2Cl_2, −23 °C , 71% of **15**, 4% of **16**; vii, DMSO, DCC, TFA, pyridine, benzene, 0 °C; viii, $NaClO_2$, NaH_2PO_4, 2-methylbut-2-ene, *t*-BuOH–H_2O (4:1); ix, CH_2N_2, THF, 55% (3 steps); x, 47% HF, MeCN, 60 °C, 87%; xi, 10% NaOH, MeOH, 80 °C, 70%.

In conclusion, we have achieved an asymmetric synthesis of (−)-mycestericin E from the achiral aldehyde **6** in twelve steps in 4.7% overall yield. The present work illustrates a new methodology of general value for the synthesis of various immunosuppressive compounds related to **1**.

This study received financial support from Uehara Memorial Foundation and Japan Society for the Promotion of Science (Grant-in-Aid for Encouragement of Young Scientists).

Received (in Cambridge, UK) 23rd July 2001, Accepted 23rd August 2001
First published as an Advance Article on the web 18th September 2001

Periodic mesoporous organosilicas (PMOs) with unusually large pores and high BET surface areas have been synthesized using triblock PEO–PPO–PEO copolymer P123 as the structure-directing agent and 1,2-bis(trimethoxysilyl)ethane (BTME) as the organically bridged silica source.

In 1999, a new way was found to incorporate organic moieties into M41S silica materials.[1–6] For the first time bridged silsesquioxane[7] precursors, *e.g.* 1,2-bis(trimethoxysilyl)ethane, were used as a silica source in the synthesis of highly ordered hybrid mesoporous materials in order to integrate bridging organic groups directly into the framework of the pore walls instead of grafting these organic species onto the pore wall surface. The obvious advantages of these periodic mesoporous organosilicas (PMOs)[8] over porous sol–gel derived or grafted hybrid materials are that they are highly ordered structures with very uniform pores, have homogeneous distributions of functional groups throughout the whole framework, have high loadings and the absence of any strong pore blocking effects that could be generated by the organic moieties.

Despite the fact that many applications require materials with larger mesopores this approach has so far almost exclusively been restricted to the synthesis of PMOs with rather small pore sizes (diameter < 4 nm).[9–10] A very limited amount of work on large pores has been published to date.[11] We have now extended this method to the application of nonionic poly(alkylene oxide) triblock copolymer surfactants which have already been widely used in the synthesis of large pore M41S pure silica materials.[12–14] By employing the commercially available triblock copolymer P123 ($HO(CH_2CH_2O)_{20}(CH_2(CH_3)CH_2O)_{70}(CH_2CH_2O)_{20}H$) as the surfactant together with BTME (1,2-bis(trimethoxylsilyl)ethane, $(CH_3O)_3Si–CH_2–CH_2–Si(OCH_3)_3$) as the organically bridged silica source we have obtained materials with pores as large as 6.5 nm.

In a typical synthesis 574.8 mg (0.0991 mmol) of P123 were dissolved in 17.31 g (0.961 mol) of water and 3.45 ml (34.5 mmol) of conc. HCl. This solution was stirred at 308 K for 20 min before 800 mg (2.95 mmol) of BTME were added. The overall composition resulted in molar ratios of 0.5 : 0.0168 : 5.85 : 163 for BTME : P123 : HCl : H_2O. Precipitation of a white solid occurred almost immediately. In order to complete hydrolysis of the methoxy groups and to evaporate the methanol evolved the stirring mixture was kept at 308 K for 1 day. To achieve a high degree of condensation the mixture was then transferred into a Teflon-lined autoclave and heated to 358 K for an additional 24 h. After thorough washing with water the precipitate was dried overnight in air to yield a fine white powder. Removal of polymers was accomplished either by extraction in ethanol at room temperature for 10 h or at more elevated temperatures by using a Soxhlet apparatus for 17 h, each with subsequent filtration of the product and drying in air.

† Electronic supplementary information (ESI) available: TG/DTA/MS data. See http://www.rsc.org/suppdata/cc/b1/b106636f/

The powder X-ray diffraction pattern of the as-synthesized product shows one strong reflection at $2\theta = 0.81°$ corresponding to a *d*-value of 10.8 nm (Fig. 1) which is similar to those of pure silica materials synthesized with the same structure-directing agent.[12–14] Both extracted samples reveal almost the same figures and therefore highlight a significant solvothermal stability since the structural order of the product remains unchanged. Even during calcination of the as-synthesized product in a thermogravimetric experiment up to 1073 K under flowing air the mesostructure remains intact to a very high extent whereas a natural shrinkage of the structure of approximately 2.4 nm occurs corresponding to the total loss of the bridging organic moieties from inside the pore walls.

FTIR spectroscopy corroborates the latter result (Fig. 2). While the as-synthesized and the extracted samples clearly show absorption bands assigned to Si–C stretching vibrations (*) at 695 and 768 cm^{-1}, and to C–H deformation vibrations (+) at 1272 and 1412 cm^{-1}, these cannot be observed in the spectra of the calcined sample. Furthermore, absorption bands which could be assigned to the triblock copolymer (#) at 1345, 1376, 1459, 2907 and 2976 cm^{-1} can only be seen in the spectra of the as-synthesized sample indicating that the surfactant is almost completely removed by extraction. In order to elucidate the exact amount of surfactant remaining in the mesostructure, much more sensitive thermoanalytical coupled TG/DTA/MS measurements were carried out.[15] During a continuous heating process, 5 K min^{-1}, all samples showed an endothermic drying step (323–448 K) which was followed by the oxidation of the block copolymer and the bridging organic groups (448–1073 K).

We detected a substantial mass loss of 39.2% in the course of the latter process for the as-synthesized sample whereas mass losses of only 11.8 and 8% were observed for the room temperature and the Soxhlet extracted samples, respectively, Soxhlet extraction being thus the superior method of extraction.

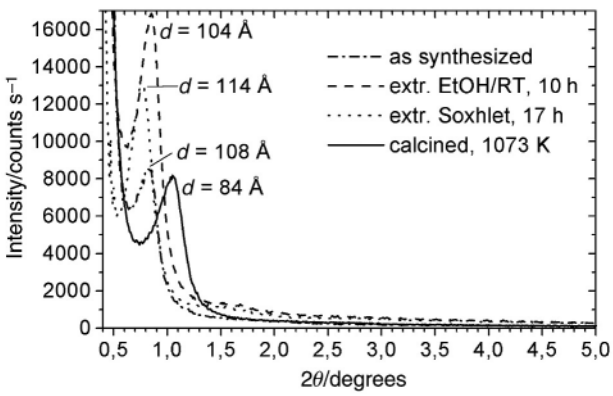

Fig. 1 Powder X-ray diffraction patterns‡ of products synthesized with 1,2-bis(trimethoxysilyl)ethane and triblock copolymer P123: as-synthesized, extracted RT/EtOH/10h, extracted Soxhlet/EtOH/17h, calcined (TG/DTA/MS, 1073 K).

 DOI: 10.1039/b106636f

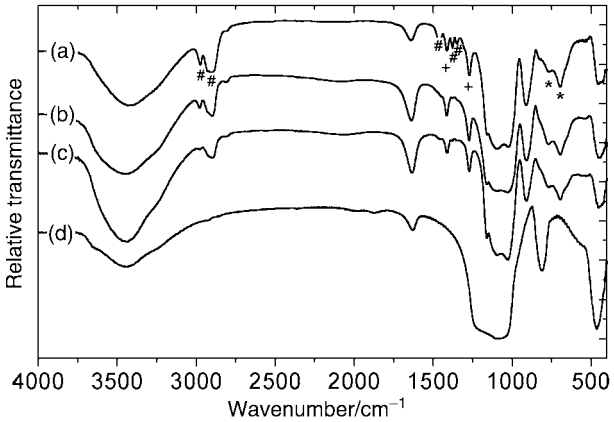

Fig. 2 FTIR spectra§ of products synthesized with 1,2-bis(trimethoxysilyl)-ethane and triblock copolymer P123: (a) as-synthesized, (b) extr. RT/EtOH/10h, (c) extr. Soxhlet/EtOH/17h, (d) calcined (TG/DTA/MS, 1073 K); (#) modes assigned to C–H stretching and deformation vibrations of P123, (+) modes assigned to C–H deformation vibrations of the framework organic groups, (*) modes assigned to Si–C stretching vibrations.

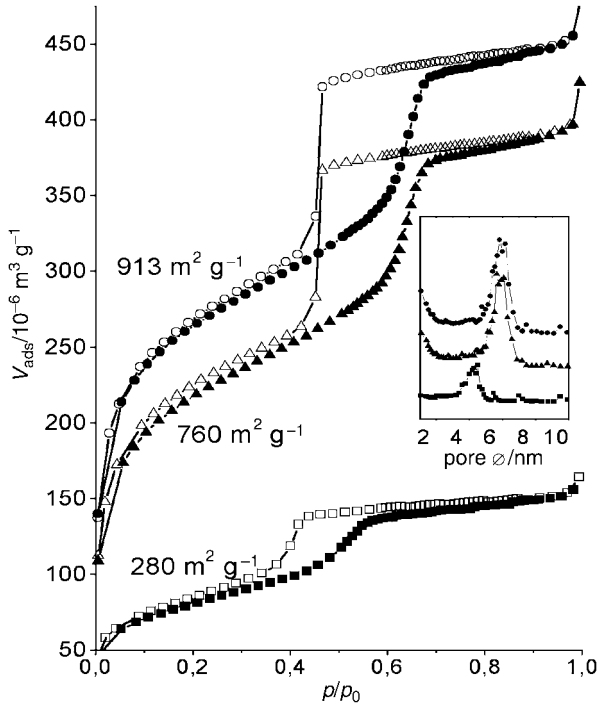

Fig. 3 N_2-physisorption isotherms¶ and BET surface areas of extracted and calcined products synthesized with 1,2-bis(trimethoxysilyl)ethane and triblock copolymer P123: (▲,△) RT/EtOH/10 h, (●,○) Soxhlet/EtOH/17 h, (■,□) calcined (TG/DTA/MS, 1073 K); the inset shows pore size distributions (BJH) calculated from the adsorption branch.

Unfortunately, prolonged extraction experiments always led to a strong reduction in structural order.

N_2-physisorption measurements at 77 K of the extracted samples show typical type IV isotherms of mesoporous materials with large pores where the capillary condensation step is shifted to high relative pressures $>0.6\ p/p_0$ (Fig. 3).

Also typical for these large pore solids is the observed large type I hysteresis. Since the course of the adsorption and desorption branches are not exactly parallel, flask-like pores or interparticle porosity must be considered to be existent in both samples. Again, Soxhlet extraction turns out to be the superior method of surfactant removal because the calculated BET surface area is *ca.* 150 m^2 g^{-1} higher for the Soxhlet extracted material (913 m^2 g^{-1}) than for the room temperature extracted sample (760 m^2 g^{-1}). Pore diameter distributions have been calculated from the adsorption branch using the Barrett–Joyner–Halenda method revealing average pore diameters of 6.5 nm for both extracted samples. A cell constant of 12.4 nm for the Soxhlet extracted sample, which could be derived from the first Bragg reflection of the powder diffraction pattern assuming a two-dimensional hexagonal pore structure, leads to a wall thickness of at least 5.9 nm. This high value is consistent in view of the applied nonionic structuring process which usually favours thick walls.

In conclusion, we have prepared the first PMO materials with pore diameters as large as 6.5 nm and BET surface areas greater than 900 m^2 g^{-1} using the nonionic poly(alkylene oxide) triblock copolymer surfactant P123 and 1,2-bis(trimethoxysilyl)ethane. In addition, we have shown that the structure-directing surfactant can be successfully removed to a very high extent by Soxhlet extraction using ethanol as solvent without loss of the mesostructure or the bridging ethane groups. In order to elucidate further the type of mesostructure, additional TEM, ^{13}C and ^{29}Si MAS-NMR investigations are currently in progress.

This work was supported by the Deutsche Forschungsgemeinschaft (DFG) and the Fonds der Chemischen Industrie (FCI). O. M. is grateful for receiving a postdoctoral scholarship from DFG within the European Graduate School 'Functional Materials'. Furthermore, the authors thank BASF for providing the block copolymer surfactants.

Nanoparticles as structural and functional units in surface-confined architectures

Andrew N. Shipway and Itamar Willner*

Institute of Chemistry, The Hebrew University of Jerusalem, Jerusalem 91904, Israel. E-mail: willnea@vms.huji.ac.il

Received (in Cambridge, UK) 12th June 2001, Accepted 22nd August 2001
First published as an Advance Article on the web 1st October 2001

The nanoscale engineering of functional chemical assemblies has attracted recent research effort to provide dense information storage, miniaturized sensors, efficient energy conversion, light-harvesting, and mechanical motion. Functional nanoparticles exhibiting unique photonic, electronic and catalytic properties provide invaluable building blocks for such nanoengineered architectures. Metal nanoparticle arrays crosslinked by molecular receptor units on electrodes act as selective sensing interfaces with controlled porosity and tunable sensitivity. Photosensitizer/electron-acceptor bridged arrays of Au-nanoparticles on conductive supports act as photoelectrochemically active electrodes. Semiconductor nanoparticle composites on surfaces act as efficient light collecting systems, and nanoengineered semiconductor 'core–shell' nanocrystal assemblies reveal enhanced photoelectrochemical performance due to effective charge separation. Layered metal and semiconductor nanoparticle arrays crosslinked by nucleic acids find applications in the optical, electronic and photoelectrochemical detection of DNA. Metal and semiconductor nanoparticles assembled on DNA templates may be used to generate complex electronic circuitry. Nanoparticles incorporated in hydrogel matrices yield new composite materials with novel magnetic, optical and electronic properties.

Introduction

Increasing interest is directed to miniaturization and the nanoscale engineering of functional chemical assemblies.[1] The development of nanoscale devices will provide dense information storage, ultra-small sensing units, and data processing elements of reduced dimensions. Another important aspect of miniaturization to the nanoscale is the breakdown of macroscopic properties and the emergence of quantum-level phenomena.[2] Metal and semiconductor nanoparticles exhibit unique properties and provide important building blocks for the construction of functional structures.[3] Nanoparticles can be synthesized from a variety of materials with controllable sizes, shapes and morphologies.[4] The electronic properties of nanoparticles, which may be tuned by the particle dimensions, give rise to unique absorbance and emission features.[5] The confined electrons in nanoparticles smaller than the wavelength of light give rise to plasmon excitons.[6] Nanoparticles also offer catalytic properties that differ from the bulk material properties, due to their high surface-area, high edge concentration and unusual electronic properties.[7] This has led to the application of modified nanoparticles in enantioselective catalysis[8] and electrocatalysis on surfaces.[9]

The surface modification of nanoparticles by functional monolayers or polymer 'shells', provides a means to generate composite materials with tunable surface properties (*e.g.* wettability, hydrophobicity, polymerizable units, photosensitive sites or molecular recognition properties).[10] In addition, the surface functionalization of nanoparticles allows their covalent attachment, self-assembly and organization on surfaces.[11] The engineering of nanoparticle surfaces has led to the construction of nanoparticle dimers and trimers,[12,13] controlled aggregates,[14,15] wires[16] ordered monolayers[17] and multilayers.[18] The integration of functional nanoparticles with surfaces has enabled the organization of nanoscale devices[19] including single-electron devices.[20] In this account we focus on the use of modified nanoparticles as structural or functional units in the assembly of composite structures on surfaces. We address the use of the nanoengineered architectures as high surface-area conductive matrices, as optical indicators, and as semiconductor composites for photoelectrochemical functions. We discuss the use of surface-confined architectures for sensoric and photoelectrochemical applications and focus on the tailoring of composite materials with novel electronic properties. We also introduce the conjugation of nucleic acids with nanoparticles for the development of DNA sensors and complex electronic circuits.

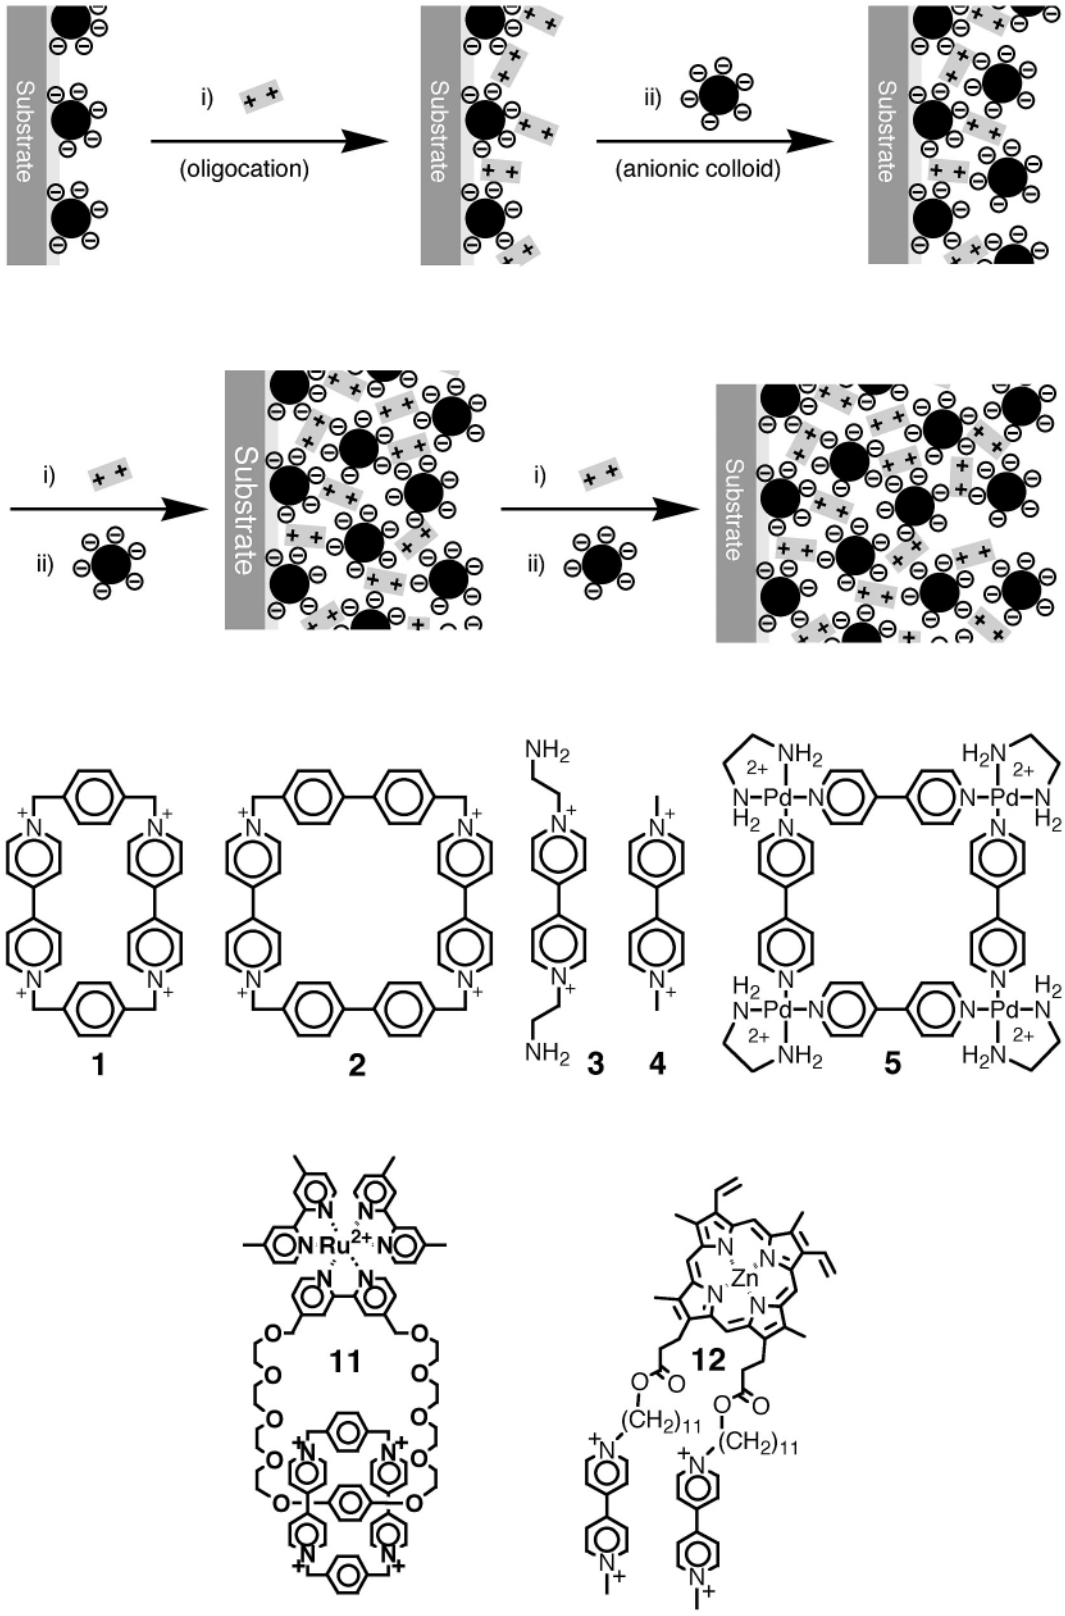
Nanoparticle multilayers in sensing applications

The use of metal nanoparticles as conductive elements in electrochemical sensing interfaces has been approached in several different ways. One direction involves the use of gold nanoparticles to contact biocatalysts either by the fabrication of nanoparticle–enzyme conjugates[21] or by the sequential immobilization of the nanoparticles and the biomaterial.[22] The small size of the nanoparticles not only gives a conductive matrix, but also enables them to approach the redox sites of some enzymes closely enough to provide electrical communication between the enzyme redox-center and the electrode, without the need for a diffusional electron mediator. The conductivity of metal nanoparticles also allows their use as gas sensors. Thin films of gold nanoparticles held apart by long chain thiols demonstrate a conductivity that is strongly dependant on gas vapors.[23] The vapors are absorbed by the nanoparticle–thiol matrix, modulating the conductivity of the film (as is also the case in carbon black–polymer composites[24]).

A series of sensors has been developed using Au-nanoparticle multilayers crosslinked by molecular host components. Scheme 1 outlines the general method for the construction of the multilayer Au-nanoparticle structures. First, a conductive glass support is functionalized with a thin film of 3-(aminopropyl)siloxane to yield a positively charged interface. The electrostatic binding of the negatively charged citrate-stabilized Au-nanoparticles (12 ± 1 nm diameter) yields the first layer of Au-nanoparticles.[25] Treatment of the negatively charged interface with the tetracationic cyclophanes cyclobis(paraquat-*p*-phenylene) **1**[26] or cyclobis(paraquat-*p*-biphenylene) **2**,[27] the bipyridinium salts **3** or **4**, or the octacationic Pd(II)-macrocycle **5**,[28] results in the electrostatic association of the molecular host

components. Further interaction of the assembly with the citrate-capped Au-nanoparticles yields the second layer of nanoparticles, and by the alternating treatment of the system with the oligocationic molecular crosslinker and the nanoparticles, an architecture of the desired thickness may be constructed. The crosslinking units need not necessarily be molecules. Analogous results have been obtained using charged polymers,[29] other nanoparticles[30] and even biomaterials.[31] Similarly, covalently linked multilayers can be constructed using gold-binding bisthiol molecules as crosslinkers.[32]

Fig. 1 shows the characterization of 1–5 layers of gold nanoparticles crosslinked by the tetracationic cyclophane cyclobis(paraquat-*p*-phenylene) **1**. The absorbance spectra [Fig. 1(A)] show the characteristic plasmon absorbance of the gold nanoparticles at *ca*. 520 nm,[33] and as more layers are added, an additional absorbance appears at longer wavelengths as a



Scheme 1 Method for the construction of oligocation-crosslinked Au-nanoparticle multilayers by electrostatic interactions. The first nanoparticle layer is formed by the interaction of a nanoparticle solution with an amine-functionalized surface.

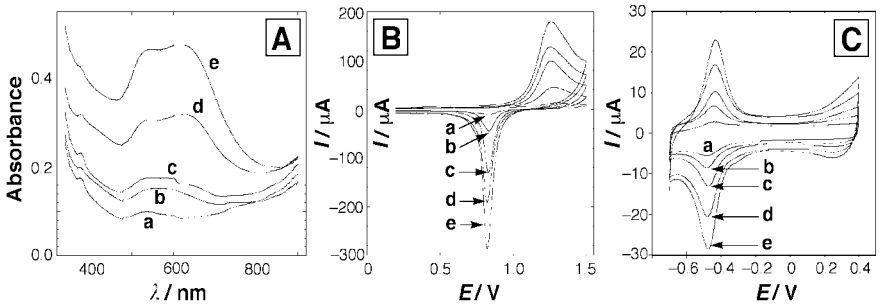


Fig. 1 (A) Absorbance spectra of a glass slide after (a–e) the deposition of 1–5 **1**-crosslinked Au-nanoparticle treatments. (B) Cyclic voltammograms of the Au-surface of **1**-crosslinked assemblies containing (a–e) 1–5 layers of Au-nanoparticles. (C) Cyclic voltammograms of **1** in (a–e) 1–5 layer arrays of **1**-crosslinked Au-nanoparticles.

consequence of interparticle plasmon coupling.[34] Electrochemical analysis of the gold surface [Fig. 1(B)] and the cyclophane crosslinking units [Fig. 1(C)] demonstrate the almost linear buildup of the structure on the conductive support. The fact that the nanoparticles and crosslinker continue to be electrochemically active throughout the crosslinked structure, demonstrates that the array is both porous and conductive. Coulometric assay of the electrical responses of the Au-nanoparticles and the bipyridinium units, indicates that the average surface coverage of the Au-nanoparticles per layer is *ca.* 1×10^{13} particles cm^{-2} and that *ca.* 100 units of **1** are associated with each Au-nanoparticle in the 3D structure.

The crosslinker **1** acts as a π-acceptor and is capable of forming π donor–acceptor complexes.[35] Thus, the association of electroactive π-donor substrates to the π-acceptor receptor sites, together with the 3D conductivity of the nanoparticle architecture, enables electrochemical sensing of the substrates. The cavity of **1** is suited to bind *p*-hydroquinone **6** and other hydroquinone derivatives such as dihydroxyphenylacetic acid **7**, dopamine **8** and adrenaline **9**. All of these substrates can be electrochemically sensed by the **1**-crosslinked Au-nanoparticle architectures assembled on the conductive glass supports.[36] The sensitivity of the functionalized electrodes is controlled by the number of nanoparticle layers in the structures.

Fig. 2(A) shows the electrochemical analysis of *p*-hydroquinone **6** by a 5-layer **1**-crosslinked Au-nanoparticle-functionalized electrode. The sensitivity limit for the sensing of **6** was estimated to be 1 μM. The substrate could not be electrochemically detected in this concentration range by a 5-layer Au-nanoparticle architecture crosslinked by the dicationic *N,N′*-dimethyl-4,4′-bipyridinium unit **3**. These results clearly indicate that the electrochemical sensing of **6** does not originate from the increase in the surface roughness of the electrode, but rather from the concentration of **6** in the receptor sites by supramolecular interactions. Fig. 2(B) exemplifies the electrochemical detection of adrenaline **9** by the **1**-crosslinked Au-nanoparticle array. The electrochemical oxidation of **9** associated with the receptor-sites reveals a broad irreversible wave that leads to a cyclic product that exhibits a reversible-redox response (wave x). The latter wave may act as an indicator for the concentration of adrenaline in the system [Fig. 2(B) inset].

The specificity of sensing by the Au-nanoparticle array is controlled by changing the structure of the crosslinking receptor units.[37] A three-dimensional array of Au-nanoparticles was constructed using the enlarged cyclophane, cyclobis(paraquat-*p*-biphenylene) **2**, Scheme 1. This larger receptor accommodates bishydroxymethylferrocene **10** as a guest. Fig. 3(A) shows the analysis of **10** (1×10^{-6} M) by the **2**-crosslinked Au-nanoparticle electrodes with different numbers of crosslinked Au-nanoparticle layers. As the number of layers increases, the electrical response of **10** is enhanced, demonstrating tunable sensitivity of the nanostructured layered electrode. Fig. 3(B) shows the amperometric responses of the Au-nanoparticle array upon the sensing of different concentrations of **10**. The resulting receptor-crosslinked arrays also reveal selectivity. While **10** is electrochemically sensed by a **2**-crosslinked Au-nanoparticle structure, the receptor **2** is too large to accommodate *p*-hydroquinone **6** in its cavity. Similarly, the **1**-crosslinked Au-nanoparticle assembly is unable to accommodate **10**, but does associate with *p*-hydroquinone, which is electrochemically sensed [Fig. 3(C)]. Selectivity is also observed upon the sensing of *p*-hydroquinone **6** by the Pd(II)-square, **5**-crosslinked Au-nanoparticle structure that is unable to detect the isomer *o*-hydroquinone. The selective sensing of **6** by the oligocationic

(B) The sensing of **10** (a–f = 0.1, 0.2, 0.4, 0.8, 1.5 and 3.0 μM, respectively) by a 5-layer **2**-crosslinked Au-nanoparticle array. (C) Cyclic voltammograms of 5-layer electrodes constructed using cyclophanes **1** (curve a) and **2** (curve b) as crosslinkers in the presence of **10** (1 μM).

macrocycle was attributed to the diagonal association of **6** to the Pd(II)-receptor, that is not possible for the *ortho* isomer.[38]

Receptor-modified Au-nanoparticles were also assembled on the gate interface of an ion-sensitive field-effect-transistor (ISFET).[39] A **1**-functionalized Au-nanoparticle ISFET device was found to effectively detect adrenaline, serotonin and dopamine. Since the ISFET gate-potential is controlled by the charge associated with the interface, the detection of receptor-bound substrates is not limited to electroactive species.

Nanoparticle multilayers in photoelectrochemical applications

The high surface-area, porous and conductive properties of Au-nanoparticle arrays can be exploited for the construction of photoelectrochemically active superstructures. Fig. 4(A) and (B) show absorbance spectra and cyclic voltammograms of a

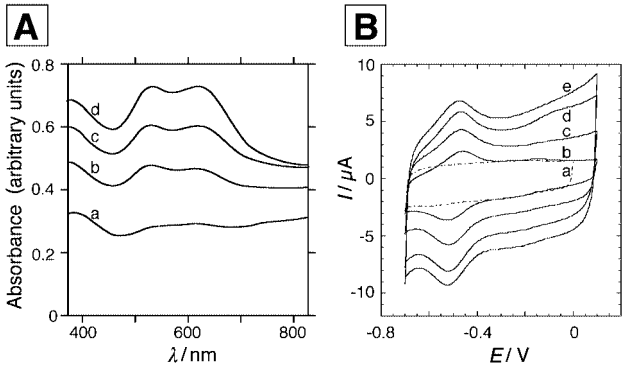

Fig. 4 (A) Absorbance spectra of (a–d) 1–4 layer Au-nanoparticle superstructures crosslinked by the catenane **11**. (B) Cyclic voltammograms of (a) a single nanoparticle layer, and (b–e) 1, 3, 4 and 5-layer **11**-crosslinked Au-nanoparticle arrays.

gold nanoparticle multilayer architecture 'crosslinked' by the hexacationic catenane **11**.[40] This catenane consists of non-covalently bound ruthenium tris(bipyridine) (photosensitizer) and bipyridinium (electron acceptor) groups.[41] The absorbance spectra show similar features to those of other molecule-crosslinked gold nanoparticle arrays, as well as an additional absorbance at 425 nm that is attributed to the ruthenium tris(bipyridinium) chromophore. Coulometric assay of the cyclic voltammograms corresponding to the bipyridinium crosslinking units reveals an almost linear increase in the surface coverage of the crosslinking units upon the build-up of the layers. The derived surface coverage of **11** per layer is 3.6×10^{-12} mol cm^{-2} and it has been estimated that on average *ca.* 45 units of the photosensitizer/acceptor crosslinker are associated with each Au-nanoparticle. Irradiation of the **11**-crosslinked Au-nanoparticle multilayer array results in the photocurrent action spectra shown in Fig. 5(A), which follows the absorbance features of the Ru(II)–tris(bipyridinium) chromophore. The photocurrent increases upon the build-up of the array and is reversibly cycled between 'ON' and 'OFF' states upon switching the light on and off, respectively. Fig. 5(B) shows the dependence of the photocurrent intensity on an applied potential. The photocurrent decreases as the potential is negatively shifted and it is blocked at a potential where the bipyridinium units are reduced to the radical cation. This observation led to the conclusion that the photocurrent originates from the primary electron transfer quenching of the excited Ru(II)–tris(bipyridine) chromophore by the bipyridinium electron acceptor. The reduced acceptor acts as an electron mediator for charge injection into the electrode, Fig. 5(C). Upon the electrochemical reduction of the bipyridinium units, intramolecular electron transfer quenching is inhibited and photocurrent generation is blocked. The nanoengineered electrode operated at a quantum efficiency of 1×10^{-4} in the generation of the photocurrent. A related nanoparticle engineered electrode for photocurrent generation using Zn(II)-protoporphyrin IX–bis(bipyridinium) photosensitizer–electron acceptor (**12**) as a crosslinker has also been developed.[42]

Photoelectrochemical electrodes based on semiconductor nanoparticles offer many advantages in the organization of

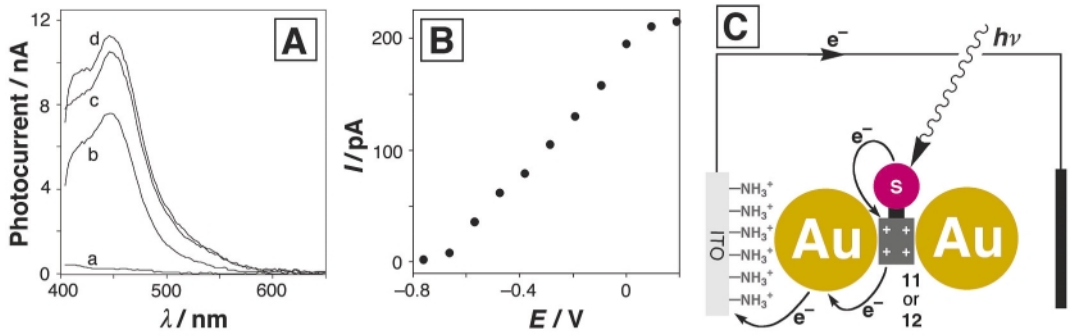

Fig. 5 (A) Photocurrent action spectra (a–d) obtained from 0-, 1-, 3- and 4-layer **11**-crosslinked Au-nanoparticle arrays. (B) Dependance of the photocurrent on the electrode potential. energy conversion and storage cells. The ability to process, engineer and chemically functionalize semiconductor nanoparticles, enables the control of the properties and functions of the resulting photoelectrochemical cells. The use of nanoparticle-functionalized electrodes for photoelectrochemical applications has been reviewed in depth,[43] and the development and commercialization of solar cells based on photosensitizer/TiO_2 nanoparticle structures[44] represent recent advances in the field. Also, a large number of diverse nanoparticle-based electroluminescent devices have been investigated.[45] The tuning of the band-gap energies and redox properties of the energy levels by controlling the nanoparticle dimensions allows the tailoring of multicomponent systems that reveal new functionalities as a result of interparticle electronic coupling, and interparticle electron or energy transfer.[46] One example of such a system would be a nanoparticle-based 'luminescent collector'.[47] This is a device consisting of a thin sheet of material doped with dyes that absorb ambient light and re-emit it within the material where it is trapped by internal reflection. In order to collect a high proportion of the incident radiation, several chromophores with complementary absorption bands are required. Previous designs have led to problems of finding sets of organic dyes with this complementarity as well as the necessary processing and stability properties,[48] but nanoparticles may offer a feasible alternative.

Interparticle energy transfer between nanoparticles of the same substance but of different sizes exemplifies how multiparticle systems might find applications. It has been shown that both for indium phosphide[49] and cadmium selenide[50] nanoparticles, energy transfer from smaller to larger particles takes place within composite films. Fig. 6 shows absorbance and emission spectra of a 4 : 1 mixture of 2.8 and 3.7 nm-diameter CdSe nanoparticles that were prepared in highly monodisperse samples by selective precipitation. In a dilute solution (curve a), the emissions of both nanoparticles are seen, but in a close-packed film (curve b), energy transfer takes place and emission only from the larger particles is observed.

Extensive recent research effort has been directed towards the assembly of composite nanocrystalline semiconductor films to enhance the activity of photoelectrochemical cells. The coupling of a large bandgap semiconductor with a smaller bandgap semiconductor not only extends the photoresponse of the system to longer wavelengths but also facilitates charge separation. The photogenerated electrons and holes are trapped

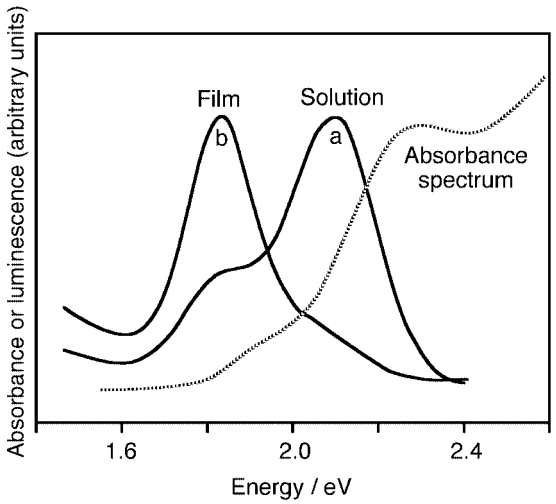

Fig. 6 Absorbance (----) and emission spectra of a 4 : 1 mixture of 2.8 nm and 3.7 nm InP 'quantum dots' (a) in solution, and (b) in a close-packed film.

into different particles, and the interparticle interface acts as a barrier for the recombination of the intermediate redox species. Fig. 7(A) shows the energetics of a SnO_2/CdSe nanocrystalline film assembled on an OTE electrode.[51] This photoelectrochemical electrode was found to operate at an efficiency of 2.25% ($I_{sc} \approx 30$ μA cm^{-2}; V_{oc} = 0.5–0.6 V; ff = 0.47), higher than for nanocrystalline CdS alone. The enhanced photoelectrochemical activity of the composite film is attributed to the charge rectification resulting from interparticle electron transfer. The role of coupled systems in enhancing charge separation has been demonstrated in other systems such as ZnO/CdS[52] and TiO_2/CdS.[53] Photosensitization of nanocrystalline composites results in charge rectification and facilitates the collection of the injected electrons by the electrode. Fig. 7(B) shows a 'core–shell' nanocomposite of TiO_2 coated with Nb_2O_5. Photoejection of electrons from an excited dye [*cis*-di(isothiocyanato)-*N*-bis(4,4′-dicarboxy-2,2-bipyridine)ruthenium(II)] to the Nb_2O_5 conduction-band followed by electron transfer to the TiO_2 conduction band results in the rectification effect. The recombination of the 'core' conduction-band electrons with the oxidized dye are retarded by means of the Nb_2O_5 'shell'.[54] This charge separation improves the photo-

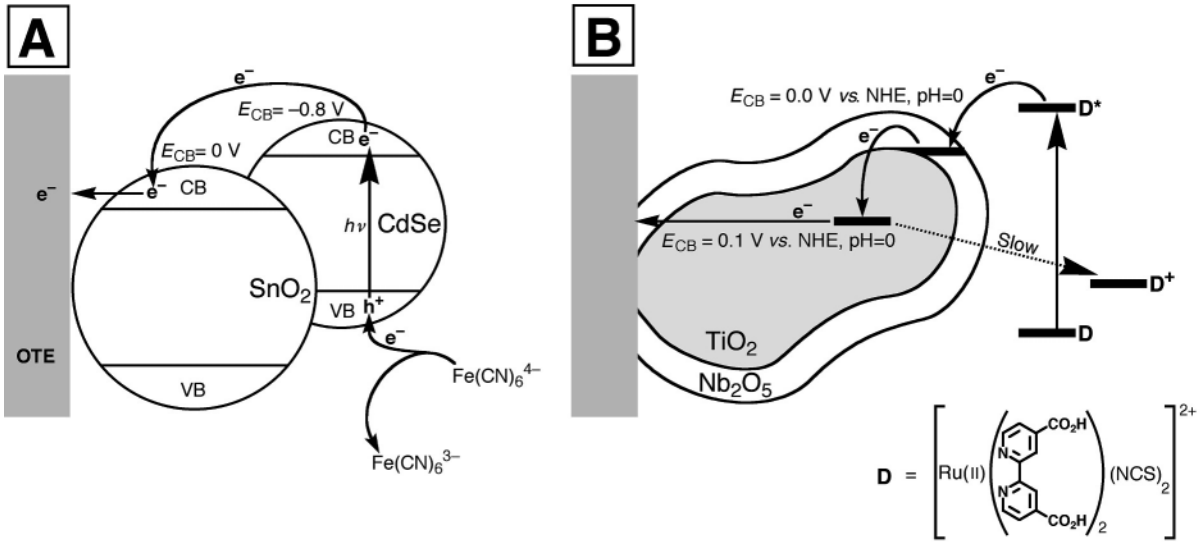

Fig. 7 (A) Suppression of charge recombination in a coupled SnO_2/CdSe system. (B) Charge separation upon photosensitization of a TiO_2/Nb_2O_5 core–shell semiconductor nanocomposite electrode.

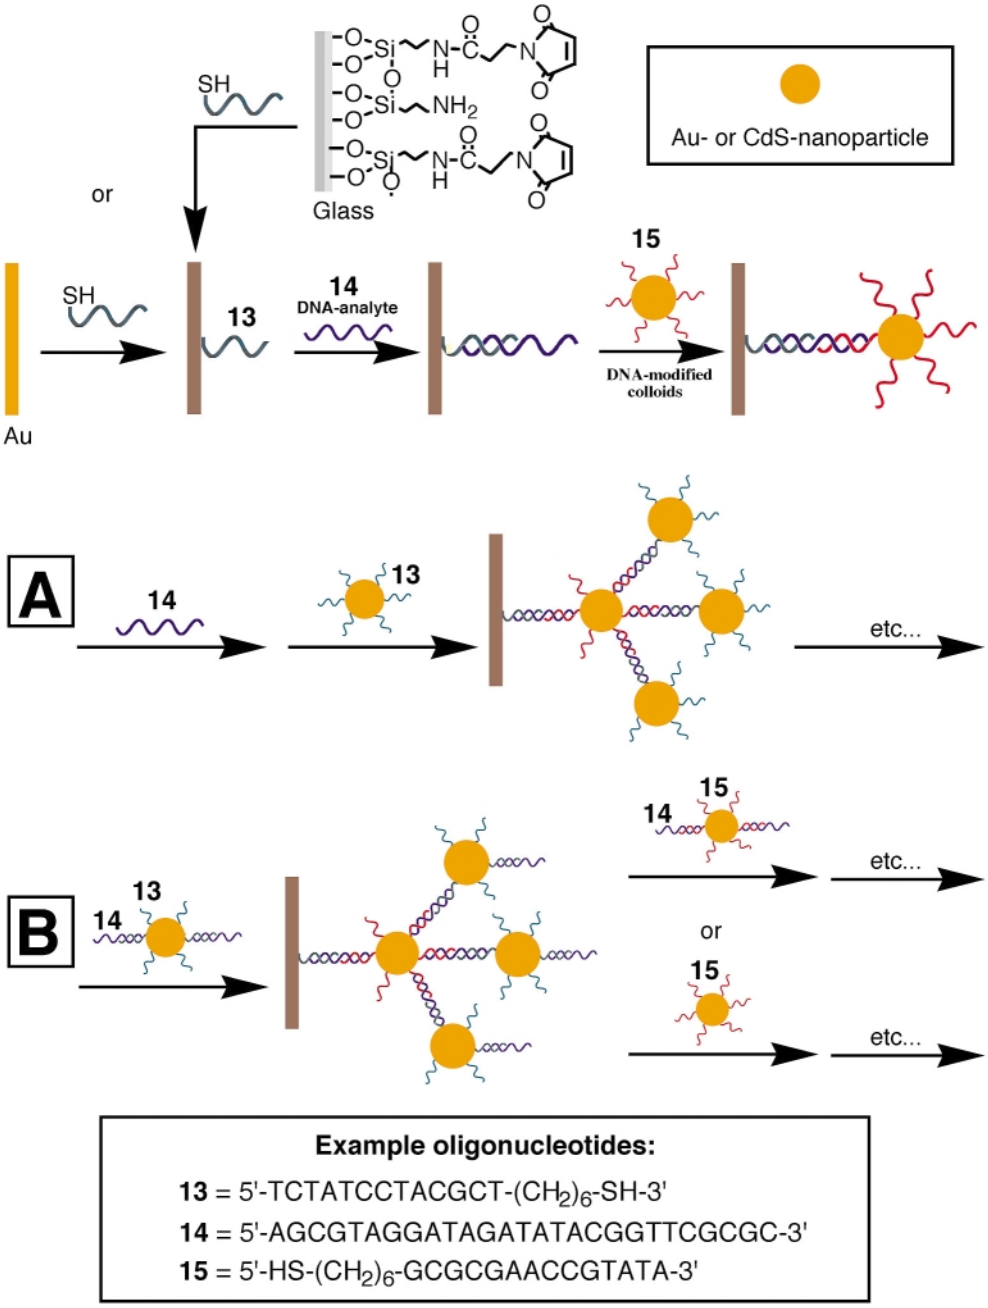
electrochemical performance of the cell as compared to the TiO_2/dye system (maximum power of the TiO_2/Nb_2O_5/dye cell is 4.70 mW cm^{-2} as compared to 3.45 mW cm^{-2} for the TiO_2/dye cell). Similar results have been observed for other photosensitized nanocrystalline systems.[55]

DNA-linked nanoparticle superstructures

The study of DNA–nanoparticle conjugates has received special attention in the past few years. DNA is of particular interest since it may be made into complex, highly designed structures.[56] The use of DNA–nucleic acid-complementary binding, along with enzymes that act specifically on DNA (*e.g.* polymerase, ligase, endonuclease for polymerization, lengthening and scission, respectively) make it a useful structural tool. The dimensions and properties of DNA are well known and may be exploited, for instance for the fabrication of conductive wires.[57] In solution, interactions between DNA-functionalized-nanoparticles and DNA-crosslinked nucleic-acid-functionalized nanoparticles have been used for the detection of DNA,[58] and more recently they have allowed the construction of nanoparticle architectures on surfaces.[59] Scheme 2 shows a general method to fabricate a crosslinked multilayer of nanoparticle–DNA composites. First, an appropriate surface (gold or functionalized glass) is reacted with a thiolated oligonucleotide (**13**). This immobilized DNA can hybridize with part of an analyte nucleic acid (**14**) that is complementary with it. The remaining part of the analyte oligonucleotide can then be used to immobilize a nanoparticle that bears an oligonucleotide complementary to it (**15**). The growth may be continued either by reacting with the analyte then a nanoparticle functionalized by **13** [Scheme 2(A)], or by reacting with both at the same time [Scheme 2(B)]. This second layer contains many more nanoparticles since the first immobilized nanoparticles constitute 'branching points'. This 'amplification' allows the microgravimetric sensing of the analyte–DNA at concentrations of 1×10^{-10} M using a quartz-crystal-microbalance as transducer.[59a] If the analyte DNA has a sequence that is not properly complementary to both the surface and the nano-



Scheme 2 Method for the construction of DNA-crosslinked metal or semiconductor nanoparticle arrays for the sensing of a DNA analyte, on gold or glass substrates. (A) Continued stepwise growth. (B) Growth with pre-hybridized nanoparticles and analyte.

particle, then the structure is not built up, and no response is measured. Fig. 8 shows results from a similar experiment, where several nanoparticle layers were constructed, and the concentration of the nucleic-acid functionalized nanoparticles and analyte DNA are sufficiently high to generate saturated Au-nanoparticle layers.[59b] Fig. 8(A) shows the absorbance spectra recorded for 1–5 nanoparticle layers. It is seen that non-linear growth only occurs for the first two layers, after which the surface is saturated with nanoparticles and a full layer is added at each step. It is also noteworthy that no additional absorbance above 600 nm appears, which indicates that the nanoparticles are not close enough to develop interparticle coupled plasmons. Finally, as the film becomes thicker, the melt transition for the DNA complex becomes sharper [Fig. 8(B)]. This observation is indicative of the cooperative effect of the nanoparticle network holding the entire assembly together.

Another way to transduce the build-up of these nanoparticle–DNA arrays is to employ functional nanoparticles. The use of cadmium sulfide nanoparticles (CdS) (instead of gold) yields a superstructure with novel fluorescence and photoelectrochemical properties.[60] Absorbance and fluorescence spectra of such a system are shown in Fig. 9(A). Irradiation of the array in the presence of a sacrificial electron donor results in a photocurrent that can also be used as a sensing signal [Fig. 9(B)]. The photocurrent is enhanced as the number of aggregated layers increases. It is also clear that the photocurrent increases non-linearly since the non-particle architecture exhibits a dendritic structure upon aggregation of the layers. Only CdS particles that are in intimate contact with the electrode support are active in the generation of the photocurrent. This was proved by the association of $Ru(NH_3)_6^{3+}$, acting as an electron acceptor, on the DNA strands. The $Ru(NH_3)_6^{3+}$ units trap the conduction-band electrons and mediate their transfer to the electrode, thus enhancing the generated photocurrent.

Hydrogel-entrapped nanoparticle systems

Polymers are extensively used as matrices for processing nanoparticles, and the advances in the assembly of polymer–nanoparticle composites have recently been reviewed.[61] As this review emphasizes the properties and functions of organized nanoparticle architectures, we will specifically discuss the functional features of nanoparticle–hydrogel composites. Hydrogels are highly swollen crosslinked polymers that are generally based on poly(acrylamide) and poly(acrylic acid). Due to the delicate balance of hydrogen bonds that stabilizes the gel's structure, the degree of swelling is highly dependent on factors such as solvent, solutes, pH, temperature and electric fields.[62]

'Ferrogels' are a class of materials that consist of magnetic nanoparticles (or 'ferrofluids') immobilized in hydrogel matrices. Poly(vinyl alcohol)[63] and poly(acrylamide)[64] hydrogels containing 10–12 nm magnetite (Fe_3O_4)[63] or maghemite (γ-Fe_2O_3)[64] particles have been investigated. These magnetic nanoparticles do not aggregate in solution as their mutual attraction is compensated for by repulsion due to surface charges and by loss of alignment of magnetic moments because of Brownian motion. The ferrogels can thus be prepared by a solution-state polymerization in the presence of the particles. Upon exposure to non-uniform magnetic fields, ferrogels deform almost instantaneously, and they return reversibly to their original state when the field is removed. Fig. 10 shows a typical experimental setup. The ferrogel is tethered to a stress-sensitive device from above, and a solenoid is placed below it.

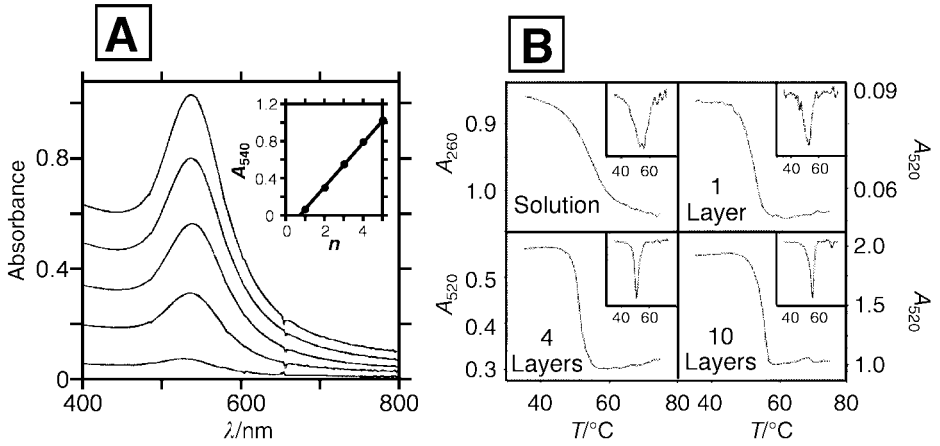


Fig. 8 (A) UV–VIS absorbance spectra of 1–5 Au-nanoparticle layers constructed on glass and linked by DNA (by method A, Scheme 2). Insert: growth of absorbance at 540 nm (A_{540}) with the number of layers (n). (B) Melt transitions of a DNA complex in solution, and the same complex as a nanoparticle linker in architectures of 1, 4 and 10 layers; monitored by absorbance at 260 nm (in solution) or at 520 nm (on surfaces). Insets: first derivatives of the melt curves.

Upon applying a current to the solenoid, the downward force and the elongation of the material can be measured. Fig. 10(B) shows typical curves for the dependence of the elongation of *ca.* 120 mm long gels. Upon applying current to the solenoid, up to a 10% deformation can be achieved. Other magnetic field geometries produce different deformation effects.

Since the swelling and shrinking behavior of hydrogels is extremely sensitive to many environmental factors, it may conceivably be used as a sensing event if a suitable transduction method can be found. Nanoparticles have been shown to provide methodologies for transducing these changes. By one method, crystalline colloid arrays (CCAs) of polystyrene particles (*ca.* 100 nm diameter) inside hydrogel matrices were constructed.[65] The assembly acts as a diffraction grating with a periodicity dependent on the interparticle spacing. It was found that the swelling and shrinking of the gel, brought about by exposure to different solutes or temperatures (depending on the nature of the gel used), causes the entire assembly to deform, thus increasing or decreasing the unit cell size of the crystallized colloid array. This change is easily detected and quantified by examination of the diffraction properties of the assembly. Fig. 11 shows absorbance spectra of a CCA immobilized in a crown ether-containing hydrogel, (**16**). Exposure of the system to Pb^{2+} causes the swelling of the gel as the metal ions are bound to the crown ether. The diffraction properties of the structure follow Bragg's law, and a 0.5% volume change causes a *ca.* 1 nm movement of the diffraction wavelength.

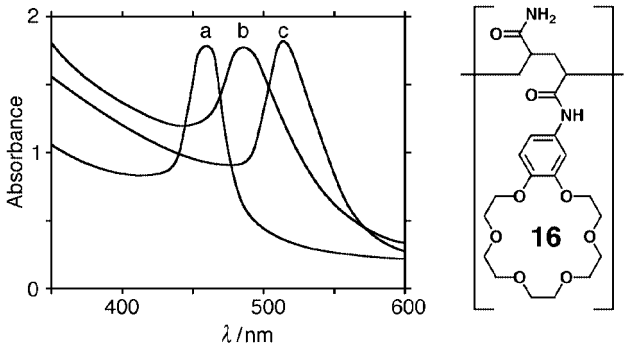

Fig. 11 Absorbance spectra of a polystyrene CCA embedded (7 wt%) in the polymer **16** (*ca.* 1 crown ether unit per 20 monomer units) in the presence of Pb^{2+} at concentrations of (a) 0, (b) 0.4 and (c) 4 ppm. Pb^{2+} can be sensed with a sensitivity limit of *ca.* 20 ppb.

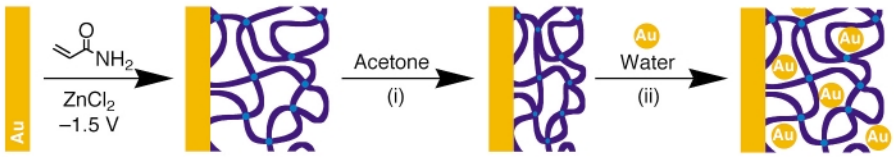
Poly(acrylamide) hydrogels adopt swollen structures in water, but undergo phase transitions to collapsed states upon exposure to less polar solvents such as acetone. Taking advantage of this phenomenon, hydrogels containing a controllable concentration of gold nanoparticles have been synthesized by the route described in Scheme 3.[66] In this procedure, the nanoparticle-free gel is first synthesized on a conductive support by electropolymerization. The nanoparticles are then introduced into the structure by a 'breathing' method. First, the gel is shrunken by immersing it in acetone. This step removes most of the solvent from the gel. The shrunken gel is then immersed in an aqueous nanoparticle solution. The water causes the gel to swell and take the solution into its structure. As it does so, nanoparticles are introduced, where they become stuck by entanglement and the hydrogen bonding network (the gold nanoparticles bear a citrate surface, so have a high hydrogen bonding potential). This 'breathing' mechanism may be repeated several times to gradually increase the nanoparticle content of the gel, and as more nanoparticles are included, the properties of the gel are modified. The electronic properties of the hydrogel are altered upon the incorporation of the Au-nanoparticles. Fig. 12(A) shows Faradaic impedance spectra (in the form of Nyquist plots) of the hydrogel after three 'breathing' cycles. The diameters of the semicircular regions in the plots are indicative of the interfacial electron transfer resistances between the electrode and a solution-solubilized redox probe.[67] As the amount of Au-nanoparticles increases in the hydrogel, the interfacial electron transfer resistance decreases, implying enhanced conductivity of the hydrogel matrix. The electronic properties of the Au-nanoparticle–hydrogel composite are strongly affected upon phase-transition of the polymer matrix. Fig. 12(B) shows chronopotentiometric transients of the polymer matrix in the swollen [curve (a)] and shrunken [curve (b)] states. For comparison, the chronopotentiometric transients of the Au–polymer composite in the swollen [curve (c)] and shrunken [curve (d)] configurations are given. These chronopotentiometric transients indicate the overpotentials required



Scheme 3 Method for the assembly of Au-nanoparticle-containing electropolymerized hydrogels by the 'breathing' technique. First the hydrogel is electropolymerized, then the nanoparticles are introduced by (i) shrinking the gel in acetone and (ii) re-swelling the gel in a nanoparticle-containing solution. Steps (i) and (ii) may be repeated to increase the nanoparticle concentration in the gel.

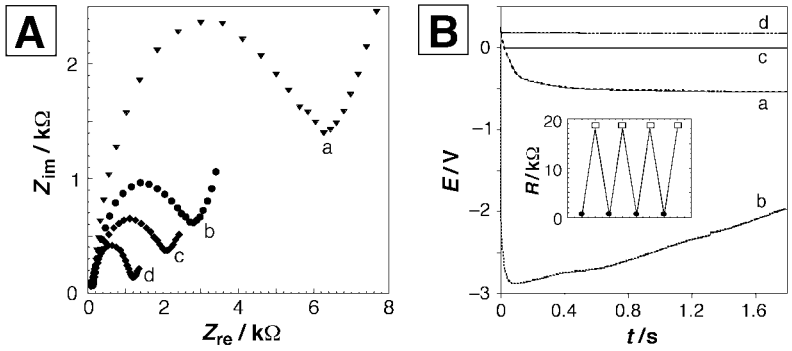


Fig. 12 (A) Faradaic impedance spectra showing the build-up of Au nanoparticles inside a polyacrylamide electrode and the decrease of the interfacial electron transfer resistance: (a) The swollen polyacrylamide gel prior to the introduction of Au-nanoparticles. (b)–(d) The swollen polyacrylamide gel after one, two and three 'breathing' cycles that introduce Au-nanoparticles into the polymer. (B) Chronopotentiometry transients of: (a) the swollen polyacrylamide electrode; (b) the shrunken polyacrylamide gel-electrode; (c) the swollen Au-nanoparticle-containing polyacrylamide electrode; (d) the shrunken Au-nanoparticle-containing polyacrylamide electrode. Inset: reversible switching of the nanoparticle-containing polyacrylamide electrode between swollen (□) and shrunken (●) states.

to retain a constant current in the cell in the presence of a redox label [$Fe(CN)_6^{3-/4-}$], and thus allows the extraction of the values of electrode resistance in the different configurations. The shrunken nanoparticle-free electrode reveals a substantially higher resistance than the swollen configuration (> 300 *vs.* 70 kΩ). On the other hand the shrunken nanoparticle-containing electrode reveals a substantially lower resistance than its swollen state (0.4 *vs.* 20 kΩ, respectively). The low resistance of the shrunken Au-nanoparticle polymer composite is attributed to electrical contact in the nanoparticle network which offers a route for electronic communication between the electrode and the electrolyte solution.

Conclusions and perspectives

The article has addressed means to tailor functional metal and semiconductor nanoparticle arrays for sensoric and electronic uses. The unique conductivity, catalytic, photonic, optical, electronic and photoelectronic properties of metallic and semiconductor nanoparticle systems, originating from the collective interactions in the crosslinked architectures, introduce new perspectives in nanotechnology. The nanostructuring of the assemblies provide high surface-area systems of controllable electronic and optical properties. Crosslinking of nanoparticles with molecular receptors yields conductive arrays with specific recognition features and controllable porosity, and the integration of nanoparticles with polymeric hydrogels paves the way to design signal-triggered materials with novel electronic properties. The conjugation of nanoparticles with nucleic acids establishes a fascinating research area that enables the amplified optical electronic and photoelectrochemical detection of DNA as well as the nanoengineering of predesigned and programmed DNA/nanoparticle circuitry. The application of these methodologies for gene analyses on DNA arrays, and the organization of wired nanoparticle assemblies that include resistance, capacitance and conductivity elements seem to be reachable goals.

We have already discussed some basic nanoparticle-based devices that have found commercial interest such as gas sensors, electrochemical sensors, photovoltaic cells, and luminescence collectors. More advanced applications that use layered nanoparticle composites may need more time to develop, yet they are certainly emerging. For example, nanoparticles may have a large impact in the area of reflective, bistable electronic displays.[68] These displays, known as 'electronic paper', promise to resemble paper in their ease of viewing and portability, without requiring a continuous input of energy to maintain a picture. These technologies are based on variously colored nanoparticles that are aligned inside microcapsules by external electrical fields. Other promising applications of nanoparticles may include displays and memory devices based on electroluminescence matrices[69] or integrated molecule/nanoparticle systems as computing devices.

One important future challenge will involve the organization of addressable nanoparticle architectures of variable composition and functions. Primary efforts in patterning of nanoparticle structures on surfaces have been reported.[70] The rapid advances in developing scanning microscopy 'writing' techniques[71] suggest that the use of 'nanoparticle inks' for nanometer-sized writing is a feasible goal. The progress in the photonic activation of nanometer-sized domains using near-field scanning optical microscopy (NSOM), indicates that the photonic addressability and imaging of nanostructures are viable concepts.

Received (in Cambridge, UK) 27th June 2001, Accepted 22nd August 2001
First published as an Advance Article on the web 17th September 2001

The presence of a phthalate in dry polymer membranes consisting of polyvinylpyrrolidone (PVP) and $AgBF_4$, $AgBF_4$–PVP, provides long-term stability and better performance for the separation of propylene/propane gas mixtures.

Olefin/paraffin separation by facilitated transport polymer membranes consisting of silver salts and polymers has attracted much interest because of its advantages of low energy consumption, compact apparatus and simple operation.[1,2] However, polymer membranes containing silver salts exhibit some disadvantages that prevent the commercialization of this separation process.[3] One major drawback observed in the membranes is the gradual decrease in membrane performance with time, possibly due to the reduction of silver ions to silver particles.

To our knowledge, however, no report has been published on the long-term stability of polymer membranes containing silver salts. It is well known that the ionic mobility and conductivity of lithium ions in PEO-based lithium polymer electrolytes can be significantly increased by the incorporation of a plasticizer such as dibutyl or dioctyl phthalate.[4] The dissociation of lithium salts into ions seems to be more facilitated by the strong interaction between the ester groups of phthalates and lithium ions. Furthermore, each dissociated lithium ion can be further stabilized by forming a chelating bond to two adjacent ester groups. In this context, we have employed phthalates as stabilizers for silver ions in dry polymer membranes containing silver salts for olefin/paraffin separation.

We report here that plasticizers such as dialkyl and diaryl phthalates are highly effective for stabilizing silver ions, thereby improving the performance of a dry polymer membrane consisting of $AgBF_4$ and polyvinylpyrrolidone (PVP), $AgBF_4$–PVP. Of the several polymer membranes containing silver salts, $AgBF_4$–PVP membranes are chosen for our study because PVP is often used for reducing silver salts to silver nanoparticles.[5,6]

$AgBF_4$–PVP membranes were prepared by dissolving $AgBF_4$ in methanol solution containing 20 wt% of PVP or 20 wt% of PVP and a phthalate. The molar ratio of $AgBF_4$:PVP and the weight ratio of phthalate:PVP were fixed at 1 and 0.02, respectively. The resulting solution was coated onto a polysulfone microporous membrane support (SEAHAN Industries Inc., Seoul, Korea) using an RK Control Coater. The solvent was evaporated in a light-protected convection oven at 25 °C under a stream of nitrogen, and then the membrane was dried completely in a vacuum oven for 24 h at room temperature. The thickness of the top polymer electrolyte layer was *ca.* 1 μm. Permeation tests were performed in a stainless steel separation module as described elsewhere.[7] The flow rates of the mixed gas and sweep gas (helium) were controlled using mass flow controllers and the gas flow rates represented by permeance were determined using a soap-bubble flowmeter. The mixed gas (50:50 vol% of a propylene/propane mixture) separation properties of the membranes were evaluated using gas chromatography (Gow-Mac) equipped with a TCD and a unibead 2S 60/80 packed column. The separation of propylene/propane mixtures was conducted to evaluate the effect of plasticizers on the performance of the $AgBF_4$–PVP membranes. As shown in Figs. 1 and 2, the selectivity of propylene over propane and permeance for the $AgBF_4$–PVP membrane without a phthalate decreases with time.

On the other hand, the incorporation of a plasticizer, such as dibutyl phthalate (DBP), dioctyl phthalate (DOP) and diphenyl phthalate (DPP), significantly improves the performance of the $AgBF_4$–PVP membranes. The selectivity and permeance for the membranes containing phthalates remain nearly constant throughout the experiments for up to 100 h. Furthermore, the

 DOI: 10.1039/b105656p

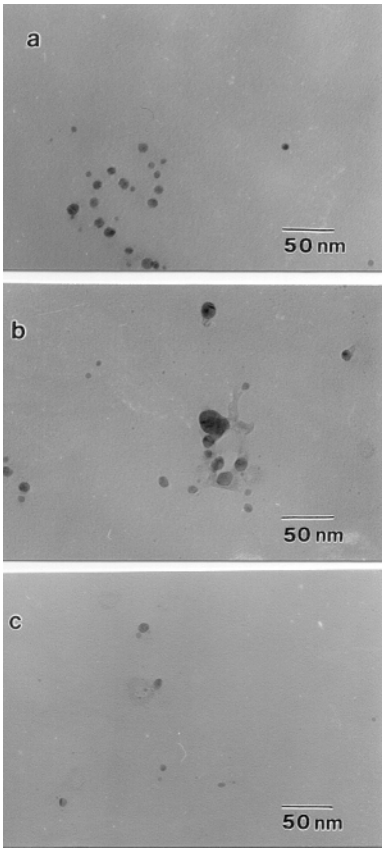

Fig. 3 Electron micrographs of $AgBF_4$–PVP membranes with or without a plasticizer: (a) $AgBF_4$–PVP membrane just after preparation, (b) $AgBF_4$–PVP membrane after one week of preparation, (c) $AgBF_4$–PVP membrane containing 2 wt% dioctyl phthalate after one week of preparation.

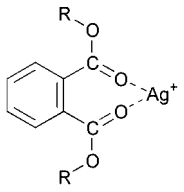
selectivity and permeance measured at 100 h are much higher for the membranes containing phthalates in comparison with those of the membranes without phthalates. From these results, it is likely that phthalates in $AgBF_4$–PVP membranes are playing an important role in preventing the reduction of silver ions as well as in increasing the mobility of the silver ions, thereby facilitating the propylene transport.

The effect of plasticizers on the reduction of silver ions in the $AgBF_4$–PVP membrane was investigated using TEM analysis. The TEM micrograph of the $AgBF_4$–PVP membrane without a phthalate taken just after preparation shows the presence of a small number of particles of approximately 5 nm in size (Fig. 3a). The TEM micrograph of the same membrane after one week shows an increase in the number of particles and in particle size (Fig. 3b). However, as shown in Fig. 3c, the TEM micrograph of a membrane containing 2 wt% dioctyl phthalate taken after one week of preparation shows a much smaller number of silver nanoparticles, indicating that dioctyl phthalate is playing an important role in preventing the reduction of silver ions in the $AgBF_4$–PVP membranes. This stabilization of silver ions in the $AgBF_4$–PVP membrane can be explained by the strong interaction of silver ions with the two carbonyl groups of the phthalate, as shown in Scheme 1. FTIR study shows that the carbonyl stretching frequency of the free DOP at 1729 cm^{-1} shifts to a much lower frequency, by about 46 cm^{-1}, upon



R = butyl, 2-ethylhexyl or phenyl

Scheme 1

interaction with $AgBF_4$, indicating the strong interaction between the carbonyl groups of DOP and silver ions.[1]

To compare the effects of phthalates and non-phthalate plasticizers, we have carried out a separation experiment using 2 wt% glycerol which is a weakly coordinating plasticizer to silver ions. Completely non-coordinating plasticizers like chlorinated paraffins were not tested due to their extremely low solubility in lower alcohols and water. As shown in Figs. 1 and 2, the membrane containing 2 wt% glycerol showed a selectivity of 103 for propylene over propane with a permeance of 4.8×10^{-6} cm^3(STP) cm^{-2} s^{-1} $cmHg^{-1}$ initially. However, the selectivity and permeance rapidly decrease as in the case without a plasticizer. Furthermore, the color of the membrane containing glycerol becomes dark brown within a day, indicating the rapid formation of silver particles. On the other hand, no color change was observed after one week for the membrane containing phthalate. These results suggest that enhanced performance of the membranes can be achieved only in the presence of a plasticizer which can strongly interact with silver ions.

In summary, the $AgBF_4$–PVP membranes show high initial selectivity for propylene/propane separation, but the selectivity was found to continuously decrease with time, most possibly due to the reduction of silver ions to silver nanoparticles. The TEM results support this argument. The addition of small amounts of plasticizer such as dibutyl phthalate, dioctyl phthalate or diphenyl phthalate significantly increase the membrane stability with an unexpected increase in the selectivity and permeance. TEM analysis shows that the formation of silver nanoparticles can be significantly retarded by the presence of small amounts of plasticizer in the membrane.

First published as an Advance Article on the web 27th September 2001

Steaming-dealuminated HZSM-5-supported molybdenum catalysts have been found to be high coking-resistance catalysts for methane aromatization reactions; compared with conventional catalysts, they give a much higher selectivity towards aromatics.

The scission of a C–H bond is the first step for a hydrocarbon transformation reaction. The main reason for the relatively low conversion obtained upon oxidation, functionalization and dehydro-aromatization activation of these hydrocarbons is the high activation energy for C–H bond scission, which requires high reaction temperatures.[1–3] At the high temperature used for aromatization of alkanes on zeolite catalysts, how to suppress coke formation during the reaction remains a big problem. This is especially the case when methane is activated and transformed to aromatics over bifunctional Mo/HZSM-5 catalysts under non-oxidative conditions.[4–12] At 973 K, *ca.* 20–40% of the methane converted is deposited on the catalyst surface as coke species,[6,9,11] lowering the selectivity to desired products as well as masking the active center for the catalytic reaction. The latter process decreases catalytic activity *vs.* time on-stream and eventually leads to the complete deactivation of the catalyst. On considering this, great attention has been paid to the suppression of coke formation in this reaction. Successful examples arise from adding a small amount of CO, CO_2 or O_2 into the reactant, which efficiently suppresses the carbonaceous deposits on the catalyst surface.[8,12] Consequently, it results in much lower coke selectivity and thus a greater durability of Mo/HZSM-5 catalysts. However, using an oxidative co-feed material increases the complicacy of the reaction requirements and at the same time enhances the cost of the potential of putting this reaction into industrial use. Here, we report an alternative but easy handling method (without the addition of oxidative gases) to suppress coke formation by pre-dealumination of the parent HZSM-5 zeolite using a steaming-treatment. Significant improvement has been realized from this method, *i.e.* in a proper-dealuminated ZSM-5-supported Mo catalyst the benzene yield increases by 32% while the selectivity to coke formation drops dramatically from *ca.* 20 to 8% when compared with the conventional Mo/HZSM-5 catalyst.

HZSM-5 with Si/Al mole ratio of 25 [denoted as HZSM-5(P), supplied by Nankai University] was used as the parent zeolite. The dealumination of the parent zeolite was realized by a steaming method, resulting in a series of dealuminated samples [HZSM-5(ST*n*), *n* = 1–3]. The steam treatment conditions (temperature/K, partial pressure of steam/kPa, time/h) of HZSM-5(ST1), HZSM-5(ST2) and HZSM-5(ST3) were (773, 38, 6), (823, 38, 6) and (823, 70, 6), respectively. With *n* varying from 1 to 3, the severity of dealumination increases. After the steam treatment, the samples were washed by 0.5 M HCl solution at room temperature in order to remove the additional extra-framework aluminium species which are expelled from the zeolite lattice during steaming. The parent HZSM-5 was treated with 0.5 M HCl prior to Mo loading and was denoted as HZSM-5(HCl) for the blank experiment. No obvious dealumination of HZSM-5(HCl) was detected compared with HZSM-5(P). Mo-containing catalysts (Mo wt% = 4%) were prepared by incipient wetness impregnation of HZSM-5(P), HZSM-5(HCl) and HZSM-5(ST*n*) (*n* = 1, 2, 3) with an aqueous solution of ammonium heptamolybdate ($(NH_4)_6Mo_7O_{24}{\cdot}H_2O$). Methane aromatization reactions were carried out in a continuous flow reactor system equipped with a quartz tube (10 mm id) packed with 1.5 ml of catalyst pellets of 40–60 mesh. A feed gas mixture of 97.5% CH_4 with 2.5% Ar was purified and then introduced into the reactor at a flow rate of 1500 ml g^{-1} h^{-1} (GHSV = 600 h^{-1}). The reaction was conducted at 973 and 1023 K under a total pressure of 1 atm. The tail gas out of the reactor was detected on-line by a six-way valve connected with two sets of gas chromatographs. The conversion of methane and selectivity to products were calculated by a method similar to that reported by Liu *et al.*[8] Details can be found from our previous publication.[11] TPO (temperature programmed oxidation) experiments of coked catalysts (after 8 h time on-stream, 1 atm, GHSV = 600 h^{-}) were performed with a 20% O_2/He mixture (20 ml min^{-1}, after dehydration) as the oxidant at a heating rate of 10 K min^{-1}. The concentrations of CO_2 in the discharged gas were monitored by gas chromatography.

Fig. 1 shows the methane conversion, benzene yield and the distribution of various products of Mo/HZSM-5 and Mo/HZSM-5(ST*n*) after 360 min time on-stream at 973 K and 1 atm. While methane conversion of heavily dealuminted catalyst Mo/HZSM-5(ST3) dropped sharply to less than 6% due to a loss in lattice cystallinity (*ca.* 60% of that of the parent, XRD pattern not shown here), it is clear that C_{CH_4} remained stable (*ca.* 9.5%) for the Mo/HZSM-5(P), Mo/HZSM-5(ST1) and Mo/HZSM-5(ST2) catalysts [Fig. 1(a)]. On the other hand, a dramatic increase in benzene yield is observed after steaming-treatment. Compared with Mo/HZSM-5(P), the benzene yield of the dealuminated catalysts gradually reaches a plateau at Mo/HZSM-5(ST2), raised by about 1/3, *i.e.* from 4.8 to 6.4%. With methane conversion being similar, an increase in benzene yield means that the product distribution of this reaction is changed. It is interesting to note that the enhancement of benzene selectivity after dealumination treatment arises from the strong suppression of coke formation [the selectivity towards toluene and naphthalene remains also intact, see Fig. 1(b)]. For the parent and HZSM-5-supported molybdenum catalysts dealuminated to different extents, the coke selectivity bottomed out at Mo/HZSM-5(ST2) [for Mo/HZSM-5(P) it is 20.3%, whereas that of Mo/HZSM-5(ST2) is 8.2%], in line with maximum benzene selectivity. Parallel, improved catalytic behavior is obtained as for the reaction conducted at 1023 K (Table 1), where the yield of aromatics from the dealumintated catalyst after 420 min time on-stream is about 32% higher than that of parent Mo/HZSM-5(P) (8.7% *cf.* 6.6%). To rule out the possible role of HCl treatment, Mo/HZSM-5(HCl) was tested in the methane aromatization reaction (Table 1). It is obvious from Table 1 that washing that catalyst with 0.5 M HCl solution at RT does not alter its catalytic performance significantly. Hence, it is concluded that suitable dealumination of the zeolite will benefit aromatics formation and coke suppression and, as a con-

Time on-stream 420 min; reaction temperature 1023 K; reaction pressure 1atm; GHSV 600 h^{-1}.

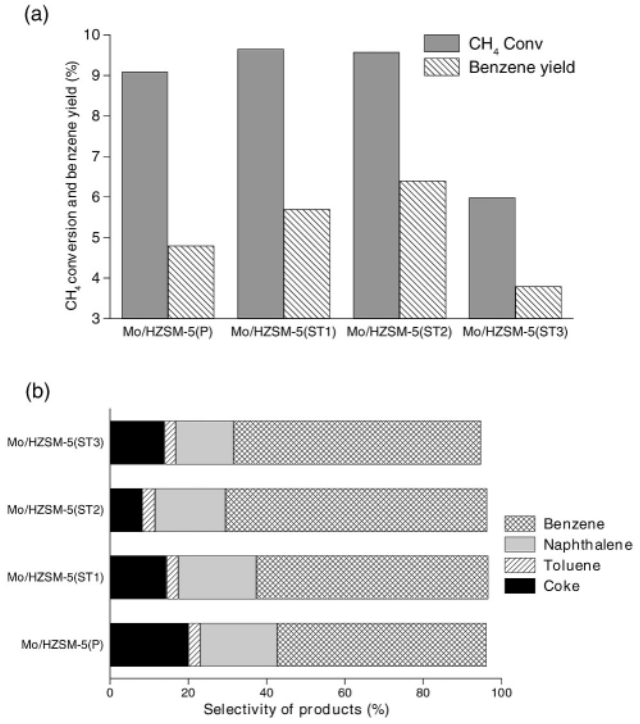

Fig. 1 Methane conversion, benzene yield (a) and product distribution (b) of Mo/HZSM-5(P) and Mo/HZSM-5(ST*n*) (*n* = 1–3) catalysts after 360 min time on-stream of methane aromatization reaction (973 K; 1 atm; GHSV = 600 h^{-1}).

sequence, will benefit the stability of the catalyst. These facts indicate that, different from previous suggestions, only a relatively small amount of Bronsted sites (aluminium connected with the zeolite framework) is necessary for Mo/HZSM-5 to be an efficient and effective methane aromatization catalyst. Superfluous framework aluminium (which is associated with bridging hydroxy) will benefit the formation of carbonaceous deposits, which may initialize and grow in the sites and then ultimately lead to channel blockage and destruction of the catalyst.[13,14] It is precisely the removal of excess framework aluminium (from these dealuminated catalysts) that inhibits the formation of harmful coke and therefore increases the benzene yield and durability of catalysts.

To further endorse these conclusions, TPO experiments of coked Mo/HZSM-5(P) and Mo/HZSM-5(ST2) catalysts were conducted and the results are displayed in Fig. 2. It is obvious that the TPO profiles of deactivated Mo/HZSM-5(P) (after 8 h reaction at 973 and 1023 K) are of double-peak structure, with the low temperature oxidation peak attributed to carbon associated with molybdenum, and the high temperature peak to the carbonaceous deposits on the zeolite Bronsted acid sites.[8,9] After pre-dealumination treatment [TPO profiles of coked Mo/HZSM-5(ST2)], the amount of coke on the catalysts decreased remarkably. In fact, only a peak which is the low temperature peak of TPO of coked Mo/HZSM-5(P) could be monitored, in conjunction with an indistinct tail in the high temperature region. This observation supports our conclusion that dealumination successfully removed the excess framework aluminum (Bronsted sites), which is the main drawback of this reaction, *i.e.* acid-associated carbonaceous depositions in the methane aromatization reaction.

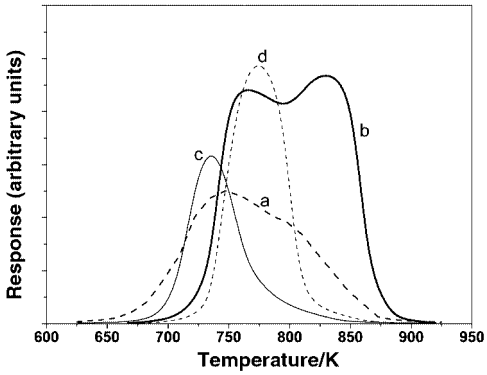

Fig. 2 TPO profiles of (a) Mo/HZSM-5(P) after reaction at 973 K for 8 h; (b) Mo/HZSM-5(P) after reaction at 1023 K for 8 h; (c) Mo/HZSM-5(ST2) after reaction at 973 K for 8 h; (d) Mo/HZSM-5(STZ) after reaction at 1023 K for 8 h. All methane aromatization reactions were conducted at 1 atm, GHSV = 600 h^{-1}.

In summary, an easy way (without addition of any oxidative gases in reactant) for modification of catalyst has been presented here that effectively suppresses coke formation in methane aromatization reactions. It gives a much higher benzene yield and a longer durability as compared with conventional Mo/HZSM-5 catalysts.

Received (in Cambridge, UK) 10th July 2001, Accepted 29th August 2001
First published as an Advance Article on the web 14th September 2001

The ligation method and an appended duplex-stabilizing dye affect both yield and sequence selectivity of a template-controlled PNA-ligation. The highest selectivity was obtained with a peptide condensation that formed an abasic site.

In key biological processes like replication, transcription and translation nucleic acids serve as templates that organize nucleic acid substrates such that ligation reactions are facilitated.[1] A great deal of research has been devoted to the construction of chemical models that can help to unravel the molecular basis of evolution.[2] Ligation reactions that proceed under the control of a DNA-like template are useful examples and illustrate how chemical reactivities can be controlled by Watson–Crick base-pairing. It is commonly accepted that the fidelity of a DNA-controlled ligation reaction, a critical issue for chemical evolution and gene diagnostics, is dependent on the selectivity of nucleic acid hybridisation. The results that will be presented in the following support the notion that it is not only the template binding that accounts for ligation selectivity but also the ligation method itself.

Several oligonucleotide modifications were developed with the aim of enhancing the affinity and the selectivity of their binding to complementary DNA and RNA.[3] Only a few artificial base-pairing systems were used in template-directed ligations.[4] None of these studies addressed the issue of ligation fidelity as far as single base mutations are concerned. We examined the ligation fidelity of one of the most successful DNA-analogues, the peptide nucleic acids (PNA).[5]

Orgel and co-workers have shown that a template-controlled ligation of PNA is possible when a peptide coupling is carried out by using a water-soluble carbodiimide in an imidazole buffer.[4b] Therefore the carbodiimide-mediated condensation of PNA-fragments **1a** and **2a** was investigated. Fig. 1A shows the kinetic monitoring of product formation. In the absence of a template the ligation reaction of the PNA-fragments was inefficient and leveled off at 6% after 24 h. In the presence of the complementary PNA-template **3a** the yield of the ligation reaction was increased but to a moderate extent. Astonishingly, the use of PNA-template **3b**, which contained a single base mismatch, led to the formation of **4a** in an even higher yield.

To enhance the ligation selectivity we envisioned incorporating an abasic site. We speculated that the introduction of an abasic site would disrupt the cooperativity of base stacking and would therefore render the ligation system less tolerant in accommodating further disturbances such as a mismatch.[6] The abasic site was integrated by replacing a central PNA-monomer such that an isosteric dipeptide would be formed upon ligation of two PNA-amino acid conjugates. Two ligation methods were compared.

According to the protocol of native chemical ligation (NCL),[7] the PNA–glycine thioester **1b** was allowed to react with the PNA-conjugate **2b** bearing an *N*-terminal cysteine residue (Fig. 1B). In the event of the ligation, conjugation proceeded smoothly reaching ligation yields of 77% after 150 min. However, ligation product **4b** was formed in high yield independently of the presence of the matched or mismatched template. In contrast, a substantial template effect was obtained by employing a carbodiimide-mediated ligation of the PNA–glycine conjugates **1c** and **2c** shown in Fig. 1C. In the absence of a template the formation of the ligation product **4c** was a slow process. The addition of the perfectly complementary template **3a** enhanced the ligation efficiency by a factor of 5 and led to the formation of **4c** in 37% yield. Importantly, this ligation displayed a remarkable sequence selectivity. The single mismatch template **3b** was ineffective in accelerating the formation of PNA–dipeptide hybrid **4c** and the kinetic profile was virtually indistinguishable from the non-templated reaction.

† PNA = peptide nucleic acid.[12]

A) PNA fragment ligation. B) Native chemical ligation forming an abasic site. C) Carbodiimide-mediated ligation forming an abasic site. Concentration of probes and templates: 160 μM; T = 25 °C; EDC = 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide hydrochloride; im = imidazole. Yields were determined by subjecting aliquots to HPLC-analysis. Data points were averaged over 3 independent experiments.

 DOI: 10.1039/b106109g

In order to facilitate the detection of the ligation products we attached a fluorescence marker. Acridine was preferred since Göbel and co-workers reported that the use of this duplex-stabilizing dye increased the yield of a template-directed oligomerisation reaction.[8] The acridine-labelled PNAs **2d** and **2e** (Fig. 2) were examined in the template-controlled ligation reactions. As shown in Fig. 2A, in the case of the carbodiimide-mediated reaction with **2d**, an increase of the reaction yield was observable. However, this effect impaired the template selectivity. The ligation of the conjugates **1c** and **2d** performed on the matched template **3a** and the mismatched template **3b** with different efficiency, but the discrimination power did not reach the level of the system in Fig. 1C. The incorporation of acridine resulted in a significant template effect when NCL was employed (Fig. 2B). Interestingly, rather than enhancing the templated ligation the presence of the acridine reduced the yield of the ligation performed in absence of a template. A selectivity to different template sequences was not detectable.

The template-directed PNA ligation system showed a remarkable sensitivity towards the different reaction conditions. It is important to note that due to the short oligomer length fragments **1** and **2** are in a rapid dynamic equilibrium between template-bound and unbound species. Taking into account the low stability of duplex structures involving only two base pairs, it was expected that a template-directed ligation at the mismatched template **3b** was unlikely to occur. However, the mismatched template **3b** was more effective in accelerating the ligation of **1a** and **2a** than the perfectly complementary template **3a**. One way of interpreting this result is that ligation reactions require some flexibility. Additional flexibility was introduced by the incorporation of an abasic site. Indeed, it was the abasic site forming ligation of **1c** with **2c** that showed the highest ligation fidelity (Fig 1C). Support for this idea comes from the pioneering work of Shabarova and the work of others, in which it has been shown that DNA-directed reactions perform well when a distorted nucleic acid duplex is produced.[9] On the contrary, the best performing oligonucleotide ligation to date produces a phosphothioate linkage, which closely resembles the phosphodiester structure as found in DNA.[10] It is therefore conceivable that additional effects influence yield and selectivity of the PNA-ligation. For example, any ligation that proceeds *via* a product-like transition state should be affected by the stability of the evolving duplex. The introduction of the abasic site is expected to disrupt the cooperativity of the "unselective" base-stacking thereby increasing the contribution of the selective Watson–Crick hydrogen-binding. It appears plausible that an unselective hybridisation or an unselective ligation process can be rendered selective when an abasic site is involved.

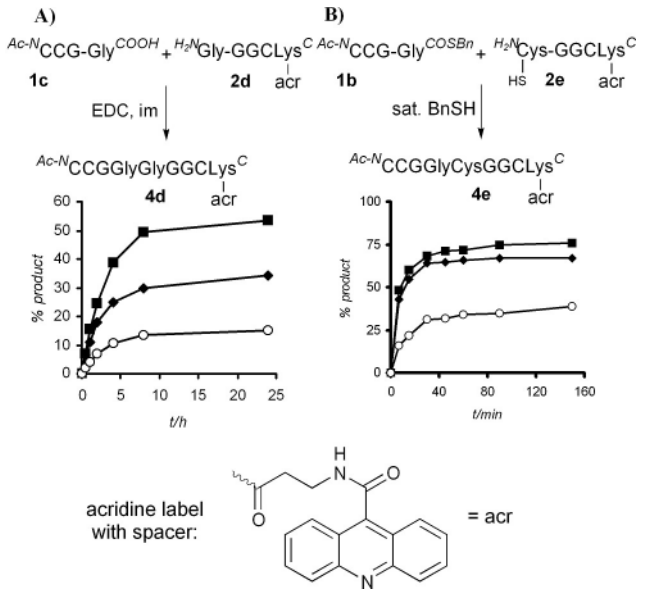

Fig. 2 A) Carbodiimide-mediated ligation of dye-labelled PNA–glycine conjugate **2d**. B) Native chemical ligation of dye-labelled PNA-cysteine conjugate **2e**. Reaction conditions: see Fig. 1.

The ligation method also plays an important role. The insensitivity of NCL to the presence of template was surprising (Fig. 1B). Ghadiri and co-workers were successful in using this ligation reaction for achieving a template-controlled self-replication of a hydrophobic coiled-coil peptide.[11] It can be speculated that nucleic acid-directed reactions that are under control of directed hydrogen bonding show an increased sensitivity to geometric constraints as compared to reactions that are controlled by hydrophobic interactions. In this context, it is a noticable observation that melting experiments with a **3a**–**4b**-mixture failed to show a sigmoidal melting curve, which suggests that binding of the template **3a** to the ligation product **4b** does not suceed.

The examination of the PNA system also provided evidence that the introduction of duplex-stabilising dyes like acridine can increase the overall ligation yield. This is in agreement with previous reports which described a substantial enhancement of oligomerisation yields on acridine-labelled hairpin templates.[8] However, the results shown in Figs 2A and 2B demonstrate that an increase of ligation yield can lead to reduced fidelity of the ligation reaction. It hence seems likely that the acridine-intercalator induced an unspecific association which stabilised both matched and single-mismatched complexes. This indicates that duplex-stabilising dyes should be used with caution when the selectivity of a ligation process is under scrutiny.

In conclusion we have shown that a careful analysis is required before employing PNA-based ligations. The abasic site ligation of PNA-glycine conjugates (Fig. 1C) displays the desired sequence selectivity and DNA-targeting applications will be reported in due course.

(η^5-Cyclopentadienyl)(κ^3-hydrotris(pyrazolyl)borate)cobalt(II)—the first high-spin cobalt organometallic complex†

Tim J. Brunker, Stephen Barlow and Dermot O'Hare*

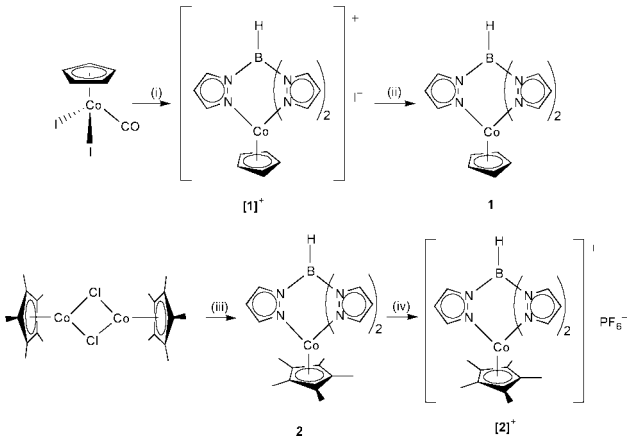
Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR

Received (in Cambridge, UK) 27th June 2001, Accepted 16th August 2001
First published as an Advance Article on the web 27th September 2001

(η^5-Cyclopentadienyl)(κ^3-hydrotris(pyrazolyl)borate)-cobalt(II) has been synthesised; magnetic and crystallographic data indicate this to be the first example of a high-spin cobalt organometallic complex whilst its pentamethylcyclopentadienyl analogue is found to have a low-spin electronic configuration.

The vast majority of transition metal cyclopentadienyl (Cp) complexes adopt low-spin ground state electronic configurations. When a molecule has a d-electron count such that the high-spin state would require occupancy of an antibonding level (in an axially symmetric system the d-orbitals of π symmetry with respect to the M-centroid axis) in preference to a vacant bonding or non-bonding level (d-orbitals of δ or σ symmetry) the low-spin state is almost invariably observed. A few exceptions that exhibit high-spin behaviour (over all temperatures studied) exist in the first-row transition metal series and include 1,1′-bis(trimethylsilyl)manganocene, bis(1,3-diisopropylindenyl)chromium and the (ferromagnetically coupled) 1,2,3,4-tetra- and 1,2,3,4,5-pentaisopropylcyclopentadienyliron(II) bromide dimers. To date no example of high-spin behaviour has been found for an element from Group 9.[1] We have been interested in synthesising mixed-sandwich compounds containing a Cp and a hydrotris(pyrazolyl)borate (Tp) ligand. In the course of our studies we have isolated CoCpTp, the first example of an organometallic cobalt complex which adopts a maximum spin configuration in preference to a potential low-spin alternative.

Reaction of $CoCp(CO)I_2$[2] with KTp gave $[CoCpTp]^+I^-$, $[\mathbf{1}]^+I^-$ as a dark purple solid (Scheme 1).[3] Reduction of $[\mathbf{1}]^+I^-$ yielded CoCpTp, **1**, as a green-yellow crystalline solid. The pentamethylcyclopentadienyl (Cp*) analogue, CoCp*Tp, **2**, was directly obtained as a red-brown solid from $[CoCp^*Cl]_2$[4] and was oxidised to $[CoCp^*Tp]^+[PF_6]^-$, $[\mathbf{2}]^+[PF_6]^-$, by reaction with $[FeCp_2]^+[PF_6]^-$.



Scheme 1 *Reagents and conditions*: (i) KTp, thf, 98%; (ii) $CoCp_2$, thf, 83%; (iii) KTp, thf, 43%; (iv) $[FeCp_2]^+[PF_6]^-$, MeCN, 72%.

† Electronic supplementary information (ESI) available: full characterisation data for all compounds. See http://www.rsc.org/suppdata/cc/b1/b105661c/

Both **1** and **2** were characterised by elemental analysis, and mass spectrometry (EI). Infra-red spectroscopy revealed characteristic ν_{B-H} at 2494 and 2448 cm^{-1} respectively.† Surprisingly **1**, in contrast to $CoCp_2$ and $CoCp^*_2$, is essentially air-stable in the solid-state and solutions only decompose slowly when exposed to air, whereas **2** is very air-sensitive in solution but less so in the solid-state. Despite being paramagnetic, **1** has a well-defined ^1H NMR spectrum whereas that of **2** is very broad.

SQUID magnetometry measurements were performed on powdered samples of both **1** and **2**. **1** gave a moment of 5.84 μ_B (± 0.1 μ_B) at 300 K which can be accounted for by a high-spin electronic configuration, *i.e.* three unpaired electrons. The large deviation from the spin-only value for $S = 3/2$ (3.87 μ_B) is due to a large spin–orbit contribution to the moment and is only slightly larger than the typical values observed for high-spin Co(II) complexes (4.77–5.40 μ_B).[5] **1** shows non-Curie–Weiss behaviour between 5 and 300 K, see Fig. 1. In contrast, **2** is in the low-spin state over the entire temperature range, and obeys the Curie–Weiss law in the range 40–300 K ($C = 0.51$ emu K mol^{-1}, $\theta = -15.46$ K). It has a moment of 1.95 μ_B at 300 K (spin–only value for $S = 1/2$ is 1.73 μ_B) falling to 1.20 μ_B at 5 K, presumably as a result of intermolecular antiferromagnetic interactions.

Electronic spectra of **1** and **2** in thf are shown in Fig. 2. Three spin-allowed d–d transitions are expected for a high-spin octahedral d^7 ion corresponding to the transitions $^4T_{1g}(F) \rightarrow {}^4T_{2g}$, $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ and $^4T_{1g}(F) \rightarrow {}^4A_{2g}$. For **1**, we observe 3 bands in the near IR/visible whose energies correlate well with reported high-spin octahedral Co(II) spectral data (10800, 20800, 24400 cm^{-1}), but whose relative intensities are increased as a consequence of the symmetry lowering in **2** from O_h.[5] In the spectrum of **2**, the d–d transitions are only poorly resolved and assignment is difficult. The spectrum is similar to that of cobaltocene where transitions to excited doublet states of similar energy overlap and are also poorly resolved.[6]

An ESR (X-band) spectrum of **2** was obtained in a frozen toluene solution at 15 K and a rhombic g tensor was observed with hyperfine coupling on all 3 components to ^{59}Co ($I = 7/2$). The spectrum is similar to those observed for cobaltocenes[7,8] and monomeric CoCp*X (X = Cl, NH_2, OEt) and CoCp*XL (X = Cl, L = PMe_3 and py) species,[4] confirming a low-spin $^2\Pi$ ground state. In comparison **1** was silent at room temperature

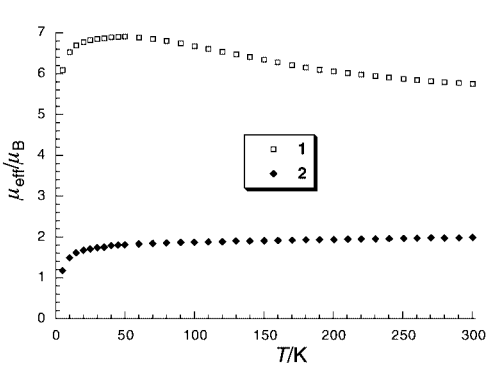


Fig. 1 Plot of μ_{eff} (μ_B) against T (K) for **1** and **2**.

 DOI: 10.1039/b105661c

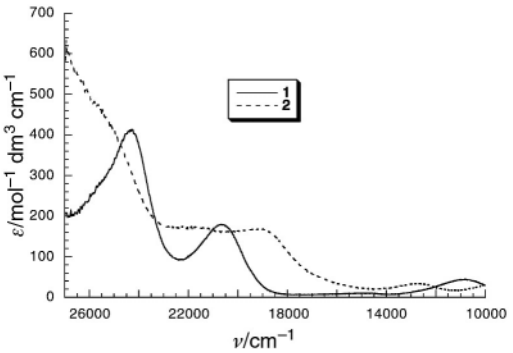

Fig. 2 Electronic spectra of **1** and **2** in thf solution.

and below 20 K in toluene solution, indicating a very different ground state electronic configuration to that of **2**.

Spectral and magnetic data support a greater ligand-field splitting in **2** as compared to **1** resulting in different electronic ground states, a phenomenon also observed in manganocenes but never before for Co.[9] The stronger electron-donating ability of Cp* in comparison to Cp has been demonstrated to lead to an increased ligand-field splitting in the decamethylmetallocenes compared to unsubstituted metallocenes,[7] and we can rationalise the difference between **1** and **2** in these terms.

Single crystals of **1** were grown by slow-cooling of a saturated pentane solution to −35 °C; the molecular structure is shown in Fig. 3.‡ Comparison of the Co–C bond lengths (average 2.290(2) Å) and the Co–Cp(centroid) distance (1.97 Å) with a range of previously reported Co(II)Cp compounds incorporating various ancillary ligands (see Table 1) indicates that these parameters lie well outside the limits previously observed for low-spin complexes. This increase is clearly consistent with the high-spin electronic configuration indicated by the other data: double occupation of the antibonding π level (assuming the symmetry can be well approximated as $C_{\infty v}$) necessary for a high-spin d^7 configuration, $[\delta^4\sigma^1\pi^2]$ or $[\sigma^2\delta^3\pi^2]$, will lead to a weakening of the Co–Cp bonds compared to the low-spin state where this is only singly occupied $[\delta^4\sigma^2\pi^1]$. The Co–N bond lengths (av. 2.091(2) Å) are slightly shorter (significant at the 3σ level) than those in $CoTp_2$ (av. 2.129(7) Å),[10] which has a high-spin configuration.[11]

The air-stable 18 electron species $[\mathbf{1}]^+I^-$ and $[\mathbf{2}]^+[PF_6]^-$ are diamagnetic and were characterised by ^1H, ^{13}C and ^{11}B NMR spectroscopy, showing resonances consistent with axially symmetric species.† IR spectroscopy revealed ν_{B-H} typical for κ^3-Tp ligands of 2501 and 2505 cm^{-1} respectively. The redox couple $[\mathbf{1}]^+/\mathbf{1}$ was measured at −590 mV *versus* ferrocenium/ferrocene in CH_2Cl_2 and the $[\mathbf{2}]^+/\mathbf{2}$ couple at −890 mV. **2** is more readily oxidised than **1** despite the high-spin ground state

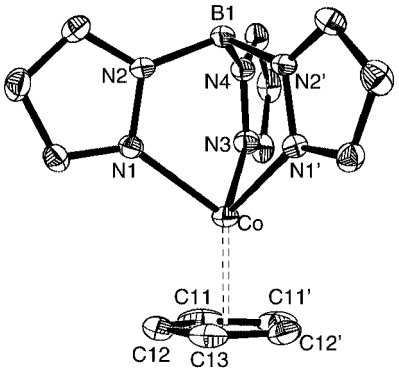

Fig. 3 Molecular structure of **1** with thermal ellipsoids at 50% probability (hydrogen atoms have been omitted for clarity). Primed atoms are generated by symmetry. Selected interatomic distances (Å): Co–N1 2.103(1), Co–N3 2.069(2), Co–C11 2.305(2), Co–C12 2.286(2), Co–C13 2.268(3).

Table 1 Summary of structural parameters for selected CpCo(II) complexes

Compound	Co–C (average)/Å	Co–Cp (centroid)/Å	Ref.
$CoCp_2$	2.096(8)	1.70	14
$Co(C_5(i\text{-}Pr)_3H_2)_2$	2.122(7)	1.75	15
CoCp*(acac)	2.089(5)	1.70	16
$[Co(C_5(i\text{-}Pr)_4H)Cl]_2$	2.061(4)	1.68	17
CoCp*(py)Cl	2.076(2)	1.70	18
CoCpTp	2.290(2)	1.97	This work

acac = acetylacetonate, py = pyridine.

of **1**. Both compounds are less readily oxidised than $CoCp_2$[12] and are more readily oxidised than $CoTp_2$.[13]

We have succeeded in isolating a hitherto unseen high-spin state for a Co organometallic compound by synthesis of a mixed-sandwich complex with Cp and the weak-field Tp ligand. Investigations utilising other metals from across the first transition series also illustrate a tendency towards high-spin configurations in such complexes and will be reported in future.

We thank the EPSRC for a studentship (T. J. B.) and A. R. Cowley and T. Hascall for crystallographic assistance.

Diastereoselectivity controlled by electrostatic repulsion between the negative charge on a trifluoromethyl group and that on aromatic rings†

Toshimasa Katagiri, Sachiko Yamaji, Michiharu Handa, Minoru Irie and Kenji Uneyama*

Department of Applied Chemistry, Faculty of Engineering, Okayama University, Tsushimanaka 3-1-1, Okayama 700-8530, Japan. E-mail: tkata@cc.okayama-u.ac.jp

Received (in Cambridge, UK) 26th June 2001, Accepted 29th August 2001
First published as an Advance Article on the web 27th September 2001

Intramolecular electrostatic repulsions between the local negative charge on a trifluoromethyl group and that on the *ortho* position of an aryl moiety of a nucleophile was found to be a controlling factor of the diastereoselectivity in a cyclopropanation reaction, in which the electrostatic repulsion was evaluated quantitatively.

Non-covalent interactions are not only the basis of the functional properties of molecules[1] but are also fundamental to the explanation and prediction of relationships between chemical structure and reactivity. In the field of organic chemistry, the exchange repulsion, or the so-called steric repulsion, has been paid much attention among so many repulsive forces. Thus have been predicted and explained the stereoselectivities of reactions using the CPK model, a substitute for the Van der Waals surface.[2] On this basis, fluorinated groups have sometimes been considered to resemble their parent non-fluorinated groups in their steric size, which is consistent with the so-called mimic effect of fluorinated bioactive compounds.[3]

In spite of the situation, the 'size' of the trifluoromethyl group (CF_3) is still of controversy.[3,4] The steric effect of CF_3, especially in nucleophilic reactions, has also been suggested to be comparable to that of isopropyl or *tert*-butyl groups.[5] This unexpected large steric effect of CF_3 has been attributed to a possible participation of electrostatic repulsions although quantitative confirmation or proof is still lacking. The primary aim of this report is to propose the electrostatic interaction of CF_3; the secondary aim is to develop a method for the quantitative estimation of the electrostatic interaction around CF_3.

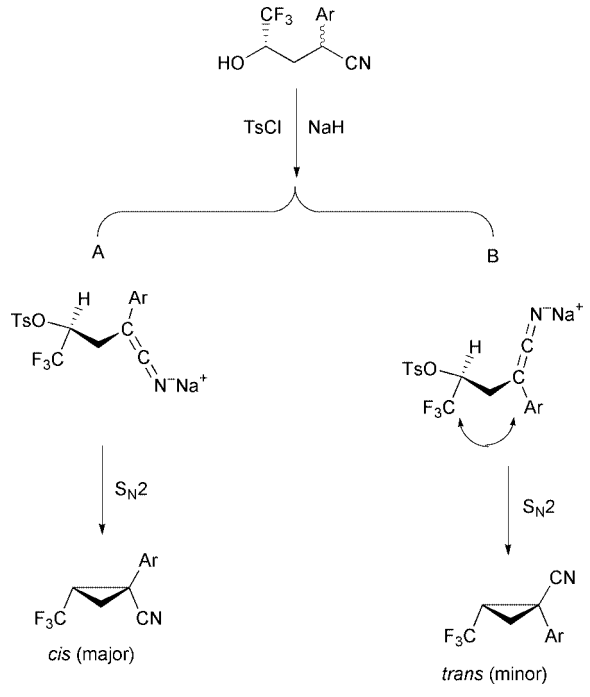
Very recently, we have developed a nucleophilic cyclization of 1-aryl-1-cyano-3-(*p*-toluenesulfonyloxy)-4,4,4-trifluorobutanes to produce cyclopropanes *via* cyano-stabilized carbanions (Scheme 1),[6] in which a stereochemical inversion on the carbon bearing the trifluoromethyl and hydroxy groups was observed.†

Detailed results of the present study on the diastereoselectivity of the cyclopropane products having various aryl moieties are summarized in Table 1. Except for Ar = C_6F_5, the major isomers were *cis* in which the CF_3 and aryl groups were *anti*. The results shown in Table 1 demonstrate that the orders of these de values are dependent upon the substituents on the aromatic rings. However, this order of de values cannot be explained in terms of electronic effects of substituents or by conventional bulkiness. For instance, the de for *p*-MeO-C_6H_4 (entry 3) is lower than that of C_6H_5 (entry 1), and the de for naphthyl (entry 2) is much lower than that of *p*-MeO-C_6H_4 (entry 3). Moreover, the compound having C_6F_5 as the aryl moiety gave the opposite diastereomer (*trans*) as a major product to those of other substituents, and whose structure was confirmed by X-ray crystallographic analysis.[7]‡ This result implies that the C_6F_5 moiety is 'less bulky' than CN or CF_3.

† Electronic supplementary information (ESI) available: general experimental methods and typical reaction procedure. See http://www.rsc.org/suppdata/cc/b1/b105602f/

The CF_3 attached with some alkyl moiety should have a negative charge due to the strong electron withdrawing effect of the group. Here, the aryl moiety of the intermediate is π-conjugated to the anion center; thus, the moiety should also be negatively charged. Therefore, the CF_3 should make a repulsive interaction toward the negatively charged aromatic ring. The diastereoselection will therefore be controlled by the energetic difference between the two conformations of the intermediates, A and B, in Scheme 1. Conformation A has a structure in which CF_3 and the aryl group are *anti*, to give the *cis* product as the major product except for when Ar = C_6F_5. Meanwhile, conformation B should have a repulsive electrostatic interaction of the negative charge on CF_3 with that of the aryl group, which makes this structure rather unstable. It is noteworthy that the local minimum structure of this *syn* intermediate, which was estimated by geometry optimization by PM3, has no direct contact of the Van der Waals surfaces of CF_3 and aryl moieties.

This *syn* structure suggests that the fluorine atoms on CF_3 should have the largest overlapping of their reflection on the *ortho* carbon of an aryl moiety (γ from the carbanion center). Thus, we estimate the effective negative charges on these positions of the anion moiety (A in Scheme 1) by the Mulliken method of PM3 level MO calculations. The sum of the electrostatic charges on these two *ortho* carbons, an estimated effective charge (*q*), is also summarized in Table 1, and the free



Scheme 1

 DOI: 10.1039/b105602f

Table 1 Diastereoselectivity depending on the substituents with the sum of charges on *ortho* carbons

Entry	Aryl moiety[a]	de (%)	ln (major/minor)	q
1		80.7 ± 3.5	2.24 ± 0.20	−0.36
2		46.6 ± 8.7	1.01 ± 0.23	−0.22
3		63.0 ± 2.4	1.48 ± 0.08	−0.29
4		83.5 ± 1.3	2.41 ± 0.09	−0.37
5		89.6 ± 1.1	2.90 ± 0.11	−0.49
6		65.8 ± 4.3	1.58 ± 0.16	−0.34
7		−77.0 ± 3.2[b]	−2.04 ± 0.15[b]	−0.04
8		>98[c]	>4.60[c]	−0.62

[a] The circles indicate the *ortho* positions for estimation of q values. [b] The major diastereomer was found to be *trans*, see text and ref. 6. [c] Only one diastereomer was found.

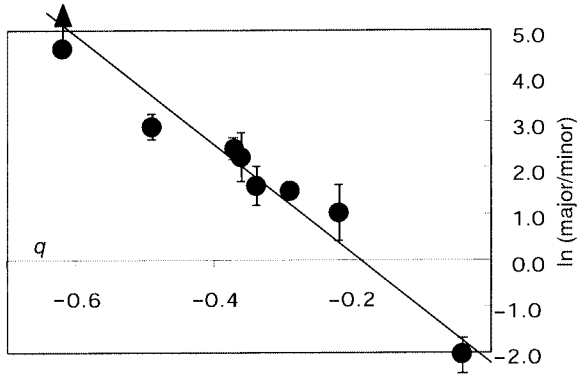


Fig. 1 Relationship between discrimination energy and the sum of charges on *ortho* positions.

energy relationship of q to the logarithm of the ratio of the two diastereomers is illustrated in Fig. 1.[8]

The correlation coefficient of this relationship shown in Fig. 1 is 0.965, that is, the relation is 'satisfactorily' linear. This linear relationship is consistent with our working hypothesis that the diastereoselectivity of the reaction is controlled by electrostatic repulsion between CF_3 and the aryl moiety.[6] Here, the destabilizing energy by the electrostatic repulsion should be $-qq'/4\pi\varepsilon_0 r$, where q is the effective negative charge on the aryl moiety, q' is that of CF_3, and r is the distance between the negative charges. In the case of C_6H_5 as the Ar group, the equation estimates a repulsion energy between CF_3 and Ar to be 2.8 kcal mol^{-1}, and that between CF_3 and CN to be 1.6 kcal mol^{-1}; thus, the energetic difference between conformers A and B in Scheme 1 is estimated to be 1.2 kcal mol^{-1}, which is very close to the known value for 80% de, 1.3 kcal mol^{-1}.[9] It is also of note that the anionized C_6F_5 group has a relatively small electrostatic repulsion toward CF_3, which is consistent with a known inverse quadrupole of hexafluorobenzene.[10] The q value for C_6F_5 was estimated to be −0.04 e, thus the repulsion energy of CF_3 to C_6F_5 is estimated to be only 0.3 kcal mol^{-1}, which is apparently smaller than that of CF_3 to CN (1.6 kcal mol^{-1}). Therefore, the diastereoselectivity of the product where Ar = C_6F_5 is inverted compared with the other cases.

In conclusion, we have clarified that CF_3 should be considered to be a negatively charged moiety, and its interaction can be estimated by the Coulomb equation. Such an electrostatic repulsion, a longer distance interaction than the Van der Waals repulsion, should be utilizable for discrimination between functional groups and/or moieties having similar sizes with different charges.[11] Further utilization of this function for CF_3 as a chiral auxiliary and chiral ligand are now in progress in our laboratory.

We thank the SC-NMR Laboratory of Okayama University for ^{19}F and ^{1}H NMR analyses, and the Venture Business Laboratory of Graduate School, Okayama University, for X-ray crystallographic analysis. We are grateful for financial support for this work from Monbusho (Grant-in-Aid for Scientific Research on Priority Areas, No.706 Dynamic Control of Stereochemistry, and No. 12650854), and by The Shorai Foundation for Science and Technology.

Solid state coordination chemistry: construction of 2D networks and 3D frameworks from phosphomolybdate clusters and binuclear Cu(II) complexes. The syntheses and structures of $[\{Cu_2(tpypyz)(H_2O)_2\}(Mo_5O_{15})(HOPO_3)_2]\cdot nH_2O$ [n = 2, 3; tpypyz = tetra(2-pyridyl)pyrazine]†

The hydrothermal reaction of MoO_3, $Cu(C_2H_3O_2)_2\cdot H_2O$, tpypyz, H_3PO_4 and H_2O yields a 2D material, $[\{Cu_2(tpypyz)(H_2O)_2\}(Mo_5O_{15})(HOPO_3)_2]\cdot 2H_2O$ (1·2H$_2$O), constructed from $\{Mo_5O_{15}(HOPO_3)_2\}^{4-}$ clusters linked through $\{Cu_2(tpypyz)(H_2O)_2\}^{2+}$ components; in contrast, use of Cu_2O in the synthesis in place of $Cu(C_2H_3O_2)_2\cdot H_2O$ yields a 3D material $[\{Cu_2(tpypyz)(H_2O)_2\}(Mo_5O_{15})(HOPO_3)_2]\cdot 3H_2O$ (2·3H$_2$O), constructed from the same building blocks as 1·2H$_2$O.
