2-Substituted 5-Nitrobenzimidazole 3-Oxides from Aldehydes

By D. W. Russell

(Twyford Laboratories, Twyford Abbey Road, London, N.W.10)

Photolysis of N-2,4-dinitrophenyl derivatives (I) of α -amino-acids in solution at pH 6 or higher yields 4-nitro-2-nitrosoaniline (II) and the corresponding aldehyde (III).^{1,2} At pH 2—5 the 2-substituted 5-nitrobenzimidazole 3-oxide (IV) is produced,³ this affording a convenient route to (IV) when the corresponding amino-acid is readily available. In other cases, in particular when R = aryl, the amino-acid must be prepared, usually from the corresponding aldehyde. A synthetic method which produced (IV) directly from the aldehyde would therefore effect a useful economy.

Without making any assumption as to the mechanism of the photochemical reaction leading to (IV), it seemed possible that 4-nitro-2-nitroso-aniline (II) might condense directly with aldehydes to yield the required compounds. When (II) was treated with $1\cdot 1$ mol. of benzaldehyde under the conditions shown, 5-nitro-2-phenylbenzimid-azole 3-oxide (IV; R=Ph), separating from the hot solution, was obtained in 46% yield after two crystallizations. It was identical with the product obtained by photolysing the C-phenylglycine derivative (I; R=Ph). The analogous compounds

(IV; R = p-chlorophenyl or p-cyanophenyl) were similarly prepared.

Since 4-nitro-2-nitrosoaniline (II) is readily accessible, the technique affords a convenient general route to (IV), particularly for R = aryl. Although these compounds have high melting points, the reaction may find use for characterizing aldehydes.
