Tris(trimethylsilyl)methyl iodide undergoes rapid reduction to tris(trimethyl)silylmethane in methanol containing sodium methoxide or silver trifluoromethanesulfonate.

After more than a century of study of reactions of alkyl and substituted-alkyl halides with alcohols, including some sixty years of detailed mechanistic investigations, it might reasonably have been assumed that all possible modes of reaction had been observed, but we describe below one we believe not to have been previously recognised.

We thought it likely that unusual behaviour towards nucleophiles might be encountered with compounds of the type  $(\text{Me}_3\text{Si})_3\text{CX}$ , where X is a potential nucleofuge such as halogen, since: (a) there should be severe steric hindrance to  $\text{S}_{\text{N}}2$ -type attack by a nucleophile at carbon; (b)  $\beta$ -elimination of HX is impossible; and (c) formation of the cation  $(\text{Me}_3\text{Si})_3\text{C}^+$  is very unlikely. (An  $\alpha$ - $\text{Me}_3\text{Si}$  group is known to be much less effective at stabilizing a carbocation than an  $\alpha$ -Me or  $\alpha$ - $\text{Me}_3\text{C}$  group,<sup>1,2</sup> and the limited experimental evidence from solution reactions<sup>1,3</sup> provides no support for predictions based on calculations<sup>2</sup> that it is more effective than  $\alpha$ -H.) We thus decided to examine the reaction of the iodide  $(\text{Me}_3\text{Si})_3\text{CI}$  **1** with methanolic sodium methoxide.

To our surprise a fast reaction occurred in refluxing  $0.1 \text{ mol dm}^{-3}$  NaOMe–MeOH and tris(trimethylsilyl)methane **2** was formed in virtually quantitative yield. In methanol alone **2** was formed very slowly (<1% per hour), but when one equivalent of  $\text{AgO}_3\text{SCF}_3$  was added it was produced rapidly and AgI separated. The reduction also took place in EtOH or Pr<sup>i</sup>OH in the presence of either the corresponding alkoxide or  $\text{AgO}_3\text{SCF}_3$ . When  $1 \text{ mol dm}^{-3}$  solutions of alcohols in benzene containing  $\text{AgO}_3\text{SCF}_3$  were used, the reduc-

tion of **1** on heating took place at comparable rates with EtOH and MeOH, but it was about five times slower with Pr<sup>i</sup>OH, and under conditions in which ca. 30% conversion into **2** occurred with MeOH and EtOH there was no significant reaction with *tert*-butyl or neopentyl alcohol. There was also no reaction when **1** was refluxed with  $\text{AgO}_3\text{SCF}_3$  in benzene alone.

The formation of **2** rules out the intermediacy of the cation  $(\text{Me}_3\text{Si})_3\text{C}^+$ , since in MeOH this would surely give  $(\text{Me}_3\text{Si})_3\text{COMe}$  or an isomer of it. In view of its known stability (reflected in the acidity of **2**<sup>4</sup>) the anion  $(\text{Me}_3\text{Si})_3\text{C}^-$  would not have been a surprising intermediate, but this was ruled out by the observation that only undeuteriated **2** was formed in  $\text{CH}_3\text{OD}$  in the presence of either MeONa or  $\text{AgO}_3\text{SCF}_3$ . Very significantly, the Ag<sup>+</sup>-catalysed reaction was much slower in  $\text{CD}_3\text{OD}$  than in  $\text{CH}_3\text{OH}$ , indicating that C–H bond formation must take place in a rate-limiting step. In 1:1  $\text{CH}_3\text{OD}$ – $\text{CD}_3\text{OD}$  in both the methoxide and Ag<sup>+</sup>-catalysed processes there was about 4–6% incorporation of deuterium, corresponding to a kinetic isotope effect  $k_{\text{H}}/k_{\text{D}}$  in the range 15–25. (Values in this range have been observed for both proton and hydrogen atom transfers to sterically hindered centres, and are commonly attributed to quantum mechanical tunnelling.<sup>5</sup>)

It seemed very likely from the above observations that the radical  $(\text{Me}_3\text{Si})_3\text{C}\cdot$  was the effective intermediate in both reactions, especially since it is known that it can be readily formed and under appropriate conditions can be highly persistent.<sup>6,7</sup> However there was also a possibility that C–I bond breaking was concerted with C–H bond formation; but this was excluded by the observation that when the methoxide- and Ag<sup>+</sup>-catalysed reactions catalysed by an equivalent of

$\text{AgO}_3\text{SCF}_3$  or  $0.1 \text{ mol dm}^{-3}$   $\text{NaOMe}$  were carried out in  $\text{MeOH}$  containing  $1 \text{ mol dm}^{-3}$   $\text{CCl}_4$  they were much slower, and that both **2** and the chloride  $(\text{Me}_3\text{Si})_3\text{CCl}$  **3** were formed. Thus whereas the reaction in refluxing  $0.1 \text{ mol dm}^{-3}$   $\text{NaOMe-MeOH}$  had a half-life of  $<10$  min, there was only *ca.* 5% conversion of **1** after 3 h in the presence of  $0.1 \text{ mol dm}^{-3}$   $\text{CCl}_4$ , and in the  $\text{Ag}^+$ -catalysed reaction under conditions in which **1** normally had a half-life of a few minutes there was only 20% conversion after 3 h. In both cases the amounts of **2** and **3** increased with time. Addition of toluene also strongly retarded the reactions.

It seems clear that the reactions are free-radical chain processes involving  $(\text{Me}_3\text{Si})_3\text{C}\cdot$  and, in keeping with this view, when photolysis of the mercurial  $[(\text{Me}_3\text{Si})_3\text{Cl}_2\text{Hg}]$ , which is known to give such radicals very readily,<sup>6</sup> was carried out in  $\text{MeOH}$  containing  $1 \text{ mol dm}^{-3}$   $\text{CCl}_4$  roughly equal amounts of **2** and **3** were produced. Furthermore, when the photolysis was repeated but in 1:1  $\text{CH}_3\text{OD-CD}_3\text{OD}$  containing  $1 \text{ mol dm}^{-3}$   $\text{CCl}_4$  (necessary because the mercurial is practically insoluble in  $\text{MeOH}$  alone) deuterium was incorporated into **2** to the extent of *ca.* 4%, corresponding to a value of  $k_{\text{H}}/k_{\text{D}}$  of *ca.* 25, within the range of approximate values for the catalysed reactions of **1** in  $\text{MeOH}$ .

In the  $\text{Ag}^+$ -catalysed process the radical  $(\text{Me}_3\text{Si})_3\text{C}\cdot$  presumably reacts with  $\text{CH}_3\text{OH}$  to give **2** and the radical  $\text{HOCH}_2\cdot$ , which then abstracts  $\text{I}\cdot$  from **1** to regenerate  $(\text{Me}_3\text{Si})_3\text{C}\cdot$ . (The  $\text{Me}\cdot$  radical is known to abstract a hydrogen atom 45 times as readily from carbon as from oxygen in  $\text{MeOH}$ .<sup>8</sup>) The other product,  $\text{ICH}_2\text{OH}$ , would break down to  $\text{HCHO}$  and  $\text{HI}$  and hence  $\text{AgI}$ . In the methoxide-catalysed reaction the hydrogen atom abstraction step might involve  $\cdot\text{OCH}_2$  rather than  $\text{HOCH}_2\cdot$ , since the latter has a  $\text{p}K_{\text{a}}$  of 10.7.<sup>9</sup> In the presence of  $\text{CCl}_4$  the radical  $(\text{Me}_3\text{Si})_3\text{C}\cdot$  is frequently trapped to give **3**. An implication of the proposed mechanism is that in the  $\text{Ag}^+$ -catalysed reaction  $\text{Ag}^+$  is not involved in the propagation steps, so that complete reduction should be possible even if less than one equivalent of  $\text{AgO}_3\text{SCF}_3$  is used, and we confirmed that under such conditions more **2** was formed than  $\text{Ag}^+$  was consumed, but the reaction was much slower.

The chain-initiating processes have still to be identified, but we note that the progressive (though slow) formation of **1** and **3** in the catalysed reactions in the presence of  $\text{CCl}_4$  implies that initiation is a continuing process, and so is not dependent on

the initial presence of traces of radical impurities. In the methoxide-catalysed reaction there may be single electron transfer from  $\text{MeO}^-$  to give the radical anion  $(\text{Me}_3\text{Si})_3\text{Cl}^{\cdot-}$  and hence  $(\text{Me}_3\text{Si})_3\text{C}\cdot$  and  $\text{I}^-$ , but the corresponding process, involving single electron transfer to  $\text{Ag}^+$  to give the radical cation  $(\text{Me}_3\text{Si})_3\text{Cl}^{\cdot+}$ , and hence  $(\text{Me}_3\text{Si})_3\text{C}\cdot$  and  $\text{I}^+$ , seems less likely.

It is noteworthy that prolonged refluxing of neopentyl iodide with concentrated ethanolic potassium hydroxide was shown many years ago to give some neopentane, among other products,<sup>10</sup> and it is likely that the mechanism of the reduction is similar to that for **1**. The reaction is many orders of magnitude slower, however, perhaps because the radical  $\text{Bu}^{\cdot}\text{CH}_2$  is much less readily formed than  $(\text{Me}_3\text{Si})_3\text{C}\cdot$ .

We thank the Research Committee of the New Zealand University Grants Committee and also the SERC for support of this work.
