

## CRYSTAL SYMMETRY CHANGE OF ZSM-5 BY VARIOUS TREATMENTS

Hiromi NAKAMOTO and Hiroshi TAKAHASHI

Institute of Industrial Science, The University of Tokyo

22-1, Roppongi 7-Chome, Minato-ku, Tokyo 106

When a  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratio was higher than about 170, the crystal structure of ZSM-5 changed from orthorhombic to monoclinic symmetry by mere calcination. The monoclinic symmetry remained unchanged by  $\text{NH}_4$ -ion exchange, but the symmetry was reformed to orthorhombic in some of the specimens by protonation. The  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratio was found to play a major role compared with the Na-content.

Zeolite ZSM-5 is a new class of high siliceous zeolite which possesses wide  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratios from about 20 to more than 8000.<sup>1)</sup> By X-ray powder diffraction profiles, the crystal system of as-synthesized ZSM-5 is identified to be orthorhombic symmetry. It has also been observed that the orthorhombic symmetry structurally changed to monoclinic one by calcination and ion-exchange.<sup>2)</sup> Wu and coworkers<sup>2)</sup> have commented that extra framework matter (a sodium content) and an aluminium content are among the critical variables which control the symmetry change of ZSM-5 from orthorhombic to monoclinic, however quantitative data on the symmetry change have been lacking.

In the present work, various forms of ZSM-5 with different sodium and aluminium contents were prepared, and the role of sodium and aluminium contents on the symmetry change of ZSM-5 was examined in detail.

Various forms of ZSM-5 samples examined have the following designations: as-synthesized, calcined, ammonium-exchanged ( $\text{NH}_4^-$ ) and protonated form ( $\text{H}^-$ ), and those prepared as described previously.<sup>3)</sup> The crystal structure of samples was identified by their X-ray powder diffraction profiles, when the data reported by Wu and coworkers<sup>2)</sup> were employed as a criterion for its identification, and some of their morphologies were observed by electronmicroscopy.

The selected chemical components and the observed crystal symmetry of ZSM-5 samples are listed in Table 1. The X-ray powder diffraction profiles of as-synthesized samples, in which  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratios varied from 50 to 2000, were very similar to the profiles consisting of orthorhombic symmetry system. In case of the sample exposed to an ambient atmosphere for 1 h after calcination at 540 °C, the X-ray powder diffraction profiles of the samples with  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratios below 160 displayed orthorhombic symmetry, while those of the samples with the ratios above 170 showed clearly monoclinic symmetry. When the samples with  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratios of about 160 were exposed to water vapor at room temperature for 24 h, their X-ray powder diffraction profiles changed from orthorhombic to monoclinic symmetry. The behavior described above is to be compared to that reported by Wu and coworkers.<sup>2)</sup> They reported that only shortly after calcination at 600 °C for 1 h, the X-ray powder diffraction profiles of the sample with a Na-content of 0.8 wt% and with a  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratio about 1600 seemed to be orthorhombic and that when the sample was further exposed to an ambient atmosphere for 3 days, its profiles consisted of monoclinic symmetry, while no symmetry change was observed with the sample with a Na-content of 1.6 wt%. They suggested that for such a behavior, water vapor presumably caused relocation of the residual sodium species which enable the framework structure to undergo a symmetry change. For the  $\text{NH}_4$ -form samples, the X-ray powder diffraction profiles of those with  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratios above about 170 showed monoclinic symmetry, while those of the samples with  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratios below about 160 showed orthorhombic symmetry. When the samples with  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratios between 730 and 860 were transformed to H-form, their X-ray powder diffraction profiles changed from monoclinic to orthorhombic symmetry.

In view of these data, the higher the  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratio is, the easier it is for the ZSM-5 framework to change from orthorhombic to monoclinic symmetry upon treatments such as calcination and ion-exchange to the  $\text{NH}_4$ - and/or H-form, which has previously been described by Wu and coworkers.<sup>2)</sup> For the calcined form, however, our results are significantly different from those of Wu and coworkers,<sup>2)</sup> that is, it was evident that some samples, as the  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratio became higher, changed from orthorhombic to monoclinic symmetry by mere calcination, and that the  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratio played a major role rather than the Na-content did on the symmetry change of ZSM-5. In addition, the reversal change, from monoclinic to orthorhombic symmetry, was also shown to occur in some samples, which has not been reported so

Table 1. Variation in crystal symmetry of ZSM-5 with various treatments.

| Sample No. | Chemical Analysis<br>(as-synthesized form) |                                                  | Crystal Symmetry    |               |                  |                       |        |

far. The particle size and morphology of samples have no relation to the symmetry change. The particle size of samples is about 0.2 to 6  $\mu\text{m}$  and their morphology is characteristic as shown in Fig. 1. It seemed probable that some samples, although being apparently identical in terms of X-ray diffraction profiles, could display substantial differences in their nature of framework structure.

Fig. 1. Scanning electronmicrograph of ZSM-5 (sample No.8).
